Contents

Preface

List of contributors

1 Mechanical engineering principles

Status of rigid bodies · Strength of materials · Dynamics of rigid bodies · Vibrations · Mechanics of fluids · Principles of thermodynamics · Heat transfer · References

2 Electrical and electronics principles

Basic electrical technology · Electrical machines · Analogue and digital electronics theory · Electrical safety · References · Further reading

3 Microprocessors, instrumentation and control

Summary of number systems · Microprocessors · Communication standards · Interfacing of computers to systems · Instrumentation · Classical control theory and practice · Microprocessor-based control · Programmable logic controllers · The z-transform · State variable techniques · References · Further reading

4 Computers and their application

Introduction · Types of computer · Generations of digital computers · Digital computer systems · Categories of computer systems · Central processor unit · Memory · Peripherals · Output devices · Terminals · Direct input · Disk storage · Digital and analogue input/output · Data communications · Computer networks · Data terminal equipment · Software · Database management · Language translators · Languages

5 Computer-integrated engineering systems

CAD/CAM: Computer-aided design and computer-aided manufacturing ·Industrial robotics and automation · Computer graphics systems · References · Further reading

6 Design standards

Standardization in design · Drawing and graphic communications · Fits, tolerances and limits · Fasteners · Ergonomic and anthropometric data · Total quality – a company culture · References

7 Materials, properties and selection

Engineering properties of materials · The principles underlying materials selection · Ferrous metals · Non-ferrous metals · Composites · Polymers · Elastomers · Engineering ceramics and glasses · Corrosion · Non-destructive testing · References · Further reading

8 Mechanics of solids

Stress and strain · Experimental techniques · Fracture mechanics · Creep of materials · Fatigue · References · Further reading

9 Tribology

Basic principles · Lubricants (oils and greases) · Bearing selection · Principles and design of hydrodynamic bearings · Lubrication of industrial gears · Rolling element bearings · Materials for unlubricated sliding · Wear and surface treatment · Fretting · Surface topography · References · Further reading

10 Power units and transmission

Power units · Power transmission · Further reading

11 Fuels and combustion

Introduction · General fuel types · Major property overview · Major fuel groupings · Combustion · Conclusions · References

12 Alternative energy sources

Introduction · Solar radiation · Passive solar design in the UK · Thermal power and other thermal applications · Photovoltaic energy conversion · Solar chemistry · Hydropower · Wind power · Geothermal energy · Tidal power · Wave power · Biomass and energy from wastes · Energy crops · References

13 Nuclear engineering

Introduction · Nuclear radiation and energy · Mechanical engineering aspects of nuclear power stations and associated plant · Other applications of nuclear radiation · Elements of health physics and shielding · Further reading

14 Offshore engineering

Historical review · Types of fixed and floating structures · Future development · Hydrodynamic loading · Structural strength and fatigue · Dynamics of floating systems · Design considerations and certification · References

15 Plant engineering

Compressors, fans and pumps · Seals and sealing · Boilers and waste-heat recovery · Heating, ventilation and air conditioning · Refrigeration · Energy management · Condition monitoring · Vibration isolation and limits · Acoustic noise · References

16 Manufacturing methods

Large-chip metal removal · Metal forming · Welding, soldering and brazing · Adhesives · Casting and foundry practice · References · Further reading

17 Engineering mathematics

Trigonometric functions and general formulae · Calculus · Series and transforms · Matrices and determinants · Differential equations · Statistics · Further reading

18 Health and safety

Health and safety in the European Community · Health and safety at work – law and administration in the USA · UK legislation and guidance · The Health and Safety at Work etc. Act 1974 · The Health and Safety Executive · Local Authorities · Enforcement Notices · Control of Substances Hazardous to Health Regulations 1988 · Asbestos · Control of lead at work · The Electricity at Work Regulations 1989 · The Noise at Work Regulations 1989 · Safety of machines · Personal protective equipment · Manual handling · Further reading

19 Units, symbols and constants

SI units · Conversion to existing imperial terms · Abbreviations · Physical and chemical constants · Further reading

Index

Preface

I was delighted when Butterworth-Heinemann asked me to edit a new edition of *Mechanical Engineer's Reference Book*. Upon looking at its predecessor, it was clear that it had served the community well, but a major update was required. The book clearly needed to take account of modern methods and systems.

The philosophy behind the book is that it will provide a qualified engineer with sufficient information so that he or she can identify the basic principles of a subject and be directed to further reading if required. There is a blurred line between this set of information and a more detailed set from which design decisions are made. One of my most important tasks has been to define this distinction, so that the aims of the book are met and its weight is minimized! I hope I have been able to do this so that the information is neither cursory nor complex.

Any book of this size will inevitably contain errors, but I hope these will be minimal. I will be pleased to receive any information from readers so that the book can be improved.

To see this book in print is a considerable personal achievement, but I could not have done this without the help of others. First, I would like to thank all the authors for their tremendous hard work. It is a major task to prepare information for a book of this type, and they have all done a magnificent job. At Butterworth-Heinemann, Duncan Enright and Deena Burgess have been a great help, and Dal Koshal of the University of Brighton provided considerable support. At the University of Central Lancashire, Gill Cooke and Sue Wright ensured that the administration ran smoothly.

I hope you find the book useful.

Ted Smith
University of Central Lancashire, Preston.

References 1/48

In general, the study of mechanics may be divided into two distinct areas. These are *statics*, which involves the study of bodies at rest, and *dynamics*, which is the study of bodies in motion. In each case it is important to select an appropriate mathematical model from which a 'free body diagram' may be drawn, representing the system in space, with all the relevant forces acting on that system.

1.1 Statics of rigid bodies

When a set of forces act on a body they give rise to a resultant force or moment or a combination of both. The situation may be determined by considering three mutually perpendicular directions on the 'free body diagram' and resolving the forces and moment in these directions. If the three directions are denoted by x, y and z then the sum of forces may be represented by ΣF_x, ΣF_y and ΣF_z and the sum of the moments about respective axes by ΣM_x, ΣM_y and ΣM_z. Then for equilibrium the following conditions must hold:

$$\Sigma F_x = \Sigma F_y = \Sigma F_z = 0 \qquad (1.1)$$

$$\Sigma M_x = \Sigma M_y = \Sigma M_z = 0 \qquad (1.2)$$

If the conditions in equations (1.1) and (1.2) are not satisfied then there is a resultant force or moment, which is given by

$$F = [(\Sigma F_x)^2 + (\Sigma F_y)^2 + (\Sigma F_z)^2]^{1/2}$$

$$M = [(\Sigma M_x)^2 + (\Sigma M_y)^2 + (\Sigma M_z)^2]^{1/2}$$

The six conditions given in equations (1.1) and (1.2) satisfy problems in three dimensions. If one of these dimensions is not present (say, the z direction) the system reduces to a set of coplanar forces, and then

$$\Sigma F_z = \Sigma M_x = \Sigma M_y = 0$$

are automatically satisfied, and the necessary conditions of equilibrium in a two-dimensional system are

$$\Sigma F_x = \Sigma F_y = \Sigma M_z = 0 \qquad (1.3)$$

If the conditions in equation (1.3) are not satisfied then the resultant force or moment is given by

$$F = [(\Sigma F_x)^2 + (\Sigma F_y)^2]^{1/2}$$

$$M = \Sigma M_z$$

The above equations give solutions to what are said to be 'statically determinate' systems. These are systems where there are the minimum number of constraints to maintain equilibrium.[1]

1.2 Strength of materials

Weight: The weight (W) of a body is that force exerted due to gravitational attraction on the mass (m) of the body: $W = mg$, where g is the acceleration due to gravity.

Centre of gravity: This is a point, which may or may not be within the body, at which the total weight of the body may be considered to act as a single force. The position of the centre of gravity may be found experimentally or by analysis. When using analysis the moment of each element of weight, within the body, about a fixed axis is equated to the moment of the complete weight about that axis:

$$\bar{x} = \Sigma \delta mg \cdot x / \Sigma \delta mg, \quad \bar{y} = \Sigma \delta mg \cdot y / \Sigma \delta mg,$$

$$\bar{z} = \Sigma \delta mg \cdot z / \Sigma \delta mg$$

where δm is an element of mass at a distance of x, y or z from the respective axis, and $\bar{x}$, $\bar{y}$ and $\bar{z}$ are the positions of the centres of gravity from these axes. Table 1.1 shows the position of the centre of gravity for some standard shapes. (See reference 2 for a more comprehensive list.)

Shear force and bending moment: If a beam subject to loading, as shown in Figure 1.1, is cut, then in order to maintain equilibrium a shear force (Q) and a bending moment (M) must be applied to each portion of the beam. The magnitudes of Q and M vary with the type of loading and the position along the beam and are directly related to the stresses and deflections in the beam.

Relationship between shear force and bending moment: If an element of a beam is subjected to a load w then the following relationship holds:

$$\frac{d^2M}{dx^2} = \frac{dF}{dx} = -w$$

Table 1.2 shows examples of bending moments, shear force and maximum deflection for standard beams.

Bending equation: If a beam has two axes of symmetry in the xy plane then the following equation holds:

$$M_Z / I_Z = E / R_Z = \sigma / y$$

where M_Z is the bending moment, R_Z is the radius of curvature, I_Z the moment of inertia, E the modulus of elasticity, y the distance from the principal axis and σ is the stress.

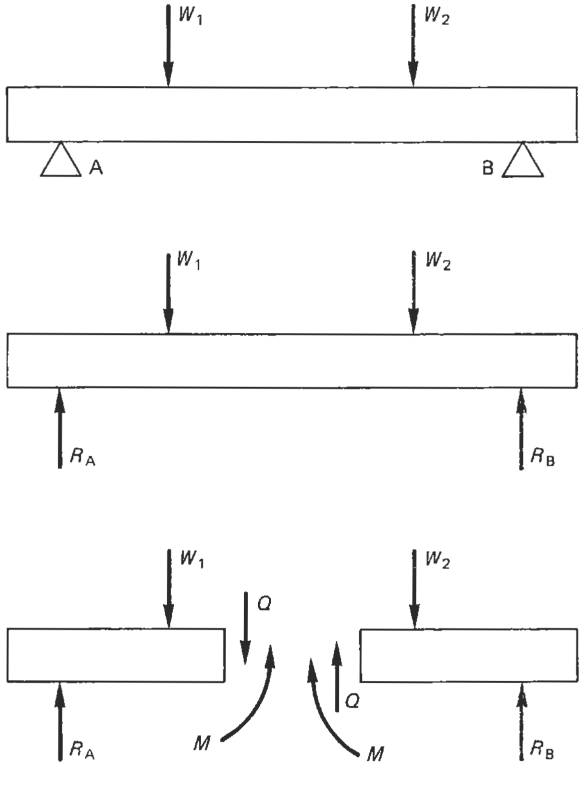

Figure 1.1

Table 1.1 Centres of gravity and moments of inertia or second moments of area for two-dimensional figures

Shape		*G*	*I*
Triangular area		$\bar{y} = h/3$	$I_{GG} = bh^3/36$ $I_{XX} = bh^3/12$
Rectangular area			$I_{GG} = bh^3/12$ $I_{XX} = bh^3/3$
Circular sector		$\bar{x} = \frac{2r}{3}\frac{\sin\alpha}{\alpha}$	$I_{XX} = \frac{r^4}{4}\left(\alpha - \frac{1}{2}\sin^2\alpha\right)$ $I_{YY} = \frac{r^4}{4}\left(\alpha + \frac{1}{2}\sin^2\alpha\right)$
Slender rod			$I_{XX} = I_{ZZ} = ml^2/12$
Rectangular prism			$I_{XX} = m(b^2 + c^2)/12$ $I_{YY} = m(c^2 + a^2)/12$ $I_{ZZ} = m(a^2 + b^2)/12$
Thin disc			$I_{XX} = mr^2/2$ $I_{YY} = I_{ZZ} = mr^2/4$
Circular cylinder			$I_{XX} = mr^2/2$ $I_{YY} = I_{ZZ} = m(3r^2 + L^2)/12$
Sphere			$I_{XX} = I_{YY} = I_{ZZ} = 2mr^2/5$
Hemisphere		$\bar{y} = 3r/8$	$I_{YY} = 2mr^2/5$
Circular cone		$\bar{x} = h/4$	$I_{XX} = 3mr^2/10$ $I_{YY} = \frac{3mr^2}{20} + \frac{mh^2}{10}$

Torsion equation: If a circular shaft is subject to a torque (T) then the following equation holds:

$T/J = \tau/r = G\theta/L$

where J is the polar second moment of area, G the shear modulus, L the length, θ the angle of twist, τ the shear stress and r the radius of the shaft.

1.3 Dynamics of rigid bodies

1.3.1 Basic definitions

1.3.1.1 Newton's Laws of Motion

First Law A particle remains at rest or continues to move in a straight line with a constant velocity unless acted on by an external force.

Table 1.2

	One concentrated load W M at A = Wx, Q at A = W M greatest at B, and = WL Q uniform throughout Maximum deflection = $WL^3/3EI$ at the free end.
	Uniform load of W M at A = $Wx^2/2L$ Q at A = Wx/L M greatest at B = $WL/2$ Q greatest at B = W Maximum deflection = $WL^3/8EI$ at the free end.
	One concentrated load at the centre of a beam M at A = $\frac{W}{2}\left(\frac{L}{2} - x\right)$, Q at A = $W/2$ M greatest at B = $WL/4$ Q uniform throughout Maximum deflection = $WL^3/48EI$ at the centre
	Uniform load W M at A = $\frac{W}{2L}\left(\frac{L^2}{4} - x^2\right)$ Q at A = Wx/L M greatest at B = $WL/8$ Q greatest at C and D = $W/2$ maximum deflection at B = $5WL^3/384EI$
	Beam fixed at ends and loaded at centre. M is maximum at A, B and C and = $WL/8$. Maximum deflection at $C = WL^3/192EI$
	Beam fixed at ends with uniform load. M maximum at A and B and = $WL/12$ Maximum deflection at C = $WL^3/384EI$
	One concentrated load W Reaction $R = 5W/16$ M maximum at A, and = $3WL/16$ M at C = $5WL/32$ Maximum deflection is $L/\sqrt{5}$ from the free end, and = $WL^3/107EI$
	Uniform load W Reaction $R = 3W/8$ M maximum at A, and = $WL/8$ M at C = $9WL/128$ Maximum deflection is $3L/8$ from the free end, and = $WL^3/187EI$

Second Law The sum of all the external forces acting on a particle is proportional to the rate of change of momentum.

Third Law The forces of action and reaction between interacting bodies are equal in magnitude and opposite in direction.

Newton's law of gravitation, which governs the mutual interaction between bodies, states

$F = Gm_1m_2/x^2$

where F is the mutual force of attraction, G is a universal constant called the constant of gravitation which has a value 6.673×10^{-11} m^3 kg^{-1} s^{-2}, m_1 and m_2 are the masses of the two bodies and x is the distance between the centres of the bodies.

Mass (m) is a measure of the amount of matter present in a body.

Velocity is the rate of change of distance (x) with time (t):

$v = \mathrm{d}x/\mathrm{d}t$ or $\dot{x}$

Acceleration is the rate of change of velocity (v) with time (t):

$a = \mathrm{d}v/\mathrm{d}t$ or $\mathrm{d}^2x/\mathrm{d}t^2$ or $\ddot{x}$

Momentum is the product of the mass and the velocity. If no external forces are present then the momentum of any system remains constant. This is known as the Conservation of Momentum.

Force is equal to the rate of change of momentum (mv) with time (t):

$F = \mathrm{d}(mv)/\mathrm{d}t$

$F = m \cdot \mathrm{d}v/\mathrm{d}t + v \cdot \mathrm{d}m/\mathrm{d}t$

If the mass remains constant then this simplifies to $F = m \cdot \mathrm{d}v/\mathrm{d}t$, i.e. Force = mass × acceleration, and it is measured in Newtons.

Impulse (I) is the product of the force and the time that force acts. Since $I = Ft = mat = m(v_2 - v_1)$, impulse is also said to be the change in momentum.

Energy: There are several different forms of energy which may exist in a system. These may be converted from one type to another but they can never be destroyed. Energy is measured in Joules.

Potential energy (PE) is the energy which a body possesses by virtue of its position in relation to other bodies: $PE = mgh$, where h is the distance above some fixed datum and g is the acceleration due to gravity.

Kinetic energy (KE) is the energy a body possesses by virtue of its motion: $KE = \frac{1}{2}mv^2$.

Work (W) is a measure of the amount of energy produced when a force moves a body a given distance: $W = F \cdot x$.

Power (P) is the rate of doing work with respect to time and is measured in watts.

Moment of inertia (I): The moment of inertia is that property in a rotational system which may be considered equivalent to the mass in a translational system. It is defined about an axis xx as $I_{XX} = \Sigma\delta mx^2 = mk^2_{XX}$, where x is the perpendicular distance of an element of mass δm from the axis xx and k_{XX} is the radius of gyration about the axis xx. Table 1.1 gives some data on moments of inertia for standard shapes.

Angular velocity (ω) is the rate of change of angular distance (θ) with time:

$= \mathrm{d}\theta/\mathrm{d}t = \dot{\theta}$

Angular acceleration (α) is the rate of change of angular velocity (ω) with time:

$= \mathrm{d}\omega/\mathrm{d}t$ or $\mathrm{d}^2\theta/\mathrm{d}t^2$ or $\ddot{\theta}$

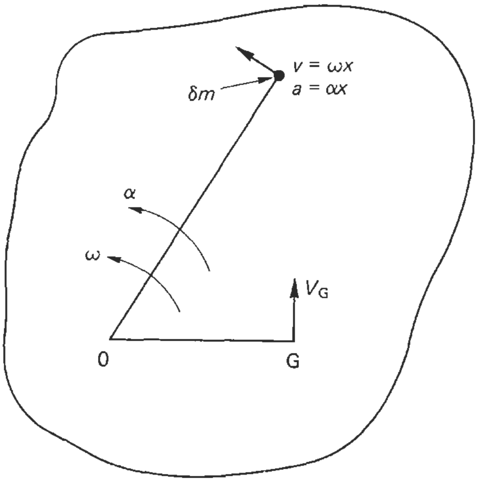

Figure 1.2

Both angular velocity and accleration are related to linear motion by the equations $v = \omega x$ and $a = \alpha x$ (see Figure 1.2).

Torque (T) is the moment of force about the axis of rotation:

$T = I_0\alpha$

A torque may also be equal to a *couple*, which is two forces equal in magnitude acting some distance apart in opposite directions.

Parallel axis theorem: if I_{GG} is the moment of inertia of a body of mass m about its centre of gravity, then the moment of inertia (I) about some other axis parallel to the original axis is given by $I = I_{GG} + mr^2$, where r is the perpendicular distance between the parallel axes.

Perpendicular axis theorem. If I_{XX}, I_{YY} and I_{ZZ} represent the moments of inertia about three mutually perpendicular axes x, y and z for a plane figure in the xy plane (see Figure 1.3) then $I_{ZZ} = I_{XX} + I_{YY}$.

Angular momentum (H_O) of a body about a point O is the moment of the linear momentum about that point and is ωI_{OO}. The angular momentum of a system remains constant unless acted on by an external torque.

Angular impulse is the produce of torque by time, i.e. angular impulse = $Tt = I\alpha \cdot t = I(\omega_2 - \omega_1)$, the change in angular momentum.

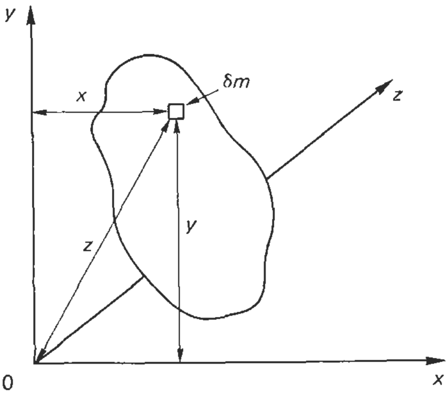

Figure 1.3

Angular kinetic energy about an axis O is given by $\frac{1}{2}I_O\omega^2$.

Work done due to a torque is the product of torque by angular distance and is given by $T\theta$.

Power due to torque is the rate of angular work with respect to time and is given by $Td\theta/dt = T\omega$.

Friction: Whenever two surfaces, which remain in contact, move one relative to the other there is a force which acts tangentially to the surfaces so as to oppose motion. This is known as the force of friction. The magnitude of this force is μR, where R is the normal reaction and μ is a constant known as the coefficient of friction. The coefficient of friction depends on the nature of the surfaces in contact.

1.3.2 Linear and angular motion in two dimensions

Constant acceleration: If the accleration is integrated twice and the relevant initial conditions are used, then the following equations hold:

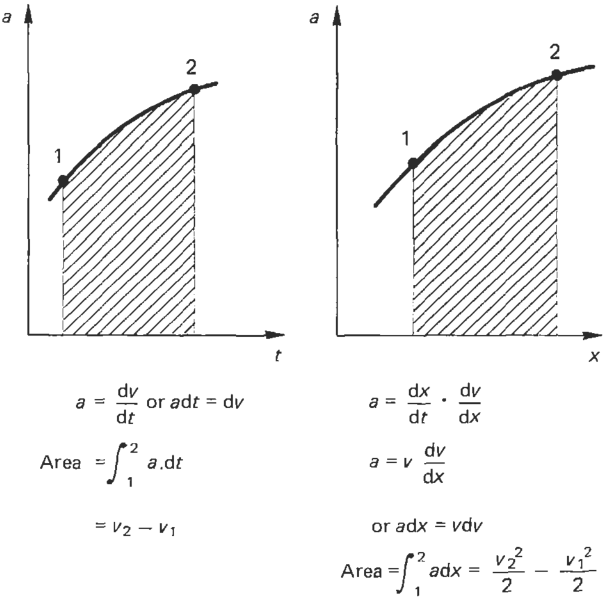
Linear motion	*Angular motion*
$x = v_1t + \frac{1}{2}at^2$	$\theta = \omega_1t + \frac{1}{2}\alpha t^2$
$v_2 = v_1 + at$	$\omega_2 = \omega_1 + \alpha t$
$v_2^2 = v_1^2 + 2ax$	$\omega_2^2 = \omega_1^2 + 2\alpha\theta$

Variable acceleration: If the acceleration is a function of time then the area under the acceleration time curve represents the change in velocity. If the acceleration is a function of displacement then the area under the acceleration distance curve represents half the difference of the square of the velocities (see Figure 1.4).

Curvilinear motion is when both linear and angular motions are present.

If a particle has a velocity v and an acceleration a then its motion may be described in the following ways:

1. *Cartesian components* which represent the velocity and acceleration along two mutually perpendicular axes x and y (see Figure 1.5(a)):



a
2
1
t
$a = \frac{dv}{dt}$ or $adt = dv$
Area $= \int_1^2 a.dt$
$= v_2 - v_1$
a
2
1
x
$a = \frac{dx}{dt} \cdot \frac{dv}{dx}$
$a = v\frac{dv}{dx}$
or $adx = vdv$
Area $= \int_1^2 adx = \frac{v_2^2}{2} - \frac{v_1^2}{2}$

Figure 1.4

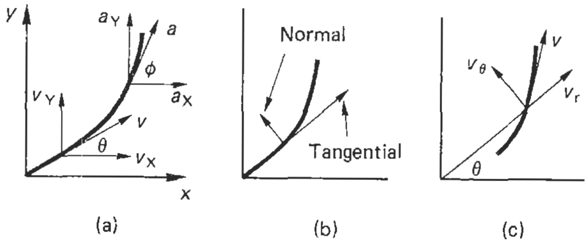


Figure 1.5

$v_X = v\cos\theta$, $v_Y = v\sin\theta$, $a_X = a\cos\phi$,

$a_Y = a\sin\phi$

2. *Normal and tangential components*: see Figure 1.5(b):

$$v_t = v = r\dot{\theta} = r\omega,\ v_n = 0$$
$$a_t = r\ddot{\theta} + \dot{r}\dot{\theta} = r\alpha + \dot{r}\omega,$$
$$a_n = v\dot{\theta} = r\omega^2$$

3. *Polar coordinates*: see Figure 1.5(c):

$$v_r = \dot{r},\ v_\theta = r\dot{\theta}$$
$$a_r = \ddot{r} - r\dot{\theta}^2,\ a_\theta = r\ddot{\theta} + 2\dot{r}\dot{\theta}$$

1.3.3 Circular motion

Circular motion is a special case of curvilinear motion in which the radius of rotation remains constant. In this case there is an acceleration towards the cente of $\omega^2 r$. This gives rise to a force towards the centre known as the *centripetal force*. This force is reacted to by what is called the *centrifugal reaction*.

Velocity and acceleration in mechanisms: A simple approach to determine the velocity and acceleration of a mechanism at a point in time is to draw velocity and acceleration vector diagrams.

Velocities: If in a rigid link AB of length l the end A is moving with a different velocity to the end B, then the velocity of A relative to B is in a direction perpendicular to AB (see Figure 1.6).

When a block slides on a rotating link the velocity is made up of two components, one being the velocity of the block relative to the link and the other the velocity of the link.

Accelerations: If the link has an angular acceleration α then there will be two components of acceleration in the diagram, a tangential component αl and a centripetal component of magnitude $\omega^2 l$ acting towards A.

When a block slides on a rotating link the total acceleration is composed of four parts: first, the centripetal acceleration towards O of magnitude $\omega^2 l$; second, the tangential acceleration αl; third, the acceleration of the block relative to the link; fourth, a tangential acceleration of magnitude $2v\omega$ known as Coriolis acceleration. The direction of Coriolis acceleration is determined by rotating the sliding velocity vector through 90° in the direction of the link angular velocity ω.

1.3.4 Linear and angular motion in three dimensions

1.3.4.1 Motion of a particle in a moving coordinate system

xyz is a moving coordinate system, with its origin at O which has a position vector $\mathbf{R}$, a translational velocity vector $\dot{\mathbf{R}}$ and an angular velocity vector $\boldsymbol{\omega}$ relative to a fixed coordinate system XYZ, origin at O′. Then the motion of a point P whose position vector relative to O is $\boldsymbol{\rho}$ and relative to O′ is $\mathbf{r}$ is given by the following equations (see Figure 1.7):

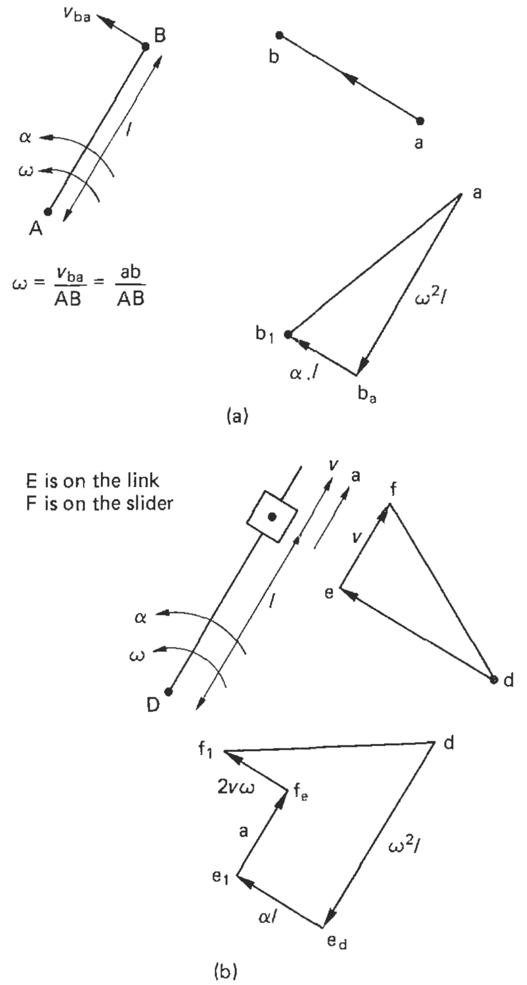

Figure 1.6

$$\dot{\mathbf{r}} = \dot{\mathbf{R}} + \dot{\boldsymbol{\rho}}_r + \boldsymbol{\omega} \times \boldsymbol{\rho}$$

where $\boldsymbol{\rho}_r$ is the velocity of the point P relative to the moving system xyz and $\boldsymbol{\omega} \times \boldsymbol{\rho}$ is the vector product of $\boldsymbol{\omega}$ and $\boldsymbol{\rho}$:

$$\ddot{\mathbf{r}} = \ddot{\mathbf{R}} + \dot{\boldsymbol{\omega}} \times \boldsymbol{\rho} + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \boldsymbol{\rho}) + 2\boldsymbol{\omega} \times \dot{\boldsymbol{\rho}}_r + \ddot{\boldsymbol{\rho}}_r$$

where $\boldsymbol{\rho}_r$ is the acceleration of the point P relative to the moving system. Thus $\dot{\mathbf{r}}$ is the sum of:

1. The relative velocity $\ddot{\boldsymbol{\rho}}_r$;
2. The absolute velocity $\dot{\mathbf{R}}$ of the moving origin O;
3. The velocity $\boldsymbol{\omega} \times \boldsymbol{\rho}$ due to the angular velocity of the moving axes xyz.

and $\ddot{\mathbf{r}}$ is the sum of:

1. The relative acceleration $\ddot{\boldsymbol{\rho}}_r$;
2. The absolute acceleration $\ddot{\mathbf{R}}$ of the moving origin O;
3. The tangential acceleration $\dot{\boldsymbol{\omega}} \times \boldsymbol{\rho}$ due to the angular acceleration of the moving axes xyz;
4. The centripetal acceleration $\boldsymbol{\omega} \times (\boldsymbol{\omega} \times \boldsymbol{\rho})$ due to the angular velocity of the moving axes xyz;
5. Coriolis component acceleration $2\boldsymbol{\omega} \times \dot{\boldsymbol{\rho}}_r$ due to the interaction of coordinate angular velocity and relative velocity.

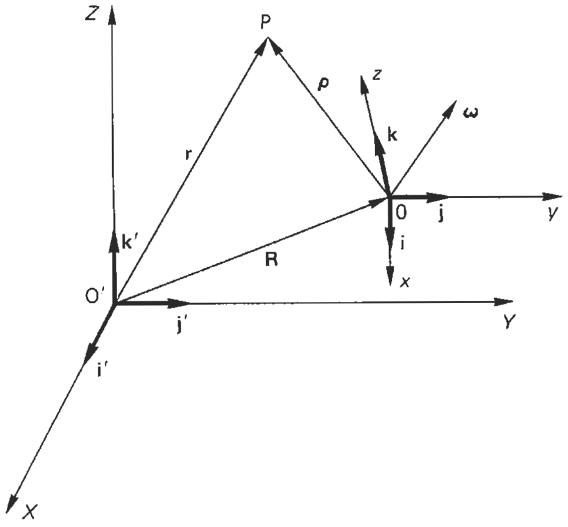

Figure 1.7

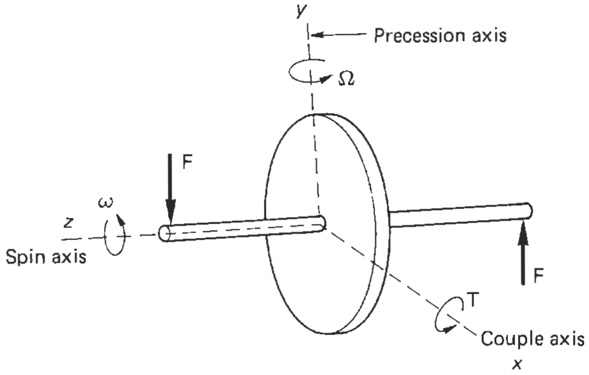

Figure 1.8

In all the vector notation a right-handed set of coordinate axes and the right-hand screw rule is used.

1.3.4.2 Gyroscopic effects

Consider a rotor which spins about its geometric axis (see Figure 1.8) with an angular velocity ω. Then two forces F acting on the axle to form a torque T, whose vector is along the x axis, will produce a rotation about the y axis. This is known as precession, and it has an angular velocity Ω. It is also the case that if the rotor is precessed then a torque T will be produced, where T is given by $T = I_{XX}\omega\Omega$. When this is observed it is the effect of gyroscopic reaction torque that is seen, which is in the opposite direction to the gyroscopic torque.[4]

1.3.5 Balancing

In any rotational or reciprocating machine where accelerations are present, unbalanced forces can lead to high stresses and vibrations. The principle of balancing is such that by the addition of extra masses to the system the out-of-balance forces may be reduced or eliminated.

1.3.6 Balancing of rotating masses

1.3.6.1 Single out-of-balance mass

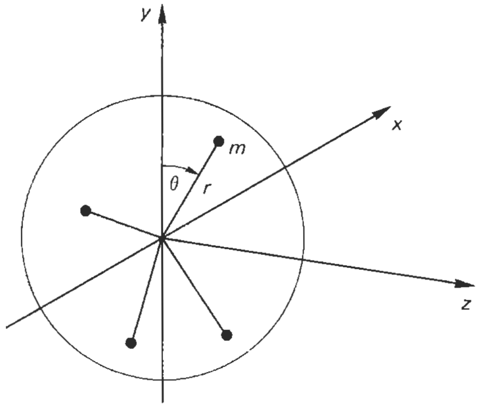
One mass (m) at a distance r from the centre of rotation and rotating at a constant angular velocity ω produces a force $m\omega^2 r$. This can be balanced by a mass M placed diametrically opposite at a distance R, such that $MR = mr$.

1.3.6.2 Several out-of-balance masses in one transverse plane

If a number of masses ($m_1, m_2, \ldots$) are at radii ($r_1, r_2, \ldots$) and angles ($\theta_1, \theta_2, \ldots$) (see Figure 1.9) then the balancing mass M must be placed at a radius R such that MR is the vector sum of all the mr terms.

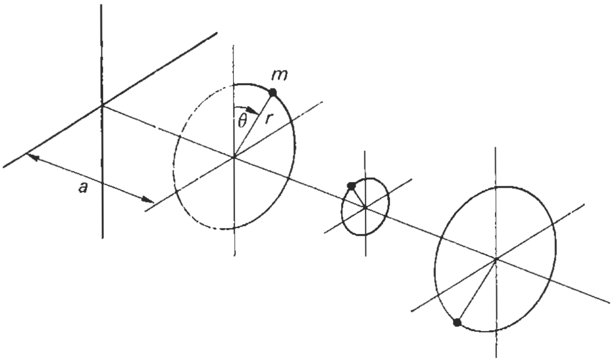
1.3.6.3 Masses in different transverse planes

If the balancing mass in the case of a single out-of-balance mass were placed in a different plane then the centrifugal force would be balanced. This is known as *static balancing*. However, the moment of the balancing mass about the



$\Sigma F_X = \Sigma m\omega^2 r \sin\theta = 0$
$\Sigma F_Y = \Sigma m\omega^2 r \cos\theta = 0$

Figure 1.9



$\Sigma F_X = \Sigma m\omega^2 r \sin\theta = 0$ and $\Sigma F_Y = \Sigma m\omega^2 r \cos\theta = 0$
as in the previous case, also
$\Sigma M_X = \Sigma m\omega^2 r \sin\theta \,.\, a = 0$
$\Sigma M_Y = \Sigma m\omega^2 r \cos\theta \,.\, a = 0$

Figure 1.10

original plane would lead to what is known as *dynamic unbalance.*

To overcome this, the vector sum of all the moments about the reference plane must also be zero. In general, this requires two masses placed in convenient planes (see Figure 1.10).

1.3.6.4 Balancing of reciprocating masses in single-cylinder machines

The acceleration of a piston as shown in Figure 1.11 may be represented by the equation[5]

$$\ddot{x} = -\omega^2 r[\cos\theta + (1/n)\cos 2\theta + (1/4n)(\cos 2\theta - \cos 4\theta) + \ldots]^*$$

where $n = l/r$. If n is large then the equation may be simplified and the force given by

$$F = m\ddot{x} \simeq -m\omega^2 r[\cos\theta + (1/n)\cos 2\theta]$$

The term $m\omega^2 r\cos\theta$ is known as the *primary force* and $(1/n)m\omega^2 r\cos 2\theta$ as the *secondary force*. Partial primary balance is achieved in a single-cylinder machine by an extra mass M at a radius R rotating at the crankshaft speed. Partial secondary balance could be achieved by a mass rotating at 2ω. As this is not practical this is not attempted. When partial primary balance is attempted a transverse component $M\omega^2 R\sin\theta$ is introduced. The values of M and R are chosen to produce a compromise between the reciprocating and the transverse components.

1.3.6.5 Balancing of reciprocating masses in multi-cylinder machines

When considering multi-cylinder machines account must be taken of the force produced by each cylinder and the moment of that force about some datum. The conditions for primary balance are

$$F = \Sigma m\omega^2 r\cos\theta = 0,\ M = \Sigma m\omega^2 r\cos\theta \cdot a = 0$$

where a is the distance of the reciprocating mass m from the datum plane.

In general, the cranks in multi-cylinder engines are arranged to assist primary balance. If primary balance is not complete then extra masses may be added to the crankshaft but these will introduce an unbalanced transverse component. The conditions for secondary balance are

$$F = \Sigma m\omega^2(r/n)\cos 2\theta = \Sigma m(2\omega)^2(r/4n)\cos 2\theta = 0$$

and

$$M = \Sigma m(2\omega)^2(r/4n)\cos 2\theta \cdot a = 0$$

The addition of extra masses to give secondary balance is not attempted in practical situations.

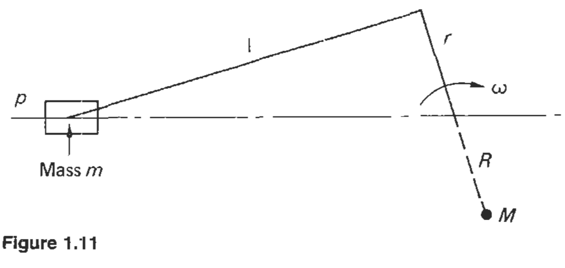


Figure 1.11

1.4 Vibrations

1.4.1 Single-degree-of-freedom systems

The term *degrees of freedom* in an elastic vibrating system is the number of parameters required to define the configuration of the system. To analyse a vibrating system a mathematical model is constructed, which consists of springs and masses for linear vibrations. The type of analysis then used depends on the complexity of the model.

Rayleigh's method: Rayleigh showed that if a reasonable deflection curve is assumed for a vibrating system, then by considering the kinetic and potential energies* an estimate to the first natural frequency could be found. If an inaccurate curve is used then the system is subject to constraints to vibrate it in this unreal form, and this implies extra stiffness such that the natural frequency found will always be high. If the exact deflection curve is used then the natural frequency will be exact.

1.4.1.1 Transverse vibration of beams

Consider a beam of length (l), weight per unit length (w), modulus (E) and moment of inertia (I). Then its equation of motion is given by

$$EI\frac{d^4y}{dx^4} - w\omega^2 y/g = 0$$

where ω is the natural frequency. The general solution of this equation is given by

$$y = A\cos\beta x + B\sin\beta x + C\cosh\beta x + D\sinh\beta x$$

where $\beta^4 = w\omega^2/gEI$.

The four constants of integration A, B, C and D are determined by four independent end conditions. In the solution trigonometrical identities are formed in β which may be solved graphically, and each solution corresponds to a natural frequency of vibration. Table 1.3 shows the solutions and frequencies for standard beams.[6]

Dunkerley's empirical method is used for beams with multiple loads. In this method the natural frequency (f_1) is found due to just one of the loads, the rest being ignored. This is repeated for each load in turn and then the natural frequency of vibration of the beam due to its weight alone is found (f_0).

---

* This equation forms an infinite series in which higher terms are small and they may be ignored for practical situations.

* Consider the equation of motion for an undamped system (Figure 1.13):

$$m\cdot\frac{d^2x}{dt^2} + kx = 0 \qquad (1.4)$$

but

$$\frac{d^2x}{dt^2} = \frac{d}{dt}\left(\frac{dx}{dt}\right) = \frac{dx}{dt}\cdot\frac{d}{dx}\left(\frac{dx}{dt}\right) = \frac{1}{2}\cdot\frac{d}{dx}\left(\frac{dx}{dt}\right)^2$$

Therefore equation (1.4) becomes

$$\frac{d}{dx}\left[\frac{1}{2}m\left(\frac{dx}{dt}\right)^2\right] + kx = 0$$

Integrating gives

$$\frac{1}{2}m\left(\frac{dx}{dt}\right)^2 + \frac{1}{2}kx^2 = \text{Constant}$$

the term $\frac{1}{2}m(dx/dt)^2$ represents the kinetic energy and $\frac{1}{2}kx^2$ the potential energy.

Table 1.3

	End conditions	*Trig. equation*	*Solutions* $\beta_1 l$	$\beta_2 l$	$\beta_3 l$
	$x = 0, y = 0, y' = 0$ $x = l, y = 0, y' = 0$	$\cos \beta l \cdot \cosh \beta l = 1$	4.730	7.853	10.966
	$x = 0, y = 0, y' = 0$ $x = l, y'' = 0, y''' = 0$	$\cos \beta l \cdot \cosh \beta l = -1$	1.875	4.694	7.855
	$x = 0, y = 0, y'' = 0$ $x = l, y = 0, y'' = 0$	$\sin \beta l = 0$	3.142	6.283	9.425
	$x = 0, y = 0, y' = 0$ $x = l, y = 0, y'' = 0$	$\tan \beta l = \tanh \beta l$	3.927	7.069	10.210

Then the natural frequency of vibration of the complete system (f) is given by

$$\frac{1}{f^2} = \frac{1}{f_0^2} + \frac{1}{f_1^2} + \frac{1}{f_2^2} + \frac{1}{f_3^2} + \ldots \frac{1}{f_n^2}$$

(see reference 7 for a more detailed explanation).

Whirling of shafts: If the speed of a shaft or rotor is slowly increased from rest there will be a speed where the deflection increases suddenly. This phenomenon is known as whirling. Consider a shaft with a rotor of mass m such that the centre of gravity is eccentric by an amount e. If the shaft now rotates at an angular velocity ω then the shaft will deflect by an amount y due to the centrifugal reaction (see Figure 1.12). Then

$$m\omega^2(y + e) = ky$$

where k is the stiffness of the shaft. Therefore

$$y = \frac{e}{(k/m\omega^2 - 1)}$$

When $(k/m\omega^2) = 1$, y is then infinite and the shaft is said to be at its critical whirling speed ω_c. At any other angular velocity ω the deflection y is given by

$$y = \left(\frac{\omega^2}{\omega_c^2 - \omega^2}\right).e$$

When $\omega < \omega_c$, y is the same sign as e and as ω increases towards ω_c the deflection theoretically approaches infinity. When $\omega > \omega_c$, y is opposite in sign to e and will eventually tend to $-e$. This is a desirable running condition with the centre of gravity of the rotor mass on the static deflection curve. Care must be taken not to increase ω too high as ω might start to approach one of the higher modes of vibration.[8]

Torsional vibrations: The following section deals with transverse vibrating systems with displacements x and masses m. The same equations may be used for torsional vibrating systems by replacing x by θ the angular displacement and m by I, the moment of inertia.

1.4.1.2 *Undamped free vibrations*

The equation of motion is given by $m\ddot{x} + kx = 0$ or $\ddot{x} + \omega_n^2 x = 0$, where m is the mass, k the stiffness and $\omega_n^2 = k/m$, which is the natural frequency of vibration of the system (see Figure 1.13). The solution to this equation is given by

$$x = A \sin(\omega_n t + \alpha)$$

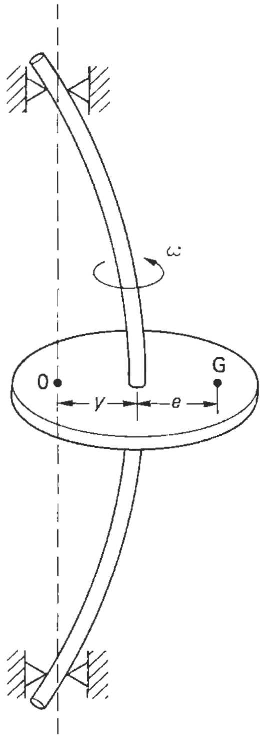

Figure 1.12

where A and α are constants which depend on the initial conditions. This motion is said to be *simple harmonic* with a time period $T = 2\pi/\omega_n$.

1.4.1.3 *Damped free vibrations*

The equation of motion is given by $m\ddot{x} + c\dot{x} + kx = 0$ (see Figure 1.14), where c is the viscous damping coefficient, or $\ddot{x} + (c/m)\dot{x} + \omega_n^2 x = 0$. The solution to this equation and the resulting motion depends on the amount of damping. If $c > 2m\omega_n$ the system is said to be overdamped. It will respond to a disturbance by slowly returning to its equilibrium posi-

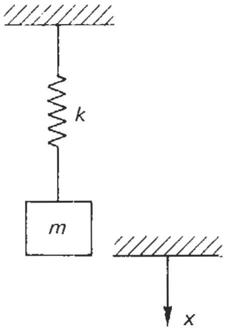

Figure 1.13

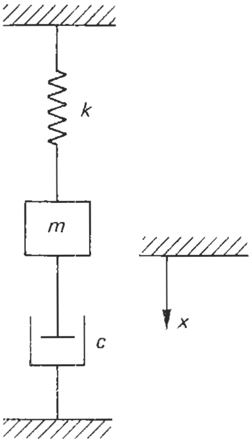

Figure 1.14

tion. The time taken to return to this position depends on the degree of damping (see Figure 1.15(c)). If $c = 2m\omega_n$ the system is said to be critically damped. In this case it will respond to a disturbance by returning to its equilibrium position in the shortest possible time. In this case (see Figure 1.15(b))

$$x = e^{-(c/2m)t(A+Bt)}$$

where A and B are constants. If $c < 2m\omega_n$ the system has a transient oscillatory motion given by

$$x = e^{-(c/2m)t}[C \sin(\omega_n^2 - c^2/4m^2)^{1/2}t + D(\cos \omega_n^2 - c^2/4m^2)^{1/2}t]$$

where C and D are constants. The period

$$T = \frac{2\pi}{(\omega_n^2 - c^2/4m^2)^{1/2}}$$

(see Figure 1.15(a)).

1.4.1.4 *Logarithmic decrement*

A way to determine the amount of damping in a system is to measure the rate of decay of successive oscillations. This is expressed by a term called the *logarithmic decrement* (δ), which is defined as the natural logarithm of the ratio of any two successive amplitudes (see Figure 1.16):

$$\delta = \log_e(x_1/x_2)$$

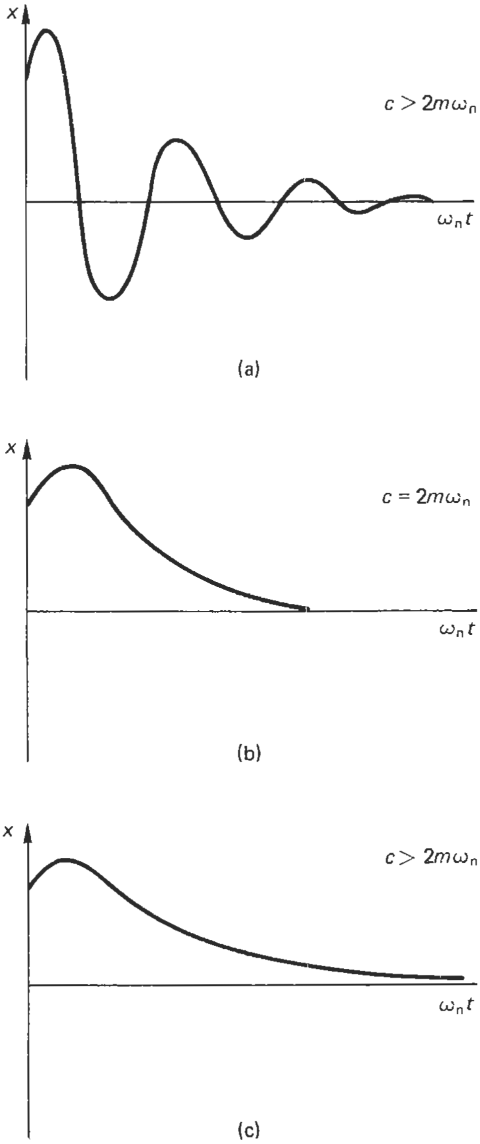

Figure 1.15

where x is given by

$$x = e^{cT/m} \sin\left[\left(\omega^2 - \frac{c^2}{4m^2}\right)^{1/2} + \phi\right]$$

Therefore

$$\delta = \log_e(e^{-cT/2m}/e^{-c(T+\tau)/2m})$$
$$= c\tau/2m$$

where τ is the period of damped oscillation.

If the amount of damping present is small compared to the critical damping, τ approximates to $2\pi/\omega$, and then

$$\delta = c\pi/m\omega_n$$

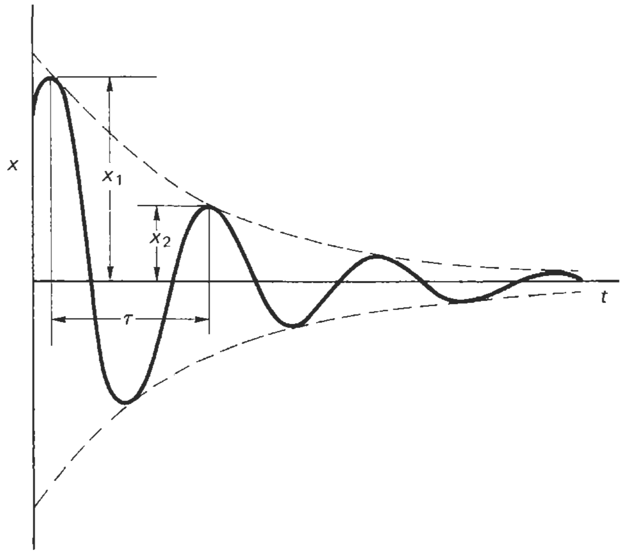

Figure 1.16

1.4.1.5 Forced undamped vibrations

The equation of motion is given by (see Figure 1.17)

$$m\ddot{x} + kx = F_0 \sin \omega t$$

or

$$\ddot{x} + \omega_n{}^2 = (F_0/m) \sin \omega t$$

The solution to this equation is

$$x = C \sin \omega_n t + D \cos \omega_n t + F_0 \cos \omega t/[m(\omega_n^2 - \omega^2)]$$

where ω is the frequency of the forced vibration. The first two terms of the solution are the transient terms which die out, leaving an oscillation at the forcing frequency of amplitude

$$F_0/[m(\omega_n^2 - \omega^2)]$$

or

$$\frac{F_0}{k}\left(\frac{\omega_n^2}{\omega_n^2 - \omega^2}\right)$$

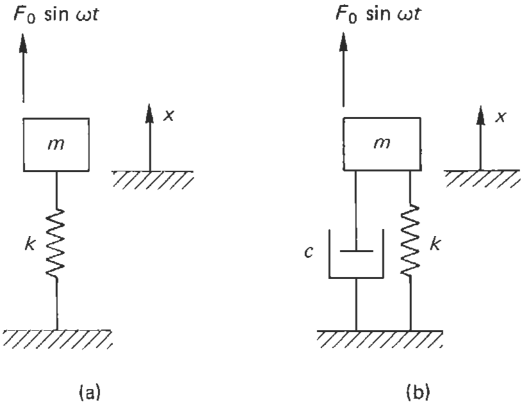

Figure 1.17

The term $\omega_n^2/(\omega_n^2 - \omega^2)$ is known as the dynamic magnifier and it gives the ratio of the amplitude of the vibration to the static deflection under the load F_0. When $\omega = \omega_n$ the amplitude becomes infinite and resonance is said to occur.

1.4.1.6 Forced damped vibrations

The equation of motion is given by (see Figure 1.17(b))

$$m\ddot{x} + c\ddot{x} + kx = F_0 \sin \omega t$$

or

$$\ddot{x} + (c/m)\dot{x} + \omega_n^2 = (F_0/m) \sin \omega t$$

The solution to this equation is in two parts: a transient part as in the undamped case which dies away, leaving a sustained vibration at the forcing frequency given by

$$x = \frac{F_0}{m}\,\frac{1}{[(\omega_n^2 - \omega^2)^2 + (c(\omega/m)^2]^{1/2}} \sin(\omega t - \alpha)$$

The term

$$\frac{\omega_n^2}{[(\omega_n^2 - \omega^2)^2 + (c\omega/m)]^2]^{1/2}}$$

is called the dynamic magnifier. Resonance occurs when $\omega \simeq \omega_n$. As the damping is increased the value of ω for which resonance occurs is reduced. There is also a phase shift as ω increases tending to a maximum of π radians. It can be seen in Figure 1.18(a) that when the forcing frequency is high compared to the natural frequency the amplitude of vibration is minimized.

1.4.1.7 Forced damped vibrations due to reciprocating or rotating unbalance

Figure 1.19 shows two elastically mounted systems, (a) with the excitation supplied by the reciprocating motion of a piston, and (b) by the rotation of an unbalanced rotor. In each case the equation of motion is given by

$$(M - m)\ddot{x} + c\dot{x} + kx = (me\omega^2) \sin \omega t$$

The solution of this equation is a sinusoid whose amplitude, X, is given by

$$X = \frac{me\omega^2}{\sqrt{[(K - M\omega^2)^2 + (c\omega)^2]}}$$

In representing this information graphically it is convenient to plot MX/me against ω/ω_n for various levels of damping (see Figure 1.20(a)). From this figure it can be seen that for small values of ω the displacement is small, and as ω is increased the displacement reaches a maximum when ω is slightly greater than ω_n. As ω is further increased the displacement tends to a constant value such that the centre of gravity of the total mass M remains stationary. Figure 1.20(b) shows how the phase angle varies with frequency.

1.4.1.8 Forced damped vibration due to seismic excitation

If a system as shown in Figure 1.21 has a sinusoidal displacement applied to its base of amplitude, y, then the equation of motion becomes

$$m\ddot{x} + c\dot{x} + kx = ky + c\dot{y}$$

The solution of this equation yields

$$\frac{x}{y} = \sqrt{\left[\frac{k^2 + (c\omega)^2}{(k - m\omega^2)^2 + (c\omega)^2}\right]}$$

where x is the amplitude of motion of the system.

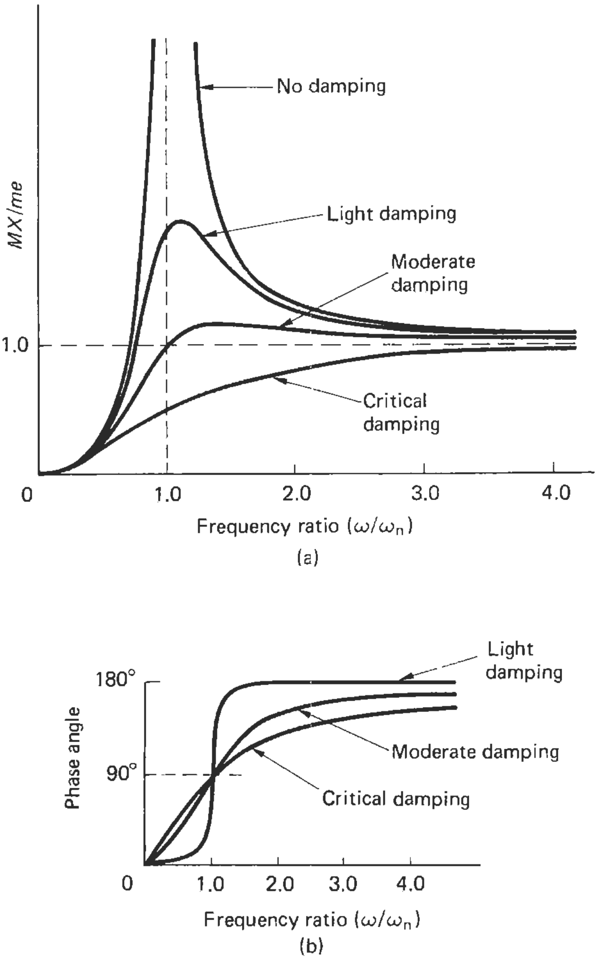
Figure 1.19



(a)

(b)

Figure 1.20

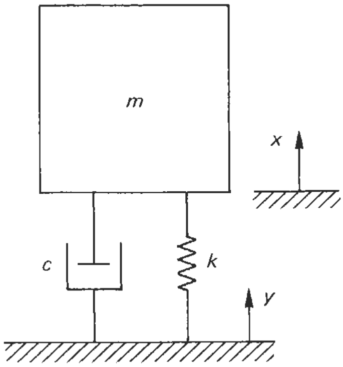


Figure 1.21

When this information is plotted as in Figure 1.22 it can be seen that for very small values of ω the output amplitude X is equal to the input amplitude Y. As ω is increased towards ω_n the output reaches a maximum. When $\omega = \sqrt{2}\,\omega_n$ the curves intersect and the effect of damping is reversed.

The curves in Figure 1.22 may also be used to determine the amount of sinusoidal force transmitted through the springs and dampers to the supports, i.e. the axis (X/Y) may be replaced by (F_t/F_0) where F_0 is the amplitude of applied force and F_t is the amplitude of force transmitted.

1.4.2 Multi-degree-of-freedom systems

1.4.2.1 Normal mode vibration

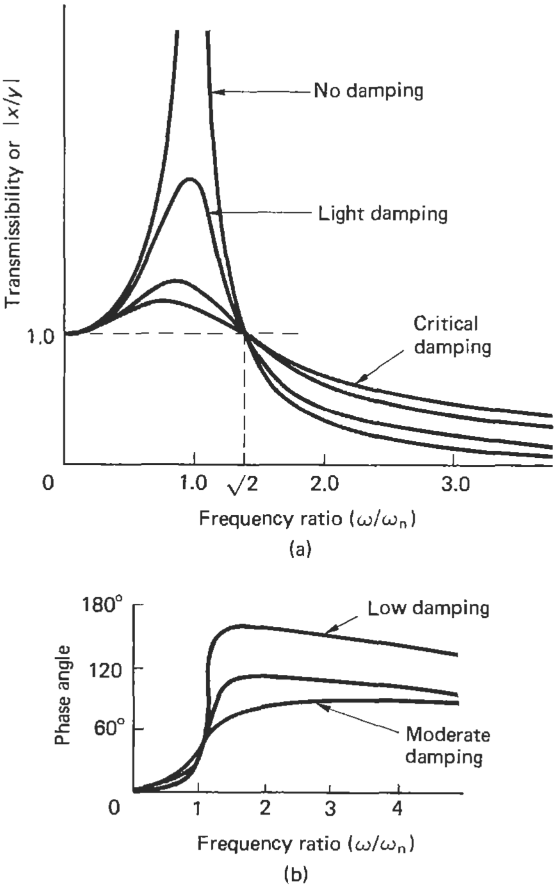
The fundamental techniques used in modelling multi-degree-of-freedom systems may be demonstrated by considering a simple two-degree-of-freedom system as shown in Figure 1.23. The equations of motion for this system are given by

$$m_1\ddot{x}_1 + (k_1 + k_2)x_1 - k_2x_2 = 0$$

$$m_2\ddot{x}_2 + (k_3 + k_2)x_2 - k_2x_1 = 0$$

or in matrix form:

$$\begin{bmatrix} m_1 & 0 \\ 0 & m_2 \end{bmatrix} \begin{Bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \end{Bmatrix} + \begin{bmatrix} (k_1 + k_2) & -k_2 \\ -k_2 & (k_3 + k_2) \end{bmatrix} \begin{Bmatrix} x_1 \\ x_2 \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \end{Bmatrix}$$



(a)

(b)

Figure 1.22

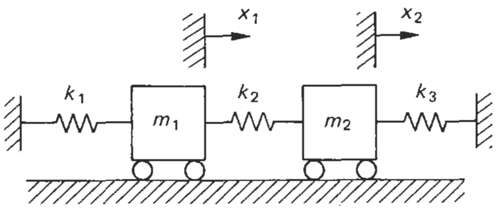


Figure 1.23

Assuming the motion of every point in the system to be harmonic then the solutions will take the form

$$x_1 = A_1 \sin \omega t$$

$$x_2 = A_2 \sin \omega t$$

where A_1 and A_2 are the amplitudes of the respective displacements. By substituting the values of x_1, x_2, $\ddot{x}_1$ and $\ddot{x}_2$ into the original equations the values of the natural frequencies of vibration may be found along with the appropriate mode shapes. This is a slow and tedious process, especially for systems with large numbers of degrees of freedom, and is best performed by a computer program.

1.4.2.2 The Holtzer method

When only one degree of freedom is associated with each mass in a multi-mass system then a solution can be found by proceeding numerically from one end of the system to the other. If the system is being forced to vibrate at a particular frequency then there must be a specific external force to produce this situation. A frequency and a unit deflection is assumed at the first mass and from this the inertia and spring forces are calculated at the second mass. This process is repeated until the force at the final mass is found. If this force is zero then the assumed frequency is a natural frequency. Computer analysis is most suitable for solving problems of this type.

Consider several springs and masses as shown in Figure 1.24. Then with a unit deflection at the mass m_1 and an assumed frequency ω there will be an inertia force of $m_1\omega^2$ acting on the spring with stiffness k_1. This causes a deflection of $m_1\omega^2/k_1$, but if m_2 has moved a distance x_2 then $m_1\omega^2/k_1 = 1 - x_2$ or $x_2 = 1 - m_1\omega^2/k_1$. The inertia force acting due to m_2 is $m_2\omega^2x_2$, thus giving the total force acting on the spring of stiffness k_2 as $[m_1\omega^2 + m_2\omega^2x_2\}/k_2$. Hence the displacement at x_3 can be found and the procedure repeated. The external force acting on the final mass is then given by

$$\sum_{i=1}^{n} m_i\omega^2 x_i$$

If this force is zero then the assumed frequency is a natural one.

1.4.3 Random vibrations

1.4.3.1 Introduction

If the vibration response parameters of a dynamic system are accurately known as functions of time, the vibration is said to be *deterministic*. However, in many systems and processes responses cannot be accurately predicted; these are called *random processes*. Examples of a random process are turbulence, fatigue, the meshing of imperfect gears, surface irregularities, the motion of a car running along a rough road and building vibration excited by an earthquake (Figure 1.25).

A collection of sample functions $x_1(t), x_2(t), x_3(t), \ldots, x_n(t)$ which make up the random process $x(t)$ is called an *ensemble* (Figure 1.26). These functions may comprise, for example, records of pressure fluctuations or vibration levels, taken under the same conditions but at different times.

Any quantity which cannot be precisely predicted is non-deterministic and is known as a *random variable* or a *probabilistic quantity*. That is, if a series of tests are conducted to find the value of a particular parameter, x, and that value is found to vary in an unpredictable way that is not a function of any other parameter, then x is a random variable.

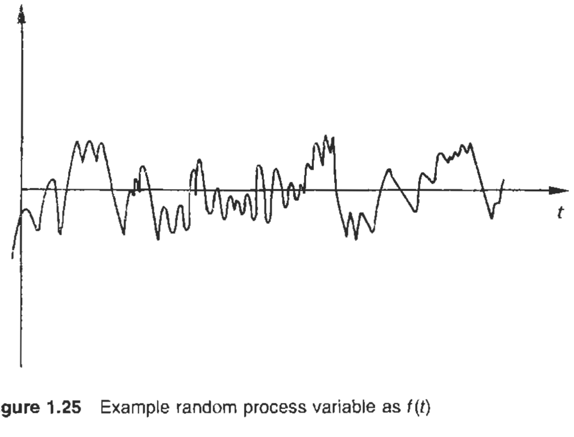

Figure 1.25 Example random process variable as $f(t)$

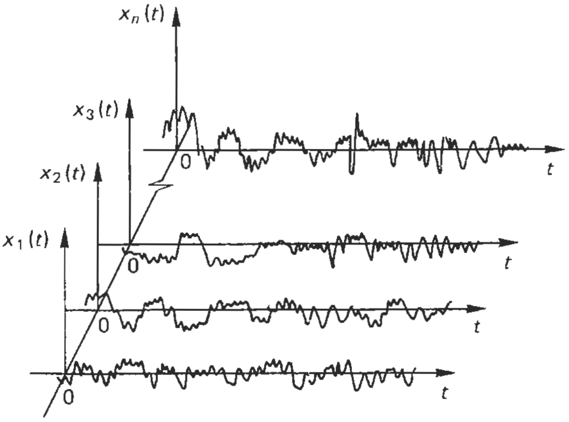

Figure 1.26 Ensemble of a random process

1.4.3.2 Probability distribution

If n experimental values of a variable x are $x_1, x_2, x_3, \ldots, x_n$, the probability that the value of x will be less than x' is n'/n, where n' is the number of x values which are less than or equal to x'. That is,

$$\text{Prob}(x \leqslant x') = n'/n$$

When n approaches ∞ this expression is the probability distribution function of x, denoted by $P(x)$, so that

$$P(x) = \underset{n \to \infty}{\text{Lt}} (n'/n)$$

The typical variation of $P(x)$ with x is shown in Figure 1.27. Since $x(t)$ denotes a physical quantity,

$$\text{Prob}(x < -\infty) = 0, \text{ and } \text{Prob}(x < +\infty) = 1$$

The *probability density function* is the derivative of $P(x)$ with respect to x and this is denoted by $p(x)$. That is,

$$p(x) = \frac{\mathrm{d}P(x)}{\mathrm{d}x}$$

$$= \underset{\Delta x \to 0}{\text{Lt}} \left[\frac{P(x + \Delta x) - P(x)}{\Delta x}\right]$$

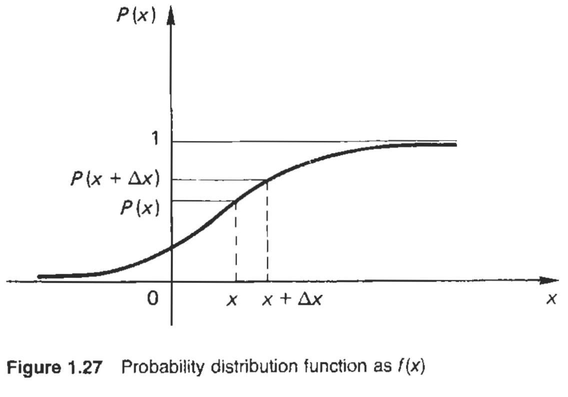

Figure 1.27 Probability distribution function as $f(x)$

where $P(x + \Delta x) - P(x)$ is the probability that the value of $x(t)$ will lie between x and $x + \Delta x$ (Figure 1.27). Now

$$p(x) = \frac{\mathrm{d}P(x)}{\mathrm{d}x}$$

so that

$$P(x) = \int_{-\infty}^{x} p(x)\mathrm{d}x$$

Hence

$$P(\infty) = \int_{-\infty}^{\infty} p(x)\mathrm{d}x = 1$$

so that the area under the probability density function curve is unity.

A random process is *stationary* if the joint probability density

$$p(x(t_1), x(t_2), x(t_3), \ldots)$$

depends only on the time differences $t_2 - t_1$, $t_3 - t_2$ and so on, and not on the actual time instants. That is, the ensemble will look just the same if the time origin is changed. A random process is *ergodic* if every sample function is typical of the entire group.

The expected value of $f(x)$, which is written $E[f(x)]$ or $\overline{f(x)}$ is

$$E[f(x)] = \overline{f(x)} = \int_{-\infty}^{\infty} f(x)p(x)\mathrm{d}x$$

so that the expected value of a stationary random process $x(t)$ is

$$E[x(t_1)] = E[x(t_1 + t)]$$

for any value of t.

If $f(x) = x$, the expected value or *mean value* of x, $E[x]$ or $\bar{x}$, is

$$E[x] = \bar{x} = \int_{-\infty}^{\infty} xp(x)\mathrm{d}x$$

In addition, if $f(x) = x^2$, the *mean square value* of x, $\bar{x}^2$ is

$$E[x^2] = \bar{x}^2 = \int_{-\infty}^{\infty} x^2 \cdot p(x)\mathrm{d}x$$

The *variance* of x, σ^2 is the mean square value of x about the mean, that is,

$$\sigma^2 = E[(x - \bar{x})^2] = \int_{-\infty}^{\infty} (x - \bar{x})^2 p(x)\mathrm{d}x = \overline{(x^2)} - (\bar{x})^2$$

σ is the *standard deviation* of x, hence

$$\text{Variance} = (\text{Standard deviation})^2$$
$$= \{\text{Mean square} - (\text{Mean})^2\}$$

If two or more random variables x_1 and x_2 represent a random process at two different instants of time, then

$$E[f(x_1,x_2)] = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x_1,x_2)p(x_1,x_2)\mathrm{d}x_1\mathrm{d}x_2$$

and if t_1 and t_2 are the two instants of time,

$$E[x(t_1), x(t_2)] = R(t_1,t_2)$$

which is the *autocorrelation function* for the random process (Figure 1.28).

For random processes which are stationary,

$$E[x(t_1), x(t_2)] = R(t_1,t_2) = R(t_2 - t_1) = R(\tau), \text{ say,}$$

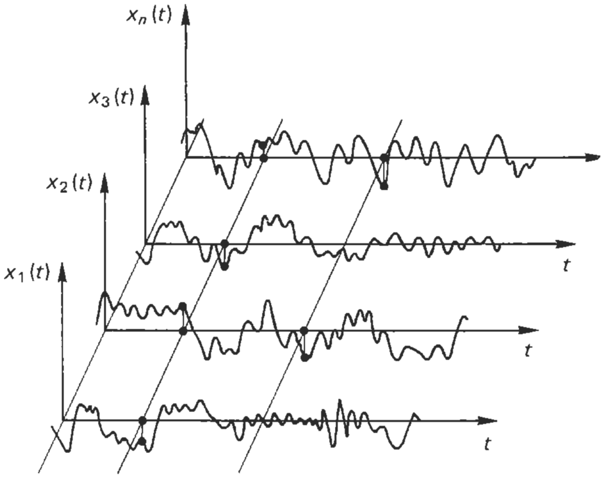

Figure 1.28 Random processes

since the average depends only on time differences. If the process is also ergodic, then

$$R(\tau) = \underset{T \to \infty}{\mathrm{Lt}} \frac{1}{2\pi} \int_{-T}^{T} x(t)x(t + \tau)\mathrm{d}t$$

It is worth noting that

$$R(0) = E[x(t)^2] = \underset{T \to \infty}{\mathrm{Lt}} \frac{1}{2T} \int_{-T}^{T} x^2(t)\mathrm{d}t$$

which is the average power in a sample function.

1.4.3.3 Random processes

The most important random process is the *Gaussian* or *normal random process*. This is because a wide range of physically observed random waveforms can be represented as Gaussian processes, and the process has mathematical features which make analysis relatively straightforward.

The probability density function of a Gaussian process $x(t)$ is

$$p(x) = \frac{1}{\sqrt{2\pi}\,\sigma} \mathrm{e}^{-1/2[(x-\bar{x})/\sigma]^2}$$

where σ is the standard deviation of x and $\bar{x}$ is the mean value of x. The values of σ and $\bar{x}$ may vary with time for a non-stationary process but are independent of time if the process is stationary.

One of the most important features of the Gaussian process is that the response of a linear system to this form of excitation is usually another (but still Gaussian) random process. The only changes are that the magnitude and standard deviation of the response may differ from those of the excitation.

A Gaussian probability density function is shown in Figure 1.29. It can be seen to be symmetric about the mean value $\bar{x}$, and the standard deviation σ controls the spread.

The probability that $x(t)$ lies between $-\lambda\sigma$ and $+\lambda\sigma$, where λ is a positive number, can be found since, if $\bar{x} = 0$,

$$\mathrm{Prob}\{-\lambda\sigma \leqslant x(t) \leqslant +\lambda\sigma\} = \int_{-\lambda\sigma}^{+\lambda\sigma} \frac{1}{\sqrt{2\pi}\,\sigma} \mathrm{e}^{-1/2(x^2/\sigma^2)}\mathrm{d}x$$

Figure 1.30 shows the Gaussian probability density function with zero mean. This integral has been calculated for a range

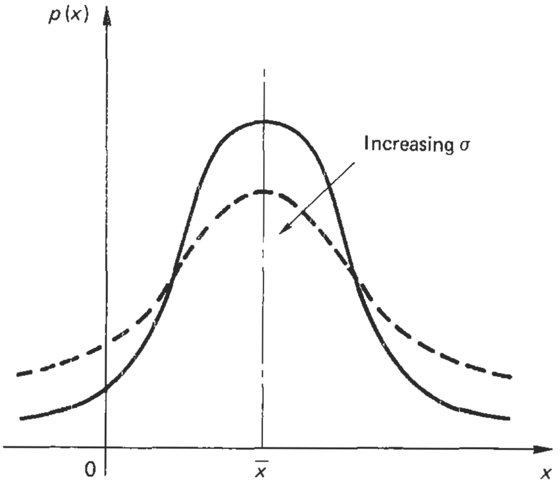

Figure 1.29 Gaussian probability density function

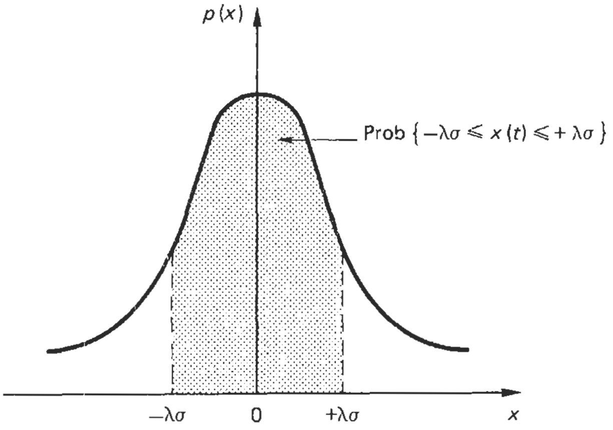

Figure 1.30 Gaussian probability density function with zero mean

of values of λ and the results are given in Table 1.4. The probability that $x(t)$ lies outside the range $-\lambda\sigma$ to $+\lambda\sigma$ is 1 minus the value of the above integral. This probability is also given in Table 1.4.

1.4.3.4 Spectral density

The spectral density $S(\omega)$ of a stationary random process is the Fourier transform of the autocorrelation function $R(\tau)$, and is given by

$$S(\omega) = \frac{1}{2\pi}\int_{-\infty}^{\infty} R(\tau)e^{-i\omega\tau}d\tau$$

The inverse, which also holds true, is

$$R(\tau) = \int_{-\infty}^{\infty} S(\omega)e^{-i\omega\tau}d\omega$$

If $\tau = 0$

$$R(0) = \int_{-\infty}^{\infty} S(\omega)d\omega$$

$$= E[x^2]$$

Table 1.4

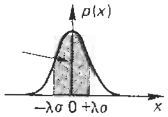
Prob[$-\lambda\sigma \leqslant x(t) \leqslant +\lambda\sigma$]



That is, the mean square value of a stationary random process x is the area under the $S(\omega)$ against frequency curve. A typical spectral density function is shown in Figure 1.31.

A random process whose spectral density is constant over a very wide frequency range is called *white noise.* If the spectral density of a process has a significant value over a narrower range of frequencies, but one which is nevertheless still wide compared with the centre frequency of the band, it is termed a *wide-band process* (Figure 1.32). If the frequency range is narrow compared with the centre frequency it is termed a *narrow-band process* (Figure 1.33). Narrow-band processes frequently occur in engineering practice because real systems often respond strongly to specific exciting frequencies and thereby effectively act as a filter.

1.5 Mechanics of fluids

1.5.1 Introduction

Fluid is one of the two states in which matter can exist, the other being solid. In the fluid state the matter can flow; it will, in general, take the shape of its container. At rest a fluid is not able to sustain shear forces.

Some 'solids' may flow over a long period (glass window panes thicken at the base after a long time in a vertical position). The substances considered in fluid mechanics are those which are continously fluid.

Fluid mechanics is a study of the relationships between the effects of forces, energy and momentum occurring in and around a fluid system. The important properties of a fluid in fluid mechanics terms are *density*, *pressure*, *viscosity*, *surface tension* and, to some extent, *temperature*, all of which are intensive properties.

Density is the mass per unit volume of the substance. *Pressure* is the force per unit area exerted by the fluid on its boundaries. *Viscosity* is a measure of the fluid's resistance to flow and may be considered as internal friction. The higher the coefficient of viscosity, the greater the resistance. *Surface tension* is a property related to intermolecular attraction in the free surface of a liquid resulting in the apparent presence of a very thin film on the surface. The meniscus at the intersection of a liquid and its container wall and capillarity are further examples of intermolecular attraction.

Temperature is more relevant to thermodynamics than to fluid mechanics. It indicates the state of thermal equilibrium between two systems or, more loosely, the level of thermal energy in a system.

1.5.2 Fluid statics

1.5.2.1 Pressure at a depth

The variation of pressure p and depth h in a fluid of density ρ is given by

$$\int_{p_1}^{p_2} \mathrm{d}p = \int_{h_1}^{h_2} \rho g \mathrm{d}h \qquad (1.5)$$

Most liquids are assumed to be of constant density ρ. In such a liquid the pressure at a depth h below a free surface is given by

$$p = p_0 + \rho g h \qquad (1.6)$$

where p_0 is the pressure above the free surface.

For gases equation (1.5) may be solved only if the relationship between ρ and h is known. A typical case is the atmosphere, where the relationship may be taken as polytropic or isothermal, depending on the altitude. Tables relating the properties of the atmosphere to altitude are readily available as the International Atmosphere (Rogers and Mayhew, 1980).

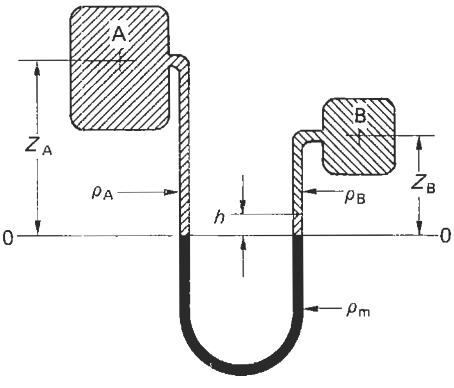
1.5.2.2 Pressure measurement

Pressure may be expressed as a pressure p in Pa, or as a pressure head h in m of the fluid concerned. For a fluid of density ρ, $p = \rho g h$. There are various instruments used to measure pressure.

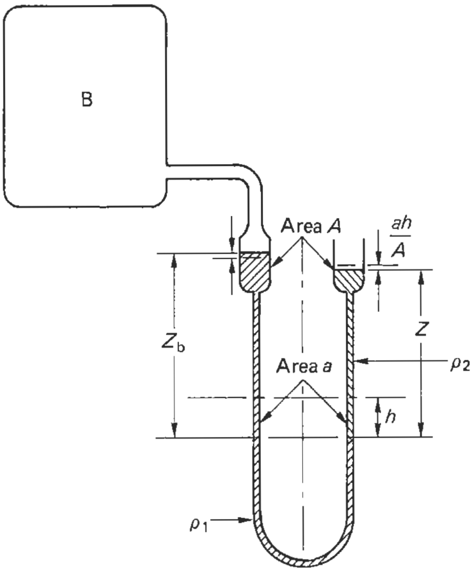
(a) Manometers Manometers are differential pressure-measuring devices, based on pressure due to columns of fluid. A typical U-tube manometer is shown in Figure 1.34(a). The difference in pressure between vessel A containing a fluid of density ρ_A and vessel B containing fluid of density ρ_B is given by

$$p_A - p_B = \rho_B g Z_B + (\rho_m - \rho_B) g h - \rho_A g Z_A \qquad (1.7)$$

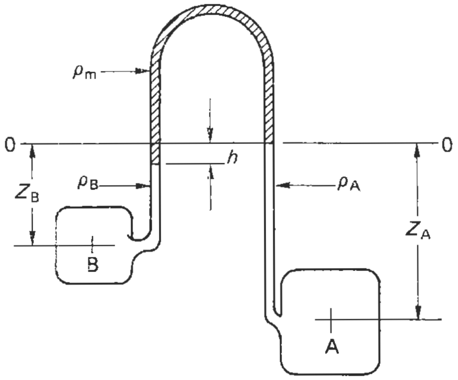
where h is the difference in the levels of the manometer fluid of density ρ_m and $\rho_m > \rho_A$ and $\rho_m > \rho_B$. If $\rho_A = \rho_B = \rho$, then the difference in pressure head is



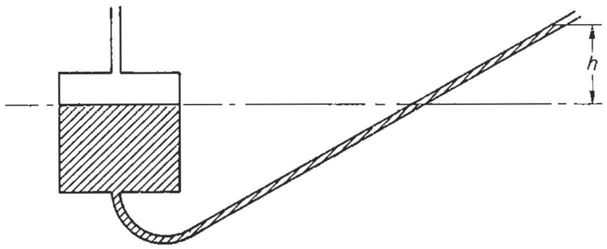
(a) U-tube manometer



(c) Enlarged end manometer



(b) Inverted U-tube manometer



(d) Inclined limb manometer

Figure 1.34

$$\frac{p_A - p_B}{\rho g} = Z_B - Z_A + \left(\frac{\rho_m}{\rho} - 1\right)h \tag{1.8}$$

If $\rho_m < \rho_A$ and $\rho_m < \rho_B$ then an inverted U-tube manometer is used as shown in Figure 1.34(b). In this case the pressure difference is

$$p_A - p_B = \rho_A g Z_A + (\rho_B - \rho_m)gh - \rho_B g Z_B \tag{1.9}$$

and if $\rho_A = \rho_B = \rho$ then the difference in pressure head is

$$\frac{p_A - p_B}{\rho g} = Z_A - Z_B + \left(1 - \frac{\rho_m}{\rho}\right)h \tag{1.10a}$$

of if $\rho_m \ll \rho$ (the manometer fluid a gas and A and B containing liquid),

$$\frac{p_A - p_B}{\rho g} = Z_A - Z_B + h \tag{1.10b}$$

The accuracy of a U-tube manometer may be increased by sloping one of the legs to increase the movement of the fluid interface along the leg for a given difference in vertical height. This may be further enhanced by replacing the vertical leg by a reservoir and the inclined leg by a small-bore tube (Figure 1.34(d)).

Another method is to increase the cross-sectional area of the ends of the legs (or one of the legs), as shown in Figure 1.34(c), so that a small movement of the free surfaces in the enlarged ends results in a large movement of the surface of separation.

(b) Dial gauges Most pressure dial guages make use of a *Bourdon tube*. This is a curved tube with an oval cross section. Increase in pressure causes the tube to straighten, decrease makes it bend. The movement of the free end turns a pointer over a scale, usually via a rack and pinion mechanism. The scale may be calibrated in the required pressure units.

(c) Diaphragm gauges In these gauges the pressure changes produce a movement in a diaphragm which may be detected by a displacement transducer, or by the output from strain gauges attached to the diaphragm surface.

(d) Piezoelectric transducers A piezoelectric crystal produces a voltage when deformed by an external force. This induced

charge is proportional to the impressed force and so the output can be used to supply a signal to a measuring device which may be calibrated in pressure units.

(e) Fortin barometer Barometers are used to measure the ambient or atmospheric pressure. In the Fortin barometer a column of mercury is supported by the atmospheric pressure acting on the surface of the mercury reservoir. The height h of the column above the reservoir surface, usually quoted as millimetres of mercury (mm Hg), may be converted to pressure units p_0 by

$$p_0 = \rho g h = 13.6 \times 9.81 h = 133.42 h \text{ Pa} \qquad (1.11)$$

(f) Aneroid barometer In this device the atmospheric pressure tends to compress an evacuated bellows against the elasticity of the bellows. The movement of the free end of the bellows drives a pointer over a dial (or a pen over a drum graph) to indicate (or record) atmospheric pressure variations.

1.5.2.3 Force due to pressure on an immersed surface

These forces are only relevant if one side of the surface is exposed to a pressure which does not depend on the depth (e.g. the sides of a vessel, an immersed gate or manhole, a dam wall, etc.).

(a) Plane surface The pressure force F_p on the surface area A in Figure 1.35 is

$$F_p = \rho g \bar{h} A \qquad (1.12)$$

where $\bar{h}$ = depth of the centroid of the surface. F_p acts normally to the surface through the point C known as the *centre of pressure*. The distance x_c of C from O, the intersection of the line of the plane of A and the free surface, is given by

$$x_c = \frac{\text{Second moment of area A about O}}{\text{First moment of area A about O}} = \frac{I_0}{A\bar{x}} \qquad (1.13)$$

The depth of the centre of pressure $h_c = x_c \sin\theta$.

The force F_p does not include the pressure above the free surface p_o, since this is often atmospheric and may also act on the opposite side of the immersed surface to F_p. If this is not the case $F_p = (\rho g \bar{h} + p_o)A$.

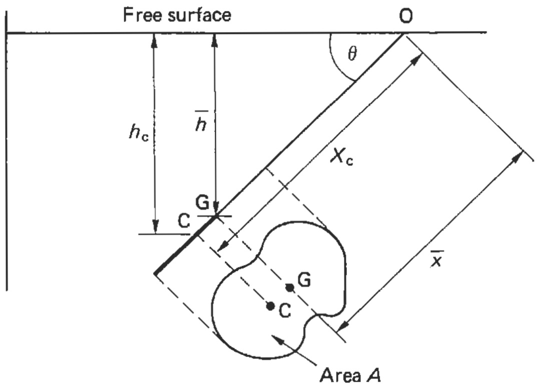


Figure 1.35 Immersed surface (G is centroid, C is centre of pressure)

Table 1.5 Second moments of area

	Parallel axis theorem $I_X = I_G + A\bar{x}^2$	
	Area A	I_G
	BD	$\frac{BD^3}{12}$
	$\frac{BH}{2}$	$\frac{BD^3}{36}$
	$\frac{\pi R^2}{2}$	$0.1102R^4$
	$\frac{\pi D^2}{4}$	$\frac{\pi D^4}{64}$

(b) Concave curved surface The pressure force on an immersed curved surface is found from the resultant F_R of its horizontal F_H and vertical F_V components. For the surface shown in Figure 1.36(a) the vertical force F_V = the weight of fluid above the curve

$$= \rho g A B \qquad (1.14)$$

and acts through G_v the centroid of the volume of liquid above the immersed surface. The horizontal force F_H = the pressure force on the projected area of the immersed surface in the vertical plane

$$= \rho g \bar{h}_{C_P} A_P \qquad (1.15)$$

and acts through the centre of pressure C_P of the projected area.

The resultant pressure force on the curved surface F_R is given by

$$F_R = (F_H^2 + F_V^2)^{0.5} \qquad (1.16)$$

The angle of inclination α of F_R to the horizontal is given by

$$\alpha = \tan^{-1}\left(\frac{F_V}{F_H}\right) \qquad (1.17)$$

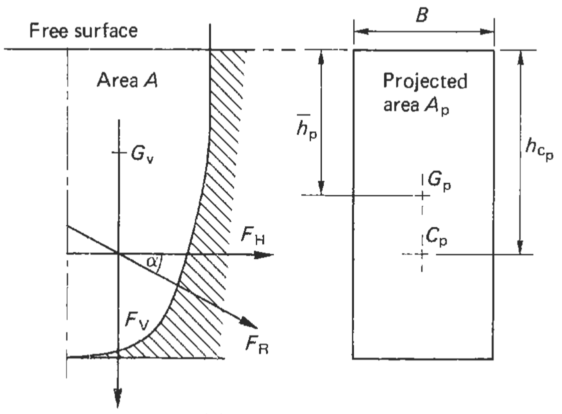
or

$$F_R = \bar{F}_H + \bar{F}_V \qquad (1.18)$$

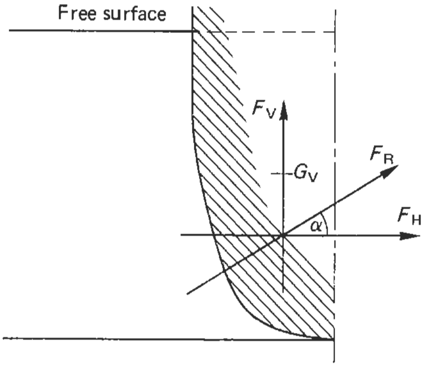
(c) Convex curved surface This is as a concave surface, except that F_V is the *buoyancy* force of the displaced volume of liquid above the immersed surface and acts vertically upwards through the centre of buoyancy (see Figure 1.36(b)).

1.5.2.4 Buoyancy

When a body is immersed in a fluid the difference in pressure over the depth of the body produces a displacement force on



(a) Concave curved surface



(b) Convex surface

Figure 1.36

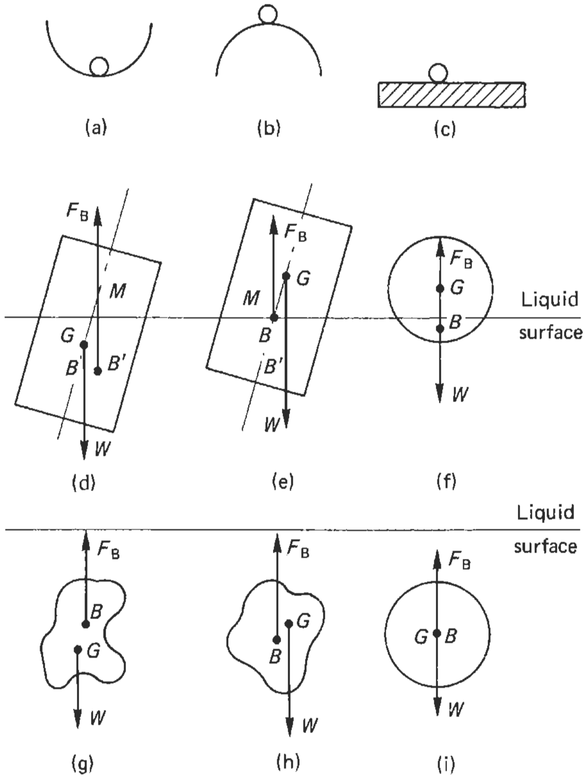


Figure 1.37 Stability

the body. The first recognition of this is attributed to Archimedes.

(a) Displacement force The buoyancy or displacement force F_B on a body fully or partially immersed in a fluid is equal to the weight of the volume of the fluid equivalent to the immersed volume of the body (the weight of the displaced volume V_D of the fluid):

$$F_B = \rho g V_D \tag{1.19}$$

This buoyancy force acts vertically upwards through the centroid of the displaced volume, which is known as the *centre of buoyancy (B)*. If the buoyancy force is equal to the weight of the body then the body will float in the fluid. If the weight of the body is greater than the buoyancy force then the body will sink. If the buoyancy force is greater than the weight of the body then the body will rise.

In a liquid, for example, a body will sink until the volume of liquid displaced has a weight which is equal to that of the body. If the body is more dense than the liquid then the body will not float at any depth in the liquid. A balloon will rise in air until the density of the air is such that the weight of the displaced volume of air is equal to the weight of the balloon.

(b) Stability of a floating body Figure 1.37 shows bodies in various stages of equilibrium. A body is in *stable* equilibrium if a small displacement produces a restoring force or moment as for the ball in the saucer in Figure 1.37(a) or the floating bodies in (d) and (g). A body is in *unstable* equilibrium if a small displacement produces a disturbing force or moment as for the ball in Figure 1.37(b) or the floating bodies (e) and (h). A body is in *neutral* equilibrium if a small displacement produces no force or moment as for the ball in Figure 1.37(c) or the floating bodies in (f) and (i).

For a partially immersed body, the point at which the line of action of the buoyancy force F_B cuts the vertical centre line of the floating body in the displaced position is known as the *metacentre* (M). For a floating body to be stable M must lie above the body's centre of gravity, G. If M lies below G the body is unstable; if M lies on G the body is in neutral equilibrium. The distance GM is known as the *metacentric height*. The distance of the metacentre above the centre of buoyancy

$$BM = \frac{I}{V_D} \tag{1.20}$$

where I = second moment of area of the body at the water line (liquid surface) about its central axis normal to the direction of displacement.

(c) Period of oscillation of a stable floating body A floating body oscillates with the periodic time T of a simple pendulum of length k^2/GM, where k is the radius of gyration of the body about its axis of rotation. The periodic time is given by

$$T = 2\pi\left(\frac{k^2}{GMg}\right)^{0.5} \tag{1.21}$$

1.5.3 Fluid flow

1.5.3.1 Definitions

(a) Continuity For almost all analysis, a fluid is considered to be a *continuum*, that is, with non-discontinuities or cavities in the flow stream. Cavitation, two-phase flow, 'bubbly' flow, etc. are special cases with non-standard relationships.

Therefore for a continuum, by considering the flow through an elemental cuboid the *continuity equation* in three dimensions may be shown to be

$$\frac{\partial}{\partial x}(\rho v_x) + \frac{\partial}{\partial y}(\rho v_y) + \frac{\partial}{\partial z}(\rho v_z) = 0 \qquad (1.22)$$

where v_x is the fluid velocity in the x direction, etc. For a fluid of constant density

$$\frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} + \frac{\partial v_z}{\partial z} = 0 \qquad (1.23)$$

That is, the velocity of an incompressible fluid flow cannot increase in all three directions at the same time without producing discontinuity or cavitation.

For two-dimensional flow:

$$\frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} = 0 \qquad (1.24)$$

For one-dimensional flow the continuity equation may be linked with the *conservation of mass*, which states that for steady flow conditions mass flow rate, $\dot{m}$, is constant throughout a flow system:

$$\dot{m} = \rho A v \qquad (1.25)$$

where A is the cross-sectional area normal to the direction of flow.

(b) Circulation Γ Circulation is defined as the line integral of the tangential velocity around a closed contour:

$$\Gamma = \oint v_s \mathrm{d}s \qquad (1.26)$$

Γ is positive if the closed contour is on the left.

(c) Vorticity ζ Vorticity is defined as the circulation per unit area, and by considering the circulation around the element in Figure 1.38(a) it can be shown that

$$\zeta = \frac{\Gamma}{\partial x \partial y} = \frac{\partial v_y}{\partial x} - \frac{\partial v_x}{\partial y} \qquad (1.27)$$

(d) Rotation ω Rotation is defined as the instantaneous mean angular velocity of two mutually perpendicular lines in a plane of the flow field. By considering the angular velocities of the two lines OA and OB in Figure 1.38(b) it can be shown that

$$\omega = \frac{1}{2}\left(\frac{\partial v_y}{\partial x} - \frac{\partial v_x}{\partial y}\right) \qquad (1.28)$$

or the rotation is equal to half the vorticity.

(e) Stream lines The stream line is a line drawn in a flow stream which is everywhere tangential to the direction of flow. A family of stream lines may be described mathematically by a stream function ψ, where $\psi = \mathrm{fn}(x,y)$. Each stream line has the same function with a value of ψ peculiar to that line.

(f) Stream tubes Since a line has no thickness, there can be no flow along a stream line. The stream tube is a concept introduced to enable flow along a stream line to be studied. It is a tube of infinitely small cross section with a stream line as its axis.

(b) Rotation

Figure 1.38

(g) Energy Energy is the stored form of *heat* and *work*. The basic concepts applied in fluid mechanics are:

- The conservation of energy
- That energy is transferred only as heat or work
- That energy in a fluid flow system is stored only as *internal energy*, *kinetic energy* or *potential energy*.

Other forms of energy (electrical, magnetic, chemical, etc.) may have to be taken into account in some circumstances, but are not usually included in general fluid mechanics relationships.

Enthalpy and *entropy* need to be considered for gas flow analysis (see Section 1.5.8). The basic energy-flow equation is the *steady-flow energy equation*:

$$\dot{Q} + \dot{W} = \dot{m}\Delta\left(h + \frac{v^2}{2} + gZ\right) \qquad (1.29)$$

where $\dot{Q}$ is the rate of heat transfer,
$\dot{W}$ is the rate of work transfer (power),
h is the specific enthalpy (if e is the specific internal energy, p the pressure and ρ the fluid density, then $h = e + (p/\rho)$),

Z is the height above some datum,
v is the mean velocity of flow.

Specific means 'per unit mass'. For non-steady flow conditions, either *quasi-steady* techniques or the integration of infinitely small changes may be employed.

(h) Momentum Momentum is the product of mass and velocity (mv). Newton's laws of motion state that the force applied to a system may be equated to the rate of change of momentum of the system, in the direction of the force. The change in momentum may be related to time and/or displacement. In a steady flow situation the change related to time is zero, so the change of momentum is usually taken to be the product of the mass flow rate and the change in velocity with displacement. Hence the force applied across a system is

$$F = \dot{m}\Delta v \tag{1.30}$$

where Δv is the change in velocity in the direction of the force F.

For flow in two or three dimensions the resultant force may be obtained by resolving the forces in the usual way. The flow round an expanding bend shown in Figure 1.39 is a typical example. The force in the x direction, F_x, and the force in the y direction, F_y, are given by

$$F_x = p_1A_1 + \dot{m}v_1 - (p_2A_2 + \dot{m}v_2)\cos\theta \tag{1.31a}$$

$$F_y = -(p_2A_2 + \dot{m}v_2)\sin\theta \tag{1.31b}$$

from which the resultant force F_R and its angle of inclination α can be found:

$$F_R = \{F_x^2 + F_y^2\}^{0.5} \tag{1.32}$$

and

$$\alpha = \tan^{-1}\left(\frac{F_y}{F_x}\right) \tag{1.33}$$

In pipe flow the pressure forces pA must not be forgotten.

1.5.3.2 Equations of motion

Application of the momentum equation in three dimensions to an irrotational, inviscid fluid flow leads to the *Euler equation*:

$$-\frac{Dv}{Dt} = \frac{1}{\rho}\nabla p + g\nabla h \tag{1.34}$$

which for steady flow along a stream tube becomes:

$$\frac{1}{\rho}\,dp + v\,dv + g\,dZ = 0 \tag{1.35}$$

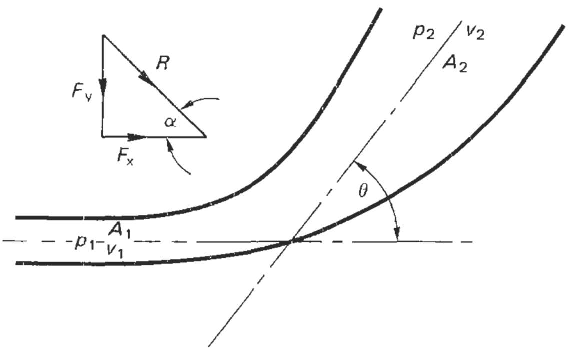

Figure 1.39 Expanding bend

Integration for a constant-density fluid gives:

$$\frac{p}{\rho} + \frac{v^2}{2} + gZ = \text{constant} \tag{1.36}$$

These energy per unit mass terms may be converted to energy per unit weight terms, or heads, by dividing by g to give:

$$\frac{p}{\rho g} + \frac{v^2}{2g} + Z = \text{constant} \tag{1.37}$$

which is the *Bernoulli* (or constant head) equation.

These equations are the generally more useful simplifications of the *Navier–Stokes* equation:

$$\frac{Dv}{Dt} = \rho B - \nabla p + \nabla\{u(\nabla v + \nabla\epsilon)\} \tag{1.38}$$

where B is the body force and ϵ the rate of expansion.

1.5.3.3 Incompressible pipe flow

(a) Flow regimes The two major flow regimes are *laminar* and *turbulent*. Laminar flow may be fairly accurately modelled mathematically. The fluid moves in smooth layers and the velocity is everywhere tangential to the direction of motion. Any perturbations are quickly dampened out by the fluid viscosity.

In turbulent flow the mathematical models usually need to be empirically modified. Viscous damping may not be sufficient to control the perturbations, so that the fluid does not move in smooth layers and the instantaneous velocity may have components at an angle to the direction of motion.

The ratio of inertia forces to viscous forces in a fluid flow is known as *Reynolds' Number* (Re). In a pipe diameter D, with a fluid of density ρ and dynamic viscosity η flowing with velocity v, Reynolds' number $Re = \rho Dv/\eta$.

A high value of $Re > 2300$ indicates relatively low damping, predicting turbulent flow. A low value of $Re < 2000$ indicates relatively high damping, predicting laminar flow. These values were suggested in an historical experiment by Osborne Reynolds.

(b) Pipe losses (friction) Liquids (and gases under small pressure changes) flowing through pipes usually behave as incompressible fluids. Within the flow there is a relationship between the shear stress in the fluid and the gradient of the change of velocity across the flow. In most light liquids and gases, the relationship approximates to the *Newtonian* one:

$$\tau = \eta\frac{dv}{dy} \tag{1.39}$$

where τ is the shear stress in the fluid, dv/dy the gradient of the velocity distribution across the pipe and η the dynamic viscosity.

The viscosity of the fluid produces not only the velocity variation across the flow but also a loss of energy along the pipe usually regarded as a friction loss. The force associated with this loss of energy appears as a shear force in the fluid at the pipe wall. A relationship between the shear stress at the pipe wall τ_0 and the *friction coefficient*, f is:

$$\tau_0 = \frac{1}{2}\rho v^2 f \tag{1.40}$$

where v is the average flow velocity.

For use in pipe flow problems with viscous fluids the Bernoulli equation (1.37) may be adapted to incude a head loss term, h_L. Applied between two positions (1) and (2) in a pipe, the head equation gives:

$$\frac{p_1}{\rho g} + \frac{v_1^2}{2g} + Z_1 = \frac{p_2}{\rho g} + \frac{v_2^2}{2g} + Z_2 + h_L \tag{1.41}$$

where the head loss term h_L is the loss of energy per unit *weight* of fluid flowing.

Note that if a pump, say, is introduced between (1) and (2) an energy gain per unit weight term h_w, equivalent to the output of the pump written as a head, should be added to the left-hand side of the equation to give

$$\frac{p_1}{\rho g} + \frac{v_1^2}{2g} + Z_1 + h_w = \frac{p_2}{\rho g} + \frac{v_2^2}{2g} + Z_2 + h_L \tag{1.42}$$

The relationship used to determine the head loss in a pipe depends on the flow regime in operation as well as the type and surface finish of the pipe wall.

A mathematical analysis of laminar flow may be used to obtain an expression for the head loss along a pipe in terms of the fluid properties, pipe dimensions and flow velocity. Relating the pressure change along a length, L, of pipe of diameter, D, to the change in shear force across the flow produces *Poiseuille's equation*:

$$h_L = 32\frac{\eta v L}{\rho g D^2} \tag{1.43}$$

If the flow regime is turbulent, then the relationships in the flow cannot be easily described mathematically, but the head loss may be derived by equating the shear force at the pipe wall to the change in pressure force along the pipe. This gives the *D'Arcy* equation:

$$h_L = \frac{4fL}{D}\frac{v^2}{2g} \tag{1.44}$$

This relationship may also be established using dimensional analysis.

Unfortunately, the friction coefficient, f is *not* a constant but depends on the type of flow and the roughness of the pipe walls. There are general relationships between f and Re which may be expressed as equations of varying complexity or as charts. For smooth pipes:

$$\frac{1}{\sqrt{f}} = 4\log_{10}(2R_e\sqrt{f}) - 1.6 \tag{1.45}$$

For rough pipes with a roughness size k this becomes:

$$\frac{1}{\sqrt{f}} = 4\log_{10}\left(\frac{D}{2k}\right) + 3.48 \tag{1.46}$$

The *Colebrook and White* equation is a general or universal friction equation:

$$\frac{1}{\sqrt{f}} = 3.47 - 4\log_{10}\left(\frac{2r}{D} + \frac{9.35}{Re\sqrt{f}}\right) \tag{1.47}$$

It is, however, usually more useful to obtain values of f from a chart such as Figure 1.40. (*Note*: the value of f used in American equations for head losses is *four times* that used in the United Kingdom, so if values of f are obtained from American texts they should be moderated accordingly or the corresponding American equation used.)

An empirical relationship widely used in water pipe work is the *Hazen–Williams* equation, usually written as:

$$v = 1.38\, C\, m^{0.63}\left(\frac{h_L}{L}\right)^{0.54} \tag{1.48}$$

where m is the ratio of the cross-sectional area of flow to the wetted perimeter known as the *hydraulic mean diameter* and C is a coefficient which depends on the condition of the pipe wall.

(c) Pipe losses (changes in section) When a fluid flows through a sharp (sudden) change in the cross section of a pipe, energy is dissipated in the resulting turbulent eddies at the edge of the flow stream, producing a loss of head (or energy per unit weight). If the flow is from a smaller area to a larger one (sudden enlargement) the head loss is

$$h_L = \frac{(v_1 - v_2)^2}{2g} \tag{1.50}$$

When the flow is from a larger area to a smaller area (sudden contraction) the narrowed flow stream entering the smaller pipe is known as a *vena contracta*. The loss of head is assumed to be that due to a sudden enlargement from the vena contracta to the full area of the smaller pipe:

$$h_L = \frac{v_2^2}{2g}\left(\frac{1}{C_c} - 1\right)^2 \tag{1.51}$$

The *contraction coefficient*, C_c, is the ratio of the vena contracta area to that of the smaller pipe area. A typical value of C_c is 0.6, which gives

$$h_L \simeq = 0.5\frac{v_2^2}{2g} \tag{1.52}$$

which is also the head loss at the sharp entry to a pipe from a reservoir. Energy dissipation at changes in section, and pipe entry and exit, may be reduced by making the changes smooth and gradual, though this may be relatively costly.

Other pipe fittings, such as valves, orifice plates and bends, produce varying values of head loss, usually quoted as a fraction of the velocity head ($v^2/2g$).

(d) Pipe networks A system of pipes may be joined together either in series (one after the other) or parallel (all between the same point). The friction head loss across a system of pipes in series is the sum of the losses along each pipe individually. The flow rate through each pipe will be the same. Using D'Arcy's head loss equation:

$$h_L = 4f_1\frac{L_1v_1^2}{D_12g} + 4f_2\frac{L_2v_2^2}{D_22g} + \ldots 4f_n\frac{L_nv_n^2}{D_n2g} \tag{1.53}$$

and

$$\dot{V} = v_1A_1 = v_2A_2 = \ldots = v_nA_n \tag{1.54}$$

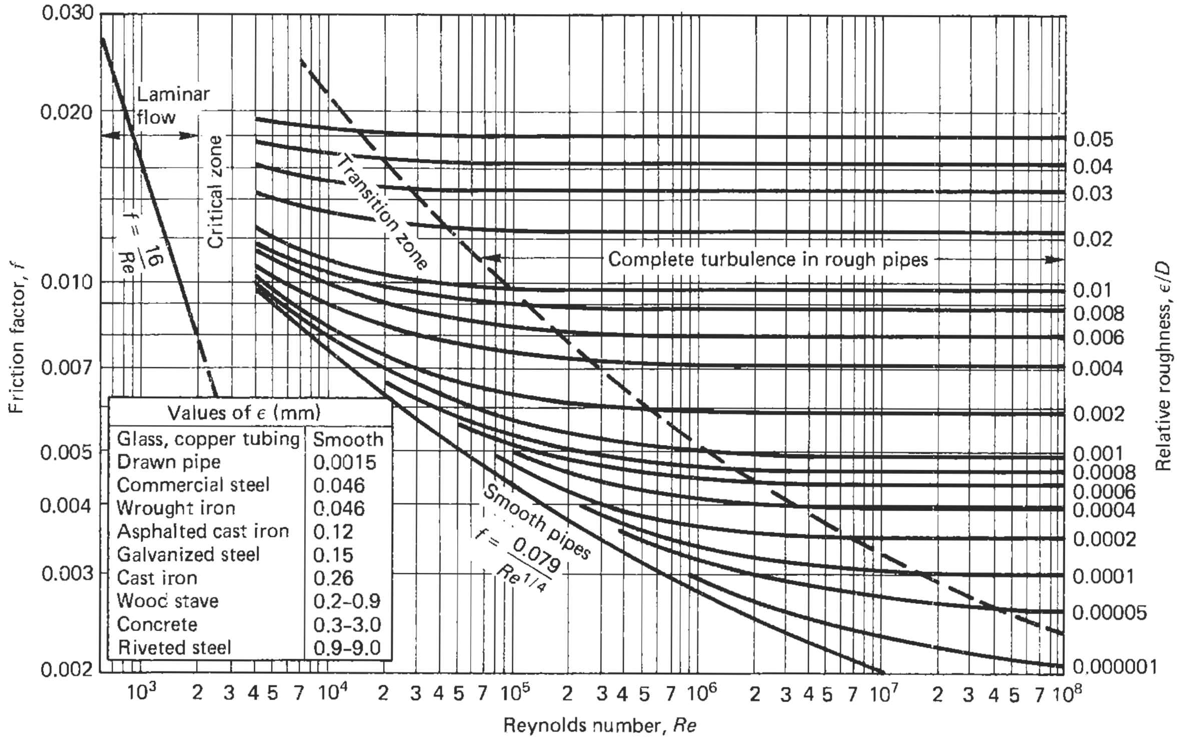
If the system of pipes is connected in parallel the head loss across the system is equal to the head loss along any one of the pipes, when the flow has settled down to steady. The flow rate through the system is the sum of the flow rates along each pipe. Again using the D'Arcy equation:

$$h_L = 4f_1\frac{L_1v_1^2}{D_12g} = 4f_2\frac{L_2v_2^2}{D_22g} = \ldots = 4f_n\frac{L_nv_n^2}{D_n2g} \tag{1.55}$$

$$\dot{V} = v_1A_1 + v_2A_2 + \ldots v_nA_n \tag{1.56}$$

In addition, the rate of flow into each junction of a network, either in series or parallel, is equal to the rate of flow out of it.

Pipe network problems are thus solved by setting up a number of such equations and solving them simultaneously. For a large number of pipes a computer program may be needed to handle the number of variables and equations. An example of a pipe network computer solution is given in Douglas *et al.* (1986).



Values of ε (mm)	
Glass, copper tubing	Smooth
Drawn pipe	0.0015
Commercial steel	0.046
Wrought iron	0.046
Asphalted cast iron	0.12
Galvanized steel	0.15
Cast iron	0.26
Wood stave	0.2–0.9
Concrete	0.3–3.0
Riveted steel	0.9–9.0

Figure 1.40

1.5.4 Flow measurement

1.5.4.1 Pipe flow

One very accurate measure of flow rate is to catch the discharge in a bucket over a known time and then weigh it. This method, made more sophisticated by the electronic timing of the balancing of a tank on a weighbridge, is often used to calibrate other devices, but may not always be acceptable.

(a) Orifices and nozzles (see Figure 1.41(a)) Another basic flow measurement technique is to introduce some restriction into the flow passage and calibrate the resulting pressure changes against known flow rates.

Often the restriction in a pipe is in the form of an *orifice plate* (a plate with a hole) or a *nozzle*. A simple application of the Bernoulli equation may be used for the design calculations, but it is always advisable to calibrate any measurement device in conditions as close to the required operating conditions as possible.

Bernoulli and the continuity equations give the flow rate:

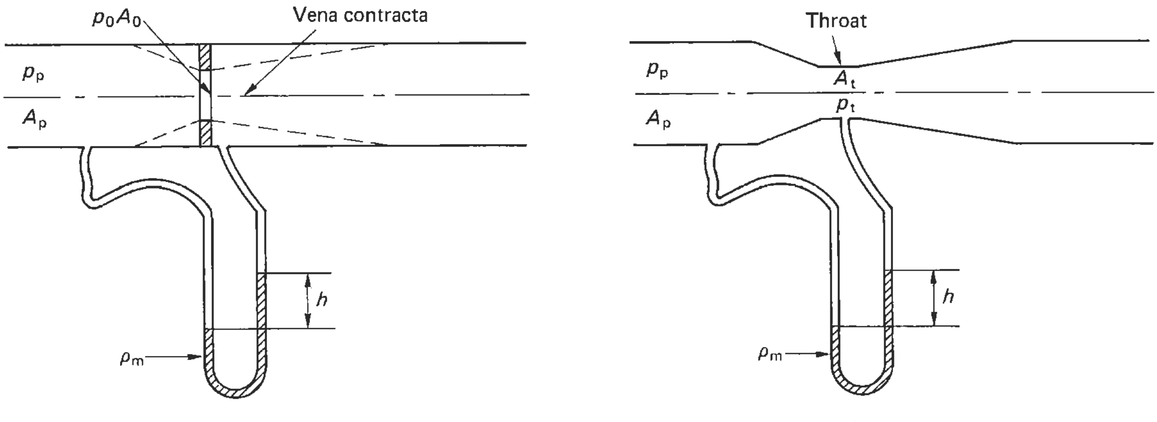
$$\dot{V} = C_d A_o \left\{ \frac{2(p_p - p_o)}{\rho[1 - (A_o/A_p)^2]} \right\}^{0.5} \qquad (1.57)$$

where A_o is the orifice (or nozzle throat) area,
A_p is the upstream pipe area,
p_p is the upstream pressure,
p_o is the pressure at the orifice or the nozzle throat, and
C_d is a discharge coefficient which takes account of losses and contraction of the flow stream through the device.

Recommended orifice and nozzle dimensions, values of C_d and methods of operation are contained in BS 1042. It is most important to place the orifice or nozzle so that its operation is not affected by perturbations in the upstream flow caused by valves, bends or other pipe fittings.

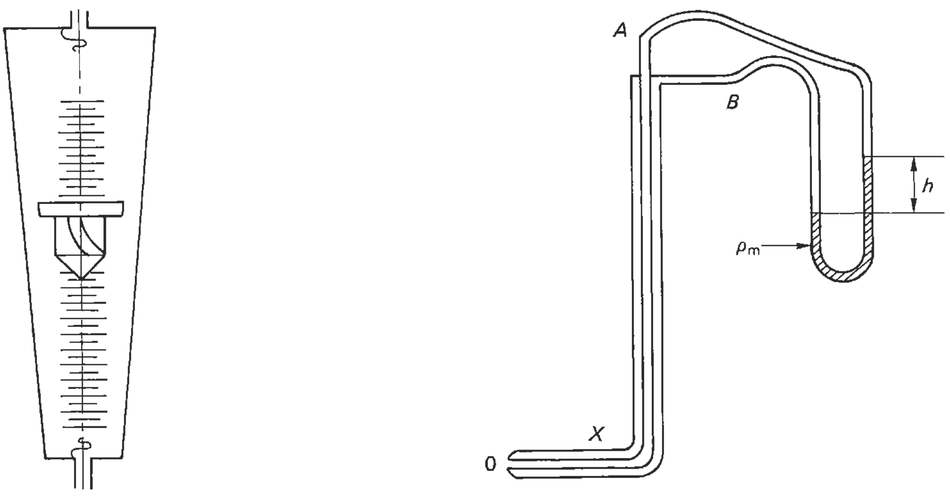
(b) Venturi meters (see Figure 1.41(b)) The introduction of any restriction, particularly a sharp-edged orifice or nozzle, in a pipe will result in a loss of head (energy). If it is required to keep this loss to a minimum, a *venturi meter* may be used. The flow passage in a venturi is gradually and smoothly reduced to a throat followed by a controlled expansion to full pipe section. In this way the head loss across the meter is greatly reduced, but the cost of producing a venturi meter is much higher than that of an orifice. Equation (1.57) may be used to calculate the flow rate $\dot{V}$, but the value of C_d will now be approximately 0.98 for a well-designed venturi meter. Again, BS 1042 should be consulted for recommended dimensions, values of C_d and methods of operation.

(c) Rotameter or gap meter (see Figure 1.41(c)) If, somewhere within the system, it is acceptable to tolerate flow up a vertical section of piping, then a *rotameter* or *gap meter* may be used. This instrument depends on the balancing of the weight of a rotating float in a tapered glass tube with the drag forces in the annular passage surrounding the float. The drag forces depend on the flow rate and the corresponding area of the annulus. As the flow rate increases, the annulus area which will produce a drag force equal to the weight of the float also increases. Therefore the float moves up the tapered tube until the annulus area is such that the forces again balance. As the flow rate decreases the float descends to a reduced annulus area to again achieve a balance of forces.



(a) Orifice plate

(b) Venturi meter



(c) Rotameter or gap meter

(d) Pitot-static tube

Figure 1.41 Flow meters

(d) Velocity meter These are devices which measure velocity and not flow rate directly. *Pitot* and *Pitot-static* tubes are examples of such velocity-measuring instruments, making use of the pressure difference between the undisturbed flow stream and a point where the flow velocity is zero. They consist of two concentric tubes bent into an L shape as in Figure 1.41(d), with the outer tube joined to the inner at the toe of the L, at O. This end is usually spherical with a hole through to the inner tube. The undisturbed flow is assumed to be in the region of the holes round the periphery of the outer tube at X. The velocity is assumed zero at the spherical end presented to the flow, at O.

The flow velocity, v may be calculated by applying Bernoulli's equation between the two points O and X to give

$$v = C_v\left[2\frac{(p_o - p_x)}{\rho}\right]^{0.5} \tag{1.58}$$

where p_o is connected to O via the inner tube to the tapping at A, p_x is connected to X via the outer tube to the tapping at B and C_v is a coefficient to cater for losses and disturbances not accounted for in Bernoulli's equation. C_v is often taken to be unity.

The pressure difference may be measured using a manometer and then written into equation (1.58) as a head, h, to give

$$v = \left[2gh\left(\frac{\rho_m}{\rho} - 1\right)\right]^{0.5} \tag{1.59}$$

As usual, it is advisable to calibrate the tube and obtain a calibration curve or an accurate value for C_v. BS 1042 should be consulted for operational instructions and placement advice.

Care should be taken when a pitot-static tube is used to measure pipe flow, since the velocity will vary across the pipe. As a rough guide to the flow rate the maximum velocity, which is at the centre of the pipe, may be taken to be twice the average velocity. Alternatively, the velocity at half the radius may be taken to be equal to the average velocity in the pipe. For an accurate evaluation the velocity distribution curve may be plotted and the flow rate through the pipe found by integration. This may be approximated to by dividing the cross section into a series of concentric annuli of equal thickness, measuring the velocity at the middle of each annulus, multiplying by the corresponding annulus area and adding to give the total flow rate.

Current meters, torpedo-shaped devices with a propeller at the rear, may be inserted into pipes. The number of rotations of the propeller are counted electrically. This number together with coefficients peculiar to the propeller are used in empirical equations to determine the velocity. These meters are more often used in open channels (see Section 1.5.4.2).

Velometers, *vaned anemometers* and *hot wire anemometers* are not usually used to measure the velocities of incompressible fluids in pipes, and will be discussed in Section 1.5.8.

1.5.4.2 Open-channel flow

(a) Velocity meters In channels of regular or irregular cross section the flow may be measured using the velocity meters described in Section 1.5.4.1(d) (current meters are often used in rivers or large channels). For this method the cross section is divided into relatively small regular areas, over which the velocity is assumed to be constant. The velocity meter is then placed at the centre of each small area, and from the velocity and area the flow rate may be calculated. Adding together the flow rates for all the small areas gives the flow rate for the channel.

It should be noted that in open channels the velocity varies with depth as well as with distance from the channel walls. Selection of the shape and location of the small areas need to take this into account.

(b) Notches, flumes and weirs As in pipe flow, flow rates in channels may be related to changes in head produced by obstructions to the flow. These obstructions may be in the form of notches, flumes or weirs and change in head observed as a change in depth of fluid. Notches may be rectangular, V-shaped, trapezoidal or semi-circular. Weirs may be sharp-edged or broad-crested. Flumes are similar to venturis, with a controlled decrease in width to a throat followed by a gradual increase to full channel wdith. They are often known as venturi flumes. For most of these devices there is a simplified relationship between the flow rate $\dot{V}$ and the upstream specific energy e:

$$\dot{V} = K\,e^{n} \qquad (1.60)$$

where K is a coefficient which may be constant for a particular type of device (and for a specific device). The index n is approximately 1.5 for rectangular notches, weirs and flumes, and 2.5 for V-notches. The specific energy e is the sum of the depth and the velocity head:

$$e = \frac{v^2}{2g} + D \qquad (1.61)$$

In many applications, particularly at the exit of large tanks or reservoirs, the upstream (or approach) velocity may be negligible and e becomes equal to either the depth D or the head above the base of the notch or weir H.

For a V-notch of included angle 2θ:

$$\dot{V} = 2.36C_d(\tan\theta)H^{2.5} \qquad (1.62)$$

For a 90° notch:

$$\dot{V} = 2.36C_dH^{2.5} \qquad (1.63)$$

For a rectangular notch of width B:

$$\dot{V} = 2.953C_dBH^{1.5} \qquad (1.64)$$

The empirical *Francis* formula may be applied to sharp-edged weirs and rectangular notches:

$$\dot{V} = 2.953C_d(B - 0.2H)\left[e^{1.5} - \left(\frac{v^2}{2g}\right)^{1.5}\right] \qquad (1.65)$$

or neglecting the approach velocity:

$$\dot{V} = 2.953C_d(B - 0.2H)H^{1.5} \qquad (1.66)$$

For a venturi flume of throat width B, or a broad-crested weir of width B, the same equation applies:

$$\dot{V} = 1.705C_dB\,e^{1.5} \qquad (1.67)$$

Since the value of e depends on the approach velocity v, which in turn depends on the flow rate $\dot{V}$, equations (1.65) and (1.67) are usually solved by an iterative method in which the first estimation of the approach velocity v is zero. Successive values of v are found from the upstream flow cross-sectional area and the preceding value of $\dot{V}$, the resulting value of e is then used in equation (1.67) for $\dot{V}$. This is repeated until there is little change in the required values. The discharge coefficient C_d in each of the flow equations (1.62) to (1.67) has a value of about 0.62.

As before, it is much more accurate to calibrate the device. For convenience, the calibration curves often plot the flow rate against the upstream depth.

(c) Floats In large rivers, where it is inconvenient to install flumes or weirs, or to use velocity meters, floats may be used. The timing of the passage of the floats over a measured distance will give an indication of the velocity. From the velocity, and as accurate a value of cross-sectional area as possible, the flow can be estimated.

(d) Chemical dilution In large, fast-flowing rivers chemical dilution may be the only acceptable method of flow measurement. The water is chemically analysed just upstream of the injection point and the natural concentration C_1 of the selected chemical in the water established. The concentration of the chemical injected is C_2 and the injection rate is R_i. Analysis of the water again at some distance downstream of the injection point determines the new concentration C_3 of the chemical. The flow rate $\dot{V}$ along the river may be estimated from

$$\dot{V} = R_i\left(\frac{C_2 - C_3}{C_3 - C_1}\right) \qquad (1.68)$$

1.5.5 Open-channel flow

An open channel in this context is one containing a liquid with a free surface, even though the channel (or other duct) may or may not be closed. A pipe which is not flowing full is treated as an open channel.

1.5.5.1 Normal flow

Normal flow is steady flow at constant depth along the channel. It is not often found in practice, but is widely used in the design of channel invert (cross section) proportions.

(a) Flow velocity The average velocity, v, of flow in a channel may be found by using a modified form of the D'Arcy head loss equation for pipes, known as the *Chezy* equation:

$$v = C(mi)^{0.5} \qquad (1.69)$$

C is the Chezy coefficient, a function of Reynolds' number Re and the friction coefficient f for the channel wall and i is the gradient of the channel bed. C may be obtained from tables or from the *Ganguillet and Kutter* equation or (more easily) the *Bazin* formula:

$$C = \frac{86.9}{1 + km^{-0.5}} \tag{1.70}$$

where k is a measure of the channel wall roughness, typical values are shown in Table 1.6. m is the ratio of the cross-sectional area of flow to the wetted perimeter (the length around the perimeter of the cross section in contact with liquid), known as the *hydraulic mean depth*.

A widely used alternative modification of the D'Arcy equation is the *Manning* equation:

$$v = Mm^{0.67}i^{0.5} \tag{1.71}$$

where M is the Manning number which depends, like the Chezy coefficient, on the condition of the channel walls. Values of M are tabulated for various channel wall materials (see Table 1.6). Some texts use Manning number $n = 1/M$.

The Chezy coefficient, C, the Manning number, M, and the roughness factor k used in equations (1.69)–(1.71) are *not* dimensionless. The equations and the tables are written in SI units and they must be modified for any other system of units.

(b) Optimum dimensions In order to produce the maximum flow rate in normal flow with a given cross-sectional area, the optimum channel shape is semi-circular. However, particularly for excavated channels, a semi-circular shape may be expensive to produce. It is easier and much cheaper to dig a rectangular or trapezoidal cross section. The optimum dimensions are: for the rectangular channel, when the width is twice the depth; for the trapezium, when the sides are tangential to a semi-circle. In both cases the hydraulic mean depth m will be equal to half the liquid depth, as for the semi-circular section.

The *maximum flow rate* through a circular pipe not flowing full will occur when the depth of liquid at the centre is 95% of the pipe diameter. The *maximum average velocity* will be achieved when the depth of liquid at the centre is 81% of the pipe diameter.

1.5.5.2 Non-uniform flow

In most instances of real liquids flowing in real channels the depth D of the liquid will vary along the length L of the channel with the relationship

$$\frac{dD}{dL} = \frac{i - j}{1 - (v^2/gD)} \tag{1.72}$$

where j is the slope of the *total energy line* (the plot of the total energy per unit weight against length). The total energy per unit weight is $(e + Z)$ at any point in the channel where the bed is at a height Z above the datum. Therefore if $i = j$ the depth is constant with L, normal flow conditions obtain and the slope of the channel i is the same as the slope of the energy line. v^2/gD is a dimensionless quantity known as *Froude's* number (Fr).

If $v = (gD)^{1/2}$, then $Fr = 1$, and from equation (1.72) the rate of change of depth with length (dD/dL) becomes infinite, which is the required condition for a *standing wave* or *hydraulic leap* to be formed in the channel (see Figure 1.42). The standing wave is a sudden increase in depth as the flow velocity is reduced from fast to slow (*supercritical* to *subcritical*), usually by channel friction or some obstruction such as a weir. The *critical velocity* v_c and the *critical depth* D_c are those which correspond to a Froude number of unity.

This phenomenon may also be explained by considering a graph of specific energy e against depth D (Figure 1.43). At the minimum value of e on the graph there is only one value of D, namely D_c, the critical depth. For a particular flow rate in a given channel it can be seen that any value of e above the minimum corresponds to two values of D. The higher value of D represents slow flow, the lower value represents fast flow. As the flow changes from fast to slow it passes through the critical value and a standing wave is formed (Figure 1.42).

The ratio of the downstream depth D_2 to the upstream depth D_1 across the standing wave is given by

$$\frac{D_2}{D_1} = \left(0.25 + \frac{2v_1^2}{gD_1}\right)^{0.5} - 0.5 \tag{1.73}$$

and the loss of energy per unit weight or head loss by

$$h_L = \frac{(D_2 - D_1)^3}{4D_1D_2} \tag{1.74}$$

Table 1.6

Type of channel	*Manning number,* M	*Bazin roughness factor,* k
Smooth cement	91	0.06

Rough, weedy earth	10	1.50

1.5.6 Boundary layer flow

When a fluid flows over a solid boundary there is a region close to the boundary in which the fluid viscosity may be assumed to have an effect. Outside this region the fluid may be assumed inviscid. The viscous effect within the region is evidenced by a reduction in velocity as the boundary is approached. Outside the region the velocity is constant. The region is known as a *boundary layer*.

It is usual to assume that at the solid surface the fluid velocity is zero and at the boundary layer outer edge it is equal to the undisturbed flow velocity v_s. This defines the boundary layer thickness δ. (In practice, δ may be taken to be the distance from the boundary surface at which the velocity is 99% of the undisturbed velocity, or 0.99 v_s.)

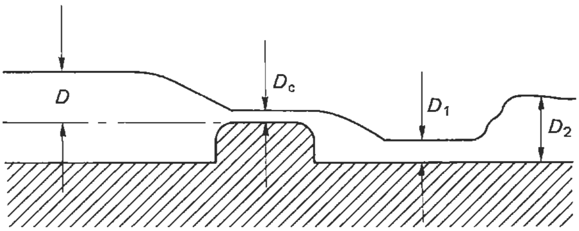

Figure 1.42 Broad-crested weir and standing wave

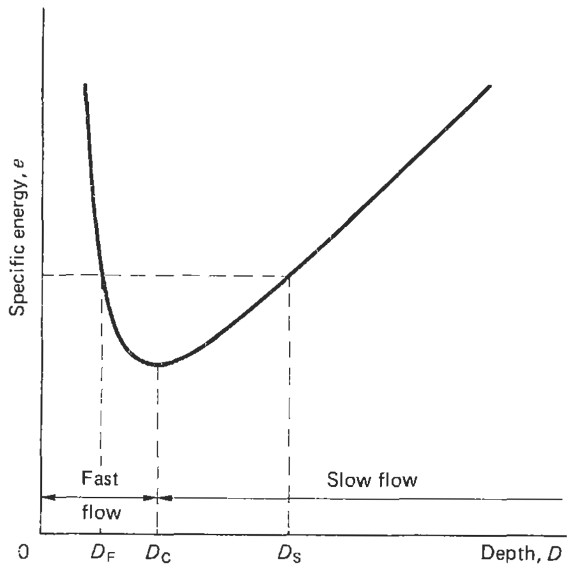

Figure 1.43 Graph of specific energy versus channel depth

When a flow stream at a velocity v_s passes over a flat plate the boundary layer thickness δ is found to increase with the distance x along the plate from the leading edge. Near the leading edge the flow inside the boundary layer may be assumed to be laminar, but as x increases the flow becomes turbulent and the rate of increase of δ with x also increases, as shown in Figure 1.44.

Within even a turbulent boundary layer there is a narrow region close to the plate surface where the flow is laminar. This is known as the *laminar sublayer* and has thickness δ_b. The reduction in velocity across the boundary layer is associated with a shear force at the plate surface, usually known as the *drag force*.

Application of the momentum equation produces *Von Karman's momentum integral*, in which the drag force per unit width, F_D, becomes

$$F_D = \rho v_s^2 \int_0^\delta \frac{v}{v_s}\left(1 - \frac{v}{v_s}\right) \mathrm{d}y \tag{1.75}$$

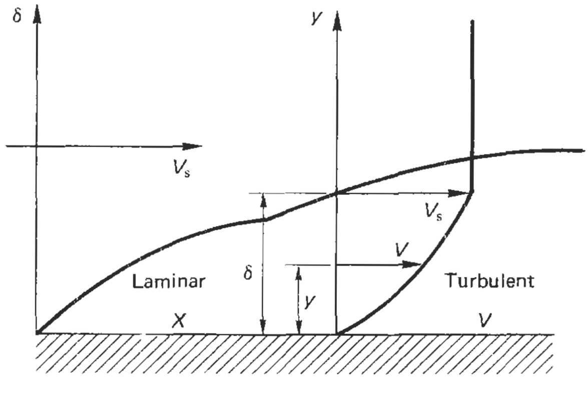

Figure 1.44 Boundary layer

where v is the velocity within the boundary layer at a distance y above the plate surface. (The integral

$$\int_0^\delta \frac{v}{v_s}\left(1 - \frac{v}{v_s}\right)\mathrm{d}y$$

may be defined as the *momentum thickness* (θ) and the integral

$$\int_0^\delta \left(1 - \frac{v}{v_s}\right)\mathrm{d}y$$

as the *displacement thickness* (δ^*) so that

$$F_D = \rho v_s^2 \theta.) \tag{1.76}$$

In order to solve the Von Karman integral equation (1.75) or equation (1.76) it is necessary to know the value of δ and the relationship between v and y, the velocity distribution. Both of these are dependent on each other and the flow regime, laminar or turbulent, within the boundary layer.

1.5.6.1 Laminar boundary layers

A laminar boundary is normally assumed if $Re_x < 500\,000$. (Re_x is Reynolds' number based on x or $\rho v_s x/\eta$.) For laminar boundary layers various simplified velocity distribution relationships may be used, such as linear, sinusoidal or cosinusoidal. The generally accepted most accurate relationship is, however, that obtained by the reduction of a four-term polynomial, which gives

$$\frac{v}{v_s} = \frac{3y}{2\delta} - \frac{1}{2}\left(\frac{y}{\delta}\right)^3 \tag{1.77}$$

From this the shear stress at the plate surface, τ_o, may be found for Newtonian fluids:

$$\tau_o = \eta \left(\frac{\mathrm{d}v}{\mathrm{d}y}\right)_{y=0} \tag{1.78}$$

The shear force

$$F_D = \int_0^x \tau_0 \mathrm{d}x \tag{1.79}$$

Substitution from equation (1.77) in equations (1.75) and (1.78) and equating F_D from equations (1.75) and (1.79) leads via a separation of variables technique to

$$\frac{\delta}{x} = 4.64\, Re_x{}^{-0.5} \tag{1.80}$$

The drag force is usually quoted in terms of a *drag coefficient*, C_D:

$$C_D = \frac{2F_D}{\rho v_s^2 x} \tag{1.81a}$$

or

$$F_D = \frac{1}{2} C_D \rho v_s^2 x \tag{1.81b}$$

By manipulation of the above equations an equation for C_D for a laminar boundary over the whole length L of the plate:

$$C_D = 1.29 Re_L{}^{-0.5} \tag{1.82a}$$

is obtained. The drag force on the whole plate surface of area A is found from:

$$F = \frac{1}{2} C_D v_s^2 A \tag{1.82b}$$

1.5.6.2 Turbulent boundary layers

For $Re_x > 500\,000$, the boundary is assumed to be turbulent. In a turbulent boundary layer the velocity distribution is often written in a power form:

$$\frac{v}{v_s} = \left(\frac{y}{\delta}\right)^{1/n} \tag{1.83}$$

The index n varies between 6 and 9, depending on Re_x.

Because of the presence of the laminar sublayer, the turbulent regime is not continuous down to the plate surface, and $(\mathrm{d}v/\mathrm{d}y)_{y=0}$ does not give a useful result.

The equation used for τ_0 is

$$\tau_o = 0.0225 \rho v_s^2 R_\delta{}^{-0.25} \tag{1.84}$$

based on work on smooth pipes by *Blasius*.

Taking $n = 7$ and using the same techniques as for laminar boundary layers gives:

$$\frac{\delta}{x} = 0.37\ Re_x{}^{-0.2} \tag{1.85}$$

and

$$C_D = 0.072\ Re_L{}^{-0.2} \tag{1.86}$$

This result assumes that the turbulent boundary layer obtains over the whole length of the plate to L.

Prandtl suggested a more realistic expression which takes into account the presence of a laminar boundary layer near the leading edge:

$$C_D = 0.074\ Re_L{}^{-0.2} - 1700\ Re_L{}^{-1} \tag{1.87}$$

This may be used for $5 \times 10^5 < Re_L < 10^7$. For $10^7 < Re_L < 10^9$ Schlichting (1960) suggests a logarithmic velocity distribution and

$$C_D = 0.44(\log_{10} Re_L)^{-2.58} = 3.91(\ln Re_L)^{-2.58} \tag{1.88}$$

Again, equation (1.82b) may be applied to find the drag force on the whole plate.

1.5.6.3 Laminar sublayers

The analyses in Sections 1.5.6.1 and 1.5.6.2 above assume that the plate surface is smooth or at least *hydraulically smooth*. A surface is regarded as hydraulically smooth if the average roughness height k is less than the laminar sublayer thickness δ_b. For a turbulent layer with a velocity distribution power index of $n = 1/7$, the laminar sublayer thickness at a point at a distance x along the plate from the leading edge is given by

$$\frac{\delta_b}{\delta} = 199\ Re_x{}^{-0.7} \tag{1.89}$$

Thus δ_b may be compared with the roughness height, k, if the boundary layer thickness, δ, is known.

1.5.7 Pressure transients (water hammer)

Water hammer is the common name for the rattling which occurs in water pipes as result of pressure transients. This phenomenon is due either to the collapse of cavitation bubbles or to rapid valve closure. The former is not uncommon in domestic water pipe work as an irritating vibration or noise on valve closure or opening (usually of the hot taps). It can be much more serious on a larger scale, where high-pressure rises over short periods may cause severe damage. Similar effects due to valve closure can be analysed on different levels of sophistication.

The simplest is the *rigid column* theory, which assumes that the fluid is incompressible, and that the valve is closed relatively slowly. This is often applied to water flow in pipes.

1.5.7.1 Slow valve closure

When a fluid flowing through a pipe with a velocity v_0 undergoes a change in velocity there is an associated change in pressure. Equating the force due to the pressure change to the rate of change of momentum during closure gives the resulting pressure rise Δp over a length of pipe L:

$$\Delta p = -\rho L \frac{\mathrm{d}v}{\mathrm{d}t} \tag{1.90}$$

The solution to this equation depends on a knowledge of the relationship between v and t (the valve closure rate in terms of the flow velocity).

Equation (1.90) is only applicable to relatively slow valve closure rates in which the closure time should not be less than $2L/C$ (where C is the speed of sound in the fluid).

1.5.7.2 Time to establish flow

The rigid column theory is also often used to calculate the time required to establish flow in a pipe on opening a valve. The theory implies that the time required to fully establish the flow is infinite and so the time t to achieve 99% of the final velocity v_0 is usually accepted:

$$t = 2.646 \frac{L v_0}{gH} \tag{1.91}$$

where H is the supply head to the pipe entrance. The time t_x required to reach x% of the final velocity is given by

$$t_x = \frac{L v_0}{2gH} \ln\left(\frac{1 + 0.01x}{1 - 0.01x}\right) \tag{1.92}$$

1.5.7.3 Rapid valve closure

When a fluid is brought to rest *instantaneously* from a velocity of v_0 by the closure of a valve at the exit of a pipe of diameter D there will be a relatively high pressure rise at the valve. If the valve closure time is *less than* $2(L/c)$ then the resultant pressure rise is as if it were instantaneous; c is the speed at which the pressure wave travels through the fluid, which is the sonic velocity.

On such a rapid valve closure the kinetic energy of the flow is converted into strain energy in both the pipe material and the fluid (even liquids are acknowledged as compressible in this context). The resulting pressure wave is transmitted through the fluid away from the valve as shown in Figure 1.45. The pressure rise produced is

$$\Delta p = \rho c v_0 \tag{1.93}$$

For a fluid of bulk modulus G, in a pipe of wall thickness x, of a material with a Young's modulus E and Poisson's ratio σ, the velocity of the pressure wave is

$$c = \Bigg[\rho\Bigg\{\frac{1}{G} + \frac{D}{Ex}\Bigg(1.25 - \sigma\Bigg)\Bigg]\Bigg]\Bigg\}^{-0.5} \tag{1.94a}$$

or

$$c = \left[\rho\left(\frac{1}{G} + \frac{D}{Ex}\right)\right]^{-0.5} \tag{1.94b}$$

if longitudinal stress is small compared to hoop stress.

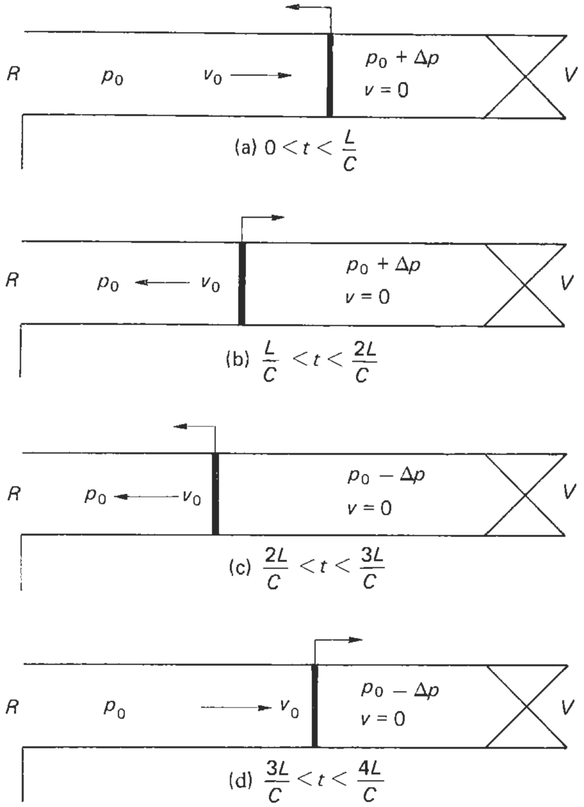

Figure 1.45 Progress of a pressure wave

Equation (1.94a) is often written as $c = [G_e/\rho]^{0.5}$, where G_e is the effective bulk modulus of the fluid and pipe combinations:

$$\frac{1}{G_e} = \frac{1}{G} + \frac{D}{Ex}(1.25 - \sigma) \tag{1.95}$$

If the valve is at the entrance to the pipe, then rapid valve closure results in a rarefaction (pressure drop) at the valve. In other words, the pressure change is

$$\Delta p = -\rho c v_0 \tag{1.93'}$$

1.5.7.4 The progress of a pressure wave

Assuming no friction and no cavitation in the fluid, the progress of a pressure wave along a pipe between a valve and a reservoir following valve closure is as shown in Figure 1.45. The fluid in the pipe is successively brought to rest by the passage of the pressure wave.

At a time $t = L/c$ after valve closure, the pressure wave reaches the reservoir. The whole of the fluid in the pipe is at rest at a pressure $p = p_0 + \Delta p$, which at the reservoir end instantaneously drops to reservoir pressure p_0. The resulting pressure wave travels along the pipe towards the valve and the fluid at the higher pressure in the pipe flows towards the reservoir at its initial velocity v_0.

At $t = 2L/c$, the situation is the same as for a rapid closure of a valve downstream of the flow, producing an instantaneous pressure drop to $p_0 - \Delta p$ and a rarefaction which travels towards the reservoir. The passage of the rarefaction successively brings the fluid to rest along the pipe.

At $t = 3L/c$, the rarefaction reaches the reservoir and the pressure instantaneously rises to reservoir pressure p_0. The resulting pressure wave travels towards the valve and fluid flows away from the reservoir at velocity v_0.

At $t = 4L/c$, the situation is the same as when the valve first closed at $t = 0$, and the cycle is repeated.

In practice, friction quickly dampens out the pressure waves and cavitation reduces the pressure decrease during the rarefactions.

A typical plot of pressure against time at a valve following rapid valve closure is superimposed on the theoretical plot in Figure 1.46.

1.5.8 Gas flow

1.5.8.1 General relationships

The behaviour of gases during processes involving thermal energy interactions and exchanges fits more properly into a study of thermodynamics. However, if only the flow mechanics are considered, the thermal and temperature effects may be restricted to those mainly relating to pressure and density.

The most straightforward approach is to consider zero thermal energy transfer (heat transfer) to or from the fluid, or adiabatic flow. If, in addition, the changes in the fluid's properties are assumed to be reversible, then the flow becomes isentropic and the relationship between pressure and density the simple and well-known one for an ideal gas:

$$\frac{p}{\rho^\gamma} = \text{constant} \tag{1.96}$$

Also, the *ideal gas law*:

$$\frac{p}{\rho} = RT \tag{1.97}$$

applies. Other useful relationships are:

1. The ratio of specific heats $\gamma = \frac{c_p}{c_v}$ (1.98)
2. The gas constant $R = c_p - c_v$ (1.99)
3. The *universal gas constant* $R_o = R \times$ molecular mass $= 8.3143\ \text{kJ kg}_{\text{mol}}^{-1}\ \text{K}^{-1}$

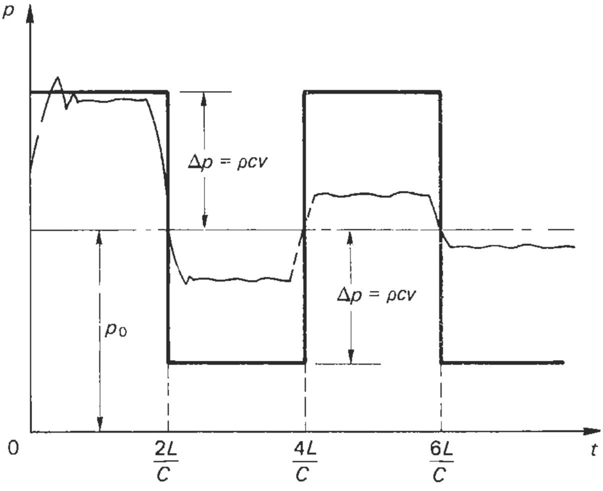

Figure 1.46 Pressure versus time at a valve

The terms *stagnation* or *total* temperature T_0 and pressure p_0 are often applied as the datum temperature and pressure of a fluid flow, even when stagnation conditions (zero velocity) do not exist in the particular situation under consideration. In gas flow the relationships between T_0 and the temperature T and p_0 and the pressure p at some point in the flow is often given in terms of the *Mach number* (M), the ratio of the flow velocity v to that of sound c, i.e.

$$M = \frac{v}{c} \qquad (1.100)$$

and

$$c = \left[\gamma \frac{p}{\rho}\right]^{0.5} = [\gamma R T]^{0.5} \qquad (1.101)$$

In these terms T_0 and p_0 may be found from Euler's equation to be

$$T_0 = T\left[1 + \frac{(\gamma - 1)}{2} M^2\right] \qquad (1.102)$$

$$p_0 = p\left[1 + \frac{(\gamma - 1)M^2}{2}\right]^{\gamma/(\gamma-1)} \qquad (1.103)$$

1.5.8.2 *Flow in ducts and nozzles*

(a) Ducts The analysis of gas flow in ducts is based on the Euler equation (1.34) and the one-dimensional continuity equation (1.25). Consideration of the differential forms of these equations will demonstrate that for subsonic flow ($M < 1$) the velocity will increase as the cross-sectional area of the duct decreases (in the converging entrance to a convergent/divergent nozzle, for example). For supersonic flow ($M > 1$) the velocity will increase as the cross-sectional area increases (in the diffuser of the convergent/divergent nozzle).

The properties of the fluid at a position in the flow stream where the local Mach number is unity are often denoted by a superscript * (p^*, ρ^*, T^*) and used as a datum, so that

$$M^* = 1; \text{ and } v^* = c^* = [\gamma R T^*]^{0.5} \qquad (1.104)$$

The ratios of the properties at any position in the flow stream to those at the * position are:

1. $$\frac{p}{p^*} = \left[\frac{\gamma + 1}{2 + (\gamma - 1)M^2}\right]^{\gamma/(\gamma-1)} \qquad (1.105)$$
2. $$\frac{\rho}{\rho^*} = \left[\frac{\gamma + 1}{2 + (\gamma - 1)M^2}\right]^{1/(\gamma-1)} \qquad (1.106)$$
3. $$\frac{T}{T^*} = \frac{\gamma + 1}{2 + (\gamma - 1)M^2} \qquad (1.107)$$
4. $$\frac{v}{v^*} = M\left[\frac{\gamma + 1}{2 + (\gamma - 1)M^2}\right]^{1/2} \qquad (1.108)$$
5. $$\frac{A}{A^*} = \frac{1}{M}\left[\frac{2 + (\gamma - 1)M^2}{\gamma + 1}\right]^{(\gamma+1)/2(\gamma-1)} \qquad (1.109)$$

For air the ratios may be calculated by substituting $\gamma = 1.4$, or obtained from published tables and charts (Houghton and Brock, 1961).

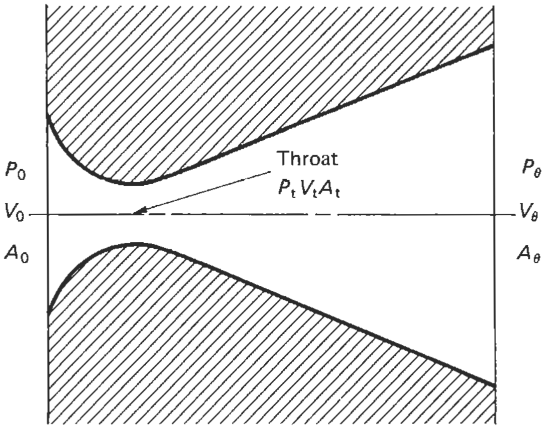

Figure 1.47 Convergent/divergent nozzle

(b) Nozzles A nozzle is an example of a duct with a smoothly decreasing cross-sectional area, followed in some cases by an increasing area (convergent/divergent nozzle) (see Figure 1.47). Since the velocity in the throat (minimum cross section) is often sonic, the approach velocity may be negligible. The throat velocity v_t and the exit velocity v_e are found by applying the Euler equation (1.34) between the upstream (entry conditions suffix $_0$) and throat and exit, respectively:

$$v_t = \left\{\frac{2}{\gamma - 1}\frac{p_0}{\rho_0}\left[1 - \left(\frac{p_t}{p_0}\right)^{(\gamma - 1)/\gamma}\right]\right\}^{1/2} \qquad (1.110)$$

For v_e the pressure term p_e replaces p_t in equation (1.110). The mass flow rate through the nozzle is usually found at the throat by substituting v_t in the mass flow equation (1.25) to give

$$\dot{m} = C_d A_t\left\{\frac{2}{\gamma - 1}\frac{p_0}{\rho_0}\left[\left(\frac{p_t}{p_0}\right)^{2/\gamma} - \left(\frac{p_t}{p_0}\right)^{(\gamma + 1)/\gamma}\right]\right\}^{1/2} \qquad (1.111)$$

where C_d is a discharge coefficient which depends on the nozzle design. For a well-designed nozzle C_d will be close to unity.

The mass flow rate will be the same at the exit as at the throat. It may be calculated from the exit conditions by substituting A_e and p_e for A_t and p_t, respectively, in equation (1.111).

Nozzles are usually designed for maximum mass flow rate. This will occur when the throat velocity is sonic ($v_t = c$). The pressure ratio which produces this situation is known as the *critical pressure ratio*, given by

$$\left(\frac{p_t}{p_0}\right)_{\text{crit}} = \left(\frac{2}{\gamma + 1}\right)^{\gamma/(\gamma - 1)} \qquad (1.112)$$

For many light diatomic gases such as air, where γ is approximately 1.4, $(pt_t)/(p_0)_{\text{crit}} = 0.528$.

The throat area will be that which gives the required mass flow rate through the throat at sonic velocity for critical pressure ratio. The exit area will be that which gives the calculated exit velocity for the given mass flow rate at the exit conditions. For convergent nozzles the throat also becomes the exit.

If nozzles, orifices or venturi meters are used to measure gas flow rates through a pipe then the approach velocity may be signficant and the mass flow rate given by

$$\dot{m} = C_d A_t \rho_0\left\{\frac{2(\rho_0/\rho_0)[\rho_t/\rho_0)^{2/r} - (\rho_t/\rho_0)^{(\gamma+1)/r}}{(\gamma - 1)[1 - (\rho_t/\rho_0)^{2/r}(\rho_t/\rho_0)^2}\right\}^{1/2} \qquad (1.113)$$

1.5.8.3 Shock waves

Under normal design conditions the flow in the nozzle downstream of the throat will be supersonic. The velocity of the gas at exit will depend on the external pressure p_b (back pressure). If the back pressure is greater than the theoretical exit pressure $p_e (p_b > p_e)$ then *shock waves* will be set up in the nozzle. These are discontinuities similar to standing waves in open-channel flow. The shock waves set up in such a way are *normal shock waves*, normal to the direction of flow.

If $p_b < p_e$ then the expansion will continue outside the nozzle (over-expansion).

If conditions upstream of a normal shock wave are denoted by suffix 1 and downstream by suffix 2, then it can be shown that the product of the up- and downstream velocities is equal to the square of the sonic velocity at $M = 1$:

$$v_1 v_2 = C^{*2} \qquad (1.114)$$

and since $M_1 > 1$, then $M_2 < 1$. Also,

1. $$M_2 = \left[\frac{2 + (\gamma - 1)M_1^2}{2\gamma M_1^2 - (\gamma - 1)}\right]^{0.5} \qquad (1.115)$$
2. $$\frac{p_2}{p_1} = \frac{2\gamma M_1^2}{(\gamma + 1)} - \frac{\gamma - 1}{(\gamma + 1)} \qquad (1.116)$$
3. $$\frac{\rho_2}{\rho_1} = \frac{v_1}{v_2} = \frac{(\gamma + 1)M_1^2}{2 + (\gamma - 1)M_1^2} \qquad (1.117)$$

These are known as the *Rankine–Hugoneot* relationships. Values for air may be obtained by putting $\gamma = 1.4$ or by the use of published tables (Houghton and Brock, 1961).

The strength of a shock wave may be defined as the ratio of the pressure change across the wave to the upstream pressure, or in terms of the upstream Mach number:

$$\text{Shock wave strength} = \frac{p_2 - p_1}{p_1} = \left(\frac{2}{\gamma + 1}\right)(M_1^2 - 1) \qquad (1.118)$$

$$= 1.167(M_1^2 - 1), \text{ for air.}$$

Oblique shock waves, at an angle β to the upstream flow direction, are produced when a supersonic gas flow is turned through an angle θ by an obstruction such as an aircraft's nose, wing or tail, the inside walls of a duct, etc. The relationships between the up- and downstream Mach numbers and the angles β and θ are published in tables and charts (Houghton and Brock, 1961).

In some cases both the up- and downstreams will be supersonic and subsequent shock waves produced, for example, at the leading and trailing edges of a wing. The effects of such shock waves produced by aircraft in flight, say, may be noted at ground level as *sonic booms*.

1.5.8.4 Gas flow measurement

Gas flow rates through ducts will normally be measured using devices and techniques similar to those used for incompressible fluids, namely orifice plates, venturi meters and nozzles. However, for gases the flow rate is usually quoted as a mass flow rate. Equations (1.110) and (1.112) may be used with orifices and venturis as well as nozzles. Relevant values of C_d for each device will be found in BS 1042, in addition to operational advice.

When pitot-static tubes are used to measure gas flow velocities equation (1.58) may be acceptable for low flows with low pressure differences. At high velocities the compressibility must be taken into account and equation (1.110) used with stream conditions at X replacing those at the throat t.

For accurate velocity measurement with little disturbance to the flow *hot wire anemometers* may be used. The resistance of an electrically heated wire is related to the temperature of the wire, which in turn is related to the velocity of the fluid flow past the wire. The wire resistance measured on a bridge may be calibrated against a known velocity, to give either direct readout or (more usually) a calibration curve. The fine wire of the anemometer is suceptible to fluid contamination.

Other velometers and anemometers (depending on the relationship between the speed of rotation of a set of blades and the velocity (or speed) of the gas flow) may be used in very large cross-sectional ducts or to measure wind speed in the open air. They may depend on the rotation to generate a small electrical current, which can be calibrated as a speed, or the number of revolutions may be inserted into an empirical formula. A typical example is the three-vaned meteorological anemometer.

1.5.9 Ideal fluid flow

The concept of using idealized conditions to establish the shape of the mathematical models of real situations is common in engineering science studies. These models may then be modified to accommodate observed relationships, for application to real situations.

Ideal fluid (or *potential*) flow is such a concept. It may be used to set up flow patterns in the region of a flow stream outside the boundary layers described in Section 1.5.6. The combination of ideal flow and the boundary layer effects may be used to predict the performance of a real situation, so long as the limitations of both are recognized. The fluid is assumed to be inviscid and the flow steady, continuous and irrotational, as defined in Section 1.5.3.1. This means that there are no cavities or discontinuities in the flow stream, and that the fluid particles do not rotate about their own axes, even though the flow may be circular.

The continuity equation (1.23) applies, and may be modified to

$$\frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} = 0 \qquad (1.119)$$

if required for two-dimensional flow. For irrotation in two dimensions equation (1.28) becomes

$$\frac{\partial v_x}{\partial y} - \frac{\partial v_y}{\partial x} = 0 \qquad (1.120)$$

1.5.9.1 The stream function

From the definitions of the stream line and stream function in Section 1.5.3.1(e) the equation to a stream line may be shown to be

$$v_x \mathrm{d}y - v_y \mathrm{d}x = 0 \qquad (1.121)$$

and since the stream function ψ is an equation which describes a family of stream lines, then, for example,

$$\psi = 2x - y$$

represents a family of parallel straight lines with a variable intercept ψ.

For unit thickness in the z direction the volumetric flow rate $\dot{V}$ between two stream lines 1 and 2 is

$$\dot{V} = \psi_1 - \psi_2 \qquad (1.122)$$

or

$$\mathrm{d}\dot{V} = \mathrm{d}\psi \qquad (1.123)$$

Stream functions may be *superposed* so that if

$\psi_1 = \text{fn}(x,y)$ describes flow pattern A,

and

$\psi_2 = \text{fn}(x,y)$ describes flow pattern B,

then $\psi = \psi_1 + \psi_2$ describes the flow pattern produced by the combination of A and B.

The x and y components of the flow velocity v are given by

$$v_x = -\frac{\partial\psi}{\partial y}; \text{ and } v_y = \frac{\partial\psi}{\partial x} \tag{1.124}$$

or

$$v_x = \frac{\partial\psi}{\partial y}; \text{ and } v_y = -\frac{\partial\psi}{\partial x}$$

depending on sign convention. In *polar coordinates* the components are

$$\text{Radial velocity } v_r = \frac{-\partial\psi}{r\partial\theta} \tag{1.125}$$

$$\text{Tangential velocity } v_\theta = \frac{\partial\psi}{\partial r} \tag{1.126}$$

1.5.9.2 *The velocity potential*

In a gravitational field there is a property the change in which is independent of the path of the change: *potential energy*. In a continuous, irrotational flow field there is also a property the change in which is independent of the path of the change. This property is the *velocity potential* (ϕ). It can be shown that

$$v_x = -\frac{\partial\phi}{\partial x}; \text{ and } v_y = -\frac{\partial\phi}{\partial y} \tag{1.127}$$

or

$$v_\theta = -\frac{\partial\phi}{r\partial\theta}; \text{ and } v_r = -\frac{\partial\phi}{\partial r} \tag{1.128}$$

Lines of constant ϕ are known as *velocity potential* lines with an equation

$$v_x\text{d}x + v_y\text{d}y = 0 \tag{1.129}$$

Figure 1.48 Simple flow patterns

which intercept the stream lines at right angles to form an orthogonal network of characteristic pattern for each flow field.

From equations (1.124) and (1.127) it can be seen that

$$\frac{\partial \psi}{\partial y} = \frac{\partial \phi}{\partial x}; \text{ and } \frac{\partial \psi}{\partial x} = -\frac{\partial \phi}{\partial y} \qquad (1.130)$$

which are the *Cauchy–Rieman* equations. In such flow fields the *Laplace* equations for ϕ and ψ must both be satisfied:

$$\nabla^2\phi = 0; \text{ and } \nabla^2\psi = 0 \qquad (1.131)$$

Because the fluid is ideal, the Bernoulli equation (1.37) may be readily applied between points in the field, both along and across the stream lines.

1.5.9.3 Flow patterns

Examples of simple flow patterns are shown in Figure 1.48 with the equations to their stream functions and velocity potentials. A *source* is mathematically a point at which fluid appears and flows radially outwards. A *sink* is a negative source at which fluid flows radially inwards to disappear at a point (similar to the plug hole in a domestic sink, where, however, there is a vortex superposed to produce a spiral vortex or whirlpool). A *vortex* is flow in concentric circles with no radial flow. A *doublet* is the superposition of a source and a sink of equal strength m, initially a distance $2a$ apart brought infinitely close together so that the product of their strength and the distance between them remains a constant k. k is the strength of the doublet and is equal to $2am$.

This is a mathematical concept which is apparently impractical but yields a useful flow pattern. It is often used in combination with other simple patterns.

1.5.9.4 Modelling

Since there can be no flow across a stream line and the fluid is assumed inviscid, any stream line in a flow pattern may be replaced by a solid surface with no effect on the rest of the pattern. A stream line forming a closed contour may be replaced by a solid body to model the flow pattern around a body of the same shape. This provides a method of writing mathematical models to describe the flow streams around various shapes.

The limitations of the model must be understood, and the effects of rotation and viscosity particularly considered, when applying the analysis to *real* situations. For example, the flow round a cylinder may be modelled by a combination of doublet and parallel flow. The drag and lift forces calculated by integrating the resulting pressure forces at the cylinder surface appear to be zero. This is obviously not correct.

In the real situation the viscosity of the fluid produces a boundary layer at the cylinder surface, which, because of curvature, separates from the surface to form a wake. The presence of the wake disturbs the downstream flow pattern and the form drag force is a consequence. Viscosity also introduces a surface friction drag.

The shedding of vortices from the cylinder surface into the wake also produces alternate positive and negative lift forces, which are not predicted by the ideal flow analysis, although telegraph wires may often be observed vibrating in the wind.

1.5.10 Conclusion

Fluid mechanics is often regarded as an empirical subject which makes use of formulae based only on observed experimental results. This misconception is further compounded by the extensive use of 'coefficients' (discharge especially) to account for effects which are difficult to model mathematically. However, almost all fluid mechanics equations in common use are based on the conservation of energy, the conservation of momentum or the fact that the rate of change of momentum may be equated to an applied force, usually a pressure force. The experimental checking and empirical amendment to derived formulae is just *good engineering practice*.

This section does not provide rigorous derivations of the various equations quoted. Some appreciation of such derivations may be required in order to establish the limitations and modifications necessary for the application of the equations, especially to non-standard situations. For this, standard textbooks on fluid mechanics as listed below should be consulted.

1.6. Principles of thermodynamics

1.6.1 Introduction

Thermodynamics is concerned with energy transfers in processes. Two modes of transfer are recognized: *work* (transfer) and *heat* (transfer). From the mechanical engineer's viewpoint the main interest is the production of shaft power (rate of work transfer) by a machine to which the energy is supplied by heat transfer obtained directly or indirectly from the combustion of a hydrocarbon fuel in air. Before proceeding, the terminology used in thermodynamics must be defined.

The particular part of the *working substance* under consideration is called the *system*, and this is separated from the *surroundings* by a *boundary*. In the *closed* or *non-flow* system the mass of working substance is constant, but in the *open* or *flow* system there is a mass flow rate across the boundary. Some processes in reciprocating plant may be considered by non-flow analysis but in steam plant, for example, most are considered by flow analysis. The *state* of a system is defined by the *properties* (pressure, temperature, etc.). Properties are normally expressed *specifically* (i.e. per unit mass) to enable charts or tables to be used. The state of simple substances can be described by two independent properties, but complex ones such as mixtures need more definition. A *change of state* is achieved by a *process* which is idealized as *reversible* with no losses. Reversible processes can be described by mathematical equations and enable analysis to be made to give answers for ideal situations. Real processes have losses and are described as *irreversible*, and the ideal results are multiplied by a coefficient or efficiency (based on measurement or experience) to predict real performance.

1.6.2 The laws of thermodynamics[9,10]

1.6.2.1 *The first law of thermodynamics*

This is a law of energy conservation. When applied to a process we write

$$Q - W = \Delta E \text{ or } q - w = \Delta e$$

where Q is the heat transfer (kJ) or q is the specific heat transfer (kJ/kg), W is the work transfer (kJ) or w is the specific work transfer (kJ/kg), and ΔE is the energy change (kJ) or Δe is the specific energy change (kJ/kg).

The change symbol Δ means final value minus initial value. ΔE embraces all forms of energy but in the non-flow process it is usual to find that the only significant change is in the internal energy (U, u) and we write the non-flow energy equation

$$Q - W = \Delta U \quad \text{or} \quad q - w = \Delta u$$

For the *steady* flow system we write

$$\dot{Q} - \dot{W}_x = \dot{m}\Delta\left(h + \frac{V^2}{2} + gz\right)$$

$$\text{or} \quad q - w_x = \Delta\left(h + \frac{V^2}{2} + gz\right)$$

where $\dot{Q}$ and $\dot{W}_x$ are the energy transfer rates and $\dot{m}$ is the steady mass flow rate across the boundary (in and out), Δh is the change in specific enthalpy ($h = u + pv$), $\Delta V^2/2$ is the change in specific kinetic energy and Δgz is the change in specific potential energy. The suffix x is used on the work transfer to denote that this is the useful work from the system as the flow work is included in the enthalpy term. In flow problems it will also be necessary to use the continuity equation

$$\dot{m} = \rho A V$$

where ρ is the density and A is the area normal to the velocity V. Analysis of non-steady flow may also be made, in which case energy terms to allow for the storage of energy in the system will be added.

Warning: A sign convention for work and heat is built into the equations above. Positive work means work obtained from the system and positive heat means heat put into the system. Care should be taken to be clear about the symbol V, which may appear as velocity or volume in many equations.

In order to allow continuous energy transfers a *cycle* is defined in which a series of processes brings the working substance back to the initial state so that the cycle can be repeated continuously. If we apply the first law to a cycle it follows that ΔE is zero and

$$\sum_{\text{cycle}} Q = \sum_{\text{cycle}} W$$

1.6.2.2 *The second law of thermodynamics*

It might be thought that the first law of thermodynamics permits all the heat transfer to a cycle to be returned as work transfer, but unfortunately the second law places restraints on the achievement of this desirable situation. The restraint takes the practical form of demanding that some of the heat transfer to the cycle *must* be rejected as a heat transfer to a lower temperature. Thus when we build a *heat engine* it has to exchange heat with (at least) two reservoirs in order to produce work (Figure 1.49). Since work is the objective, the amount produced per unit heat input is vital information and we define the *thermal efficiency* of a heat engine as

$$\eta_{\text{thermal}} = \frac{\text{Net work transfer from the cycle}}{\text{Heat transfer to the cycle}} = \frac{W}{Q_1}$$

Since the first law states $Q_1 - Q_2 = W$ we see that efficiency is less than unity.

The second law makes further investigations and determines the maximum possible efficiency of a heat engine using reversible isothermal processes to transfer heat from two reservoirs as

$$\eta_{\text{thermal maximum}} = 1 - (T_{\text{min}}/T_{\text{max}})$$

This efficiency is known as the Carnot efficiency and is not attainable due to losses. It is also found that constant temperature processes, except during phase change, are not practical and real processes of heat transfer take place at approximately constant volume or constant pressure. One positive product of the second law is that it tells the engineer that thermal efficiency will be increased by making the maximum cycle temperature as high as possible (a materials constraint) and by making the minimum cycle temperature as low as possible (ambient conditions)

The losses in a real cycle are due to internal fluid friction and the necessity of having a temperature difference to cause a heat transfer. The larger the temperature difference, the greater the losses. The fluid friction losses in a work-producing process are defined by the process efficiency

$$\eta_{\text{process}} = \frac{\text{Actual work produced}}{\text{Ideal work produced}}$$

which is inverted for work-absorbing processes (compression). The most common application of this efficiency is in steady flow *adiabatic* processes. Ideally, these are processes with no heat transfer which are often used as models for real processes in which the heat transfers are negligible compared with the work transfers (turbine expansion). In such processes the

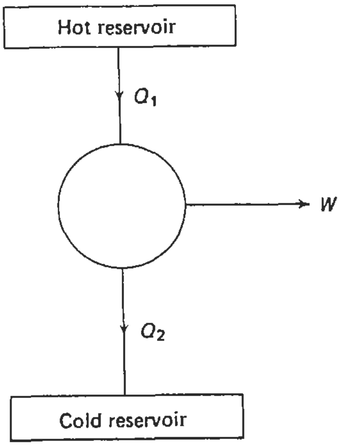

Figure 1.49 A heat engine

efficiency is known as the isentropic efficiency because the ideal adiabatic process has constant entropy (*qv*).

Losses due to fluid friction and losses due to heat transfer across finite temperature differences are found to result in an increase in the value of the entropy that would be expected in a reversible process. Thus an expected increase would be larger and an expected decrease would be smaller. It is not easy to define entropy except mathematically. In practical use as the abscissa of charts it enables work transfers in ideal adiabatic processes to be represented as vertical lines if enthalpy is used as an ordinate, and in this guise is a valuable visual method of presentation.

1.6.3 Thermoeconomics[11,12]

When a more detailed study of a flow process is made by the second law of thermodynamics is is found that specific entropy ($kJ.kg^{-1}K^{-1}$) appears as part of a property known as availability. In a flow process we write $b = h - T_0 s$, in which b is the specific *availability* function, h is the specific enthalpy, T_0 is the temperature (absolute) of the surroundings and s is the specific entropy. The second law shows that the maximum work potential or *exergy* of any state in surroundings at state 0 is given by $b - b_0$. Thus for a change of state in a flow process from 1 to 2 the maximum specific work obtainable is given by the exergy change, $w_{x_{\max}} = (b_1 - b_0) - (b_2 - b_0) = (b_1 - b_2) = -\Delta b$. If we measure or predict by analysis the actual work achieved it is possible to determine numerically the lost work or irreversibility in the process. If engineering plant is to be designed to the best advantage it is clear that processes should be chosen to minimize this loss. The lost work may be associated with costs and we move into the developing field of thermoeconomics. Clearly, this is a complex subject but it is important in that it unites thermodynamics with costs and can help in the design of long-life expensive plant.

1.6.4 Work, heat, property values, process laws and combustion[9,10]

To deploy the laws of thermodynamics outlined above we need more information. To perform simple cycle analysis the data below is vital.

1.6.4.1 Work

In a non-flow process work transfer can be determined from $w = \int p\mathrm{d}v$. The mathematical relation for the process is known as the process law (*qv*). In most flow processes used in engineering cycles the adiabatic approximation is used so that the steady flow energy equation, neglecting changes in kinetic and potential energy, gives

$$w_x = \Delta h$$

1.6.4.2 Heat

This is usually an unknown quantity and is found by the application of the energy equation. As stated earlier, many processes are approximately adiabatic so that heat transfer is zero and in others heat transfer is obtained from combustion data or, if a heat exchange process, by heat exchanger efficiency. In heating plant such as boilers which do no useful work the steady flow energy equation shows $q = \Delta h$.

1.6.4.3 Property values[13]

These are found in tables or from charts for common substances. Computer formulations are also available.

1.6.4.4 Process laws

This is a particularly important step in thermodynamic analysis because an idealized reversible process has to be chosen to represent as closely as possible the real process in order to calculate energy changes. When the working substance is a gas it is convenient in an elementary analysis to use perfect gas laws with the process calculation. These are

$$pv = RT \quad \text{or} \quad pV = mRT$$

$$u = c_v\Delta T \quad \text{and} \quad h = c_p\Delta T$$

where c_v and c_p are the specific heat capacities at constant volume and constant pressure, respectively, which are related as follows:

$$c_p - c_v = R \quad \text{and} \quad c_p/c_v = \gamma$$

where R is the specific gas constant and γ is the isentropic index.

Ideal processes commonly used are *constant pressure*, *constant volume*, *constant temperature* (which for a perfect gas becomes pv = constant) together with two other more general relations: the *adiabatic process*, pv^k = constant (which for a perfect gas becomes pv^γ = constant) and the *polytropic process*, pv^n = constant. The last process is a general relation between pressure and volume which is used if none of the other clearly special cases are considered valid. Usually $1 < n < 1.4$.

It is possible (by using the gas laws) in adiabatic and polytropic gas processes to rearrange the relations to involve pressure and temperature or temperature and volume to yield very useful relations:

$$\frac{T_1}{T_2} = \left(\frac{p_1}{p_2}\right)^{(\gamma-1)/\gamma}; \frac{T_1}{T_2} = \left(\frac{V_2}{V_1}\right)^{\gamma-1}; \frac{T_1}{T_2} = \left(\frac{p_1}{p_2}\right)^{(n-1)/n};$$

$$\frac{T_1}{T_2} = \left(\frac{V_2}{V_1}\right)^{n-1}$$

Processes may be represented on property diagrams to enable cycle visualization (Figures 1.50–1.54).

1.6.4.5 Combustion

To avoid involving complex chemical equations, engineers often use the calorific value of a fuel coupled with a combustion efficiency to estimate the energy transfers in combustion processes. Thus the rate of energy input by combustion is

$$\dot{E} = \dot{m}_f \cdot CV \cdot \eta_{comb}$$

where $\dot{m}_f$ is the fuel mass flow rate, CV the calorific value of the fuel and η_{comb} the combustion efficiency.

1.6.5 Cycle analysis

One example will be given of the simple analysis of the ideal Joule cycle for a gas turbine plant (Figure 1.55). The cycle consists of four flow processes described in Table 1.7 and analysed by the steady flow energy equation.

From the data in the table it can be seen that the specific work $w = c_p(T_3 - T_4) - c_p(T_2 - T_1)$ and the thermal efficiency

$$\eta_{thermal} = \frac{c_p(T_3 - T_4) - c_p(T_2 - T_1)}{c_p(T_3 - T_2)}$$

If allowance is made for the isentropic efficiency of the compression and expansion processes the cycle diagram is changed to show the associated entropy increases but the expressions for work and efficiency above are still valid with

Process	*Description*	$q - w_x = h$
1 to 2	Reversible adiabatic compression pv^γ = constant	$-w_x = h_z - h_1$ $= c_p(T_2 - T_1)$
2 to 3	Reversible constant pressure heat transfer *to* the cycle	$q = h_3 - h_2$ $= c_{\lvert}p(T_3 - T_2)$
3 to 4	Reversible adiabatic expansion pv^γ = constant	$-w_x = h_4 - h_3$ $w_x = c_p(T_3 - T_4)$
4 to 1	Reversible constant pressure heat transfer *from* the cycle	$q = h_1 - h_4$ $= c_p(T_1 - T_4)$

the changed values of T_2 and T_4 (Figure 1.56). These values are determined from the use of the reversible adiabatic process relation and the isentropic efficiency as

$$T_2 - T_1 = T_1(r_p^{(\gamma-1)/\gamma} - 1)/\eta_c$$

and

$$T_3 - T_4 = \eta_t T_3(1 - 1/r_p^{(\gamma-1/\gamma)})$$

where r_p is the cycle pressure ratio,

$$\eta_c = \frac{T_2' - T_1}{T_2 - T_1}$$

and

$$\eta_t = \frac{T_3 - T_4}{T_3 - T_4'},$$

η_c and η_t being the isentropic efficiencies of compression and expansion. If these values are substituted into the work and thermal efficiency expressions they become more useful in that they involve the thermodynamically significant maximum and minimum cycle temperatures which are fixed by material and ambient conditions respectively, so that the only variable is the cycle pressure ratio (Figure 1.57). If the expressions are differentiated with respect to this pressure ratio it is possible to find the pressure ratio for maximum work and that for maximum efficiency. The cycle designer then has a choice, depending on the proposed application and Figure 1.58 shows that it would be expected that the chosen ratio would fall between these two maxima. Obviously, this simple approach is not the complete answer to gas turbine cycle analysis but it illustrates the use of the laws of thermodynamics, and similar work may be done for other plant cycles.

1.7 Heat transfer

1.7.1 Introduction

Whenever a temperature difference occurs there is an energy flow from the higher temperature to the lower. A study of heat transfer is concerned with the determination of the instananeous rates of energy flow in all situations. We determine heat transfer rates in watts. These rates will be constant in situations where the temperature difference remains constant but variable (transient) when the temperature difference varies either due to the heat transfers or to other energy changes such as internal chemical reaction.

There are three modes of heat transfer:

1. *Conduction*, which is of greatest interest in solid bodies but also occurs in fluids where it is often overshadowed by convection;
2. *Convection*, which occurs in fluids when energy is transferred due to the motion of the fluid:
3. *Radiation*, which occurs between two systems at different temperatures which need not be in contact provided any intervening medium is transparent to the radiation.

In practice, all three modes occur simultaneously and it is necessary to draw up a balance at a boundary. For example, energy may be conducted to the surface of an electric storage heater and is then convected and radiated to the surroundings. Thus calculations can become complex, and in this particular case where energy is added at certain times this is a continuously varying situation.

Three approaches to heat transfer will be discussed below:

1. A simple method suitable for many estimations;
2. A more detailed appraisal of the field;
3. Comments on the use of computers.

1.7.2 Basic principles of heat transfer[14–16]

1.7.2.1 *Conduction*

Fourier's law for conduction states

$$\dot{Q}'' = -k\frac{\mathrm{d}T}{\mathrm{d}x}$$

The thermal conductivity $k(\mathrm{Wm^{-1}K^{-1}})$ is a property of the material which varies with temperature but for small temperature ranges is usually considered constant. Typical values are shown in Table 1.8. With constant k Fourier's equation can be integrated for four common situations.

Table 1.8

Substance	*Thermal conductivity*, $\mathrm{Wm^{-1}\,K^{-1}}$, *at 20° C*
Aluminium	204
Iron	52

Water	0.597
Air	0.026 (100 kPa)
Glass wool	0.04

Plane surfaces Integration gives

$$\dot{Q}'' = k_{12}\frac{(T_1 - T_2)}{x_2 - x_1} = \Delta T/\left(\frac{\Delta x}{k}\right)_{12}$$

(see Figure 1.59). The quantity $(\Delta x/k)$ is known as the thermal resistance in $\mathrm{m^2\,K\,W^{-1}}$. Thermal resistances can be added in a similar way to electrical resistances so that for a multilayer plane surface there are a number of resistances in series (Figure 1.60). Thus we can write

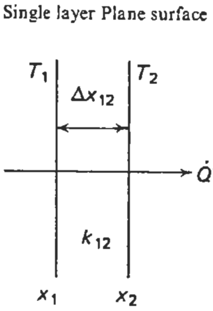

Figure 1.59 One-dimensional conduction through a single-layer plane wall

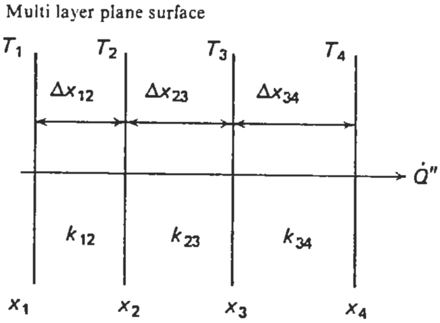

Figure 1.60 One-dimensional conduction through a multi-layer plane wall

$$\dot{Q}' = (T_1 - T_4)/\sum\frac{\Delta x}{k}$$

Cylindrical surfaces For tubes it is more convenient to evaluate heat transfer rates per unit length, and integration gives

$$\dot{Q}' = (T_1 - T_2)/\frac{\ln r_2/r_1}{2\pi k_{12}} = \Delta T/\frac{\ln r_2/r_1}{2\pi k_{12}}$$

(see Figure 1.61), and in this case the thermal resistance is $\left(\frac{\ln r_2/r_1}{2\pi k_{12}}\right)$ in $\mathrm{m\,K\,W^{-1}}$.

For a multilayer tube, thermal resistances are added to give

$$\dot{Q}' = (T_1 - T_4)/\sum\left(\frac{\ln\,(r_{\text{outer}}/r_{\text{inner}})}{2\pi k}\right)$$

(see Figure 1.62).

1.7.2.2 *Convection*

The fundamental equation for convective heat transfer at a solid–fluid interface is

$$\dot{Q}'' = h\theta$$

where θ is the temperature difference between surface and fluid. The surface heat transfer coefficient h ($\mathrm{W\,m^{-2}\,K^{-1}}$) is not a property of the fluid or the surface but depends on the flow pattern, the fluid properties and the surface shape. The coefficient has to be determined for each situation and can

vary considerably (Table 1.9). Although the determination of h is crucial to convection calculations it is an extremely difficult process, and accurate prediction of convective heat transfer is not always possible.

If we express the convection equation in a thermal resistance form suitable for plane surfaces

$$\dot{Q}'' = \theta \bigg/ \left(\frac{1}{h}\right)$$

it can be seen that the thermal resistance is $(1/h)$ m^2 K W^{-1}. For tubular surfaces it is again more convenient to work per unit length, so that

$$\dot{Q}' = \theta \bigg/ \left(\frac{1}{2\pi r h}\right)$$

and the thermal resistance is $(1/2\pi r h)$ m K W^{-1}.

1.7.2.3 Overall heat transfer coefficients

A common heat transfer situation is a solid wall separating two fluids, and for this problem the thermal resistances for conduction and convection can be added to enable the heat transfer rate to be determined in terms of the two fluid temperatures.

For a plane surface (Figure 1.63)

$$\dot{Q}'' = (T_{f_1} - T_{f_2}) \bigg/ \left(\frac{1}{h_1} + \sum \frac{\Delta x}{k} + \frac{1}{h_2}\right)$$

For a tubular surface (Figure 1.64)

$$\dot{Q}' = (T_{f_1} - T_{f_2}) \bigg/ \left(\frac{1}{2\pi r_1 h_1}\right) + \sum \left(\frac{\ln(r_{\text{outer}}/r_{\text{inner}})}{2\pi k}\right) + \frac{1}{2\pi r_2 h_2}$$

It can be seen that the added resistances may be inverted to give an overall *conductance* which is known as a 'U-value' or overall heat transfer coefficient.

For a plane surface

$$\frac{1}{U} = \frac{1}{h_1} + \sum \frac{\Delta x}{k} + \frac{1}{h_2}$$

For a tubular surface

$$\frac{1}{U'} = \frac{1}{2\pi r_1 h_1} + \sum \left(\frac{\ln(r_{\text{outer}}/r_{\text{inner}})}{2\pi k}\right) + \frac{1}{2\pi r_2 h_2}$$

The heat transfer rate is then simply written

Figure 1.64 *U'*-value for a cylindrical surface

For a tubular surface

$\dot{Q} = U'l(T_{f_1} - T_{f_2})$ where l is the length

The situations in which this technique is commonly used include walls of buildings, double glazing and hot water pipes, and the method is also used in heat exchanger design. It should suffice for simple calculations provided suitable values of the surface heat transfer coefficients for convection can be obtained. Values of U can be found for buildings, but care should be taken to ensure that the quoted figures include convection effects, as some only account for conduction and will need the effect of convection to be added.[17] If the temperature difference is not constant then a mean value should be used. A suitable equation for a mean can be found in the heat exchanger section which follows.

1.7.2.4 Radiation

Heat transfer due to radiation effects is of increasing importance as temperature increases because the rate of energy emitted by an ideal black body is given by the Stefan–Boltzmann law, in which the *absolute* temperature (Celsius + 273) is raised to the fourth power:

$$\dot{E}''_b = \sigma T^4$$

where σ is the Stefan–Boltzmann constant 5.67×10^{-8} W m^{-2} K^{-4} and the subscript b refers to the ideal black body. Real bodies emit less radiation and the monochromatic emissivity is defined by

$$\varepsilon_\lambda = \left[\frac{\dot{E}''_\lambda}{\dot{E}''_{b\lambda}}\right]_T$$

The value of ε varies with λ and T because real bodies are selective emitters, but for simple calculations it is often assumed that emissivity is constant. The calculations associated with this assumption are based on grey body theory, for which the rate of energy emission is given by

$$\dot{E}''_g = \varepsilon\sigma T^4$$

Some emissivity values are shown in Table 1.10, but it must be clearly understood that with such wide-ranging values it would be unwise to estimate unknown emissivities, and measurements would need to be made unless suitable data could be found.

Radiation incident on a body may be absorbed, reflected or transmitted. Thus we write $\alpha + \rho + \tau = 1$ where α, ρ and τ are the absorbtivity, reflectivity and transmissivity, respectively. Ideal black bodies absorb all incident radiation but real bodies do not. Gases are often assumed to transmit all radiation, but this is not always true, particularly with hydrocarbon combustion products. Solids have a transmissivity of zero. With these simple ideas it is necessary to know the values of only α and ρ. It can be shown that a grey body has absorbtivity equal to emissivity, $\alpha = \varepsilon$. Thus, provided the transmissivity is zero, a knowledge of the grey body emissivity enables reflectivity to be determined, since

$$\rho = 1 - \varepsilon$$

Table 1.10

Material	*Emissivity*
Rusted iron plate	0.69 at 19°C
Molten iron	0.29 at 1300–1400°C
Polished brass	0.06 at 100°C
Asbestos board	0.96 at 21°C

The only simple radiation problem that can be solved with the simple approach above is that of a grey body in *large* surroundings. The word 'large' implies that radiation not incident on the grey body which will be incident on the surroundings and will therefore be reflected will not be re-incident on the grey body. Thus the surroundings are effectively black. (This might be true with a linear size factor greater than 10.) In this simple case it can be shown that the heat transfer rate is

$$\dot{Q} = \varepsilon\sigma A(T^4 - T_s^4)$$

where ε is the emissivity of the body, A is the area of the body, T is the temperature of the body in K and T_s is the temperature of the large (black) surroundings in K.

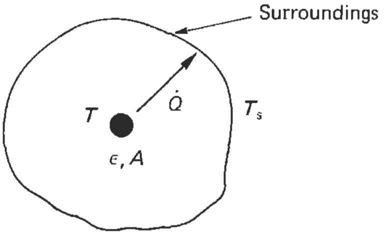

Figure 1.65 A small grey body in large (black) surroundings

1.7.2.5 Simple transient problems

If a body is being cooled or heated by convection or radiation and the thermal conductivity is large so that the rapid heat transfer rates within the body enable it to be assumed that the body temperature distribution is uniform, then the situation is known as a lumped capacity system. For such a system the complex methods of transient heat transfer are not required and a simple energy balance equation may be drawn up and integrated. The most common case is quenching, a convective boundary problem for which in time dt a small heat transfer δQ occurs when the body temperature changes from T by an amount dT (Figure 1.66). Thus

$$\delta Q = \rho c_p V \mathrm{d}T = -hA(T - T_f)$$

where T_f is the fluid temperature, A the body surface area, V the body volume, ρ the body density, c_p the body specific heat and h is the surface heat transfer coefficient. Integration gives

$$\frac{\theta}{\theta_0} = \mathrm{e}^{-(hAt/\rho c_p V)}$$

where θ_0 is the initial temperature difference between fluid and body and θ is the temperature difference at any future time t. The quantity $(\rho c_p V/hA)$ may be regarded as the time constant of the system.

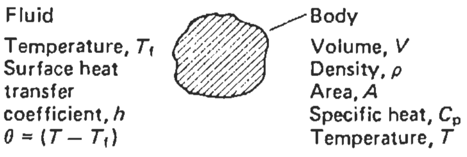

Figure 1.66 A lumped-capacity system with convection

1.7.3 Analysis of heat transfer[14–16]

1.7.3.1 Conduction

By considering the thermal equilibrium of a small, three-dimensional element of solid, isotropic material it can be shown that for a rectangular coordinate system

$$\frac{\partial T}{\partial t} = \alpha\left[\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}\right] + \frac{\dot{Q}'''}{\rho c_p}$$

where $\partial T/\partial t$ is the rate of change of temperature with time, α is the thermal diffusivity of the material $\alpha = k/\rho c_p$ and $\dot{Q}'''$ is the internal heat generation rate per unit volume, which may be due, for example, to electric current flow for which $\dot{Q}''' = i^2 r$, where i is the current density and r the resistivity. The solution to this equation is not easy, and numerical approximation methods are often used. One such method is the finite difference technique in which continuously varying temperatures are assumed to change in finite steps. Consider the three planes shown a distance Δx apart (Figure 1.67).

At A $\dfrac{\partial T}{\partial x} = \dfrac{T_1 - T_2}{\Delta x}$ and at B $\dfrac{\partial T}{\partial x} = \dfrac{T_2 - T_3}{\Delta x}$

so that at C $\dfrac{\partial^2 T}{\partial x^2} = \dfrac{T_1 + T_3 - 2T_2}{\Delta x^2}$. Similarly, $\partial T/\partial t$ may be written $\dfrac{T_{n,1} - T_{n,0}}{\Delta t}$ where $T_{n,1}$ is the temperature at layer n at time 1 and $T_{n,0}$ is the temperature at layer n at time 0.

For steady state situations $\partial T/\partial t = 0$ and a two-dimensional plane surface will be used for illustration requiring a solution of

$$\alpha\left[\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2}\right] + \frac{\dot{Q}'''}{\rho c_p} = 0$$

Consider the surface to be divided by a grid (Figure 1.68). It is then found that the solution for any point in the plane for steady state conduction without heat generation is

$$T_1 + T_2 + T_3 + T_4 - 4T_0 = 0$$

or with heat generation is

$$T_1 + T_2 + T_3 + T_4 - 4T_0 = -\frac{a^2\dot{Q}'''}{k}$$

At the boundary of the plane conditions are usually isothermal, in which case T = constant, or convective when an energy balance yields for a straight boundary (Figure 1.69)

$$\frac{T_1}{2} + T_2 + \frac{T_3}{2} + \frac{ha}{k}\cdot T_f - T_0\left(2 + \frac{ha}{k}\right) = 0$$

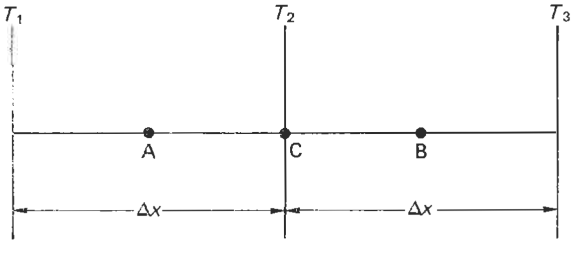

Figure 1.67 One-dimensional finite difference formulation

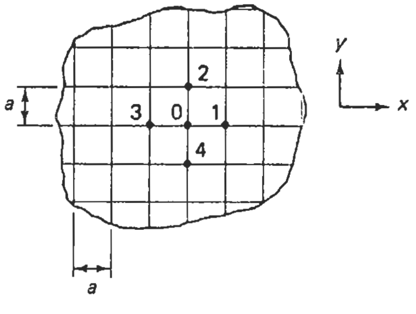

Figure 1.68 The two-dimensional grid concept

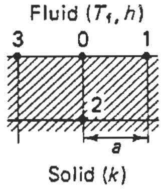

Figure 1.69 Convective surface nomenclature

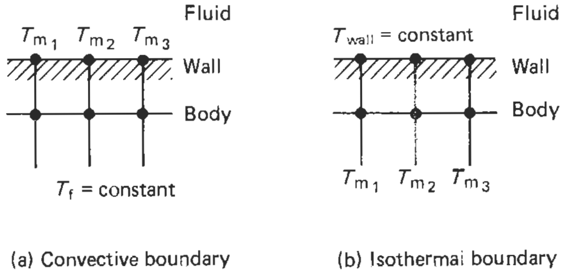
where h is the surface heat transfer coefficient, T_f is the fluid temperature and a is the grid size. Similar expressions can be derived for corners, curves, etc. at the boundary.

For a large number of grid points, a large number of simultaneous equations are obtained which can be solved by iteration or Gaussian elimination. Computer programs may be used to advantage. The solution obtained will be the temperature distribution in the plane, and the heat transfer rates may be found at the boundary (Figure 1.70):

With an isothermal boundary $\dot{Q} = \Sigma k(T_m - T_{wall})$

With a convective boundary $\dot{Q} = \Sigma ha(T_f - T_m)$



(a) Convective boundary

(b) Isothermal boundary

Figure 1.70 Calculation of heat transfer rate

For transient heating or cooling for which $\partial T/\partial t \neq 0$, a one-dimensional illustration is used. The equation to be solved is

$$\frac{\partial T}{\partial t} = \alpha\frac{\partial^2 T}{\partial x^2}$$

when there is no heat generation (Figure 1.71). When expressed in finite difference form this becomes

$$T_{n,1} = F\left(T_{n-1,0} + T_{n+1,0} + T_{n,0}\left(\frac{1}{F} - 2\right)\right)$$

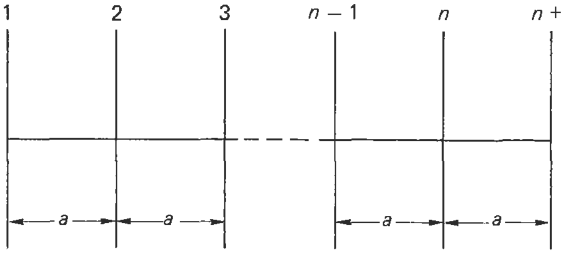


Figure 1.71 One-dimensional transient conduction formulation

where F is the non-dimensional grid size Fourier number $F = \alpha\Delta t/a^2$. The only unknown in this equation is $T_{n,1}$, the temperature at layer n after one time internval Δt. Thus from a knowledge of the initial conditions successive temperatures in each layer can be found directly for each time interval. This is the *explicit* method and is used for tabular or graphical (Schmidt method) solutions. If $F > 0.5$ the solution is unstable and in three dimensions the criterion becomes severe. The boundary conditions may be isothermal or convective and in the latter case the solution is

$$T_{n,1} = 2F \cdot T_{n-1,0} + T_{n,0}[1 - 2F - 2F \cdot B] + 2F \cdot BT_{\mathrm{f}}$$

where B is the non-dimensional grid Biot number, $B = ha/k$. For this case the solution is unstable if $(F + FB) > 0.5$. The solutions obtained give the temperature distribution in the one-dimensional plane and the heat transfer is found at the boundary

$$Q = \sum_{t} kA\left(\frac{\partial T}{\partial x}\right)_{1,t} \Delta t$$

or from the temperature profile

$$Q = \sum_{\text{layer}} mc_{\mathrm{p}}(T_{\text{final}} - T_{\text{initial}})$$

The stability problems of the explicit method can be overcome by the use of *implicit* methods for which there is no direct solution, but a set of simultaneous equations are obtained which may be solved by Gaussian elimination. A computer program may be used to advantage. A satisfactory implicit method is that due to Crank and Nicolson. The importance of a stable solution is that if the choice of F is limited then the grid size and time interval cannot be freely selected, leading to excessive calculations for solution. The implicit method releases this constraint but care is still needed to ensure accuracy.

Although the finite difference method has been chosen for demonstration because the method is easy to understand most modern computer programs are based on the finite element technique. However, the mathematical principles are involved, and would not lend themselves to simple programming. Before the availability of computer software analytical solutions were obtained and presented as graphs of transient solutions for slabs, cylinders and spheres. These graphs enable solutions for other shapes to be obtained by superposition methods. Such methods should be used to avoid or validate computer solutions.

Warning: If fibre-reinforced materials are used in which the lay-up is arranged to give directional structural strength it will be found that the thermal conductivity has directional variation and the methods above will need considerable amendment.

1.7.3.2 Convection

A knowledge of the surface heat transfer coefficient h is essential in determining heat transfer rates. Fluid flow over a solid surface is a boundary layer problem, and the heat transfer depends on boundary layer analysis. This analysis may be by differential or integral approach, but solution is difficult and the modelling of turbulence is complex. Computer solutions based on numerical approximations may be used to advantage, but simple approaches have been used for many years and are still extremely useful. These methods are based on Reynolds' analogy (modified by later workers) and dimensional analysis backed by experimentation.

Convection may be free or forced. In *forced convection* it is found that the heat transfer coefficient can be included in a non-dimensional relation of the form

$$Nu = \phi(Re,Pr) = \text{constant} \cdot Re^a \cdot Pr^b$$

where Nu is the Nusselt number ($Nu = hl/k$), Re is the Reynolds number ($Re = \rho Vl/\mu$) and Pr is the Prandtl number ($Pr = \mu c_{\mathrm{p}}/k$). In these relations l is a representative length dimension (diameter for a pipe and some chosen length for a plate), V is the bulk or free stream velocity outside the boundary layer. The values of the constants a and b depend on whether the flow is laminar or turbulent and on the geometry of the situation, and are usually found by experiment.

The determination of whether flow is laminar or turbulent is by the value of the Reynolds number;

For plates, $Re < 500\,000$, flow is laminar: $Re > 500\,000$, flow is turbulent

For tubes, $Re < 2000$, flow is laminar: $Re > 4000$, flow is turbulent

(between these two values there is a transition zone). There are many relations to be found in texts which allow for entry length problems, boundary conditions, etc. and it is not feasible to list them all here. Two relations are given below which give average values of Nusselt number over a finite length of plate or tube in forced, turbulent flow with Mach number less than 0.3 using total plate length and diameter for representative length dimension. Care must be taken in any empirical relation to use it as the author intended.

Plate; $Nu = 0.036Re^{0.8}Pr^{0.33}$

In this relation fluid properties should be evaluated at the film temperature, $T_{\text{film}} = (T_{\text{wall}} + T_{\text{bulk}})/2$.

Tube; $Nu = 0.023Re^{0.8}Pr^{0.4}$

In this relation fluid properties should be evaluated at the bulk temperature, $0.6 < Pr < 160$ and $(l/d) > 60$.

It should be noted that the index of Reynolds number of 0.8 is characteristic of turbulent flow; in laminar flow 0.5 is found.

It must be emphasized that reference to other texts in all but these simple cases is essential to estimate heat transfer coefficients. It should also be pointed out that the values obtained from such relations could give errors of 25%, and a search of the literature might reveal equations more suited to a particular situation. However, an estimate within 25% is better than no knowledge, and is a suitable starting point which may be modified in the light of experience.

For complex heat exchange surfaces such as a car radiator, empirical information is usually presented graphically (on these graphs the non-dimensional group St (Stanton number) may appear:

$$St = \frac{Nu}{RePr} = \frac{h}{\rho Vc_{\mathrm{p}}}$$

In *free convection* the relationship used is $Nu = \phi(Pr \cdot Gr)$ where Gr is the Grashof number, $\rho^2\beta g\theta l^3/\mu^2$ in which β is the coefficient of cubical expansion of the fluid and θ is a temperature difference (usually surface to free stream temperature). The transition from laminar to turbulent flow is determined by the product $(Pr \cdot Gr)$ known as the Rayleigh number, Ra. As a simple example, for plane or cylindrical, vertical surfaces it is found that;

For $Ra < 10^9$, flow is laminar and $Nu = 0.59(Pr \cdot Gr)^{0.25}$

For $Ra > 10^9$, flow is turbulent and $Nu = 0.13(Pr \cdot Gr)^{1/3}$

The representative length dimension is height and the resulting heat transfer coefficients are average values for the whole height. Film temperature is used for fluid properties. Warnings similar to those given for forced convection apply to the use of these equations.

Phase change convection heat transfer (condensing and evaporation) shows coefficients that are, in general, higher than those found in single-phase flow. They are not discussed here but information may be found in standard texts.

1.7.3.3 Radiation

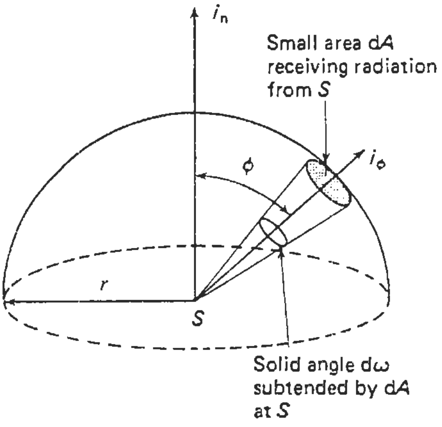
When an emitting body is not surrounded by the receiver the spatial distribution of energy from the radiating point needs to be known. To determine this distribution the intensity of radiation i_ϕ is defined in any direction ϕ as

$$i_\phi = \left(\frac{d\dot{E}''}{d\omega}\right)_\phi$$

where $d\omega$ is a small solid angle subtended at the radiating point by the area intercepting the radiation, $d\omega = dA/r^2$ (Figure 1.72) (the solid angle represented by a sphere is 4π steradians). Lambert's law of diffuse radiation states that $i_\phi = i_n \cos\phi$ where i_n is the normal intensity of radiation which can be determined for black and grey bodies;

Black i_n $\sigma T^4/\pi$ Grey i_n $\varepsilon\sigma T^4/\pi$

With this knowledge of the radiation intensity in any direction it is only necessary to determine the amount that any body can see of any other body to calculate the heat transfer rate. For this purely geometric problem mathematical analysis (Figure 1.73) suggests a quantity variously known as the geometric, configuration or shape factor, which is defined as the fraction of the energy emitted per unit time by one surface that is intercepted by another surface. The geometric factor is given by



i_n
Small area dA receiving radiation from S
ϕ
i_ϕ
r
S
Solid angle dω subtended by dA at S

Figure 1.72 Spatial distribution of radiation

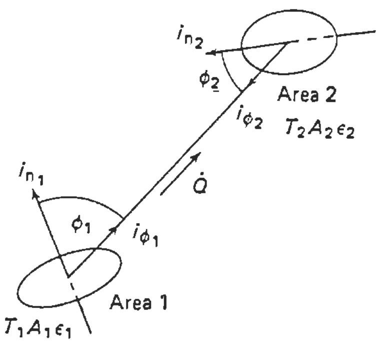


Figure 1.73 Heat transfer by radiation between two arbitrarily disposed grey surfaces

$$F_{12} = \frac{1}{A_1}\int_{A_1}\int_{A_2} \frac{\cos\phi_1 \cos\phi_2 \, dA_1 dA_2}{\pi x^2}$$

It can be seen that $A_1F_{12} = A_2F_{21}$, a useful reciprocal relation. It is also clear that the equation will require skill to solve in some situations, and to overcome this problem geometric factors are available for many situations in tables or on graphs (Hottel charts). The charts can give more information than anticipated by the use of shape factor algebra, which enables factors to be found by addition, subtraction, etc. (Figure 1.74).

Having established the intensity of radiation and the geometric factor, problems may be solved by an electrical analogy using the radiosity of a surface. Radiosity is defined as the total emitted energy from a grey surface:

$$\dot{J}'' = \dot{E}''_g + \rho\dot{G}''$$

where $\dot{J}''$ is the radiosity and $\rho\dot{G}''$ the reflected portion of the incident radiation $\dot{G}''$. Since $\dot{E}''_g = \varepsilon\dot{E}''_b$ the net rate of radiation leaving a grey surface of area A becomes

$$\frac{\dot{E}''_b - \dot{J}''}{\rho/A\varepsilon}$$

which may be envisaged as a potential difference, $\dot{E}''_b - \dot{J}''$, divided by a resistance, ρ/AE. A similar geometric resistance of $1/AF$ can be established to enable complete circuits to be drawn up. Thus for a three-body problem we may sketch the analogous electrical circuit (Figure 1.75) and apply Kirchhoff's electric current law to each $\dot{J}''$ node to obtain three simultaneous equations of the form

$$\frac{\dot{E}''_{b_1} - \dot{J}''_1}{\rho_1/A_1\epsilon_1} + \frac{\dot{J}''_2 - \dot{J}''_1}{1/A_1F_{12}} + \frac{\dot{J}''_3 - \dot{J}''_1}{1/A_1F_{13}} = 0$$

If there are more than three bodies sketching becomes complex and the equation above can be rearranged and generalized. For N surfaces ($j = 1$ to N) there will be N equations, the ith of which ($i = 1$ to N) will be

$$J''_i - (1 - \varepsilon_i) \sum_{j=1}^{N} F_{ij}\dot{J}''_j = \varepsilon_i \dot{E}''_{b_i}$$

When $j = i$, F_{ii} will be zero unless the the surface is concave and can see itself. This set of N simultaneous equations may be solved by Gaussian elimination for which a computer program may be used. The output of the solution will be N values of $\dot{J}''$

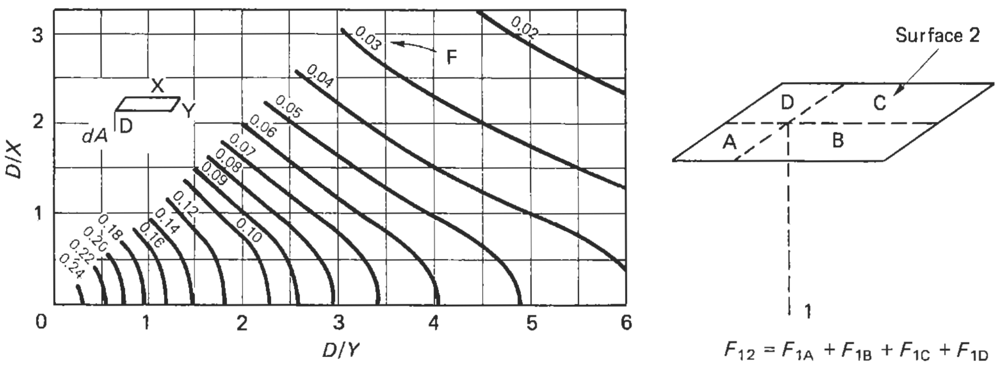

Figure 1.74 The geometric factor chart

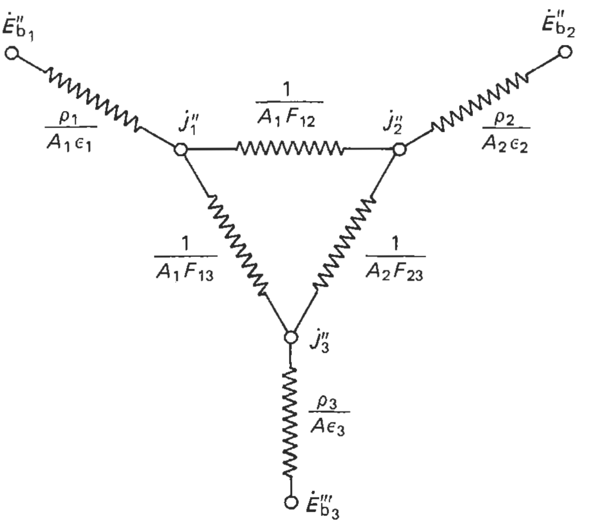

Figure 1.75 The electrical analogy for grey-body radiation problems

and any required heat flux can be found. In the three-body problem, for example, the heat transfer from 1 to 2

$$\dot Q_{12} = \frac{\dot J_1'' - \dot J_2''}{1/A_1F_{12}}$$

or the total heat transfer from body 1 is

$$\frac{\dot E_1'' - \dot J''_1}{\rho_1/A_1\epsilon_1}$$

Special cases are:

1. If $N - 1$ bodies are in large surroundings then for this Nth body $\dot J'' = \dot E_b''$;
2. An insulated or refractory surface has no black body potential but contributes to the heat transfer by taking up an equilibrium temperature T given by $\sigma T^4 = \dot J''$;
3. Radiation shield problems will show six resistances in series rather than the series-parallel circuits used previously.

In all the discussion on radiation above no account has been taken of the selective emitter for which emissivity is not constant. Additional techniques are required to solve these real problems and care should be exercised if widely varying emissivity is encountered. In new situations it will be necessary to determine emissivity by experiment before proceeding. No account has been taken of intervening media for which transmissivity is not unity. Gas absorption and radiation needs further information. For gases such as oxygen, nitrogen and hydrogen with symmetric, diatomic molecules the above work is adequate, but asymmetric molecular structures cause problems. In particular, hydrocarbon fuel combustion products (H_2O), CO_2, CO, SO_2) are important in engineering calculations and account must be taken of their radiation properties. Solar radiation problems also need special consideration.

1.7.3.4 *Finned surfaces*

In many heat exchange problems involving the determination of a *U*-value it is found that the surface heat transfer coefficient on one side of the solid interface is much smaller than that on the other. The smaller coefficient will dictate the heat transfer rate achieved, and in order to overcome this problem fins may be added to this poor convection surface to increase the area for heat transfer. This problem will occur in liquid to gas exchangers on the gas side. The addition of fins will alter the flow pattern so that a new coefficient should if possible be determined. It is also possible that there may be variation of coefficient over the fin surface.

Simple fin theory in which conduction along the fin is balanced with convection from the surface can be used to determine the temperature distribution and heat transfer rate of the fin. For example, when a long fin of constant cross-sectional area is examined (Figure 1.76) it is found that the temperature distribution is

$$\frac{\theta}{\theta_0} = \frac{\cosh(m(l - x))}{\cosh(ml)}$$

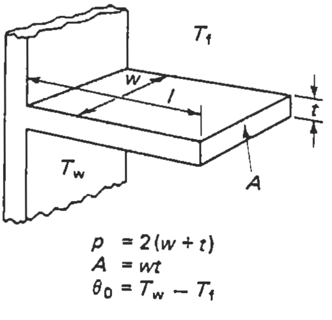

Figure 1.76 Simple rectangular fin nomenclature

and the heat transfer rate is

$$\dot{Q} = mkA\theta_0 \tanh(ml)$$

where θ is the temperature difference between fin and fluid and θ_0 is the difference at the fin root, $m = hp/kA$, p is the fin perimeter and A is the cross-sectional area.

A fin efficiency is then defined to compensate for the varying temperature difference along the fin as

$$\eta_{\text{fin}} = \frac{\text{Actual heat transfer rate}}{\text{Heat transfer rate if whole fin were at the wall temperature}}$$

which for the simple case above is $\eta_{\text{fin}} = \tanh(ml)/ml$. Fins are usually fitted in arrays and the efficiency of a fin system can be established in the form of an area weighted fin efficiency, η'

$$\eta' = \eta_{\text{fin}}\beta + 1 - \beta$$

where

$$\beta = \frac{\text{total fin area}}{\text{total area including fins}} = \frac{A_{\text{fin}}}{A}$$

The U value based on the enhanced area A is then

$$\frac{1}{U_A} = \frac{1}{(A_1/A)h_1} = \sum\frac{\Delta x}{R} + \frac{1}{\eta' h_2}$$

For complete surfaces β is supplied by the manufacturer.

When fins of more complex shape are used (tapered fins or annular fins) the cross-sectional area is not constant and fin efficiency data are obtained from graphs. Care should be taken in the interpretation of such graphs since the equations above may not agree with the definitions used for the graphs.

1.7.3.5 Heat exchangers[18]

It is possible to 'design' a heat exchanger with the information above and obtain a basic idea of size and configuration of simple tubular structures. It is first necessary to realize that temperature differences change along a heat exchanger, and that flow may be parallel or counter in direction. The latter is to be preferred, as it leads to smaller sizes. To allow for the changing temperature difference a log mean temperature difference is used (Figure 1.77):

$$\theta_{\text{LMTD}} = \frac{\theta_1 - \theta_2}{\ln(\theta_1/\theta_2)}$$

and to allow for varying flow patterns (which are neither counter nor parallel flow) graphs are available to give a factor F to modify the (usually) counterflow value of mean temperature difference. Thus for any heat exchanger

$$\theta_{\text{mean}} = F,\theta_{\text{LMTD}}$$

If an estimated mean U-value for the surface is then determined the heat exchange equation is

$$\dot{Q} = UAF\theta_{\text{LMTD}}$$

Thus the area is determined. There are many solutions to this equation to satisfy all the constraints which will include:

Energy for each stream $\dot{Q} = (\dot{m}\Delta h)_{\text{hot}} = (\dot{m}\Delta h)_{\text{cold}}$

(Δh = enthalpy change)

Continuity of each stream $\dot{m} = \rho AV$

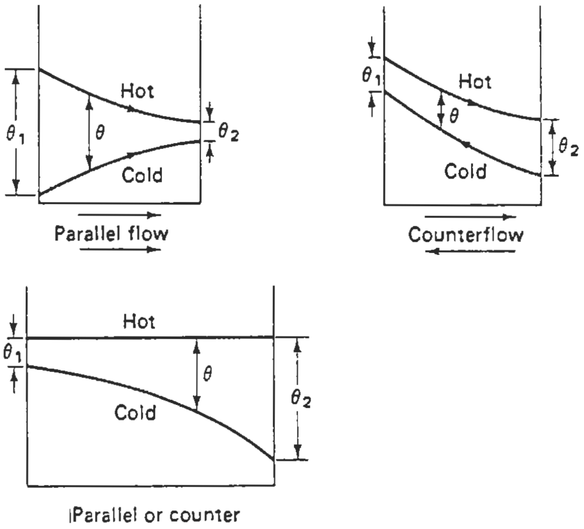

Figure 1.77 The mean temperature difference in heat exchangers

Heat transfer area $A = \pi dl$

The above equations will involve options with varying tube numbers and diameters which will affect the determination of heat transfer coefficients (and hence the U-value), and a number of solutions will be obtained. The optimum choice will involve allowable pressure drops, velocities and exit temperatures. It is not a difficult calculation, but, because of the choice, a computer program may be used. There are short cuts to this approach based on the interrelation between pressure drop and heat transfer (modified Reynolds' analogy) to determine heat transfer coefficients and a method based on graphs of effectiveness (E), capacity ratio (c) and number of transfer units (NTU) is sometimes used.

By whatever method a 'design' is achieved, it will, unless the application is very simple, be necessary to consult a professional heat exchanger designer with experience and full computer programs.

1.7.4 Use of computers

Computers may be used as an aid to heat transfer calculations at various levels of skill. At the simplest level, computer programs may be written for a home computer to determine, for example, heat losses in buildings, heat inputs from pipes and radiators, etc. This will save repetitive calculations and build a small library of useful programs. To aid those whose heat transfer and computing skills are slight Bacon[19] gives a simple approach to problems. At a higher level of skill Adams and Rogers[20] is a considerable advance in both programming and heat transfer technique. Both books use BASIC and the latter emphasizes the finite difference technique. Both books include programs. Supplementary reading from other heat transfer books would be advantageous. For more detail on the mathematics of finite difference techniques in heat transfer Myers[21] is useful.

An alternative approach to numerical approximations in computer work is to use finite element methods. For heat transfer applications Myers[21] is again useful. Very few people will find the need for finite element programming skills as there is an ever-increasing range of software which is aimed at the solution of many engineering problems, including heat transfer. Many of these are mainframe or PC packages in which there is integration between design, drawing, manufacture and analysis of stress, vibration, heat transfer, etc.

Whenever numerical approximation techniques are used large-scale analysis leads to considerable demand on data storage and computing time, which is expensive. It is therefore essential to do as much as possible with simple methods before becoming committed to large-scale finite element packages. If it is decided that the use of such a package is necessary it is vital to be sure of the requirements of the problem, for volume of input data and output results will be large and unpalatable. To assist with this problem, preprocessing packages are used for data input and mesh generation with graphic display, and post-processing packages are used for graphic display of the results. For example, the temperature distribution in a combustion chamber or piston displayed by colour graphics enables easier identification of problem areas.

Finally, it must be emphasized that computing is not a substitute for understanding heat transfer problems. It is an aid to enable a more detailed investigation to be achieved and presented in a fashion to enable engineers to improve their designs.

1.7.5 Heat transfer: nomenclature

A	area
B	Biot number
c_p	Specific heat capacity at constant pressure
$\dot{E}''_b$	Black-body emissive power
$\dot{E}''_g$	Grey-body emissive power
F	Fourier number, geometric factor, mean temperature factor
g	gravitational constant
Gr	Grashof number
h	surface heat transfer coefficient
i_ϕ	intensity of radiation in direction ϕ
i_h	normal intensity of radiation
$\dot{J}''$	radiosity
k	thermal conductivity
l	length
m	mass, fin parameter
$\dot{m}$	mass flow rate
Nu	Nusselt number
p	perimeter
Pr	Prandtl number
Q	heat transfer
$\dot{Q}$	heat transfer rate
$\dot{Q}'$	heat transfer rate per unit length
$\dot{Q}''$	heat transfer rate per unit area
$\dot{Q}'''$	heat transfer rate per unit volume
r	radius
Ra	Rayleigh number
Re	Reynolds number
St	Stanton number
T	temperature
t	time
U	overall heat transfer coefficient per unit area
U'	overall heat transfer coefficient per unit length
V	velocity
x,y,z	rectangular coordinates

Greek letters

α	thermal diffusivity, absorbtivity
β	coefficient of cubical expansion
Δ	change in
η	efficiency
ε	emissivity
λ	wavelength
μ	viscosity
ϕ	angle
ρ	density, reflectivity
σ	Stefan–Boltzmann constant
Σ	summation
θ	temperature difference
τ	transmissivity
ω	solid angle

2.1 Basic electrical technology

2.1.1 Flux and potential difference

The concept of flux and potential difference enables a unified approach to be adopted for virtually all the 'field' type of problems. Generally, the flowing quantity is termed the flux and the quantity which drives the flow is called the potential difference. This consistency of method is equally applicable to problems in fluid flow, heat transfer, electrical conduction, electrostatics and electromagnetism, to name but a few.

In general terms, the flux may be written as

$$\text{Flux} = \frac{(\text{Field characteristic}) \times (\text{Cross-sectional area}) \times (\text{Potential difference})}{(\text{Length})} \tag{2.1}$$

In specific terms, for the flow of an electric current through a conducting medium, equation (2.1) takes the form:

$$I = \frac{\sigma a V}{l} \tag{2.2}$$

where I is the current in amperes (A),
σ is the conductivity of the medium (siemens/m), i.e. the field characteristic,
a is the cross-sectional area of the medium (m^2),
l is the length of the medium (m), and
V is the applied potential difference, or voltage (V).

The group ($\sigma a/l$) is termed the conductance, denoted by G and measured in siemens, thus:

$$I = GV \tag{2.3}$$

The reciprocal of conductance is referred to as the resistance, R and is measured in ohms (Ω). Hence

$$I = V/R \tag{2.4}$$

Equation (2.4) is the familiar 'Ohm's law', which defines a linear relationship between voltage and current in a conducting medium. If the resistance, R, varies with the magnitude of the voltage, or the current, then the resistance is non-linear. Rectifiers constitute one particular class of non-linear resistors.

Comparing equations (2.4) and (2.2) gives:

$$R = l/(\sigma a) \tag{2.5}$$

It is more usual, however, to quote the 'resistivity' as opposed to the conductivity, and resistance is generally written as:

$$R = \rho l/a \tag{2.6}$$

where ρ is the resistivity of the conductor in ohm-metres.

The resistance of all pure metals is temperature dependent, increasing linearly for moderate increases in temperature. Other materials, including carbon and many insulators, exhibit a decreasing resistance for an increase in temperature.

2.1.2 Simple resistive circuits

The effective total resistance of a series arrangement is the algebraic sum of all the resistances in series, i.e.

$$R_t = R_1 + R_2 + R_3 \tag{2.7}$$

where R_t is the total resistance of the circuit.

For resistors in parallel the effective total resistance obeys an inverse summation law, i.e.

$$\frac{1}{R_t} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} \tag{2.8}$$

2.1.3 Electromotive force and potential difference

In a metallic conductor which has a potential difference applied across opposite ends, free electrons are attracted to the more positive end of the conductor. It is this drift of electrons which constitutes the electric current, and the effect is simply Nature's attempt to redress an energy imbalance. Although the negatively charged electrons actually drift towards the positive end of the conductor, traditional convention gives the direction of the current flow from positive to negative. There is nothing really at issue here, since it is only a simple sign convention which was adopted long before the true nature of the atom and its associated electrons were postulated.

A current of 1 A is associated with the passage of 6.24×10^{18} electrons across any cross-section of the conductor per second. The quantity of charge is the coulomb, Q, and

$$Q = I \cdot t \tag{2.9}$$

where 1 coulomb of charge is passed when a current of 1 A flows for a period of 1 s.

The electromotive force (e.m.f.) is that which tends to produce an electric current in a circuit, and is associated with the energy source. Potential difference is simply the product of current and resistance across any resistive element in a circuit, irrespective of the energy source. For circuit elements other than purely resistive, the potential difference across the element becomes a time-dependent function.

2.1.4 Power and energy

Power is the rate at which energy is expended, or supplied. The potential difference across any two points in a circuit is defined as the work done in moving unit charge from a lower to a higher potential. Thus the work done in moving Q coulombs of charge across a constant potential difference of V volts is:

$$W = Q \cdot V \tag{2.10}$$

Therefore

$$\text{Power} = \frac{dW}{dt} = \frac{dQ}{dt} V$$

From equation (2.9) (dQ/dt) = I, thus

$$\text{Power} = IV \tag{2.11}$$

Using Ohm's law, the power dissipated across a simple resistive circuit element is

$$\text{Power} = IV = I(I \cdot R) = I^2R \tag{2.12}$$

2.1.5 Network theorems

A network consists of a number of electrical elements connected up in a circuit. If there is no source of electromotive force in the circuit it is said to be passive. When the network contains one or more sources of electromotive force it is said to be active.

A number of well-established theorems have been developed for the analysis of complex resistive networks[1-3] and are listed below:

Kirchhoff's first law: The algebraic sum of the currents entering (+ve) and leaving (−ve) a junction is zero.

Kirchhoff's second law: The algebraic sum of potential differences and e.m.f.'s around any closed circuit is zero.

Superposition theorem: In a linear resistive network containing more than one source of e.m.f. the resultant current in any branch is the algebraic sum of the currents that would be produced by each e.m.f. acting on its own while the other e.m.f.'s are replaced with their respective internal resistances.

Thevenin's theorem: The current through a resistor R connected across any two points in an active network is obtained by dividing the potential difference between the two points, with R disconnected, by $(R + r)$, where r is the resistance of the network between the two connection points with R disconnected and each e.m.f. replaced with its equivalent internal resistance. An alternative statement of Thevenin's theorem is: 'Any active network can be replaced at any pair of terminals by an equivalent e.m.f. in series with an equivalent resistance.' The more concise version of Thevenin's theorem is perhaps a little more indicative of its power in application.

Norton's theorem: Any active network can be replaced at any pair of terminals by an equivalent current source in parallel with an equivalent resistance. It may appear that Norton's theorem is complementary to Thevenin's theorem and both can be equally well used in the analysis of resistive networks.

Other useful network analysis techniques include 'mesh analysis', which incorporates Kirchhoff's first law, and 'nodal analysis', which is based on Kirchhoff's second law. Mesh and nodal analysis are also essentially complementary techniques.

2.1.6 Double-subscript notation

To avoid ambiguity in the direction of current, e.m.f. or potential difference, a double-subscript notation has been adopted. Figure 2.1 shows a source of e.m.f. which is acting from D to A. The e.m.f. is therefore E_{da}. The current flows from A to B, by traditional convention, and is designated I_{ab}. From this simple circuit it is apparent that $I_{ab} = I_{bc} = I_{cd} = I_{da}$.

The potential difference across the load R is denoted V_{bc} to indicate that the potential at B is more positive than that at C. If arrow heads are used to indicate the potential difference, then they should point towards the more positive potential.

2.1.7 Electrostatic systems

Electrostatic systems are quantified by the physical behaviour of the 'charge'. Fortunately, the unified field approach lends itself well to the quantification of electrostatic systems.

Figure 2.2 shows two parallel, conducting metal plates separated by an evacuated space. A potential difference is applied across the plates such that they become charged at equal magnitude but opposite sign. For the electrostatic system, equation (2.1) is written

$$Q = \frac{\varepsilon_0 a V}{l} \tag{2.13}$$

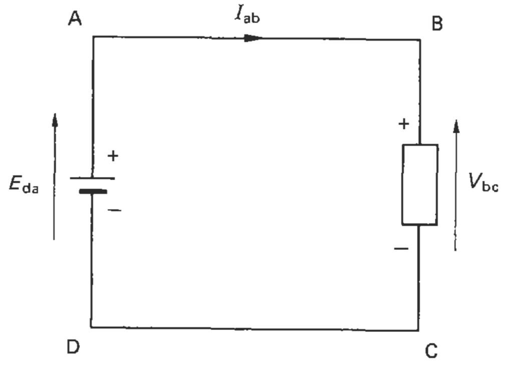

Figure 2.1 Double-subscript notation

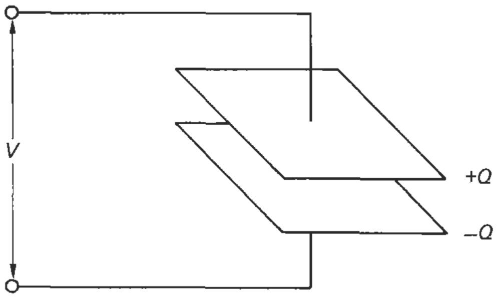

Figure 2.2 Electrostatic system

where Q is the total charge in coulombs,
ε_0 is the permittivity of free space in Farads/m, i.e. the field characteristic,
a is the cross-sectional area of the plates,
l is the distance separating the plates, and
V is the applied potential difference.

The group $(\varepsilon_0 a/l)$ is termed the capacitance of the system. It is usually denoted by C, and is measured in farads (F). Thus

$$Q = C \cdot V \tag{2.14}$$

It is more common to use the microfarad (μF) or the picofarad (pF) as the unit of measurement.

NB: 1 μF = 10^{-6} F: 1 pf = 10^{-12} F

If the plates are separated by an insulating medium other than free space, then these so-called dielectric media have a different value of permittivity. The actual permittivity is related to the permittivity of free space by the relative permittivity of the dielectric, i.e.

$$\varepsilon = \varepsilon_0 \cdot \varepsilon_r \tag{2.15}$$

where ε_r is the relative permittivity of the dielectric. The permittivity of free space, ε_0, is numerically equal to $(1/36\pi) \times 10^{-9}$. The relative permittivity of some of the more common dielectric materials are listed in Table 2.1.

2.1.8 Simple capacitive circuits

For three capacitors connected in a simple parallel arrangement, the equivalent total capacitance is given as the algebraic sum of all the capacitances in the circuit, i.e.

$$C = C_1 + C_2 + C_3 \tag{2.16}$$

where C is the total capacitance. For a series capacitance arrangement of three capacitors, the total equivalent capacitance is related through the inverse summation given as

$$\frac{1}{C} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} \tag{2.17}$$

Table 2.1 Relative permittivities of some typical dielectric materials

Material	*Relative permittivity*
Air	1
Paper	2–2.5
Porcelain	6–7
Mica	3–7

Equations (2.16) and (2.17) can be used to reduce series and parallel capacitor circuits to a single equivalent capacitor.

Composite capacitors, involving different dielectric media, may also be treated in the same manner as a series capacitor arrangement.

2.1.9 Charging a capacitor

Figure 2.3 shows a parallel plate capacitor which is connected in series with a resistor to a source of e.m.f. (say, a battery) through a switch. Initially, the capacitor is uncharged before the switch is closed. When the switch is closed a charging current will flow until such time that the potential difference across the capacitor is equal to the e.m.f. available from the source. The charging process consists of taking electrons from plate A and transferring them through the external wiring to plate B. The energy required to do this is derived from the battery. The build-up of electrons from the negative terminal of the battery to plate B of the capacitor induces a dielectric flux between the plates and a balancing positive charge is developed on plate A. As long as the dielectric flux is changing, a current will flow externally. Eventually a state of equilibrium will be reached. Note that no electrons can pass through the dielectric since it is an insulator.

The instantaneous current during charging is

$$i = \mathrm{d}Q/\mathrm{d}t$$

From equation (2.14), this may be written for a capacitor as

$$i = \mathrm{d}Q/\mathrm{d}t = C(\mathrm{d}v/\mathrm{d}t) \qquad (2.18)$$

where v is the instantaneous voltage. The instantaneous power is therefore

$$p = iv = Cv(\mathrm{d}v/\mathrm{d}t)$$

The energy supplied over the time period, $\mathrm{d}t$, is

$$Cv(\mathrm{d}v/\mathrm{d}t)\mathrm{d}t = Cv\mathrm{d}v$$

Hence the total energy supplied is

$$\int_0^V Cv\mathrm{d}v = \frac{1}{2}CV^2 \qquad (2.19)$$

2.1.10 Dielectric strength

If the potential difference across opposite faces of a dielectric material is increased above a particular value, the material breaks down. The failure of the material takes the form of a small puncture, which renders the material useless as an insulator. The potential gradient necessary to cause breakdown is normally expressed in kilovolts/millimetre and is termed the 'dielectric strength'. The dielectric strength of a given material decreases with increases in the thickness. Table 2.2 gives approximate values for some of the more common dielectric materials.

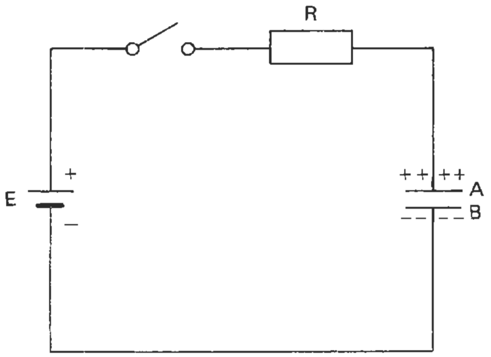

Figure 2.3 Charging a capacitor

2.1.11 Electromagnetic systems

The magnetic field can be defined as the space in which a magnetic effect can be detected, or observed. An obvious magnetic field is observable around a straight length of conductor carrying a current. In particular, exactly the same magnetic field as that produced by a bar magnet is observed when the current-carrying conductor is formed into a helical type coil. The equipotential loops describe the path of the magnetic flux, ϕ, and although the flux lines have no physical meaning, they provide a convenient vehicle to quantify various magnetic effects.

The direction of the magnetic flux is governed by the so-called 'right-hand screw rule'. This states that the direction of the magnetic field produced by a current corresponds with the direction given by turning a right-hand screw thread. The direction of the current corresponds with the translational movement of the screw.

2.1.12 Magnetic field of a toroid

Figure 2.4 shows a toroidal coil, of N turns, which is wound round an annular former. A resultant magnetic flux, shown as broken lines in the figure, is generated when the coil carries a current. For the magnetic field, equation (2.1) takes the general form:

$$\phi = \frac{\mu a F}{l} \qquad (2.20)$$

where ϕ is the magnetic flux(in webers),
μ is the permeability of the medium (in henrys/m),
a is the cross-sectional area of the flux path in the toroid,
l is the length of the flux path, and
F is the magnetic potential difference, or magnetomotive force (in amperes).

The magnetomotive force (m.m.f.) is equal to the product of the number of turns on the coil and the current carried, i.e.

$$F = IN \qquad (2.21)$$

Note that the m.m.f. is descritively expressed in 'ampere-turns'. Since the number of turns is already a dimensionless quantity, the accepted unit of magnetomotive force is the ampere (A).

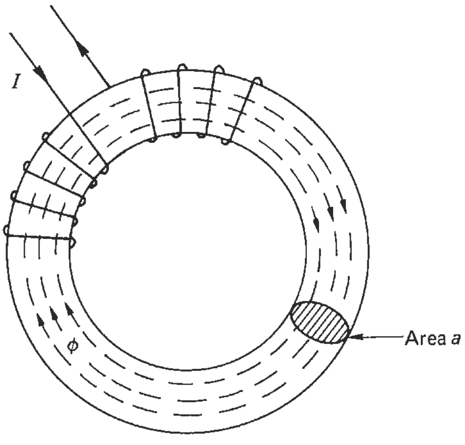

Figure 2.4 Toroid

The group ($\mu a/l$) is termed the permeance and the inverse of permeance is the reluctance, S. Thus equation (2.20) may be rewritten as

$$\phi = F/S \qquad (2.22)$$

Equation (2.22) represents an electromagnetic version of Ohm's law.

Alternatively, equation (2.20) can be expressed as

$$\frac{\phi}{a} = \mu \frac{F}{1}$$

or

$$B = \mu H \qquad (2.23)$$

where $B = \phi/a$ is the magnetic flux density (in webers/m^2, or Tesla (T)) and $H = F/l$ is the magnetic intensity (in A/m).

2.1.13 Permeability

The permeability of free space, μ_0, is numerically equal to $4\pi \times 10^{-7}$. The absolute permeability of other materials is related to the permeability of free space by the relative permeability, i.e.

$$\mu = \mu_0 \cdot \mu_r \qquad (2.24)$$

For air and other non-magnetic materials, the absolute permeability is the same constant. For magnetic materials, absolute permeability is not a fixed constant but varies non-linearly with the flux density. The non-linear variation of permeability is conveniently displayed as a functional plot of magnetic flux density, B, against magnetic intensity, H. Figure 2.5 illustrates a number of B–H curves for some common materials.

Also shown in Figure 2.5 is the B–H curve for air, the only straight-line relationship in the diagram. It is apparent that for an applied magnetic intensity, the magnetic flux developed in a coil with a ferrous core is many times greater than that through a similar coil with an air core. In most practical systems, therefore, a ferrous core is normally used, since it greatly facilitates the establishment of a magnetic flux.

2.1.14 Faraday's law

Faraday's law states that the e.m.f. induced in a magnetic circuit is equal to the rate of change of flux linkages in the circuit, and is given as

$$e = N(\mathrm{d}\phi/\mathrm{d}t) \qquad (2.25)$$

where e is the instantaneous induced e.m.f.

Equation (2.25) forms the basis of all electrical power generation machines and is a statement of the fact that an electric current can be produced by the movement of magnetic flux relative to a coil. In all rotating electrical generators it is actually the coil which is moved relative to the magnetic field. The net result, however, is exactly the same.

The direction of the induced e.m.f. is always such that it tends to set up a current to oppose the motion (or the change of magnetic flux) which was responsible for inducing the e.m.f. This is essentially a statement of Lenz's law. In many texts, therefore, the right-hand side of equation (2.25) is often shown as a negative quantity.

The motion, or change of flux, is associated with the application of a mechanical force which ultimately provides the torque required to drive the electric generator. Figure 2.6 shows a single conductor of length l metres, carrying an induced current I and lying perpendicular to a magnetic field of flux density, B T.

The force applied causes the conductor to move through a distance $\mathrm{d}x$ metres. The mechanical work done is therefore $F \cdot \mathrm{d}x$. The electrical energy produced is given as the product of the power developed and the time duration, i.e. $e \cdot I \cdot \mathrm{d}t$.

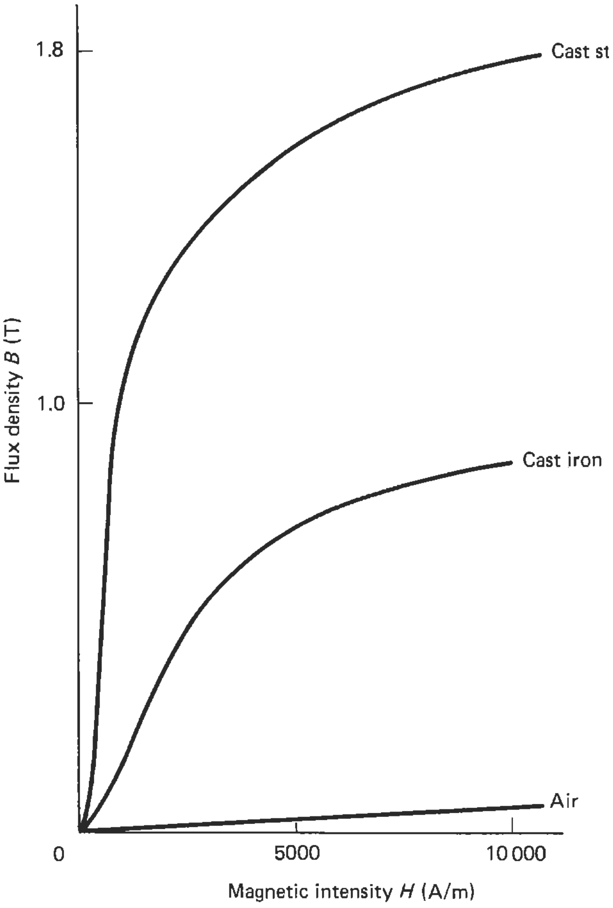

Figure 2.5 *B–H* curves for some common materials

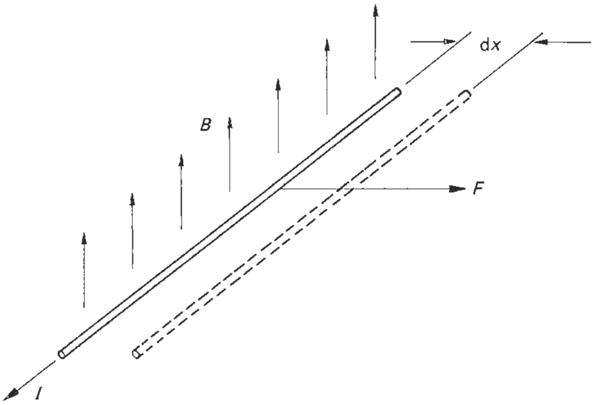

Figure 2.6 Generation of e.m.f.

For no external losses, the mechanical work done is converted into electrical energy. Thus

$$e \cdot I \cdot \mathrm{d}t = F \cdot \mathrm{d}x \tag{2.26}$$

Using equation (2.25) the induced e.m.f. is equal to the rate of change of flux linkage. For a single conductor, $N = 1$, and in consequence

$$e = (B \cdot l \cdot \mathrm{d}x)/\mathrm{d}t$$

Therefore

$$(B \cdot l \cdot \mathrm{d}x/\mathrm{d}t) \cdot I \cdot \mathrm{d}t = F \cdot \mathrm{d}x$$

i.e.

$$F = B \cdot l \cdot I \tag{2.27}$$

Equation (2.27) relates the applied force to the corresponding current generated in a conductor moving through a magnetic field. The equation applies equally to an electric generator or, conversely, to a motor, in which case the electrical power supplied is converted into a mechanical torque via the electromagnetic effect.

2.1.15 Self-induced e.m.f.

If a current flows through a coil a magnetic flux links that coil. If, in addition, the current is a time-varying quantity, then there will be a rate of change of flux linkages associated with the circuit. The e.m.f. generated will oppose the change in flux linkages.

When dealing with electric circuits it is convenient if the voltage across individual elements can be related to the current flowing through them. Figure 2.7 shows a simple circuit comprising a coil having N turns and resistance R, connected in series with a time-varying voltage. The voltage drop across the terminals A and B can be split into two components. First, there is the voltage drop due solely to the resistance of the coiled element. Second, there is a voltage drop which is a consequence of the self-induced e.m.f. generated through the electromagnetic effect of the coil. Thus

$$v = vr + vl$$

$$= iR + N\frac{\mathrm{d}\phi}{\mathrm{d}t} \tag{2.28}$$

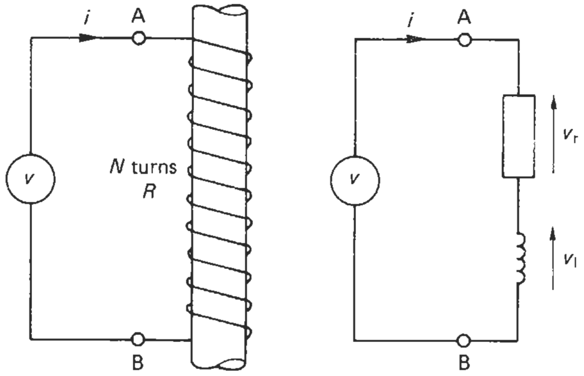

Figure 2.7 Self-induced e.m.f.

From equations (2.20) and (2.21)

$$\phi = \frac{\mu a F}{l} = \frac{\mu a i N}{l}$$

Therefore

$$v = iR + N\frac{\mathrm{d}}{\mathrm{d}t}\left[\frac{\mu a i N}{l}\right]$$

$$= iR + N^2\left[\frac{\mu a}{l}\right]\frac{\mathrm{d}i}{\mathrm{d}t} \tag{2.29}$$

The group $N^2(\mu a/l)$ is called the 'self-inductance' of the coil and is denoted by L. The unit of self-inductance is the henry (H). Therefore

$$v = iR + L\frac{\mathrm{d}i}{\mathrm{d}t} \tag{2.30}$$

By comparing equations (2.28) and (2.30) it is apparent that

$$L\frac{\mathrm{d}i}{\mathrm{d}t} = N\frac{\mathrm{d}\phi}{\mathrm{d}t}$$

Integration then gives

$$L = N\phi/i \tag{2.31}$$

The nature of the self-induced e.m.f. (i.e. $L\mathrm{d}i/\mathrm{d}t$) is such that it will oppose the flow of current when the current is increasing. When the current is decreasing the self-induced e.m.f. will reverse direction and attempt to prevent the current from decreasing.

2.1.16 Energy stored in an inductor

Instantaneous power $= vi$

$$\text{Energy stored} = W = \int_0^t vi\mathrm{d}t$$

$$= \int_0^t L\frac{\mathrm{d}i}{\mathrm{d}t}i\mathrm{d}t$$

$$= L\int_0^I i\mathrm{d}i = \frac{1}{2}LI^2 \tag{2.32}$$

2.1.17 Mutual inductance

Two coils possess mutual inductance if a current in one of the coils produces a magnetic flux which links the other coil.

Figure 2.8 shows two such coils sharing a common magnetic flux path in the form of a toroid. The mutual inductance between the two coils is

$$M = \frac{N_2\phi}{I_1}\ (\mathrm{H}) \qquad (2.33)$$

where N_2 is the number of turns on coil 2,
I_1 is the current through coil 1, and
ϕ is the magnetic flux linking coils 1 and 2.
The mutual inductance effect finds great application both to electrical transformers and to rotating electrical machines.

2.1.18 Hysteresis in magnetic circuits

Hysteresis can be described with reference to a toroidal coil wound on an iron core (see Figure 2.4). The current supplied to the coil can be imagined to be taken through a cyclic process where it is increased from 0 to $+I$ A, back through 0 to $-I$ A and again back through 0 to $+I$ A. Measurement of the flux density in the core, as the current varies, results in a B–H curve as depicted in Figure 2.9.

The behaviour of the B–H relationship is termed a 'hysteresis loop'. This behaviour is typical for ferrous cores and is an illustration of the fact that all the electrical energy supplied to magnetize an iron core is not returned when the coil current is reduced to zero. The loss of energy is called 'hysteresis loss', and it is manifested as heat in the iron core.

Hysteresis is characterized by two parameters, which are the 'remanent flux density' (or 'remanence') and the 'coercive force'. The remanent flux density is the flux density which remains in the core when the magnetic intensity (i.e. the coil current) has been reduced to zero. The remanent flux density is represented by line OA in Figure 2.9. The coercive force is the magnetic intensity required to reduce the remanent flux density to zero, and is represented by line OC in Figure 2.9.

2.1.19 Eddy current loss

Faraday's law (equation 2.25)) shows that a time-varying magnetic flux will induce an e.m.f. in a coil. If the ends of the coil are connected and form a closed circuit, then the induced voltage will circulate a current around the closed loop. Consider now an iron core, in which a time-varying magnetic flux exists. Since iron is a conductor then there will be a multitude of arbitrary closed paths within the iron matrix. These closed paths constitute effective conduction routes and the varying magnetic flux will generate a flow of current round them. The currents are called 'eddy currents' and, because of the ohmic resistance of the core, the end result is an energy loss as the eddy currents are dissipated as heat.

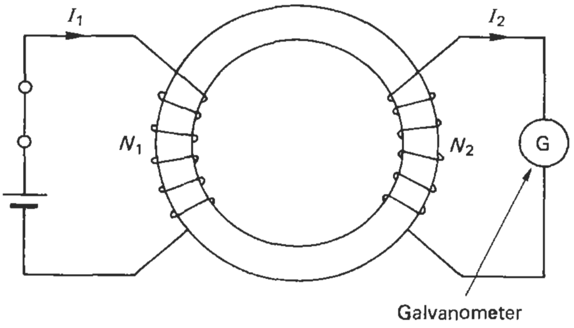

Figure 2.8 Mutual inductance

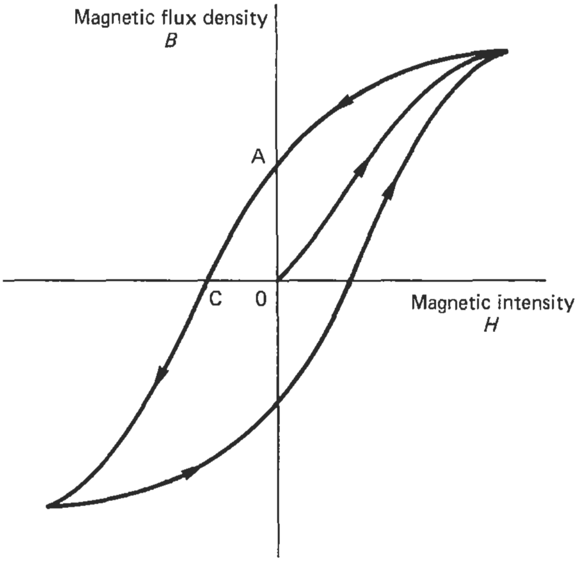

Figure 2.9 Hysteresis loop for an iron-cored toroid

Eddy current losses can be greatly reduced by building the iron core in the form of laminations which are insulated from one another. The laminated assembly confines the path lengths for the eddy currents to each respective lamination. The cross-sectional area of the eddy current path is also reduced and the eddy current loss is approximately proportional to the square of the thickness of the laminations. A practical minimum thickness for any lamination is about 0.4 mm. Increasing manufacturing costs could not justify the use of much thinner laminations.

2.1.20 Kirchhoff's laws and the magnetic circuit

Figure 2.10 shows a magnetic circuit in which a magnetizing coil is wound on one of the limbs and another limb incorporates the usual feature of an 'air gap'. Using the analogy between the magnetic and the conduction circuits, the magnetic circuit can be represented in terms of an energy source (or m.m.f.) and each limb of the magnetic circuit is written in terms of the appropriate reluctance, S. This is illustrated in Figure 2.11.

Given all the relevant dimensions and material properties, the problem is resolved to one of calculating the current required to establish a prescribed magnetic flux density in the air gap. The solution invokes the use of Kirchhoff's laws as they apply to magnetic circuits:

First law: At any instant in time, the sum of the fluxes flowing into a node is equal to the sum of the fluxes flowing out.
Second law: Around any closed magnetic circuit the total magnetomotive force is equal to the sum of all the m.m.f.'s round the circuit.

Manipulation of equations (2.20) and (2.24) then yields the required solution. The self-inductance of the coil (if required) may be calculated from equation (2.31), or from the definition

$$L = N^2(\mu a/l) = N^2/S \qquad (2.34)$$

It has already been shown that the lowest permeability is that of air, and that the m.m.f. required to produce a flux density in air is many times greater than that required to produce the same flux density in a ferrous material. It may

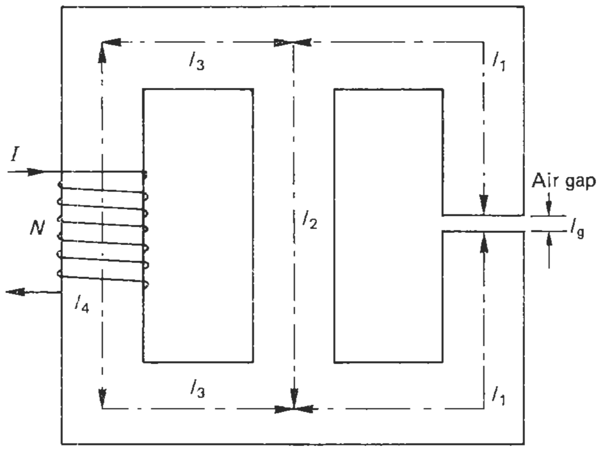

Figure 2.10 Magnetic circuit

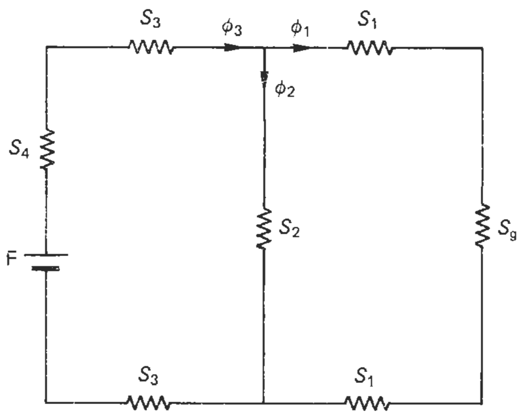

Figure 2.11 Representation of the magnetic circuit of Figure 2.10

reasonably be questioned therefore why air gaps are used at all in iron-cored magnetic circuits. The only function of the air gap is to provide a measure of linearity to the magnetic system such that the inductance remains reasonably constant over a range of operating currents.

2.1.21 Alternating quantities

If an electrical quantity varies with time, but does not change its polarity, it is said to be a direct current (d.c.) quantity. If the quantity alternates between a positive and a negative polarity, then it is classified as an alternating current (a.c.) quantity.

The period, T, is the time interval over which one complete cycle of the alternating quantity varies. The inverse of the period is the frequency, f, in Hertz (Hz). Circular frequency, ω, in radians per second is also commonly used.

Instantaneous values of the quantities encountered in electrical systems are usually denoted by lower-case letters. Since the instantaneous values are difficult to measure and quantify, a.c. quantities are usually expressed as 'root mean square' (r.m.s.) values. For a periodically varying a.c. quantity, the r.m.s. value is given by

$$\text{r.m.s.} = \left[1/t \int_0^t (\text{quantity})^2 \mathrm{d}t\right]^{1/2} \qquad (2.35)$$

Many electrical quantities vary in a sinusoidal manner and it can easily be shown that the r.m.s. value is simply related to the maximum value by

$$\text{r.m.s.} = \text{max}/(\sqrt{2}) = 0.707 \text{ max} \qquad (2.36)$$

2.1.22 Relationship between voltage and current in *R*, *L* and *C* elements

For a simple resistive element, current is directly proportional to voltage. The current waveform will therefore be essentially the same shape as the voltage waveform.

For an inductive coil with negligible resistance, the relation between voltage and current is given by equation (2.30), i.e.

$$v = L\frac{\mathrm{d}i}{\mathrm{d}t}$$

Thus

$$i = \frac{1}{L}\int v\,\mathrm{d}t \qquad (2.37)$$

The relation between voltage and current for a capacitive element is given by equation (2.18), i.e.

$$i = C\frac{\mathrm{d}v}{\mathrm{d}t}$$

For the capacitive element it can be seen that a current will flow only when the voltage is changing. No current can flow if the voltage is constant since $\mathrm{d}v/\mathrm{d}t$ will then be equal to zero. The capacitor then, will block any steady d.c. input and indeed is sometimes used for this express purpose.

2.1.23 *RL* and *RC* circuits under transient switching conditions

Circuits involving a single resitor, capacitor or inductance are rare. It is more usual to find circuits involving some or other combination of these elements in both d.c. and a.c. applications. Figure 2.12 illustrates two simple RL and RC circuits.

2.1.23.1 RL circuit

With the switch open there is no flow of current in the circuit. At the instant of switching, the current will rise and eventually reach a steady-state value of V_s/R. The transient period is governed by equation (2.30), which represents a first-order, ordinary differential equation in i. The solution of equation (2.30) involves separating the variables to allow integration. The general solution is

$$i = I[1 - \exp(-Rt/L)] \qquad (2.38)$$

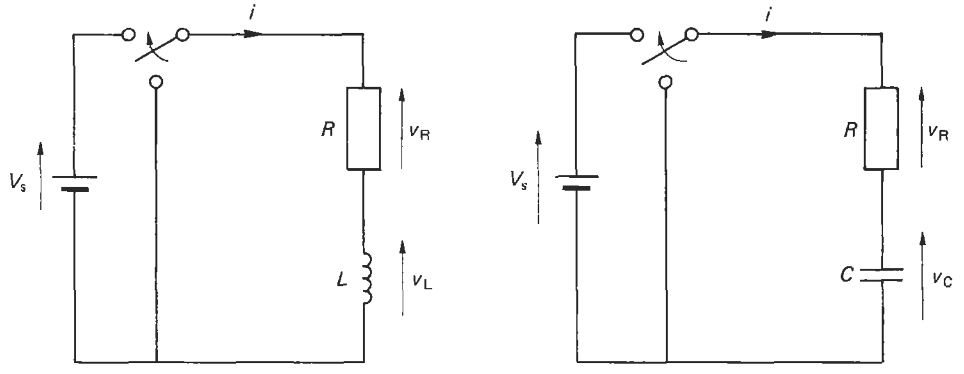
Equation (2.38) shows that the current growth in the circuit will rise exponentially to reach a steady state value as time, t, increases. It may also be shown that

$$v = L\frac{\mathrm{d}i}{\mathrm{d}t} = V_s \cdot \exp(-Rt/L) \qquad (2.39)$$

The 'time constant', T, for the RL circuit is L/R.

2.1.23.2 RC circuit

In Figure 2.12(b), with the switch open there is zero potential difference across the capacitor. On closing the switch the



(a) (b)

Figure 2.12 Simple *RL* and *RC* circuits under transient switching conditions

voltage across the capacitor will rise in an asympototic manner, reaching a steady-state value of V_s. From Kirchhoff's second law:

$$V_s = iR + v_c \tag{2.40}$$

where v_c is the instantaneous voltage across the capacitor.

From equation (2.18) we can write:

$$V_s = RC\frac{dv_c}{dt} + v_c \tag{2.41}$$

Equation (2.41) shows that the instantaneous voltage across the capacitor also conforms to a first-order system. The solution gives

$$v_c = V_s[1 - \exp(-t/RC)] \tag{2.42}$$

The time constant for the simple *RC* circuit is

$$T = RC \tag{2.43}$$

Both the simple *RL* and *RC* circuits are first-order systems with a generalized form of transient behaviour. In circuits containing both inductive and capacitive elements the transient behaviour is governed by a second-order ordinary differential equation. The transient behaviour of these circuits is, however, less important than their response to sinusoidally varying inputs.

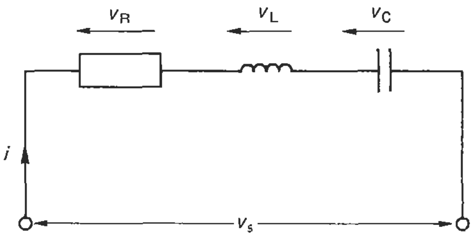


Figure 2.13 Series *RLC* circuit

2.1.24 Steady-state alternating currents

In most practical applications in electrical engineering the voltages and currents are sinusoidal. A simple series *RLC* circuit is depicted in Figure 2.13. Since the current is common to each of the circuit elements, it is used for reference purposes. The instantaneous current is defined as

$$i = I_m \sin(\omega t) \tag{2.44}$$

where I_m is the maximum (or peak) value of the current and ω is the angular, or circular frequency in radians/s.

The voltage drop across the resistor is

$$v_R = iR = I_m R \sin(\omega t) \tag{2.45}$$

Equation (2.45) indicates that the voltage drop across the resistor is in phase with the current. In other words, v_R reaches a positive maximum at the same instant as the current, i. The voltage drop across the inductor is

$$\begin{aligned} v_L = L\frac{di}{dt} &= L\frac{d}{dt}[I_m \sin(\omega t)] \\ &= LI_m\omega \cos(\omega t) \\ &= \omega L I_m \sin(\omega t + 90) \end{aligned} \tag{2.46}$$

The relationship between current and voltage drop across the inductor is shown in Figure 2.14.

It can be seen that there is a phase difference between the voltage drop and the current through the inductor. In fact, v_L reaches a positive maximum 'before' i and v_L is said to 'lead' the current by 90°. For the capacitor, the voltage drop is given by

$$\begin{aligned} v_c = 1/C\int i\,dt &= 1/C\int I_m \sin(\omega t)dt \\ &= -\frac{I_m}{\omega C}\cos(\omega t) \\ &= +\frac{I_m}{\omega C}\sin(\omega t - 90) \end{aligned} \tag{2.47}$$

The voltage drop across the capacitor therefore reaches its positive maximum after that of i. In general terminology, v_c 'lags' i by 90°.

Equations (2.45)–(2.47) are all of similar form in that they can be expressed as

Voltage drop = constant × current

In equation (2.46) the constant ωL is termed the 'inductive reactance' and is denoted by X_L. In equation (2.47) the

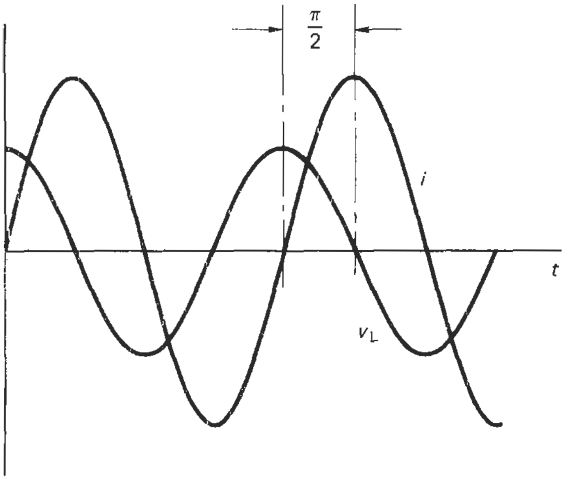

Figure 2.14 Current and voltage drop across an inductor

constant ($1/\omega C$) is the 'capacitive reactance', which is denoted as X_c. Both of these reactances have units of ohms.

The total voltage drop across the three circuit elements is

$$v = v_R + v_L + v_C$$
$$= iR + L\frac{di}{dt} + \frac{1}{C}\int i dt$$

Therefore

$$v = I_m R \sin(\omega t) + \omega L I_m \sin(\omega t + 90°) + \frac{I_m}{\omega C} \sin(\omega t - 90°) \tag{2.48}$$

While equation (2.48) defines the total instantaneous voltage drop in mathematical terms, it is rather cumbersome to deal with. To simplify the analysis, the addition of a.c. voltages is conveniently performed using a graphical technique involving 'phasors'.

2.1.25 Phasor diagrams

Any sinusoidally varying quantity can be represented as a phasor, which is a vector quantity. The length of the phasor is proportional to the magnitude of the product of the reactance and the maximum current. The direction of the phasor is determined by the phase angle and its relation to some common reference.

For the *RLC* circuit of Figure 2.13 the voltage drop across the inductance may be arbitrarily assumed greater than that across the capacitor. The total voltage drop in the circuit is then given as the phasor addition of the three individual potential difference components. This is illustrated in Figure 2.15.

The vector addition of the three phasors shows that the source voltage leads the current by an angle of ϕ degrees, i.e.

$$\bar{V} = V_m \sin(\omega t + \phi) \tag{2.49}$$

The circuit is therefore essentially inductive and, using the standard notation, the total phasor voltage is designated by a capital letter with an overbar.

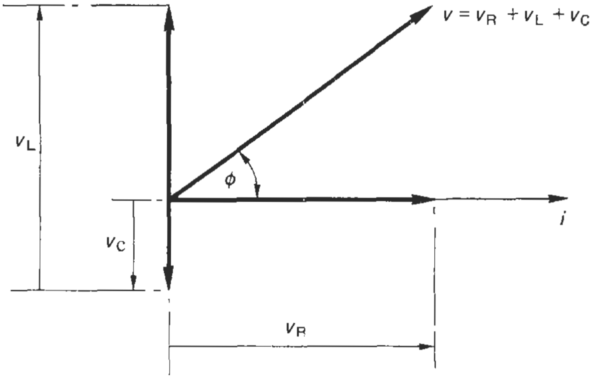

Figure 2.15 Phasor diagram for series *RLC* circuit

2.1.26 Complex notation

Since inductive and capacitive elements in a.c. circuits involve a phase shift of +90° and −90°, respectively, the complex number notation is used extensively to manipulate phasor quantities. The complex operator *j* (defined as $\sqrt{-1}$) is a unit operator which, when multiplying a phasor, shifts it by 90° in an anti-clockwise direction. Thus for the series *RLC* circuit

$$\bar{V}_R = \bar{I}R,\ \bar{V}_L = j\bar{I}X_L \text{ and } \bar{V}_c = -j\bar{I}X_c$$

where $\bar{I}$ can be taken as the r.m.s. value of the current. The voltage drop across the complete circuit can then be written as

$$\bar{V} = \bar{I}R + j\bar{I}X_L - j\bar{I}X_C$$
$$= \bar{I}[R + j(W_L - X_C)] \tag{2.50}$$

The term in the square brackets is called the 'impedance' of the circuit and is denoted by $\bar{Z}$. Thus

$$\bar{V} = \bar{I} \cdot \bar{Z} \tag{2.51}$$

Equation (2.51) represents Ohm's law for a.c. circuits. The phase angle between the source voltage and the current is

$$\phi = \tan^{-1}[(X_L - X_C)/R] \tag{2.52}$$

2.1.27 The parallel *RLC* circuit

A parallel *RLC* circuit is shown in Figure 2.16. The applied voltage is common to all the circuit elements and it is therefore chosen as the reference.

Using Ohm's law, the currents through each of the circuit elements are

$$\bar{I}_R = \bar{V}/R;\ \bar{I}_L = \bar{V}/X_L;\ \bar{I}_C = \bar{V}/X_C$$

Applying Kirchhoff's first law, the total current is the vector sum of the three currents $\bar{I}_R$, $\bar{I}_L$ and $\bar{I}_C$. The magnitude and phase of the total current may subsequently be determined from a phasor diagram, or calculated using the complex number notation. Using the latter and noting that the current through an inductor lags the voltage while the current through a capacitor leads the voltage, it may be shown that

$$\bar{I} = \bar{I}_R + \bar{I}_L + \bar{I}_C$$
$$= \bar{V}\left[\frac{1}{R} - j\left(\frac{1}{X_C} - \frac{1}{X_L}\right)\right] \tag{2.53}$$

and the phase angle,

$$\phi = \tan^{-1}\left[\frac{R(X_L - X_C)}{X_L \cdot X_C}\right] \tag{2.54}$$

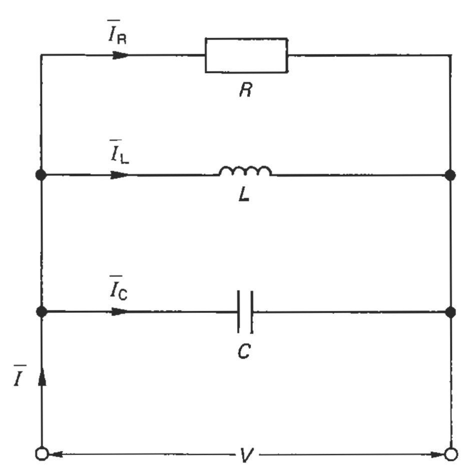

Figure 2.16 Parallel *RLC* circuit

2.1.28 Power and power factor in a.c. circuits

Denoting the phase angle between the voltage and the current as ϕ, it may be shown[2] that the average power is

$$P_{av} = \frac{V_m}{\sqrt{2}} \frac{I_m}{\sqrt{2}} \cos(\phi)$$

In terms of r.m.s. values:

$$P_{av} = VI \cos(\phi) \tag{2.55}$$

where $\cos(\phi)$ is called the 'power factor'.

Power factor is an important parameter when dealing with electrical transformers and generators. All such machines are rated in terms of kilo-volt amperes (kVA), which is a measure of the current-carrying capacity for a given applied voltage. The power that can be drawn depends both on the kVA rating and the power factor of the load. Figure 2.17 shows the relationship between kVA, kilowatts (kW) and power factor, sometimes referred to as the power triangle. It can readily be seen that

$$\text{kW} = \text{kVA} \cos(\phi) \tag{2.56}$$

and

$$\text{kVA}_R = \text{kVA} \sin(\phi) \tag{2.57}$$

where kVA_R is the reactive power. Thus knowing the kVA rating and the power factor of a number of various loads, the power requirements from a common supply may be determined.

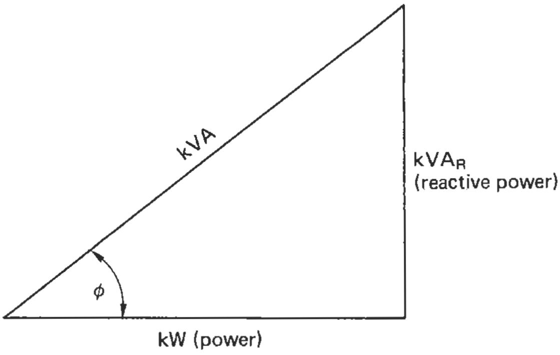

Figure 2.17 Power triangle

When quoting power factor in practical applications it is usual to state the phase of the current with respect to the voltage. For an inductive load the current lags the voltage and the power factor is said to be lagging. For a predominantly capacitive load the current leads the voltage and the power factor is leading.

If the power is supplied from, say, an alternator rated at 400 V and 1000 A, then these are the highest voltage and current that the machine can tolerate without overheating. The phase difference between the voltage and current is entirely dependent upon the load. Thus if the power factor of the load is unity then the 400 kVA alternator can supply 400 kW of power to the load. Neglecting losses, the prime mover which drives the alternator must also be capable of supplying 400 kW. If, on the other hand, the power factor of the load is 0.5, then the power supplied will only be 200 kW. This means that although the generator will be operating at its rated kVA, the prime mover which drives the genrator will be operating at only half of its capacity.

An alternative way of looking at this phenomenon is to consider a load of, say, 100 kW, with a lagging power factor of 0.75. If the supply voltage is 50 V, then the required current, from equation (2.55), is 2.67 A. If, however, the power factor of the load were to be increased to unity, then the required current would be reduced to 2 A. This means that the conducting cables, in supplying a reduced current, may have a correspondingly reduced cross-sectional area.

In general, the size of an electrical system including transmission lines, switchgear and transformers is dependent upon the size of the current. It is economically viable therefore to ensure that the current is minimized. As a further incentive to industrial consumers, the electricity supply authorities normally operate a two-part tariff system. This consists of a fixed rate depending on the kVA rating of the maximum demand and a running charge per unit kilowatts consumed per hour.

For these reasons it is advantageous to try to increase the power factor such that it is close to (but not quite) unity. A unity power factor is in fact avoided, because it gives rise to a condition of resonance (see Section 2.1.29). In practice, capacitors connected in parallel are often used to improve the power factor of predominantly inductive loads such as electric motors. For large-scale power systems, a separate phase advance plant is used.

2.1.29 Frequency response of circuits

The 'frequency response' of a circuit is usually presented as a plot of the ratio of output over input against the frequency as base. The ratio plotted could be one of voltages, currents or powers. Since the range of frequencies involved may be quite large, a logarithmic scale is normally employed. A logarithmic scale is also usually adopted for the vertical axis and the output/input ratio quoted in decibels (dB), i.e.

$$\text{Voltage ratio in dB} = 20 \log_{10}\left[\frac{V_{out}}{V_{in}}\right] \tag{2.58}$$

Considering the series *RLC* circuit shown in Figure 2.13 and taking the voltage across the resistor as an output,

$$V_{out} = IR$$
$$V_{in} = I[R + j(\omega L - 1/\omega C)]$$

Therefore

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{R}{R + j(\omega L - 1/\omega C)}$$

Using the complex conjugate and calculating the modulus of the voltage ratio gives

$$\left|\frac{V_{\text{out}}}{V_{\text{in}}}\right| = \frac{R}{[R^2 + (\omega L - 1/\omega C)^2]^{1/2}} \qquad (2.59)$$

The phase angle

$$\phi = -\tan^{-1}\left[\frac{(\omega L - 1/\omega C)}{R}\right] \qquad (2.60)$$

The voltage ratio will have a maximum value of unity when the frequency

$$\omega = \frac{1}{\sqrt{LC}} \qquad (2.61)$$

Equation (2.61) defines the 'resonance' condition at which the inductive and capacitive reactances are equal and self-cancelling. The resonant frequency is usually denoted ω_0 and it is the frequency at which the power transferred through the circuit is maximum. At any other frequency above or below ω_0 the power transferred is reduced.

The impedance of the circuit is given by

$$\overline{Z} = R + j(X_L - X_C) \qquad (2.62)$$

At the resonant frequency the total reactance is zero and the circuit behaves as if only the resistive element were present.

The general variation of the voltage ratio (or amplitude ratio) and phase angle with frequency is illustrated in Figure 2.18. Also shown in the figure are the two frequencies, ω_1 and ω_2, at which the amplitude ratio is −3 dB. The −3 dB amplitude ratio is chosen because it corresponds to a halving in the power transmitted.

The 'bandwidth' is the frequency range between ω_1 and ω_2. A quality parameter, used with respect to resonant circuits, is the so-called 'Q factor', which is defined as the ratio of the resonant frequency to the bandwidth.

2.1.30 Semiconductors

The materials commonly used for semiconductors are germanium and silicon. In recent times silicon has all but replaced germanium as a semiconductor material. These materials have a crystalline structure such that each atom is surrounded by equally spaced neighbours. The basic structure can be visualized as a two-dimensional grid where the node points represent the central nucleus and the inner shell electrons, while the connecting lines of the grid represent the four valence electrons associated with each nucleus. This grid concept is adequate to describe an intrinsic (or 'pure') semiconductor.

At absolute zero temperature the crystalline structure is perfect and the electrons are all held in valence bonds. Since there are no current carriers available, the crystal behaves as a perfect insulator. As the temperature rises above absolute zero an increasing number of valence bonds are broken, releasing pairs of free electrons and their associated 'holes'. In the absence of an applied field the free electrons move randomly in all directions. When an electric field is applied the electrons drift in a preferential direction to oppose the field and a net flow of current is established.

The covalent bond, with a missing electron, has a large affinity for electrons such that an electron from a neighbouring bond may easily be captured. This will leave the neighbouring atom depleted of electrons and the flow of electrons is generally associated with a counterflow of so-called holes. The mobile hole, to all intents and purposes, is essentially a simple positive charge.

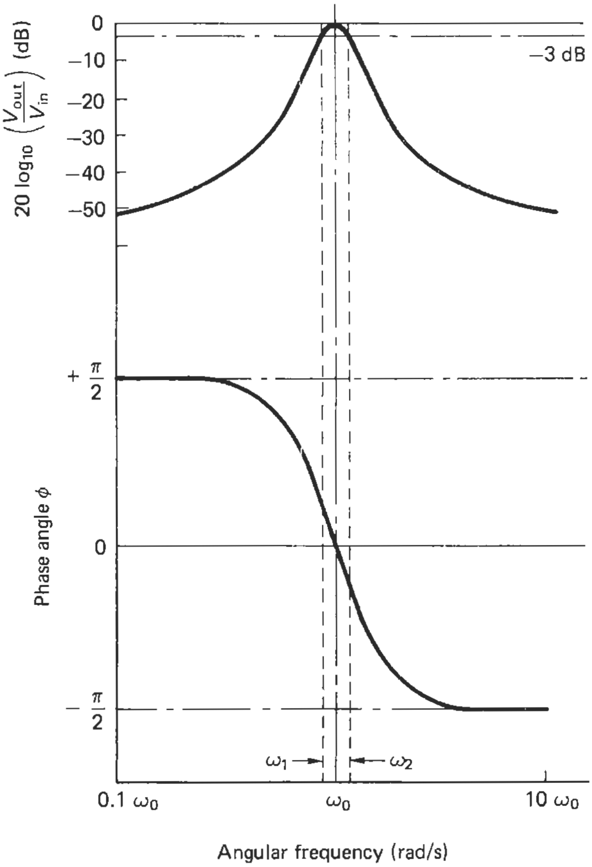

Figure 2.18 Voltage ratio and phase angle versus frequency (series *RLC*)

2.1.31 Doped semiconductors

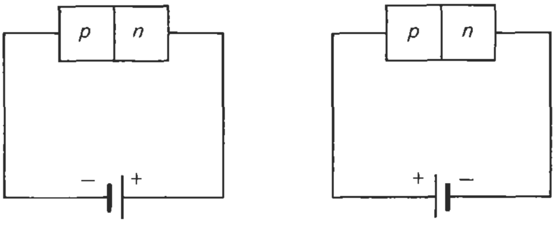
Doped semiconductors are those in which an impurity has been introduced into a very pure intrinsic silicon. The nature of the impurity depends on the type of semiconductor required:

1. *n-type*: Impurities with five valence electrons can be added to produce a negative type of semiconductor. These impurities are referred to as 'donors', since the additional electron is very easily freed within the matrix. In the n-type semiconductor the free electrons are the dominant current carriers.
2. *p-type*: the p-type semiconductor is one in which the added impurities have only three valence electrons. Such impurities are called 'acceptors' and they produce a positive type of semiconductor within which hole conduction is the dominant current carrier.

2.1.32 *pn* junction diode

A *pn* junction is formed by doping a crystal in such a way that the semiconductor changes from p- to n-type over a very short length (typically 10^{-6} m). The transition zone from *p*- to *n*-type is called the 'carrier depletion layer' and, due to the high concentration of holes on one side and electrons on the other, a potential difference exists across this layer. The diffusion of holes from *p* to *n* and electrons from *n* to *p* is the majority carrier movement, called the 'diffusion current'. The drift of electrons from *p* to *n* and holes from *n* to *p* is the minority carrier movement, referred to as the 'drift current'. When there is no externally applied potential difference, the diffusion current and the drift current are balanced in equilibrium. If an electric field is applied across the device then two situations can exist, as illustrated in Figure 2.19. Figure 2.19(a) shows the reverse-bias mode in which the potential barrier is increased. The diffusion current is reduced while the drift current is barely altered. Overall, the current is negative and very small. When forward bias is applied, as in Figure 2.19(b), the potential barrier is reduced and a large diffusion current flows. Overall, the current is positive and large. These general characteristics are the basis of a semiconductor diode which displays the typical current/voltage relationship depicted in Figure 2.20.

This figure shows clearly that a very high impedance is presented by the diode to an applied voltage of reverse polarity. A low impedance is presented to a forward polarity voltage. In simple terms, the diode accommodates a forward flow of current but greatly inhibits a reverse flow. The diode may be likened therefore to a switch which is activated 'on' for forward voltages and 'off' for reverse voltages. The reverse saturation current, I_s, is typically of the order of a few nano-amperes and can sensibly be regarded as zero.



(a) Reverse bias (b) Forward bias

Figure 2.19 *pn* junction with applied potential difference

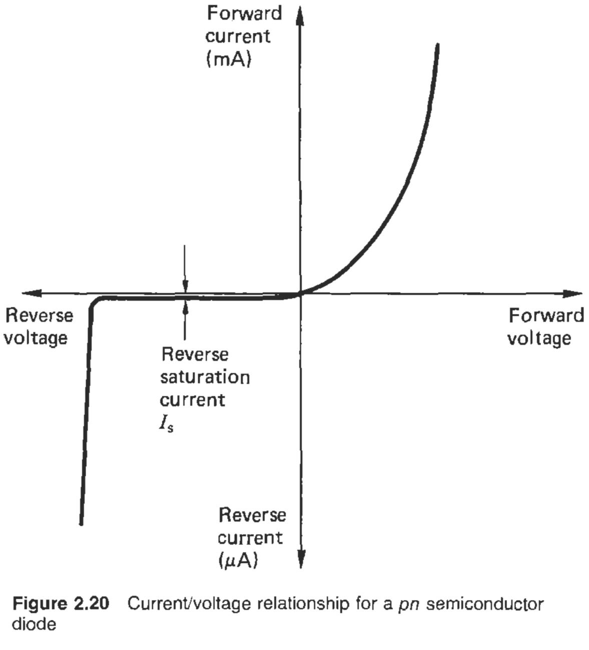


Figure 2.20 Current/voltage relationship for a *pn* semiconductor diode

The general characteristic also shows that the reverse voltage has a critical limiting value at which a 'breakdown' occurs. Depending upon the diode construction, the breakdown (or 'Zener' voltage) may range from as low as one volt to as much as several thousand volts. Up to the breakdown voltage, the reverse saturation current is independent of the reverse voltage.

Since the current/voltage relationship for a diode is a non-linear exponential function, the analysis of circuits involving diodes can become complicated. A simple awareness of the diode's practical function as a rectifier is perhaps more important than a proficiency in analysing circuits involving diode elements.

2.1.33 A.C. rectification

Figure 2.21 shows an a.c. circuit with a diode in series with a load resistor. When the diode is forward biased a current will flow in the direction indicated by the arrowhead. No current can flow when the diode is reverse biased, provided that the applied voltage does not exceed the breakdown value. The resultant current waveform through the resistor, for a sinusoidal voltage input, will therefore consist of positive only half sine waves. Since the output waveform is positive only, then it is, by definition, a d.c. voltage. It can be shown that the r.m.s. voltage across the resistor is

$$V = \frac{V_m}{2} \cdot \frac{R_L}{R_L + R_F} \tag{2.63}$$

where R_L is the load resistance, R_F is the diode forward resistance and V_m is the peak input voltage. Determination of R_F is problematic, however, and models of varying complexity are used to simulate the diode in the circuit.

The single-diode circuit results in half-wave rectification. To obtain full-wave rectification a diode bridge circuit can be used. The diode bridge is shown in Figure 2.22. When A is positive with respect to B then diodes D_1 and D_3 are conducting. When B is positive with respect to A then diodes D_2 and D_4 are conducting. The circuit arrangement ensures that the current, which consists of a continuous series of positive half sine waves, is always in the same direction through the load R_L.

With full-wave rectification there are twice as many half sine pulses through the load than there are with half-wave rectification. In addition, there are always two diodes effectively in series with the load. The resultant r.m.s. voltage across the load resistor for the full-wave diode bridge rectification circuit is

$$V = \frac{V_m}{\sqrt{2}} \cdot \frac{R_L}{(R_L + 2R_F)} \tag{2.64}$$

The 'peak inverse voltage' (PIV) is defined as the maximum reverse-biased voltage appearing across a diode. When used as a rectifier the diodes must have a sufficiently high reverse voltage rating in excess to the peak inverse voltage that the circuit can generate. For both the half- and the full-wave rectification circuits considered, the peak inverse voltage is equivalent to the maximum supply voltage, V_m. Additional manufacturers' diode specifications would normally include the maximum power rating and the maximum allowable forward current.

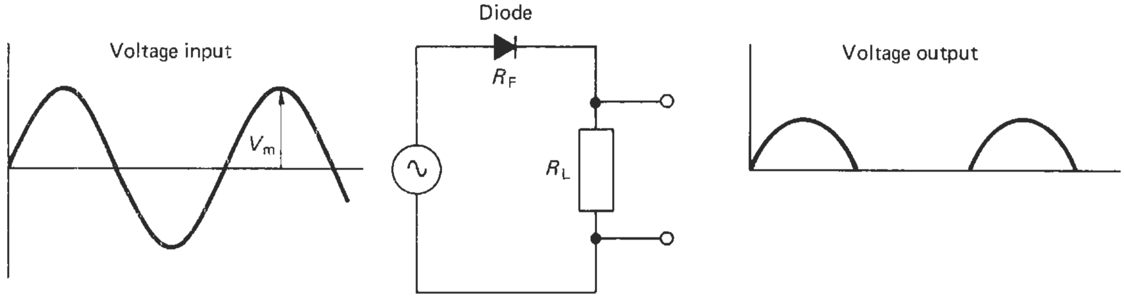

Figure 2.21 Half-wave rectification circuit

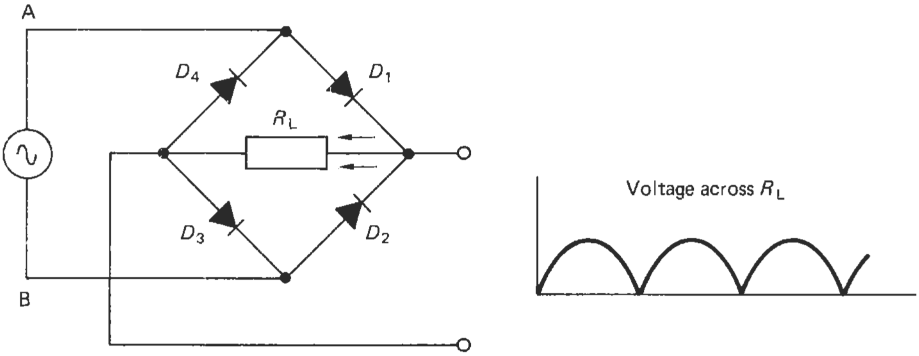

Figure 2.22 Full-wave rectification with a diode bridge

2.1.34 The Zener diode

The diode breakdown effect is also used in a variety of circuits to provide a stabilized reference voltage. Special diodes which are designed to operate continuously in the reverse bias mode are called 'Zener diodes'. These diodes are manufactured with a range of breakdown voltages from between 3 to 20 V. Figure 2.23 shows a Zener diode being used in a circuit to give a stable voltage which is essentially independent of the current flowing through the device. The series resistor in the circuit is included to limit the reverse current through the diode to a safe value.

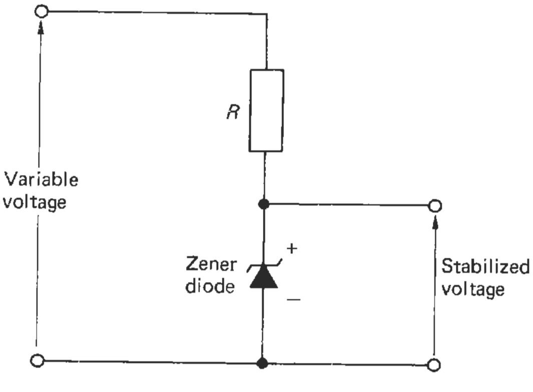

Figure 2.23 Zener diode as a reference voltage source

2.2 Electrical machines

The function of a rotating electrical machine is to convert mechanical power into electrical power, or vice versa. The conversion from mechanical to electrical power is made with a 'a generator' and the conversion of electrical to mechanical power with a 'motor'. Electrical machines may be further sub-divided into a.c. or d.c. machines. The major part of all electrical energy generated in the world today is produced by a particular type of a.c. machine called an 'alternator'. The applications of electric motors are no less substantial and they are used in a great variety of industrial drives. It is usually the mechanical features of a particular application which determines the type of electric motor to be employed, and the torque–speed characteristics of the machine are therefore very important.

2.2.1 The d.c. generator

All conventional electrical machines consist of a stationary element and a rotating element which are separated by a air gap. In d.c. machines – generator or motor – the stationary element consists of salient 'poles' which are constructed as laminated assemblies with coils wound round them to produce a magnetic field. The function of the laminations is to reduce the losses incurred by eddy currents. The rotating element is traditionally called the 'armature', and this consists of a series of coils located between slots around the periphery of the armature. The armature is also fabricated in laminations which are usually keyed onto a locating shaft. A very simple form of d.c. generator is illustrated in Figure 2.24.

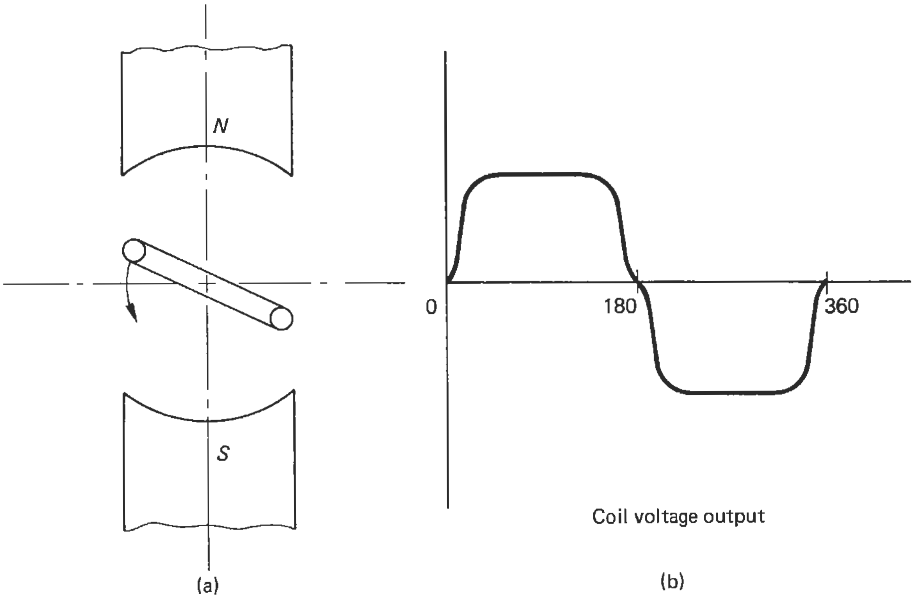

Figure 2.24 Single-coil, two-pole d.c. generator

In the figure the single coil is rotated at constant speed between the opposite poles, north and south, of a simple magnet. From Faraday's law (equation (2.25)) the voltage generated in the coil is equal to the rate of change of flux linkages. When the coil lies in the horizontal plane there is maximum flux linking the coil but a minimum rate of change of flux linkages. On the other hand, when the coil lies in the vertical plane there is zero flux linking the coil but the rate of change of flux linkages is a maximum. The resultant variation in generated voltage in the coil, as it moves through one revolution, is shown in Figure 2.24(b). It is apparent that the generated voltage is alternating with positive and negative half-cycles. To change the a.c. output voltage into a d.c. voltage, a simple yet effective mechanical device called a 'commutator' is used. The commutator (Figure 2.25) incorporates brass segments separated by insultating mica strips. External connection to the armature coil is made by stationary carbon 'brushes' which make sliding contact with the commutator. Referring to Figures 2.24(a) and 2.25(a), as the coil rotates from the horizontal plane through 180° the right-hand side of the coil is under the north pole and is connected via the commutator to the upper brush. Meanwhile, the left-hand side of the coil is under the south pole and is connected to the lower brush. A further 180° of rotation effectively switches the coil sides to the opposite brushes. In this manner the coil side passing the north pole is always connected to the positive upper brush, while the coil side passing the south pole is always connected to the negative lower brush. The resultant output voltage waveform is shown in Figure 2.25(b).

If two coils, physically displaced by 90°, are now used, the output brush voltage becomes virtually constant, as shown in Figure 2.26. With the introduction of a second coil, the commutator must have four separate segments. In a typical d.c. machine there may be as many as 36 coils, which would require a 72-segment commutator.

The simple d.c. generator of Figure 2.24 can be improved in perhaps three obvious ways. First, the number of coils can be increased, second, the number of turns on each coil can be increased and third, there is no reason why another pair of

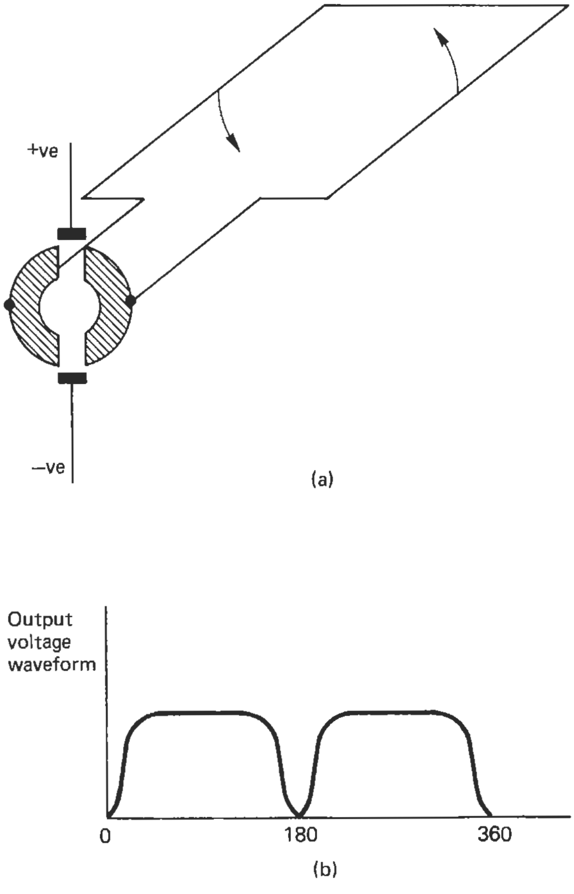

Figure 2.25 Commutator connections to armature

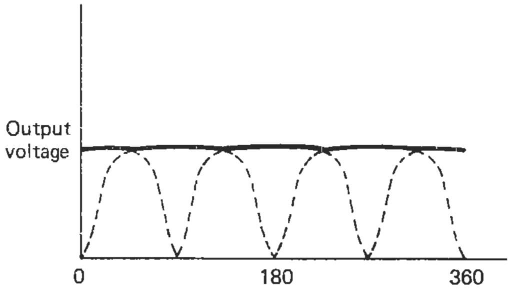

Figure 2.26 Two-coil, two-pole d.c. generator output voltage

poles cannot be introduced. A typical d.c. machine would therefore normally incorporate four poles, wired in such a way that each consecutive pole has the opposite magnetic polarity to each of its neighbouring poles. If the e.m.f.'s generated in the armature coils are to assist each other then while one side of the coil is moving under a north pole, the other side must be moving under a south pole. With a two-pole machine the armature coils must be wound such that one side of the coil is diametrically opposite the other. With a four-pole machine the armature coils can be wound with one side of the coil physically displaced 90° from the other. The size of the machine will generally dictate how many coils and the number of turns on each coil that can be used.

2.2.1.1 *Armature e.m.f.*

If a conductor cuts flux then a voltage of 1 V will be induced in the conductor if the flux is cut at the rate of 1 Wb/s. Denoting the flux per pole as Φ and the speed in revolutions per second as N, for the single-turn coil and two-pole generator of Figure 2.24(a) the e.m.f. induced in the coil is

$$E_{\text{coil}} = \frac{\text{Flux per pole}}{\text{Time for half revolution}} = \frac{\Phi}{1/(2N)} = 2N\Phi$$

For a machine having Z_s armature conductors connected in series, i.e. $Z_s/2$ turns, and $2p$ magnetic poles, the total induced e.m.f. is

$$E = 2N\Phi \frac{Z_s}{2} 2p = 2N\Phi Z_s\, p \text{ volts} \tag{2.65}$$

Z_s depends on the type of armature winding, and the two main types are 'lap-wound' and 'wave-wound'.

The lap winding is characterized by the fact that the number of parallel paths through the winding is equal to the number of poles. In the alternative wave winding the number of parallel paths through the winding is always equal to two. If Z denotes the total number of armature conductors then for the lap winding

$$Z_s = \frac{Z}{\text{Number of parallel paths}} = \frac{Z}{\text{Number of poles}} = \frac{Z}{2p} \tag{2.66}$$

and for the wave winding

$$Z_s = \frac{Z}{\text{Number of parallel paths}} = \frac{Z}{2} \tag{2.67}$$

Lap windings are generally used in low-voltage, heavy-current machines and wave winding in all other cases.

2.2.1.2 *Armature torque*

The force on a current-carrying conductor is given by equation (2.27), i.e.

$F = BIl$

The torque on one armature conductor is therefore

$$T = Fr = B_{av} l I_a r \tag{2.68}$$

where r is the radius of the armature conductor about the centre of rotation,
I_a is the current flowing in the armature conductor
l is the axial length of the conductor, and
B_{av} is the average flux density under a pole. Note that

$$B_{av} = \frac{\Phi}{(2\pi rl)/2p}$$

The resultant torque per conductor is

$$T = \frac{\Phi 2plI_a r}{2\pi rl} = \frac{\Phi p I_a}{\pi}$$

For Z_s armature conductors connected in series the total torque on the armature is

$$T = \frac{\Phi p I_a Z_s}{\pi} \text{ Newton-metres} \tag{2.69}$$

2.2.1.3 *Terminal voltage*

Denoting the terminal voltage by V, the induced e.m.f. by E and the armature resistance by R_a,

$$V = E - I_aR_a \quad \text{(for a generator)} \tag{2.70}$$

$$V = E + I_aR_a \quad \text{(for a motor)} \tag{2.71}$$

For the motor, the induced e.m.f. is often called the 'back e.m.f.'.

2.2.2 Methods of connection

The methods of connecting the field and armature windings may be grouped as follows:

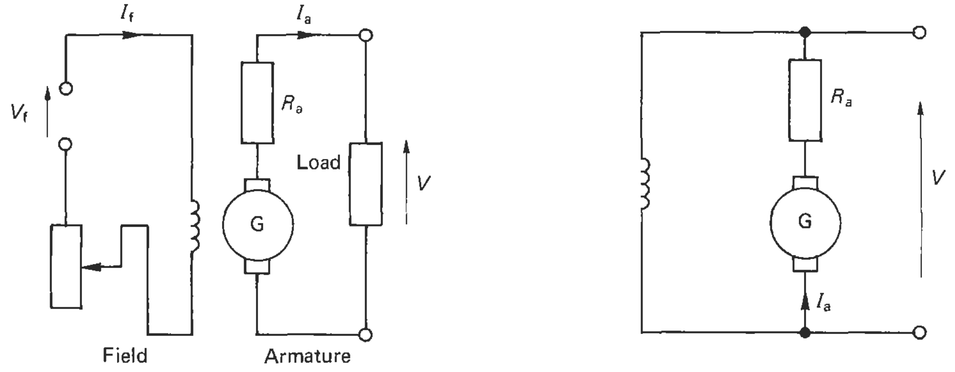
1. *Separately excited* – where the field winding is connected to a source of supply independently of the armature supply;
2. *Self-excited* – which may be further sub-divided into:
   (a) *Shunt-wound* – where the field winding is connected across the armature terminals;
   (b) *Series-wound* – where the field winding is connected in series with the armature winding;
   (c) *Compound-wound* – which is a combination of shut and series windings.

The four alternative methods of connection are illustrated in Figure 2.27.

2.2.3 The separately excited generator

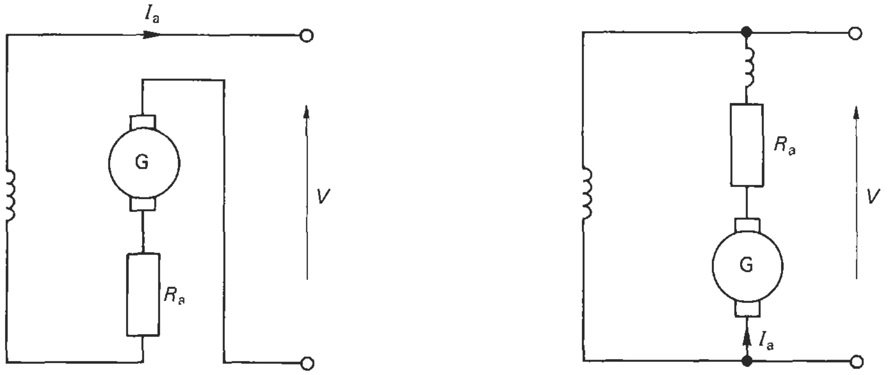
Consider the separately excited generator, shown in Figure 2.27(a), running at a constant rated speed with no load across the output. It is assumed that initially the poles were completely de-magnetized. If the field current, and hence the magnetic field, is gradually increased then a plot of terminal voltage against field current takes the form shown in Figure 2.28.

As the field current increases, the iron poles begin to saturate and the proportionality between the flux and the field current no longer exists. If the field current is then reduced,



(a) Separately excited

(b) Shunt-wound



(c) Series-wound

(d) Compound-wound

Figure 2.27 Methods of field connection

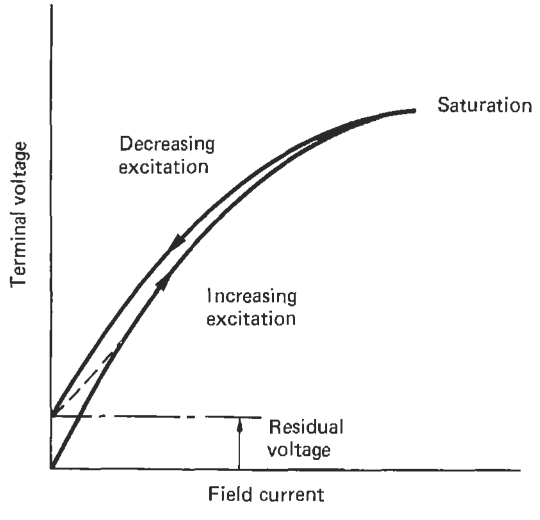


Figure 2.28 Open-circuit characteristics of a separately excited generator

the magnetic hysteresis causes the terminal voltage to have a slightly greater value than that obtained when the field current was being increased. When the field current is reduced to zero, a 'residual voltage' remains. On increasing the field current once more, the curve follows the broken line to merge with the original lower curve. These curves are termed the 'open-circuit characteristics' of the machine.

If the generator is now connected to a variable external load and driven at constant speed with a constant field current, I_f, the terminal voltage variation with armature current is as shown in Figure 2.29. The decrease in terminal voltage with increase in load is due mainly to the voltage drop across the armature resistance, R_a. Additionally, the decrease in terminal voltage is attributed to a decrease in flux caused both by the de-magnetizing ampere-turns of the armature and the magnetic saturation in the armature teeth. These effects are collectively known as 'armature reaction'. Figure 2.29 is referred to as the 'load characteristic' of the generator.

The separately excited generator has the disadvantage inherent with a separate source of direct current required for the field coils. They are, however, used in cases where a wide range in terminal voltage is required.

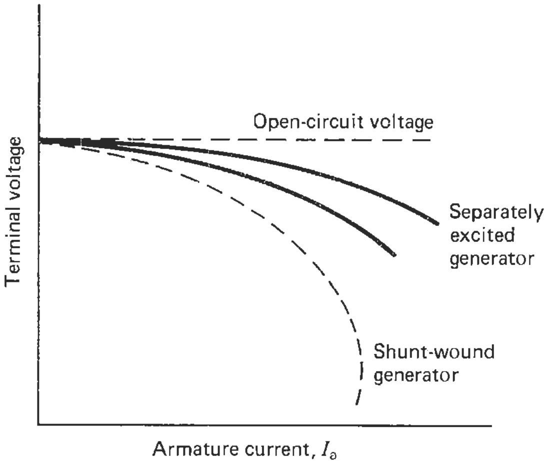

Figure 2.29 Load characteristic of a separately excited generator

2.2.4 The shunt-wound generator

The field winding in the shunt-wound generator is connected across the armature terminals as shown in Figure 2.27(b) and is therefore in parallel (or 'shunt') with the load. A shunt generator will excite only if the poles have some residual magnetism and the resistance of the shunt circuit is less than some critical value.

If, when running at constant speed, the field is disconnected from the armature, the voltage generated across the armature brushes is very small and entirely due to the residual magnetism in the iron. When the field is connected, the small residual voltage generates a flow of current in the field winding. The total flux in the field winding will gradually build up and the final terminal voltage will depend on the resistance of the field winding and the magnetization curve of the machine. The general characteristic is shown in Figure 2.30.

When connected to an external load the shunt-wound generator exhibits a drop in terminal voltage as the armature current is increased (see Figure 2.29). The drop in voltage in the shunt-wound generator is much greater than that in the separately excited generator. This stems from the fact that, as the terminal voltage drops, the field current also reduces, which causes a further drop in terminal voltage.

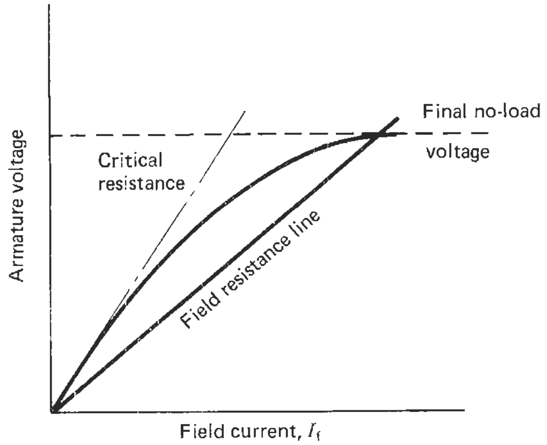

Figure 2.30 No-load characteristic of a shunt-wound generator

The shunt-wound machine is the most common type of d.c. generator employed. The load current, however, must be limited to a value well below the maximum value to avoid excessive variation in terminal voltage.

2.2.5 The series-wound generator

For the series-wound generator the field winding is connected in series with the armature terminals as shown in Figure 2.27(c). The armature current therefore determines the flux. The constant speed load characteristic (Figure 2.31) exhibits an increase in terminal voltage as the armature (or load) current increases.

At large values of load current the armature resistance and reactance effects cause the terminal voltage to decrease. It is apparent from Figure 2.31 that the series-wound generator is totally unsuitable if the terminal voltage is required to be reasonably constant over a wide range of load current.

2.2.6 The compound-wound generator

The compound-wound generator (Figure 2.27(d)) is a hybrid between the shunt- and the series-wound generators. Normally, a small series field is arranged to assist the main shunt field. This is termed 'cumulative compounding'. The shape of the load characteristic (Figure 2.32) depends upon the number of turns on the series winding. If the series field is arranged to oppose the main shunt field ('differentially compounded') a rapidly falling load characteristic is obtained. The number of turns on the series coil can be varied to give an over-compounded, level-compounded or an under-compounded characteristic as shown in Figure 2.32.

2.2.7 The d.c. motor

There is no difference in basic construction between a d.c. generator and a d.c. motor. The only significant distinction between the two machines is quantified by equations (2.70) and (2.71). These illustrate the fact that, for a d.c. generator, the generated e.m.f. is greater than the terminal voltage. For the d.c. motor, the generated e.m.f. is less than the terminal voltage.

Equation (2.65), which gives the relationship between the induced e.m.f. and the speed of a d.c. generator, applies

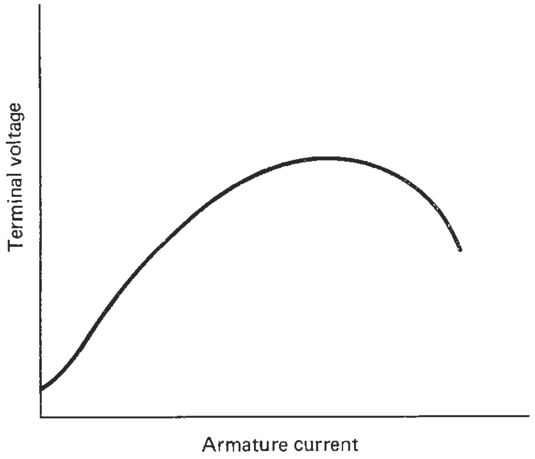

Figure 2.31 Constant speed load characteristic for the series-wound generator

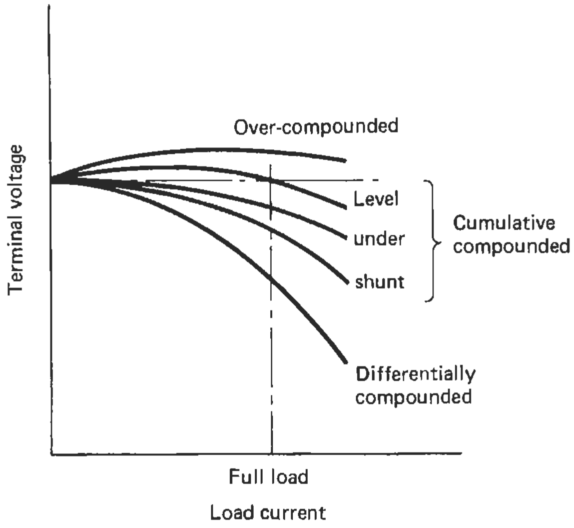

Figure 2.32 Load characteristic for the compound-wound generator

equally well to the d.c. motor. Since the number of poles and number of armature conductors are fixed, a proportionality relationship can be derived to relate speed as a function of induced e.m.f. and flux, i.e.

$$N = E/\phi \tag{2.72}$$

or, using equation (2.71),

$$N = (V - I_aR_a)/\Phi \tag{2.73}$$

The value of I_aR_a is usually less than about 5% of the terminal voltage such that, to a reasonable approximation,

$$N \approx V/\Phi \tag{2.74}$$

Similarly, equation (2.69), which gives the armature torque on a d.c. generator, also applies to the d.c. motor. A proportionality relationship for the d.c. motor torque is therefore

$$T = I_a\Phi \tag{2.75}$$

Equation (2.74) shows that the speed of a d.c. motor is approximately proportional to the voltage applied to the armature and inversely proportional to the flux. All methods of controlling the speed of d.c. motors are based on these proportionality relationships. Equation (2.75) indicates that the torque of a given d.c. motor is directly proportional to the product of the armature current and the flux per pole.

2.2.8 The shunt-wound motor

The shunt-wound motor is shown schematically in Figure 2.33. Under normal operating conditions the field current will be constant. As the armature current increases, however, the armature reaction effect will weaken the field and the speed will tend to increase. The induced voltage will decrease due to the increasing armature voltage drop, and this will tend to decrease the speed. The two effects are not self-cancelling, and, overall, the motor speed will fall slightly as the armature current increases.

The motor torque increases approximately linearly with the armature current until the armature reaction starts to weaken the field. These general characteristics are shown in Figure 2.34, along with the derived torque–speed characteristic.

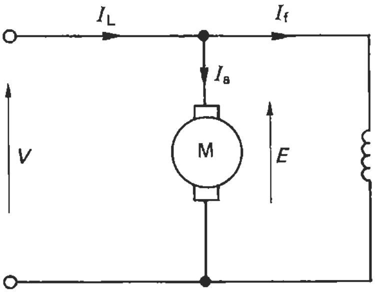

Figure 2.33 The shunt-wound motor

Figure 2.34(a) shows that no torque is developed until the armature current is large enough to supply the constant losses in the machine. Since the torque increases significantly for a slight decrease in speed, the shunt-wound motor is particularly suitable for driving equipment such as pumps, compressors and machine tool elements, where the speed must remain 'constant' over a wide range of load.

2.2.9 The series-wound motor

The series-wound motor is shown in Figure 2.35. As the load current increases, the induced voltage, E, will decrease due to reductions in the armature and field resistance voltages. Because the field winding is connected in series with the armature the flux is directly proportional to the armature current. Equation (2.74) therefore suggests that the speed/armature current characteristic will take the form of a rectangular hyperbola. Similarly, equation (2.75) indicates that the torque/armature current characteristic will be approximately parabolic. These general characteristics are illustrated in Figure 2.36 along with the derived torque–speed characteristic.

The general characteristics indicate that if the load falls to a particularly low value then the speed may become dangerously high. A series-wound motor should therefore never be used in situations where the load is likely to be suddenly relaxed.

The main advantage of the series-wound motor is that it provides a large torque at low speeds. These motors are eminently suitable, therefore, for applications where a large starting torque is required. This includes, for example, lifts, hoists, cranes and electric trains.

2.2.10 The compound-wound motor

Compound-wound motors, like compound generators, are produced by including both series and shunt fields. The resulting characteristics of the compound-wound motor fall somewhere in between those of the series- and the shunt-wound machines.

2.2.11 Starting d.c. motors

With the armature stationary, the induced e.m.f. is zero. If, while at rest, the full voltage is applied across the armature winding, the current drawn would be massive. This current would undoubtedly blow the fuses and thereby cut off the supply to the machine. To limit the starting current, a variable external resistance is connected in series with the armature. On start-up the full resistance, is connected in series. As the machine builds up speed and increases the back e.m.f., the external resistance can be reduced until the series resistance is disconnected at rated speed.

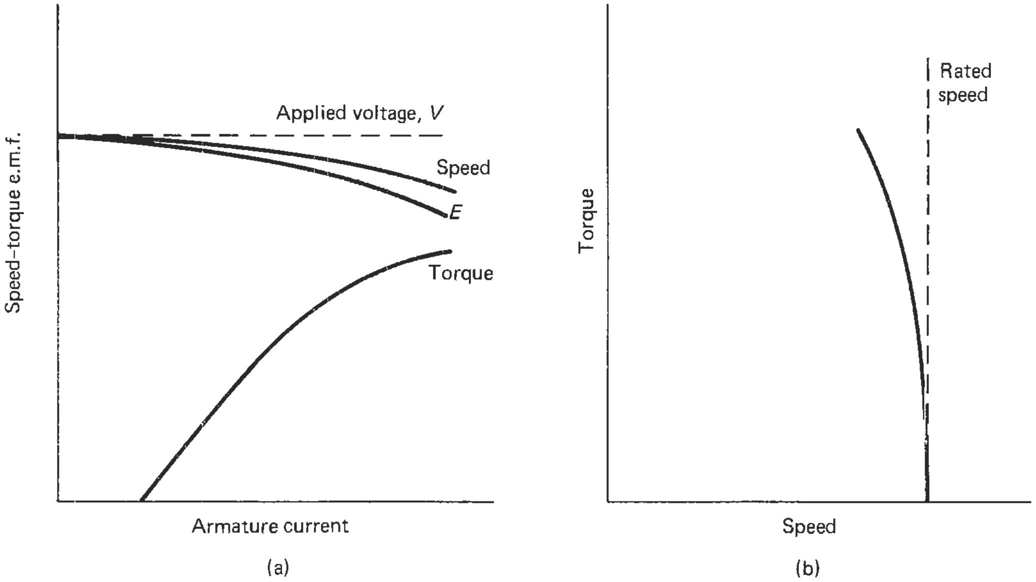

Figure 2.34 The shunt-wound motor load characteristics

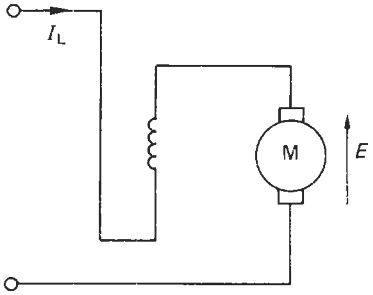

Figure 2.35 The series-wound motor

Variable-resistance 'starters' are also usually equipped with a return spring and an electromagentic 'catch plate'. The latter keeps the starter in the zero resistance position while the machine is running at its rated speed. The electromagnet is powered by the field current and, in the event of a supply failure, the electromagnet is de-energized and the return spring pulls the starter back to the full-resistance 'off' position. This ensures that the full starting resistance will always be in series with the armature winding when the machine is re-started.

An overload cut-out switch is another normal feature incorporated into the starter mechanism. The overload cut-out is another electromagnetic switch which this time is powered by the supply current. The overload switch is normally 'off', but if the supply current becomes excessive, the switch is activated and it short-circuits the supply to the electromagnetic catch plate. This, in turn, de-energizes the catch plate and the return spring takes the starter back to the 'off' position. Figure 2.37 illustrates the essential features of a starter device for a shunt-wound motor.

2.2.12 Speed control of d.c. motors

Equation (2.74) shows that the speed of a d.c. motor is influenced both by the applied voltage and the flux. A variation in either of these parameters will therefore effect a variation in the motor speed.

2.2.12.1 Field regulator

For shunt- and compound-wound motors a variable resistor, called a 'field regulator', can be incorporated in series with the field winding to reduce the flux. For the series-wound motor the variable resistor is connected in parallel with the field winding and is called a 'diverter'. Figure 2.38 shows the various methods of weakening the field flux for shunt-, compound- and series-wound motors.

In all the above methods of speed control the flux can only be reduced, and from equation (2.74) this implies that the speed can only be increased above the rated speed, and may, in fact, be increased to about three or four times the rated speed. The increased speed, however, is at the expense of reduced torque, since the torque is directly proportional to the flux which is reduced.

2.2.12.2 Variable armature voltage

Alternatively, the speed can be increased from standstill to rated speed by varying the armature voltage from zero to rated value. Figure 2.39 illustrates one method of achieving this.

The potential divider, however, carries the same current as the motor, and this limits this method of speed control to small machines. Additionally, much of the input energy is dissipated in the controller, which consequently renders the system inefficient.

2.2.12.3 Ward Leonard drive

In this case the variable d.c. voltage for the speed-controlled motor is obtained from a separate d.c. generator which is itself driven by an induction motor (see Figure 2.40). The field coil for the d.c. generator is supplied from a centre-tapped potential divider. When the wiper arm is moved from O to A the armature voltage of the d.c. motor is increased from zero and the motor speed will rise. In moving the wiper from A to O

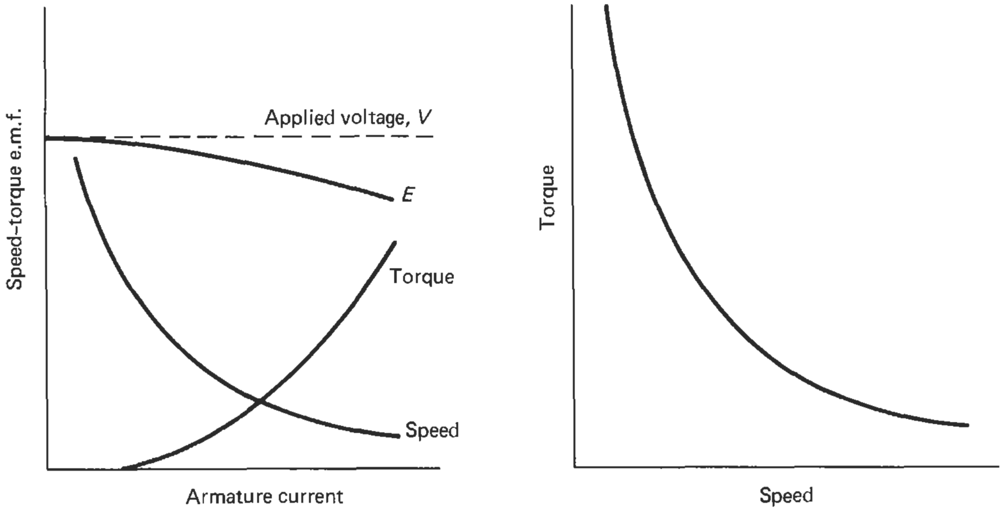

Figure 2.36 The series-wound motor load characteristics

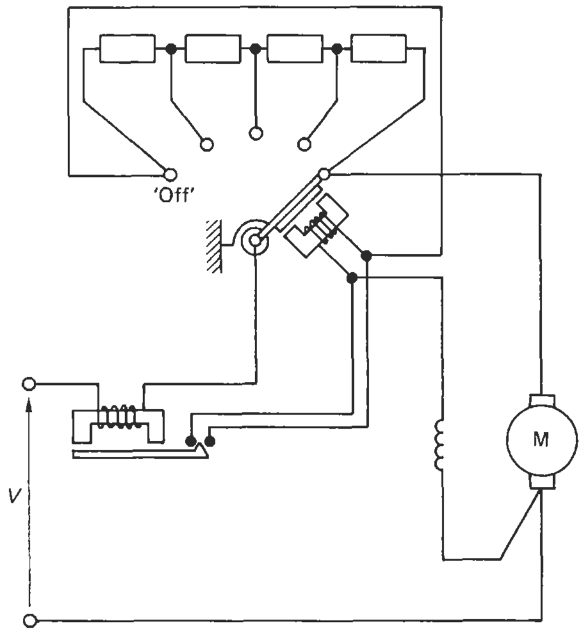

Figure 2.37 Starter-device for d.c. motors

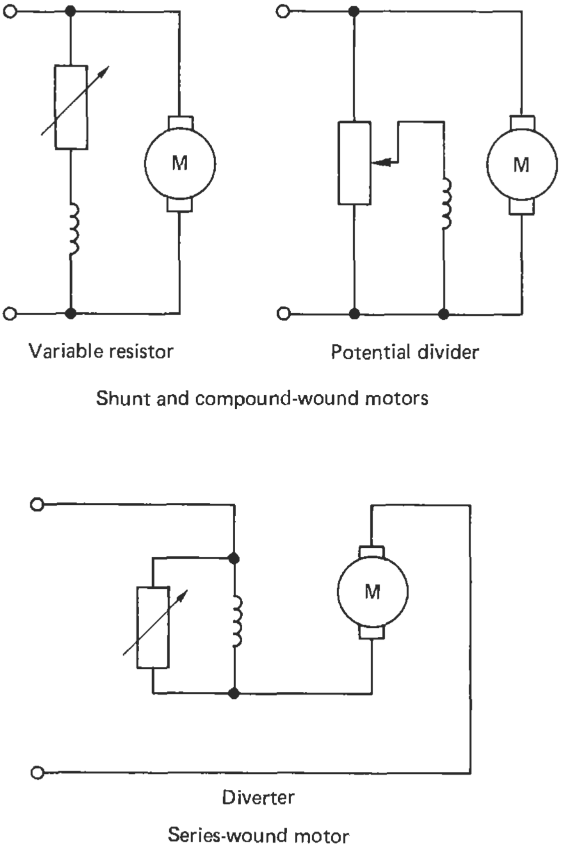

Figure 2.38 Speed control for flux reduction

and on through to B the motor will decelerate to a standstill and then increase in speed again, but in the opposite direction of rotation. The Ward Leonard drive is smooth and accurate in either direction and also provides for very responsive braking. Its complexity, however, makes it a very expensive system, and it is only used in high-quality applications.

2.2.12.4 Chopper control

Figure 2.41 shows a thyristor circuit connected in series with the armature of a d.c. motor. The thyristor circuit is triggered such that it operates essentially as a high-speed on/off switch. The output waveform across the armature terminals is depicted in Figure 2.42. The ratio of time on to time off (i.e. the 'mark/space ratio') can be varied, with the result that the average voltage supplied to the armature is effectively between zero and fully on. The frequency of the signal may be up to about 3 kHz and the timing circuit is necessarily complex.

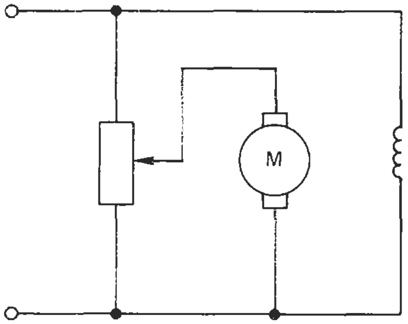

Figure 2.39 Speed control by varying armature voltage

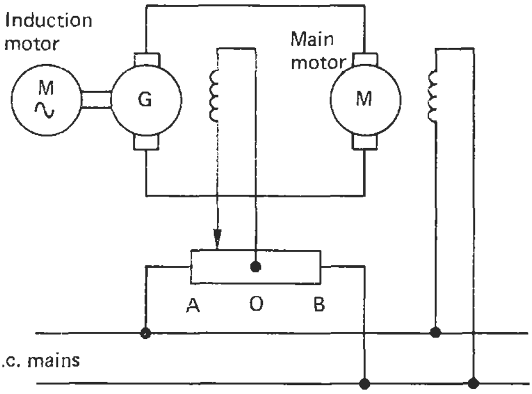

Figure 2.40 Ward Leonard drive

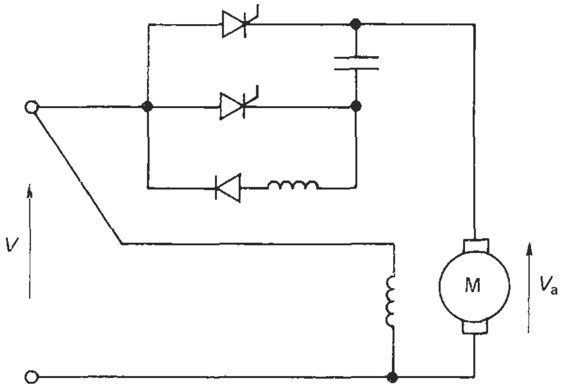

Figure 2.41 Speed control using thyristors

Speed control of d.c. motors using thyristors, is, however, effective and relatively inexpensive.

2.2.13 Efficiency of d.c. machines

The losses in d.c. machines can be generally classified as:

Armature losses,
Iron loss,
Commutator losses,
Excitation loss, and
Bearing friction and windage

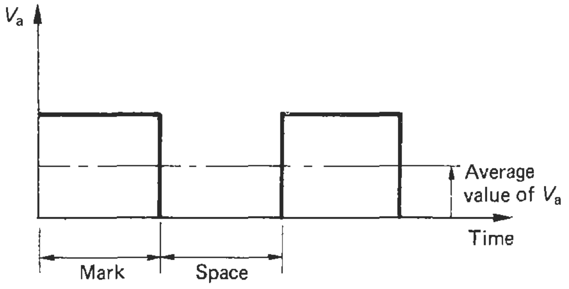

Figure 2.42 Voltage across armature terminals

Despite the variety and nature of the losses associated with d.c. machines, they have, nonetheless, a very good performance with overall efficiencies often in excess of 90%.

2.2.14 Three-phase circuits

Since a.c. machines are generally associated with three-phase systems it is necessary to consider some aspects of three-phase circuits before a meaningful discussion of a.c. machines can be undertaken. The limiting factor of a d.c. machine is related to the commutator which restricts the maximum voltage that can be generated. Because of their efficiency and performance, three-phase machines have emerged as the dominant type of electrical generator and motor and, on a worldwide basis, three-phase electrical distribution networks are the norm.

2.2.15 Generation of three-phase e.m.f.'s

Figure 2.43 shows three similar coils displaced at 120° relative to each other. Each loop terminates in a pair of 'slip-rings' and if the coils are to be isolated from one another, then six slip-rings are required in total. If the three coils are rotated in the anti-clockwise direction at constant speed, then each coil will generate a sinusoidally varying e.m.f. with a phase shift of 120° between them.

2.2.16 Star and delta connections

The three coils shown in Figure 2.43 can be connected together in either of two symmetrical patterns. These are the 'star' (or 'wye') connection and the 'delta' (or 'mesh') connection. The two types of connection are shown in Figure 2.44.

The star pattern is made by joining R_0, Y_0 and B_0 together. This connection point is referred to as the 'neutral point'. The delta pattern is formed by connecting R_0 to Y_1, Y_0 to B_1 and B_0 to R_1.

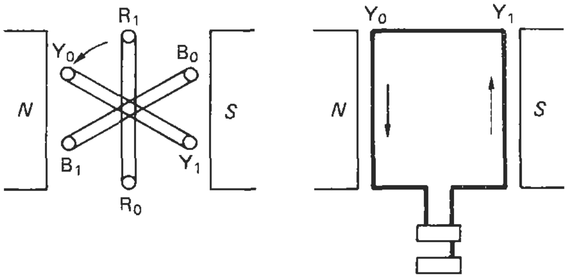

Figure 2.43 Generation of three-phase e.m.f.'s

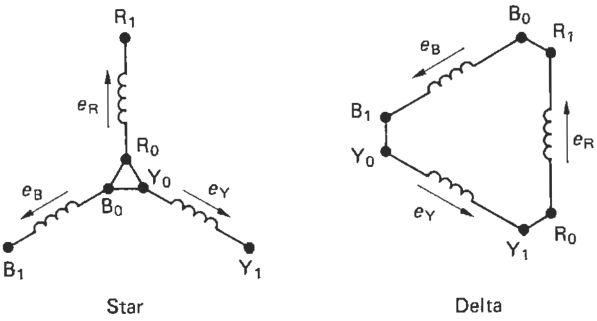

Figure 2.44 Star and delta connections for three-phase systems

2.2.17 Three-phase voltage and current relations

Figure 2.45 shows a three-phase star connected alternator supplying currents I_R, I_Y and I_B to a balanced (or equal) resistive–inductive load. This gives the usual 'four-wire' star-connected system. Since there are only four transmission cables involved, the alternator connected in a star pattern will only require four slip-rings.

For a balanced system the phase voltages V_{RN}, V_{YN} and V_{BN} are all equal in magnitude and equally displaced by a phase angle of 120°. The currents I_R, I_Y and I_B are also equal in magnitude and equally displaced in phase angle but they all lag their respective phase voltages by some angle ϕ. Phasor addition of the currents shows that the neutral current, I_N, is zero.

The voltages between the transmission cables are called the 'line' voltages. If the phase voltages are all equal then phasor addition shows that the line voltages are given by

$$V_{\text{line}} = 2V_{\text{phase}} \cos(30)$$

or

$$V_L = \sqrt{3} \times V_P \tag{2.76}$$

For the star connection, the line currents, I_L, are equal to the phase currents, I_p. Figure 2.46 shows the alternator windings connected in the delta pattern. In this pattern the line voltages are equal to the phase voltages. Phasor addition of the currents shows that if the phase currents are equal then the line currents are given by

$$I_L = \sqrt{3} \times I_p \tag{2.77}$$

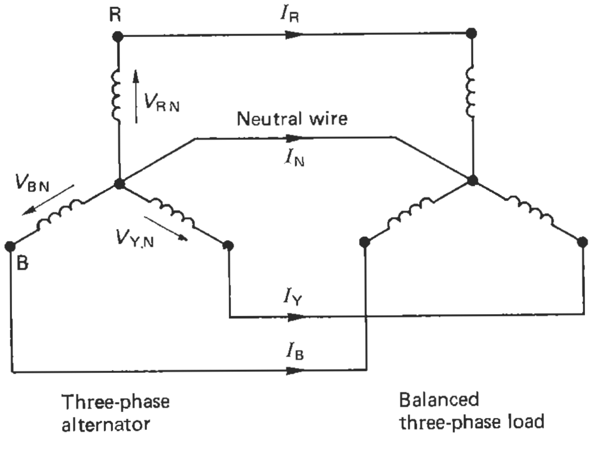

Figure 2.45 Three-phase supply connections

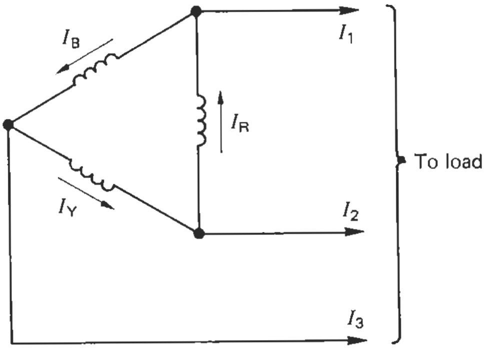

Figure 2.46 Alternator windings in delta connection

2.2.18 Power in three-phase circuits

The power per phase is given by

$$P_{\text{phase}} = V_P I_P \cos(\phi) \tag{2.78}$$

where V_P is the phase voltage,
I_P is the phase current, and
ϕ is the phase angle between V_P and I_P.

The total power for a three-phase circuit is simply three times the power for one of the phases, i.e. three times equation (2.78).

For a star connection:

$$P = 3\frac{V_L}{\sqrt{3}} I_L \cos(\phi) = \sqrt{3} \times V_L \times I_L \cos(\phi) \tag{2.79}$$

For a delta connection:

$$P = 3V_L \frac{I_L}{\sqrt{3}} \cos(\phi) = \sqrt{3} \times V_L \times I_L \cos(\phi)$$

The same relation is obtained. In terms of line voltages and currents therefore, the power in a three-phase circuit is independent of the winding connection and is given by equation (2.79). This equation does not, however, apply if the system is unbalanced. In an unbalanced system the total power can only be obtained as the summation of the powers in each of the individual phases.

2.2.19 Three-phase alternators

Alternators are constructed with a stationary a.c. winding and a rotating field system. This reduces the number of slip-rings required to two, and these have to carry only the field-exciting current as opposed to the generated current. The construction is thereby simplified and the slip-ring losses are minimized. In addition, the simpler arrangement enables heavier insulation to be used and, in consequence, much higher voltages can be generated. The robust mechanical construction of the rotor also means that higher speeds are possible and substantially higher power outputs can be generated with an alternator. A simple form of three-phase generator is depicted in Figure 2.47.

The three coils on the stator are displaced 120° and the rotor, which is a salient pole type, is supplied via the two slip-rings with a d.c. current. As the rotor is driven by some form of prime mover, a rotating magnetic field is established and the e.m.f.'s generated in the coils will be displaced with a

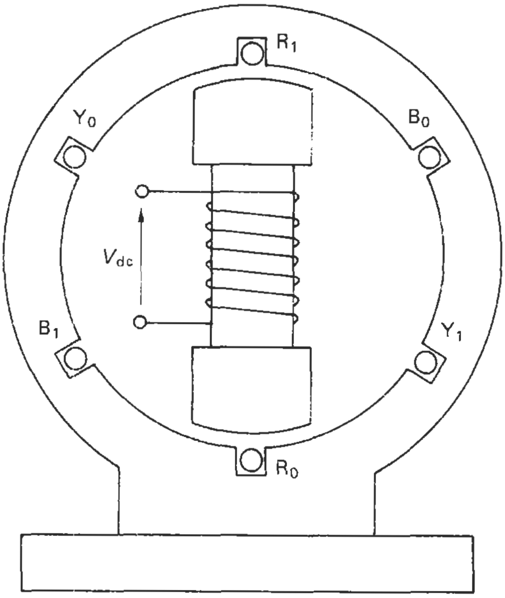

Figure 2.47 Simple three-phase generator

phase shift of 120°. The magnitude of the generated voltages are dependent on the flux produced by the rotor, the number of turns on the stator coils and the speed of rotation of the rotor. The rotor speed will also dictate the frequency of the generated voltage.

The no-load and load characteristics of an alternator are very similar to those of the d.c. separately excited generator (Figures 2.28 and 2.29, respectively). In constant speed operation the terminal voltage exhibits a drooping characteristic, where the decrease in terminal voltage is due to 'armature' resistance and reactance effects. For an alternator, the term 'armature' is taken to imply the stator windings.

As the load on an alternator is increased, the speed of the prime mover will drop. This is an unacceptable situation, because the speed controls the frequency of the generated voltage. To maintain a constant frequency, the prime mover must be governed to run at constant speed over the entire range of expected loads. This is particularly important where many alternators are to be run in parallel to supply a distribution system such as the National Grid. In such cases the prime movers are always speed controlled and the output voltage is regulated to comply with the rated values. In the UK, alternators are usually two-pole machines driven at 3000 rev/min to produce the rated frequency of 50 Hz. In the USA a great deal of the electrical power consumed is generated from hydroelectric power stations. The water turbines used in these installations are fairly low-speed machines and the alternators, which are directly driven, are equipped with multiple poles to produce the rated frequency of 60 Hz. An alternator running at 240 rev/min, for example, must have 30 poles to give the rated output frequency.

The production of the rotating magnetic field may also be activated using three, 120° displaced, rotor coils supplied with three-phase current. The rotational speed of the field is related to the frequency of the currents, i.e.

$$N_s = \frac{f \times 60}{\text{Number of pole pairs}} \tag{2.80}$$

where N_s is the speed of the field (rev/min) and f is the frequency of the supply currents. The speed of the rotating field is termed the 'synchronous speed' and for an equivalent single pair of poles (i.e. three coils) this is 3000 rev/min when the frequency of the supply currents is at 50 Hz.

The use of a.c. excited rotor coils to produce the rotating magnetic field simplifies the mechanical construction of the rotor and greatly facilitates the dynamic balancing of the machine. An added advantage is that the waveform of the generated voltage is improved. The a.c. method of exciting the field is used extensively in large alternators. Salient pole rotors are normally restricted to the smaller machines.

2.2.20 Synchronous motors

Synchronous motors are so called because they operate at only one speed, i.e. the speed of the rotating field. The mechanical construction is exactly the same as the alternator shown in Figure 2.47. The field is supplied from a d.c. source and the stator coils with a three-phase current. The rotating magnetic field is induced by the stator coils and the rotor, which may be likened to a permanent bar magnet, aligns itself to the rotating flux produced in the stator. When a mechanical load is driven by the shaft the field produced by the rotor is pulled out of alignment with that produced by the stator. The angle of misalignment is called the 'load angle'. The characteristics of synchronous motors are normally presented in terms of torque against load angle, as shown in Figure 2.48. The torque characteristic is basically sinusoidal, with

$$T = T_{\max} \sin(\delta) \tag{2.81}$$

where $T_{\max}$ is the maximum rated torque and δ is the load angle.

It is evident from equation (2.81) that synchronous motors have no starting torque and the rotor must be run up to synchronous speed by some alternative means. One method utilizes a series of short-circuited copper bars inserted through the outer extremities of the salient poles. The rotating magnetic flux induces currents in these 'grids' and the machine accelerates as if it were a cage-type induction motor (see

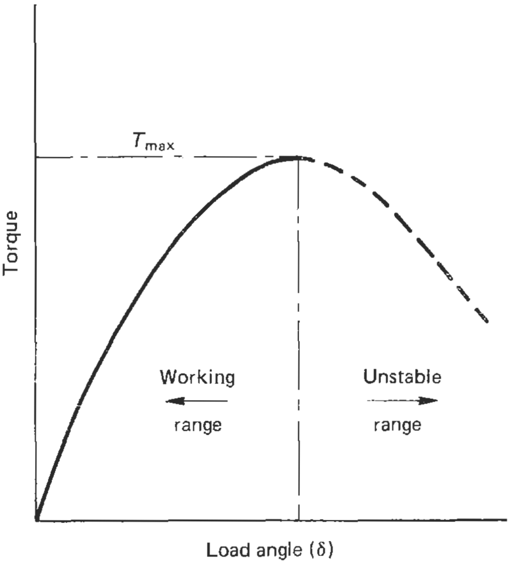

Figure 2.48 Torque characteristic for a synchronous motor

Section 2.2.21). A second method uses a wound rotor similar to a slip-ring induction motor. The machine is run up to speed as an induction motor and is then pulled into synchronism to operate as a synchronous motor.

The advantages of the synchronous motor are the ease with which the power factor can be controlled and the constant rotational speed of the machine, irrespective of the applied load. Synchronous motors, however, are generally more expensive and a d.c. supply is a necessary feature of the rotor excitation. These disadvantages, coupled with the requirement for an independent starting mode, make synchronous motors much less common than induction ones.

2.2.21 Induction motors

The stator of an induction motor is much like that of an alternator and, in the case of a machine supplied with three-phase currents, a rotating magnetic flux is produced. The rotor may be either of two basic configurations: the 'squirrel-cage' or the slip-ring type. In the squirrel-cage motor the rotor core is laminated and the conductors consist of uninsulated copper (or aluminium) bars driven through the rotor slots. The bars are brazed or welded at each end to rings or plates to produce a completely short-circuited set of conductors. The slip-ring machine has a laminated core and a conventional three-phase winding, similar to the stator and connected to three slip-rings on the locating shaft.

Figure 2.49 shows a schematic representation of an induction motor having three stator coils displaced by 120°. If the stator coils are supplied with three-phase currents a rotating magnetic field is produced in the stator. Consider the single-rotor coil shown in the figure. At standstill the rotating field will induce a voltage in the rotor coil since there is a rate of change of flux linking the coil. If the coil forms a closed circuit then the induced e.m.f. will circulate a current in the coil. The resultant force on the current-carrying conductor is a consequence of equation (2.27) and this will produce a torque which will accelerate the rotor. The rotor speed will increase until the electromagnetic torque is balanced by the mechanical load torque. The induction motor will never attain synchronous speed because, if it did, there would be no relative motion between the rotor coils and the rotating field. Under these circumstances there would be no e.m.f. induced in the rotor coils and subsequently no electromagnetic torque. Induction motors therefore always run at something less than synchronous speed. The ratio of the difference between the synchronous speed and the rotor speed to the synchronous speed is called the 'slip', s, i.e.

$$s = \frac{N_s - N}{N_s} \tag{2.82}$$

The torque–slip characteristic is shown in Figure 2.50. With the rotor speed equal to the synchronous speed, i.e. $s = 0$, the torque is zero. As the rotor falls below the synchronous speed the torque increases almost linearly to a maximum value dictated by the total of the load torque and that required to overcome the rotor losses. The value of slip at full load varies between 0.02 and 0.06. The induction motor may be regarded therefore as a constant-speed machine. In fact the difficulties of varying the speed constitutes one of the induction motor's main disadvantages.

On start-up, the slip is equal to unity and the starting torque is sufficiently large to accelerate the rotor. As the rotor runs up to its full-load speed the torque increases in essentially inverse proportion to the slip. The start-up and running curves merge at the full-load position.

2.2.22 Starting induction motors

As with d.c. motors, the current drawn during starting of a.c. motors is very large, up to about five times full-load current. A number of devices are therefore employed to limit the starting current but they all involve the use of auxiliary equipment, which is usually quite expensive.

2.2.22.1 *Star–delta starter*

The star–delta switch (Figure 2.51) is the cheapest and most common method employed. With the machine at standstill and the starter in the 'start' position, the stator coils are connected in the star pattern. As the machine accelerates up to running speed the switch is quickly moved over to the 'run' position, which reconnects the stator windings in the delta pattern. By this simple expedient the starting supply current is reduced to one third of what it would have been had the stator windings been connected in the delta pattern on start-up.

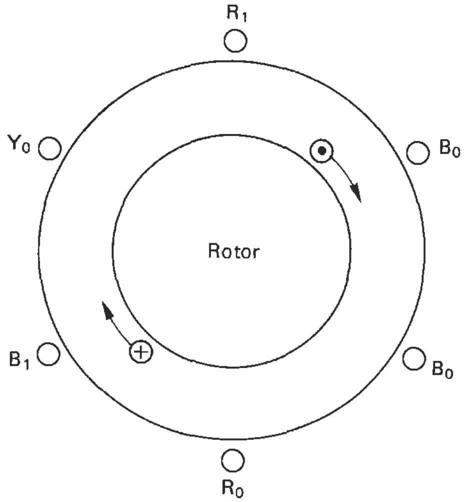

Figure 2.49 Schematic representation of an induction motor

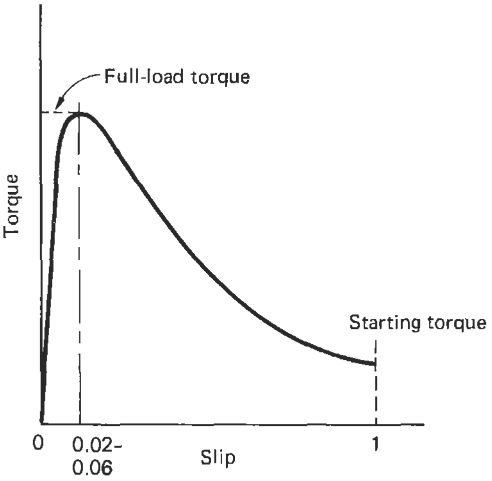

Figure 2.50 Torque–slip characteristic for an induction motor

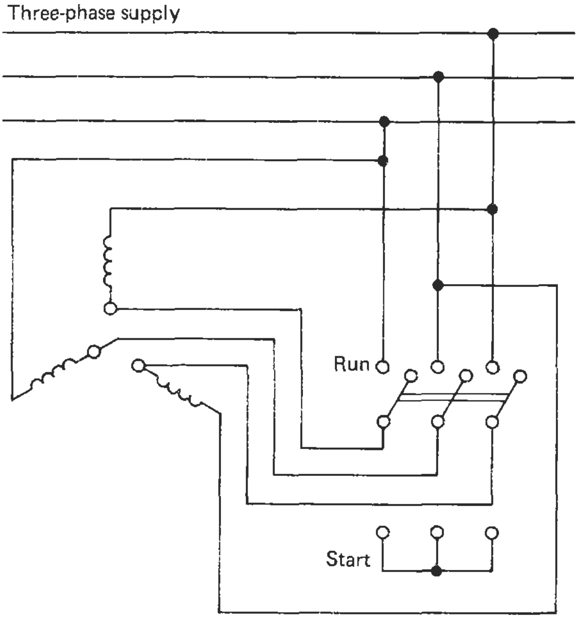

Figure 2.51 Star–delta starter

2.2.22.2 *Auto-transformer starter*

The auto-transformer represents an alternative method of reducing the starting current drawn by an induction motor.

2.2.22.3 *Rotor resistance*

With slip-ring induction motors it is possible to include additional resistance in series with the rotor circuit. The inclusion of extra resistance in the rotor provides for reduced starting current and improved starting torque.

2.2.23 Braking induction motors

Induction motors may be brought to a standstill by either 'plugging' or dynamic braking':

1. *Plugging*: This refers to the technique where the direction of the rotating magnetic field is reversed, and is brought about by reversing any two of the supply leads to the stator. The current drawn during plugging is, however, very large and machines which are regularly plugged must be specially rated.
2. *Dynamic braking*: In this technique the stator is disconnected from the a.c. supply and reconnected to a d.c. source. The direct current in the stator produces a stationary uni-directional field and, as the rotor will always tend to align itself with the field, it will come to a standstill.

2.2.24 Speed control of induction motors

Under normal circumstances the running speed of an induction motor will be about 94–98% of the synchronous speed, depending on the load. With the synchronous speed given by equation (2.80) it is clear that the speed may be varied by changing either the frequency of the supply current or the number of poles.

2.2.24.1 *Change of supply current frequency*

Solid state variable-frequency drives first began to appear in 1968. They were originally applied to the control of synchronous a.c. motors in the synthetic fibre industry and rapidly gained acceptance in that particular market. In more recent times they have been used in applications such as pumping, synchronized press lines, conveyor lines and, to a lesser extent, in the machine-tool industry as spindle drives. Modern a.c. variable-frequency motors are available in power ratings ranging from 1 kW to 750 kW and with speed ranges from 10/1 to 100/1.

2.2.24.2 *Change of number of poles*

By bringing out the ends of the stator coils to a specially designed switch it becomes possible to change an induction motor from one pole configuration to another. To obtain three different pole numbers, and hence three different speeds, a fairly complex switching device would be required.

Changing the number of poles gives a discrete change in motor speed, with little variation in speed over the switched range. For many applications, however, two discrete speeds are all that is required and changing the number of poles is a simple and effective method of achieving this.

2.2.24.3 *Changing the rotor resistance*

For slip-ring induction motors additional resistance can be coupled in series with the rotor circuit. It has already been stated that this is a common method used to limit the starting current of such machines. It can also be employed for marginal speed control. Figure 2.52 shows the torque characteristics of a slip-ring induction motor for a range of different resistances connected in series with the rotor windings. As the external resistance is increased from R_1 to R_3 a corresponding reduction in speed is achieved at any particular torque. The range of speeds is increased at the higher torques.

The method is simple and therefore inexpensive, but the decrease in speed is accompanied with a reduction in overall efficiency. Additionally, with a large resistance in the rotor circuit (i.e. R_3) the speed changes considerably with variations in torque.

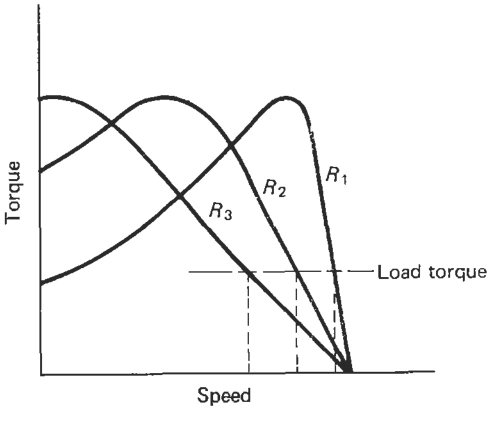

Figure 2.52 Torque–speed characteristics for various rotor resistances

2.2.24.4 *Reduced stator voltage*

By reducing the applied stator voltage a family of torque–speed characteristics are obtained, as shown in Figure 2.53. It is evident that as the stator voltage is reduced from V_1 to V_3, a change in speed is effected at any particular value of torque. This is provided, of course, that the torque does not exceed the maximum load torque available at the reduced stator voltage. This latter point is obviously a limiting factor which places a constraint on this method of speed control. Generally, only very small speed ranges can be obtained using a variable stator supply voltage.

2.2.25 Single-phase induction motors

The operation of an induction motor depends upon the creation of a rotating magnetic field. A single stator coil cannot achieve this, and all the so-called single-phase induction motors use some or other external means of generating an approximation to a two-phase stator supply. Two stator coils are therefore used and these are displaced by 90°. Ideally, the currents which supply each coil should have a phase difference of 90°. This then gives the two-phase equivalent of the three-phase induction motor.

2.2.25.1 *The shaded-pole motor*

The stator of the shaded-pole motor consists of a salient pole single-phase winding and the rotor is of the squirrel-cage type (see Figure 2.54). When the exciting coil is supplied with alternating current the flux produced induces a current in the 'shading ring'. The phase difference between the currents in the exciting coil and the shading ring is relatively small and the rotating field produced is far from ideal. In consequence, the shaded-pole motor has a poor performance and an equally poor efficiency due to the continuous losses in the shading rings.

Shaded-pole motors have a low starting torque and are used only in light-duty applications such as small fans and blowers or other easily started equipment. Their advantage lies in their simplicity and low cost of manufacture.

2.2.25.2 *The capacitor motor*

A schematic layout of a capacitor motor is given in Figure 2.55. The stator has two windings physically displaced by 90°.

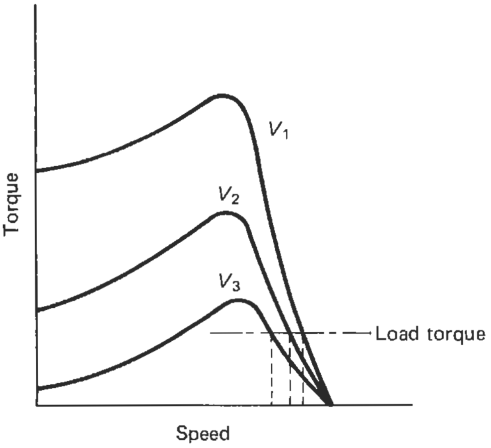

Figure 2.53 Torque–speed characteristics for various stator voltages

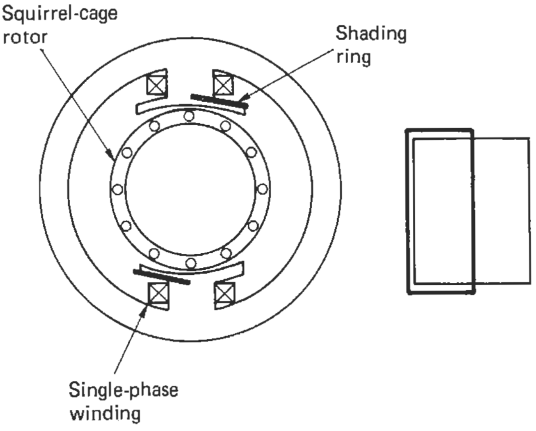

Figure 2.54 Shaded pole motor

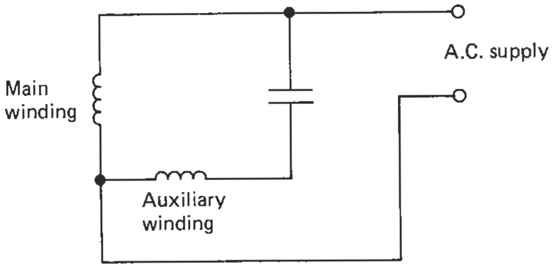

Figure 2.55 Capacitor motor

A capacitor is connected in series with the auxiliary winding such that the currents in the two windings have a large phase displacement. The current phase displacement can be made to approach the ideal 90°, and the performance of the capacitor motor closely resembles that of the three-phase induction motor.

2.2.25.3 *The universal motor*

These are small d.c. series-wound motors which operate at about the same speed and power on direct current, or on single-phase current with approximately the same root mean square voltage. The universal (or plain-series) motor is used mainly in small domestic appliances such as hair dryers, electric drills, vacuum cleaners, hedge trimmers, etc.

2.2.26 The d.c. permanent magnet (PM) motor

The d.c. permanent magnet (PM) motor is a continuous-rotation electromagnetic actuator which can be directly coupled to its load. Figure 2.56 shows the schematic representation of a d.c. PM motor. The PM motor consists of an annular brush ring assembly, a permanent magnet stator ring and a laminated wound rotor. It is particularly suitable for servo systems where size, weight, power and response times must be minimized and where high position and rate accuracies are required.

The response times for PM motors are very fast and the torque increases directly with the input current, independently of the speed or the angular position. Multiple-pole machines maximize the output torque per watt of rotor power. Commercial PM motors are available in many sizes from 35 milli-

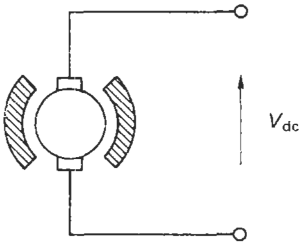

Figure 2.56 D.C. permanent magnet motor

Newton-metres at about 25 mm diameter to 13.5 Newton-metres at about 3 m diameter.

Direct-drive rate and position systems using PM motors utilize d.c. tachogenerators and position sensors in various forms of closed-loop feedback paths for control purposes.

2.2.27 The stepper motor

A stepper motor is a device which converts a d.c. voltage pulse train into a proportional mechanical rotation of its shaft. The stepper motor thus functions both as an actuator and as a position transducer. The discrete motion of the stepper motor makes it ideally suited for use with a digitally based control system such as a microcomputer.

The speed of a stepper motor may be varied by altering the rate of the pulse train input. Thus if a stepper motor requires 48 pulses to rotate through one complete revolution then an input signal of 96 pulses per second will cause the motor to rotate at 120 rev/min. The rotation is actually carried out in finite increments of time, but this is visually indiscernable at all but the lowest speeds.

Stepper motors are capable of driving a 2.2 kW load with stepping rates from 1000 to 20 000 per second in angular increments from 45° down to 0.75°. There are three basic types of stepper motor:

1. *Variable reluctance*: This type of stepper motor has a soft iron multi-toothed rotor with a wound stator. The number of teeth on the rotor and stator, together with the winding configuration and excitation, determines the step angle. This type of stepper motor provides small to medium-sized step angles and is capable of operation at high stepping rates.
2. *Permanent magnet*: The rotor used in the PM-type stepper motor consists of a circular permanent magnet mounted onto the shaft. PM stepper motors give a large step angle, ranging from 45° to 120°.
3. *Hybrid*: The hybrid stepper motor is a combination of the previous two types. Typically, the stator has eight salient poles which are energized by a two-phase winding. The rotor consists of a cylindrical magnet which is axially magnetized. The step angle depends on the method of construction and is generally in the range 0.9–5°. The most popular step angle is 1.8°.

The principle of operation of a stepper motor can be illustrated with reference to a variable-reluctance, four-phase machine. This motor usually has eight stator teeth and six rotor teeth (see Figure 2.57).

If phase 1 of the stator is activated alone then two diametrically opposite rotor teeth align themselves with the phase 1 teeth of the stator. The next adjacent set of rotor teeth in the clockwise direction are then 15° out of step with those of the stator. Activation of the phase 2 winding on its own would cause the rotor to rotate a further 15° in the anti-clockwise direction to align the adjacent pair of diametrically opposite rotor teeth. If the stator windings are excited in the sequence 1, 2, 3, 4 the rotor will move in consecutive 15° steps in the anti-clockwise direction. Reversing the excitation sequence will cause a clockwise rotation of the rotor.

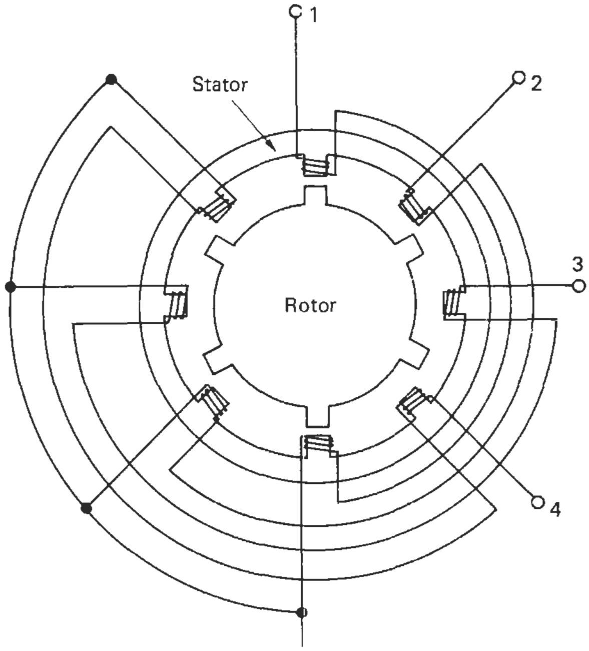

Figure 2.57 Variable-reluctance stepper motor

2.2.27.1 *Stepper motor terminology*

Pull-out torque: The maximum torque which can be applied to a motor, running at a given stepping rate, without losing synchronism.

Pull-in torque: The maximum torque against which a motor will start, at a given pulse rate, and reach synchronism without losing a step.

Dynamic torque: The torque developed by the motor at very slow stepping speeds.

Holding torque: The maximum torque which can be applied to an energized stationary motor without causing spindle rotation.

Pull-out rate: The maximum switching rate at which a motor will remain in synchronism while the switching rate is gradually increased.

Pull-in rate: The maximum switching rate at which a loaded motor can start without losing steps.

Slew range: The range of switching rates between pull-in and pull-out in which a motor will run in synchronism but cannot start or reverse.

The general characteristics of a typical stepper motor are given in Figure 2.58. During the application of each sequential pulse the rotor of a stepper motor accelerates rapidly towards the new step position. However, on reaching the new position there will be some overshoot and oscillation unless sufficient retarding torque is provided to prevent this happening. These oscillations can cause rotor resonance at certain pulse frequencies, resulting in loss of torque, or perhaps even pull-out conditions. As variable-reluctance motors have very little inherent damping they are more susceptible to resonances

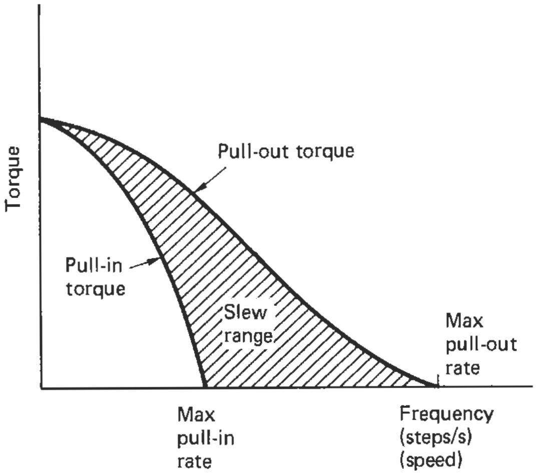

Figure 2.58 Stepper motor characteristics

than either the permanent magnet or the hybrid types. Mechanical and electronic dampers are available which can be used to minimize the adverse effects of rotor resonance. If at all possible, however, the motor should be selected such that its resonant frequencies are not critical to the application under consideration.

Because of their unique characteristics, stepper motors are widely used in applications involving positioning, speed control, timing and synchronized actuation. They are prevalent in X-Y plotters, punched-taped readers, floppy disc head drives, printer carriage drives, numerically controlled machine tool slide drives and camera iris control mechanisms.

By far the most severe limitation on the purely electric stepper motor is its power-handling capability. Currently, this is restricted to about 2.25 kW.

2.2.28 Brushless d.c. motors

These motors have position feedback of some kind so that the input waveforms can be kept in the proper timing with respect to the rotor position. Solid-state switching devices are used to control the input signals, and the brushless d.c. motor can be operated at much higher speeds, with full torque available at those speeds. The brushless motor can normally be rapidly accelerated from zero to operating speed as a permanent magnet d.c. motor. On reaching operating speed the motor can then be switched over to synchronous operation.

The brushless motor system consists of a wound stator, a permanent magnet rotor, a rotor position sensor and a solid-state switching assembly. The wound stator can be made with two or more input phases. Figure 2.59 gives the schematic representation of a two-phase brushless motor. The torque output of phase A is

$$T_A = I_A(Z\Phi/2\pi)\sin(p\theta/2) = I_A K_T \sin(p\theta/2) \qquad (2.83)$$

where I_A is the current in phase A,

$K_T = (Z\Phi/2\pi)$, is the torque constant of the motor,

p is the number of poles, and

θ is the angular position of the rotor.

In the expression for the torque constant, Z is the total number of conductors and Φ is the magnetic flux.

Similarly, the torque output of phase B is

$$T_B = I_B K_T \cos(p\theta/2) \qquad (2.84)$$

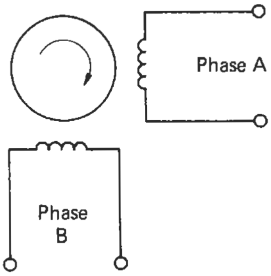

Figure 2.59 Two-phase brushless motor

If the motor currents are arranged to be supplied in the following relationships:

$I_A = I\sin(p\theta/2)$ and $I_B = I\cos(p\theta/2)$

then the total torque for a two-pole motor becomes

$$T = T_A + T_B = IK_T[\sin^2(\theta) + \cos^2(\theta)]$$
$$= IK_T \qquad (2.85)$$

Equation (2.85) shows that if all the above conditions are satisfied then the brushless d.c. motor operates in a manner similar to the conventional d.c. motor, i.e. the torque is directly proportional to the armature current. Note that the armature current in this context refers to the stator windings.

Excitation of the phases may be implemented with sinusoidal or square-wave inputs. The sine-wave drive is the most efficient, but the output transistors in the drive electronics must be capable of dissipating more power than that dissipated in square-wave operation. Square-wave drive offers the added advantage that the drive electronics can be digitally based.

The brushless d.c. motor will duplicate the performance characteristics of a conventional d.c. motor only if it is properly commutated. Proper commutation involves exciting the stator windings in a sequence that keeps the magnetic field produced by the stator approximately 90 electrical degrees ahead of the rotor field. The brushless d.c. motor therefore relies heavily on the position feedback system for effective commutation. It might also be apparent that the brushless motor as described is not strictly a d.c. machine but a form of a.c. machine with position feedback.

The further development of the brushless d.c. motor will depend to a large extent upon future advances in semiconductor power transistor technology. It is likely, however, that within the next decade the true brushless d.c. motor, using solid-state swiching, will become commercially viable and will progressively dominate the d.c. servosystem market.

This brief discussion of rotating electrical machines is in no way comprehensive. A fuller discourse on a.c. and d.c. machines is given by both Gray[4] and Sen.[5] Orthwein[6] presents an interesting practical discussion on the mechanical applications of a.c. and d.c. motors and Kenjo and Nagamori[7] provide a detailed in-depth study of permanent-magnet d.c. motors.

2.2.29 Transformers

One of the major advantages of a.c. transmission and distribution is the ease with which an alternating voltage can be increased or decreased. Common practice in the UK is to generate voltages at 11–22 kV and then transform up to 33 kV (or 132 kV) for transmission on the National Grid to the consumer centres. At these centres, the voltages are transformed back down to 415 V (or 240 V) and then distributed for industrial and domestic use.

2.2.30 Basic transformer action

Figure 2.60 illustrates a simple single-phase transformer in which two separate coils are wound onto a ferrous core. The coil connected to the supply is called the 'primary winding' and that connected to the load is the 'secondary winding'. The ferrous core is made in laminations, which are insulated from one another, to reduce eddy current losses.

If a sinusoidal voltage, V_1, is applied across the primary winding a current, I_1, in the coil will induce a magnetic flux, ϕ, in the core. From Faraday's law (equation (2.25)) the induced e.m.f. in the primary coil is

$$E_1 = N_1(\mathrm{d}\phi/\mathrm{d}t) \tag{2.86}$$

Since the magnetic flux is common to both coils the e.m.f. induced in the secondary winding is

$$E_2 = N_2(\mathrm{d}\phi/\mathrm{d}t) \tag{2.87}$$

Hence

$$\frac{E_1}{E_2} = \frac{N_1}{N_2} \tag{2.88}$$

The ratio of primary coil turns to secondary turns, N_1/N_2, is called the 'transformation ratio'. The primary and secondary winding impedances, Z_1 and Z_2, respectively, are both very small such that when the secondary winding is on open circuit, then $V_1 \doteqdot E_1$ and $V_2 \doteqdot E_2$. Therefore

$$\frac{V_1}{V_2} = \frac{N_1}{N_2} \tag{2.89}$$

When a load is connected across the secondary winding a current, I_2, will flow in the secondary winding. From Lenz's law this will set up a flux which will tend to oppose the main flux, ϕ. If the main flux is reduced then E_1 would be correspondingly decreased and the primary current, I_1, would then increase. This increased primary current would tend to produce a flux to oppose that induced by the secondary current. In this manner the main flux is generally maintained. In steady state the ampere-turns in the primary and secondary windings are balanced, i.e.

$$I_1N_1 = I_2N_2$$

or

$$\frac{I_1}{I_2} = \frac{N_2}{N_1} \tag{2.90}$$

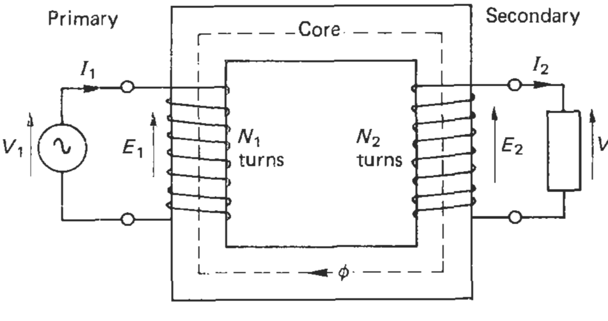

Figure 2.60 Single-phase transformer

2.2.31 Transformer voltage equation

In normal operation the flux may be considered to be a sinusoidally varying quantity, i.e.

$$\phi = \Phi \sin(\omega t) \tag{2.91}$$

The induced e.m.f., from Faraday's law, is

Primary side, $e_1 = N_1(\mathrm{d}\phi/\mathrm{d}t) = N_1\Phi\omega \cos(\omega t)$

The r.m.s. value of the induced e.m.f. is

$$E_1 = \frac{2\pi f N_1 \Phi}{\sqrt{2}} = 4.44\, fN\Phi \tag{2.92}$$

Similarly, for the secondary side,

$$E_2 = 4.44\, fN_2\Phi$$

2.2.32 Transformer losses

Equations (2.89) and (2.90) define the ideal transformer in which there are no resistive or inductive losses. An actual transformer, of course, does involve some losses, which are:

1. *Copper losses*: These are associated with the I^2R loss in both of the coils. They may be represented therefore as a resistance in series with each coil.
2. *Iron loss*: These are associated with magnetic hysteresis effects and eddy current losses in the iron core. The iron losses are essentially constant for a particular value of supply voltage. Iron losses can be represented as a resistor in parallel with the primary coil.
3. *Flux leakage*: The useful (or main) flux is that which effectively links both coils. In practice, some of the flux will escape, or otherwise fail to link both coils. The e.m.f.'s produced by the leakage fluxes are proportional to (and lead the fluxes by) 90°. The effect of flux leakage may be likened therefore to having an additional inductive coil in series with the primary and secondary coils. In practice, the flux leakage loss is usually lumped together with the iron loss.

2.2.33 Determination of transformer losses

2.2.33.1 Open-circuit test

The secondary coil is on open-circuit and the full-rated voltage is applied to the primary winding. The transformer takes a small no-load current to supply the iron loss in the core and the copper losses are essentially zero. Since the normal voltage and frequency are applied, a wattmeter connected to the primary side will give a measure of the iron loss. The iron loss can then be taken as a constant, irrespective of the load.

2.2.33.2 Closed-circuit test

With the secondary winding short-circuited the transformer requires only a small input voltage to circulate the full-load current. The wattmeter on the primary side then gives an indication of the full-load copper losses. If the load is expressed as a fraction of the full load, the copper losses at reduced loads are proportional to the load squared. At half load, for example, the copper losses are one quarter of the full-load value.

2.2.34 Referred values

In dealing with transformers it is usual to base all calculations on one side of the transformer. Parameters on the neglected side are accounted for by 'referring' them over to the side on which the calculation is to be based. The transformation ratio is used to scale the equivalent values. For example, the copper loss on the secondary side, $I_2^2R_2$, can be referred to the primary side through the relation

$$I_2'^2R_2' = I_2^2R_2 \tag{2.93}$$

where the prime denotes the referred values. Using equation (2.90) the referred resistance becomes

$$R_2' = \{N_1/N_2\}^2R_2 \tag{2.94}$$

Thus equation (2.94) gives an equivalent resistance, R_2', in the primary side which accounts for the actual resistance, R_2, of the secondary winding. Reactances may be similarly referred to one or other side of the transformer for calculation purposes.

2.2.35 Transformer efficiency

The transformer efficiency, as with any machine, is the ratio of the output power to the input power. The difference between the output and the input power is the sum of the losses, which, for the case of a transformer, is the copper and the iron losses, i.e.

$$\eta = \frac{\text{Output}}{\text{Input}} = \frac{\text{Output}}{\text{Output + copper loss + iron loss}}$$

Therefore

$$\eta = \frac{V_2I_2\cos(\theta_2)}{V_2I_2\cos(\theta_2) + I_2^2\cdot R_e + F_e} \tag{2.95}$$

Note that R_e represents an equivalent resistance, which consists of the resistance of the secondary winding and that of the primary winding referred over to the secondary side, i.e.

$$R_e = R_2 + (N_2/N_1)^2R_1 \tag{2.96}$$

The iron loss, F_e, is assumed to be constant and $\cos(\theta_2)$ is the load power factor, also assumed constant.

By dividing the numerator and the denominator of equation (2.95) by I_2, then differentiating the denominator with respect to I_2, and equating the result to zero, it can be shown that for maximum efficiency, $I_2^2\cdot R_e = F_e$. Maximum transformer efficiency then occurs when the copper loss is equal to the iron loss. The general efficiency characteristics for a transformer are shown in Figure 2.61.

Equation (2.95) also shows that the output will be influenced by the load power factor. At unity power factor the output (and hence also the efficiency) is maximized. As the power factor decreases, the transformer efficiency also reduces proportionally.

2.2.36 Voltage regulation

As the load current drawn from a transformer is increased, the terminal voltage decreases. The difference between the no-load output voltage and the output voltage on load is called the 'regulation'. The percentage regulation is defined as

$$\frac{\text{No-load voltage} - \text{load voltage}}{\text{No-load voltage}} \times 100 \tag{2.97}$$

Figure 2.62 shows the two voltages in terms of phasors referred to the primary side. In the figure V_1 is the no-load primary voltage and V_2' is the secondary-side voltage referred to the primary. R_e and X_e denote the equivalent resistance and reactance, respectively, including the referred secondary values. Since δ is very small, then, to a reasonable approximation,

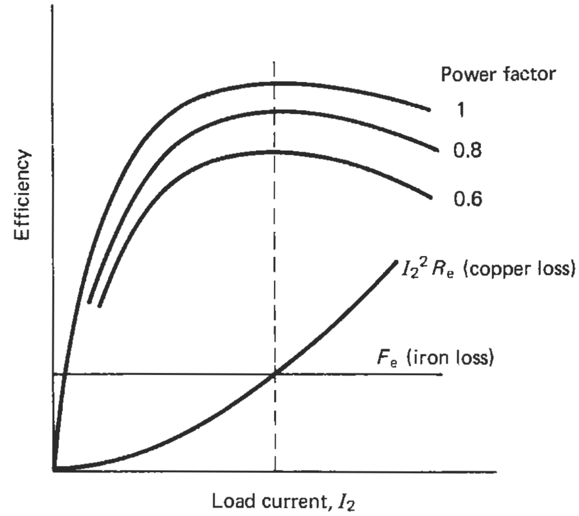

Figure 2.61 Transformer efficiency characteristics

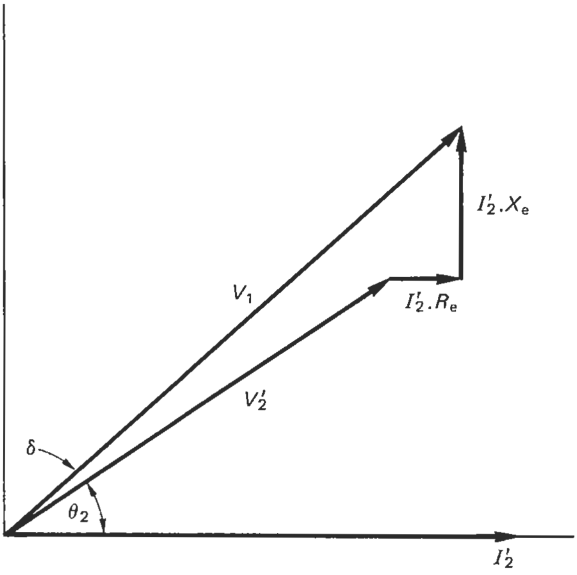

Figure 2.62 Phasor diagram for a transformer with a lagging power factor load current

$$V_1 = V_2' + I_2'\cdot R_e\cdot\cos(\theta_2) + I_2'\cdot X_e\cdot\sin(\theta_2) \tag{2.98}$$

The percentage regulation is therefore

$$(100/V_1)[I_2'R_e\cos(\theta_2) + I_2'X_e\sin(\theta_2)] \tag{2.99}$$

Equation (2.99) is based on the assumption that the load power factor is lagging, and this is the normal situation. If, however, the load power factor is leading, the plus operator within the term in square brackets must be replaced with a minus operator.

2.2.37 Three-phase transformers

Modern large three-phase transformers are usually constructed with three limbs as shown in Figure 2.63. In the figure

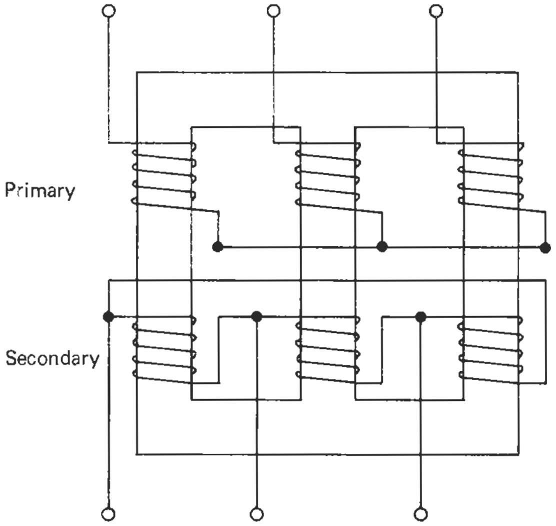

Figure 2.63 Three-phase transformer

the primary windings are star-connected and the secondary windings are delta-connected. In fact, the primary and secondary windings can be connected in any pattern, depending upon the conditions under which the transformer is to operate. It is important, however, to know how the three-phase transformer is connected, particularly when two or more transformers are to be operated in parallel. It is essential, for instance, that parallel operation transformers belong to the same main group and that their voltage ratios are perfectly compatible.

2.2.38 Auto-transformers

The auto-transformer is characterized by having part of its winding common to both the primary and secondary circuits (see Figure 2.64). The main application of auto-transformers is to provide a variable voltage, and it is used, for example, to limit the starting current drawn by an induction motor (see Section 2.2.22).

A major disadvantage of the auto-transformer is that the primary and secondary windings are not electrically isolated from one another. This presents a serious risk of shock, and therefore auto-transformers cannot be used for interconnecting high- and low-voltage systems.

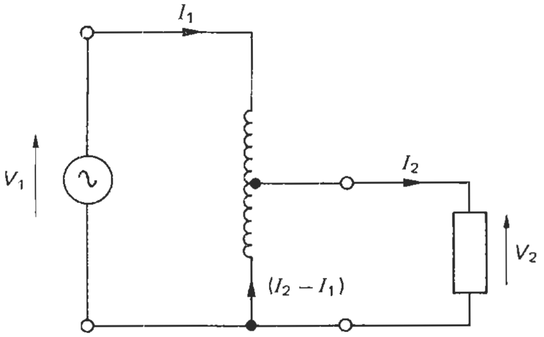

Figure 2.64 Auto-transformer

2.3 Analogue and digital electronics theory

2.3.1 The bipolar (or junction) transistor

The term 'transistor', derived from 'transfer resistor', describes a device which can transfer a current from a low-resistance circuit to a high-resistance one with little change in current during the process. The junction transistor consists of two *pn* diodes formed together with one common section, making it a three-layer device (see Figure 2.65).

Current flow in the transistor is due to both electron and hole conduction. The common central section is referred to as the 'base' and is typically of the order of 25 μm in length. Since the base can be made either an *n*-type or a *p*-type semiconductor, two basic configurations are possible. These are the *npn* and the *pnp* types, as illustrated in Figure 2.65. The two other terminals are called the 'emitter' and the 'collector'. An arrowhead is traditionally shown between the emitter and the base to indicate the conventional direction of the current flow in that part of the circuit.

A brief description of the physical operation of the junction transistor can be made with respect to the *npn* type. The mode of operation of the *pnp* type is the same as that of the *npn* type, except that the polarities of all applied voltages, currents and charge carriers are reversed.

In normal use, as a linear amplifier, the transistor is operated with the emitter to base junction forward biased and the collector to base junction reversed biased. For the *npn* transistor, the emitter is therefore negative with respect to the base while the collector is positive with respect to the base (see Figure 2.66). The junction n_1p is forward biased such that the free electrons drift from n_1 to p. On the other hand, junction n_2p is reverse biased and it will collect most of the electrons from n_1. The electrons which fail to reach n_2 are responsible for the current at the base terminal, I_B. By ensuring that the thickness of the base is very small and that the concentration of impurities in the base is much lower than either that of the emitter or the collector, the resultant base current will be limited to some 2% of the emitter current. The basic transistor characteristic is therefore

$$I_C = h_{FB} \cdot I_E \tag{2.100}$$

where I_C is the collector current, I_E is the emitter current and h_{FB} is the current gain between the collector and the emitter. Normally, h_{FB} would range between 0.95 and 0.995 for a good-quality transistor.

2.3.2 Common-base characteristics

Figure 2.67 shows an *npn* transistor connected in a circuit to determine its static common-base characteristics. The emitter

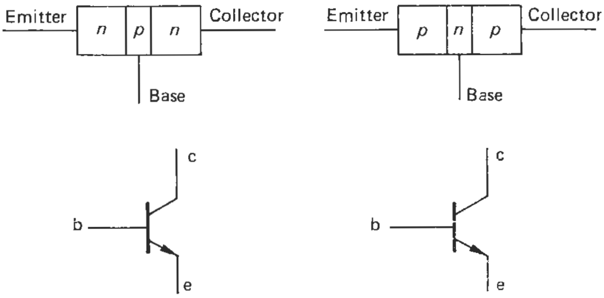

Figure 2.65 *npn* and *pnp* junction transistors

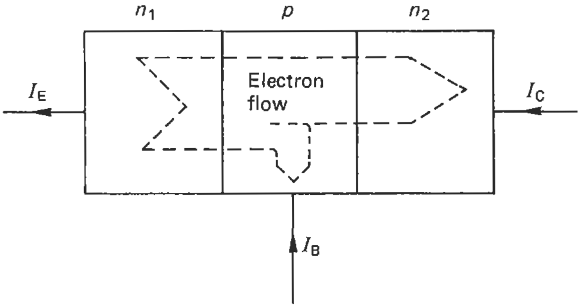

Figure 2.66 *npn* transistor in normal operation

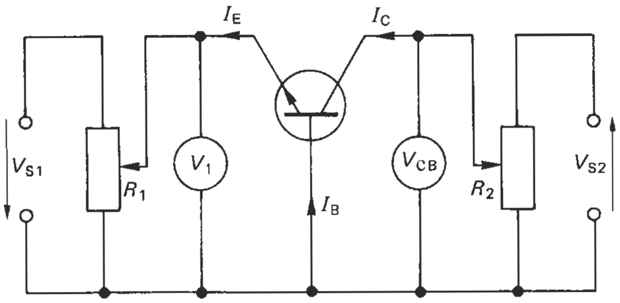

Figure 2.67 *npn* transistor in common base circuit

current, I_E, is kept constant by varying R_1 and a range of values for I_C are imposed by varying R_2. The value of V_{CB}, the collector-base voltage, is noted. The test is repeated for another fixed value of I_E and the results are as depicted in Figure 2.68.

It is found that over a wide range of collector-base voltages the collector current is essentially independent of the collector-base voltage. This is because most of the electrons entering the *npn* junction are attracted to the collector. In effect, the collector circuit has a very high impedance and acts as a constant current source. The actual value of the collector current is determined by the emitter current and the two are related through equation (2.100), which is the common-base characteristic. The general characteristics also show that the collector-base voltage must be reversed (i.e. collector negative with respect to base) in order to reduce the collector current to zero. Finally, at a high collector-base voltage, the collector current increases rapidly in consequence of the Zener effect. The same characteristics are observed with the *pnp* transistor, except that the signs are in the reverse direction to that shown in Figure 2.67.

2.3.3 Common-emitter characteristics

Figure 2.69 shows the *npn* transistor with its emitter terminal connected to both the base current and the collector current circuits. Using the same test procedure as before, the resulting characteristics are as shown in Figure 2.70. The first significant observation is that the collector-emitter voltage, V_{CE}, must be positive to produce a positive collector current. At low values of V_{CE} the collector current I_C is also low, but when V_{CE}

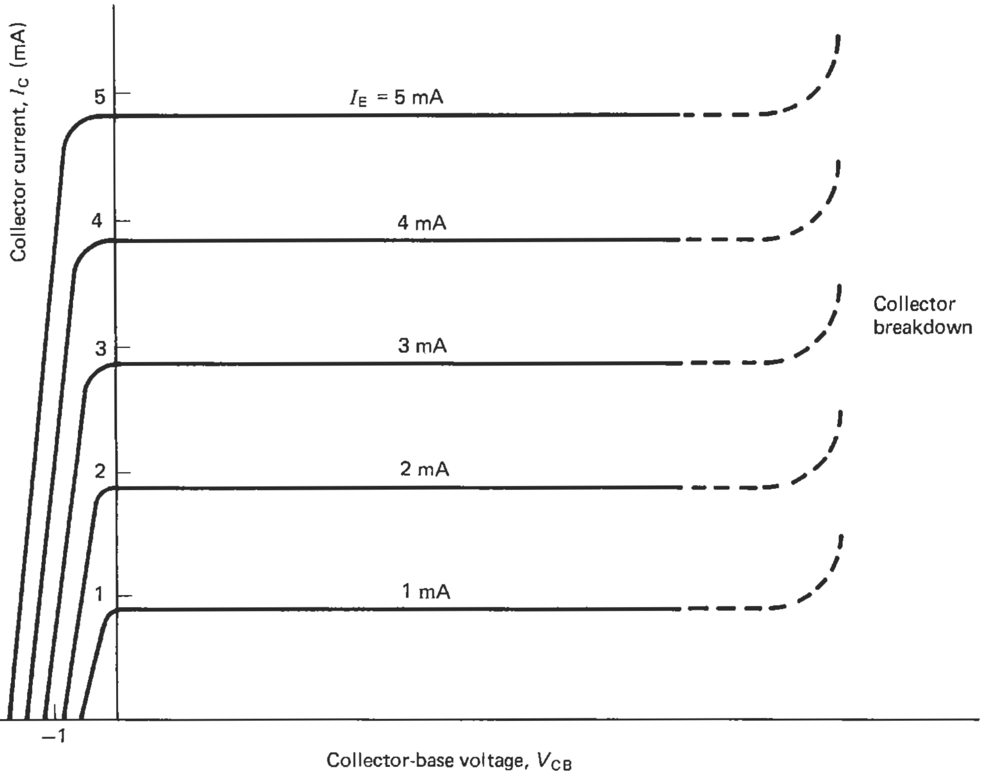

Figure 2.68 Common-base characteristics

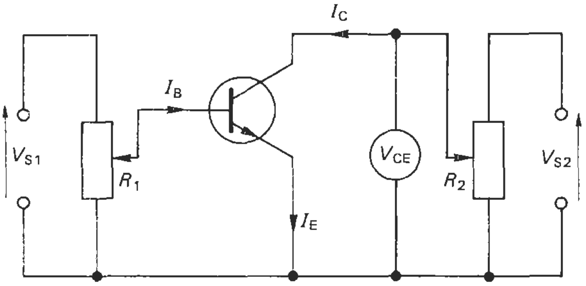

Figure 2.69 *npn* transistor in common emitter circuit

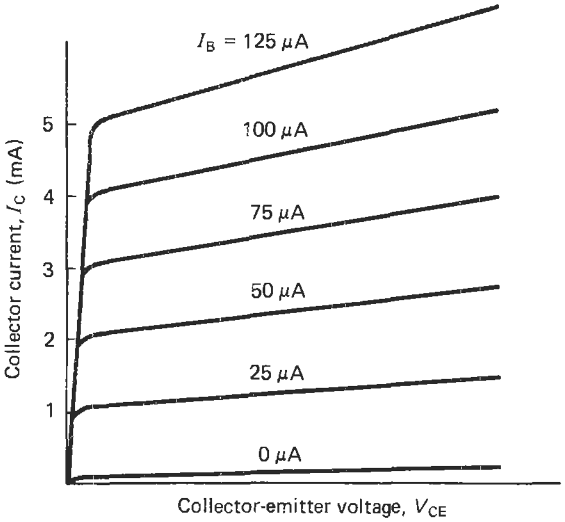

Figure 2.70 Common-emitter characteristics

exceeds the so-called 'knee' voltage the characteristic assumes a linear relationship. The gradient of the linear region is generally much higher than that for the common-base configuration and the collector impedance is therefore lower than that for the common-base circuit. When the base current is zero the collector current still has a positive finite value.

The common-emitter characteristic is generally written as

$$I_C = h_{FE} \cdot I_B \tag{2.101}$$

where h_{FE} is the current gain between the collector and base. Application of Kirchhoff's first law to the common-emitter circuit gives

$$I_E = I_C + I_B$$

Using equation (2.100) and eliminating I_E, it can be shown that

$$\frac{I_C}{I_B} = \frac{h_{FB}}{1 - h_{FB}} = h_{FE} \tag{2.102}$$

For a transistor with a steady-state current gain in common base of 0.95 the common-emitter gain is

$$h_{FE} = \frac{0.95}{1 - 0.95} = 19$$

If, due to some temperature effect, h_{FB} undergoes a minor change to, say, 0.96, the new value of h_{FE} becomes 24. It is clear therefore that the common-emitter gain, h_{FE}, is much more sensitive to small-order effects than the common-base gain, h_{FB}.

For a *pnp* transistor the characteristics of the common-emitter circuit are the same, except that the polarity of all voltages and currents are again in reverse order to that shown in Figure 2.69.

2.3.4 The transistor in a circuit

In most practical applications transistors are operated in the common-emitter mode where the emitter terminal forms the common connection between the input and output sections of the circuit (see Figure 2.71).

The transistor collector characteristics are shown again in Figure 2.72. The load line for the resistor, R_C, is superimposed and the operating point is given by the intersection of the load line with the collector characteristic. The operating point will therefore be dependent on the base current, since this controls the collector characteristic. Also shown in Figure 2.72 is the maximum power dissipation curve (broken line), which represents the locus of the product of collector current and collector-emitter voltage. The maximum power dissipation curve represents a physical limitation and the operating point must be constrained to lie below the curve at all times.

As the base current is reduced the operating point moves down the load line. When I_B reaches zero the collector current will be minimized and the transistor is said to be 'cut-off'. Alternatively, as the base current is increased the operating point moves up the load line and eventually reaches a maximum value at which the transistor is said to be 'bottomed', or 'saturated'. When saturated, the collector-emitter voltage is at a minimum of about 0.1–0.2 V and the collector current is a maximum. The two extremes between cut-off and saturation represent a very high and a very low impedance state of the transistor, respectively. These extremes have great practical application to rapid, low-power switching, and transistors operating between cut-off and saturation are frequently used in digital electronics circuitry. The low-impedance state represents a switch closed (or on) and the high-impedance state represents the switch open (or off). When operating as a linear

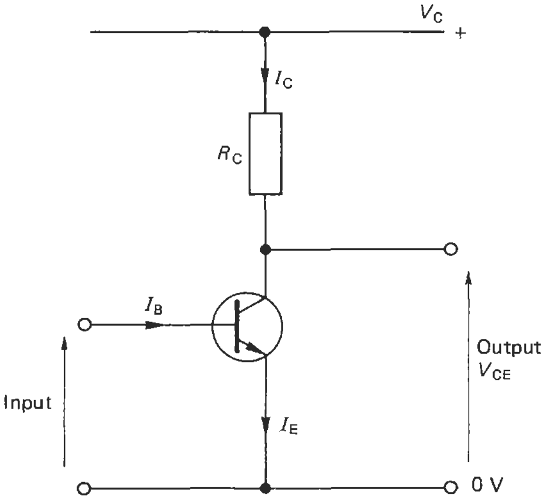

Figure 2.71 *npn* transistor in a practical common-emitter circuit

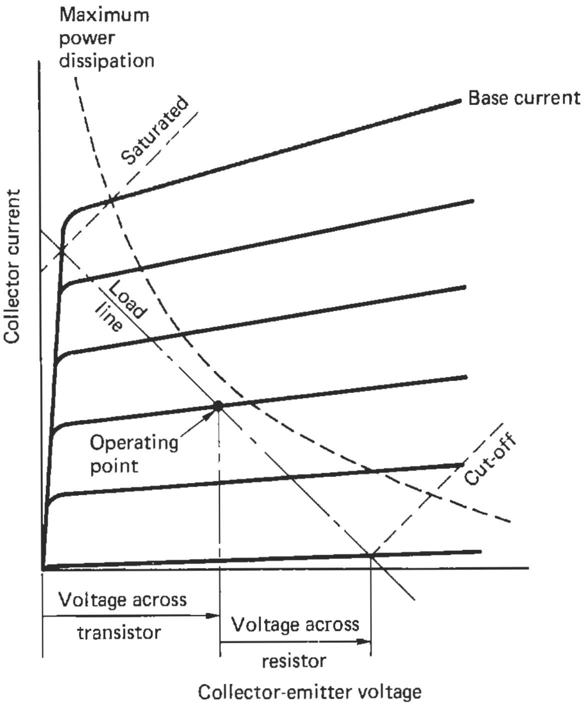

Figure 2.72 Common-emitter characteristics with superimposed load line

current amplifier the operating point is ideally located in the centre of the active region of the characteristic.

The analysis of circuits involving transistors is conveniently dealt with by representing the transistor in terms of an equivalent circuit and using the conventional current flow direction from positive to negative. Consideration of the charge carriers (i.e. holes or electrons) is only necessary to describe the internal physical operation of the transistor. Fully detailed worked examples are particularly informative, and these are usually provided in all standard textbooks on electrical and electronics technology.

2.3.5 The field effect transistor (FET)

Field effect transistors (or FETs) are a much more recent development than bipolar transistors and they operate on a substantially different mechanism in achieving signal amplification. Operationally, FETs are voltage-controlled devices as opposed to the bipolar transistor, which is current-operated. FETs are often described as unipolar, since conduction in the FET is the result of only one predominant charge carrier.

The junction field effect transistor (JFET) consists of a thin bar of semiconductor which forms a channel between its two end-connections that are referred to as the 'source' and the 'drain'. If the semiconductor used in the construction of the FET is *n*-type, the device is called an '*n*-channel'. Conversely, a FET made from a *p*-type semiconductor is called a '*p*-channel' device.

If the channel consists of a uniformly doped semiconductor, the conductivity will be constant and the FET will function as a linear resistor. By introducing two opposite type semiconductor layers on either side of the channel the effective thickness of the channel (and hence the current flow) can be controlled. The opposite type layers are denoted as 'gates' and in normal operation they are reverse biased by a d.c. potential, V_{GS}, referred to as the 'gate source voltage'. The reverse bias ensures that no current can flow between the two gates and the gate inputs have an extremely high impedance. By using a lightly doped semiconductor for the channel the gate depletion layer, which is determined by V_{GS}, can be made to extend well into the channel width. This controls the resistance of the path between the source and the drain. The general characteristics of such a FET are shown in Figure 2.73.

For a given value of V_{GS} an increase in drain-source voltage from zero initially gives a linear rise in drain current. Further increases in drain-source voltage result in a so-called 'pinch-off' in the drain current, which then becomes independent of the drain-source voltage. Finally, at a particular limiting value of drain-source voltage a breakdown is initiated. The similarities between Figures 2.73 and 2.70 or 2.72 are clear, and it is evident therefore that the bipolar junction transistor and the unipolar FET can perform essentially a similar function in any given application. Many other types of transistor (for example, the metal oxide semiconductor FET, or MOSFET) use alternative means to control the resistance of the source to drain channel. The general characteristics of these devices, however, are all very similar to that shown in Figure 2.73.

2.3.6 Integrated circuits

While transistor-based amplifiers are still found as individual elements in many working circuits, the modern trend is towards the development of integrated circuits, where all the circuit elements are housed within a single silicon wafer. MOSFET technology is predominant in this area, since the number of components on a single silicon chip can be packed up to twenty times more densely than with bipolar technology.

The integrated circuit components include diodes and transistors which may be either bipolar junction type or FETs. Resistors can be deposited on top of the wafer in the form of tantalum, which is a poor conductor, or built into the wafer as 'pinch' resistors, which are partially turned-off FETs. Capacitors can also be produced within the silicon wafer. Capacitive elements may be formed when a *pn* junction diode is reverse biased. The *p*- and *n*-type layers form the plates of the capacitor and the carrier-depletion layer acts as a dielectric. The capacitance is, however, limited to a few picofarads.

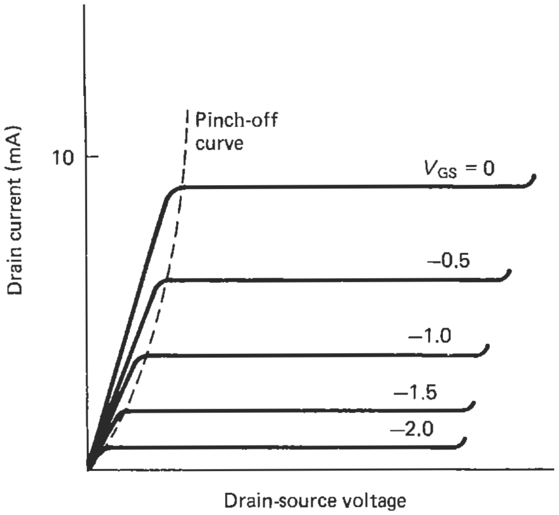

Figure 2.73 Characteristics of a FET

is no microelectronic equivalent for an inductor, but most circuit designs can generally avoid the requirement for coiled inductive elements.

When the integrated circuit is complete it is usually encapsulated as a 'dual-in-line' (DIL) package. This is the normal form in which the integrated circuit is sold. An eight-pin DIL package may contain a relatively simple circuit, but a 40-pin DIL could easily contain all the electronics associated with a central processing unit (CPU) for a computer system. These latter devices contain a very large number of transistors and diodes (approaching 10 000 on a chip of less than 10 mm square). The technology to produce this density of integration is commonly called 'very large-scale integration', or VLSI.

2.3.7 The thyristor

Both the bipolar transistor and the FET can be utilized for switching operations. These devices, however, are usually associated with low-power switching. For switching very large currents and voltages a special device called a 'thyristor' (formerly known as a silicon-controlled rectifier, SCR) is normally used. The thyristor is a four-layer, unidirectional semiconductor device with three connections referred to as the anode, cathode and the control gate (see Figure 2.74).

The current flow is from the anode to the cathode only and, with the cathode positive with respect to the anode, the device has a very high impedance. Under normal circumstances the thyristor will fail to conduct current in any direction. If a voltage is applied such that if the thyristor were a diode it would conduct in the forward-biased direction, then application of a very small current between the gate and the cathode will cause the thyristor to abruptly change from non-conducting to conducting mode. The turn-on is rapid (within a few microseconds) and, once turned on, the thyristor will remain on, even if the gate current is removed.

Once triggered into conduction the thyristor will turn off again only when the current flowing through it is reduced below a critical value. This minimum conducting current is called the 'holding current' and may range between a few microamps to a few tens of milliamps. Thyristors are additionally connected in series with a resistor, which serves to limit the current to a safe value. The basic thyristor function is that of a power-control device, and thyristors are used extensively for switching mains electricity and as speed controllers for d.c. motors.

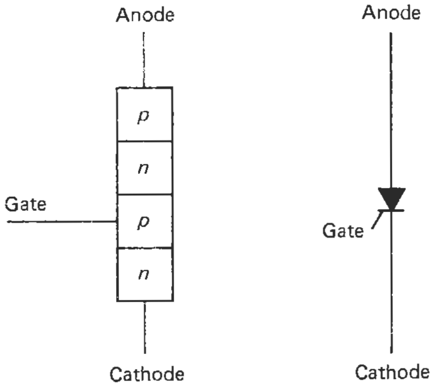

Figure 2.74 Thyristor device and circuit symbol

2.3.8 The triac

The triac (or bidirectional thyristor) is similar in operation to the thyristor but differs in that it can be switched into conduction in either direction. In essence, the triac is equivalent to two thyristors mounted back to back. Triacs find application to switching in full-wave alternating power supplies.

2.3.9 Amplifiers

In general, electronic amplifiers are supplied with energy from a d.c. source. An input signal to the circuit controls the transfer of energy to the output, and the output signal should be a higher-power version of that supplied to the input. The amplifier does not, however, function as some magical source of free energy. The increased power across the amplifier is invariably drawn from the supply.

The term 'amplifier' is actually a shortened form for the complete specification 'voltage amplifier'. This has transpired because most amplifiers are intended to magnify voltage levels. Any other type of amplifier is normally prefixed with the name of the quantity which is amplified (e.g. current amplifier, charge amplifier or power amplifier).

Amplifiers may be broadly classified with reference to the frequency range over which they are designed to operate. In this respect there are two general categories: 'wide-band' and 'narrow-band' amplifiers. The names are self-explanatory in that the wide-band amplifier exhibits a constant power gain over a large range of input signal frequencies. The narrow-band (or 'tuned') amplifier, on the other hand, provides a power gain over a very small frequency range. This gain is usually expressed in decibels and is defined by equation (2.58).

The bandwidth of an amplifier is used in the same context as in Section 2.1.29, i.e. to define the operating frequency range. In this respect the -3 dB amplitude ratio is used consistently to define the upper and lower input signal frequencies at which the power transferred across the amplifier is halved.

Using the system model, the amplifier can be represented as shown in Figure 2.75. In the figure the amplifier is shown enclosed within the broken lines. There is a single input, a single output and one common connection. The amplifier also features an internal input impedance, shown as resistance R_i, and an internal output impedance, shown as resistance R_o. In fact, the input and output impedances could have both inductive and capacitive components as well as the simple resistances, as shown in the figure.

Connected to the input stage of the amplifier is a voltage source, V_s, and its associated internal resistance, R_s. This could be taken to represent some form of transducer having a

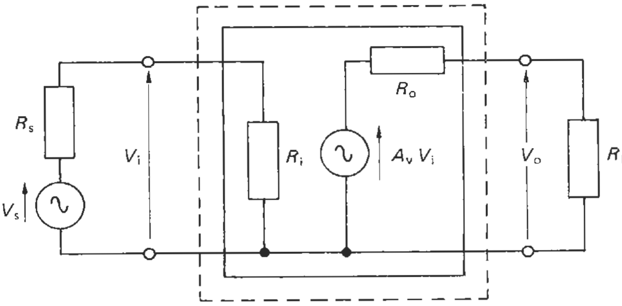

Figure 2.75 System representation of an amplifier

low-voltage output in the millivolt range. At the output stage the amplifier acts as a voltage source where A_v is the voltage gain. The output is shown connected to an external load, R_L, which might be considered to be a recording instrument such as a digital voltmeter.

Considering the input stage, it may be shown, from Ohm's law, that

$$V_i = \frac{V_s}{(1 + R_s/R_i)} \qquad (2.103)$$

This equation indicates that the voltage applied to the amplifier input stage, V_i, will approach the source voltage, V_s, only when R_i tends to infinity. The amplifier should therefore ideally have a very large input impedance to prevent serious voltage attenuation at the input stage. By a similar argument, the output impedance, R_0, should be very small in comparison to the load resistance, R_L, for maximum voltage gain.

2.3.10 Effect of feedback on amplifiers

The amplifier illustrated in Figure 2.75 is specified by its input and output impedances and its open-circuit gain, A_v, this gain being obtained when the load resistance is infinite. These parameters are not fixed, but will vary with ambient temperature, power supply voltage and variation with age. The adverse effects of these variabilities can be minimized through the application of 'negative feedback'.

One particular method of obtaining negative feedback is the so-called 'series voltage' method (see Figure 2.76). The feedback system in Figure 2.76 is applied by connecting a potentiometer across the output terminals and tapping off a fraction, β, of the output signal. This fraction is connected in series with the input and with a polarity which will always oppose the input signal. Assuming both that the input impedance of the amplifier is very large in comparison to the internal resistance of the voltage source and that the resistance of the potentiometer is very large in comparison with the output impedance of the amplifier,

$$V_i = V_s - \beta \cdot V_o \qquad (2.104)$$

Since, $V_o = A_v \cdot V_i$, then $V_o = A_v \cdot V_s - \beta \cdot A_v \cdot V_o$. The overall gain of the system with feedback, A_f, is

$$A_f = \frac{V_o}{V_s} = \frac{A_v}{1 + \beta A_v} \qquad (2.105)$$

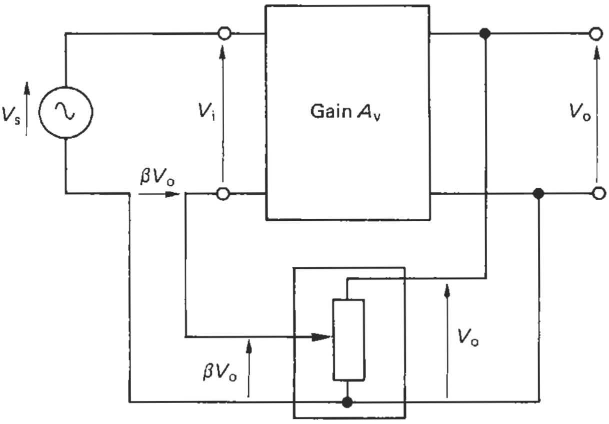

Figure 2.76 Series voltage method of negative feedback

Equation (2.105) shows that the feedback loop has reduced the original gain by the factor $(1 + \beta \cdot A_v)$. If, in addition, the original gain A_v was in itself very large such that $\beta \cdot A_v \gg 1$, then

$$A_f = A_v/(\beta \cdot A_v) = 1/\beta \qquad (2.106)$$

Under the above circumstances the overall gain of the system with feedback is essentially dependent only on the feedback fraction, β. Any changes therefore which alter the original gain, A_v, of the amplifier will not affect the gain of the overall system with feedback.

Consideration of the system with and without the feedback loop shows that the effect of series voltage negative feedback is to increase the input resistance by the factor $1 + \beta \cdot A_v$ and to reduce the output resistance by the same factor. Both these effects are of benefit to the operation of the system. These comments refer only to a negative feedback system using the series voltage method. Other methods of obtaining negative feedback can be used, including series current feedback, shunt current and shunt voltage feedback. These alternative methods have different effects on the overall gain and on the input and output impedances of the amplifier.

2.3.11 Noise and distortion in amplifiers

Noise is inherently present in all electronic amplifier systems. The source of the noise is due to a number of effects, which include the random charge movements within solid-state devices, thermoelectric potentials, electrostatic and electromagnetic pick-up and interference from the standard 50 Hz or 60 Hz mains power supply. The noise is fairly evenly distributed across the whole frequency spectrum and appears superimposed upon the amplified input signal. If the noise is generated at the input stage of the amplifier then the 'signal-to-noise' ratio is not improved by feedback. This ratio can, however, be improved if an intermediate amplifying stage, free from noise effects, can be included in the system.

Distortion is another undesirable feature which arises when the amplifier input/output (or transfer) characteristic deviates from an ideal linear relationship. If the transfer characteristic is linear then the output signal will be a faithful amplified replica of the input. A non-linear characteristic will give a distorted output, and a non-sinusoidal output will be generated from a sinusoidal input. Distortion is usually associated with a high level of input signal, which overextends the linear operating range of the amplifier.

2.3.12 Amplifier frequency response

The frequency response of an amplifier is usually illustrated as a plot of the gain in decibels against the input signal frequency. The graph is called a 'Bode plot' and the phase relationship between the output and input is also shown for completeness. Figure 2.77 illustrates the frequency characteristics for a typical wide-band amplifier.

In the figure the bandwidth between the −3 dB cut-off frequencies is determined either by the characteristics of the active devices used to make the amplifier or by other frequency-dependent elements in the amplifier circuit. The upper limiting frequency is fixed by the charge transit time through the active device. In practice, any stray capacitance, which is manifested as a parallel capacitance in the system, will considerably reduce the upper limiting frequency. In theory, the active device will respond to frequencies down to 0 Hz but, because of the variabilities due to ageing effects, a lower cut-off frequency is often imposed by including series capacitors on one or both of the input connections.

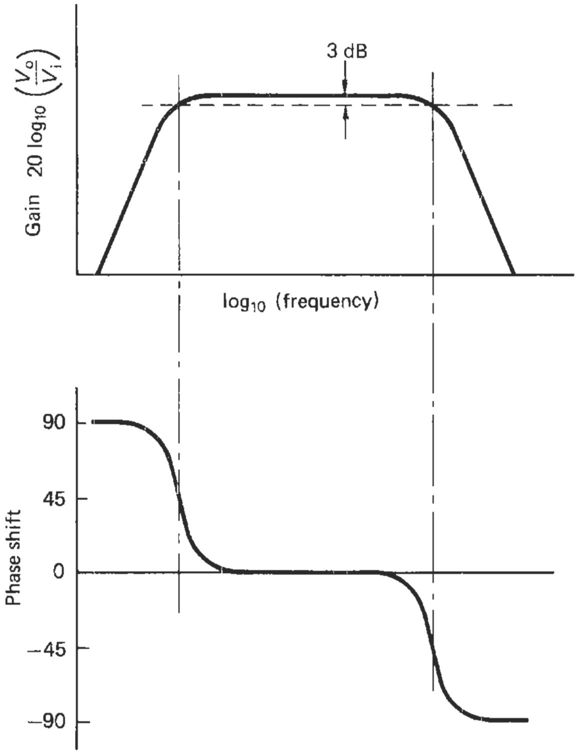

Figure 2.77 Frequency response for a wide-band amplifier

2.3.13 Positive feedback and stability

In Figure 2.76 a negative feedback signal is produced by using a series voltage. If the phase of the series voltage was changed such that the feedback signal augmented the input, then the nature of the feedback loop would become positive. With this positive feedback system the overall gain would then become

$$A_f = A_v/(1 - \beta \cdot A_v) \qquad (2.107)$$

Positive feedback therefore increases the overall system gain. If indeed the product $\beta \cdot A_v$ is made equal to unity then the overall gain becomes infinite. Positive feedback, however, is inherently unstable, since the output signal tends to increase indefinitely in an uncontrolled manner. Systems with positive feedback are found, nonetheless, in oscillator circuits where the amplifier produces its own input signal via a positive feedback loop.

2.3.14 The operational amplifier

Modern amplifier systems rely less on discrete active devices such as transistors and much more on the large range of integrated circuits which are readily available. One of the most prevalent operational amplifiers based on integrated circuit technology is the generic type SN72741, or, as it is often abbreviated, the 741. The 741 is available as an eight-pin DIL package and internally consists of 20 bipolar transistors, 11 resistors and one capacitor. The DIL package takes up less area than a small postage stamp and costs less than a cup of coffee. Figure 2.78 shows the usual representation of the 741 operational amplifier (or 'op-amp') in its DIL form.

The internal circuitry is quite complex but is conveniently reduced to the basic schematic form shown in the figure. The operational amplifier consists of an output, an inverting input and a non-inverting input. The circuitry in addition, requires a bipolar power supply which may range between ±3 to ±18 V. There is also provision for an offset null on connection pins 1 and 5. For the most part, the offset pins can be ignored.

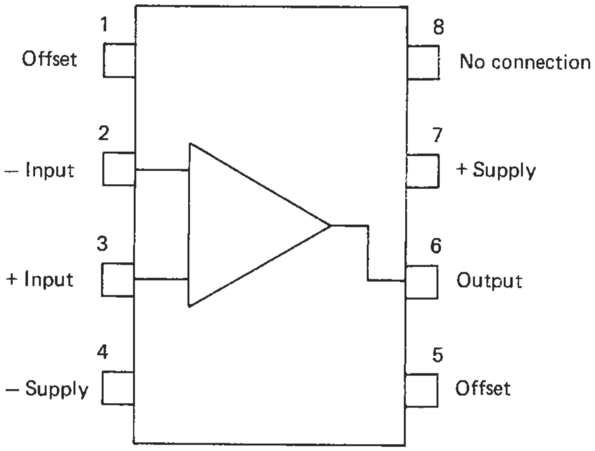

Figure 2.78 SN72741 operational amplifier

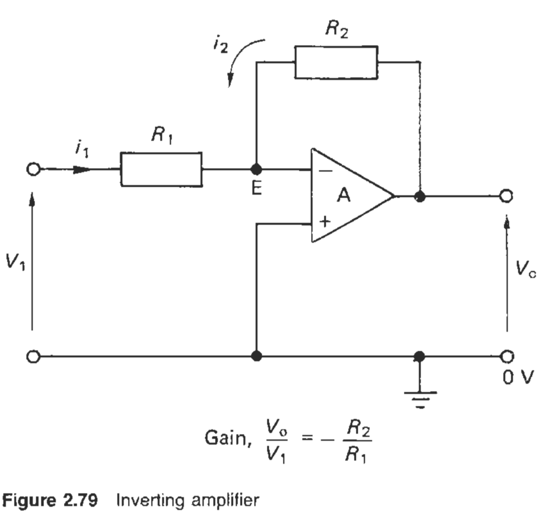
The operational amplifier has a high input impedance, a low output impedance and a very high open-circuit gain, A. Ideally, the gain should be infinite. The bandwidth should also be infinite but the 741, for example, has an effective bandwidth limited between 0 Hz and about 1 MHz.

For operational amplifiers such as the 741 there are a number of standard circuits which are used routinely to perform specific functions.

2.3.14.1 *Inverting amplifier*

Figure 2.79 shows an op-amp wired up for an inverted output. The input current i_1 is given as V_1/R_1 and, because the amplifier input impedance is very high, the current flowing into the input terminal is approximately zero. This is equivalent to having the potential available at point E equal to zero. For this reason, E is referred to as a 'virtual earth'. From



$$\text{Gain, } \frac{V_o}{V_1} = -\frac{R_2}{R_1}$$

Figure 2.79 Inverting amplifier

Kirchhoff's first law, it is apparent that $i_1 = -i_2$. Thus $V_1/R_1 = -V_o/R_2$, and the gain can be written as

$$\frac{V_o}{V_1} = -\frac{R_2}{R_1} \tag{2.108}$$

Provided the open-circuit gain of the amplifier is very high, the overall gain with this negative feedback system is given by the ratio of the two external resistors and is independent of the open-circuit gain.

2.3.14.2 *Unity gain amplifier*

Figure 2.80 depicts a unity gain amplifier in which no external resistors are wired into the circuit. The unity gain amplifier is also known as a voltage follower or as a buffer amplifier. This type of amplifier circuit is often used in instrumentation systems where the internal resistance of a voltage-generating transducer and that of the voltage-recording instrument are so poorly matched that the transducer voltage is seriously attenuated. This situation arises when the transducer internal resistance is large in comparison to that of the recording instrument. Since the buffer amplifier has a large input impedance and a low output impedance it can be interfaced between the transducer and the recording instrument to provide optimum impedance matching. This gives a low source impedance and high destination impedance between both the transducer and amplifier and also between the amplifier and the instrument.

Summing the voltages round the amplifier in Figure 2.80 gives

$$V_1 + V_a = V_o$$

Since the internal impedance of the amplifier is very large then V_a is effectively zero and the gain is

$$V_o/V_1 = 1 \tag{2.109}$$

2.3.14.3 *Non-inverting amplifier*

Figure 2.81 shows the operational amplifier connected up for a non-inverting output. Assuming that the currents through resistors R_1 and R_2 are equal and that point E is a virtual earth,

$$\frac{V_i}{R_1} = \frac{V_o - V_i}{R_2}$$

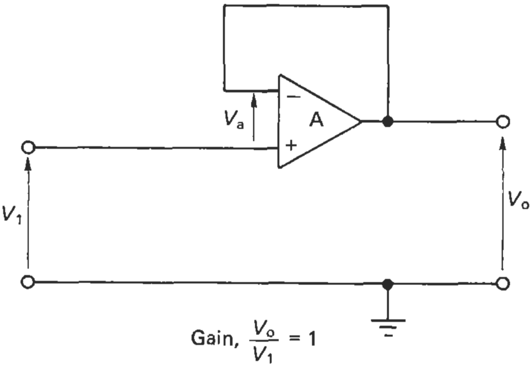


Figure 2.80 Unity gain amplifier

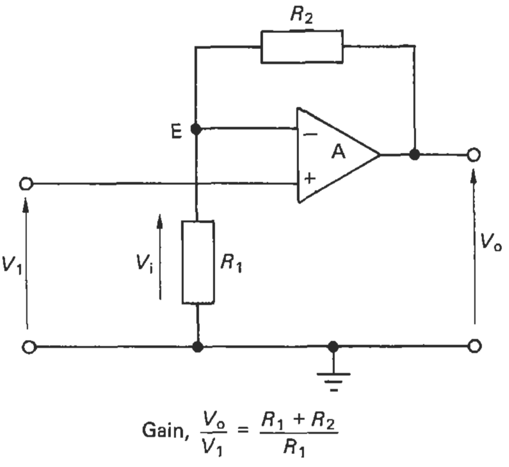

Figure 2.81 Non-inverting amplifier

Hence

$$\frac{V_o}{V_i} = \frac{R_2 + R_1}{R_1}$$

Since E is a virtual earth, then $V_i = V_1$ and

$$\frac{V_o}{V_1} = \frac{R_2 + R_1}{R_1} \tag{2.110}$$

If, in addition, $R_2 \gg R_1$,

$$\frac{V_o}{V_1} \doteqdot \frac{R_2}{R_1} \tag{2.111}$$

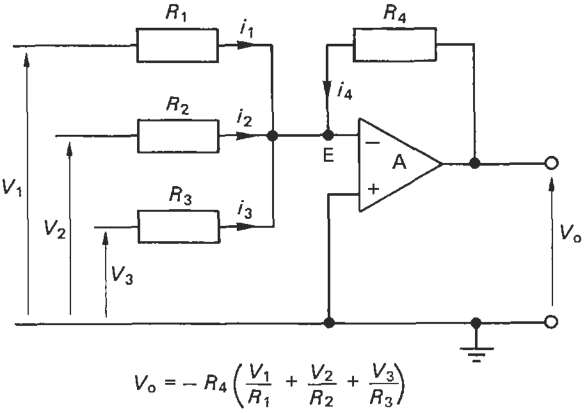
2.3.14.4 *Summing amplifier*

The summing amplifier is shown in Figure 2.82. As point E is a virtual earth, then

$$-i_4 = i_1 + i_2 + i_3$$

Therefore

$$\frac{V_o}{R_4} = -\left[\frac{V_1}{R_1} + \frac{V_2}{R_2} + \frac{V_3}{R_3}\right]$$



R_1
i_1
R_4
R_2
i_2
i_4
E
A
R_3
i_3
V_1
V_2
V_3
V_o
$V_o = -R_4\left(\frac{V_1}{R_1} + \frac{V_2}{R_2} + \frac{V_3}{R_3}\right)$

Figure 2.82 Summing amplifier

or

$$V_o = -R_4\left[\frac{V_1}{R_1} + \frac{V_2}{R_2} + \frac{V_3}{R_3}\right] \tag{2.112}$$

If the resistances used in the circuit are all of equal value, the output voltage will be equivalent to the summation of all the input voltages and with a reversed sign. Subtraction of any of the voltages can be performed by reversing its polarity, i.e. by first passing the voltage through a unity gain inverting amplifier before it is passed on to the summing amplifier.

2.3.14.5 Integrating amplifier

The integrating amplifier uses a capacitor, as opposed to a resistor, in the feedback loop (see Figure 2.83). The voltage across the capacitor is

$$1/C \int_0^t i_2 \mathrm{d}t$$

Since E is a virtual earth then $i_1 = -i_2$, therefore $i_2 = -(V_1/R_1)$. The voltage across the capacitor, which is, in effect, V_o, is

$$V_o = -(1/C)\int_0^t (V_1/R_1)\mathrm{d}t = -(1/CR_1)\int_0^t V_1\mathrm{d}t \tag{2.113}$$

Thus the output voltage is related to the integral of the input voltage.

Apart from various mathematical processes, operational amplifiers are also used in active filtering circuits, waveform generation and shaping, as a voltage comparator and in analogue-to-digital (A/D) and digital-to-analogue (D/A) conversion ICs.

2.3.15 The differential amplifier

The differential amplifier (or subtractor) has two inputs and one output, as shown in Figure 2.84. The differential amplifier yields an output voltage which is proportional to the difference between the inverting and the non-inverting input signals. By applying the superposition principle, the individual effects of each input on the output can be determined. The cumulative effect on the output voltage is then the sum of the two separate inputs. It can be shown therefore that

$$V_o = (R_2/R_1)[V_2 - V_1] \tag{2.114}$$

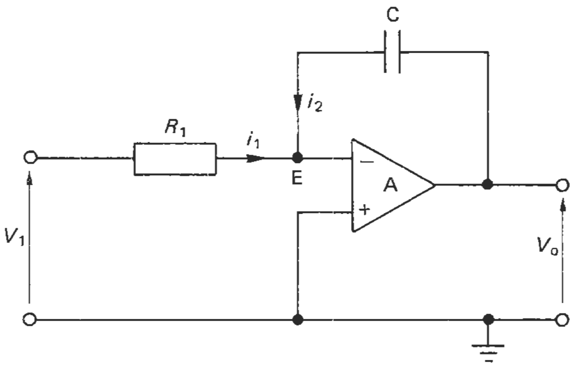


Figure 2.83 Integrating amplifier

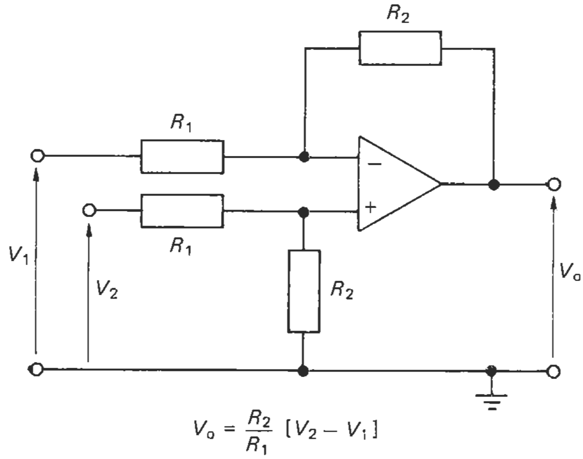

Figure 2.84 The differential amplifier

The input signals to a differential amplifier, in general, contain two components; the 'common-mode' and 'difference-mode' signals. The common-mode signal is the average of the two input signals and the difference mode is the difference between the two input signals. Ideally, the differential amplifier should affect the difference-mode signal only. However, the common-mode signal is also amplified to some extent. The common-mode rejection ratio (CMRR) is defined as the ratio of the difference signal voltage gain to the common-mode signal voltage gain. For a good-quality differential amplifier the CMRR should be very large.

Although particularly important to the differential amplifier, the common-mode rejection ratio is a fairly general quality parameter used in most amplifier specifications. The 741 op-amp has a CMRR of 90 dB and the same signal applied to both inputs will give an output approximately 32 000 times smaller than that produced when the signal is applied to only one input line.

2.3.16 Instrumentation amplifier

Instrumentation amplifiers are precision devices having a high input impedance, a low output impedance, a high common-mode rejection ratio, a low level of self-generated noise and a low offset drift. The offset drift is attributable to temperature-dependent voltage outputs. Figure 2.85 shows the schematic representation of a precision instrumentation amplifier.

The relationship between output and input is

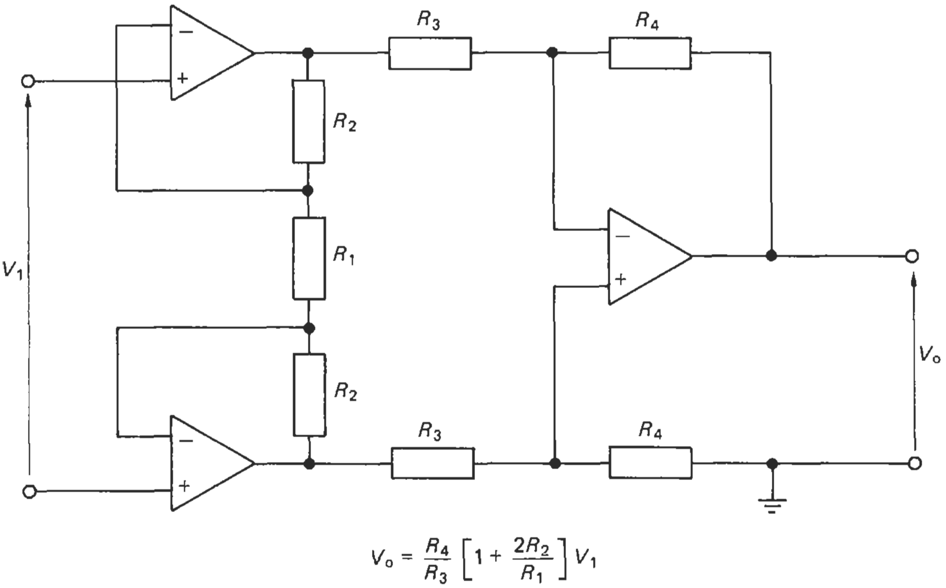
$$V_o = (R_4/R_3)[1 + 2(R_2/R_1)]V_i \tag{2.115}$$

The first two amplifiers appearing in the input stage operate essentially as buffers, either with unity gain or with some finite value of gain.

A number of instrumentation amplifiers are packaged in IC form and these are suitable for the amplification of signals from strain gauges, thermocouples and other low-level differential signals from various bridge circuits. Kaufman and Seidman[8] give a good practical coverage on the general use of amplifiers.

2.3.17 Power supplies

In Section 2.1.33 the use of *pn* junction diodes were illustrated as a means of a.c. voltage rectification. Both the half-wave and full-wave rectification circuits give outputs, which, although varying with respect to time, are essentially d.c. in that there is



$$V_o = \frac{R_4}{R_3}\left[1 + \frac{2R_2}{R_1}\right]V_1$$

Figure 2.85 Precision instrumentation amplifier

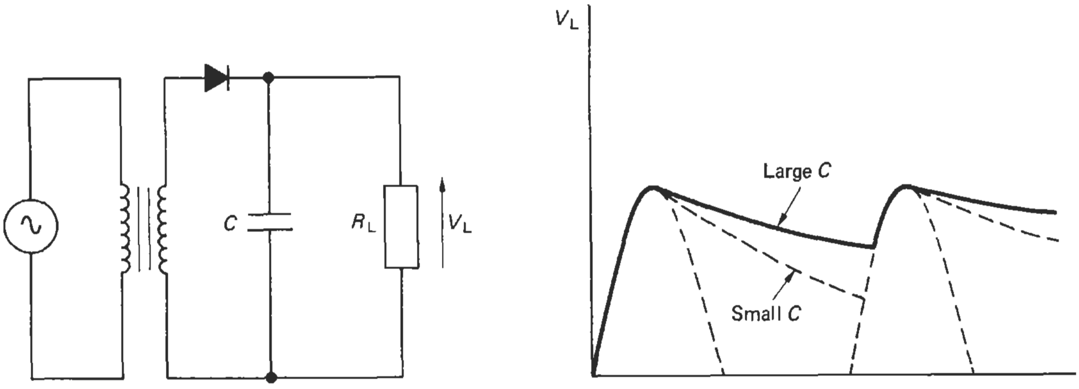


Figure 2.86 Half-wave rectification circuit with reservoir capacitor

no change in polarity. These rectification circuits provide a first stage in the production of a steady d.c. voltage from an a.c. power supply. Some further refinements are, however, added to the circuits to reduce the variation (or 'ripple') in the d.c. output voltage. The ripple factor can be greatly reduced by adding a 'reservoir capacitor', as shown in Figure 2.86, which is connected in parallel with the load.

A further reduction in ripple can be achieved by using a full-wave rectification circuit, since there are then twice as many voltage pulses and the capacitor discharge time is halved. The reservoir capacitor is, of necessity, quite large, and electrolytic capacitors are often used in this application. A leakage resistor is also frequently connected in parallel with the reservoir capacitor as a safety feature. In the event that the load is disconnected leaving the reservoir capacitor fully charged, the leakage resistor will dissipate the charge safely. For applications where the reservoir capacitor still cannot reduce the ripple to an acceptable level an additional ripple filtering circuit may be added.

Further enhancement might include a variable resistor either in series or in parallel with the load. The function of the variable resistor is to allow regulation of the voltage supplied to the load. The Zener diode discussed in Section 2.1.34 is often used in this capacity to provide a stabilized voltage supply.

For high-power systems, thyristors are used in place of diodes as the rectification element. The controlled conduction properties of thyristors allow close control to be exercised on the power supplied to the load.

2.3.18 Analogue and digital systems

Thus far, this chapter has been concerned with purely analogue systems in which the circuit currents and voltages are infinitely variable. Digital systems, on the other hand, operate between one of two possible states, i.e. 'off' or 'on' (conducting or not conducting) and, as such, digital systems are essentially discrete in their operation.

2.3.19 Boolean algebra

The basic rules of Boolean algebra are conveniently described with reference to simple manually switched circuits. In the binary notation a '0' denotes that the switch is off and a '1' that the switch is on. The '0' and '1' can also be taken to represent the absence or presence, respectively, of a voltage or a current.

2.3.19.1 Logical AND

Figure 2.87 shows a simple AND circuit. Obviously, the lamp will light only when both switches A AND B are closed. Writing this as a Boolean expression

$$F = A \text{ AND } B \qquad (2.116)$$

where A, B and F are Boolean variables denoting switches A, B and the lamp, respectively. The logical operator AND is denoted by a dot, thus:

$$F = A.B$$

or

$$F = AB \qquad (2.117)$$

2.3.19.2 Logical OR

Figure 2.88 shows the simple OR circuit. It is clear that the lamp will light in the OR circuit when either switch A OR switch B is closed. As a Boolean expression, the OR function is written

$$F = A \text{ OR } B$$

i.e. $F = A + B$ (2.118)

The + sign is used to denote the logical OR and must not be confused with the arithmetical meaning.

The AND and the OR are the basic logical functions, and quite complex switching circuits can be represented by them in Boolean form.

2.3.19.3 Logical NOT

The NOT function is the inverse complement, or negation of a variable. The negation of the variable A is $\overline{A}$. Thus if $A = 1$, then $\overline{A} = 0$ and vice versa.

2.3.19.4 Logical NAND

The NAND function is the inverse of AND.

2.3.19.5 Logical NOR

Similarly, the NOR is the inverse of OR.

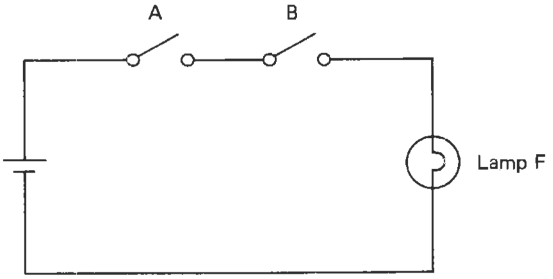

Figure 2.87 Simple AND circuit

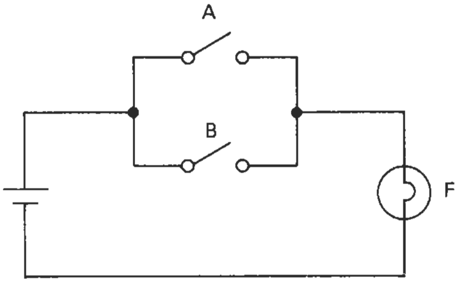

Figure 2.88 Simple OR circuit

2.3.19.6 Exclusive OR

In Figure 2.88 it can be seen that the lamp will also light when both switches A and B are closed. The exclusive OR is a special function which does not enable an output when both switches are closed. Otherwise the exclusive OR functions as the normal OR operator.

The logical functions may also be represented in a tabular form known as a 'truth table'. This table indicates the output generated for all possible combinations of inputs, and is illustrated in Figure 2.89 for the AND and NAND operators with three inputs A, B and C.

Using the basic logical functions, the Boolean identities are specified in Table 2.3.

Table 2.3 Boolean identities

$A + 0 = A$	$A \,.\, A = A$
$A + 1 = 1$	$A + \overline{A} = 1$
$A \,.\, 0 = 0$	$A \,.\, \overline{A} = 0$
$A \,.\, 1 = A$	$\overline{\overline{A}} = A$
$A + A = A$	$\overline{A + B} = \overline{A} \,.\, \overline{B}$
	$\overline{A \,.\, B} = \overline{A} + \overline{B}$

In this table a '0' can be taken to represent an open circuit while a '1' represents a short circuit.

Using a truth table, it is easy to prove the validity of various logical expressions by evaluating both sides, e.g.

$$A(B + C) = AB + AC$$

$$(A + B).(A + C) = A + BC$$

$$A + \overline{A}B = A + B \qquad \text{etc.}$$

A	B	C	$A.B.C$	$\overline{A.B.C}$
0	0	0	0	1
0	0	1	0	0
0	1	0	0	0
0	1	1	0	0
1	0	0	0	0
1	0	1	0	0
1	1	0	0	0
1	1	1	1	0

Figure 2.89 Truth table for AND and NAND operators with three inputs

The first example shows that the parentheses may be removed by multiplying out, as in normal arithmetic. The second two examples have no arithmetic counterpart.

De Morgan's theorem states that, in any logical expression, AND can be replaced by OR and vice versa, provided that each term is also replaced with its inverse complement. The resulting expression is then the inverse of the original.

Example 1
From ABC we negate to

$\overline{AB}C = \bar{A} + \bar{B} + \bar{C}$

Hence

$ABC = \overline{\bar{A} + \bar{B} + \bar{C}}$

Example 2
From $F = AB + CD$ we negate to

$\bar{F} = (\bar{A} + \bar{B}) + (\bar{C} + \bar{D})$

Applying De Morgan again,

$F = \overline{(\bar{A} + \bar{B}).(\bar{C} + \bar{D})}$

The equivalence of the original and the final expressions in the above two examples may be checked by using a truth table.

2.3.20 Digital electronic gates

The principles of Boolean algebra have been considered with respect to manually switched circuits. In modern digital systems the switches are formed with transistors for speed of operation, and they are generally referred to as 'gates'. Over the years, various technologies have been developed in the manufacture of logic gates. The earliest forms of electronic gate were based on the unidirectional conduction properties of diodes. Diode logic gates have now been superseded by transistor–transistor logic gates (TTL) or the more recent CMOS family of logic gates.

The internal construction and operation of modern logic gates may be quite complex, but this is of little interest to the digital systems designer. Generally, all that the designer need to know is the power supply voltages, the transient switching times, the 'fan out' and the 'fan in'. Fan out refers to the number of similar gates which can be driven from the output of one gate. Fan in, on the other hand, denotes the number of similar gate outputs which can be safely connected to the input of one gate.

2.3.20.1 TTL

The TTL family is based on the bipolar junction transistor, and was the first commonly available series of logic elements. TTL logic gates are rapid-switching devices (the SN7400, for example, takes just 15 ns to change state). The standard power supply is 5 V with a low tolerance band of ±0.25 V. This, in turn, necessitates a reliable power supply regulation which is reasonably facilitated through the great variety of supply regulators which are now available in IC form. For the SN74 series TTL ICs, the fan out is about 10.

A TTL-based system can draw quite large instantaneous loads on a power supply, and this can result in substantial interference 'spikes' in the power lines. Since the spikes can upset the normal operation of the system it is common practice to connect small capacitors directly across the power lines, as close to the TTL ICs as possible. One capacitor, 0.1–10 μF, per five ICs is sufficient in most instances.

TTL circuits are continually being improved and a major recent advance has been the introduction of the low-power 'Schottky' TTL circuits. These use the same generic code numbers as the standard series, but have 'LS' inserted before the type code (e.g. SN74LS00). The operating speed is about twice as high and the power consumption is about 20% of the standard series. Schottky devices are, however, slightly more expensive.

2.3.20.2 CMOS

The problematic features of the power supply associated with the TTL family of logic devices has been largely responsible for the growth of its major competitor, CMOS. CMOS ICs are based on the field effect transistor and can operate off a range of power supply voltages between ±3 V to ±18 V. CMOS devices dissipate very little power, are very cheap and are simple in operation. The fan out is about 50 and they have a far greater immunity to power supply noise. The noise immunity of CMOS devices means that there is no requirement for smoothing capacitors to the extent that they are generally found in TTL circuitry.

There are also some disadvantages associated with CMOS devices, the main one being that CMOS is slower than TTL, roughly about one tenth of the equivalent TTL circuit. CMOS ICs are also very sensitive to electrostatic voltages. Manufacturers do build in some safety features to reduce the electrostatic sensitivity, but CMOS devices must still be handled with due care. Table 2.4 gives a brief comparison between TTL and CMOS devices.

Table 2.4 Comparison between TTL and CMOS devices

Property	*TTL*	*CMOS*
Power supply	5 V ± 0.25 V	3 V to 18 V d.c.
Current required	Milliamps	Microamps
Input impedance	Low	Very high
Switching speed	Fast – 10 ns	Slow – 300 ns
Fan out	10	50

2.3.21 Gate symbols

Having defined a system output in terms of a Boolean expression, the actual circuit can be constructed using the required gates selected from the logic family chosen. Generally, the design will be centred round the more readily available NAND and NOR logic gates. In laying out a gate interconnection diagram, standard symbols are used to represent the individual gates. Unfortunately, no universal set of symbols has emerged, and several systems are in current use. Figure 2.90 summarizes the most common gate symbol systems.

2.3.22 Logic systems using simple gates

A vending machine which dispenses either tea or coffee can serve as an illustrative example. The logic circuit may be realized using AND gates as shown in Figure 2.91.

The money input is common to both gates, and the system, although workable, has a minor fault in that if both buttons are pressed, after the money criterion is satisfied, then the output will be both tea and coffee. This fault can be designed out of the system by extending the logic circuit as shown in Figure 2.92.

The extended system incorporates a NAND gate and an additional AND gate. If both buttons are now pressed then the output from G_3 will be 0. With the output 1 from G_1, the output from G_4 will be 0 and the machine will dispense tea. On

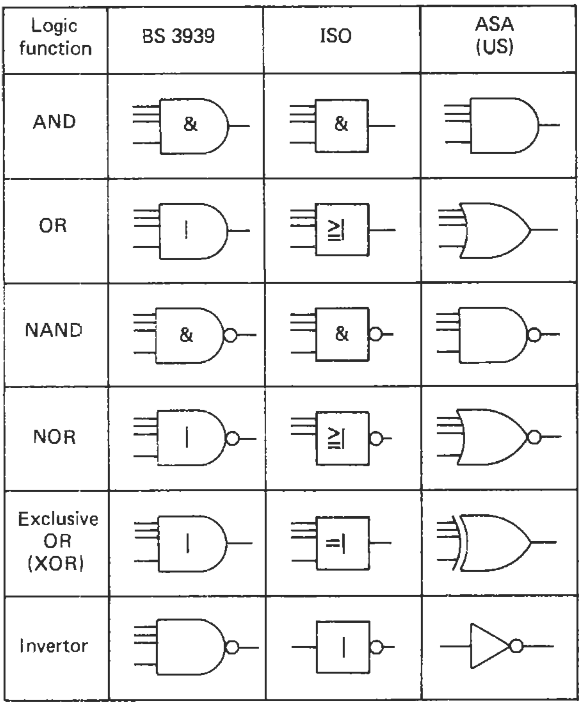

Figure 2.90 Gate symbol systems in current use

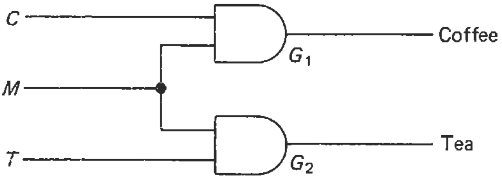

Figure 2.91 Logic circuit for drinks-vending machine

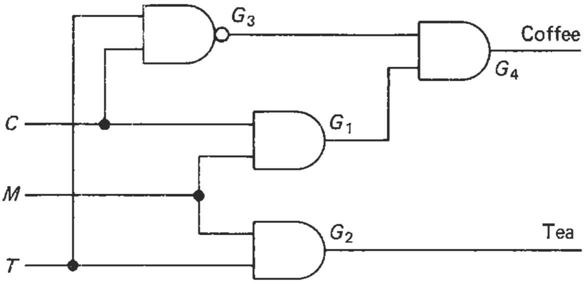

Figure 2.92 Extended logic circuit for drinks-vending machine

pressing either button on its own and satisfying the money input criterion the correct drink will be output. The operation of the extended system is verified in the truth table shown in Figure 2.93.

By inspection of Figure 2.92, the system can be represented in Boolean expressions as

$$\text{Coffee} = (CM) \cdot (\overline{CT}) \tag{2.119}$$

$$\text{Tea} = TM \tag{2.120}$$

Inputs			Outputs	
C	*M*	*T*	Coffee	Tea
0	0	0	0	0
0	0	1	0	0
0	1	0	0	0
0	1	1	0	1
1	0	0	0	0
1	0	1	0	0
1	1	0	1	0
1	1	1	0	1

Figure 2.93 Truth table for drinks-vending machine

where *C*, *T* and *M* represent the coffee button, tea button and money input, respectively, and the overbar represents the inverse complement as usual.

Using De Morgan's theorem the system may alternatively be written as

$$\text{Coffee} = \overline{(\overline{C} + \overline{M}) + \overline{(\overline{C} + \overline{T})}} \tag{2.121}$$

$$\text{Tea} = \overline{\overline{T} + \overline{M}} \tag{2.122}$$

Thus the same logic system can be implemented using one OR and three NOR gates, as shown in Figure 2.94.

The validity and equivalence of equations (2.119)–(2.122) may easily be checked using a truth table. Four logic gates are again required but the circuit operates with inverted input signals. This means that three inverters are also required in the circuit as shown.

It is apparent that the logical function can be realized in several different ways, e.g.

$$\text{Coffee} = \overline{(\overline{C} + \overline{M})} \cdot (\overline{C} + \overline{T}) \text{ and Tea} = TM$$

Using the above realization, the circuit takes the form shown in Figure 2.95.

2.3.23 Logic systems using NAND and NOR gates only

Logic gates are packaged as arrays of the same type in IC form. A typical example is SN7408, which is a 14-pin DIL package containing four separate two-input AND gates. Because the logic gates are marketed in this particular form it is advantageous to design the logic circuit using only one type of gate. This normally minimizes the number of IC packages required. Figure 2.96 shows a two-input NAND gate driving into a single-input NAND gate.

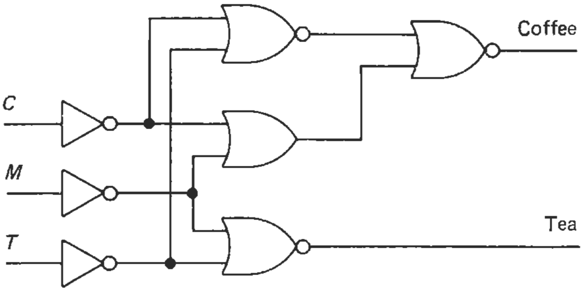

Figure 2.94 Logic circuit for drinks-vending machine using OR and NOR gates

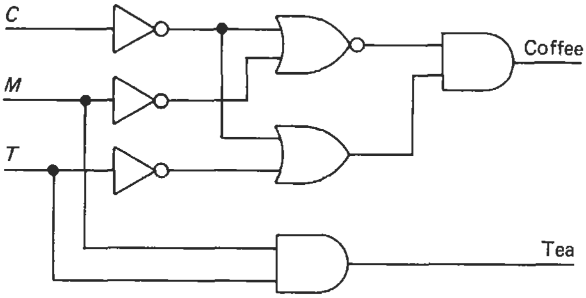

Figure 2.95 Alternative logic circuit for drinks-vending machine

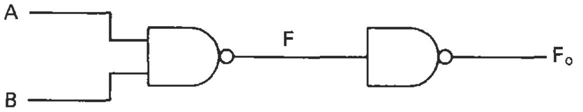


A	B	$A.B$	$\overline{A.B}$	$\overline{\overline{A.B}}$
0	0	0	1	0
0	1	0	1	0
1	0	0	1	0
1	1	1	0	1

Figure 2.96 AND realization using NAND gates

For the two-input NAND gate, the Boolean expression is

$$F = \overline{A\ .\ B}$$

Since F is then fed into a single-input NAND gate, which operates as an inverter, then the final output is

$$F_o = \overline{\overline{F}} = \overline{\overline{A\ .\ B}} = A\ .\ B$$

It is apparent therefore that the circuit given in Figure 2.96, using NAND gates, performs the same function as the logical AND operator.

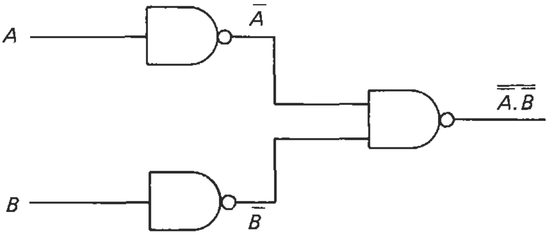
Figure 2.97 shows two single-input NAND gates with their outputs driving into a two-input NAND gate. Following through the truth table it can be seen that the circuit performs the logical OR function. If the output F is then fed to another single-input NAND gate (not shown in the figure) then the function performed will be a logical NOR. It can be seen, therefore, that suitable combinations of NAND gates can be made to perform the logical functions AND, OR and NOR. Similarly, it can be shown that the AND and OR functions can be realized using NOR gates only. This is illustrated in Figure 2.98. The conclusion which can be drawn is that any logic circuit can be realized using NAND gates or NOR gates alone.

Considering again the drinks-vending machine depicted in Figure 2.94, the single OR gate may be replaced with a two-input NOR gate which then feeds directly into a single-input NOR gate. This is shown in Figure 2.99. Note that NOR gates are also used in place of invertors in the input signal lines.

By inspection of the circuit diagram the governing Boolean expressions are

$$\text{Coffee} = \overline{\overline{(\overline{C} + \overline{M})} + \overline{(\overline{C} + \overline{T})}}$$

$$= \overline{(\overline{C} + \overline{M}) + \overline{(\overline{C} + \overline{T})}} \qquad (2.123)$$



A	B	$\overline{A}$	$\overline{B}$	$\overline{A}.\overline{B}$	$\overline{\overline{A}.\overline{B}}$
0	0	1	1	1	0
0	1	1	0	0	1
1	0	0	1	0	1
1	1	0	0	0	1

Figure 2.97 OR realization using NAND gates

$$\text{Tea} = \overline{\overline{T} + \overline{M}} \qquad (2.124)$$

Equations (2.123) and (2.124) are identical to equations (2.121) and (2.122), respectively. This, of course, must be true, since the circuits from which the expressions were deduced perform identical logical functions.

Similarly, the circuit in Figure 2.92, involving one NAND and three AND gates, may be replaced by an equivalent circuit using only NAND gates. This equivalent circuit is shown in Figure 2.100. Inspection of the circuit gives the Boolean expressions

$$\text{Coffee} = \overline{\overline{\overline{(C\ .\ M)}}\ .\ \overline{(C\ .\ T)}}$$

$$= (C\ .\ M)\ .\ \overline{(C\ .\ T)} \qquad (2.125)$$

$$\text{Tea Q} = \overline{\overline{(T\ .\ M)}} = TM \qquad (2.126)$$

Perhaps as expected, the Boolean expressions are identical to equations (2.119) and (2.120), which were deduced from the logic circuit of Figure 2.92.

The realization of Boolean expressions in either all NAND or all NOR gates can be stated in the following simple rules:

1. *NAND realization*
   First, obtain the required Boolean expression in AND/OR form and construct the circuit required. The final output gate must be an OR gate. Replace all gates with NAND gates and, starting with the output gate, number each level of gates back through to the inputs. The logic level at the inputs to all 'odd' level gates must be inverted.
2. *NOR realization*
   Obtain the required Boolean expression in OR/AND form. The final output gate must be an AND gate. Replace all gates with NOR gates and number each level of gates from the output back through to the input. The logic level at all inputs to 'odd' level gates must be inverted.

Application of these rules is best illustrated by e.g.

NAND realization of $F = AB + C(D + E)$

Figure 2.101 shows the realization of the function in AND/OR form. As inputs D and E appear at an odd level of gate input they must be inverted. In terms of the actual circuit this will

mean that inputs D and E are inverted, using NAND gates, prior to entering the NAND gate at level 4.

A similar procedure is adopted for a NOR realization of a Boolean expression. The exclusive-OR function serves as an interesting example. Written as a Boolean expression, the exclusive-OR is

$$F = A\,.\,\overline{B} + \overline{A}\,.\,B \qquad (2.127)$$

For the NOR realization, however, it is necessary that the final output gate is an AND. The exclusive-OR function must therefore be manipulated such that the final logical function in the expression is an AND. Using De Morgan's theorem,

$$F = \overline{(A\,.\,\overline{B})\,.\,(\overline{A}\,.\,B)}$$
$$= \overline{(\overline{A} + B)\,.\,(A + \overline{B})}$$

Multiplying out this expression gives

$$= \overline{\overline{A}\,.\,A + \overline{A}\,.\,\overline{B} + A\,.\,B + B\,.\,\overline{B}}$$

Since $A\,.\,\overline{A} = B\,.\,\overline{B} = 0$, the expression simplifies to

$$= \overline{\overline{A}\,.\,\overline{B} + A\,.\,B}$$
$$= (\overline{\overline{A}\,.\,\overline{B}})\,.\,(\overline{A\,.\,B})$$

Using De Morgan again gives

$$F = (A + B)\,.\,(\overline{A} + \overline{B}) \qquad (2.128)$$

The realization of this equation is shown in Figure 2.102.

2.3.24 Unused inputs

Multi-input gates are also commonly available. In practical circuits, however, it is important that any unused inputs are tied, i.e. they are connected either to the positive voltage supply or to the zero voltage supply. The unused inputs are therefore set at either logic level 1 or at logic level 0, as required. In connecting an unused input to the positive supply the connection should be made through a 1 kΩ resistor. Failure to connect any unused inputs can result in intermittent malfunction of the circuit or in harmful oscillations with attendant overheating.

2.3.25 Latches

It is often useful to 'freeze' a particular binary sequence, and devices called 'latches' are used for this purpose. A latch has four inputs and four outputs. Normally the outputs assume the same state as the inputs. However, when a control signal (known as a 'strobe' input) is taken to logic '1' the outputs are locked in whatever state they were in at the instant of the strobe input going high. This enables the binary sequence to be 'captured' without affecting the ongoing processes, whatever they may be. The latch therefore serves as a temporary

2.3.26 The Karnaugh map

The Karnaugh map provides an alternative representation of a Boolean expression for all possible Boolean input combinations. In some respects the Karnaugh map is like a truth table in that identical logical expressions display an identical pattern on a Karnaugh map. The Karnaugh map, however, also has a great utility in simplifying Boolean expressions in a systematic manner.

The Karnaugh map consists of a set of boxes in which each box represents one possible combination of the Boolean input variables. The boxes are assigned either a '1' or a '0' to indicate the value of the Boolean expression for the particular combination of input variables that the box represents. The number of boxes required is 2^n, where n is the total number of input variables. Although any number of input variables can be represented, a practical limitation is about seven. Figure 2.103 shows the Karnaugh map for a four-input system. Within each box the unique Boolean input combination is represented by assigning each variable the logic values indicated along the horizontal and vertical axes. These values conform to the binary Gray code in which adjacent consecutive characters differ only in one variable. This imparts a property to the Karnaugh map in that the adjacent squares (vertically or horizontally) differ only in one variable.

10	$\overline{A}\,\overline{B}C\overline{D}$	$\overline{A}BC\overline{D}$	$ABC\overline{D}$	$A\overline{B}C\overline{D}$

Figure 2.103 Karnaugh map for a four-input system

As an example, The Boolean expression, $F = \overline{A}\overline{B}CD + A\overline{B}C\overline{D} + \overline{A}B\overline{C}D$ is represented by the Karnaugh map given in Figure 2.104. The maps are drawn up by placing a '1' in each box for which the combination of input variables makes the logical expression have a value of 1. All the other boxes represent the combination of input variables which make the expression have a logical value of 0. Usually the '0' is not entered in the box.

A second example for consideration is

$$F = \overline{A}\overline{B}CD + AC + \overline{C}\overline{D}$$

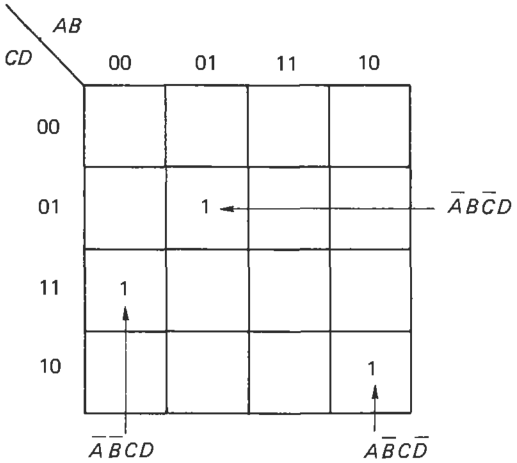

Figure 2.104 Karnaugh map for a Boolean expression (1)

The Karnaugh map for this expression is shown in Figure 2.105. It can be seen that the term AC includes all four squares in which both A and C are included. Similarly, the term $\bar{C}\bar{D}$ also encompasses four squares on the map. It may be concluded that in a four-variable expression any term which contains the four variables will occupy one square on the Karnaugh map. Any term which contains only three of the variables will occupy two squares and any which contains only two of the variables will occupy four squares. A term containing only one of the variables will occupy eight squares in the Karnaugh map. The Karnaugh map may be used in a reverse mode to deduce the Boolean expression.

2.3.27 Minimization of Boolean expressions

The principle of minimization is based on the Boolean identity $A + \bar{A} = 1$. Thus

$$F = ABCD + ABC\bar{D} = ABC(D + \bar{D}) = ABC \qquad (2.129)$$

The grouping of squares along any axis therefore enables the minimization which is typified by equation (2.129). An extension of this principle is shown in Figure 2.106. The Boolean expression depicted in this figure can be written as

$$F = AB\bar{C}\bar{D} + ABC\bar{D} + \bar{A}\bar{B}CD + A\bar{B}CD$$
$$= AB\bar{D}(C + \bar{C}) + \bar{B}CD(\bar{A} + A)$$
$$= AB\bar{D} + \bar{B}CD$$

Minimization in the above example reduces the four terms in the expression to two, each involving three variables. The groupings in the example are akin to the idea of rolling the map into a cylinder about either axis to complete the two groupings as shown.

In extending the minimization principle to five variables the number of squares required is $2^5 = 32$. This is best handled as two sets of 16 squares in a top and bottom arrangement. The 16-square layers represent the first four-input variables and each layer accommodates the two possible input combinations for the fifth variable. Higher numbers of input variables can be dealt with, but the map becomes increasingly more difficult to handle.

In certain situations involving a number of input variables, particular combinations of the variables never actually occur in practice. Under these circumstances the output which would occur with these combination of variables is irrelevant. The output can therefore have any value, since it is a situation that never occurs. Such input combinations are called 'don't care' conditions, and they can be incorporated into a system to allow a simpler circuit realization.

The principle can be illustrated by means of an example:

$$F = \bar{A}B\bar{C}D + AB\bar{C}D + \bar{A}BCD$$

It is stated that the combination $ABCD$ will never occur. Including the don't care condition in the expression gives

$$F = \bar{A}B\bar{C}D + AB\bar{C}D + \bar{A}BCD + \{ABCD\}_x \qquad (2.130)$$

The don't care combination is usually enclosed within parentheses and subscripted with either x or 0.

The Karnaugh representation for the expression is shown in Figure 2.107 and the don't care condition is clearly indicated in the figure. By ignoring the don't care condition, minimization of the expression results in

$$F = B\bar{C}D + \bar{A}BD$$

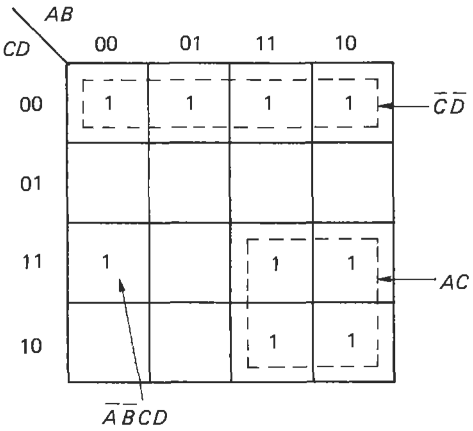

Figure 2.105 Karnaugh map for a Boolean expression (2)

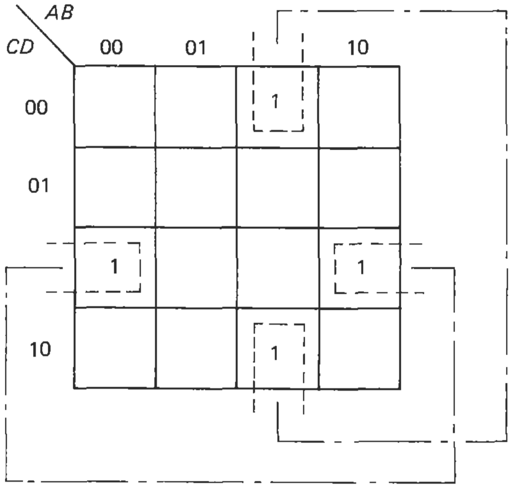

Figure 2.106 Extended minimization principle

CD \ AB	00	01	11	10
00				
01		1	1	
11		1	ϕ	
10				

Figure 2.107 Karnaugh representation for equation (2.130)

If the network output is allowed to be 1 for the don't care condition, the minimization yields

$F = BD$

The example evidently shows that considerable savings in the realization of an expression can be made by including a relevant don't care condition.

It is also worth bearing in mind that although the Karnaugh map can yield a minimum gate solution to a given problem, it might not be an optimum solution. In the real world other considerations may well dictate in terms of parts, design, assembly costs and the number of IC packages required.

2.3.28 Positive and negative logic

In considering the digital logic systems so far, no mention has been made of the significance of the logic levels in terms of the actual voltages applied. Two possibilities exist to differentiate between logic 1 and 0. In a positive logic system, logic level 1 is represented by a more positive voltage level than logic level 0. Both logic voltage levels could actually be negative, but many digital systems operate with a voltage between 0 V and 0.8 V, denoting logic level 0 and a voltage between 2.4 V and 5 V, denoting logical level 1. This standard is used in the TTL and CMOS series of logic devices.

In a negative logic system, logic level 1 is represented by a less positive voltage than logic level 0. This standard applies to data-transmission interfaces where a voltage in the range −3 V to −15 V denotes logic 1 and a voltage in the range +3 V to +15 V logic 0. The large differentiation between 0 and 1 ensures good immunity to electrical noise. These voltages, however, are not compatible with TTL and CMOS devices, and interconversion ICs are required within the data-transmission interface.

As an alternative to using the terms logic 1 and logic 0, 'high' and 'low' are often substituted. In a positive logic system a transition from logic 0 to logic 1 can be termed a transition from low to high.

The logic level definitions also influence the function of the logic device. Figure 2.108 shows two types of two input NOR gates. In Figure 2.108(a) the inputs are negative logic and the output is positive logic. The NOR gate therefore performs the logical AND function. In Figure 2.108(b) the inputs are positive logic while the output is negative logic. This NOR gate therefore performs the logical OR function.

$\bar{F}$
$\bar{F} = \overline{A + B} = A + B$
(b)

Figure 2.108 NOR gates using positive and negative logic input/output systems

2.3.29 Tri-state logic

Tri-state logic does not represent three logic levels but denotes three states which may be logic 1, logic 0, or 'unconnected'. A separate 'enable' input determines whether the output behaves as a normal output or goes into the third (open-circuit) state. Tri-state devices are used in applications where different logic devices are required to be connected into output lines which are common to other logic devices (for example, computer data buses). While one set of logic devices is transmitting signals the other set is temporarily disconnected or disabled.

2.3.30 Sequential logic circuits

The logic circuits considered so far are all examples of combinational logic systems where the output is determined by the combination of input variables present at that time. Sequential logic circuits are those in which the outputs depend upon the sequence of prior inputs. The main difference between sequential and combinational logic systems is that the former circuits must possess some semblance of 'memory'. The basic memory element in sequential logic systems is provided by one of several 'bistable' gates, so called because of the two different but stable outputs which the gates produce.

2.3.30.1 The SR bistable (flip-flop)

The term 'flip-flop' is traditionally used with respect to basic memory elements, and in the SR flip-flop the 'S' denotes Set and 'R' denotes Reset. The SR flip-flop was an early development, commonly constructed using discrete transistors. The internal operation, in which two transistors alternate between the cut-off and saturated states, is of less importance than the external function which the device performs.

Using the systems approach, the SR flip-flop can be represented as shown in Figure 2.109. The system shows the two inputs S and R and the two output lines traditionally denoted as Q and $\overline{Q}$. For sequential circuits the truth table is more usually called a state table. The state table for the SR flip-flop is given in Figure 2.110. Each set of input variable values is considered for both possible states of the output. This is necessary because the output values depend not only on the

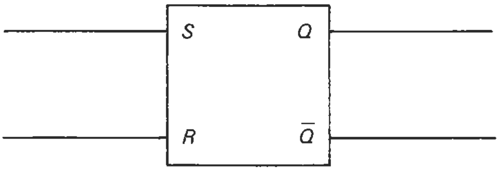

Figure 2.109 The SR flip-flop

1	0	1→1	0→0
1	1	Not available	
1	1		

Figure 2.110 State table for the SR flip-flop

input variable values but also on the current values of the outputs themselves.

The operation of the SR flip-flop may be summarized as follows:

1. With $S = 0$ and $R = 0$, the output is not affected and remains as it was.
2. With $S = 1$ and $R = 0$, the output will change to $Q = 1$ if previously Q was 0. Q will remain at 1 if previously Q was 1.
3. With $S = 0$ and $R = 1$, the output will change to $Q = 0$ if previously Q was 1. Q will remain at 0 if previously Q was 0.
4. In all cases considered, the output $\bar{Q}$ will be the inverse complement of Q.

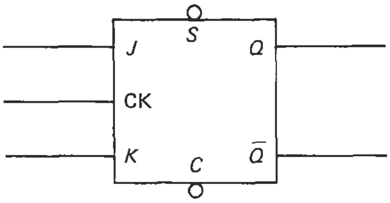
The SR flip-flop may be constructed using cross-coupled NOR or NAND gates, as shown in Figure 2.111.

2.3.30.2 The T (Trigger) flip-flop

The T flip-flop is another bistable circuit having two outputs, Q and $\bar{Q}$, but only one input, T. The T flip-flop changes state on every T input signal and then remains in that state while the T input remains low.

2.3.30.3 The JK flip-flop

The JK flip-flop uses integrated-circuit technology and, since it can perform both the SR and T flip-flop functions, it has become the most common flip-flop in current use. Figure 2.112 gives the state table and logic symbol for the JK flip-flop. The state table is identical to the SR flip-flop with the exception that the input condition $J = 1$, $K = 1$ is allowed. For these latter inputs the JK flip-flop functions as a T flip-flop using an input clock signal, in the form of a pulse train, as the trigger.



Inputs		Outputs
J	K	$Q_n - Q_{n+1}$
0	0	0→0
0	0	1→1
0	1	0→0
0	1	1→0
1	0	0→1
1	0	1→1
1	1	0→1
1	1	1→0

Figure 2.112 JK flip-flop and corresponding state table

The JK flip-flop operates in a clocked or synchronous mode. In synchronous mode, the J and K inputs do not in themselves initiate a change in the logic outputs but are used to control inputs to determine the change of state which is to occur. A pulsed input to the clock terminal (CK) then determines the timing of the state changes. The clocked mode allows for precise timing of the state changes in a sequential circuit.

JK flip-flops may also be provided with additional Set, S, and Clear, C, inputs which can be used to set output Q to 1, or clear output Q to 0 at any time. Muliple J and K inputs are also commonly available to enable logical ANDing of multiple-input signals.

A slightly more complicated flip-flop arrangement is the JK master–slave flip-flop. This consists of a pair of SR flip-flops connected together by various logic gates as shown in Figure 2.113. The JK master–slave flip-flop differs from the simpler arrangement in that if the clock pulse is at logic 1, a logic 1 applied to either J or K will not set the outputs. The new data, however, are accepted by the 'master'. When the clock pulse returns to 0, the master is isolated from the inputs but its data are transferred to the slave, with the result that Q and $\bar{Q}$ can then change state. In a circuit involving many such flip-flops,

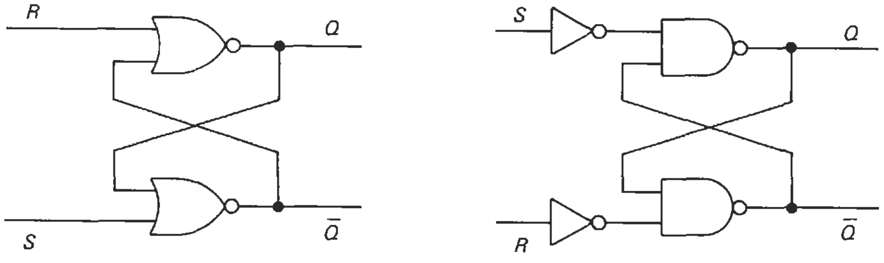


Figure 2.111 SR flip-flops using cross-coupled gates

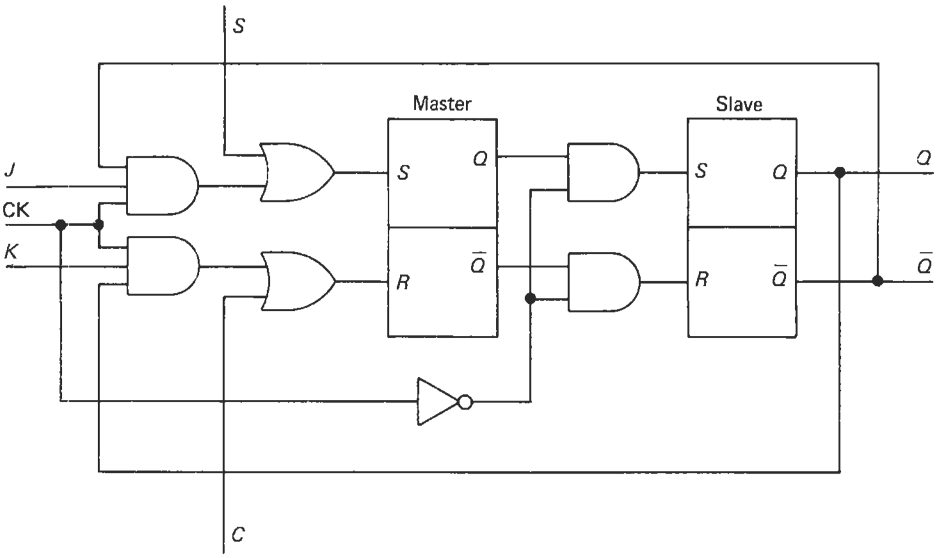

Figure 2.113 The JK master–slave flip-flop

the advantage of the master–slave arrangement is that it can allow for synchronization of all the output state changes.

2.3.31 Registers and counters

In the previous section it was shown that a logic level of 1 on a particular input line to a flip-flop can set an output line to 1. In this way the flip-flop can perform an elementary memory function. For a binary signal of length n bits, n flip-flops are required to construct a memory device for the n-bit input signal. A group of flip-flops used together in this manner constitutes a 'register'.

Data may be entered into the register in a serial or a parallel manner. In the parallel method the n-bit binary 'word' is available on n input lines. Each line is connected to its own flip-flop and the n data bits are entered simultaneously into the register. In the serial entry method the data are available on only one input line in a time sequence. They are entered consecutively and are timed into the register by a system clock. Serial entry registers are also called 'shift' registers, since the data bits are entered into the first flip-flop and moved consecutively along into the next flip-flop as the next data bit arrives at the first flip-flop, and so on. The serial method of data entry requires as many shift and store operations as the number of bits in the binary word. This means that the serial entry method is much slower than the parallel method. Serial entry, however, is also much less expensive than parallel entry.

Yet another type of register is the counting register. This consists of a number of flip-flops arranged to store a binary word which is representative of the number of input pulses applied at the input terminal. Using n flip-flops, a total count of 2^n can be made.

Counting registers (or 'counters') may be synchronous in which the state changes in all the flip-flops occur simultaneously, or asynchronous in which the state changes in various flip-flops do not occur at the same time. Figure 2.114 illustrates an asynchronous, 3-bit binary counter composed of JK flip-flops.

All J and K inputs are held at logic level 1 and the input signal consists of a pulse train fed to the clock input of the first flip-flop. In this mode the JK flip-flop is operating as a T flip-flop. The output Q from the first flip-flop provides an input for the clock of the second flip-flop, and so on through the network. The outputs Q also form the binary representation of the counter, where A is the least significant bit, increasing through to C, which represents the most significant bit. The state table and timing diagram for the counter are shown in Figure 2.115.

The state table shows that each flip-flop changes state when the next less significant flip-flop output changes from 1 to 0. The output signal from each flip-flop, moving through the network, is at half the frequency of that of the previous flip-flop. These output signals thus provide the correct binary count of the number of input pulses applied to the input. The 3-bit binary counter can count up to a maximum of 8 decimal. If a ninth pulse is applied at the input, the count reverts back to the initial zero setting and the count continues again as normal for further input pulses.

Asynchronous counters are also referred to as 'ripple' counters because of the way that the changes of state ripple through the network of flip-flops.

A synchronous version of the counter can also be realized using a network of JK flip-flops. The synchronous counter additionally uses the outputs Q and $\bar{Q}$ of each flip-flop, in logic gate networks, to produce the necessary control signals for the J and K inputs. This ensures that all flip-flops change state correctly to the desired state table for each clock pulse. The synchronous counter alleviates the problems associated with transient operation inherent in the asynchronous counter.

There are, of course, many other types of flip-flop available, but the only one of significant practical importance is the D flip-flop (see Figure 2.116), where the 'D' refers to Data.

In the D-type flip-flop the D input is fed directly into the J input line and the inverse complement of D is fed to the K input line. This ensures that J and K are always the inverse complement of one another. A logic 0 or 1 on the data input will then flip (or flop) the outputs when the clock pulse is at logic 0.

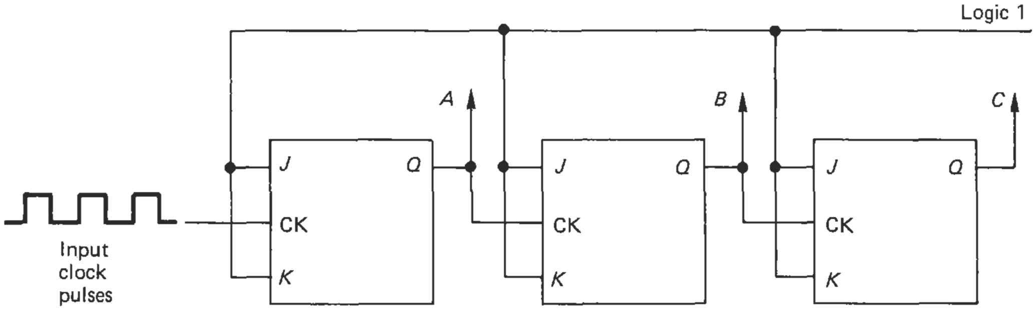

Figure 2.114 Asynchronous, 3-bit binary counter

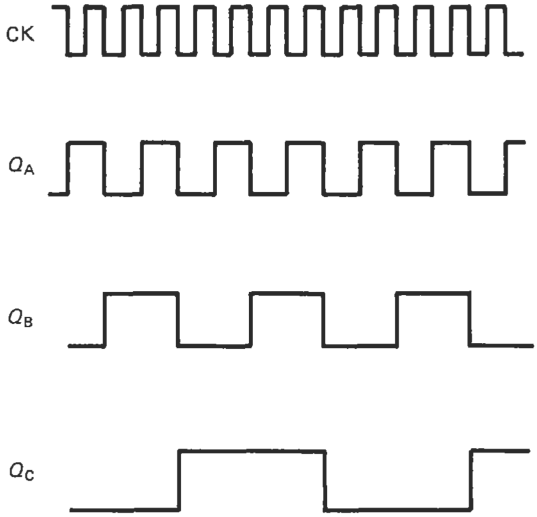

Clock pulses	Flip-flop		
	C	*B*	*A*
0	0	0	0
1	0	0	1
2	0	1	0
3	0	1	1
4	1	0	0
5	1	0	1
6	1	1	0
7	1	1	1
0	0	0	0

2.3.32 Timers and pulse circuits

An essential feature of the flip-flop circuits described in the previous two sections was the provision of a pulsed clock signal. Although timers can be designed using discrete components, it is normal to design round the commonly available timers which are already available in IC form. The most prevalent timer currently in use is the NE555, which is manufactured as an 8-pin DIL package. The CMOS equivalent to the TTL-based NE555 is the ICM7555. These packages are essentially identical, and ICM7555 can be used to replace NE555, although the converse is not always applicable. The so-called '555' timer is very versatile and can be used in either 'monostable' or 'astable' mode.

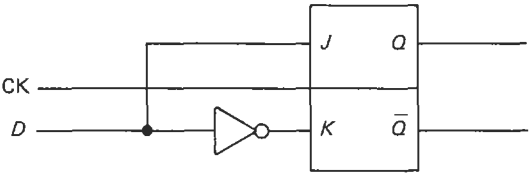

Figure 2.116 D-type flip-flop

2.3.32.1 Monostable

Figure 2.117 shows the 555 wired up for monostable operation. When the 'trigger' is taken from +5 V to 0 V (i.e. high to low) the output will go high for a period determined by the values selected for *R* and *C*. The length of the output pulse is given by $1.1RC$.

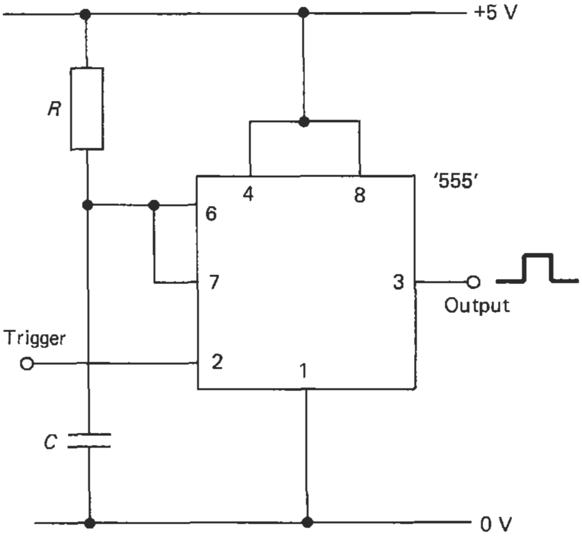

Figure 2.117 555 timer in monstable operation

The timer can deliver currents of more than 100 mA, and it can therefore be used to drive a DIL reed relay directly. When such a relay is switched off, however, the back e.m.f. generated by the relay coil could damage the timer. As a precaution, a diode is normally connected in parallel with the relay coil, in the opposite direction to the current flow, to absorb the high induced voltage.

2.3.32.2 *Astable*

Figure 2.118 depicts the 555 wired up for astable operation. The 100 nF capacitor is only required for TTL-based timers. In astable operation the output is a continuous pulse train. The ON and OFF times can be controlled independently within certain limitations with

$$\text{ON time} = 0.693(R_1 + R_2)C \qquad (2.131)$$

$$\text{OFF time} = 0.693(R_2)C \qquad (2.132)$$

Obviously, the ON time can only be equal to or greater than the OFF time. The output signal, however, can always be inverted if, in a particular application, short-duration positive pulses are required.

The maximum operating frequency for the 555 timer is about 500 kHz and the minimum frequency, limited by the leakage of the capacitor, is about one cycle per several hours.

Alternative pulsed output circuits can be constructed using TTL or CMOS gates (see Kaufman and Seidman[8] and Watson[9]).

2.3.33 Digital computers and microprocessors

No coverage of digital electronics, however brief, can fail to give some cognizance to the impact of the digital computer and its associated microprocessor. The modern digital computer, although a complex digital system, consists of no more than the basic logical sub-systems previously discussed. This includes AND, OR, NAND and NOR gates, registers, counters and communication interfaces. Space limitations do not allow a detailed description of computer systems and microprocessors in this chapter. However, Chapter 3 of this book contains specific details related to microprocessor technology, number systems and interfacing techniques for digital computers.

The main advantages of the microprocessor-based system are that the logical functions for a particular application can be developed and implemented in software, as opposed to electronic hardware. In many instances the microprocessor-based system may actually be the cheaper alternative to a hardwired logic gate circuit. The software is easy to alter in the event of incorrect system operation and the complete system can be tested as a simulation before being committed.

For relatively small logical switching applications (up to, say, 32 inputs) the single-card (or single-chip) microcomputer represents an ideal low-cost solution (see Milne and Fraser[10]). These micro-systems can be used as dedicated devices where all the system components reside on a single card or a single chip, respectively. The major applications for these devices are in the high-volume production markets such as automotive electronics, washing machines, bus ticket dispensers and time-attendance recorders.

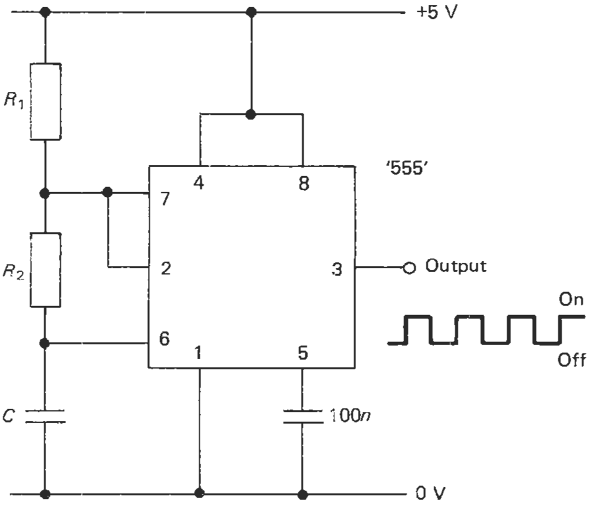

Figure 2.118 555 timer in astable operation

2.3.34 Application-specific integrated circuits (ASICs)

Application-specific integrated circuits are programmable logic devices (PLDs) which have their internal logic configuration determined by the user, as opposed to the manufacturer. The systems design engineer therefore customizes the actual silicon building blocks to meet the requirements of the system. Such customization provides for performance, reliability, compactness, low cost and design security. PLDs are available in both TTL and CMOS technology. The latter are erasable and can be reprogrammed almost indefinitely. PLDs represent the fastest-growing segment of the semiconductor industry in recent times, and it can be expected that they will play an increasingly important role in the design of digital logic systems in the future.

Internally, PLDs consist of an array of AND gates connected to an array of OR gates, with input and output blocks containing registers, latches and feedback options. Figure 2.119 shows the general architecture of a programmable logic device.

In customizing the PLD the user essentially determines which of the interconnections between the gate arrays will remain open and which will be closed. The customization procedure, however, requires additional development 'tools' which consists of:

1. A word processor to generate the source code;
2. Development software to transform the high-level language source code into a fuse pattern for the PLD. The code which is generated is referred to as a 'JEDEC' file;
3. A PLD programmer to implement the program within the device.

The PLD programmer, connected to the parallel printer port of an IBM-PC or a true compatible programs the PLD by 'burning' the fuse pattern in the memory array of the device. When returned to its normal operating mode, the PLD then performs the customized logic function. Horowitz and Hill[11] provide a reasonably detailed coverage on applications of programmable logic devices.

2.4 Electrical safety

The definitive document on electrical safety in the UK is The Electricity at Work Regulations 1989, which came into force on 1 April 1990. The full text of the regulations is set out in

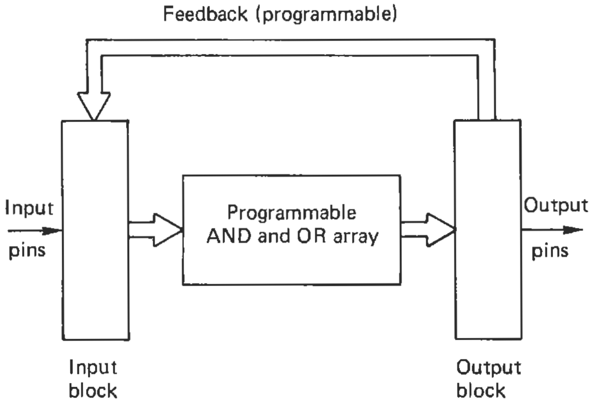

Figure 2.119 General architecture of a PLD

Statutory Instrument 1989, No. 635, available from HMSO. The notes included here are based on the Health & Safety series booklet HS(R)25, which forms part of the Electricity at Work Regulations.[12] The regulations are made under the Health and Safety at Work Act 1974, and the Act imposes the responsibility for people at work on both the employer and the employee. It is partly the individual's responsibility therefore to ensure that safe working practices are observed in the workplace.

2.4.1 Electric shock

Most serious injuries and deaths from electric shock occur from contact with the mains electricity supply. In the UK, the mains supply is about 240 V a.c. and in the USA it is about 110 V a.c. The live wire (colour coded brown) is at a higher potential with respect to the earth. If a person is in contact with the ground, an electric shock can be sustained by touching the live wire only. When a shock is received the passage of the electric current through the body may cause muscular contractions, respiratory failure, fibrillation of the heart, cardiac arrest or injury from internal burns. Any one of these can be fatal. The greatest danger occurs when the current flows across the chest. This can happen either when the current flows from one arm to the other or when it flows from one arm to the opposite leg.

The magnitude of an electric shock depends on the strength of the current, which in turn depends on the voltage and the ohmic resistance of the body. The resistance of the human body varies in different persons and is primarily dependent on the resistance of the skin. This variability in skin resistance means that a 'safe' voltage cannot be readily specified, and all voltages in excess of about 50 V must therefore be regarded as being ppotentially lethal. If the skin is damp, either from water or from perspiration, then the skin resistance is considerably reduced. Under such circumstances the chances of an electric shock proving to be fatal are greatly increased.

Injury can also be caused by a minor shock, not serious in itself but which has the effect of contracting the muscles sufficiently to result in a fall.

2.4.2 Electric burn

Burns can be caused either by the passage of heavy current through the body or by direct contact with an electrically heated surface. They may also be caused by the arcing across a short circuit or as a result of an electrically originated fire or explosion.

Any circuit brought near an induction heater will receive energy and heat will be generated extremely rapidly. No rings or other metal objects should therefore be worn when in the vicinity of an induction heater, neither should any metal be held in the hands. In general, no part of the body should come within close proximity (about a metre) to an induction heater.

2.4.3 Rescue

To render assistance to a person undergoing an electric shock the rescuer should first attempt to isolate the circuit by switching off the supply. If the rescuer cannot isolate the supply, he or she should try to break the victim's contact with the live apparatus by using insulating material. This material is essential to prevent the rescuer from becoming a second victim.

If the victim is unconscious the rescuer should send for medical assistance and start artificial resuscitation. This assumes, of course, that the rescuer is trained in modern methods of such resuscitation.

2.4.4 Protection

2.4.4.1 Insulation

Electrical cables consist of one or more metal cores which may be single wires but are more usually stranded wire and surrounded by insulation. The insulation serves to contain the flow of current and prevent a person from touching the live metal and thereby receiving a shock.

2.4.4.2 Fuses

A fuse is a device which will melt when the current exceeds a predetermined value. In operation, fuses serve as current-limiting devices, and they are used for overload protection of electrical equipment. Two types of fuses are generally available: rewirable and cartridge.

Fuses are specified by the maximum current that they can transmit and the correctly rated fuse must be used at all times. A high-rating fuse must never be substituted for a low-rating one.

2.4.4.3 Circuit breakers

A circuit breaker is a mechanical device in the form of a switch which opens automatically if the circuit which it controls becomes overloaded. Circuit breakers may be operated magnetically or thermally and they can also be manually reset and adjusted. Plug-in circuit breakers are available and are recommended for use with small electric power tools.

2.4.4.4 Earth-leakage protection

Normally there is no net flow of electricity to an electrical device. The flow in from the live wire is exactly balanced by the return flow in the neutral cable. If an earth fault develops, however, a leakage current will result, and this can be detected by the earth-leakage apparatus. Modern earth-leakage devices are so sensitive that the supply is immediately disconnected before a lethal current can be drawn from the mains. It should be noted that earth leakage protection will operate only when the fault occurs between line and ground.

2.4.4.5 Isolation

Effective means of disconnecting cables or apparatus from the source of supply must be provided so that maintenance, repair or alteration may be carried out safely. This is achieved by isolating switches which have no automatic features. Various circuits and motors should not 'share' an isolation switch unless it is clear that under no circumstances will it be necessary, or convenient, to use one circuit while the other is being serviced.

Isolation switches should be capable of being locked in the 'off' position but not in the 'on' one. If the isolation switch cannot be locked it should be possible to remove the fuse on the power line so that the line cannot be energized by inadvertant closing of the isolation switch.

2.4.5 Earthing

The external metal casing of electrical apparatus and cables must be earthed for three reasons:

1. To prevent the casing rising to a dangerous voltage if there is a fault such as a short circuit between the conductor and the casing;
2. To conduct any current away by a safe path;
3. To ensure that the faulty circuit is automatically disconnected from the supply by drawing sufficient current to blow the protective fuse or operate the circuit breaker.

Earthing consists of connecting the metal casing by means of a conductor to an earth electrode. The earth electrode may be a buried pipe or other such conductor which is known to be making an effective connection to the 'general mass of the earth'. Where the earth connection to a casing is made with a nut and bolt a spring washer or other similar locking device must be used. Earthing is a legal requirement and must be effective at all times.

2.4.6 Double insulation

Although the electricity regulations require all portable apparatus used at normal mains voltage to have an earthing conductor, these can introduce their own hazards. As a result 'double-insulated' or 'all-insulated' apparatus is made which does not require earthing. Double insulation means what its name says, and all live conductors are separated from the outside world by two separate and distinctive layers of insulation. Each layer of insulation would adequately insulate the conductor on its own, but together they virtually negate the probability of danger arising from insulation failure. Double insulation avoids the requirement for any external metalwork of the equipment to be protected by an earth conductor.

2.4.7 Low-voltage supplies

Portable tools (particularly hand inspection lamps) can be a source of danger because they are subject to severe wear and tear and are likely to be used in confined spaces where the skin resistance could easily be reduced by damp conditions. In cases where work is carried out within confined metal enclosures, mains voltage equipment must not be used. A double-wound transformer with a secondary centre tap to earth is allowable in these cases. This transformer gives 50 V for lighting and 100 V for portable tools.

These few notes on general electricity safety are by no means extensive or authoritative. Reference should always be made to the full guide to the reguations.[12] Further recommended reading on electrical safety guidelines can be obtained from references 13 and 14.

3.1 Summary of number systems

In the manipulation of data within a computer a two-state numbering system is used. This is termed the binary system, and it is based on a simple ON/OFF principle. For the semiconductor integrated circuits which make up the computer system, 5 V denotes ON (or logic level '1') while 0 V denotes OFF (or logic level '0'). In practice, a tolerance band is adopted, with 2.4–5 V representing logic '1' and 0–0.8 V logic '0'.

The microelectronic devices in the system handle the transfer of information in 1's and 0's which are referred to as 'BITs', being a short form for BInary digiT. A group of eight bits is termed a 'byte' and a number of computer systems are based on 8-bit technology with the handling of data codes as 8-bit 'words'. Sixteen- and 32-bit machines are also available.

The computer operates with three numbering systems, which are decimal, binary and hexadecimal (often simply called 'hex'). Numerical data would normally be entered by a human operator in decimal form since this is the most familiar number system. The computer, however, must ultimately convert the decimal number into a binary code, since this is the eventual form in which the number will be processed and stored. The hexadecimal system is an in-between state and represents a particularly compact method of handling binary numbers as groups of four bits.

In binary representation the only possible logic levels are 0 and 1. The base is chosen as 2 and integer numbers can be represented using 8-bit codes as shown below:

bit number	7	6	5	4	3	2	1	0
	2^7	2^6	2^5	2^4	2^3	2^2	2^1	2^0
	128	64	32	16	8	4	2	1
	Most significant bit (MSB)							Least significant bit (LSB)

The conversion from binary to decimal is illustrated as follows:

binary number 1 0 1 1 1 0 0 1
giving 128 + 0 + 32 + 16 + 8 + 0 + 0 + 1
= 185 decimal

Conversion from decimal to binary is the reverse process to the above.

It is apparent that the highest number which can be accommodated in 8-bit binary notation is 1111 1111, which is equivalent to 255 decimal. Generally, therefore, computer systems handle integer numbers in four consecutive bytes, i.e. as 32-bits. The most significant bit is used to denote the sign of the number and the resulting range of integer numbers is

$-2^{31} - 1$ to 2^{31}, or −2, 147, 483, 648 to 2, 147, 483, 647

Real numbers are handled in five bytes with the most significant byte representing an exponent and a sign bit and the other four bytes the mantissa and a sign bit. The resultant range of real numbers is 2^{-128} to 2^{127}, with either a positive or a negative sign for the mantissa.

The handling of numbers in binary notation is extremely cumbersome for a human and a shorthand notation is adopted for convenience. This is the hex system in which the binary number is arranged into groups of four bits. Four bits, which is half of a byte, is called a 'nibble'. A byte therefore consists of an upper and a lower nibble.

Since there are only ten unique symbols in the decimal numbering system, the first six letters of the alphabet are used to denote the additional six symbols in the hexadecimal system, i.e.

Decimal	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
Hexadecimal	0	1	2	3	4	5	6	7	8	9	A	B	C	D	E	F

Using hex notation then, 8-bit binary numbers may be replaced by two hex symbols, e.g.

167 decimal = 1010 0111 binary = A7 hex

Higher numbers are similarly handled:

6836 decimal = 0001 1010 1011 0100 binary = 1AB4 hex

3.1.1 ASCII code

In the interchange of information between the constituent parts of a computer or a peripheral device a binary code is used to represent the alphanumeric characters. The most commonly used code for digital communication links is the American Standard Code for Information Interchange (ASCII, pronounced Askey). ASCII is a 7-bit code which can accommodate 128 definable characters.

When communication takes place in a serial fashion the ASCII code is extended to 8-bits, usually by inserting a zero in the most significant bit. Additionally, one or two start bits, a parity bit and a stop bit are also included. The start bit(s) inform the receiving device that a character code follows. The parity bit provides a check that no bits have been corrupted during transmission, by ensuring that the sum of all the 1's in the ASCII group give either an even number for 'even parity' or an odd number for 'odd parity'. The stop bit, set to logic '1', terminates the transmission of the character.

The transmission rate in bits/second is termed 'baud'. Since there are 11 bits associated with the transmission of one character, a speed of 2400 baud corresponds to 2400/11 = 218 characters per second.

3.1.2 Gray code

The Gray code is but one of many binary codes in which only one of the digits change between successive consecutive numbers. The main application is in the sensing of rotational and translational position in mechanical systems (see Section 3.5.2.7).

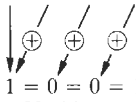
In converting from Gray to binary code the most significant bit of the binary number, B, is equal to the most significant bit of the Gray code, G. For all other bits, the relationship between binary and Gray is given by

$$B(n) = G(n) \oplus B(n+1) \qquad (3.1)$$

where n denotes the bit reference number and $\oplus$ is an exclusive-OR logic comparison.

The conversion of 1101 Gray to binary is shown below:

bit number 3 2 1 0
Gray code 1 1 0 1



binary number 1 = 0 = 0 = 1
i.e. 1101 Gray = 1001 binary

In practical position-sensing applications the conversion process can be programmed in the software or implemented in a hardwired logic circuit using logic gates.

3.2 Microprocessors

3.2.1 System architecture

Since the mid-1970s there are currently a number of different microprocessor designs available in several versions. The 'popular' designs are produced by a few manufacturers, and these include such companies as Intel, Motorola, Rockwell, Texas Instruments and Zilog.

Microprocessor-based systems require additional family support chips and, in true digital form, all microelectronic components which constitute a microcomputer are designated numerically rather than by name. Some of the more popular microprocessors available are as follows:

1. *8-bit*: Binary data handled in a word, 8-bits wide, defining the accuracy of the number handling representation, e.g.
   Intel 8080 and 8085
   Motorola 6800 series
   Rockwell 6502 series
   Zilog Z80
2. *16-bit*: Binary data handled in a word of 16-bits width, e.g.
   Intel 8086
   Motorola 68000
   Zilog Z8000

The 8086 is one of the most powerful and versatile 16-bit microprocessors available, and it has been widely adopted by industry. Further enhancements include the 32-bit versions – 80286, 80386 and 80486 – which provide increased processing power.

Although it is unnecessary for the user of the technology to understand in detail how each individual chip actually functions, it becomes essential to have at least a working knowledge of the logical organization of the system hardware and how each component relates to each other. The composition of this hardware structure is known as the system architecture.

A digital computer system comprises three main constituent parts: the *microprocessor*, the *memory* and the *input/output*. Digital signals which have a common function are transmitted between the main components by a group of wires or conduction tracks, termed a bus. In a microcomputer there are three buses, i.e. the data bus, the address bus and the control bus. The interconnection between the basic hardware components in a microcomputer is illustrated in Figure 3.1.

The microprocessor is a very large-scale integrated circuit (VLSI), which is the brain of the microcomputer system and acts as the central processing unit (CPU). Integrated circuits are generally classified according to the number of components on the silicon chip, and VLSI has tens of thousands. The Intel 8086 microprocessor, introduced in 1979, has 29 000 transistors packed on the 225 mm^2 chip.

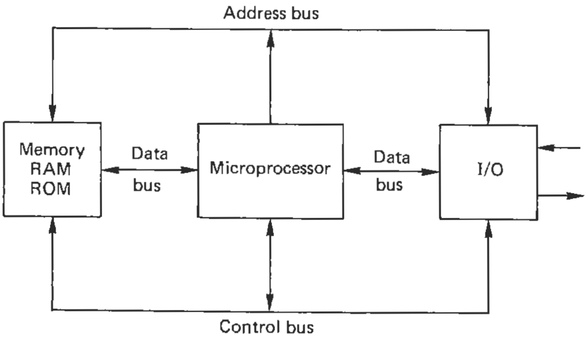


Figure 3.1 Basic components in a microcomputer

The main feature of the microprocessor is the arithmetic and logic unit (ALU). The ALU allows the arithmetical manipulation of data, addition and subtraction with 8-bit systems and multiplication with 16-bit systems. Logical operations (AND, OR, etc.) can also be performed. In addition to the ALU, the CPU contains a number of temporary data storage registers to fetch, decode and execute instructions, and to time and control circuits to manage the internal and external operation of the complete microprocessor system.

The processing power of the CPU is influenced by such factors as word length, instruction set, addressing modes, number of available registers and information transfer rates. For word processors or the manipulation of large quantities of data as in CAD packages, 16- or 32-bit microprocessors are essential. In the field of measurement and control, 8-bit systems are usually adequate.

The system clock, accurately controlled by a quartz crystal maintaining a constant frequency, acts as the heartbeat for the system and provides all the timing reference points.

All the basic components (CPU, memory and I/O) and their interconnections may reside in a complete microcomputer system encompassing the traditional keyboard, monitor, etc. Alternatively, they may reside on a single card, or even on a single chip to give a single-chip microcomputer.

3.2.2 Bus structure

As outlined in Section 3.2.1, the connection between the system components is made by an arrangement of three buses:

1. *The data bus* transmits the words in binary form representing the program instructions for the CPU to execute. It can also carry the information transmitted between the CPU and memory or I/O devices. Although the popular PCs use a 16-bit data bus, 8-bit data transfer operations remain the norm in data acquisition and control applications.
2. *The address bus* transmits the memory address related to the data bus information. In 8-bit systems this bus commonly has 16 lines to give 64K of addresses. PCs usually have an effective 20 lines to give 1M byte of available addresses, although software limitations often restrict this to 640K.
3. *The control bus* transmits the collection of timing and control signals which supervise the overall control of the system operation.

The physical format of a bussing system is basically a circuit board with a number of connectors. Different types of microprocessors require different hardware interfaces, and to alleviate the problems, standard bus structures have been developed in order to facilitate the connection of hardware components. In industrial-type systems, cards for various microcomputer functions such as processor, memory, digital and analogue I/O, power switching, etc. slot into a standard backplane or motherboard rack. This offers the advantage of being able to plug any specific card, designed to the bus standard, into a free slot in the rack to build up the system as required.

The physical form of the bus is represented by its mechanical and electrical characteristics. Such information as card dimensions, input and output pin-out connections, signal levels, loading capability and type of output gates must be known.

Standard buses are compatible with cards from different manufacturers, and the most popular bus structures include Multibus, S-100 Bus, STD Bus and the STE Bus.

3.2.3 Memory devices

Memory devices consist of those used to store binary data, which represents the user program instructions, and those which are necessary for the user to operate the system. Memory takes the form of one or more integrated circuits. These basically hold locations capable of storing a binary word. Each location is assigned a unique address within the system and data can be selected through the address bus. As a binary code is deposited by the CPU on the address bus, defining a specific location in memory, the contents of that location are selected and placed on the data bus. The appropriate piece of memory hardware and specific location is selected by means of an address-decoding circuit built up from logic gates within the microcomputer system. The end result is a highly flexible data manipulation arrangement.

In an 8-bit microcomputer (i.e. 8-bit data bus) the address bus is 16-bits wide. This enables $2^{16} = 65\,536$ locations to be addressed, and the total memory capacity of the machine is said to be 64K. The memory is further sub-divided into pages with the high-order byte of the address denoting the page number and the low-order byte indicating one of the 256 locations available on each page.

In machines with 8086/8088 microprocessors an additional four bits are effectively made available on the address bus. This theoretically constitutes one megabyte of addressable memory. Microcomputers such as the IBM-PS2, employing the 80286 and 80386 microprocessors, have an address bus which is 24-bits wide and can address up to 16M bytes of physical memory. This releases new levels of processing power to accelerate the processing speed in measurement and control applications.

The types of memory chips built into the system basically divide into two categories:

1. *Random Access Memory (RAM)*, where data can be read from or written to any specified location. RAM is more correctly defined as read/write memory and data retention is dependent upon power being applied to the device. This type of memory is normally employed for the temporary storage of the computer programs, at the editing or execution stage, or the storage of data from measuring transducers prior to permanent storage as a disc file. In a number of systems available, the RAM is made non-volatile by providing battery back-up.
2. *Read Only Memory (ROM)*, where data are held in a secure manner and can be read in any specified sequence. Once the chip is configured it cannot be overwritten, and the programs which specify the system operation (termed the monitor program) are 'burnt' into ROM when they are known to operate in a satisfactory manner. Basic ROM is inflexible since the software contained therein is developed by the system manufacturer. It is often useful, however, to have all programs which are to be permanently stored in the microcomputer in a non-volatile form, held in an Erasable and Programmable Read Only Memory (EPROM). This is undoubtedly the most popular type of ROM used because the write process is reversible. These chips are available in popular memory capacities of 2K, 4K, 8K, 16K and 32K, and they are respectively designated as 2716, 2732, 2764, 27128 and 27256. The numbers following the '27' indicate the number of kilobits of memory available within the device.

EPROMs are supplied in an uncommitted form with each location holding FF hex. They are configured using an EPROM programmer which 'burns' or 'blows' the required data, in machine code form, onto the chip. If an error in the data exists, or an alteration is to be made, then the complete EPROM can be returned to its uncommitted state by exposing the small 'window' in the device to intense ultraviolet light for about 20–30 min. EPROM erasers are available for this purpose. Once programmed as required, it is usual to cover the window with opaque material. If uncovered, it would normally take some months before program corruption was experienced through the effects of natural sunlight.

A similar type of memory device is an Electrically Erasable Read Only Memory (EEPROM or E^2PROM). This is essentially similar to the EPROM but enables the user to alter any particular byte of data rather than wiping the entire chip. E^2PROM is not so popular as the EPROM for economic reasons.

3.2.4 Input/output (I/O) structure

With the microprocessor acting as the brain of the microcomputer system and the memory chips storing the system-operating software and application programs, the other essential hardware required is that associated with the input and output of data in essentially binary form. Interface support chips associated with the various microprocessor families are available to enable communication with such hardware essentials as keyboards, display monitors, disc drives and printers.

The same I/O interface circuits are used in measurement and control applications and the main functions required of the devices are:

1. Digital I/O logic lines which can be read or set by the microprocessor;
2. Data direction register to configure lines as either input or output;
3. Handshake lines to supervise data transfer via the I/O lines;
4. Timing and counting facilities.

The software used for controlling the communication between the microcomputer and other external devices is dependent upon the I/O interfacing technique employed. The two most common methods are either 'memory mapped' or 'dedicated port addressed'.

3.2.4.1 Memory mapped I/O

In this method the I/O chip is connected into the system in the same way as the memory illustrated in Figure 3.1. The I/O lines are contained in groups of 8-bits termed a 'port' and this byte is addressed in the same manner as any other location in memory. The port is accessed using memory transfer instructions like PEEK and POKE in high-level BASIC, or LDA and STA in low-level 6502 assembly language.

Since the interface is connected into the bus structure in exactly the same way as the RAM and ROM, no additional decoding hardware is required. Memory addresses are, however, used up for I/O, and as a result, communication is slower than the port addressed alternative.

3.2.4.2 Dedicated port addressed I/O

This method involves a second dedicated I/O data bus as shown in Figure 3.2. When data are to be input or output the necessary control signals are sent from the CPU to the I/O interface chip and the port data are transmitted via the dedicated I/O data bus. This does not effect the addressing of memory within the system and results in faster data transfer than with the memory mapped technique. The ports (or channels) are assigned unique addresses (numbers) on the dedicated bus and are accessed using the additional software

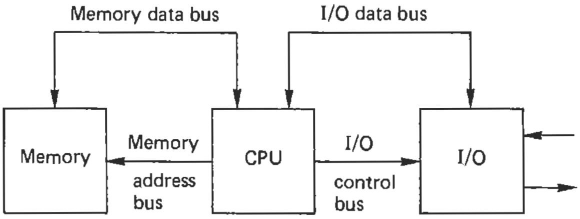

Figure 3.2 Port addressed I/O

instructions of IN (or INP) and OUT in both low- and high-level programming languages.

Although a number of I/O support chips are available, there are essentially two which figure prominently with the memory mapped and port addressed techniques. These are the 6522 versatile interface adapter, (VIA), usually associated with the memory mapped 6502 microprocessor systems and the 8255 programmable peripheral interface, (PPI), associated with such processors as the 8080, Z80 and 8086 in port addressed systems.

3.2.4.3 The 6522 VIA

This is a general interface chip which provides such interface functions as two 8-bit parallel bi-directional ports, each with a pair of handshake lines and two 16-bit counter timers. The ports, often designated as data registers A and B ('DRA' and 'DRB') each have an associated data direction register ('DDRA' and 'DDRB'), which is used for setting a bit on a port as either an input or an output. The addresses follow the sequence PORTB, PORTA, DDRB and DDRA.

If a.c. or d.c. loads such as solenoids, motors or lamps are to be driven from the port logic signal levels, then a power scaling interface, such as a Darlington Driver, compatible with the microprocessor VIA must be used (see Section 3.4.1).

The VIA control lines CA1, CA2, CB1 and CB2 can be set to operate in various read/write modes. This is achieved through the peripheral control register (PCR) in the VIA. CA1 has no output capability, but CA2, CB1 and CB2 can all be used as either input or output. These lines are incapable, however, of switching a power-scaling device.

The two programmable timers within the 6522 are generally referred to as T1 and T2. These are 16-bits wide and implemented as two 8-bit registers with a low-byte/high-byte arrangement. The modes of operation, selected by writing the appropriate code to the auxiliary control register (ACR), are:

1. Generate a single time interval.
2. Generate continuous time intervals (T1 only).
3. Produce a single or continuous pulses of bit 7 of DRB (T1 only).
4. Count high to low transitions on bit 6 of DRB (T2 only).

3.2.4.4 The 8255PPI

All microprocessor families have parallel I/O interfaces and these are designed for use with the particular type of CPU. The 8255PPI is used basically with Intel 8 and 16-bit devices such as the 8080 and 8086/8088. The 8255PPI provides three 8-bit bi-directional ports which may be operated in three modes. No other functions such as timing or additional handshaking are available. The ports are designated as A, B and C, and data direction is specified by writing to a write-only Control Register.

If hardware timing is required then a separate counter/timer device must be used. One commonly adopted with an 8255PPI is the Intel 8253 chip, which provides three independent 16-bit counters, each with a count rate of up to 2.6 MHz. The 8253 has various modes of operation but works basically on the same principle as the timers in the 6522VIA.

3.2.4.5 Direct Memory Access (DMA)

In data-acquisition systems involving analogue and digital signals suitably conditioned for inputting to a microcomputer there is a limitation of about 100 kHz on the sampling rate when using direct program control to transfer data to memory. If it was necessary to acquire the maximum amount of data at the highest speed, using the maximum amount of the computer's resources, then the DMA technique might be employed.

This is a hardware technique which causes the microprocessor to momentarily abandon control of the system buses so that the DMA device can directly access the memory. The DMA controller, connected to the I/O interface, needs to know how many bytes are to be transferred and where in memory the input data are to be stored. The data transfer rate is much faster than in an interrupt servicing method and data-sampling rates of the order of 1 MHz are possible for most microcomputers.

3.2.5 Memory map

The memory locations in RAM and ROM, which the processor can address, must accommodate space for such requirements as system monitor and utilities, user software and input/output. The manufacturer of the microcomputer assigns an area of memory for each functional requirement and provides the necessary information in a system memory map.

In 8-bit systems, with 64K of addressable memory, the memory map is usually composed of 32K of RAM and 32K of ROM or EPROM. The ROM holds the operating system software and normally some space is available in EPROM form for user firmware. In addition to providing space for user programs, the RAM area contains the system stack and the visual monitor data storage. The I/O facilities are also assigned an area of memory in a memory mapped system.

In a 6502 or 6800 based system the RAM is usually low down in memory and the ROM is high up. A typical memory map is shown in Figure 3.3. The I/O is accommodated

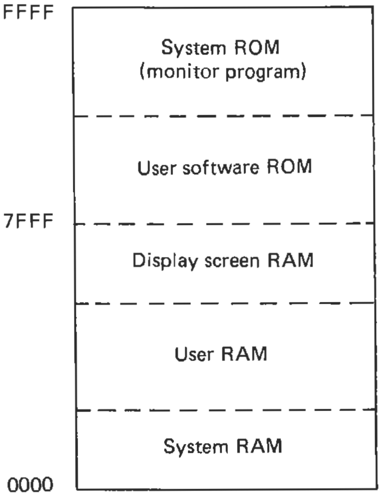

Figure 3.3 System memory map

anywhere within the above structure and varies from one manufacturer to another.

The display screen RAM is often fitted with a moveable boundary in order to set variable resolution modes for graphics. Typically, the screen memory need only be 1K for a text mode to give a 40 × 25 character display. This would be insufficient for computer graphics and a high resolution would require 20K of memory to MAP the screen. It should be noted that this greatly reduces the amount of RAM available to the user.

8080- and Z80-based systems have a distribution of memory similar to that as shown in Figure 3.3. The ROM, however, is usually low down and the RAM high up in the memory map. The 16-bit PCs, with a 20-bit address bus, have 1M byte of addressable memory with the RAM comprising the first three quarters and ROM occupying the last quarter. A general memory map showing the distribution of RAM/ROM for a PC is given in Figure 3.4.

A familiarity with the memory map of the system to be used in any data-acquisition application is essential, since it indicates the areas reserved for the operating system. The programmer can then knowledgeably determine the locations available for data storage and machine-code programs.

3.3 Communication standards

Various standards have been drawn up to define the protocol for the transmission of binary data from within the microcomputer bus structure to external devices such as display monitors, printers and other peripheral equipment. Most microcomputers are equipped with this facility and manufacturers of data measurement and control instrumentation usually offer an external communication port as an extra.

The most commonly accepted standards are those defined by the American Electronic Industries Association (EIA) and the Institute of Electrical and Electronics Engineers (IEEE). The standards fall into the two categories of serial and parallel data communication. The difference between the two relates to the number of bits of information transmitted simultaneously between the devices. The serial method is the slower of the two, with the bits denoting the characters of information travelling sequentially along a single path. In the parallel method the data word is sent as a parallel code, invariably 8-bits wide, resulting in a 'bit parallel, byte serial' transmission of information.

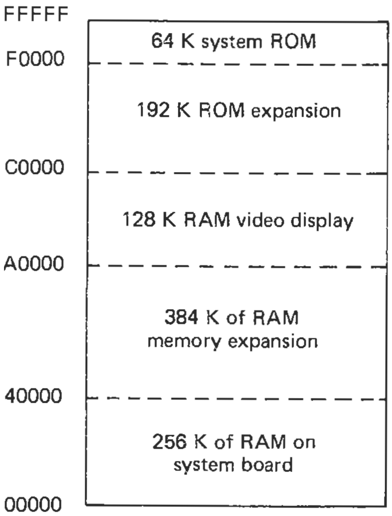

Figure 3.4 General memory map for a PC

3.3.1 Serial communication

Serial communication is the most common method used for the interconnection of a microcomputer to the relatively slow peripheral hardware, or between two computers, when transferring a low volume of information. The (EIA) RS232C, or its successors the RS422 and RS423, is the most widely adopted standard employed and connection between devices is made via a standard 25-pin connector. This allows communication with one peripheral device only. Twenty-one of the signal lines are defined in the standard although only five (or even three) are all that are usually required.

The three main connections are 'transmitted data' (pin 2), 'received data' (pin 3) and 'signal ground or common return' (pin 7). These would normally be connected as shown in Figure 3.5. For communication in both directions, i.e. full duplex, the two handshaking control lines – 'request to send' (pin 4) and 'clear to send' (pin 5) – are also required.

The standard applies to data transmission interchange usually at rates between 110 and 9600 baud. A logic '1' is represented by a voltage in the range of −3 to −15 V and a logic '0' by a range of +3 to +15 V. This large differential between '1' and '0' ensures good immunity against electrical noise. However, the voltages used are not compatible with the TTL logic semiconductor family and interconversion chips are required within the interface.

The RS232C is limited to short communication links of about 30 m, although the RS422 and RS423 standards, succeeding the RS232, have extended communication distances and increased transmission speeds. The RS423, which is compatible with the RS232, has superior driving and receiving interfaces, allowing communication over distances of up to 1500 m at 9600 baud, or 15 m at 100K baud.

It should be noted that while the voltages and signal connections for the plug are defined in the standard, the data protocol is not identified. This must be known for the devices which are to be connected and can be set accordingly by software. The requirements are:

1. Baud rate;
2. Number of bits in the ASCII group defining the character being transmitted;
3. Odd, even or no parity;
4. Number of stop bits.

3.3.2 Parallel communication

The RS232 serial standard for communication was developed essentially for the connection of microcomputers via a telephone link. The parallel standard emerged from the need to

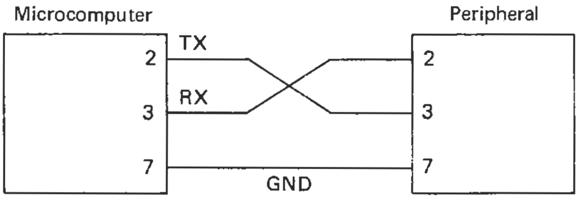

Figure 3.5

establish a means of interfacing a variety of instruments for data-logging applications. The most common standard for the integration of automated test systems, developed by Hewlett-Packard, is referred to as the IEEE-488 interface bus, and has achieved wide recognition among instrument manufacturers since the start of the 1980s.

The bus consists of 24 lines, accommodated within standard stacked type connectors. The eight bi-directional data lines carry information as 7-bit ASCII codes between the microcomputer (controller), and an instrument (listener) on the bus. The roles may be reversed when data are being logged. To process the information on the data bus, up to eight control and status signals are available.

The bus is designed to interface with up to 15 instruments, within a localized area, involving a total cable length of not more than 20 m. Each instrument is uniquely numbered within the range of 0–30 and the overall activity is controlled by one of the devices, termed the Controller. This is usually the microcomputer with an appropriate interface. Each device number is switch selectable within the instrument. Other functional aspects of the devices on the bus are that they must be capable of acting as a 'Listener' or a 'Talker'. A 'Listener' is a device that can receive data over the bus and a 'Talker' is capable of transmitting data. There may be several Listeners active on the bus at any one time, but there can only be one Talker. Most devices, including the microcomputer Controller, can act as either Listeners or Talkers.

When setting up an instrument to measure some physical variable, codes devised by the instrument manufacturer are sent on the bus, in ASCII format, as a data string to the numbered device. In the case of a multichannel DVM, this could take the form of the channel number to be monitored, voltage range to be selected and a terminating character. An example of the corresponding string to be put on the bus is

'C9R2T'

which denotes channel 9, range number 2 (say, 0–10 V) and 'T' is the string terminating character recognized by the instrument.

Manufacturers of add-on cards, to give IEEE-488 facilities with microcomputers, usually supply software for initializing the bus, setting it up for transmitting data from controller to instrument and returning data from instrument to controller. The measured quantity is also sent to the computer in the form of an ASCII string from which the actual numerical value can be extracted.

One of the most important management control lines is the service request (SRQ). This is a type of interrupt line that is activated low by a device residing on the bus and needing service from the controller. It is used as a means of indicating that the instrument is ready to transmit the current reading onto the bus.

Thus, a typical software sequence for implementing the control of an instrument on the IEEE-488 bus for data acquisition is:

1. Initialize bus and set instrument as a Listener.
2. Put control string on the bus to set up the instrument as required.
3. Check for SRQ line to go low indicating that data can be read.
4. Set instrument as a Talker.
5. Read returned string and convert into a numerical value.

When operating in high-level BASIC, high data-collection rates are not possible. However, since most instrument manufacturers offer the standard as an option it provides an intelligently controlled flexible arrangement for test and measuring instruments.

3.4 Interfacing of computers to systems

The serial and parallel communication standards are the basic interfacing links between computers and their associated peripheral devices, or between computers and a comprehensive range of measurement instrumentation. In general computer control applications, however, two other common interfaces are fundamental. These are the digital interface which implements the controller output and the analogue interface associated with the measured variable input.

3.4.1 Digital interfacing

The computer output port may be used to transmit control signals on any one of the available lines by writing the appropriate number to the port address. When a line (or bit) is set 'high' (i.e. a logic level of 1) the voltage on the line is approximately 5 V. The current available, however, is fairly minimal (of the order of 1 mA) and no load can be connected directly to the port. There is in fact a danger of causing extensive damage to the computer by connecting a load directly to the port. An interface must therefore be provided to enable the computer to switch in power loads using the logic level control signals from the output port. The most common interface device used for this purpose is the power transistor. In typical applications the power transistor, operating on logic level control signals, switches in a mechanical relay which in turn switches in the load.

The 'Darlington Driver' is a popular power transistor available as an integrated circuit and which normally includes a number of separate stages. Figure 3.6 shows the wiring diagram for a single stage in a Darlington Driver. The Darlington Driver can switch up to 500 mA at 50 V and each stage is diode protected for the switching of inductive loads.

To provide a total isolation from high voltages, port output signals can be coupled through an 'opto-isolator', which, interfaced between the computer output port and the power control device, is not an essential element in the digital interface. Opto-isolation, however, ensures that no hardwired connections are made between the computer and the power device. An added advantage is that the opto-isolator acts as a buffer to spurious noise signals which can corrupt the digital logic values being transmitted on the buses.

The opto-isolator (Figure 3.7) transmits signals by means of infrared radiation, emitting from a source and sensed at a photo-transistor. When a computer based on transistor/transistor logic (TTL) is powered up the state of the lines of the output port 'float high'. That is, each output line becomes set to a logic value of 1. Since a logic 1 is normally associated with the function of switching a device ON, then a port which floats high could inadvertently activate some power device. Obviously, this is a dangerous precedent, which requires an additional element in the digital interface to counteract the effect. The device commonly used is the 'inverter' (or NOT gate) which has the simple function of inverting all logic signals from 1 to 0 and vice versa (Figure 3.8). Following power up, a logic 0 must then be sent to the relevant line of the output port, to become a logic 1 after inversion and to operate the control function.

The composite digital interface for a computer output port suitable for power switching is depicted in Figure 3.9. In high-frequency switching applications electromechanical relays are not suitable. Semiconductor devices such as silicon controller rectifiers (SRCs, alternatively called thyristors or triacs) may be more appropriate. Also particularly suitable are the various solid-state relays which can operate directly from logic level signals.

3.4.2 Controller output interface hardware

The digital interfaces discussed above are suitable for switching in power loads in an ON/OFF control system. For a digital control algorithm based on a PID strategy, some means is required of discretely varying the output power supplied to the controlled device (Figure 3.10). A number of different methods are used to supply variable power to the system and these include the following.

3.4.2.1 The digital-to-analogue converter (DAC)

The required control effort value, U, is calculated in the program according to the control strategy employed. This value is converted to an equivalent binary number and output to the computer port where it is then transmitted to a DAC. The DAC converts the binary input into a proportional output voltage which may then be suitably amplified to drive the controlled device. The controlled device could, for example, be a d.c. motor whose speed is directly related to the supply voltage. The interface is illustrated in Figure 3.11.

Two basic types of DAC are available: the adder converter and the ladder converter. The adder converter can be illustrated as a simple example of Ohm's law. A 4-bit adder type DAC is shown in figure 3.12. The resistance value of the line resistors are halved for each consecutive increasing 'bit' and

Figure 3.10 Variable power output device

the supply voltage is common. The current drawn through each line, if it is connected, is 1, 2, 4 and 8 mA, corresponding with bits 0, 1, 2 and 3. The summation of the currents at output therefore equates on a decimal to binary basis with the input. Figure 3.12 shows a digital or switched input of 1011 binary. This gives a current summation of 11 mA, equivalent to the corresponding decimal number. The output, a proportional current, can be converted to a proportional voltage through an operational amplifier. Because of the range of resistor values required, the adder converter is less popular than the ladder converter, which uses only two resistor values, i.e. R and $2R$.

The ladder converter DAC (Figure 3.13) must be analysed using the network theorems of Thevenin and Norton. The end result is similar, however, with a proportional voltage output corresponding to the digital switched input on a decimal-to-binary basis.

3.4.2.2 *Pulse Width Modulation (PWM)*

Output power from the interface hardware can be varied by sending ON/OFF pulses to the power device. The frequency range is normally between 2 and 10 kHz. If the time ON and the time OFF periods are equal, then rapid switching of the power supply will transmit 50% of the total power available. Due to the relatively high switching frequencies and the levels

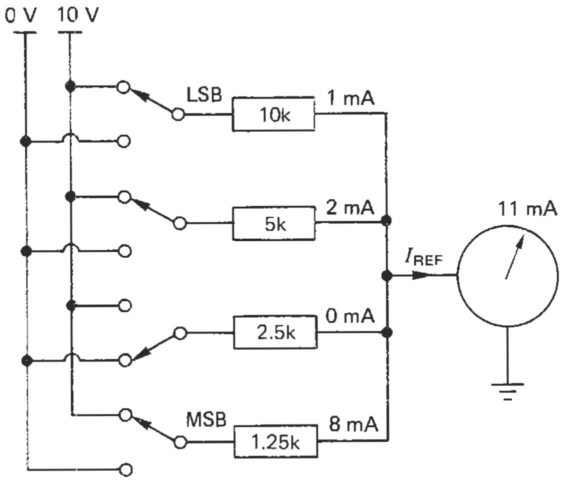

Figure 3.12 4-bit, adder-type DAC

of power transmitted, the solid-state relays are more suitable for this application. The time ON is called the 'MARK' and the time OFF is the 'SPACE'. The MARK/SPACE ratio can be evaluated from the controller output value calculated in the software. PWM can be achieved either by keeping the MARK fixed and varying the SPACE (i.e. varying the signal frequency) or by varying both the MARK and the SPACE within a constant period.

If the PWM output is supplied by the controller, then it is not possible to allow the MARK+SPACE period to extend over the complete control loop cycle. There must be some time allowed to sample the process transducer and to calculate the required controller output value. The problem is overcome by using a synchronization ('sync') pulse signal with a longer period than the MARK+SPACE time. The excess time during the sync pulse is used to read the transducer output and to process the information. The MARK/SPACE ratio is then implemented over the remainder of the sync pulse. Two separate timing loops are used to control the MARK and SPACE times, respectively. Due to the relatively high frequency of the output signal, the control software must be written in assembly language for speed. An alternative to this is to use hardware support chips to output the PWM signal under the control of the computer's CPU.

3.4.2.3 Controlling a.c. power by control of thyristor phase angle

Various applications, such as temperature control, require a.c. power adjustment and solid-state relays can be used effectively to vary output power between 0% and 100%. The power is controlled by varying the phase angle between the supply voltage and that which appears across the load when current conduction begins. A phase control device operating off a 0–5 V signal from a DAC can be used to alter the phase angle between voltage and current in the range 0–180°. The control of the power output to the load is non-linear, but linearization between output and input can be accomplished in the software.

3.4.2.4 Controlling flow control valves

In level-control systems, fluid flow rates are controlled by varying the degree of opening of a gate-type valve. Because of the forces involved, a pneumatic 'actuator' is normally employed, working off a controlled pressure in the range between 3–15 pounds per square inch (i.e. psi). (*Note*: The industry still favours the Imperial unitary system but the approximately equivalent pressures in the metric system are 20–100 kN/m^2.) An applied pressure of 3 psi is equivalent to the valve being fully open, 15 psi corresponds to the valve being fully closed.

Most flow control valves are fitted with a 'positioner', which operates off a current signal in the range 4–20 mA. The current range generally corresponds on a linearly proportional basis to the pressure range. Since the computer interface usually involves a DAC, then an additional element (a voltage-to-current converter) is required to interface between

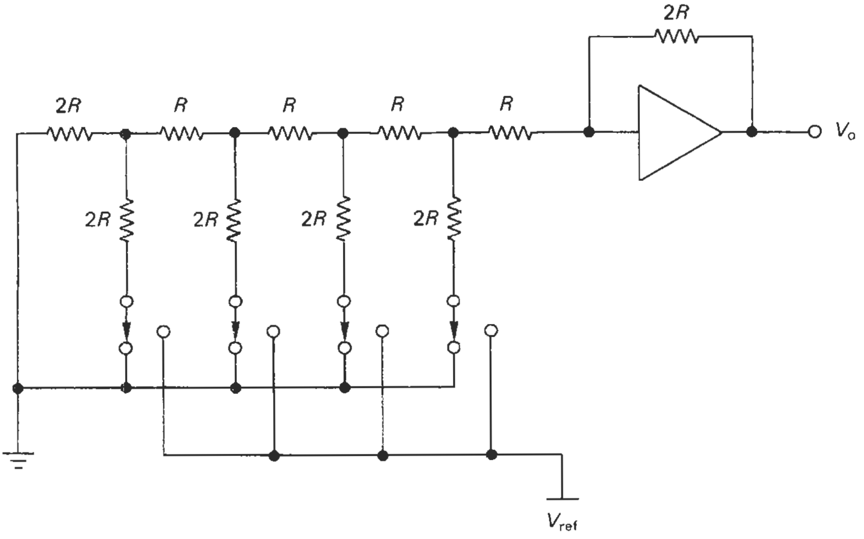

Figure 3.13 Ladder-type DAC

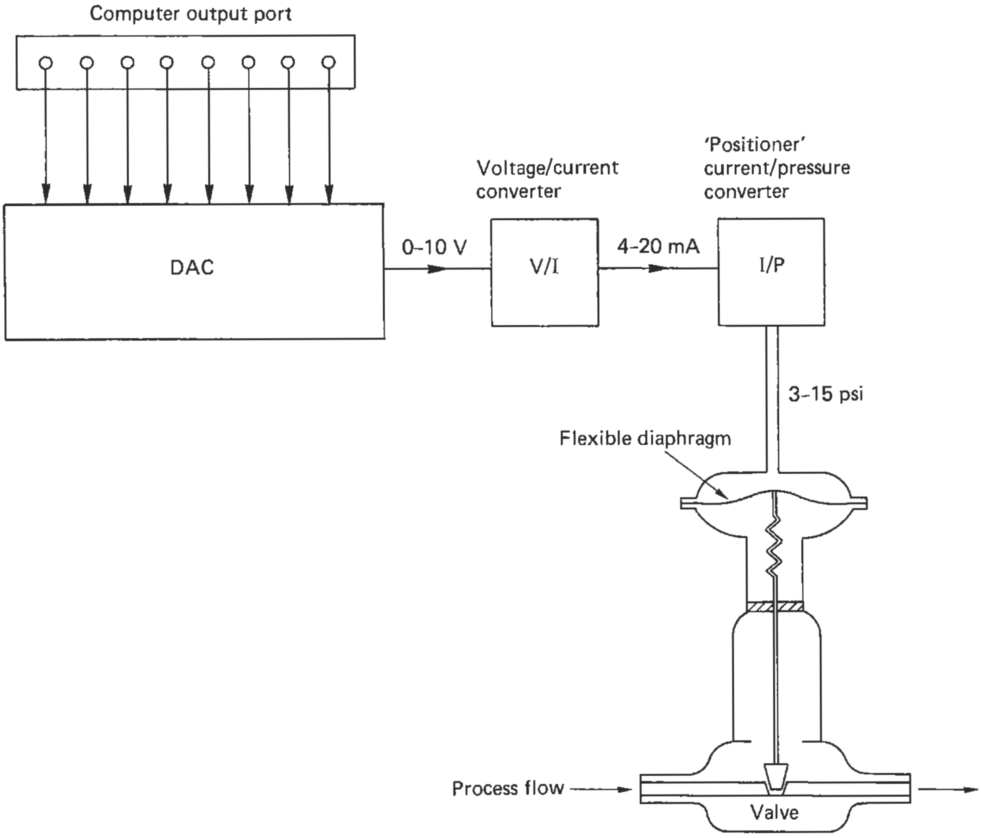

Figure 3.14 Digital interface for a flow control valve

the DAC and the valve positioner. The complete interface is shown in figure 3.14.

3.4.3 Analogue interfacing

The basic role of the analogue interface is one of conversion of the continuous analogue signals, from process measuring transducers to the digital representation that the computer requires to operate on. In all practical applications, the monitoring and acquisition of the data is the necessary precursor to the subsequent control functions that might be actioned.

The process variables are ultimately represented as voltages. Using the appropriate signal-conditioning circuits, these voltages would ideally be processed to range between zero and some reference value. The final task is the digitization of the analogue signal, which is accomplished through an analogue-to-digital converter (ADC). The ADC samples the analogue signal, performs the conversion and outputs a digitally encoded binary number which is directly proportional to the magnitude of the input voltage. The essential elements in the signal train are shown in Figure 3.15.

This figure indicates a sample and hold (S/H) element between the signal conditioner and the ADC. Since the analogue input may be varying while the conversion is taking place, there is a degree of uncertainty in deciding the instant in time which the output code represents. The sample and hold element removes this uncertainty by capturing the instantaneous 'snapshot' of the input for the ADC to convert before moving on to the next sample. The S/H element is only essential if the input signal is varying very rapidly. The ADC and S/H functions are often packaged within a composite integrated circuit.

ADCs are available in a number of different forms and these include the following.

3.4.3.1 Staircase and comparator

The staircase and comparator is the simplest form of ADC (Figure 3.16). The device incorporates a DAC which generates a voltage increasing in small steps as shown. At each step the staircase input is compared with the analogue input. When the generated staircase is approximately equal to the input, the process is halted and a binary count is made of the number of steps taken during the process. The binary count from zero represents the coded digital output.

The staircase and comparator ADCs have relatively slow conversion times (typically, 20 ms). They are, however, cheap and are essentially immune to electronic noise.

3.4.3.2 Integrating type ADC (or dual slope)

The major elements comprising a dual-slope ADC are illustrated in Figure 3.17. At the start of conversion a voltage-to-current converter is switched to the integrator, causing it to ramp up a slope which is proportional to V_{in}. This occurs over a fixed period of time at the end of which the input is switched over to the reference current source. At the instant of switching the integrator output voltage is proportional to V_{in},

a counter is enabled and counting begins at a rate set by the internal clock. Meanwhile, the reference current causes the integrator to ramp down at a slope which is proportional to V_{ref} (i.e. a constant slope). When the integrator output again reaches ground the comparator switches the counter off and the counter then contains a digitally encoded value proportional to V_{in}. Figure 3.18 shows the voltage variation at the integrator output.

From this figure it can be seen that there are two similar triangles such that

$$V_{in} = V_{ref}(T_v - T_f)/(T_{max} - T_f) \qquad (3.2)$$

T_v is directly proportional to the counter output and with T_{max}, T_v and V_{ref} all known, the input voltage, V_{in}, is determined by proportion.

The integrating types of ADC have similar operating characteristics and conversion times to that of the staircase and comparator types. For faster analogue-to-digital conversion, the 'successive' or 'counter' type are generally employed.

3.4.3.3 Successive approximation type ADC

In this ADC the input signal is compared with a number of standard reference voltages, generated from a DAC, until the

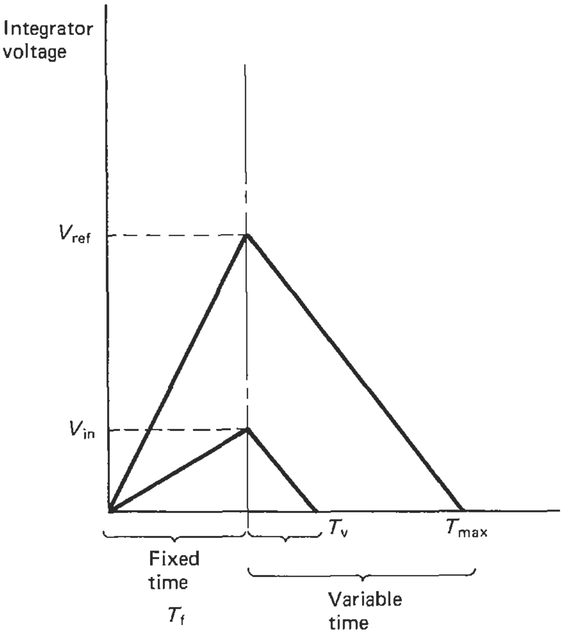

Figure 3.18 Integrator voltage variation

combination of standard voltages required to make up the input value has been determined. The main components of the converter are a clock, a counter, a comparator and a DAC.

When an analogue signal is input to the converter the counter starts a count and passes a digital value to the DAC. The DAC generates a voltage to represent the most significant bit and the comparator assesses this against the analogue input. If the analogue signal is greater than the voltage from the DAC then the logic 1 in the MSB is retained. If the analogue signal is smaller then a logic 0 is assigned to the MSB. This process is then repeated on the next most significant bit and so on for all the other bits down to the LSB. The conversion time for these types of converters may be of the order of 10–25 μs, but this will depend upon the hardware design. Figure 3.19 outlines the essential features of a successive approximation ADC.

3.4.3.4 Parallel conversion type ADC

The parallel type ADC has by far the fastest conversion time (at about 1 μs) but it is also the most expensive. With parallel conversion, the analogue input is fed simultaneously to a number of comparator circuits, each having a different reference voltage. The resulting comparator outputs are fed to a logical coding network which generates the appropriate digital values to represent the state of the comparator outputs.

Regardless of the type of ADC used, the pin functions on the integrated circuit are basically similar and generally comprise the power supply, the data bits, the start conversion pin ($\overline{\text{SC}}$ or $\overline{\text{CONVERT}}$) and the end of conversion pin ($\overline{\text{EOC}}$ or $\overline{\text{STATUS}}$). The overbar signifies that the pin is active low.

The conversion is software initiated by sending a 'pulse' (logic 0, followed by logic 1) to the $\overline{\text{CONVERT}}$) pin. On the negative edge of this pulse the counter in the successive approximation ADC is set to zero and on the positive edge the counter starts incrementing. At the start of conversion the $\overline{\text{STATUS}}$ pin goes from low to high, and when it again goes low, the conversion is complete (Figure 3.20).

The end of conversion may be readily detected using suitable software. As an alternative, it is possible to include a software-generated time delay following the start conversion pulse to allow conversion to complete before reading the value at the input port. The length of the delay can generally be found by trial and error.

In choosing the appropriate ADC for a particular application the four main features to be considered are:

1. *Conversion time*: The conversion time is a measure of the operating speed of the converter and is the time taken for the complete translation of an analogue signal to digital form. In many of the staircase and comparator and the integrating types of ADC this may be dependent on the level of the analogue input signal. Faster conversion times are obtained with low-level inputs due to the manner in which the conversion is completed. Successive approximation and parallel conversion types of ADC have a fixed conversion time. This is because the same conversion process is performed, regardless of the analogue input level.

   The conversion time of the ADC does not, however, indicate the fastest rate at which data can be captured. If the data are to be stored in the computer's RAM, then this must be done in a sequential and ordered manner. This involves setting a base address and incrementing various registers to step the storage addresses of each byte of data placed in memory. Further time delays could be accrued in a sample and hold device. The minimum data capture period is often therefore many times greater than the specified conversion time of the ADC.
2. *Resolution*: The resolution of an ADC is the number employed to represent the digital output in binary form. For example, the resolution of an 8-bit ADC is limited to

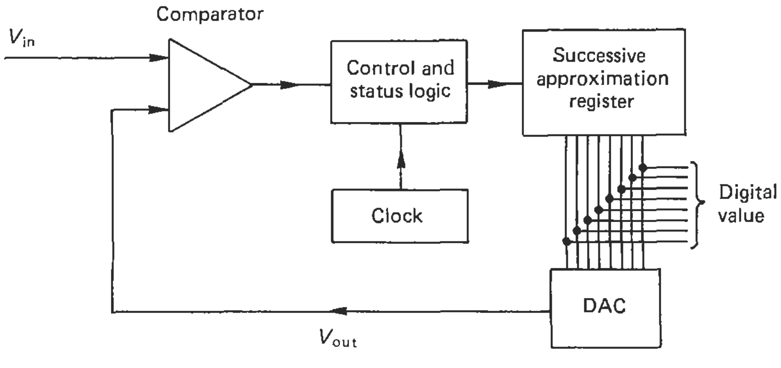

Figure 3.19 Successive-approximation ADC

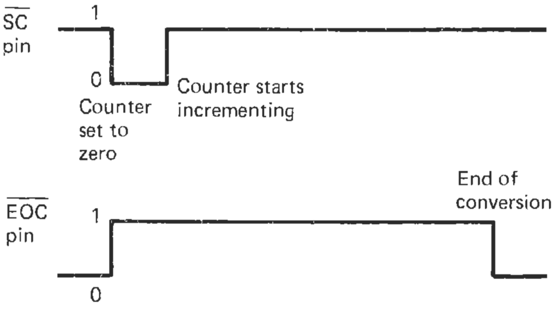

Figure 3.20 Start conversion and end of conversion pin signals

one part in 256 of the maximum voltage corresponding to the full-scale setting. An improvement in resolution can be obtained with a 12-bit converter, with one part in 4096. Table 3.1 summarizes the relation between the number of bits and the resolution.

Table 3.1

n-bits	2^n	*Resolution* (%)
8	256	0.4
10	1 024	0.1
12	4 096	0.025
16	65 536	0.0015

3. *Accuracy*: The accuracy is related to linearity defects, zero error and calibration defficiencies in the electronics of the converter and should not be confused with the resolution.
4. *Cost*: Cost will depend on the quality required in the three areas previously described and on the means of conversion employed. It is closely associated with the speed of the conversion and with the resolution and accuracy. Cost generally rises with increases in all or either of the three other variables.

3.4.4 Multiplexing

In applications where a number of transducers are to be sampled, a multiplexer (MUX) can be used to switch in various channels as and when required to a single ADC. The switching is software controlled from the computer and Figure 3.21 illustrates the basic principle.

The multiplexer and ADC often form an integral part of a complete system. In some cases, even the signal conditioning can be software controlled, with all the necessary hardware mounted on a single 'card' and plugged directly into the computer's bus system. Multiplexers (or analogue switches) are available with various numbers of input channels.

Minimum cost conditions usually dictate whether multiplexing will be implemented or not, but the reduced cost must be balanced against an inevitable reduction in sampling rate. Figure 3.22 shows three possible arrangements of signal conditioning, multiplexing and conversion for analogue interfaces.

System A is the most common, while B and C can provide for virtually simultaneous sampling. System C gives the most representative snapshot at a particular period in time, but it is also the most costly.

3.4.5 Machine tool interfaces

The control system for a machine tool slide is shown in Figure 3.23. Typically, there are two negative feedback loops, one for position and one for velocity in a cascade arrangement as shown in the figure. The position sensor is usually an optical grating device (or an inductosyn) and the speed sensor a tachometer.

The CNC interface initially has to decode the manual or control tape input data. This consists of a sequence of commands, including feed and speed data, essential dimensional reference points and other constraints to be observed by the machine during its operation. In operation, the interface is required to monitor the slide position and speed and check various limit switch settings for compliance with the sequential program instructions. The transducer input signals would normally be switched in through a multiplexer prior to digitization with a fast conversion type ADC. Limit switches would also be checked or set through additional digital I/O lines. If any errors are detected, the interface must be able to indicate these and take the appropriate action. The interface includes a real-time clock which generates an interrupt every few milliseconds. The clock acts as a monitor of operator actions, enables the output of error signals to the machine servos and checks all current signals from each of the feedback sensors.

For a typical CNC milling machine there are three independent axes, and each would have the same monitoring and control functions applied to them. In addition, the spindle speed would be monitored and controlled and the machine might also incorporate a tool-changing facility based on a simplified robot arm.

Further refinements could include a load transducer in an additional feedback loop to measure the cutting forces during machining. Force sensing may be used as the basis for an adaptive control loop. In the context of machine tools, adaptive control is usually associated with the alteration of feed rates and cutting speeds to maximize the cutting power. Figure 3.24 shows an adaptive control option on an NC turning machine.

The adaptive loop can optimize the cutting operations, prevent spindle overload, maximize tool life, reduce time loss in 'air cuts' and simplify the programming. The additional sensors and their protection in the harsh machining environment means, however, that the adaptive loop is much more costly to implement. The adaptive control interface, which has no manual input data facility, is also necessarily complex and requires considerable memory capacity.

3.4.6 Robot control interfaces

The machine tool interface described in the previous section can be programmed to perform a series of operations which might be described as 'sequenced automation'. Many of the simpler robots (e.g. pick-and-place machines) use the same technology and perform essentially similar tasks. These machines are not, however, robots in the strictest sense. The essential feature of a true robot is its capability of exercising independent control in each of its axes, or rotating joints, such that its 'hand' can reach any position and any orientation within the working volume.

Each joint on the robot has an actuator, an associated position sensor and a velocity sensor. Six actuators are required for full flexibility in position and orientation, although in most cases only five or less are used. The computer must at all times be able to ascertain the current and desired locations of the hand. The position sensor data processing therefore involves the manipulation of various coordinate transforma-

Force sensing within the 'gripper' is commonly featured in many industrial robots. The obvious application is to prevent the proverbial 'vice-like' grip on some fragile object. Force sensing is also incorporated by inserting a sensor between the gripper and the wrist. Many wrist force sensors are strain gauge based and can respond to applied forces and moments in each of the three Cartesian directions. The wrist sensor provides feedback signals for static and inertial loading on the robot arm. Robots which operate a control strategy based on wrist force sensor data are termed 'active compliant'. The active compliant robot system has the capability of modifying the joint positions and motion to minimize the effect of external forces. Many wrist force sensors have been successfully developed for robot manipulators engaged in pin insertion type operations. Whitney[1] reports on some detailed investigations on wrist force sensor applications.

The sensors producing signals related to position, velocity and force form the main feedback loops in many industrial robot assemblies. These signals are converted through ADCs and the digital control algorithm, often based on a PID strategy, is then solved to determine the required controller output values at that given time. Power is subsequently output to the actuators either through DACs or using pulse width modulation techniques. In most respects the above process is exactly the same as that which would be used to control a CNC machine tool with an adaptive loop. The robot arm motion, however, is much more complex and the computation involved is far more extensive than that required for the CNC machine tool. The computer used in robotic manipulators therefore requires a large memory capacity and a fast processing speed to accommodate the multiplicity of tasks associated with the control functions. The control algorithm is itself complicated by the multiple feedback loops for position, velocity and force, and a 'hybrid' control strategy is normally adopted. This strategy allows force to be controlled along certain Cartesian axes, while position is controlled along the remaining degrees of freedom. Velocity is controlled along the same degrees of freedom as position. The computational effort is significant due to the many coordinate transformations required, and hybrid control can only be implemented when the robot is moving slowly.

Recent advances in robot technology are centred on the development of tactile sensors, range finders and machine vision. Tactile sensors ideally simulate the human sense of touch. They should therefore be able to detect presence, shape, location and orientation. In addition, the ideal tactile sensor should be able to respond to applied forces and moments in terms of magnitude, direction and location. Varying degrees of success have been achieved with tactile sensors (see Bejczy,[2] Harmon[3] and Rebman and Trull[4]).

Many range-finding devices are based on optical proximity sensors or on ultrasonic echo-sounding transducers in applications to short and long range finding, respectively. The function of the rangefinder is twofold; either to locate the gripper in the correct position relative to the object to be picked up or to avoid potential collisions with other objects. Like tactile sensors, however, many range-finding devices have not yet been developed to the stage where they are consistently reliable for routine use.

Perhaps the most useful additional sensory attribute that a robot can have is that of vision. Industrial machine vision is currently the subject of considerable worldwide research and development and a number of effective systems are already available.

The first problem with a machine vision system is the formation of a digital image. There are a number of different digital imaging devices in use but they all have the common function of converting light energy into voltage (see Ballard and Brown[5]). The voltage output is inevitably processed through a fast ADC to produce the digital representation of the light intensity, in terms of 256 possible grey levels. The resolution of the digital image depends on the number of discrete lines and points per line which are used in the construction of the picture. The use of 512 lines, with 512 discrete points in each line, results in 262 144 individual picture cells (or 'pixels') to define the image. Each pixel is represented as an 8-bit number and these can be stored in memory as a two-dimensional array. Note that this would use up 262 144 bytes of computer memory for the storage. With such large amounts of data to be handled, a separate 'preprocessor' is often used in the system. The preprocessor interprets the visual information and then transmits the result to the robot controller.

Since the image can be represented numerically and stored in memory, it can also be retrieved and processed according to the particular requirements. In many robot vision applications the vision task is that of part recognition and orientation of the part. Often a two-dimensional projection of the part shape is all that is required, and a single solid-state camera can be used to generate the two-dimensional image. Part recognition is based on the part silhouette and the image-processing technique requires only a brightness threshold level to distinguish between 'object' and 'background'. The level of vision is crude but can be sufficient for many automated assembly processes. Control of the lighting arrangements can greatly enhance the vision system but, in general, machine vision still leaves much to be desired at its current stage of development.

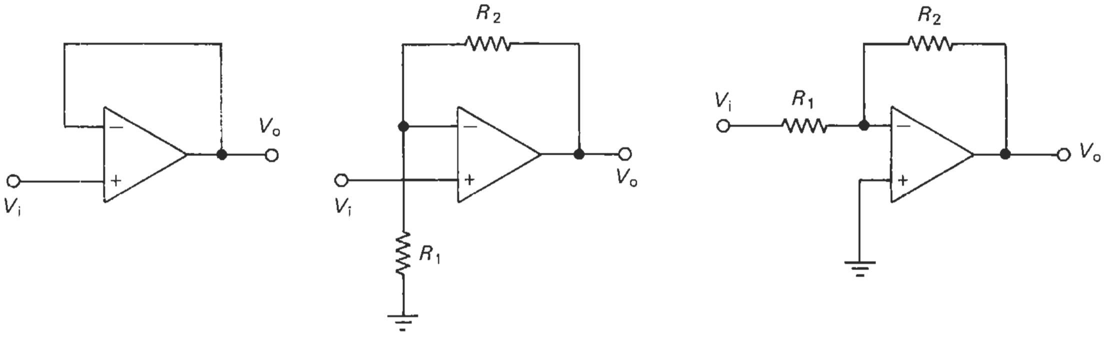
The three major development areas of tactile sensing, range finding and machine vision are all being actively researched at present. It is apparent that these sensory functions all involve considerable amounts of additional input data and this imposes further limitations on the system in general. The limitations are related to the data-processing speed and the communication interfaces. Recent new microprocessors (e.g. Intel's 80486) operate at much higher speeds than any of its predecessors and future developments in communications are likely to be centred on applications using light signals transmitted along fibre-optic cables. These advances should open up the possibilities for further enhancements in robot sensory perception systems.

3.4.7 Signal conditioning

Although the output signal from many sensors and transducers is already in the necessary voltage form, it is only very rarely that the voltage is high enough to be directly interfaced to a measurement system. In most instances the transducer output will require some form of amplification.

The term 'amplifier' is a shortened form of the full description 'voltage amplifier'. Most amplifiers amplify voltage but other types are encountered and these are normally given their full description (e.g. current amplifier, charge amplifier and power amplifier). Amplifiers are further classified as a.c. or d.c. The d.c. amplifier will accept a.c. inputs but the a.c. amplifier will block any d.c. input. The input signal may be either single ended with one, or differential with two active signal lines. Finally, the amplifier may be 'inverting', with a reversal of sign at the output, or 'non-inverting'.

The most common amplifier configuration embodies a differential input, single-ended output voltage amplifier with either inverted or non-inverted output. These type are referred to as 'operational amplifiers'. Figure 3.25 illustrates some typical idealized operational amplifier circuits.



(a) Non-inverting unity gain

(b) Non-inverting gain: $V_o = \left(\frac{R_1 + R_2}{R_1}\right) V_i$

(c) Inverting gain: $V_o = -\left(\frac{R_2}{R_1}\right) V_i$

Figure 3.25 Operational amplifier circuits

The important characteristics of an operational amplifier are its gain and its bandwidth. The gain (which can be as high as 10^6) is related to the combination of passive resistors which make up the external circuit. The gain is constant only over a restricted range of input signal frequencies. Outside this range the gain is attenuated as shown in Figure 3.26.

The 3 dB 'cut-off' frequencies are used to define the bandwidth of the amplifier. The product of gain and bandwidth (GBW) is quoted by some manufacturers as a quality parameter. Other descriptive parameters associated with amplifiers are:

1. *Common-mode rejection ratio*: Ability of an amplifier to reject differential input gain variation.
2. *Offset voltage*: Voltage output attributed to input and output voltages generated by component variations.
3. *Offset drift*: Temperature-dependent voltage output.
4. *Non-linearity*: Departures from linear input/output characteristics.
5. *Distortion*: Frequency-dependent non-linearities.

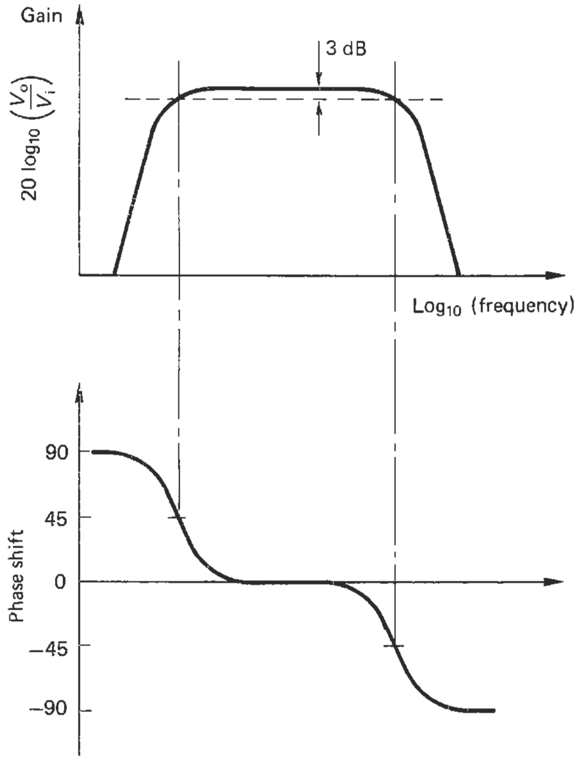


Figure 3.26 Gain and phase shift characteristics of an operational amplifier

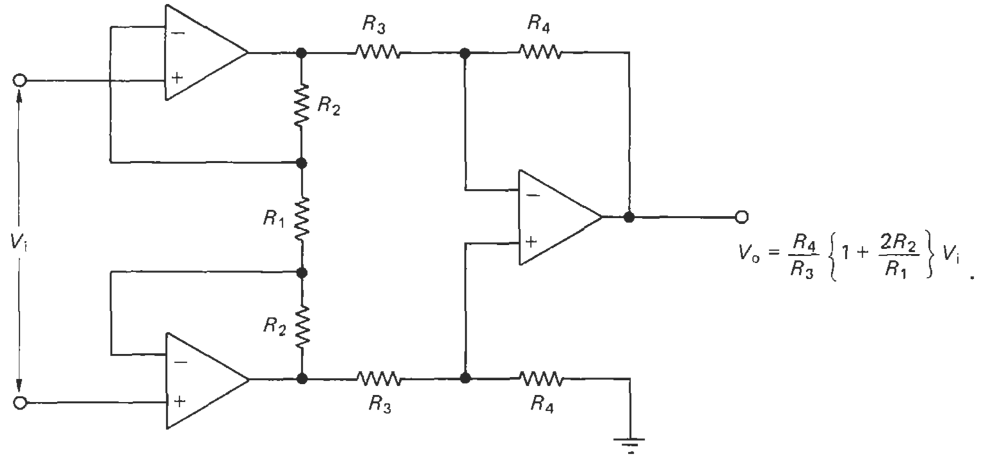
Popular and inexpensive general-purpose operational amplifiers are those in the so-called '741' family. For high-accuracy measurements, where low drift and low noise are also essential, an instrumentation amplifier with a high input impedance and high common-mode rejection ratio would normally be required (Figure 3.27).

The problem of impedance mismatch is frequently encountered in instrumentation systems. This occurs when a transducer having an internal resistance and functioning as a small voltage source is coupled to a recording instrument which also has an internal resistance. If the internal resistance of the transducer is many times smaller than that of the recording instrument then the problem is insignificant. If, on the other hand, the internal resistances are of similar orders of magnitude then the error in the measurement and the loss of the signal can be quite large. The standard solution to the impedance mismatch problem is to interface an amplifier with a high-input impedance and a low-output impedance between the transducer and the recording equipment. Such amplifiers are usually configured to have unity gain since their primary function is the prevention of serious signal loss.

For many measurement applications, custom-built special-purpose amplifiers are available in integrated circuit form. These greatly ease and facilitate the signal-conditioning circuitry. Fraser and Milne[6] give a practical guide to many of the signal-conditioning interfaces required for the amplification of signals from strain bridges, thermocouples and other low-level voltage output sensors.

3.4.8 Analogue and digital filtering

Noise is inherently present in all physical systems where measurements are made. In sampled data systems (i.e. when an ADC is employed) the effect of noise, illustrated in Figure



R_3
R_4
R_2
R_1
R_2
R_3

V_i
$V_o = \frac{R_4}{R_3}\left\{1 + \frac{2R_2}{R_1}\right\}V_i$.

Figure 3.27 Instrumentation amplifier

3.28, can give rise to further misinterpretation in the form of 'aliases' (see also Section 3.7.4).

Discrete sampling (shown in Figure 3.28) results in an output signal which suggests that the measured variable is increasing linearly but with a superimposed sinusoidal fluctuation. The apparent sinusoidal variation is entirely the effect of background noise, and it is obviously good practice to try to eliminate noise in the measurement system. It is perhaps fortuitous in mechanical systems that background noise is generally manifested at much higher frequencies than that associated with the primary variable of interest.

The sources of noise are varied and may originate from thermoelectric effects, electrochemical action, electrostatic and electromagnetic pick-up, self-generated component noise, offset voltages and common earth loops. If the frequency content of the signal to be measured is known beforehand, then positive steps can be taken to eliminate most of the unwanted effects of noise by the inclusion of suitable filters. Filters exist in three broad categories: (1) lowpass, (2) highpass and (3) bandpass. The gain characteristics for each type are shown in Figure 3.29.

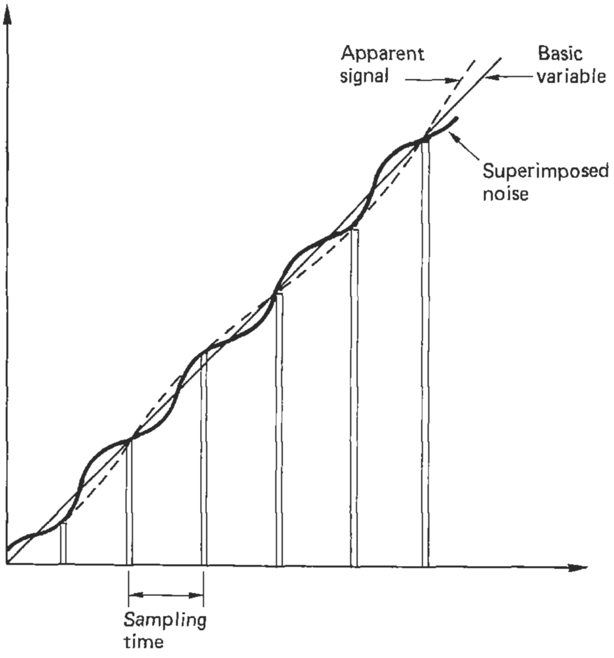

Figure 3.28 Noise generated 'aliases' in a sampled-data signal

A lowpass filter is one which allows the transmission of signals below a particular cut-off frequency. Signals whose frequencies are above the selected cut-off are progressively attenuated. The highpass filter, in contrast, transmits only that part of the signal whose frequencies are above the cut-off value. The bandpass filter transmits, without attenuation, the signal contained within an upper and a lower cut-off value. The cut-off frequency, is defined as that at which the signal attenuation is −3 dB.

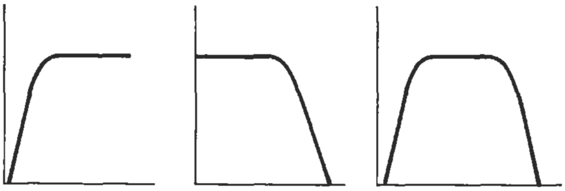
The simplest forms of analogue filter are those which incorporate only passive resistive, capacitive or inductive elements:

1. *Lowpass filter* (Figure 3.30): The transfer function for a lowpass filter is given as equation (3.18) in Section 3.6, with the gain, $k = 1$. The time constant, τ, is equal to the product of the values of resistance and capacitance, RC. The −3 dB cut-off frequency is given by

   $$f = 1/(2\pi RC) \quad (3.3)$$

   A suitable choice of resistor and capacitor can therefore allow any desired cut-off frequency to be imposed in the signal-conditioning train.
2. *Highpass filter* (Figure 3.31): The transfer function, in terms of the Laplacian variable, for the highpass filter is

   $$(V_o/V_i) = (sRC)/(1 + sRC) \quad (3.4)$$



(a) Highpass (b) Lowpass (c) Bandpass

Figure 3.29 Filter performance curves

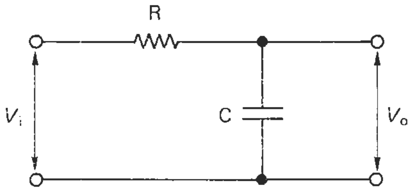


Figure 3.30 Lowpass filter

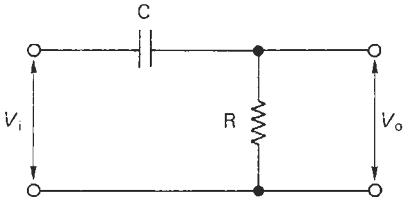

Figure 3.31 Highpass filter

The cut-off frequency is similarly selected through a judicious choice of resistor and capacitor.

Bandpass filters might be thought of as a series arrangement of a lowpass and a highpass filter. With the appropriate combinations of resistors and capacitors, the low- and high-frequency noise components in the signal can be suitably attenuated as required.

Filters which include an amplifier in the circuit are referred to as active and the relationship between input and output is a much more complex function of time. Williams[7] gives a comprehensive discourse on filter design.

Figures 3.30 and 3.31 illustrate the simplest forms of passive analogue filter which are used to suppress background noise. The governing equations (3.4) and (3.18) may equally well be expressed in terms of finite differences. In finite difference form, the equations can be used to action the filtering process on a discretized version of the input signal. This is the basis of a digital filter which can be implemented in software and requires no external hardwired components.

The setting of the cut-off frequencies in the digital filter are achieved through adjustment of the constants appearing in the finite difference approximating function. These numerical constants are simply related to the physical time constant in the equivalent analogue filter and also the digital sampling rate.

The advantages that the digital filter has over its analogue counterpart are the ease with which the cut-off frequencies can be adjusted. The −3 dB cut-off frequency can also be set exactly, since no hardwired components, with physical tolerance bands, are used. The digital signal may also be filtered any number of times simply by processing the data repetitively through the filtering algorithm. The disadvantage incurred is that digital filtering takes longer in real time to perform. The results of digital filtering on the signal are exactly the same as would be obtained using an analogue filter. That is, any time-varying signal whose frequency is outside the cut-off value is subject to attenuation with a corresponding phase shift.

3.5 Instrumentation

3.5.1 Introduction

Many aspects of mechanical engineering depend essentially on the ability to make measurements of relevant quantities. In some areas, such as non-destructive testing or experimental stress analysis, the techniques for making the measurements are linked so closely to the rest of the subject that they are better dealt with in their particular context. Here, we consider the more general measurements encountered throughout the whole field and the instrumentation that makes them possible.

In later sections, techniques are described under the headings of the quantities to be measured – sometimes referred to as measurands. First, it is useful to discuss topics that are of importance in many instrumentation systems.

Sometimes the process of measurement is a simple one, with the human operator playing a direct part: putting a rule alongside a component to determine a length, or measuring time using a stopwatch. More often a more complex system is used, which can be understood by thinking of the elements that make it up. Such a system is shown in Figure 3.32. Many variations are possible.

The measurand acts on a transducer and produces a signal corresponding to its value. This output signal is commonly electrical, but may be pneumatic or optical. The signal can then be transmitted as needed. We show the transmission or telemetry as a distinct part of the system in Figure 3.32 to indicate its importance. Some processing of the signal is often needed before it is displayed or recorded. Often a computer is used to control the whole operation, probably covering many transducers, partly in the light of the information given by the measurements.

For instance, temperatures might need to be determined at many points on a plant. Thermocouples could be used as transducers, other equipment being some distance away, more accessible and in a less severe environment. Temperatures should be recorded at regular intervals; maxima, minima and averages being extracted and an alarm given if any temperature exceeds a pre-chosen limit. Such a system might be part of the control of operational plant, signals being available as inputs for actuators. Alternatively, it might be logging the results of an experiment.

Most data processing and computing use digital signals, as does complex telemetry; simple, short-range telemetry can be analogue. Most transducers have analogue outputs, so an analogue-to-digital converter (ADC) is needed at the input to data processors. If the transducer gives an output in the form of frequency, the ADC can operate simply by counting the number of cycles in a given time.

Communicating to operators the results of measurement is a distinct phase of the whole. It may amount to recording permanently for study later, possibly simply on paper, more probably in some form suitable for computer input. Alternatively, an indication (called Display) may be needed to show immediately the output of the instrumentation system. This is all part of the human/machine interface that is dealt with in Chapter 4.

3.5.1.1 *Accuracy*

The accuracy of any instrumentation system is, of course, of great importance. When making a measurement it is possible to distinguish systematic and random errors. When a measurement of what should be the same thing is repeated it will be found that the readings are not identical; the spread of readings corresponds to random errors between individuals. The final error can be reduced by repetition and averaging

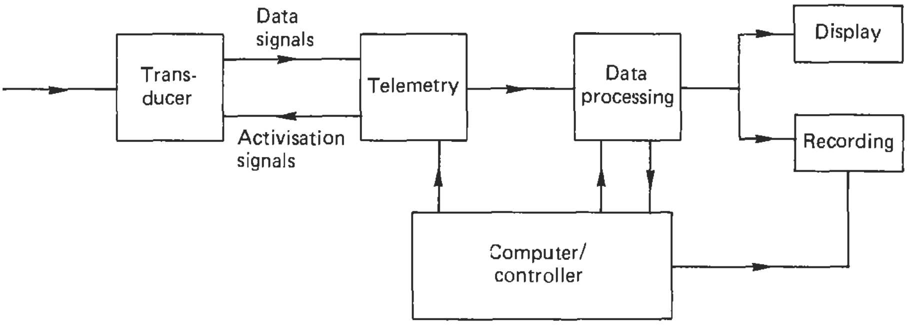

Figure 3.32 Typical instrumentation system

(provided time allows). However, even the average is not necesssarily correct, because it contains the systematic error. Systematic errors can be greatly reduced by careful calibration under conditions resembling the operating ones as closely as possible. Calibration is in fact an important feature of all systems where it is required to relate the readings taken back to absolute values of the quantities concerned. The word 'traceability' is used to describe building up links in this chain. Absolute values of measurands are not always important. Sometimes it is 'repeatability' – the capability of giving the same reading (even if it is the wrong one!) under the same conditions – that matters. The 'precision' of a reading relates to the smallest difference in value that can be detected.

When considering how faithfully an instrument represents what it is supposed to be measuring, the idea of 'influence quantities' should be taken into account. The resistance of a strain gauge, for instance, varies with strain, and so is used to measure it; but it also varies with temperature, so a one-to-one correspondence with strain will only hold provided temperature is constant. Temperature is an influence quantity. Reducing the errors introduced by influence quantities is facilitated by making 'bridge measurements'. This idea is most familiar in electrical circuits, when two components are connected so that changes in them affect the output in opposite directions. It can then be arranged that influence quantities affect them equally and so cancel, while the measurand either only affects one component or affects them oppositely.

Another concept that is helpful in understanding transducer performance is that of 'gauge factor'. This is the ratio of the fractional change in output to the fractional change in measurand. Again it is easily understood in the frequently quoted example of the resistance strain gauge, where it is given by the formula

$$\delta R/R = \delta l/l$$

However, the concept is more generally applicable, with the expectation that a transducer with a higher gauge factor will be more immune to influence factors.

'Hysteresis' is observed in many instruments. This is the name given to the defect of indicating a different output according to whether the quantity measured is increasing or decreasing (see Figure 3.33). Non-linearity is also shown in Figure 3.33. This is the situation when the relation between input and output cannot be exactly represented by a straight line.

3.5.1.2 *Reliability*

The reliability of any equipment is often of the utmost importance, and instrumentation systems are no exception. Attempts have been made to develop the concept of reliability, putting it on a semi-quantitative – though necesarily probabilistic – basis, so allowing the chances of failure to be calculated. While carrying out such an exercise, lessons can be learned of features that have been identified as significant. With large systems, the configuration in which different items are connected can make an unexpected difference. The schedule of servicing plays a large part in the down time that is to be expected. The consequences of any particular failure, which may be very diverse, should be analysed. The idea of 'independence' may be developed; this implies that it is safer for two measurements, if they are intended to corroborate one another, to be made with essentially different components – or even techniques – because they are then less likely to suffer from a common fault. In all considerations of instruments and their installations due weight must be placed on reliability. High accuracy has little value if it cannot be counted on, or perhaps it may be put that the possibility of a very large error can be more damaging than the probability of a small one.

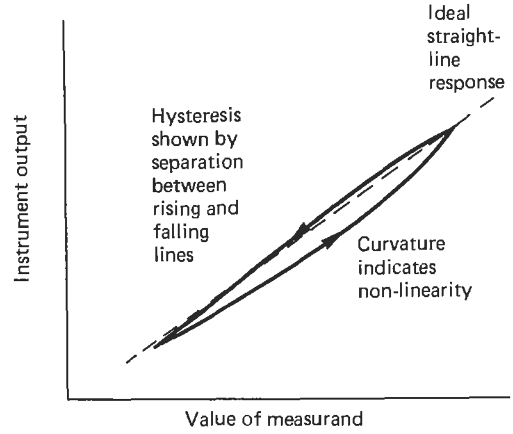

Figure 3.33 Hysteresis and non-linearity errors

3.5.1.3 *Environmental conditions*

In a broad way, it is always recognized that there are limits to the conditions under which instruments can be used. The working temperature range may well be specified. Users should be aware of other significant conditions. The atmosphere can be harmful, from moisture or other corrosive effects; dust in the atmosphere is an enemy to many instruments. Subjection to mechanical abuse (notably excessive vibration) must also be guarded against. More sophisticated hazards include electrical interference and nuclear radiation. The capabilities of particular items to withstand all these are often not spelt out. Common sense is often called for to judge what is reasonable to expect. Sometimes precise limits are quoted by suppliers, but it should be noted that approaching these limits closely may reduce accuracy and especially reliability.

3.5.1.4 Frequency coverage

A simple description of what an instrument does may imply that there is an indefinite amount of time in which to make a measurement – the steady-state or d.c. behaviour. Sometimes this is not the whole relevant story. There are certain devices that cannot be used for steady-state measurements but only for varying ones. There is always an upper limit to the frequency at which an instrument will operate faithfully. This may restrict the number of readings that can be taken in a limited time and is very often of concern when the measurement process is part of a closed control loop (see Section 3.7). It is therefore of great importance to take account of this feature of an instrument's performance.

3.5.2 Dimensional/geometrical measurements

The lengths that people have been interested in and hence wanted to measure range from perhaps 10^{-15} to 10^{18} metres. At the extremes, the interest is mainly from nuclear physicists and astronomers, and we shall here concentrate more on the middle distances that feature more in mechanical engineering.

Of course, there are simple, manual instruments that will continue to be used: rules, micrometers, calipers. A 'dial gauge' incorporates gears to provide magnification so that a movement of even a fraction of a millimetre gives an observable rotation of a pointer. Gauge blocks should be mentioned – elements with accurately parallel faces a precise distance apart; they can be thought of as coming into a calibration exercise, or as forming references allowing the dimensions of other parts to be compared with them.

However, a large part of modern dimensional instrumentation involves converting lengths into electrical (or, occasionally, optical or pneumatic) signals. The three electrical quantities – resistance, inductance and capacitance – are all used in transducers for this purpose.

3.5.2.1 Resistance transducers

In one form of transducer a slider moves over an extended resistance element, which may be either wire-wound or made of some non-metal. The resistance between the contact of the slider and either end of the element varies with the position of the former. Such devices are simple and only need simple electrical equipment. They can be made to obey some non-linear law if that should be wanted. However, they are not of the highest accuracy, and, because rubbing and friction occur, cannot be expected to have indefinitely long lives.

A different form of resistance transducer is the strain gauge. These are described in detail in Chapter 8. In essence, a small element is bonded to a structural unit and changes its resistance with the dimensional changes brought about by the latter being strained. Two gauges being installed are shown in Figure 3.34. The length changes are small (typically a fraction of a per cent) and the resistance changes are generally only a little larger. However, because it is possible to measure electrical resistance very precisely, strain gauges can still be used in accurate work. When directly measuring strain, they are, of course, measuring very small movements – and needing a large force to act on them. The range can be increased and the force reduced by having the movement to be measured applied to a flexible strip on which the gauge is mounted, as shown in Figure 3.35.

Figure 3.34 Strain gauges being installed (courtesy HBM)

3.5.2.2 Inductance transducers

The inductance of a coil is given approximately by

$$L = N^2 \frac{A}{l} \mu$$

where N is the number of turns, A the cross-sectional area, μ the effective permeability and l the length of the magnetic path. For an iron-cored coil with an air gap as shown in Figure 3.36 two very different values of μ arise, and the formula becomes

$$L = \frac{N^2 A}{(l_{\text{iron}}/\mu_{\text{iron}}) + (l_{\text{air}}/\mu_{\text{air}})}$$

Even for small values of the air gap, $(l_{\text{iron}}/\mu_{\text{iron}}) \ll (l_{\text{air}}/\mu_{\text{air}})$ and L is very sensitive to changes in l_{air}. Many inductance transducers make use of this principle.

If extreme sensitivity is not required, the 'iron circuit' need not be so nearly closed. An example of an instrument of this

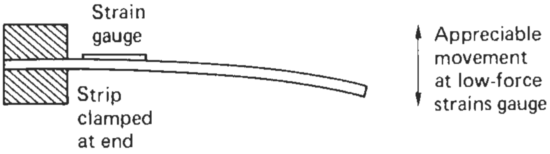

Figure 3.35 Strain gauge on flexible strip

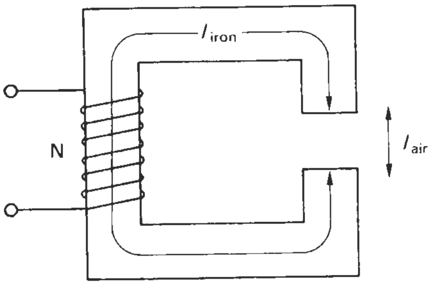

Figure 3.36 Coil with air gap

type is the linear variable differential transformer (LVDT), where there are two further refinements shown in Figure 3.37:

1. A differential system is used so that the inductance of one winding increases at the same time as that of another decreases; and
2. By having a further winding, a *mutual inductance* or transformer replaces the self-inductance.

These additions increase the magnitude and linearity of the output and give an inbuilt bridge system, so increasing the effective gauge factor. Figure 3.38 shows how small these devices can be made.

While most practical devices employ ferromagnetic (iron) cores, it is, in principle, possible to have an air-cored inductor serving as a transducer.

3.5.2.3 Capacitance transducers

The electrical capacitance in farads between a pair of parallel plates (as shown in Figure 3.39) is

$$C = \varepsilon_0 \varepsilon \frac{A}{d}$$

where ε_0 is the permittivity of free space ($= 8.9 \times 10^{-12}$ F/m),
ε is the relative permittivity of the material between the plates,
A is the area of either plate, or of their overlap if they are not exactly equal and opposite, and
d is the separation between the plates.

C can therefore be changed by changing either A or d. Since d can be a millimetre or less, while the lengths involved in A are likely to be a centimetre or more, and the percentage change in C equals the percentage change in A or d, it can be seen that variable-d transducers are more sensitive than variable-A ones, i.e. those in which the overlap is changed. On the other hand, the proportionality between C and A makes the second type inherently linear, unlike the inverse C/d relationship when the gap is varied. A differential arrangement, in which the same movement increases one capacitance and decreases another, is often used and can improve linearity.

A variety of constructions have been used. One example is shown in Figure 3.40, where it can be seen that movement of an earthed screen alters the capacitance between the central, cylindrical electrode and one of the outer, co-axial electrodes, while the reference capacitance to the other electrode remains constant. Figure 3.41 shows an embodiment of this principle, the super-linear variable capacitor (SLVC).

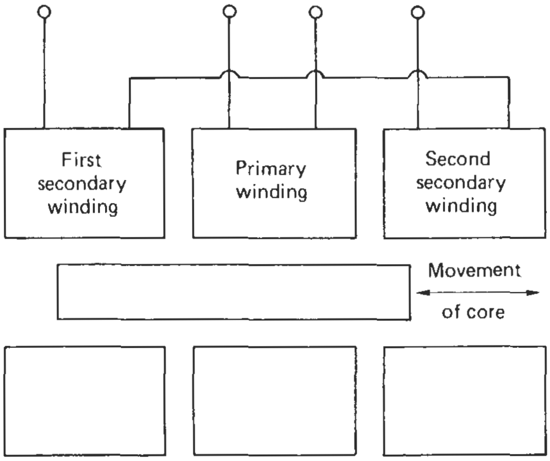

Figure 3.37 Linear variable differential transformer (LVDT)

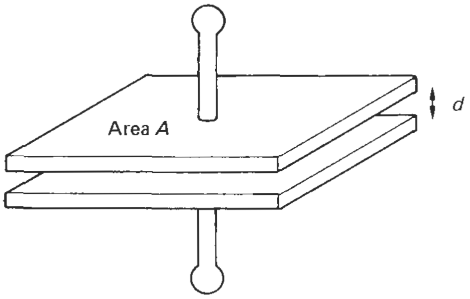

Figure 3.39 Parallel plate capacitor

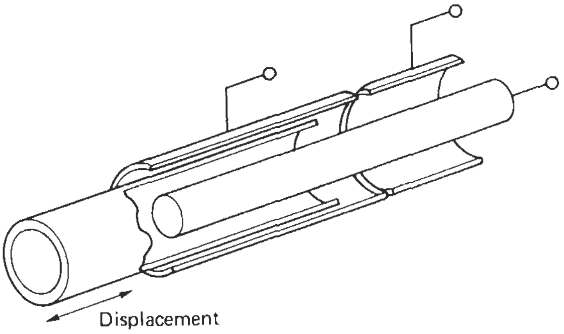

Figure 3.40 Cylindrical form of variable-area capacitance transducer (courtesy Automatic Systems Laboratories)

3.5.2.4 Electrical circuits and comparison of techniques

Resistance measurements are simple and straightforward for the large changes involved in sliding contact devices; the basic accuracy of the transducer may not be high enough to justify elaborate circuitry. The much smaller changes in devices using strain gauges call for the use of bridge circuits, and some form of bridge configuration is usual for inductance and capacitance

Figure 3.41 Super-linear variable capacitor (SLVC) (courtesy ASL)

transducers. Audiofrequency (AF) power supplies are used for resistance and inductance measurements, though d.c. is, of course, also effective for resistance.

Circuits used for capacitance measurement must take account of the stray capacitance that occurs between nearby conductors unless they are specifically screened from each other. Thus in Figure 3.42 capacitance variations between its lead and earth (either within or outside the screened cable) are indistinguishable (to the measuring circuit) from transducer capacitance changes. Various arrangements can be adopted to overcome this problem. The relatively small capactiance in most transducers corresponds to a very high impedance at lower frequencies and this is an argument for working at higher frequencies, but in fact AF bridge systems with very high sensitivities are available and give good performance when spurious effects are eliminated.

Many considerations come into the choice of transducer technique. As a very simple summary, it may be suggested that resistance devices are simple and inexpensive, inductance devices, while tending to be larger and more complicated, have a long history of development and mass production. Capacitance devices, simple and sensitive in principle, need more elaborate circuitry, but may well give the best approach for particualrly onerous requirements. Sometimes the force needed to move a transducer element is important. In general, the force is less for capacitors than for inductors, while with variable resistors it may be less repeatable.

3.5.2.5 *Optical methods of position measurement*

Some classical experiments in physics depend on optical interference. If two coherent light beams are superposed they reinforce or cancel each other, according to whether they are in or out of phase, and this phase difference depends on the different lengths of the paths they have travelled. If they have travelled the same distance or their paths differ in length by an integral number of wavelengths then they reinforce, while if their paths differ by an odd number of half wavelengths they cancel.

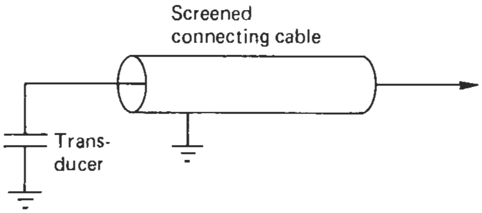

Figure 3.42 Effects of stray capacitance

Figure 3.43 shows how this can be used for an accurate measurement of movement. As the mirror M moves, the light intensity changes from maximum to minimum and back for successive distances of half a wavelength – a fraction of a micrometre, making the system highly sensitive. Refinements are needed to determine the direction of motion, and to give general stability; a corner cube reflector instead of a simple mirror eliminates the otherwise high sensitivity to the angle of the mirror. A laser is a convenient source of coherent radiation. The output signal, going through a succession of peaks, is essentially digital.

Moiré fringes are sometimes used to measure movement. Figure 3.44 shows two adjacent gratings as seen from above. If they are positioned as in (a) light can pass through, but if one is moved by half a 'wavelength' as in (b) the path is blocked and the combination appears dark. The 'wavelength' or pitch can be very short, as small as a few micrometres (the name Moiré comes from the silk weave in which the effect can be observed), giving a high potential accuracy. Again there is a basically digital output and the need to determine the direction of movement.

As shown in Figure 3.44, the interrogating light is transmitted through the gratings; it is, of course, possible to have a mirror system when the light source and detector are both on the same side of the gratings. The gratings may be at an angle to each other (Figure 3.45), when the alternate bright and dark areas form fringes perpendicular to the gratings; the fringes move bodily with linear displacement of either grating, while the separation between them depends on the angle between the two.

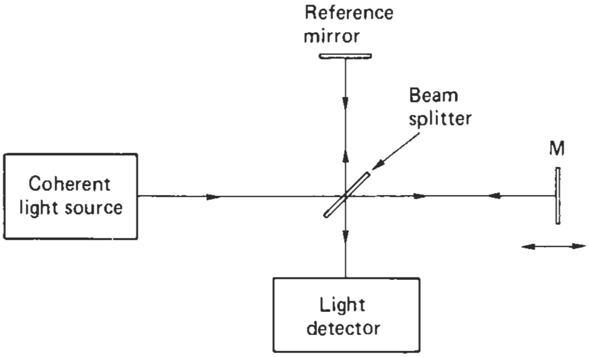

Figure 3.43 Movement measured by optical interference

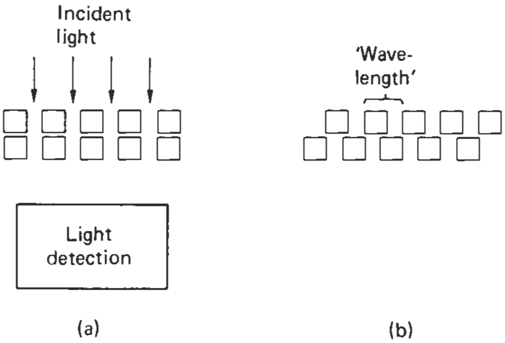

Figure 3.44 Principle of Moiré fringes

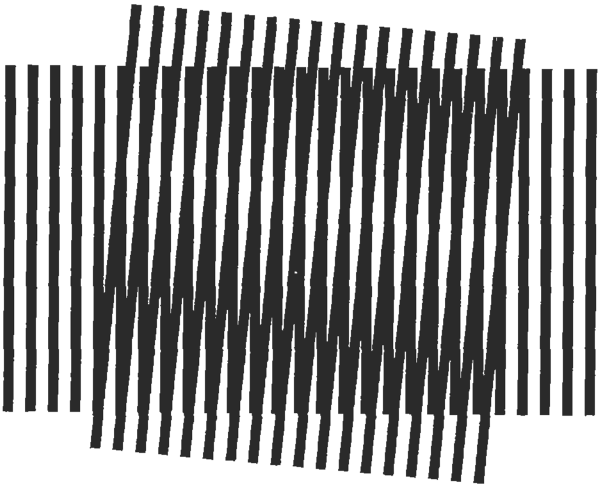

Figure 3.45 Moiré gratings at an angle

If the gratings do not have quite the same pitch, there are fringes parallel to the grating elements (Figure 3.46). This principle is sometimes used in strain measurement, when the strain to be measured is arranged to alter the pitch. In all these arrangements there is an effective magnification, so that small movements, on the scale of the small pitch of the gratings, give rise to much larger movements of the fringes.

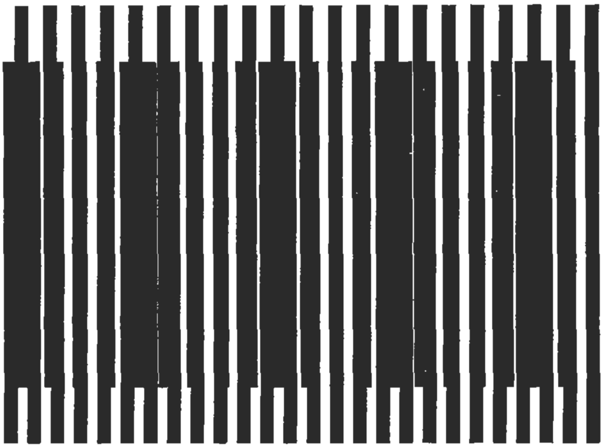

Figure 3.46 Unequally spaced Moiré gratings

3.5.2.6 *Pneumatics*

Currently, pneumatic instrumentation systems are used less than electronic ones. They have the drawbacks of needing somewhat delicate mechanical devices and of introducing significant delays when signals are transmitted over long distances. However, they are by no means extinct and have the great safety advantage that there need be no question of their introducing electric sparks.

The heart of a pneumatic instrument is a flapper adjacent to a nozzle as shown in Figure 3.47. As the separation, *d*, between these is changed, the air flow through the nozzle changes markedly and hence also the pressure drop across the 'series' restrictor. A typical relation between *d* and the pressure *P* just upstream of the nozzle is shown in Figure 3.48. The effect can be amplified by the introduction of further elements in the shape of valves and a pressure-sensitive diaphragm. The primary behaviour is inherently non-linear, but the use of a pressure-feedback device with levers and a spring-controlled bellows allows a movement of the order of a millimetre to give a proportional pressure change of some tens of kilopascals.

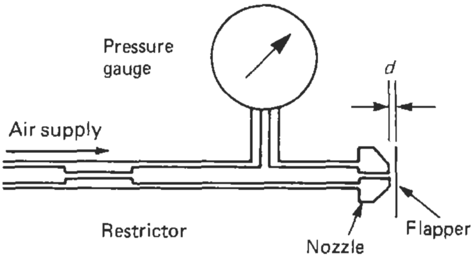

Figure 3.47 Pneumatic nozzle and flapper (courtesy Foxboro Company)

3.5.2.7 *Angular displacement*

The synchro – sometimes called a Magslip or Selsyn – is widely used in the measurement of angles. If a.c. is applied to the central element (rotor) of such a device (left-hand side of Figure 3.49) then the voltages induced in the three circumferential windings depend on the angular position of the rotor

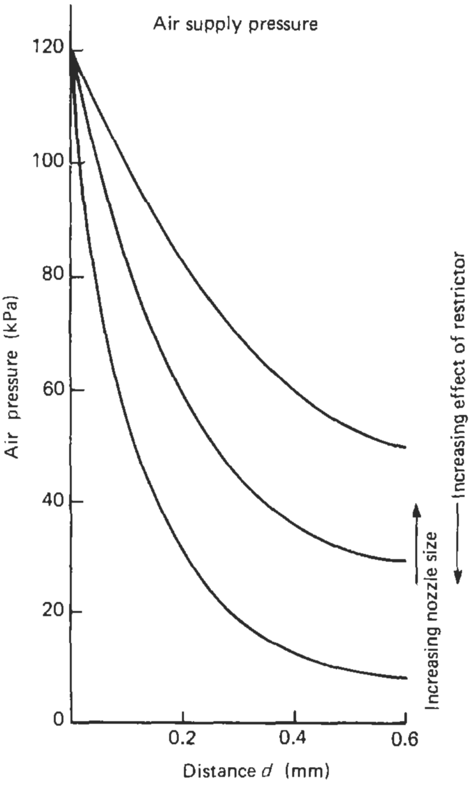

Figure 3.48 Relation between pressure and gap for pneumatic device (courtesy of Foxboro Company)

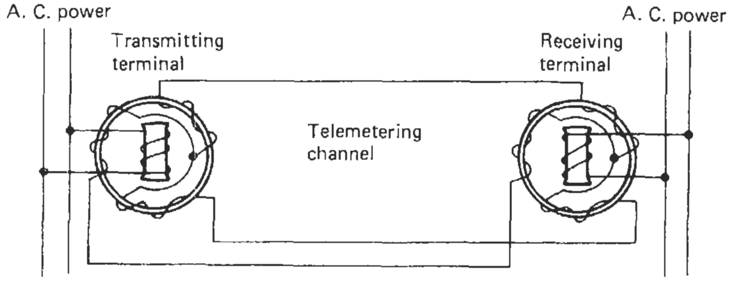

Figure 3.49 Principle of synchro

relative to them. This system has the particular advantage that if a second, identical unit is connected appropriately (right-hand side of Figure 3.49) forces will act within it until the two rotors take up identical angles. This is a robust and widely used technique for telemetering an angular position.

Capacitive transducers with variable overlap readily give a measurement of angle. The arrangement is in fact just that of the orthodox variable capacitor.

Encoders are used to give a digital signal corresponding to angular position. Moving clockwise round the disc shown in Figure 3.50, it can be seen that successive positions 1,2,3 . . correspond to successive binary numbers if black and white areas give digits 1 and 0, respectively, for powers of 2 starting at the largest radius. Black can be distinguished from white using six optical beams in the example shown, or a single beam can be traversed radially across the encoder. Alternatively, the distinction can be between conducting and insulating material, detected electrically.

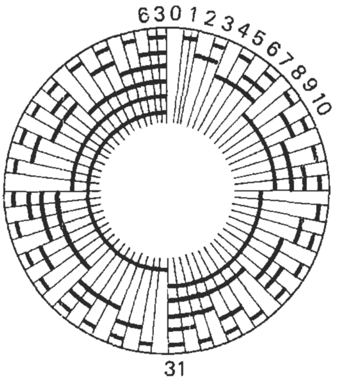

Figure 3.50 Encoding for angular position

A difficulty with this form of coding follows from imperfections of manufacture. Considering, for instance, the move from position 7 to position 8, if the outermost black should turn white slightly before the others, the configuration will momentarily correspond to position 6, while premature changes of the other blacks would indicate 5 or 3, respectively. The problem arises from the need for simultaneous changes at more than one radius, and to overcome this, codes have been devised in which only one change occurs at a time. As indicated previously, small changes of angle can also be detected with Moiré fringes.

3.5.2.8 Velocity measurement

Angular velocity is commonly measured employing electrical induction. Using the fundamental law that induced voltage is proportional to rate of change of flux, generators, either d.c. or a.c., can be made for which output voltage gives a direct measure of the speed of rotation. Under a completely different principle, a technique is to mount markers on the circumference of a rotor and count the number passing a stationary point in a given time, or alternatively, the time lapse between successive passages, which can be detected optically, magnetically or electrostatically. This system, of course, provides a digital output; it requires a finite time to give an indication.

Linear velocity is sometimes deduced from angular velocity as in a car's speedometer. It can also be calculated as the rate of change of position or as the integral of acceleration, and this is particularly relevant to vibration studies (Section 3.5.4). Measurement of fluid velocity is discussed under Flow in Section 3.5.7.

3.5.3 Volume and level

Volume, as such, is a quantity that is seldom measured. Instrumentation for rate of change of volume (or flow) is widely applied and can be integrated to give total volume; this is dealt with in a later section. Volume and mass are simply related through density and mass can be measured as weight. Again, the volume of material in a container can be inferred from the level it reaches, and this is a common measurement.

Measuring level, we can distinguish between continuous, normally analogue methods and digital techniques, in which the action is really detection rather than measurement. The presence or absence of the material in question at a particular level is indicated. The second category can be used, as shown in Figure 3.51, to move a 'follower' outside the container under study so that it remains opposite the internal interface, allowing the height to be measured in a more accessible place.

The level of a liquid conductor can be found from resistance measurement. Figure 3.52 shows two resistive wires that are effectively short circuited where they enter the liquid, so that the resistance seen at their terminals decreases as the level rises.

For an insulating liquid, capacitance measurement is appropriate. With the arrangement of Figure 3.53, capacitance increases as the level rises and a larger area of the overlapping plates is separated by a dielectric of higher permittivity. A sonar-ranging system can also be used in which the time taken for an echo to return from the surface being studied gives an indication of its position (Figure 3.54).

A sophisticated single-point technique involves passing gamma rays through the container. These will be more attenuated if there is a denser material in their path, so the intensity of radiation received at the detector shows whether liquid (or solid) rather than just gas is present. In Figure 3.55 it can be recognized that the detector output will be larger if the level of liquid in the container falls below the line from source to detector.

Different types of probe have been devised for detecting the presence of a liquid that depend on refractive index or resistivity or permittivity, all of which may have different values above and below the interface whose level is to be detected. Yet another technique is to measure level as a differential pressure. If one pressure transducer is mounted internally at the bottom of a vessel and another at the top, then the difference between the pressures they show will depend on how much of the height between them is occupied by liquid and how much by gas (i.e. on the level of the former).

3.5.4 Measurement of vibration

Wider aspects of vibration, which may be thought of as movement over small distances at comparatively high frequencies, are discussed in Chapter 1. Here we touch briefly on techniques of measurement.

In sinusoidal motion at frequenty ω, linear amplitude s, velocity v and acceleration a are simply related as

$$a = \omega v = \omega^2 s$$

$$v = \omega s$$

Displacement can be measured using techniques described in Section 3.5.2, or velocity with a generator, commonly a coil moving in the field of an electromagnet. If a nearby point is known to be stationary, either measurement can be relative to this. Alternatively, part of the transducer can be an element with sufficient inertia not to move, when the measurement can be made relative to that. The criterion whether the inertia is large enough is that the resonant frequency of the element – decided by its mass and its flexible mounting – should be much lower than any frequencies in the vibration.

Vibrational accelerations are very often measured, using the associated force F, where $F = ma$, and m is an inertial mass. In this case, the element's resonant frequency must be much greater than the highest vibrational frequency to ensure that a is the same as the acceleration of the part on which the transducer is mounted. A piezoelectric device often forms the link to the intertial mass, the charges excited in it providing the output signal, while its high degree of stiffness gives a high resonant frequency. The wide range of mass and the variety of piezoelectric elements that may be used give scope for a wide range of applicability for vibration pick-ups.

We may want to know the frequencies contributing to the vibration studied. For this, some form of spectrum analyser will be desirable.

3.5.5 Force/weight measurement

This field of instrumentation gives good examples of some general principles mentioned in Section 3.5.1. Concerning speed of response, in many instances the measurement called for is a static one, but sometimes a quickly varying force is to be studied, and this calls for a different approach. The potential accuracy varies more than a thousandfold – with corresponding price ranges for equipment. Sensitivity to extraneous influences is also a factor in accurate force measurement, where errors from temperature, wrong location of the force and other things must be guarded against. Weight, of course, is a force, and, in general, it is measured in similar ways to other forces, though the measurement is always a static one.

Lever-type instruments, such as the classical analytical balance, are basically devices for comparing forces – often the weights of different masses. Unequal lever arms allow widely different forces to be compared; an arm of variable length allows a precise ratio to be established without the need for an adjustable force. The spring balance is the most familiar member of a large family of instruments in which the force to be measured is balanced by the reaction from an elastically strained member whose distortion can be measured.

The proving ring illustrated in Figure 3.56 is a refined form of spring balance. The applied force, which may be compressive or tensile, distorts the ring from its intially circular shape. The change in diameter (measured mechanically with a dial gauge or electronically) indicates the force. Much smaller movements are measured than with a coil-spring spring balance, making the total system more compact.

In a strain-gauge load cell the process is taken rather further, the elastic strains in a member being directly measured with strain gauges, allowing very compact devices to be constructed. The principle of a simple, columnar load cell is shown in Figure 3.57; the four strain gauges are connected into the four arms of a bridge. Structures in which shear strains are measured are also widely used; their readings are less dependent on the position where the load is applied. Two instruments of this type are shown in Figure 3.58. In hydraulic load cells the unknown force alters the pressure in a liquid system, allowing it to be measured as a pressure. Load cells can be built into the supports of hoppers to weigh their contents, or included in weighbridges.

Systems of particular value for dynamic measurement of quickly changing forces include piezoelectric elements, mentioned in connection with vibration instrumentation. Force balance systems are also used. Figure 3.59 shows how the displacement produced by a force to be measured can control the restoring force in a coil, the current in which gives a direct indication of the first force provided the gain is large and the displacement small – with due attention paid to stability.

Table 3.2 summarizes the features of different ways of measuring force.

3.5.6 Pressure

Pressure is easily measured from the difference in level of the liquid in two arms of a U-tube (Figure 3.60):

$$P_1 - P_2 = h\rho$$

where ρ is the density of the liquid. Mercury is commonly used as the working liquid. Its high density means that a large pressure difference can be measured without the equipment becoming too big in order to accommodate a large h. There is greater sensitivity if mercury is replaced by water. Further movement for a given pressure difference can be achieved if such a manometer is at a small angle to the horizontal instead of being held vertical. Care must be taken that the liquid can move freely over the inside surface of the tube (otherwise there will be hysteresis) and that any distortion of the surface from surface tension is the same in both limbs.

Integral loading boss suitable for tensile & compressive forces

Figure 3.56 Proving ring

Note that it is pressure *differential*, $P_1 - P_2$, that is of concern. Three situations should be distinguished:

1. Absolute pressure, where P_2 is zero, corresponding to a vacuum;
2. Gauge pressure, where P_2 is the atmospheric pressure in the neighbourhood of the equipment;
3. Differential measurements where both P_1 and P_2 may vary but it is their difference that is significant.

Pressure can be measured in terms of its fundamental definition of force per unit area. In Figure 3.61 if the cross-sectional area of the cylinder with its piston is known, then the pressure, P, is directly given by the force, F (usually a weight), needed to balance it. This method can give high accuracy, but there are practical complications, notably to ensure that the piston can move freely without the liquid leaking, so it is used mainly to calibrate other pressure gauges.

Neither of these approaches uses compact equipment or leads directly to an output signal, so they are often replaced by the use of transducer elements. Various configurations change shape with pressure and the consequent displacement can be used for measurement.

A Bourdon tube has an elliptical (or otherwise unsymmetrical) cross-section and is bent into a circular arc (Figure 3.62). If the pressure inside the tube increases, it tends to make the cross-section more nearly circular, and this in turn straightens the arc. With some further mechanical amplification, the movement is large enough to be read against a scale.

A metal diaphragm distorts according to the difference in pressure of the fluid on either side of it. The sensitivity varies widely with the dimensions. A wide, thin diaphragm moves appreciably under small pressures, and the danger of its rupturing under overload can be greatly reduced by the provision of 'stops'. The movement can be detected pneumatically or by capacitive or inductive devices.

An alternative approach is to measure strain in the diaphragm. Since different parts are strained in different senses, strain gauges connected in different arms of an electrical bridge can be mounted on a diaphragm so that their pressure-induced outputs sum while the spurious changes from, for example, temperature variation cancel each other out. A development from this is to have the strain gauges integral with the diaphragm. Using appropriate fabrication techniques, a silicon member can serve as diaphragm and can have certain parts modified and electrically insulated so that their strain-sensitive properties can be used to give an electrical output.

Stiff diaphragms – with a high natural frequency – allow rapidly changing pressures to be measured. Other devices have much slower responses, but often the measurement required is only of quasi-static pressure. Pressure transducers including piezoelectric force measurement have a quick response but cannot be used statically.

3.5.6.1 Vacuum

Some widely different methods are available for measuring vacuum (i.e. a pressure less than atmospheric). As conditions approach the zero of absolute vacuum, measurements become increasingly difficult.

Table 3.2

Method	*Type of loading*	*Force range, N (approx.)*	*Accuracy % (approx.)*	*Size*
Lever balance	Static	0.001 to 150 k	Very high	Bulky and heavy
Force balance	Static/dynamic	0.1 to 1 k	Very high	Bulky and heavy

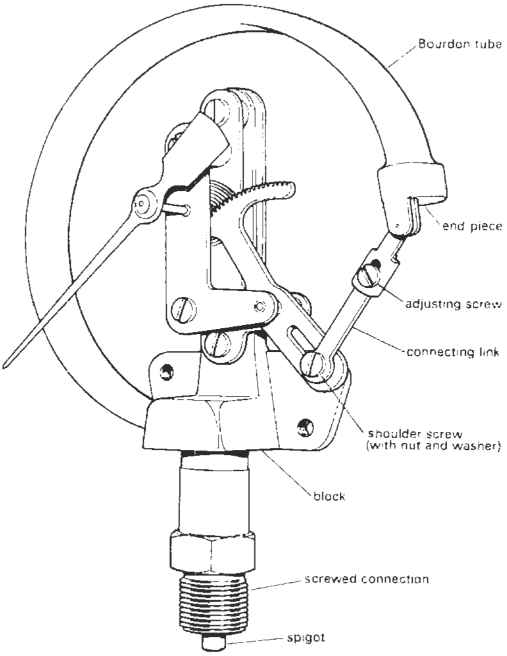

Figure 3.62 Bourdon tube pressure gauge (courtesy Budenberg Gauge Company)

In a low vacuum (i.e. an appreciable fraction of an atmosphere) instruments described in the previous section can be used. The McLeod gauge is a development from the U-tube manometer, in which a sample of gas is compressed by a known amount before its pressure is measured; this allows much lower initial pressures to be measured. Two other broad techniques are used for high vacua.

With thermal conductivity instruments (notably the Pirani) use is made of the fact that the larger number of molecules in a gas at higher pressure increase its heat transfer, so that measurement of the temperature of a heated member can indicate the degree of vacuum surrounding it. In ionization instruments (Buckley, Penning, Bayard-Alpert) the current resulting from ions in the vacuum is measured. This gives the population density of ions and hence the pressure.

The ranges over which different techniques can be used are shown in Table 3.3.

3.5.7 Flow

An important and widely applied field of instrumentation is the measurement of fluid flow. Sometimes the concern is to measure velocity at a 'point'. More often the requirement is for a single measurement representing the total volume of fluid passing along a pipe or other container – though this can be achieved by integrating from 'point' values. Instantaneous readings for flow are of primary interest; often their time integral (i.e. the total volume that has passed) needs to be known. Gases, as well as liquids, come under study. Occasionally, the main interest is with the mass rather than the volume that is passing.

Conceptually, the most direct form of instrumentation for flow measurement is the positive displacement meter, in which it is arranged that a known volume is repeatedly filled and emptied and the number of times that this takes place is counted. Of this type is the common, domestic gas meter, whose operation is illustrated in Figure 3.63. The capacities of chambers A and B are altered by a known volume as the diaphragm between them moves between the limits of its travel. A suitably phased slide valve ensures that the two chambers are connected alternately to the inlet manifold and to the outlet. For smoother operation, A and B are duplicated by C and D, running out of phase with them.

In other types, the volumes that are alternately filled and emptied are defined by rotating parts, either on a single axis or by two meshing rotors as shown in Figure 3.64. Care must be taken that sealing – usually by a liquid – is effective while still allowing free movement under the small forces associated with gas at low pressure.

3.5.7.1 Positive displacement for liquid flow

Similar devices are available as flow meters for liquids. A rotating piston, mounted eccentrically in a larger cylinder, is a common arrangement. Reciprocating pistons are also used as well as the sort of rotary systems described for gases. A turbine meter (Figure 3.65) may be thought of as a positive displacement instrument, having been designed so that the angle its bladed rotor turns through is proportional to the volume of liquid that has passed (axially) through the meter.

With all these meters, the number of rotations or excursions must be counted, the flow rate, of course, being given by the number occurring in a particular time. Information about internal movements must be conveyed through a container wall to the outside, and this is often done by the passage of permanent magnetic poles past external pick-ups.

Table 3.3 Comparison of vacuum gauge techniques

Technique	*Pressure range* (Pa)	*Accuracy* (±%)	*Cost*[a]	*Advantages*	*Limitations*
Bourdon tube	10^{5}–10^{2}	10	A	Simple, robust	Poor accuracy below 100 Pa
Diaphragm	10^{5}–10	5	B	Good general-purpose gauge	Zero setting varies
Liquid manometer	10^{5}–10^{2}	5–10	A	Simple, direct reading	Vapour may contaminate vacuum
McLeod	10^{5}–10^{-3}	5–10	C	Wide range. Used for calibration	Intermittent. Measures *gas* pressures only
Thermal conductivity	10^{3}–10^{-2}	10–20	C	Can be robust, with fast response	Risk of zero variation
Ionization	10^{2}–10^{-8}	20	D	Sensitive, fast response	Care needed in use

3.5.7.2 *Differential pressure*

Where the cross-sectional area of a pipe changes, so does the pressure of a liquid flowing in the pipe, and the magnitude of the pressure change depends on the flow rate. This is often used as the principle of a flow meter. Two configurations of changing cross section may be distinguished: the Venturi throat and the orifice plate.

In the former, a smooth profile serves to reduce the area (Figure 3.66); in the latter, changes are more abrupt (Figure 3.67). The Venturi has the advantage that less energy is absorbed, but at the cost of greater size and expense. Profiles different from either of these are sometimes used. In the Venturi, the difference in pressure between the throat and a point upstream is measured. With an orifice plate, the two relevant pressures are simply those upstream and immediately downstream of the plate, since for some distance downstream the effective area is still that of the orifice.

There is a square-law relation between the flow-rate Q (m^3/s) and the differential pressure, Δp:

$$Q^2 \propto \Delta p \quad \text{or} \quad Q = k\sqrt{\Delta p}$$

In some circumstances this is an inconvenience.

One of the factors in the proportionality is the area A at the point of restriction:

$$Q = cA\sqrt{\Delta p}$$

and in one type of flow meter, the Rotameter, Δp is kept constant and A made variable. This is achieved as shown in Figure 3.68 by having the liquid flow up through a tapered tube in which is placed a plummet whose weight causes the differential pressure. Increasing flow carries the plummet to a point where the annular area around it is such as to satisfy the equation.

Superficially similar to differential pressure types is the Target Flowmeter, in which the force exerted on a body obstructing the flow is used as an index of that flow. This again follows a square-root law.

3.5.7.3 *Open channels*

The measurement of flow in an open channel (or a closed duct that is not completely filled with liquid) calls for a different approach. Flow over a weir may be measured by noting the level to which the liquid rises in a 'notch' in the weir. If there is not an adequate head of liquid to allow construction of a weir, the channel may have a 'flume' built into it; this is a construction similar to the throat of a Venturi tube, and again the pressure readings at appropriate points allow the flow rate to be calculated. In either case, the water level corresponding to a particular point in the flow is measured in another chamber – a 'stilling well' – connected by a small pipe.

Maximum flow rate due to maximum annular area is obtained with float at large end of tube
Noting position of edge of float referred to capacity scale on glass gives flow rate reading
Metering float suspended freely in fluid being metered
Tapered transparent metering tube (borosilicate glass)
Minimum annular area and minimum flow rate is obtained
Fluid passes through this annular opening between periphery of float head and I.D. of tapered tube. Of course, flow rate varies directly as area of annular opening varies

Figure 3.68 Rotameter (courtesy Fischer and Porter)

3.5.7.4 *Newer flow-meter principles*

Three techniques may be mentioned that have more recently been developed to measure flow. When an obstruction is mounted in a pipe, the flow can be disturbed so that vortices are shed alternately from its opposite sides, and the frequency of this shedding is accurately proportional to flow rate. Sensitive detectors are needed to detect the vortices, commonly using their pressure or cooling effects, or their modulation of an ultrasonic beam. The method has the advantage of not being dependent on the exact sensitivity of the detector; in fact it uses a digital signal, namely frequency.

Electromagnetic flow meters use the principle of Faraday's law of electromagnetic induction. This states that a conductor moving in a magnetic field will give rise to an electromotive force (i.e. potential or voltage). The field, the movement and the potential are all mutually perpendicular. In a conventional electrical generator the conductor is a wire, but it can equally be a conducting liquid such as water. All that is needed is to provide a magnetic field – commonly non-sinusoidal at a low frequency – and suitably insulated electrodes in contact with the liquid.

A time-of-flight ultrasonic flow meter depends on the fact that sound pulses are transmitted more quickly downstream than upstream. The transmission time across flowing liquid which is the medium thus depends on which is transmitter and which receiver. The transmission path must not be straight across a pipe, but it does not have to be strictly axially along it, and an arrangement as in Figure 3.69 is adopted. Various forms of electronic processing are usefully applied to the primary time-of-flight data.

3.5.7.5 *Measurement of velocity at a point*

The flow meters described so far are concerned with measuring the total flow rate in a stream. It is also sometimes of interest to measure the local velocity in an extended volume of fluid. This approach can be used to measure total flow by having a representative number of points to cover the complete cross section of a stream.

The Pitot tube comes into this category. This has a small orifice facing into the fluid flow, and closed so that fluid cannot escape. The pressure build-up will then be velocity dependent, in fact with a square-root relationship

$$v \propto \sqrt{p}$$

The Pitot can thus be thought of as a differential pressure device, with p the difference between what is measured in the tube and the static pressure in the fluid nearby, only the primary measurement is of point velocity rather than total flow rate, as is the case with an orifice plate.

The hot-wire anemometer uses the fact that the cooling effect of a flowing fluid increases with the fluid's velocity. A wire is heated and the temperature excess above its surroundings is measured. With a fine wire, the instrument can respond very quickly, particularly if a feedback system is introduced so that the heating power supplied is altered to maintain a nearly constant excess temperature.

The turbine meter is used to measure 'point' velocities, particularly in surveys of large stretches of water.

Doppler techniques, where the frequency of some radiation is changed at reflection from a moving object, should also be mentioned under this heading. The ultrasonic Doppler flow meter is shown in Figure 3.70. A frequency, f_t, is sent out from the transmitter and the receiver registers a frequency f_r. The flow velocity V is then given by

$$V = \frac{c(f_t - f_r)}{2f_t \cos\theta}$$

where c is the velocity of sound in the flowing fluid – which must contain some discontinuities to give reflections. As described, this refers to reflection from a single point; in practice the method is used for total flow measurement taking the mean f_r as corresponding to the average of the different values of V across a pipe.

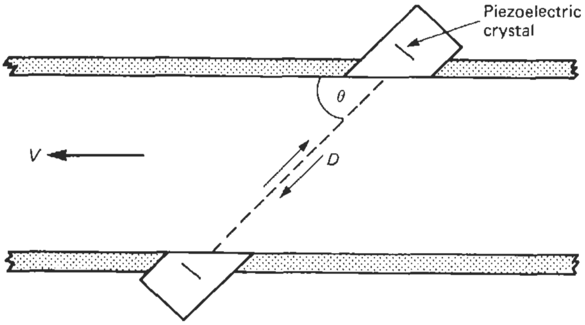

Figure 3.69 Time-of-flight ultrasonic flow meter

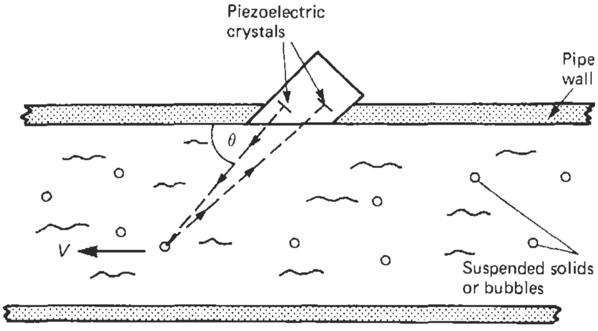

Figure 3.70 Ultrasonic Doppler flow meter

Laser Doppler techniques are a development from this, using electromagnetic instead of acoustic radiation. The closer positional control that is possible with laser beams allows more precise location of the point of reflection – at the cost of more complicated equipment.

3.5.8 Temperature measurement

Although we daily experience its effects, the scientific concept of temperature is an involved one, linked with energy on an atomic scale and not directly accessible. To measure it we therefore need some property that varies consistently as temperature varies.

3.5.8.1 *Thermal expansion*

A simple effect is thermal expansion. Mercury-in-glass thermometers depend on the expansion coefficient (defined as the fractional change in volume for one degree change in temperature) of mercury being larger than that of glass. The well-known shape of a bulb opening into a fine capillary tube allows the change in relative volumes to show as a change in position of the top of the thread of mercury in the capillary. Note that the space above the mercury must be evacuated so that pressure in it does not build up, and that the whole of the bulb should be at the temperature to be measured.

The linear expansion of a solid can also be used for a thermometer. Unless a reference frame at a known temperature should happen to be available, it will again really be a question of relative expansions of different materials. A 'bimetal strip', as shown in Figure 3.71, is used to magnify the movement. In such a strip, two metals of very different expansion coefficients, e.g. brass and Invar, are bonded together, when their combined curvature will alter as they warm up in order to equalize tensile and compressive forces in the strip. A direct pointer thermometer can be made by coiling the bimetal into a suitable spiral or helix as shown in Figure 3.72.

3.5.8.2 *Thermo-couples*

Other temperature-dependent properties are electrical. Thermocouples are widely used. They depend on an e.m.f. being set up in the circuit if two different metals are connected in series and their two junctions are not at the same temperature. Knowing one temperature and the controlling law, the other temperature may be deduced.

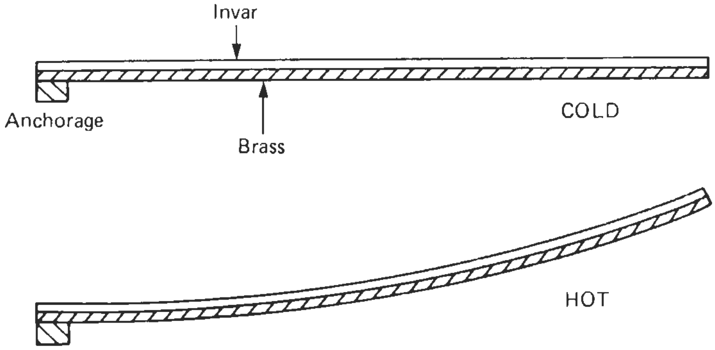

Figure 3.71 Bimetal strip

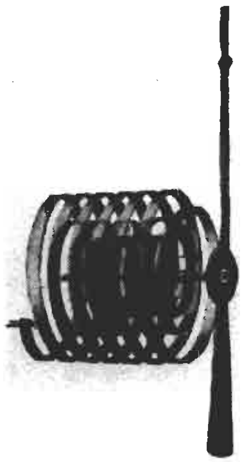

Figure 3.72 Bimetal thermometer

The provision of measuring circuitry is greatly simplified because additional series junctions at intermediate temperatures (but with the same pair of metals) do not affect the aggregate e.m.f., and also further metals can be included provided all their junctions are at the same temperature. As shown in Figure 3.73, a parabolic relation generally holds, for a given cold junction, between e.m.f. and hot junction temperature. If the peak of the parabola is far enough away from the temperatures to be measured (as is the case for some metal pairs) the characteristic will be approximately linear. However, a firm limit for the working range is set by the reduced sensitivity in the neighbourhood of the peak and, worse, by the ambiguity that arises for temperatures beyond the peak, because two temperatures then correspond to the same voltage output.

Questions of corrosion also limit the type of thermocouple that can be used at high temperatures. Base metals are satisfactory below perhaps 1000°C; the more expensive noble metals and alloys are necessary to cover higher ranges. Some characteristics of common thermocouples are given in Table 3.4.

Potentials generated by thermocouples are never more than a small fraction of a volt. To measure this so as to give an acceptable accuracy calls for a precision of a few microvolts, but great sensitivity is easily achieved in electrical measurements so that problems arise more from the errors introduced by spurious effects than from the absolute low signal level.

Calculations are often based on the 'cold' junction being held at 0°C. Rather than do this physically with a thermostat, it may be more convenient to introduce compensation from a component whose resistance varies with temperature in a known way (see Figure 3.74). Since it is only necessary to cover a small temperature range, changes can be thought of as linear.

If the e.m.f. of a thermocouple were translated into a current, the resistance of the leads in the circuit would come into the equation and unknown variations along their length, caused by the temperature changes there, would cause errors. This is eliminated if the working current is reduced to zero, either by using the 'null' technique of a potentiometer (when an equal and opposite potential opposes the output of the couple) or by having a detector with a high-input impedance.

With base-metal couples or short cable runs it is not impossible to use the same metals from hot junction to cold, and the additional circuitry can be at nearly constant, room temperature. The expense of a long run of noble metal can be avoided by replacing it, for most of its length, by a cheaper alloy, chosen so that its thermoelectric behaviour matches that of the noble metal over the limited temperature range to which most of the cable is subjected.

The two metals making up the thermocouple are commonly in the form of wires, forming leads as well as a junction. Bare wires welded or even twisted together can make an effective device, having, in fact, the advantage of a quick response. Note that if there are several points of contact it will be the coldest that is measured – the higher potential of the hotter junction being short-circuited through the colder. It is often convenient, however, for the couple to be supplied in a sheath having appropriate internal insulation and the whole forming a robust, replaceable unit. Metallic sheaths are the most common, but at the highest temperatures a ceramic construction gives greater protection against corrosion.

A mineral-insulated form of construction (MI) is widely used. In this, wires of the two different materials are located within a metal sheath and insulated from it and from each other by ceramic powder. It has been established that good insulation and stability are maintained even when the whole combination is drawn down to a very small cross section, perhaps as little as 1 mm overall. Figure 3.75 shows how the junction may either be insulated or welded to the tip of the sheath; the latter gives a quicker thermal response but consequences for the electrical circuit may be undesirable. Some of

Table 3.4 Characteristics of some common thermocouples

Type	*Composition*	*Approx. temp range* (°C)	*Typical output (cold junction at 0°C)*
B	Platinum – 30% rhodium/ platinum – 6% rhodium	0–1500	1.2 mV at 500°C
E	Nickel – chromium/ constantan	−200–850	6.3 mV at 100°C
J	Iron/constantan	−200–850	5.3 mV at 100°C
K	Nickel–chromium/nickel –aluminum (called chromel/alumel)	−200–1100	4.1 mV at 100°C
R	Platinum – 13% rhodium/ platinum	0–1500	4.5 mV at 500°C
S	Platinum – 10% rhodium/ rhodium	0–1500	4.2 mV at 500°C
T	Copper/constantan	−250–400	4.3 mV at 100°C
	Rhodium – iridium/rhodium	0–2000	6 mV at 1200°C
	tungsten – 5% rhenium/ tungsten – 26% rhenium	0–2300	9 mV at 500°C
	tungsten/molybdenum	1250–2600	5 mV at 2000°C

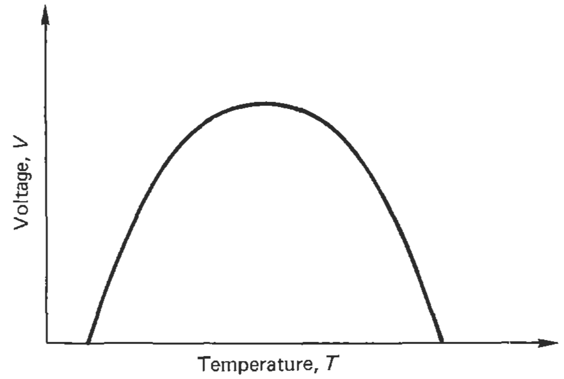

Figure 3.73 Thermoelectric potential

the wide variety of housings that are available are shown in Figure 3.76.

Spot checks on metal temperatures can be made with special devices. In one of these a two-pronged fork has its sharpened prongs made from the two different couple materials. When the prongs are pressed against the metal surface whose temperature is to be measured, it follows from the law of intermedate materials that the thermal e.m.f. will be that of a couple at the required temperature.

To measure temperatures as high as those of molten steel (which is often called for) a permanently protected probe would be both expensive and slow-acting. It is therefore economic to have an expendable hot-junction, with the rest of the probe arranged for easy replacement after a reading has been taken.

3.5.8.3 Resistance thermometers

One of the important properties that varies with temperature and so is used in thermometers is electrical resistance. This

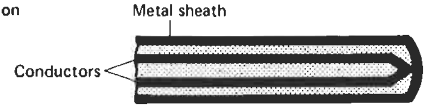
Advantages: insulation resistance can be checked before and after installation

Bonded hot junction



The conductors and sheath are welded together

Advantages: very fast response and very accurate

Figure 3.75 Thermocouple construction

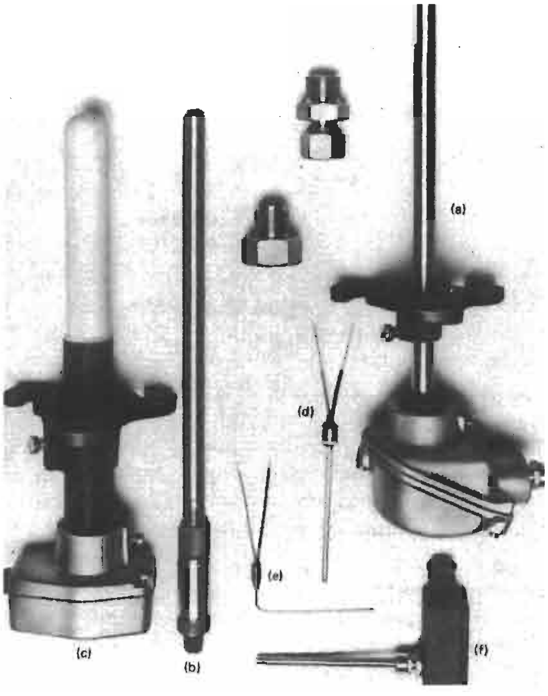


Figure 3.76 Housings for thermocouples (courtesy Kent Industrial Measurements)

shares with thermocouples the advantage of leading into the convenience and precision of electrical measurements.

The electrical measurement of a resistance is easier when it is not too small – 100 Ω is a convenient value for a resistance thermometer. That means that comparatively long, fine wire will be needed. A consequent danger is the susceptibility to corrosion, because even a very shallow, surface attack would make a proportionately large change in cross section, making the resistance rise:

$$R = \frac{\rho l}{A}$$

i.e. resistance is given by resistivity times length, divided by area, and we are looking for changes in ρ, not spurious changes in A.

Because of these considerations, platinum is the favourite material for accurate resistance thermometry. A further advantage is that platinum can be made very pure, allowing reproducible characteristics, even though resistivities are highly susceptible to small impurities. For less accurate, lower-temperature operation, nickel may be used.

It is important to avoid unpredictable stressing of the element – which would alter the resistance. Several ways of doing this are shown in Figure 3.77. Metallized film tracks on glass or ceramic are alternatives. The protective outer housing that is added means that, to outward appearance, there is not much difference between thermocouple and resistance transducers.

Conventional bridge and other circuits are used with resistance thermometers. Whereas with thermocouples it can be arranged that lead resistance does not play a large part, when the active element is itself a resistance, the lead resistance cannot be ignored, and unless the associated circuitry is very close, compensation must be introduced for variations in lead resistance due to unknown temperature changes along the length. It can be achieved by introducing one or two extra wires (according to the bridge configuration) in the cable that connects the transducer to the measuring circuit. A.C. circuits have the advantage that they avoid introducing errors from thermal e.m.f.s in leads or temperature elements but with them some care must be taken over stray inductance or capacitance in the transducer.

In the act of measurement a finite current flows through a resistance thermometer element. This generates heat and raises its temperature above that of its surroundings – which, of course, is what is really to be measured. This error, which depends on the thermal insulation of the element, can generally be neglected if the power dissipation is below 10 mW. Film-type resistors have the advantage of introducing particularly small errors of this type.

3.5.8.4 Thermistors

Semiconductors, with a different physical basis for their electrical conduction, can show a much greater change of resistance with temperature than metals do. This is exploited in thermistors, whose behaviour is illustrated in Figure 3.78.

Thermistors can be supplied as beads or in rod, disc, washer or film form; they have the advantage that they can be very small. Their characteristic is given approximately by the law

$$\alpha = -B/T^2$$

where α is the temperature coefficient (ohms per Kelvin), B is a constant and T is absolute temperature. Their high sensitivity makes thermistors attractive for many applications, though an individual's characteristics cannot be predicted to a tight tolerance and may show a drift equivalent to the order of 0.1 K over a year.

The characteristic of a different device, the 'switching thermistor', is also shown in Figure 3.78. It is used for protection purposes rather than continuous control. The switching device, unlike a conventional thermistor, has a positive temperature coefficient. Over a small span of temperature its resistance increases a thousandfold, so drastically reducing the current flowing through it. The critical temperature at which this happens can be chosen, for instance, to prevent electrical insulation being burnt out.

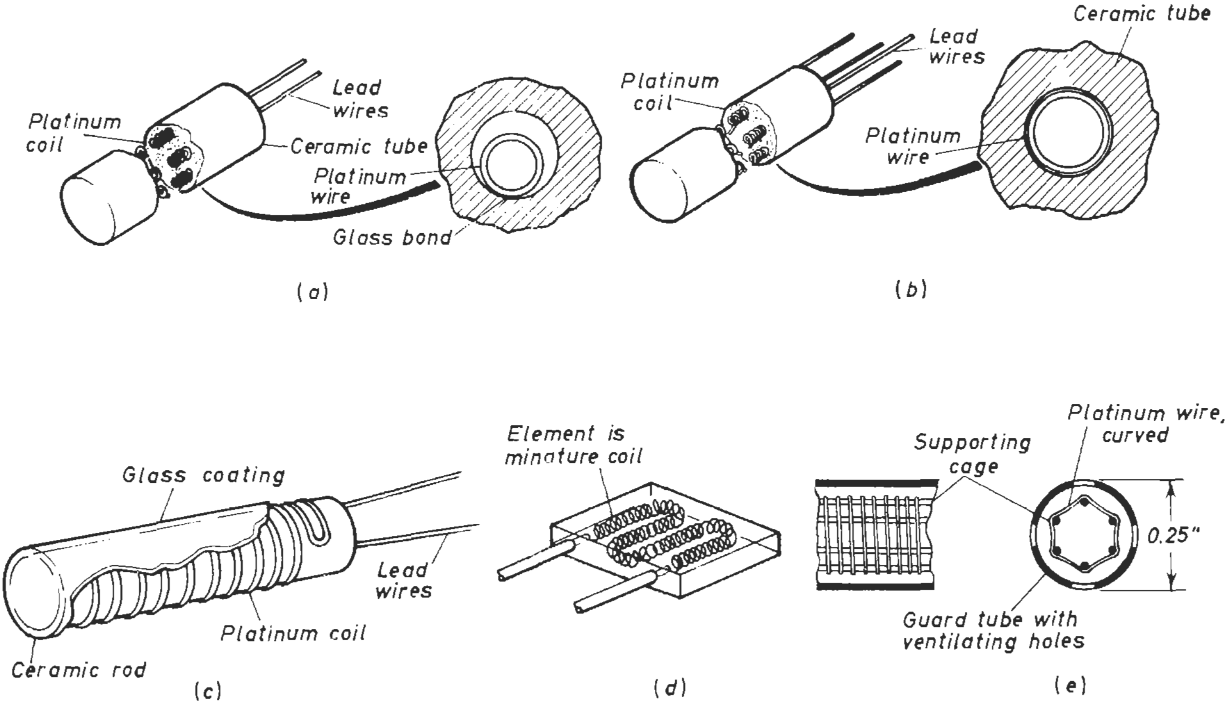

Figure 3.77 Construction of resistance thermometers (courtesy Rosemount Engineering)

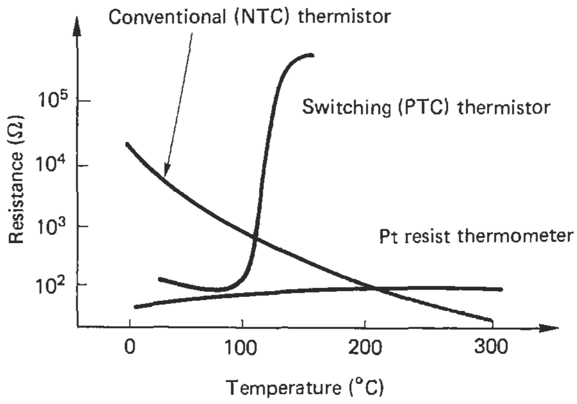

Figure 3.78 Thermistor characteristics

3.5.8.5 Radiation thermometers

Radiation thermometers (which were formerly known as pyrometers) are not based on any change of property with temperature but use the electromagnetic radiation from a body to be measured. As the body warms up, the total radiation it emits increases rapidly (with the fourth power of the absolute temperature) and the spectral distribution shifts to shorter wavelengths. The temperature can thus be determined by measuring the radiation, and there is the clear advantage that all the detecting equipment is remote from the hot body. Limitations to the technique are that it is more difficult to measure lower temperatures, where the energy emitted is much less, and that the emissivity of the radiating surface comes into the equation as well as its temperature.

In this type of thermometer the radiation is focused on a detector. A lens may be used for this purpose (it must be made of a material that transmits the appropriate radiation) or sometimes a mirror to give complete spectral coverage. A thermopile, consisting of a number of thermoelectric junctions connected in series to increase their output, may be used as detector. Alternatively a pyroelectric device may be employed; in this, charges are liberated as the temperature changes. These latter devices do not respond to steady-state signals, so the radiation must be 'chopped', which is commonly effected by having a segmented disc rotating in its path. The semiconductor photodiode is another detector that is sometimes used at shorter wavelengths.

Surface emissivity is much less important when the radiation to be measured has emerged from a 'window' in a hollow body. This makes the technique particularly applicable to furnaces. Dependence on emissivity is also reduced in the arrangement shown in Figure 3.79. If the reflectivity of the hemi-spherical mirror there approaches unity, the effective emissivity of the surface also tends to unity, though with this set-up the advantage of having all equipment remote from the hot surface is, of course, sacrificed.

Sometimes the measurement is of total radiation, sometimes of that within a particular band of wavelengths, which are chosen from considerations of detector sensitivity and material transmission. Shorter wavelengths are appropriate for hotter bodies, longer for colder. By working in the far

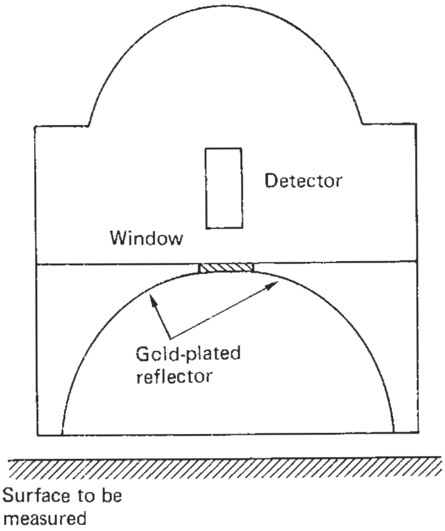

Figure 3.79 Arrangement to reduce emissivity dependence

material transmission. Shorter wavelengths are appropriate for hotter bodies, longer for colder. By working in the far infrared (at 30 μm wavelength) temperatures as low as -50°C have been measured, but applications are much more common upwards from 50 to 100 K higher.

When, as is often the case, radiation thermometers are used in dusty atmospheres, an air purge will be desirable to keep the front optical surface clean. In some designs, the detector is kept further outside a hostile environment by using optical fibres as links.

3.5.8.6 Gas and vapour thermometers

In pneumatic instrumentation systems there is an advantage in having the temperature signal, not in an electrical form, but as something more immediately compatible with pneumatics. This is an attraction of gas and vapour thermometers.

With both of these a sealed bulb is situated where temperature is to be measured and connected by capillary tubing to a pressure-sensitive device. The bulb is either completely filled with a permanent gas or partially filled with a suitable liquid, which means that the pressure in the bulb changes with bulb temperature, according either to the gas laws or to the liquid's vapour pressure. Pressure measurements can thus indicate bulb temperature.

3.5.8.7 Practical considerations

With such a multiplicity of methods for measuring temperature the choice between them depends on many factors. The following line of thought may be helpful as a first, crude guide:

1. Use gas or vapour techniques if and only if they have to feed into a pneumatic system.
2. Failing them, use thermocouples (base metals for lower temperatures, noble metals for higher) unless
3. The highest accuracies are needed, when resistance elements have attractions or
4. Contact with the object studied is difficult or impossible, when radiation thermometers are the solution.
5. Remember that the large signals from thermistors may be an advantage if their limited range is acceptable.
6. For the highest temperatures, radiation techniques may prove much cheaper than thermocouples.

Speed of response is sometimes an important matter, but it depends more on details of construction than on the basic type of thermometer.

When deciding the details of an installation, several points should be borne in mind. The requirement is often to measure the temperature of a fluid, but when a transducer is immersed in a fluid its equilibrium temperature is decided not only by the conductive and convective heat exchange with the fluid but also (if the fluid is transparent, as are most gases) by radiative heat exchange with the walls. Therefore the transducer takes up a temperature that is intermediate between fluid temperature and wall temperature. The error so caused can be greatly reduced by introducing 'radiation shields'. A further error arises when, as is normal, the transducer is mounted from the walls of the container, so providing a heat-conducting path through the mounting. The tendency to bring the transducer's temperature closer towards that of the walls is especially marked if it is housed inside a more permanent pocket (the American term is 'Thermowell') in order to facilitate replacement.

There can be 'sampling errors' when measuring temperature. For instance, if the fluid of concern is flowing inside a pipe and has a temperature different from that of its surroundings, there will be a 'temperature profile' which relates the local fluid temperature to its (radial) position in the pipe. As shown in Figure 3.80, at only one radius will the temperature correspond strictly to that of the mean. However, such errors can be positive or negative, and it is sometimes possible to make them offset the radiation and conduction errors referred to above.

3.5.9 Bar code readers

A form of optical data input which is finding increasing application is the bar code reader. The code consists of a series of black and white vertical lines which are printed onto the object (Figure 3.81).

The code is read by an optical sensor which incorporates a lamp, a phototransistor and a number of optical focusing lenses. The decoding software is, however, necessarily complex, since the speed at which the code is read can vary.

A typical bar code might consists of a start pattern, 101, five 7-bit characters, a check sequence, a second group of five characters and an end pattern. Two consecutive black bands

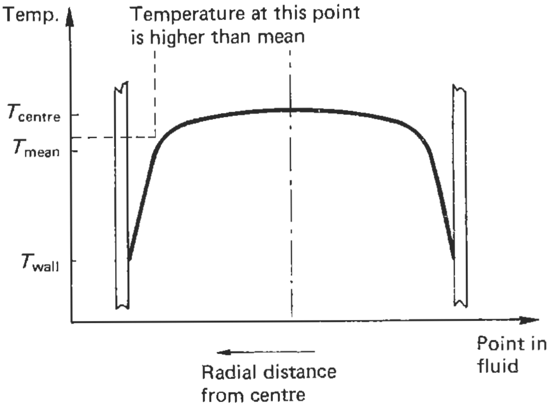

Figure 3.80 Errors caused by temperature profile

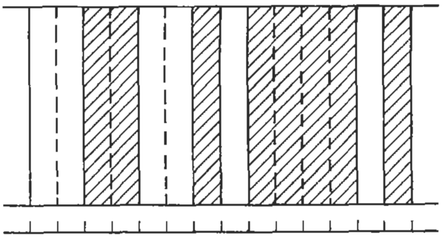

Figure 3.81 Section of a bar code

represent a bit value of 1, while two consecutive white bands represent a bit value of 0. The code is designed such that every character starts with a white band and ends with a black band. This ensures that every character starts and ends with a 1-0 transition. Additionally, every character code includes at least one 1-0 transition within the code.

The decoding program must include a timing loop to determine the speed of reading. The timing is usually based on a count of the 1-0 transitions. With the reading speed established, the code can then easily be translated. Bar code readers are very much evident in large supermarkets and libraries, but they have applications to manufacturing stock control and automatic assembly lines for component counting and identification purposes.

3.6 Classical control theory and practice

3.6.1 Introduction

Control engineering is based on the linear systems analysis associated with the development of feedback theory. A control system is constituted as an interconnection between the components which make up the system. These individual components may be electrical, mechanical, hydraulic, pneumatic, thermal or chemical in nature, and the well-designed control system will provide the 'best' response of the complete system to external, time-dependent disturbances operating on the system. In the widest sense, the fundamentals of control engineering are also applicable to the dynamics of commercial enterprise, social and political systems and other non-rigorously defined concepts. In the engineering context, however, control principles are more generally applied to much more tangible and recognizable systems and subsystems.

Invariably, the system to be controlled can be represented as a block diagram, as in Figure 3.82. The system is a group of physical components combined to perform a specific function. The variable controlled may be temperature, pressure, flow rate, liquid level, speed, voltage, position, or perhaps some combination of these. Analogue (continuous) or digital (discrete) techniques may individually (or simultaneously) be employed to implement the desired control action. In more recent times the advances made in microelectronics have resulted in an emphasis towards digital techniques, and the majority of modern control systems are now microprocessor based.

3.6.1.1 Classification of control systems

Engineering control systems are classified according to their application, and these include the following:

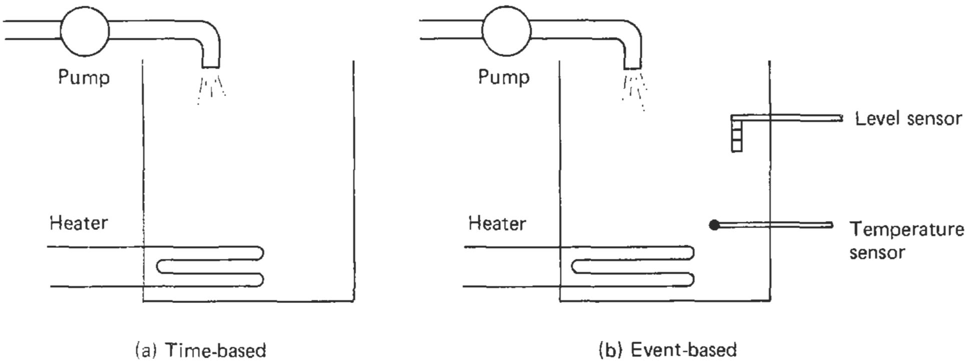
Input
SYSTEM
Output

Figure 3.82 System to be controlled

1. *Servomechanisms*: Servomechanisms are control systems in which the controlled variable (or output) is a position or a speed. D.C. motors, stepper motor position control systems and some linear actuators are the most commonly encountered examples of servomechanisms. These are especially prevalent in robotic arms and manipulators.
2. *Sequential control*: A system operating with sequential control is one where a set of prescribed operations are performed in sequence. The control may be implemented as 'event based', where the next action cannot be performed until the previous action is completed. An alternative mode of sequential control is termed 'time based', where the series of operations are sequenced with respect to time. Event-based sequential control is intrinsically a more reliable 'fail-safe' mode than time based. Consider, for example, an industrial process in which a tank is to be filled with a liquid and the liquid subsequently heated. The two control systems are depicted in Figure 3.83.

   The time-based sequential control system is the simplest. The pump is switched on for an interval which would discharge enough liquid into the tank to fill it to approximately the correct level. Following this, the pump is switched off and the heater is switched on. Heating is similarly allowed to continue for a preset time, after which the liquid temperature would approximately have reached the desired value. Note that the control function is inexact and there are no fail-safe features. If the drive shaft between the motor and the pump becomes disengaged or broken, the heater will still come on at the prescribed time, irrespective of whether there is liquid in the tank or not. The event-based sequential control system has fail-safe features built in and is much more exact. In operation the pump is switched on until the liquid-level sensor indicates that the tank is filled. Then (and only then) is the pump switched off and the heater switched on. The temperature of the liquid is also monitored with a sensor and heating is applied until such time that the temperature reaches the desired value.

   Obviously, with two additional sensors, the event-based system is the more expensive. The advantages it offers over the time-based system, however, far outweighs its disadvantages and event-based sequentially controlled systems are by far the most common. Time-based systems do exist, nonetheless, and they are found in applications where the results of malfunction would be far less potentially catastrophic than those occurring in the example described. The essential difference between the two systems is that event-based sequential control incorporates a check that any operation has been completed before the next is allowed to proceed. The modern automatic washing machine and automatic dishwasher are good examples of sequentially controlled systems.
3. *Numerical control*: In a system using numerical control the numerical information, in the form of digital codes, is stored on a control medium which may be a paper tape, a magnetic sensitive tape or a magnetic sensitive disc. This information is used to operate the system in order to control such variables as position, direction, velocity and speed. There are a large variety of manufacturing opera-



(a) Time-based (b) Event-based

Figure 3.83 Simple sequential control systems

tions involving machine tools which utilize this versatile method of control.

4. *Process control*: In this type of control the variables associated with any process are monitored and subsequent control actions are implemented to maintain the variables within the predetermined process constraints. The word 'process' is all-encompassing and might include, for example, electrical power generation. The generation of 'electricity' can be considered as a manufacturing process where the 'product' is kilowatt hours. In the control of power generation, the variables which are measured include temperature, pressure, liquid-level, speed, flow-rate, voltage, current and a range of various gas concentrations. This is further complicated by the need to satisfy the power demand, and it is apparent that the control of such a system is necessarily complex. Similarly complex examples exist in the oil and paper-making industries, in automative assembly plants and in any entity which aspires to the designation of a 'flexible manufacturing system'.

3.6.1.2 *Open- and closed-loop control*

The basic open-loop system is shown in Figure 3.82 and is extended in Figure 3.84 to illustrate a more complete picture. The input element supplies information regarding the desired value, X, of the controlled variable. This information is then acted on by the controller to alter the output, Y.

External disturbances are fed in as shown and will cause the output to vary from the desired value. The open-loop system may be likened to the driving of a vehicle where the driver constitutes the input element. Essentially, two variables are controlled by the driver – the speed and the direction of motion of the vehicle. The controller, in the case of speed, is the engine throttle valve and in the case of direction, is the steering system.

In order that the system becomes closed-loop, two further elements must be added:

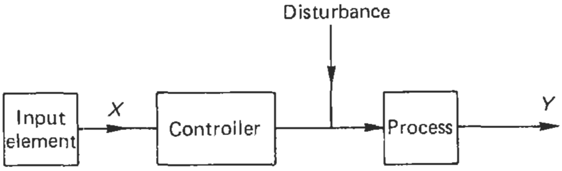


Figure 3.84 Open-loop control system

1. A monitoring element, to measure the output, Y;
2. A comparing element, to measure the difference between the actual output and the desired value, X.

The monitoring and comparing elements are connected through the 'feedback' link as shown in Figure 3.85.

It can be argued that the driver in the previous example also performs the functions of monitoring and comparing. The vehicle driver, therefore, if considered to be part of the complete system, constitutes a closed-loop feedback control. For the purpose of definition, however, any system which incorporates some form of feedback is termed closed-loop. With no feedback mechanism, the system is categorized as open-loop. For the most practical engineering purposes, control systems are of the closed-loop variety to take advantage of the benefits of feedback, which may be either 'positive' or 'negative'. A positive feedback signal aids the input signal. It is possible therefore to have output with no input when using a positive feedback signal and, since this is detrimental to the control function, positive feedback systems are very rare.

3.6.1.3 *Linear and non-linear control systems*

For a control system to be linear it must satisfy both the amplitude proportionality criteria and the principle of superposition. If a system output at a given time is $Y(t)$ for a given input $X(t)$, then an input of $kX(t)$ must produce an output of $kY(t)$ if amplitude proportionality is satisfied. Similarly, if an input of $X_1(t)$ produces an output of $Y_1(t)$, while an input of $X_2(t)$ produces an output of $Y_2(t)$, then if an input of $(X_1(t) + X_2(t))$ produces an output of $(Y_1(t) + Y_2(t))$ the superposition principle is satisfied. Non-linear systems do not necessarily satisfy both these criteria, and generally these

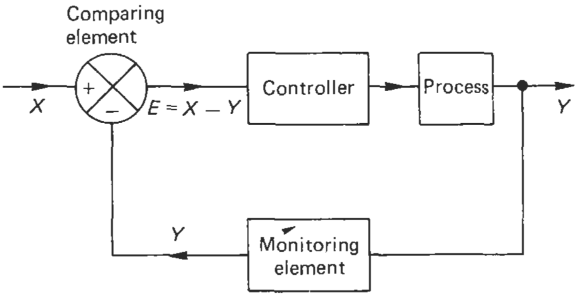

Figure 3.85 Closed-loop feedback control system

systems are 'compensated' such that their behaviour approaches that of an equivalent linear system.

3.6.1.4 *Characteristics of control systems*

The characteristics of a control system are related to the output behaviour of the system in response to any given input. The parameters used to define the control system's characteristics are stability, accuracy, speed of response and sensitivity.

The system is said to be 'stable' if the output attains a certain value in a finite interval after the input has undergone a change. When the output reaches a constant value the system is said to be in steady state. The system is unstable if the output increases with time. In any practical control system, stability is absolutely essential. Systems involving a 'time delay' or a 'dead time' may tend to be unstable and extra care must be taken in their design to ensure stability. The stability of control systems can be analysed using various analytical and graphical techniques. These include the Routh-Hurwitz criteria and the Bode, Nichols and Nyquist graphical methods.

The accuracy of a system is a measure of the deviation of the actual controlled value in relation to its desired value. Accuracy and stability are interactive and one can in fact be counter-productive to the other. The accuracy of a system might be improved, but in refining the limits of the desired output, the stability of the system might be adversely affected. The converse also applies.

The speed of response is a measure of how quickly the output attains a steady state value after the input has been altered.

Sensitivity is an important factor and is a measure of how the system output responds to external environmental conditions. Ideally, the output should be a function only of the input and should not be influenced by undesirable extraneous signals.

3.6.1.5 *Dynamic performance of systems*

The dynamic performance of a control system is assessed by mathematically modelling (or experimentally measuring) the output of the system in response to a particular set of test input conditions:

1. *Step input*: This is perhaps the most important test input, since a system which is stable to a step input will also be stable under any of the other forms of input. The step input (Figure 3.86) is applied to gauge the transient response of the system and gives a measure of how the system can cope with a sudden change in the input.
2. *Ramp input*: A ramp input (Figure 3.87) is used to indicate the steady-state error in a system attempting to follow a linearly increasing input.
3. *Sinusoidal input*: The sinusoidal input (Figure 3.88) over a varying range of input frequencies is the standard test input used to determine the frequency response characteristics of the system.

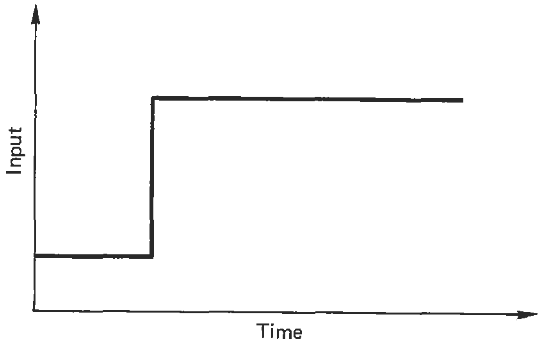

Figure 3.86 Step input

Although the three standard test inputs may not be strict representations of the actual inputs to which the system will be subject, they do cover a comprehensive range. A system which performs satisfactorily under these inputs will, in general, perform well under a more natural range of inputs. The system response to a parabolically varying test input can also be analysed or measured, but this is a less commonly used test signal compared to the previous three.

3.6.1.6 *Time domain and frequency domain*

The time domain model of a system results in an output $Y(t)$ with respect to time, for an input $X(t)$. The system model is

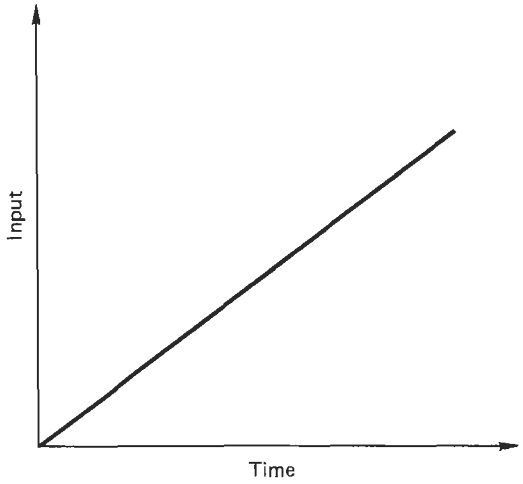

Figure 3.87 Ramp input

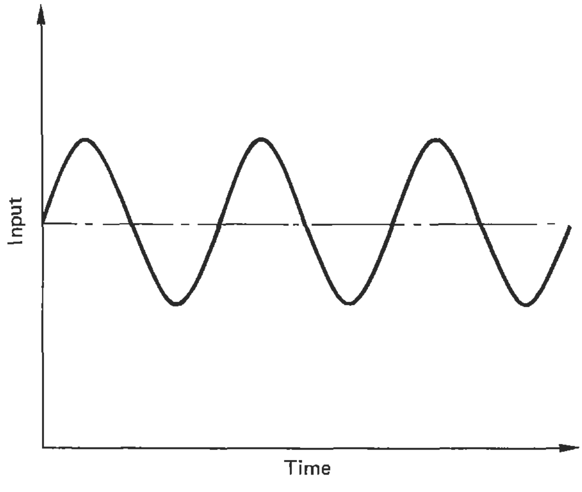

Figure 3.88 Sinusoidal input

expressed as a differential equation, the solution of which is displayed as a graph of output against time.

In contrast, a frequency domain model describes the system in terms of the effect that the system has on the amplitude and phase of sinusoidal inputs. Typically, the system performance is displayed in plots of amplitude ratio, $(Y(t)/X(t))$ or 20 $\log_{10}(Y(t)/X(t))$, and phase angle, against input signal frequency.

Neither system model has an overriding advantage over the other and both are used to good effect in describing system performance and behaviour.

3.6.2 Mathematical models of systems – time domain analysis

Differential equations are used to model the relationship between the input and output of a system. The most widely used models in control engineering are based on first- or second-order linear differential equations.

3.6.2.1 First-order systems

Some simple control systems (which includes the control of temperature, level and speed) can be modelled as a first-order linear differential equation:

$$\tau\frac{\mathrm{d}Y}{\mathrm{d}t} + Y = kX \tag{3.5}$$

where X and Y are the input and output, respectively. τ denotes the system time constant and k is the system gain. When the input X is a step of amplitude A then the solution to equation (3.5) gives the result shown in Figure 3.89. The solution curve shown in this figure has the analytical form

$$Y(t) = kA[1 - \mathrm{e}^{-t/\tau}] \tag{3.6}$$

Equation (3.6), which is the time-domain solution, is an exponential function which approaches the value (kA) as t approaches infinity. Theoretically, the output never reaches (kA) and the response is termed an exponential lag. The time constant τ represents the time which the output would take to reach the value (kA) if the initial rate of response were maintained. This is indicated by the broken line which is tangent to the solution curve at time, $t = 0$. For practical purposes the final steady-state output is taken to have been reached in a time of about (5τ).

If the input is a ramp function then the response of a first-order system is as shown in Figure 3.90. The ramp input is simulated by making the right-hand side of equation (3.5) a linear function of time, i.e. kAt. With this input, the time domain solution becomes

$$Y(t) = kA[t - \tau(1 - \mathrm{e}^{-t/\tau})] \tag{3.7}$$

The solution equation shows that as t becomes large the output tends to $kA(\mathrm{t} - \tau)$. The output response is asymptotic therefore to a steady-state lag $(kA\tau)$.

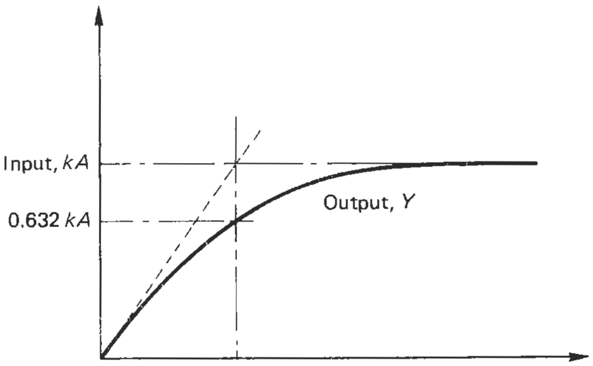

Figure 3.89 Response of a first-order system to a step input

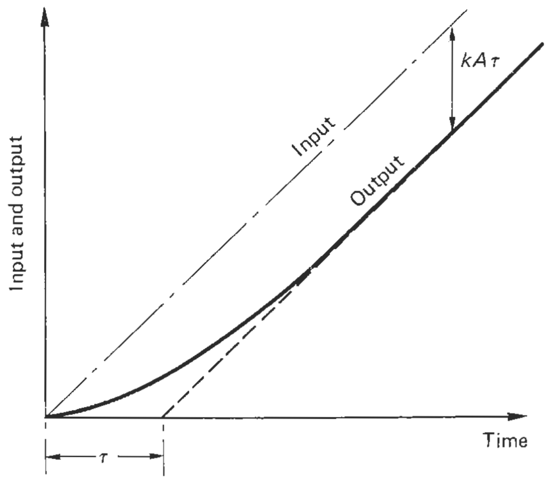

Figure 3.90 First-order system response to a ramp input

The response of a first-order system to a sinuosoidal input can be obtained by setting the right-hand side of equation (3.5) equal to $kA\sin(\omega t)$, where ω is a constant circular frequency in radians/second. The time-domain solution yields

$$Y(t) = \frac{kA}{\sqrt{(1 + \tau^2\omega^2)}}[\sin\alpha \cdot \mathrm{e}^{-t/\tau} + \sin(\omega t - \alpha)] \tag{3.8}$$

where $\alpha = \tan^{-1}(\tau\omega)$

The response is shown in Figure 3.91. The output response exhibits a decaying transient amplitude in combination with a steady-state sinuosidal behaviour of amplitude, $kA/[\sqrt{1 + \tau^2\omega^2})]$ and lagging the input by the angle α.

3.6.2.2 Second-order systems

While some control systems may be adequately modelled as a first-order linear differential equation, many more practical systems, including position control, are more conformably represented by a differential equation of the second order. The second-order differential equation has the general form:

$$\frac{\mathrm{d}^2Y}{\mathrm{d}t^2} + 2\zeta\omega_n\frac{\mathrm{d}Y}{\mathrm{d}t} + \omega_n^2Y = kX \tag{3.9}$$

where ζ is termed the damping ratio and is defined as the ratio of the actual damping in the system to that which would produce critical damping. ω_n is the undamped natural frequency of the system and k, again, is the system gain.

The time-domain solution depends on the magnitude of ζ and three solutions for a step input are possible:

1. *Light damping, $\zeta < 1$.*

$$Y(t) = \exp(-\zeta\omega_n t)[A\cos(\omega_n\sqrt{(1 - \zeta^2)}t) + B\sin(\omega_n\sqrt{(1 - \zeta^2)} \cdot t)] \tag{3.10}$$

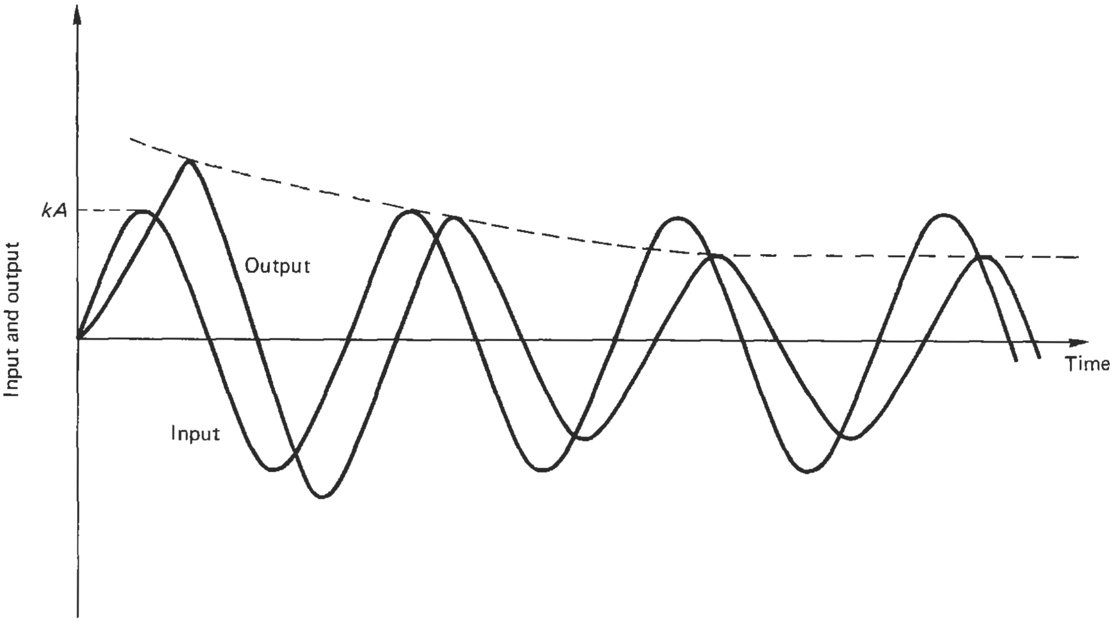

Figure 3.91 First-order system response to a sinusoidal input

2. *Critical damping,* $\zeta = 1$.

$$Y(t) = \exp(-\zeta\omega_n t[At + B] \tag{3.11}$$

3. *Heavy damping,* $\zeta > 1$.

$$Y(t) = A\exp\{-\zeta\omega_n t - [\omega_n \surd(\zeta^2 - 1]t\} + B\exp\{-\zeta\omega_n t + [\omega_n \surd(\zeta^2 - 1)]t\} \tag{3.12}$$

The three possible solutions for a step input are shown in Figure 3.92. The output, $Y(t)$, is plotted as a percentage of the step input, X, against the parameter, $(\omega_n t)$.

For ζ equal to unity, the system is critically damped and the steady-state value is attained in the shortest possible time without any oscillatory response. With ζ greater than unity, the system is overdamped and the response curve is again exponential in form. Overdamped systems may have an undesirably sluggish response. Indeed, since the effect of $\zeta > 1$ simply delays the response to the steady-state value there is no real advantage to be gained in using high ζ values.

For cases where ζ is less than unity, the system is said to be underdamped and the response curve is oscillatory with an exponential decay. A number of performance measures are used to describe the response of an underdamped system to a step input, and these are illustrated in Figure 3.93.

The speed of the response is reflected in the rise time, τ_R, and the peak time, τ_P. For underdamped systems, the rise time is the time taken for the output to reach 100% of the step input. The peak time is that taken to the first maximum in the output response. For critically damped and overdamped systems, the time taken for the output to change between 10% and 90% of the input is used alternatively as a measure of the speed of the response.

The degree in which the actual output response matches the input is measured by the percentage overshoot, PO, and the settling time. The percentage overshoot is defined as

$$PO = \frac{M_{PT} - 100}{100} \tag{3.13}$$

where M_{PT} is the peak value of the output.

It may further be shown that the percentage overshoot is given analytically as

$$PO = 100\ e^{-\zeta\pi/\surd(1-\zeta^2)} \tag{3.14}$$

Another useful relation is derived from the ratio of successive peaks, i.e.

$$\ln\left(\frac{A_n}{A_{n+1}}\right) = \frac{2\pi\zeta}{\surd(1 - \zeta^2)} \tag{3.15}$$

where n is an integer to denote the peak number (i.e. first, second, etc.). Equation (3.15) is referred to as the 'logarithmic decrement'. The settling time, τ_S, is the time taken for the oscillatory response to decay below a percentage of the input amplitude, δ, often taken as ±2%. Finally we have the steady-state error, ε_{ss}, which is self-explanatory.

The response of the second-order system to a ramp input is shown in Figure 3.94. The form of the response curves again depends on the value of the damping ratio, but in each case the output asymptotes to a steady-state lag. The lag is not the same in each case, however, since this is also dependent on the damping ratio.

The response of a second-order system to a sinusoidal input may also be considered. Generally, the output response will lag behind the input with a transient decaying amplitude depending on the nature of the damping ratio. It is more informative, however, to study the response of second-order systems to sinuosoidal inputs using frequency-domain methods.

3.6.3 Laplace notation for differential equations – frequency-domain analysis

For analyses in the frequency domain it is customary to write the differential equation in terms of the Laplace operator, s. This gives rise to the system 'transfer function' which is formed

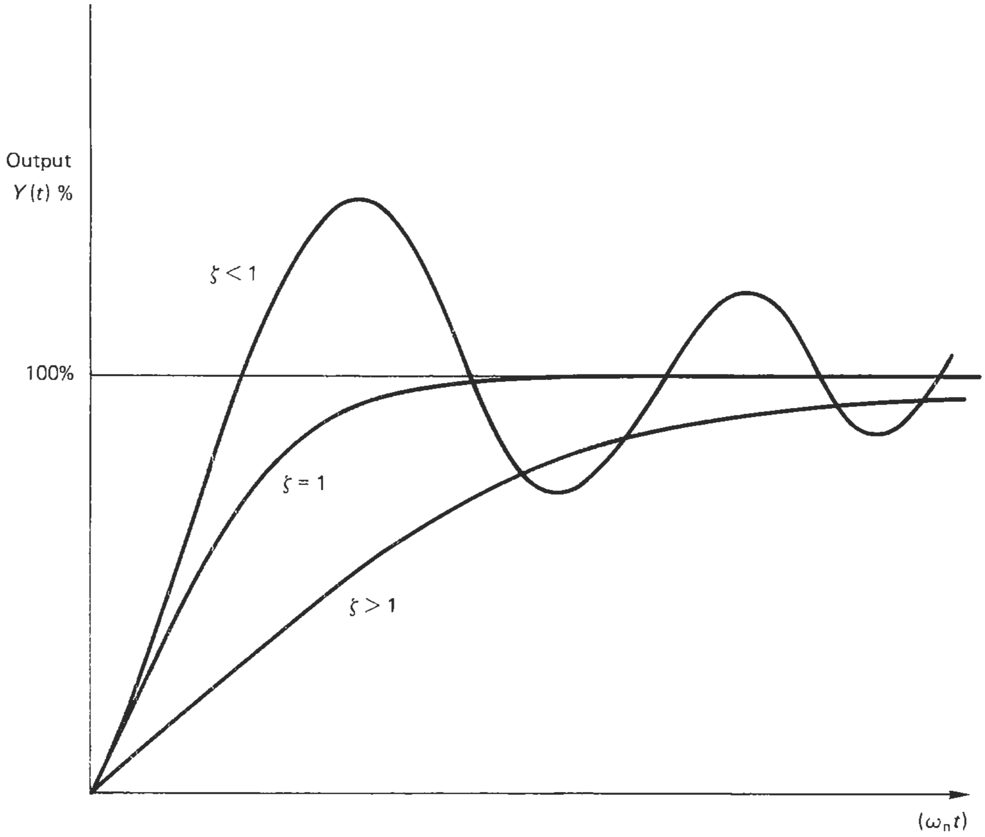

Figure 3.92 Response of a second-order system to a step input

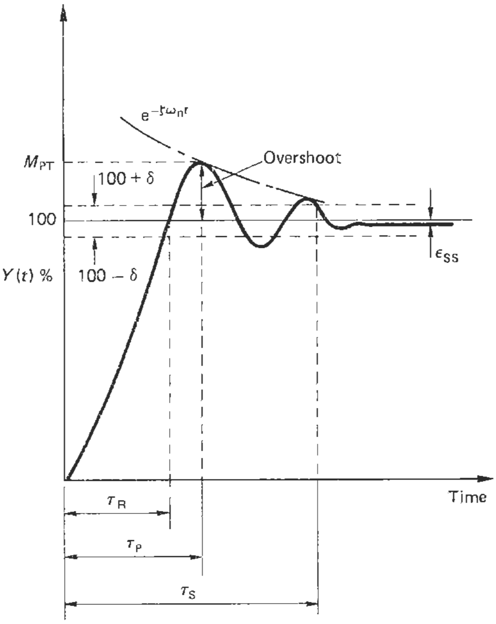

Figure 3.93 Respponse curve for an underdamped system to a step input

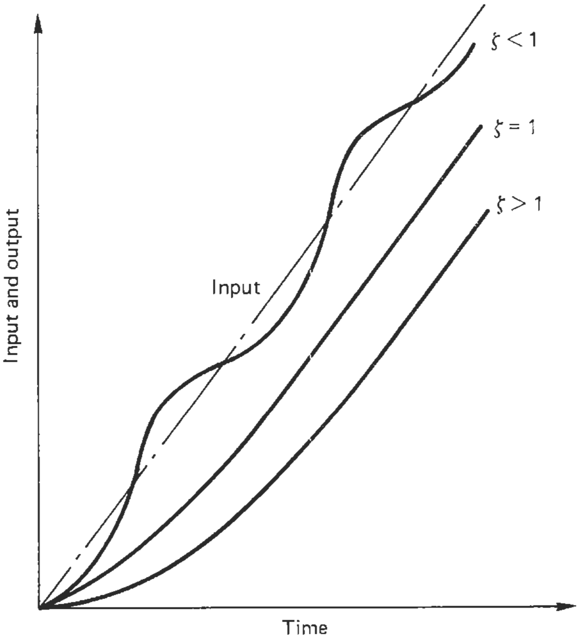

Figure 3.94 Response of a second-order system to a ramp input

by replacing the input and output (X and Y, respectively) with their corresponding Laplace transforms, $X(s)$ and $Y(s)$. The method applies only to linear differential equations. In practice, many systems would contain some degree of nonlinearity, and various assumptions would have to be made to simplify and approximately linearize the governing equation.

The advantage in using the Laplace transform method is that it allows the differential equation to be expressed as an equivalent algebraic relation in s. Differentiation is represented by multiplication with the Laplace variable, s. Thus $\mathrm{d}Y/\mathrm{d}t$ becomes $sY(s)$ and $\mathrm{d}^2Y/\mathrm{d}t^2$ is replaced with $s^2Y(s)$.

3.6.3.1 *First-order systems*

The governing equation is rewritten with the appropriate Laplace transforms replacing the differential operators. Thus equation (3.5) becomes

$$\tau \cdot s \cdot Y(s) + Y(s) = kX(s) \tag{3.16}$$

Hence

$$Y(s)[1 + \tau s] = kX(s) \tag{3.17}$$

The system transfer function is defined as the ratio of the output to the input and is

$$\frac{Y(s)}{X(s)} = \frac{k}{1 + \tau s} \tag{3.18}$$

Equation (3.18) enables the convenient facility of incorporating the transfer function within the usual block structure representation of a control system. Thus a first-order, open-loop control system can be systematically depicted as shown in Figure 3.95.

For analyses in the frequency domain we are predominantly concerned with the system response to sinusoidal inputs. Differentiation (or integration) of a sinusoidal function does not alter the shape or frequency. There is simply a change in amplitude and phase, e.g.

$$\text{Input} = A\sin(\omega t) \tag{3.19}$$

$$\frac{\mathrm{d}}{\mathrm{d}t}(A\sin(\omega t)) = \omega A\cos(\omega t)$$

$$= \omega A \sin\left(\omega t + \frac{\pi}{2}\right) \tag{3.20}$$

Comparing equations (3.19) and (3.20) it can be seen that differentiation has changed the amplitude from A to ωA and that there is a phase shift of 90° associated with the process.

Equation (3.20), in fact, describes the steady-state output from a first-order, open-loop control system. The transient part of the output, which the time-domain solution illustrated in Figure 3.91, is not apparent in the frequency-domain solution.

The Laplace operator, s, may be replaced with $j\omega$, where j is the complex operator $\sqrt{-1}$. Equation (3.18) then becomes

$$\frac{Y}{X} = \frac{k}{1 + j\omega\tau}$$

Using the complex conjugate it may be shown that the modulus of the amplitude ratio is

$$\left|\frac{Y}{X}\right| = \frac{k}{\sqrt{(1 + \omega^2\tau^2)}} \tag{3.21}$$

Equation (3.21) shows how the output amplitude will be influenced by the input sinusoidal frequency. Note that this agrees with the time domain solution (equation (3.8)) for large values of t after which the steady state is achieved.

The technique shown above is general and may be used to determine the amplitude ratio for any second- or higher-order system. *Note*: Common practice, especially in graphical representations, is to express the amplitude ratio in decibels:

$$\text{i.e. dB} = 20\log_{10}(Y/X) \tag{3.22}$$

3.6.3.2 *Second-order systems*

Using the Laplace transfer operator the governing equation (3.9) may be rewritten as

$$s^2 \cdot Y(s) + 2\zeta\omega_n \cdot s \cdot Y(s) + \omega_n{}^2 \cdot Y(s) = kX(s) \tag{3.23}$$

$$\therefore Y(s)[s^2 + 2\zeta\omega_n \cdot s + \omega_n{}^2] = kX(s) \tag{3.24}$$

The system transfer function is

$$\frac{Y(s)}{X(s)} = \frac{k}{s^2 + 2\zeta\omega_n \cdot s + \omega_n{}^2} \tag{3.25}$$

Thus a second-order, open-loop control system can be represented schematically as in Figure 3.96.

For a sinusoidal input of the form $X = X_0\sin(\omega t)$, the frequency-domain analysis gives the following steady-state solutions for the amplitude ratio and the phase lag:

$$\left|\frac{Y}{X}\right| = \frac{1}{\sqrt{[(1 - r^2)^2 + (2\zeta r)^2]}} \tag{3.26}$$

and

$$\phi = \tan^{-1}[(2\zeta r)/(1 - r^2)] \tag{3.27}$$

where $r = (\omega/\omega_n)$.

The above frequency response characteristics are shown in Figure 3.97. When the input signal frequency is equal to the system's natural frequency the amplitude ratio has the value of $(1/2\zeta)$ and the phase lag is −90°. Note that if the damping ratio is zero the amplitude ratio theoretically approaches infinity under this resonance condition. In practice, if the damping ratio is moderately low, very large output amplitudes can be expected if the input frequency is in the vicinity of the system natural frequency.

Thus far we have considered the open-loop system response for first- and second-order systems. Such systems are unconditionally stable. The addition of a feedback loop, however, increases the order of the system and there is always the possibility that the second-order system with feedback may be unstable. Furthermore, if any system, first or second order, incorporates a 'time delay' (also known as a 'dead time' or a 'transportation lag'), then unstable operation is more likely to occur.

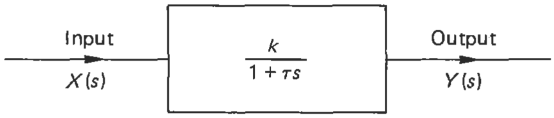

Figure 3.95 First-order open-loop control system

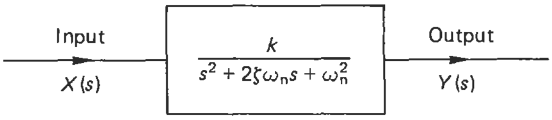

Figure 3.96 Second-order open-loop control system

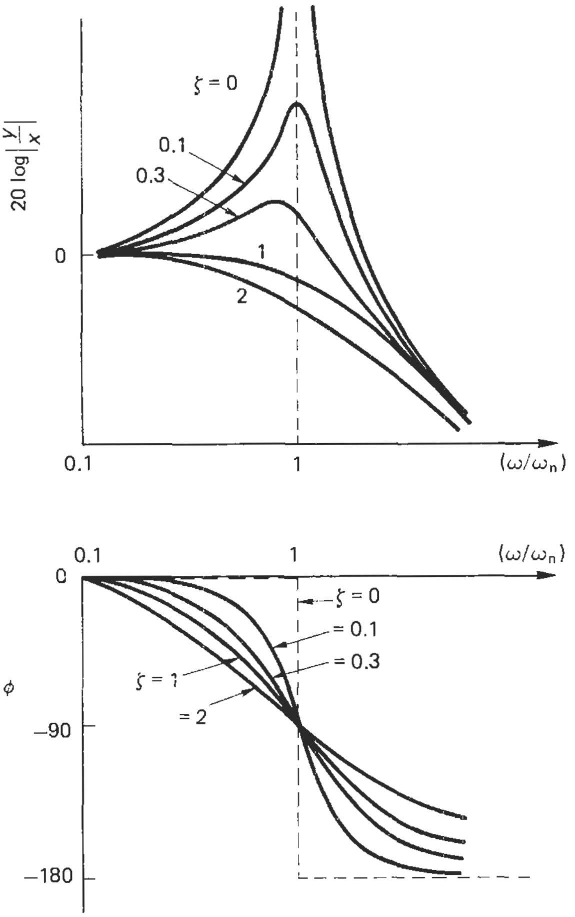

Figure 3.97 Second-order open-loop control system frequency response

3.6.4 Stability criteria

Time delays are very difficult to handle mathematically when they occur in differential equations and the inclusion of multiple feedback loops can greatly increase the order of the governing equation. For these two reasons solutions in the time domain become extremely difficult, and frequency domain methods are almost exclusively used to assess the behaviour of the more complex control systems. The main consideration in frequency-domain analyses is the stability of the system and how it can be adjusted if it happens to be unstable. Various graphical methods are used and these include the Bode and Nyquist plots.

The Bode plot is a graph of amplitude ratio and phase angle variation with input signal frequency. The resulting normalized plot for an open-loop first-order system is shown in Figure 3.98. Note that when the input frequency is equal to the inverse of the system time constant, the output amplitude has been decreased (or attenuated) by 3 dB. The phase lag at this point is −45°. This is characteristic of first-order systems.

The Nyquist plot represents the same information in an alternative form. The plot is in polar coordinates and combines the amplitude ratio and phase lag in a single diagram. Figure 3.99 shows the Nyquist plot for the open-loop, first-order system.

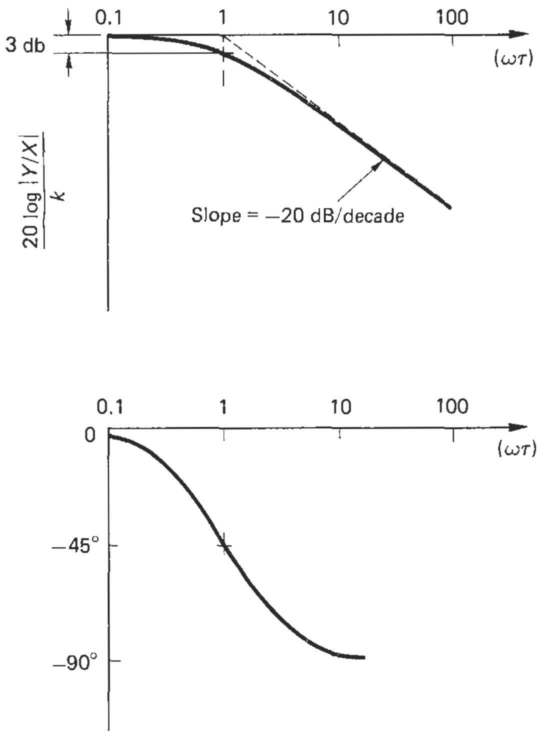

Figure 3.98 Bode plot for an open-loop first-order system

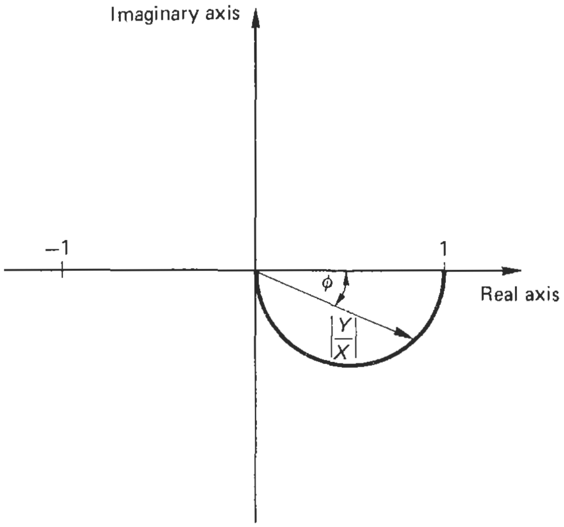

Figure 3.99 Nyquist plot for an open-loop first-order system

3.6.4.1 *Bode and Nyquist stability criteria*

The Bode[8] criterion for stability is that the system is stable if the amplitude ratio is less than 0 dB when the phase angle is −180°. This is illustrated graphically in Figure 3.100. This figure represents a stable system since Bode's criterion is satisfied. The 'gain margin' (GM) and 'phase margin' (PM) are used as measures of how close the frequency response

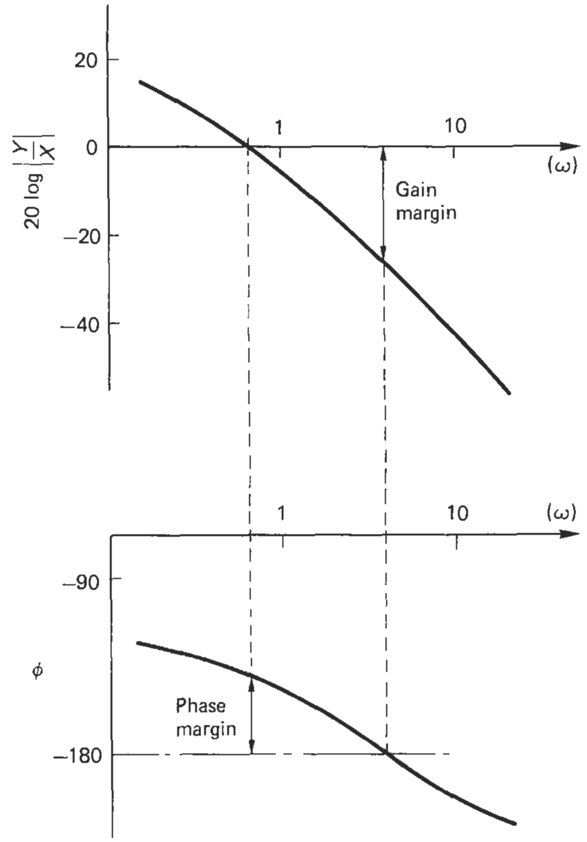

Figure 3.100 Bode's stability criterion

curves are to the 0 dB and −180° points and are indicative of the relative stability of the system.

The Nyquist[9] criterion for stability is that the system is stable if the amplitude ratio is greater than −1 at a phase angle of −180°. In effect, this means that the locus of the plot of amplitude ratio and phase angle must not enclose the point −1 on the real axis. A stable response curve is shown plotted in Figure 3.101. Also indicated in this figure are the gain margin and phase margin in the context of the Nyquist plot.

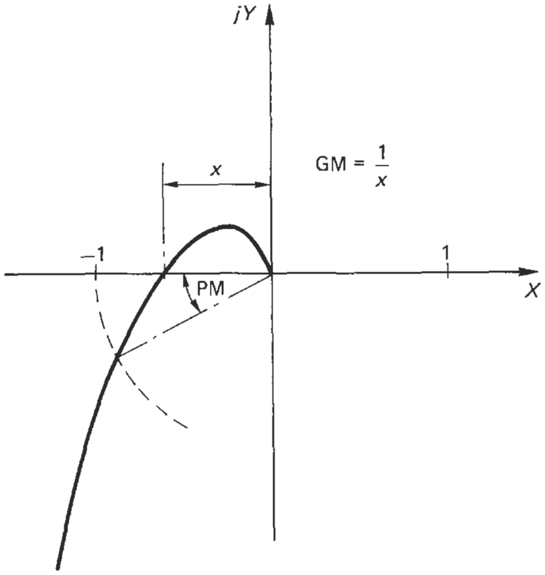

Figure 3.101 Nyquist's stability criterion

3.6.4.2 *System stability with feedback*

In a closed-loop system the transfer function becomes modified by the feedback loop. The first task therefore is to determine the overall transfer function for the complete system.

For simple open-loop systems the transfer functions are combined according to the following rules:

1. For elements in series, the overall transfer function is given by the product of the individual transfer functions (see Figure 3.102).
2. For elements in parallel, the overall transfer function is given by the sum of the individual transfer functions (see Figure 3.103).

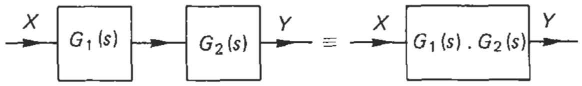

Figure 3.102 Transfer functions in series

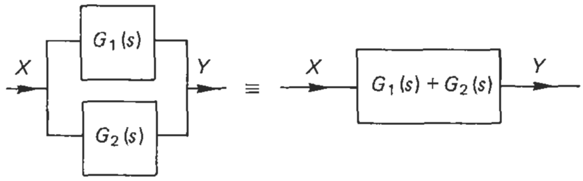

Figure 3.103 Transfer functions in parallel

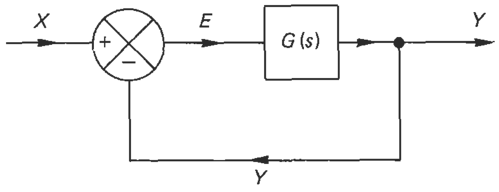

Figure 3.104 Control system with unity feedback

For a system with feedback, the overall transfer function can be evaluated using a consistent step-by-step procedure. Series and parallel control elements are combined in the manner as shown above to reduce the system to a single block, which then represents the overall transfer function.

Consider the simple control system depicted in Figure 3.104. Since the feedback line does not include any transfer function it is termed a 'unity feedback' system, i.e. the output is compared directly with the input to produce the error signal. The closed-loop transfer function is obtained as follows:

$$Y = G(s) \cdot E = G(s)[X - Y]$$

Thus

$$\frac{Y}{X} = \frac{G(s)}{1 + G(s)} \tag{3.28}$$

If the element whose open-loop transfer function, $G(s)$, is a first-order sub-system, then $G(s)$ may be replaced with the expression given in equation (3.18). The closed-loop transfer function may then be written as

$$\frac{Y}{X} = \left(\frac{k}{1 + \tau s}\right) \Big/ \left(1 + \frac{k}{1 + \tau s}\right)$$

$$= \frac{k}{1 + k + \tau s} \tag{3.29}$$

Dividing top and bottom by $(1 + k)$ results in

$$\frac{Y}{X} = \left(\frac{k}{1 + k}\right) \Big/ \left(1 + \frac{\tau s}{1 + k}\right) \tag{3.30}$$

We define the following terms as

$$k_c = \frac{k}{1 + k} \tag{3.31}$$

and

$$\tau_c s = \frac{\tau s}{1 + k} \tag{3.32}$$

where k_c is the closed-loop gain and τ_c is the closed-loop system time constant. The final closed-loop transfer function may be expressed as

$$\frac{Y}{X} = \frac{k_c}{1 + \tau_c \cdot s} \tag{3.33}$$

Equations (3.31) and (3.32) show, respectively, that both the closed-loop system gain and the time constant are less than those associated with the open-loop system. This means that the closed-loop response is faster than the open-loop one. At the same time, however, the closed-loop gain is reduced.

Using the procedures outlined in the example, any other complex control system may be similarly analysed to determine the closed-loop transfer function. Thus knowing the gain constants and other characteristics of the elements which make up the system, the frequency response may be obtained. The stability of the system may then be assessed and any corrective measures taken as necessary. In practice, it is often found that the gain of some of the system elements must be altered in order to ensure stable operation. Another commonly applied corrective measure is to add a phase advance circuit into the system. The procedure might also be operated in reverse, where, starting with a desired response, a suitable control system can be configured and adjusted to meet the response.

The practising control engineer will use many techniques to assess system stability. These might include the numerical Routh–Hurwitz criterion, which determines only whether a system is stable or not. Alternative graphical methods include the use of Hall charts, Nichols charts, Inverse Nyquist plots and Root Locus plots. The graphical methods additionally indicate the relative stability of a system.

Numerous commercial computer packages are available[10–12] to assist the designer of control systems. These include the usual graphical representations and can be obtained from the suppliers whose addresses are given in the references. The reader is also referred to the Further Reading at the end of this chapter for a more comprehensive coverage of these methods and techniques.

3.6.4.3 Effect of transport delay

The influence of a transport (or time) delay on the response of an underdamped second-order system to a step input is shown in Figure 3.105. Although it is virtually impossible to account for a time delay in a differential equation it is simply accommodated in the frequency-domain model as an additional element in the system block diagram. In the frequency-domain model, the time delay effects a phase shift of $-\omega T$ and can be expressed as

$$\text{Time delay} = e^{-sT} = e^{-j\omega T} \tag{3.34}$$

Consider the open-loop response of a first-order system incorporating a time delay as illustrated in Figure 3.106. The open loop transfer function becomes

$$\frac{Y}{X} = \frac{Y(s)}{X(s)} = G(s) = \frac{ke^{-sT}}{1 + \tau s} \tag{3.35}$$

$$\text{Amplitude ratio} = \left|\frac{Y}{X}\right| = \frac{k}{\sqrt{(1 + \omega^2\tau^2)}} \tag{3.36}$$

$$\text{Phase lag} = \phi = -[\omega T + \tan^{-1}(\omega\tau)] \tag{3.37}$$

The first-order, open-loop system response with a time delay is shown in Figure 3.107.

Similarly, a time delay in a system with feedback does not alter the amplitude ratio but adds a phase shift to the frequency response. The system therefore becomes less stable, and in some cases it may be necessary to reduce the closed-loop gain in order to obtain a stable response. The penalty to be paid for increasing the stability in this manner is an increase in the steady-state error.

3.6.5 Control strategies

The basic closed-loop system with common symbol representation is given in Figure 3.108. The nomenclature used in this figure is defined as follows:

$SP(s)$ is the set point (required value, $r(t)$, is sometimes used);
$PV(s)$ is the process value (corrected value, $c(t)$, is sometimes used);
$E(s)$ is the error signal, which is the difference between *SP* and *PV*;
$U(s)$ is the control effort output from the controller to the process;
$C(s)$ is the controller transfer function;
$G(s)$ is the process transfer function.

The transfer function for the closed loop system is obtained as before:

$$PV(s) = C(s) \cdot G(s) \cdot E(s) \tag{3.38}$$

$$= C(s) \cdot G(s) \cdot [SP(s) - PV(s)]$$

Hence

$$\frac{PV(s)}{SP(s)} = \frac{C(s) \cdot G(s)}{1 + C(s) \cdot G(s)} \tag{3.39}$$

3.6.5.1 ON/OFF control

In many applications a simple ON/OFF strategy is perfectly adequate to control the output variable within preset limits. The ON/OFF control action results in either full or zero power being applied to the process under control. A mechanical type of thermostat provides a good example of an ON/OFF-based controller. The ON/OFF control strategy results in an output

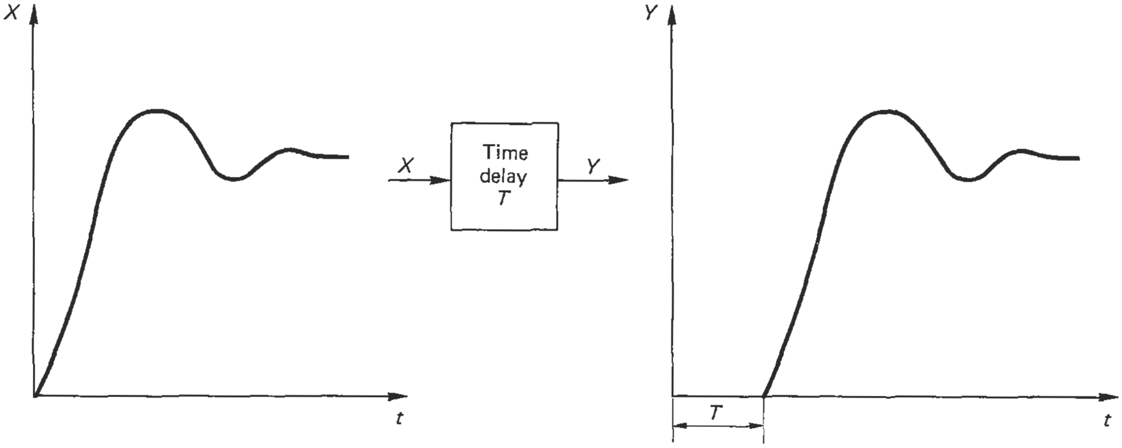

Figure 3.105 Effect of transport delay

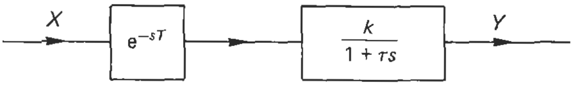

Figure 3.106 First-order system with a time delay

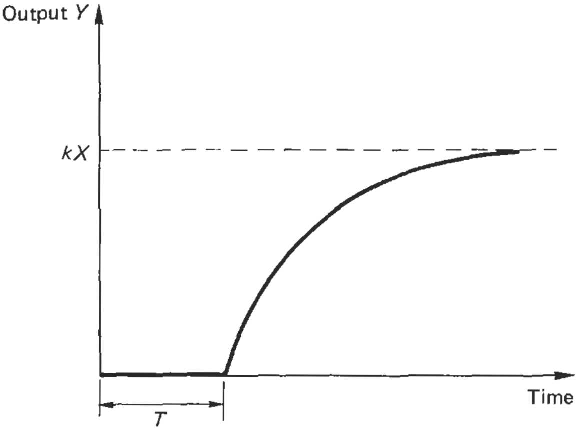

Figure 3.107 First-order open-loop system response with a time delay

which fluctuates about the set point as illustrated in Figure 3.109.

ON/OFF controllers usually incorporate a 'dead band' over which no control action is applied, which is necessary to limit the frequency of switching between the ON and OFF states. For example, in a temperature-control system, the ON/OFF control strategy would be:

If temperature < T_{min}, the heater is to be switched ON;
If temperature > T_{max}, then heater is to be switched OFF.

The dead band in the above case is ($T_{\text{max}} - T_{\text{min}}$) and while the temperature remains within the dead band no switching will occur. A large dead band will result in a correspondingly large fluctuation of the process value about the set point. Reducing the dead band will decrease the level of fluctuation but will increase the frequency of switching. The simple ON/OFF control strategy is mostly applicable to processes and systems which have long time constants and in consequence have relatively slow response times (e.g. temperature and level control).

While being simple in concept, ON/OFF control systems are, in fact, highly non-linear and they require some complex non-linear techniques to investigate their stability characteristics.

3.6.5.2 Three-term or PID control

Since complicated transfer functions can be very difficult to model, the most common strategy used to define the con-

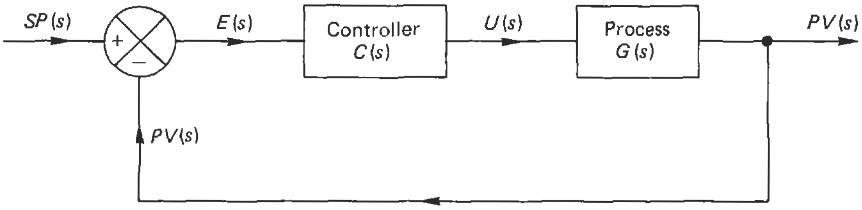

Figure 3.108 Basic closed-loop control system

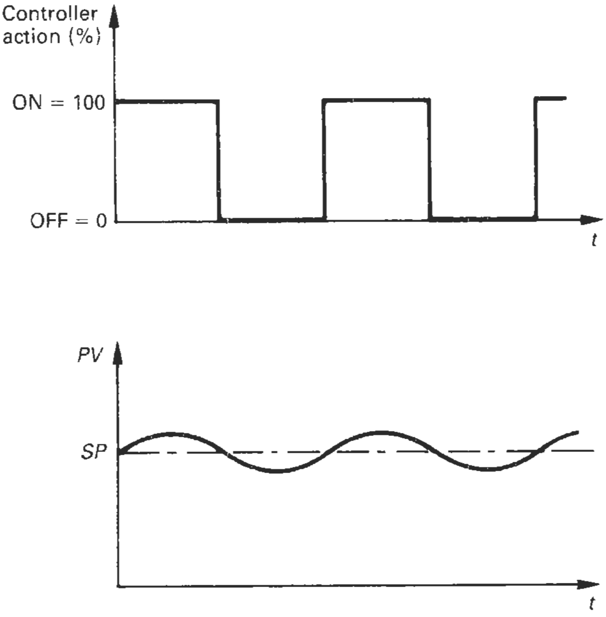

Figure 3.109 Output variation with ON/OFF control

troller transfer function is the so-called 'three term' or PID controller. PID is the popular short form for Proportional, Integral and Derivative. The three elements of the controller action, U, based on the evaluated error, E, are as follows.

(a) Proportional action

$$\text{Controller output} = K \cdot E \tag{3.40}$$

where K is the controller gain. Manufacturers of three-term controllers tend to favour the parameter 'proportional band' (PB) in preference to gain, K. The proportional band represents the range of the input over which the output is proportional to the input. The PB is usually expressed as a percentage of the input normalized between 0 and 100% (see Figure 3.110).

To illustrate the concept of proportional band a temperature-control application can be considered where the set point is, say, 80°C and the proportional band is set to, say, 5% over a measured temperature span of 0–100°C. The actual proportional band is therefore 5°C and proportional action will apply over the temperature range between 75°C and 80°C. If the temperature is below 75°C then 100% of the available power will be supplied to the heating device. Between 75°C and 80°C, a proportion of the available power will be applied to the heating device as shown in Figure 3.110. For temperatures in excess of 80°C, 0% of the available power is supplied.

It should be apparent that proportional band is a more meaningful term than gain. The two parameters are, however, very simply related, i.e.

$$\text{PB\%} = 100/K \tag{3.41}$$

It is also apparent from Figure 3.110 that as the proportional band is decreased, the control action is tending towards an ON/OFF strategy. A very large proportional band will result in a somewhat sluggish response.

It must also be noted that for proportional control only, there must always be an error in order to produce a control action. From equation (3.39) proportional control only gives a transfer function of the form

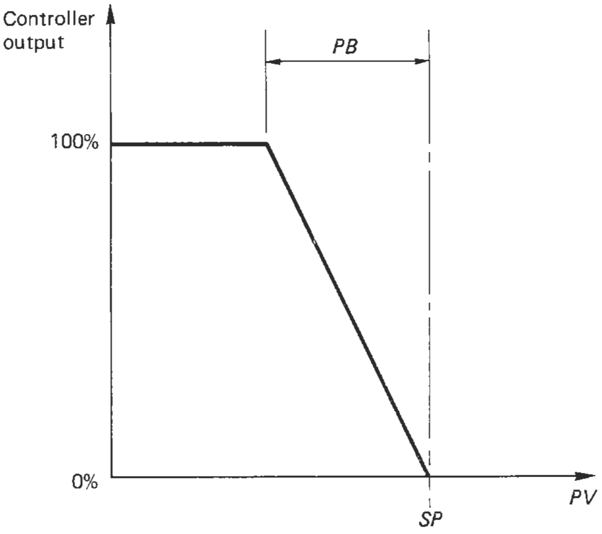

Figure 3.110 Illustration of the proportional band

$$\frac{PV(s)}{SP(s)} = \frac{KG(s)}{1 + KG(s)} = \frac{1}{(1/KG(s)) + 1} \tag{3.42}$$

For steady-state conditions, s tends to 0 and $G(s)$ tends to a constant value. Equation (3.42) shows therefore that the gain must theoretically tend to infinity if $PV = SP$ and the steady-state error is to approach zero.

This is simply another manifestation of the classical control problem, i.e. stability at the expense of accuracy and vice versa. With a very high gain (i.e. low proportional band) the steady-state error can be very much reduced. A low proportional band, however, tends to ON/OFF control action and a violent oscillation may result in sensitive systems.

(b) Integral action The limitations of proportional control can be partly alleviated by adding a controller action which gives an output contribution that is related to the integral of the error value with respect to time, i.e.

$$\text{Controller output} = K_i \int E \cdot dt \tag{3.43}$$

where K_i is the controller integral gain ($= K/T_i$) and T_i is the controller 'integral time' or 'reset'.

The nature of integral action (equation (3.43)) suggests that the controller output will increase monotonically as long as an error exists. As the error tends to zero the controller output tends towards a steady value. The general behaviour of the controller output with integral action is shown in Figure 3.111.

If T_i is very large, the integral action contribution will be low and the error may persist for a considerable time. If, on the other hand, T_i is too small the magnitude of the integral term may cause excessive overshoot in the output response. Unstable operation is also possible when T_i is too small and the controller output value then increases continuously with time.

(c) Derivative action The stability of a system can be improved and any tendency to overshoot reduced by adding derivative action. Derivative action is based on the rate of change of the error, i.e.

$$\text{Controller output} = K_d \cdot \frac{dE}{dt} \tag{3.44}$$

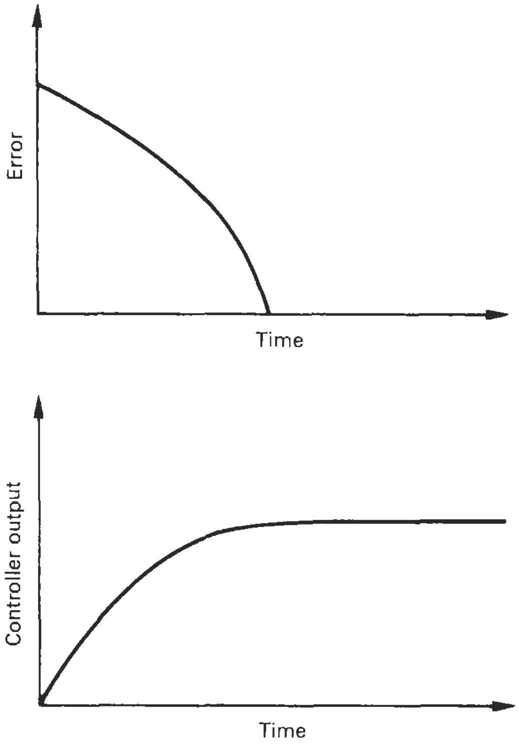

Figure 3.111 Controller output with integral action

where K_d is the controller derivative gain ($= K \cdot T_d$) and T_d is the controller 'derivative time' or 'rate'.

Equation (3.44) indicates that the derivative action is dependent on how quickly or otherwise the error is changing. Derivative action tends therefore only to come into operation during the early transient part of a system's response.

The full three-term control strategy may be written as

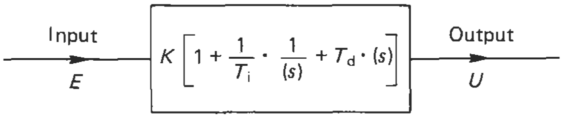
$$K\left[E + \frac{1}{T_i}\int E \cdot \mathrm{d}t + T_d \cdot \frac{\mathrm{d}E}{\mathrm{d}t}\right] \tag{3.45}$$

To summarize, the proportional action governs the speed of the response, the integral action improves the accuracy of the final steady state and the derivative action improves the stability. Note that derivative action may result in poor performance of the system if the error signal is particularly noisy. In Laplace notation, the three term controller transfer function is as shown in Figure 3.112.

3.6.5.3 *Empirical rules for PID controller settings*

A simple and still popular technique for obtaining the controller settings to produce a stable control condition is due to Ziegler and Nichols.[13] The method is purely empirical and is based on existing or measurable operating records of the system to be controlled.

(a) Open-loop 'Reaction Curve' method The process to be controlled is subjected to a step-input excitation and the system open-loop response is measured. A typical open-loop response curve is shown in Figure 3.113. Any system which has a response similar to that given in the figure has a transfer function which approximates to a first-order system with a time delay, i.e.



Input
E
$K\left[1 + \frac{1}{T_i} \cdot \frac{1}{(s)} + T_d \cdot (s)\right]$
Output
U

Figure 3.112 Three term or PID control

$$G(s) = \frac{k\mathrm{e}^{-sT_1}}{1 + T_2 \cdot s} \tag{3.46}$$

In general industrial applications, oscillatory open-loop responses are extremely rare and Figure 3.113 is in fact representative of quite a large number of real practical processes. In the figure, N is the process steady-state value for a controller step output of P. The system steady-state gain is

$$k = N/P \tag{3.47}$$

From the process response curve the 'apparent dead time', T_1, and the 'apparent time constant', T_2, can be measured directly. The three parameters, k, T_1 and T_2, are then used in a set of empirical rules to estimate the optimum controller settings. The recommended controller settings are given in Table 3.5.

In fast-acting servomechanisms, where T_1 may be very small, the method is none too successful. For moderate response systems, however, the method will yield very reasonable first-approximation controller settings.

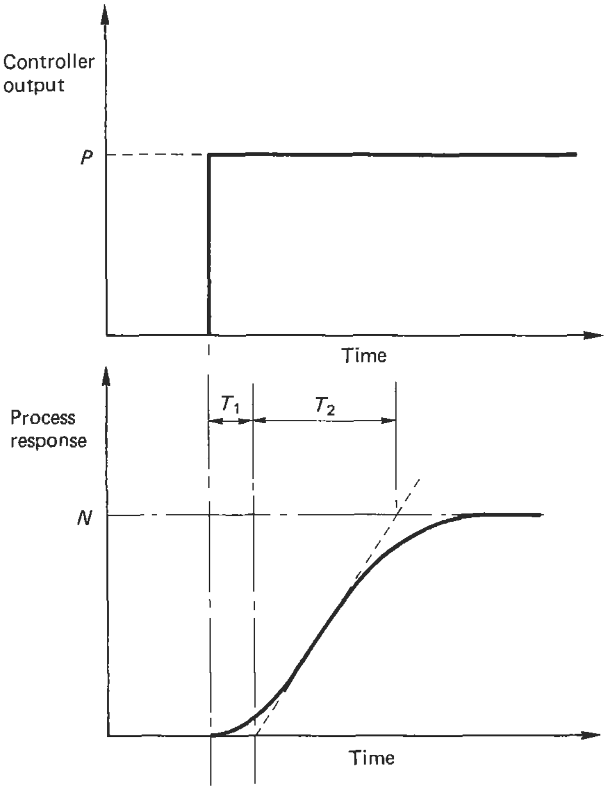


Figure 3.113 Open-loop system response to a step input

Table 3.5 Optimum controller settings according to Ziegler and Nichols

Control action	K	T_i	T_d
P	$T_2/(T_1k)$	–	–
$P + I$	$(0.9T_2)/(T_1k)$	$T_1/0.3$	–
$P + I + D$	$(1.2T_2)/(T_1k)$	$2T_1$	$0.5T_1$

(b) Closed-loop 'Continuous Cycling' method The process to be controlled is connected to the PID controller and the integral and derivative terms are eliminated by setting $T_d = 0$ and $T_i = \infty$. In some industrial controllers the integral term is eliminated with $T_i = 0$. A step change is introduced and the system run with a small controller gain value, K. The gain is gradually increased for a step input until constant-amplitude oscillations are obtained as illustrated in Figure 3.114.

The gain, K_u, which produces the constant-amplitude condition is noted and the period of the oscillation, T_u, is measured. These two values are then used to estimate the optimum controller settings according to the empirical rules listed in Table 3.6.

For a temperature-control system, typical values of T_u are about 10 s for a tungsten filament lamp, 2 min for a 25 W soldering iron and from 10 to 30 min for a 3 kW heat treatment furnace.

The PID settings obtained according to the methods of Ziegler and Nichols are approximate only, and some 'fine tuning' would almost certainly be required in practice.

Table 3.6 Optimum controller settings according to Ziegler and Nichols

Control action	K	T_i	T_d
P	$0.5K_u$	–	–
$P + I$	$0.45K_u$	$T_u/1.2$	–
$P + I + D$	$0.6K_u$	$T_u/2$	$T_u/8$

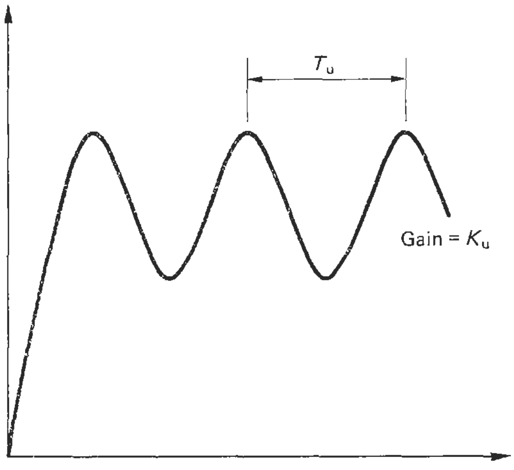

Figure 3.114 Continuous cycling method

3.6.5.4 Three-term controller with a first-order system

The block diagram of the system is depicted in Figure 3.108 and equation (3.39) defines the closed-loop transfer function. If a $P + I$ controller is to be used (i.e. no derivative action) the controller transfer function is

$$C(s) = K\left[1 + \frac{1}{T_i s}\right] \tag{3.48}$$

The process is modelled as a first-order system and its open-loop transfer function is given by equation (3.18).

Substituting equations (3.18) and (3.48) into equation (3.39) results, after some manipulation, in

$$\frac{PV(s)}{SP(s)} = \frac{(kK/\tau T_i)(1 + sT_i)}{\{s^2 + [(1/\tau) + (kK/\tau)]s + (kK/\tau T_i)\}} \tag{3.49}$$

Comparing the denominator with that for the generalized second order system (i.e. equation (3.25) it can be shown that

$$2\zeta\omega_n = \left(\frac{1}{\tau} + \frac{kK}{\tau}\right) \tag{3.50}$$

and

$$\omega_n^2 = (kK/T_i\tau) \tag{3.51}$$

For the system being controlled, both k and τ are known either via a mathematical model or an open-loop test. The controller settings, K and T_i, can then be calculated for a chosen damping ratio, ζ, and natural frequency, ω_n. Alternatively, a controller gain can be imposed and the corresponding natural frequency evaluated.

For full PID control, an initial value of $T_d = T_i/4$ can be used. Other systems can be similarly handled to obtain the approximate PID controller settings. In all cases some fine adjustment would probably be necessary to obtain the optimum output response.

3.6.5.5 Disturbance sensitivity

The main problem with the classical single-loop control system is that it is not truly representative of the natural environment in which the system operates. In an ideal single-loop control system the controlled output is a function only of the input. In most practical systems, however, the control loop is but a part of a larger system, and it is therefore subject to the constraints and vagaries of that system. This larger system, which includes the local ambient, can be a major source of disturbing influences on the controlled variable. The disturbance may be regarded as an additional input signal to the control system. Any technique therefore which is designed to counter the effect of the disturbance must be based on a knowledge of the time-dependent nature of the disturbance and also its point of entry into the control system. Two methods commonly used to reduce the effect of external disturbances are 'feedforward' and 'cascade' control.

(a) Feedforward control The principle of a feedback loop is that the output is compared with the desired input and a resultant error signal acted upon by the controller to alter the output as required. This is a control action which is implemented 'after the fact'. In other words, the corrective measures are taken after the external disturbance has influenced the output. An alternative control strategy is to use a feedforward system where the disurbance is measured. If the effect of the disturbance on the output is known, then, theoretically, the corrective action can be taken before the disturbance can significantly influence the output. Feedforward can be a

practical solution if the external disturbances are few and can be quantified and measured. The block diagram illustrating the feedforward concept is shown in Figure 3.115.

Feedforward control can be difficult to implement if there are too many or perhaps unexpected external disturbances. In Figure 3.115 the path which provides the corrective signal appears to go back. The strategy is still feedforward, however, since it is the disturbance which is measured and the corrective action which is taken is based on the disturbance, and not the output signal. Some control systems can be optimized by using a combination of feedforward and feedback control.

(b) Cascade control Cascade control is implemented with the inclusion of a second feedback loop and a second controller embodied within a main feedback loop in a control system (see Figure 3.116). The second feedback loop is only possible in practice if there is an intermediate variable which is capable of being measured within the overall process. Cascade control generally gives an improvement over single-loop control in coping with disturbance inputs. The time constant for the inner loop is less than that for the component it encloses, and the undamped natural frequency of the system is increased. The overall effects of cascade control are an increase in the system bandwidth and a reduction in the sensitivity to disturbances entering the inner loop. Disturbances entering the outer loop are unaffected. Cascade control works best when the inner loop has a smaller time constant than the outer one.

3.6.5.6 Direct digital control

Most of the standard texts on control engineering are centred on the mathematical modelling of systems and processes and, subsequently, the stability considerations of these entities. This approach requires detailed knowledge of the system constituent parts to enable the formulation of a suitable differential equation to describe the dynamic behaviour. It is often only in the idealized world of servomechanisms that adequate models can be derived. For many real processes an adequate system model can be difficult (if not impossible) to obtain. The modern emphasis is therefore on an application of computer-based control strategies which can be made to work with real systems.

The recent developments in microelectronics, particularly microprocessors, has made microcomputer devices the natural choice as controllers for many systems. The microcomputer provides the ability to implement such functions as arithmetic and logic manipulation, timing and counting. With many analogue input/output modules available to interface to the microcomputer, the overall 'intelligence' of the system is greatly enhanced.

The basic elements of the computer-based control system include the microprocessor, memory, an input interface to measure the process variable and an output interface to supply power to the controlled process. The control effort output to the process is determined by the control strategy, which takes the form of an algorithm incorporated within the computer software. The fundamental digital-based control system is depicted in Figure 3.117.

In the generalized layout given in this figure the microcomputer performs a number of tasks which would require separate elements in an equivalent analogue system. The two inputs to the microcomputer are the desired set point and a signal from the process via a feedback loop. The term 'process' is being used in a quite arbitrary sense in this context.

The microcomputer first performs the function of comparing the process value with the set point to establish the error. The control strategy is then applied to the error value to determine the corrective action necessary. The microcomputer subsequently outputs the appropriate signal to the process via other additional elements in the system. These include the input/output interfaces between the digital-based computer and the otherwise analogue-based control system. Digital-to-analogue converters (DACs) and analogue-to-digital converters (ADCs) are featured in Section 3.4. The transducer, which provides the link between the physical world and the electronically based control system, is covered in its various forms in Section 3.5. The essential fundamentals of microprocessor technology are outlined in Section 3.1 and the applications of microcomputer-based control are described in Section 3.7.

3.6.5.7 Adaptive and self-tuning control

The concept of adaptive control is based on the ability to measure the system behaviour at any time and to alter the controller settings automatically to provide an optimum system response. Adaptive control has been a very active research topic over the last years, but it is only recently that practical applications using adaptive controllers have appeared.

The simplest approach to adaptive control is the so-called 'gain scheduling' method (Figure 3.118). The principle of gain scheduling is that some relevant external parameter is measured and an appropriate value of gain is then selected for the controller. Gain scheduling was first developed for aileron control in high-altitude aircraft. The low air density at high

altitude has a profound effect on the in-flight dynamics, and the purpose of gain scheduling was to provide the pilot with a more consistent 'feel' for the aircraft's handling independently of altitude. Gain scheduling has the advantage that the system stability margins can be well established for any value of gain and the technique is generally fast acting. The method is limited, however, since the gain adjustment is a function of only one measured parameter. In most systems the process may be subject to any number of external parameters and the more modern adaptive controllers use some mathematical model as a basis of comparison with the actual control system (Figure 3.119).

The mathematical model in Figure 3.119 receives the same input as the actual system and an error is created relating the difference between the actual and the model system output. The error may then be used as a basis for altering the controller settings. Obviously, the quality of the control will depend on how well the model reflects the actual system. The usual implementation of model reference adaptive control is illustrated in Figure 3.120.

It is worth noting that the original feedback loop is left intact such that failure of the adaptive loop will not render the system inoperative. External disturbances operating on the actual plant will change the actual/model error signal and provide the basis for re-tuning the controller settings via the adaptive loop. The adjustment of the controller settings implies that there must be some well-defined strategy to determine the level and nature of the adjustments made.

Self-tuning control takes the adaptive concept one stage further in that the mathematical model of the system is also updated as more input and output data from the actual system are acquired. The schematic diagram of a self-tuning controller is shown in Figure 3.121.

The computer-based self-tuning controller estimates the system dynamics and then uses this estimate to implement the optimum controller settings. The continuous updating of the system parameters at each sampling interval is called 'recursive parameter estimation'. Previously estimated parameters are also available, and these can be used in perhaps a 'least-squares' method to provide some overall smoothing of the control function. With the latest system parameters available, the self-tuning controller then goes through a 'design' procedure to optimize the controller settings. This 'design' is usually based on the desired output response of the system. One particular design procedure is based on the root locus method for stability analysis. By adjustment of gains and time constants in the control algorithm, the method seeks to tune the transfer function and thereby govern the output response. Other procedures are often based on the rules of Ziegler and Nichols.[13] The final process in the self-tuning control cycle is the physical imposition of the optimized controller settings on the actual system.

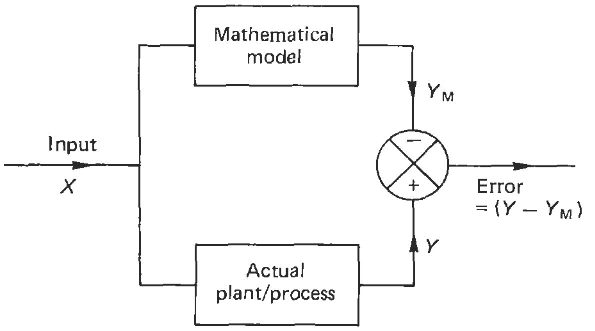

Figure 3.119 Model/actual error generation

Self-tuning control is generally applied to the more complex processes where transportation delays, non-linearities and multiple-control loops greatly add to the complexity. The stability of such systems is, in most cases, non-deterministic since there is no generalized theory available. Traditionally, most self-tuning controllers are based on well-established three-term control principles, but with the added enhancement of adaptability. A number of proprietary self-tuning controllers are available commercially (e.g. Kraus and Myron[14] describe the Foxboro Company's 'EXACT' controller). The EXACT controller is based on PID principles and uses the rules of Ziegler and Nichols in the self-tuning mode.

3.6.5.8 Sampled-data systems

The two previous sub-sections gave an overview of direct digital control and the natural progression to adaptive and self-tuning controllers. The common factor which relates these concepts is the use of a computer (or microcomputer) as a central feature of the control system. The computer acts as the compensator in the control loop and the analogue-to-digital and digital-to-analogue interfaces provide the link between the digital-based computer and the otherwise analogue-based controlled system. Being digitally based, the computer operates in discrete time intervals and indeed the control strategy, which exists in the software, must also take a finite time for its evaluation and implementation.

Time delays are also inevitable in the analogue to digital and the digital to analogue conversion processes and these cumulative time delays result in what is called a 'sampled-data system'. The difference between a sampled-date or discrete signal and its continuous counterpart is shown in Figure 3.122. In the figure, the closure time, q, is the time taken to complete the digitization of the instantaneous signal. Generally, $q \ll T$.

It is apparent that much less information is available in the sampled-data signal as it exists only as a pulse train, interspaced with gaps in the information between the sampled points. If the sampling frequency is high enough then this need not be troublesome (see also Section 3.7.4). The inevitable additional time delays in a sampled-data system, however, have implications regarding the overall stability of the system.

The Laplace transform method cannot be used to analyse a sampled-data system but there is a related transform which is applicable to discrete time systems known as the z-transform. The relation is

$$z = e^{sT} \tag{3.52}$$

The symbol z is associated with a time shift in a difference equation in the same way that s is associated with differentiation in a differential equation. Equation (3.52) then gives a conformal mapping from the s-plane to the z-plane and provides the means for the analysis of discrete time systems. The general method of solution involves the derivation of the closed-loop transfer function in terms of the Laplace variable. The equivalent discrete time system is then represented by introducing a 'zero-order hold' to account for the additional time delays in the discrete system (Figure 3.123).

The transfer function for a zero-order hold is

$$\frac{1 - e^{-sT}}{s} \tag{3.53}$$

The zero-order hold is simply included in the evaluation of the closed-loop transfer function for the discrete time system. The next step is to replace the Laplace transforms with their

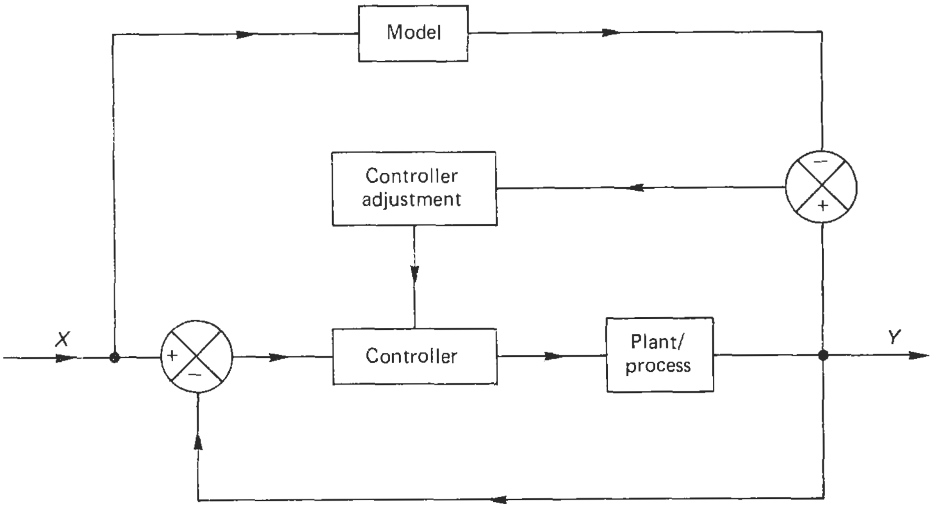

Figure 3.120 Model reference adaptive control

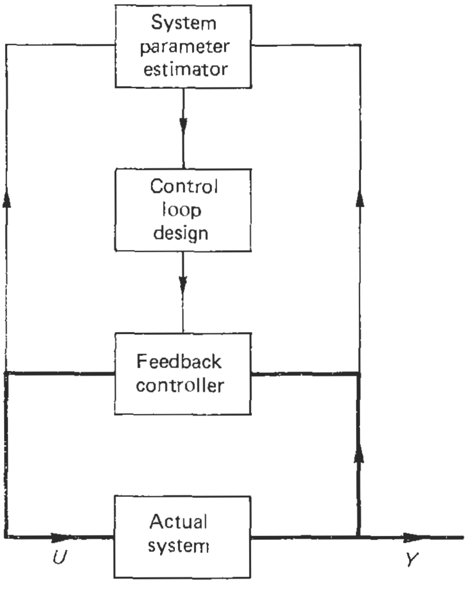

Figure 3.121 Self-tuning controller

equivalent z-transforms. The resulting transfer function in terms of z-transforms can then be analysed for stability in much the same manner as the root locus method is used for continuous systems. Sampled-data systems and the application of the z-transform method is considered in Section 3.9. A comprehensive coverage of z-transform techniques and their application to the stability analysis of sampled-data systems is given by Leigh.[15]

3.6.5.9 *Hierarchical control systems*

The ultimate aim in industrial optimization is the efficient control of complex interactive systems. Recent hardware developments and microprocessor-based controllers with extensive data-handling power and enhanced communications have opened up the possibilities for the control of interlinked systems. What is required (but not yet realized) is a theoretical framework on which to base the analysis of such systems. Nonetheless, and in the absence of theory, hierarchical control systems do exist and are currently being used effectively in the control of various large-scale plant and processes.

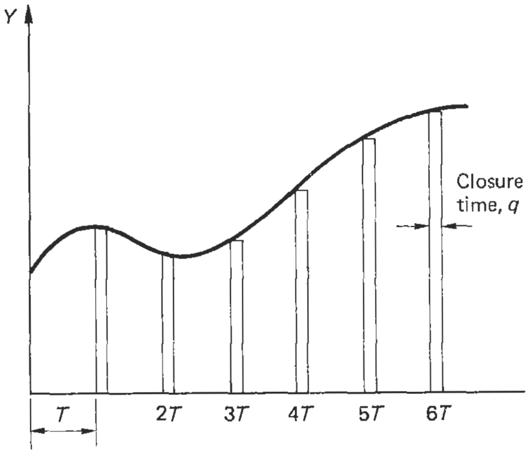

Figure 3.122 Digitization of a continuous signal

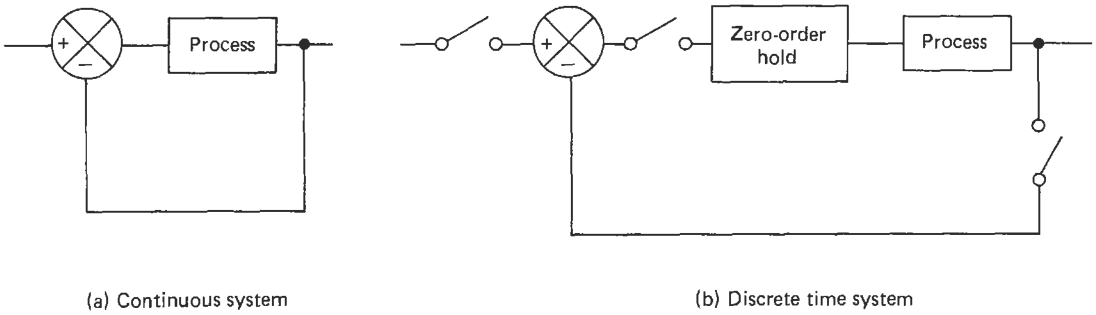
The usual approach adopted is to sub-divide the complex system into a number of more manageable parts. This is the concept of hierarchical control which might be thought of as a sub-division in decreasing order of importance. Hierarchical control exists in two basic forms; multi-layer and multi-level. Multi-layer control is that in which the control tasks are sub-divided in order of complexity. Multi-level control, on the other hand, is that where local control tasks are coordinated by an upper echelon of supervisory controllers.

Multi-layer control is illustrated concisely in an elaborate adaptive-type controller, and the hierarchy is depicted in Figure 3.124. The first level is that of regulation, which is characterized by the classical single closed-loop control system. Moving up the hierarchy, we have optimization of the controller parameters. Optimization is representative of the basic adaptive controller, using simple gain scheduling or a



(a) Continuous system

(b) Discrete time system

Figure 3.123 Continuous and discrete closed-loop control systems

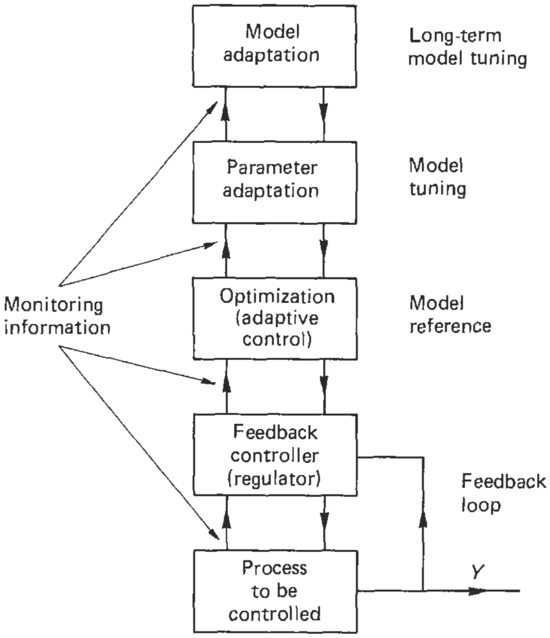


Figure 3.124 Multi-layer control system

model reference criterion. The next highest level is that of parameter adaptation. Parameter adaptation is embodied in the self-tuning controller which represents the beginnings of an 'expert system' approach. The highest level is that of model adaptation, which is based on long-term comparisons between the model and the actual performance. If the system is modelled accurately to begin with, the model adaptation level might only rarely be entered.

Multi-level control is characterized as local controllers whose actions are governed by higher levels of supervisory controllers. The local controllers operate independently to achieve local targets. The function of the supervisory controller is to reconcile the interaction of the local controllers to achieve the 'best' overall performance. The multi-level concept has some similarity with cascade control but is not so amenable to analysis.

Multi-level control gives rise to a pyramid-like structure, typified by that in Figure 3.125. At the base of the pyramid are the local controllers, monitoring and adjusting individual parameters in the overall process. At the next highest level the supervisory controllers 'oversee' a more complete picture of the process. The intermediate supervisory controllers have more input data to contend with, and they might perhaps relax the control of one of the process variables while tightening up on another. This, of course, would only be done to benefit the process overall.

The highest level of supervisory controller has the responsibility for the entire process. This controller may have access to additional input data which are not available to any of the lower-level controllers. The main supervisory controller is then in overall 'command' and can influence any of the 'subordinate' controllers. The similarity between multi-level control and the organizational structure of an industrial company is not just coincidental. The latter is the structural model upon which the former is based.

3.7 Microprocessor-based control

Technological developments in microcomputers with their associated input/output hardware and software tools have enabled the designers of automatic control systems to incorporate a higher degree of intelligence than was possible in the past. Digital computers are now used extensively to control machines and processes. The physical appearance of these controllers vary considerably according to the application, and may range from single-chip microcontrollers (SCMs), where all microcomputer components reside on one IC, to desktop personal computers (PCs).

SCMs provide very cheap computing power and they are mainly associated with high-volume applications such as washing machines, automotive electronics, taxi meters, ticket machines and time-attendance recorders. They can just as easily, however, be used in the control of manufacturing processes in the same way as PLCs, industrial rack-based controllers and PCs.

Since its first appearance in 1981 the IBM PC and its associated compatibles has been adopted as an industry standard. In addition to an increase in processing power, there are a number of advantages in using a PC-based control system.

This integration of the disciplines of microelectronics, computer science and mechanical engineering is the basis of the developing technology of mechatronics. It has been defined as the synergetic combination of mechanical engineering, microelectronics and systems thinking in the design of products and processes.

Typical examples of mechatronic products include robots, CNC machine tools, automatic guided vehicles, video recorders, automatic cameras and autoteller machines.

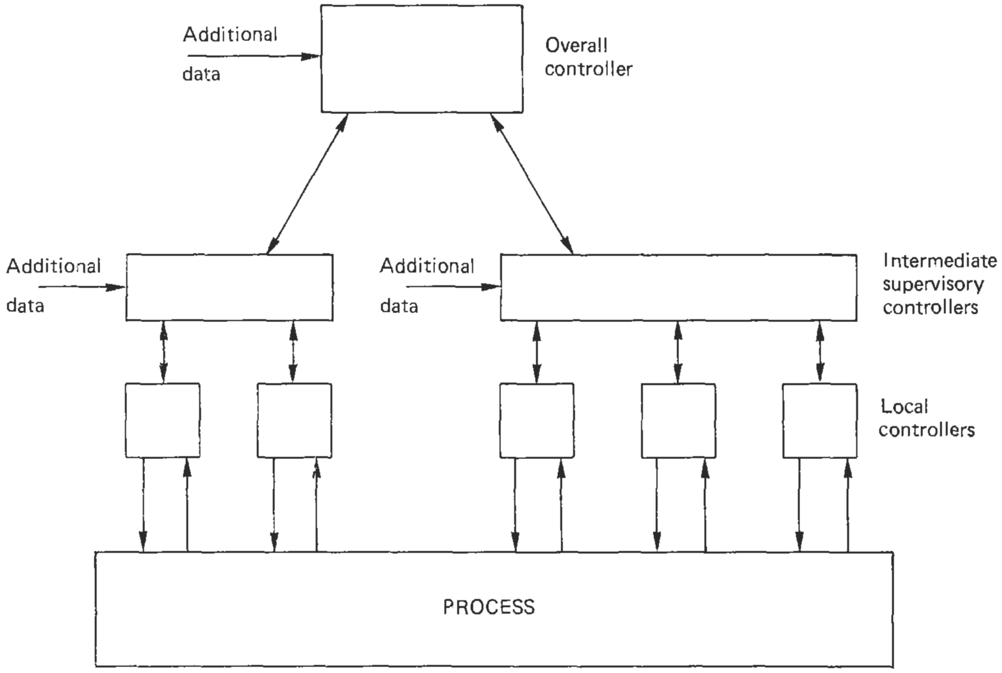

Figure 3.125 Multi-level control system

3.7.1 Direct digital control

Direct digital control (DDC), as outlined in Section 3.6, is employed in systems where such physical quantities as temperature, pressure, flow, position and speed are to be constantly monitored and regulated. The design and operation of a DDC system incorporates formal control theory with computer-related hardware and software to achieve a chosen control strategy. The end product of a real-time control system is a computer-based system which runs the plant efficiently and safely under all operating conditions.

In addition to providing the necessary control functions related to the direct manipulation of valves, drives and other actuators, there are a number of non-control functions available from the system, i.e.:

1. Logging and storage of data;
2. Processing and display of data;
3. Communicating with operators through graphic displays of the plant;
4. Informing of abnormal operating conditions through alarm facilities.

The benefits of DDC are directly identifiable with more precise control, which leads to increased production, improved quality of product and the efficient use of energy and raw materials. There is also a reduction in maintenance requirements and a savings in capital investment through the minimization of recorders, instruments and other control elements. The intangible benefits include an improvement in the handling of engineering and accounting data, increased knowledge of the process from the data collected and displayed, and improved safety.

3.7.2 Hardware requirements

Figure 3.117 in Section 3.6.5 displays the elements of a real-time direct digital control system which constitutes a microprocessor-based controller with the associated input/output interfaces. Digital and analogue interfacing techniques for connecting to external sensors and actuators are described in Section 3.4.

In industrial applications the transducers used for measuring the loop variable normally transmit a current in the range 4–20 mA in proportion to the measured value. This is in preference to using a voltage due to the attenuation over long distances. Also, current signalling can offer a better performance than voltage signalling methods in rejecting electrical noise. At the immediate controller input, the 4–20 mA current signal is converted into a voltage prior to the digital conversion. In control loops the actuators may also operate on a current standard. Since a variable voltage is usually generated through a D/A convertor then voltage to current, (*V*/*I*), conversion is also required.

The function of the controller is to monitor the operating conditions of the process and to evaluate, according to a specified strategy, the necessary output control action to ensure that the controlled system operates in a safe and efficient manner. A large variety of digital control devices are available to the system designer, ranging from single-chip microcontrollers, single-card computers and programmable logic controllers (see Section 3.8) to complete personal computer systems (see Section 3.7.7).

3.7.2.1 Low-level control devices

Following the inception of the microprocessor in the mid-1970s the logical progression was to increase component density and incorporate memory and input/output interface facilities onto the one device. These so-called single-chip microcomputers (SCMs) are usually referred to as microcontrollers, and they provide the intelligence required for such applications as measurement and industrial control.

The architecture of a typical SCM is similar to that of a traditional 'single-card computer' and comprises:

1. A CPU;
2. Memory – RAM and ROM;
3. Parallel and Serial Ports;
4. Timers;
5. Hardware Interrupt lines;
6. A/D converters.

There are a large number of SCMs now available and some display all the above features. This greatly simplifies the designer's task, since many of the functions that previously necessitated separate chips in a microprocessor system are now included on a single integrated circuit. Examples of some popular devices currently available include the following.

(a) The Mitsubishi series 740 of 8-bit CMOS microcontrollers These are ultra-low-cost devices which are available in a variety of different forms. For example, a Mitsubishi designer's kit based on the M50734 SCM including a user's manual and software manual, with designer's notes, can be purchased for less than £40. This particular model comes complete with such facilities as four 8-bit I/O ports, a four-channel multiplexed 8-bit A/D converter, timers and counters, a pulse-width modulation output and a single-channel full-duplex Universal Asynchronous Receiver Transmitter (UART) with a built-in baud rate generator.

There is, unfortunately, no internal memory and external RAM and EPROM must be memory mapped through appropriate decoding chips into the system. With a 16-bit address bus, 64K bytes of memory can be accessed, but an area is specified for special function registers associated with the I/O availability, system stack and interrupt vectors. A typical arrangement for the memory map in a control application would be 2K bytes of RAM at the bottom end of memory (i.e. 0000-07FF) and an 8K EPROM at the top end (i.e. C000-FFFF).

The additional hardware required to make the microcontroller functional is a 5 V ±10% power supply, a crystal clock oscillator at 8 MHz and a RESET control. The architecture is based on six main registers similar to those used in the popular 6502 microprocessor and the instruction set is upwards compatible but includes additional mnemonic coding.

An alternative to the Mitsubishi M50734 is the M50747-PGYS, which has an 8K EPROM, mounted piggyback style onto the top of the SCM. Since 192 bytes of internal RAM are available, no external memory with associated decoding is necessary. This model has a number of bi-directional 8-bit I/O ports and timers but has no A/D conversion facilities.

(b) The Motorola MC 68705R3 microcontroller[16] This is a powerful SCM which comprises an 8-bit CPU with 112 bytes of RAM, about 4K bytes of EPROM, four 8-bit I/O ports, a timer and a four-channel A/D converter. The IC which makes this possible requires more on-board transistors than the 16-bit microprocessor used in the Apple Macintosh microcomputer.

The EPROM facility for the user software is not of the piggyback variety, but is embedded into the package which has the disadvantage of requiring a specialized software development system. The inherent A/D converter is extremely useful in control systems which involve analogue measurements. It uses the successive approximation technique with an internal sample-and-hold circuit and the conversion time is 30 μs with a 4 MHz crystal clock. The external reference voltage which is to correspond to the full 8-bit resolution is connected directly onto the SCM package.

(c) The Rockwell R6500/1 one-chip microcomputer This is an easy-to-use SCM which contains 64 bytes of RAM and 2K (R6500/1EB1) or 3K (R6500/1EB3) of addressable EPROM fixed piggyback fashion onto the package. This allows a standard EPROM such as a 2716 or 2732 to be easily removed, programmed or reprogrammed, then reinserted as often as desired.

Thirty-two bi-directional TTL compatible I/O lines from four ports are available with a 16-bit timer/counter that can operate in four modes. This makes a useful and versatile sequential controller which can be used with pneumatic or hydraulic systems. To make the IC package functional a power supply, clock and reset switch must be connected.

The EPROM contains the reset vectors which direct the program counter to the start address of the code which is to be executed in sequence to carry out the specified control task. The RAM available must also be used for stack operation and the stack pointer must be set up at the start of the applications software.

3.7.2.2 Industrial controllers

These are usually modular industrial microcomputers which are built to internationally recognized bus standards such as STD or EURO and selected cards are held in a standard rack. The ability of these systems to acquire data, control equipment and analyse the logged data make them particularly suited to process-control applications where performance monitoring is required. The system also lends itself well to laboratory data acquisition where the function is to collect data from a range of different instruments.

The development of applications software, usually in some form of real-time high-level language, is now usually carried out by communication between the controller and an IBM PC or compatible. This makes life easier for the system builder by adding enhanced editing and data-storage facilities. These rack-mounted industrial controllers are generally more expensive than PLCs although they offer more flexibility.

Since most practical industrial processes tend to be poorly defined and it is often difficult to derive an accurate mathematical model of the system, the control strategy usually adopted is the 'three-term' one. This has led to the emergence of microprocessor-based PID controllers, whose control output is based on the error signal (evaluated from the declared set point and measured process variable) and the chosen settings of gain, integral and derivation time. Self-tuning PID controllers are now available.[14] Some of these employ a process 'pattern-recognition' technique with an 'expert system' approach based upon the tuning rules usually employed by skilled control engineers.

3.7.3 Software considerations

The power in the digital control of a system is in the software, and any controller requires a real-time language. This is one which can synchronize its operations with events occurring in the so-called 'real world' and thereby respond to and control interfaced mechanisms and processes. The facilities required of a real-time software language are:

1. Ease of switching external devices on and off using software;

2. Ease of deciding whether external devices are on or off at any time;
3. Ease of timing the duration of a process;
4. Ease of making a process run for a predetermined time;
5. Ease of making the program respond to things that happen in the outside world.

Although high-level languages such as BASICA, QUICKBASIC, TURBOBASIC, FORTRAN and PASCAL can, to some extent, meet the above requirements there are a variety of real-time languages which have been specifically designed for control applications.

3.7.3.1 Real-time high-level languages

BASIC This is a programming language commonly used for engineering applications, and real-time interpreted dialects such as CONTROL BASIC and RTBASIC[17] figure prominently. These can be used with both memory mapped and port addressed I/O organization (see Section 3.2.4) and provide keywords which enable the individual bits on a digital port to be read or written to for switching devices on or off. A/D and D/A converters are also easily operated through keywords not usually available in ordinary dialects of BASICs. Timing operations can also be easily implemented.

In addition to the digital and analogue I/O keywords available to assist in the development of control software, floating-point arithmetic is included for data-processing requirements.

FORTH[18] This is an interpreted threaded language developed specifically for control applications. The instructions which constitute an application are stored as a list of previously defined routines. This list is threaded together during the entry of source code from either the computer keyboard or the mass-storage buffers. The process of producing the list is often termed compilation, but this is not strictly correct since the result of the true compiling of source code produces pure machine code.

FORTH is a most unusual language since arithmetic calculations do not follow traditional methodologies. Before calculations can be made it is first necessary to understand how the stack operates in FORTH. Most high-level languages use one or more stacks for their internal operations, but languages such as PASCAL and FORTRAN are designed so that the user does not have to understand how the stack functions. FORTH allows the user full control of the values stored in the stack and their manipulation.

One of the main features of FORTH (and one of the most powerful) is that, once the program has been written, a single word which defines the complete program can be entered into the FORTH dictionary as a command. This dictionary contains words defining, say, routine control operations, and a single word could trigger a series of actions as its threads its way throughout the dictionary.

Programs can be typed in at the keyboard and executed directly, but to save programs for execution at a later date the mass-storage buffers and the FORTH editor must be used. Unlike other high-level languages, FORTH performs only a very limited number of error checks. The errors detected are those which are most likely to cause the system to crash if allowed to pass undetected. The main reason for the lack of error checking is that it would slow FORTH down, and since the main use of FORTH is in time-critical control situations, this would be prohibitive.

C This is a general-purpose programming language which cannot be truly classed as either high-level or low-level. It has all the features expected of a high-level language but allows the programmer to access the computer's hardware and has the high performance usually expected of low-level languages.

Although the language was developed during the 1970s, it is now gaining rapid popularity in a range of industrial applications which include real-time control. There are a number of versions of C available but the accepted standard for the programming language can be found in the book by Kernighan and Ritchie.[19]

Accessing the input and output of data at external ports is easily accomplished and another exceptionally important feature is the use of timing operations which have a resolution of the computer system clock period.

Using C, it is possible to construct concise, well-structured and well-documented programs that can include a variety of useful library functions such as are needed for DOS input/output calls for hardware, screen handling and real-time clock-timing facilities.

3.7.3.2 Low-level languages

At the machine level the program is stored in the memory in a binary format. It is conceivable to write the program immediately in machine code, but this would entail an unjustifiable amount of labour. It is easier to use mnemonic programming, where each instruction is accorded a symbolic name close to colloquial language. The name is easier to remember and the resulting program is much easier to read than pure machine code. This so-called assembly language program can be translated into the necessary machine code for a particular microprocessor by using an assembler program.

The main attraction of using machine code for a particular application is its speed of operation, and if a single-chip microcontroller is to be used the problem of software development must, nonetheless, be faced. This requires the writing of a program into the system memory when no keyboard, display monitor or operating system software exists.

The inexpensive approach is to choose a SCM which supports an external EPROM, in piggyback fashion. The software code for the specific task may then be developed using an appropriate assembler program which operates on an IBM PC or compatible. The resulting code is then used to blow the EPROM. This method can, however, be very time consuming, since the debugging process will require the continual updating of the EPROM data as the program is edited to achieve the specified requirements.

An alternative is to use an EPROM emulator inserted into the target system to temporarily hold the program which is transmitted from the host computer memory. This enables the user to easily alter the program as required and then finally blow the EPROM for permanent use. EPROM emulation should not be confused with the technique of In Circuit Emulation, which involves the removal of the microprocessor from the target system. The In Circuit Emulator then takes complete control by emulating in real time all the functions of the removed microprocessor it replaces.

A software development system should therefore comprise the following:

Hardware
A host microcomputer with keyboard and display monitor;
A printer for a hardcopy of listings and disassemblies;
Disc drives for the permanent storage of data and programs;
An EPROM emulator;
An EPROM programmer.
Software
An editor;
Translation tools such as an assembler or cross-assembler, disassembler, debugger and linker.

Traditional cross-assemblers will only assemble for one microprocessor, and it can be very expensive if a number of upgrades or different types are to be accommodated. These very sophisticated and dedicated development systems are generally too expensive and complicated for producing the operational programs to control a fairly basic and ordered sequence of events, as usually occurs in mechanical systems.

An alternative is to employ an IBM PC or compatible with an assembler which can handle multiple instruction sets. The processor to be used is specified in the source code and the assembler adapts automatically to the correct format.

Tailoring a general-purpose and readily available machine such as the IBM PC to a semi-dedicated role requires a relatively low investment and low software production costs. For one-offs this approach is the only real economic proposition.

3.7.4 Sampling frequency in digital control loops

A DDC loop contains both hardware and software contributions. Transducer measurements of the process variable must be regularly made and the invariably analogue values converted into sequences of numbers that can be handled by the controller. The measured value is compared with some set condition and a control algorithm implemented in software evaluates the necessary control effort. This effort is calculated as a numerical value in the computer, and a conversion of the output is necessary to obtain a form which is suitable to drive the required control elements or actuators. A sampling rule for the measured variable is used to determine the rate at which the sampling is performed.

Digital sampling gives a sequence of 'snapshots' of an analogue variable. The controller only holds representations of the variables at the times when the samples are taken as illustrated in Figure 3.126. The sampling rate must obviously be matched to the rapidity of the variations in the process variable. High-performance control systems require the sampling interval, Δt, to be short, although very rapid sampling will increase the computational load. Δt is usually specified in terms of other system parameters.

The classic reference related to digital sampling is that due to Shannon and Weaver,[20] which states that a signal that is band-width limited can be recovered without any distortion provided samples are taken at a rate of twice that of the highest frequency. 'Twice' may be regarded as an absolute minimum, and a value of five to ten times the highest frequency produces a more realistic digital representation of a sinusoidally varying continuous signal.

Real industrial plant have limited bandwidth, and in applications with long time constants a sampling frequency of twice the highest plant frequency is adequate. In practice, for the great majority of control loops involving the control of such variables as temperature, pressure, flow and level, sampling rates of 0.2–1 s usually prove to be fast enough. These are the rates normally fixed in the commercially available industrial PID controllers.

Fast-acting electromechanical servosystems require much shorter sampling intervals (down to a few milliseconds). Shannon's sampling theorem cannot strictly be applied if the system maximum frequency is unknown. However, practical experience and simulation have produced useful empirical rules for the specification of the minimum sampling rate. One such rule is based on the dominant time constant (see Section 3.6.2), which can be obtained from an open-loop test on the process. A suitable sampling interval for use in a closed-loop control digital algorithm is

$$\Delta t < (\tau/10) \qquad (3.54)$$

This may, however, prove to be unsatisfactory with systems which have a large time constant when a fast closed-loop response is forced by the controller settings.

3.7.5 PID digital control algorithm

A mathematical model which produces a transfer function (see Section 3.6.3) for the process to be controlled can usually be derived for servomechanisms, and specifications in terms of damping ratio, natural frequency and bandwidth can realistically be defined. This is not the case, however, for the

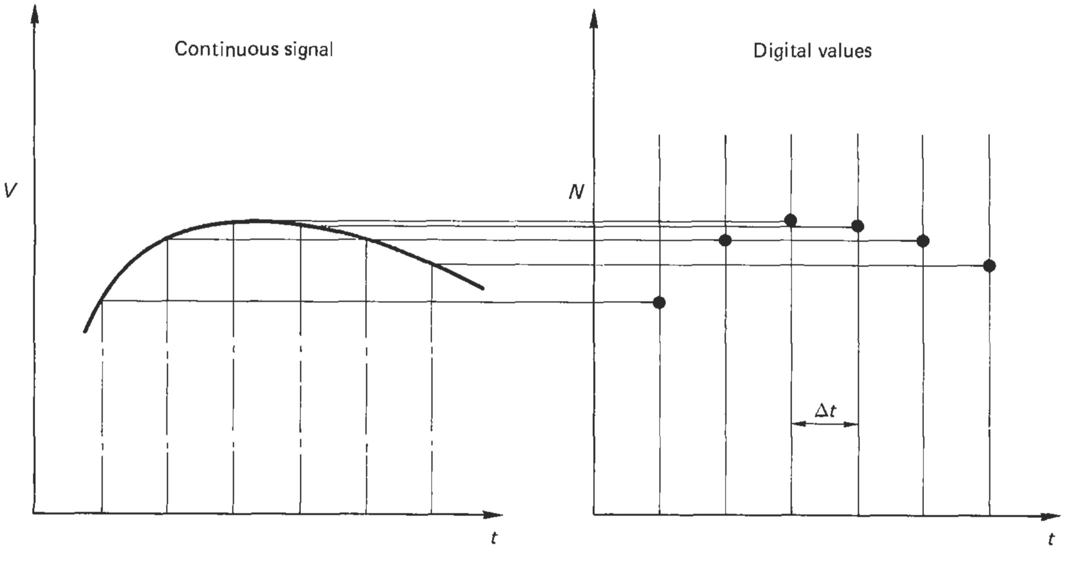

Figure 3.126 Digital sampling of a continuous signal

majority of industrial processes. For this reason, a three-term controller implementation (see Section 3.6.5) is preferred in practice.

The five essential steps required to achieve good process control are:

1. The variable, PV, that best represents the desired condition of the final product must be measured. Measurements such as temperature, pressure, flow, position and speed are commonly used.
2. This measurement must then be compared with the desired set-point, SP, value of the variable to yield an error signal, E, where $E = SP - PV$.
3. This error is then applied as an input to the controller.
4. The controller output, U, must then be applied to a final control device such as a powerstat, a valve or a motor-drive system.
5. A source of energy or material flow is then adjusted in response to the controller output until the deviation between PV and SP will be as near zero as the sensitivity of the system permits.

This is the basic principle of negative feedback as used in most automatic control systems. The sequence of operations at a chosen sample rate is measure, compare and correct.

The function of a digital controller is to apply a control algorithm based on the error value. An algorithm is a computer procedure that performs mathematical functions on a given set of variables. The computational procedure that converts $(SP - PV)$ into a controller output is commonly called the PID algorithm. This algorithm is robust and performs well in practice. Although it may appear inferior as a scientific method, it is difficult to improve on significantly.

The controller output from a PID control strategy is as given in equation (3.45):

$$U = K[E + (1/T_i) \int E\mathrm{d}t + T_d(\mathrm{d}E/\mathrm{d}t)] \qquad (3.45)$$

For implementation on a digital controller this must be transformed into the appropriate software for the system being controlled. This transformation from a continuous to a discrete form can be achieved by either the use of z-transforms or difference equations. The latter are easier to understand and implement, and the steps in deriving any digital algorithm by the difference equation method are:

1. Express the output requirement in a differential equation form.
2. Replace the equation in difference form using the discrete digital approximation:

   $$\mathrm{d}Y/\mathrm{d}t = (Y_i - Y_{i-1})/\Delta t \qquad (3.55)$$

   where Δt is the sampling interval.
3. Solve for the present value of the variable Y_i from the previous value Y_{i-1}.

Applying these steps to the three-term controller yields:

$$U_i = K[E_i + (\Delta t/T_i) \cdot \Sigma E_i + (T_d/\Delta t) \cdot (E_i - E_{i-1})] \qquad (3.56)$$

The error at any particular time, i, is best evaluated as a percentage of the transducer span, and the above algorithm would give the controller output as a percentage value which must be contained within the range of 0-100%.

This PID digital algorithm can be easily programmed directly in a high-level language and the framework for a program in BASIC is as follows:

1. The values for the chosen set point and the controller setting requirements K, T_i and T_d must first be input to the program.
2. A sampling time Δt is often chosen and specified in the program.
3. Since a summation of the error value is required, a variable termed, say, *SUM* must be set to zero. This also applies to the 'previous error' value E_{i-1} in order to start the control loop.
4. Numerical constants can be calculated, e.g.

   $IC = \Delta t/T_i$ and $DC = T_d/\Delta t$
5. The program listing continues:

```
100  REM a routine is required to measure the process variable value
200  E=100*(SP-PV)/SPAN
300  SUM=SUM+E
400  OUTPUTI=IC*SUM
500  OUTPUTD=DC*(E-EP)
600  U=K*(E+OUTPUTI+OUTPUTD)
700  IF U<0 THEN U=0
800  IF U>100 THEN U=100
900  REM the output U must then be output from the controller in a form
1000 REM which is appropriate to the power requirement of the process
1010 REM being controlled.
1020 REM e.g. an A/D converter or PWM (see Section 3.4.2)
1030 EP=E
1040 REM repeat control loop from line 100
```

   Note: It is essential that the sampling interval Δt is greater than the time taken to complete the control algorithm. The above routine would generally be called from a main program which contained a time adjustment such that the complete sequence was contained exactly within the specified sampling time Δt.

The program reveals the general method of programming PID control algorithms for use with a computer and forms the basis of the software incorporated into various commercially available controllers.

3.7.6 Speed control

Many industrial processes require variable speed drives using electric motors. Electromechanical methods of motor speed control, such as Ward Leonard motor/generator sets, have largely been superseded by using digital controllers interfaced to power semiconductor devices. The common types of motor are those which are operated by either d.c. or a.c. Alternating machines are also referred to as synchronous motors.

3.7.6.1 D.C. drives

D.C. motors can rotate in either a clockwise or an anticlockwise direction, depending upon the direction of current flow to the coils via the brushes. The speed is load dependent and it can be varied by altering the supply voltage. Arcing at the brushes generates interference which may cause problems when using computer control through corruption of logic levels representing input/output data. It is essential that the spikes generated at the high interference frequencies are filtered out. This can be achieved by fitting a capacitor across the contacts close to the motor and adding an inductance in series with the power supply. A typical direct digital control loop is illustrated in Figure 3.127.

Details of typical methods of measuring rotational speed are given in Section 3.5. The digital controller invariably implements a three-term strategy as outlined in Section 3.7.5 and

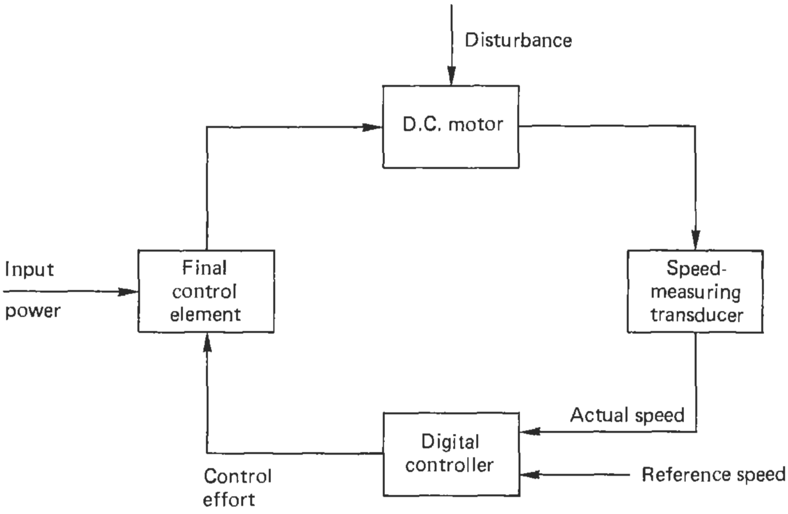

Figure 3.127 Closed-loop control of a d.c. motor

the numerical value calculated must be converted into a motor input through a final control element. This may take the form of a D/A converter and a power amplifier. D.C. servomotor control modules are commercially available for a range of motors, and with a variable input from the D/A converter the motor speed can be varied over its complete operating range. The speed and nature of response to an external disturbance such as a change in load are dependent upon the controller settings.

3.7.6.2 A.C. drives

The a.c. motor does not have brushes and hence the problem with interference when using digital control does not exist. They are also less expensive, more robust and require less maintenance, since they do not have a commutator. However, being a synchronous device, the speed is locked to the frequency of the supply. To control the speed of an a.c. induction motor over a wide range the frequency as well as the amplitude of the applied voltage must be varied. The classic method of acheving this is to use a d.c./a.c. inverter in which a positive and negative d.c. supply is alternatively switched to the motor. This switching arrangement is shown in Figure 3.128.

In order to avoid short-circuiting the d.c. supply any one of the two switches must be off before the other is switched on. The switching may be achieved by using either transistors or thyristors which can operate with a turn-on/turn-off time of typically 5 μs. Thyristors have been developed for this purpose and have current- and voltage-handling capabilities of 1000 A and 4000 V, respectively. The corresponding figures for power transistors are 400 A and 800 V.

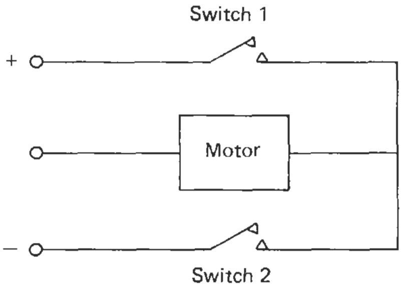

Figure 3.128 Principle of a d.c./a.c. inverter

The control loop for the a.c. drive is identical in principle to that shown in Figure 3.127, where the final control element constitutes the high-frequency switching of an inverter circuit to produce a pulse width modulation (see Section 3.4.2) technique for varying the input power to the machine. The transistor or thyristor based on a.c. drive at powers up to 500 kW is a viable proposition and has the advantages of close speed control in both directions, controlled acceleration or deceleration and high efficiency with a good power factor.

3.7.6.3 Stepper motors

An alternative method of obtaining a variable speed is to use a stepper motor. This is a power device which converts a d.c. voltage pulse train into a proportional mechanical movement of its shaft. There are a range of commercially available motors which are designed for a variety of operating conditions.

The motor is designed with a number of phases which must be supplied with current in a specified preset continuous sequence according to the number of phases. Reversing the sequence causes the motor to rotate in the opposite direction. The motor shaft rotates by a finite amount for each pulse received. Thus if a motor is designed for 48 pulses/revolution then a pulse train received at the rate of 96 pulses/second will cause the motor to rotate at a speed of 120 rev/min. Stepper motors having outputs in the order of kilowatts are available and they are used for applications involving accurate position or speed control such as $X-Y$ plotters, numerically controlled machine tool slide drives and in carburettors for internal combustion engines.

Interfacing a stepper motor to a digital computer is relatively straightforward and a number of integrated circuits and power driver cards are available for a variety of popular digital controllers.

3.7.7 The PC as a controller

The IBM PC and its compatibles are firmly established as the standard for industrial computing throughout the UK and Europe. They are relatively cheap, plentiful and fairly easy to use. As they are integrated into the industrial environment it is evident that they have a high potential as control devices on the factory floor.

In addition to an increase in processing power, there are many other advantages in using a PC-based control system:

1. There is large choice of software which is not available for dedicated controllers.
2. There is a good selection of available tools to produce applications software efficiently.
3. The PC is available in a variety of forms ranging from a single card, a portable, a desktop and an industrial version for use on the factory floor.
4. Expansion plug-in slots to the PC bus structure are available and a large range of cards for digital or analogue I/O have been produced by a number of manufacturers.
5. The PC-based controller is more flexible than the dedicated or minicomputer system and can be easily configured indefinitely to suit different applications.

Data acquisition and control add-ons for PCs are either external rack-mounted systems or plug-in boards. The external box approach usually involves attaching a separate rack-type enclosure with power supply to the host PC. The connection is via either the included serial or the parallel data communication link. Various modules based on a standard card format (such as the Eurocard) can be plugged into the enclosure housing as required.

There are two options for capturing data with PCs. The first is to use an analogue-to-digital converter card that plugs directly into the host computer's backplane. The cards are generally 'port addressed' and may be driven by any language having IN/OUT commands. The base address is usually switch selectable on the card. The second option uses instruments such as digital voltmeters and frequency meters which have an interface board that enables data transfer from or to the controlling PC. The most common standard is the IEEE-488 (GPIB), where data in bit-parallel, byte-serial manner are transmitted from the PC (as an ASCII string) to the instrument, informing it of the settings required for the measurement to be made. Once read, a control signal is sensed and a string representing the measured value is returned to the PC. It is, of course, necessary to have an IEEE-488 card installed into an available slot in the PC. Up to 15 instruments can be accessed in this way from one card.

The quickest, easiest and least expensive way to get measured data into the PC or control signals out is to use I/O cards. These are available for many applications and include:

1. Multi-channel digital I/O with opto-isolation and Darlington Driver facilities;
2. Pulse counting and timing;
3. Multiplexed analogue-to-digital conversion with programmable gain;
4. Digital-to-analogue conversion;
5. Thermocouple input.

Recently there have been rapid advancements made in the software available for data capture and control. Packages are now available which provide the user with a development system having an environment of windows and pull-down menus. The National Instruments[21] 'Lab Windows', for use on PCs, is a library of function modules for programming specific instruments with the IEEE-488 interface. These modules are accessed in the development program via function panels to interactively set up and acquire data from instruments. In addition, a suite of programs are included for data presentation, analysis and formatting in an interactive environment using either QUICKBASIC or C.

A number of manufacturers of rack-mounted microcomputer controllers and programmable logic controllers (PLCs) have united their product with a PC and provide user-friendly software to assist in the development of the required control programs. Such aids are invaluable for displaying, storing and printing PLC ladder relay diagrams as an alternative to the hand-held programmer and EPROM blower. Logged data can also be transferred from the controller to the PC where they can be displayed on a mimic diagram of the plant with animated symbols, updated values of controlled parameters, alarm messages and bar graphs.

Software development for PCs has at last begun to catch up with the hardware, and the data acquisition and control market has been long overdue for reliable development systems.

3.8 Programmable logic controllers

Automation systems generally involve the application of such microprocessor-related equipment as CNC machine tools, pick-and-place machines and industrial robots. As shown in Table 3.7, there has been a greater involvement in the application of programmable logic controllers (PLCs) in manufacturing industry than any other automation devices.[22] The figures in Table 3.7 have been obtained from a survey of all UK manufacturing industries employing 20 or more people.

Table 3.7 Usage of automation equipment[22]

Equipment used	*1983 ('000)*	*1985 ('000)*	*1987 ('000)*	*1989 ('000: estimate)*
CNC machine tools	17	19	27	42
PLCs	34	59	73	110
Pick-and-place machines	4	11	10	15
Robots	1	2	3	6

PLCs are mostly employed in the relatively straightforward control of a single process or piece of equipment. They are particularly common in the food processing, chemical and automotive industries. PLCs first appeared in the 1970s in place of relay circuits, and they have been continually developed as a result of the rapid progress in microelectronics. Some of the current more powerful PLCs overlap with microcomputers or process computers, and it is often impossible to distinguish between them.

3.8.1 The PLC in automation systems

The PLC is particularly useful for controlling manufacturing processes which constitute a sequence of operations that are either event or time driven. PLCs have had a significant impact on industrial control because of their ruggedness, versatility and reliability. They have virtually replaced hard-wired relay, counter and timer logic systems due to their cost, flexibility and relative size. Additionally, the number of applications in which PLCs are being used has increased substantially in recent times.

The principal criteria for determining size is the input/output availability and they can broadly be divided into the following categories:

1. Small PLCs, up to 128 I/O lines, with typically 12 inputs and eight outputs in the basic form. These are designed as stand-alone items and can usually be expanded with respect to digital I/O requirements. A typical system with the associated hand-held controller is shown in Figure 3.129. Such systems basically perform logic, counting and timing operations but have no arithmetical manipulation capabilities.
2. Medium-size systems (128 to 1000 I/O lines), which are generally contained in a rack arrangement. These offer more extensive I/O including analogue-to-digital and digital-to-analogue options with some enhanced programming features.
3. More powerful rack-mounted systems, with over 1000 I/O lines.

The latter PLCs offer data communication for operation within a complete computer-integrated manufacturing arrangement. They embody quite sophisticated man/machine interfaces which employ real-time operating systems and advanced computer graphics. Three-term PID control, digital filtering and vision capabilities can be implemented in many modern PLCs and a variety of operator interfaces are available to allow easy entry of desired settings and process variables.

Recent developments have seen a move from the automation of single machines towards that of the whole manufacturing process. The PLC is a typical representative. The modern concept is the automated factory, where computer-integrated manufacturing (CIM) combines the basic functions of production into a single system. The system incorporates the highest level of automation economically feasible for each function involved. The PLC constitutes one of the building blocks in such a distributed hierarchical control system which is based on a 'pyramid' structure. The peak of such an arrangement contains the mainframe computer, which is responsible for handling the databases for production scheduling, sales and other management needs. The PLC or microcomputer immediately precedes the machine and process applications located at the base of the pyramid.

However, although the small single-purpose basic PLC is relatively secure in its role in the market, the medium and large PLCs face considerable competition from microcomputers. This is particularly the case in applications where much arithmetical manipulation must be performed. It is now possible to get IBM PCs and other microcomputers in a 19-inch rack format which can be mounted within standard control panels. This represents a serious competitor to many PLC-based systems.

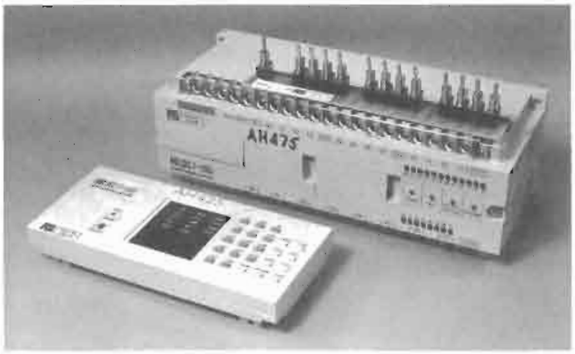

Figure 3.129 A typical small PLC

3.8.2 The PLC versus the microcomputer

The PLC and the microcomputer contain the same basic constituent components such as central processing unit, memory devices, input/output interfaces, decoding logic and a connecting bus structure. They are, however, entirely different in physical appearance and operation.

3.8.2.1 The case for the microcomputer

The dominance of the International Business Machines Company (IBM) in the microcomputer market has led to an accepted industry standard machine in the form of the IBM PC. Since its appearance several manufacturers have produced so-called compatibles, which are based on the associated 16- and 32-bit technology. The latest processors now allow the programmer to write programs that use more memory than is actually available in a given system. This is done by exchanging data between the main memory and secondary storage devices. It is this processing power, memory availability and peripheral hardware that has made a significant impact on the engineer's acceptance of PCs for control applications.

In addition to this increase in processing power, there are many other advantages in using a PC-based control system:

1. The large choice of available storage ranging from high-level language interpreters and compilers to sophisticated man/machine software interfaces which include a range of selectable data processing and graphical display routines;
2. The selection of available tools to produce applications software efficiently;
3. The variety of forms available, which range from the small portable type for use in the field to the rugged industrial version for the factory floor;
4. The large range of plug-in cards available for use with the PC bus structure to provide both digital and analogue I/O facilities;
5. The ease with which the system can be reconfigured to enable, for example, the application of word processing, spreadsheets or databases to be carried out. There is no need to purchase a new system for every new application.

However, in order to truly harness the flexibility that accompanies the personal computer some knowledge of microprocessor technology is required, and the ability to understand or develop applications software is essential.

3.8.2.2 The case for the PLC

The alternative to the microcomputer for control applications is the PLC, which may be described as less intelligent but is ideally suited for carrying out logical sequential operations to produce outputs which are conditional on input states. The advantages of using a PLC for controlling machines and processes may be summarized as follows:

1. The PLC is relatively inexpensive compared with a microcomputer.
2. The construction is exceptionally rugged and it requires very little space in the control cabinet.
3. Reliability is high, immunity to electrical noise is good and maintenance is low.
4. Memory is used economically due to the method adopted for the processing of the data. The PLC processor is

tailor-made to execute logical operations (AND, OR, etc.) as they occur in the control program.

5. The operating speed is fast.
6. An in-built interface provides for the easy connection to a variety of input/output devices connected directly to the machine or process.

The PLC is, however, less interactive than the microcomputer, partly due to the fact that relay ladder logic is generally used as the programming language because of its alleged wide acceptance by those who design, operate and maintain control systems. During program execution the ladder is continuously scanned and outputs are set in accordance with input conditions. It is reputed that ladder logic is straightforward and easily understood, but software development can be a problem for the non-specialist in systems which involve a number of timer and counter requirements.

In conclusion, there is probably an equal support, at present, for both PC and PLC systems. Both systems, then, should continue to play an important part in manufacturing operations for the foreseeable future.

3.8.3 Ladder logic programming

The most commonly used programming language for use with a PLC is the ladder diagram. For the popular small PLCs it is usually possible to enter the input, output, timer and counter instructions directly into the controller using a hand-held programmer. The mnemonic codes are displayed on a small screen within the programmer prior to conversion into machine language and transfer into the PLC battery back-up memory. Although the program can be edited, the main disadvantage of using this method is that there is no way of saving and printing the developed program.

A preferable alternative is to use a PC with an appropriate software package available from the PLC manufacturer to develop and display the ladder diagram on the PC monitor. Use is made of the PC drives and printer as required. Once completed, the resulting file is transmitted from the PC to the PLC for execution. This is by far the best method of developing ladder logic software.

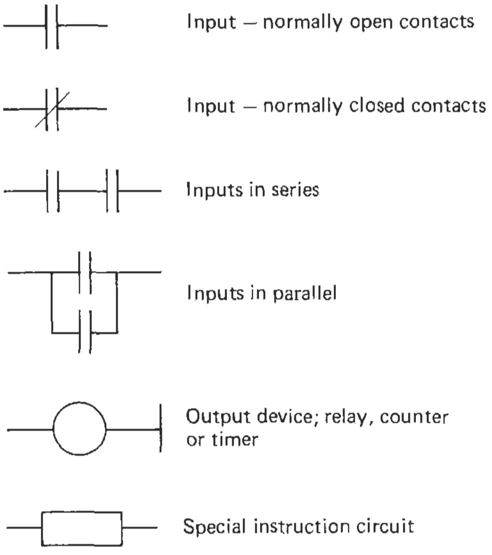
In a ladder diagram the power source is represented by the two vertical rails of the ladder and the various instructional requirements which represent the control circuits make up the rungs. The symbolic ladder circuit layout is constructed using standard graphic logic symbols to represent input contacts, output loads, timers and counters, as shown in Figure 3.130. When using a PC to develop the program, comments can be added to each instruction rung. This makes the program easier to understand and facilitates fault finding.

Each rung on the ladder starts with an input condition and finishes with an output to a load, timer or counter. When used to automate a machine, the ladder is continuously scanned in a sequential manner and sets the outputs on or off according to the requirements based on the sensed input conditions.

3.8.3.1 *Inputs*

The most common symbol used in programming a PLC is the input contact, which may be active in either the normally open (NO) or normally closed (NC) mode of operation. The 'NO' contact symbol is a request to examine if the switch is ON in order to proceed along the run. For the 'NO' condition to be satisfied the contact must be OFF.

A popular real-world input device is the switch. This is basically used to open and close an electrical circuit. The PLC supplies the voltage across the switch which is usually either 24 V d.c. or 100 V a.c. A large number of switch designs are used to control systems. The limit switch is one such example, and it is designed to open and close when a machine part reaches a specified position or a physical variable obtains a required value. Once the limit switch condition has been sensed, the PLC takes appropriate action as defined in the ladder program.



Input – normally open contacts
Input – normally closed contacts
Inputs in series
Inputs in parallel
Output device; relay, counter or timer
Special instruction circuit

Figure 3.130 Instruction set ladder logic symbols

3.8.3.2 *Outputs*

The most common output devices are the electromagnetic relay and the solenoid. The relay provides isolation of the load voltage and current from the PLC and is ideal for the switching of high loads via the controller's in-built I/O interface. Alternatively, the solenoid, which consists of wire surrounding a movable plunger, allows electrical control of any mechanical device attached to the plunger. This arrangement is applied in electropneumatic systems to control the position of a valve spool in order to direct the air path through a pneumatic system.

Due to the nature of the sensed input and the switched output load, the PLC I/O module normally provides a safe electrical separation between internal and external circuits. This is effectively carried out by an opto-isolator, which ensures that there is no physical hard-wired connection between the PLC and the external I/O device.

A typical rung in a ladder diagram including I/O with logic operations is shown in Figure 3.131. Thus rung may be written for a particular PLC as:

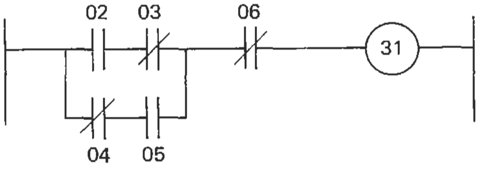


Figure 3.131 A typical ladder rung

Step	*Instruction*	*I/O number*
000	LD	02
001	AND NOT	03
002	LD NOT	04
003	AND	05
004	OR BLK	
005	AND NOT	06
006	OUT	31
007	END	

Note: the 'OR BLK' statement 'ORs' the blocks grouped under the preceding two load (i.e. LD) statements.

Different PLCs use various ways of translating the ladder programs into mnemonics, but the principle is basically the same as that illustrated. This translation is necessary if the program is to be entered into the controller via a hand-held programmer. However, if a PC-based software development system is used the ladder diagram is entered directly by pressing the appropriately specified function keys.

3.8.3.3 Timers

Time delays are commonly used in control applications and in a PLC program a timer is used to activate an output following an elapsed time as specified by a value stored in the memory. The timing base units are usually tenths or hundredths of a second.

There is no standard way of specifying timer routines and manufacturers use different methods, but the same basic principles of operation apply. This entails an enabling input condition to start the timer. At the end of the timed period the timer must be reset by disenabling the input.

It must be noted that during the program execution the ladder is *continuously* scanned rung by rung and outputs set according to input conditions. There can be no hold on any particular rung. However, in implementing timing operations the timer output can be used as an input on any rung, thus making outputs dependent upon the specified time period to have expired. This is illustrated in Figure 3.132. In this figure the timer number 50 is set for a timing operation of 1 s and is enabled by switching input number 05 to an ON state. In the next rung the output number 30 will not be energized until the specified time has elapsed. The timer must then be reset by setting the output 05 to OFF.

3.8.3.4 Counters

A counter is used to activate an output after a predetermined number of counts as stored in the PLC memory. It operates in much the same manner as a timer but, rather than counting time, the counter counts the number of times that an event occurs. The event is some specified input condition in the process. The counter is reset from another input switch and it can be used as an input to any other rung in the ladder. This is illustrated in Figure 3.133. Each time that switch 02 is activated a count is produced up to the specified value of 10. Once the count is completed the output load number 30 is switched ON. The counter is then reset by switching input 01 OFF. An incrementing or decrementing mode for the counter operation is usually possible with most PLCs.

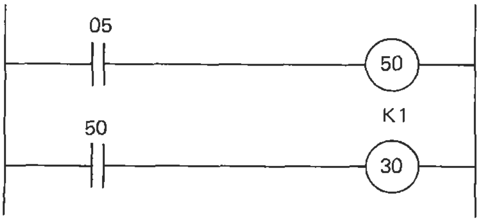

Figure 3.132 Example of a timing operation

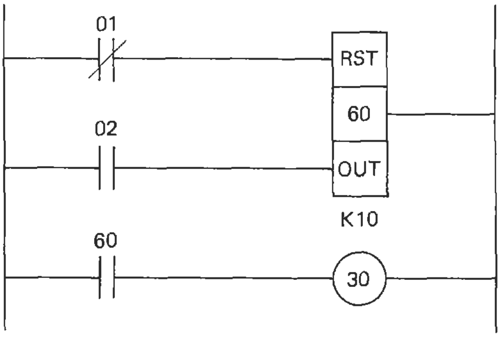

Figure 3.133 Example of a counter operation

3.8.3.5 Auxiliary relays

Most PLCs are equipped with various special function input/output facilities that exist in the development of safe and efficient control programs. The auxiliary relay is one such device which operates internally and is assigned an address that is different from that of any other real output device in the system. It is basically a 'dummy relay' which is used as an aid to developing the program. For example, consider an output condition which is dependent upon, say, six inputs and a rung is restricted to four inputs. The auxiliary control relay can be used to connect two rungs into a logical equivalence of the requirement as shown in Figure 3.134.

3.8.3.6 Input/output numbering

Different PLC manufacturers use different numbering systems for the controller's available I/O. The addresses assigned for the small Mitsubishi type F-20M PLC are typical:

12 inputs:	00–07; 10–13
8 outputs:	30–37
8 timers with a range of 0.1–99 s:	50–57
8 counters with a range of 1–99 counts:	60–67
48 auxiliary relays:	100–157

(Note the octal numbering system adopted)

3.8.4 Controlling pneumatic and hydraulic systems

Consider the sequencing of a double-acting pneumatic cylinder with digital sensing devices of mechanical, optical or

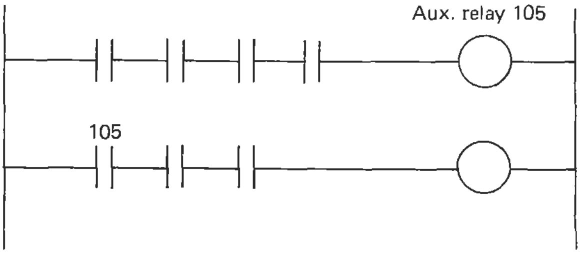

Figure 3.134 Use of an auxiliary relay

magnetic construction to detect the end-of-stroke condition. The direction of motion is controlled by an electropneumatic five-port spool valve which is solenoid/pilot operated. The air supply to the system manifold is enabled by an ON/OFF switch connected to a solenoid-operated three-port valve.

The control program is required to switch on the air, extend the cylinder rod to the end of the stroke, wait 5 s then retract the rod and repeat to complete 10 cycles. The main ON/OFF switch is to be used to reset the counter and it must also stop the cycling at any time. The input/outputs are assigned as follows:

INPUTS
ON/OFF switch – 00
Sensor to detect retracted position – 01
Sensor to detect extended position – 02
OUTPUTS
Air supply valve – 30
Direction control valve solenoid to extend cylinder rod – 31
Direction control valve solenoid to retract cylinder rod – 32
TIMER – 50 and COUNTER – 60

Figure 3.135 shows the ladder diagram to satisfy the specified sequence. Note that de-activating the ON/OFF switch will stop the system at any time and that the rod will not extend once the counter has completed the required number of cycles.

With solenoid/pilot valves the solenoid need only be pulsed since the pilot line in the valve supplies air to move the spool, and it is usually unnecessary to maintain the solenoid in an energized condition. This is evident in the ladder diagram with inputs 01 and 02 from the end-of-stroke sensors returning to the OFF state once the cylinder rod moves from the end condition.

With solenoid only operated valves, however, it is necessary to latch the output load ON in order to maintain the rod motion. The ladder relay logic for rung 4 to latch on solenoid 31 in order to extend the cylinder rod is illustrated in Figure 3.136. Once the rod has left the sensor 01, power is transmitted to the output via the switched output acting as an input. This latches the control solenoid ON and it is switched OFF once the end of stroke is reached and sensor 02 is switched ON.

3.8.5 Safety

Since the equipment generally associated with PLCs often involve high voltages and currents, electrical safety procedures must be followed at all times. In addition, when testing a developed program to perform a specific task it is is essential that a simulation is first carried out in order to avoid the incorrect movement of large pieces of machinery which would result in dangerous operating conditions. Most PLCs contain a test-mode facility where outputs can be simulated by LED indication for a switched input requirement. The process is simulated by the manual manipulation of switches at specific times. The effects of the control program on the process may then be observed by the status of the PLC LED indicators on the I/O modules. If necessary, the program can be edited in the program mode and then retested prior to connecting to the actual system which is to be controlled.

3.8.6 Networking of PLCs

Computer-integrated manufacturing incorporates the highest level of automation economically feasible from each computer-based activity within a complete system. The overall control task is divided into a number of individual routines assigned to specific control elements such as CNC machine tools, robots and PLCs. The PLC thus constitutes one of the building blocks of the automated factory pyramid concept. This requires a suitable network to enable the various elements to exchange information and utilize a control database.

The manufacturers of PLCs have addressed the problem of networking, but the major disadvantage is that each manufacturer adopts their own standards. Communicating with a variety of other control devices is not a strength of PLC networks due to the number of data-transmission protocols and data formats adopted. However, most manufacturers provide a dedicated Local Area Network (LAN) for communication between controllers within their own product range and examples are given in Table 3.8.

Table 3.8 Typical PLC networks

Manufacturer	*Network*
Allen Bradley	Allen Bradley Data Highway
Festo	PC-IFS
General Electric	GE Net Factory LAN
Mitsubishi	Melsec-NET
Texas Instruments	TI-WAY

The basic concepts relating to the standards of communication in digital systems are covered in Section 3.3. In a decentralized network structure the sensing, actuating and processing associated with each controlled element in a system is connected to a supervisory or master computer. This evaluates signals supplied by each component and returns the necessary control requirements. A PLC, PC, single-board or single-chip computer could be used as the controller for the controlled element and a process computer, PC, minicomputer or mainframe can be employed in the supervisory role.

3.8.6.1 Network structures

Although there are various methods adopted for the networking of computer-based products they all possess certain common features. Each element must be equipped with a suitable interface associated with the LAN chosen and each element in the system must be connected into the network by means of wire or fibre-optic cabling to transmit the data from one station to another. Software is also necessary to handle all data transfer within the system correctly.

The physical arrangement of the elements or stations on the network are usually of a 'star' or 'ring' pattern. In the star-shaped network, as shown in Figure 3.137, the stations are connected on a line parallel to one another and connected to a central computer referred to as the 'file server'. With this method, each user station must decide on whether data sent by the file server are for itself or another station. The cable length is limited in this system, but signal amplifiers can be used if required.

In the ring structure as shown in Figure 3.138 the file server master computer transmists data to the first station on the network. These data are checked, evaluated and passed on to the second station if not required. The data are hence transmitted from one station to another until the user for whom they are intended is found. Data can therefore be passed around great distances but the failure of any one station causes the system to break down.

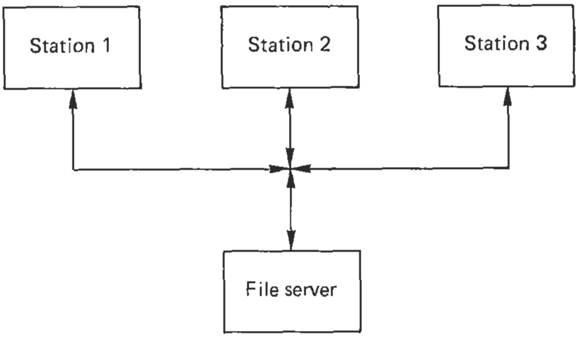

Figure 3.137 A star-shaped network

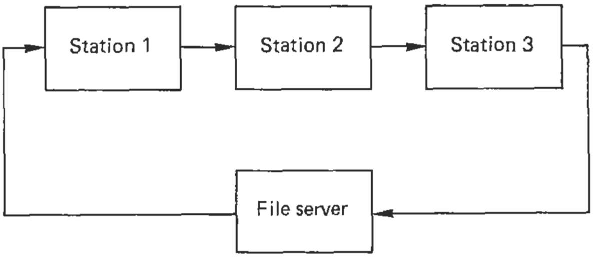

Figure 3.138 A ring network

The integration of all intelligent elements into an automation system requires that all devices communicate with each other. Due to the different suppliers having different communication specifications, international communication standards based on the Open System Interconnection Model (OSI) have evolved. Widespread adoption of such standards will make it easier and cheaper to link devices together.

One such standard is the Manufacturing Automation Protocol (MAP), which was initiated by General Motors to integrate all levels of control systems such as PLCs, robots, welding systems, vision systems, etc, irrespective of the manufacturer. Another very popular LAN standard adopted for industrial and commercial application is ETHERNET, which was created by Digital Equipment Corporation, Intel and Xerox.

Users of automation systems will make their purchasing decisions based on the amount of software packages and support services that the distributed control system vendors can provide.[23] Only those vendors who are capable of supplying such products and services to provide a complete solution to a control problem will be successful in the future.

3.9 The z-transform

As outlined in Section 3.7, the availability of inexpensive and continually improving microprocessors has led to their application to direct digital control techniques in the closed-loop feedback control of processes. With the introduction of these sampled-data systems mathematical techniques have been developed specifically to provide a design method for digital controllers. The technique generally employed is similar to the Laplace transform used in continuous systems.

The Laplace transform, through the s operator, is used to transform linear differential equations into a linear algebraic form which can then be appropriately manipulated to produce open- and closed-loop transfer functions for a system. This is illustrated in Section 3.6.3 and the method forms a basis for the design of continuous controllers.

In a discretely sampled system the z-transform is used to provide an algebraic way of representing a sequence of digital data with respect to time measurements. The symbol z for the digital system is analogous to s in the continuous system. The z-transform is associated with the time shifting in a difference equation as s is associated with differentiation in a differential equation.

The operators may be mathematically defined as follows:

$$s = \mathrm{d}/\mathrm{d}t = j\omega$$

$$z = \mathrm{e}^{sT}$$

where T is the discrete time sampling interval and z^{-1} is a delay operator which represents a delay of one sampling period.

3.9.1 Representation of discretely sampled data

The characteristics of a digital control loop are related to the sampling process associated with the conversion of transducer analogue data into a digital format and the converse between the controller output and the system being controlled. The sequence of events are as follows:

1. The process variable (PV) is measured and the corresponding analogue signal is converted into a digital value using an A/D converter.
2. This value is compared with the declared set point (SP) to give on error value (E) on which the controller transfer function operates to produce a control effort (U) as a numerical value preferably expressed as a percentage within the range 0–100%.
3. The control effort derived is then converted by means of a final control element into the actual power supplied to the plant or process. This element invariably involves a D/A converter which holds the value of the impulse received until the next value arrives in a staircase fashion. This is referred to as a 'zero-order-hold' device.

The overall time for the sequencing cycle is the sampling frequency

$$f_s = 1/T$$

where T is the sampling interval.

It is most important to appreciate the physical nature of the variables at each stage in the loop and this is illustrated in Figure 3.139. The discretely sampled data associated with the process variable, PV, and its related derived values of error and control effort are displayed at time intervals of T. These are suffixed by an asterisk to indicate that they are snapshots of the plant state at a particular time. The z-transform provides an algebraic way of mathematically presenting such sequences of digital information.

Consider in detail the variation in the derived error signal, E, as shown in Figure 3.140. Numerical values, quoted as percentages of the range of the measuring transducer, are inserted to illustrate the mathematical form of the z-transform equation to represent the variation of E with time. The sequence is shown as:

$$E(n) = 80,60,40,25,12,6,0,0,\ldots$$

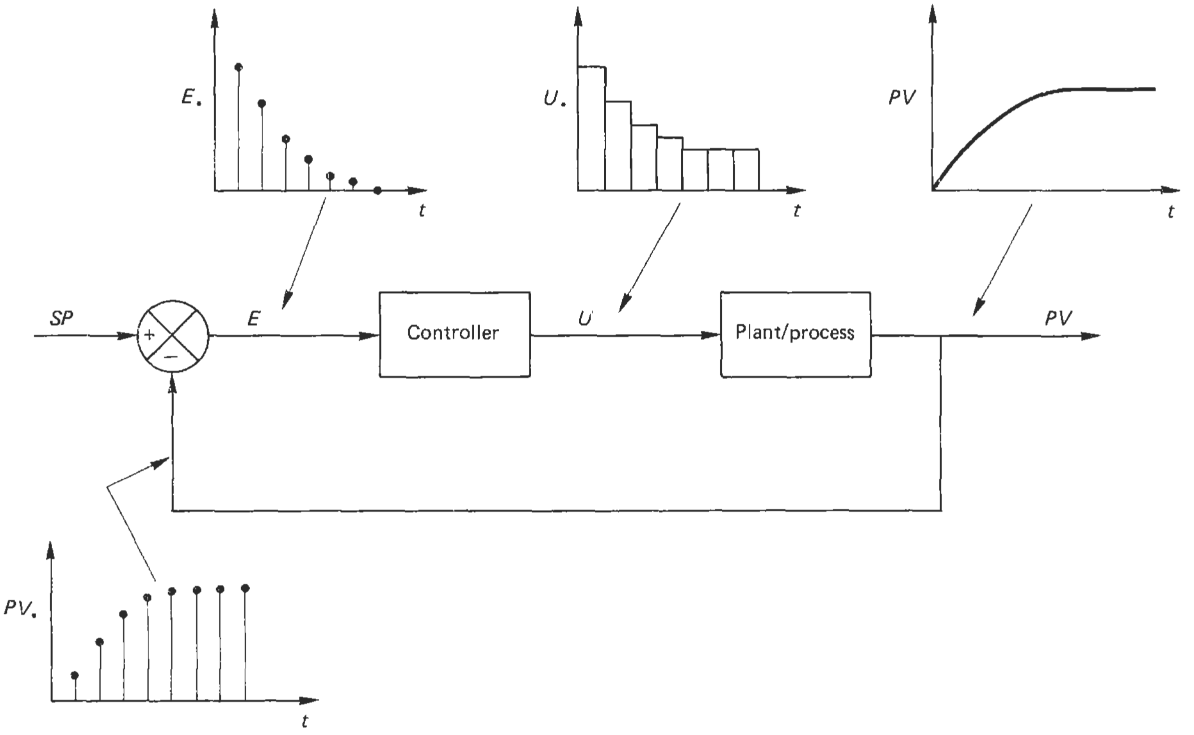

Figure 3.139 Nature of the variables in a digital control loop

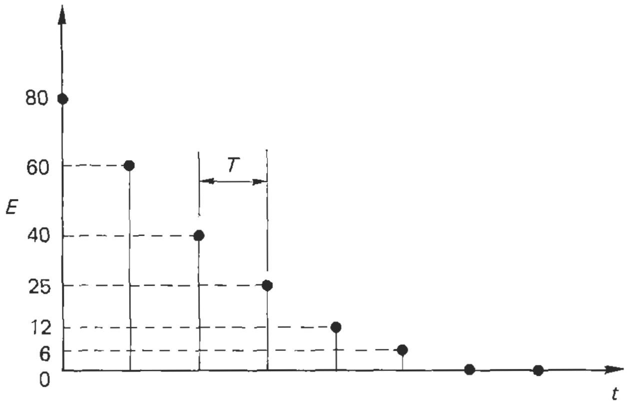

Figure 3.140 Variation of discrete error values with time

and the corresponding z-transform of the sequence is defined by the sum

$$E(z) = 80 + 60z^{-1} + 40z^{-2} + 25z^{-3} + 12z^{-4} + 6z^{-5}$$

This method of representation is particularly useful for handling time delays. For example, if the sequence was delayed by one sampling interval then it becomes

0,80,60,40,25,12,6,0,0, . . .

and the corresponding z-transform

$$80z^{-1} + 60z^{-2} + 40z^{-3} + \ldots$$

which is the first sequence multiplied by z^{-1}. Thus multiplication by z^{-1} denotes a one sampling period delay. Similarly, multiplication by z^{-2} would denote a delay of two sampling periods.

Generally, z-transform models of digitally sampled data or its derivatives can be obtained provided the relationship between the continuous variation of the data with time is known in a mathematical form. For example, say that the error value can be expressed in the form

$$E(t) = 100e^{-t}$$

which for the data sampled at intervals of T would yield:

$$E(z) = 100(1 + e^{-T}z^{-1} + e^{-2T}z^{-2} + e^{-3T}z^{-3} + \ldots)$$

This is the sum of a geometric series given by

$$\begin{aligned} \text{SUM} &= 100/(1 - e^{-T}z^{-1}) \\ &= 100z/(z - e^{-T}) \end{aligned}$$

which is the z-transform $E(z)$.

If the data were sampled at a frequency of 10 Hz (i.e. $T = 0.1$ seconds) then

$$E(z) = \frac{100z}{(z - 0.905)}$$

In order to aid the design process associated with digital techniques, z-transforms of common sampled functions are tabulated in a way similar to Laplace transforms. Examples of some common time functions with their corresponding Laplace transform and z-transforms are given in Table 3.9.

When applying digital techniques the z-transform, $G(z)$, must usually be derived from the corresponding transfer function for the operation expressed in terms of s, $G(s)$. It should be noted that it is not simply a case of substituting z for s in the function. The basic approach is generally to obtain the partial fraction expansion of $G(s)$ to yield individual components which translate directly into z-transforms using a standard table such as Table 3.9.

For example, consider the transfer function $G(s)$ given by

$$G(s) = 1/s(1 + 2s)$$

Although this form appears explicitly in Table 3.9 it can be used to illustrate the technique of partial fraction expansion. Using partial fractions it can be assumed that

$$G(s) = A/s + B/(1 + 2s)$$

from which $A = 1$ and $B = -2$. Hence $G(s) = 1/s - 2/(1 + 2s)$. Rearranging the second term to conform to the appropriate Laplace transform in the table gives

$$G(s) = 1/s - 1/(s + 0.5)$$

The constitutent parts produce the z-transform from the table as

$$G(z) = z/(z - 1) - z/(z - e^{-0.5T})$$

and after algebraic manipulation gives

$$G(z) = z(1 - e^{-0.5T})/(z - 1)(z - e^{-0.5T})$$

This is as expected from the Laplace transform, $a/s(s + a)$, in Table 3.9.

Table 3.9 Table of z-transforms

Time function	*Laplace transform*	*z-transform*
Unit step input	$1/s$	$z/(z - 1)$
t(ramp input)	$1/s^2$	$Tz/(z - 1)^2$
$t^2/2$	$1/s^3$	$\dfrac{T^2z(z + 1)}{2(z - 1)^3}$
e^{-at}	$1/(s + a)$	$z/(z - e^{-aT})$
te^{-at}	$1/(s + a)^2$	$\dfrac{Tze^{-aT}}{(z - e^{-aT})^2}$
$1 - e^{-at}$	$a/s(s + a)$	$\dfrac{z(1 - e^{-aT})}{(z - 1)(z - e^{-aT})}$

3.9.2 The z-transform of a closed-loop system

Before z-transforms for the digital control loop illustrated in Figure 3.139 can be derived, it is first necessary to consider the nature of the input and output to the plant/process. The input, associated with digital-to-analogue conversion hardware, is basically a 'zero-order-hold' element which effectively supplies a control effort to the process in a pulsed form. The nature of the output from the controller relates to the analogue-to-digital conversion which effectively is indicative of the discrete sampling process. Thus the input is a step and the output sets the sampling characteristics of the loop on the basis of a sample time T.

This arrangement, with the nature of the appropriate signals, is shown in Figure 3.141. What is required is the z-transform for this complete arrangement, $G(z)$, and not simply the equivalence of $G(s)$ alone. This is usually referred to as the 'pulse transfer function'. The total sampled response consists of the difference between the positive stepped input to the process and the same value delayed by one sample period.

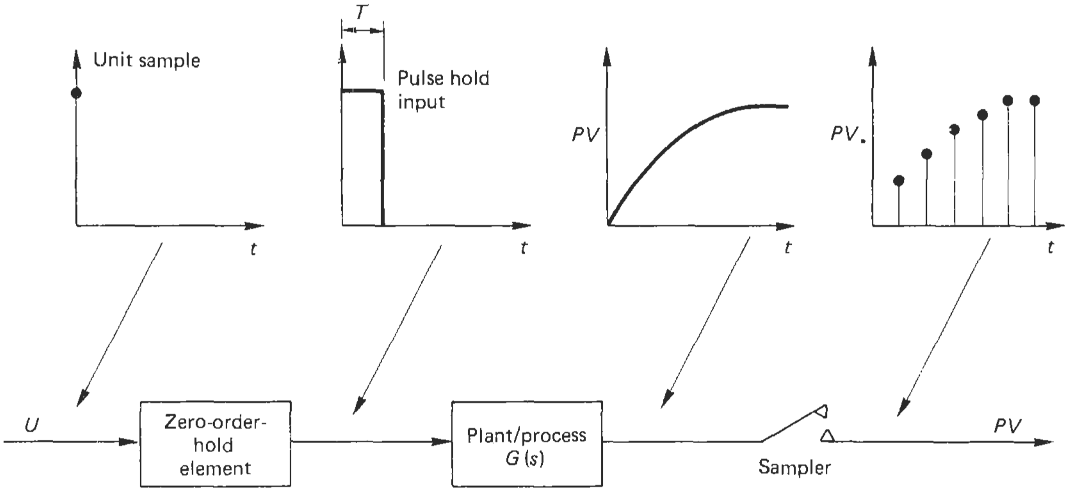

Figure 3.141 Discrete sampling in a control loop

This will give the required pulse transfer function, and it can be written as

$$G(z) = \frac{1}{s} \cdot G(s) - e^{-sT} \frac{1}{s} G(s)$$

$$= (1 - z^{-1}) * \text{ the } z\text{-transform of } \left(\frac{1}{s} \cdot G(s)\right)$$

or

$$G(z) = (z - 1)/z * \text{ the } z\text{-transform of } \left(\frac{1}{s} G(s)\right) \qquad (3.57)$$

which is the z-transform equivalence of all the elements shown in Figure 3.141.

It should be noted that the discrete sampling process effectively introduces a phase lag into the system with its associated inherent stability problems. The closed-loop transfer function in terms of the z-transform is derived in a way similar to that for a continuous system, with $G(z)$ representing the pulse transfer function associated with the hold, plant/process and sampling routine.

Consider the basic loop as shown in Figure 3.142. The forward path transfer function is

$$PV(z) = G(z)U(z)$$
$$= G(z)C(z)E(z)$$

and the closed-loop transfer function is

$$PV(z)/SP(z) = (C(z)G(z))/(1 + C(z)G(z)) \qquad (3.58)$$

which has a form similar to that for the transfer function of a system with a continuous feedback control loop.

The procedure for evaluating the response of a plant/process to a step input with digital control using a sample time of T is as follows:

1. Obtain the pulse transfer function $G(z)$ from the known form for $G(s)$:

   $G(z) = (z - 1)/z$ * the z-transform of $[G(s)/s]$
2. Express the controller transfer function $C(s)$ in z-transform format.
3. Evaluate the closed-loop transfer function for $PV(z)/SP(z)$.
4. Algebraically manipulate this expression to yield a discrete time-ordered equation which formulates the current value of PV (say, PV_i) in terms of the past values of PV and SP. This is obtained using the relationships:

   $PV(z)z^{-1} = PV_{i-1}$ where $i - 1$ denotes one period back in time

   $PV(z)z^{-2} = PV_{i-2}$

   etc.

3.9.3 Proportional control using digital techniques

For a proportional control strategy as outlined in Section 3.7.5 the controller transfer function $C(s)$ and the corresponding z-transform is simply the gain, K. Taking as an example the plant transfer function to be that for a first-order system of the form

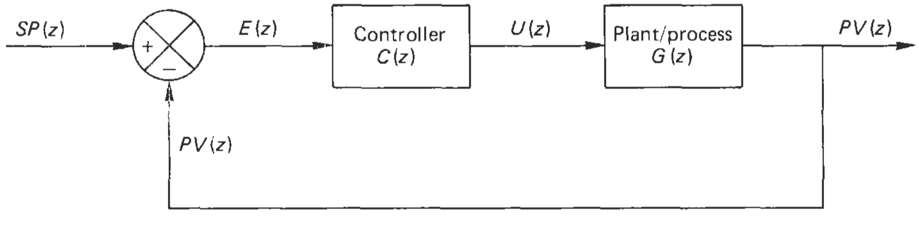

Figure 3.142 Closed loop in terms of a z-transform

$G(s) = 1/(1 + \tau s)$

the procedure outlined in Section 3.9.2 gives the required pulse transfer function as

$$G(z) = (z - 1)/z * \text{ the } z\text{-transform of } [1/s(1 + \tau s)]$$

$$= \frac{(z-1)}{z}\left[\frac{z}{(z-1)} \cdot \frac{(1 - \mathrm{e}^{-T/\tau})}{(z - \mathrm{e}^{-T/\tau})}\right]$$

$$= C_1/(z - C_2)$$

where $C_1 = 1 - \mathrm{e}^{-T/\tau}$ and $C_2 = \mathrm{e}^{-T/\tau}$. Hence the z-transform for the closed loop is

$$PV(z)/SP(z) = (C(z)G(z))/(1 + C(z)G(z))$$

$$= ((KC_1)/z - C_2))/1 + KC_1/(z - C_2))$$

$$= \mathrm{a}/(\mathrm{z} + \mathrm{b})$$

where $a = KC_1$ and $b = (KC_1 - C_2)$.

It is now necessary to transform this equation into a discrete time-stepped form which expresses the current value of the process variable, PV_i, as a function of past values. This can be obtained by dividing the numerator and denominator by z to the power corresponding to the maximum value in the denominator. In this example the dividing factor is simply z, i.e.

$$PV(z)/SP(z) = az^{-1}/(1 + bz^{-1})$$

or

$$PV(z) = aSP(z)z^{-1} - bPV(z)z^{-1}$$

Writing this as a time-difference equation yields

$$PV_i = aSP_{i-1} - bPV_{i-1} \tag{3.59}$$

For a step input, $SP = 1$ for $i > 1$ and starting values are, say,

$i = 1$; $t = 0$; $SP = 1$ and $PV = 0$

Equations of this form are easily programmed on a computer to produce a graphical time response of PV to a step input for declared values of system time constant τ, controller gain K and sample time T.

Figures 3.143 and 3.144 illustrate the effect of the sample time, T, on the predicted response of the system using the z-transform technique outlined with $\tau = 1$ and $K = 10$. These are clearly illustrative of the introduction of a delay into the system due to the incorrect sampling of the process, and leads to a transient behaviour or, eventually, an unstable condition. The choice of a satisfactory sampling interval, T, is covered in Section 3.7.4, but it should be noted that it is dependent upon the system time constant and the controller settings. Hence one advantage of the z-transform technique in obtaining a simulation of the performance of a mathematically modelled system is the ability to investigate the effect of the sample rate for chosen controller settings.

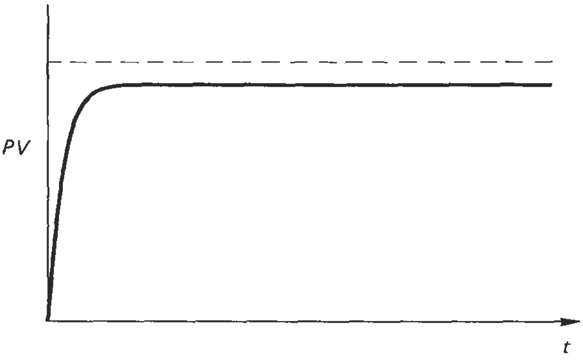

Figure 3.143 System response with $T = 0.01$ s

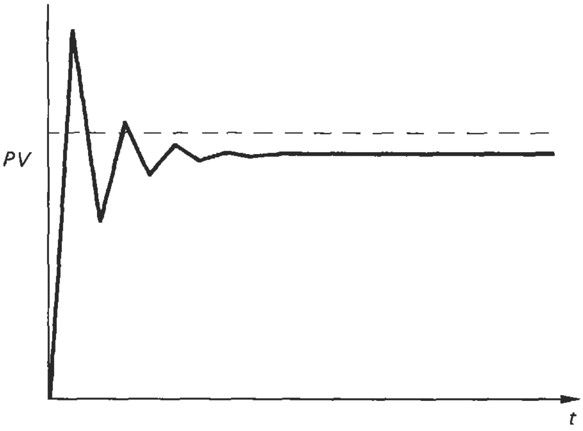

Figure 3.144 System response with $T = 0.15$ s

3.9.4 The z-transform for a PID controller

The PID control law for a continuous controller as outlined in Section 3.7.5 is

$$U = K[E + 1/T_i \int E\mathrm{d}t + T_\mathrm{d}\mathrm{d}E/\mathrm{d}t]$$

The integral term can be approximated numerically as a summation of rectangular elements which at any time t can be expressed as

$$I_i = I_{i-1} + E_iT$$

where I_{i-1} is the value of the integral term up to the instant $t - T$, or in z-transform notation:

$$I(z) = I(z)z^{-1} + E(z)T$$

i.e. $I(z) = (Tz/(z - 1))E(z)$

Similarly, the derivative term can be approximated as the slope of the line joining the current E value and the previous value, i.e.

$$D_i = (E_i - E_{i-1})/T$$

or $D(z) = (E(z) - E(z)z^{-1})/T$

i.e. $D(z) = [(z - 1)/Tz]E(z)$

The integral and derivative terms in z-transform notation can now be substituted into the full three-term expression to give $C(z)$:

$$C(z) = U(z)/E(z) = K\left[1 + \frac{1}{T_i} \cdot \frac{Tz}{(z-1)} + T_\mathrm{d}\frac{(z-1)}{Tz}\right] \tag{3.60}$$

3.9.5 A $P + I$ strategy using digital techniques

For a $P + I$ strategy

$$C(z) = K\left[1 + \frac{1}{T_i} \cdot \frac{Tz}{(z-1)}\right]$$

Applied to a first-order system, $G(s) = 1/(1 + \tau s)$ gives a corresponding pulse transfer function of

$$G(z) = C_1/(z - C_2)$$

with $C_1 = (1 - e^{-T/\tau})$ and $C_2 = e^{-T/\tau}$.

Substituting for $C(z)$ and $G(z)$ into the closed-loop transfer function and manipulating the result in a manner similar to that illustrated in Section 3.9.3 yields the time-sequence equation as:

$$PV_i = aSP_{i-1} - bSP_{i-2} + CPV_{i-1} + dPV_{i-2} \qquad (3.61)$$

where:

$$a = K(1 - e^{-T/\tau})(1 + T/T_i)$$

$$b = K(1 - e^{-T/\tau})$$

$$c = (1 + e^{-T/\tau}) - K(1 - e^{-T/\tau})(1 + T/T_i)$$

$$d = K(1 - e^{-T/\tau}) - e^{-T/\tau}$$

For $t < 0$ then $SP = 0$. At $t = 0$: $PV = 0$ and $SP = 1$ for a unit step input.

Figure 3.145 illustrates the response of a first-order system with $\tau = 1$ when a $P + I$ control strategy is applied using a gain K of 2 and an integral time T_i of 0.1. When the discrete sample time T is taken as 0.01 seconds, the result compares favourably with that for continuous control. If, however, the time step is increased to 0.35 seconds then the plant responds in a much more oscillatory manner for the same controller settings. This is illustrated in Figure 3.146. When T is increased beyond the value of 0.35 then the system behaves in an unstable manner. With digital control the sampling time, T, which would cause the system to go unstable depends upon the value of the system time constant and the controller settings.

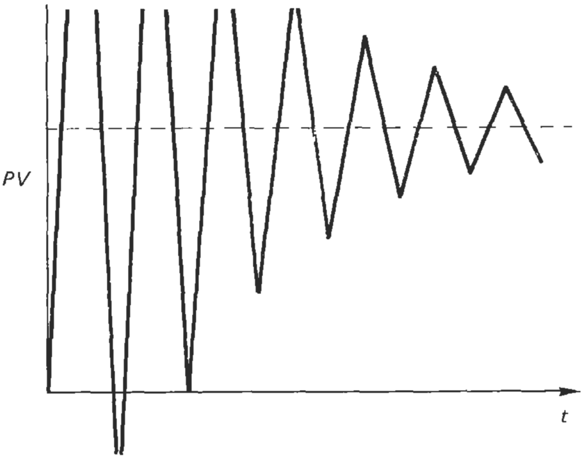

Figure 3.146 System response with $K = 2$, $T_i = 0.1$ s and $T = 0.35$ s

3.9.6 Stability in discrete time systems

As seen in the previous sections, an incorrectly chosen sample time can result in a system becoming unstable due to the imposed delay. This initial value of T can be obtained by considering the representation of the poles of the pulse transfer function $G(z)$ in the z-plane.

If the closed-loop transfer function in z-transform notation is written in terms of a numerator $N(z)$ and a denominator $D(z)$ then the poles are defined as the roots of the equation $D(z) = 0$. These roots may contain a real and imaginary component and take the form $a + jb$ with the resulting plot termed the 'z-plane'. Systems whose poles are all inside the unit circle in the z-plane are stable and those with any poles outside it are unstable. The position of the poles within the unit circle are indicative of the degree of the resulting oscillatory motion which may result following a step input. A z-plane plot is shown in Figure 3.147.

When using the z-transform method of analysis for the digital control of a system the position of the poles in the z-plane are dependent upon the magnitude of the sample time taken. For example, consider a process having a transfer function $G(s) = 1/s$ and controlled using a proportional control strategy. Using the method outlined in Section 3.9.2 the corresponding pulse transfer function and closed-loop z-transfer function are, respectively,

$$G(z) = T/(z - 1)$$

and $PV(z)/SP(z) = KT/(z - 1 + KT)$

i.e. $D(z) = z - 1 + KT$

For the loop to be stable the poles of the real axis should lie in the range of $-1 < z < +1$, which means, by putting $z = -1$, that $KT = 2$ for the limit of stability. If $K = 5$ then the sample time T must be less than 0.4 for the system to remain stable.

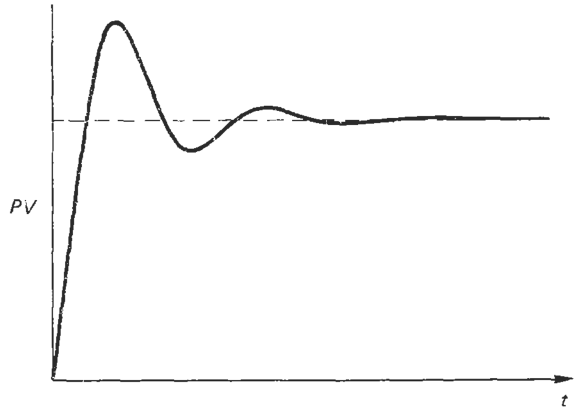

Figure 3.145 System response with $K = 2$, $T_i = 0.1$ s and $T = 0.01$ s

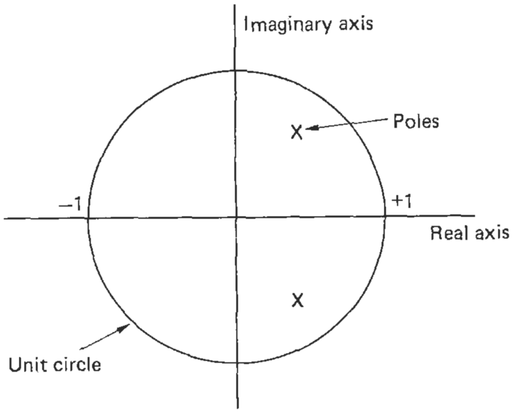

Figure 3.147 The z-plane

It can be seen that the position of the poles in the z-plane is a useful concept in determining whether a system will be stable for a chosen sample time.

3.10 State variable techniques

3.10.1 State variable representation of systems

The state variable approach to system modelling involves the use of matrix and vector methods which provide a consistent solution procedure for the analysis of complex control problems. While these methods can be applied to any single-input–single-output control system, their real power lie in their application to multiple-input–multiple-output systems. The state space representation also finds application to the analysis of non-linear control systems where the non-linear elements of a system are accounted for in a self-consistent manner.

In order to generate a system of state variable equations the system must be adequately defined in terms of the governing differential equations in a continuous system or of the difference equations in a discrete one. A convenient method of representing the mathematical operations and equations is by means of a block diagram made up of the appropriate sequence of operators. In a continuous control system the most common operators are shown in Figure 3.148. The simple damped spring and mass system serves as a useful illustrative example (see Figure 3.149).

The relation which governs the motion of the mass as a function of time is given as a second-order linear differential equation, i.e.

$$\frac{d^2y}{dt^2} + 2\xi\omega_n \frac{dy}{dt} + \omega_n{}^2 y = u \qquad (3.62)$$

or

$$\ddot{y} + 2\xi\omega_n\dot{y} + \omega_n{}^2 y = u \qquad (3.63)$$

Solving for the highest derivative gives

$$\ddot{y} = u - 2\xi\omega_n\dot{y} - \omega_n{}^2 y \qquad (3.64)$$

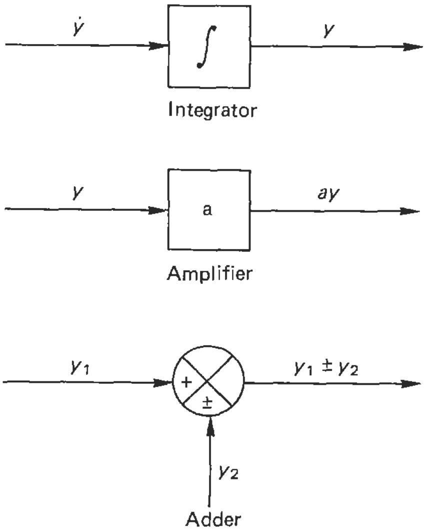

Figure 3.148 Mathematical operators in continuous-control systems

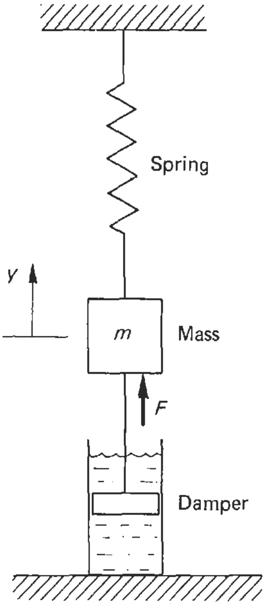

Figure 3.149 Simple damped spring and mass system

where u is the input forcing function.

The block diagram representation of equation (3.64) may be developed by first integrating y twice, as shown in Figure 3.150. The loop may then be closed by satisfying the requirement of equation (3.64) as shown in Figure 3.151.

The quantities y and y are called state variables. These are not unique and there is an endless range of possible combinations which may be chosen. It is normal, however, to select as state variables those quantities which are significant to the problem under consideration. In this respect the output, the first derivative of the output and any higher-order derivatives of the output would make the most suitable choice of state variables. In choosing the set of state variables it should be recognized that the state variables must be related through a differential or a difference equation. In a continuous-control system the normal practice is to select the output from any integrator as an appropriate state variable.

For the damped spring mass system the following state variables are selected:

$X1 = y$: $X2 = \dot{y}$

Consideration of the block diagram of Figure 3.151 shows that

$$\dot{X}1 = X2 \qquad (3.65)$$

$$\dot{X}2 = -\omega_n{}^2 X1 - 2\xi\omega_n X2 + u \qquad (3.66)$$

It transpires therefore that the state variable representation reduces the original second-order differential equation to two simultaneous first-order differential equations. Similarly, a third- or higher-order differential equation could be represented as a set of three or a higher number of first-order differential equations.

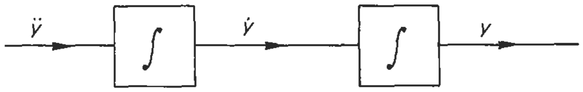

Figure 3.150 Double-integration process

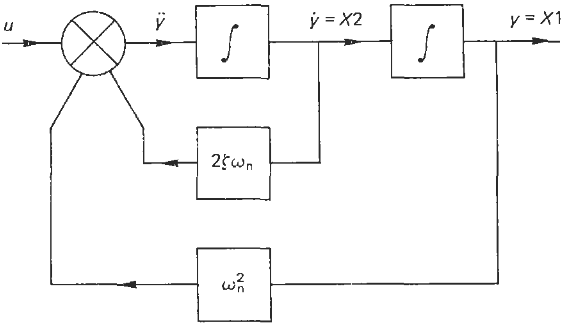

Figure 3.151 Block diagram representation of equation (3.64)

Writing equations (3.65) and (3.66) in matrix notation gives

$$\begin{bmatrix}\dot{X}1\\ \dot{X}2\end{bmatrix} = \begin{bmatrix}0 & 1\\ -\omega_n{}^2 & -2\xi\omega_n\end{bmatrix}\begin{bmatrix}X1\\ X2\end{bmatrix} + u\begin{bmatrix}0\\ 1\end{bmatrix} \tag{3.67}$$

and

$$y = [1 \quad 0]\begin{bmatrix}X1\\ X2\end{bmatrix} + u[0] \tag{3.68}$$

Any suitable matrix method can be used to solve for $X1$ which is equivalent to the system output (i.e. the position of the mass as a function of time) for any given input u. Alternatively equations (3.65) and (3.66) may be written as simple finite difference approximations and solved simultaneously over an appropriate time increment. For free vibration following a step disturbance to the system, $u = 0$, the finite difference approximation may be written as

$$\Delta X2_i = \Delta t[-2\xi\omega_n X2_{i-1} - \omega_n{}^2 X1_{i-1}] \tag{3.69}$$

$$X2_i \ = X2_{i-1} + \Delta X2_i \tag{3.70}$$

$$\Delta X1_i = \Delta t[X2_i] \tag{3.71}$$

$$X1_i \ = X1_{i-1} + \Delta X1_i \tag{3.72}$$

With suitable values assigned to ξ and ω_n and initial values designated to $X1$ and $X2$ at time = zero, the solution can march forward in time using a suitably small time increment Δt. A plot of $X1$ (which is the system output) against time gives the solution to the equation in the time domain. The more usual state variable representation, however, is shown as a plot of the state variables $X2$ against $X1$. For the damped spring mass system considered, this state space plot is a record of the instantaneous values of the velocity of the mass against its position with time as parameter. Figure 3.152 shows a set of results for selected values of ξ ranging between 0 and 1, with initial conditions of $X1(0) = -0.25$ and $X2(0) = 0$.

The set of curves which result from the solutions of the state variable equations are referred to as trajectories in the state space. For a second-order system, the plot is more generally called the phase plane. The values of the state variables are said to represent the state of the system. With a knowledge of future inputs and the governing state space equations, the phase plane trajectory can be predicted and hence also the behaviour of the system in general. Figure 3.153 shows another set of phase-plane trajectories for the damped spring mass system. In these plots the system is subject to heavy damping and the trajectories start from a range of different initial conditions. Plots such as these are referred to as phase-plane portraits.

One further example is included where a negative damping factor of -1 has been imposed and the computation started from $X1(0) = -0.10$ and $X2(0) = 0$. The resultant phase-plane plot is shown in Figure 3.154.

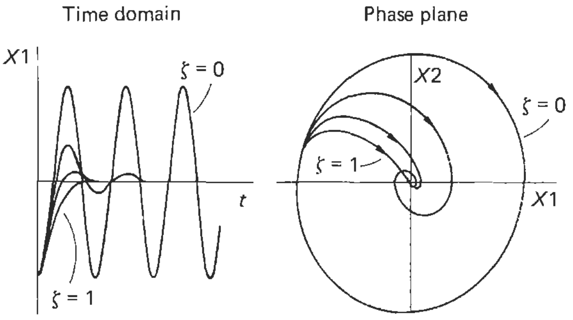

Figure 3.152 Time-domain and state-space representation of the damped spring mass system

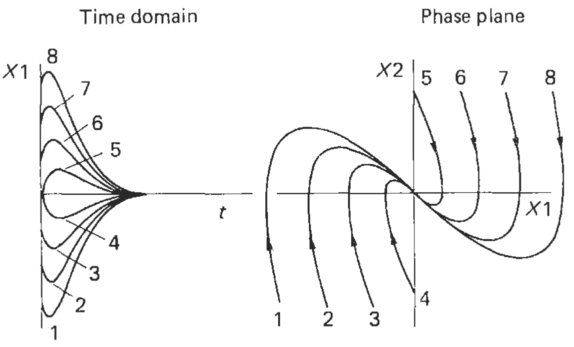

Figure 3.153 Phase-plane characteristic for the spring mass system with very heavy damping

Negative damping renders the system unstable and the amplitude of the oscillation increases with time as shown in the time-domain plot. The phase-plane plot indicates a trajectory which is spiralling outwards, and this is the general state-space representation of an unstable system.

Other information which may be easily gleaned from the phase-plane trajectory are an indication of whether the system reponse is over- or underdamped and the extent of any system overshoots.

3.10.2 Application to a first-order system with a $P + I$ controller

Figure 3.155 shows the control block diagram for a process which has an open-loop transfer function which can be modelled as a first-order differential equation. The control effort, U, is determined through a controller which utilizies a combination of proportional and integral action as shown. The closed-loop transfer function may be written as

$$\frac{PV(s)}{SP(s)} = \frac{K[1 + 1/(T_i s)][k/(1 + \tau s)]}{1 + K[1 + (1/T_i s)][k/(1 + \tau s)]} \tag{3.73}$$

Some algebraic manipulation results in

$$\frac{PV(s)}{SP(s)} = \frac{(kK/\tau T_i)(1 + T_i s)}{s^2 + [(1/\tau) + (kK/\tau)]s + (kK/\tau T_i)} \tag{3.74}$$

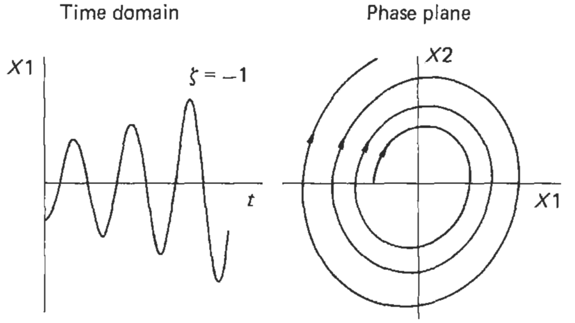

Figure 3.154 Phase-plane trajectory for the spring mass system with negative damping

Cross-multiplication gives

$$\frac{d^2(PV)}{dt^2} + \left[\frac{1}{\tau} + \frac{kK}{\tau}\right]\frac{d(PV)}{dt} + \frac{kK}{\tau T_i}(PV)$$
$$= \frac{kK}{\tau}\left[\frac{(d(SP)}{dt} + \frac{(SP)}{T_i}\right] \tag{3.75}$$

The differential equation (3.75) may be represented in block diagram form as shown in Figure 3.156.

Choosing the state variables as the outputs from the two integrators gives

$X1 = (PV) : X2 = (\dot{PV})$

Thus

$$\dot{X}1 = X2 \tag{3.76}$$

$$\dot{X}2 = \frac{-kK}{\tau T_i}X1 - \left[\frac{1 + kK}{\tau}\right]X2 + \frac{kK}{\tau}\left[S\dot{P} + \frac{SP}{T_i}\right] \tag{3.77}$$

The state variable equations can be written again as finite-difference approximations and a solution marched forward in time from specified initial conditions. The step response of the system for various settings of system gain, controller gain, integral time setting and system time constant are illustrated in Figure 3.157.

3.10.3 Application to a second-order system with a *P* + *I* controller

If the process to be controlled can be represented as a second-order differential equation then the open-loop transfer function for the process is

$$G(s) = \frac{k}{s^2 + 2\xi\omega_n s + \omega_n^2} \tag{3.78}$$

The closed-loop transfer function may be written as

$$\frac{PV(s)}{SP(s)} = \frac{kK(1 + T_i s)}{(T_i s^3 + 2\xi\omega_n T_i s^2 + \omega_n^2 T_i s + kKT_i s + kK)} \tag{3.79}$$

or

$$\frac{d^3(PV)}{dt^3} + 2\xi\omega_n\frac{d^2(PV)}{dt^2} + (\omega_n^2 + kK)\frac{d(PV)}{dt} + \frac{kK}{T_i}(PV)$$
$$= kK\left[\frac{d(SP)}{dt} + \frac{SP}{T_i}\right] \tag{3.80}$$

The corresponding state variable representation is

$$\dot{X}1 = X2 \tag{3.81}$$

$$\dot{X}2 = X3 \tag{3.82}$$

$$\dot{X}3 = -2\xi\omega_n X3 - (\omega_n^2 + kK)X2 - \frac{kK}{T_i}X1$$
$$+ kK\left[(S\dot{P}) + \frac{(SP)}{T_i}\right] \tag{3.83}$$

where $X1 = PV$, $X2 = (\dot{PV})$ and $X3 = (\ddot{PV})$.

The three ordinary differential equations involving the three state variables may be solved simultaneously and a phase-plane trajectory plotted as before. Strictly, the trajectory should be plotted, for this example, in three-dimensional state space. This would involve a plot of the trajectory in terms of the state variables $X1$, $X2$ and $X3$ with time as parameter. This would be difficult to plot and for still higher-order systems might be difficult even to visualize. Note, however, that the simple two-dimensional phase plane still has some significance and can be used as an indication of the system's general stability.

3.10.4 Non-linear system elements (method of isoclines)

In many real control systems there is often some form of non-linear element within the control loop which eliminates the use of linear theory to predict the closed-loop system response. In some cases, a linear approximation can be devised for the non-linear element but the approximation will always imply that there is some degree of error involved in the system model.

The phase plane represents one viable method of accounting for those non-linearities which cannot be either ignored or approximately linearized. It is not always necessary to plot the phase-plane trajectory in its entirety but rather to approximate the curve by estimating its slope at a number of locations in the phase plane. The approximate trajectory can then be fitted to match the known slopes in the phase plane. This is the so-called method of isoclines, which is best illustrated by an example.

3.10.4.1 Saturation characteristics

Saturation can occur, for example, when an amplifier is operated outside its linear range. This non-linear effect can be depicted as shown in Figure 3.158.

There are three distinct regions over which the amplifier has a significantly different characteristic:

1. $E \geqslant 0.5$; $U = 0.5$
2. $-0.5 < E < 0.5$; $U = E$
3. $E \leqslant -0.5$; $U = -0.5$

In all regions

$$PV = 10U/[s(0.5s + 1)]$$

or $10U = (0.5s^2 + s)PV = (0.5s^2 + s)(SP - E)$

Thus

$$10U = \frac{1}{2}\frac{d^2(SP)}{dt^2} + \frac{d(SP)}{dt} - \frac{1}{2}\frac{d^2E}{dt^2} - \frac{dE}{dt}$$

For a step input at time $t > 0$,

$$\frac{d^2(SP)}{dt^2} = \frac{d(SP)}{dt} = 0$$

The equation reduces to

$$\frac{d^2E}{dt^2} + 2\frac{dE}{dt} + 20U = 0$$

In region (i), (U = constant = 0.5)
Thus

$$\frac{d^2E}{dt^2} + 2\frac{dE}{dt} + 10 = 0$$

Choosing as a suitable state variable, $X1 = dE/dt$,

$$\dot{X}1 = -10 - 2X1$$

Defining the slop S as

$$S = \frac{\dot{X}1}{X1} = \frac{-10 - 2X1}{X1} = -2 - \frac{10}{X1}$$

Alternatively,

$$X1 = \frac{-10}{S + 2} \qquad (3.84)$$

Equation (3.84) is the isoclinal equation which applies in the region $U > 0.5$. The isoclinal equation defines a set of curves along which the slope of the trajectory in the phase plane of dE/dt against E will be constant. In selecting a suitable range of values for S, the isoclines may then be plotted in the phase plane. Equation (3.84) shows that these isoclines will be manifested as a set of lines which would be parallel to the horizontal axis.

In region 2 (U = E)
The governing equation becomes

$$\frac{d^2E}{dt^2} + \frac{2dE}{dt} + 20E = 0$$

Again choosing $X1 = dE/dt$ gives

$$S = \frac{\dot{X}1}{X1} = \frac{-20E - 2X1}{X1} = \frac{-2 - 20E}{X1}$$

i.e. $X1 = \dfrac{-20E}{S + 2}$ (3.85)

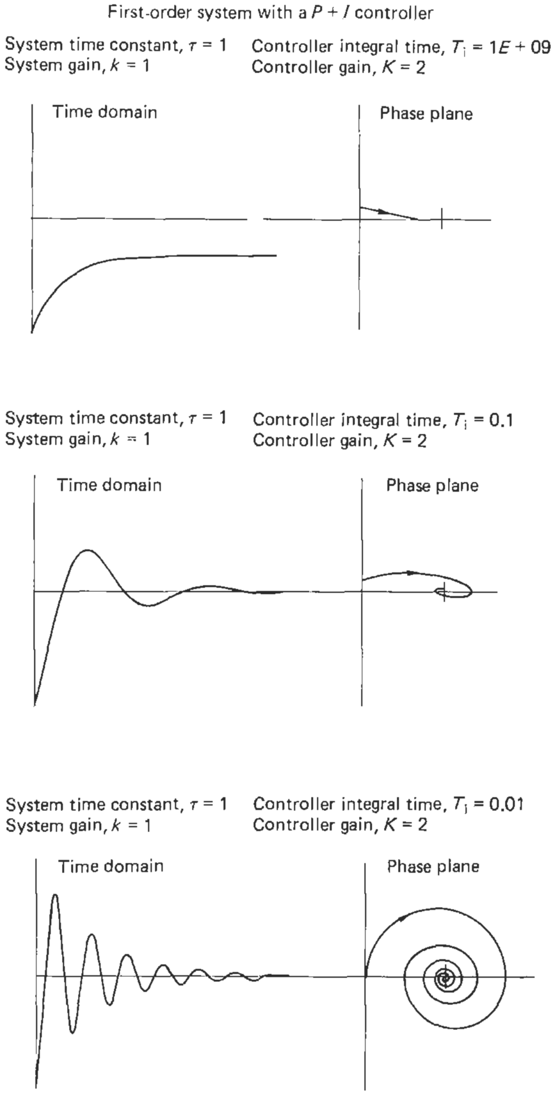

Figure 3.157 System response to a step input

The isoclinal equation in region 2 (equation 3.85)) defines a family of curves of constant slope, passing through the origin, with a gradient given by $-20/(S + 2)$.

In region 3 (U = constant = −0.5)
Region 3 is similar to region 1 with the isoclinal equation given by

$$X1 = \frac{+10}{S + 2} \tag{3.86}$$

Equations (3.84) to (3.86) define the isoclines for the phase-plane trajectory of the error response, and these are shown in Figure 3.159. From any given initial conditions the phase-plane trajectory may be patched in by smoothing a curve through the known values of S for each of the isoclines shown in the figure. For the particular system constants given a step input of 1 radian, the phase-plane trajectory of the error response shows that the system is stable and that the amplifier does not saturate on the first overshoot.

3.10.4.2 System with a dead-band characteristic

Figure 3.160 shows a non-linear system element which exhibits a dead-band characteristic. As in the previous example, there are three distinctive regions in which the behaviour of the non-linear element may be uniquely described:

1. $E > 0.1$, $U = 1(E - 0.1)$
2. $-0.1 < E < +0.1$, $U = 0$, i.e. the dead band
3. $E < -0.1$, $U = 1(E + 0.1)$

Following a similar approach to that adopted earlier in all regions

$$\frac{\mathrm{d}^2E}{\mathrm{d}t^2} + 2\xi\omega_n\frac{\mathrm{d}E}{\mathrm{d}t} + U\omega_n^{\,2} = 0$$

Choosing the state variable as $X1 = \mathrm{d}E/\mathrm{d}t$,

$$X1 = \frac{-U\omega_n^{\,2}}{2\xi\omega_n + S} \tag{3.87}$$

In region 1 the isoclinal equation becomes

$$X1 = \frac{-\omega_n^{\,2}(E - 0.1)}{S + 2\xi\omega_n} \tag{3.88}$$

Equation (3.88) defines a family of isoclines as a set of constant slope lines with origin (+0.1,0). Region 3 is similar to region 1 and the isoclinal equation defines a family of constant

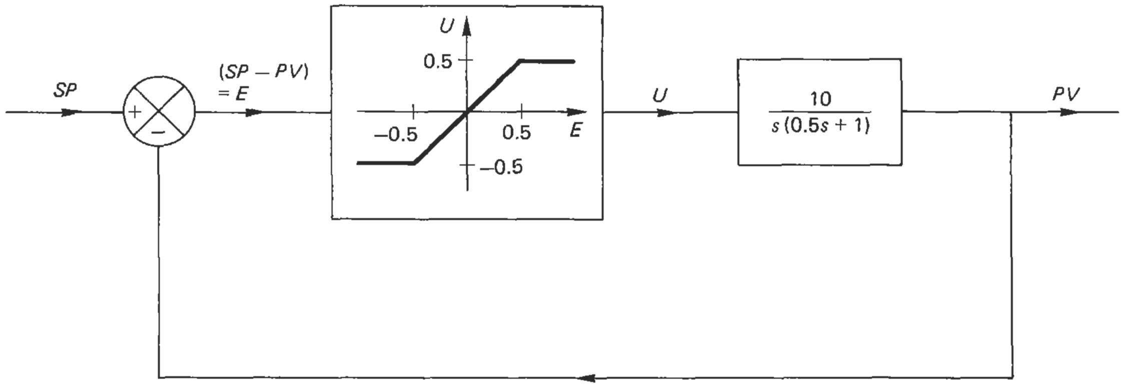

Figure 3.158 Position-control servo with saturation characteristic

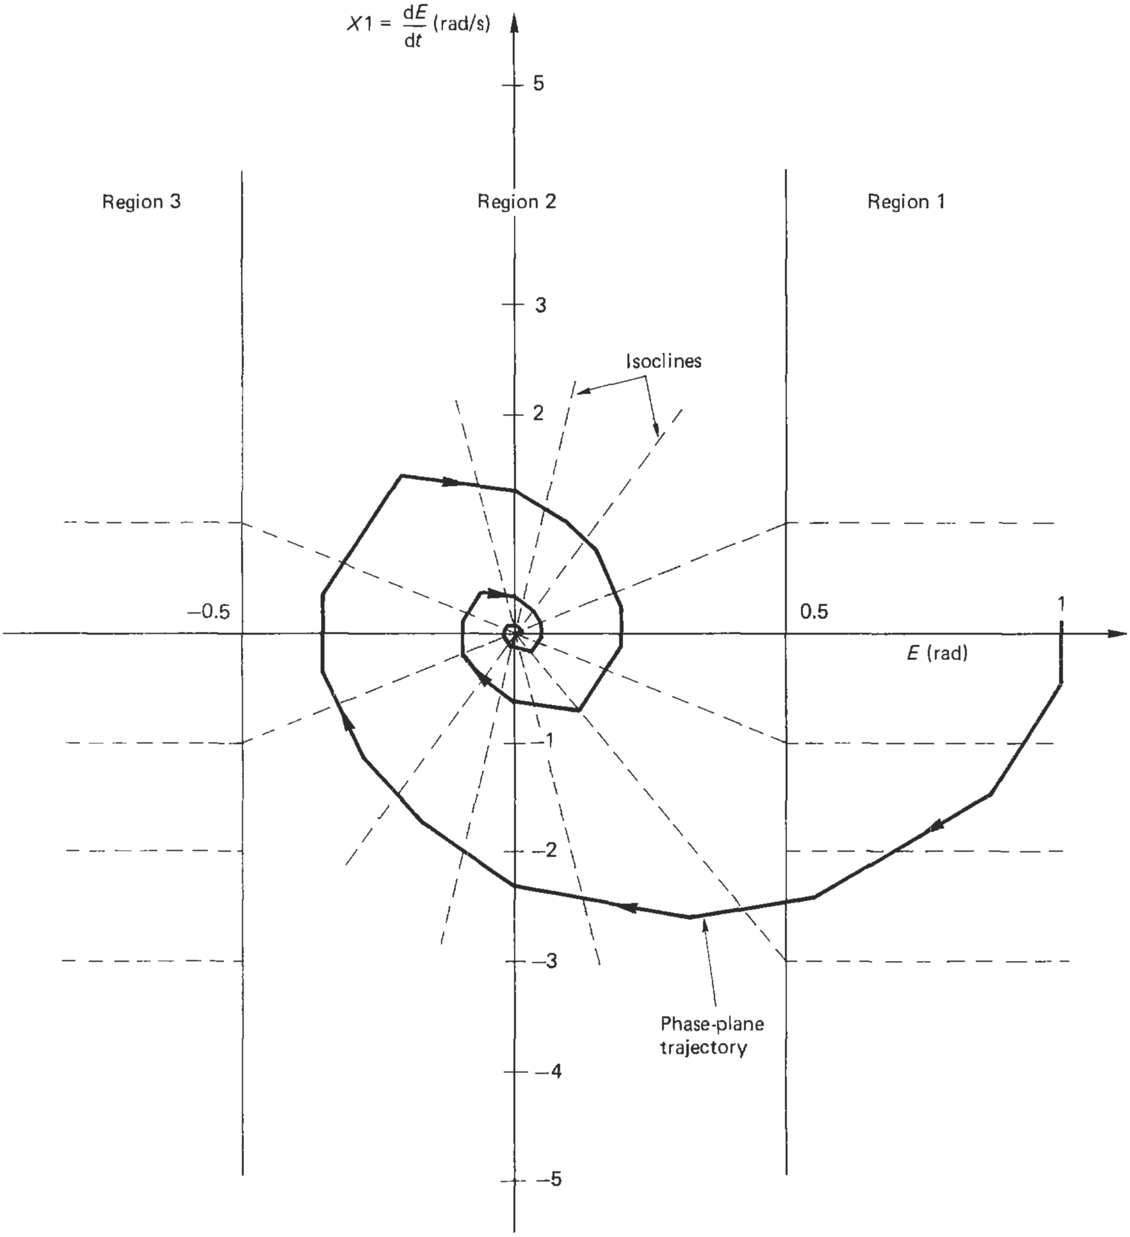

Figure 3.159 Phase-plane trajectory for saturation characteristic

slope with origin $(-0.1,0)$. In the dead-band region (2) $U = 0$ and the slope becomes

$$\text{Slope} = S = \frac{-2\xi\omega_n X1}{X1} = -2\xi\omega_n$$

The resulting phase-plane trajectory takes the form shown in Figure 3.161.

Other system non-linearities may be handled similarly. These may include, for example, the on/off characteristics of a relay or hysteresis effects as typified by backlash in geared systems. The general representation and typical phase-plane trajectories for some of the common types of system non-linearities are shown in Figure 3.162.

The two examples which include hysteresis effects result in a phase-plane trajectory which traces out a limit cycle. Limit cycles are characterized by isolated closed curves in the phase plane and all stable near trajectories approach the limit cycle as time approaches infinity. The stable limit cycle corresponds to a stable periodic motion in the physical system. Limit cycles may also be unstable, in which case the near trajectories move away from the closed curve.

Unfortunately, the phase-plane approach is generally limited to unforced second-order systems. In theory, the

phase-plane concepts may be extended to higher-order state space. This, however, has not been successful, due to the problems of determining, presenting and visualizing trajectories in n-dimensional state space.

3.10.5 Sampled-data systems

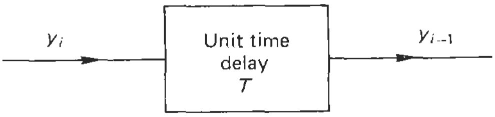
In a discretely sampled system the relationship between output and the input can be represented in terms of z-transforms or, ultimately, as a time-difference equation. In any system described by linear difference equations a block diagram can be similarly constructed using the basic building elements of the adder, the amplifier and the unit time delay. The unit time delay, which is analogous to the integrator in continuous systems, is depicted in Figure 3.163. In the figure the input to the unit delay appears at the output one period later, or delayed by a time T.

If the difference equation has, for example, the form given in equation (3.89) the block diagram for the system is represented as that shown in Figure 3.164, i.e.

$$y_i + ay_{i-1} + by_{i-1} = x_i \tag{3.89}$$

or $y_i = x_i - ay_{i-1} - by_{i-2}$

The system may also be handled in z-transform notation and a block diagram constructed to represent the system in terms of the appropriate operators.



y_i
Unit time delay
T
y_{i-1}

Figure 3.163 The unit time delay

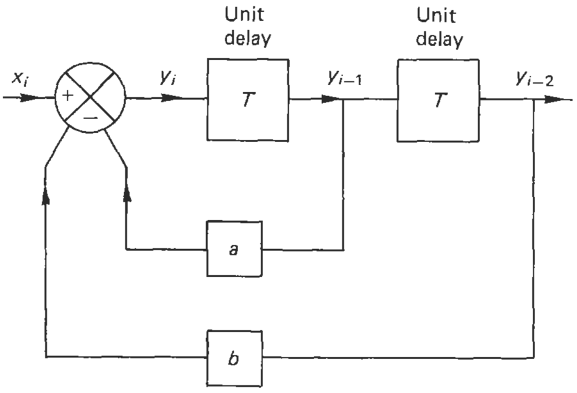


Figure 3.164 Block representation of equation (3.89)

Following the procedures outlined in Section 3.9, a closed-loop digital control system can be represented by the appropriate z-transform operators. The closed-loop transfer operator may subsequently be manipulated and reduced to a finite-difference or time-sequence equation. For the $P + I$ control strategy used in conjunction with a process which can be represented as a first-order differential equation (see Section 3.9.5) the resulting time-sequence equation is

$$PV_i = aSP_{i-1} - bSP_{i-2} + cPV_{i-1} + dPV_{i-2} \qquad (3.61)$$

where a, b, c and d are as defined in Section 3.9.5 and i is an integer variable used to denote the time periods.

The block diagram to represent the difference equation is shown in Figure 3.165. The appropriate state variables are chosen as

$X1 = PV_{i-2}$: $X2 = PV_{i-1}$

The state variable equations can be written in the forms

$$X1_{k+1} = X2_k \qquad (3.90)$$

$$X2_{k+1} = aSP_k - bSP_{k-1} + cX2_k + dX1_k \qquad (3.91)$$

where k is an integer variable used to denote the time periods. In matrix notation the state variable representation is

$$\begin{bmatrix} X1_{k+1} \\ X2_{k+1} \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ d & c \end{bmatrix} \begin{bmatrix} X1_k \\ X2_k \end{bmatrix} + (aSP_k - bSP_{k-1}) \begin{bmatrix} 0 \\ 1 \end{bmatrix} \qquad (3.92)$$

$$PV_i = [0 \quad 1] \begin{bmatrix} X1_{k+1} \\ X2_{k+1} \end{bmatrix} + (aSP_k - bSP_{k-1})[0] \qquad (3.93)$$

With any given initial conditions, equations (3.90) and (3.91) may be solved simultaneously for discrete time steps in T. Figure 3.166 shows the response to a step input when $K = 2$, $T_i = 0.1$ and T is set at 0.2 s. The phase-plane trajectory is shown in two forms in the figure. In one form the plot is given of $X2$ against $X1$, these being the chosen state variables. This trajectory shows that the system is stable under the imposed conditions. An alternative representation is shown where the parameter $(X2 - X1)/T$ is plotted against $X2$. In terms of the actual control system, this second plot is equivalent to a graph of the discrete time rate of change of the process variable against the process variable itself. The second plot is included therefore to give a direct comparison with the equivalent continuous system outlined in Section 3.10.2. In either plot, however, the stability of the system is adequately depicted in graphical form.

3.10.6 State variable transformations

The concept of state variables, introduced in Section 3.10.1, was applied to the solution of closed-loop feedback control systems in Sections 3.10.2 and 3.10.3. Writing the state variable equations in matrix form for the example given in Section 3.10.3 gives

$$\begin{bmatrix} \dot{X}1 \\ \dot{X}2 \\ \dot{X}3 \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ \dfrac{-kK}{T_i} & -(\omega_n{}^2 + kK) & -2\xi\omega_n \end{bmatrix} \begin{bmatrix} X1 \\ X2 \\ X3 \end{bmatrix} + kK\left(\dot{S}P + \frac{SP}{T_i}\right) \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} \qquad (3.94)$$

In addition, the system output PV, or $X1$, can be written in matrix form as

$$PV = [1 \quad 0 \quad 0] \begin{bmatrix} X1 \\ X2 \\ X3 \end{bmatrix} + kK\left(\dot{S}P + \frac{SP}{T_i}\right)[0] \qquad (3.95)$$

These matrix relations fall into a generalized form which are also apparent in the pairs of equations given as (3.67) and (3.68). In shorthand notation, the equations can be written as

$$\dot{X} = AX + Bu \qquad (3.96)$$

$$y = CX + Du \qquad (3.97)$$

The matrix A is said to be in companion form and the components of X are the state variables $X1$, $X2$, $X3$,...X_n. It can be seen that in this form the highest subscripted $\dot{X}_n$ will always be a function of all the state variables. In many applications it is more useful to have the state variables 'decoupled', in which case each $\dot{X}_i$ is a function of X_i and the input only. This implies that the A matrix will then be in a convenient diagonal form.

Matrix B is the input matrix and C is the output matrix. For a single-input–single-output system, the matrix D is always zero. If, however, the system has multiple inputs and multiple outputs then the input u and the output y are vectors and the matrix D then has a finite value.

The conversion of the state equations to form a diagonal A matrix can be accomplished using a variety of techniques. One method is included here for example.

Consider the transformation where

$$X = Mq \qquad (3.98)$$

Substituting this transformation into equations (3.96) and (3.97) gives

$$M\dot{q} = AMq + Bu$$

and $y = CMq$

or $\dot{q} = M^{-1}AMq + M^{-1}Bu$

i.e. $$\dot{q} = A_1q + B_1u \qquad (3.99)$$

and $$y = C_1q \qquad (3.100)$$

where $A_1 = M^{-1}AM$, $B_1 = M^{-1}B$ and $C_1 = CM$.

The procedure involved in transforming the state equations are best illustrated in a simple example. Suppose a particular dynamical system can be represented by the differential equation

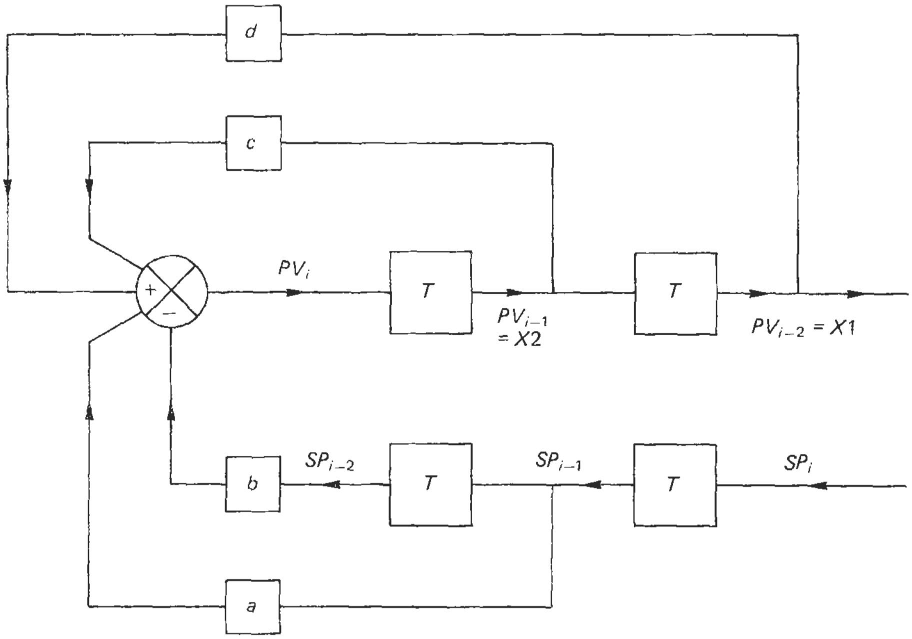

Figure 3.165 Block diagram representation of equation (3.61)

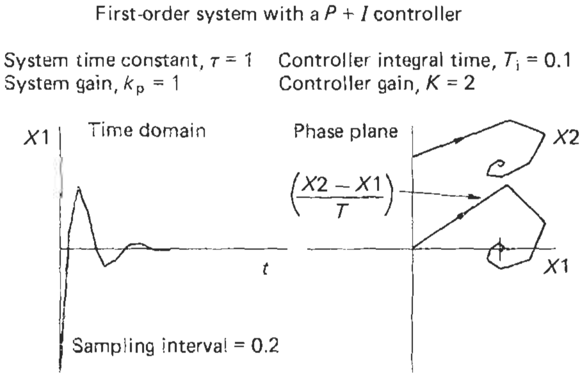

Figure 3.166 System response to a step input

$$\dddot{y} - 2\ddot{y} + \dot{y} - 2y = u \tag{3.101}$$

The state equations in companion form are

$$\begin{bmatrix} \dot{X}1 \\ \dot{X}2 \\ \dot{X}3 \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 2 & -1 & 2 \end{bmatrix} \begin{bmatrix} X1 \\ X2 \\ X3 \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} u \tag{3.102}$$

and

$$y = [1 \quad 0 \quad 0] \begin{bmatrix} X1 \\ X2 \\ X3 \end{bmatrix} \tag{3.103}$$

The characteristic equation of A is

$$[\lambda I - A] = \lambda^n + a_{n-1}\lambda^{n-1} + a_{n-2}\lambda^{n-2} + a_1\lambda^1 + a_0 = 0 \tag{3.104}$$

where I is the unit matrix, λ_i are the eigenvalues of A and a_i are the coefficients associated with the left-hand side of equation (3.101). Thus

$$\lambda^3 - 2\lambda^2 + \lambda - 2 = 0$$

i.e. $(\lambda - 2)(\lambda^2 + 1) = 0$

Hence $\lambda_1 = 2$, $\lambda_2 = i$ and $\lambda_3 = -i$.

where $i = \sqrt{-1}$

Defining the modal matrix, M, such that

$AM = A_1M$

where

$$A_1 = \begin{bmatrix} \lambda_1 & 0 & 0 \\ 0 & \lambda_2 & 0 \\ 0 & 0 & \lambda_3 \end{bmatrix}$$

Then $A_1 = M^{-1}AM$ (3.105)

It can be shown that

$$M = \begin{bmatrix} 1 & 1 & 1 & - & - & 1 \\ \lambda_1 & \lambda_2 & \lambda_3 & & & \lambda_n \\ \lambda_1^2 & \lambda_2^2 & \lambda_3^2 & - & - & \lambda_n^2 \\ - & - & - & - & - & - \\ \lambda_1^{n-1} & \lambda_2^{n-1} & \lambda_3^{n-1} & - & - & \lambda_n^{n-1} \end{bmatrix} \tag{3.106}$$

Thus, for this example,

$$M = \begin{bmatrix} 1 & 1 & 1 \\ 2 & i & -i \\ 4 & -1 & -1 \end{bmatrix}$$

and

$$M^{-1} = \frac{1}{10}\begin{bmatrix} 2 & 0 & 2 \\ 4 + 2i & -5i & -1 + 2i \\ 4 - 2i & +5i & -1 - 2i \end{bmatrix}$$

$$\therefore B_1 = M^{-1}B = \frac{1}{10}\begin{bmatrix} 2 & 0 & 2 \\ 4 + 2i & -5i & -1 + 2i \\ 4 - 2i & +5i & -1 - 2i \end{bmatrix}\begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}$$

$$\therefore B_1 = \frac{1}{10}\begin{bmatrix} 2 \\ -1 + 2i \\ -1 - 2i \end{bmatrix}$$

And, $C_1 = CM$,

$$\therefore C_1 = [1 \quad 0 \quad 0]\begin{bmatrix} 1 & 1 & 1 \\ 2 & i & -i \\ 4 & -1 & -1 \end{bmatrix}$$

$$= [1 \quad 1 \quad 1]$$

The transformed state equations become

$$\begin{bmatrix} \dot{q}1 \\ \dot{q}2 \\ \dot{q}3 \end{bmatrix} = \begin{bmatrix} 2 & 0 & 0 \\ 0 & i & 0 \\ 0 & 0 & -i \end{bmatrix}\begin{bmatrix} q1 \\ q2 \\ q3 \end{bmatrix} + \frac{1}{10}\begin{bmatrix} 2 \\ -1 + 2i \\ -1 - 2i \end{bmatrix} u \qquad (3.107)$$

and

$$y = [1 \quad 1 \quad 1]\begin{bmatrix} q1 \\ q2 \\ q3 \end{bmatrix} \qquad (3.108)$$

Equations (3.107) and (3.108) represent a decoupled system of state equations due to the fact that the A matrix is diagonal. These are referred to as the normal form for the state equations, and they enable full computational use to be made of the diagonality of A.

3.10.7 The state of transition matrix

Given the vector matrix form for a linear system of equations (i.e. equation (3.96), this can be rearranged and premultiplied by the matrix e^{-At}, i.e.

$$e^{-At}(\dot{X} - AX) = e^{-At}Bu$$

$$\therefore \frac{d}{dt}(e^{-At} \cdot X) = e^{-At}Bu$$

On integration this becomes

$$e^{-At}X(t) - X(0) = \int_0^t e^{-A\tau}Bu(\tau)d\tau \qquad (3.109)$$

The matrix e^{At} is termed the state transition matrix and is denoted by $\Phi(t)$, i.e.

$$\Phi(t) = e^{At} \qquad (3.110)$$

For the unforced system, when $u(t) = 0$, the solution of equation (3.109) becomes

$$X(t) = \Phi(t)X(0) \qquad (3.111)$$

Equation (3.111) shows that $\Phi(t)$ transforms the system from its state $X(0)$ at some initial time, $t = 0$, to the state $X(t)$ at some subsequent time, $t > 0$.

The calculation of the state transition matrix may be performed in several different ways. The most convenient method, for many problems, involves the use of Laplace and inverse Laplace transforms. It may be shown that the state transition matrix can be written as

$$\Phi(t) = e^{At} = \mathcal{L}^{-1}\{[sI - A]^{-1}\} \qquad (3.112)$$

Suppose that a system is characterized by the state equation

$$\begin{bmatrix} \dot{X}1 \\ \dot{X}2 \end{bmatrix} = \begin{bmatrix} 0 & 2 \\ -1 & -3 \end{bmatrix}\begin{bmatrix} X1 \\ X2 \end{bmatrix} + \begin{bmatrix} 0 \\ 1 \end{bmatrix} u \qquad (3.113)$$

If the forcing function $u(t) = 1$ for $t > 0$ and

$$X(0) = \begin{bmatrix} 1 \\ -1 \end{bmatrix}$$

then the state X of the system at any time t is determined as follows:

$$[sI - A] = \begin{bmatrix} s & -2 \\ 1 & s + 3 \end{bmatrix}$$

$$[sI - A]^{-1} = \frac{1}{s(s + 3) + 2}\begin{bmatrix} s + 3 & 2 \\ -1 & s \end{bmatrix}$$

$$= \frac{1}{(s + 1)(s + 2)}\begin{bmatrix} s + 3 & 2 \\ -1 & s \end{bmatrix}$$

$$= \begin{bmatrix} \dfrac{s + 3}{(s + 1)(s + 2)} & \dfrac{2}{(s + 1)(s + 2)} \\ \dfrac{-1}{(s + 1)(s + 2)} & \dfrac{s}{(s + 1)(s + 2)} \end{bmatrix}$$

The matrix $[sI - A]^{-1}$ is called the resolvent matrix. To evaluate the inverse transforms it is necessary to express each element of the resolvent matrix in partial fraction form:

$$\therefore [sI - A]^{-1} = \begin{bmatrix} \dfrac{2}{s + 1} - \dfrac{1}{s + 2} & \dfrac{2}{s + 1} - \dfrac{2}{s + 2} \\ -\dfrac{1}{s + 1} + \dfrac{1}{s + 2} & -\dfrac{1}{s + 1} + \dfrac{2}{s + 2} \end{bmatrix}$$

$$\mathcal{L}^{-1}\{[sI - A]^{-1}\} = \begin{bmatrix} 2e^{-t} - e^{-2t} & 2e^{-t} - 2e^{-2t} \\ -e^{-t} + e^{-2t} & -e^{-t} + 2e^{-2t} \end{bmatrix}$$

This gives

$$\Phi(t)X(0) = \begin{bmatrix} 2e^{-t} - 2e^{-2t} & 2e^{-t} - 2e^{-2t} \\ -e^{-t} + e^{-2t} & -e^{-t} + 2e^{-2t} \end{bmatrix}\begin{bmatrix} 1 \\ -1 \end{bmatrix}$$

$$= \begin{bmatrix} e^{-2t} \\ -e^{-2t} \end{bmatrix} \qquad (3.114)$$

The above is the complementary function which applies to the unforced system. On consideration of the particular integral it can be noted that

$$\mathcal{L}[u(t)] = \frac{1}{s}$$

Thus

$$[sI - A]^{-1}Bu(s) = \frac{1}{(s + 1)(s + 2)} \cdot \frac{1}{s}\begin{bmatrix} s + 3 & 2 \\ -1 & s \end{bmatrix}\begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

$$= \begin{bmatrix} \dfrac{2}{s(s + 1)(s + 2)} \\ \dfrac{1}{(s + 1)(s + 2)} \end{bmatrix}$$

Expanding the above into partial fractions gives

$$\begin{bmatrix} \dfrac{1}{s} - \dfrac{2}{s+1} + \dfrac{1}{s+2} \\ \dfrac{1}{s+1} - \dfrac{1}{s+2} \end{bmatrix}$$

Taking the inverse Laplace transform gives

$$\begin{bmatrix} 1 - 2e^{-t} + e^{-2t} \\ e^{-t} - e^{-2t} \end{bmatrix}$$

The complete solution is given as the sum of the complementary function and the particular integral, i.e.

$$X(t) = \begin{bmatrix} e^{-2t} \\ -e^{-2t} \end{bmatrix} + \begin{bmatrix} 1 - 2e^{-t} + e^{-2t} \\ e^{-t} - e^{-2t} \end{bmatrix}$$

$$\begin{bmatrix} X1(t) \\ X2(t) \end{bmatrix} = \begin{bmatrix} 1 - 2e^{-t} + 2e^{-2t} \\ e^{-t} - 2e^{-2t} \end{bmatrix} \tag{3.115}$$

Equation (3.115) defines the state of the system at any time t and provides a direct solution to the state equations.

Results obtained from the solution of equation (3.115) and that obtained from a finite-difference approximation of the state equation (3.113) show no significant difference in the numerical results generated.

An alternative approach to the evaluation of $\Phi(t)$ is to expand e^{At} as a series, and to truncate the series at an appropriate point. This is well suited to a computer.

Further consideration of the state-variable approach is essentially beyond the scope of this chapter. The reader is therefore referred to the texts by DeRusso *et al*[24] and by Burghes and Graham[25] for comprehensive, in-depth coverage.

4.1 Introduction

Although the advent of computers in our everyday lives may seem very recent, the principles of the modern computer were established before the existence of any electronic or electromechanical technologies as we know them today, and electronic computers were beginning to take shape in laboratories in 1945.

The work of Charles Babbage, a Cambridge mathematician of the nineteenth century, in attempting to build an 'analytical engine' from mechanical parts, remarkably anticipated several of the common features of today's electronic computers. His proposed design, had he been able to complete it and overcome mechanical engineering limitations of the day, would have had the equivalent of punched-card input and storage registers, the ability to branch according to results of intermediate calculations, and a form of output able to set numeric results in type.

Many purely mechanical forms of analogue computer have existed over the last few centuries. The most common of these is the slide rule, and other examples include mechanical integrators and even devices for solving simultaneous equations.

Much of the development leading to modern electronic computers, both analogue and digital, began during World War II with the intensified need to perform ballistics calculations. The development of radar at this time also provided the stimulus for new forms of electronic circuits which were to be adopted by the designers of computers.

A further development of momentous importance to the technology of computers, as it was for so many branches of electronics, was that of the transistor in 1949. Continued rapid strides in the field of semiconductors have brought us the integrated circuit, which allows a complete digital computer to be implemented in a single chip.

4.2 Types of computer

Although there are two fundamentally different types of computer, analogue and digital, the former remains a somewhat specialized branch of computing, completely eclipsed now, both in numbers of systems in operation and in breadth of applications, by digital computers. While problems are solved in the analogue computer by representing the variables by smoothly changing voltages on which various mathematical operations can be performed, in a digital computer all data are represented by binary numbers held in two-state circuits, as are the discrete steps or instructions for manipulating the data, which make up a program.

4.2.1 Analogue computers

An analogue computer consists of a collection of circuit modules capable of individually performing summation, scaling, integration or multiplication of voltages, and also function-generating modules. On the most up-to-date systems these modules contain integrated-circuit operational amplifiers and function generators. Several hundred amplifiers are likely to be used on a large analogue computer.

To solve a given problem in which the relationship of physical quantities varying with time can be expressed as differential equations, the inputs and outputs of appropriate modules are interconnected, incorporating scaling, feedback and setting of initial conditions as required, with voltages representing the physical quantities. In this way, single or simultaneous equations can be solved in such applications as engineering and scientific calculation, modelling and simulation.

The interconnection and setting of coefficients and initial conditions required is normally done by means of a patch panel and potentiometers. An analogue computer may also have a CRT display or chart recorder for the display or recording of the results of a computation. Where an analogue computer is being used for design work, the designer may choose to observe immediately the effect of changing a certain design parameter by varying the appropriate potentiometer setting, thus altering the voltage representing that parameter. In a simulation application, outputs from the analogue computer may be used as input voltages to another electrical system.

Except in some specialized areas, the work formerly done by analogue computers is now most likely to be carried out on the modern high-speed, cost-effective digital computer, using numerical methods for operations such as integration. Digital computers can work to high precision extremely accurately, whereas using analogue techniques, there are inherent limits to precision, and accuracy suffers through drift in amplifiers.

4.2.2 Hybrid computers

The analogue part of a hybrid computer is no different in its circuitry and function to that of a stand-alone analogue system. However, the task of setting up the network required to solve a particular problem is carried out by a digital computer, linked to the analogue machine by analogue/digital converters and digital input/output. Thus, the digital computer sets potentiometers and can read and print their values, and can monitor and display or log voltages at selected parts of the analogue network.

Linking the two technologies in this way brings the advantage of programmability to the mathematical capabilities of the analogue computer. Set-up sequences for the analogue circuitry can be stored and quickly and accurately reproduced at will. Tasks can be carried out in the part of the system best adapted to performing them. In particular, the ability of the digital computer to store, manipulate and present data in various ways is particularly advantageous.

The use of hybrid systems in, for example, the simulation of aircraft and weapon systems, has helped to perpetuate analogue computing as a technique applicable in certain narrow areas.

4.2.3 Digital computers

Digital computers in various forms are now used universally in almost every walk of life, both in business and in public service. In many cases unseen, computers nonetheless influence people in activities such as travel, banking, education and medicine. There is also a very wide range of computers designed for use by people, without technical skills or training, in their own homes. These are generally used for some form of entertainment or for introduction to the wider subject of computing, but some are large enough and powerful enough to support small businesses. There is also a growing range of truly portable computers now available that will fit into briefcases or even pockets.

As can be imagined from the variety of applications, computers exist in many different forms, spanning a range of price (from the smallest personal system to the largest supercomputer) of more than 1 million:1. Yet there are certain features which are common to all digital computers:

1. Construction from circuits which have two stable states, forming binary logic elements;

2. Some form of binary storage of data;
3. Capability to receive and act on data from the outside world (input) and to transmit data to the outside world (output);
4. Operation by executing a set of discrete steps or instructions, the sequence of which can be created and modified at any time to carry out a particular series of tasks. This ability to be programmed, with a program stored in the system itself, is what gives great flexibility to the digital computer. Recent advances have enabled changes to be made to a program dynamically while it is in operation. In addition, modern techniques permit processing to be carried out on the same set of discrete steps on more than one CPU at the same time within the same 'logical' computer. This technique is referred to as 'parallel processing'.

The computer has also given rise to a whole new series of professions – those of the computer programmer, systems analyst, data specialist, business analyst, computer operator – as well as the industry of designing, building and maintaining computers themselves.

4.3 Generations of digital computers

Beginning with circuits consisting of relays, the history of the digital computer can be seen as having fallen into four generations between the 1940s and today.

4.3.1 First generation

These computers were built with valve circuits and delay-line storage, physically very massive, taking up complete rooms, requiring very large amounts of electricity with corresponding high heat dissipation, and low overall reliability, requiring extensive maintenance often resulting in engineers being on-site 24 hours per day. Input/output was rudimentary (teleprinters, punched cards) and programming very laborious, usually in a binary form that the machine could understand without further interpretation.

4.3.2 Second generation

Developed during the 1950s with transistorized circuits, these computers were faster, smaller and more reliable than the first generation, but still large by today's standards. Magnetic core main stores with magnetic drums were used with tapes as back-up, and line printers were employed for faster printed output. Programming language translators emerged, resulting in the widespread use of Assembler-type languages.

4.3.3 Third generation

Developed during the mid-1960s these computers were heralded by the integrated circuit, allowing more compact construction and steadily improving speed, reliability and capability. The range and capabilities of input/output and mass storage devices increased remarkably. In the software area, high-level languages (e.g. FORTRAN, COBOL, BASIC) became common and manufacturers offered operating system software developed, for example, to manage time-sharing for a large number of computer users or real-time process control.

Most significantly, a trend of downward cost for given levels of performance was established. The minicomputer, aimed at providing a few or even one single user with direct access to and control over their own computing facilities, began to gain in numbers over the large, centrally managed and operated computer system.

4.3.4 Fourth generation

While a great many third-generation computer systems are in use, and will remain so for some time, the semiconductor technology of large-scale integration (LSI) of the 1970s brought complete computers on a chip, known as microprocessors, allowing further refinement and enhancement of third-generation equipment.

Semiconductor memory has almost completely replaced core memory, and the continuing reduction in size and cost has brought the 'personal computer', numbered in hundreds of thousands of units supplied, truly within the reach of individuals in their own homes or offices.

The 1980s saw the arrival of very large scale integration (VLSI) and ultra large scale integration (ULSI) applied to semiconductor memory and processor circuit design. This has resulted in a scalar increase in the density of memory capacity that can be packed onto a single board, as well as the proliferation of multi-processors on a single board. Many computers of power and memory capacity equal to or greater than that of the earliest minis can now be found on a single printed circuit board.

The turn of the decade also saw the introduction of 'surface mount technology', which broke through the previous barrier of physical limitation of the number of connections that could be built between the memory or processor chip and the outside world with which they communicated. This has also permitted closer packing of chips onto each board.

4.4 Digital computer systems

A digital computer system is a collection of binary logic and storage elements combined in such a way as to perform a useful task. Any computer system, whether a microcomputer held in one hand for data collection, or a large data-processing system consisting of many cabinets of equipment housed in a specially built air-conditioned computer room, invariably contains a combination of the parts described in detail in the following sections and shown in Figure 4.1.

4.4.1 Central processor unit

The CPU is where instructions forming the stored program are examined and executed, and is therefore in control of the operation of the system. Instructions and data for immediate processing by the CPU are held in main memory, which is linked directly to the CPU. This general term covers the units that perform logic decisions and arithmetic, collectively known as the Arithmetic and Logic Unit (ALU).

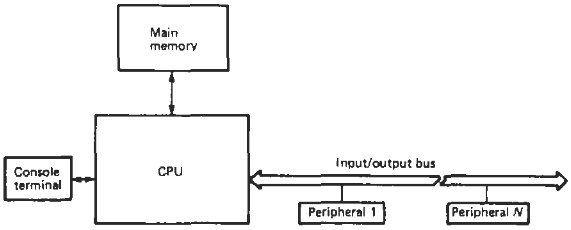

Figure 4.1 Components of a computer system

In recent years considerable progress has been made on computers that contain more than one discrete CPU. These are referred to as 'Multiple processor computers'. The main area of difficulty in the development of these machines has not been in the physical co-location of processors but rather in the design of the operating system. It has to know which instructions can be operated upon simultaneously and which require prior instructions to be completed. It should also be noted that multiple processor computers can operate in two distinct modes. In 'parallel' processing each processor is operating on the same instruction at the same time. This is particularly useful in fail-safe or non-stop critical applications. In 'multi' processing, each processor is operating on a different instruction and each instruction is processed once only. This does not give the 'fail-safe' advantages, but does provide large gains in speed of processing overall.

4.4.2 Input/output

This is the structure which provides optimum communication between the CPU and other parts of the system.

4.4.3 Peripherals

These are the devices external to the CPU and memory which provide bulk storage, human/machine interaction and communication with other electronic systems.

4.4.4 BUS paths

These act as the vehicle for the passing of data and program instructions between all other parts.

4.5 Categories of computer systems

In going from microcomputer to large-data processing systems there are many differences in complexity, technology, system cost or performance. However, there are many similarities between systems from different manufacturers.

Several distinct categories of computer system can be identified. Going from least to most comprehensive and powerful, these are described in subsequent sections.

4.5.1 Pocket computers

These derive their name from their ability to literally fit into their owners' pockets! Though some early prototypes were available to a limited market, they first made a general appearance in 1990. They are typically of two-piece construction with one section folding over the other. Normal facilities include an LCD screen, a reduced-size keyboard (though with a full key set) and removable self-powered memory cards that act as logical disk drives. Many also include an internal modem or the ability to interface with an external one. They provide most of the features of laptop or personal computers without the size or weight penalties. They are ideal for carrying in a briefcase and for use on long journeys on public transport.

4.5.2 Laptop computers

These have the ability to fit onto their owners' laps while they are being used! They are also sometimes referred to as 'portable' computers, though the earliest models required considerable human strength and stamina to enable their 'portability'.

They were first available on a general basis in the late 1980s and were initially scaled-down versions of existing personal computers. In the last few years they have benefited from a design approach aimed at ease of use and true lightweight portability. Recent models have been reduced to A5 size when opened, leading to smaller laptops referred to as 'notebook' computers.

They are typically of two-piece construction, with one section folding over the other. Normal facilities include an LCD screen, a full-size keyboard, a standard IBM format $3\frac{1}{2}$-inch floppy disk, non-removable $5\frac{1}{4}$-inch Winchester disks of up to 100 megabyte capacity each and a 'windows' type operating system such as Microsoft Windows. Most also include an internal modem and additional facilities for the connection of external peripherals such as lightweight bubble printers or fax equipment. While they cannot fit into a normal briefcase, their shape, size and weight means that they can be carried *as* one.

4.5.3 Microcomputers

The first microcomputers were appearing in the mid-1970s and were mainly intended for use by specialist engineers requiring computing power remote from central resources for large and intricate calculations (an example being the Olivetti Pnnn series). However, they were still large and expensive by modern standards and so did not come into general use.

The second half of the 1970s saw the introduction of mass-produced (and hence cheap) microcomputers, often with an integral CRT, such as the APPLE, NASCOM and the COMMODORE PET. These were aimed initially at the personal market and great numbers were sold on the basis of video games provided for them. As the novelty wore off, the personal computer market did not grow to the size predicted and the manufacturers had to look to another market sector to finance continued growth and, in some cases, just to be able to maintain production at current levels. This led to microcomputers being developed for and marketed in the business sector. These possess memories and facilities far exceeding those of early minicomputers and, in some cases, on a par with smaller mainframes.

Many microcomputers have been specially adapted to cater for a specific market sector such as CAD/CAM and graphics use by a single person while offering any networking and multi-user options as required. A large number are covered by the generic term 'Workstation' and are intended to permit persons to carry out many different functions without having to leave their desks, examples being SUN Microsystems, Hewlett Packard, COMPUTERVISION and the Digital Equipment Corporation VAX stations.

Many of these workstations now run under a 'windows' operating system. The principle behind this is that the screen is split into virtual windows that act as display areas for different applications running at the same time on the same terminal or workstation. Indeed, windows may be related to applications that are running on an entirely separate computer or terminal from the one that is displaying the required information.

Windows can overlap each other, be shrunk or re-sized, can be recalled and need not even be running under the same operating system. The technique used to support this is to separate the management of the display hardware from the management of the hardware that is actually running the application. Users may have as many windows on their display screens as can be physically supported, though they may only be 'active' in one at any one moment. The 'active' window is selected using a mouse to indicate which window is required on the display. Thus users may have windows from systems running UNIX, VMS, MS-DOS or MVS on their screens at the same time.

4.5.4 Minicomputers

Since its introduction as a recognizable category of system in the mid-1960s, with machines such as the Digital Equipment Corporation PDP8, the minicomputer has evolved rapidly. It has been the development which has brought computers out of the realm of specialists and large companies into common and widespread use by non-specialists.

The first such systems were built from early integrated-circuit logic families, with core memory. Characteristics were low cost, ability to be used in offices, laboratories and even factories, and simplicity of operation allowing them to be used, and in many cases programmed, by the people who actually had a job to be done, rather than by specialist staff remote from the user. These were also the first items of computer equipment to be incorporated by original equipment manufacturers (OEMs) into other products and systems, a sector of the market which has contributed strongly to the rapid growth of the minicomputer industry.

Applications of minicomputers are almost unlimited, in areas such as laboratories, education, commerce, industrial control, medicine, engineering, government, banking, networking, CAD/CAM, CAE and CIM. There is also a growing use of minicomputers combined with artificial intelligence for problem solving that benefits from deduction and backward chaining as opposed to predefined procedural stepping.

With advancing technology, systems are now built using large-scale and more often very large scale integrated circuits, and memory is now almost entirely semiconductor. While earlier systems had a very small complement of peripherals (typically, a teleprinter and punched paper-tape input and output) there has been great development in the range and cost-effectiveness of peripherals available. A minicomputer system will now typically have magnetic disk and tape storage holding thousands of millions of characters of data, a printer capable of printing up to 2500 lines of text per minute, 16–512 CRT display terminals (often in colour), low-cost matrix printers for local or operator's hardcopy requirements and a selection of other peripherals for specialist use such as a graphic colour plotter or a laser printer for high-quality output.

4.5.5 Superminis

The word 'supermini' has been coined to describe a type of system that has many similarities in implementation to the minicomputer, but, by virtue of architectural advances, has superior performance. These advantages include:

1. Longer word length. The amount of information processed in one step, or transferred in a single operation between different parts of the system, is usually twice that of a minicomputer.
2. As well as increasing the rate of information handling, the longer word length makes it possible to provide a more comprehensive instruction set. Some common operations, such as handling strings of characters or translating high-level language statements into CPU instructions, have been reduced to single instructions in many superminis.
3. Longer word length provides larger memory addressing. A technique called virtual memory (see Section 4.7.11) gives further flexibility to addressing in some superminis.
4. Higher data transfer speeds on internal data highways, which allow faster and/or larger numbers of peripheral devices to be handled, and larger volumes of data to be transmitted between the system and the outside world.

Despite providing substantial power, even when compared with the mainframe class of system described below, superminis fall into a price range below the larger mainframes. This is because they have almost all originated from existing minicomputer manufacturers, who have been able to build on their volume markets, including, in most cases, the OEM market.

4.5.6 Mainframes

The mainframe is the class of system typically associated with commercial data processing in large companies where a centralized operation is feasible and desired, and very large volumes of data are required to be processed at high processor speeds, or where a large user base (often in excess of 500 simultaneous users) requires immediate responses during interactive sessions. Today's mainframes, all products of large, established companies in the computer business (except for systems which are software-compatible emulators of the most popular mainframe series) are the successors to the first and second generation as described in Section 4.3. They inherit the central control and location, emphasis on batch processing and line printers, third- and fourth-generation programming and the need for specialized operating staff.

Mainframes are capable of supporting very large amounts of on-line disk and magnetic tape storage as well as large main memory capacity, and data communications capabilities supporting remote terminals of various kinds. Although some of the scientific mainframes have extremely high operating rates (over 100 million instructions per second), most commercial mainframes are distinguished more by their size, mode of operation and support than by particularly high performance.

4.5.7 Combination technology

There have also been some significant developments in methods of combining computing resources to provide more security and faster processing. These fall into the following categories.

4.5.7.1 Tightly coupled systems

In the first instance, certain parts of the system are duplicated and operate in parallel, each mirroring the work performed by the other. This provides security of availability of resource and of data by redundancy, the ultimate being total duplication of every part of the system, with the system designed to continue should one of anything fail. TANDEM and STRATUS machines are early examples of this being applied, though most manufacturers have since offered machines of this type.

The second technique is to have more than one processor within the same CPU, with each one performing different tasks from the others, but with one having overall control. This provides security of availability should a processor fail, since the system will continue automatically with any remaining processor(s) without any human intervention, albeit with a reduced processing capacity overall.

4.5.7.2 Loosely coupled systems

This method employs the technique of sharing all resources across a common group of machines, sometimes known as 'clustering'. Each CPU within the cluster is an independent unit but it knows of the existence of other members of the cluster. It is generally not necesssary to stop processing ('bring down') the cluster in order to add or remove a new member. Each CPU can have its own peripherals attached to it which it decides whether or not to share with other members. The cluster itself will also own peripherals that are available for use by any member. It is also possible to arrange for communications controllers to monitor the load of each member in order to attempt to spread the workload as evenly as possible across the cluster. Should any item, including a CPU, fail within the cluster, then processing can be continued on another part of the cluster. Through careful planning of these clusters it is now common to find a logical system (i.e. a cluster) that rarely has to be stopped for hardware maintenance, operating system upgrades, hardware or software failure, etc. The management of all members of the cluster can be carried out from any member machine.

4.6 Central processor unit

This part of the system controls the sequence of individual steps required for the execution of instructions forming a program. These instructions are held in storage, and when executed in the appropriate order, carry out a task or series of tasks intended by the programmer.

Within any particular computer system, the word length is the fixed number of binary digits of which most instructions are made up. Arithmetic operations within the CPU are also performed on binary numbers of this fixed word length, normally 8, 16, 24, 32, 36, 64 binary digits or bits. The CPU is connected via a memory bus, as in Figure 4.2, to a section of memory organized as a number of randomly accessible words, each of which can be written to or read from individually. The time for reading one word from or writing one word into main memory is typically in the range of 0.05 to 0.6 μs, depending on CPU and memory BUS speed. Each word or location of memory can contain either an instruction or data. Apart from simple systems, some form of magnetic tape or disk memory peripheral is present on a system as file storage and back-up to main memory.

Control and timing circuits in the CPU enable instructions and data to be fetched from memory for processing and the results of any instructions which require to be stored for further processing to be written into memory. The program counter holds the memory address of the next instruction to be fetched after each instruction has been processed. Frequently, the next instruction is held in the next location in memory and the counter need simply be incremented by one. However, some systems work by placing one or more parameters for the instruction immediately after it in memory, thereby causing the next instruction to be displaced further down-memory. At other times, the sequence of the program dictates that a new value be written into the program counter. Instructions which alter the sequence of a program calculate and insert a new value into the program counter for the next instruction.

In order to start the CPU when no programs are already in memory, the program counter is loaded with a predetermined address, usually by the action of switching power onto the system, and a simple loader program held in ROM is loaded into memory. Its function is to load a comprehensive general-purpose loader, which automatically loads user or system programs. This process is known as bootstrapping, or booting the system, and the initial ROM program is known as the bootstrap loader. However, today most systems perform all these functions as a result of switching on the power automatically and are ready for use almost immediately, only requesting date and time if they are not held in any form of battery backed-up memory.

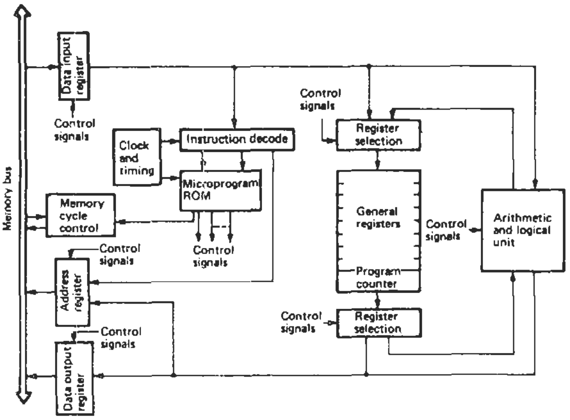

Figure 4.2 CPU block diagram

4.7 Memory

In order to provide storage for program instructions and data in a form where they can be directly accessed and operated upon, all CPUs have main memory which can be implemented in a variety of technologies and methods of organization.

4.7.1 Memory organization

Memory is organized into individually addressable words into which binary information can be loaded for storage and from which the storage data pattern can be read. On some systems, memory is arranged in such a way that more than one word at a time is accessed. This is done to improve effective memory access rates, on the basis that by accessing, say, two consecutive words, on most occasions the second word will be the one which the CPU requires next. This is generally referred to as 'interleaved' memory.

A memory controller is required between the memory arrays and the CPU, to decode the CPU requests for memory access and to initiate the appropriate read or write cycle. A controller can only handle up to a certain maximum amount of memory, but multiple controllers can be implemented on a single system. This can be used to speed up effective memory access, by arranging that sequentially addressed locations are physically in different blocks of memory with different controllers. With this interleaved memory organization, in accessing sequential memory locations the operation of the controllers is overlapped, i.e. the second controller begins its cycle before the first has completed. Aggregate memory throughput is thus speeded up.

In some more complex computer systems, all or part of the memory can be shared between different CPUs in the multiprocessor configuration. Shareable memory has a special form of controller with multiple ports, allowing more than one CPU access to the memory.

It is sometimes appropriate to implement two types of memory in one system: random access or read/write memory (RAM) and read-only memory (ROM). Programs have to be segregated into two areas:

1. Pure instructions, which will not change, can be entered into ROM;
2. Areas with locations which require to be written into (i.e. those containing variable data or modifiable instructions) must occupy RAM.

Read-only memory is used where absolute security from corruption of programs, such as operating system software or a program performing a fixed control task, is important. It is normally found on microprocessor-based systems, and might be used, for example, to control the operation of a bank's cash dispenser.

Use of ROM also provides a low-cost way of manufacturing in quantity a standard system which uses proven programs which never require to be changed. Such systems can be delivered with the programs already loaded and secure, and do not need any form of program-loading device.

4.7.2 Memory technology

The most common technologies for implementing main memory in a CPU are described in the following sections.

4.7.3 MOS RAM

This technology is very widely used, with the abundant availability, from the major semiconductor suppliers, ranging in size from 4 Kbytes to 128 Kbytes. In the latter form, very high density is achieved, with up to 128 megabytes of memory available on a single printed circuit board.

Dynamic MOS RAMs require refresh circuitry which, at intervals, automatically rewrites the data in each memory cell. Static RAM, which does not require refreshing, can also be used. This is generally faster, but also more expensive, than dynamic RAM.

Semiconductor RAMs are volatile, i.e. they lose contents on powering down. This is catered for in systems with back-up storage (e.g. disks) by reloading programs from the back-up device when the system is switched on, or by having battery back-up for all or part of the memory.

In specialized applications requiring memory retention without mains for long periods, battery operations of the complete CPU and CMOS memory can be used. The latter has a very low current drain, but has the disadvantage of being more expensive than normal MOS memory. Where it is essential to use CMOS, circuit boards with on-board battery and trickle charger are now available.

4.7.4 ROM

Read-only memories, used as described in Section 4.7.1, can be either erasable ROMs or a permanently loaded ROM such as fusible-link ROM.

4.7.5 Bubble memory

Bubble memory has not produced the revolution in memory that it seemed to promise at the start of the 1990s. It remains at a comparatively higher price-to-performance ratio than semiconductor memory and is not used on any large scale on a commercial basis.

4.7.6 Core memory

Core memory remains in some applications, but although it has come down substantially in cost under competition from semiconductor memory, more recently MOS RAMs of higher capacity have been much cheaper and have largely taken over.

4.7.7 Registers

The CPU contains a number of registers accessible by instructions, together with more that are not accessible but are a necessary part of its implementation. Other than single-digit status information, the accessible registers are normally of the same number of bits as the word length of the CPU.

Registers are fast-access temporary storage locations within the CPU and implemented in the circuit technology of the CPU. They are used, for example, for temporary storage of intermediate results or as one of the operands in an arithmetic instruction. A simple CPU may have only one register, often known as the accumulator, plus perhaps an auxiliary accumulator or quotient register used to hold part of the double-length result of a binary multiplication.

Large word length, more sophisticated CPUs typically have eight or more general-purpose registers that can be selected as operands by instructions. Some systems such as the VAX use one of its 16 general-purpose registers as the program counter, and can use any register as a stack pointer. A stack in this context is a temporary array of data held in memory on a 'last-in, first-out' basis. It is used in certain types of memory reference instructions and for internal housekeeping in interrupt and subroutine handling. The stack pointer register is used to hold the address of the top element of the stack. This address, and hence the stack pointer contents, is incremented or decremented by one at a time as data are added to or removed from the stack.

4.7.8 Memory addressing

Certain instructions perform an operation in which one or more of the operands is the contents of a memory location (for example, arithmetic, logic and data-movement instructions). In most sophisticated CPUs various addressing modes are available to give, for example, the capacity of adding together the contents of two different memory locations and depositing the result in a third.

In such CPUs instructions are double operand, i.e. the programmer is not restricted to always using one fixed register as an operand. In this case, any two of the general-purpose registers can be designated either as each containing an operand or through a variety of addressing modes, where each of the general-purpose registers selected will contain one of the following:

1. The memory address of an operand;
2. The memory address of an operand, and the register contents are then incremented following execution;
3. The memory address of an operand, and the register contents are then decremented following execution;
4. A value to which is added the contents of a designated memory location (this is known as 'indexed addressing');
5. All of the above, but where the resultant operand is itself the address of the final operand (known as 'indirect' or 'deferred' addressing).

This richness of addressing modes is one of the benefits of more advanced CPUs, as, for example, it provides an easy way of processing arrays of data in memory, or of calculating the address portion of an instruction when the program is executed. Further flexibility is provided by the ability on many processors for many instructions to operate on multiples of 8 bits (known as a byte), on single bits within a word and, on some more comprehensive CPUs (such as that of the Digital Equipment VAX series), on double- and quadruple-length words and also arrays of data in memory.

4.7.9 Memory management

Two further attributes may be required of memory addressing. Together, they are often known as memory management.

4.7.9.1 Extended addressing

This is the ability, particularly for a short word length system (16 bits or less), for a program to use addresses greater than those implied by the word length. For example, with the 16-bit word length of most minicomputers the maximum addresses that can be handled in the CPU is 65,536. As applications grow larger this is often a limitation, and extended addressing operates by considering memory as a number of pages. Associated with each page at any given time is a relocation constant which is combined with relative addresses within its page to form a longer address. For example, with extension to 18 bits, memory addresses up to 262,144 can be generated in this way. Each program is still limited at any given time to 65,536 words of address space, but these are physically divided into a number of pages that can be located anywhere within the larger memory. Each page is assigned a relocation constant, and as a particular program is run, dedicated registers in the CPU memory management unit are loaded with the constant for each page (Figure 4.3).

Thus many logically separate programs and data arrays can be resident in memory at the same time, and the process of setting the relocation registers, which is performed by the supervisory program, allows rapid switching between them in accordance with a time-scheduling scheme that is usually based upon resource usage quota, time allocation or a combination of both. This is known as multi-programming. Examples of where this is used are a time-sharing system for a number of users with terminals served by the system, or a real-time control system where programs of differing priority need to be executed rapidly in response to external events.

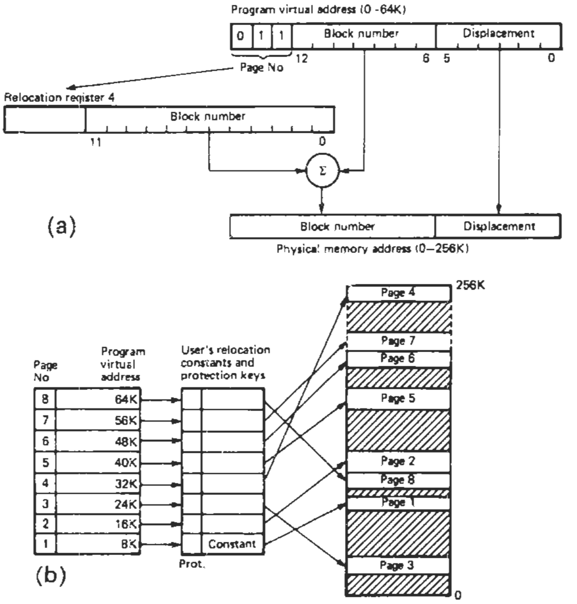

Figure 4.3 Memory management for a 16-bit CPU. (a) Generation of a physical address in the range 0 to 256K by combination of user's program virtual address in the range 0 to 64K with a relocation constant for the page concerned. Memory is handled in 64-byte blocks, with eight relocation registers, giving segmentation into eight pages located anywhere in up to 256K of physical memory. (b) The user's program is considered as up to eight pages, up to 8K bytes each. Relocation constants for that program map these pages anywhere in up to 256K bytes of physical memory. Protection per page can also be specified

4.7.9.2 Memory protection

As an adjunct to the hardware for memory paging or segmentation described above, a memory-protection scheme is readily implemented. As well as a relocation constant, each page can be given a protection code to prevent it being illegally accessed. This would be desirable, for example, for a page holding data that are to be used as common data among a number of programs. Protection can also prevent a program from accessing a page outside of its own address space.

4.7.10 Multi-programming

Memory addressing and memory management are desirable for systems performing multi-programming. In such systems the most important area to be protected is that containing the supervisory program or operating system, which controls the running and allocation of resources for users' programs.

4.7.11 Virtual memory

Programmers frequently have a need for a very large address space within a single program for instructions and data. This allows them to handle large arrays, and to write very large programs without the need to break them down to fit a limited memory size.

One solution is known as virtual memory, a technique of memory management by hardware and operating systems software whereby programs can be written using the full addressing range implied by the word length of the CPU, without regard to the amount of main memory installed in the system. From the hardware point of view, memory is divided into fixed-length pages, and the memory management hardware attempts to ensure that pages in most active use at any given time are kept in main memory. All the current programs are stored in a disk backing store, and an attempt to access a page which is not currently in main memory causes paging to occur. This simply means that the page concerned is read into main memory into the area occupied by an inactive page, and that if any changes have been made to the inactive page since it was read into memory then it is written out to disk in its updated form to preserve its integrity.

A table of address translations holds the virtual physical memory translations for all the pages of each program. The operating system generates this information when programs are loaded onto the system, and subsequently keeps it updated. Memory protection on a per-page basis is normally provided, and a page can be locked into memory as required to prevent it being swapped out if it is essential for it to be immediately executed without the time overhead of paging.

When a program is scheduled to be run by the operating system, its address translation table becomes the one in current use. A set of hardware registers to hold a number of the most frequent translations in current use speeds up the translation process when pages are being repeatedly accessed.

4.7.12 Instruction set

The number and complexity of instructions in the instruction set or repertoire of different CPUs varies considerably. The longer the word length, the greater is the variety of instructions that can be coded within it. This means, generally, that for a shorter word length CPU a larger number of instructions will have to be used to achieve the same result, or that a longer word length machine with its more powerful set of instructions needs fewer of them and hence should be able to perform a given task more quickly.

Instructions are coded, according to a fixed format, allowing the instruction decoder to determine readily the type and detailed function of each instruction presented to it. The general instruction format of the Digital Equipment Corporation VAX is shown as an example in Figure 4.4. Digits forming the operation code in the first (sometimes also the second) are first decoded to determine the category of instruction, and the remaining bytes interpreted in a different way, depending into which category the instruction falls.

There are variations to the theme outlined above for CPUs from differing manufacturers, but generally they all employ the principle of decoding a certain group of digits in the instruction word to determine the class of instruction, and hence how the remaining digits are to be interpreted.

The contents of a memory location containing data rather than an instruction are not applied to the instruction decoder. Correct initial setting of the program counter (and subsequent automatic setting by any branch instruction to follow the sequence intended by the programmer) ensures that only valid instructions are decoded for execution. In the cases where operands follow the instruction in memory, the decoder will know how many bytes or words to skip in order to arrive at the next instruction in sequence.

Logic and arithmetic instructions perform an operation on data (normally one or two words for any particular instruction) held in either the memory or registers in the CPU. The addressing modes available to the programmer (see Section 4.7.8) define the range of possible ways of accessing the data to be operated on. This ranges from the simple single operand type of CPU (where the accumulator is always understood to contain one operand while the other is a location in memory specified by the addressing bits of the instruction) to a multiple-operand CPU with a wide choice of how individual operands are addressed.

In some systems such as the VAX, instructions to input data from (and output data to) peripheral devices are the same as those used for manipulating data in memory. This is achieved by implementing a portion of the memory addresses at the high end as data and control registers in peripheral device controllers.

There are certain basic data transfer, logical, arithmetic and controlling functions which must be provided in the instruction sets of all CPUs. This minimum set allows the CPU to be programmed to carry out any task that can be broken down and expressed in these basic instructions. However, it may be that a program written in this way will not execute quickly enough to perform a time-critical application such as control of an industrial plant or receiving data on a high-speed communications line. Equally, the number of steps or instructions required may not fit into the available size of memory. In order to cope more efficiently with this situation (i.e. to increase the power of the CPU) all but the very simplest CPUs have considerable enhancements and variations to the basic instruction set. The more comprehensive the instruction set, the fewer are the steps required to program a given task, and the shorter and faster in execution are the resulting programs.

Basic types of instruction, with the examples of the variations to these, are described in the following sections.

4.7.12.1 Data transfer

This loads an accumulator from a specified memory location and writes the contents of the accumulator into a specified memory location. Most CPUs have variations such as adding contents of memory location to the accumulator and exchanging the contents of the accumulator and memory locations.

CPUs with multiple registers also have some instructions which can move data to and from these registers, as well as the accumulator. Those with 16-bit or greater word lengths may have versions of these and other instruction types which operate on bytes as well as words.

With a double operand addressing mode (see Section 4.7.8) a generalized 'Move' instruction allows the contents of any memory location or register to be transferred to any other memory location or register.

4.7.12.2 Boolean logical function

This is a logical 'AND' function on a bit-by-bit basis between the contents of a memory location and a bit pattern in the accumulator. It leaves ones in accumulator bit positions which are also one in the memory word. Appropriate bit patterns in the accumulator allow individual bits of the chosen word to be tested.

Many more logical operations and tests are available on more powerful CPUs, such as 'OR', exclusive 'OR', complement, branch if greater than or equal to zero, branch if less than or equal to zero, branch if lower or the same. The branch instructions are performed on the contents of the accumulator following a subtraction of comparison of two words, or some other operation which leaves data in the accumulator. The address for branching to is specified in the address part of the instruction. With a skip, the instruction in the next location should be an unconditional branch to the code which is to be

followed if the test failed, while for a positive result, the code to be followed starts in the next but one location.

Branch or skip tests on other status bits in the CPU are often provided (e.g. on arithmetic carry and overflow).

4.7.12.3 Input/output

CPUs like the VAX, with memory mapped inout/output, do not require separate instructions for transferring data and status information between CPU and peripheral controllers. For this function, as well as performing tests on status information and input data, the normal data transfer and logical instructions are used.

Otherwise, separate input/output instructions provide these functions. Their general format is a transfer of data between the accumulator or other registers, and addressable data, control or status registers in peripheral controllers. Some CPUs also implement special input/output instructions such as:

1. *Skip if 'ready' flag set.* For the particular peripheral addressed, this instruction tests whether it has data awaiting input or whether it is free to receive new output data. Using a simple program loop, this instruction will synchronize the program with the transfer rate of the peripheral.
2. *Set interrupt mask.* This instruction outputs the state of each accumulator bit to an interrupt control circuit of a particular peripheral controller, so that, by putting the appropriate bit pattern in the accumulator with a single instruction, interrupts can be selectively inhibited or enabled in each peripheral device.

4.7.12.4 Arithmetic

1. Add contents of memory location to contents of accumulator, leaving result in accumulator. This instruction, together with instructions in category (2) for handling a carry bit from the addition, and for complementing a binary number, can be used to carry out all the four arithmetic functions by software subroutines.
2. Shift. This is also valuable in performing other arithmetic functions, or for sequentially testing bits in the accumulator contents. With simpler instruction sets, only one bit position is shifted for each execution of the instruction. There is usually a choice of left and right shift, and arithmetic shift (preserving the sign of the word and setting the carry bit) or logical rotate.

Extended arithmetic capability, either as standard equipment or a plug-in option, provides multiply and divide instructions and often multiple-bit shift instructions.

4.7.12.5 Control

Halt, no operation, branch, jump to sub-routine, interrupts on, interrupts off, are the typical operations provided as a minimum. A variety of other instructions will be found, specific to individual CPUs.

4.7.13 CPU implementation

The considerable amount of control logic required to execute all the possible CPU instructions and other functions is implemented in one of two ways.

4.7.13.1 Random logic

Random logic uses the available logic elements of gates, flip-flops, etc., combined in a suitable way to implement all the steps for each instruction, using as much commonality between instructions as possible. The various logic combinations are invoked by outputs from the instruction decoder.

4.7.13.2 Microcode

This is a series of internally programmed steps making up each instruction. These steps or micro-instructions are loaded into ROM using patterns determined at design time, and for each instruction decoded, the micro program ROM is entered at the appropriate point for that instruction. Under internal clock control, the micro-instructions cause appropriate control lines to be operated to effect the same steps as would be the case if the CPU were designed using method (1).

The great advantage of microcoded instruction sets is that they can readily be modified or completely changed by using an alternative ROM, which may simply be a single chip in a socket. In this way, a different CPU instruction set may be effected.

In conjunction with microcode, bit-slice microprocessors may be used to implement a CPU. The bit-slice microprocessor contains a slice or section of a complete CPU, i.e. registers, arithmetic and logic, with suitable paths between these elements. The slice may be 1, 2 or 4 bits in length, and, by cascading a number of these together, any desired word length can be achieved. The required instruction set is implemented by suitable programming of the bit-slice microprocessors using their external inputs controlled by microcode.

The combination of microcode held in ROM and bit-slice microprocessors is used in the implementation of many CPU models, each using the same bit-slice device.

4.7.14 CPU enhancements

There are several areas in which the operating speed of the CPU can be improved with added hardware, either designed in as an original feature or available as an upgrade to be added in-field. Some of the more common areas are described below.

4.7.14.1 Cache memory

An analysis of a typical computer program shows that there is a strong tendency to access repetitively instructions and data held in fairly small contiguous areas of memory. This is due to the fact that loops (short sections of program re-used many times in succession) are very frequently used, and data held in arrays of successive memory locations may be repetitively accessed in the course of a particular calculation. This leads to the idea of having a small buffer memory, of higher access speed than the lower-cost technology employed in main memory, between CPU and memory. This is known as cache memory. Various techniques are used to match the addresses of locations in cache with those in main memory, so that for memory addresses generated by the CPU, if the contents of that memory location are in cache, the instruction or data are accessed from the fast cache instead of slower main memory. The contents of a given memory location are initially fetched into cache by being addressed by the CPU. Precautions are taken to ensure that the contents of any location in cache which is altered by a write operation are rewritten back into main memory so that the contents of the location, whether in cache or main memory, are identical at all times.

A constant process of bringing memory contents into cache (thus overwriting previously used information with more currently used words) takes place completely transparently to the user. The only effect to be observed is an increase in execution speed. This speeding up depends on two factors: hit rate (i.e. percentage of times when the contents of a required location are already in cache) and the relative access times of main and cache memory. The hit rate, itself determined by the size of cache memory and algorithms for its filling, is normally better than 90%. This is dependent, of course, on the repetitiveness of the particular program being executed. The increased speed is achieved by using faster, more expensive memory (sometimes core memory). The additional expense for the relatively small amount of memory being used is more than offset by the speed advantage obtained.

4.7.14.2 RISC computers

Most computers require an instructions set of considerable size and complexity in order to provide all the facilities contained in the operating systems that support and manage them. This arrangement has many advantages, especially for commercial organizations, but also suffers from a distinct disadvantage—the more complex the instruction set, the more processor time and effort is required to decode and carry out each instruction. This can (and does) lead to significant reductions in overall processor performance for very large and complex operating systems such as MVS and VMS.

Research into ways of solving this problem began in the late 1970s, principally in the USA, but it was not until 1984 that the first commercially available computer with a 'reduced' instruction set was sold by Pyramid Technology. This design gave rise to the term 'reduced instruction set computer', or RISC as it is more commonly referred to today. In order to distinguish between these processors and the normal complex instruction set computers that preceded them, the term 'complex instruction set computer' (or CISC) was also brought into general use.

Within a RISC processor all superfluous or little-used instructions are removed from the operating system. All instructions will generally be of the same length and take the same amount of time to process. Both of these characteristics enable pipelining and other techniques to be used to effect savings in the time taken to execute each instruction. Typically, all instructions are hardwired in the processor chip (also faster than resorting to microcode). Much use is made of a higher number of registers than normal, thus many more instructions address registers as opposed to main memory. Where memory is addressed, it is often within the very large cache memories that are another feature of RISC processors. All these characteristics contribute to the faster processing speed *per instruction* with a RISC architecture. However, since the instructions are simpler and microcode is not used, then some fucntionality requires many more instructions on RISC than on CISC processors. Overall, there appears to be savings in the region of 25–30% of RISC over CISC for computer-intensive applications. Note that direct comparisons of MIPs (million of instructions per second) between RISC and CISC processors are not a good guide to overall performance that will be obtained.

Most RISC processors run under the UNIX operating system (or one of its clones), since this system is simpler and easier to gain entry to than most proprietary operating systems. Two important players in the RISC arena are Sun Microsystems Inc. and MIPS Computer Systems Inc., both in the USA, the former for its open SPARC (Scalable Processor ARChitecture) RISC architecture, the latter for the fact that all its efforts as a corporation are aimed at the development and sale of RISC-based technology. It is likely that the use of RISC technology will grow over the next decade, though the extremely large existing investments in current operating systems and CISC technology mean that this progress will not be as rapid and as widespread as some of the players in the RISC game would hope for. All the major computer manufacturers have already undertaken research in this area or have announced their intention to do so in the near future.

4.7.15 Fixed and floating-point arithmetic hardware

As far as arithmetic instructions go, simpler CPUs only contain add and subtract instructions, operating on single-word operands. Multiplication, of both fixed and floating-point numbers, is then accomplished by software subroutines, i.e. standard programs which perform multiplication or division by repetitive use of the add or subtract instructions, which can be invoked by a programmer who requires to perform a multiplication or division operation.

By providing extra hardware to perform fixed-point multiply and divide, which also usually implements multiple place-shift operations, a very substantial improvement in the speed of multiply and divide operations is obtained. With the hardware techniques used to implement most modern CPUs, however, these instructions are wired in as part of the standard set.

Floating-point format (Figure 4.5) provides greater range and precision than single-word fixed-point format. In floating-point representation, numbers are stored as a fraction times 2^n, where n can be positive or negative. The fraction (or mantissa) and exponent are what is stored, usually in two words for single-precision floating-point format or four words for double precision.

Hardware to perform add, subtract, multiply and divide operations is sometimes implemented as a floating-point processor, an independent unit with its own registers to which floating-point instructions are passed. The floating-point processor (sometimes called co-processor) can then access the operands, perform the required arithmetic operation and signal the CPU, which has meanwhile been free to continue with its own processing until the result is available.

An independent floating-point processor clearly provides the fastest execution of these instructions, but even without that, implementing them within the normal instruction set of the CPU, using its addressing techniques to access operands in memory, provides a significant improvement over software subroutines. The inclusion of the FPP into 'standard' CPUs is becoming almost standard.

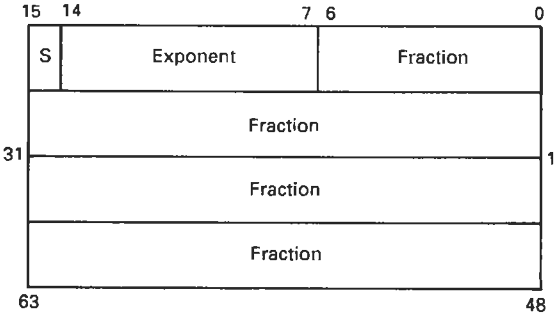

Figure 4.5 32-bit double floating-point format

4.7.16 Array processors

Similar to an independent floating-point processor described above, an optional hardware unit which can perform complete computations on data held in the form of arrays of data in memory, independent from the CPU and at high speed, is known as an array processor. These are used in specialized technical applications such as simulation, modelling and seismic work. An example of the type of mathematical operation which would be carried out by such a unit is matrix inversion. The ability of these units to perform very high-speed searches based upon text keys has also led to a growing use of them for the rapid retrieval of data from large data banks, particularly in areas such as banking, where real-time ATM terminals require fast response to account enquiries from very large data sets.

4.7.17 Timers and counters

For systems which are used in control applications, or where elapsed time needs to be measured for accounting purposes (as, for example, in a time-sharing system where users are to be charged according to the amount of CPU time they use), it is important to be able to measure intervals of time precisely and accurately. This measurement must continue while the system is executing programs, and must be 'real time', i.e. related to events and time intervals in the outside world.

Most CPUs are equipped with a simple real-time clock which derives its reference timing from 50–60 Hz mains. These allow a predetermined interval to be timed by setting a count value in a counter which is decremented at the mains cycle rate until it interrupts the CPU on reaching zero.

More elaborate timers are available as options, or are even standard items on some CPUs. These are driven from high-resolution crystal oscillators, and offer such features as:

1. More than one timer simultaneously;
2. Timing random external events;
3. Program selection of different time bases;
4. External clock input.

The system supervisory software normally keeps the date and time of day up to date by means of a program running in the background all the time the system is switched on and running. Any reports, logs or printouts generated by the systems can then be labelled with the date and time they were initiated. To overcome having to reset the data and time every time the system is stopped or switched off, most CPUs now have a permanent battery-driven date and time clock which keeps running despite stoppages and never needs reloading once loaded initially (with the exception of change to and from Summer Time).

Counters are also useful in control applications to count external events or to generate a set number of pulses (for example, to drive a stepping motor). Counters are frequently implemented as external peripheral devices, forming part of the digital section of a process input/output interface.

4.7.18 Input/output

In order to perform any useful role, a computer system must be able to communicate with the outside world, either with human users via keyboards, CRT screens, printed output, etc. or with some external hardware or process being controlled or monitored. In the latter case, where connection to other electronic systems is involved, the communication is via electrical signals.

All modern computer systems have a unified means of supporting the variable number of such human or process input/output devices required for a particular application, and indeed for adding such equipment to enhance a system at the user's location. As well as all input/output peripherals and external mass storage in the form of magnetic tape, compact disk and disk units, some systems also communicate with main memory in this common, unified structure. In such a system (for example, the VAX) there is no difference between instructions which reference memory and those which read from and write to peripheral devices. The benefits of a standard input/output bus to the manufacturer are:

1. It provides a design standard allowing easy development of new input/output devices and other system enhancements;
2. Devices of widely different data transfer rates can be accommodated without adaptation of the CPU;
3. It permits development of a family concept.

Many manufacturers have maintained a standard input/output highway and CPU instruction set for as long as a decade or more. This has enabled them to provide constantly improving system performance and decreasing cost by taking advantage of developing technology, while protecting very substantial investments in peripheral equipment and software. For the user of a system in such a family, the benefits are:

1. The ability to upgrade to a more powerful CPU while retaining existing peripherals;
2. Retention of programs in moving up- or down-range within the family;
3. In many cases the ability to retain the usefulness of an older system by adding more recently developed peripherals, and in some cases even additional CPU capacity of newer design and technology (see Section 4.5.7).

4.7.19 Input/output bus

The common structure for any given model of computer system is implemented in the form of an electrical bus or highway. This specifies the number, levels and significance of electrical signals and the mechanical mounting of the electrical controller or interface which transforms the standard signals on the highway to ones suitable for the particular input/output or storage device concerned. A data highway or input/output bus needs to provide the following functions.

4.7.19.1 Addressing

A number of address lines is provided, determining the number of devices that can be accommodated on the system. For example, six lines would allow 63 devices. Each interface on the bus decodes the address lines to detect input/output instructions intended for it.

4.7.19.2 Data

The number of data lines on the bus is usually equal to the word length of the CPU, although it may alternatively be a sub-multiple of the word length, in which case input/output data are packed into or unpacked from complete words in the CPU. In some cases data lines are bi-directional, providing a simpler bus at the expense of more complex drivers and receivers.

4.7.19.3 Control

Control signals are required to synchronize transactions between the CPU and interfaces and to gate address and data signals to and from the bus. Although all the bits of an address or data word are transmitted at the same instant, in transmission down the bus, because of slightly different electrical characteristics of each individual line, they will arrive at slightly different times. Control signals are provided to gate these skewed signals at a time when they are guaranteed to have reached their correct state.

4.7.20 Types of input/output transactions

Three types of transaction via the input/output bus between CPU and peripheral device are required, as described below.

4.7.20.1 Control and status

This type of transfer is initiated by a program instruction to command a peripheral device to perform a certain action in readiness for transferring data or to interrogate the status of a peripheral. For example, a magnetic tape unit can be issued with a command to rewind, the read/write head in a disk unit to be positioned above a certain track on the disk, the completion of a conversion by an analogue-to-digital converter verified, or a printer out of paper condition may be sensed.

Normally, a single word of control or status information is output or input as a result of one instruction, with each bit in the word having a particular significance. Thus multiple actions can be initiated by a single control instruction, and several conditions monitored by a single status instruction. For the more complex peripheral devices, more than one word of control or status information may be required.

4.7.20.2 Programmed data transfer

For slow and medium-speed devices (for example, floppy disk units or line printers) data are input or output one word at a time, with a series of program instructions required for every word transferred. The word or data are transferred to or from one of the CPU registers, normally the accumulator. In order to effect a transfer of a series of words forming a related block of data (as is normally required in any practical situation) a number of CPU instructions per word transferred are required. This is because it is necessary to take the data from (or store them into) memory locations. As a minimum, in a simple case, at least six CPU instructions are required per word of data transferred.

In a system such as the VAX, where instructions can reference equally memory locations, peripheral device registers and CPU registers, the operation is simplified since a MOVE instruction can transfer a word of data directly from a peripheral to memory without going through a CPU register. This applies equally to control and status instructions on the VAX, with a further advantage that the state of bits in a peripheral device status register can be tested without transferring the register contents into the CPU.

The rate of execution of the necessary instructions must match the data transfer rate of the peripheral concerned. Since it is usually desired that the CPU continue with the execution of other parts of the user's program while data transfer is going on, some form of synchronization is necessary between CPU and peripheral to ensure that no data are lost. In the simplest type of system, the CPU simply suspends any other instructions and constantly monitors the device status word, awaiting an indication that the peripheral has data ready for input to the CPU or is ready to receive an output from it. This is wasteful of CPU time where the data transfer rate is slow relative to CPU instruction speeds, and in this case the use of 'interrupt' facilities (see Section 4.7.21) provides this synchronization.

4.7.20.3 Direct memory access

For devices which transfer data at a higher rate (in excess of around 20 000 words per second) a different solution is required. At these speeds, efficiency is achieved by giving the peripheral device controller the ability to access memory autonomously without using CPU instructions. With very fast tape or disk units which can transfer data at rates in excess of 6 million bytes per second, direct memory access (DMA) is the only technique which will allow these rates to be sustained.

The peripheral controller has two registers which are loaded by control instructions before data transfer can begin. These contain:

1. The address in memory of the start of the block of data;
2. The number of words which it is desired to transfer in the operation.

When the block transfer is started the peripheral controller, using certain control lines in the input/output bus, sequentially accesses the required memory locations until the specified number of words has been transferred. The memory addresses are placed on address lines of the input/ouput bus, together with the appropriate control and timing signals, for each word transferred. On completion of the number of words specified in the word-count register the peripheral signals to the CPU that the transfer of the block of data is completed.

Other than the instructions required initially to set the start address and word-count registers and start the transfer, a DMA transfer is accomplished without any intervention from the CPU. Normal processing of instructions therefore continues. Direct memory access (more than one peripheral at a time can be engaged in such an operation) is, of course, competing with the CPU for memory cycles, and the processing of instructions is slowed down in proportion to the percentage of memory cycles required by peripherals. In the limit, it may be necessary for a very-high-speed peripheral to completely dominate memory usage in a burst mode of operation, to ensure that no data are lost during the transfer through conflicting requests for memory cycles.

4.7.21 Interrupts

The handling of input/output is made much more efficient through the use of a feature found in varying degrees of sophistication on all modern systems. This is known as 'automatic priority interrupt', and is a way of allowing peripheral devices to signal an event of significance to the CPU (e.g. in some systems a terminal keyboard having a character ready for transmission, or completion of DMA transfer) in such a way that the CPU is made to suspend temporarily its current work to respond to the condition causing the interrupt. Interrupts are also used to force the CPU to recognize and take action on alarm or error conditions in a peripheral (e.g. printer out of paper, error detected on writing to a magnetic tape unit).

Information to allow the CPU to resume where it was interrupted (e.g. the value of the program counter) is stored when an interrupt is accepted. It is necessary also for the device causing the interrupt to be identified, and for the program to branch to a section to deal with the condition which caused the interrupt (Figure 4.6).

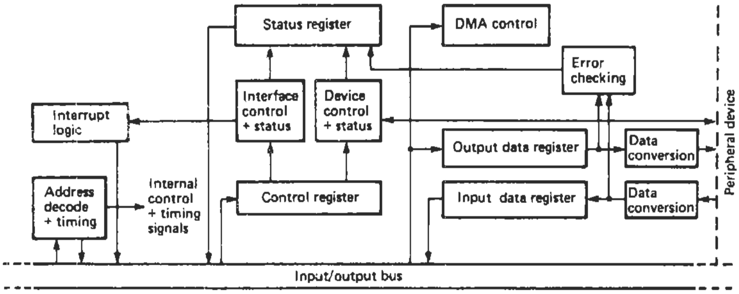

Figure 4.6 Block diagram of peripheral interface

Examples of two types of interrupt structure are given below, one typical of a simpler system such as an 8-bit microprocessor or an older architecture minicomputer, the other representing a more sophisticated architecture such as the VAX. In the simpler system, a single interrupt line is provided in the input/output bus, onto which the interrupt signal for each peripheral is connected. Within each peripheral controller, access to the interrupt line can be enabled or disabled, either by means of a control input/ouput instruction to each device separately or by a 'mask' instruction which, with a single 16-bit word output, sets the interrupt enabled/disabled state for each of up to 16 devices on the input/output bus. When a condition which is defined as able to cause an interrupt occurs in a peripheral, and interrupts are enabled in that device, a signal on the interrupt line will be sent to the CPU. At the end of the instruction currently being executed this signal will be recognized.

In this simple form of interrupt handing the interrupt servicing routine always begins at a fixed memory location. The interrupt forces the contents of the program counter (which is the address of the next instruction that would have been executed had the interrupt not occurred) to be stored in this first location and the program to start executing at the next instruction. Further interrupts are automatically inhibited within the CPU, and the first action of the interrupt routine must be to store the contents of the accumulator and other registers so that on return to the main stream of the program these registers can be restored to their previous state.

Identification of the interrupting device is done via a series of conditional instructions on each in turn until an interrupting device is found. Having established which device is interrupting, the interrupt-handling routine will then branch to a section of program specific to that device. At this point or later within the interrupt routine an instruction to re-enable the CPU interrupt system may be issued, allowing a further interrupt to be received by the CPU before the existing interrupt-handling program has completed. If this 'nesting' of interrupts is to be allowed, each interruptable section of the interrupt routine must store the return value of the program counter elsewhere in the memory, so that as each section of the interrupt routine is completed, control can be returned to the point where the last interrupt occurred.

A more comprehensive interrupt system differs in the following ways from that described above:

1. Multiple interrupt lines are provided, and any number of devices can be on each line or level.
2. The CPU status can be set to different priority levels, corresponding to different interrupt lines. Only interrupt on a level higher than the current priority are immediately serviced by the CPU. This provides a more adaptable way of dealing with a wide range of devices of different speeds and with different degrees of urgency.
3. When an interrupt is accepted by the CPU the interrupting device sends a vector or pointer to the CPU on the input/output bus address lines. This points to a fixed memory address for each device, which holds the start address of its interrupt routine, and in the following memory word, a new status word for the CPU, defining its priority level and hence its ability to respond to other levels of interrupt during this interrupt routine. By avoiding the need for the CPU to test each device until it finds the interrupting one, response to interrupts is much faster.
4. The current value of the program counter and processor status word are automatically placed on a push-down stack when an interrupt occurs. A further interrupt accepted within the current interrupt routine will cause the program counter and status word to be stored on the top of the stack, and the existing contents to be pushed down into the stack. On return from an interrupt routine, the program counter and status word stored when that interrupt occurred are taken from the top of the stack and used by the CPU, allowing whatever was interrupted to continue as before. This can take place for any number of interrupts, subject only to the capacity of the stack. Thus 'nesting' to any level is handled automatically without the need for the programmer to store the program counter at any stage.

4.8 Peripherals

Peripheral devices fall into the following three categories.

4.8.1 Interactive

These are designed to allow humans to interact with the system by outputting information in the form of voice, readable alphanumeric text or graphics, either on paper or on a display screen, and accepting information from humans through manual devices such as keyboards, voice-recognition devices or by scanning printed text or images. The general function performed by devices in this class is sometimes referred to as human–machine interaction.

4.8.2 Storage

These act as a back-up form of storage to supplement the main memory of the system. The most simple of these (now largely superseded) was punched paper tape or cards, and the most complex now ranges up to very large disks and magnetic tapes, each capable of holding up to thousands of millions of characters of information. Peripherals of this type are generally known as mass-storage devices.

Recent developments in the field of mass storage include both compact disks (CDs) and solid-state disks. The CD used is essentially the same material and technique employed for commercial recording of music, etc., with the majority of equipment able to operate on a 'read only' basis. The advantage is the considerable increase in data-storage density over conventional magnetic tape or disk. Solid-state disks are not really physical disks at all, but rather fast large-capacity CMOS memory, which the operating system treats logically as if it were a disk drive. The advantage is speed over conventional media, but at a cost premium. Solid-state disks are still not yet large enough for long-term data storage or archiving, but this will change as memory technology improves and the unit costs fall in relation to disk technology. Units holding up to 1 gigabyte of information which can then be transferred at a speed of 36 megabytes per second have already been developed.

4.8.3 Communication

These are interfaces between the computer system and other systems or electronic devices. Analogue/digital converters, digital input/output and communication line interfaces are good examples.

An example of progress made with respect to communication principles between the computer and its environment is a device often called the 'laser glove'. This technique combines many of the traditional input/output principles into a single new dimension. In some areas of industry or research (such as nuclear physics) it is undesirable for parts of the human body to come into contact with certain substances such as radioactive material. Yet in many cases a degree of precision of movement that is difficult to predefine is called for, thus eliminating the use of pre-programmed robotics. In such instances the combined skills of the human hand, eye and brain are still required. The laser glove is able to project a hologram of the material being worked on in front of the operator. The operator wears a tight-fitting glove that is able to sense every minute movement of the hand. Any such movement is instantly replicated by a robotic device located in the unsafe environment. Thus the operator is able to carry out tasks on a hologram, and have those same tasks carried out safely by a robot in what, for a human, would be an unsafe environment.

4.9 Output devices

Either interactive or communications peripherals (or both) are required in every system. The existence of storage depends on the need for additional storage over and above main memory. All peripheral devices in a system are connected via the input/output structure (as described in Section 4.13) to the CPU, memory, and in some systems to a separate input/output processor.

The throughpout rates and flexibility of the input/output structure determine the number and variety of peripheral devices which can be handled in a system before the input/output requirements begin to saturate the system and prevent any processing of instructions being done by the CPU. In deciding on the configuration of a particular system it is important to analyse the throughput requirement dictated by peripheral devices, to ensure the system does not become input/output bound, and that data from any peripheral device are not lost due to other devices taking too many of the input/output resources.

Historically, in the computer industry independent manufacturers as well as the large computer systems companies have developed and manufactured peripherals. The products of the independent manufacturers are either bought by system manufacturers for design into their systems or are sold by the independent manufacturers directly to users of the more popular computers, with an interface providing compatibility with the input/output bus of the system. This has fostered the development of many of the widely used, cost-effective peripherals available today, such as floppy disks and printers.

Certain storage devices with removable storage media, where the format recording data on the media have been standardized, can be used for exchanging data between systems from different suppliers. This is important where data may be gathered on one system and need to be analysed on a different one more suitable for that purpose. However, due to the very large growth of networking in the 1980s, even between equipment from different manufacturers, the moving of data from one machine to another is most commonly achieved by file transmission, though for very large files magnetic tapes are used for this purpose.

4.10 Terminals

A data terminal is essentially an output device at which a computer user sits, either to receive data in alphanumeric or graphic form or to input data through a keyboard or other form of manual input, or both. Terminals range in cost and complexity from a 100 characters per second serial printer to a graphics terminal with a large colour CRT screen. Most are connected to the CPU by data-communications interfaces and can therefore be situated at some distance from the system within a building (e.g. on a LAN – local area network), or indeed remote from the computer site communicating over the public telephone network or over a company's private network (WAN – wide area network).

4.10.1 Dot matrix printers

Only a small proportion of low-speed printers are now supplied with any means of input such as a keyboard. This is due to the widespread use of interactive terminals for data input and to the fact that many of these printers are themselves attached in some way to a terminal to act as a slave by producing hardcopy output through the terminal.

The most common use for printers with keyboards is as operators' consoles on large computers, where a typical speed is in the range 100–250 characters per second. The print head consists of seven or more needles held in a vertical plane in the head assembly which is positioned with the needles perpendicular to the paper and spaced a short distance from it, with a carbon ribbon interposed between. Each needle can be individually driven by a solenoid to contact the paper through the ribbon, thus printing a dot. A complete character is formed by stepping the head through five or more positions horizontally, and at each position energizing the appropriate solenoids. The head is then stepped onto the position for the next character.

When the end of a line is reached the paper is advanced one line and the print head either returns to the left margin position or, in some faster printers, prints the next line from right to left. This is possible where the printer is provided with storage for a line or more of text, and the characters can be extracted from this store in the reverse order. Throughput speed is improved where this technique is used, by saving redundant head movement. The 7 × 5 dot matrix within which this type of printer forms each character allows an acceptable representation of alpha and numeric characters. Better legibility, particularly of lower-case characters with descenders, can be achieved by using a larger matrix such as 9 × 7, i.e. a head with nine needles stepping through seven positions for each character. Manufacturers can now supply 24-pin dot matrix printers, in order to provide higher-quality print and a larger character set.

Character codes are received for printing, sent from the keyboard in asynchronous serial form, on a line driven by a data-communications interface in the computer, whose transmission speed determines the overall printing and keying throughput. Buffer storage for up to 4 million characters is provided in printers which use serial data communications, to make the most efficient use of communication lines, and in printers with built-in intelligence, to allow look-ahead so that the print head can skip blanks and take the shortest route to the next printable character position.

Character sets can be readily changed by replacing the ROM chip which contains the dot patterns corresponding to each character code or, more usually, by sending the character patterns over the network to the printer from the host CPU, often referred to as 'downline loading'. The latter method has the advantage of character selection at any time under program control and without any human intervention. Some printers already contain in-built multiple character sets.

4.10.2 Letter-quality printers

The earliest models of dot matrix printers could not form and print characters of a complex nature or produce a high-quality print image. To overcome this, printers which used a metal wheel, with the characters pre-formed on the end, were used for occasions where the quality of the image was paramount (e.g. business correspondence). These became known as the daisywheel printers. Since dot matrix printers have continued to make large improvements in this respect, some offering different quality of print aacording to requirement and selectable by program control, these letter-quality printers have receded in sales and use due to their higher cost of construction and maintenance.

Other types of serial printer which give high print quality are the ink jet printer and the laser printer.

4.10.3 Visual display unit

A VDU is a terminal in which a CRT is used to display alphanumeric text. It is normally also equipped with a keyboard for data input, and occasionally a printer may be slaved to the VDU to produce a permanent paper copy of the information displayed on the screen at a particular time.

The format for the layout of text on the screen is most commonly 24 lines of text (sometimes with a twenty-fifth line reserved for system messages to the terminal user), each with up to 80 character positions. Most VDUs also allow 132 columns to be displayed in a line, using a special compressed character set. The latter feature is useful for compatibility with computer printouts that normally have up to 132 columns of print. Displaying of new text on the screen takes place a character at a time, starting in the top left-hand corner and continuing line by line. When the screen is full, the page of text moves up one line, allowing a new line to be added at the bottom.

Characters are caused to be displayed either by outputting data from the CPU through a serial communications interface or by the operator typing on a typewriter-like keyboard.

VDUs are classified depending on which of the following modes of message composition they use:

1. *Block mode.* A full screen of text is composed and (if need be) edited by the operator, and the corresponding character codes held in a buffer store in the VDU. Transmission of the text from the buffer store to the CPU is then done as a continuous block of characters, when a 'transmit' key is pressed.
2. *Character mode.* Each character code is transmitted to the CPU as the corresponding key is pressed. Characters are 'echoed' back from the CPU for display on the screen. This function, plus editing of entered data, is performed by program in the CPU.

To assist with character positioning on the screen, a cursor is displayed showing the position in which the next character will appear. On most VDUs its position can be altered by control characters sent by program to the VDU or by the operator using special keys, so that inefficient and time-consuming use of 'space' and 'new line' controls is unnecessary.

Other functions, some or all of which are commonly provided depending on cost and sophistication, are:

1. Blinking;
2. Dual intensity;
3. Reverse video (black characters on a white or coloured background);
4. Underline;
5. Alternate character sets;
6. Protected areas.

Each of these can be selected on a character-by-character basis. Additionally, the following are attributes of the whole screen:

1. Bi-directional scrolling;
2. Smooth scrolling (instead of jumping a line at a time);
3. Split-screen scrolling;
4. Enlarged character size;
5. Compressed characters.

The most commonly used colours for displayed characters on monochrome VDUs are white, green and amber, all on a dark background, or the reverse of these where reverse video is available. Almost all VDUs currently produced have keyboards separate from the body of the VDU for ease of use and the comfort of the user, as well as some form of graphics capability ranging from simple graphics to very high-resolution colour monitors that produce an image that is difficult to distinguish from a fine-grain colour photograph. The level of sophistication on 'standard' VDUs has risen considerably since the start of the 1990s and high-resolution multi-choice colour terminals are no longer confined to specialist areas such as CAD/CAM, television and engineering.

Industries and professions such as aircraft and vehicle manufacture, electronics, and structural and civil engineering use VDUs in the design of items such as car bodies, printed circuit boards and building frameworks, by creating and modifying two- or three-dimensional representations of these objects on the CRT screen. Keyboards and devices such as joysticks, rolling balls and light pens are provided for modification of displayed information, as shown in Figure 4.7.

A graphics terminal normally has its own graphics processor to interpret picture information output from the CPU and held in a picture store. Thus, the program in the CPU need only supply parameters such as the start and end points of a vector, or the centre and radius of a circle, and the necessary

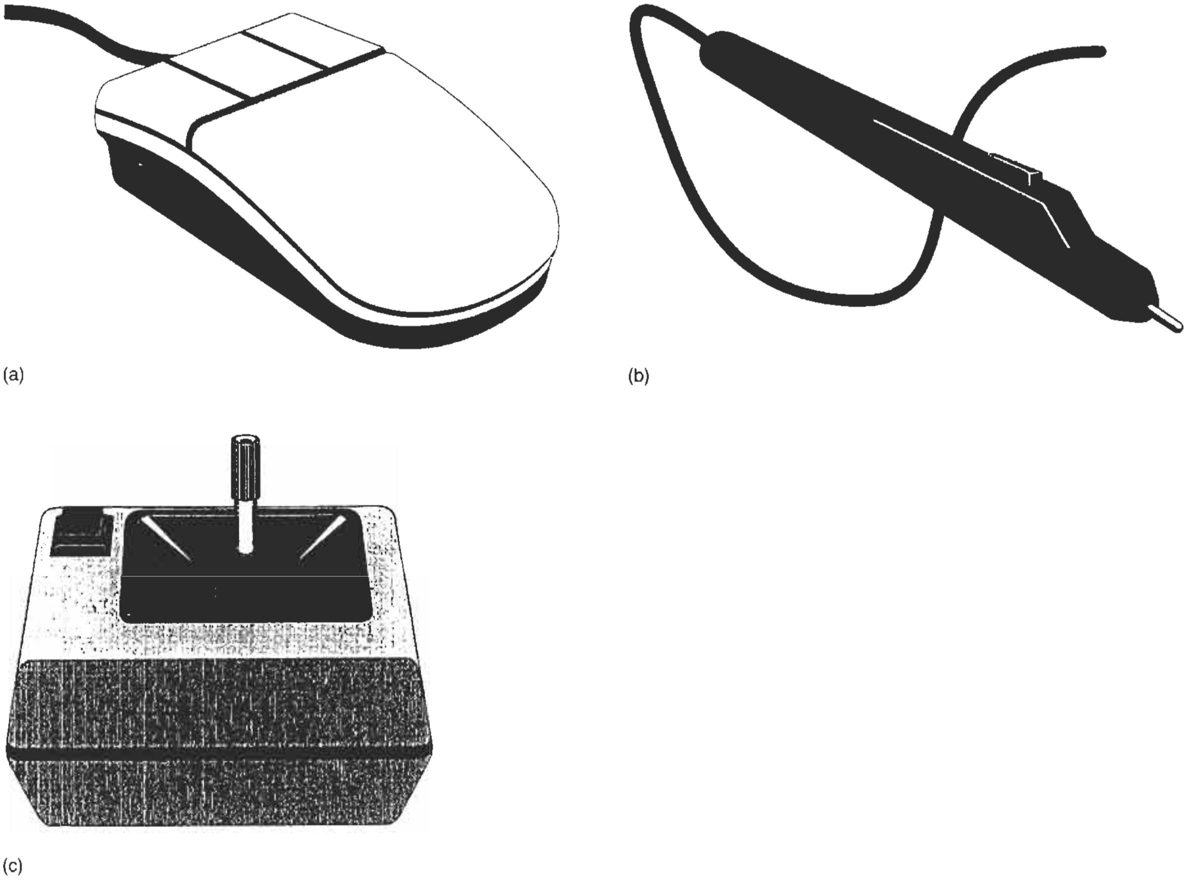

Figure 4.7 Interactive devices. (a) Mouse. (b) Light pen. (c) Joystick

processing is done within the terminal to display them on the screen. As with dot matrix printers, characters are formed as a series of dots within a matrix.

The development of visual display units with very powerful graphics processors, networking capabilities and large-capacity disk-storage facilities has given rise to a new term to describe this revolutionary concept. Such a combination of equipment is commonly referred to as a 'workstation', from the assumption that operatives would have everything that they required to work within one 'station'. Initially, this expression covered the desk and other communications equipment (such as telephones) that was used, but today the term 'workstation' is usually confined to the computer equipment. Though this explanation is given under the heading 'Visual Display Unit', it should be appreciated that workstations are blurring the dividing line between the different types of peripherals attached to computers, with much more emphasis on integrating them into single units.

Specialized terminals are common in areas such as:

1. Shops, as point-of-sale terminals, i.e. sophisticated cash registers linked to an in-store computer which is often adjusting a stock control system at the same time as registering the sale and debiting the customer's bank or credit card account. These are referred to as EFTPOS (Electronic Funds Transfer at Point Of Sale) terminals;
2. Banking for customer cash dispensing, enquiries and other transactions, or for teller use, including the ability to print entries in passbooks or to read a card's magnetic strip containing details of the customer's account and so eliminate the need for completion of a cheque or paying-in slip;
3. Manufacturing for shopfloor data collection and display.

These typically use features found in the terminals described above, and, in addition, may have the capability to read magnetic stripes on credit cards, punched plastic cards or identity badges, or bar codes on supermarket goods or parts in a factory.

4.10.4 High-speed printers and plotters

4.10.4.1 Line printer

For greater volume of printed output than can be achieved with serial printers, line printers that can produce a whole line of characters almost simultaneously are available. Using impact techniques, speeds up to 3500 full lines (usually 132 characters each) per minute are possible. Continuous paper in fan-fold form, which may be multi-part to produce copies, is fed through the printer a line at a time by a transport system consisting of tractors which engage sprocket holes at the edges of the paper to move it upwards and through the printer from front to rear. A paper tray at the rear allows the paper to fold up again on exit from the printer.

As well as advancing a line at a time, commands can be given to advance the paper to the top of the next page, or to advance a whole page or line. This is important, for example, where pre-printed forms are being used.

Two types of line printer are in common use: drum printers and band printers. Both use a horizontal row of hammers, one per character position or, in some cases, shared between two positions. These are actuated by solenoids to strike the paper through a carbon film against an engraved representation to print the desired character. In a drum printer a print drum the length of the desired print line rotates once per print line. In each character position the full character set is engraved around the circumference of the drum. A band printer has a horizontal revolving band or chain of print elements, each with a character embossed on it. The full character set is represented on the band in this way. To implement different character fonts involves specifying different barrels in the case of a drum printer, whereas a change can be made readily on a band printer by an operator changing bands, or individual print elements in the band can be replaced.

The printer has a memory buffer to hold a full line of character codes. When the buffer is full (or terminated if a short print line is required) a print cycle is initiated automatically. During this print cycle the stored characters are scanned and compared in synchronism with the rotating characters on the drum or band. The printer activates the hammer as the desired character on the drum or band approaches in each print position.

4.10.4.2 Laser printers

These are available to meet three different types of printing requirements:

1. Very high volumes of output at speeds exceeding 200 pages per minute. They are normally used by those requiring a constant high-volume printing service, since this equipment is expensive to buy, run and service.
2. Departmental printing requirements, usually consisting of medium to high volumes on an *ad hoc* basis. This equipment would normally be networked to many CPUs and shared by a group of common users. They print at speeds of up to 40 pages per minute.
3. Desktop printing uses laser printers small enough to fit on an individual's desk, designed for intermittent low-volume personal printing requirements.

However, the technology used is common to all three. The principle used is that of the everyday photocopier, the difference being that the image to be copied is set up according to digital signals received from the host CPU instead of from a photoscan of the document to be copied. The main advantage of this form of output is the clarity and quality of the image printed. It is so good that it is possible not only to print data but also to print the 'form' or 'letterhead' of the paper at the same time, thus avoiding the cost of pre-printed stationery. The disadvantage is that it is currently not possible to print multiple copies simultaneously.

4.10.4.3 Pen plotter

Another form of hard copy output is provided by pen plotters. These are devices aimed primarily at high-complexity graphics with a limited amount of text. Their uses range from plotting graphs of scientific data to producing complex engineering drawings in computer-aided design applications such as drawings used in integrated-circuit chip design.

The plotter has one or more pens held vertically above a table on which the paper lies. These can be of different colours, and as well as being raised or lowered on to the paper individually by program commands, they can be moved in small steps, driven by stepping motors. They plot in the X and Y directions, or achieve control in one axis by moving the paper back and forth between supply and take-up rolls under stepping motor control, and in the other axis by pen movement. Diagonal lines are produced by combinations of movements in both axes.

With step sizes as small as 0.01 mm, high accuracy plots can be produced (in multiple colours where more than one pen is used) and annotated with text in a variety of sizes and character sets. Supporting software is usually provided with a plotter. This will, for example, scale drawings and text and generate alphanumeric characters.

4.10.4.4 Electrostatic plotter

The objectives of the electrostatic plotter are the same as those of the pen plotter, the production of high-quality graphics in hardcopy form. However, electrostatic plotters achieve their output by setting an electrostatic charge on the paper in the same pattern as the required output image, and then attracting and retaining ink particles according to that pattern. This ink is then fused onto the paper in order to make a permanent image. This can even be accomplished in colour with almost unlimited ability to recreate the spectrum. The advantage of this approach over conventional pen plotters is speed, with electrostatic plotters achieving speeds up to 50 times faster. There is also considerably less movement of paper and equipment parts. However, electrostatic plots incur heavy production costs when compared to pen plotters, and have not come into large-scale general use for this reason.

4.11 Direct input

Other forms of direct input, eliminating the need for typing on the keyboard of a teleprinter or VDU, are described in this section.

4.11.1 Character recognition

This technique offers a high-speed method for the capture of source data as an alternative to keyboard input and for processing documents such as cheques. Several types of device exist, with varying capabilities and functions:

1. Page and document readers, with the capability to read several special fonts, plus, in some cases, lower-quality print including hand printing and hand marked forms as opposed to written or printed documents. Most character readers have some form of error handling, allowing questionable characters to be displayed to an operator for manual input of the correct character. A wide range of capabilities and hence prices is found, from simple, low-speed (several pages per minute) devices handling pages only, to high-speed readers for pages and comments, the former at up to two pages per second with the latter several times faster.
2. Document readers/sorters which read and optionally sort simple documents such as cheques and payment slips with characters either in magnetic ink or special font. These are

geared to higher throughputs (up to 3000 documents per minute) of standard documents.
3. Transaction devices, which may use both document reading and keyboard data entry, and where single documents at a time are handled.

4.11.2 Writing tablets

Devices using a variety of techniques exist for the conversion of hand-printed characters into codes for direct input to a CPU. The overall function of these is the same – the provision of a surface on which normal forms (typically, up to A4 size) can be filled in with hand-printed alphanumeric characters, using either a normal writing instrument in the case of pressure-sensitive techniques or a special pen. The benefits of this type of device include:

1. Immediate capture of data at source, avoiding time-consuming and error-prone transcription of data;
2. By detecting the movements involved in writing a character, additional information is gained compared with optical recognition, allowing characters which are easily confused by Optical Character Recognition (OCR) to be correctly distinguished.

4.12 Disk storage

Even though computer main memories are very large when compared to those produced during the 1970s (512 million characters is not uncommon), this is still nowhere near approaching the total memory storage capability required to retain and process all data. Backing storage provides this capability and has the added advantage in that it can be copied and stored away from the CPU for security and safekeeping. For backing storage to be most suitable it should be price-effective, reliable and easy to exchange and access. It is for this reason that the use of disk storage has grown considerably over the last ten years.

Disks are connected to CPU by a controller which is normally a DMA device attached to the input/otuput bus or to a high-speed data channel, except in the case of the slowest of disks, which may be treated as a programmed transfer device. The controller is generally capable of handling a number of drives, usually up to 16 or 32. Having multiple-disk drives on a system, as well as providing more on-line storage, allows copying of information from one disk to another and affords a degree of redundancy since, depending on application, the system may continue to function usefully with one less drive in the event of a failure. A disk controller is relatively complex, since it has to deal with high rates of data transfer, usually with error code generation and error detection, a number of different commands and a large amount of status information.

Four types of disk drive will be described in the following sections: floppy disk, cartridge disk, removable pack disk and 'Winchester Technology' disk. The following elements are the major functional parts common to all the above types of drive, with differences in implementation between the different types.

4.12.1 Drive motor

This drives a spindle on which the disk itself is placed, rotating at a nominally fixed speed. The motor is powered up when a disk is placed in the drive, and powered down (normally with a safety interlock to prevent operator access to rotating parts) until it has stopped spinning, when it is required to remove the disk from the system.

4.12.2 Disk medium

The actual recording and storage medium is the item which rotates. It is coated with a magnetic oxide material, and can vary from a flexible diskette of less than one megabyte capacity recording on one surface only (single-sided floppy disk) to an assembly of multiple disks stacked one above the other on a single axle (disk pack) holding thousands of megabytes of data).

4.12.3 Head mechanism

This carries read/write heads, one for each recording surface. The number of recording surfaces ranges from only one on a single-sided floppy disk to ten or more for a multi-surface disk pack. In the latter case, the heads are mounted on a comb-line assembly, where the 'teeth' of the comb move together in a radial direction between the disk surfaces.

During operation, the recording heads fly aerodynamically extremely close to the disk surface, except in the case of floppy disks, where the head is in contact with the surface. When rotation stops, the heads either retract from the surface or come to rest upon it, depending on the technology involved.

The time take for the read/write head to be positioned above a particular area on the disk surface for the desired transfer of data is known as the access time. It is a function partly of the rotational speed of the disk, which gives rise to what is known as the average rotational latency (i.e. one half of the complete revolution time of the disk). Out of a number of accesses, the average length of time it is necessary to wait for the desired point to come below the head approaches this figure. The second component of access time is the head-positioning time. This is dependent upon the number of tracks to be traversed in moving from the current head position to the desired one. Again, an average figure emerges from a large number of accesses. The average access time is the sum of these two components. In planning the throughput possible with a given disk system the worst-case figures may also need to be considered.

4.12.4 Electronics

The drive must accept commands to seek (i.e. position the head assembly above a particular track) and must be able to recover signals from the read heads and convert these to binary digits in parallel form for transmission to the disk controller. Conversely, data transmitted in this way from the controller to the disk drive must be translated into appropriate analogue signals to be applied to the head for writing the desired data onto the disk.

4.12.5 Drive control

Various other functions concerned with control of the drive and sensing of switches on the control panel are performed. On some more advanced drives, much of the operation of the drive and electronics can be tested off-line from the system, allowing fault diagnosis to be performed without affecting the rest of the system.

Information is recorded in a number of concentric, closely spaced tracks on the disk surfaces, and in order to write and thereafter read successfully on the same or a different drive it must be possible to position the head to a high degree of accuracy and precision above any given track. Data are recorded and read serially on one surface at a time, hence transfer of data between the disk controller and disk surface involves conversion in both directions between serial analogue and parallel digital signals. A phase-locked loop clock system is normally used to ensure reliable reading by compensating for variations in the rotational speed of the disk.

Data are formatted in blocks or sections on all disk systems. generally in fixed block lengths pre-formatted on the disk medium at the time of manufacture. Alternatively, 'soft sectoring' allows formatting into blocks of differing length by program. The drive electronics are required to read sector headers, which contain control information to condition the read circuitry of the drive, and sector address information, and to calculate, write and check an error-correcting code – normally a cyclic redundancy check – for each block.

Finding the correct track in a seek operation, where the separation between adjacent tracks may be as little as 0.01 mm, requires servo-controlled positioning of the head to ensure accurate registration with the track. All rigid-disk systems have servo-controlled head positioning, either using a separate surface pre-written with position information and with a read head only or with servo information interspersed with data on the normal read/write tracks being sampled by the normal read/write head. Floppy disk systems, where the tolerances are not so fine, have a simpler stepping motor mechanism for head positioning.

4.12.6 Floppy disk

The floppy disk, while having the four elements described above, was conceived as a simple, low-cost device providing a moderate amount of random access back-up storage to microcomputers, word processors and small business and technical minicomputers. As the name implies, the magnetic medium used is a flexible, magnetic oxide-coated diskette, which is contained in a square envelope with apertures for the drive spindle to engage a hole in the centre of the disk and for the read/write head to make contact with the disk. Diskettes are of three standard diameters, approximately 203 mm (8-inch), 133 mm ($5\frac{1}{4}$-inch) and 89 mm ($3\frac{1}{2}$-inch). The compactness and flexibility of the disk makes it very simple to handle and store, and possible for it to be sent by post.

One major simplification in the design of the floppy disk system is the arrangement of the read/write head. This runs in contact with the disk surface during read/write operations and is retracted otherwise. This feature and the choice of disk coating and the pressure loading of the head are such that, at the rotational speed of 360 rev/min, the wear on the recording surface is minimal. Eventually, however, wear and therefore error rate are such that the diskette may have to be replaced, copying the information onto a new diskette.

Capacities vary from the 256 kilobytes of the earliest drives, which record on one surface of the diskette only, to a figure of over 2 megabytes on more recent units, most of which use both surfaces of the diskette. Access times, imposed by the rather slow head-positioning mechanism using a stepping motor, are in the range of 100–500 ms. Transfer rates are below 300 kilobytes per second.

Another simplification is in the area of operator controls. There are generally no switches or status indicators, the simple action of moving a flap on the front of the drive to load or removing the diskette being the only operator action. The disk motor spins all the time that a disk is present.

4.12.7 Cartridge disk

This type of disk system is so called because the medium – one or two rigid disks on a single spindle, of aluminium coated with magnetic oxide and approximately 350 mm in diameter – is housed permanently in a strong plastic casing or cartridge. When the complete cartridge assembly is loaded into the drive, a slot opens to allow the read/write heads access to the recording surfaces. As well as providing mechanical mounting, the cartridge provides protection for the disk medium when it is removed from the drive.

Drives are designed either for loading from the top when a lid is raised or from the front when a small door is opened allowing the cartridge to be slotted in. Power to the drive motor is removed during loading and unloading, and the door is locked until the motor has slowed down to a safe speed. On loading and starting up, the controller cannot access the drive until the motor has reached full speed. Operator controls are normally provided for unload, write protection and some form of unit select switch allowing drive numbers to be re-assigned on a multiple-drive system. Indicators typically show drive on-line, error and data transfer in progress.

Access times are normally in the region of 30–75 ms, aided by a fast servocontrolled head-positioning mechanism actuated by a coil or linear motor, the heads being moved in and out over the recording surface by an arm which operates radially. Heads are lightweight, sprint loaded to fly aerodynamically in the region of 0.001 mm from the surface of the disk when it is rotating at its full speed (usually 2400 or 2600 rev/min). Because of the extremely small gap, cleanliness of the oxide surface is vital, as any particle of debris or even smoke will break the thin air gap, causing the head to crash into the disk surface. In this rare event, permanent damage to the heads and disk cartridge occurs. Positive air pressure is maintained in the area around the cartridge, in order to minimize the ingress of dirt particles. Care should be taken to ensure cleanliness in the handling and storage of cartridges when not mounted in the drive.

The capacity of cartridges is in a range up to 100 megabytes, with data transfer rates in the region of 1 megabyte per second. Up to 16 drives can be accommodated per controller, and, because of the data transfer rate, direct memory access is necessary for transfer of data to or from the CPU. Progress made with other disk forms have almost eliminated the use of cartridge disks.

4.12.8 Disk pack

The medium used in this type of drive has multiple platters (five or more) on a single spindle, and is protected when removed from the drive by a plastic casing. When loaded on the drive, however, the casing is withdrawn. The drives are top loading, and, unlike cartridge disks which can generally be rack mounted in the cabinet housing the CPU, are free-standing units.

Other than this difference, most of the design features of disk pack drives follow those of cartridge units. The significant difference is the larger capabilities (up to 1000 megabytes) and generally high performance in terms of access times (25–50 ms) and transfer rates (in the region of 2.5 megabytes per second).

4.12.9 Winchester drive

So-called from a name local to the laboratory in the USA where it was developed, this is a generic name applied to a category of drive where the disk medium itself remains fixed in the drive. The principal feature of the drive – the fixed unit – is known as a head disk assembly (HDA). By being fixed and totally sealed, with the read/write heads and arm assembly within the enclosure, the following benefits are realized:

1. Contaminant-free environment for the medium allows better data integrity and reliability, at the same time

having less stringent environmental requirements. Simpler maintenance requirements follow from this.
2. Lighter-weight heads, flying to tighter tolerances closer to the recording surface, allow higher recording densities. Since the disk itself is never removed, instead of retracting, the heads actually rest on special zones of the disk surface when power is removed.
3. The arrangement of read/write heads is two per surface, providing lower average seek times by requiring less head movement to span the whole recording area.

The head-positioning arrangement differs mechanically from that of the drives previously described by being pivoted about an axis outside the disk circumference.

Three general types of Winchester drive exist, with approximate disk diameters of 133, 203 and 355 mm, providing capacities from 25 megabytes to over 1000 megabytes. Performance, for the reason described above, can exceed that for disk cartridge or pack drives of corresponding capacity.

The smallest versions of Winchester drive are becoming popular as the storage medium for microcomputers and smaller configurations of minicomputer, offering compact size with very competitive prices and fitting above the top end of the floppy disk range. Operationally, the fact that the disks are not removable from the drive means that a separate form of storage medium which is removable must be present on a system using a Winchester drive. Back-up and making portable copies is done using this separate medium, which is usually another type of disk drive, or a magnetic tape system matched to the disk speed and capacity.

4.12.10 Magnetic tape

Reliable devices for outputting digital data to and reading from magnetic tape have been available for a considerable time. The use of this medium, with agreed standards for the format of recorded data, has become an industry standard for the interchange of data between systems from different manufacturers. In addition, low-cost magnetic tape cartridge systems exist providing useful minimal-cost large-scale back-up storage plus a convenient medium for small-volume removable data and the distribution of software releases and updates.

4.12.11 Industry-standard tape drives

These allow reels of 12.7 mm wide oxide-coated magnetic tape, which are normally 731 m in length on a 267 mm diameter reel (or 365 m on a 178 m reel) to be driven past write and read head assemblies for writing, and subsequent reading, at linear densities from 800 to 6250 bits per inch. Tapes are written with variable-length blocks or records with inter-record gaps in the region of 12.7 mm. Each block has lateral and longitudinal parity information inserted and checked, and a cyclic redundancy code is written and checked for each block. The latter provides a high degree of error-correction capability. The tape motion and stop-start characteristics are held within precise limits by a servocontrolled capstan around which the tape wraps more than 180° for sufficient grip.

Correct tape tension and low inertia is maintained by motors driving the hubs of the two tape reels in response to information on the amount of tape in the path between the two reels at any time. One of the following forms of mechanical buffering for the tape between the capstan and reels is used:

1. *Tension arm.* This uses a spring-loaded arm with pulleys over which the tape passes, alternating with fixed pulleys such that, when loaded, the tape follows a W-shaped path. The position of the arm is sensed and the information used to control the release and take-up of tape by the reel motors. This technique has almost univerally been overtaken by the vacuum method described below.
2. *Vacuum chamber.* This technique, used on modern higher-performance tape drives, has between each reel and the capstan a chamber of the same width as the tape, into which a U-shaped loop of tape of around 1 to 2 m is drawn by vacuum in the chamber. The size of the tape loops is sensed photo-electrically to control the reel motors.

To prevent the tape from being pulled clear of the reel when it has been read or written to the end or rewound to the beginning, reflective tape markers are applied near each end of the reel. These are sensed photo-electrically, and the resulting signal used to stop the tape on rewind, or to indicate that forward motion should stop on reading or writing.

Three different forms of encoding the data on the tape are encountered, dependent upon which of the standard tape speeds is being used. Up to 800 bits per inch, the technique is called 'non-return to zero' (NRZ), while at 1600 bits per inch 'phase encoding' (PE) and at 6250 bits per inch 'group code recording' (GCR) are used. Some drivers can be switched between 800 bits per inch NRZ and 1600 bits per inch PE. Very few systems below 1600 bits per inch are now manufactured.

Block format on the tape is variable under program control between certain defined limits, and as part of the standard, tape marks and labels are recorded on the tape and the inter-block gap is precisely defined. Spacing between write and read heads allows a read-after-write check to be done dynamically to verify written data. Writing and reading can only be carried out sequentially. These tape units do not perform random access to blocks of data, though those units that permit selective reverse under program control do make it possible for the application to access data other than by sequential read of the tape. However, this requires prior knowledge by the application of the layout and contents of the tape and is particularly slow and cumbersome, such applications being far better serviced by a disk-storage device.

Up to eight tape drives can be handled by a single controller. For PE and GCR, a formatter is required between controller and drive to convert between normal data representation and that required for these forms of encoding.

Tape drives can vary in physical form from a rack-mountable unit that is positioned horizontally to a floor-standing unit around 1.75 m in height.

Operator controls for on-line/off-line, manually controlled forward/reverse and rewind motion, unit select and load are normally provided. To prevent accidental erasure of a tape containing vital data by accidental write commands in a program, a write protect ring must be present on a reel when it is to be written to. Its presence or absence is detected by the drive electronics. This is a further part of the standard for interchange of data on magnetic tapes.

4.12.12 Cartridge tape

Low-cost tape units storing many megabytes of data on a tape cartridge are sometimes used for back-up storage.

4.12.13 Tape streamer unit

The emergence of large-capacity, non-removable disk storage in the form of Winchester technology drives has posed the problem of how to make up copies of complete disk contents for security or distribution to another similarly equipped system. An alternative to tape cartridges is a tape drive very similar to the industry-standard units described in Section 4.12.11 but with the simplification of writing in a continuous stream, rather than in blocks. The tape controller and tape motion controls can, therefore, be simpler than those for the industry-standard drive. Many modern tape units are able to operate in both 'block' and 'streamer' mode, according to operater or program selection, but not on the same tape. A streamer unit associated with a small Winchester drive can accept the full disk contents on a single reel of tape.

4.13 Digital and analogue input/output

One of the major application areas for minicomputers and microcomputers is direct control of and collection of data from other systems by means of interfaces which provide electrical connections directly or via transducers to such systems. Both continuously varying voltages (analogue signals) and signals which have discretion or off states (digital signals) can be sensed by suitable interfaces and converted into binary form, for analysis by programs in the CPU. For control purposes, binary values can also be converted to analogue or digital form by interfaces for output from the computer system.

In process and/or machine control and monitoring, data acquisition from laboratory instruments, radar and communications (to take some common examples) employ computer systems equipped with a range of suitable interfaces. They may be measuring other physical quantities such as temperature, pressure and flow converted by transducers into electrical signals.

4.13.1 Digital input/output

Relatively simple interfaces are required to convert the ones and zeros in a word output from the CPU into corresponding on or off states of output drivers. These output signals are brought out from the computer on appropriate connectors and cables. The output levels available range from TTL (±5 V) for connection to nearby equipment which can receive logic levels, to over 100 V d.c. or a.c. levels for industrial environments. In the former case, signals may come straight from a printed circuit board inside the computer enclosure, while in the latter, they require to go through power drivers and be brought out to terminal strips capable of taking plant wiring. The latter type of equipment may need to be housed in separate cabinets.

Similarly, for input of information to the computer system, interfaces are available to convert a range of signal levels to logic levels within the interface, which are held in a register and can be input by the CPU. In some cases, input and output are performed on the same interface module.

Most mini and micro systems offer a range of logic level input/output interfaces, while the industrial type of input and output equipment is supplied by manufacturers specializing in process control. Optical isolators are sometimes included in each signal line to electrically isolate the computer from other systems. Protection of input interfaces by diode networks or fusible links is sometimes provided to prevent damage by overvoltages. In industrial control, where thousands of digital points need to be scanned or controlled, interfaces with many separately addressable input and output words are used.

Although most digital input and output rates of change are fairly slow (less than 1000 words per second), high-speed interfaces at logic levels using direct memory access are available. These can, in some cases, transfer in burst mode at speeds up to 3 million words per second. High transfer rates are required in areas such as radar data handling and display driving.

4.13.2 Analogue input

Analogoue-to-digital converters, in many cases with programmable multiplexers for high- or low-level signals and programmable gain preamplifiers covering a wide range of signals (from microvolts to 10 V), allow conversion commands to be issued and the digital results to be transferred to the CPU by the interface. Industrial-grade analogue input subsystems typically have a capacity of hundreds of multiplexer channels, low-level capability for sources such as thermocouples and strain gauges, and high common-mode signal rejection and protection. As with digital input/output, this type of equipment is usually housed in separate cabinets with terminal strips, and is supplied by specialized process control equipment or data logger manufacturers

For laboratory use, converters normally have higher throughput speed, lower multiplexer capacity and often direct cable connection of the analogue signals to a converter board housed within the CPU enclosure. Where converters with very high sampling rates (in the region of 100 000 samples per second) are used, input of data to the CPU may be by direct memory access. Resolution of analogue-to-digital converters used with computer systems is usually in the range 10–12 bits, i.e. a resolution of 1 part in 1024 to 1 part in 4096. Resolutions of anything from 8 to 32 bits are, however, available. Where a programmable or auto-ranging preamplifer is used before the analogue-to-digital converter, dynamic signal ranges of 1 million:1 can be handled.

4.13.3 Analogue output

Where variable output voltages are required (for example, to drive display or plotting devices or as set points to analogue controllers in industrial process control applications), one or more addressable output words is provided, each with a digital-to-analogue converter continuously outputting the voltage represented by the contents of its register. Resolution is normally no more than 12 bits, with a usual signal range of ±1 V or ±10 V. Current outputs are also available.

4.13.4 Input/output subsystems

Some manufacturers provide a complete subsystem with its own data highway separate from the computer system input/output bus, with a number of module positions into which a range of compatible analogue and digital input/output modules can be plugged. Any module type can be plugged into any position to make up the required number of analogue and digital points.

4.14 Data communications

4.14.1 Introduction

Since 1980 there has been a large growth in the use of data communications between different types and makes of equipment both within a physical location or building and between different buildings situated anywhere in the world. Even when this communication appears to take place between two points on earth it has very often done so by means of a geo-stationary satellite positioned in orbit. The creation and maintenance of such 'networks' is now nearly always the role of network managers and their staff, a function that is separate from (though working closely with) the traditional computer departments.

The requirement for the communication of data is not, of course, new, but what has changed is the basis for that requirement. Previously, the only other means available for the transfer of data between machines was a copy by magnetic media (such as tape or disk) or to key in the data again, with the consequent high risk of error and increased time taken. It was seen that data transmission would be faster and more accurate than both of these methods. Interestingly, data communication was not regarded as a replacement for the data in hardcopy form. Today, more emphasis is being placed on eliminating hardcopy transactions, such as the growing use of EDI (Electronic Data Interchange) to replace paper as the medium for moving order information between companies.

Large-scale integration and consequent lower costs have made very powerful computers much more readily available, which can contain the sophisticated software required to handle complex networks and overcome complex problems such as finding alternative routes for messages when a transmission line is broken. With the computer 'space' thus available, programmers can produce complex programs required to transmit data from a terminal connected to one computer to a program running in another, without the operator being aware of the fact that two or more computers are involved. Interface devices between the computer and the data network are very intelligent and powerful, and are usually minicomputers themselves. Thus they relieve the main computer of much of the previous load that it historically handled for data communications.

Computers have always been able to communicate with their peripheral devices such as card readers, mass-storage devices and printers, but in the 1960s it was not typical for the communications to extend beyond this. Data were transcribed onto 'punching documents' by functional departments within an organization. Now, the widespread use of interactive VDUs by users at their desks has eliminated almost all these departments. Even the very large traditional data-entry organizations such as the utility companies are now introducing data capture at source using hand-held terminals or OCR techniques.

However, in the late 1960s and 1970s the development of both hardware and software technology made it increasingly attractive to replace these terminals with more intelligent remote systems. These systems varied in their sophistication. At one end of the spectrum were interactive screen-based terminals that could interrogate files held on the central computer. Greater sophistication was found in data-validation systems which held sufficient data locally to check that, for example, part numbers on a customer order really existed, before sending the order to the computer for processing. More sophisticated still were complete minicomputers carrying out a considerable amount of local data processing before updating central files to be used in large 'number-crunching' applications such as production scheduling and materials planning.

From these systems have grown a whole range of requirements for data communications. We have communications between mainframe computers, between minis, between computers and terminals, between terminals and terminals and so on.

4.14.2 Data communications concepts

Computers communicate data in binary format, the bits being represented by changes in current or voltage on a wire, or, more recently, by patterns of light through an optic-fibre cable. There are various ways that characters are represented in binary format. One of the earliest of these was the 5-bit Baudot code, invented towards the end of the nineteenth century by Emile Baudot for use on telegraphic circuits. Five bits can be used to represent 32 different characters, and, while this was adequate for its purpose, it cannot represent enough characters for modern data communications. Nonetheless, Baudot gave his name to 'baud', the commonly used unit of speed, which although strictly meaning signal events per second, is frequently used to denote 'bits per second'.

Nowadays, one of the most commonly used codes is the ASCII (American Standard Code for Information Interchange) code (Figure 4.8). This consists of seven information bits plus one parity (error checking) bit. Another is EBCDIC (Extended Binary Coded Decimal Interchange Code), an 8-bit character code used primarily on IBM equipment (Figure 4.9).

Within the computer and between the computer and its peripheral devices such as mass-storage devices and line printer, data are usually transferred in parallel format (Figure 4.10). In parallel transmission a separate wire is used to carry each bit, with an extra wire carrying a clock signal. This clock signal indicates to the receiving device that a character is present on the information wires. The advantage of parallel transmission is, of course, speed, since an entire character can be transmitted in the time it takes to send one bit. However, the cost would prove prohibitive where the transmitter and receiver are at some distance apart. Consequently, for sending data between computers and terminal devices and between computers which are not closely coupled, serial transmission is used.

Here a pair of wires is used, with data being transmitted on one wire while the second acts as a common signal ground. As the term implies, bits are transmitted serially, and so this form of transmission is more practical for long-distance communication because of the lower cost of the wiring required. In addition, it is simpler and less expensive to amplify signals rather than use multiple signals in order to overcome the problem of line noise, which increases as the distance between the transmitter and receiver grows. Data transmission frequently makes use of telephone lines designed for voice communication, and since the public voice networks do not consists of parallel channels, serial transmission is the only practical solution.

Parallel data on multiple wires are converted to serial data by means of a device known as an interface. In its simplest form, an interface contains a register or buffer capable of storing the number of bits which comprise one character. In the case of data going from serial to parallel format, the first bit enters the first position in the register and is 'shifted' along, thereby making room for the second bit (Figure 4.11). The process continues until the sampling block which is strobing the state of the line indicates that the correct number of bits has been received and that a character has been assembled. The clock then generates a signal to the computer which transfers the character in parallel format. The reverse process is carried out to convert parallel to serial data.

This 'single-buffered' interface does have limitations, however. The computer effectively has to read the character immediately, since the bit of a second character will be arriving to begin its occupation of the register. This makes no allowance for the fact that the computer may not be available instantly. Nor does it allow any time to check for any errors in the character received.

To overcome this problem, a second register is added creating a 'double-buffered' interface (Figure 4.12). Once the signal is received indicating that the requisite number of bits have been assembled, the character is parallel transferred to the second (or holding) register, and the process can continue.

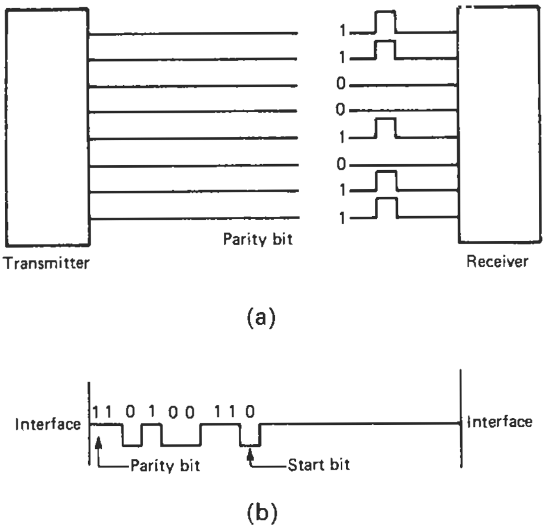

Figure 4.10 Data transmission; (a) parallel, (b) serial

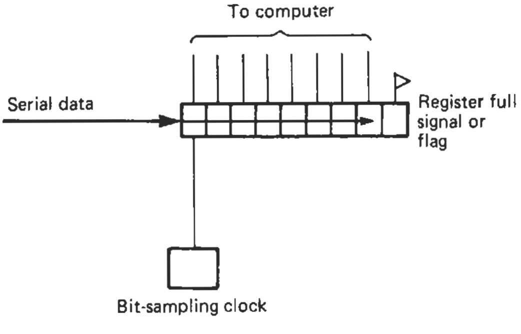

Figure 4.11 Serial-to-parallel interface

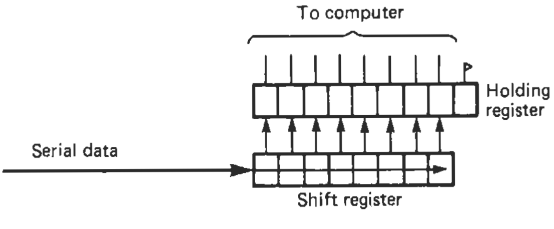

Figure 4.12 Double-buffered interface

The computer now has as much time as it takes to fill the shift register in order to check and transfer (again in parallel format) the character.

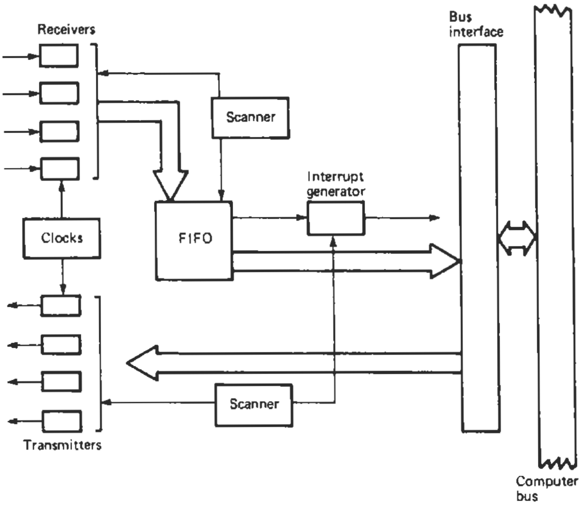

Figure 4.13 Schematic diagram of a multi-line interface

4.14.3 Multi-line interface

With the development of technology, the transmitter and receiver functions are now carried out by an inexpensive chip. Therefore the major costs in the interface are those of the mechanism used to interrupt the CPU when a character has been assembled and the connection to the computer's bus used to transmit the received data to the CPU, or, in some cases, direct to memory. The interrupt mechanism and the bus interface are not heavily used. Indeed, they function only when a character is received or transmitted. These facilities are shared in a multi-line interface, sometimes (though not strictly correctly) known as a 'multiplexor' (Figure 4.13). To achieve this the device has several receivers and transmitters and a first-in, first-out (FIFO) buffer for received characters. The receivers are scanned and when a flag is found indicating that a character has been received the character is transmitted into the FIFO buffer, along with its line number. An interrupt tells the CPU that there are characters in the buffer and they are communicated over the bus to the computer. Similarly, a scanner checks the transmitters and when it discovers a flag indicating that a transmitter buffer is empty, it interrupts the CPU. Typically, the number of lines supported by a multi-line interface increases by powers of two for convenient binary representation, 4, 8, 16, 32, 128, 256 being common. The economies of scale in such an interface mean that further sophistications can be included such as program-selectable formats and line speed, and modem control for some or all of the lines.

However, the term 'multiplexing', strictly, actually refers to the function of sharing a single communications channel across many users. There are two commonly used methods of achieving this. One is a technique called time-division multiplexing (TDM), which consists of breaking down the data from each user into separate messages which could be as small as one or two bytes and meaningless when taken individually. The messages, together with identifying characters, are interleaved and transmitted along a single line. They are separated at the other end and the messages reassembled. This is achieved by use of devices known as concentrators or multiplexors. The second technique used to achieve this objective of making maximum use of a communication line is frequency division multiplexing. The concept is similar to that of time-division multiplexing. It is achieved by transmitting complete messages simultaneously but at different frequencies.

4.14.4 Modem

A significant complication of using public voice networks to transmit data is that voice transmission is analogue whereas

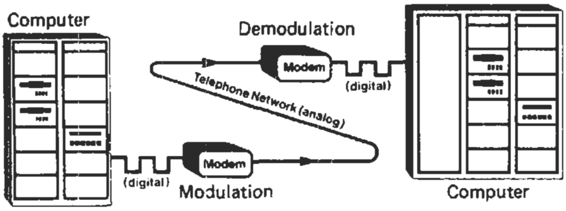

Figure 4.14 The use of modems in a communications link

data generated by the computer or terminal are digital in format. Thus an additional piece of equipment is required between the digital sender/receiver and the analogue circuit. This device modulates and demodulates the signal as it enters and leaves the analogue circuit, and is known by the abbreviated description of its functions, as a modem (Figure 4.14). Modems are provided by the common carrier such as British Telecom or by private manufacturers. In the latter case, however, they must be approved by the carrier and must contain or be attached to a device which provides electrical isolation.

4.14.5 Fibre-optic cable

Cabling for transmissions has traditionally been constructed of a copper-based core, this being a viable compromise between cost and conductivity for anything other than the very shortest communication paths. It is difficult to imagine a gold cable being laid from London to Birmingham and remaining in place for very long! However, copper has its own limitations, such as weight, resistance, noise, etc. The development of fibre-optic cable to the stage where a set light pattern can be sustained over long distances without distortion and then be sensed and interpreted at the other end is signalling the beginning of the end of copper as a standard communication medium. The main advantages of fibre-optic are:

1. Very lightweight;
2. Greater communication capacity (number and speed of channels) for the same size;
3. Digital transmission;
4. Immunity from most causes of interference and noise associated with copper;
5. Cost decreasing as volumes increase.

4.14.6 Laser

This works on exactly the same principle as fibre-optic except that the light signal is passed between two laser/receivers on a point-to-point 'line-of-sight' basis. It is ideal, therefore, in situations where communications are required between two different buildings but neither party owns or controls the land between them. The only other method would be to use a common carrier, resulting in a higher cost and probably lower speed and quality of communication.

4.14.7 Microwave

Where an organization requires extremely large volumes of data to be transmitted, or a very high speed to be achieved, then it is sometimes viable for it to set up its own microwave network. It should be stressed that this is an extremely costly operation and specialist advice should be sought prior to embarking upon it.

4.14.8 Transmission techniques

There are two techniques commonly used to transmit data on serial lines. One varies the current and the other varies the voltage in order to indicate the presence or absence of bits on the line.

4.14.8.1 Current variable

The 'current-based' technique communicates binary data by turning on and off a 20 mA current flowing through both the transmitter and receiver. Current on indicates a 'mark' or '1' bit and current off signifies a 'space' or '0' bit. This technique of turning a current on and off is less suceptible to noise than the technique of varying the voltage. However, it does have some drawbacks. Optical isolators are needed to protect logic circuits from the high voltages which may be required to drive the loop. Since there is one current source, an active interface and a passive interface are required, and finally, since a 20 mA system cannot carry the necessary control information, it cannot be used with modems.

4.14.8.2 Voltage variable

The EIA (Electronic Industries Association) and CCITT (Comité Consultatif Internationale de Telegraphie et Telephone) systems contain specifications and recommendations for the design of equipment to interface data terminal equipment (computers and terminals) to data communication equipment (modems). The specific EIA standard to which most modem equipment is designed is RS232C. The CCITT, being formed by the United Nations to consider all aspects of telecommunications across several national boundaries, was unable to publish firm standards, and instead produced a list of recommendations. Its equivalent of RS232C is known as 'V.24 – List of Definitions of Interchange Circuits Terminating Equipment'. The EIA/CCITT systems communicate data by reversing the polarity of the voltage; a '0' is represented by a positive voltage and a '1' by a negative voltage.

The signals in the EIA/CCITT specifications are not recommended for use over distances greater than 50 feet (15.5 m). Consequently, the modem and interface should not be more than 50 feet apart, though in practice distances in excess of 1000 feet (300 m) have been operated without problems.

4.14.9 Transmission types

Different communications applications use one of two types of transmission: asynchronous or synchronous. Slower devices such as VDUs and low-speed printers typically use asynchronous (or 'start–stop') transmission in which each character is transmitted separately. In order to tell the receiver that a character is about to arrive, the bits representing the character are preceded by a start bit, usually a zero. After the last data bit and error checking bit the line will return to the 1-bit state for at least one bit time – this is known as the stop bit.

Asynchronous transmission has the advantage that it requires relatively simple and therefore low-cost devices. It is, however, inefficient, since at least two extra bits are required to send eight data bits, and so would not be used for high-speed communication.

In synchronous transmission, characters are assembled into blocks by the transmitter and so the stream of data bits travels along the line uninterrupted by start and stop bits. This means that the receiver must know the number of bits which make up a character so that it can re-assemble the original characters from the stream of bits. Preceding the block of data bits, synchronization characters are sent to provide a timing signal for the receiver and enable it to count in the data characters. If the blocks of data are of uniform length, then this is all that is required to send a message. However, most systems would include some header information which may be used to indicate the program or task for which the data are destined and the amount of data in the block. In addition, if the messages are of variable length, some end-of-message characters will be required.

Because it does not contain start and stop bits for every character, synchronous transmission is more efficient than asynchronous. However, it can be inappropriate for some character-oriented applications since there is a minimum 'overhead' in characters which can be high relative to small transmitted block sizes, and the equipment required to implement it is more expensive.

4.14.10 Direction of transmission

There are three types of circuit available for the communication of data and, correspondingly, three direction combinations: simplex, half-duplex and full duplex. However, it is possible to use a channel to less than its full potential.

Simplex communication is the transmission of data in one direction only, with no capability of reversing that direction. This has limitations and is not used in the majority of data-communications applications. It can be employed, however, for applications that involve the broadcasting of data for information purposes in, for example, a factory. In this instance, there is neither a need nor a mechanism for sending data back to the host. The simplex mode of operation could not be used for communication between computers.

Half-duplex, requiring a single, two-wire circuit, permits the user to transmit in both directions, but not simultaneously. Two-wire half-duplex has a built-in delay factor called 'turnaround time'. This is the time taken to reverse the direction of transmission from sender to receiver and vice versa. The time is required by line-propagation effects, modem timing and computer-response time. It can be avoided by the use of a four-wire circuit normally used for full duplex. The reason for using four wires for half-duplex rather than full duplex may be the existence of limitations in the terminating equipment.

Full-duplex operation allows communication in both directions simultaneously. The data may or may not be related, depending on the applications being run in the computer or computers. The decision to use four-wire full-duplex facilities is usually based on the demands of the application compared to the increased cost for the circuit and the more sophisticated equipment required.

4.14.11 Error detection and correction

Noise on most communications lines will inevitably introduce errors into messages being transmitted. The error rates will vary according to the kind of transmission lines being used. In-house lines are potentially the most noise-free since routing and shielding are within user control. Public switched networks, on the other hand, are likely to be the worst as a result of noisy switching system and dialling mechanisms, though this problem is being addressed by many common carriers by the introduction of digital switching exchanges that themselves use computers to perform switching and routing instead of electromechanical switching devices.

Whatever the environment, however, there will be a need for error detection and correction. Three systems are commonly used: VRC, LRC and CRC.

VRC, or vertical redundancy check, consists of adding a parity bit to each character. The system will be designed to use either even or odd parity. If the parity is even, the parity bit is set so that the total number of ones in the character plus parity is even. Obviously, for odd parity the total number will be odd. This system will detect single bit errors in a character. However, if two bits are incorrect the parity will appear correct. VRC is therefore a simple system designed to detect single bit errors within a character. It will detect approximately nine out of ten errors.

A more sophisticated error-detection system is LRC (longitudinal redundancy check), in which an extra byte is carried at the end of a block of characters to form a parity character. Unlike VRC, the bits in this character are not sampling an entire character but individual bits from each character in the block. Thus the first bit in the parity character samples the first bit of each data character in the block. As a result, LRC is better than VRC at detecting burst errors, which affect several neighbouring characters.

It is possible to combine VRC and LRC and increase the combined error detection rate to 99% (Figure 4.15). A bit error can be detected and corrected, because the exact location of the error will be pinpointed in one direction by LRC and the other by VRC.

Even though the combination of LRC and VRC significantly increases the error-detection rate, the burst nature of line noise means that there are still possible error configurations which could go undetected. In addition, the transmission overhead is relatively high. For VRC alone, in the ASCII code, it is 1 bit in 8, or 12.5%. If VRC and LRC are used in conjunction it will be 12.5% plus one character per block.

A third method which has the advantage of a higher detection rate and, in most circumstances, a lower transmission overhead is CRC (cyclic redundancy check). In this technique the bitstream representing a block of characters is divided by a binary number. In the versions most commonly used for 8-bit character format, CRC-16 and CRC-CCITT, a 16-bit remainder is generated. When this calculation has been completed, the transmitter sends these 16 bits – two characters – at the end of the block. The receiver repeats the calculation and compares the two rremainders. With this system, the error detection rises to better than 99.9%. The transmission overhead is less than that required for VRC/LRC when there are more than 8 characters per block, as is usually the case.

The disadvantage with CRC is that the calculation overhead required is clearly greater than for the other two systems. The

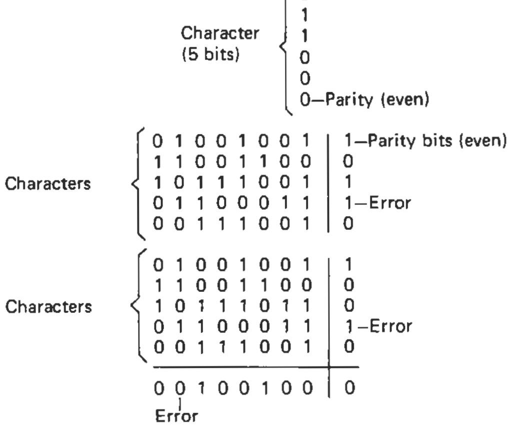

Figure 4.15 VRC, LRC and VRC/LRC combined (with acknowledgements to Digital Equipment Co. Ltd)

check can be performed by hardware or software but, as is usually the case, the higher performance and lower cost of hardware is making CRC more readily available and commonly used.

Once bad data have been detected, most computer applications require that they be corrected and that this occurs automatically. While it is possible to send sufficient redundant data with a message to enable the receiver to correct errors without reference to the transmitter, the effort of the calculation required to achieve this in the worst possible error conditions means that this technique is rarely used. More commonly, computer systems use error-correction methods which involve retransmission. The two most popular of these are 'stop and wait retransmission' and 'continuous retransmission'.

'Stop and wait' is reasonably self-explanatory. The transmitter sends a block and waits for a satisfactory or positive acknowledgement before sending the next block. If the acknowledgement is negative, the block is retransmitted. This technique is simple and effective. However, as the use of satellite links increases, it suffers from the disadvantage that these links have significantly longer propagation times than land-based circuits and so the long acknowledgement times are reducing the efficiency of the network. In these circumstances, 'continuous retransmission' offers greater throughput efficiency. The difference is that the transmitter does not wait for an acknowledgement before sending the next block, it sends continuously. If it receives a negative acknowledgement it searches back through the blocks transmitted and sends it again. This clearly requires a buffer to store the blocks after they have been sent. On receipt of a positive acknowledgement the transmitter deletes the blocks in the buffer up to that point.

4.14.12 Communications protocols

The communications protocol is the syntax of data communications. Without such a set of rules a stream of bits on a line would be impossible to interpret. Consequently, many organizations – notably computer manufacturers – have created protocols of their own. Unfortunately, however, they are all different, and consequently, yet another layer of communications software is required to connect computer networks using different protocols. Examples of well-known protocols are Bisync and SDLC from IBM, DDCMP from Digital Equipment Corporation, ADCCP from the American National Standards Institute (ANSI) and HDLC from the International Standards Organization (ISO). The differences between them, however, are not in the functions they set out to perform but in the way they achieve them. Broadly, these functions are as follows.

4.14.12.1 Framing and formatting

These define where characters begin and end within a series of bits, which characters constitute a message and what the various parts of a message signify. Basically, a transmission block will need control data, usually contained in a 'header' field, text – the information to be transmitted – held in the 'body', and error-checking characters, to be found in the 'trailer'. The actual format of the characters is defined by the information code used such as ASCII or EBCDIC.

4.14.12.2 Synchronization

This involves preceding a message or block with a unique group of characters which the receiver recognizes as a synchronisation sequence. This enables the receiver to frame subsequent characters and field.

4.14.12.3 Sequencing

This numbers messages so that it is possible to identify lost messages, avoid duplicates and request and identify retransmitted messages.

4.14.12.4 Transparency

Ideally, all the special control sequences should be unique and, therefore, never occur in the text. However, the widely varied nature of the information to be transmitted, from computer programs to data from instruments and industrial processes, means that occasionally a bit pattern will occur in the text which could be read by the receiver as a control sequence. Each protocol has its own mechanism for preventing this, or achieving 'transparency' of the text. Bisync employs a technique known as 'character stuffing'. In Bisync the only control character which could be confusing to the receiver if it appeared in the text is DLE (data link escape). When the bit pattern equivalent to DLE appears within the data a 'second' DLE is inserted. When the two DLE sequences are read, the DLE proper is discarded and the original DLE-like bit pattern is treated as data. This is 'character stuffing'. SDLC, ADCCP and HDLC use a technique known as 'bit stuffing' and DDCMP employs a bit count to tell the receiver where data begin and end.

4.14.12.5 Start-up and time-out

These are the procedures required to start transmission when no data have been flowing and recovering when transmission ceases.

4.14.12.6 Line control

This is the determination, in the case of half-duplex systems, of which terminal device is going to transmit and which to receive.

4.14.12.7 Error checking and correction

As described in Section 4.14.11, each block of data is verified as it is received. In addition, the sequence in which the blocks are received is checked. For data accuracy all the protocols discussed in this section are capable of supporting CRC (cyclic redundancy check). The check characters are carried on the trailer or block check character (BCC) section.

4.14.12.8 RS232C

This is a standard issued by the United States Electronic Industries Association (EIA) to define the interface between Data Circuit-terminating Equipment (DCE) and Data Terminal Equipment (DTE). In plain language these are usually referred to as the 'modem' and 'terminal' respectively. The 'C' at the end of the standard designation indicates the latest revision of this standard that is applicable. This standard is in widespread use in the United States and formed the basis for the European CCITT standard V.24, which defines the interchange circuits and their functionality. Thus V.24 can be considered a subset of the full RS232C standard. In Europe the other components of RS232C are covered by other standards, CCITT V.28 for the electrical characteristics and ISO 2110 for the pin connector allocations. The terms RS232C and V.24 are often interchanged, and for practical purposes an

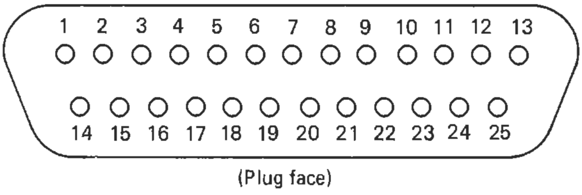

Figure 4.16 D-type connector pin assignments

interface that is said to be 'V.24-compliant' means that it also complies with RS232C.

The full interface specification deals with more than 40 interchange circuits, though, in practice, this number is almost never used. The most common form of connection is the 'D type' connector, so called because of the shape of the male and female plugs used to terminate the cable. A schematic of this connector is shown in Figure 4.16. These interchange circuits are collated into two distinct groups. The '100' series are used for data, timing and control circuits, whereas the '200' circuits are used for automatic telephone calling.

The principle of operation is simple in that both the modem and the terminal are able to indicate their readiness or not to accept/transmit data by adjusting the voltage on a predetermined circuit. A positive voltage represents a binary 0 or logical 'OFF' condition and a negative voltage a binary 1 or logical 'ON' condition. This change in voltage level can then be detected by the other end of the interface. Some circuits are kept constantly in a defined state (usually ±12 V) at all times during transmission to indicate that a piece of equipment continues to be available. Once readiness to transmit data has been achieved, then other circuits are used to pass data to/from each end of the interface. This is carried out by raising or lowering voltage levels on the send or receive circuits phased according to a clock source, which may be external to the modem or internal to it. Both instances use different circuits for the timing signals, and they may not be used together.

The physical arrangement of the connectors can vary, but the female connector (socket) is usually found on the modem, whereas the male connector (plug) is on the terminal. The connector design itself does *not* form part of the standards but the 'D type' is in such widespread use throughout the world that it has, in practice, become a standard in its own right. The pin connections are defined in ISO 2110 and are shown in Table 4.1. Note that some pin allocations are left to the discretion of national bodies and thus complete compatibility is never certain, though this is not generally a problem in practice.

There are many instances in computing where it is desirable to connect terminals directly to computer or other equipment without physically routing through a modem device. This can be achieved through the use of a special 'switch-over' device or, more simply, by crossing over some of the connections at either end. This cross-over pattern is shown in Figure 4.17. Earlier, such devices were often referred to as 'null modems' and cables wired in this way are still called 'null modem cables'.

Table 4.1 RS232C/V. 24 pin/circuit assignments

V.24 (RS232) Circuit	*Name*	*Pin Number*
101 (AA)	Cable screen	1
102 (AB)	Signal ground or common return	7
103 (BA)	Transmitted data	2
104 (BB)	Received data	3
105 (CA)	Request to send	4
106 (CB)	Ready for sending (Clear to send)	5
107 (CC)	Data set ready	6
108 (CD)	Connect data set to line/Data terminal ready	20
109 (CF)	Data channel received line signal detector	8
110 (CG)	Data signal quality detector	–
111 (CH)	Data signalling rate selector (DTE source)	23
113 (DA)	Transmitter signal element timing (DTE source)	24
114 (DB)	Transmitter signal element timing (DCE source)	25
115 (DD)	Receiver signal element timing (DCE source)	17
116	Select standby	(24)
118 (SBA)	Transmitted backward channel data	14
119 (SBB)	Received backward channel data	16
120 (SCA)	Transmit backward channel line signal	19
121 (SCB)	Backward channel ready	13
122 (SCF)	Backward channel received line signal detector	12
125 (CE)	Calling indicator	22
126	Select transmit frequency	11
140	Remote loopback for point-to-point circuits	21
141	Local loopback	18
142	Test indicator	25

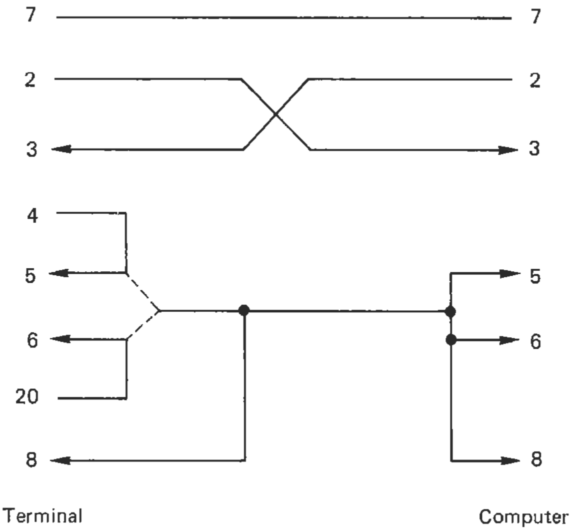

Figure 4.17 Null modem cable connections

4.14.12.9 *FDDI*

In the mid 1980s it became apparent that the existing high-speed network technology such as Ethernet (see later) would, in the future, become the limiting factor in the transmission of data. Contrast this with the advance that Ethernet gave initially over the then-existing hardware and computer technology, which was the limiting factor. It was anticipated that in the 1990s the network would reverse roles and start to limit transmission capabilities. At the time of writing there is already evidence of Ethernet LANs being overloaded from the volume of data now moved between computers and other networks.

In order to overcome these limitations a new network standard was developed, based upon fibre-optic cables, called the Fibre Distributed Data Interface (FDDI). Most of the components of this standard are agreed under ANSI Standard X3T9.5. Much of the basics of FDDI were originally based upon the IEE 802.5 standard for Token Ring networks.

The network design and functionality has proved to be ideal for real-time process control and voice due to the small minimum packet size of 9 bytes, but also efficient for large file/data transfers such as bit-imaged graphics due to the maximum packet size of 4500 bytes.

Gateways can be provided to/from FDDI to PBX, ISDN, ETHERNET, Token Ring and other communication protocols. It is also particularly good for military applications such as ships because of its high fault tolerance rate, lack of electrical radiation for eavesdropping and absence of fire risk on breaking the circuit.

Within the Open Systems Interconnect FDDI equates to the first two layers (Physical and Data Link) of the OSI communications model. In terms of functionality this network standard has been designed for connecting CPUs, high-speed storage devices, workstations, file servers, data terminals, multi-speed circuits and other external services such as the Public Switched Telephone Network (PSTN).

One of the main aims of the network design is to provide rapid and automatic recovery from failure of one or even multiple points in the network. Up to 500 connections (referred to as 'stations') can be on a single LAN, with a maximum cable length of up to 100 km. Stations can be located up to 2 km apart with optical links connecting them.

The network topology is based upon a ring structure with dual circuits, transmitting data at the rate of 100 Mbs. Stars (or spurs) are permitted to hang off the ring, but stations on such spurs do not benefit from the fail-safe facilities that stations on the ring provide. In ring operation one station, designated as the Cycle Master (CM), is responsible for the generation of the cycle structure onto the ring. The CM also acts as a buffer to match data arrival and dispatch rates.

Two types of station exist: Dual Attachment and Single Attachment stations. They are termed Classes 'A' and 'B' stations, respectively. Class A stations have dual-ring connections with traffic moving in opposite directions on each ring. Therefore two physical rings exist: Primary and Secondary. Primary is usually considered the 'live' ring. A problem on the Primary ring causes adjacent stations to switch that leg of the circuit to the Secondary ring, thus making up a complete logical ring from the remaining working components of both rings.

Each Class A station has a passive switching capability that enables a station to be taken out of service without disrupting traffic or lowering service capability on the ring as a whole. It is this combination of a redundant physical ring, alternate routing and station switch-out that gives FDDI a very high degree of fault tolerance. Note that Class B stations must be attached to the network through a Class A station (usually in clusters). Class B stations form part of the logical ring of the network, but not the physical one (all their traffic must pass to/from them via a Class A station).

The right to transmit is gained by 'capturing' a token that is circulating on the ring. Stations detect a token that is 'free', which is then removed from the ring by that station. The station then transmits its packet(s) and finally places a free token on the ring to replace the one that it took in the first place.

Packets are put onto the ring by an 'originating' station, intended for another 'destination' station. Each station regenerates the packet for onward transmission, but the destination station copies it into its own internal buffer as it passed it on. When the packet arrives back at the originating station, then it is deleted from the ring. Security is assured through a 32-bit Frame Check Sequence cyclic redundancy check at the end of each packet.

Since transmission timing is independent for each and every section of the network, all stations require a phase-lock loop to control receive functions and autonomous transmit clocks for re-clocking the output data stream. The transmit clock runs at 125 Mbs and is used to measure the cycle time of the incoming data and adjust it if required to plus or minus 3 bits.

4.15 Computer networks

In the early days of data communications information travelled along a single, well-defined route from the remote computer to the 'host'. The reason for this was that the remote computer was fairly restricted in its computing and data-storage capabilities and so the 'serious' computing was carried out at the data centre. Most large organizations have retained their large data-processing centres but have changed emphasis on the use to which they are put. They are used principally for batch processing of data where either the volume is too large to be processed by the remote systems or where the processing itself is not time-critical. The advent of very powerful 'mini' computers (some much more powerful than earlier 'mainframes'), coupled with the marked increase in the reliability and speed of networks, has moved much of the data processing out to the world of the user onto the shop floor, into the laboratory, within an office department and even to individuals on the desks in their own homes.

In the motor industry, for example, the European headquarters of a US corporation would have its own designs and engineering department with a computer capable of processing, displaying and printing design calculations. However, it may still require access to the larger US machine for more complex applications requiring greater computer power. In addition, there may be a number of test units, testing engines and transmissions, each controlled by its own mini and supervised by a host machine. If there is a similar engineering department in, for example, Germany, it may be useful to collect and compare statistical data from test results. Also, since people must be paid, it may be useful to have a link with the mainframe computer in the data centre for the processing of payroll records. So it goes on. The demand for the linking of computers and the sharing of information and resources is increasing constantly.

A communications network may exist within a single site. Previously, it was not possible to connect buildings or sites divided by a public thoroughfare without using the services of a common carrier. However, with the advent of laser 'line-of-sight' devices it is possible to do so provided that 'line-of-sight' can be obtained between the points to be connected. Thus an organization may connect its systems together to form its own internal network. Because of the cost and disruption associated with laying cables, many companies are using internal telephone circuits for data communications.

For the factory environment many computer manufacturers offer proprietary networks for connecting terminal equipment to circuits based on 'tree' structures or loops. Connections to the circuit may be from video terminals for collection of, for example, stores data, special-purpose card and badge readers used to track the movement of production batches, or transducers for the control of industrial processes.

Throughout the 1980s the growth of multi-vendor sites, where computers and other equipment from different manufacturers are required to communicate with each other, has highlighted the need for a common means of doing so that is independent of any one manufacturer. Of the various systems initially developed for this purpose, one has become very widespread in its use, with more than 80% of all Local Area Network (LAN) installations using it. The system is 'Ethernet', originally promoted by Xerox, Digital Equipment and Intel.

4.15.1 Ethernet

Ethernet was developed in its experimental form at the Xerox Palo Alto Research Center in 1972. By the early 1980s a revised and more practical version was produced as a result of the cooperative venture between Digital Equipment Corporation, Intel and Xerox. This formed the basis for the standard Ethernet in use today. The prime objective of this system is to enable high-speed communication between computer equipment and other hardware, irrespective of the make or design of that equipment. Until the arrival of Ethernet most inter-machine communication, except that between equipment from the same manufacturer, was limited in practice to around 4800 bps on twisted pairs.

Ethernet is a multi-access communications system for transporting data between distributed computer systems that reside in close proximity to each other. The technique used to transfer data under controlled conditions is packet switching, whereby data are composed into discrete 'packets' for onward transmission without regard to their 'logical' use within an application. There is no central point of management in an Ethernet system. Each station may attempt to transmit when it needs to, and control of packet reception is ensured by the use of unique addresses for every Ethernet device ever manufactured. Only if the packet address matches its own address will a station pick up and use a packet on the network.

Communication occurs on a shared channel that is managed through a concept known as 'carrier sense multiple access with collision detect', or CSMA/CD for short! There is no pre-defined or pre-allocated time slots or bandwidth. Stations wishing to initiate a transmission attempt to 'acquire' control of the communications channel (which is often referred to as the 'Ether') by sensing the presence of a carrier on the network. If so, then the station delays its transmission until the channel is 'free', at which point transmission begins. A station that has detected collision will also jam the channel for a very brief period to ensure that all stations have detected and reacted to the collision it has itself detected.

During transmission the station will listen in to ensure that no other station has started to transmit at the same time. Should this be the case (i.e. a collision has been detected), then both stations will stop transmitting for a randomly generated delay period (called the 'collision interval'). Since all stations will wait a different period of time before attempting to retransmit, the chances of further collision are considerably reduced. It is important that the collision interval is based upon the round-trip propagation time between the two stations on the network that are furthest apart. Software is available that will monitor the collision level on the network and advise on capacity planning and physical network structure to ensure maximum throughput. A CRC check is applied to all packets on transmission and is checked by the receiver before handing the packet over to the station for further processing. Damaged packets are generally retransmitted. Maximum theoretical speed on the network is 10 Mbs but collisions, framing, CRCs, preambles, etc. reduce the level of 'usable' data available to the connected computer systems to 40–60% of this in practice.

4.15.2 Open Systems Interconnect (OSI)

In the past few years much emphasis has been placed on the concept of a standard that would permit equipment from any manufacturer or supplier to communicate with any other equipment, irrespective of the supplier. This would mean the ability to interconnect between systems in a completely 'open' manner, which led to the name Open Systems Interconnect (OSI).

The concept breaks down the whole business of communicating between systems into seven different 'layers'. Thus the problem of physical connection is separated from the method of controlling the movement of data along that connection. Each layer is subject to an individual standard compiled by the ISO. Some of these standards also incorporate earlier standards issued by other bodies such as the IEEE. The seven layers are as follows:

Layer 1 Application. The traditional computer program (application) that determines what need is to be met, what data are to be processed or passed by whom to whom for what purpose.
Layer 2 Presentation. Interfaces between the Application and other layers to initiate data transfer and establish data syntax.
Layer 3 Session. Manages communication session connection/severance, synchronization and reports on exception conditions.
Layer 4 Transport. Manages end-to-end sequencing, data flow control, error recovery, multiplexing and packeting.
Layer 5 Network. Maintains the availability and quality of the overall network, and manages network flow and logical division.
Layer 6 Data Link. Detects and attempts to correct physical errors, and manages data linkages, station identification and parameter passing.
Layer 7 Physical. Provides the actual physical mechanical and electrical services required to establish, maintain and use the physical network.

4.15.3 Network types

There are a number of network types.

4.15.3.1 Point to point

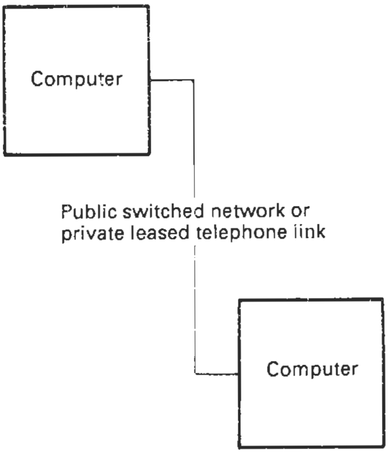
This is the simplest form of network and involves the connection of two devices – two computers or a computer and a terminal. If the communication line goes down for any reason then the link is broken, and so it is usual to back up leased lines with dial-up facilities (Figure 4.18).

4.15.3.2 Multi-point

As the name implies, Multi-point describes the connection of several tributary stations to one host. It is usual for the host to 'poll' the tributary stations in sequence, requesting messages, and for the network to be based on leased lines. In the case of one 'spur' being disconnected, the tributary station will dial into the host using a port reserved for that purpose (Figure 4.19).

4.15.3.3 Centralized

Also known as a 'star' network, in this type of network the host exercises control over the tributary stations, all of which are connected to it. The host may also act as a message-switching device between remote sites (Figure 4.20).



Computer
Public switched network or private leased telephone link
Computer

Figure 4.18 A point-to-point link

4.15.3.4 *Hierarchical*

A hierarchical structure implies multiple levels of supervisory control. For example, in an industrial environment special-purpose 'micros' may be linked to the actual process equipment itself. Their function is to monitor and control temperature and pressure. These 'micros' will then be connected to supervisory 'minis' which can store the programs and set points for the process computers and keep statistical and performance records (Figure 4.21). The next link in the chain will be the 'resource management computers', keeping track of the materials used, times taken, comparing these with standards, calculating replenishment orders, adjusting forecasts and so on. Finally, at the top of the network, the financial control system records costs and calculates the financial performance of the process.

4.15.3.5 *Fully distributed*

Here a station may be connected to several others in the network. The possibility then exists to share resources such as

specialized peripheral devices or large memory capacity and to distribute the database to the systems that access the data most frequently. It also provides alternative routes for messages when communication lines are broken or traffic on one link becomes excessive (Figure 4.22). However, the design of such systems requires sophisticated analysis of traffic and data usage, and even when set up is more difficult to control than less sophisticated networks.

4.15.4 Network concepts

Whatever the type of network, there are a number of concepts which are common.

4.15.4.1 File transfer

A network should have the ability to transfer a file (or a part file) from one node to another without the intervention of programmers each time the transfer takes place. The file may contain programs or data, and since different types (and possibly generations of computers) and different applications are involved, some reformatting may be required. This requires a set of programs to be written to cover all foreseen transfer requests and a knowledge of all local file access methods and formats.

One good example of the need for this is the application known as archiving. This involves the transmission of copies of files held on computer to another system in another location.

In the event of original files being lost as a result of fire, the files can be re-created using the archived information.

4.15.4.2 *Resource sharing*

It may be more cost-effective to set up communication links to share expensive peripheral devices than to duplicate them on every computer in the network. For example, one computer may have a large sophisticated flatbed printer/plotter for producing large engineering drawings. To use this, the other computers would store the information necessary to load and run the appropriate program remotely. This would be followed by the data describing the drawing to be produced.

4.15.4.3 *Remote file access/enquiry*

It is not always necessary or desirable to transfer an entire file, especially if only a small amount of data is required. In these circumstances what is needed is the ability to send an enquiry from a program (or task) running in one computer and remotely load, to the other system. This enquiry program will retrieve the requisite data from the file and send them back to the original task for display or processing. This comes under the broad heading of 'task-to-task communications'.

4.15.4.4 *Logical channels*

Users of a computer network will know where the programs and data, which they want to access, exist. They do not want to concern themselves with the mechanics of how to gain access to them. They expect there to be a set of pre-defined rules in this system which will provide a 'logical channel' to the programs and data they wish to reach. This logical channel will use one or more logical links to route the user's request and carry back the response efficiently and without errors. It may be that there is no direct physical link between the user's computer and the machine he or she is trying to access. In these circumstances the logical channel will consist of a number of logical links. The physical links, in some cases, may be impossible to define in advance, since in the case of 'dial-up' communication using the public switched network the route will be defined at connection time.

4.15.4.5 *Virtual terminal*

This is a very simple concept, and describes a terminal physically connected to computer A but with access (via A) to computer B. The fact that one is communicating via A should be invisible to the user. Indeed, to reach the ultimate destination, the user may unknowingly have to be routed through several nodes.

The use of common systems such as Ethernet and the promotion of common standards such as Open Systems Interconnect has bred a new concept in connecting terminals to computers, with the emphasis placed more on the 'service' that a user requires. Whereas previously the user had only to know to where the connection was required and not how to get there, with Ethernet-based 'servers' he or she need only know the name of the service that is required and no longer needs to specify where it resides. The terminal will be connected to Ethernet through a computer acting as a router. The server will know on which machine or machines the service required is currently available, and needs to know if the service has been moved, whereas the user does not. Furthermore, if the service is available on more than one machine, then the server will be capable of balancing the terminal workload given to each machine, all without the user even having to know or being aware of from where the service is being provided.

Many terminal servers are even capable of running more than one terminal to computer 'sessions' simultaneously on the same terminal, enabling the user to switch between them as desired without the host computer thinking that the session has been terminated. Workstations are able to carry out this 'sessions' service for themselves.

In all these examples the terminal is considered to be 'virtual' by any of the host machines to which it is connected via the terminal server. This concept and the facilities that it offers is quickly eroding many of the problems associated with previous methods of connecting terminals to computers, and the 'switching' and physical 'patching' that was required to connect a terminal to a new machine.

4.15.4.6 *Emulator*

As the name implies, this consists of one device performing in such a way that it appears as something different. For example, a network designer wrestling with the 'virtual terminal' concept may define that any terminal or computer to be connected to this network should be capable of looking like a member of the IBM 3270 family of video terminals for interactive work and the IBM 2780/3780 family for batch data transfer. In other words, they must be capable of 3270 and 2780/3780 emulation. Indeed, along with the Digital VT200/300, these two types of emulation have been among the most commonly used in the computer industry.

4.15.4.7 *Routing*

As soon as we add a third node, C, to a previously point-to-point link from A to B, we have introduced the possibility of taking an alternative route from A to B, namely via C. This has advantages. If the physical link between A and B is broken, we can still transmit the message. If the traffic on the AB link is too high we can ease the load by using the alternate route.

However, this does bring added complications. The designer has to balance such factors as lowest transmission cost versus load sharing. Each computer system has to be capable of recognizing which messages are its own and which it is required merely to transmit to the next node in the logical link. In addition, when a node recognizes that the physical link it was using has, for some reason, been broken, it must know what alternative route is available.

4.15.5 Network design

Network design is a complicated and specialist science. Computer users do not typically want to re-invent the wheel by writing from scratch all the network facilities they require. They expect their supplier to have such software available for rent or purchase, and, indeed, most large computer suppliers have responded with their own offerings.

There are two main network designs in use in the computer industry today.

4.15.5.1 *SNA*

IBM's Systems Network Architecture (SNA) is a hierarchical network that dominates the many networks hosted by IBM mainframes throughout the world. It is a tried and trusted product developed over a number of years.

4.15.5.2 *DNA*

Digital Equipment Corporation's Digital Network Architecture (DNA), often referred to by the name of one of its components (DECNET), is a peer-to-peer network, first announced in 1975. Since that time, as with SNA, it has been subject to constant update and development, with particular emphasis recently on compliance with OSI.

4.15.6 Standard network architecture

The fact remains, of course, that there is yet still no standard network architecture in common use permitting any system to talk to any other, hence the need for emulators. However, the PTTs (Post, Telephone and Telegraph operators) of the world have long recognized this need and are uniquely placed as the suppliers of the physical links to bridge the gap created by the computer manufacturers. They have developed the concept of public 'packet-switched networks' to transmit data between private computers or private networks.

4.15.6.1 Public packet-switched networks (PPSNs)

Package switching involves breaking down the message to be transmitted into 'packages' that are 'addressed' and introduced into the network controlled by the PTT. Consequently, the user has no influence over the route the packets take. Indeed, the complete contents of a message may arrive by several different routes. Users are charged according to the volume of data transmitted, giving generally greater flexibility and economy. The exception is the case where a user wants to transmit very high volumes of data regularly between two points. In this instance, a high-speed leased line would probably remain the most viable option.

What goes on inside the network should not concern the subscriber, provided the costs, response times and accuracy meet expectations. What does concern the user is how to connect to the network. There are basically two ways of doing this:

1. If one is using a relatively unintelligent terminal one needs to connect to a device which will divide the message into packets and insert the control information. Such a device is known as a PAD (package assembler/disassembler) and is located in the local packet-switching exchange. Connection between the terminal and the PAD may be effected using dedicated or dial-up lines.
2. More sophisticated terminals and computer equipment may be capable of performing the PAD function themselves, in which case they will be connected to the network via a line to the exchange, but without the need to use the exchange PAD.

4.15.6.2 CCITT X25

The CCITT has put forward recommendation X25 ('Interface between data terminal equipment for terminals operating in the packet mode in public data networks') with the aim of encouraging standardization. X25 currently defines three levels within its recommendations:

1. The physical level defines the electrical connection and the hand-shaking sequence between the data terminals equipment (DTE; see Section 4.16) and the data communications equipment (DCE; e.g. a computer).
2. The link level describes the protocol to be used for error-free transmission of data between two nodes. It is based on the HDLC protocol.
3. The package level defines the protocol used for transmitting packets over the network. It includes such information as user identification and charging data.

Packet-switched networks are now available in most countries in Europe and North America, as well as a smaller but growing number in other parts of the world. Most PTTs offer an international as well as national service under agreements with other PTTs.

4.16 Data terminal equipment

The most basic all-round terminal is the teleprinter which has been almost completely superseded by the video terminal. The most widely used terminal is the video display or VDU. VDUs may be clustered together in order to optimize the use of a single communications line. In this instance a controller is required to connect the screens and printers to the line (Figure 4.23).

Batch terminals are used when a high volume of non-interactive data is to be transmitted. Most commonly, the input medium is punched cards with output on high-speed line printers. As with VDUs, it is quite feasible to build intelligence into batch terminals in order to carry out some local data verification and local processing. However, the middle of the 1980s saw the large-scale introduction of very small but powerful free-standing micros and these are now in commmmon use as local pre-processors in communication with larger processors at remote sites. The advantage of this method is that the raw data, usually in punch card or magnetic tape format, can be read onto the local machine, verified, reformatted if required and then transmitted to the central site and processing initiated; all automatically done by the local micro.

In addition to these commonly found terminals, there are a host of special-purpose devices, including various types of optical and magnetic readers, graphics terminals, hand-held terminals, badge readers, audio response terminals, point of sale terminals and more.

Finally, of course, computers can communicate directly with each other without the involvement of any terminal device.

4.17 Software

4.17.1 Introduction

Software is the collective name for programs. Computer hardware is capable of carrying out a range of functions represented by the instruction set. A program (the American spelling is usually used when referring to a computer program) simply represents the sequence in which these instructions are to be used to carry out a specific application. However, this is achieved in a number of ways. In most cases, the most efficient

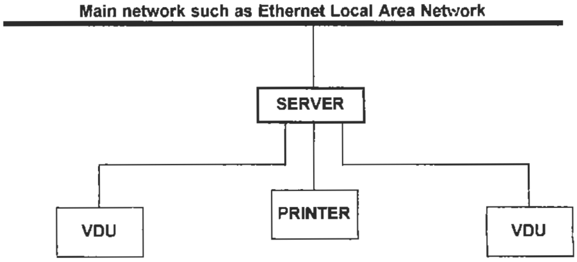

Figure 4.23 Typical network 'server' structure

method of using the hardware is to write in a code that directly represents the hardware instruction set. This is known as machine code and is very machine-dependent. Unfortunately, it requires a high level of knowledge of the particular type of computer in use, and is time consuming. In practice, therefore, programmers write in languages in which each program instruction represent a number of machine instructions. The programs produced in this high-level 'language' clearly require to be translated into code that can operate upon the computer's instruction set.

It would be possible, of course, to buy computer hardware and then set out to write every program one needed. However, this would take a very long time indeed. Most users require their system to perform the same set of basic functions such as reading, printing, storing and displaying data, controlling simultaneous processes, translating programs and many others. Consequently, most computers are supplied with pre-written programs to carry out these functions, and these fall into four basic categories:

1. Operating systems
2. Data-management systems
3. Language translators
4. Windows

4.17.2 The operating system

The operating system sits between the application program designed to solve a particular problem and the general-purpose hardware. It allocates and controls the system's resources such as the CPU, memory, storage and input/output, and allocates them to the application program or programs. Part of the operating system will be permanently resident in main memory and will communicate with the operator and the programs that are running. The functions it will carry out will typically be:

1. The transfer into memory of non-resident operating system routines;
2. The transfer into memory of application programs or parts of them. In some cases, there is insufficient memory to hold an entire program and so little-used portions of the program are held on disk and 'overlaid' into memory as they are required;
3. The scheduling of processor time when several programs are resident in memory at the same time;
4. The communication between tasks. For ease of programming, a large program can be broken down into sections known as tasks. In order to complete the application it may be necessary to transfer data from task to task;
5. Memory protection, ensuring that co-resident programs are kept apart and are not corrupted;
6. The transfer of data to and from input and output devices;
7. The queueing of input/output data until the appropriate device or program is ready to accept them.

There are several ways to use the resources of a computer system and each makes different demands on an operating system. The four main distinctions are as follows.

4.17.3 Batch processing

This was the original processing method and is still heavily used where large amounts of data have to be processed efficiently without a major emphasis on timing. Data are transcribed onto some input medium such as punched cards or magnetic tape and then run through the system to produce, typically, a printed report. Classical batch jobs include such applications as payroll and month-end statement runs.

Batch-operating systems require a command language (often known as JCL – job control language) that can be embedded between the data and that will load the next program in the sequence. Jobs are frequently queued on disk before being executed, and the operating system may offer the facility of changing the sequence in which jobs are run, as a result of either operator intervention or pre-selected priorities. Many operating systems are now capable of running multiple-batch 'streams' at the same time, and even of selecting a batch stream in which a particular job should run. Thus the person submitting the job is instructing the computer to run it under the best possible circumstances without necessarily knowing in advance where it will be run. This technique is particularly effective in a clustered environment, where batch streams may run across an entire cluster, and the operating system will not only choose the best stream but will also select the best processor on which it can run. Many current JCLs are almost programming languages in their own right, with great flexibility offered to the person submitting the job. However, there is a cost to pay for this flexibility, since the language is translated into machine code at the time of running (this is referred to as an 'interpretive language'), which is much slower than executing a pre-compiled language. Generally, though, the ratio of instructions to data to be processed is low, and this disadvantage is not considered significant.

The advantage of batch processing is its efficiency in processing large amounts of data. The major disadvantage is that once a user has committed a job he or she must wait until the cycle is completed before any results are received. If they are not correct one must re-submit the job with the necessary amendments. Some operating systems, however, do permit intermediate 'break points' in a job, so that results so far can be obtained and, if suspended, the job restarted without any loss of data. Others allow a batch job to submit data to another batch job for processing, which is very useful if the other batch stream exists to serve a printer, since intermediate results can then be printed without suspending or affecting the running of the original job submitted.

4.17.4 Interactive processing

This involves continuous communication between the user and the computer – usually in the form of a dialogue. The user frequently supplies data to the program in response to questions printed or displayed on the terminal whereas in batch processing all data must be supplied, in the correct sequence, before the job can be run. Where an operating system does permit a batch job to seek data during the running of the job, human attendance is required, which reduces the benefits of the batch stream principle.

A single person using a keyboard does not use the power of a computer to any more than a fraction of its capacity. Consequently, the resources of the system are usually shared between many users in a process known as 'time sharing'. This should not be apparent to the individual user who should receive a response to a request in one or two seconds under normal loading of the CPU and other resources. Time sharing, as the name suggests, involves the system allotting 'time slices', in rotation, to its users, together with an area of memory. Some users may have a higher priority than others, and so their requests will be serviced first. However, all requests will be serviced eventually.

Requirements of interactive time-sharing operating systems are efficient system management routines to allocate, modify and control the resources allocated to individual users (CPU time and memory space) and a comprehensive command language. This language should be simple for the user to understand and should prompt the inexperienced operator while allowing the experienced operator to enter commands swiftly and in an abbreviated format.

There are many situations today where the use of an interactive system provides an ideal solution to business and administrative problems. An area very close to the heart of computing is the development of programs and systems to run on them. In the earliest days of computing, engineers sat at large consoles and laboriously keyed in binary machine code instructions using toggle swiches. Punched cards and paper tape as a means of input for programmers were quickly adopted due to the time saved. Then it would have taken 20–30 minutes to compile and check a program of average length. Today, most machines perform the same task on much larger programs in a few minutes and sometimes in seconds. The proportion of time spent keying onto punched cards or tape became too high, and the person keying in was rarely the programmer. Therefore delays occurred while the program coding was written out longhand by the programmer, passed to data preparation, keyed in, verified and then sent back to the programmer. This process often took days, leading to very long development time and unproductive programmers. The solution was simple – get the programmers to key in directly themselves. The developments in interactive computing have made this possible, and indeed were for the most part driven by the needs highlighted by this problem.

To overcome the lack of typing and formatting skills of the average programmer, a new tool has been developed called the 'Language Sensitive Editor' (LSE). This checks what the programmer is keying in as part of a program's coding as he or she keys it in for spelling, syntax and format, and highlights any errors at the time of entry. It can even offer a pre-formatted statement framework for the programmer to fill in.

This is just one of the many uses of interactive computing but there are many others such as order input and enquiry, warehouse control, flight planning and booking, Automated Teller Machines, etc. Note that these are not 'real-time' applications in the strict sense of the phrase, since instant response to an event is not guaranteed, and requests for information and resource usage are queued and only seem to be instant.

4.17.5 Transaction processing

This is a form of interactive processing which is used when the operations to be carried out can be pre-defined into a series of structured transactions. The communication will usually take the form of the operators 'filling out' a form displayed on the terminal screen, a typical example being a sales order form. The entered data are then transmitted as a block to the computer which checks them and sends back any incorrect fields for correction. This block method of form transmission back to the computer is very efficient from a communications perspective, but can be inefficient from the point of view of the terminal operator if there are many fields in error, or if the validation of any of the fields is dependent on the contents of other fields on the same form. Some systems, therefore, send back the input character by character and are able to validate any field immediately, and not let the operator proceed past a field until it is correct. The options available to the operator will always be limited and he or she may select the job to be performed from a 'menu' displayed on the screen.

Typical requirements of a transaction-processing operating system are as follows:

1. Simple and efficient forms design utilities;
2. The ability to handle a large volume of simultaneous interactive users;
3. Efficient file-management routines, since many users will be accessing the same files at the same time;
4. Comprehensive journalling and error recovery. Journalling is a recording of transactions as they occur, so that in the event of a system failure the data files can be updated to the point reached at the moment of failure from a previously known state of the system (usually a regular back-up).

4.17.6 Real time

This is an expression sometimes used in the computer industry to refer to interactive and transaction-processing environments. Here it means the recording and control of processes. In such applications, the operating system must respond to external stimuli in the form of signals from sensing devices. The system may simply record that the event has taken place, together with the time at which it occurred, or it may call up a program that will initiate corrective action, or it may pass data to an analysis program.

Such a system can be described as 'event' or 'interrupt' driven. As the event signal is received it will interrupt whatever processing is currently taking place, provided that it has a higher priority. Interrupt and priority handling are key requirements of a real-time operating system. Some operating systems may offer the user up to 32 possible interrupt levels, and the situation can arise in which a number of interrupts of increasing priority occur before the system can return to the program that was originally being executed. The operating system must be capable of recording the point reached by each interrupted process so that it can return to each task according to its priority level.

4.17.7 Common concepts

There are some concepts that are common to most operating systems.

4.17.7.1 Foreground/background

The simplest form of processing is 'single user', either batch or interactive. However, a more effective use of a computer's resources is to partition the memory into two areas. One (background) is used for low-priority, interruptable programs, the other (foreground) is occupied by a program requiring a faster response to its demand. The latter will therefore have higher priority. The recent increases in both the memories and power of many mini and micro systems has relegated the use of this technique to the smaller end of the micro range, particularly home-based PCs.

4.17.7.2 Multiprogramming

This is an extension of foreground/background in which many jobs compete for the system's resources rather than just two. Only one task can have control of the CPU at a time. However, when it requires an input or output operation it relinquishes control to another task. This is possible because CPU and input/output operations can take place simultaneously. For example, a disk controller, having received a request from the operating system, will control the retrieval of data, thus releasing the CPU until it is ready to pass on the data it has retrieved.

4.17.7.3 Boostrapping (booting)

The operating system is normally stored on a systems disk or on a Read Only Memory (ROM) chip. When the computer is started up, the monitor (the memory resident portion of the operating system) must be read from storage into memory. The routine which does this is known as the 'bootstrap'.

4.17.7.4 System generation (sysgen)

When a computer is installed or modified, the general-purpose operating system has to be tailored to the particular hardware configuration on which it will run. A sysgen defines such items as the devices attached to the CPU, the optional utility programs that are to be included and the quantity of memory available, and the amount to be allocated to various processes.

It is unlikely that any single operating system can handle all the various processing methods if any of them is likely to be very demanding. An efficient batch-processing system would not be able to handle the multiple interrupts of a real-time operating system. There are, however, multi-purpose systems that can handle batch interactive and real time.

4.17.7.5 Data-management software

Data to be retained are usually held in auxiliary storage rather than in memory, since if they were held in memory without long-term power back-up they would be lost when the system was turned off. To write and retrieve the data quickly and accurately requires some kind of organization, and this is achieved by data-management software. This is usually provided by the hardware manufacturer, although independent software houses do sell such systems which, they claim, are more efficient or more powerful or both.

The most commonly used organizational arrangement for storing data is the file structure. A file is a collection of related pieces of information. An inventory file, for example, would contain information on each part stored in a warehouse. For each part would be held such data as the part number, description, quantity in stock, quantity on order, and so on. Each of these pieces of data is called a 'field'. All the fields for each part form a record and, of course, all the inventory records together constitute the file.

The file is designed by the computer user, though there will usually be some guidelines as to its size and structure to aid swift processing or efficient usage of the storage medium. With file-management systems the programs using the files must understand the type of file being used and the structure of the records with it. There are six types of file organization:

1. Sequential
2. Chain
3. Direct
4. Physical
5. Relative
6. Indexed

4.17.7.6 Sequential file organization

Before the widespread use of magnetic storage devices, data were stored on punched cards. The program would cause a record (punched card) to be read into memory, the information was updated and a new card punched. The files thus created were sequential, the records being stored in numeric sequence. A payroll file, for example, would contain records in employee-number sequence.

This type of file organization still exists on magnetic tapes and disks. However, the main drawback is that to reach any single record, all the preceding records must be read. Consequently, it is efficient only when the whole file requires to be processed from beginning to end, and random enquiries to individual records are rarely made.

4.17.7.7 Relative file organization

Relative files permit random access to individual records. Each record is numbered according to its position relative to the first record in the file and a request to access a record must specify its relative number. Unfortunately, most user data, such as part number, order number, customer number and so on, does not lend itself to such a simplistic numbering system.

4.17.7.8 Physical file organization

Another version of the Relative technique is used to retrieve a specific 'block' of data relative to the first block in a file from disk. This is done irrespective of where the actual data records reside in the block, and it would be the responsibility of the application program, not the operating system, to separate out individual records (unpacking). Consequently, situations where this method is advantageous are rare, but if the record size equals that of a physcial block on disk then this technique offers considerable advantages in speed of retrieval of the data, particularly if the file is in a physically continuous stream on the disk. This type of file is often referred to as a 'physically direct' file.

4.17.7.9 Chain file organization

This is, in effect, a file that is required to be read sequentially but where not all the data are available at one time. Earlier file systems did not permit the extension of a sequential file once it was written, and adding data to a file meant reading the whole file, writing it out to a new file as it was read and then adding the new data onto the end of the new file.

To overcome this limitation, the chain file technique was introduced. Each record was written to the file using relative file techniques with the application specifying to where each record was to be written. However, each record contained a pointer to the location of the next record in logical (not physical) sequence in the file, or some method of indicating that there were no more records in the chain (usually a zero value pointer). This then enabled the application program to read the file in sequence, irrespective of where the data resided on disk or when the data were put there. The widespread use of sequential files that can be extended coupled with a considerable improvement in database and indexed file techniques has largely made this technique redundant.

4.17.7.10 Direct (hashed) file organization

This is a development of the relative file organization and is aimed at overcoming its record-numbering disadvantage. The actual organization of the file is similar. However, a hashing algorithm is introduced between the user number identifying a particular record and the actual relative record number which would be meaningless to the user. The algorithm is created once and for all when the system is designed and will contain some arithmetic to carry out the conversion.

This file organization permits very fast access but it does suffer from the disadvantage in that most algorithms will occasionally arrive at the same relative record number from different user record-identification numbers, thus creating the problem of 'synonyms'. To overcome this problem, the file management software must look to see if the record position indicated by the algorithm is free. If it is, then a new record can be stored there. If it is not, then a synonym has occurred and the software must look for another available record position. It is, of course, necessary to create a note that this has occurred so that the synonym can subsequently be retrieved. This is usually achieved by means of points left in the original position indicating the relative record number of the synonym.

The user-numbering possibilities permitted with direct files may be more acceptable to the user since they are not directly tied to the relative record number. However, the need for an algorithm means that these possibilities are limited. In addition, the design of the algorithm will affect the efficiency of recording and retrieval since the more synonyms that occur, the slower and more cumbersome will be these operations.

4.17.7.11 Indexed file organization

The indexed method of file organization is used to achieve the same objectives as direct files, namely, the access of individual records by means of an indentifier known to the user, without the need to read all the preceding records. It uses a separate index which lists the unique identifying fields (known as keys) for each record together with a pointer to the location of the record. Within the file the user program makes a request to retrieve part number 97834, for example. The indexed file management software looks in the index until it finds the key 97834 and the pointer it discovers there indicates the location of the record. The disadvantage of the system is fairly apparent; it usually requires a minimum of three accesses to retrieve a single record and is therefore slower than the direct method (assuming a low incidence of synonyms in the latter). However, there are a number of advantages:

1. It is possible to access the data sequentially as well as randomly, since most data-management systems chain the records together in the same sequence as the index by maintaining pointers from each record to the next in sequence. Thus we have indexed sequential or ISAM (indexed sequential access method) files.
2. Depending on the sophistication of the system, multiple keys may be used, thus allowing files to be shared across different applications requiring access from different key data (Figure 4.24).
3. Additional types of keys can be used. Generic keys can be used to identify a group of like records. For example, in a payroll application, employee number 7439 may identify K. Jones. However, the first two digits (74) may be used for all employees in the press shop. It is therefore possible to list all employees who work in this department by asking the software to access the file by generic key.
4. Another possibility is that of asking the system to locate a particular record that contains the key value requested, or the next highest, if the original cannot be found. This is known as using approximate keys.
5. It is also possible to retrieve records within a given range of keys.
6. Most computer manufacturers provide multi-key ISAM systems and so the users do not need to concern themselves about the mechanics of data retrieval.

4.18 Database management

Files tend to be designed for specific applications. As a result, the same pieces of information may be held several times within the same system, and are often held many times within the same business or organization. This has many disadvantages:

1. It is wasteful of space and effort.
2. It is very difficult to ensure that the information is held in its most recent form in every location.
3. Security maintenance is much more difficult with multiple dispersed copies than it is with a single copy.

It is, of course, possible to share files across applications. However, a program usually contains a definition of the formats of the data files, records and fields it is using. Changes in these formats necessitated by the use of the data within new programs will result in modifications having to be made in the original programs.

The database concept is designed to solve these problems by separating the data from the programs which use them. The characteristics of a database are:

1. A piece of data is held only once.
2. Data are defined so that all parts of the organization can use them.
3. It separates data and their description from application programs.
4. It provides definitions of the logical relationships between records in the data so that they need no longer be embedded in the application programs.
5. It should provide protection of the data from unauthorized changes and from hardware and software.

The data definitions and the logical relationships between pieces of data (the data structures) are held in the schema (Figure 4.25).

The database is divided into realms – the equivalent of files – and the realms into logical records. Each logical record contains data items that may not be physically contiguous.

Records may be grouped into sets which consist of owner and member records. For example, a customer name and address records may be the owner of a number of individual sales order records.

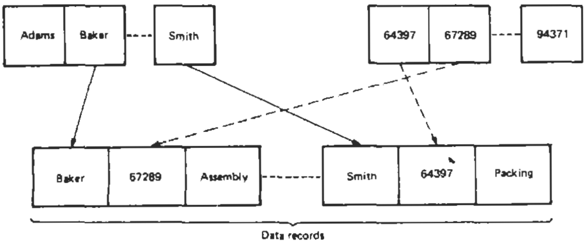

Figure 4.24 Multi-key 'ISAM' file organization

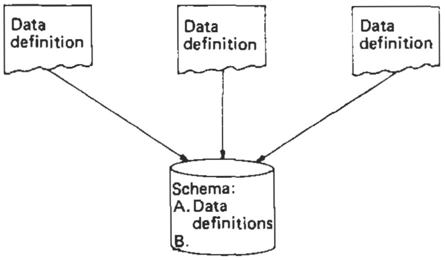

Figure 4.25 The schema

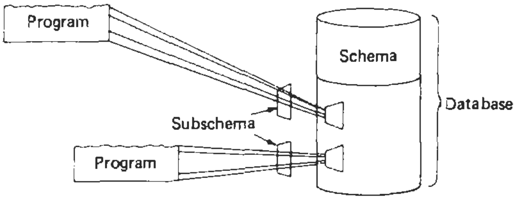

Figure 4.26 The subschema

When an application is developed a subschema is created defining the realms to be used for that application. The same realm can appear in other subschemas for other applications (Figure 4.26).

There are four major definitions of the logical relationships between the data (Figure 4.27):

1. *Sequential* (sometimes known as chain). Here each record is related only to the immediately preceding and following records.
2. *Tree or hierarchical.* In this structure each record can be related to more than one record following it. However, records along separate 'branches' are not directly linked with each other and the relationship can be traced only by travelling along the branches.
3. *Networks.* These are the most complex structures. They are effectively groups of trees where records can be related across branches. Any record can, in fact, be related to any other.
4. *Relational.* A Relational Database stores data in two-dimensional, tabular arrays. Each table (file) of the database is referred to as a relation, and each row of the table (record) is referred to as a tuple. Through the use of normalization (the successive breaking down of data into groups of two-dimensional arrays where each group's data are functionally dependent upon the group's key) the data are defined in a logical format suitable for use with a Relational Database. The result is a totally 'flat' file which, using a Relational Database Management System, has the flexibility to dynamically create new relations from extracts of one or more existing relations.

Because, within a database management system, data are separated from the programs which use them, the data are regarded as a corporate asset. Management of this asset is in the hands of a database administrator. He or she maintains the schema and works with application programmers to define the parts of the database to which they may have access and to help them create subschemas for their particular applications.

Codasyl began to take an interest in developing database standards in 1965 when the database task group was formed. There now exist Codasyl standards for database design.

4.19 Language translators

A programming language is a convention comprising words, letters and symbols which have a special meaning within the context of the language. However, programs have to be translated into the binary language understood by computers. The programmer writes a 'source' program which is converted by the language translator into an 'object program'. Usually, during this process checks are made on the syntax of the source program to ensure that the programmer has obeyed the rules. Any errors discovered will be noted, usually in two categories – terminal and warning. Terminal errors indicate that the translator has found a definite error that is so serious as to either prevent translation from completing or indicate that it is not worth doing so. A warning is generated when an item is encountered and the translator would have expected something different, but that it may not actually be an error. Program errors are known as 'bugs' and the process of removing them, as 'debugging'. Bugs are sometimes humorously referred to as 'planned features'!

Programs are normally stored in both their original code format (known as 'source') and in their final format that is understandable and executable directly by the computer (known variously as 'object', 'binary' or 'executable' formats). On disk, programs are often stored as individual files since they can be accessed directly and quickly. However, to store individual programs on individual magnetic tapes would use up too many tapes and have computer operators constantly loading and unloadding them. To overcome this limitation, the 'library' principle was introduced. Using this method, many different program files are combined into a single file called a library, and facilities exist within the operating system to extract whichever program is next needed from the library without changing the magnetic tape.

The working program is the object program, but when changes have to be carried out, these will be made to the source program which will then be translated to produce a new object program.

There are two kinds of language translators: assemblers and compilers.

4.19.1 Assemblers

An assembler is a language processor designed for use on a particular type of computer. In assembly language there is generally a one-to-one relationship between most of the language mnemonics (abbreviated instruction codes which can be read and interpreted by humans) and the computer binary instructions, although pre-defined sets of instructions can be 'called' from the assembly program.

There are four parts to a typical assembly language instruction:

1. *Label.* This is a name defined by the programmer. When he or she wants to refer to the instruction this can be achieved by means of the label. It is this facility that enables a programmer to alter the sequence in which instructions within a program are obeyed by 'jumping' from the current position to another identified by its label.
2. *Operation code.* This will contain a 'call' or an instruction mnemonic. If a call is used the assembler will insert a pre-defined code during the assembly process. If the programmer used a mnemonic this will define the operation to be carried out.
3. *Operand.* This represents the address of the item to be operated on. An instruction may require one or two operands.
4. *Comments.* This is an optional field used for ease of interpretation and correction by the programmer.

Assembly languages are generally efficient and are consequently used for writing operating systems and routines that require particularly rapid execution. However, they are machine-dependent, slow to write and demanding in terms of programmer skills.

4.19.2 Compilers

These are used to translate high-level languages into binary code. These languages are relatively machine-independent, though some modifications are usually required when transferring them from one type of computer to another. The instructions in the high-level language do not have a one-for-one relationship with the machine instructions. Indeed, in some languages a single statement could generate many hundreds of machine instructions.

Most compilers read the entire source program before translating. This permits a high degree of error checking and optimization. An incremental compiler, however, translates each statement immediately into machine format. Each statement can be executed before the next is translated. Although it does not allow code optimization, it does check syntax immediately and the system prompts the programmer to correct errors as they occur. These incremental compilers are often referred to as 'interpreters', since they interpret and then act upon each instruction.

4.20 Languages

4.20.1 Introduction

All computers work with and understand instructions in the same format – binary. The content of an instruction to achieve the same objective may well differ from one machine to another, but the instruction will be coded in a binary format. This first format of computer language is called the first generation. It is almost unheard of today to find anyone other than compiler writers who work at this level.

Programming in this first generation of languages was complex, lengthy, skilful and extremely prone to error. It became obvious that improvements were essential and that assistance was required. What better tool to assist than the very computer that was being programmed? If a code system could be developed that was easier to write and read, and which could then be translated by the computer into machine instructions, then programming would become easier. These languages formed the second generation of computer languages and are referred to as 'assembly' languages (from the action of the translator of assembling everything together to validate it). Many of the original languages have long since gone or have been replaced by easier and more powerful alternatives, but assembly languages are still the best language for writing programs where flexibility and speed of execution are paramount (such as the operating systems themselves).

4.20.2 Third-generation languages (3GLs)

These languages were developed to bring the nature and structure of the instructions much nearer to the programmer's native language, principally to speed up the programming process and reduce the level of skill required. Since many of these languages were developed in the UK or the USA, the 'native' language was English, and this is still the predominant, almost universal, language of computing today. Some examples of third-generation languages are given below.

4.20.2.1 BASIC (Beginners' All-purpose Symbolic Instruction Code)

This is an easy-to-learn, conversational programming language which enables beginners to write reasonably complex programs in a short space of time. The growth in the popularity of time-sharing systems has increased its use to the point where it is used for a whole range of applications, from small mathematical problems, through scientific and engineering calculations and even to commercial systems.

A BASIC program consists of numbered statements which contain English words, symbols and numbers such as 'LET', 'IF', 'PRINT', 'INPUT', * (multiple), + and so on.

BASIC was developed at Dartmouth College in the USA, and while there is a standard there are many variations developed by different manufacturers. There are available both BASIC interpreters and compilers.

4.20.2.2 Fortran (FORmula TRANslation)

This originated in the 1950s and was the first commercially available high-level language. It was designed for technical applications and its strengths lie in its mathematical capabilities and its ability to express algebraic expressions. It is not particularly appropriate when the application requires a large amount of data editing and manipulation.

In 1966 an attempt was made by ANSI to standardize the Fortran language. However, manufacturers have continued to develop their own extensions.

A Fortran program consists of four types of statement:

1. Control statements (such as GOTO, IF, PAUSE and STOP) control the sequence in which operations are performed.
2. Input/output statements (such as READ, WRITE, PRINT, FIND) cause data to be read from or written to an input/output device.
3. Arithmetic statements, such as * (multiplication), ** (exponentiation), / (division), perform computation.
4. Specification statements define the format of data input or output.

The language has become more structured with the introduction of FORTRAN 77 and further revisions are being planned.

4.20.2.3 COBOL (COmmon Business-Oriented Language)

This is the most frequently used commercial language. The first Codasyl (Conference of Data Systems Languages) specifications for Cobol were drawn up by 1960, the aims of which were to create a language that was English-like and machine independent.

Cobol is a structured language with well-defined formats for individual statements. A Cobol program consists of four divisions:

1. *Identification*, which names and documents the program;
2. *Environment*, which defines the type of computer to be used;
3. *Data*, which names and describes data items and files used;
4. *Procedures*, which describes the processing to be carried out.

The 'sentences' within Cobol can contain 'verbs' such as ADD, SUBTRACT, MULTIPLY and DIVIDE and are readable in their own right. For example, in an invoicing program you may find the line:

```
IF INVOICE TOTAL IS GREATER THAN 500 THEN GO
TO DISCOUNT ROUTINE
```

As a result, by intelligent use of the language the programmer can produce a program which is largely self-documenting. This is a significant advantage when modifications have to be made subsequently, possibly by a different programmer.

A general-purpose, structured language like Cobol is not as efficient in terms of machine utilization as assembly language or machine code. However, in a commercial environment, programmer productivity and good documentation are generally the most important factors. The calculations are usually not complex and therefore do not require great flexibility in terms of number manipulation.

4.20.2.4 PL1 (Programming Language 1)

Primarily an IBM language. PL1 was introduced to provide greater computational capabilities than Cobol but better file handling than Fortran.

4.20.2.5 APL (A Programming Language)

Introduced through IBM, APL is generally used interactively. At one end of the scale it allows the operator to use the terminal as a calculator. At the other, it enables one to perform sophisticated operations such as array manipulation with the minimum of coding.

4.20.2.6 RPG (Report Program Generator)

This language was originally introduced by IBM for 360 and System 3 machines. A commercially orientated very structured language, it processes records according to a fixed cycle of operations, although developments have been made in the language to make it more suitable for transaction-processing environments.

4.20.2.7 PASCAL

This is a strongly typed, block structured, procedural third-generation programming language, which is becoming more popular. This may be due to its extensive use in educational establishments in recent years. It is now widely used for a variety of differing applications in commercial environments.

PASCAL lends itself readily to modern design techniques (including top down, stepwise refinement, etc. . . .) and has built into it the necessary building blocks to make the most of structured programming. Additionally, because of its strong enforcement of data type, scope and syntax rules, PASCAL is a language less prone to programmer errors than many others.

All of the above points assist programmers in writing well-designed programs and produce very supportable code.

4.20.2.8 The 'C' language

The C language is a general purpose language. It has a close association with the UNIX operating system which is written in C. However, not being tied to any operating system or machine has made it a popular choice for the development of portable programs that can be run on a variety of hardware. This has been enhanced with the publication of an ANSI standard for the C language, based on the original C reference manual, which includes a definition of the language itself and also of a set of library routines for accessing the operating system such as file operations, memory allocation and string manipulation.

The basic data types available in C are characters, integers and floating point numbers. More complex data types can be created using structures, unions and arrays. A fundamental data type is the pointer. Use of pointers allows programs to be written to take full advantage of dynamic memory allocation and for those programs to be independent of the underlying machine architecture.

The basic language constructs are 'if-else' for decision making, 'for', 'while' and 'do' loops and switch statements for selecting from of a number of possible cases. Statements can be enclosed within brackets '{}' to group them together. There are the usual assignment operators such as '=' and additionally operators such as '++' for auto-increment and '−−' for auto-decrement. There are also a number of bitwise operators such as a logical AND (&) and shift (<<).

Much of the C language is based upon a language called BPCL, developed by Martin Richards. BPCL was the influence behind the language B, written by Ken Thompson in the early 1970s. Following on from B, C itself was designed by Dennis Ritchie, originally for the UNIX operating system running on a DEC PDP-11.

4.20.2.9 ADA

This language was developed primarily to support the development and implementation of complex, real-time software for embedded (i.e. usually contained in ROM) software in military hardware and applications. Its history can be traced back to a US DOD decision in January 1975 to set up the High Order Language Working Group to pursue the development of such a language. In April 1979 a language called 'Green' was selected as the new language for the DOD. It had been developed at a French subsidiary of the Honeywell Corporation and was renamed ADA when adopted by the DOD.

ADA uses PASCAL techniques for control and data typing. It also permits the segregation of regions within a program that enables separate development of each other. Routines can be written in a generic sense (say, for sorting) and then rapidly customized to perform the same operation on different data. It is able to do this since explicit data typing is not required initially. ADA supports multi-tasking in the same program, but the sequence of operation is not guaranteed to the programmer. Exception handling is possible under programmer control, even to the extent of permitting re-entry into routines that under normal circumstances would have crashed the system! Each compiler created for ADA under licence has to be periodically revalidated against a defined ADA standard, in an attempt to ensure that this standard is not compromised. However, the standard ADA 'functionality' is very large and has been a disincentive for many organizations to support development on its machines under ADA.

It has now been adopted as the standard preferred language by many Federal and international organizations including the US Department of Defense, the Federal Aviation Authority, NASA, NATO and the ministries of defence in many western European countries. Despite these advances, the use of ADA is not widespread and is mainly limited to defence contracts, with limited uses in commercial environments.

4.20.3 Fourth-generation languages

These are the closest yet to native language, enabling a person with very little knowledge or skill in a programming language to write instructions performing complex and lengthy tasks on a computer. They do not generally produce code that is as 'efficient' as previous generations, and the amount of machine resource that is required to support their use is sometimes either misunderstood by those using them or misrepresented by those selling them, and very often both.

Unlike previous generations of programming languages, few 4GLs demand that the instructions given to them need to follow the exact procedure and sequence in which they are required to execute. They are capable of breaking complex English-like statements down into many component instruction parts and then deducing the optimum order in which to carry them out. For this reason they are often referred to generically as 'non-procedural' languages.

These languages are most powerful when used in conjunction with some form of database management system, since they can simplify the interface between the programmer/program by undertaking all necessary communication with the database system. Many of these language/data interfaces have developed so far that the user need not know, and will often be unaware of, how the data are organized or formatted within the system. Some examples of these languages are POWERHOUSE, FOCUS, SQL, DATATRIEVE and QUERY.

4.20.4 Programmer emphasis

In broad terms, the increased speed of processing and data handling currently available and the low cost of memory have reduced the pressures on programmers to code for maximum speed and efficiency. It is frequently more economic to spend more money on hardware than to allow programmers to spend time optimizing the performance of their programs.

This, coupled with the shortage of trained programmers has resulted in increased emphasis on simple languages, good program development tools and a general emphasis on programmer productivity.

5.1 CAD/CAM: Computer-Aided Design and Computer-Aided Manufacturing

5.1.1 Introduction

Computer-Aided Design and Computer-Aided Manufacturing (CAD/CAM) is now one of the most important applications of computer science, affecting everybody who makes or buys engineering products. It has a very diverse range of uses and is frequently treated as a computer discipline in its own right. Many of the specialists in the field are not computer scientists but rather experts in the engineering functions who have become involved with the technology. Knowedge of the engineering disciplines is often a prerequisite for understanding CAD/CAM applications.

5.1.1.1 Engineering design

Design and drawing have been an integral part of modern man's development from the cave paintings of 30 000 years ago. The Romans, well known for their engineering achievements, appreciated the need for design and planning before embarking on major engineering projects, and the engineering drawings of Leonardo da Vinci are renowned. Modern engineering design owes much to the nineteenth-century engineers such as Brunel and Stephenson, whose drawings for their engines, ships and bridges are often considered works of art.

Today, product engineering is an essential part of the manufacturing process. Many products are the result of a great deal of engineering effort to develop the optimum design. Over the years, engineers have always been keen to take advantage of any tools available to enable them to put more 'Engineering' into the product. The development of CAD/CAM owes much to their desire to exploit the power of computer systems for this purpose.

5.1.1.2 Early CAD/CAM development

One of the earliest developments in CAD/CAM was Automatically Programmed Tools (APT), a language for programming numerically controlled (NC) machine tools, developed in the mid-1950s. It is regarded as one of the first application languages for digital computers.

The Finite Element Method for structural analysis was conceived in the nineteenth century, but it was only with the advent of digital computers that it would be properly exploited, and the 1960s saw the growth of computer systems for this purpose.

The history of interactive CAD can be traced back to Sutherland and Hanratty, who experimented with systems for graphics and drawing during the early 1960s. Much of the early work was undertaken in large aerospace and automotive companies, with the development of computer systems to mathematically model surfaces for aircraft and car bodies.

By the late 1960s companies such as Calma, Applicon and Computervision began to specialize in the supply of 'turnkey' computer systems for CAD. Today, CAD/CAM is a multi-billion pound industry, actively supported by major computer companies, specialist suppliers and manufacturing firms.

5.1.2 Scope

CAD/CAM embraces a broad range of applications in the fields of engineering design and manufacturing, and systems vary greatly. CAD/CAM software is available for microcomputers at 'give-away' prices, but a large installation may require a multi-million-pound investment.

5.1.2.1 What is CAD/CAM?

The CAD/CAM industry has, like many others, developed a language of its own. Its acronyms and vocabulary are often misunderstood outside the industry as sometimes the meanings are context dependent. CAD/CAM can be defined as the application of computer systems technology to the design and manufacturing process, where CAD refers to the design process and CAM to the preparation of data for the planning and control of manufacturing process.

CAD is often thought of only in terms of drawing or draughting. However, it should encompass the whole of the engineering design process, including preliminary scheming and engineering analysis.

CAM includes manufacturing functions, ranging from production planning and scheduling to process monitoring and control. Some CAM applications involve conventional data processing, and are often treated outside the realm of CAD/CAM.

Computer-Aided Engineering (CAE) is often used to describe the functions of design, analysis and testing, together with those CAM applications closely associated with design and engineering, but excluding conventional DP applications. Thus it encompasses those areas that are usually embraced by integrated CAD/CAM systems.

The integration of CAD and CAM systems (referred to as *CIE* and *CIM* – Computer-Integrated Engineering and Computer-Integrated Manufacturing) is of particular interest. The need is for systems that are able to communicate and exchange information which is essential for realizing many of the benefits of CAD/CAM.

The application areas Within a single company there is usually a requirement for a variety of different CAD/CAM applications. Table 5.1 gives a list of the applications that would be of interest to a company involved with the production of electrical/mechanical components. With such a range of applications, many of which depend on each other for their data, the integration of CAD/CAM systems is of a high priority.

Table 5.1 CAD/CAM for an electromechanical engineering company

Conceptual Design	Design scheming/layout Performance analysis Two- and three-dimensional modelling
Mechanical Design	Three-dimensional geometric modelling Finite element analysis Simulation and kinematics Computer-aided draughting
Electronic Design	Circuit diagram schematics Electronic simulation/analysis PCB design and draughting Harness design/development
Production Engineering	Process planning NC machine programming Jig and tool design
Production Planning	Manufacturing resource planning Shopfloor simulation Production scheduling/control
Manufacturing	Shopfloor scheduling/control Process monitoring and control Quality measurement/control

Other computer systems in a manufacturing company (for example, in finance and administration) may also need an interface to the CAD and CAM systems. Purchasing and stock control systems require information on components and cost control systems need data on processes.

5.1.2.2 The users

The principal users of CAD/CAM systems are engineers, designers, draughtsmen and production engineering staff. They are not usually experienced computer users. Rather, they are trained engineers who understand about the design and/or manufacture of products in their particular field. Until comparatively recently, CAD/CAM applications have generally required an understanding of computer systems in order to make best use of them. While it is evident that future generations of engineers with a greater degree of computer literacy are likely to join the profession, current users need tools that minimize the reliance on the user being able to understand the technology.

Fortunately, with the advent of new computer technologies, particularly in the development of user interfaces, this is happening. Companies are also reorganizing in order to take advantage of CAD/CAM and ease its integration into the design and manufacturing departments.

5.1.3 Hardware

CAD/CAM systems have been made available on many different types of hardware. Some, especially those supplied by specialist vendors, are provided on hardware tailored to suit the needs of particular CAD applications. Others have been developed for standard computer systems ranging from microcomputers to powerful mainframes. A particular feature of the majority of CAD/CAM systems is that they employ 'interactive computer graphics'.

5.1.3.1 The CAD/CAM system

A typical CAD/CAM system provides a 'workstation' which will have either an on-board computing capability or be connected to a time-sharing computer system which runs the application software. The user's workstation will include a screen capable of displaying both text and graphical information, input devices such as a mouse or a digitizing tablet and a keyboard (which is becoming less essential with the latest systems). The cost of a system may range from a few pounds for some application software to run on a 'home computer' to a six-figure sum for a powerful 'engineering workstation' with wide-ranging functionality.

Early systems were often developed on mainframe computers with a user interface provided through graphics terminals employing storage tubes. Later, specialist vendors provided systems with customized CAD/CAM workstations, attached to a minicomputer. Some of the latest systems use powerful engineering workstations together with high-resolution screens to provide the optimum level of performance.

Major manufacturing companies have large CAD/CAM installations, comprising many individual systems connected through a computer network, perhaps serving several hundred users with a large number of different applications.

5.1.3.2 Processors for CAD/CAM

There are still a number of applications in the field of CAD/CAM that run on mainframe computer systems, although many of these tend to be on the border of CAD/CAM and conventional data-processing tasks. Mainframe-based systems are most suited to applications where there is a need for access to a large database, or there is a substantial I/O requirement, and the amount of on-line interactive processing required is small. Typical examples include manufacturing planning and scheduling and the engineering analysis of complex structures.

For a network of CAD/CAM systems, a mainframe computer is often an essential part of the installation, providing for the storage and management of the data. It may also provide the engineering users with access to other systems and other parts of the company through national and international networking facilities. However, for the basic applications in design and manufacturing, the majority of current systems are either stand-alone workstations or minicomputers serving a small number of users.

Minicomputer-based systems A few of the systems in industry are based on the 'small' minicomputer. They are typical of CAD/CAM systems supplied through the late 1970s to middle 1980s which were particularly appropriate for 'turnkey' systems, i.e. complete systems comprising hardware and software supplied as a package by a single vendor. Figure 5.1 shows an example of a typical system. Some installations in large automotive and aerospace plants include 30 or more processors providing for over 200 CAD/CAM workstations.

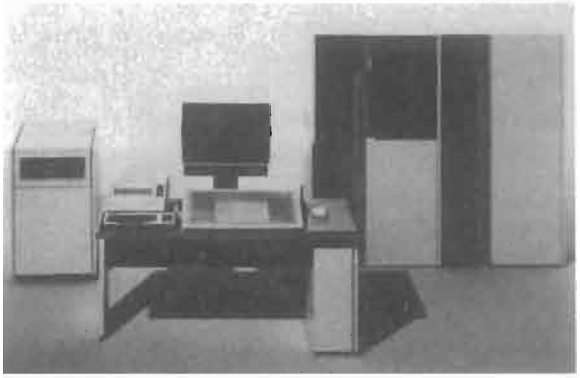

Figure 5.1 A mini-computer-based CAD/CAM system

A typical CAD/CAM minicomputer-based system included a processor together with a magnetic tape drive (for ½-inch tape), and one or more fixed and/or exchangeable disk drives (typically, 300 Mbyte). Such a system may support four to ten users, the response and performance of such systems being dependent on the type of work and the number of users. To improve performance, some turnkey systems incorporated special graphics processors to handle vector arithmetic and to speed up graphical operations.

The main attraction of such systems was that they were usually simple to implement and operate. They could be installed in a design office and be managed by the design staff. Thus, the processor was dedicated to the CAD system and the user department had control of the facility.

The engineering workstation Stand-alone computer workstations are becoming the current standard for CAD/CAM systems. They provide a great deal of flexibility plus the power to handle some of the very demanding tasks involved in CAD/CAM.

Figure 5.2 CAD/CAM on an engineering workstation

These workstation-based systems are usually dedicated to the needs of a single user with specific software applications. The stand-alone computer system generally comprises a processor with integral fixed disk drives and a cartridge tape drive for software loading and data back-up (Figure 5.2).

Currently, a typical system is based on a RISC-based processor such as the SUN SPARCstation™ offering 40–80 MIPS. However, the hardware technology is advancing rapidly, and more powerful workstations are becoming available. The manipulation of graphically displayed information is an important feature of such systems, and some workstations may incorporate additional hardware to speed up operations such as the scrolling and rotating of three-dimensional models of components.

Improved networking facilities have also enabled systems to be developed which employ 'disk-less' workstations to provide the user interface but enable resources such as disk drives to be shared from a 'file-server', thus providing more economically the benefits of the workstation.

The great advantage of stand-alone workstations is their flexibility. Each workstation can be tailored to the specific needs of particular users, and they do not suffer from the same performance degradation as do time-shared systems. The latest workstations, employing powerful processors using RISC architectures, are able to offer systems which satisfy many of the current requirements for CAD/CAM. The systems can also be run in an office environment, without air conditioning. Thus they can be installed in a location convenient for the user.

The personal computer Personal computer systems have revolutionized many areas of computing. In CAD/CAM they have provided cheaper applications for a number of design and manufacturing tasks, enabling CAD/CAM techniques to be applied cost-effectively to many engineering problems.

Basic PC-based CAD systems will run on PCs such as the 'Intel 80286™'-based systems, with an EGA screen to provide a sufficient level of resolution and 20–40 Mbytes of hard disk to allow adequate space for the software and CAD data. For the more demanding CAD applications, the PC will need high-resolution graphics, a maths co-processor and additional disk space. The more powerful PCs based on processors such as the 'Intel 80386™' provide some good CAD/CAM tools very economically.

PC-based systems do not provide the performance and functionality of the more powerful workstation systems but they do make CAD/CAM available to almost anyone who needs it. They are of particular value in education, enabling schools and colleges to introduce CAD/CAM into the curriculum. They are also very useful for first-time users, enabling them to explore the possibilities for cost-effective CAD/CAM in their organization.

5.1.3.3 Input devices – the CAD/CAM seat

A user accesses a CAD/CAM system through a workstation or 'CAD/CAM seat'. The computer hardware is sometimes built into a desk or table which also provides additional space for drawings and papers. Such stations have been the subject of a considerable amount of ergonomic design since they are becoming the designers' principal workplace.

There are almost as many variations on the CAD/CAM seat as there are systems. However, they have one important feature – a screen capable of displaying information and allowing the user to interact directly with the graphic display. Communication of commands to the system may be via a keyboard or a keypad, or by selections from menus on a tablet or a screen. In addition, there may also be devices to digitize information directly from existing drawings. The user's workstation may also include a small printer and/or plotter.

Screens for CAD/CAM The provision of a suitable screen is most important for many applications. It must generally be capable of supporting high-resolution graphics to enable drawings to be displayed with reasonable detail.

Some early systems used direct view storage tubes (DVSTs) which displayed graphical information by stroking vectors across the screen. They provided high-resolution, high-quality graphics, particularly suitable for curves and surfaces and for shape design in the aerospace and automotive industries. Storage tubes could display very complex drawings, but when the drawing was edited the screen had to be 're-painted', which could take some time.

Initially, raster scan screens generated the image from a vector file and maintained it by continually refreshing the screen. Drawings displayed on the screen could easily be edited but their complexity was limited by the time taken to refresh the image.

Decreasing hardware costs have enabled the development of raster scan screens to generate the image from a pixel map of the drawing. However, if the resolution of the raster display is too low, diagonal lines appear jagged, as was the case with early versions. Raster scan screens now provide the very high resolution required, typically of the order of 1024 × 1024 pixels, and are also able to display the high-quality pictures needed for some CAD/CAM tasks.

A colour screen is useful for many applications. It enables the designer to use colours to separate and analyse component characteristics and features, and greatly simplifies the design task. Indeed, in some cases it is almost essential. Colour screens today can display very high-quality images with subtle changes in shade and colour, enabling computer-generated images to almost mimic a photograph. For many tasks in the design of complicated mechanical components, and in architectural design, this high level of visualization is very necessary.

Some systems have made use of multiple screens, a separate screen being used for the display of text, and/or a second graphical image, so that it does not interfere with the graphics on the first screen. However, with the sophisticated windowing capabilities provided by modern engineering workstations, the trend is towards the use of a single high-resolution screen that can display the graphical image, textual information and commands generated by the system, and icons for interacting with menu-driven user interfaces.

Keyboards, keypads, pens and mice There are many different ways in which the user communicates commands to the system. The traditional method has been via a standard keyboard on which the user types commands. This is still an essential part of many systems, and is a convenient way for entering text and keying in menu selections from a list. Some systems also incorporate a 'keypad', a rectangular array of keys which enables the user to select a command from a menu provided by an overlay on the keypad.

An essential requirement of most CAD/CAM applications is for the user to be able to interact with the graphical display. This may be to enable a feature on the drawing to be identified or to indicate a position in the displayed image. Communication through the screen may also be used to allow the user to select the next command or command parameter from a set of options displayed on the screen.

Graphical displays provide a cursor in the form of a cross, or horizontal and vertical crossed lines, which can be moved around the screen by the user through devices such as a joystick, rollerball, a pair of thumbwheels or a mouse. Once the cursor has been positioned, a key depression or a button signals to the system that the position on the screen is to be noted and the appropriate action taken, which, depending on context, could be to record the location in the drawing, identify a graphical entity, or action a command.

Other devices for indicating graphical positions include the 'digitizing pen' and tablet, and 'light pen'. A light pen is pointed at the screen to identify a position or to make menu selections. Digitizing pens are used in conjunction with a tablet – a flat rectangular pad which varies in size from about 30 × 30 cm upwards and is sensitive to the position of the pen. The ergonomics of light pens versus digitizing pens has been much debated. A light pen, used to point to a position on the screen, was thought to be more natural for the designer, but most users found that being able to rest the pen on a tablet was more comfortable.

The most usual way of communicating through the screen on modern systems is by a mouse, which is now generally considered to be the most comfortable and user-friendly way to position the cursor. However, to satisfy the exacting needs of CAD/CAM applications it is important that the mouse has a sufficiently high displacement resolution.

Digitizers and scanners There is frequently a need to trace or capture information from an existing drawing. This can be achieved by using either a digitizing tablet, which is essentially a manual technique, or a scanner if an automatic drawing capture system is required.

In digitizing, the drawing is placed on a digitizing tablet and positions on the drawing translated to cursor positions on the screen, and hence to computer-stored geometry, with a 1:1 (or a suitable scaling factor) correspondence with the original drawing. This method is an extension of the use of the digitizing pen and tablet for input, and many systems equipped with digitizing tablets for command input can also use them to digitize existing drawings. For specialist applications there are large purpose-built digitizers, some capable of digitizing three-dimensional information and generating computer-based geometry from full-size models.

If there is a need to enter existing paper drawings into a CAD system automatically then a scanner is required to 'read' a drawing and generate a computer-based representation of it. The drawing is created as a raster image, i.e. each line on the drawing is represented by a row of pixels, because the scanner reads the drawing as a pixel image. Although the resultant computerized drawing can be plotted directly, it would have to be converted to a vector format if there was a need to manipulate it through the CAD system. Scanner resolutions are typically 100–400 dpi (dots per inch).

Scanners are useful for entering large numbers of drawings automatically but are susceptible to error. Extra marks on the drawing, dirt and fold marks may also be reproduced and some drawings may not be easy to scan because the lines are too faint, although scanners can usually be set to read at a threshold level. Also, the vector conversion of the raster file may not always generate the original design intent. If a digitizer is used a vector is generated directly, and the user can control precisely what is entered, but it is considerably more time consuming.

5.1.3.4 Output devices, plotters and printers

All CAD/CAM systems need some ability to output hard-copy information, typically a plotter and/or printer. In addition, some CAM systems may need the ability to generate punched tape to drive numerically controlled machines, and there are occasionally requirements for more exotic output devices.

Plotters for CAD/CAM Plotting is an important function since, in many organizations, communication of information is still largely paper based. The plotting facility for most current CAD/CAM installations is provided by either a pen plotter or an electrostatic plotter.

The traditional drawing is most closely mimicked by a pen plotter, since the finished drawing can be provided as an inked plot, providing a very high-quality result. Pen plotters vary from small A4 size plotters (approx. 210 × 300 mm) to large draughting machines of 4 m or more, capable of drawing to a tolerance within 0.05 mm. These are essential in aerospace, shipbuilding and automotive applications where the need is for large-scale drawings of cars, cross sections of aircraft wings, ships' hulls, etc. Pen plotters can often be driven directly from the drawing file on the CAD system. Many pen plotters provide multiple pens, a necessary requirement now because many drawings require colour and/or varying pen thickness.

To output a drawing via an electrostatic plotter the drawing must first be rasterized and then transferred to the paper as individual dots (the ink is transferred by electrostatic charge to the specially treated paper). In recent years the quality of plots from electrostatic plotters has increased substantially, with the development of colour plotters and resolutions of the order of 400 dpi, and they now provide a satisfactory output for most applications, even those requiring a high standard of drawing. However, the CAD data must usually be converted to a raster file, and this can be time consuming for a large and complex drawing. Electrostatic plotters vary in size from about A4 up to A0 (approx. 1200 × 840 mm).

Electrostatic plotters are usually preferred for high-volume drawing because of the simplicity of operation and the fact that they can be left to run unattended (they can be used for plotting overnight if necessary). Pen plotters have to be monitored, and ink flow can frequently be a particular problem (draft plots are often produced using ballpoint). For some of the modern CAD applications, involving the display of shaded images, electrostatic plotters are the only practical solution, and some of the latest plotters provide very high-quality shaded colour drawings.

The technology for plotting is developing rapidly, and there have been considerable improvements in the quality of all plotters in the last few years. The latest development is the 'thermo-transfer' plotter, which is similar to an electrostatic plotter, working with a rasterized drawing, but it builds up the image by using heat to transfer the ink. It has the advantage that it is smaller and more portable and it does not require specially treated paper.

Very often some form of textual output is required, and in many cases this can be output via the plotter. However, for larger systems, and applications involving a substantial amount of textual output, access to a conventional printer is preferable.

There are several more exotic devices which satisfy the need for output of data for special tasks. The following are particularly appropriate for some applications in a design engineering environment.

Large-screen displays Plotting is a frequent activity during the course of design and design problems are often discussed around a copy of the current drawing. Large-screen displays enable several engineers to study the design simultaneously and hence eliminate some of the need for plotting.

Computer output to microfilm Many design and engineering offices store their libraries of drawings on microfilm. Direct computer output to microfilm (COM) from a CAD database eliminates the need for plotting the drawings first.

Photoplotters For some electronic applications in printed circuit board design, photoplotters may be linked to the CAD system to generate photographic negatives (for PCB artwork, for example) direct from CAD data.

5.1.3.5 Networking and communications

While there are still many cases where the need is for a single stand-alone CAD/CAM workstation or system, the more usual requirement now is for systems that can communicate with each other and with other computer systems and equipment through a network. The development of computer networking over the last few years has been particularly beneficial to CAD/CAM.

Networked computer systems are needed in CAD/CAM to satisfy a number of specific requirements.

Workstation-to-workstation communication With the development of workstation-based systems there is often a need for users to be able to pass CAD/CAM information to each other and/or to share library data. This is particularly important if the systems run different applications. For example, one system may create component designs to be passed to other systems for engineering analysis and/or NC programming.

Workstation to file-server In larger design offices there is usually a need to provide for the central storage of CAD/CAM databases and libraries. This is often handled by one system which acts as a 'file-server' providing a substantial amount of on-line storage on disk.

Local area systems to mainframes Mainframes are often used to provide for the large-volume storage of engineering databases. The CAD/CAM users may also need to extract information from mainframe-based systems and/or generate data to be passed to other company systems. They may also use the mainframe to run engineering analysis packages and other specialist applications.

CAD/CAM systems to manufacturing NC programmers generate data to drive machine tools. Direct NC (DNC) provides the means to transfer NC data directly from a CAM system to the machine tool. Networking of design and manufacturing systems also enables the integration of CAD/CAM with the manufacturing processes and allows data to be interchanged between the divisions. The ability to be able to put CAD/CAM systems on a company's computing network is a key requirement for many manufacturing organizations.

5.1.3.6 Networking standards for CAD/CAM

To satisfy the networking requirements of CAD/CAM a number of standard networking protocols are used, of which the following are particularly significant.

Local Area Networks (LAN) Many systems based on Unix (a trademark of AT&T), which are becoming the standard for CAD/CAM Engineering Workstations, provide a LAN facility to IEEE 802.3 Standard using Ethernet^{TM} (a trademark of the Xerox Corporation). NFS (Network File System), developed by Sun^{TM}, provides a powerful and versatile network facility permitting the exchange of data and remote logging into other systems, often a necessary requirement to properly exploit a system network for CAD/CAM applications.

Transmission Control Protocol/Internet Protocol (TCP/IP) In many CAD/CAM installations TCP/IP is used as the standard for communicating between different types of processor, enabling them to exchange data and establish host/terminal relationships. It is well established and widely supported by many vendors.

Manufacturing Automation Protocol (MAP) The need for a standard for factory networking systems has led to the development of MAP. This specifies a standard for communication and control between computer systems, and machines and other equipment on the shopfloor, and has been developed to satisfy the needs of large-scale manufacturing organizations.

Technical and Office Protocols (TOP) This provides a set of international OSI (Open Systems Interconnection) standards to enable different computer systems in engineering to exchange data across a network intelligently. It specifies standards for both physical connections and transactions.

5.1.3.7 A CAD/CAM installation

While a number of CAD/CAM installations are single standalone systems running on PCs and engineering workstations, many large companies have major installations comprising several individual systems, perhaps from more than one vendor, and networked with the company's mainframe-based installation. Figure 5.3 shows an example of the configuration for a typical installation to provide a variety of applications for different parts of an engineering organization.

5.1.4 Software

Some turnkey systems comprise several million lines of code, the result of several thousand man-years of program development. Software development for CAD/CAM systems covers many different aspects of computing, ranging from databases, screen manipulation and real-time systems to highly specific engineering applications.

5.1.4.1 The multi-level CAD/CAM machine

A CAD/CAM system involves program development at several levels. The concept of the 'multi-level machine', used for current computer design strategies, represents the com-

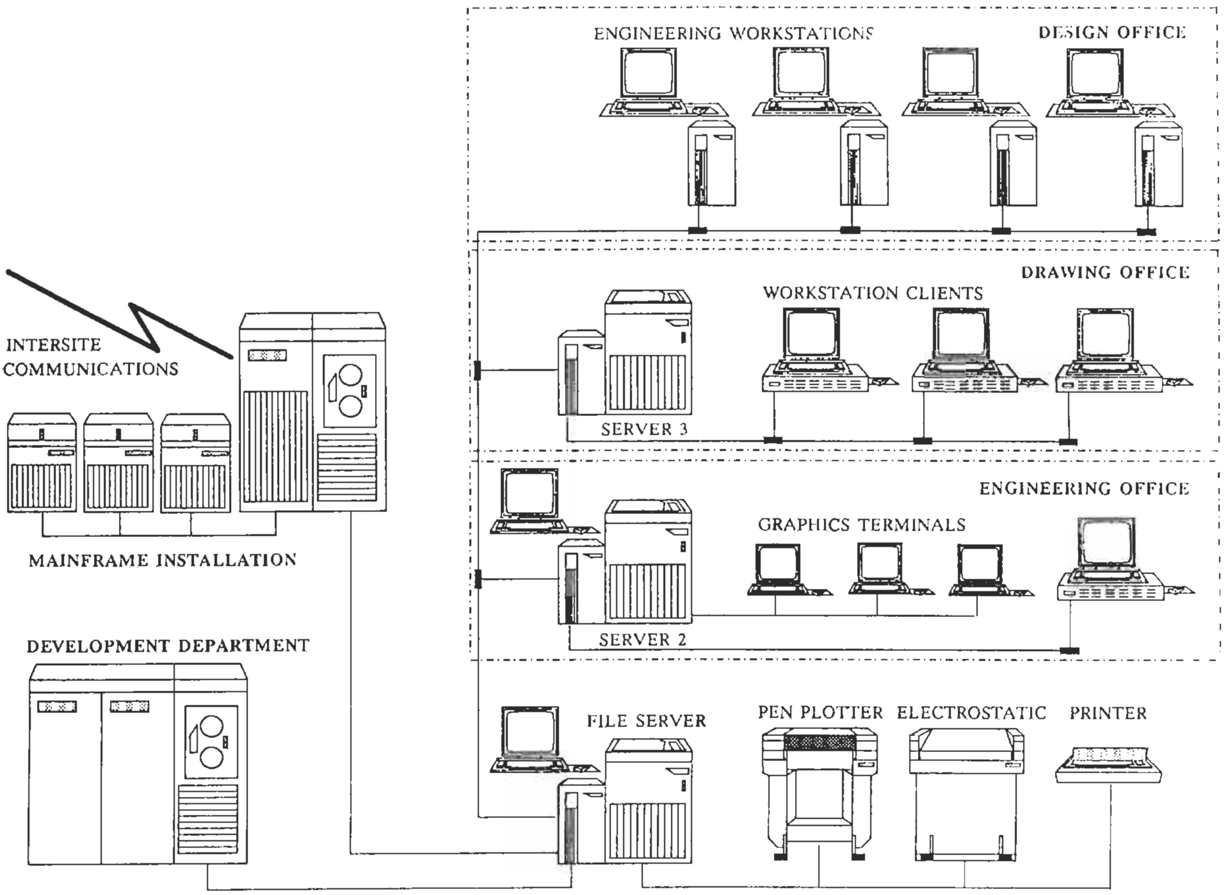

Figure 5.3 An integrated CAD/CAM installation

Table 5.2 The multi-level machine concept extended for CAD/CAM

Level 9	User-tailored software for specific company requirements to automate engineering tasks
Level 8	High-level application software for specific design and manufacturing tasks (e.g. draughting)
Level 7	Problem-oriented tools appropriate to CAD/CAM applications, such as geometric modelling
Level 6	Basic CAD/CAM functionality, such as graphics, vector manipulation and database handling
Level 5	The problem-oriented language level – high-level languages (e.g. Fortran)
. . .	
Level 0	The digital logic level

puter at a series of levels from Level 0 (the Digital Logic) to Level 5 (the Problem-oriented Language).[1] The applications at Level 6 and above can be used to model a CAD/CAM system, as shown in Table 5.2.

The levels provided with the typical CAD/CAM systems are as follows. *Level 5* represents the programming language (typically, Fortran and 'C' for many CAD/CAM applications). *Level 6* includes tools to handle the following:

1. The User Interface, to decode commands, or menus;
2. Graphics Manipulation, to handle screen graphics;
3. Database Handling, to store and retrieve data;
4. Basic routines to provide standard mathematical and geometric functionality.

The basic software functionality required to support CAD/CAM applications is further discussed in Section 5.1.4.2. *Levels 7 and 8* encompass the application-oriented features of a CAD/CAM system, provide engineering users with the software functionality necessary for their work, and are further discussed in Sections 5.1.5 and 5.1.6. *Level 9* represents the level for system tailoring and bespoke software development, which build on CAD/CAM system tools already provided to automate specific processes for particular company needs and is further discussed in Section 5.1.7. The model of CAD/CAM as a multi-level computer application helps in the design of CAD/CAM systems and in the understanding of their operation.

5.1.4.2 CAD/CAM software fundamentals

The fundamental components of a CAD/CAM system are the user interface, the graphics manipulation and the database-handling facilities. The design and development of effective software requires a good understanding of the appropriate computer science disciplines, unlike the higher levels, which rely heavily on an in-depth knowledge of the applications.

The user interface The functionality of a CAD/CAM system is usually driven by the user through the input of commands. The two most usual techniques for inputting commands to the system are through a command language or by menu selections.

Command languages Many systems are driven by 'English-like' command statements which are typically of the form:

INSERT LINE X1Y1 X2Y2

This would be interpreted as 'create a line a between the locations given by the coordinates x1y1 & x2y2'. The command statements may include code words, coordinate locations and references to existing geometry. They may be issued to the system in a purely textual form, or by using a combination of text, and screen digitized locations and references to displayed geometry. There are many well-established techniques for developing comman language-driven systems, the main requirement being that the command syntax and complexity of the language are able to reflect the functionality required of the system.

Hierarchical menus Command input by menu selection has been implemented in a number of different ways. In the earliest systems, selection by number from a list of options enabled a simple keyboard interface. However, the development of improved graphics capabilities allowed direct selection by highlighting the command required in a list displayed on the screen, and many of the latest systems provide menu selection through 'icons'. Operating systems for workstations and PCs often provide software tools to assist in the development of menu systems.

Menu-based systems are attractive because they lead the user through the system. However, command language-based systems tend to offer a more flexible approach. They can be adapted to off-line input techniques and support the creation of programs and procedures to automate the tasks.

The provision of sophisticated tools for user interfaces has enabled menu-driven interfaces to be developed for essentially command language-driven systems, thus offering the benefits of both.

CAD/CAM graphics Much of the success of CAD/CAM systems is dependent on the ability of these systems to manipulate the graphics and allow the user to interact with it. They have provided routines to draw lines, circles and other standard shapes and perform operations such as limiting or 'clipping' the displayed graphics within a 'window' on the screen, translating and rotating the screen image. and locating drawn entities from a digitized position.

There is less need for such functionality in some CAD/CAM systems as developments have provided the ability to perform many basic graphics functions through hardware. As a result, CAD/CAM systems are beginning to standardize their graphics output, using standards such as PHIGS (Programmers' Hierarchical Interactive Graphics Standard), to be able to take advantage of these new hardware features as they become available.

CAD/CAM databases The primary purpose of most CAD/CAM systems is to create and/or manipulate engineering information. Thus the organization and structure of the data which represent that information is most important.

Much of CAD/CAM is about the handling of geometric data. For the CAD representation of components, systems need to handle the following types of geometrical entities:

1. Simple linear – points, lines, arcs and circles, conics, free-form curves;
2. Surface – cylindrical, conical and spherical surfaces, complex double-curvature surface geometry;
3. Solid geometry – cuboids, conical solids, complex swept solids.

Simple systems for drawing usually only need to store two-dimensional geometric data while more sophisticated systems which allow complex component design must hold the data as three-dimensional geometry. Since such information is the 'core' data on which many operations are performed, efficient methods for handling it are required.

CAD/CAM databases may also have to store information which is specific to particular applications such as the dimensions on drawings and the names of electronic components. A very flexible database structure is required to enable this. For example, dimensions require information such as the location of leader lines, the shape of arrowheads and additional dimensional text such as tolerances, etc. Additional data to describe the line fonting may also be stored in order to describe the way in which entities are to be displayed.

Intelligent databases are required for some applications to enable the connectivity of data to be stored. In electronic design, for example, there is a need to know how individual components are connected. The use of intelligence in CAD/CAM applications is discussed later.

Information to describe the way in which a three-dimensional object is to be displayed on the screen and the views of it that are required for drawing must also be recorded in the database. Other CAD/CAM systems that output data for post-processing may need to hold instructions to support the re-processing of those data.

5.1.4.3 Languages for CAD/CAM

The development process for CAD/CAM software is similar to that for other computer applications, involving systems analysis, software engineering, development and test. However, CAD/CAM is both a multi-level and a multi-discipline application. Hence the development problems are often compounded by the need to use a variety of different programming languages.

Conventional languages Fortran is probably the most common high-level application language for CAD/CAM, being the one most widely used in scientific and engineering applications. However, there is often a need for some operations to be performed in a very efficient way, and thus low-level assembler code is often 'incorporated'. In recent years, with the use of Unix-based systems, the C language has become popular.

Operating system tools With the growth of workstation-based systems, tools provided by the operating system have assisted in the development of user interfaces and other functions required for CAD/CAM systems. The development of graphics standards also helps the development of output interfaces.

Relational database management systems A number of CAD/CAM systems have specific database-handling requirements that may be best satisfied by a 4GL RDBMS application. If the application is one part of an integrated CAD/CAM system then care is needed in the design of the user interface to ensure that a consistent approach is adopted.

Artificial intelligence Many engineering tasks rely greatly on the engineers' knowledge and experience. Thus, there is considerable potential for the use of AI and Expert System tools in CAD/CAM applications, although their use has so far been somewhat limited. However, as AI techniques become more proven, their use in CAD/CAM will almost certainly increase.

5.1.5 Modelling techniques

CAD/CAM systems provide the computer tools for a wide range of engineering applications. Central to many of the tasks is the computerized model of a product replacing a traditional engineering representation.

The use of computer-based systems for engineering design has introduced the concept of 'geometric modelling'. Traditionally, a description of an object has been developed and conveyed using two-dimensional drawings on paper, but the use of a computer system enables designers to create and present the necessary information in an entirely different way. Computer technology offers scope for providing not only a better description of a product but also one which can, with the use of other computer-based tools, automate some of the downstream processes.

The modelling techniques in CAD/CAM are not restricted to geometric ones. There are many applications for which some form of 'schematic modelling' is required (e.g. for plant design and electronics).

5.1.5.1 Geometric modelling

Geometric modelling is the CAD tool for generating a computer representation of a 'solid' component. All CAD/CAM systems in mechanical engineering must provide some facility for different levels of geometric modelling from 'wire-frame' to 'surface' and 'solid' modelling, and at each level different techniques are required.

Wire-frame modelling A 'wire-frame' model is the simplest form of geometric modelling and components may be modelled in two or three dimensions. Component descriptions consist of geometric entities such as lines, arcs, conics and curves.

At the simplest level, two-dimensional geometry is the computerized equivalent of a drawing, and many components can be adequately described in this way. It suits 'flat' objects such as those made from plate or sheet metal and also axi-symmetric (round) components, which can be adequately represented for many purposes by a cross-section through the component.

Additional data may be required to provide enough information about the object. This may be an additional two-dimensional drawing showing another view or further textual information providing details of the material. Although the representation is simple it can still provide sufficient information, and it is a practical solution for many downstream applications (for example, planning and NC programming, or where the required end result is simply a drawing of the component).

Many CAD systems provide a facility for creating wire-frame geometry in three dimensions. The component is still represented by the same type of geometric entities but is defined in three-dimensional space. They are used typically to represent the hard edges of a component, or where the shape of the component changes from a flat surface to a curved one. Free-form curves in three-dimensional space are used in the design of complex surfaces.

Wire-frame models in three dimensions provide a great deal of information about the component but they do not give a complete description of it and the shape between the edges must be inferred. In many cases the shape of the faces is obvious, particularly those that are flat, but complex surface changes cannot be adequately described and the models can be misinterpreted.

Although users can perform quite complex tasks with wire-frame geometry (such as calculations of volume), the operations cannot easily be performed automatically by the system, and it is sometimes very difficult to accurately visualize the component.

Surface modelling Surface modelling enables complex faces of a component to be accurately described. In a complete surface model each of the component faces will be represented by one or more surfaces which meet at coincident edges.

There have been many different algorithms for mathematically modelling surfaces. Surface modelling was initially developed in the mid-1960s, to satisfy the requirements of the aerospace, automotive and shipbuilding industries for more accurate ways of defining complex surfaces. Many of the early systems were based on the 'Coons patch', developed by Coons in the early 1960s, and some derivatives of these systems are still in use today.

Curve- and surface-fitting algorithms attempt to mimic an 'engineering spline'. The algorithms were initially based on piecewise polynomials. For most applications, fourth-order polynomials were usually sufficient to maintain continuity of slope and curvature across boundaries and provide smooth surfaces, the minimum requirement for most engineering applications. Some applications requiring very smooth flowing curves, such as automotive body design, require higher-order polynomials.

Modern algorithms for curve and surface fitting are based on the B-spline curve fitting algorithm, a derivative of the work by Bezier. This is now preferred because it is mathematically more robust than the polynomial-based curves that were used earlier. The latest systems use NURBs (Non-Uniform Rational B-splines (and B-surfaces)) which can precisely model a wide range of curve functions and give, for example, exact representations of arcs and conics.

Surface modelling provides more information about the component than wire-frame geometry and is of value in describing the complex shapes of aircraft surfaces, ships' hulls and car bodies, as well as for the design of a wide range of general products, such as glass bottles. Surfaces also enable the model to be more easily visualized, and are often provided as an adjunct to the wire-frame representation for additional information.

Modern surface modelling systems, in conjunction with high-technology display devices, provide high-quality surface shading, enabling a very realistic rendering of an object and excellent visualization. Thus many aesthetic design tasks can be performed on the computer screen rather than by building actual models.

Solid modelling The most complete approach to geometric modelling is through solid modelling. The ability to generate solid models has been available for a number of years, but because of the heavy processing requirement it is only as a result of the recent developments in hardware technology that it has been possible to exploit it in a practical way. Solid models can provide all the geometric information required to describe a component and there have been a number of different techniques for representing a solid, but the majority of current systems make use of one of two methods.

In constructive solid geometry (CSG) the solid model is represented as a set of primitive solids such as cuboids and cylinders, together with operators to combine or subtract them, i.e. a circular hole through a solid is the subtraction of a cylinder from the solid. The user creates and develops the solid by adding and subtracting the appropriate primitives. However, the representation is restricted to solids that can be composed from the given set. It is a compact method of representing a solid but can be time consuming to process for subsequent operations.

In Boundary representation (B-rep) the solid model is represented by a set of 'faces'. These are surface descriptions referencing 'boundary edges' which are made up of lines, arcs and curves meeting at 'vertices' (the faces, edges and vertices relating to those of the object being modelled). The solid may be constructed by Boolean operations on primitives as with the CSG method as well as by sweeping or rotating an 'edge', thus permitting the construction of the highly complex faces required for some solid objects. Processing and downstream applications can exploit the direct availability of the edges but some B-rep models have a large data-storage requirement.

Some solid modellers use a 'faceted' model to represent the solid, rather than an exact mathematical representation of the faces, to speed up processing. The calculations are fast and robust, but may be inaccurate in some instances. For an exact representation of the faces the system must handle all the different curve types, and the routines require a high degree of accuracy in mathematical calculations. It is possible to unify the algorithms by using Non-Uniform Rational B-surfaces and satisfy most modelling requirements.

Solid modelling has distinct benefits over other types of modelling since it models the real solid component and it enables the object to be properly visualized. The model can be shaded and edges hidden, and very realistic pictorical representations can be obtained as the examples in Figures 5.4 and 5.5 show. In addition, mass properties (e.g. volumes and centre of gravity) can be calculated automatically, and models for structural analysis may also be generated.

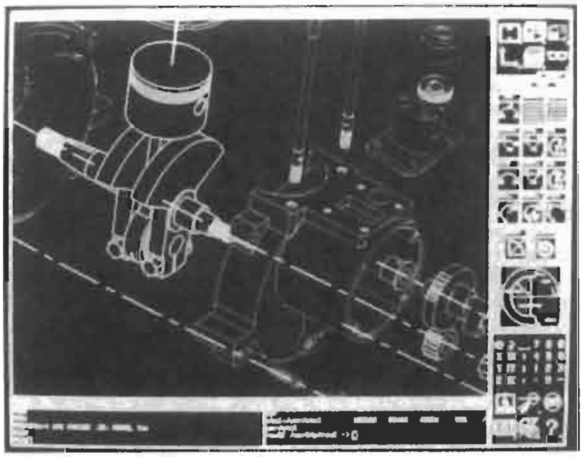

Figure 5.4 A solid model showing hidden line removal

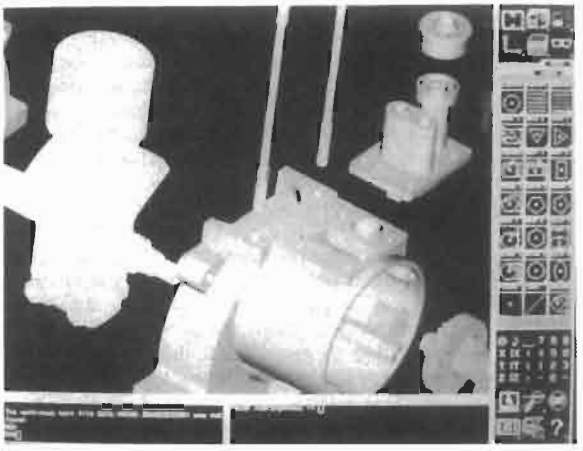

Figure 5.5 The same model as a pictorial image

Feature modelling In the real world, components are actually made up of features such as faces, grooves and holes. Some CAD/CAM applications need to know not just the geometric representation of the component but the features it contains. For example, a cylinder may represent a hole, but it is the characteristics of the hole such as depth, diameter and direction and its surface finish and tolerances that are important when it is manufactured.

Feature-based modelling addresses this problem. It is another representation of the component, which provides a set of related features that reference the geometric entities in the conventional geometric model.

Feature-based modelling offers advantages to the designer. The model can be described in engineering and/or functional terms, and properties can be attached to the features to provide additional information for manufacturing purposes.

Other advantages are that the model conveys the design intent, but more importantly, because the purpose of the geometry is described, it can enable automatic processing for NC programming and process planning. The use of knowledge engineering techniques and artifical intelligence are needed to make full use of feature-based modelling in CAM applications.

Finite element modelling The finite element method of analysis is a technique used for stress analysis and other analytical problems. It involves modelling a component as a matrix of small elements and then determining the effect of the applied loading on each of the individual elements. The method involves the solution of a large number of individual equations, hence its suitability for computer resolution.

The finite element model is a mesh of individual elements, typically brick- and/or wedge-shaped blocks connected at grid points, which model the component geometry. This model is an approximation to the geometry for the purpose of analysis. The finer the mesh, the more accurate the analysis, but the more time consuming is the computation. The mesh is generally designed to reflect the changes in stress in the component, highly stressed areas and areas where there is a marked change in the geometry being given a finer mesh. (The analysis results in Figure 5.8 have been displayed on the original finite element model.)

5.1.5.2 Schematic modelling

In some design tasks there is a requirement for creating circuit diagrams and schematic modelling. In electronics they are essential for the design description, but schematic modelling also has applications in plant layout and mechanical design. Schematic modelling may be purely diagrammatic or it may be used to represent a complex three-dimensional structure.

Schematic diagrams A schematic diagram comprises a set of symbols connected together by lines. The symbols, representing components, may be stored as a single entity within the database, referencing a library component which is used for the graphical representation of the symbol. Many applications require a standard set of symbols developed to meet company or even international standards.

Some systems support connectivity within the database, so that the line joining a symbol or a particular component within the symbol (e.g. a pin or a transistor) is represented in the database by entities that are connected. Text displaying component names and other information may also be linked to the component within the database. Thus the database is an intelligent representation of the diagram, enabling the connectivity of the model to be automatically processed.

The use of intelligent databases for schematic diagrams enables information to be extracted from the diagram for use by downstream processes as discussed in Section 5.1.6.2 on CAD electronic design.

Schematic geometry A number of applications, such as a wiring harness or plant design, have a requirement for a schematic representation of the geometry, in which the model is not a true geometric one but rather a diagrammatic representation showing the location of major components and the way they are interconnected.

The components themselves (for example, valves and tanks) are often symbolically represented and the pipes joining them are shown by lines. The schematic representation offers a quick and easy method for design, and permits connectivity and other information to be extracted. Many such systems also provide software to convert the diagrammatic representation into a more realistic geometric model for visualization, as shown in Figure 5.6, a picture generated from a plant schematic.

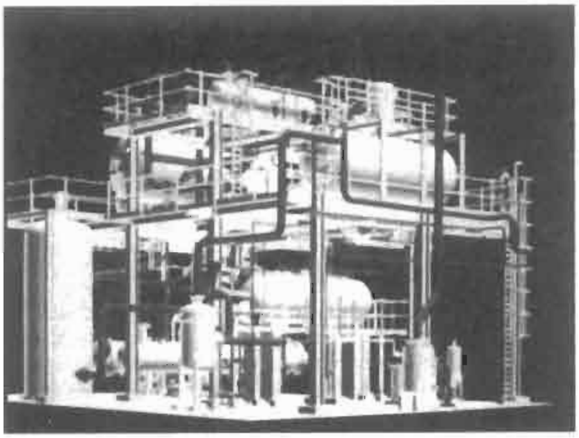

Figure 5.6 A pictorial image from a plant design schematic

5.1.5.3 CAD/CAM modelling practice

Modelling is an essential part of the design process, and in CAD/CAM computer-based models replace the traditional engineering techniques, which in some cases involved building full-size physical representations of the product.

The CAD/CAM model may often be the ultimate reference for the finished component and it must accurately reflect the actual component, to the level required for its subsequent use, which may be purely geometric, or in some cases also functional.

5.1.6 Applications

Many applications in engineering design and manufacturing are addressed by CAD/CAM systems. They may supply the tools for specific applications and be dedicated to providing 'niche solutions', or answers to particular engineering problems, or a large variety of tools capable of handling many different applications within a single integrated system.

The following sections give a brief overview of the different areas of application together with the CAD/CAM tools to satisfy their requirements. It is not a review of any particular CAD/CAM system but rather of the system features that are required to support the applications.

5.1.6.1 The design to manufacturing process

CAD/CAM systems assist in automating tasks within design and manufacturing. The overall design to production process is broadly similar in most manufacturing establishments, and is illustrated in Figure 5.7.

The different functional areas and the different disciplines in those areas often require specific CAD/CAM solutions to satisfy the needs of the tasks involved. In an integrated CAD/CAM environment information must be passed from step to step in a computer-based form. The process is often an iterative one, and the need to be able to cycle through a series of tasks is an important aspect of the systems.

5.1.6.2 CAD applications

The purpose of engineering design is to define the product and generate information for manufacturing. The tasks involved vary considerably in different engineering disciplines, and hence CAD systems for one discipline may provide very different facilities to those for another.

CAD systems are employed for a number of applications outside the design office. For example, other parts of a company may use CAD for the preparation of drawings for marketing and product support, and illustrations for manuals for input to a desktop publishing system. Many other organizations outside engineering also use CAD as a general tool to create drawings.

The following sections provide an overview to the CAD application requirements for various tasks in a number of different design disciplines.

Mechanical design engineering Mechanical engineering encompasses a wide variety of products ranging from aircraft and cars to zip fasteners. The design of mechanical components involves developing a geometric description of a component to satisfy the needs and functionality of the product, which very often includes a large amount of analytical work. The resultant CAD output may include manufacturing drawings for individual components and assemblies, parts lists, and a variety of other documentation to support the product.

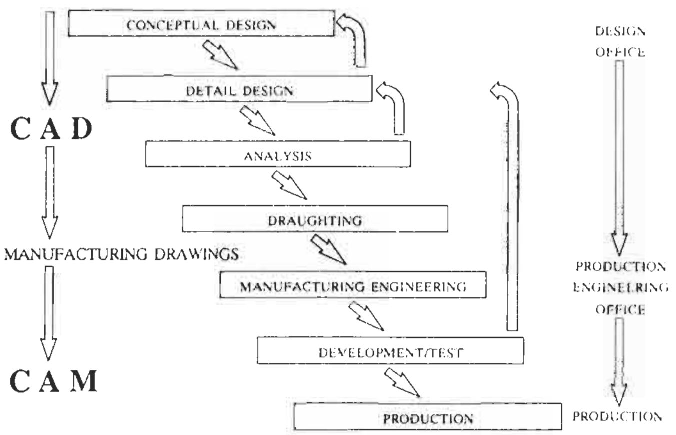

Figure 5.7 The design to manufacturing process

A range of CAD/CAM tools is required to support a mechanical design engineering process from initial scheming, through detailed design and analysis to the preparation of manufacturing drawings.

The initial product design and scheming is likely to make use of schematic design systems, simple CAD tools for two-dimensional draughting and geometric construction, and more powerful systems for three-dimensional modelling of solids and complex surfaces. Ease of manipulation of the computer-based data is a key feature for conceptual design since many different ideas may be tried and modified as the designer optimizes the product.

Conceptual design often involves the use of special programs to generate information to meet pre-specified design criteria (for example, to produce aerofoil sections to meet aerodynamic characteristics). Thus the ability to integrate CAD systems with other computer-based applications is often important.

A powerful geometric modelling tool is a fundamental requirement for the mechanical engineering of new, high-technology products. A high degree of visualization is often required together with the ability to easily perform analytical operations on the component being modelled, such as the calculation of volumes and weights. Many products are the result of the assembly of a number of smaller items. Thus the ability to bring together models of different components to check interfaces and the fit of the product is essential.

Many mechanical design problems can only be resolved by simulating the mechanism. Computer simulation may be used in both conceptual and detail design. The systems enable the component to be modelled as a mechanism, and are able to determine loadings and displacements of linkages, springs and other moving parts, as well as helping the designer to confirm the required mechanical operation of the system.

Many mechanical components are highly stressed, and must be optimized to minimize weight. Hence structural analysis is often an integral part of the design process. There are many finite element analysis packages available. Some of the latest systems make use of high-resolution colour graphics to display the results of the analysis visually, such as that shown in Figure 5.8, as well as providing detailed listings of the results.

Although CAD systems are able to provide computer-based data for the production departments directly, the preparation of manufacturing drawings is still a requirement in many engineering companies. Most CAD systems for mechanical design provide a draughting capability. Computer-aided draughting is discussed below.

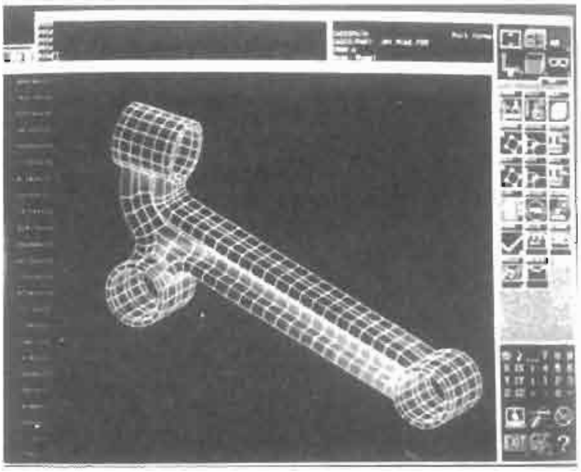

Figure 5.8 A finite element model of a component

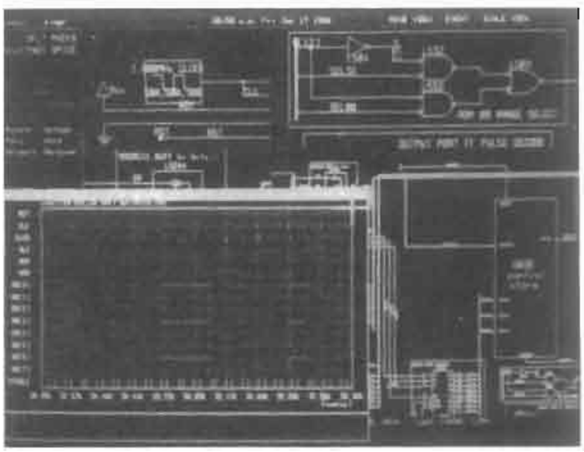

Figure 5.9 Electronic circuit design with analysis results

Mechanical design is frequently an iterative process and therefore the ability to integrate the tools for these different tasks is an important aspect of CAD. This field of engineering is very diverse and, because of its nature and the long traditions in the industry, it is difficult to develop standard techniques. Thus turnkey systems which support a wide range of mechanical design applications must be very flexible and easily able to adapt to the different requirements of engineering companies.

Electronic engineering Electrical/electronic design requires CAD systems with features very different to those for mechanical engineering. The design process is similar but involves circuit design, electrical analysis of the circuit, design of PCBs and/or ICs, and preparation of information for production.

A good schematic modelling package is the basic requirement for the design of electronic circuits. It should provide a component symbol library to suit the company's products. Systems may also provide tools for design rule checking of the circuit as it is created. Additionally, an intelligent schematic database is also necessary to enable automatic generation of data for output.

Systems are available to perform an electronic analysis of the circuit, providing both analogue and digital simulation. Such systems provide the ability to define the electronic inputs, measure and display the outputs, and generate test data. The interfacing of electronic simulation with circuit design is an important part of an integrated system for electronic design.

Systems to assist in the design of PCBs have become increasingly more automated in recent years. The job involves positioning components on the board followed by routing of the tracks. The routing can be a particularly difficult problem, but CAD systems provide automatic routers that are now able to accomplish the task on complex multi-layer boards with nearly 100% success. Other features provided include the facility to perform thermal analysis of the PCB board.

Systems are available to assist in the design of integrated circuits. They enable IC designers to build up masks for IC manufacture by positioning components in the CAD drawing. CAD tools are now essential for IC design, as the number of circuit elements to be interconnected has become so large.

Like mechanical design, the integration of systems for electronic design is also important. The interfacing of circuit schematic systems with systems for simulation enables logic design to be tackled as one integrated process. Figure 5.9 shows an example of such a system. Intelligent databases enable the generation of 'net lists' to assist in the automatic generation of PCBs from circuit diagrams and automatic updating of PCB layouts to reflect changes in the circuit design. The output to manufacturing may include data for silk screening for printing and etching the boards, and NC drilling information.

The implementation of CAD for electronic design is often easier than for mechanical design. Since the design process has developed along with the CAD tools, it is more formalized and thus more easily adapted to automatic processing. As electronic systems have become more sophisticated so have the CAD systems required to design them, and CAD is now an essential tool for many electronic design applications.

Civil and architectural engineering There is some similarity between mechanical design and particular aspects of civil engineering and plant design, and they require similar tools. However, for many areas of civil engineering, specialized CAD features are needed. One significant difference is the way in which the product is modelled. Many civil engineering applications are developed around schematic geometry rather than a true geometric representation of components.

Site engineering involves mapping and modelling the terrain. CAD systems provide a means of modelling the land in three-dimensions, and generating contour maps and cross sections. The ability to visualize the terrain together with the construction is an important feature.

CAD systems for architectural design need to provide effective tools to draw buildings, and to enable the buildings to be accurately visualized. Systems may provide the facility to lay in patterns of bricks and tiles and other decorative features to generate very realistic pictures. As well as providing the tools for design and visualization, it is also important to be able to create traditional architectural drawings, a particular feature of which is the cross sections which use different styles of hatching to show different materials.

The design of structural steelwork is often treated initially as a schematic problem. Structural analysis is important and therefore a link to an appropriate finite element analysis package is necessary. Systems for structural engineering must also enable the generation of materials lists from the schematic models of the structures, manually a difficult and time-consuming task.

Plant design provides the classic example of a 'geometric schematic' system. Systems enable a plant layout to be developed as a three-dimensional schematic, providing symbolic representations of components. These can then be converted to models, providing a high level of visualization such as that shown in Figure 5.6 (Section 5.1.5).

The use of civil engineering CAD applications is widespread. As well as the obvious candidates in the construction and marine engineering industries, many companies in mechanical engineering and manufacturing use the systems for plant design and factory layout.

Mapping itself, although originally regarded as a CAD application is now becoming a more highly specialized application area. The current needs are for the more wide-ranging 'Geographic Information Systems' (GIS), which, as well as providing a mapping capability, also supply a versatile geographical database.

Computer-aided draughting Probably the most widespread use of CAD is in the creation of drawings using computer-aided draughting techniques. Indeed, a very large number of systems are acquired for just this purpose, to provide an 'electronic drawing board'.

Computer-aided draughting systems require a basic capability to create two-dimensional geometry, and provide a set of entities which include points, lines, arcs, circles, conics and free-form curves. A draughting system which is integrated with a three-dimensional modeller must provide the ability to generate two-dimensional views, cross sections and scrap views from the three-dimensional model. The creation of geometry to represent the component is usually the least difficult part of the problem. Having created the geometry, the draughtsman's task is to dimension and annotate the drawing.

One of the most complex tasks is dimensioning. The major problem that most systems face is handling the variety of standards to meet different company requirements. These may include BS (British), ISO (European/International), DIN (German), ANSI (American) and JIS (Japanese), together with variations and restrictions to suit individual companies. Different disciplines also have different dimensioning standards (for example, the dimensioning style of architectural drawings is quite different to that for mechanical components).

Dimensioning often requires 'creativity'. Dimensioning a large drawing of a complex engineering component so that all the dimensions do not excessively overlap is very difficult. Draughtsmen often resort to 'draughting licence'. Thus it can be a difficult task to automate fully.

Drawings often contain as much text as geometry, and many engineering disciplines have symbolic codes which must be incorporated into the text. A drawing is usually presented on a company standard 'form sheet', which also needs to be available to the CAD system. Some computer-aided draughting applications do not require the sophisticated functionality of integrated turnkey systems, and a number of draughting systems are available to run on PC-based computer systems.

5.1.6.3 CAM applications

Computer-aided manufacturing encompasses applications ranging from planning and scheduling to process monitoring and control. In the context of CAD/CAM, however, it is appropriate to restrict this review to those areas of manufacturing which are directly associated with CAD, and in particular those tasks that can be closely integrated with the CAD applications. In this context the most significant CAM applications are those related to 'manufacturing engineering' (see Figure 5.7). The production engineering office is generally responsible for taking information from design, such as drawings and parts lists, and generating the information required for the factory floor. It encompasses the functions of process planning, NC programming and tool design, and is the main interface between design and manufacturing. In an integrated CAD/CAM environment it is important for production engineering to be able to receive information in a computerized form that it is able to use to generate data for the production departments.

Process planning Process planning is the task of determining the production processes required to manufacture a component or a product. Traditionally, it is a task undertaken by engineers with a detailed knowledge of the engineering processes in the factory, and able to determine those that are appropriate for manufacturing the product within the company's capabilities.

Computer-aided process planning (CAPP) offers many advantages over traditional manual methods. It reduces the time and effort that it takes to produce a plan and ensures a greater degree of conformity between planners. CAPP systems have developed along two main directions, variant and generative.

Variant planners are based on the premise that existing plans (or previously prepared partly completed plans for a similar component) can be retrieved and then edited to create new plans. Many variant planners make use of 'group technology' (GT).

GT is the concept of classifying and coding parts according to geometric and other attributes of the component. The value of GT is that, if two parts have the same or similar classification, then they are likely to require a similar manufacturing process. Thus GT can be used to retrieve existing plans for editing. GT also has applications in a design office to avoid repetitious designs.

Generative planners create a new plan from scratch for each component. They make use of a database of processes and rules that a planner would use and, by examining the features of the component and using in-built knowledge, determine the appropriate manufacturing processes for the given component.

Generative process planners require the use of planning knowledge and need to make intelligent decisions in much the same ways as a planner. Thus the development of generative planners is seen as one of the key applications for knowledge engineering and artificial intelligence in manufacturing.

Generative planners enable the process planning task to become more automated, since they can replace most of a planning engineer's task. However, they require the development of computer tools and the use of techniques which are themselves still being researched. The development of feature-based modelling is important to generative planning systems, since generative planners need to understand the component as a set of features rather than as a geometric model.

Computer-aided process planning is a key element in developing computer systems for manufacturing because it captures some of the basic information required for the manufacturing tasks. It can also be a prerequisite to NC programming, one of the key areas for the application of CAD/CAM.

NC programming NC programming is the task of preparing data to drive NC (numerical control) machine tools. The instructions to an NC machine are input in the form of codes which drive the cutting tool and control machine functions. The data are typically provided via eight-track magnetic tape.

Traditionally, NC machines have been programmed directly, the codes being entered into the machine controller. However, the development of NC programming languages such as APT (Automatically Programmed Tools) enabled component geometry to be defined and hence cutting paths in terms of that geometry. NC programming integrated with a CAD/CAM system allows the NC toolpath to be defined with reference to the CAD model geometry.

NC programming systems vary in functionality according to the capability of the machines for which they prepare data. Numerically controlled machines include drills, lathes and machining centres. They may be classed according to the number of axes, or degrees of freedom, in which the cutter may move simultaneously, the most common being 2½-, 3- and 5-axis NC machines.

In 2½-axis NC the cutter may move simultaneously in two axes, typically x and y, but there are positional movements in the z direction. This permits the machining of mainly orthomorphic components (with orthogonal faces, edges and axes) and those with constant angle faces. These make up more than 80% of the components in mechanical engineering.

In 3-axis NC machining in all three coordinate axes allows the machining of complex surfaces as well as orthogonal faces. An example of 3-axis NC programming is shown in Figure 5.10. It can satisfy the machining requirement of many complex components, but may restrict the cutting angle and ease of access for some of the more complex surface shapes.

In 5-axis NC machining in five-axis also permits the machine tool to be rotated, as well as providing all translation movements. It can, for example, maintain a constant cutting angle with the complex surface being machined, a feature which is particularly important in the manufacture of aerofoil shapes and press tools for the automotive industry, where there is a need for a very high-quality finish on complex surface shapes. NC systems for 3- and 5-axis machining usually need to be integrated with a CAD/CAM system which provides a powerful geometric modelling tool to enable the design of complex surfaces.

There are some applications suited to 4-axis machining, especially in the aerospace industry. NC is also used to drive punching machines for sheet metal work and other manufacturing processes.

Most NC systems employ a language that enables the user to create a program of NC machining statements to drive the cutter and perform the operations required, together with an editor to enable the program to be modified or corrected

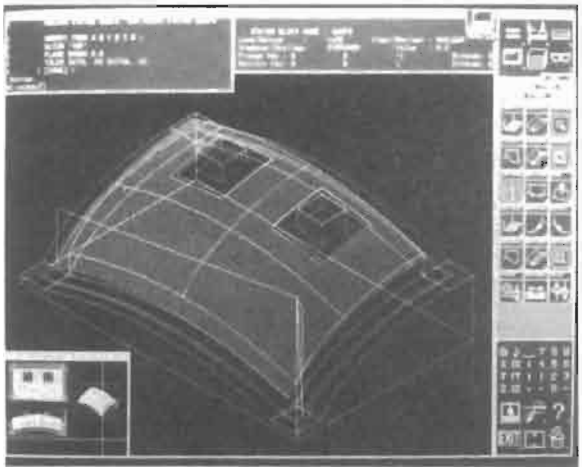

Figure 5.10 An NC 3-axis machining toolpath

easily. Integrated CAD and NC allows references to the CAD data to be included within the program.

Post-processing Individual machine/controller combinations are driven by specific machine codes. NC programming systems often generate a neutral file output, such as a 'cutter location (CL) path', which can then be post-processed to generate the codes appropriate to a particular machine. DNC, mentioned in Section 5.1.3.5, is an important development, enabling a direct link to an NC machine to download the data and eliminate the need for transfer by tape. NC is one of the most widespread of CAM applications. Many products and processes now rely on NC machining techniques to meet design and manufacturing criteria.

Robotics Robots are becoming more widespread in the manufacturing industry. Their use, in conjunction with flexible manufacturing systems (FMS), is one of the key ways in which productivity and performance on the factory floor can be improved.

The programming of a robot is similar in some respects to that of other machine tools. However, because of the complexity of the robot's movements, the ability to simulate them, to handle collision detection, and present a visual check are usually prerequisites for robot programming. Thus robotics systems require high-quality graphics and a considerable amount of computing power.

Robotics offers potential applications for artificial intelligence. It may be used to determine the most efficient movements, given the relatively large number of degrees of freedom in a typical robot. Techniques of 'computer vision' may also be used to help the robot to locate components and check their orientation.

Tooling and specialist applications Tool design tends to be a specialized form of mechanical design. Indeed, for some complex tools there is as much design and analysis effort involved in the tool as in the original component. In addition, there are particular tool design problems which require special application software, of which the following are examples.

The design of moulds requires specialist software to help determine material flow and calculate cooling rates and the allowances for shrinkage of the component. A particularly difficult problem is the determination of the correct shape of the forge tools at the various stages in a forging process, which must be carefully designed to ensure that the component is manufactured correctly.

The flattening of sheet metal components involves calculation of bending allowances which can be applied to a three-dimensional model as it is unfolded. General solutions can only be applied to components which have straight uniform bends. The flattening of complex doubly curved surfaces requires an understanding of the method of production, since uneven deformation is involved.

Many of the tasks in manufacturing engineering require knowledge and experience of the company's production processes. The rules are often empirical in nature, and thus there is much potential for the use of artificial intelligence.

5.1.7 Implementation

A satisfactory implementation of CAD/CAM may be crucial to the future success of a company. CAD/CAM installations need careful planning and management if they are to achieve the desired results.

5.1.7.1 People, methods, organization and the technology

CAD/CAM technology affects three aspects of a company, and each must be addressed during the implementation.

People In many other applications of computer technology the direct involvement of the users with the system is minimal. However, CAD/CAM systems actively involve the users. This is because the systems, although complete in themselves, can only provide a set of tools to do the work, and hence must rely on the users to apply them to the job in hand in an appropriate way.

Methods CAD/CAM frequently results in changes to the company's working methods. Although it often happens that an existing process is merely computerized, in order to reap the benefits of the technology it is sometimes necessary to change entirely the way in which a job is tackled.

Organization The changes as a result of CAD/CAM often embrace several different areas within the organization. The complete integration of these areas may be necessary to enable the company to gain all the advantages of the CAD/CAM installation.

In order for the system to be effective, it frequently relies on the engineering staff who are to use the system becoming fully conversant with it. It also depends upon the company understanding the best way of applying the technology to its product process and exploiting it to advantage.

5.1.7.2 System implementation

The initial implementation of CAD/CAM in a company can be treated as a two-stage process. The first step is the installation and system introduction. This is followed by a period of system tailoring which may involve the development of specialist system features, together with appropriate software enhancements.

Introducing the system When a CAD/CAM system is first introduced into a company it is often important that it is up and running and in productive use as soon as possible. There are three things that must be addressed – the installation itself, the management and administration of the system, and training and support for the users.

Installation Many modern workstation-based CAD/CAM systems can be located in standard design office environments. Although, nowadays, there may not be the need for environmental control (disk drives are usually more sensitive to temperature fluctuation than other devices), it is often beneficial for the system administration if the main units are installed in a purpose-built room.

Careful consideration should be given to the location of workstations. It is usually preferable to install them in the engineering offices close to the users' workplace, so that they can be readily accessed by the users and become well integrated within the office. The move towards desktop systems is of great benefit in this respect.

Systems management In many cases the management and administration of a CAD/CAM system is handled by design office staff who do not have a background in computer systems. Fortunately, much of the day-to-day systems administration can be enacted by well-established procedures, many of which can be automated, thus minimizing the need for specialist personnel.

It is usually beneficial to employ experienced staff, who have some understanding of the operating system, to develop company procedures and provide systems support for the users. Large installations comprising several systems, and a network and communications with a mainframe, usually require staff who are computer literate to operate the systems.

The engineering data which are to be created on the system are a valuable asset to the company and must be properly managed. In particular, careful consideration must be given to the aspects of security and integrity.

Training and support Proper training for the staff is essential if all the benefits of CAD/CAM are to be gained. To exploit its full potential, the system users need to understand its capabilities as well as be able to drive it. A training programme should provide for basic training, following by advanced training and courses in special features appropriate to their work.

The education programme should also include 'awareness training' for managers and other staff who are indirectly affected by the system. CAD/CAM has far-reaching consequences for the company, therefore it is crucial that all staff are kept informed, especially those who are not directly involved with the system.

Tailoring the system CAD/CAM systems provide a standard 'toolkit' for design and engineering offices, and these are sufficient to perform all the basic tasks. However, since all companies have different procedures and standards, the system becomes more efficient if it is further tailored to the specific needs of the organization. There are a number of ways in which this may be achieved.

System parameters Some systems provide versatile commands to allow different standards to be met for tasks such as dimensioning. The setting of system parameters enables the command defaults to be set to meet the company's own standards. In addition, standard company forms should be established for the users as pro formas for their work.

Library components Many applications require a library of components comprising industry standard items supplemented by company-specific parts. The provision of effective component libraries, and frequently used features of components, is essential to save continual re-creation of the same data and ensure that the system is used effectively. The tailoring of the system to automate a particular process or company procedure will usually require the development of special software. There are two levels at which customized software development may be undertaken.

Use of 'macro' languages Many CAD/CAM systems provide specialist languages, often as an integral part of the system, but incorporating additional programming commands for arithmetic, data input/output, etc. These languages enable users to develop procedures to automate processes and provide complete frequently used command sequences with a single command.

Bespoke software development To satisfy specific processing needs will usually involve the development of software using one of the standard programming languages available for the machine. Macro languages are often tailored for ease of use so that, with a little training, engineering staff can develop their own procedures. Bespoke software development would normally be undertaken by experienced computer personnel.

Tailoring the system to improve the performance and increase the productivity of the users is an essential part of the longer-term development plan for a CAD/CAM system. Such tailoring should be coupled with the development of internal procedures and working practices to make the most effective use of the system.

5.1.7.3 Systems integration

As has already been observed, CAD/CAM encompasses a wide range of activities within the design and manufacturing environment, although many systems only address specific areas. The integration of computer systems throughout the engineering departments is the third stage in the implementation of CAD/CAM. The objective should be for all systems to be able to exchange data, and make use of the data created by other applications where appropriate.

For many applications the flow of information is one way, and in some cases a satisfactory system interface can be implemented quite easily. However, CAD/CAM applications often need a two-way communication of geometric data. It may also be necessary for different applications to be able to access the same geometric database. In these instances a totally integrated system is required.

Interfacing of systems A simple level of interface can generally be provided with a suitable piece of software that extracts the required information from one system and delivers it to the application that needs it, preferably in a form suited to the receiver. Updates to the data may be a particular problem, especially if they need to be incremental (usually the case if some further processing has already taken place on the data). To exchange geometric data between different CAD systems a standard for a neutral file format has been established.

International Graphics Exchange Standard (IGES) IGES provides a mechanism for exchanging graphical information by specifying the format of a neutral file.[2] Any CAD system with the ability to read and write data to the neutral format can pass graphics information to another CAD system. One problem is that only a common subset of the two systems can be successfully exchanged. Often it is the intelligent information in the database that is difficult to transfer. Drawings, too, are sometimes difficult because of the different standards for annotation and dimensioning. Pure geometric information can usually be passed successfully.

To overcome the limitations of IGES, and meet the needs of companies for more powerful data-exchange mechanisms, newer standards such as Product Design Exchange Specification (PDES) are being developed.

5.1.8 The future

The future of CAD/CAM will be determined by changes in current technology and in the way in which the changes are applied.

5.1.8.1 Hardware developments

Many CAD/CAM applications are very CPU-intensive, particularly tasks such as solid modelling and engineering analysis. With increased processing power, solid modelling is a practical solution to many design problems and is affordable. Thus many more design applications are likely to be centred around the use of solid modelling.

Declining hardware prices will make it cost effective for companies to move towards fully computerized engineering offices. As costs decrease and companies can provide a workstation for every engineer, all the tasks can be accomplished through a single computing facility. Networking and communications will enable access to the information required for all the tasks of the user.

The quality of graphic displays will have a considerable impact on CAD/CAM since visual representation is fundamental to many applications. The improved resolution will enable more designers to use these displays for studying results, thus eliminating the need for paper-based output. Applications that may particularly benefit are those that involve aesthetic design of shape, such as automotive body design.

The development in data-storage devices will also benefit CAD/CAM. Many applications have a substantial data-handling requirement. The ability to store data more compactly will enable CAD/CAM applications to benefit from large amounts of on-line data. The permanent storage of data is important in many engineering applications and more reliable methods for the archiving of computer-based data will help to eliminate traditional paper-based storage methods.

5.1.8.2 Software techniques

The development of 4GL languages and expert systems will have a significant impact on future CAD/CAM solutions, as will the use of object-oriented programming techniques. Existing applications are continually being enhanced as better mathematical algorithms and improved programming methods are developed to overcome limitations in the software.

The particular benefits of 4GL languages are likely to be felt in the development of specially tailored software. They will provide better tools for customizing software, thus making it easier and quicker to develop solutions for problems that were previously too costly or time consuming.

However, in the long term, the greater impact on CAD/CAM is likely to be through the use of artificial intelligence and knowledge engineering. Much of the work of engineers is based on experience and knowhow acquired through years of practice. Existing systems often only automate the engineering processes, but AI techniques enable knowledge and experience to be captured and retained for future users. Systems which make use of AI will be able to make the decisions that could previously only be made by experienced designers.

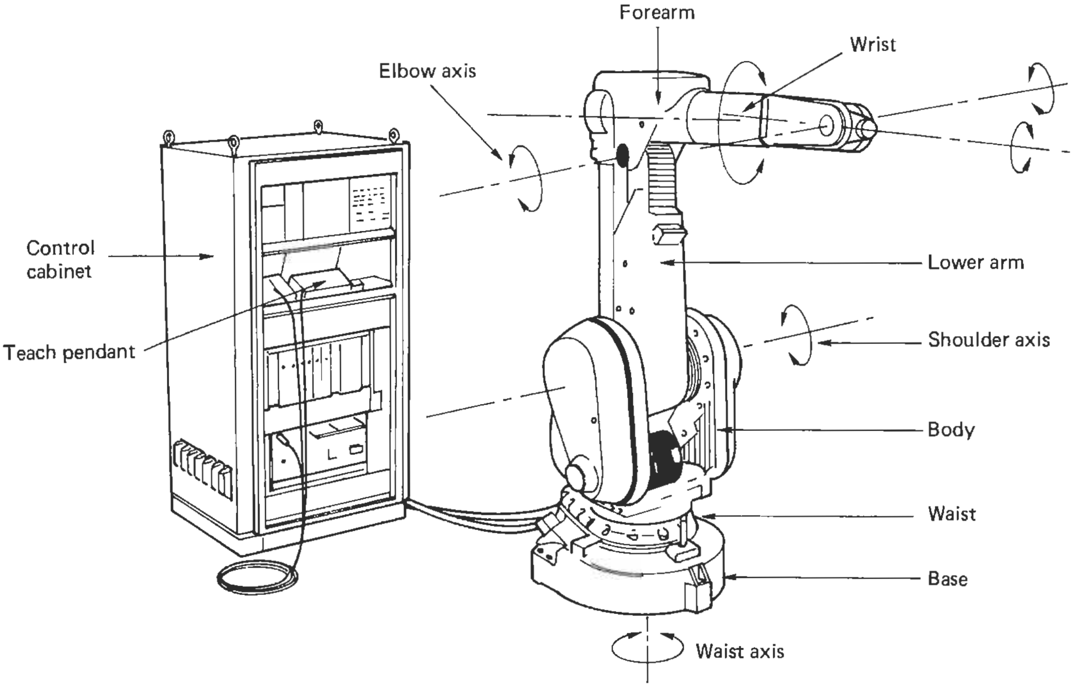

Figure 5.11 ASEA IRB 2000 industrial robot (courtesy ABB)

5.2 Industrial robotics and automation

This section examines the 'robotic' equipment used in manufacturing industry and includes reprogrammable automation equipment. NC machine tools and automated assembly equipment are excluded except where industrial robots are involved. Similarly, 'hard' automation (e.g. cam-controlled mass-production equipment) is omitted. Thus the main subjects of interest will be industrial robotics and artificial vision.

5.2.1 Industrial robotics

5.2.1.1 Definition

It is important, in an industrial context, to have an unambiguous definition of a robot. All the major industrialized countries have adopted definitions with some more complex than others. The British Robot Association definition is succinct and is therefore selected for use here, i.e. 'An industrial robot is a reprogrammable device designed to both manipulate and transport parts, tools or specialized manufacturing implements through variable programmed motions for the performance of specific manufacturing tasks'. Industrial robots are therefore *reprogrammable manipulators* of tools, materials or components. A typical robot is shown in Figure 5.11. They should be easily reprogrammed to carry out work on new tasks and they should have a degree of dexterity. Thus an NC machine tool is not a robot since, although it is easily reprogrammable, it is not designed to do anything other than cut material. Neither is the type of arm used to manipulate radioactive material in the nuclear industry; these devices are constantly under the control of a human operator and are therefore remotely controlled, i.e. they are not programmed to operate autonomously.

5.2.1.2 Reasons for using industrial robots

In modern manufacturing there are many advantages in using robots rather than human labour or hard automation. In relation to human labour:

- Robots work to a constant level of quality.
- Waste, scrap and rework is minimized.
- They can work in areas that are hazardous or unpleasant to humans.
- No jobs are boring, tiring or stressful to robots.
- Continuous 24-hour production is possible for many days.
- They are a single investment; salaries do not have to be paid each year at increasing rates, and there are no burden costs such as pension and insurance schemes, holidays, sick pay, etc.
- Investment in a robot involves a once-only capital expenditure, whereas human labour requires an ongoing salary cost that increases annually.
- Robots are advantageous where strength is required, and in many applications they are also faster than humans.

Also, in relation to special-purpose dedicated equipment, robots are more easily reprogrammed to cope with new products or changes in the design of existing ones. Dedicated equipment usually requires expensive strip-down and rebuild in these situations and often has to be discarded as obsolete.

As well as these obvious reasons there are other, indirect, advantages to be gained from robotization:

- When changing from manual to robotic methods, the product components will often have to be redesigned to provide simplicity of presentation, positive gripping points, unambiguous orientation and location, adoption of the stacking principle for assembly, and ease of location for screws, etc. This usually results in a simplified, better and cheaper design for the product.
- Quality will be improved in many areas as automatic inspection techniques are adopted.
- Design changes can be implemented more quickly and new products introduced efficiently.
- Lead times can be reduced.
- Work in progress can be reduced.
- In comparison to dedicated equipment, smaller batch sizes can be handled and downtime between product changeovers is reduced.

It should be remembered that robots are simply one alternative and that human labour and dedicated special-purpose equipment also have their place in the manufacturing environment. Although much simplified, Figure 5.12 shows the cost-to-volume region in which robots are most attractively employed. Generally, unless there are severe environmental or hazardous conditions, human labour is suitable for low-volume high-variety work. Conversely, for very-high-volume/low-variety work dedicated equipment, or 'hard' automation, is probably the most cost-effective.

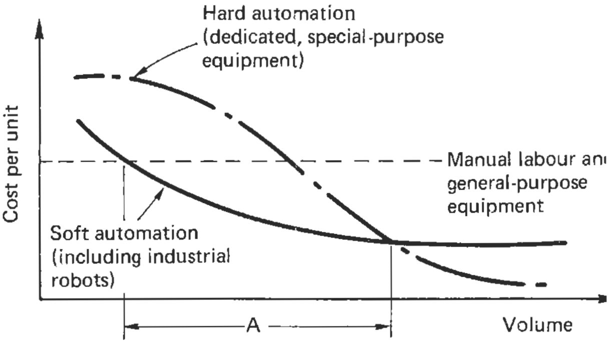

Figure 5.12 Product-volume region 'A' is most suited to robots

5.2.1.3 The construction of industrial robots

Essentially an industrial robot consists of two elements – the manipulator (or 'arm') and the robot controller. The controller contains the microprocessor system and the power control units. Hydraulic and pneumatic robots also have pump and compressor units, respectively. The particular geometry of the arm will provide an associated work envelope; the arm will be powered by electrical, hydraulic or pneumatic means; it will be non-servo or servo controlled; it will be programmed on-line, off-line or both; and will be capable of point-to-point, point-to-point with coordinated path, or continuous path movement. The following is a brief explanation of each of these terms.

The control unit This unit interfaces with the robot's internal and external sensors, drive units, peripheral equipment, and the programmer and operator. It is therefore usually capable of handling serial and parallel data transmission at various rates, and can carry out digital-to-analogue and analogue-to-digital conversion as necessary. Communication with the programmer is via a visual display unit and keyboard, or a teach pendant. There will also be floppy disk drives for loading and saving programs and a printer for hard copy.

Program interpretation will be carried out within the controller. Some robots are capable of using more than one language. In this case the language and operating system is usually loaded from disk at the beginning of the programming session. Within the unit there will be ample memory space to store all necessary data for coordinate transformation, trajectory computation, monitoring and decision making.

The unit will also perform the functions necessary for full servo control. In some robots each axis has its own microprocessor system supervised by a 'master' system. There may also be a system dedicated to handling the sensory data input. Thus in a six-axis robot there may be eight integrated microprocessor systems within the control unit.

Control of the power units is effected by the control unit. In electric-drive robots, low-voltage control signals are sent out to the motor drive amplifiers, one for each axis, to produce power for the motors. Servo control is maintained by monitoring feedback from internal sensors. In fluid power systems, solenoids and servo-valves are also controlled in this way.

Robot geometry The robot arm is composed of links and joints. The joints, also referred to as articulations or kinematic pairs, will normally each have only one degree of freedom. In robots this means that a joint will probably be (1) revolute (i.e. rotation about one axis), (2) prismatic (i.e. linear movement along one axis) or (3) screw (i.e. a combination of linear and rotational movement along one axis with translation defined by the screw pitch and the rotational displacement). Other types of joint with more than one degree of freedom (e.g. a ball joint) are more difficult to control.

The number and relationship of these link and joint arrangements defines the dexterity of the robot arm. There is a maximum number of six degrees of freedom available to any free body in space. For many industrial applications (e.g. arc welding, fettling and spray painting) six degrees of freedom are desirable. With a minimum of six joints it is possible to achieve this. However, the design of the robot must be carefully considered as there will be 'no-go' regions into which the robot arm will not be able to reach due to its physical limitations. Also, even though a robot may have a large number of joints, it may not have the equivalent number of degrees of freedom. For example, an arm with six revolute joints whose axes are all parallel will only have three degrees of freedom.

Usually a robot arm has three major axes providing three degrees of freedom. These axes allow the robot to position its end effector or gripper at any point in space within its work envelope. In addition to the major axes there will also be one, two or three additional axes, normally in the form of a 'wrist' at the extremity of the arm. These will allow the robot to orientate its end effector, which will be fixed to the wrist, about any point in space. As mentioned previously, the number of degrees of freedom required depends on the task to be performed. For example, population of a printed circuit board will only require four degrees of freedom. This operation is essentially a pick-and-place type, with one vertical, two horizontal and one rotational movement for component orientation. However, for arc welding a complex three-dimensional seam (say, at the intersection of two cylinders) a robot with the full six degrees of freedom wil be necessary. This is to ensure that the welding gun is constantly maintained at the correct orientation to the work as welding proceeds. Indeed, this particular task may demand additional axes to be employed by clamping the work on a multi-axis servo-motor controlled worktable whose movements wil be integrated with those of the robot and controlled by the same control unit. Some typical robot configurations and work envelopes are shown in Figure 5.13.

Robot drive and control systems Many of the first industrial robots were hydraulically driven. However, most robots now produced are electrically powered. The previous definition of a robot implies relatively sophisticated control, and this is verified by the fact that nearly all industrial-quality robots are fully servo controlled. Non-servo controlled robots, just on the borderline of the definition between robots and simple pick-and-place units, are usually driven pneumatically. Some very light-duty devices, and often the orientation axes on SCARA robots, use non-servoed stepping motors.

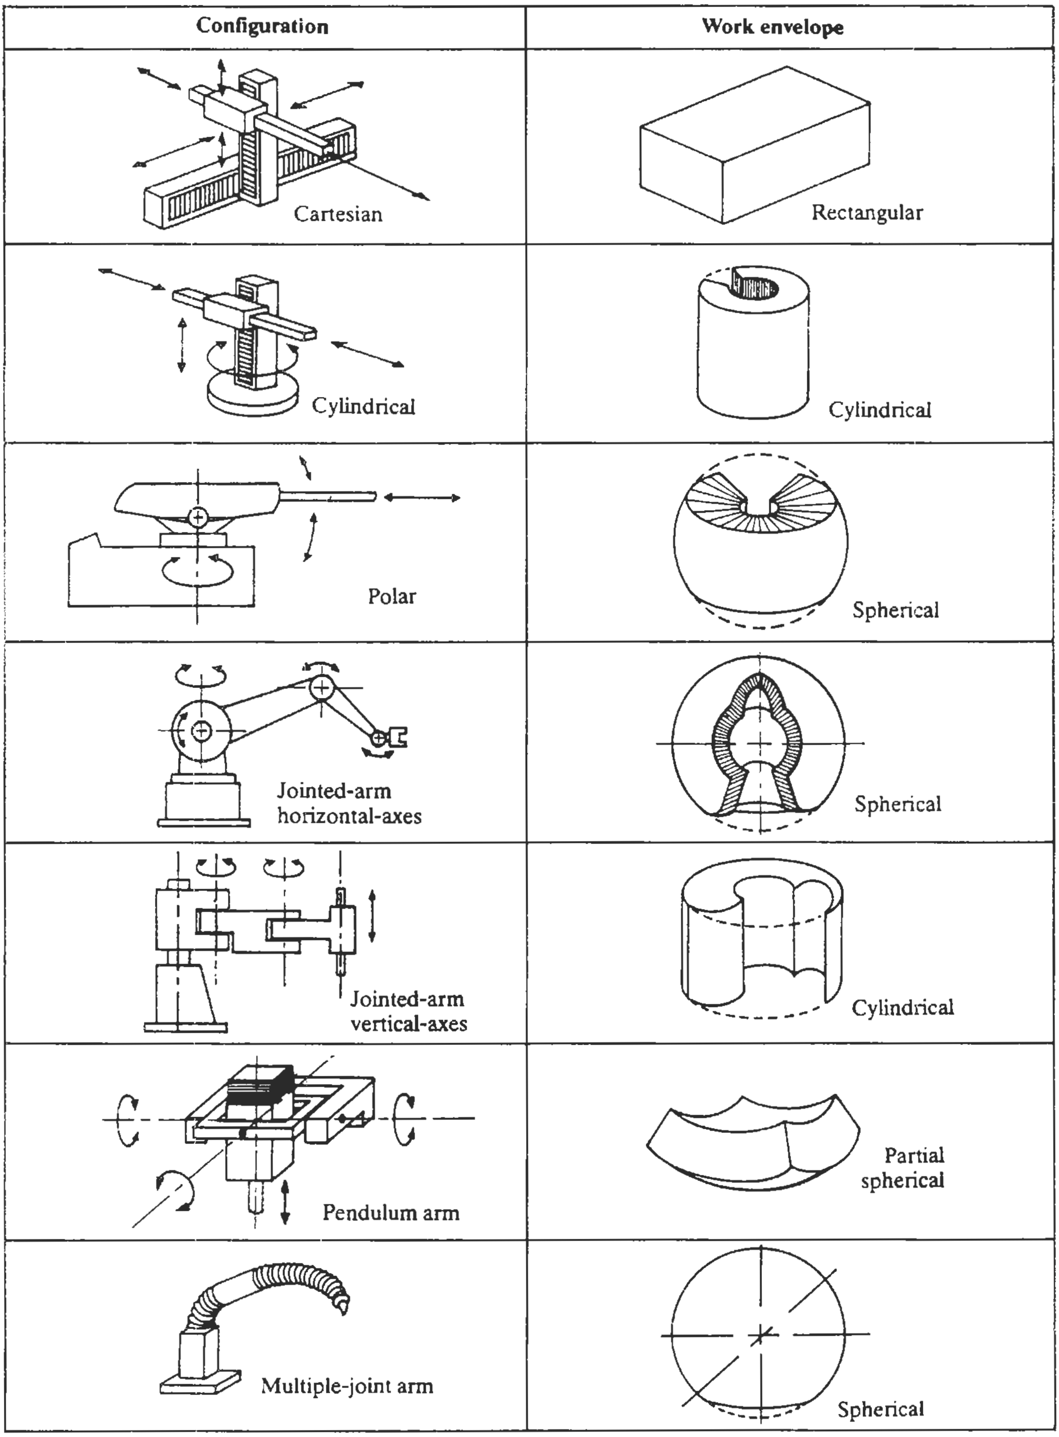
Electric robots are usually driven by d.c. permanent magnet servo motors, brushless motors or, occasionally, stepping motors. Electric-drive systems are relatively clean and quiet when compared to fluid power machines. They are easily maintained and repaired and are well suited to electronic control. Recent developments in the use of rare-earth materials for permanent magnets mean that power-to-size ratios are increasing, and the use of brushless motors reduces maintenance costs. Brushless motor drives can also be used in areas such as clean rooms, since contamination particles are reduced, and in situations where there would previously have been a fire risk due to the possibility of brush arcing. Unless incorporating direct-drive motors, electrically driven robots do have the disadvantage of requiring transmission systems. These add cost and weight, and also reduce precision due to gear backlash and other unwanted movement.

Hydraulically powered robots still have some advantages. For example, they have very good power-to-size ratios and hydraulic force can be applied directly at the desired point without the need of a transmission system. Hydraulic fluid is incompressible and therefore there are no backlash problems. Assuming the power pack, which contains the electrically driven hydraulic pump, is located remotely, then the robot can be used in high fire-risk areas. This is because only very low voltages for control and feedback purposes will be present on the actual robot arm. Because of their necessarily sturdy construction due to the high hydraulic pressures experienced, they can withstand higher shock loads than other robot types. However, it is their disadvantages that have led to their reduction in popularity. A noisy power pack, even when protected by an acoustic muffler, makes them environmentally unattractive. Historically, they have tended to be less reliable than electric robots with leakages occurring which contaminate work areas and cause performance loss. Servo control of hydraulics is not as simple as that for electrics and availability of skilled personnel is more scarce. The viscosity of the hydraulics fluid can be affected by temperature and this can cause variations in performance. Finally, cost is not directly proportional to size. Smaller hydraulic robots tend to be much more expensive than their electric counterparts.

Pneumatic powered robots are the cheapest and least sophisticated type. They are usually not servo controlled but will be able to carry out complex movement sequences if necessary. They are fast, simple, reliable and easily understood by most factory technicians and maintenance personnel. They also have the advantage of being intrinsically safe and can therefore be used in explosive atmospheres. The major disadvantage of pneumatic robots is that precise servo control is not practical. This is due to the compressibility of air, particularly when moving heavier loads. Thus pneumatic robots are usually found in limited-sequence, light-load fixed-speed applications.

5.2.1.4 Path control

The application will influence the choice of the robot path control system. Robots with simple point-to-point control are suitable for assembly, palletizing and other materials-handling



Configuration

tasks. Point-to-point with coordinated path control is suitable for tasks such as arc welding, sealant application and spot welding of moving components (e.g. car bodies on a conveyor system). Continuous path control is used where the dexterous movement of a human operator has to be mimicked (e.g. in spray painting, or where complex contouring movements are necessary).

In point-to-point control the robot will move between defined points without regard to the path taken between them. In some robots an additional software facility allows the choice of movement between points in either the shortest travel time or in a straight line. In revolute robots movement in an 'elbow up' or 'elbow down' mode can also be selected. When using robots with simple PTP control particular care has to be exercised to ensure that collisions with obstacles will be avoided when the robot is running.

In point-to-point with coordinated path the control software allows the path the end effector will follow between points to be determined. Straight lines, circles, arcs and other curves can be defined. Two points are all that is necessary to define a line; circular movement can be programmed by specifying three points on a circumference or a centre point and a radius.

Full continuous path control is most often obtained by playing back the information recorded from physically leading the robot through a desired task. Every movement of the arm is recorded in real time by sampling joint positions at a high frequency, and this is used in on-line programming. Continuous path control is also employed in off-line programming in some systems where there exists the facility to insert the mathematical equations for desired curves. These curves will then be followed by the end effector.

5.2.1.5 Robot programming methods

Industrial robots may be programmed using a number of techniques. The most basic methods, employed in some very early hydraulic robots, used rotating drums on which pegs could be set to close microswitches. These switches operated solenoid valves, so controlling the flow of fluid to the actuators. Adjustable mechanical stops were fixed on the moving members to contact limit switches at appropriate points. These mechanical programming methods provided control of sequence and distance moved. More recently, the use of programmable logic controllers has been applied to sequence the movement of pneumatic robots and modular units. These are all non-servo control systems employing simple feedback from limit switches or proximity sensors.

Full servo controlled robots employ dedicated microprocessor-based controller units as described earlier. This allows sophisticated on- and off-line programming techniques to be employed.

On-line programming Here the robot arm itself is used during the direct programming operation. This method has the following advantages.

1. The robot can be observed as programming progresses; this increases confidence in the finished program since possible collisions and other robot 'no-go' areas will be easily identified.
2. In applications such as spray painting and welding where human experience is important, the direct programming of the arm by an expert effectively produces a transfer of skill from the human to the robot.
3. This type of programming is easy to learn and can often be accomplished by the personnel that the robot is replacing.
4. Less expensive computing hardware and software is involved than in on-line programming.

On-line programming also has one main disadvantage. Where the task being programmed is complex the programming time may be prohibitively long. For example, if a deburring operation is to be carried out and the robot has to be taught the shape of every hole and curve, the programmer will find the exercise extremely tedious and the cost benefits may be trivial. It is therefore a technique suited to tasks which are highly repetitive in nature, i.e. one sequence of movements can be repeated automatically a number of times.

There are basically two methods of on-line programming: teach by lead-through and teach by pendant. It is also possible to program directly from a computer terminal attached to the controller, which is similar in principle to the teach by pendant method.

Off-line programming Off-line programming involves creating the program for a robot task, without the need to be connected physically to the robot or even to be anywhere near its physical presence. In fact, when coupled with simulation techniques, off-line programming can be carried out before deciding on which robot to purchase for a specific application. Some of the advantages of off-line programming are as follows:

1. The robot for which the program is being made can continue working on its old task until ready for the new program. This obviously reduces robot down-time and increases productivity.
2. If the control system and language allows, it is possible to build into the program collision avoidance, error recovery and other contingency routines.
3. Compared to on-line programming, it is easier to make alterations to cope with variations in products and design changes.
4. Off-line programming is suited to full computer integration of a facility. For example, if a robotized computer-controlled machining cell is in operation, then with off-line programming the problems of downloading programmes to the robot at the appropriate times is greatly reduced.

There are also some disadvantages:

1. Real-world contact is lost.
2. More expensive hardware and software is required.
3. More programming skill is needed.
4. Fine adjustments under production conditions on the shopfloor are usually necessary.

Simulation Graphical simulation of the robot and its environment offers many benefits to the industrial engineer and programmer. Figure 5.14 shows an example of a low-cost simulation system display. This particular software, called 'Workspace', runs on a PC. Simulation packages provide the ability to model the robot kinematically and often dynamically to give an animated, real-time, visual representation of how the robot will work under programmed conditions. Three-dfimensional wire frame – sometimes with colour shading or solid modelling – techniques are used.

There are a number of advantages associated with simulation:

1. Simulation allows a prospective robot purchaser to try out various models at relatively little cost before making a decision. Parameters such as work envelope, cycle times and joint configuration limitations can be compared for all the robots held in the library.
2. The immediate robot work area can be simulated and various permutations of machines and operation sequences experimented with before finalizing the layout.

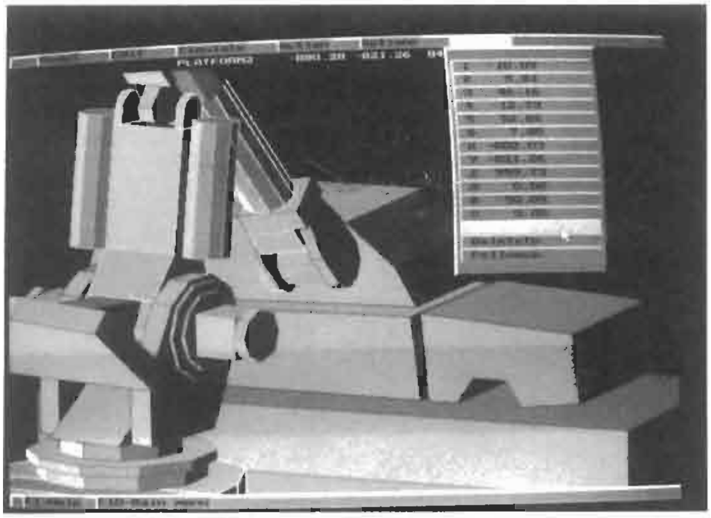

Figure 5.14 Robot simulation on a PC using 'Workspace' as an aid to programming (courtesy Robert Simulations)

3. Potential collisions can be detected at an early stage and programs and layouts modified to suit.
4. Simulation is very suitable for teaching and training purposes. Mistakes in programming can be observed and learned from without the hazards and potential costly damage that would be experienced in the real world.
5. At the robot design stage, simulation delays the need for physical prototypes to be built, thus reducing research and development costs.

These advantages, coupled with improving computing power-to-cost ratios, mean that simulation is becoming an increasingly popular robot-programming tool in industry, education and research.

5.2.1.6 *Using industrial robots*

Suitable applications The potential advantages of robotization can be maximized by making wise application selections. Industrial robots realize their full economic potential in applications where product volume is large enough to recoup the expenditure on hardware, programming and engineering costs, yet is sufficiently low to prevent justification of dedicated special-purpose equipment. However, high-volume work with frequent model or option changes, such as is found in automobile assembly, is suitable for robotization. The effect of robots on the cost per unit, in relation to volume, is shown in Figure 5.15. The following are some further indicators as to applications that should provide suitable opportunities:

1. Tasks which are carried out in (or create) an unpleasant or hazardous environment. For example, toxic or flammable atmospheres are created by processes such as arc welding and spray painting, and removing human operators from these jobs can improve quality and increase production rates.
2. Jobs that are tiring or boring. Robotization of these eliminates absenteeism and labour turnover problems and usually improves quality.

Variety

Figure 5.15 Effect of robots and other reprogrammable automation systems on cost per unit. (From Mair G. M., *Industrial Robotics*, Prentice-Hall, 1988)

3. Repetitive and simple operations requiring simple movements allow the least expensive robots to be used and minimize installation and programming problems.
4. Desired cycle times should not be too short. For example, if the cycle time is greater than, say, 3 seconds then the choice of robot is relatively wide. However, if very short cycle times are required, as in PCB component placement, then more specialized and expensive high-speed robots will be necessary.
5. The tolerances on the components and tools should allow robots of average precision to tackle the work.
6. The variety of products expected to be handled by the robot should not be large nor changes from one product to another too frequent. This will keep engineering and reprogramming costs to a minimum.

The following points are also relevant. If the task being considered has an integral inspection element, then additional costs will be incurred when vision or other sensing methods are added to carry out that inspection. In materials-handling applications very heavy loads will demand larger and more expensive robots. If an ordered environment exists (or can be made to exist) around the robot then robotization is simplified. If possible, work should be oriented and positioned at the previous operation before presentation to the robot. Most robots available commercially have limited reasoning ability, therefore tasks should demand little in the way of intelligence or judgement.

Once the task to be robotized has been selected the next stage is the selection of an appropriate robot.

Selecting the robot Robot selection should be carried out after listing task demands such as cycle time, payload required, necessary precision, and cost. These demands will be compared against the specifications provided by the robot supplier or manufacturer, some of which are now listed.

1. *Speed*. Having decided the speed required of the robot from the work analysis, the detailed specification should now be examined. Some manufacturers may give maximum speeds for each axis of the robot, some the maximum speed of the end effector. These should be given for maximum load and at maximum reach as well as for under optimal conditions. It should be remembered, however, that maximum speed is not necessarily a very useful piece of information, because a robot arm must accelerate to and decelerate from this speed. Figure 5.16 shows a typical robot velocity curve. For some applications, particularly assembly, a 'goalpost' time is a more useful specification. This is the time, supplied by the robot manufacturer, that it should take the robot to complete a standard series of movements carrying a standard load. For example, the movement may be close gripper, move up 30 mm, move across 300 mm, move down 30 mm, open gripper. This will prove more useful for estimating than a maximum speed figure.

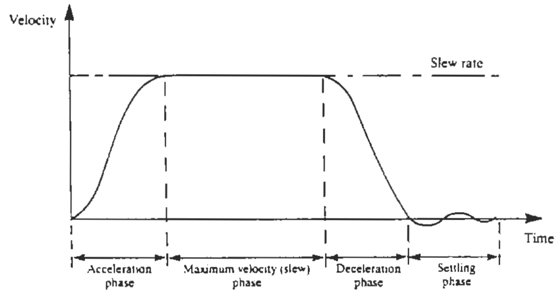

Figure 5.16 Robot velocity curve

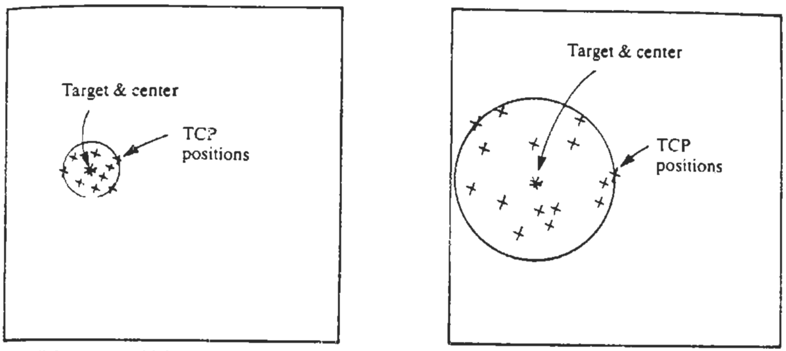
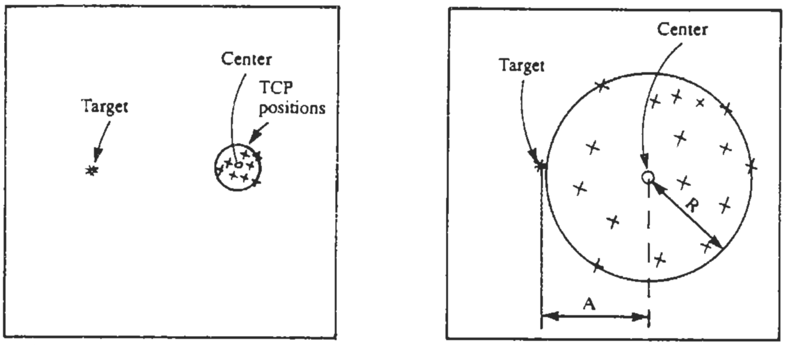
2. *Payload*. The maximum load expected to be encountered will have been determined, and a robot with sufficient strength to handle a considerably greater load should be selected. The specification should show whether the maximum load capacity is given with the arm close to the body or at full extension where the capacity will be much less due to leverage. Robots are available with capacities ranging from a few grams to 2 tonnes.
3. *Precision*. The overall precision of a robot is composed of three elements, i.e. resolution, repeatability, and accuracy. The resolution of a robot is normally a feature that is transparent to the user and is therefore not included in standard specification sheets. It refers to the smallest controlled movement the end effector is capable of making. This is determined by (a) the resolution of the computer controller (i.e. the number of bits used to define a position over a given range), (b) the resolution of the drive system (e.g. the number of steps per revolution provided by a stepper motor and associated gearing) and (c) the resolution of the feedback elements such as shaft encoders. The repeatability of a robot is determined by its resolution plus clearances and wear on moving parts plus any other inaccuracies and errors in the total system. It is a statistical term describing how well the robot can return consistently to a taught point. This is the most common figure relating to precision to be included in robot specification sheets. Repeatabilities of ±1 or 2 mm medium-duty work, ±0.05 to ±0.03 mm for medium assembly, and ±0.01 mm for precision assembly are typical.
4. *Accuracy*. Assume that a computer-controlled robot is to move to a point in space. This point is defined by entering the coordinates into the control system. The difference between the taught target point and the actual position achieved by the robot, in the real world, is the 'accuracy'. This will be determined by the resolution, inaccuracies in the 'model' of the robot held in memory and other factors such as bending or thermal expansion of the robot arm. The relationship between accuracy and repeatability is shown in Figure 5.17.
5. *Configuration*. The supplier will provide information on the geometric configuration and dimensions for the effective work envelope of the robot. These can then be used to construct templates either on card or on computer to enable an appropriate work layout to be designed.
6. *Control system and programming method*. The specification will provide information on whether point-to-point, point-to-point with coordinated path or continuous path control is provided. It will also state the programming methods used. For CP programming by lead-through a slave arm may be available and for PTP or PTP-CP teach by pendant methods may be used. For many robots programming using a computer terminal and a high-level language will also be available.
7. *Cost*. The cost of a complete robot installation can vary considerably from that of the basic robot. The robot chosen can influence this total cost. Ease of programming, and interfacing capabilities will influence the engineering costs. Cost of fixturing, parts presentation and orientation devices, and end-of-arm tooling will have to be included in the total. Also, if working to a fixed budget for the robot, there will probably have to be a trade-off between precision, speed, strength and reach.



(a) High accuracy, high repeatability

(b) High accuracy, low repeatability



(c) Low accuracy, high repeatability

(d) Low accuracy, low repeatability

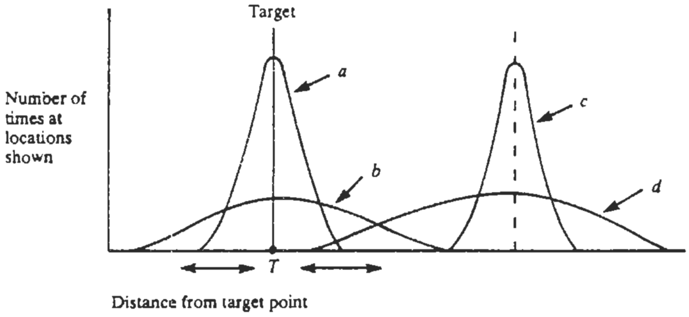


Figure 5.17 Schematic representation of accuracy and repeatability. (From Mair G. M., *Industrial Robotics*, Prentice-Hall, 1988)

Other specifications that should be considered include drive system, number of degrees of freedom, type and number of input and output ports, and memory size.

Robot safety As well as presenting the normal safety problems associated with moving equipment that is electrically, hydraulically or pneumatically powered, and machines that are under microprocessor control, industrial robots present some additional problems that are unique:

1. While executing a program the robot appears to the inexperienced observer to be moving spontaneously and unpredictably, each movement being difficult to anticipate. This applies particularly when the robot is at a 'dwell' point in its work cycle. It may appear to be deactivated but in fact it will spring into action as soon as it receives an appropriate command from the system controller.
2. Most robot arms sweep out a work volume much larger than that occupied by their base. With a six-degree-of-freedom robot the arm movements and positions are therefore difficult to visualize.
3. The integrity of the control system hardware and software is particularly crucial since faults will produce erratic and unpredictable behaviour.
4. Heavy-duty robots are built to be rugged and inelastic, and fast-moving arms are therefore extremely dangerous. Size is not necessarily important as was proved when one person was killed when struck on the back of the neck by a small teaching robot. Accidents can be caused by human

carelessness, insufficient training, poor robot or installation design, poor quality components used in the system, and software errors. Most accidents occur to those familiar with the robot such as programmers, maintenance engineers and operators. Those unfamiliar with robots tend to be more wary – it is the complacency caused by familiarity that is dangerous.

Industrial robot safety should be considered at the stages of robot design, supply, installation, programming and everyday usage. The designer should ensure all controls conform to good ergonomic practice. Controls and displays should obey standard conventions, mushroom-shaped stop buttons should protrude from surfaces and there should only be one start button, which should be recessed. All emergency stops should be hardwired into the power supply and not rely on software execution. Conventional good design practice should be observed, moving parts should not be exposed and there should be no trapping points for limbs or fingers, with no unnecessary protrusions capable of inflicting injury.

The robot supplier should ensure that proper instruction and training is given to appropriate personnel designated by the purchaser. The supplier should also make the user fully aware of the robot's limitations and any possible hazards that may be encountered.

When the user is planning and implementing the installation full consideration should be given to the robot's position within the factory, e.g. it should not be located near any trapping points such as roof pillars or stanchions, and it should not be possible for it to reach into passageways or manual work areas. Preparation of safety manuals, or safe working procedure documentation may also be carried out at this stage. Reference should always be made to appropriate rules, regulations and guidelines. In the UK there is the Health and Safety Executive (HSE) guidance booklet *Industrial Robot Safety*, and the MTTA booklets *Safeguarding Industrial Robots* Parts 1 and 2. There is also the British Standard 5304 Code of Practice – Safeguarding of Machinery which contains the basic principle of safeguarding, i.e. unless a danger point or area is safe by virtue of its position, the machinery should be provided with an appropriate safeguard which eliminates or reduces danger. Light curtains and pressure-sensitive mats are commonly used around the immediate vicinity of the robot. For maximum safety a 2 m high cage around the robot is recommended. This should have doors electrically interlocked to the power supply to ensure that unauthorized entry deactivates the robot.

During everyday operation management must ensure that only fully trained personnel operate the robot. Established safety procedures must be adhered to, appropriate warning signs given high visibility and, generally, a state of continual safety 'awareness' cultivated.

5.2.2 Industrial vision systems

5.2.2.1 Vision system components

The basic elements of an industrial vision system are shown in Figure 5.18. A camera is first necessary to acquire an image. This camera may be a vacuum-tube or a solid-state type, the latter now being the most popular. The signal from the camera is then processed in the vision system computer. The image observed by the camera and the digitized image used for computer processing are observed on a monitor which is switchable between them, or two monitors may be used, one for each image. A means of communicating with the system is necessary and this would take the form of a computer terminal and visual display unit. A means of allowing an automated physical reaction in response to the vision analysis is required.

This demands an interfacing unit connected to a robot or other device (say, a simple pneumatic cylinder for rejecting bad parts). Finally, to ensure optimum viewing conditions special lighting arrangements may be necessary to avoid distracting shadows or glare.

5.2.2.2 Vision system types and operation

Vacuum-tube cameras provide an analogue voltage proportional to the light intensity falling on a photoconductive target electrode. This electrode is scanned by an electron beam and the resulting signal is sampled periodically to obtain a series of discrete time analogue signals. These signals are then used to obtain digital approximations suitable for further processing. For example, if an A/D converter has a sampling capability of 100 ns, the image is scanned at 25 frames per second and each scan is composed of 625 lines, then there will be 640 picture elements, or 'pixels', per line.* Since some time is lost as the electron beam switches off when moving from one line to the next, the number of pixels in a frame will be 625 × 625, which gives a total of almost 400 000 pixels.

This is difficult and expensive to handle computationally in real time, especially if mathematical analysis of the image is to be carried out. For this reason, the number of pixels can be reduced, depending on the application, to provide a more manageable image.

Solid-state cameras use arrays of photosensitive elements mounted on integrated circuits. The light from the scene is focused by the camera lens onto the IC chip. Charge-coupled devices (CCDs) or photodiode arrays are scanned to provide a voltage signal from each light-sensitive element. These solid-state arrays are available in many densities, often from 32 × 32 to 1000 × 1000 pixel arrays. The larger pixel densities are too high for real-time vision analysis but they do provide high-quality video pictures. The voltage signals from the photosites are again digitized before further processing. In a 'line scan' camera linear arrays of photosites are used rather than the area type. Line scan cameras can be used where the object is moving steadily across the field of view. For example, an object passing under the camera on a conveyor belt can be scanned repeatedly and an image built up in the vision system memory.

Recently, solid-state cameras have become widely available and relatively inexpensive due to their large-volume production. They have a number of advantages over the vacuum-tube type, i.e. they are much smaller and lighter, more robust, more reliable, use less power, have a broader temperature operating range at lower temperatures, and are less likely to be damaged by high light intensities.

---

* *Pixel* is derived from '*pic*ture *el*ement' and usually represents the smallest possible display feature or point on the display device.

The pixel voltage signals from the camera are now assigned to a finite number of defined amplitude levels. The number of these 'quantization' levels is the number of 'grey levels' used by the system. An 8-bit converter will allow 256 grey levels to be defined. In practice, this number of levels is often unnecessary and processing time can be reduced by using only 16 grey levels. In some cases only two grey levels, i.e. black and white, are necessary, this is termed 'binary' vision.

Each grey level is next 'encoded', i.e. it is given a digital code, and the data stored in memory. In a computer vision system this is done for one picture 'frame' and the data stored in memory in what is termed a frame buffer or picture or frame store. Various algorithms are then used to minimize the data for analysis and organize them in such a way as to allow feature extraction and object recognition. Objects are usually recognized by the system by first showing it a sample of the object. The system 'remembers' the object by storing information on features such as object area, perimeter length, number of holes, and minimum and maximum radii from the centre of gravity. The sequence of all these processes is shown in Figure 5.19.

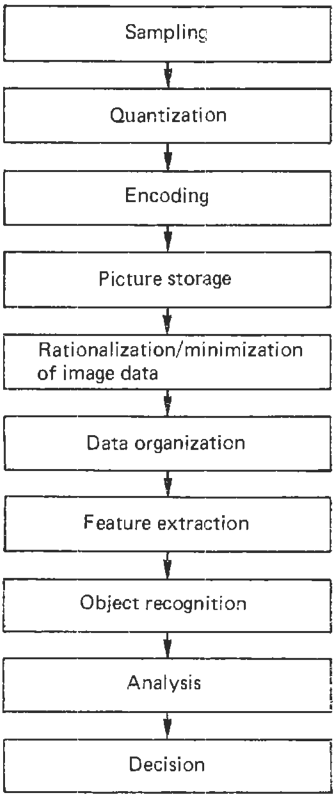

Figure 5.19 Typical operation sequence implemented in a vision system

5.2.2.3 Vision system applications

As the capabilities of vision systems increase so also does their popularity. Custom-designed hardware and developments in algorithms mean that the systems are becoming faster and more reliable. They are now found in a wide variety of industrial applications and are sometimes supplied as integral components or programmable electronic component placement machines and other robotic systems. Three main areas of application are listed below.

Identification Here the system is used to identify a product or individual component. For example, it may involve character recognition, as in reading alphanumeric data on a product label or recognizing a component on a workbench prior to assembly.

Inspection This is one of the major applications of vision systems as it is estimated that visual inspection accounts for around 10% of total manufacturing labour costs. This percentage can be very much higher in some industries (e.g. electronic product manufacturing such as PCBs, computers and other consumer goods). Sensible application choices can prove very cost-effective. Inspection is generally further divided into 'qualitive' and 'quantitive' inspection. In qualitive inspection it is attributes that are examined (e.g. glass bottles may be checked for flaws or castings checked for cracks, or the number of pins on an IC chip verified). In quantitive inspection dimensional or geometric features of a product are measured and checked (e.g. the diameter of a component turned on a lathe or the width of a steel strip coming from a rolling mill).

Decision making This is a general term which implies a number of applications. For example, a vision system could be used to guide the welding head of a robotic welder along the seam of a fabrication, or it could assist an automatic guided vehicle find its way around a factory shopfloor. In conjunction with artificial intelligence techniques vision can be used to provide the information input necessary to provide autonomous working of rotobic devices in unstructured environments.

In conclusion, vision system technology can be said to be rapidly improving and, in conjunction with advances in related technologies, it will continue to make a significant impact on factory automation for many years to come.

5.3 Computer graphics systems

5.3.1 Introduction

Before desk-top or home computers were readily available computer graphics was considered to be an expensive tool for industry, requiring large computing resources and custom interfaces. Some limited graphic representations used line printers or computer terminals but with very low resolution since images were constructed from printable characters.

Early microcomputers with a screen resolution of 256 × 256 pixels made simple line drawings possible. The computation required to process such an image is well within the capability of 8-bit microprocessors and the frame buffer and display hardware is simple and low-cost.

Microcomputers such as the Apple II and the BBC introduced colour and improved resolution to the graphics display so that most programmers could think in terms of presenting output in a graphical manner. Even if the output was a pure text display, then at least these data could be shown formatted with some overall layout in mind. These computers were usually programmed in BASIC which had graphics instructions such as MOVE, PLOT and DRAW added to the language. The graphics procedures were mostly unstructured in that objects were defined in terms of absolute coordinates using straight lines. Only later did graphics primitives appear, so that circles, ellipses and rectangles could be drawn in one instruction.

The basic display was a binary one where each point or pixel could be displayed in either black or white. If colour were used, then pixels would be displayed in black, red, green, blue or combinations of these three colours. Thus eight different colours are possible with such a system. This does not permit completely realistic displays to be constructed but it can allow useful representations of objects to be shown. If a monochrome display is used instead, then the colour information can be employed to generate eight different shades of grey, ranging from black to full white (referred to as the *grey-scale*).

5.3.1.1 Applications of low-resolution systems

There are many uses even for such simple systems. Waveforms, graphs and barcharts can present tabular data in a visual manner. Engineering drawings, architectural plans or printed-circuit board layouts can likewise be shown with sufficient accuracy. Early attempts at computer art successfully used these comparatively low-resolution, colour displays. Lack of a sufficient range of colours or an extended grey-scale was compensated for by the use of 'dithering' or 'hatching' patterns. By these means, a small group of adjacent pixels are integrated by the eye to form a single pixel of another hue. Thus spatial resolution is exchanged for increased colour resolution.

Computer-Aided Design (CAD) usually benefits from a graphics display and most early packages were of the line-drawing type (e.g. PCB design, wire-frame representations of solid objects and building plans). Animated drawings are possible but the computations required for even simple objects limits the maximum rate at which the display can be updated. The computer games repertoire includes aircraft flight simulators but the display cannot be realistic, as only a few wire-frame objects with a limited number of sides are possible.

5.3.1.2 High-resolution systems

Once the market had been established for computer graphics, the demand for higher resolution and more colours required an increase in performance which was even greater than the new 16- and 32-bit microprocessors could provide. The development of new graphics processing software could not completely close the gap in performance. The display hardware and frame buffer architecture had to be changed as well. New graphics processors and display devices began to appear. In this way, interactive and high-resolution graphics displays have been developed where resolutions of 1024 × 1024 are common and 2048 × 2048 displays (or greater) are readily available but expensive.

There is always a price to pay for increased resolution; 256 × 256 binary displays have 65 536 pixels or 8196 bytes for each frame, 1024 × 1024 × 8-bit displays require 1Mbyte of storage. Each pixel in an image must potentially be calculated before the display frame is complete. As resolutions and the number of bits per pixel increase, the processing overhead and the requirements of the display hardware rise exponentially! Whereas 256 × 256 displays require a data rate of only 5 Mbps between the frame buffer and the monitor screen, high-resolution displays have a data rate of well over 100 Mbps so that the physical as well as the electrical design of such systems is no longer trivial.

5.3.1.3 Current applications

The largest usage of computer graphics is in the realm of CAD. Design and drafting tools are available for the production of working drawings. Modelling and simulation tools allow designs to be verified. Using shading and rendering of three-dimensional objects, the visual appearance of objects can be created. For example, stresses in mechanical systems can be calculated and the design altered to keep stresses within certain limits (Figures 5.20 and 5.21).

All the features described above can be obtained before any prototype is built, which saves time and money. The cycle of design, simulation, verification and rectification can be very short – far shorter than could be achieved by building physical prototypes. The number of faults in the new system is much reduced, many systems working first time!

Image Processing is a separate field where real images are processed so that features are enhanced, extracted or modified (Figures 5.22 and 5.23).

5.3.1.4 Interacting with the picture

Input devices are used to define or modify the image (see Section 5.3.3.3). These might directly change the attributes of the image (real-time update) or alternatively, the input device could mark or describe the desired changes which are then implemented when the display is next updated.

5.3.2 Creating a computer graphics image

The essential features required of a computer graphics system are as follows:

1. Hardware to output images to the screen and input devices to control the display. This might be called the *computer graphics system.*
2. A set of commands to generate the image. This is therefore a program and is called the *application*. The interface between the application and the computer graphics system is usually defined by a standard (e.g. GKS*) so that the application level is independent of the hardware which produces the image.
3. A processing device which supports the application. This converts high-level commands from the application into the low-level commands of the computer graphics system. This is usually incorporated into a desktop computer or *workstation* and the graphics may be displayed on the workstation's screen. Alternatively, a separate screen can be used for displaying the final image which is especially useful if very high-resolution images are being created.

These three modules, the *computer graphics system*, the *application* and the *workstation*, are now dealt with in detail.

5.3.3 Computer graphics systems

These are treated in three sections: (1) displays, (2) graphics generation and manipulation and (3) the human–machine interface.

5.3.3.1 Displays

CRT/LCD Most graphics displays are based on the *cathode ray tube* (CRT). A CRT contains an electron beam which is focused onto a phosphor-coated glass screen when light is

---

* Graphics Kernel System.

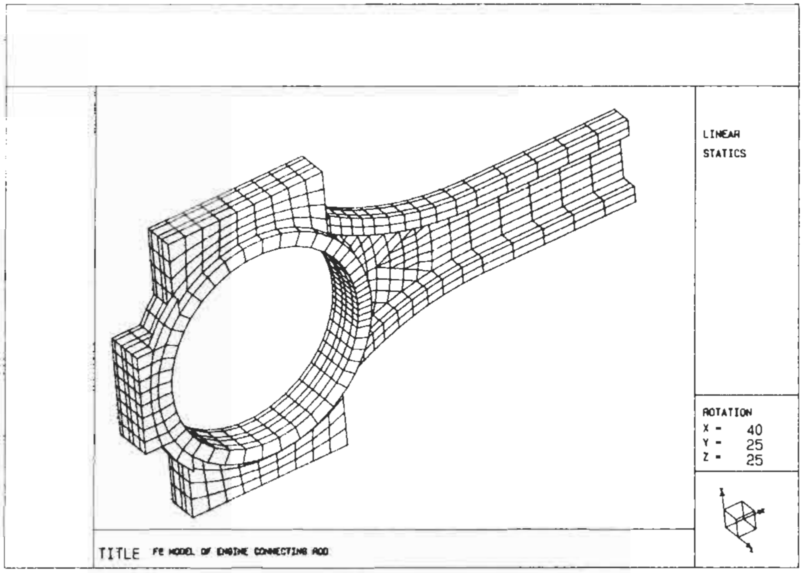

Figure 5.20 Finite-element mesh on connecting rod (Pafec)

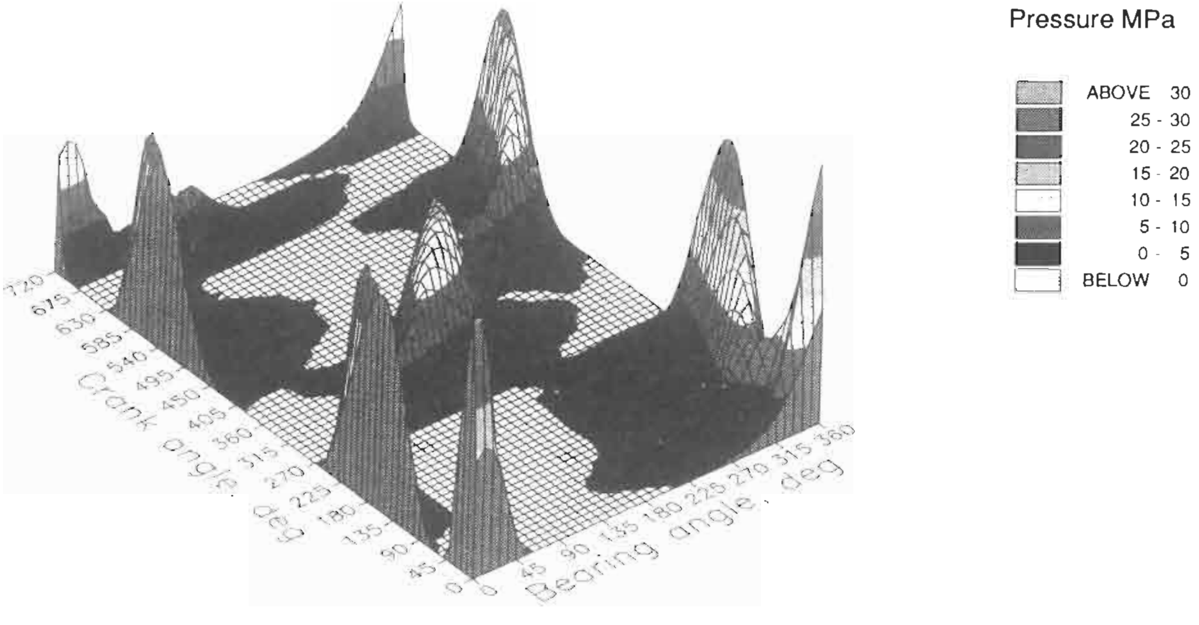

Figure 5.21 Pressure distribution on big-end bearing (Uniras)

emitted. High-quality CRTs allow the spot to be focused down to a very small area which improves the resolution of the device. The *resolution* is the maximum number of points which can be displayed per centimetre in the horizontal or vertical directions. The electron beam must be deflected in order to draw points anywhere on the whole screen surface. For high-resolution systems this requires a fast scan rate and complex deflection systems in order to maintain a linear display, and the video monitor is an expensive item in such systems. The electron beam may be modulated in intensity to give a range of grey tones in a monochrome system or to offer a range of hues in a colour system. The maximum rate of

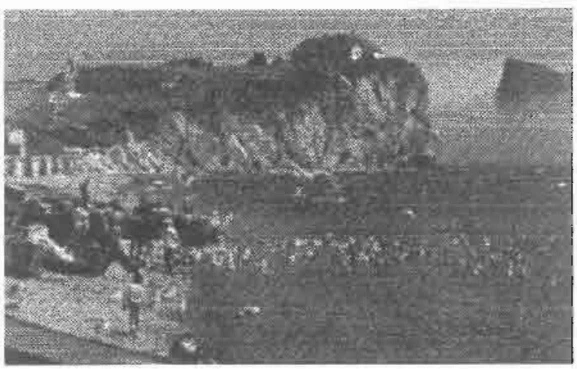

Figure 5.22 Original image

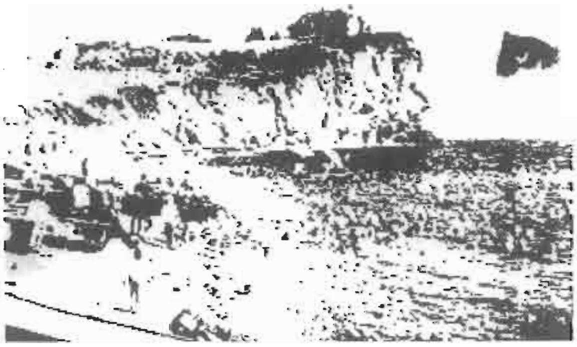

Figure 5.23 Figure 5.22 processed using *threshold* operation

modulation determines the detail which can be displayed in the image and is the *video bandwidth* of the monitor.*

Most displays are now full colour where the screen is coated with phosphor dots or stripes in red, green or blue. However, the shadow mask required in such CRTs limits the ultimate resolution to the *dot pitch* of the phosphor stripes. Monochrome screens are not subject to this limitation, and thus offer improved resolution where the use of colour is not essential.

Vector and raster scan The electron beam in a CRT may be deflected by drawing the image one line or vector at a time. Since each line could be in any direction this is known as a random-scan display. The alternative is to scan the whole area of the screen repeatedly (raster-scan) and to modulate the intensity of the beam such that an image is shown only at the desired points on the screen. While vector scan displays are capable of higher resolution, the refresh rate is dependent on the number of vectors, and this becomes a limitation where there are a large number of vectors to draw. Raster-scan displays have a fixed screen refresh rate of between 25 and 80 frames per second and this is independent of the complexity of the image.

An alternative form of display uses plasma-panel or liquid-crystal (LCD) technologies. Here, transparent electrodes are deposited onto a glass screen. By placing a voltage across the electrodes the plasma may be made to glow (plasma-panel) or the cell may become opaque (LCD). In this way, pixels may be displayed to form the image. Resolutions exceeding 1024 × 1024 are possible.

Hard copy The displays above do not give a permanent representation of the image. Hard-copy devices produce an image on paper or film.

Printers Although printers usually print text they can generally be used to produce a low-resolution image. For example, the head of a dot-matrix printer can print dots in a regular array. Since this is similar to the arrangement of an image split into individual pixels, images can be produced. However, all dots are printed with the same intensity, and so this technique is only suitable for line drawings. An attempt at shading can be produced by grouping pixels or by using dithering techniques, although at the expense of resolution. Standard dot-matrix printers can offer a graphics resolution of about 60 dots per inch (dpi) or with interpolation requiring multiple passes this may be doubled. Twenty-four-pin dot-matrix printers allow a resolution of over 200 dpi with ink-jet printers and laser printers starting at 300 dpi as standard. These are usually monochrome displays. It is possible to use colour ink-jet or laser printers to produce colour displays.

Plotters Plotters produce an image by moving a pen over the paper and constructing the image as a series of vectors. Some plotters, for convenience, move the pen across the paper width (in one direction) and then move the paper itself under the pen in the orthogonal direction in order to draw the vectors. In this way, very large plots can be drawn. A plotter does not have to use ink; photoplotters use light-pens of varying widths which print onto photographic film contained in a light-proof box. This allows photographic masters (either negative or positive) to be produced. This technique is often used in the production of printed circuit board (PCB) artwork.

5.3.3.2 Graphics generation and manipulation

Frame buffer architecture The frame buffer for a vector-scan system is a display-list of the vectors required to form the image. A raster-scan frame buffer typically requires more memory since the intensity of each pixel on the screen needs to be defined and this could require up to 24 bits per pixel. For a 1024 × 1024 pixel display, this equates to 3 Mbytes of frame buffer! The data in the frame buffer are also accessed at very high speeds (10 ns per pixel in high-resolution systems). One technique for giving this performance is to use dual-port memory (or video RAM) where a random-access port allows the display to be updated and a fast serial access port is used to transfer data to the screen. Other techniques using FIFOs and Shift Registers are employed to achieve the desired performance.

Frame grabbers Not all images can be described by simple mathematical functions. Real images need to be displayed and processed sometimes with computer graphics superimposed. To acquire a real image, a camera is used. The camera signal is captured and digitized using a frame grabber. This allows single frames or a succession of frames to be transferred to the computer's memory as blocks of data. These can be manipulated and incorporated in the output image.

Scanners and digitizers Instead of using a camera, as in a frame grabber, documents may be scanned at high resolution and converted into a bit-mapped image suitable for further processing. A digitizing tablet is used to extract information from existing documents rather than merely to scan the whole image and so this requires a human operator. The pointer (usually a cross-hair device) selects the major features of the document and the coordinates of these points are transferred to the processing system where the image feature may be reconstructed.

---

* This is the combination of the bandwidth limitation of the driving electronics and the CRT bandwidth.

Drawing The drawing operation takes the image parameters and converts them into a set of pixels in the frame buffer which define the display. The frame buffer contents are then a map of what is seen on the output device and this is therefore a bit-map or pixel-map of the image.

Converting the image parameters into pixels is not always simple. The change from a continuous function such as a straight line to a discretized version (pixels on a screen) can create unusual effects which are discussed in Section 5.3.4.2.

Graphics processors Processing graphical data requires considerable processing power. If this processing is performed in software then the range of processing operations is large, limited only by the ability of the programmer. The more computing-intensive the operation, the more the throughput suffers, in terms of frames processed per second. One way of alleviating the problem is to perform some processing operations using dedicated hardware. Such devices include convolvers for filtering and masking images and SIMD or MIMD devices for post-processing images. Parallel-processing techniques are used to increase the speed of these computing-intensive operations. In addition to the architectures mentioned above, the transputer is often used for graphics applications.

Colour look-up tables (palettes) If a display were to offer a realistic range of colours then the information that would need to be stored would require a very large frame buffer. Fortunately, not all colours need to be available at once in a given image. For example, a programmer may select 64 out of 4096 possible colours. This implies that while the system is capable of representing 4096 *physical* colours, only 64 *logical* colours are used. A means of mapping the logical colours to the physical colours is provided by the Colour Look-up Table (CLUT) or Palette. Thus the programmer writes the Palette once per image and can then refer to physical colours using one of the 64 logical colour numbers. These logical numbers may be re-used for another image to represent other colours by rewriting the Palette. In a similar way, monochrome images can be given a *false-colour* rendering by assigning colours (using the Palette) to each intensity level.

5.3.3.3 *Human–machine interface*

Input devices In order to define a graphical display, two main methods exist. The first describes the desired display using some form of 'language'. This is a *text-based* system where each element on the screen and its position is described by a set of alphanumeric commands entered using a *keyboard*. To modify the display, a text file is edited or special editing commands are issued and the screen is recompiled.

The second method uses *schematic entry*, where the user directly manipulates the screen interactively by using a *pointing device* to select the position on the screen where drawing or editing operations are to take place. This is more akin to drawing with pencil and paper and thus is preferred by most users. It is also essential for computer art, where the image cannot be easily described textually.

For formal graphics (e.g. electronic circuit diagrams) where the number of symbols to be drawn is limited and conventions are defined, either textual entry or schematic capture methods can be used. Experienced users will often prefer textual entry, being a faster method (especially for repetitive features) and in which error checking is simplified. This method only requires the use of a keyboard for data entry. Inexperienced users tend to prefer a direct representation where they can see what they are drawing. If a hard-copy output is required, this is often the only suitable technique. For schematic entry systems a pointer device is required to enter coordinates to the system and such devices are described below. Pointer devices are often used in conjunction with a keyboard in order to enter data by the most efficient means for greater productivity. However, they may sometimes be used alone.

Mouse, tracker ball, cursor key and joystick These are devices capable of passing orthogonally related coordinates to the application. All except the cursor keys are able to enter two coordinates simultaneously. Cursor keys are usually part of the keyboard assembly and are the slowest of the above devices to use. The amount that the coordinate is incremented for each depression of the key is usually variable to give coarse and fine positioning of the desired point.

A mouse device contains a small ball which is moved across the surface of a desk. The movement of the ball is detected optically or mechanically and is converted to digital pulses, the number and rate of which determine the distance to move and the rate of movement. The mouse often contains switches so that the terminal position can be marked. In this way, the mouse can be driven 'single-handed'. Using a mouse requires a free area of around 300 × 300 mm.

To overcome this restriction, the tracker ball inverts the mouse so that the ball is moved directly by hand. The body of the tracker ball does not move but the ball may be freely moved in any direction without limit. Again, switches may be fitted to make a self-contained input device.

A joystick operates in a similar way to the tracker ball except that movement of the joystick arm is limited to a few centimetres either side of a central position. The joystick may be biased to return to the central position when pressure is removed. Because of the limitation of movement of the joystick, it is more useful where absolute positioning is required, whereas the mouse or tracker ball indicate a relative position. However, using velocity sensing for the joystick, this limitation may be overcome.

Graphics tablet The graphics tablet represents a drawing area where information is transferred to the application. The tablet has sensors embedded in its surface which detect the position of a stylus. These sensors are often arranged in a matrix. When used with a stylus, data are entered free-hand in much the same way as a user would sketch a design using pencil and paper. The stylus may have a switch in the tip so that pressing the stylus indicates a selection. When existing drawings are to be digitized, these are attached to the tablet and reference points on the drawing are converted to coordinates using a cross-hair device and switch. The application can then use the reference points to recreate the drawing. When used in this way, the graphics tablet is more commonly known as a digitizer. The graphics tablet area may also have a reserved space around its perimeter which is not used for drawing, but which is divided into small areas used for the selection of parameters.

Light-pen and touch screen These operate in a similar way to the graphics tablet, except that the monitor screen is used. The light-pen detects the light generated when the CRT electron beam strikes the phosphor coating and the position of the pen is determined from the timing of the electrical pulse generated. A touch screen may have sensors arranged around the perimeter of the screen which detect when a light beam is broken by the pointing finger. Other forms of touch screen exist (for example, two transparent panels with electrically conducting surfaces will make contact when light pressure is applied at a point).

The disadvantage of these forms of input is that the screen is obscured. The chief advantage is that the choice of items to select is infinitely variable. However, the resolution of these systems is limited; a touch screen to the area of a finger tip and a light-pen by the problem of focusing or refraction since the CRT faceplate is quite thick and light from a number of adjacent pixels can trigger the light-pen.

5.3.4 Applications

At the applications level, graphics instructions from a display list or one of the input devices are interpreted so that an image is drawn on an output device.

5.3.4.1 World, normalized and device coordinates

Most graphics systems use the Cartesian coordinate system. A single coordinate system is not usually possible since the graphics representation and the image it represents differ in scale and reference frame. Thus three coordinate systems are commonly used. *World* coordinates are those specified by the user. If the image represents a real object, then the world coordinates might be a set of physical coordinates describing the real-world object. For convenience and ease of processing, world coordinates are usually converted into *normalized* coordinates which have a range of values from 0 to 1 and are real numbers. This system allows processing operations to proceed without having to worry about arithmetic overflows where numbers grow too large to be represented by 32 bits, for example. Physical devices require the normalized coordinates to be mapped to a set of *device* coordinates. In this way, a number of output devices can be driven from the same application but with a particular set of mappings from normalized to device coordinates for each device. If the output device has different resolutions along each axis, then the scaling factor will alter with the resolution.

The use of these coordinate systems is important when the image is transformed by rotation, zooming or clipping (see Sections 5.3.4.4 and 5.3.4.5).

5.3.4.2 Output primitives

Line drawing This requires converting each point along the line into a pixel coordinate which must then be written into the frame buffer for display. For example, a diagonal line is represented by a set of pixels which are in fixed positions on the pixel matrix. In most cases the result is adequate (Figure 5.24) using an algorithm which calculates the pixel position by simple integer division. However, for a line which is close to the vertical or horizontal axis, this algorithm does not give acceptable results. A better algorithm is required which calculates the *nearest* pixel to the ideal line so that even steps are produced (Figure 5.25). Such an algorithm was proposed by Bresenham (see Appendix) which has the advantage of only requiring addition operations in order to plot the line after a few initial calculations have been performed (Figure 5.26).

Circle drawing The advantage of circle drawing is its symmetry. Once one x,y pair has been calculated, then eight points on the circle can be defined (Figure 5.27). Calculating the plotted points using equal increments along the x axis is unsatisfactory as shown in Figure 5.28. Better results are obtained when points are plotted at equal angular rotations. However, the calculation involves evaluating a *sine* and *cosine* function; trigonometric functions use a lot of CPU time. Some means of reducing the number of trigonometric functions which need to be evaluated is desirable.

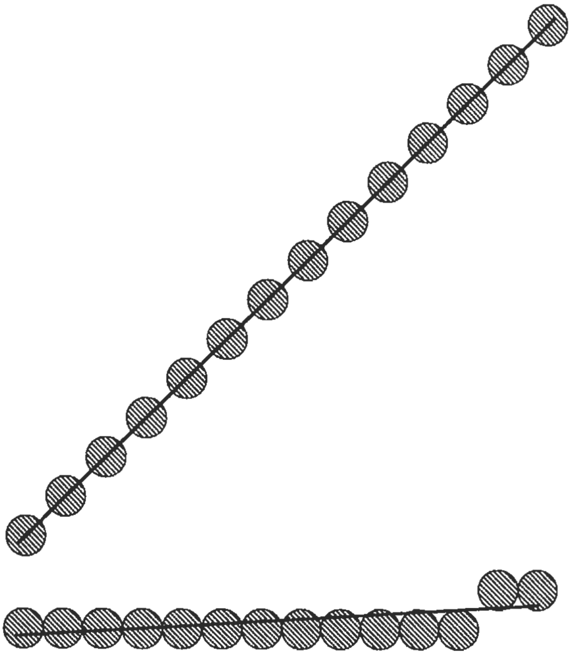

Figure 5.24 Pixels plotting using integer division

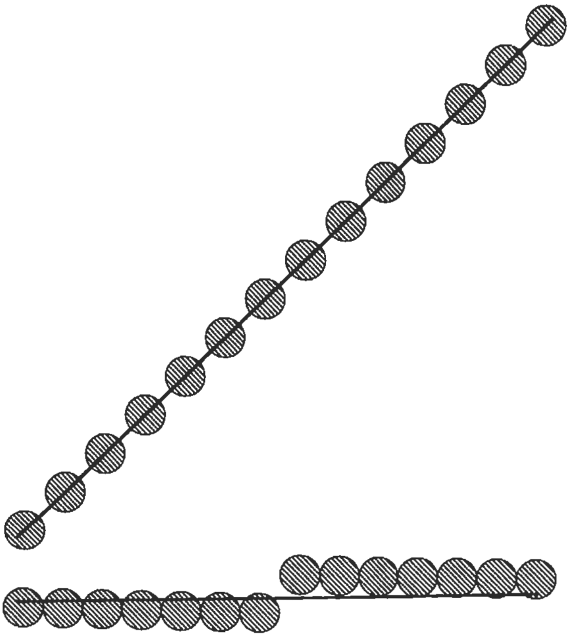

Figure 5.25 Pixels plotted using *nearest-pixel* algorithm

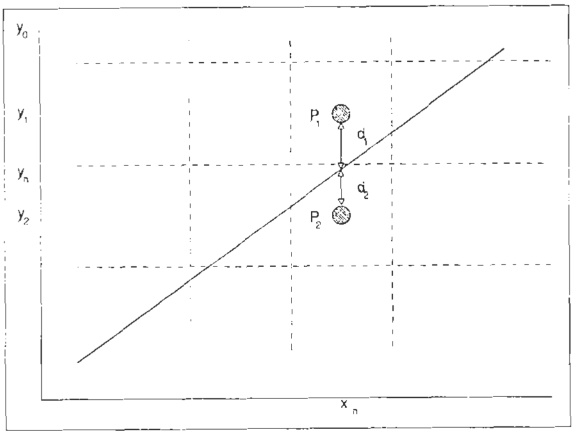

Figure 5.26 Bresenham's line-drawing algorithm

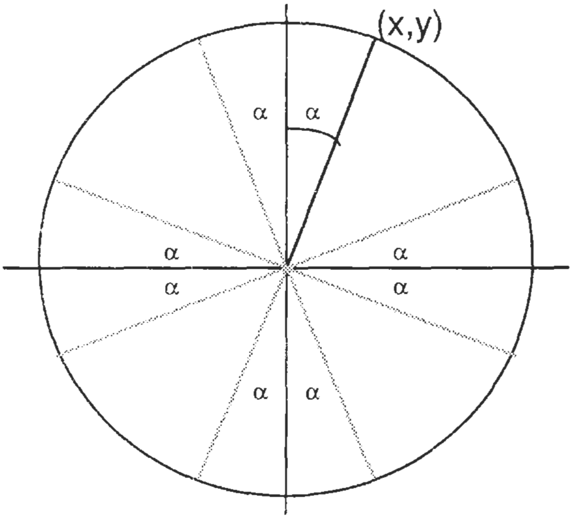

Figure 5.27 Using the circle's symmetry, eight points can be plotted for each (*x*,*y*) coordinate pair

Polygon method If the circle is drawn as a polygon, then only a few calculations are required to determine the vertices after which a straight-line algorithm is used to join the vertices.

Use is made of the following relationships:

$$\sin(A + B) = \sin(A)\cos(B) + \cos(A)\sin(B)$$

$$\sin(A - B) = \sin(A)\cos(B) - \cos(A)\sin(B)$$

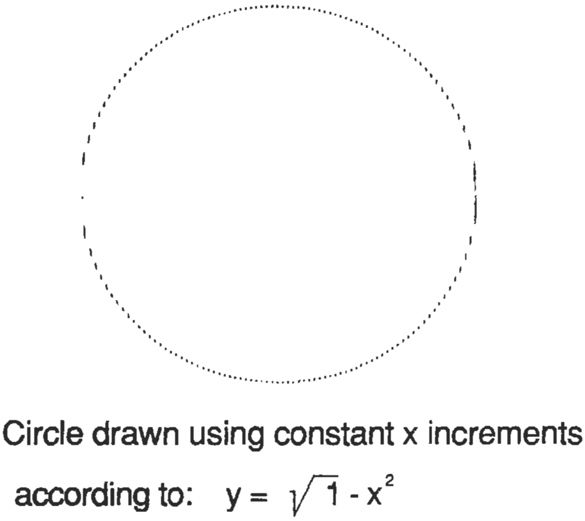
$$\cos(A + B) = \cos(A)\cos(B) - \sin(A)\sin(B)$$

$$\cos(A - B) = \cos(A)\cos(B) + \sin(A)\sin(B)$$

For this polygon, the 'radius' is incremented by $2\pi/n$ radians for each of the n vertices. If the angle A represents the current vertex, then the next vertex is found at an angle of $A + 2\pi/n$. Instead of calculating the sine and cosine of this new angle, the previous values of sine and cosine are incremented according to the expressions above. Thus:

$$\sin(A + 2\pi/n) = \sin(A)\cos(2\pi/n) + \cos(A)\sin(2\pi/n)$$

$$\cos(A + 2\pi/n) = \cos(A)\cos(2\pi/n) - \sin(A)\sin(2\pi/n)$$



Circle drawn using constant x increments
according to: $y = \sqrt{1 - x^2}$

Figure 5.28 Circle plotted using equal increments along the *x*-axis

Now sin(A) and cos(A) become the new sine and cosine values which will be updated for the next vertex. The two multiplication operations and one addition operation per function considerably reduce the computation required since $\cos(2\pi/n)$ and $\sin(2\pi/n)$ only need to be calculated once. The initial sine and cosine values can be selected to be '0' and '1' if a full circle is to be drawn. Only the first $2\pi/8$ radians need to be calculated as shown above if one takes advantage of the circle's symmetry. This method is prone to cumulative errors, but if these are less than half a pixel in total, then the method is satisfactory.

Other curves Functions in which the gradient is predictable or always less than unity (e.g. a circle) can always be plotted by incrementing in unit steps along one axis and calculating the other coordinate. Complex curves may require the computation of the inverse function especially when the gradient is large, if gaps in the curve are to be avoided. This is computationally expensive. Curve-fitting techniques and straight-line approximations (e.g. polygon methods) considerably reduce the computation required if the resulting accuracy is acceptable.

Characters Most applications require text to be displayed. The most common form of manipulating text is to hold *bit-mapped fonts* in memory, individual characters of which are copied to the screen at the desired position. These characters may be rotated in increments of 90° by manipulating the matrix to allow vertical or inverted text. Different font sizes may be produced by scaling the matrix although this only gives acceptable results for a small range of font sizes. A better solution is to hold each font in a variety of font sizes.

The above techniques only permit text to be aligned to one of the axes. For text to be produced at any angle or orientation, matrix transformations are possible but do not give good results. Using a *stroked font* where characters are represented by a small number of curves (or strokes) means that the character definitions are independent of angle and also the displayed size.

Most applications allow the user to define custom characters or symbols. In this way, fonts containing other than Roman characters may be used.

Move and copy Defined areas of the image can be quickly and easily *copied* using BitBlt operations, thus avoiding repetition of previous calculations. This method is commonly used to enter text from the font table to the display. However, not all parts of the image can be so simply copied since overlapping blocks may be present. In this case the block will have to be recalculated and redrawn at the new coordinates. *Move* operations require the steps above and, in addition, the original block must be erased by recalculating and subtracting from the frame buffer. Alternatively, to erase the image, a rectangular area enclosing the image could be set to the background colour (thus erasing overlapping blocks within the area) and then any blocks partly defined in the area are redrawn with windowing applied to reconstitute the image. The options available in move and copy operations are discussed in Section 5.3.4.3.

Area-fill If the shape of filled area is known, then the operation employs a polygon-drawing algorithm using a plot colour or pattern. When a pre-drawn area is to be filled, the shape of the area may not be known so a *flood-fill* algorithm is required. To fill such an area with a colour or pattern, a closed area is essential and a seed point within that area must be supplied from which the fill will be determined. The fill operation will set the pixels one row at a time within the desired area until a boundary is reached. For example, boundary may be defined as a foreground colour or the background colour. Fill operations on areas containing patterns give uncertain results if the pattern contains the boundary colour. Most fill algorithms are recursive so that complex areas may be filled. In such cases, the fill routine keeps a list of start points for each line of pixels which are to be filled. When it meets a boundary, it returns to the seed point and looks in other directions where the fill might proceed.

Narrow areas of one or two pixels in width might prematurely terminate a fill operation. Since the fill proceeds one row at a time, the narrow section might become blocked and appear to be a vertex of the enclosed area, thus terminating the fill. Section 5.3.4.3 describes some of the attributes of fill operations.

Aliasing Since pixels can only be drawn on a finite matrix, continuous functions, when displayed, appear to have edges which do not exist. This artifact is called *aliasing* and its effect is to give diagonal lines a jagged appearance. In order to reduce this effect, various means of anti-aliasing are employed. If data in the frame buffer are processed to search for edges some will be found to be true edges (i.e. exist in the real image) and can be ignored. Where aliasing is found to occur the intensity of these and adjacent pixels can be modified to mask the edge. A form of Bresenham's line algorithm may be used to detect the relative position of a pixel from the true line and the intensity is then set in inverse proportion.

Hardware techniques exist to reduce the 'jaggies' which include pixel phasing and convolution operations.

Grids A deliberate form of aliasing is used where the application demands that all points be plotted on a grid or in an orthogonal-only mode. For example, all pixel positions calculated by the application or entered by an input device which fall within predefined areas are converted to the same pixel position – that is, the centre of the defined area. The defined areas depend on the grid spacing, which may be altered.

In an orthogonal-only mode, one coordinate from the previously displayed point is fixed and only the other coordinate is free to change (usually constrained to a grid).

5.3.4.3 *Attributes of output primitives*

Attributes may be defined for drawing operations which affect line styles, colour and intensity. Line-style options include the line width and pattern. The pattern may be a hatching pattern in one colour or a pattern using a number of colours. The pattern will typically repeat every 8 or 16 pixels and may be considered to be 'tiled' across the whole display. Only where the line coincides with the tiled pattern are those pixels plotted as part of the image. The most common line style is *solid*.

Note that some attributes are not relevant or possible for certain display devices. While the intensity of a line can be varied for display on a CRT monitor, the same image will lose intensity information when plotted on a monochrome laser printer, for example. Referring to attributes individually, they are called *unbundled*. When used in this way, the application might require modification acccording to the display device used. Similarly, colour information will not remain constant when different displays are used, even for devices capable of using colour. As an example, a CRT display normally draws in white on a black background whereas a colour plotter would draw in black on white paper; both would display a red line in red. Thus attribute tables are often used which define the foreground and background colours to be used when the image is displayed on a CRT, to give one example. A whole set of attributes may be defined for each display device, or even for similar devices by different manufacturers. When arranged in this fashion, they are given the name *bundled attributes*. Similar attributes are available to control fill styles.

When a block is moved or copied this may be combined with a logical operation. For example, the source block may be ANDed, ORed or Exclusive-ORed with destination and addition or subtraction operations may be set as attributes.

5.3.4.4 *Two-dimensional transformations*

Translation This is a movement of a graphics object in a straight line (Figure 5.29). If the distance (dx, dy) is added to each point in the object then the object will be translated

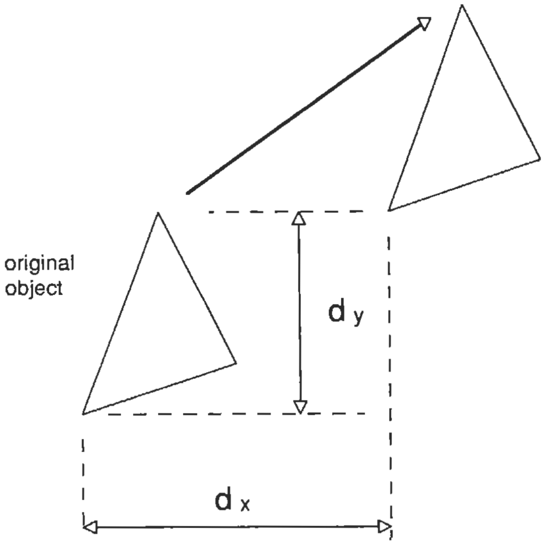


Figure 5.29 Linear translation of an object

linearly when redrawn. This is acceptable for lines or polygons (which can be represented as a set of lines). For circles and arbitrary curves, the offset is applied to the reference point (e.g. the centre of the circle) and the object redrawn.

Note that when an object is complex the redrawing of translated objects can be quite slow. In an interactive mode this can be a drawback. Hence some applications do not update the display completely except on request. This possibly leaves some extraneous pixels set in the display but which are cleared on the next display refresh operation. If BitBlt operations are not possible (due to overlapping objects, for example) then some applications calculate a bounding box and a few reference marks on its edge in order to temporarily describe the object. This *outline* image can be moved interactively at high speed and the object is only fully redrawn when the destination is fixed.

Scaling requires all relative distances of points within an object to be multiplied by a factor (Figure 5.30). This factor is usually the same for horizontal and vertical directions to retain the proportions of the original object. If the scaling factor differs in each direction, then the object will appear to be stretched or compressed.

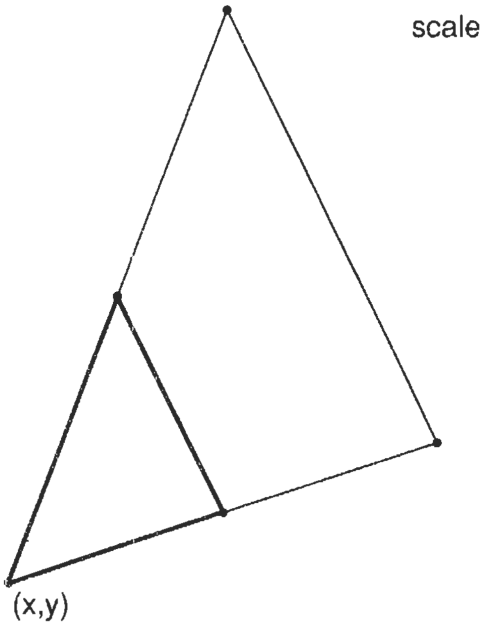

Figure 5.30 Scaling operation. A scale factor of 2 is applied to the object relative to the point (*x*,*y*)

Rotation requires multiplication of coordinates by $\sin\theta$ and $\cos\theta$, where θ is determined from the pivotal point. The new coordinate is calculated from its position relative to the pivotal point (Figure 5.31).

Reflection produces an image which may be mirrored with respect to the *x*-axis, *y*-axis or a user-defined axis (Figure 5.32). Changing the sign of one or both sets of world coordinates will convert a point so that it is mirrored about one or both orthogonal axes.

Shear transformations can distort images (or correct for perspective distortions) by making the transformation factor a function of the coordinate values (Figure 5.33). Thus the transformation factor varies across an object.

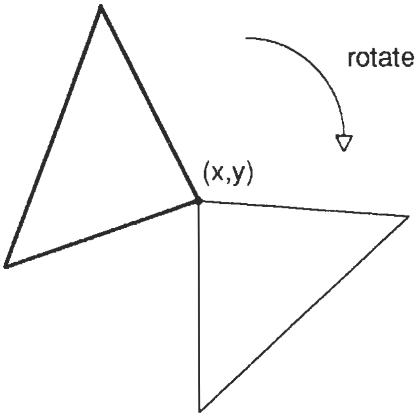

Figure 5.31 Rotation of an object about the pivotal point (*x*,*y*)

Matrix representations All of the transformations above can be reduced to a sequence of basic operations, each of which can be represented as a 3 × 3 matrix for a two-dimensional display. For example, a *linear translation* of an object by a distance (d*x*, d*y*) requires the coordinate [*x y 1*] to be multiplied by the matrix:

$$\begin{vmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ \mathrm{d}x & \mathrm{d}y & 1 \end{vmatrix}$$

Successive translations are additive such that two translations of (d*x*, d*y*) and (δ*x*, δ*y*) are equivalent to a translation of (d*x* + δ*x*, d*y* + δ*y*):

$$\begin{vmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ \mathrm{d}x & \mathrm{d}y & 1 \end{vmatrix} \cdot \begin{vmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ \delta x & \delta y & 1 \end{vmatrix} = \begin{vmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ \mathrm{d}x + \delta x & \mathrm{d}y + \delta y & 1 \end{vmatrix}$$

The *scaling* process requires more than one operation. The first *translates* the object to the graphics origin. Thus the second (*scaling*) operation can multiply all coordinates by the same factor (i.e. with respect to the origin). The final operation translates the object back to its original position. Thus one scalar and two translation operations are required in the following order:

$$\begin{vmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ -\mathrm{d}x & -\mathrm{d}y & 1 \end{vmatrix} \cdot \begin{vmatrix} mx & 0 & 0 \\ 0 & my & 0 \\ 0 & 0 & 1 \end{vmatrix} \cdot \begin{vmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ \mathrm{d}x & \mathrm{d}y & 1 \end{vmatrix}$$

where *mx* and *my* are the scaling factors and d*x* and d*y* are the distance of the object from the origin. These matrices may be combined to give the scaling matrix:

$$\begin{vmatrix} mx & 0 & 0 \\ 0 & my & 0 \\ (1 - mx)\mathrm{d}x & (1 - my)\mathrm{d}y & 1 \end{vmatrix}$$

The *rotation* process also requires translation to the origin before the rotate operator is applied and the inverse translation (as above). The *rotation* matrix is:

$$\begin{vmatrix} \cos\theta & \sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{vmatrix}$$

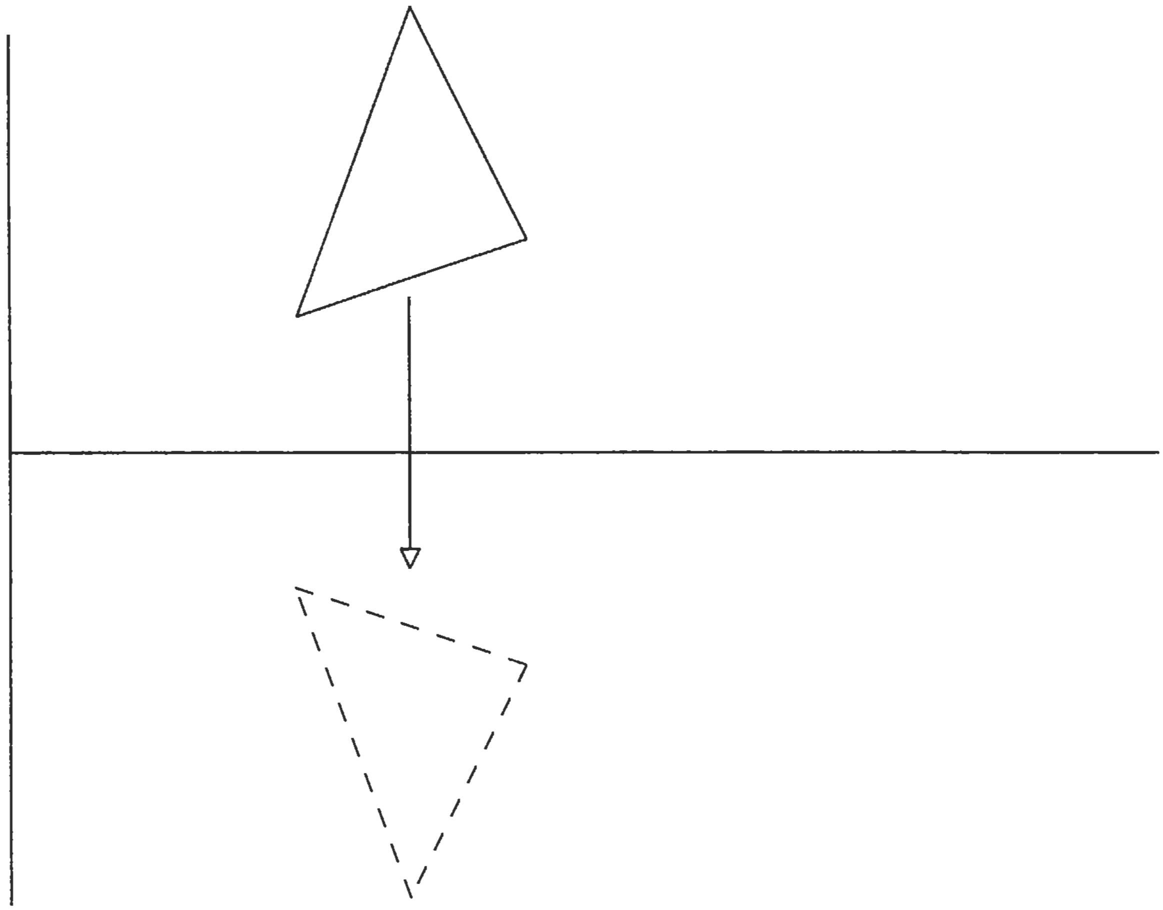

Figure 5.32 Reflection of an object about the *x*-axis

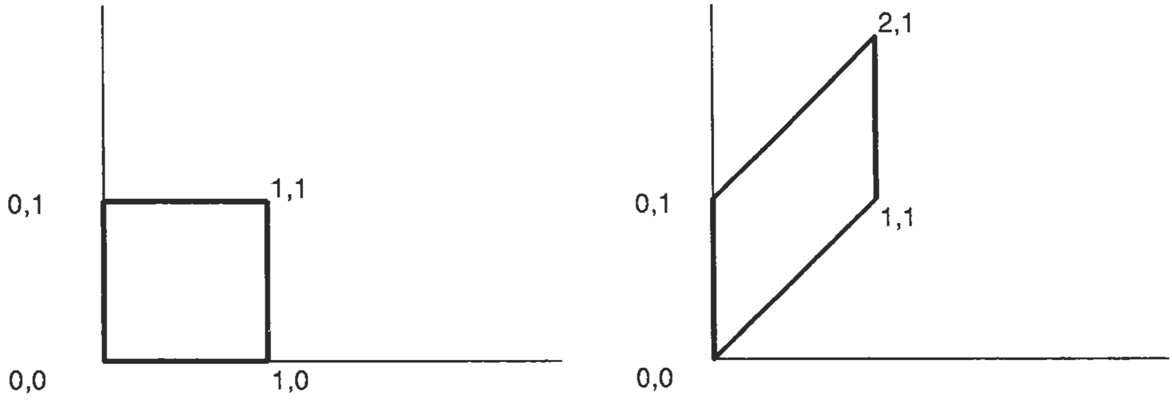

Figure 5.33 A *y*-direction shear transformation on a unit square using a shear factor of 1

where θ is the angle of rotation. With the two translation operations added, the overall matrix becomes:

$$\begin{vmatrix} \cos\theta & \sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ (1-\cos\theta)dx + dy\sin\theta & (1-\cos\theta)dy - dx\sin\theta & 1 \end{vmatrix}$$

Since all matrices can be multiplied together, then complex transformations can be constructed by applying the matrix operations in the desired order.

5.3.4.5 Windowing and clipping

Windowing A window is a rectangular display area. There is normally a single window displayed which occupies the whole screen. However, it is now common to find software which uses windows freely and there may be several windows displayed at once. An architecture which allows only a single process to run at any one time may display multiple windows, but only one can be an *active* window. Multi-tasking or multi-processor systems may have several windows which are active, i.e. each is controlled by a different *process* which is running.

Where multiple windows are displayed they will often overlap so that the window which has lower precedence (or is a *background* window) is partially or totally obscured (Figure 5.34). Hardware techniques are available to manage such overlaps, but more commonly this is performed in software. *Clipping* operations are performed when the contents of a window are being displayed so that only pixels within the permitted window limits are drawn; pixels outside the window area are *clipped* (Figure 5.35). The window boundaries and attributes are defined in a higher layer of the software – the *window manager*, which is conceptually part of the operating system. The window manager may draw a border around the window itself and label the border appropriately, but this is transparent to the process using the window. It is possible to define the windowing operation in terms of world or display coordinates (see Section 5.3.4.1) and 'window' is often used interchangeably when referring to either coordinate system. Where a distinction needs to be made between the two, the term *viewpoint* refers to the rectangular area on the display device.

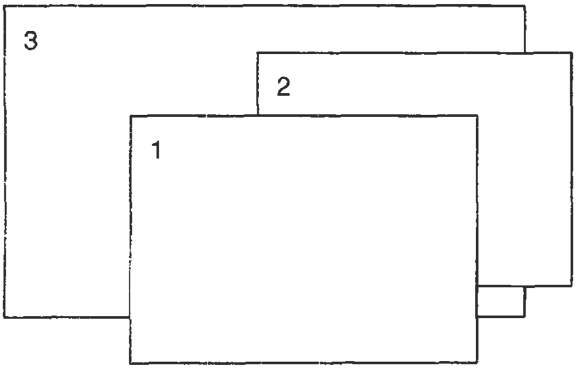

Figure 5.34 Multiple overlapping windows

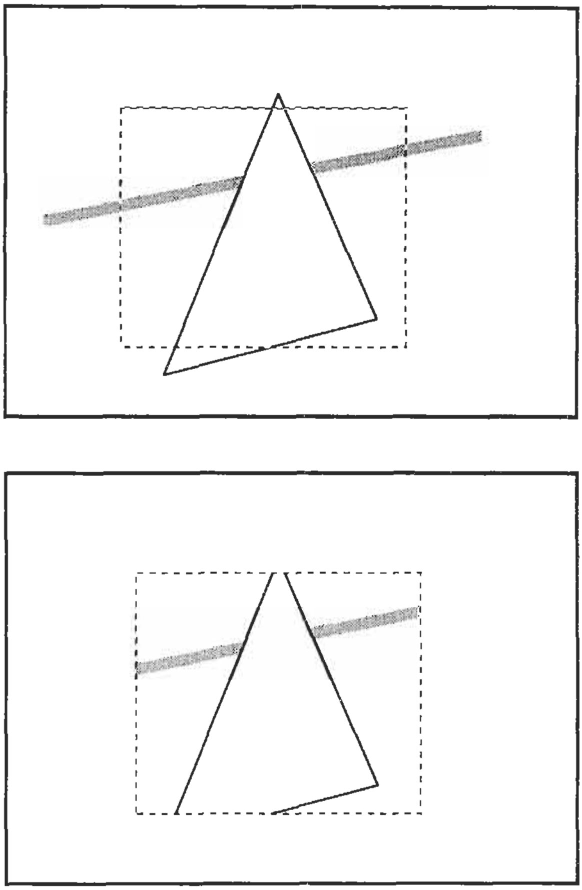

Figure 5.35 Clipped graphics

The most common operations to be performed on a window are described below and are implemented by calls to the window manager.

1. *Create* The dimensions and position of the new window are given and a *handle* is returned if the window is successfully created. This handle is used in future graphics calls to specify the window in which drawing operations are to take place. A newly created window will normally have the highest priority so that it may obscure parts of existing windows.
2. *Clear and delete (close)* The window handle is used to specify the window to be cleared or closed. It may not be possible to close a window if the process which owns it is still active.
3. *Drag (move)* The size and contents of the window are unchanged, but the position in the display is altered (Figure 5.36). A translation operation is used to perform this. The window position is normally constrained so that no part may be dragged off the display, otherwise further clipping may become necessary.
4. *Resize* The dimensions of the window are changed by altering the clipping parameters. The contents of the window which are visible before and after this operation remain unchanged (Figure 5.37).

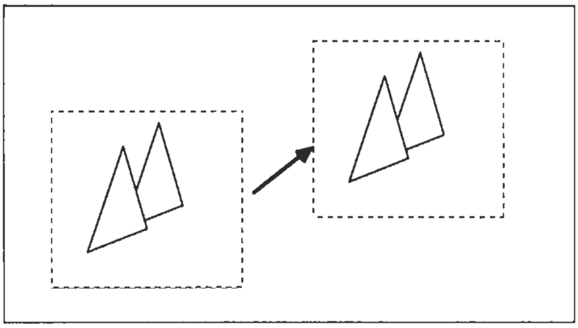

Figure 5.36 Dragging a window

5. *Zoom* The contents of the window are recalculated using a new scaling factor (Figure 5.38).
6. *Pan* Here, the *viewport* is unchanged in position and size, but the window moves 'behind' the viewpoint. This is a translation operation but the clipping attributes do not 'move' with the window (as for *drag*) but rather remain constant as far as the display coordinates are concerned (Figure 5.39).
7. *Priority* A window can be brough to the foreground or sent to the background by assigning it the highest or lowest priority attribute. If an intermediate priority is assigned, then the window may obscure parts of some windows and may itself be partly obscured by other windows (Figure 5.40).

Clipping text Where the clipped object comprises text, then clipping at the window boundary can leave partial characters visible in the same way as graphics objects are clipped at the pixel level. Sometimes this is visually undesirable. Thus text may be treated differently such that if any part of a character would be clipped, then that character is not displayed (Figure 5.41).

Updating the display When an operation takes place which disturbs the boundaries of the viewpoint then it is not only the window itself which needs to be redrawn; any part of the display which was partially obscured by the old viewport will also need to be redrawn (Figure 5.42).

If the background is now visible, the revealed areas are simply cleared to the background colour. If parts of other windows are revealed then two strategies exist. Either the whole window is redrawn and the window manager clips the pixels according to the window's priority, or an 'intelligent' process will only redraw those parts of the image that had previously been obscured. The first strategy is the simplest, but has the disadvantage of redrawing even those parts of the image that are correctly displayed – which means that overall system performance suffers. The second strategy is the most efficient in that only the area which requires redrawing is changed. This requires that the process itself can determine which objects or parts of objects were obscured and then require redrawing. This is not always easy to do or to calculate.

If the windowing is performed in hardware, then the display buffers do not become corrupted where windows overlap as each window has its unique, non-overlapping buffer. Thus when moving a window reveals another, no redrawing of the image buffer is required. The display hardware fetches data from the appropriate buffer as each window or part thereof is displayed on the output device.

5.3.4.6 *Segments*

Graphics objects may sometimes be repeated within an image. it is wasteful to store the same information several times so such objects may be stored as subpictures or *segments*. These objects are not restricted to being identically portrayed in the output image since variations of the same object can be produced by changing the attributes of the object.

A related hardware technique involves the use of *sprites*. In this way a graphics object can be predefined and held in memory. Whenever this object is required, it can be quickly copied into the frame buffer at the required position without requiring graphics processing operations to draw it. However, there is usually the restriction that attributes cannot be changed and so the sprite is fixed in size and colour.

5.3.5 Workstations

Workstation configurations vary from a single personal computer with its own screen, through a host computer with a graphics coprocessor using a separate screen, to a high-resolution multi-processor system incorporating many input and output devices.

5.3.5.1 Integrated workstations

This describes the standard 'personal computer' configuration where the processor runs the application, and the graphics hardware and the screen are contained in essentially one unit. Coprocessors may be used to accelerate certain operations, but they are under the control of the main processor. The processor itself is likely to be a fast 32-bit device with memory management. It will also allow multi-tasking and support multiple windows.

5.3.5.2 Host/slave configuration

In this case, the host computer provides mass storage, keyboard entry and interfaces for printers and plotters. The slave graphics processing unit contains the frame buffer, drawing and display hardware and is semi-autonomous. The two units are linked by a bus. In this way, the host runs the high-level application software and produces a display list to the slave. The slave is optimized to interpret the display list and perform the drawing operations at high speed.

The two parts of the system partition the process into high- and low-level operations and can work in parallel for much of the time.

5.3.5.3 Operating systems

Many PC-based systems use MS-DOS or some form of display manager. Only '386 systems and later allow true multi-tasking. The virtue of such a system is that it is multi-purpose and can provide a system for both word processing and graphics processing, it is therefore cost-effective.

UNIX[*]-based systems are multi-tasking and usually multi-user as well, although only a limited number of high-resolution terminals are allowed per node before the system performance suffers. UNIX allows several input and output devices to be added to the system and accessed by various users. Portability of applications between UNIX systems of different manufacture is a strong advantage. UNIX systems may range from a desk-top computer to a large main-frame installation.

VMS[†] systems based around the VAX architecture are not generally as portable to third-party hardware. However, VAX installations are fairly common for this not to be a severe drawback. A large resource of VMS-based graphics software is available.

An increasingly common feature is *networking*, where a number of high-performance graphics workstations are networked together to share central resources (or distributed resources). Since each workstation has its own processor (or processors) other users of the network are not disadvantaged when one user initiates some computing-intensive task. Only when simultaneous access is made by two workstations to a shared resource (e.g. a fileserver) is any drop in performance apparent.

5.3.6 Three-dimensional concepts

Three-dimensional concepts and operations are simply an extension of the two-dimensional concepts described in Section 5.3.4.4. For display purposes on two-dimensional devices further transformations must take place to give a three-dimensional *representation* in two dimensions.

5.3.6.1 Introduction

The coordinate system used is normally three orthogonally related axes: x, y and z. Translation, scaling, rotation reflection and shear operations are performed in a similar manner to the two-dimensional operations but for three dimensions. For example, the *linear translation* of an object by a distance (dx, dy, dz) requires the coordinate $[x\ y\ z\ 1]$ to be multiplied by the matrix:

$$\begin{vmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ \mathrm{d}x & \mathrm{d}y & \mathrm{d}z & 1 \end{vmatrix}$$

Compare this with the two-dimensional linear translation matrix and observe the similarity:

$$\begin{vmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ \mathrm{d}x & \mathrm{d}y & 1 \end{vmatrix}$$

More three-dimensional transformations are given in Section 5.3.6.4.

5.3.6.2 Three-dimensional display techniques

A three-dimensional object will be projected onto a two-dimensional plane for display. If the z-axis is arranged to be normal to the plane of the display then no transformation of

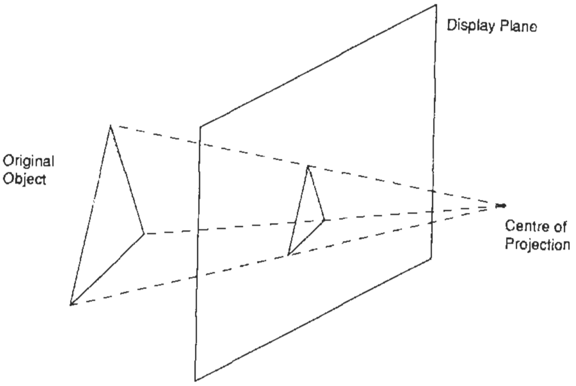

Figure 5.43 Perspective projection

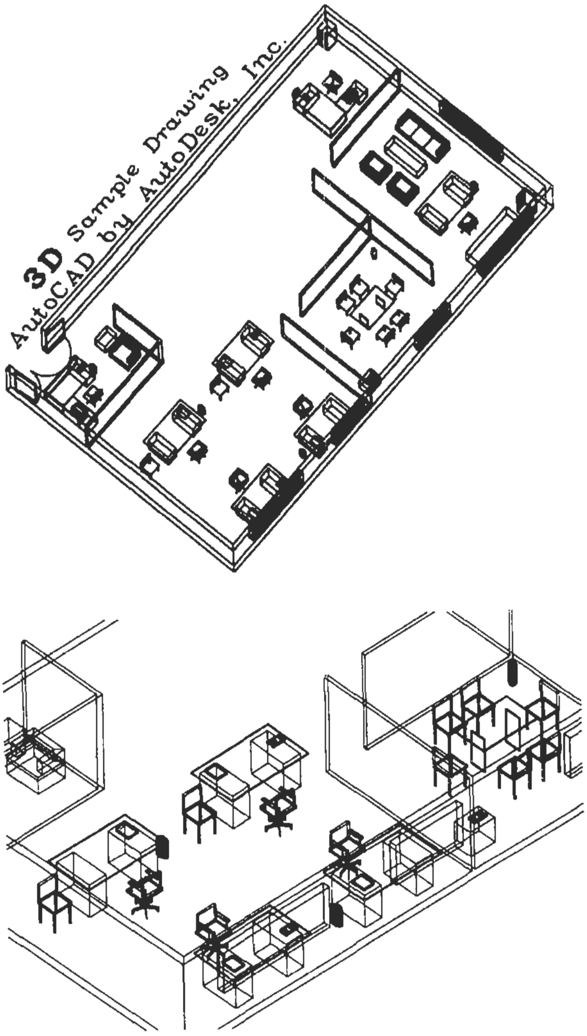

Figure 5.44 Two views of an office from different viewpoints (courtesy of AutoCAD)

the x and y planes is required. However, depth information can be represented by allowing the z distance to offset the x and y coordinates by an amount proportional to the distance from the front of the object. This results in a *parallel projection* onto the viewing surface (flat perspective).

---

[*] UNIX is a Trademark of AT&T Bell Laboratories, Inc.
[†] VMS is a Trademark of the Digital Equipment Corporation.

For a more realistic *perspective projection*, the depth-modified coordinates are calculated from the distance of a point from the Centre of Projection. Thus distant objects appear smaller, as shown in Figure 5.43.

5.3.6.3 Three-dimensional representations

It is not always desirable to view an object along the z-axis as described above. Any arbitrary *viewing point* could be chosen so that views from any point around an object and from any distance could be chosen (Figure 5.44). Indeed, the viewing point may be inside an object, giving an internal view. The projection onto the display plane requires the translation, scaling and rotation operations described in Section 5.3.6.4.

If all points in an object are translated from the three-dimensional object onto the viewing plane, then a *wire-frame* drawing results (Figure 5.45). This is acceptable as a representation, but is not realistic. In a solid object, many points are hidden from view by parts of the object itself. The image can be processed to determine which points would normally be hidden from the chosen viewpoint and these points are not plotted (Figure 5.46). This process is called *hidden-line removal*.

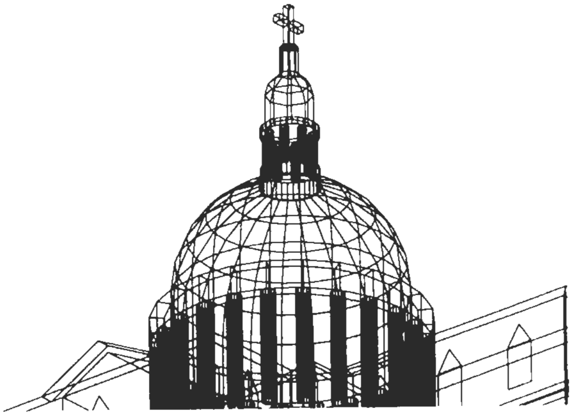

Figure 5.45 Wire-frame drawing (courtesy of AutoCAD)

Shading Once hidden line removal has been performed, the object appears solid. A better impression of depth can be given if the facets or surfaces are *shaded*. This implies that an imaginary light source is introduced into the model. Those surfaces at an angle which would reflect light from the light source to the viewpoint appear bright, and as surfaces differ from this angle, so their intensity is reduced. The facets are still clearly visible at this point. In order to model a smoothly curved surface some form of intensity interpolation is employed, the most common being *Gouraud shading*.

This idea can be extended to model *shadows* for a high degree of realism and to perform *ray-tracing* so that the effect of transparent and refracting objects can be represented (Figure 5.47).

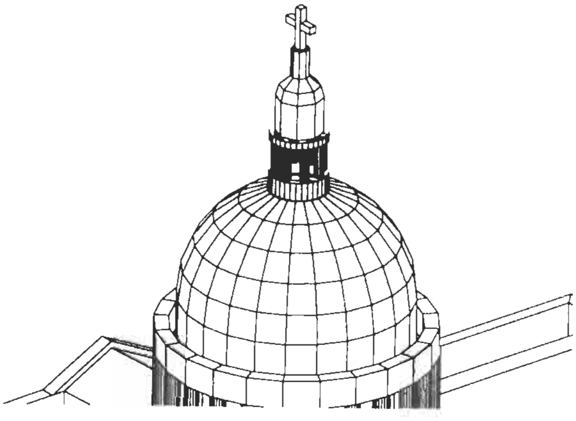

Figure 5.46 Figure 5.45 with hidden-line elimination (courtesy of AutoCAD)

Shading itself can be performed in a number of ways. *Dithering* retains a fixed pixel size and density but groups pixels into *superpixels* which may contain 2 × 2, 3 × 3 or larger arrays. This is also called *half-toning*. A 2 × 2 array may represent five grey levels according to the number of pixels set in the superpixel (0 to 4), but the resolution is halved in this example. *Continuous tone* is used to give 'photographic' quality since the density of a pixel may be varied over a continuous range from black to white. The final displayed resolution is not affected by this process.

5.3.6.4 Three-dimensional transformations

The transformation mentioned in Section 5.3.6.1 can be reduced to a sequence of basic operations, each of which can be represented as a 4 × 4 matrix. Only the basic operations are described here.

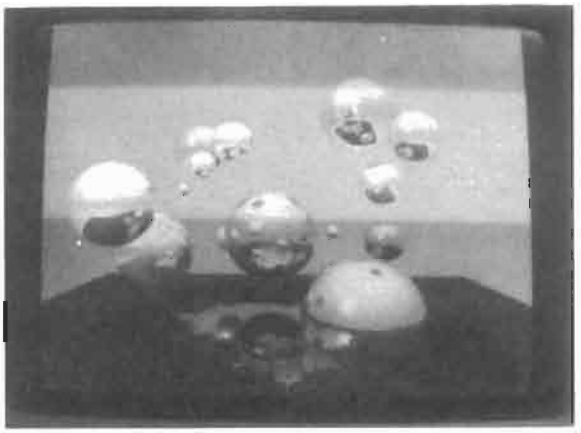

Figure 5.47 Ray-traced image (Acorn Archimedes computer, software by Beebug)

The *linear translation* of an object by a distance (dx, dy, dz) requires the coordinate $[x\ y\ z\ 1]$ to be multiplied by the matrix:

$$\begin{vmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ \mathrm{d}x & \mathrm{d}y & \mathrm{d}z & 1 \end{vmatrix}$$

The *scaling* process requires more than one operation. The first *translates* the object to the graphics origin. The second *scaling* operation can scale all coordinates by the scaling factor with respect to the origin. The final operation translates the object back to its original position. The scaling matrix is:

$$\begin{vmatrix} mx & 0 & 0 & 0 \\ 0 & my & 0 & 0 \\ 0 & 0 & mz & 0 \\ 0 & 0 & 0 & 1 \end{vmatrix}$$

where mx, my and mz are the scaling factors in each dimension. If dx, dy and dz are the distances of the object from the origin in each dimension, then the combined scaling operation with translation becomes:

$$\begin{vmatrix} mx & 0 & 0 & 0 \\ 0 & my & 0 & 0 \\ 0 & 0 & mz & 0 \\ (1-mx)\mathrm{d}x & (1-my)\mathrm{d}y & (1-mz)\mathrm{d}z & 1 \end{vmatrix}$$

The *rotation* process also requires translation to the origin before the rotate operator and the inverse translation are applied (as above). In the three-dimensional case, the axis of rotation is arbitrary and is not necessarily aligned to any of the three axes. Taking the simple case where a z axis rotation is performed, the *rotation* matrix is:

$$\begin{vmatrix} \cos\theta & \sin\theta & 0 & 0 \\ -\sin\theta & \cos\theta & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{vmatrix}$$

where θ is the angle of rotation. It can be seen that this is similar to the two-dimensional case.

Appendix: Bresenham's line algorithm

In Figure 5.26 the line is assumed to have a slope of less than 1. The straight line is plotted for constant x increments which are equal to the x pixel increment. Thus the position x_n is an integral pixel coordinate and the distance $x_n - x_{n+1}$ is equal to the x pixel increment. In order to plot the line, the equivalent y pixel positions must be found for each x pixel coordinate.

The real y coordinate is given by:

$$y_n = mx_n + b \tag{5.1}$$

This will normally not fall onto an integer pixel position so the *nearest* y pixel must be found.

In Figure 5.26 the distance of the point (x_n, y_n) from the neighbouring y pixel positions (P_1 and P_2) are shown to be d_1 and d_2. The smaller of d_1 or d_2 is used to select the pixel to be plotted. These distances are calculated as follows:

$$d_1 = y_1 - y_n$$

$$= y_1 - mx_n - b \tag{5.2}$$

$$d_2 = y_n - y_2$$

$$= mx_n + qb - y_2 \tag{5.3}$$

The difference $d_1 - d_2$ is calculated. If the result is positive, then the line is closer to P_2. If the result is negative, the line is closer to P_1. Now,

$$d_1 - d_2 = y_1 + y_2 - 2mx_n - 2b \tag{5.4}$$

Here, $y_2 = y_1 - 1$ since y_1 and y_2 are integer pixel coordinates which simplifies equation (5.4), as shown later.

Once the start of the line has been calculated and the nearest pixel found, it is not necessary to calculate $y = mx + b$ each time and then calculate the nearest y pixel position. Instead, a constant (Δy) is added to the previous real y value for each increment of Δx along the x axis, where Δx is the x pixel increment and $\Delta y = m\Delta x$.

Substituting for y_2 in equation (5.4) and multiplying by Δx gives:

$$(d_1 - d_2)\Delta x = 2\Delta x y_1 - 2\Delta y x_n - (2b + 1)\Delta x \tag{5.5}$$

The left-hand side of the expression is positive if the line is closer to P_2 or negative if closer to P_1. It is possible to calculate the new lhs of the expression from the previous one as shown below, where the lhs is denoted ω_n. The final term in equation (5.5) is a constant term, therefore:

$$\omega_n = 2\Delta x y_1 - 2\Delta y x_n - c$$

where $c = \Delta x(2b + 1)$ and

$$\omega_{n+1} = 2\Delta x y_0 - 2\Delta y x_{n+1} - c$$

Therefore ω_{n+1} may be derived from ω_n since

$$\omega_{n+1} - \omega_n = 2\Delta x(y_0 - y_1) - 2\Delta y$$

since $x_{n+1} = x_n + 1$.

For the first point in a line, ω_1 is calculated from $2\Delta y - \Delta x$. Thereafter, ω_{n+1} is evaluated using

$$\omega_{n+1} = \omega_n + 2\Delta x(y_0 - y_1) - 2\Delta y \tag{5.6}$$

The sign of this expression determines whether the upper or lower pixel is plotted.

It can be seen that multiplication by an integer and addition and subtraction operations are required, and these operations are easily performed by digital processors.

6.1 Standardization in design

6.1.1 Introduction

Standardization in design is the activity of applying known technology and accepted techniques in the generation of new products. This may be interpreted as almost a contradiction in terms: if something is standard then there is little left to design. On the other hand, if standardization is seen as a means to promote communication in design and manufacture then its usefulness is clearer: time is not wasted in redesigning the wheel. Again, if standardization is seen as providing targets that products must attain then we have criteria for acceptance in performance and quality: you know what you are getting.

These points illustrate the difficulty in understanding the role of standardization within industry at large, and why it is too often ignored by designers and management. One does not want to be constrained. In fact, the converse is usually true, that by adopting standards in an appropriate manner, the designer is freed from many detail decisions that would otherwise hinder the overall scheme. It has to be acknowledged that some standards are inherently retrospective. That is, a standardized design method or procedure is bound to be based on past practice, and in some circumstances this may inhibit flexibility in adopting new methods. But to counteract this, the designer may well contribute to updating and development of new standards. Indeed, the standards organizations have development groups and committee structures for this very purpose.

6.1.2 Modular design

Standardization in design may be applied by the idea of modularization. That is, a range of products of related type or size may be designed (or redesigned) so that complex assemblies may be made up from a few simple elements or modules. For example, a vast range of electric motors and gearboxes can be made from a few each of motors, bases, flanges, gear cases, gears, shafts and extensions.

This approach applies particularly well to complex, low-volume production of products where each customer wants his or her own version or specification. The economics of individually designing for each customer would be prohibitive but the design of a few well-chosen modules would cover the majority of requirements. Other examples where modular design may be applied are: overhead travelling cranes, water turbines, hydraulic cylinders, machine tools (BS 3884: 1974).

6.1.3 Preferred sizes

Related to the modular design concept is the idea of preferred sizes. In any range of products there is usually some characteristic feature such as size, capacity, speed, power. It is observable that an appropriate series of numbers can cover a large proportion of requirements. For many practical situations the geometric series known as the Renard Series may be used (BS 2045: 1965 = ISO 3). The key point in application is the product-characteristic feature to which the Series is applied. This application of standardization is one of the best ways of promoting economy in manufacture by variety reduction. it also facilitates manufacture by sub-contracting and eases the problems of spares availability for maintenance. A further discussion is given in reference 3.

6.1.4 Levels of standardization

Standardization can operate at different levels: company, group, national, international, worldwide. It can be applied to many aspects of the activities of design and manufacture, e.g. terminology and communication, dimensions and sizes, testing and analysis, performance and quality. It is a broad-ranging subject and standardization will be exemplified below in further detail but only in so far as it serves the design function. The descriptions are drawn largely from experience with British Standards, but at the time of writing (1988) considerable efforts are continuing to harmonize BSI activities with European counterparts. Indeed, many British standards are entirely compatible with ISO standards and are listed as such in the BSI Catalogue which is published annually.

6.1.5 Machine details

Standard proportions are laid down and specified precisely with dimensions and preferred sizes. This is the most obvious use of standardization in design and is employed widely, almost without conscious effort.

6.1.5.1 Examples

BS 3692: 1967 Metric nuts bolts and screws (ISO 4759)
BS 1486: 1982 Lubricating nipples
BS 4235: 1986 Parallel and taper keys for shafts (ISO 774)
BS 6267: 1982 Rolling bearing boundary dimensions (ISO 15) (also BS 292: 1982 for more detailed dimensional specifications)
BS 1399: 1972 Seals, rotary shaft, lip. Shaft and housing dimensions
BS 3790: 1981 Belts – vee section. Dimensions and rating (ISO 155)
BS 11: Railway rails (ISO 5003)

6.1.6 Design procedure

A procedure, algorithm or method is described for application in circumstances where long experience has established satisfactory results. This is often very useful to the designer as a starting point but evolution beyond the standards is very probable in particular industries. Such standards are among those most likely to be influenced and developed by designers themselves. They may, however, be adopted as part of a commercial contract and thereby promote confidence in safety and reliability.

6.1.6.1 Examples

BS 436: 1986 Spur gears, power capacity (ISO 6336)
BS 545: 1982 Bevel gears, power capacity (ISO 677, 678)
BS 721: 1983 Worm gears, power capacity
(note the recent revisions of these very well-established standards)
BS 2573: 1983 Stresses in crane structures (ISO 4301)
BS 1726: 1964 Helical coil springs
BS 4687: 1984 Roller chain drives (ISO 1275)
BS 1134: 1972 Surface finish (ISO 468)
BS 5078: 1974 Jigs and fixtures
BS 5500: 1985 Unfired welded pressure vessels (ISO 2694)

6.1.7 Codes of practice

Methods for design, manufacture and testing are recommended in these types of standard, and, like 'design procedures' described above, they may form the basis of a commercial contract. Again, they are codes that may or may not be followed entirely but may be regarded as facilitating effective communication between vendor and purchaser or any other interested parties.

6.1.7.1 Design: Examples

BS 5070: 1974 Graphical symbols and diagrams
BS 308: Part 1: 1984 Engineering drawing practice (ISO 128):
BS 308: Part 2: 1985 Dimensioning (ISO 129) (see also reference 1)
BS 4500: 1969 Limits and fits (ISO 286)
BS 5000: Part 10: 1978 Induction motors (CENELEC HD231)
BS Au 154: 1989 Hydraulic trolley jacks
BS CP117: Part 1: 1965 Simply supported beams
BS 4618: 1970 Presentation of plastics design data

6.1.7.2 Manufacture: Examples

BS 1134: 1972 Surface texture assessment (ISO 468)
BS 5078: 1974 Jig and fixture components
BS 5750: 1987 Quality assurance system (ISO 9000) (see also reference 2)
BS 970: 1983 Steel material composition (ISO 683)
BS 6323: Parts 1–4 Steel tubes, seamless
BS 4656: Parts 1–34 Accuracy of machine tools (ISO various) (e.g. Part 34: 1985 Power presses = ISO 6899)
BS 4437: 1969 Hardenability test (Jominy) (ISO 642)
BS 6679: 1985 Injection moulding machine safety (EN 201)

6.1.8 Abbreviations used

BS	British Standard
BSI	British Standards Institution
Au	Automobile Series (BS)
ISO	International Standards Organization
EN	European Normalen
CP	Code of Practice

Notes: 1. Some standards are divided into separately published parts. Details are given in the BS Catalogue.
2. Many colleges, polytechnics, universities and public libraries hold sets of standards. A list is given in the BS Catalogue.

6.2 Drawing and graphic communications

Since the days of cave dwellers, drawings have been a prime means of communications and today, with all the latest hi-tech innovations, drawings and graphics still hold a pre-eminent position. The needs are the same – all that has changed is the methods by which drawings are made, stored, retrieved and used. Never was a saying more true than 'One picture is worth a thousand words'.

In the world of engineering, drawings are absolutely essential. They may first be sketches arising from customers' needs or competitive designs but, from several sources, ideas can be given a form around which discussions can take place as to the idea's marketability, usefulness, etc. From this point, a component design starts to emerge. It will undergo many changes to satisfy the demands of various departments, e.g. production, servicing, installation, stress analysis, marketing, etc. All these changes will be documented, particularly if the company is adhering to the BS 5750 quality assurance code.

Because we see in a three-dimensional way, perspective and isometric three-dimensional drawings always provide a quicker appreciation of a design than the more familiar plans and elevations. Perspective and isometric drawings are, however, more difficult and time consuming to produce, require special skills and do not lend themselves to dimensioning. Thus the communication of an idea to the shopfloor for manufacture has generally been through the medium of plans and elevations of the item.

In preparing such drawings, dimensions should always be taken from datum lines which, ideally, should be coincident with the hardware itself rather than being a mere line in space. Using such a datum as a reference avoids a dimensional build-up of accumulated errors.

In the late nineteenth and early twentieth centuries, when life progressed at a more leisurely pace, engineering drawings and architectural plans were often works of art. Parts were shaded and coloured. This practice died out in the 1920s, although even today many architects' drawings not only use shading and colour but widely employ isometrics and perspectives. However, the audience for these drawings is rather different to that viewing engineering drawings. Architects' ideas and proposals are largely for public consumption and will be read by lay people as well as by builders and other planners. The public are often bemused by plans and elevations, particularly when some practices use third-angle projection and others first-angle projection.

Engineering drawings are mainly read by craftsmen who are, however, well trained in reading such drawings. A notable exception was during the Second World War, when many engineering companies found it necessary to include isometric or perspective drawings on the plans to give a visual appreciation of the part in question to the wartime workers on the shopfloor, many of whom had no knowledge or training of either mechanical engineering or drawings.

While a drawing will detail the geometry of a part and its method of assembly it cannot define graphically such things as finish, smoothness or material, although there are standard symbols which give a measure of surface roughness. Nevertheless, for these, annotations are required. Text and tables are often included on drawings and, together with drawn lines, complete a total engineering drawing.

Design is essentially a 'doing' activity and design skills develop through practice. Design learning needs a structured approach aimed at building up confidence and competence with definite educational objectives at each phase. Much of the first year at college is spent on learning drawing skills such as orthographic projection, sketching, tolerances and assembly drawings. These are essential for later work, and much emphasis is placed on the fact that drawings are the medium used by engineers to communicate ideas.

Ideally, a drawing should transmit from one person to another every aspect of the part – not only its shape but also what is is for and how it should be made and assembled.

6.2.1 Drawing references

Not the least important aspect is how the parts are referenced. It may seem a simple enough task to apply a number to a drawing or part and listing it in a register, but subsequent identification may prove more of a problem. Therefore specific numbering systems are introduced. Depending on the users' requirements, systems can be simple or complicated. For instance, every drawing of a part belonging to one complete assembly may be given a prefix, either character or number (for example, A/1234, where A defines the particular assembly and 1234 the individual part). This means that if a spare is required, the first sort (A) in the drawing register defines a particular assembly while the number will locate the individual part. This can be developed further by taking, say, the first two digits of the number 1234 (i.e. 12) and stating that all parts bearing the first two digits are made from flat metal sheet as distinct from, say, 13 for castings, 14 for plastics parts and so on. The original part A/1234 would thus be defined as belonging to a particular assembly (A) and would be seen as a part made from flat metal sheet (12) with the individual part number of 34. This can be further enhanced (or complicated) by the addition of a modification number or character which introduced the part or represents the year of manufacture and/or a part modified in shape or dimension. The whole purpose of the system is to locate the part number and/or its drawing from a part in service which may be damaged or overpainted, eliminating the part number.

Spares lists often carry exploded drawings in which a particular assembly is shown as a set of parts approximating in position to the assembled location. All these ploys help to identify any particular part whose title (for example, plate, angle, strut) is usually insufficient to positively identify the part. It is therefore obvious that, when preparing drawings, some thought should be given to the title. This should, as far as possible, within the limits of space, be brief but also describe the part such that its position and actual duty is defined.

Identification of parts is not only desirable for new designs but sometimes it is worthwhile being able to recall a part from a previously made assembly to see if it can be used in a new design. If this were possible, there would be several advantages:

1. The drawing would exist so that a redraw would be unnecessary;
2. There should be a history of the part showing the reason for its introduction and any modifications and why these were necessary, following perhaps, a malfunction in service;
3. A manufacturing routine would exist for the production of the part; and
4. Jigs and fixtures would also exist.

It may well be that in order to preserve the drawing-identification system the part may be given a new number and called a new part. But it is always an advantage to annotate the drawings so that their origins are preserved. It is more than possible that, although these parts were originally identical, subsequent modifications may have led to an entirely different part which could lead to confusion if they both bore the same part number.

Several systems have been devised to store and retrieve information on like parts. These often rely on comparative geometries (for example, cylindrical shapes where the aspect ratio of length to diameter is large). Another example would be flat plates where thickness or surface shape/area are a criterion. Another way of segregating the parts would be by use; for example, (a) rotating shafts, bearings and supports, (b) structural channels, etc.

Each company will have to work out its own philosophy as regards a drawing numbering system. Obviously, a company whose product range is small and whose subsequent models still have a strong family relation to earlier models will have a totally different system to one with a wide range of differing products.

6.2.2 Management and organization of engineering information

Engineering organization is concerned with the relationship between work and the people who do it. It varies greatly in complexity, depending on the range of products, whether, for example, they are aircraft or lawnmowers. However, each company must have facilities for conceiving a design and developing and then producing it. The prime task of engineering management is to create and sustain such an organization and direct it to the achievement of the declared objective.

Behavioural science focuses attention on the nature of individual and group interaction in an organization; that is, how people can work together in harmony. It emphasizes people rather than jobs, and underlines the simple truth that every organization must solve the problem of relationships among its staff if an efficient working environment is to be realized. Argysis[4] has stated:

> The individual and the organization are living organisms each with its own strategy for survival and growth. The individual's strategy for existence is, at crucial points, antagonistic to the strategy that guides the formal organization. This may lead to continual conflict between the individual and the organization. The conflict, however, can be a source for growth as well as a stimulant for disintegration.

Management has to solve problems within the context of the organization. The individual cannot usually work without a relevant organization structure, and the organization, in turn, depends almost entirely on the individual. However, their interests differ, and the manager's job is to develop a properly balanced interaction of individual needs and organizational demands.

Engineering design is a corporate activity, involving teams of people whose job it is to provide a prescription of what is to be produced. How people interact can be determined by the shape of the organization.

The resources of design are not like production facilities. In a machine shop it is possible to programme work for optimum utilization in accordance with machine capabilities. Designers, however, cannot be so programmed and their performance, for many valid reasons, is often unpredictable. Nevertheless, a design organization is expensive, and it is essential to study its function in the same way as machine functions.

In design and development organizations a careful balance between order and flexibility has to be obtained. Should, for example, a design office be centralized for several production groups or decentralized? Where there is little change, formal policies, procedures and rules to obviate communication difficulties and aid designers would be preferable. Where change is more or less continuous, a more dynamic grouping or task forces may work better in relation to specific jobs.

Over the years, considerable research has been undertaken (1) to find out what information designers want and how it should be best presented and (2) to develop convenient methods by which relevant information and data can be transferred to others. Several universities, polytechnics and colleges have been involved in this particular work and, since 1971, the Design Group at Southampton University have set up a series of seminars to discuss these various activities. During the 1960s a number of commercial systems were devised to provide designers with product data. Most fell by the wayside over the years although one, TI Index, not only survived but has been developed to take advantage of today's technology in microfilm and computer-aided storage and retrieval.

6.2.3 Microfilm and computer technologies

In addition to providing input data for a company, these advanced technologies have simplified the handling, storage and retrieval of engineering drawings and made possible the implementation of control systems for the issue of drawings.

Apart from microfilm leading to a reduction in the number of drawings being copied, it has contributed towards the continual process of identifying those areas which require further control and standardization.

The introduction of computers to the design office has considerably altered the role that microfilm can play. No longer need microfilm be looked upon as a stand-alone technology but can now be integrated into computer and manually controlled drawing-office information systems.

The introduction of CAD increased the speed with which design drawings could be completed and gave designers the freedom and ability to produce exploded and sectional views which previously were economically impossible. These extra drawings, which help communication with the shopfloor, also added to the problem of drawing storage. There was also the risk of drawing losses, not only through the normal risks of fire and theft but also through a computer crash or accidental erasure of storage tape and disk.

Through the years, a growing confidence in the permanence of microfilm records and widespread acceptance has not entirely overcome fears on how to modify a drawing held only on a 35 mm microfilm or how to produce true to scale drawings. However, the use of plain paper print technology and polyester film has overcome most of these problems. To meet the difficulties of controlling the sheer bulk in microfilm libraries a computerized drawing registry offers an engineer quick access to all the data associated with a drawing. Drawing number, issue date, levels of modification, source of drawing, application and schedule of materials can all be made available. The automatic marriage of a computer-held index of information and the physical microfilm image is now possible. The advantage of computer-held drawing graphics has been proven in CAD systems and now hardcopy and microfilm drawings can be incorporated into a CAD system. In essence, this allows conversion of hardcopy and microfilm into a raster digital format. Images can be stored on either magnetic or optical systems.

The days have gone when designers could remain isolated from manufacturers and confine their activities to creating what they considered the best possible designs without thought for the subsequent conversion of their designs into realizable products. Moreover, with the gradual replacement of paper drawings by digitized data, it is important that all concerned should have the means of exchanging the relevant data, which, in turn, means that all parties need compatible systems that intercommunicate.

Full-size CAD-produced designs can be transferred to microfilm either by conventional film camera or by using a microfilm plotter which reads the information from disk or tape outputting directly onto microfilm using laser technology. Alternatively, the cathode ray tube (CRT) may be used to imprint the image on film. For those wanting the ultimate quality, the microfilm plotter must be the first choice.

Microfilm originally came to be seen as an archival activity and as a positive insurance against loss of drawings. Microfilm cards can now be titled, indexed and have distribution data added by computer printing, optical character recognition (OCR) printing, bar codes or punched holes entered direct from the camera control panel. Information from the drawing can be fed directly from this keyboard into the design office data-processing system. As revised cards are issued, the computer can automatically update and re-issue all scheduling and listing. Today's microfilm camera can be upgraded to an electronic information management tool.

Microfilm, in its many forms, is a practical and economical technology to install within a drawing office system. Looking to the future, it is not without interest that an ultra-powerful electron microscope with a beam diameter of only 5 Å has been recently commissioned. Funded by SERC and housed at Liverpool University, the machine is capable of writing the entire contents of the 29 volumes of *Encyclopedia Britannica* on the head of a pin. Each of the dots making up a character is only 10 nm in diameter. Some exciting applications exist, one of which is the possibility of storing information by drilling an array of holes in a given pattern in a manner similar to that used for piano rolls which stored music to be read by a pianola. Information could be stored at densities at least one thousand times greater than in the latest computer storage device.

Another area for future developments can be seen from a recent contract won by SD-Scion to advise the European Space Agency (ESA) on the use of expert systems technology. The contract involves investigating how expert systems can help ESA's European Space Research Institute (ESRIN) in information retrieval. The study will also investigate the needs of ESA's new information systems to be used for project documentation handling, spacecraft payload data and other information. The study will involve several technologies in addition to expert systems, on-line data retrieval, intelligent access to databases, distributed knowledge bases and the use of hypertext to browse through text files.

It was, however, inevitable that with the proliferation of software and hardware, companies each would go their own way for various reasons and would finish up with systems that were incapable of communicating with each other without the use of some form of translator. Standards now coming into use should prevent the same degree of proliferation in the future, but for those systems which do exist (and many of them are highly efficient in their particular sphere), a translator is required. Possibly the best-known data exchange format is IGES (Initial Graphics Exchange Specification), which is a means of transferring data between two incompatible CAD systems by creating an intermediate neutral file that contains elements common to both systems. Data are fed from one system into IGES file and subsequently from IGES to the output translator. If a particular CAD system is to exchange data it needs to have software interfaces for reading (Pre-processor) and writing (Post-processor).

Studies show that designers spend an average of 30–50% of their time on documentation plus 50–70% on seeking relevant information, which leaves little time for creative design activities. These figures reveal an obvious need for tools to help manage product development by managing the documents that control it. Engineering processes in many industries involve interaction among many engineers and even among several divisions or even companies. Engineers must therefore cooperate in creating product concepts, proposals, requirements and specifications.

Tools to support these processes need to be readily available to engineers and be able to incorporate text, graphics and tabular data from an engineering database. To support evolution or change, these tools also need to be able to simplify the process while dealing with formal and informal controls.

An ideal documentation and document change control system would provide true-to-type pagination software with a full set of automatically maintained features as well as the tools to manage the evolution of the documents. The system should run on general-purpose engineering workstations and support very large team documents by demand, paging the latest version of reference text or graphics from anywhere on the network.

It is abundantly clear that the ability to manage change has become crucially important in developing a product and managing it throughout its life cycle. Providing the necessary support with accurate and reliable change-management tools paves the way to better products and product management within the company, which leads to increased competitiveness in the industrial marketplace.

6.3 Fits, tolerances and limits

The successful functioning of any assembly depends to a large degree on the interrelationship of the individual items. Whether machined or fabricated, the amounts by which the sizes of the items can deviate from the ideal or norm must be stated on the drawings so that the shopfloor can know to what tolerances they are expected to work.

In this respect the designer has a great responsibility, since tighter than necessary tolerances can escalate costs while too relaxed tolerances can mean difficulties in assembly and in the overall efficiency of the structure or machine. The degree of tolerance is also strongly influenced by surface finish which, like dimensional limits, can escalate the costs if very fine finishes are called for unnecessarily. Each design has to be considered on its merits. For instance, the bore of a cylinder or valve body may require a high degree of finish if it is to remain leakproof and not unduly wear a soft rubber or plastics seal.

With a shaft revolving in a bearing the clearances are more important than the surface finish, since there must be sufficient clearance to maintain an oil film but not so much that radial float is present. The surface finish is less important since, in most cases, the shaft is revolving on a film of oil and any small asperities can be catered for within the thickness of the oil film. While surface finish and dimensional tolerances are interrelated they can, in an operational sense, be considered independently.

6.3.1 Conditions of fit

Using a shaft and a housing as a practical example, there are five broad conditions of fit:

1. Running fit
2. Push fit
3. Driving fit
4. Force fit
5. Shrinkage fit

With the last three it is obvious that the diameter of the shaft exceeds that of the hole but by different amounts. With the first two, the shaft must be less than the hole diameter. In all cases the crucial question is, by how much?

For example, with a shaft of a nominal diameter of 50 mm, a machining tolerance may be given of +0.00 mm and − 0.05 mm. Its housing may be bored to a maximum diameter of 50.08 mm and a minimum diameter of 50.01 mm. Thus clearances could vary between 0.13 mm maximum and 0.01 mm minimum and consideration has to be given to the effect that these values could have on the efficient running of the machine. The clearances quoted may also be affected by what tolerances can be achieved in manufacture (e.g. the accuracy of a machine tool). It is no use specifying a tolerance of ±0.002 mm if the machine tool can only work to ±0.005 mm.

The ISO system (BS 4500) is designed to provide a comprehensive range of limits and fits for engineering purposes and is based on a series of tolerances to suit all classes of fits. The limits put on the shaft and the bore will determine these conditions and will vary according to the diameter of the shaft and bore. In selecting a fit for a given application, it is necessary to choose an appropriate tolerance for each member so that functional requirements are achieved.

While shafts and holes given in BS 4500 are referred to explicitly, the recommendation can apply equally well to other sections, and the term 'hole' or 'shaft' can be taken as referring to the space contained by or containing two parallel faces or tangent planes.

In the ISO system, 18 tolerance grades are provided and are designated as IT 01, IT 0, IT 1, IT 2, IT 3, . . . , IT 16 (see Table 6.1). The system provides 27 different fundamental deviations for sizes up to and including 500 mm and 14 for larger sizes to give different types of fit ranging from coarse clearance to heavy interference. The values associated with each of these deviations vary with size so as to maintain the same fit characteristics. In each case, the variation is determined by an empirical formula again based on extensive practical investigations.

Tables 6.2 and 6.3 contain the standardized values for the 27 deviations. Each deviation is designated by a letter. Letter (a) represents a large negative deviation (interference fit) while the letter (z) represents a positive deviation (clearance fit). The ISO system provides for the use of both hole-basis and shaft-basis fits. If the hole-basis is used, a series of deviations for shafts is required: if the shaft-basis is employed, a series of deviations for holes is needed. The 27 deviations of the system can be used for shafts or holes. The same letters are used for designations in each case but upper-case (capital) letters designate hole deviations and lower case (small) letters define shaft deviations. Shaft deviations are opposite in sign to those for holes.

6.3.2 Definition of terms

At this stage it is appropriate to define some of the terms used in BS 4500:

Deviation The algebraic difference between a size (actual, maximum, etc.) and the corresponding basic size.

Actual deviation: The algebraic difference between the actual size and the corresponding basic size.

Upper deviation: The algebraic difference between the maximum limit of size and the corresponding basic size. This is designated (ES) for a hole and (es) for a shaft.

Lower deviation: The algebraic difference between the minimum limit of size and the corresponding basic size. This is designated (EI) for a hole and (ei) for a shaft.

Zero line: In a graphical representation of limits and fits, the straight line to which deviations are referred. The zero line is the line of zero deviation and represents the basic size. By convention, when the zero line is drawn horizontally, positive deviations are shown above and negative deviation below it (Figure 6.1).

Tolerance: The difference between the maximum limit of size and the minimum limit of size (the algebraic difference between the upper and lower deviation). The tolerance is an absolute value without sign.

Tolerance zone: In a graphical representation of tolerance the zone between the two lines representing the limits of tolerance and defined by its magnitude (tolerance) and by its position in relation to the zero line.

Fundamental deviation: That one of the two deviations, being the one nearest to the zero line, which is conventionally chosen to define the position of the tolerance zone in relation to the zero line.

Grade of tolerance: In a standardized system of limits and fits a group of tolerances considered as corresponding to the same level of accuracy for all basic sizes.

Standard tolerance: In a standardized system of limits and fits, any tolerance belonging to the system.

Standard tolerance unit: In the ISO system of limits and fits a factor expressed only in terms of the basic size and used as a basis for the determination of the standard tolerances of the

[b] Not applicable to sizes below 1 mm.

system. (Each tolerance is equal to the product of the value of the standard tolerance unit for the basic size in question by a coefficient corresponding to each grade of tolerance.)

Clearance: The difference between the sizes of the hole and shaft, before assembly, when this difference is positive.

Interference: The magnitude of the difference between the sizes of the hole and the shaft, before assembly, when this difference is negative.

Clearance fit: A fit which always provides a clearance. (The tolerance zone is entirely above that of the shaft.)

Interference fit: A fit which always provides an interference. (The tolerance zone of the hole is entirely below that of the shaft.)

Transition fit: A fit which may provide either a clearance or interference. (Tolerance zones of the hole and shaft overlap.)

Minimum clearance: In a clearance fit the difference between the minimum size of the hole and the maximum size of the shaft.

Maximum clearance: In a clearance or transition fit the difference between the maximum size of the hole and the minimum size of the shaft.

Minimum interference: In an interference fit the magnitude of the (negative) difference between the maximum size of the hole and the minimum size of the hole before assembly.

Maximum interference: In an interference or transitional fit the magnitude of the (negative) difference between the minimum size of the hole and the maximum size of the shaft before assembly.

* In determining K, M, N up to Grade 8 and P to ZC up to Grade 7, add the Δ value appropriate to the grade as indicated, e.g. for P7 from 18 to 30, Δ = 8 therefore ES = −14.

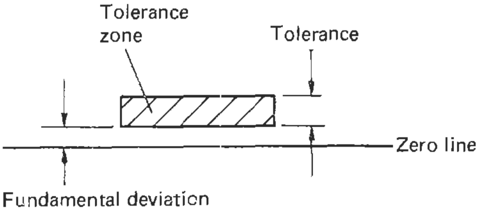

Figure 6.1 Zero line and its meaning

6.3.3 Selecting fits

In a national standard it is impossible to recommend selection of fits which are appropriate to all sections of industry. While the ranges shown will meet many requirements, there will be some sections of industry which will need coarser or finer qualities. The principles around which BS 4500 is founded provides for engineers to determine their own tolerances should this be necessary to suit the particular applications.

A typical fit is illustrated conventionally as in Figure 6.2, where the two rectangles represent the hole and the shaft tolerance zones in magnitude and position with respect to the basic size or zero line. The illustration shows a hole-basis clearance fit but the same convention can be used to represent any type of fit.

The characteristics which determine the nature of a hole-basis fit are the magnitude and sign of the fundamental deviation of the shaft and the magnitudes of the hole and shaft tolerances. When the shaft fundamental deviation is positive in sign, the fit becomes either a transition fit or an interference fit, depending on the magnitude of the fundamental deviation and the tolerances. The converse applies in the case of a shaft-basis fit, where the fundamental deviation of the hole and the magnitude of the hole and shaft tolerances determine its character.

For example, instead of H8 and f7, the qualities of H7-f6 or H9 and f8 could be used. Alternatively, instead of H7-h6, the qualities H8-h7 or H6-h5 could be employed. In all cases, however, the starting point should be the provision of the minimum number of tolerance grades for the basic member of the fit.

BS 4500A contains a range of hole-basis fits derived from the selected hole and shaft tolerances given in BS 4500: Part 1. When using a shaft-basis fit, the equivalents of hole-basis fits are given in BS 4500B. The ISO system is so comprehensive and flexible that it can provide a considerable range of fits based on an almost infinitely variable combination of deviations and tolerances. In practice, however, most normal engineering requirements can be met by a more limited selection of hole and shaft tolerances.

The advantages of standardizing on a limited range cannot be overemphasized. If a user selects three or four standard holes and perhaps 10 standard shafts (or vice versa) they can be combined in numerous ways to provide clearance, transition and interference fits but will be able to use the same range of tools and gauges for all of them.

'Force fit' is a term used when a pin or shaft is forced into a hole of slightly smaller size. As a rule, force fits are restricted to parts of small to medium size whereas shrinkage fits are specially applicable where maximum seizure or accurate knowledge of the stresses induced are required.

The most important point to consider when calculating shrinkage fits is the stress in the housing into which the shaft is shrunk; this stress will depend largely on the shrinkage allowance. If the allowance is excessive, the elastic limit of the material will be exceeded and either permanent set will occur or the housing will fracture or burst. The intensity of the grip will depend on the wall thickness of the housing – the greater the thickness, the greater the grip.

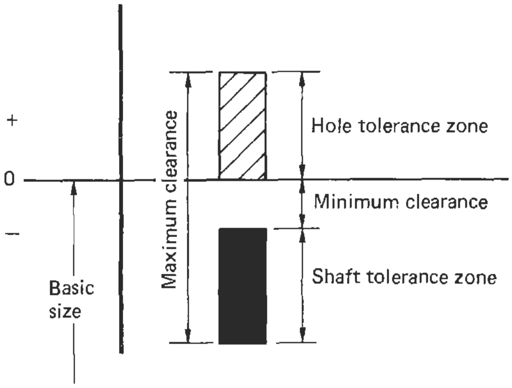

Figure 6.2 A typical fit

6.3.4 Tolerance and dimensioning

Tolerance (see also Section 6.3.2) is the amount of variation permitted on dimensions or surfaces of parts. The tolerance is equal to the difference between the maximum and minimum limits of any specified dimension. As applied to the fitting of machined parts, the word 'tolerance' means the amount that duplicate parts are allowed to vary in size in connection with manufacturing operations. Tolerance may also be defined as the amount that duplicate parts are permitted to vary in order to secure sufficient accuracy without unnecessary refinement. The designer should always be aware that in manufacture, steps can be taken on the shopfloor to ensure that parts mate. However, in service, the replacement of parts in the field can only be easily effected if interchangeability is considered at the design stage. The degree of tolerance and the way in which parts are dimensioned can profoundly affect interchangeability.

In practice, tolerances should show the permissible amount of variation in the direction that gives the least cause for concern. When a variation in either direction is of equal importance a bilateral tolerance should be given. When a variation in one direction is more dangerous than a variation in the other, a unilateral tolerance should be given in the less dangerous direction.

Where tolerances are required between holes they are usually bilateral, as variations in either direction are usually of equal concern. With shafts for gears the tolerance on shaft centres should be unilateral to avoid the possibility of gears meshing too tightly. A small amount of backlash is likely to be of less consequence.

Only one dimension in the same straight line can be controlled within fixed limits. That is the distance between what would be the cutting surface of the tool and the locating or registering surface of the part being machined. It is therefore important not to locate any point or surface with tolerances from more than one point in the same straight line.

Every part of a mechanism must be located in each plane and every moving part must be given appropriate clearances. Dimensions should be given between those points or surfaces that are essential to hold them in correct relation to each other. This applies particularly to those surfaces in each plane which control the location of other component parts. It is good practice to establish a common locating point in each plane and give, as far as is possible, all dimensions from this common locating point.

Although ordinary limits of size, in themselves, only comprise limiting sizes between which the measured size of the features at any cross-section must fall, conventions have been established by which such limits exert some control on geometric form. In selecting limit of sizes for mating features it is important to consider whether this degree of control is adequate or whether a specific form of tolerance should be applied.

The recommendations in BS 4500 enable limits of size for mating features to be derived from a standard series of tolerances and deviations in order to provide various types of fit. However, the mating features of a fit are composed of surfaces, and the surface texture and geometric form of these surfaces frequently have a considerable bearing on satisfactory functioning. Surface texture is particularly important in the case of precise fits involving relative movement.

6.3.5 **Surface condition and tolerance** (see also Chapter 9)

All surfaces which have been finished by turning, milling, grinding, honing or other means consist of minute irregularities. These may be compounded by waviness attributable to vibration and machine deflections. There are a number of ways by which surface roughness can be measured and expressed numerically but the two best known are (1) root mean square (rms) value and (2) centreline average (cla). The latter has been brought into line with ISO recommendations and is now known as the R_a value (arithmetical mean deviation).

With the rms designation the heights and depth of the irregularities are measured from a central reference line which is at the mean of the heights and valleys. These measurements are taken at equal intervals and if the sum of such measurements is divided by the number of points at which the measurements are made, the resulting average can be used for comparative purposes:

$$\text{rms} = \sqrt{\frac{a + b + c}{m}} \; \ldots\ldots$$

Table 6.4 gives an indication of the sort of surface roughness values (R_a) to be expected from various manufacturing processes. These values should not be placed on the drawings without taking into account all other relevant factors such as load, lubrication, speed, temperature, types of materials, direction of movement and last, but not least, cost. To specify a surface texture value is virtually an instruction to the shopfloor with ultimate inspection routines. To specify an unnecessarily smooth surface can be economically unsound. Figure 6.3 shows the increase in production time needed to achieve smoother surfaces and this would, in cost terms, be increased also by the higher capital costs of equipment and higher running costs.

Control of surface texture is generally instituted to secure a surface texture of a known type and roughness value which experience has proved to be most suitable to give that particular part a long life, fatigue resistance, maximum efficiency and functional interchangeability at lowest cost together with attendant benefits such as reduction in vibration wear and power consumption.

BS 1134 deals with the assessment of surface texture and is in two parts. Part 1 covers method and instrumentation and Part 2 gives general information and guidance regarding the application of the method of Part 1.

Two schools of thought exist regarding control of surface roughness. One view is that all surfaces should be specified and the other is to apply control only to essential parts, leaving the rest to the standard and, hopefully, good practices of the company. It is not the function of BS 1134 to advocate either and to do so would be unmerited. However, it is important to bear in mind that quoting any form of surface control mut be done with the full understanding of the definition and attributes of a surface.

6.4 Fasteners

Fasteners embrace a wide range of common and specialized components, but the emphasis for the designer of today is on fastening systems largely because economy in production demands overall consideration of the assembly process. Fasteners inserted by hand are labour intensive and therefore make the assembly expensive.

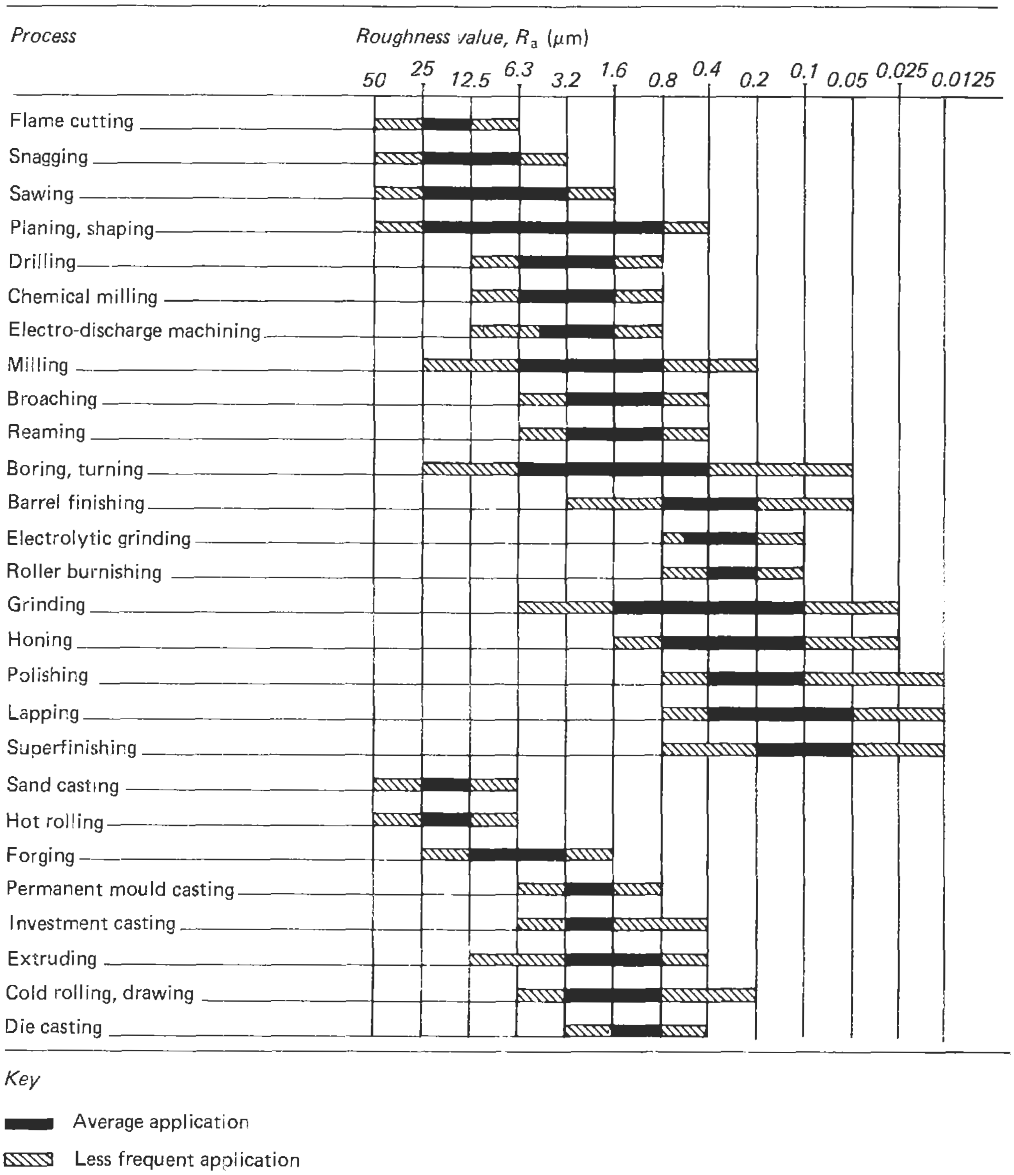
Designers have to ask themselves which fastening system will serve the design purpose at the lowest overall cost. Does the design warrant fasteners and, if so, is it for assembly, maintenance, transport, etc.? The reason for a fastening device will lead to the choice of system, ranging from welding through adhesives, bolts, rivets, etc. to highly specialized fastening devices. Despite the growing popularity of structural adhesives, mechanical fasteners are still widely used but it must be emphasized again that the cost of inserting a fastener is likely to outweigh that of the individual fastener. Therefore the designer must be convinced that a mechanical fastener is really the best answer for the job in hand. At this point it would be convenient to enumerate questions such as:

1. Is a fastener really necessary?
2. Will the minimum number of fasteners be consistent with reliability and safety as well as economical in production?
3. Will the fastener specified perform its task efficiently?
4. Will it be simple to install and be capable of being placed by automatic methods?
5. Will the fastener have to be removed during service for maintenance and repair and will it be readily accessible with standard tools?
6. If the fastener is to be removed during service, is it of a type that can be safely used again?
7. Will the fastener material be compatible with that of the products?
8. Bearing in mind the additional cost involved, will it be necessary to specify a special fastener instead of a standard one?

There are other questions that could be asked and these depend on the type of assembly being considered, but the questions given above are basic to most designs.

The choice of fastener systems currently available is bewilderingly wide, but it is the designer's responsibility to select from the right category, to assess performance from the suppliers' data, and to consider in-place costs. Fasteners that fail in service are not only unreliable but uneconomic. The conditions under which the fastener operates must be known and the selected fastener must resist these conditions, which could include extremes of temperatures, corrosive environments, vibration and impact loads.

Table 6.4 Surface roughness values produced by common production process and materials (courtesy BSI)



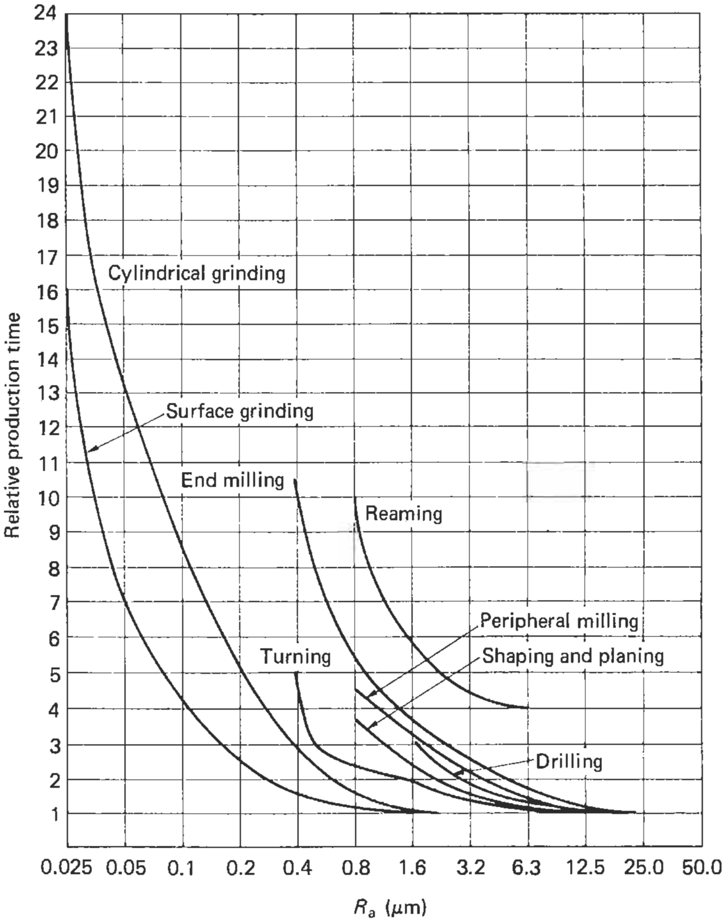
Note: The ranges shown above are typical of the processes listed. Higher or lower values may be obtained under special conditions.

6.4.1 Automatic insertion of fasteners

Depending on specific applications, most fasteners in use today can be installed automatically and since some 80% of the total cost of fastening is on-assembly cost, a mere saving of 10% in assembly costs is more significant than a 40% saving in piece part costs. Nevertheless, 80% of manufacturers assembling products with automated or robotic screwdriving equipment claim to have difficulties with their fasteners. This is the finding of a recent research survey carried out for European Industrial Services (EIS), who manufacture Nettlefolds screws. Faulty fasteners brought machinery to a halt and, in a significant number of instances, caused damage to machine or products.

For 23% of all users of automated equipment the problem is a continuing one which production engineers appear prepared to live with either because they are unaware that a solution exists or because they believe that any solution must be too expensive. It is against this background that European Industrial Services introduced, in 1987, a fault-free product known as Nettlefolds Gold Seal to the robot-user market. However, there appear to be just as many problems being experienced by people with automatic assembly equipment. Now, EIS are offering the Gold Seal products for use with automated screwdriving equipment.

Virtually all the screw products used in robotic and automated screwdriving are hardened, mainly fastening metal to



Example: If a given area of surface is surface ground to 3.2 μm R_a taking approximately 1 minute, then to achieve 0.2 μm would take approximatly 2.5 minutes.

Figure 6.3 Relative production times for commonly used processes and materials (courtesy BSI)

metal but with a growing proportion joining plastics or plastics to metal. The Gold Seal error-scanned products therefore cater for these requirements with a variety of self-tapping screws for metal applications and Polymate, a specially designed EIS patented screw for thermoplastics.

The Pemserter is a high-volume automated fastener insertion press from PEM International for inserting any of the range of bushes in the PEM range. The press has an intelligent main cylinder containing an optical encoder which transmits absolute ram position to a microprocessor-based logic control system. Operating and safety windows coupled with an end-of-ram sensor allow the machine to perform at its maximum rate while providing operator and tooling safety.

During a set-up procedure, these safety windows are automatically determined. Any variation from the initial parameters such as the operator removing the anvil, or the presence of a foreign object such as a finger, will cause the ram to immediately stop and return. The company claims that their press achieves new standards in performance, safety and ease of operation.

Another example of a modern assembly tool is the fully automated twin-headed Heatserter capable of installing up to 45 fasteners per minute in plastics mouldings (see Figure 6.4). The new CNC machine from PSM International plc can be pre-programmed in three axes $-x$, y and $z-$ to cater for plastics mouldings of a wide range of shapes and sizes. Pre-heating circuitry is used to facilitate high-speed post-moulding fastener installation and the equipment features light guarding to provide easy tool changing. The Heatserter can be interfaced with moulding presses to form a link in an automated production line and is capable of installing the full range of PSM proprietary fasteners for thermoplastics.

The problems of automated assembly are not just handling and orientation but are often those of quality and consistency. Design for automated assembly will therefore embrace both component design and the manufacturing process.

Figure 6.4 PSM Automated Systems new CNC Heatserter (courtesy Fox Photography)

6.4.2 Joining by part-punching

A very effective way of fastening sheets together is by part-punching the top sheet into the bottom one. Material is partly cut from the top sheet and pushed through the lower sheet. The lower sheet is formed simultaneously so that an overlap between top and bottom sheet occurs. As the partial cut is connected to the upper sheet by webs, a join of considerable strength is produced.

The Trumpf TF300 power fastener has been developed to cut and form the sheets at the rate of two strokes per second and consists of a three-part tool set comprising punch, stripper and die. Developed for static or portable use, an optional coordinate table ensures the accurate positioning of joints. The power tool is particularly useful where box-shape enclosures are being assembled or where flat strips are to be joined together.

6.4.3 Threaded fasteners

Where threaded parts are concerned, designers have been bedevilled by the numerous thread forms that have been available in the past, and many are still with us today, in spite of the UK's declared policy to recommend the adoption of the ISO metric screw thread system. Existing thread systems include Whitworth, British Standard Fine (BSF), British Association (BA) as well as a range of pipe threads, gas threads, oil industry threads and fire service threads. However, there has been a part change typified by the use of ISO inch series of threads (Unified Coarse and Unified Fine). Nevertheless, wherever possible, new designs and updates should call for ISO metric thread systems.

The choice between Unified Coarse and Unified Fine threads depends on the complete understanding of the assembly in which screws and bolts are used. In general terms, the coarse thread (UNC) can fulfil most design requirements. One small practical advantage with the fine threads (UNF) is when they are used in conjunction with a slotted nut and split pin. To align the slot in the nut with the hole in the bolt, less torque is required with UNF for a given bolt tension.

Where bolts are used in tapped holes, a failure under tension loads should be by breakage at the core of the bolt thread rather than by stripping of the thread. Where bolts are in shear, designers should ensure that the loads are carried on the bolt shank rather than on the threaded portion. Another important aspect is the clearance of the bolt in the hole, particularly when several bolts appear in a row. The tolerance for dimensions must be carefully considered, otherwise undue strain will be put upon a single bolt rather than being equally distributed among them all.

With nuts and bolts there will always be a problem of making certain that, in field replacements, the bolt removed is replaced by one of similar strength. Members of the British Industrial Fasteners Federation (BIFF) all produce bolts of high quality and standards, and these can be readily identified from their head markings. Additional markings also indicate tensile strength and thread forms. Figures 6.5–6.7 show the most commonly used head forms for screws, bolts and nuts.

Threaded fasteners in general are used to provide a clamping force between two or more parts and where there is likely to be a need to dismantle at some time in the future, whether for access or for maintenance. Clamping force can be a major problem, particularly when clamping soft materials which may shrink in service and cause loosening of the bolts. In cases like this, locking the nuts and bolts together may not always give a satisfactory answer.

6.4.4 Load sensing in bolts

Much research has been carried out on problems relating to bolt tension and, in many critical applications, ranging from car engine cylinder heads to sophisticated chemical and nuclear plants, it is necessary to apply the right amount of torque, usually through the use of a torque spanner. A clever idea to indicate bolt tension is to be found in the new fastener, which is the brainchild of John Hirst, who heads Exotech, a design and development company based on the University of Warwick's Science Park. West Midlands-based T. W. Lench, one of the UK's leading nut and bolt manufacturers, is currently setting up a special manufacturing unit at its Warley factory to produce the new Hi-Bolt fastener as it is called (see Figure 6.8).

The system involves a structural bolt with an in-built load-sensing device. It is identical to a standard bolt apart from the actual sensor – a steel pin running through the shank which is gripped as the nut is tightened. Before tightening, the pin is free to move. As the nut is tightened, the bolt shank contracts and grips the pin. When this happens, the maximum pre-load in the bolt has been reached.

Using the same principle in a different way is the RotaBolt, in which the internal pin is secured at one end within the shank of the bolt. The free end holds a Rota washer and cap clear of the bolt head. As the bolt stretches under the tension imposed by tightening the nut, it pulls the Rota washer into contact with the bolt head and locks it. The gap between the Rota washer and bolt head has been set previously at the manufacturing stage, so when the Rota washer locks, the predetermined tension in the bolt has been achieved.

To determine the actual bolt tension required for a particular application is far more complicated and, as previously

mentioned, particularly so when dealing with soft materials such as glass fibre-reinforced plastics (GRP). A research team at Imperial College London undertook an extensive test programme to determine the static strength of bolted joints in several forms of GRP. The experimental results were used to produce design charts for both single- and multi-bolt joints subjected to tensile/shear loading. While design methods established for structural joints in metals are applicable in a general way to GRP joints, the physical nature of the material does introduce problems not encountered with metals. The anisotropic stiffness and strength means that unexpected failure modes may be introduced, the low interlamina shear and through-thickness tensile strengths being a particular difficulty in this respect. Joint strengths were found to be strongly dependent on choice of reinforcing fabric.

Many technical devices have been used to prevent the unscrewing of nuts and bolts, and a selection is shown in Figures 6.7 and 6.11. Each has its own advantages and

Figure 6.7 Free-spinning lock nuts. Figure 6.8 A close-up of the Hi-Bolt load-sensing system from Lench (courtesy Caters Photographic)

disadvantages. Some can only be effectively used once and, once removed, should be discarded. Serrations which effectively lock the bolt head or nut to a surface could initiate cracks in sensitive parts. In other cases, although the nut is locked, the bolt can turn. The most effective way of preventing relative rotation is by the use of liquid adhesives or anaerobic cements.

6.4.5 Threadlocking

The selection of a chemical threadlocking compound will depend on the following criteria:

1. The ultimate shear strength of the fastener must not be exceeded, although this is usually only of importance for screw sizes of 5/16-inch diameter and less;
2. The severity of the loosening tendencies;
3. The size of the threads and therefore the viscosity of the compound to ensure thread filling;
4. The method of application and requirements for testing and putting into service;
5. The environmental requirements of temperature and chemical resistance.

The viscosity should be such that the compound can be easily applied, not run off, and will fill threads which have the maximum clearance. Pre-applied dry materials are available for application situations where liquids are not acceptable. They are easy to inspect and provide some re-use. The application is usually carried out by the bolt supplier and at least four formulations are available:

Low-strength locking and sealing
Medium strength – plated fasteners
Medium strength
High strength

PSM Fasteners, for example, provide a comprehensive range of bolts and studs with the pre-applied process for locking and sealing thread components. Their Scotch-Grip two-part epoxy system microencapsulates the resins while the hardener is freely carried in the coating substance. When the fastener is engaged with its mating thread, the capsules are crushed and the shearing action of the rotating fastener mixes the epoxy and hardener initiating the adhesive cure. An alternative but similar system uses microencapsulated anaerobic adhesives and sealants.

Fastening systems, whether they be adhesives, nuts and bolts, welding or any other method, are inherent in the design of the product or structure destined to be assembled as a one-off, by batch production or mass production. However, despite the popularity of adhesives, mechanical fasteners still have a prime role to play, but unless sufficient care is taken in their selection the installation of such fasteners can lead to increased costs and possibly to a decrease in the required level of mechanical efficiency or in-service reliability.

To provide a comprehensive list of all of the various types of fasteners available is impossible in this text, but it may be helpful to the reader if they can be grouped as follows.

Bolts, screws, studs, nuts and washers
Self-tapping screws
Locking and stiff nuts
Blind bolts/screws
Rivets (including blind rivets)
Spring-steel fasteners
Plastics fasteners
Quick-release fasteners
Self-sealing fasteners
Threaded inserts and studs

Some of these are illustrated for general guidance but with each manufacturer producing a wide range of products for similar applications, the reader would be wise in the final analysis to obtain specific data from these manufacturers. Several are listed in Section 6.4.16.

6.4.6 Threaded inserts and studs for plastics

A method of securing a threaded bore in sheet is by the use of bushes which are designed to bite into the sheet and prevented from rotating by its hexagon shape, serrated shoulder or spigot. A large variety of these types of bush is available.

Whenever components have to be fastened with screws to a plastics moulding, thread inserts which only require standard machine threads have distinct advantages:

1. The total re-usability of the assembly screw;
2. Unlike self-tapping or thread-forming screws which are applied directly into the plastics, there is no risk of thread stripping;
3. Often the assembly screw must remain tight and maintain its clamping effect. Threaded inserts allow this as they do not cause problems of stress relaxation in the material which is common when screws are driven directly into plastics.

The advantages of placing inserts after moulding instead of moulding-in are:

1. Reduced moulding time and therefore unit costs;
2. No expensive damage to tools due to misplaced inserts;
3. No metal swarf from inserts to contaminate a moulded surface; and
4. Availability of cost-effective assembly methods for post-moulded inserts.

Obviously, each job has to be considered on its merits, and post-moulded inserts tend to come into their own on long production runs. For small numbers, moulding-in can often be advantageous, in spite of the points made above.

6.4.7 Ultrasonic welding

Ultrasonics are widely used for joining plastics assemblies and for securing threaded inserts. The main limitation is joining parts made from different thermoplastics. A difference of only a few degrees in the softening temperature will cause one material to flow before the other. The pressure applied during ultrasonic welding is also a critical factor, and the most up-to-date ultrasonic welding equipment is microprocessor controlled to give the optimum pressure and heating conditions.

6.4.8 Adhesive assembly

Since its introduction, the Evo-Stik Thermaspray range of adhesives is finding increasing application in industry. The Thermaspray adhesives are pressure-sensitive, hot-melt spray-applied materials which offer distinct health and safety benefits, as well as an adhesion performance superior to conventional neoprene or polyurethane adhesives.

The Thermaspray products are high-tack adhesives based on a blend of synthetic rubbers, tackifying resins and liquid modifiers. The necessary investment in spray equipment and adhesive does mean that the Thermaspray system is not suitable for low-quantity production. However, given a sufficient production run, the Thermaspray system becomes one of the most efficient methods of applying adhesive evenly, economically and swiftly in the context of existing production lines. Several large manufacturing companies have invested in the system and are finding that the economics are working for them as efficiently as the adhesive.

Heat-sensitive substrates will not be damaged by the application of Thermaspray adhesives due to the low heat intensity of the spray deposit. The permanent tack of the adhesive provides a long open time, which means that large assemblies can be made with components being joined several minutes after the application of the spray deposit. Some low-stress assemblies have been tested successfully at up to 120°C. Higher-stressed component assembly may only be successful at lower temperatures.

The adhesives can be used to bond laminating panels, thin-gauge plastics and fibrous panels such as cork, fibreglass and rockwool. Other suitable materials for Thermaspray bonding include painted and unpainted metals, carpet materials, polyurethane, polythene and polypropylene sheet and foams.

6.4.9 Self-tapping screws

These screws fall into two main categories: (1) true self-tapping screws which, like a tap, cut their own threads in a prepared hole; and (2) thread-forming screws which form their own threads by a rolling or swaging action (Figures 6.9 and 6.10). Typical of the latter are the proprietary types Taptite and Swageform. Taptite incorporates machine screw threads formed on a trilobular shank and the Swageform has special lobes at 120° intervals along the tapered portion of the shank to impart a three-dimensional swaging action to form the threads.

Self-tapping screws are widely used in the assembly of sheet metal components in which the thread-cutting action results in a good fit and is resistant to vibration and shock loads. Thread-forming screws are more applicable to thicker ma-

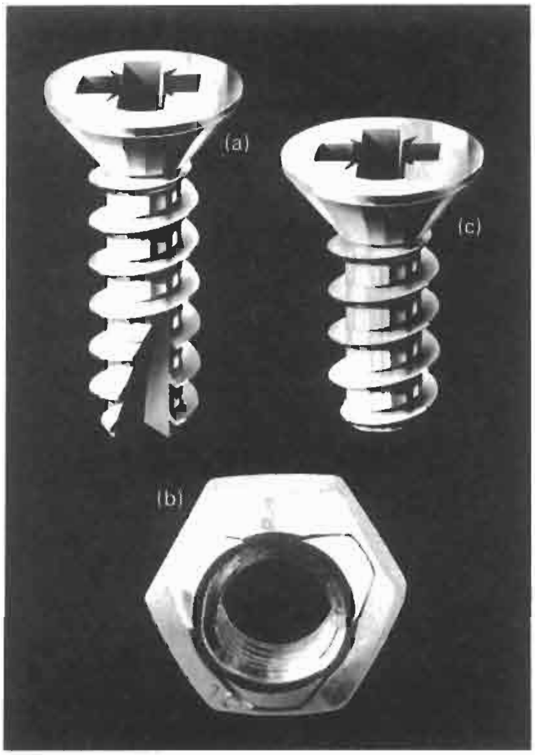

Figure 6.10 *(Left to right)* Plastform thread-cutting screw; Toploc re-usable locking nut; Plastform screw for plastics

terials and blind holes. The self-drilling versions (for example, Teks and Drill-kwik) are designed with a true drill point to produce the necessary pilot hole for the threads.

6.4.10 Stiff nuts

Stiff nuts, as distinct from free-spinning nuts, generally incorporate either a locking element to generate an elastic contact between the nut and bolt threads or a differential pitch or deformed threads to create the required friction between the mating threads. Examples are shown in Figure 6.11.

6.4.11 Washers

Washers are used to provide a seating for nuts and bolts in order to distribute the load over an area greater than that provided by the bolt head or nut. They also prevent damage to the surfaces being joined due to rotation of the nut or bolt. Washers can also seal, cover up oversize holes and act as a spring take-up between fastener and workpiece. They also have the special task of preventing unwanted rotation of the nut or bolt. These include spring washers and serrated tooth types as shown in Figure 6.12.

6.4.12 Spring-steel fasteners

Although these include certain standard parts (for example, caged nuts), most spring-steel fasteners are designed for specific applications where speed of assembly is important and the cost of the fasteners is low. They are mass-produced from hardened and tempered steel strip and are used in non-critical applications in cars and domestic electrical appliances and in the sheet metal industries. Some of the various shapes which can be produced are shown in Figure 6.13.

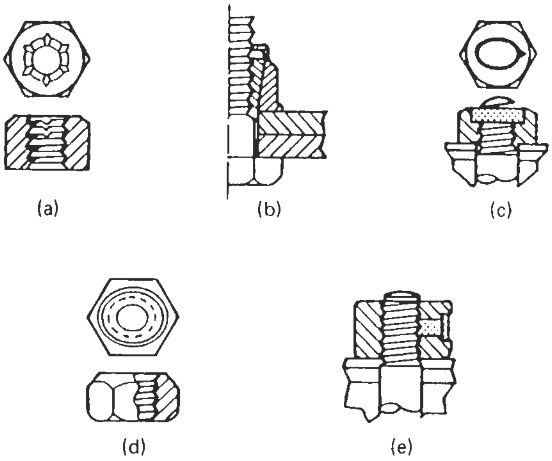

Figure 6.11 Stiff nuts. (a) Deformed thread has depressions in the face of the nut to distort a few threads; (b) slotted section forms beams that deflect inward and grip bolt; (c) threaded elliptical spring-steel insert produces locking; (d) non-metallic plug insert grips bolt threads; (e) out-of-round threads cause wedging action

6.4.13 Plastics fasteners

These products fall into two categories: standard thread forms made from plastics such as nylon and the specially configured fasteners for specific applications. These can be self-coloured and are non-corrosive. Some examples are shown in Figure 6.14.

6.4.14 Self-sealing fasteners

Bolts, screws, washers and nuts can be made into self-sealing elements by the addition of a sealing element in applications where it is necessary to seal the fastener hole against the leakage of liquids or gases (see Figure 6.15). The choice of the fastener and the sealing material is dependent on the specific application.

6.4.15 Rivets

Rivets are low-cost permanent fasteners suitable for manual and automatic setting. They can be classified as solid, tubular, semi-tubular, bifurcated and blind, all of which are available in several different materials and head styles. Correct joint design and preparation together with the right fastener will ensure a strong, trouble-free and cost-effective assembly. A range of available types is shown in Figures 6.16 and 6.17.

6.5 Ergonomic and anthropometric data

Physical appearance has, in the past, been associated with mental, physiological and behavioural characteristics of the iandividual and was studied by Hippocrates, the Greek physician, in the fifth century BC as well as psychiatrists in the nineteenth century. Such studies are of little use for today's engineers, who need human dimensions and physical capabilities in physical units in order to design hand tools, equipment and workstations to fit human dimensions and capabilities.

Every ergonomist knows the normal measurements of the average person (arithmetical mean) but it is sometimes necessary for designers of products and equipment using a human/machine interface, to consider certain limits, for instance, the 5th and 95th percentile or, for safety reasons, the 1st and 99th percentile of the respective population.

Average people are more prevalent than extremes and it is possible to present this in a frequency distribution chart shown in Figure 6.18, where frequency is plotted vertically against man/woman height plotted horizontally. Since the curve is symmetrical, 50% of the population are shorter than average and 50% are larger. Thus the mean is equal to the 50th percentile. The 5th and 95th percentile, being the shortest distance along the horizontal axis, encloses 90% of the population and this, in the main, represents the normal distribution used in designing workstations.

A more scientific approach to the problem and supported by a mass of useful anthropometric data for those wishing to study the subject more deeply is given in the book *Bodyspace* by Stephen Pheasant,[16] which also provides a considerable number of relevant supporting references. It is also worth repeating the author's five fundamental fallacies.

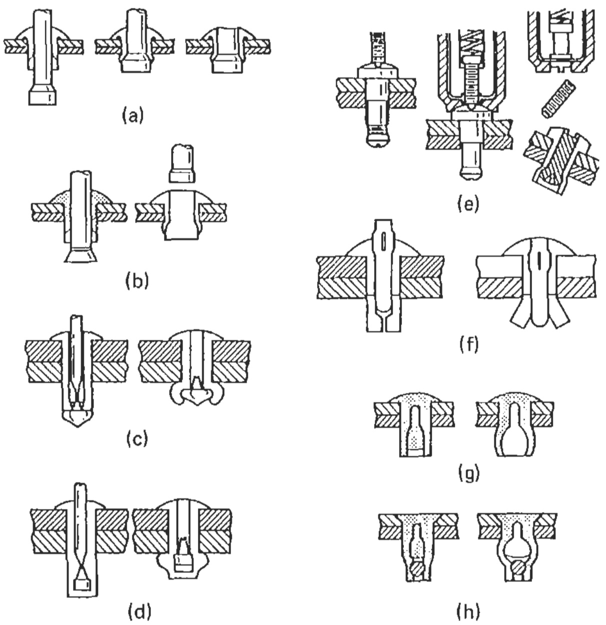

Figure 6.17 Blind rivets. (a) Break-stem mandrel; (b) pull-through mandrel; (c) break-stem mandrel (open end); (d) break-stem mandrel (closed end); (e) threaded mandrel; (f) drive pin; (g) chemical expanded (open end); (h) chemical expanded (closed end)

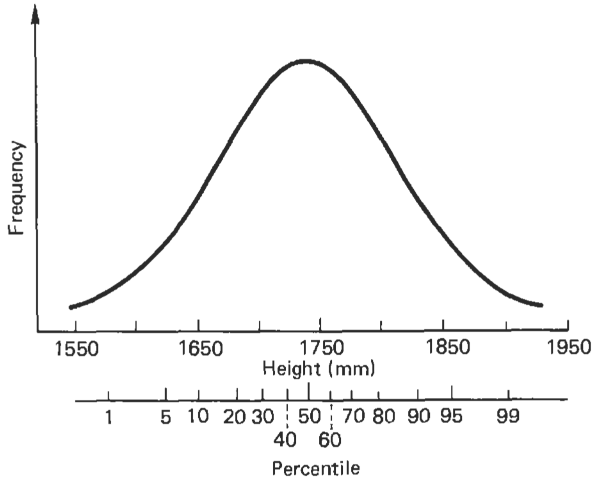

Figure 6.18 Size distribution in a population

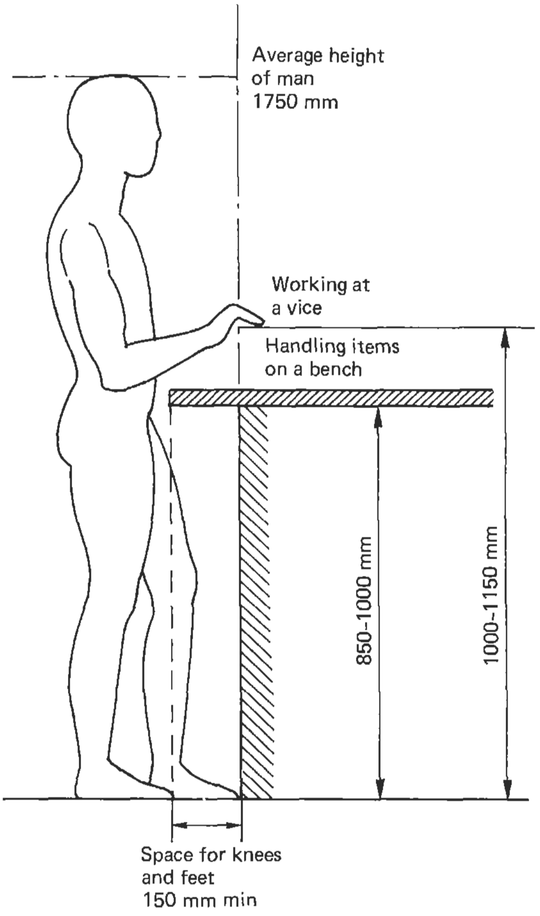
1. This design is satisfactory for me – it will, therefore, be satisfactory for everybody else.
2. This design is satisfactory for the average person – it will, therefore, be satisfactory for everybody else.
3. The variability of human beings is so great that it cannot possibly be catered for in any design – but since people are wonderfully adaptable, it does not matter anyway.
4. Ergonomics is expensive and since products are actually purchased on appearance and styling, ergonomic considerations may conveniently be ignored.
5. Ergonomics is an excellent idea. I always design things with ergonomics in mind – but I do it intuitively and rely on my common sense so I do not need tables of data.

Figures 6.19 and 6.20 give the generally accepted dimensions for the 5th and 95th percentile female/male, but using these normal dimensions of the average female/male without careful consideration of the range of possible dimensional combinations is, for example, one of the reasons for uncomfortable seats. It is very often assumed that people with short legs have a short trunk. In fact they can have a long trunk. In the same vein, long-legged people can have long or short trunks. This is compounded by variations in arm length and distances between joints (e.g. ankle and knee, wrists and elbow; see Table 6.5). Therefore it is not always satisfactory to take a proportional dimension from a person's overall height. Large-scale surveys have provided an opportunity to compare the morphology of different populations and gain some idea of the differences. Another factor can arise in respect of posture. Different people, geometrically similar, sit differently in the same seat.



Average height of man 1750 mm
Working at a vice
Handling items on a bench
850-1000 mm
1000-1150 mm
Space for knees and feet 150 mm min

Figure 6.19 Worker standing at a bench

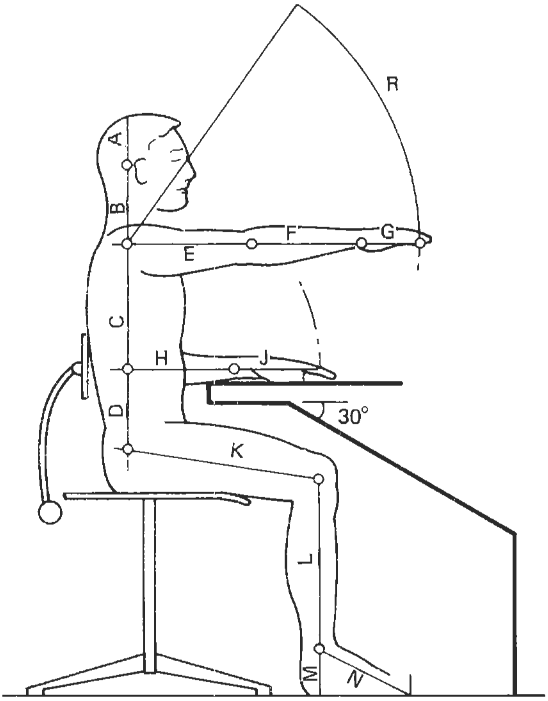


Figure 6.20 Sitting posture with limb dimensions (see Table 6.5)

Table 6.5 Dimensions between joints for woman/man (see also Figure 6.20)

Limb	*Female* (mm)	*Male* (mm)
A	105	125
B	170	185
C	290	295
D	170	185
E	290	295
F	200	255
G	160	195
H	200	255
J	160	195
K	430	460
L	370	395
M	110	105
N	220	240

In 1972 a set of three-dimensional data was collected on 281 subjects in a US Federal Aviation Administration-sponsored study of female flight attendant trainees. Each subject was asked to sit in the same hard seat as if she were in a commercial aircraft. The anthropometrist then attempted to align her mid-saggittal plane coincident with the mid-line of the seat. A multitude of mid-points were measured and posture was found to be not standardized. In fact, the variety of postures which an individual or a group of individuals may assume, is, for all practical purposes, infinite. Therefore the designer can only set limits and, within these limits, provide all the support that is needed, irrespective of posture.

Ergonomics or human engineering has four main disciplines:

- Anatomy and physiology (human structure and functioning)
- Anthropometry (body size)
- Physiological psychology (brain and nervous system)
- Experimental psychology (human behaviour)

It is not suggested that designers should be experts in these disciplines – these are largely the area for the scientists. Nevertheless, designers and engineers should be aware of the need to address the problems of a human/machine interface, which, of course, includes human comfort if the maximum output is to be obtained with minimum input.

Many factors are involved – not just the position, for example, of a person in relation to controls and instruments or working geometry of seats or workstations, but also to climate, comfort, noise, light and vision, body balances and the senses. Instrument and control knobs are a study in themselves. Should instruments be analogue or digital? Should they display up and down or from left to right or vice versa? Is colour important? Should control knobs be of a particular shape or texture? Should they be pulled or pushed? Rotated to left or right? And so on.

Considerable research has been carried out into these aspects and a number of conclusions have been formed upon which modern controls and instrumentation layout is based. Nowhere is this more critical than in aircraft cockpit layouts, PSVs and train controls, where speed and accuracy of human response is all-important, perhaps to the extent of a few milliseconds between safety and disaster.

Having decided upon a basic layout, the next problem is often a knowledge of forces that the human limbs can exert. Pedals and levers in particular must be designed to accommodate the appropriate human forces, bearing in mind that while a maximum force can be applied, to do this repeatedly will exhaust the operator in a very short time. As a guide, loads used in repeated movements should be no more than 10% of the maximum. Static loads such as those arising from a cramped work posture add considerably to fatigue and impair efficiency. Static loading cannot be entirely eliminated, as the stability of the human frame and the control of precise movements all necessitate certain static muscular loads. Wherever possible, the number of groups of muscles used at any one time to perform a given task should be limited and torsional loads around the vertical axis of the body avoided.

The amount of force that can be exerted by any limb depends largely on body posture and the direction of the force (see Figure 6.21). It must also be borne in mind that movements are less taxing when they are in alignment or sympathy with the natural movements of the human body. For example, in moving objects on a table it is less fatiguing to move them at 45° to the table edge than parallel and at 90° (see Figure 6.22).

The amount of information available on forces that can be generated during specific types of movement is considerable. Research has been carried out on sports such as golf, tennis, running, bowling, etc. where forces and reactions have been measured. Thus, there is no reason for manufacturers getting their designs wrong for lack of information.

The types of control should permit the efficient use of the limbs (see Figure 6.23). Hands, for example, should be used for quickness and accuracy; feet can exert considerable force. Controls in general should follow the movements of the objects being controlled, and where there are several controls in a group, sufficient space (certainly not less than 50 mm)

The amount of force that can be exerted by the limbs depends largely on the body posture and on the direction of the force.

should be left between them. For pushbuttons and toggle switches, this separation should not be less than 15 mm.

The force to operate pushbuttons can vary between 2.5 and 11 Newtons having in mind frequency of operation. Foot-operated pedals usually mean an ankle movement which should be limited to an arc of less than 25°. The maximum force applied from a standing position can be between 90 and 900 N, again depending on frequency of operation and holding time. Where the leg is used to apply a pressure, the diagram in Figure 6.24 offers some guidance.

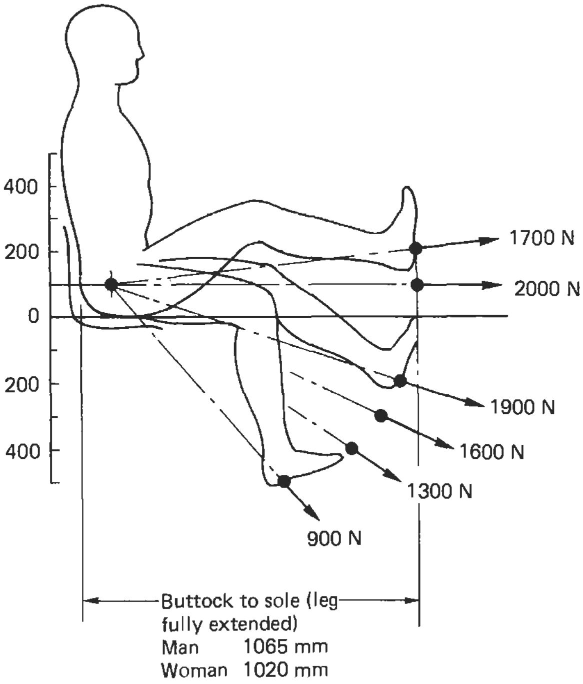

Figure 6.24 Forces from leg movements (based on information from Vademecum Ergonomics in Industry, Philips Technical Library)

Long levers are preferable to short ones, as they require less force in operation and the arm movement is more linear. Hand motion of short levers describes more of an arc. Levers necessitating considerable force should be at shoulder level for standing work and at elbow level when seated (see Figure 6.25). In both cases they should be slightly to one side of the operator and move towards the axis of the body so that the body is subjected to as little torsion as possible. Operating angles of levers should ideally not exceed 90° and the necessity perhaps of additional sideways movement (e.g. car gear lever) should be kept in mind. Maximum force that can be applied fore and aft should not exceed 130 N. Not the least important aspect is the feel of the lever or control knob, since in some applications the grasping of the lever is a reflex action which is an automatic reaction to a stimulus. Conditioned reflex is a reaction not natural to a specific stimulus but can be developed by association and repetition until it becomes automatic and appears to be a natural reaction. Many industrial tasks of a repetitive nature become conditioned reflex actions. An example is driving a car.

An important criterion is response initiate time, i.e. the time taken from the application of a stimulus to the start of a reaction. This, in turn, depends on which of the senses is being motivated – touch, hearing, sight, smell. The rate of response, in turn, depends on the sex, age, health and arousal of the subject.

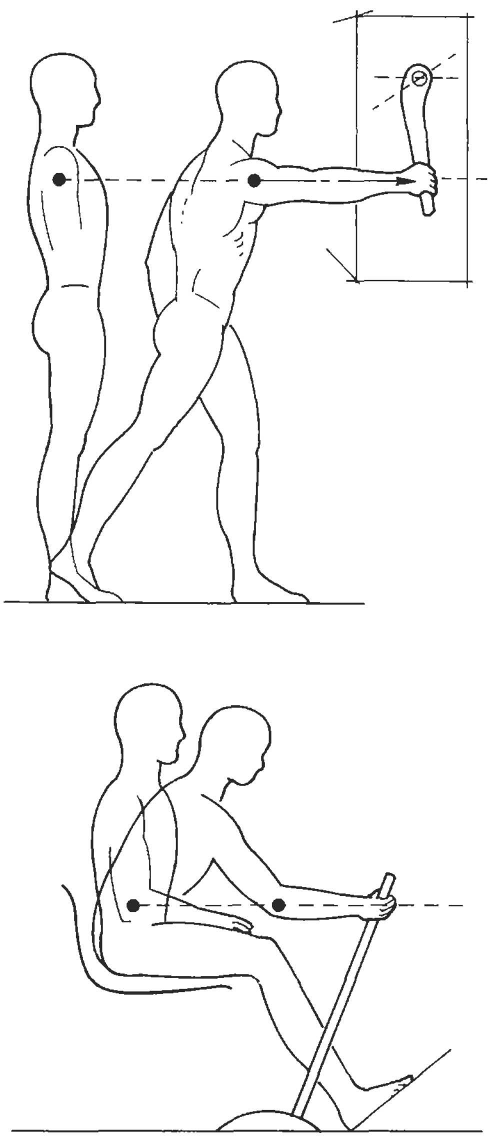

Figure 6.25 Lever positions (courtesy Human Factors Engineering, McGraw-Hill Ltd)

In many work situations the eyes and ears can be overloaded, therefore tactile sensing comes into play, and the shape and feel of a control knob becomes more important than being just a device to effect control. In working in a dim light it is important that the shape and feel and size of the knob indicates what it does and whether it should be pulled, pushed or turned. In all cases, there should be a logical connection between the direction of movement of a control and the reaction of the object being controlled.

An important area in human/machine relationship is instrumentation, the ability to see what is happening to a process and to be able to interepret variations to detect a possible calamity and to be able to reach relevant alarms and other controls in an emergency (see Figure 6.26).

The cockput of a modern aircraft provides a typical example of the importance of instrument placing. While each application will demand its own particular answer, it is generally accepted that in an instrument control panel the most important instruments and the most often used controls should be placed in the lower right-hand area, while those requiring less attention are spaced in the remaining area. Each application, of course, may have over-riding considerations and these must be taken into account. Again, in general, the instruments should be within the normal field of vision, i.e. immediately in front of the observer and in the zone from eye-level to approximately 30° below.

There are very many types of visual indicators, ranging from the simple circular dial through linear or logarithmic displacement indicators to digital readouts. Each has its own particular advantages and disadvantages. Digital readouts are, for example, excellent for reading absolute values. Dial and linear indicators provide an indication of values within the context of limits (e.g. zero and a maximum). For example, it is more comforting to drive a car knowing the fuel tank is half-full of petrol than knowing there are 5 gallons in the tank, because the driver has to mentally calculate what proportion 5 gallons is to a full or empty tank. Where displays are calibrated, care should be taken that the legends are readable. Colour can play an important part in defining certain areas.

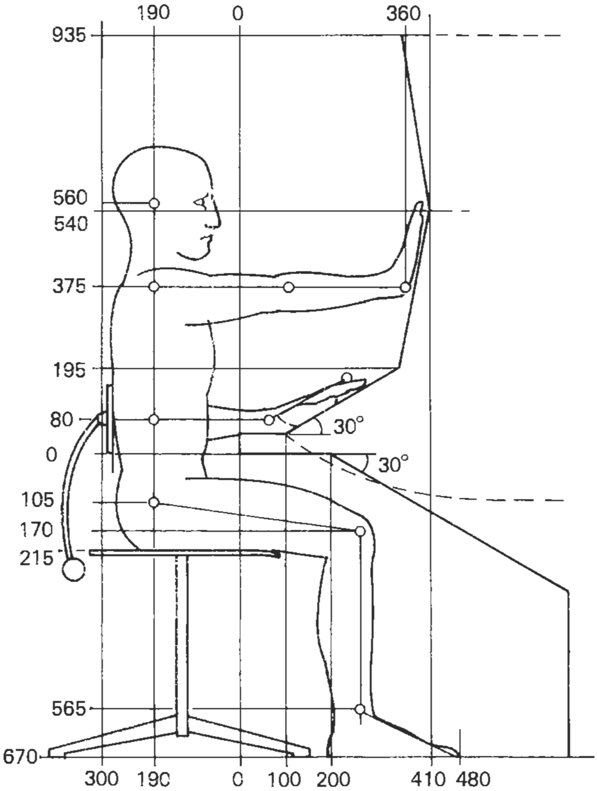

Figure 6.26 Layout of instrument panel in relation to sitting operative (based on information from Vademecum Ergonomics in Industry, Philips Technical Library)

In production engineering, flexible manufacturing systems (FMS) are now being widely employed to improve productivity and quality as well as the quality of life for the operator. The new techniques will have a major impact on economic factors. Research, however, has been mainly in the development of the technical aspects of software and hardware. Not so much has been directed to identify specific ergonomic problem areas, although universities worldwide have been studying problems of ergonomics and anthropometry. In the UK these include:

Loughborough University
University of Aston, Birmingham
City of London University
John Moores University
University of Surrey

More specifically directed research is being undertaken by

Central Electricity Generating Board, Barnwood, Glos
ITT Europe – ESC Research Centre, Harlow
RAE, Farnborough
National Institution of Agricultural Engineers, Silsoe
MRC Applied Psychology Unit, Cambridge

Much has been learned but there is much more to know – all of which will be invaluable for improving human/machine relationships.

6.6 Total quality – a company culture

Quality is and must be an emotional issue – largely a question of attitudes to be taken seriously. Failure to understand how to improve quality and value of goods and services on an ongoing basis means dissatisfied customers, declining markets, vanishing profits, reduced salaries and benefits and, ultimately, loss of jobs.

Customers expect quality. Once goods and services are delivered, reworking them to correct deficiencies is expensive both for the manufacturer and the customer. The purpose of quality management is to enhance the ability to improve products and services, to remove obstacles that prevent this and to use the collective talents and skills of the entire workforce. It means designing work processes so that each person has the right information, equipment, systems, procedures and training whenever and wherever it is needed.

Robert Gavin, the chairman of Motorola, regards people as the ultimate high technology. Companies that can best mobilize the collective insight and the talents of their employees have a great competitive advantage.

Quality is defined in the *Shorter Oxford English Dictionary* as 'Character, disposition, nature, capacity, ability or skill; excellence of disposition; an accomplishment or attainment; rank or position, nobility; an attribute, degree or grade of excellence'. As a company culture and a means of improving a product or service, quality is synergistic.

To achieve quality in products and service each company must lay its own stepping-stones to achieve the elimination of defects and to ensure consistency in the end product or service. It must first measure and review the current situation and then see where defects are occurring and, more importantly, why. This must include the setting up of feedback routines from the marketplace. People are of vital importance and training and retraining schemes must be envisaged.

Demand from companies wanting help in setting up quality management systems and meeting the requirements of BS 5750 are growing. Smaller companies now require this support as large firms increase their demands for improved quality standards from their suppliers. Today, major purchasers demand proof of a company's ability to produce quality products and provide a quality service and the provision of this proof in the form of independent third-party certification is possibly the most important factor in the successful marketing of a supply company. BS 5750 registration is going to become increasingly a condition of contract supply as currently practised by many large establishments such as British Gas, the CEGB and motor manufacturers such as Ford.

The BSI (British Standards Institution), through its certification and assessment services, provides industry with BS 5750, a first-class product certification and company quality-assessment scheme that will efficiently and effectively satisfy the customer. BS 5750 is divided into three distinct parts:

Part 1 – Specification for design, manufacture and installation
Part 2 – Specification for manufacture and installation
Part 3 – Specification for final inspection and test

Part 1 would cover a company engaged in the total activity of design and manufacture. Part 2 is for those companies only manufacturing and assembling to designs other than their own, while Part 3 is for companies engaged in final testing and distribution.

To be registered by BSI means that the company in question has been independently assessed by a team experienced in quality assurance and the technical conditions applied to that particular industry. The first essential for assessment is that a quality system is being operated which meets the requirements of BS 5750, and this must be documented. Registration commences when the assessment team is satisfied that the firm is operating its acceptable quality system and have agreed to the required level of audit tests.

From a realistic point of view, it is essential that the top person, whether he or she be Chairman, Managing Director or Chief Executive, is committed to quality assurance. Only he or she can inspire the workforce and generate the enthusiasm necessary to get the job right first time.

To do this it is necessary to have effective and continuing market research on the customers' quality needs. Unless these needs are fully understood, the designer will be unable to cater for them. Marketing must also ensure accurate promotion of the product and service, delivery on time as specified and efficient servicing and maintenance.

In the majority of cases a company will buy in raw materials and basic components. It is in the firm's interest that the quality of these parts is beyond doubt. Pressure should be exerted on supply companies to ensure that goods have zero defects. It is also important to bear in mind that true costs of poor materials, unreliable components and shoddy sub-assemblies far outweigh the savings made through the purchase of inferior stock. This becomes even more important when the JIT (Just in Time) technique is being used on the shopfloor. One of the implications of JIT is the requirement to issue parts from suppliers direct to the manufacturing lines without the more conventional goods-inward inspection operation to detect failing batches.

It is worth considering the conventional inspection process. At the end of the line, it only weeds out the faults that should never have happened in the first place. It does not place quality into the product. Inspection is a waste of effort if expensive equipment and skills are inspecting quality at the end of the manufacturing line. They should be part of the manufacturing process.

Because it is axiomatic that the customer is always right, complaints from customers are generally interpreted as being caused by a product or service failure. But research finds that the customer often contributes directly or indirectly to the cause of the problem. An example concerns the use of a product. If the customer fails to carry out specific directions for the product's use and/or maintenance then a defect may arise. The answer is to ensure that adequate instructions are provided and that there is no question of such instructions being misinterpreted. If manufacturers concentrate on the more traditional aspects of quality assurance then they may be forced to make extensive and expensive modifications to the product, whereas the provision of adequate instructions together with, perhaps, a HELP telephone number, would be just as effective and much less expensive.

Typical causes of customer dissatisfaction fall into four categories. Only those in one category (i.e. problems caused by production defects) can be totally fixed within the plant. In the other categories – (1) customer based, (2) marketing/delivery based and (3) product design – customers often constitute a part of the problem either because they have not adhered to the instructions or because the company has not fully allowed for customer behaviour.

Making a product 'idiotproof' is nearly always possible (at a price) but rarely practised. A manufacturer has to make a product 'pro idiotproof' in line with what constitutes a reasonable attitude on the part of an average customer. Sometimes they get it wrong, but too often it is because the company wants to keep down costs.

This is where designers can exercise their ingenuity by assessing the problem and approaching a solution by lateral thinking. Taking a simple example would be a hook on which fingers and clothes could be caught. Instead of redesigning the hook, would it not be possible to create a different design approach in which the hook could be eliminated?

Other defects arise from incorrect handling of components during installation because the designer had failed to appreciate handling problems. For example, heavy valves were being loaded/unloaded by threading a chain through the flow area, creating internal damage which caused the valve to malfunction. The blame must be laid on the lack of instructions on the way to load and unload the valves. A more meaningful ploy would have been to fit an eyebolt in an obvious and prominent position on the valve, thus drawing attention to the loader that here was a point to which a chain and hook could be attached. Not only would this prevent internal damage but it would also make the task of loading and unloading easier and quicker.

Humans, like rivers, will also take the path of least resistance. It is no good designing a path laid as two sides of a triangle to get from A to B when the hypotenuse is the shorter route. As mentioned earlier, quality is an emotional experience and it is important that this is at the back of the mind of every designer and that he or she is aware of human shortcomings.

There are five major routes for feedback from customers to manufacturers:

1. Direct customer complaints
2. Complaints from sales force/retailers
3. Warranty returns
4. Direct sampling
5. Customer-satisfaction survey

Each route has its own limitations and therefore all five sources of complaints must be used to get to the kernel of the problem.

Companies have discovered that pre-emptive education is cheaper than later repairs. One motor manufacturer is compensating its sales force for providing a 20-minute customer-education session on how to use the vehicle and to appreciate maintenance. This can have a significant impact on the

long-term satisfaction and loyalty of customers. Another manufacturer provides similar information via video tapes.

The first move for any company wishing to improve the quality of its products is to study BS 5750. First impressions may be that it is too generalized in its approach, but it has to apply to a wide range of very different industries and allow scope for its recommendations to be incorporated into existing management structures. It seeks to formalize the various stages in design and manufacture so that each step can be analysed and documented. As time goes by, the results so obtained can be used for comparisons, to seek out weak spots and where high costs are involved. With these data available, remedial measures can be adopted.

There is no magic in BS 5750. It really states the obvious – obvious, that is, to many companies who have had an efficient scheme to check the development of a product from concept to marketing. What BS 5750 does do is to bring some degree of standardization to these states.

Numerous bodies exist that are well qualified to help in setting up quality assurance. For example, there is EnTra (Engineering Training Authority), which took over from the original EITB (Engineering Industries Training Board) in the UK. Field training advisors are listed by the DTI (Department of Trade and Industry) as consultants, and their services are available to any company which seeks to introduce or improve its quality-assurance system.

More recently, the Danbury Park Management Centre has set up what is the first Total Quality Management Unit. Its overall purpose is to create a centre of excellence for the development and provision of training programmes and consultancy in Total Quality Management. The unit will also provide a forum for managers to compare quality initiative plans and performance and learn from each other through sharing experiences.

- To provide an open access facility which would offer a range of open-learning opportunities and tutorial help and support in all aspects of quality management.
- To assist with the identification of training and development needs of quality management staff in the engineering and associated industries and to provide a range of training programmes to meet those needs.
- To provide a focal point for the design and development of short courses and seminars for quality management and related staff.
- To provide a forum for directors, senior management and quality managers to share experiences, ideas and approaches to the resolution of problems related to quality management.
- To create a central location for the collection of information relevant to quality management – books, journals, articles, courses, etc.

It is obvious that a company would benefit from the services of a trained quality assurance manager or someone who can be a focal point for quality matters. Various training courses are available, either externally or within a company, from establishments such as PERA and Cranfield Institute of Technology. There is also an Institute of Quality Assurance as well as MSc courses for Quality Assurance so that there is no excuse for not being able to find a person highly qualified in quality matters. With the cooperation of the DTI there are also free consultancies for companies wishing to set up systems to conform to BS 5750. PERA and Cranfield are but two establishments geared up to this activity.

Not without interest is a self-appraisal kit from the Chartered Institute of Management Accountants for identifying and measuring quality related costs in the manufacturing industry.

A designer should always seek to reduce the complexity of an assembly and thereby improve the quality of the finished product. As an example, in an electronic assembly it was possible to reduce the number of fasteners from 120 to just 40 and, and in consequence, to decrease the number of adjustments in final test from 200 to 30. All these contribute to improved quality, reliability and serviceability as well as reducing manufacturing costs.

Quality should not be confused with reliability. The two are quite different. Establishing a quality assurance programme should ensure that reliability is consistent for each similar product. In other words, if a product has a designed life of three operating years, then every one of the same line of products should have this life span within narrow limits, whereas without quality control, the life may vary between wider limits such as 88–120%.

Measurement and documentation, which are part of the requirements of BS 5750 approval, are important for keeping track of modifications and improvements in a quantitative sense. The emphasis on measurement is comforting, as it focuses attention on the fact that better control is required.

The importance of selecting appropriate measurements in order to track improvements in any process, direct or indirect, is unquestionable. The ability to select those areas for improvement which gives the greatest return on investment in either equipment or skills depends in itself on the measurement of existing processes.

For quality management to be seen as effective and taking its true position in management planning it is essential that its performance be measured. Without an effective system for quality cost associated data gathering and analysis management are unaware of the true costs of not getting things right and hence are unable to target areas of improvement.

RAPRA Technology is investigating what quality costing systems (if any) are being used currently within the plastics and rubber industries. With this as background and in consultation with companies participating in a multi-client project, a system to complement companies' existing management systems will be produced.

More and more designing is being carried out with the aid of computers and appropriate software. CAD/CAM/CAE/CIM (Comptuer Aided Design/Computer Aided Manufacture/Computer Aided Engineering/Computer Integrated Manufacture) are essential to the designer and these techniques are ideal for keeping track of design modifications and to ensure that the maintenance of quality always prevails during the process of manufacture.

Software specific to the maintenance of quality is now available, and under the terms of a recent agreement, quality control and assurance software produced by the Valisys Corp. (a subsidiary of FMC Corp.) is being made available by McDonnell-Douglas to satisfy manufacturing industry requirements in the UK.

Valisys software complements McDonnell-Douglas' UNIGRAPHICS II CAD/CAM/CAE software, widely used by industry and available as nine fully integrated modules. In combination, they provide an unparalleled degree of automation in quality assurance inspection, evaluation and accept/reject tasks. A high degree of quality intelligence is built into the software to ensure that integrity of the original design can be realized throughout the entire production process.

Valisys verifies dimensioning and tolerancing specifications, speeds and simplifies tooling and fixturing, and executes automatically generated inspection paths. It allows for the correct orientation of machine tools with respect to part and feature location and compares finished parts against soft gauges (functional inspection gauges created in software form using UNIGRAPHICS II). Benefits claimed by McDonnell-Douglas for Valisys include:

- 70% reduction in inspection machine programming time
- 50% saving in cost/procurement of hard gauging
- 40% less time needed to set up critical machining operations
- 80% fewer hours spent reworking complex parts.

It is all too easy for a designer to get sidetracked. Starting with a concept and finding that other problems arise, be they manufacturing or costs, it is all too easy to concentrate on these new issues and alter the design, overlooking some of the earlier concepts and reasons. Every alternative design must be considered in the light of previous considerations.

In a paper to the Institution of Engineering Designers, G. J. Baker points out that:

> Quality points affecting design and design procedures come under the headings of Safety, Reliability, Life, Conformance, Interchangeability, Identification, Traceability, Communications, Verification, Unambiguity, Clarity etc. This means that most of the tangible design activities are of interest and concern to the QA engineer but in the main, the intangible activities are not. The intangible activities in general are the creative thought and artistic processes essential to the overall design exercise. They are a combination of natural flair, imagination and perception that enable the design engineer to arrive at the shape, colour and texture of a particular item, which when coupled with fundamental engineering principles, interest and effort in the work, form the basis of design solution conceptions.

It is stressed that the work carried out at the design stage lays the keystone of quality in the final product because the manufacturing drawings, as the final medium of expression of the design, form the basic work instructions for the production phases. Figure 6.27 presents the tangible design activities involved in a full project/product work programme and covers the pre-production, concurrent and post production phases.

Many companies are recognizing the value of ensuring quality design and manufacture and are producing various ideas for ensuring this. Sigma Ltd, for example, have announced a computerized data-collection system that, they say, will improve quality control and productivity. Their 769 DataMyte Attributes Collector is a complete system for the checking and analysing of attributes at any stage of manufacture or even in a service industry, where defects are not normally quantifiable. For example, it records whether there are dents, scratches, assembly errors, textile faults, etc. and the regularity of their occurrence. The basis of the DataMyte 769 system is a hand-held battery powered data-collector featuring a two-line character display. It is menu-driven with application-specific functions programmable through either the keyboard or a computer (see Figure 6.28).

Another company, Mari Advanced Microelectronics Ltd, has been awarded a certification of approval for the prestigious quality management system BS 5750: Part 1. Mari specializes in the provision of CAD/CAM equipment, support and consultancy with the emphasis on mechanical engineering. With BS 5750 being increasingly demanded by end users in the aerospace, automotive, defence and engineering industries, the approval will enable Mari to comply with the quality assurance standards required of suppliers to these and other industries.

Yet another example of a company's desire to provide quality products concerns the 1989 Ford Fiesta, which went on sale in the spring of that year. As part of a major quality campaign, Ford earlier set up a special fleet of pre-production cars which it placed with selected business and public users in European countries (Figure 6.29). These vehicles were monitored weekly for quality, reliability, durability and operating economy. The information was analysed by Ford in order to detect and correct any quality concerns before any units were actually sold to the public.

7.1 Engineering properties of materials

7.1.1 Elastic properties

Elastic or Young's modulus, E (units are GPa). The stress required to produce unit strain in the same direction, i, in the absence of restraint in the orthogonal directions:

$$E_i = \sigma_i \epsilon_i^{-1} \tag{7.1}$$

where σ is the stress and ϵ the strain which it produces. A standard testing method is described in ASTM E231.

Shear modulus, G (units are GPa). The shear stress required to produce unit angular rotation of a line perpendicular to the plane of shear:

$$G = T \cdot \phi^{-1} \tag{7.2}$$

where T is the shear stress and ϕ the angular rotation in radians.

Bulk modulus, K (units are GPa). The hydrostatic pressure p required to effect unit change in volume V:

$$K = p \cdot V \cdot (\Delta V)^{-1} \tag{7.3}$$

Poisson's ratio, ν. The ratio of the strain in a direction orthogonal to the direction of stress to the strain in the direction of stress:

$$\nu = \epsilon_{j,k} \cdot \epsilon_i^{-1} \tag{7.4}$$

These four basic elastic properties apply to homogeneous and isotropic materials and are related by the equations

$$\begin{aligned} E &= 3K\,(1 - 2\nu) && (7.5)\\ &= 2G\,(1 + \nu) && (7.6) \end{aligned}$$

In the case of a material which has anisotropic elastic properties the terms used may have different meanings and stresses and strains should be related using tensor analysis.

7.1.2 Tensile-testing parameters

When considering the properties obtained from the tensile test it should be realized that the results are always reported as though the load was applied to the initial cross section, A_o, of the test piece. Any reduction of this cross section is ignored. The test subjects a sample of material of circular or rectangular cross section, of a specific gauge length and equipped with end pieces of larger section which taper smoothly to the gauge length.

When subjected to uniaxial tension beyond the limit of proportionality the material within the gauge length elongates plastically, contracts uniformly or locally transversely and work hardens. The stress σ in the material increases but, because of the decrease in the cross-sectional area, A, the stress, S, calculated from the load the original cross-sectional area, A_o, increases more slowly, attains a maximum value S_u and (usually) declines before the specimen breaks.

Limit of proportionality. The stress at which elastic behaviour of a material is replaced by a combination of elastic and plastic behaviour. This is normally expressed either as

Yield stress S_y, MPa or as

Proof stress $S_{\left\{\begin{smallmatrix}0.5\\0.2\\0.1\end{smallmatrix}\right\}\%}$, MPa

where

$$S = \frac{P\left(\begin{array}{l}\text{yield or}\\ \text{strain offset}_{\left\{\begin{smallmatrix}0.005\\0.002\\0.001\end{smallmatrix}\right\}}\end{array}\right)}{A_o} \tag{7.7}$$

where P is the load.

Ultimate tensile stress, S_u (MPa), is the maximum load at which a ductile material fractures in the tensile test divided by the original cross-sectional area. S_u is not to be confused with σ_u, the true stress:

$$\sigma_u = S_u \cdot A_o \cdot A_u^{-1} \tag{7.8}$$

where A_u is the cross-sectional area at the time of failure.

S_u depends on the dimensions of the specimen (the length of the gauge length is normally $0.565\ \sqrt{A_o}$ but it may be 50 mm or some other value), and the rate of application of stress. Both these parameters should be recorded.

Fatigue endurance is related to S_u rather than S_y. The difference between S_u and S_y is a measure of the safety margin against accidental overload.

Most modern design codes base the permissible stress in a material on a factor (say, 66%) of S_y. Some other codes use a factor of S_u as a design criterion. This is cost effective and safe when using a ductile material such as mild steel.

Tensile ductility is reported either as

Elongation e (%),

$$e = \frac{\delta}{L} = \frac{L - L_o}{L_o} \times 100 \tag{7.9}$$

where δ is the extension to fracture, or

Reduction in area, A_R(%):

$$A_R = \frac{A_o - A_u}{A_o} \times 100 \tag{7.10}$$

Ductility is the property that confers tolerance to flaws to a material, and is also an indication of material quality and correct heat treatment. Standards usually specify a minimum ductility. Standard procedures for tensile testing are given in BS 18 and ASTM E8, E345 and B557.

Flexural strength S (MPa) is the calculated maximum stress on the tensile side of a beam which failed when stressed in bending. It is used to measure the strengths of materials such as cast iron and ceramics which are too brittle to be tested by the standard tensile test. A beam stressed in three-point loading has the maximum stress applied only on one line on the surface.

Multiple testing is required to produce results which can be used in design and much higher safety factors (see Section 7.7) are required than are used for ductile materials tested by the standard tensile test. A standard testing method is described in ASTM C580.

7.1.3 Hardness

Hardness is the resistance of a material to permanent deformation by indentation or scratching. It is not a simple intrinsic property of a material but a complex response to a test. Vickers, Brinell and Knoop compare the load and the area of the impression produced by an indenter, Rockwell the load and the depth of the impression, Shore the rebound of an indenter and Mohs the ability of one material to scratch another.

Vickers Hardness HV (strictly, the dimensions are those of force per unit area but in practice Vickers and Brinell hardnesses are comparative numbers) is the quotient obtained by dividing the load F (kgf) by the sloping area of the indentation left in the surface of the material in mm^2 by a 136° pyramidal diamond indenter:

$$HV = \frac{2F \sin(136/2)}{d^2} = 1.854\ Fd^{-2} \qquad (7.11)$$

where d is the diagonal of the indentation.

Hardness is a measure of the wear resistance of a material. Used on metals the Brinell hardness value of a medium-carbon steel is directly related to the UTS, the Vickers hardness to the proof stress. Vickers, Brinell and Rockwell can be used to ensure that heat treatment has been correctly carried out.

Hardness testing of ceramics is performed with very light loads to avoid failure of the material.

Standards for hardness testing are

Vickers	BS 427, ASTM E92
Brinell	BS 240, ASTM E10
Rockwell	BS 891, ASTM E18
Schleroscope	ASTM 4448

7.1.4 Fracture toughness and impact testing

7.1.4.1 Fracture toughness testing

Plane strain fracture toughness K_{1c} (Nm$^{-3/2}$). The limiting stress intensity required to cause crack extension in plane strain at the tip of a crack when the stress is transverse to the crack. K_{2c} and K_{3c} are parameters corresponding to stresses in the plane of the crack. Standard testing methods are BS 5447, ASTM E399.

Elastic-plastic fracture toughness, J_{1c}. The limiting value of the J integral (which is a line or surface integral used to characterize the fracture toughness of a material having appreciable plasticity before fracture) required to initiate crack intension from a pre-existing crack.

Stress intensity to initiate stress corrosion, K_{1scc} (Nm$^{-3/2}$). The limiting stress intensity required to initiate propagation of a crack in a specific environment at a specific temperature.

7.1.4.2 Impact testing

In contradistinction to fracture toughness testing which quantifies a material property, Izod cantilever and Charpy beam type impact test results are a function of the method of testing. They particularly use a machined, rather than a fatigue-propagated notch. Results are expressed as the energy J (in joules) required to break the cross-sectional area behind the notch.

Testing a number of specimens of body-centred metals, ceramics and polymers over a range of temperature will reveal a transition temperature below which brittle behaviour is observed. This is reported as the fracture appearance transition temperature (f.a.t.t) (°C) at which half of the fracture surface is fibrous and half crystalline or as the fracture energy transition temperature (°C) at the inflection in the energy curve. This is a criterion of use for assessing material composition, treatment and behaviour. Standards for impact testing are BS 131, ASTM E23, E812 and E602 (sharp notch tension testing).

7.1.5 Fatigue

S–N curve. Graphical relationship between stress, S, and number of cycles, N, required to cause failure of a material in a fatigue test. This depends on mean stress, frequency and shape of stress cycle, temperature and environment, all of which should be specified. Note that this applies to high cycle fatigue.

High strain fatigue is strain, not stress related and plastic strain per cycle, ϵ_p, is inversely proportional to $N^{1/2}$ for almost all engineering materials.

Fatigue endurance limit, σ_e (MPa). The maximum stress below which a material is presumed to be able to endure an infinite number of cycles. This applies only to certain specific engineering materials such as steel and titanium.

Fatigue limit, σ_{10^7} (MPa). The maximum stress below which a material is presumed to be able to endure a specific number of cycles, usually 10^7 to 10^8 but may be lower for specific applications. Fatigue endurance limit and fatigue limit are both statistical quantities and depend on the same parameters as are detailed under the S–N curve.

Standard methods for fatigue testing are BS 3518, ASTM E513, E912, E206, E742, E466, E606, E468, E739. There are other ASTM standards in Vol. 03;01.

Fatigue life for p% survival (MPa). The maximum stress below which not less than p% of tested specimens will survive.

Fatigue notch factor, K_f. Ratio of the fatigue strength of a notched to that of an unnotched specimen.

Fatigue notch sensitivity g (ratio)

$$g = \frac{(K_f - 1)}{(K_t - 1)} \qquad (7.12)$$

where K_t is the stress concentration factor. When g approaches 1 a material is fully sensitive. When g approaches 0 a material is insensitive.

7.1.6 Creep and stress rupture

Creep range. The temperature range, usually above half the melting point temperature in °K, at which the design stress computed from creep or stress rupture is lower than that calculated from yield or 0.2% proof.

Stress to rupture, σ_R. (MPa). The tensile stress at which a material will fail if held at a specific temperature for a specific time, depending on the type of application.

Stress to a certain creep strain, σ_ϵ. (MPa). The tensile stress at which a material will creep to a specific strain, ϵ (ignoring the initial strain on loading), if held at a specific temperature for a specific time. σ_ϵ and σ_R are related for a specific material.

Creep rupture elongation, (%). The percentage of the original length by which a creep rupture specimen extends before failure.

Larson–Miller Parameter, P. A parameter used to extrapolate the results of creep rupture tests carried out at relatively short times to longer times. The rate equation is

$$P = T(\log t_R + C) \qquad (7.13)$$

where T is the absolute temperature and C an empirically determined constant. Other rate equations have been derived by Sherby-Dorn and Manson-Haferd.

Standards for creep and stress rupture testing are BS 5447 and ASTM E1 329 for metals and BS 4618 for plastics.

7.1.7 Thermal properties

Specific heat per unit mass, C_p (Jkg^{-1}K^{-1}). The rate of change of heat content of 1 kg of the material with temperature. Specific heats are often quoted as Jg^{-1}K^{-1} or in compilations of thermodynamic data as cal.mole^{-1}K^{-1}. They may also be quoted as mean specific heats over a range of temperature, usually 25°C to a specific elevated temperature.

Specific heat per unit volume. C_v (Jm^{-3}K^{-1}). Specific heat C_v of a gas at constant volume does not include the work required to expand the gas and is therefore lower than C_p.

Thermal expansion. Linear thermal expansion α (K^{-1}). The fractional increase in length, l, per degree rise in temperature at a specific temperature, T:

$$\alpha(T) = l^{-1}\frac{dl}{dT} \tag{7.14}$$

More commonly, a mean expansion between two temperatures

$$\bar{\alpha} = l_0^{-1}\frac{\Delta l}{\Delta T} \tag{7.15}$$

when Δl is the change in length from l_0 at temperature T_0 when the temperature is changed by $\Delta T = T - T_0$, is quoted. In data compilations T_0 is often 25°C.

In anisotropic materials (single crystals or materials with preferred orientation), the thermal expansion coefficient may differ between each of the three orthogonal directions x_i, x_j and x_k.

Thermal conductivity, λ (Wm^{-1}K^{-1}) is the heat flow per unit area generated by unit temperature gradient

$$\lambda = A^{-1}\frac{dQ}{dt}\cdot\frac{dl}{dT}$$

where dQ/dt is the rate of heat flow across area A and dT/dl is the temperature gradient. λ is normally a function of temperature and, in anisotropic materials, of direction.

Thermal diffusivity, D (m^{2}s^{-1}), is a measure of how fast a heat pulse is transmitted through a solid:

$$D = \frac{\lambda}{\rho C_p}$$

where λ is the thermal conductivity, ρ the density and C_p the specific heat. Thermal diffusivity varies with temperature but can be measured more quickly and accurately than thermal conductivity.

7.1.8 Electrical properties

Volume resistivity, ρ (Ωm). The resistance in ohms of a metre cube of the material:

$$R = \rho l A^{-1} \tag{7.16}$$

where R is the resistance of a body, l its length and A its uniform cross section.

Dielectric breakdown. No standard symbol (KVmm^{-1} or KV). Measured according to IEC 672, BS 1598:1964, ASTM D116 or DIN 40685.

Relative permittivity. The ratio of the charge storage capacity of a material in an electric field which results from crystal realignment of its structure compared with the charge storage capacity of empty space.

Permittivity ($AsV^{-1}m^{-1}$), where A is current in amps, s time in seconds, V electric potential in volts and m metres.

Dielectric loss, tan δ. The phase angle introduced by the time taken for polarization to occur on application of a field. Tan δ is frequency and (usually) temperature dependent.

7.1.9 Optical properties

Spectral absorption coefficient, K (mm^{-1}). The log of the ratio of the incident to the transmitted light intensity through unit thickness:

$$K = (\log I_0 - \log I)\, x^{-1} \tag{7.17}$$

where I_0 is the incident intensity, I is the transmitted intensity and x the thickness in mm. K varies according to the wavelength of the incident light.

Refractive index, μ. The ratio of the velocity *in vacuo* to that in the medium:

$$\mu = \mathrm{V}_{\mathrm{vacuo}}\cdot \mathrm{V}^{-1}_{\mathrm{medium}} \tag{7.18}$$
$$= \mathrm{Sin}\, i \cdot \sin^{-1} r$$

where i and r are the incident and refracted angles of the beam to the surface.

7.2 The principles underlying materials selection

7.2.1 Introduction

The requirement for selection of a material may arise from a number of circumstances, including:

1. An entirely new component is to be developed to perform functions not hitherto visualized;
2. A component is required to perform an increased duty which has rendered the performance of the material previously used unsatisfactory;
3. The incidence of failure in the material which has so far been specified is too high, or occurs at too early a stage in the life of the component;
4. Some material shortcoming not strictly related to operational performance has become apparent. A material which was acceptable initially may become unsatisfactory because:
    (a) it has become so expensive, relatively or absolutely, that the equipment, of which the component is a part, can no longer fulfil an economic function;
    (b) it is no longer available locally or globally (or might become unavailable in the event of an emergency);
    (c) it is no longer acceptable on grounds of health, safety, aesthetics or public sentiment.

Examples of materials which have been developed in answer to the listed circumstances are:

1. The 'magnox' can for the first-generation gas cooled power reactor;
2. Superalloy blades of progressively increasing creep resistance, culminating (so far) in the directionally solidified castings now used;
3. Notch ductile aluminium killed steels to replace the materials which failed by brittle fracture in the 'liberty' ships;
4. (a) Steel-cored aluminium instead of copper conductors for overhead power lines;
    (b) Nickel-based superalloys for military jet aircraft after it was realized that the sources of cobalt in cobalt-based superalloys were situated in volatile African or Iron Curtain countries;
    (c) Ceramic fibres to replace asbestos as a binder for heat insulation because of the hazard of 'Asbestosis'.

All of these examples of material choice were developed by means of the techniques which will be described later in this section. The materials selected have performed entirely satisfactorily, and in those cases where operational parameters were not the cause of replacement the substitute material has in fact performed better than the original.

7.2.2 Techniques of materials selection

There are at least three different techniques by which the optimum material for use in a specific component may be selected:

1. The 'Classical Procedure' using functional analysis and property specification;
2. The 'Imitative Procedure' which consists of finding out what material has been used for a similar component;
3. The 'Comparative Procedure' which consists of postulating that the component be made from some cheap and well-understood engineering material, assessing in what ways such a material's performance would be inadequate and from this arriving progressively at the right material.

The Classical Procedure is the only one that is universally applicable and it is essential, even when procedures 2 or 3 are followed, to check the findings by functional analysis and property specification. By itself, however, the Classical Procedure is expensive and time consuming and requires a considerable amount of prototype testing to ensure that no critical requirement or essential property has been overlooked.

The Imitative and Comparative Procedures, where applicable, will provide invaluable shortcuts, save a great expenditure of time and money and will help to ensure that no essential parameter has been overlooked. The materials engineer will be wise to employ all three techniques in parallel wherever practicable.

7.2.3 Preliminary examination of design

It is essential, whichever procedure is employed, to commence with the analysis of the function of a component, the critical examination of the design and the establishment of materials property requirements. Design affects materials selection procedure at all stages. A component may fulfil its function in more than one way using different designs which result in different materials property requirements and hence different optimum materials, and different manufacturing routes. For example, a box with a hinged lid may be made from two pieces of thin metal sheet and a pin or from one piece of polypropylene.

The effect of design on manufacturing process is particularly important when considering a materials change in an existing product (for example, from metal to plastic or ceramic). Design and materials selection constitutes an iterative process: design affects the optimum material which, in turn, affects the optimum design.

7.2.4 The Classical Procedure

7.2.4.1 Functional analysis

Functional analysis is a formal way of specifying material properties starting from the function of a component. This involves specifying

1. The functions of a component
2. The requirements for a component
3. The requirements for material properties

Function The overall function should be specified as broadly as possible to allow the greatest number of options in design. Where there are several functions all must be specified. This latter requirement is essential even when the choice of material has been necessitated by the failure of a material to perform one specific function, because a change in a material to make it capable of fulfilling one function may make it incapable of fulfilling another. Using a higher-tensile steel to carry an increased load may result in brittle fracture under shock, for example.

Component requirements When the functions have been established the component requirements can be identified. For example, the one-piece box mentioned above must be capable of being opened and closed an indefinite number of times.

In specifying component requirements it is important to remember that it must be possible to produce the article in the required form, and that the component must withstand the environment in which it is operating at least for its design life.

Materials property requirements From the component requirements the materials property requirements can be established. The material for the one-piece box must have an almost infinite resistance to high strain fatigue in air at room temperature. This is obtainable from a polypropylene component manufactured in a specific way.

The property requirements established by functional analysis may be quantitative or qualitative. For example, the material for an automotive exhaust *must* be sufficiently strong and rigid to withstand weight and gas pressure forces. Quantitative requirements must be established by analysis of the design and operating conditions. In comparison, the requirement to resist corrosion and oxidation is qualitative. Property requirements may also be classified as essential and desirable. The strength requirement in the material for the exhaust is essential. Environmental resistance is often sacrificed to minimize initial cost (even when, as in this example, a more resistant material may have superior economics considered over the total life of an automobile).

7.2.4.2 Materials requirement checklist

The next stage is the formulation of a materials requirement checklist, and the properties which will feature in this checklist are given in Section 7.1.

The reader should not be discouraged by the length and complexity of this list. It will, in many cases, become evident that whole ranges of properties (and materials) may safely be ignored at first glance. For example, if the component is required to transmit or refract light the choice of material is immediately limited to a glass, mineral or polymer and design and property specification is restricted. If electrical conductivity is significant, choice is limited to conducting metals, resistive or semiconducting materials or insulators.

Important characteristics The important characteristics requiring consideration for many engineering components are: mechanical properties; stiffness, strength and ductility; physical properties, thermal, electrical, magnetic and optical properties; environmental resistance and wear including applicability of corrosion protection; capacity for fabrication and cost which includes material, manufacturing, operating and replacement cost.

Mechanical properties Resistance to manufacturing and in-service loads is a requirement of all products. The material must not buckle or break when the component comes under load. It must also have an economic life in fatigue or under creep conditions. Where a number of materials meet the minimum strength and stiffness requirements a preliminary shortlist can be made on the basis of cost per unit strength or unit stiffness (or, in the case of space or transport applications, strength per unit weight).

Physical properties Physical properties such as specific gravity are important for most applications. For some, as noted above, optical or electrical properties may be paramount.

Environmental resistance (corrosion) Environmental resistance is a property whose universal importance has been obscured by the circumstance that it has been inherent in the choice of materials for most common applications.

Corrosion resistance requirements vary, from the absolute, where even a trace of contamination in a fine chemical food or cosmetic is unacceptable, to the barely adequate, where the cheapest material whose integrity will survive the minimum economic life should be chosen.

When assessing corrosion resistance, attention should be paid not only to the rate of general corrosion but also to the possibility of localized corrosion which, as described in Section 7.8, may destroy component integrity without significant dimensional changes. Corrosion mechanisms may cause the disintegration or deterioration of metals, polymers, ceramics, glasses and minerals.

Wear resistance Wear is the product of relative movement between one component and another or its environment. Its prevention depends principally on design and operation, but can be minimized or eliminated by the correct choice of material, material pair, or coatings.

Manufacture and cost Manufacturing routes are selected on the basis of lowest total cost to produce the desired performance. In the past, performance requirements have favoured certain processes such as forging instead of casting, but more recently attention to quality improvement techniques in casting have levelled up in-service properties and cost is emerging as the deciding factor.

It is difficult to assess the relative total costs of different material/manufacturing route combinations at the early stage of a design and, wherever possible, finalizing precise geometries should be delayed until possible materials and manufacturing routes have been identified, otherwise there will be an avoidable cost penalty.

Cost of a component includes:

In-position costs which comprise, material cost influenced by quality and quantity, manufacturing cost, quality control cost and administration cost and
Lifetime costs which comprise servicing, maintenance, warranty, outage and replacement cost.

Costs which accrue at different periods must be discounted to a common date. Differences in discounting rates between different countries or organizations can lead to the selection of different materials for applications which are, in all other respects, identical.

Comprehensive knowledge of the application is important in assessing the relative importance of cost and performance. Cost is paramount in the case of a widely marketed consumer item where small differences in reliability and life have little influence on saleability but performance is paramount for certain sporting or military applications.

There may, for example, be no advantage to be gained by incurring additional expense to prolong the life of a car exhaust system from 5 to 7 years when the purchaser intends to replace the car after 2 years. The sales department must always be consulted before the final material choice is made in cases such as this.

On the other hand, the material from which a racing-car spring is made must have the maximum possible specific rigidity, regardless of cost. The potential rewards for employing the optimum material far outweigh any cost saving which might be obtained by choosing the second-best.

Material selection When the properties of candidate materials have been ascertained (by procedures which will be discussed later) a shortlist should be established. If it is immediately obvious that one material is outstandingly superior the choice is straightforward. Often there is one property requirement that outweighs all the others. When this is the case the choice is simplified. There may, however, be a number of possible materials, or none may meet all requirements.

A number of procedures have been proposed for eliminating all but one of a number of possible materials. These include an advantage/limitation table, an elimination grid[1] and ranking methods for properties, and number of properties, that meet requirements.

Often, local factors (i.e. using a material which is familiar locally, using a material which has a margin in one specific property that may be of value in a future marque of component or using a material that is suitable for a locally available fabricating or machining technique) will influence the final choice. When no material meets the requirement, a careful re-examination may reveal that a change in design, environment or operating conditions will enable satisfactory performance at minimum extra cost. As a last resort, it may be possible to arrange for easy replacement after a fixed time, and to hold a supply of spares.

7.2.5 Drawbacks of the Classical Procedure

The application of the procedures outlined above guarantees success if followed logically and completely and design, operating and material parameters are thoroughly understood. However, this is seldom the case in practice. Designs cannot always be evaluated precisely, material properties are seldom specified fully and it is impossible to predict exactly what an operator will do.

In most cases the Classical Procedure requires a considerable amount of mechanical property evaluation, possibly materials and process development and a substantial programme of prototype testing, before satisfactory performance can be guaranteed. Time may not be available to undertake this. The easiest way to a short cut is the Imitative Procedure.

7.2.6 The Imitative Procedure

Find out what material has been used for the same component or a component as similar as possible and use this, an improved material, or a material modified for the difference in conditions. Successful implementation of this procedure not only verifies design and reduces material property evaluation but also very substantially reduces prototype testing because the most likely causes of failure have already been experienced and cured.

The problem is to ensure that the information obtained is accurate, comprehensive and fully understood. Even within an organization, operators' reports are not completely reliable. A report of satisfactory performance may merely mean that operators know when the component is about to fail so that they can replace it without extra outage. One operator may have found out how to handle this component and a similar component may fail disastrously in the hands of another. These difficulties are compounded when information is obtained from an outside source, whether rival or friendly. Informants do not mean to mislead. The information they withhold is usually information that they cannot imagine that the recipient does not already possess.

The ability to obtain information when it is required depends on appropriate organization. There should be a materials engineer who combines knowledge of all the materials and requirements of the organization with an acquaintanceship or, ideally, friendship with all similar persons throughout the world. The right person is, when presented with a problem, able to contact someone who already has experience of the matter wherever he or she may be and obtain the benefit of that experience. His or her knowledge of the other organization would be sufficiently comprehensive to enable him or her to assess the effect of different procedures between the two organizations. The chemical industry (as described by Edeleanu[2]) operates a worldwide information system with personnel of this type and has found that information on what can be done and how to do it may most efficiently and quickly be obtained in this way.

7.2.7 The Comparative Procedure

The Comparative Procedure for materials selection operates by selecting a cheap, tolerant and well-understood material and investigating to what extent its properties fall short of those required for the component to operate satisfactorily. A typical example, and one for which this procedure is extremely suitable, is the specification of a material for chemical process plant.[3] A scheme design is produced using carbon steel which is cheap, readily produced, easily fabricated, ductile and therefore tolerant of flaws and geometrical irregularities and corrodes uniformly at a predictable rate. If carbon steel is shown not to be satisfactory the unsatisfactory property or properties can be modified. The necessary change may impair other properties but will do so in a predictable way. Thus:

> Improved corrosion resistance may be obtained by the use of a steel with a higher chromium and possibly a higher nickel content. This will increase cost and probably also delivery time, render design and fabrication more sensitive and may enhance sensitivity to localized corrosion.

Improved strength may be obtained by the use of a steel with increased carbon and alloy content with drawbacks similar to those that applied in the case of the improved corrosion-resistant material.

A higher temperature of operation may require the use of a creep-resisting steel, again with similar disadvantages. Operating at a lower temperature may require a steel with guaranteed low-temperature properties or may, in the limit, require an aluminium alloy.

Evidently, this procedure, with the exception of the case where a change is made to a completely different material, involves changes which are progressive, and whose effects can be foreseen. Therefore the chances of encountering some unexpected drawback are minimized and the requirement for component testing is minimized also.

7.2.8 Information sources

It has so far been assumed that staff charged with material selection have at their disposal a complete range of information on material properties. This may be the case when electronic databases[4] now being developed are perfected. In the meantime they should have available for reference, British, American and possibly German materials standards, and such volumes as the *ASM Metals Handbook*, the *Plastics Encyclopaedia* and as up-to-date a ceramics work as is then available. In addition, the *Fulmer Materials Optimizer*, which shows properties of all types of engineering material in the form of comparative diagrams, will prove an invaluable guide to materials selection.

When the field has been narrowed down to a few materials the materials manufacturer should be consulted. Organizations such as steelmakers or polymer manufacturers possess more information on their products than has been published and also experience in their application. They can provide valuable guidance on final selection, design and manufacture.

Furthermore, it should be remembered that a standard steel obtained from one manufacturer may differ in some relevant characteristic from the same steel purchased from a competitor. A reputable manufacturer is aware of this and should warn of problems which will have to be overcome in addition to extolling advantages.

7.2.9 Computerization of materials selection

Much effort is at present deployed on the production of databases for material properties. Three recent international conferences have been devoted to this subject[4] and a directory of databases for materials is available.[5] These databases are not necessarily material-selection systems and much interest has been directed to providing systems which will undertake material selection by the classical functional analysis and property-specification procedure.

It is not possible, legitimately, to computerize the Imitative Procedure because no organization can be expected knowingly to provide another (possibly competing) organization with access to programs intimately concerned with its own design philosophy and development programme. There is, on the other hand, no difficulty in computerizing the Comparative Procedure of materials selection. So long as (1) the materials involved form a very closely related family with very similar properties, (2) no novel and unforeseen failure mechanism takes over and (3) the properties of the candidate materials have been determined comprehensively, a computer program which will select the optimum material for a specific application can easily be produced.

Two such programs are known to exist. They are ICI (EPOS) for the selection of polymers and a Sandvik program for selection of cutting tools. These are knowledge-based systems dealing with families of essentially similar materials. A computer program for selection of process plant materials as described in Section 7.2.7 would be equally straightforward, provided the requirements could be met by a steel and no unforeseen failure mechanism took over.

The requirements for a computer program to undertake selection by the Classical Procedure are much more general and much less well defined. The starting point is a product design specification (PDS), which is a functional and formal statement of what is required from the product to be designed, not a description of the product. The PDS contains a material design specification (MDS) which, like the PDS, is incomplete and ill-defined. The computer must match this MDS to descriptions of existing materials and materials specifications (MS) which may be incomplete and reflect various levels of confidence. The result of the analysis may be a requirement to modify the PDS, to develop a new material or to acquire additional information concerning specific materials.

A computer system capable of selecting materials requires:

1. The ability to deal with simple and complex data structures;
2. Powerful structures for data acquisition and updating by augmentation and modification;
3. The ability to manage sparse data;
4. The ability to compare incomplete descriptions;
5. The ability to distinguish the relationships, and sometimes

lack of relationships between materials, or parameters nominally in the same classification;

6. The ability to be easily extensible.

It must take into consideration:

1. The duty or function of the component;
2. The materials properties;
3. The manufacturing route;
4. Shape, dimensions and failure mode;
5. The relative cost of the materials, manufacturing routes and designs considered.

It must, in addition, have the following user characteristics so that it can be operated by designers and engineers and free the materials engineer for long-term, difficult and strategic problems. It should:

1. Be rapid in use;
2. Require a minimum of learning;
3. Be accessible at different levels to suit different levels of user;
4. Have text and graphical output; and
5. Have recording facilities.

Various procedures for optimized decision making have been put forward, including linear programming methods[6] and numerical algorithms.[7] There is a tendency to rely on ranking methods which allocate a rank from 0 to 3 for each material property. This introduces an imprecision which should not be necessary in the application of a computer capable of relating property variation with overall cost.

There exists at least one system, which is claimed to be applicable at the innovation stage in design. A brief description of this system is given as an example of methods which could be employed.

PERITUS[8] is a knowledge-based system which comprises three main stages:

1. A Director stage which directs the non-specialist to data and knowledge modules. The structure of this is shown in Figure 7.1;
2. A Presort stage which produces a shortlist of candidates from the materials indicated by the Director stage utilizing ranking lists;
3. An Evaluation and Optimization stage. This can either display the shortlist with deviations compared with the ideal or, where the required modules exist, optimize according to failure modes, component dimensions and properties (presumably including overall cost).

The system is modular and additional modules may be added as required or when available (see Figure 7.2). Further information on the PERITUS system is to be found in references 9 and 10.

7.2.10 An example of the application of the Classical Procedure

In conclusion, the principles governing materials selection are illustrated by a description of the choice of materials for the core of the magnox reactors. Design and materials selection for the magnox reactors had to fulfil the following terms of reference:

> The reactors must operate on natural uranium because enrichment would not be available within the required time scale. The reactors must produce electricity safely, reliably and economically and their construction must meet a time scale.

Figure 7.1 The structure and features of the Director stage of the PERITUS knowledge-based system for the selection of engineering materials. (Reproduced by permission of *Metals and Materials*)

The requirement to operate on natural uranium required, from nuclear considerations, that the fuel elements should be based on bars of almost pure uranium between 2.5 and 3 cm diameter and restricted the choice of moderator material to a dense form of carbon, beryllia or heavy water. Adequate supplies of heavy water would not become available within the time scale. Beryllia was hazardous and little was known about the effect on it of the helium that would be produced during irradiation. The core therefore had to be a graphite structure which must be self-supporting and provide channels for the coolant. A research programme demonstrated that this was practicable. Information available from abroad indicated that pure uranium distorted severely under irradiation. A research programme also showed that it also swelled severely.

An intensive programme resulted in the development of 'β quenched uranium', a dilute alloy with aluminium and iron. Distortion is minimized by means of a fine random-grain structure and swelling by a precipitate of uranium aluminium intermetallic which restricts diffusion of fission product gases.

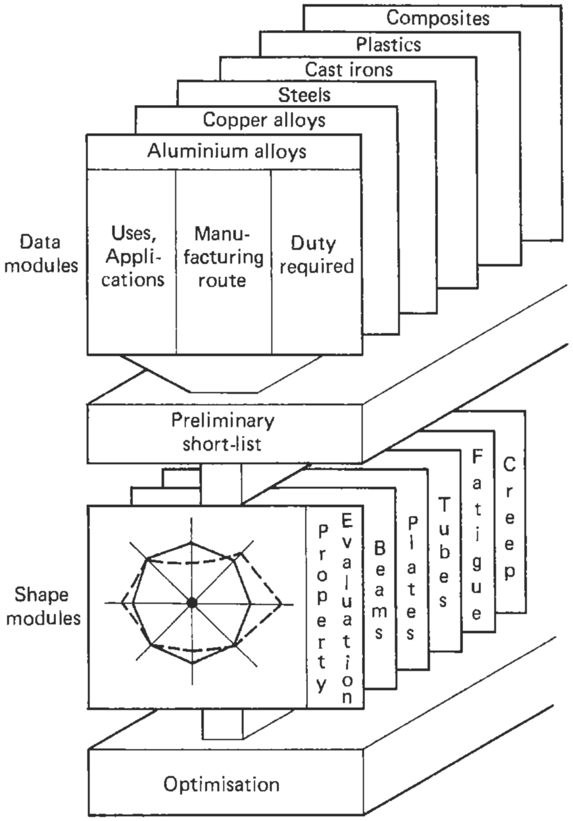

Figure 7.2 A representation of the organization of the pre-sort, evaluation and optimization stages of the PERITUS knowledge-based system. (Reproduced by permission of *Metals and Materials*)

The size of the gas bubbles is thereby minimized and their growth is restrained by surface tension. This keeps swelling to an acceptable value.

The development programme also showed that the uranium must not be heated long or often into the β phase. This limited the temperature of the centre of the fuel elements, and therefore their rating.

The next step was to choose a gaseous coolant and a canning material that was impermeable to uranium, fission products, plutonium, the chosen coolant, atmospheric air and water. The possible gaseous coolants were helium, hydrogen, oxygen, steam, air, nitrogen and CO/CO_2. Hydrogen was eliminated on grounds of safety, nitrogen on nuclear grounds (a loss of nitrogen coolant would greatly increase reactivity) and oxygen or steam would attack graphite. It was doubtful whether adequate supplies of helium could be made available. Carbon dioxide (which would equilibrate in the circuit with carbon monoxide) was cheap, readily available, had good heat-transfer properties and a low neutron capture cross section, and was relatively inert. Provided that a suitably compatible canning material could be found, carbon dioxide would serve.

The canning material had to have a low neutron absorption cross section. It had to be compatible with uranium, carbon dioxide and, unless a suitable separating material could be incorporated, with graphite. The material had to be fabricated, and sealed into an impervious can in direct contact with uranium and the can had to be finned to increase heat transfer. It had to be strong enough for the fins to withstand coolant forces at an operating temperature up to, say, 500°C and to be ductile enough to deform rather than fracture when subjected to the permanent strains imposed by the distortion of uranium under irradiation (which had been minimized but not eliminated) and by the cyclic strains caused by differential expansion.

The materials permitted by nuclear considerations were carbon, beryllium, magnesium, aluminium and zirconium. Carbon lacked the necessary ductility for a can of the size required in direct contact with uranium. (Although it has since been used successfully in the form of small spheres containing uranium oxide or carbide with a helium coolant. This solution was ruled out because of the enrichment required.) Beryllium lacked the required ductility and alloyed with uranium at reactor operating temperatures. Aluminium had been shown to alloy with uranium in a way that destroyed the integrity of the can at reactor operating temperatures. Satisfactory cans could be made from either magnesium or zirconium.

Zirconium as mined and extracted contains hafnium, which has a high neutron capture cross section and would have to be removed before the zirconium could be used for cans. This process would have to be developed, the resulting zirconium would be very expensive and the fabrication cost of cans would also be high and require a long period of development.

Magnesium was therefore chosen, but because of its known tendency to oxidize in air (not in carbon dioxide) beryllium was added in the form of an aluminium beryllium alloy so that the cans would be immune from oxidation in the event of an incident in which air gained access to the reactor charge of cans at high temperature.

Economic methods of fabricating finned magnox cans for service with uranium and methods of sealing which guaranteed less than 1 in 10^4 defective cans were developed. Many millions of cans have been manufactured and have operated without fault, and the use of the classical functional analysis and property specification method of materials selection is fully vindicated.

7.2.11 An example of problems which may arise during information transfer

In the early days of operation of the magnox reactors discussions were held with an organization engaged in developing the same type of reactor. The specification and performance of the successful magnox cans were described, but the other organization decided to use instead of the magnox composition a magnesium–zirconium alloy whose mechanical properties were superior. It was very much later, when very large numbers of cans had been produced, that it was discovered that, while both materials were completely impervious to uranium, plutonium which was produced during irradiation diffused through the aluminium-free cans. Although the amount diffusing through was too small to have any effect on operation, or even, when the cans had been removed from the reactor, on health, it was sufficient to interfere with the operation of the burst-slug detection gear and if continued would eventually have made the reactors inoperable.

This information had not been withheld intentionally. It was appreciated that plutonium could and might diffuse through magnesium but the possible influence of this diffusion on burst-cartridge detection and the effectiveness of aluminium in blocking it had not been recognized at this early stage.

7.3 Ferrous metals

7.3.1 Introduction and standards for wrought steels

The development of alloys of iron (which include wrought iron, steel and cast iron) has been essential to a technological society. Iron ore is widespread, cheap and easily mined, and from it can be produced alloys with the widest range of properties of any material. Steels may be manufactured with properties which vary continuously from soft and ductile to strengths and hardnesses which, until the very recent development of the sialons, exceeded those of any relatively inexpensive material.

There are a very large number of wrought steels and numbering systems. German specifications alone include 1400 grades. Because of the rapid evolution of ferrous metallurgy none of these classifications and numbers are ever fully up to date. In engineering, standard steels are commonly referred to by their AISI/SAE number[11] based on composition (Table 7.1). The last two figures indicate the carbon content in the case of non-stainless steels: the corresponding general British specification[12] is BS 970: 1983 and earlier. In it steels are identified by a three-digit number denoting the type of steel followed (in the case of non-stainless steels) by a letter denoting the type of specification – A for analysis, H for hardenability or M for mechanical properties, followed by two numbers denoting carbon content. For stainless steels the first three figures are identical with the AISI figures; the letter is S, and the final two numbers are coded. Wherever possible, in the account of classes of steel which follows, the AISI/SAE and BS ranges will be given. There are also a number of specifications depending on product or application which do not always follow the BS 970 or AISI/SAE numbering system. In addition to the standard steels, there are well-known steels which are recognized by designations used by their originators and are in no way inferior to standard steels. Many steels of this kind are recognized and used worldwide in aircraft specifications and are made by many different steelmakers, although they have not yet been recognized by the several national bodies that govern steel specifications. Cast irons and cast steels have separate specification numbering systems.

Table 7.1 Basic numbering system for AISI/SAE steels

Numerals and digits	*Type of steel and average chemical contents* (%)
	Carbon steels
10XX	Plain carbon (Mn 1.00% max)
11XX	Resulphurized
12XX	Resulphurized and rephosphorized
15XX	Plain carbon (max Mn range – over 1.00–1.65%)
	Manganese steels

94XX	Ni 0.45; Cr 0.40; Mo 0.12
97XX	Ni 0.55; Cr 0.20; Mo 0.20
98XX	Ni 1.00; Cr 0.80; Mo 0.25
	Nickel–molybdenum steels
46XX	Ni 0.85 and 1.82; Mo 0.20 and 0.25
48XX	Ni 3.50; Mo 0.25
	Chromium steels
50XX	Cr 0.27, 0.40, 0.50 and 0.65
51XX	Cr 0.80, 0.87, 0.92, 0.95, 1.00 and 1.05
501XX	Cr 0.50
511XX	Cr 1.02
521XX	Cr 1.45
	Chromium–vanadium steels
61XX	Cr 0.60, 0.80 and 0.95; V 0.10 and 0.15 minimum
	Tungsten–chromium steels
71XXX	W 13.50 and 16.50; Cr 3.50
72XX	W 1.75; Cr 0.75
	Silicon–manganese steels
92XX	Si 1.40 and 2.00; Mn 0.65, 0.82 and 0.85 Cr 0.00 and 0.65
	Low-alloy high tensile steels
9XX	Various
	Stainless steels AISI (*not* SAE)
2XX	Chromium–manganese nickel nitrogen austenitic steels
3XX	Chromium–nickel austenitic steels
4XX	Chromium–ferritic & martensitic steels
5XX	Silicon–chromium steels
	Boron-intensified steels
XXBXX	B denotes boron steel
	Leaded steels
XXLXX	L denotes leaded steel

7.3.2 Types of wrought steel

There are at least eleven separate classes of wrought steel most of which are further sub-divided.

Carbon steel (AISI 1006–1572–BS 970 000–119) is the basic type which far exceeds all other metals in tonnage produced. Low-carbon steels are sub-divided into hot-rolled (see Manufacturing Procedures below) and cold-rolled steel.

Hot-rolled steel has low strength (although the higher-carbon versions can be heat treated to high hardness in small sections) and low toughness but is readily available at low cost and is easily formed, welded and machined. Cold-rolled steel is harder, has good surface finish and dimensional tolerances, high strength at low cost and good machinability.

High-strength low-alloy steels are proprietary steels with low carbon made to SAE 950. They have significantly higher strength and are easily formed and welded.

Hardened and tempered steels (AISI/SAE 31–98 BS 970 500–599, including higher-carbon steels) are steels containing sufficient carbon and alloy to enable them to be heat treated to the desired strength and toughness at the design thickness. They may have high toughness and high strength at elevated temperature but they are more expensive than carbon steels and the higher-alloy steels have poor weldability and machinability.

Case-hardening steels are of relatively low carbon content (final BS specification Nos 12 to 25). They may be surface hardened by carburizing, carbonitriding or nitriding when heat treatment will produce a very hard surface and a softer (but, where necessary, strong) ductile core. They are used when wear resistance must be combined with core toughness.

Stainless steels (AISI 200–499, BS 970 300S–499S) contain chromium in amounts above 12% so that the magnetite layer formed on the surface of iron becomes, at lower chromium levels, a spinel and at higher levels chromic oxide. The introduction of chromium into the oxide layer greatly increases its stability and integrity and provides much-increased resistance to corrosion and oxidation, but also influences significantly the structure and properties of the underlying metal. The addition of further alloying elements results in five separate classes of stainless steel. These are, respectively:

1. *Ferritic stainless steels* are alloys of iron with up to 18% chromium and relatively small amounts of other alloy. They are ductile, the high-chromium versions have good corrosion resistance, and they are, relative to other stainless steels, inexpensive. They have a tendency to grain growth and are therefore difficult to weld. The recently developed 'Low Interstitial' ferritic stainless steels have chromium contents between 17% and 30% and very low carbon contents. These are claimed to have outstanding corrosion resistance but may be difficult to obtain.
2. *Martensitic stainless steels* are limited in chromium content to about 17% so that they may be hardened by quenching to give high hardness and strength.
3. *Austenitic stainless steels* avoid the problems which result from the addition of chromium to the ferrite matrix by the addition of nickel and other elements which change the structure to the high-temperature gamma form. The resultant alloys may have very high corrosion resistance, good ductility and/or high hot strength. Their very highly alloyed versions merge at iron contents below 50% into nickel alloys (see Section 7.4.5) and the very high creep strength versions are described as 'superalloys of iron'.
4. *Duplex stainless steels* have compositions which produce a mixed ferrite/austenite structure. They have excellent mechanical strength and corrosion resistance but may be difficult to obtain.

Precipitation-hardening stainless steels combine very high mechanical strength with excellent corrosion resistance. They require complex treatments.

Intermetallic strengthened (maraged) steels may be formed or machined in the soft condition and then aged. The maraged steels are very strong and very tough but very expensive.

The steel classes described so far have been based on composition and structure. Other classifications based mainly on application (which, to some extent, cut across the classification already described) include:

- *Electrical steels*: very low-carbon steels containing about 3% silicon supplied as strip, hot or cold rolled, with the surfaces insulated;
- *Spring steels*: in which a very high hardness can be produced by working, quenching or precipitation hardening. They may be carbon, alloy or stainless;
- *Tool steels*: used for forming or cutting materials. Their essential properties are high hardness, resistance to wear and abrasion, reasonable toughness and, in the case of high-speed steels, high hot hardness;
- *Creep-resisting steels*: with high creep and creep rupture strengths at high temperatures. They may range from bainitic through martensitic to austenitic steels and superalloys. The higher-temperature steels are also oxidation resistant because of chromium additions;
- *Valve steels*: with high-temperature tensile and creep strengths and good high-temperature oxidation and corrosion resistance. In the UK the title is restricted to certain martensitic and austenitic steels but in other countries it includes all steels which may be used for IC engine poppet valves.

7.3.3 Steel making and ingot casting

The raw materials for steelmaking (iron ore and coke) are converted in the blast furnace to molten iron containing about 3% carbon at a rate which varies up to about 8 million tons per annum. (This makes the blast furnace by far the most economic process for producing steel, but economies which have not the capacity to utilize steel production of this magnitude may utilize the direct reduction of iron ore to sponge and powder instead.) Figure 7.3 depicts a typical blast furnace.

The conversion of the iron from the blast furnace to flat products, billet bar and sections has, since World War II, undergone a revolutionary change due to the development of oxygen argon lancing, vacuum treatment, continuous casting and rapid in works analysis. Iron from the blast furnace is conveyed while still molten to the basic oxygen converter (BOC or BOF) (see Figure 7.4) where oxygen gas is passed through it reducing its carbon content to approximately that of the specified steel. It may then proceed direct to the pouring ladle, where alloying additions are made and slagging processes undertaken. The molten steel is poured into a lander which conveys it to a water-cooled mould whose base is formed by the previously poured solid metal. This metal is retracted through the mould which may oscillate in a vertical axis. The whole of the blast furnace output may pass through a single mould of this type (Figure 7.5(a)) and the cast metal may be fed directly into a rolling mill which reduces it to plate bar or section as required (Figure 7.5(b)). The process as described is applicable to very large throughputs but there is no reason successive ladle charges should not differ in composition, the different alloys being separated later in the mill train. Where higher-quality or special steels are required the liquid steel from the BOC may be transferred to a vacuum plant for further treatment prior to pouring[13] (see Figure 7.6).

The Dortmund Harder (DH) and Ruhrstahl Heracus (RH) processes transfer the metal from a ladle into a superimposed vessel, the DH by sucking it up by vacuum, the RH by driving it up by pressure of argon. A further improvement has been to equip a vacuum argon treatment vessel with electric arc heating (Vacuum Arc Deoxidation (VAD))[14] and effectively to produce a secondary steel-making process (see Figure 7.7).

Most special steels, particularly stainless steels, cannot be decarburized by the BOF because the oxygen which reduces the carbon present also oxidizes chromium. Oxidation may be prevented by blowing oxygen in a vacuum but there are practical problems involved. These may be overcome by the AOD process, in which an artificial vacuum (so far as the partial pressure of carbon monoxide is concerned) is produced by diluting the blown oxygen with argon. This process is carried out in a tiltable vessel[15] (see Figure 7.8) with base tuyères which agitate the vessel contents. With this process removal of carbon, slag reduction, metal dioxidation, desulphuration and alloying are easily achieved.

Conversion of the molten iron from the blast furnace direct to the finished product in an integrated steelworks not only gives significant economies in energy and labour but can also provide steel of a quality equal or better than was previously available from electric arc melting.

In the first place, oxygen blown steel is naturally low in nitrogen so that the toughness problems associated with strain ageing are eliminated. However, where, as in austenitic stainless steels, nitrogen has a beneficial effect on tensile strength, controlled amounts may be introduced by replacing some or all of the argon in the AOD process.

The greatest improvement in liquid metal quality is, however, gained by vacuum treatment. Raising and lowering the steel in the DH or RH vessel very significantly reduces the partial pressures of hydrogen and carbon monoxide in the melt and the

$$C + Fe\,O \rightarrow CO + Fe$$

reaction proceeds until equilibrium between carbon and oxygen is established at a lower oxygen level. Line A in Figure 7.9 represents the oxygen carbon equilibrium at 1013 mbar (1 atm) over the carbon range 0.03–0.13%; the effect of reducing the pressure (e.g. by vacuum degassing) to 133.3 and 13.33 mbar appears in curves B and C, respectively. Since carbon is lost to the system as well as oxygen the theoretical effect on a steel initially at 0.05% C is shown in line 1 connecting the three curves. The actual effect on steels with various vacuum degassing techniques is shown in lines 2–5. Vacuum degassing thus effects reduction of the oxygen content to levels less than half those obtained in the best practice in steels air melted and refined at atmospheric pressure. Consequently, final residual deoxidation can be effected with much smaller amounts of aluminium or silicon and much cleaner steel can be produced with (if required) lower carbon levels. Vacuum carbon deoxidation is extremely beneficial in the production of plate with good through-thickness ductile properties because it virtually eliminates planar concentrations of non-metallic inclusions.

Vacuum degassing techniques, properly applied to permit carbon deoxidation, are the most economical way of upgrading steels and, in particular, low-carbon steels. It is further possible to make injections in a stream of inert gas of such elements as calcium or calcium carbide which can reduce sulphur and phosphorus and to replace the sometimes damaging inclusion of silicons and aluminium with other inclusions which improve transverse ductility, fatigue and machinability.

Additional advantages are gained by the substitution of continuous for ingot casting. Carbon, sulphur and phosphorus have been shown to segregate enough to give a concentration ratio of 3 or 4 to 1 between the top and bottom of a large conventionally poured ingot. Silicate inclusions segregate to different parts of the ingot. No longitudinal segregation can develop in a continuously cast ingot once the casting process has reached equilibrium. The only longitudinal variation of composition is that between one ladle charge and another, and this is revealed by analysis and may be corrected before pouring. There will be some compositional variation across the section, and possibly between dendrites, but at the outside this is unlikely to exceed 5% on either side of the mean. Continuous casting has the further advantage that the cross section of the ingot can be much better matched to that of the final rolled product than is possible with a conventionally cast

ingot. A large plate requires a large ingot, which in conventional casting must be of large cross section and may be too large for the available rolls. With continuous casting the size of plate is only limited by handling down the line and the metal quality is improved by the finer structure achieved by casting a smaller section.

However, it is seldom that the quantity of special and stainless steels warrants production from hot metal in proximity to the blast furnace. Such steels are generally produced from cold metal in the arc furnace. Here the quality of the steel is dependent on careful selection of the charge, so that quantities of tramp elements tin, arsenic, antimony, bismuth, copper, etc., which have serious effects upon ductility and cannot be reduced by steel making are minimized. Electric arc furnace steel is usually considered superior to steel made in the BOF, but the application of AOD and VAD can produce equivalent steel from either.

There are other steel-making processes that will produce very high-quality metal, but all depend on the use of good-quality raw material. The vacuum high-frequency furnace will produce metal of low oxygen, nitrogen and hydrogen content, but is not well adapted to a continuous casting process. It is mainly used to produce small quantities of metal as small ingots (or castings). The highest-quality steel is produced by the consumable vacuum arc or the ESR processes. In both of these an electrode (or electrodes) is made of steel of the target composition and this electrode is progressively melted by striking an arc between it and a starting pad which is progressively withdrawn (or the electrode is withdrawn), thereby producing a semi-continuous casting (see Figure 7.10). The metal is refined on passing through the vacuum in the case of the consumable vacuum arc or through a low melting point slag in the case of the ESR. The solidifying metal is very well fed from the pool of molten metal and inclusions are dispersed and very substantially reduced in size. The consumable vacuum arc removes all gaseous or gasifiable inpurities but does not significantly influence the proportion of non-metallics.

ESR can transfer non-metallic inclusions into the slag but does not remove hydrogen. ESR consumables must therefore be hydrogen-free.

The influence of these melting processes on such important properties as ductility or fatigue strength is very significant. The highest property values are not usually improved significantly compared with conventionally melted steel, but the proportion of values falling below a specific standard is very significantly reduced so that a much higher component performance may be guaranteed. A small proportion of steel is electron beam or plasma melted.

The proportion of steel that is continuously (or semi-continuously) cast has greatly increased.[15] The large integrated steelworks may have its entire throughput fed to a one stream continuous casting of 1 m × 2 m section[16], but batch metal from an electric arc melting shop is often semi-continuously cast in sections down to approximately 10 cm. Mould costs are reduced and throughputs and metal recovery considerably increased compared with the older type of mould. The proportion of wastage at the feeding head and the chances of segregation in the pipe are reduced.

Ingot is still employed where the quantity of steel required is insufficient to justify the use of continuous casting or for very large forgings, where the cross section of the ingot required to withstand the reduction needed is too large for it to be continuously cast.

7.3.4 Mechanical working of metals

A metal is worked mechanically either to generate a shape more economically than can otherwise be obtained or to provide improved properties in one or all of strength, ductility or fatigue (not creep, for which a cast structure is superior). The improvement in properties may be overall, directional to resist a directional stress system, or statistical to ensure that a lower percentage of components fall below a specified level of properties.

Metals can be mechanically worked because they differ from other crystalline solids in that the atoms in a crystal are not linked by valency bonds to adjacent atoms. The free electron metallic bond is non-specific, pulling equally hard in all directions. Metal atoms are therefore bound tightly in certain regular crystalline structures. There are seven crystal systems giving 14 possible space lattices and all engineering metals crystallize in one of three of these lattices (see Table 7.2 and Figure 7.11). Some metals are polymorphic: for example, in the case of iron, austenite is face-centred-cubic, ferrite is body-centred-cubic.

These crystalline structures are resistant to tensile stress but can be sheared along certain crystallographic planes. The planes of lowest resistance to shear have the closest packing of atoms in the plane. Each trio of atoms in a close-packed layer surrounds a space (or hollow) in which an atom in the next layer can rest. Slip occurs when the atoms in a plane move into the next hollow in the adjacent plane. The shear stress required to move a whole plane of atoms is very high and a perfect metal crystal (such as occurs in 'whiskers') would deform elastically between 3% and 10% before deforming plastically in shear.

The crystals in massive metals are not perfect. 'Dislocation' rows occur in the lattice where an atom is missing or an additional atom is present. These dislocations allow the planes to shear one row of atoms at a time, thus greatly reducing the critical shearing force. More dislocations come into play as the metal is deformed and in most cases, two or more dislocations may interact and stop each other. The critical shear stress therefore increases and the metal work hardens, increasing its tensile strength. Finally, no more shear is possible and the metal fractures. If temperature is increased, diffusion and recrystallization can release stopped dislocations. In hot working, diffusion occurs while the metal is worked, but in cold working and annealing the two processes occur separately. In either case the grain of the metal may, if the conditions are chosen correctly, be refined.

Hexagonal close packed	Titanium,[a] chromium,[a] cobalt,[a] nickel,[a] magnesium, zinc

[a] Metals having polymorphic habit.

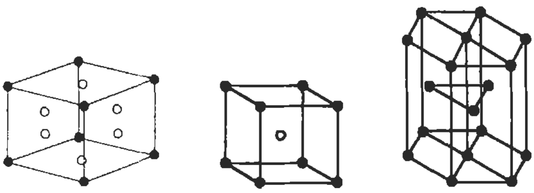

Figure 7.11 Three simple space-lattice systems unit cells

Mechanical working has other beneficial effects. The structure of cast metal may contain micro segregates, lumps and planes of constituents which separate out during casting. Mechanical working, correctly applied, may break up and disperse these to a size at which they can be diffused during heat treatment.

Castings may contain cracks, voids and non-metallic inclusions. Mechanical working, correctly applied, may close up and remove the cracks and voids (or aggravate them so that the part must obviously be rejected) and break up non-metallic inclusions. Alternatively, defects may be aligned and elongated in the direction of the tensile component of stress so that they do not impair resistance to fracture caused by tension or fatigue. Of the three space lattice systems shown in Figure 7.11 the face-centred-cubic has more planes on which slip can occur than the other two (which are themselves greatly superior to other lattice systems). Face-centred-cubic austenite is therefore more ductile than body-centred-cubic ferrite, and steel is usually hot worked in the austenite (γ) phase.

7.3.4.1 *Hot working*

Before working, the steel (unless already hot from continuous casting) is reheated into the γ-phase. Care must be taken to prevent excessive scaling and to avoid overheating (or burning) the steel. The limiting temperatures for carbon steels can be estimated from Figure 7.12 and are given in Table 7.3. Further forging temperature ranges are given in Table 7.4. Grain growth occurs when steel is held in the γ-phase, but subsequent working reduces grain size. Figure 7.13 illustrates these effects. The grain size of mild steel increases from ASTM 10 to ASTM 6 on heating to 900°C but six rolling passes reduce it to ASTM 10. Heating to 900°C has no effect on the grain size of two other steels but in both cases heating to higher temperatures increases grain size and rolling reduces it again. The finer austenite resulting from hot working transforms to a finer grain ferrite on cooling.

0.7	1215
0.9	1176
1.1	1133

[a] Maximum forging temperatures for alloy steels may be up to 50°C lower.

7.3.4.2 Rolling

Rolling is the most economic way of working steel if adequate quantities are produced. Steel for strip is cast into slabs, scarfed to ensure a defect-free slab and hot rolled using automatic gauge control. Carbon steels may be 'controlled rolled', that is, finish rolled at relatively low temperatures thereby inducing a fine ferritic gain structure with improved tensile strength and notch toughness.

Hot-rolled strip is cold rolled to reduce thickness and give the required surface finish and forming qualities. Finishing capabilities include rewinding to coil or cutting to length, side trimming and oiling. Roll trains for producing hot- and cold-rolled strip are shown in Figure 7.14.

By the use of a cluster mill, such as the Sendzimir (see Figure 7.15) strip down to 0.1 mm thickness can be produced. Grooved rolls are used to manufacture blooms, billets, bar and sections. Hollow sections can be produced by suitably designed mill trains and strip can be passed through forming rolls which turn the edges towards each other to form a seamed tube which is then welded continuously by inert metal arc or electric resistance. Seamless tube may be formed by cross rolling a billet in a Mannesman piercer in which the rolling action produces a tensile stress at the centre of the workpiece.

7.3.4.3 Forging

Forging is the process of working hot metal between dies either under successive blows or by continuous squeezing. It may be used to break down an ingot into a bloom or bar, to work down an ingot or billet to a rough finished shape before finishing or to make a forging. There are two essential differences compared with rolling. It is almost always possible (1) to design the dies and to arrange the sequence of forging to impose a higher ratio of compression to tension forces than is possible by rolling and (2) to ensure that the grain of the metal is in a preferred direction and not purely longitudinal as in rolling. For breaking down an ingot in, for example, tool, high-speed and some stainless and heat-resisting steels that have a two-phase structure, hot rolling would (at least before the development of ESR or vacuum arc casting) lead to ruptures due to the strong tension forces induced. Such ingots are usually broken down by hammer cogging. Forging is also used for making very large components such as turbine rotors which are usually 'open-die' forged in a press. Large forging ingots have a cross section whose circumference comprises a number of arcs meeting at cusps, because this shape minimizes surface cracking during casting. The first forging operation removes the cusps to form an approximately circular cross section and the forging is then drawn out through successive shape changes from octagon to square and back to octagon using dies of shapes shown in Figure 7.16. If the geometry of forging and press permits, the forging is upended and upset to produce some radial grain flow and it is then drawn out again.

Hollow forgings are made by punching a hole in the centre of a cylindrical workpiece and 'becking', working the die against a stiff bar passing through the forging and supported on 'V' blocks.

Small closed-die forgings are made in two dies attached, respectively, to the hammer ram and bed which have successive cavities to mould the stock progressively into a final shape in the last or finish cavity. For larger forgings a number of dies are made to perform one operation each. A wide variety of shapes can be made, depending only on ability to make and extract the component from two meeting dies with a parting line which may or may not be planar.

Steel from a basic oxygen furnace is either continuously cast into slabs or cast into ingots which are then rolled to slabs. Prior to re-heating machine scarfing is used to ensure a defect free slab. Automatic gauge control ensures strict control of thickness throughout hot rolling. Hot rolled coil may be supplied mill finish or pickled and oiled before despatch either in coil or sheet form.

The cold rolling processes not only reduce the thickness of the input hot rolled coil, but also give it the required surface finish and forming qualities. Finishing capabilities include re-winding or cutting to length, side-trimming, tension levelling, oiling and branding to the customers' requirements.

Galvatite is produced on continuous coating lines, incorporating furnaces in which the strip is heat treated/annealed before coating. The lines incorporate equipment for controlling coating masses, surface finish and flatness of the strip after coating. Where an iron-zinc alloy finish is produced an additional furnace alloys the coating with the steel base after coating.

Figure 7.16 Die shapes for open-die forging

Most of the steels listed in BS 970 can be forged and will give properties appropriate to their section. Carbon steel forgings for engineering purposes are listed in BS 24 and BS 29 and forgings for fired and unfired pressure vessels in BS 1503.

The most demanding requirements for aircraft and similar requirements are met by ESR or consumable vacuum arc cast ingot usually made to manufacturers' own specifications (agreed, where appropriate, by official inspecting bodies). There are some 30 hot and cold metal-working processes which can be considered to be some version of forging.

7.3.4.4 Drawing and extrusion

A third important group of metal-working processes involves shaping metal by pushing ('extruding') or pulling through a die ('drawing'). Extrusion is usually performed hot, drawing, usually cold.

Extrusion Hot extrusion consists of placing a hot cylindrical billet into a container and either forcing a die with a centrally placed orifice onto one end (indirect extrusion) or applying pressure to a ram at the other end, the die being held stationary (direct extrusion). In either case metal is extruded though the die in the form of an elongated bar having the same cross section as the orifice.

Extrusion is applied widely to non-ferrous metals which soften at lower temperatures than the steel or hard metal dies. Bar and very complex sections can be economically produced and cut into a wide variety of shapes. Tubes and hollow sections can be made either by extruding metal through bridge-type dies in which the metal stream separates and rewelds at a later point or by extruding a hollow billet over a central mandril. Non-ferrous metals are extruded hot or cold. Only the softer steels are extruded cold.

Hot extrusion of steel requires a glass lubricant. Very rigid and powerful presses are required and their high cost plus the need for machined billets limits the process to high-cost steel, unusual shapes and tubes (which are mandril extruded). There are besides extrusion other methods of tube production

Drawing Usually after a 'semi' has been produced hot it is cold drawn to reduce diameter, wall thickness or both. Cold drawing through dies is used to produce wire, tube and light bar. This process requires considerable skill and attention to detail in die design, lubricants, wire rod cleansing and baking to remove hydrogen introduced during cleansing.

7.3.5 Constitution and heat treatment of ferritic steels

The versatility and adaptability of steel depends on the ability to vary and control the constitution, distribution and nature of the microstructure constituents by varying chemical composition, heat treatment and hot and cold working. This provides a wide variation in mechanical properties over a range extending from very low temperatures to around 1000°C. To indicate how this variation and control is achieved it is necessary to consider matters such as allotropy, solid solutions, constituents, phases, equilibrium, and the iron-carbon constitution diagram.

7.3.5.1 Allotropy of iron

Each of the allotropic modifications of pure iron (see Figure 7.12) is stable within certain ranges of temperature as shown in Table 7.5. The change from one modification to the other which occurs on heating or cooling through the critical temperatures 910°C and 1400°C is accompanied by recrystallization.

7.3.5.2 Solid solutions

Solid solutions are formed when a metallic solid dissolves one or more elements or compounds. The solute elements can diffuse as in liquid solutions. If the atomic size of the solvent and solute atoms is similar, the solute atoms tend to replace the solvent atoms in an unchanged space-lattice, but if they are substantially smaller they will most probably be situated interstitially between the solvent atoms.

Pure iron at room temperature is composed of grains of alpha iron (ferrite). Ferrite is capable of dissolving in limited quantity elements such as silicon, phosphorus, nickel, copper, arsenic, etc., so that commercial steel of ultra-low carbon content will have ferrite grains with these elements in solid solution. Alpha iron in commercial steel is referred to as ferrite. Gamma iron (austenite) also dissolves elements to form solid solutions. If, as is usually the case, gamma iron dissolves an element to a greater extent than alpha iron, when the change to alpha iron occurs, on cooling through the critical temperature, the alpha must accommodate more atoms of the element than its solubility allows and becomes supersaturated. Under suitable conditions, excess atoms will precipitate to arrive at a stable condition.

The high solubility of iron carbide (Fe_3C), 'cementite' in austenite and its relatively low solubility in ferrite is the basis for the heat treatment of hardened and tempered steel. Although steels containing cementite are strictly metastable, for all practical purposes they may be considered as stable because the precipitation of graphite (which is the stable form of carbon) occurs too slowly to be of interest except under special conditions.

Table 7.5 Stable temperature ranges of the allotropic modifications of pure iron

Modification	*Crystal structure*	*Temperature range of stability* (°C)
Delta, δ	Body-centred	1535–1400
Gamma, γ	Face-centred	1400–910
Alpha, α	Body-centred	910 and below

7.3.5.3 Phases, equilibrium and the iron–carbon phase diagram

Constituents are the components of a metal alloy revealed by the microscope after suitable etching. Phases are physically and chemically homogeneous entities separated from the rest of the alloy by definite bounding surfaces. Phases in solid steel are austenite, ferrite, cementite, graphite, alloy carbides and other intermetallics. All phases are constituents but some constituents are not necessarily phases, e.g. pearlite is a constituent but it consists of the phases cementite and ferrite in a particular arrangement.

The phase diagram represents the phases present, at given temperatures, which are in equilibrium with each other. Equilibrium is attained by slow heating or cooling to allow constitutional changes to be completed.

The iron–carbide phase diagram (Figure 7.12) shows the effect of adding carbon to molten iron on the temperature ranges of stability of the delta, gamma and alpha phases in the solidified alloy and the effect of the varying solubility of iron carbide (cementite) on the phases present at temperatures from solidification downwards. The diagram represents nominally pure alloys; similar diagrams for other iron alloy systems (Fe–Cr, Fe–Mn, etc.) show the effect of other elements such as chromium, manganese, etc. on the range of stability of the phases. Since commercial plain carbon steels contain manganese and other elements in varying degree, Figure 7.12 does not accurately represent the critical temperatures, but it is a useful starting point for heat treatment.

7.3.5.4 Equilibrium decomposition of austenite: consideration of the iron–carbon constitution diagram

Point A in Figure 7.12 is at 1535°C, the highest temperature for the existence of solid delta-phase in carbon-free iron; line ABC shows the fall in the temperature, at which the first phase to separate from the solidifying liquid appears, as carbon content is increased. Line AHJEF (the solidus line) shows the temperatures below which all alloys are solid. As is shown in Figure 7.17, pure iron changes from face-centred- (austenite) to body-centred-cubic (ferrite) at 910°C; adding carbon lowers this temperature, as shown by line GS and, as the solubility of cementite in ferrite is less than in austenite, the change results in an increase in the carbon content of the remaining austenite, which, on further cooling, then forms more ferrite with again an increase in carbon content of the remaining austenite. This process continues until the last small amount of austenite contains 0.80% carbon, which changes at the fixed temperature of 723°C to a mixture of cementite and ferrite called Pearlite or Eutectoid, PSK being the Eutectoid line.

Alloys below and above 0.8% carbon (hypo- and hyper-eutectoid) both contain ferrite and cementite when cooled to room temperature but the mode of occurrence (the microstructural constituents of hypo-eutectoid steels being ferrite and pearlite, those of hyper-eutectoid being cementite and pearlite) of the phases is different with markedly different effect on mechanical properties. Descriptive sketches or actual photomicrographs may be used to illustrate the mode of occurrence of the phases. The constituents in the phase field and the changes in constituents on cooling for pure iron, 0.10%C and 0.80%C steel are shown schematically in Figure 7.17 when equilibrium conditions exist at extremely slow cooling or heating so that the diffusion of carbon is not inhibited.

Figure 7.17 Steel portion of iron–carbon constitution diagram. Changes in grain structures and constituents with falling temperatures. The Ar$_3$, Ar$_1$ line GS, SK is the line at which austenite transforms on *cooling* during heat-treatment. The Ac$_3$ Ac$_1$ line (not shown) is the line at which ferrite/pearlite/cementite transforms to austenite on *heating* and is a few degrees higher, depending on the rates of heating and cooling, than the Ar$_3$ Ar$_1$ line

The solid solubility of carbon in gamma iron is 1.7% (point E). Hyper-eutectoid steels between 0.8% and 1.7%C precipitate cementite (6.8%C) when cooled to line SE, which reduces the carbon level of the remaining austenite thus requiring a further lowering of temperature before more cementite can precipitate. Continuous cooling down to the eutectoid line PSK results therefore in continuous precipitation of cementite until, at the eutectoid, the austenite contains 0.8%C and precipitates ferrite and cementite simultaneously to produce pearlite. Steels contain up to 1.7%C, cast irons more than 1.7%C.

It is common practice to use terms such as 'primary austenite' to differentiate austenite which freezes out of hypo-eutectoid alloys from austenite formed by heating up into the austenite phase field. Also, ferrite formed along line GS from steels with less than 0.8%C is called 'pro-eutectoid ferrite' and cementite formed along SE is called 'pro-eutectoid cementite. The ferrite phase in the eutectoid constituent pearlite is called pearlitic ferrite and the cementite pearlitic cementite.

The microstructural constituents shown schematically in Figure 7.17 are the basis of most commercial steels but the proportions in which they occur and the mode of their occurrence (distribution and form) are profoundly influenced by rate of cooling from the austenite phase field. The equilibrium conditions necessary to the behaviour shown in Figure 7.17 and the approximate temperature indicated do not obtain in steel heat treatment practice except possibly when very large forging ingots are annealed.

Moreover, there is a thermal lag in the allotropic change so that the eutectoid line PSK is at an approximately 3°C higher temperature during heating up than on cooling down. With normal rates of heating and cooling of steel the eutectoid change is raised or lowered with faster heating or cooling. Consequently, in practice, a plain carbon steel has a temperature range in which the eutectoid temperature can vary according to heating or cooling rates. This also applies to the position of the austenite to ferrite change line GS.

However, Figure 7.17 illustrates an essential feature of steel heat treatment, namely, that austenite in transforming through the lines GS, SE or PSK develops a number of grains of the new constituents in each austenite grain, thereby refining the grain structure. The mechanical properties of steels consisting of ferrite and pearlite are strongly influenced by the average grain size of ferrite as well as the amount and type of pearlite (coarse lamellar, fine lamellar, etc.). The yield stress varies linearly with the reciprocal of the square root of the grain size.

On heating steel through the critical temperatures into the austenitic phase field the behaviour observed on cooling is reversed in the following manner:

Steel with 0.1%C. On passing through the lower critical temperature (Ac_1), which is higher than Ar_1, the pearlite areas first transform to austenite of 0.8%C content. This austenite grows by dissolving the surrounding ferrite grains as the temperature is raised and its carbon content is reduced. However, the austenite areas developing from the pearlite consist of numerous crystals so that just above line GS, when the structure is wholly austenitic containing 0.1%C, it consists of numerous small austenite grains. Heating to higher temperatures in the austenite phase field causes grain growth, some grains growing by absorbing smaller ones around them.

Eutectoid steel, 0.8%C. On heating above the lower critical temperature Ac_1 (which coincides with the upper critical temperature Ac_3 at the eutectoid composition), theoretically the pearlite should transform to austenite of 0.8%C content. In practice, it does so over a temperature range, the ferrite lamellae absorbing cementite to form a lower carbon austenite which then dissolves the remaining cementite. Grain growth follows on heating to higher temperatures in the austenite phase field.

Hyper-eutectoid steel, 1.2%C. At the eutectoid line the pearlite starts to transform to austenite of 0.8%C content. As the temperature is raised through the austenite plus cementite phase field, pro-eutectoid cementite is gradually dissolved by the austenite adjacent to it and eventually, by carbon diffusion, above the upper critical temperature the austenite attains a uniform carbon content at 1.2%. Grain growth follows on heating to higher temperatures in the austenite phase field.

The above simple behaviour of carbon steel relies on adequate time for diffusion of carbon being available.

When time at temperature is reduced, the diffusion is inhibited in varying degrees with a pronounced effect on the transformation changes. Thus, in plain carbon steels, increasing the rate of cooling through the critical temperature range Ar_3–Ar_1 lowers this range and alters the proportions of ferrite and pearlite. Steels with less than 0.25%C show refinement of ferrite grains, the growth of individual grains being suppressed, and the pearlitic constituent has finer cementite lamellae. Steels with more than 0.25%C show an increased amount of pearlite and decreased ferrite.

If the steel contains 0.35 or higher %C it is possible by a sufficient increase in cooling rate to produce a structure consisting entirely of pearlite. This pearlite will differ from equilibrium pearlite in having very thin cementite lamellae separated by wide ferrite lamellae. Since pearlite (with hard cementite lamellae) is the main contributor to tensile strength in ferrite–pearlite steels, its proportion and morphology in the structure are a prime consideration for heat-treatment practice. If the cooling rate through the critical range is increased still further, the austenite transformation may be entirely suppressed, and the steel remains as unstable austenite down to a lower temperature, when transformation begins with the formation of lower-temperature products (e.g. martensite, bainite). When this happens the steel has been cooled at its 'critical rate'.

Martensite has special characteristics which are of great importance in the heat treatment of steel. The essential difference between the mode of formation of martensite and that of pearlite is that the change from the face-centred-cubic austenite lattice to the body-centred-cubic ferrite lattice occurs in martensite formation without carbon diffusion, whereas to form pearlite, carbon diffusion must take place, producing cementite and ferrite. The effect of this is that the carbon atoms strain the alpha martensite lattice producing micro-stresses and considerable hardness. The higher the carbon content, the greater the hardness of martensite (Figure 7.18), and the lower the temperature at which the change to martensite begins.

Furthermore, martensite, which is characterized by an acicular appearance, forms progressively over a temperature range as the temperature falls; if the temperature is held constant after the start no further action takes place. Martensite formation produces an expansion related to the carbon content. The mechanical properties of martensite depend on the carbon content; low-carbon martensites (less than 0.08%C) have reasonable ductility and toughness, high-carbon martensites have no ductility or toughness and extreme hardness and, because of the state of internal stress, are very liable to spontaneous cracking. Thus low-carbon martensite can be used for industrial purposes, e.g. welded 9% Ni steels for low-temperature applications have low-carbon martensitic heat-affected zones. High-carbon martensite must be tempered before it is allowed to cool to room temperature, e.g. carbon tool steels are water quenched to exceed the critical cooling rate but the tool is withdrawn from the bath while still hot and immediately tempered.

7.3.5.5 *Isothermal decomposition of austenite*

Reference was made in the previous section to the fact that if the gamma to alpha transformation is suppressed by fast

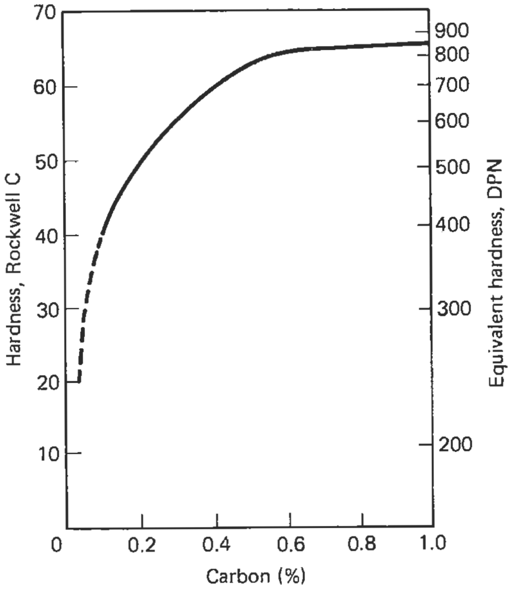

Figure 7.18 Hardness of martensite related to carbon content

cooling, the austenite is in an unstable condition. If, before reaching the temperature at which martensite begins to form, the cooling is arrested and the steel held at a constant temperature, the unstable austenite will transform over a period of time to a product which differs markedly from pearlite and has some visual resemblance to martensite in being acicular. This structure is called bainite; it is formed over a range of temperatures (about 550–250°C) and its properties depend to some degree on the transformation temperature. Bainite formed at a lower temperature is harder than bainite formed at a higher temperature. It is tougher than pearlite and not as hard as martensite. It differs fundamentally from the latter by being diffusion dependent, as is pearlite.

This type of transformation, at constant temperature, is important in the heat treatment of steel and is called isothermal transformation. It is characterized by an induction period, a start and then a gradual increase in speed of decomposition of the austenite which reaches a maximum at about 50% transformation and then a slow completion.

An isothermal transformation diagram which gives a summary of the progress of isothermal decomposition of austenite at all temperatures between Ac_3 and the start of martensitic transformation can be constructed. This is done by quenching small specimens of a steel (which have been held for the same time at a fixed temperature in the austenite field above Ar_3) to the temperature at which transformation is desired, holding for various times at this temperature and determining the proportion of transformed austenite. Such a diagram provides information on the possibilities of applying isothermal heat treatment to bring about complete decomposition of the austenite just below Ac_1 (isothermal annealing) or just above M_s (austempering), or of holding the steel at sub-critical temperatures for a suitable period to reduce temperature gradients set up in quenching without breakdown of the austenite, as in martempering or stepped quenching. Furthermore, if the steel is air hardening or semi-air hardening, the cooling rate during most welding processes exceeds the 'critical rate'. Therefore by using the isothermal diagram, the preheat temperatures and time necessary to hold a temperature to avoid martensite and obtain a bainitic structure can be assessed.

The principle of the isothermal diagram (also known as T–T–T diagrams) is illustrated schematically in Figure 7.19. The dotted lines showing estimated start and finish of transformation indicate the uncertainty of determining with accuracy the start and finish. The main feature of isothermal transformation – the considerable difference in time required to complete transformation at different temperatures within the

pearlitic and bainitic temperature ranges – is to be noted. These diagrams vary in form for different steels. They also differ according to the austenitizing temperature (coarseness of gamma grains) and the extent to which carbides are dissolved in the austenite.

In alloy steels containing chromium, molybdenum or tungsten, segregation and carbide banding (size of carbides) varies and can affect the extent of carbide solution. In applying these diagrams it is usual to allow a considerably longer time for completion of transformation than that indicated on the diagram to cover the inherent uncertainties in individual consignments of steels.

7.3.5.6 Effect of carbon and alloying elements on austenite decomposition rate

As carbon content is increased the isothermal diagram is moved to the right, which indicates that austenite transformation is rendered more sluggish. Alloying elements increase the induction period, thus delaying the start, and they also increase the time necessary for completion. Furthermore, the effect of adding alloying elements is cumulative, but because they have different specific effects on transformation in the pearlitic or bainitic ranges it is not generally possible to predict the behaviour of multi-alloy steels.

7.3.5.7 Decomposition of austenite under continuous cooling conditions

It will be appreciated that while the isothermal transformation diagram provides the basic information about the characteristics of isothermal transformation for austenite of given composition, grain size and homogeneity, the common heat treatments used in steel manufacture such as annealing, normalizing or quenching are processes which subject the austenite to continuous cooling. This does not necessarily invalidate the use of isothermal diagram data for continuous cooling conditions because, as the steel passes through successively lower temperatures, the microstructures appropriate to transformation at the different temperatures are formed to a limited extent, depending on the time allowed, instead of proceeding to completion. The final structure consists of a mixture which is determined by the tendency to form specific structures on the way down, this tendency being indicated by the isothermal diagram.

The time allowed for transformation in the ferrite–pearlite and intermediate (bainite) regions obviously depends on cooling rate. A continuous transformation diagram will therefore have, as its essential features, means for indicating the amount of ferrite, pearlite, bainite and martensite which is obtained at various defined cooling rates; these are usually appropriate to heat treatment or selected welding cooling rates. Such a diagram is shown schematically in Figure 7.19.

The effect of continuous cooling is to lower the start temperatures and increase the incubation period so the transformation time tends to be below and to the right of the isothermal line for the same steel, these effects increasing with increasing cooling rate. As indicated in Figure 7.19, the time axis may be expressed in any suitable form; transformation time in Figure 7.20(a), bar diameter for bars as in Figure 7.20(b).

The positions of the lines defining the transformation products obviously vary according to the steel composition and austenitizing temperature. Diagrams for welding applications which have five cooling rates appropriate to the main fusion welding processes applied to various steel thicknesses have been produced by the Welding Institute, Cambridge, and by other welding research institutions in connection with the development of weldable high-tensile steels. Manipulation of composition and heat treatment give rise to the several classes of steel already listed.

7.3.6 Carbon/carbon manganese steels

Rolled or hollow sections of carbon steels with carbon below about 0.36% constitute by far the greatest tonnage of steels used. In addition to the general specification of steels by analysis, they are sold by specifications depending on product form, and BS 970 is applied mainly to bar.

7.3.6.1 *Weldable structural steels* (Specification Nos BS 4360: 1970 and ISO R630)

These steels have yield strengths depending on section between 210 and 450 M Nm^{-2} achieved by carbon additions between 0.16% and 0.22%, manganese up to 1.6% and, for some qualities, niobium and vanadium additions.

7.3.6.2 *Structural plates*[17]

These products exemplify more than any others the quality improvements that the improvements in steel making described in Section 7.3.3 have produced in the tonnage steels. Plates can now be obtained with

- Lower maximum sulphur levels (as low as 0.008%);
- Improved deoxidation with low inclusions and controlled morphology;
- Very low hydrogen levels resulting from vacuum degassing;
- Greater control of composition resulting from secondary steel-making units and rapid in plant analysis, low inclusions and controlled morphology;
- Guaranteed high impact and elongation in the transverse direction;
- High impact values at low temperature in heat-affected zones.

There are many private specifications, primarily for material for offshore structures. For example, the British Steel Corporation's 'Hized' Plate will give reduction in area values through the plate thickness of around 25%.

Plates with superior properties (such as are used for oil pipelines) are made by controlled rolling steels such as BS 4360, grade 50E containing up to 0.1% Nb and/or 0.15% V and, although this is not explicitly specified, small amounts of nitrogen. Controlled rolling produces appreciably extra strength, e.g. yield and tensile values up to 340 and 620 MPa in a very fine-grained steel due to precipitation of carbonitrides and the low-carbon equivalent promotes weldability.

Besides plates, weldable structural steels are available in the form of flats, sections, round and square bars, blooms and billets for forging, sheet, strip and tubes. The range of flats, sections and bar is slightly restricted compared with plates and properties show minor variations. A very wide range of beams, guides and columns may be fabricated by automatic welding of plate steels.

Increased use is being made of hollow sections as they take up less space than angles or 'I' sections, decrease wind resistance and allow increased natural lighting and because, with care in design, they need not be protected on the inside and are cheaper to paint. Cold-forming sections increases strength and improves finish.

Forgings in weldable structural steels are included in BS 970. Tubes specified in BS 6323 may be hot or cold finished, seamless or welded in various ways. Yield strengths of hot-finished carbon steel tubes vary between 195 and 340 MPa and cold finished between 320 and 595 MPa. Cold-finished tubes are available in a variety of heat treatments.

The cheapest available steels to the specifications listed may, if purchased from a reputable steel maker, be used with confidence for most engineering purposes (with the exception of pressure vessels). If service conditions are known to be onerous, more demanding specifications and increased testing may be required.

7.3.6.3 *Pressure vessel steels*

The range of engineering plates, tubes, forgings (and, included here for convenience, castings) is matched by equivalent specifications for pressure vessel steels. Pressure vessel plate steels, specified in BS 1501: Part 1: 1980, are similar to structural steels but differ in that:

- Pressure vessel steels are supplied to positive dimensional tolerances, instead of the specified thickness being the mean. A batch of pressure vessel plates will therefore weigh more than the equivalent batch of structural plates (and cost more). A tensile test must be carried out on every plate (two for large plates) instead of one test per 40 tonne batch.
- Elevated temperature proof tests are specified for all pressure vessel plates.
- All pressure vessel plates have the nitrogen content specified and some the soluble aluminium content.
- All pressure vessel plates are supplied normalized.
- Pressure vessel tube steels are similar to those used for plates but, to facilitate cold bending, some of the grades are softer.
- The relevant specifications are, for seamless tube, BS 3601: 1974, for electric welded tube BS 3602: 1978 and for submerged arc welded tube BS 3603: 1977.
- Yield points lie between 195 and 340 MPa and Charpy V-notch impact must exceed 27 J at −50°C. (For lower-temperature service steels with up to 9% nickel, austenitic stainless or even martempered steels should be used.)

Carbon–manganese steel forgings for pressure vessels are specified in BS 1503: 1980. Materials are available with yield strengths varying (depending on section) between 215 and 340 MPa.

Carbon–manganese steel castings for pressure vessels are specified in BS 1504: 1976. These castings may contain up to about 0.25% of chromium, molybdenum, nickel and copper (total max. 0.8%) and 0.2% proof stresses range between 230 and 280 MPa.

7.3.6.4 *Coil and sheet steel*

BOF steel is continuously cast into slabs and rolled hot to coil or cut sheet. Hot-rolled strip is available in thicknesses above 1.6 mm up to 6.5 mm pickled and oiled and 12.7 mm as rolled in widths varying up to 1800 mm in:

- Forming and drawing quality aluminium killed
- Commercial quality
- Tensile qualities to BS 1449: Part 2 and BS 4360

in a variety of specified minimum yield strengths above 280 MPa. Weathering steel which develops an adherent coating of oxides and raised pattern floor plate is also available hot rolled.

Cold-reduced strip is available in thicknesses above 0.35 mm up to 3.175 mm and in widths varying up to 180 mm in:

- Forming and drawing qualities (typically, 180 MPa yield UTS 620–790 MPa to BS 1449: Part 1)
- Tensile qualities with yield points for low-carbon phosphorus-containing steels of 125 and 270 MPa and micro-alloyed with niobium of 300 and 350 MPa.

Cold-rolled narrow strip is available to BS 1449 and other more exacting specifications in thicknesses between 0.1 and 4.6 mm and widths up to 600 mm. Cold-rolled strips may be supplied in a variety of finishes, hot-dip galvanized to BS 2989, electro-galvanized, electro-zinc coated, ternplate (coated with a tin–lead alloy which facilitates forming and soldering) or coated with a zinc–aluminium alloy with exceptional corrosion resistance.

7.3.6.5 Steel wire

Wire with carbon contents ranging from 0.65% to 0.85% is specified in BS 1408. Carbon steel wire in tensile strengths 1400–12050 MPa (for coiled springs) and 1400–1870 MPa for zig-zag and square-form springs are listed, respectively, in BS 4367: 1970 and BS 4368: 1970.

The heat treatment of wires, including annealing and patenting, differs appreciably from other heat treatment processing. The increase in tensile strength as the amount of drawing increases for three carbon ranges is shown in Figure 7.21. Ductility falls as the tensile strength increases (Figure 7.22). When the limit of reduction has been reached the wire must be heat treated to remove the hard-drawn structure and replace it by a suitable structure for further reduction. For low-carbon steel this treatment is an anneal, just below the lower critical temperature, which recrystallizes the ferrite grains to an equiaxed form.

Medium- and high-carbon wires are generally patented (fairly fast cooling from above the upper critical point by air cooling or quenching in lead) to give a coarse pearlitic structure which will draw to very high tensile strengths. In addition to sub-critical annealing and patenting, the heat treatments used in wire production include normalizing, annealing, hardening and tempering and austempering, all designed to confer structures and properties which have particular relevance to the requirements of specific wire applications.

The tensile strength obtainable depends on carbon content and an approximate indication of the relationship for annealed, patented and hardened and tempered wire is shown in Figure 7.23. Wire has a relatively large surface-to-volume ratio so that any decarburization due to heat treatment has a proportionately more significant effect than in heavier steel products. Consequently, wire heat treatment is conducted in specialized equipment (i.e. salt baths, atmosphere-controlled furnaces, etc.) aimed at minimizing any such difficulties.

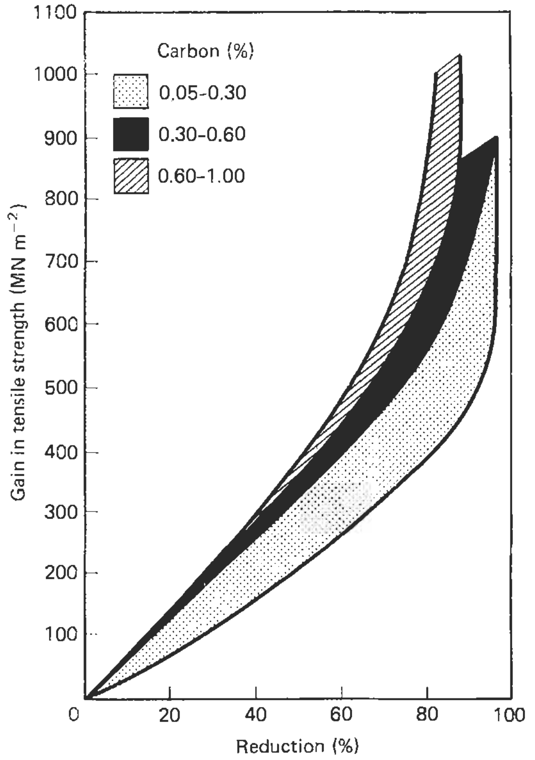

Figure 7.21 Increase in tensile strength related to amount of reduction in wire drawing for three levels of carbon

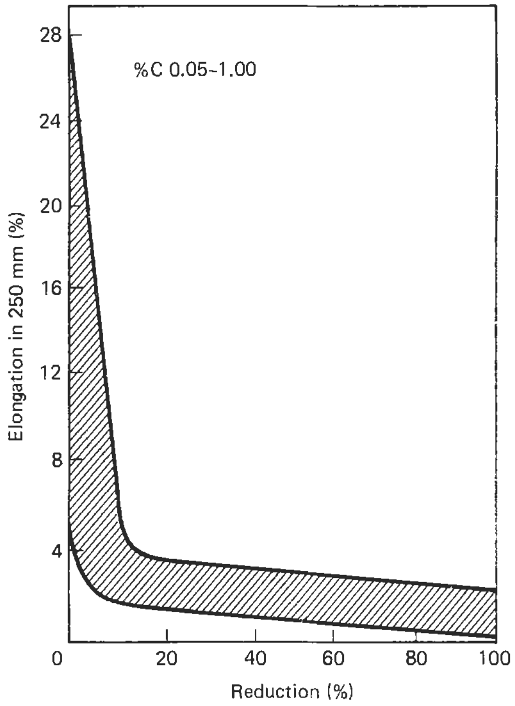

Figure 7.22 Decrease in ductility related to amount of reduction in wire drawing

Cold drawing through dies requires considerable skill and attention to detail in die design, lubricants, wire rod cleansing and baking to remove hydrogen introduced during cleaning.

7.3.7 High-strength low-alloy steels (HSLA steels)

High-strength low-alloy steels are proprietary steels manufactured to SAE 950 or ASTM 242 with carbon max. 0.22%, manganese max. 1.25% and such other alloying elements as will give the minimum yield point prescribed for various thicknesses ranging between 12 and 60 mm. Steels are available with yield points from 275 to 400 MPa, and the restriction on carbon and manganese content is intended to ensure weldability. Quenched and tempered weldable steels with significantly higher yields are also available.

Reduction in weight of steel gained by utilizing the higher yield stress in design is unlikely to reduce the cost of the material compared with that of the greater weight of a standard weldable structural steel purchased from BSC. Cost benefits arise, however, from handling the smaller quantity and welding the reduced thickness of the steel, and in transport applications from increased pay load, decreased fuel costs, freedom from weight restrictions and reduced duty imposed on other components of the vehicle.

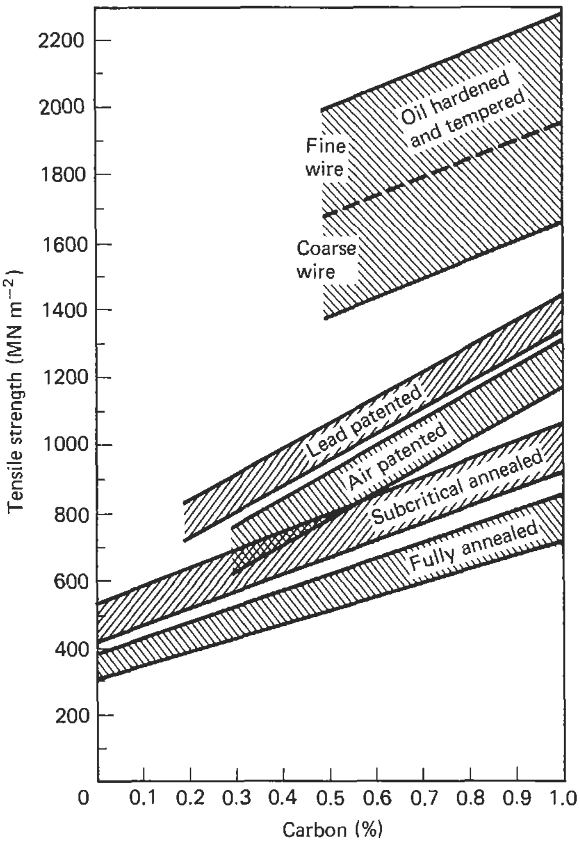

Figure 7.23 Tensile strength/carbon content relationship for wire

Attention must be paid to the following considerations:

1. The modulus of elasticity of an HSLA steel is the same as that of other ferritic steels. Any design which is buckling critical will require stresses and therefore sections identical to those of steels with lower strengths, and there will be no saving in quantity of steel.
2. Stress intensity is proportional to the second power of stress and fatigue growth rate per cycle is proportional to the fourth power of the range of stress per cycle. If brittle or fatigue fracture is a ruling parameter in design, a much more severe standard of non-destructive testing is needed for a component made from steel operating at a higher stress. In the limit, the critical defect size may fall below the limit of detection.
3. The notch ductility of an HSLA steel varies greatly according to the alloying elements used by the steel maker. If there is a risk of brittle fracture, values of Charpy V-notch energy and transition temperature should be specified by the designer.

Spectacular failures have resulted from ignoring these precepts.

7.3.8 Electrical steels

Electrical steels are a class of steel strip which is assembled and bolted together in stacks to form the magnetic cores of a.c. plant, alternators, transformers and rotors. Its essential properties are low losses during the magnetizing cycle arising from magnetic hysteresis and eddy currents, high magnetic permeability and saturation value, insulated surfaces, and a low level of noise generation arising from magnetostriction.

These parameters are promoted by maintaining the contents of carbon, sulphur and oxygen to the minimum obtainable and increasing grain size (which together minimize hysteresis loss) and incorporating a ferrite soluble element (usually silicon at a level of 3% to increase resistivity and therefore eddy current loss). The thickness of the steel must be optimized – reduction in thickness minimizes the path available for eddy currents but reduces the packing fraction and hence the proportion of iron available and increases handling problems. The surfaces are coated with a mineral insulant to prevent conduction of eddy currents from one lamination to the next. Accurate control of thickness and flatness minimizes stress when the laminations are bolted together and therefore reduces magnetostrictive noise which is promoted by stress.

There are two principal grades of electrical steel, differing essentially in loss characteristics. Hot-rolled strip is supplied to ASTM 840–85 in gauges of 0.47 and 0.64 mm with guaranteed losses of 13.2 and 16 W kg^{-1} at 15 Kilogauss induction and 60 Hz. Cold-rolled strip is supplied to ASTM 843–85 in gauges of 0.27, 0.3 and 0.35 mm with respective guaranteed losses of 1.10, 1.17 and 1.27 W kg^{-1} at 17 Kilogauss induction and 50 Hz.

Cold-rolled strip is manufactured by first rolling a sulphurized steel, followed by a programme of rolling and heat treatment which eliminates sulphur and produces a Goss or 'rooftop' texture. In this structure the [100] crystallographic direction which is most easily magnetized lies longitudinally in the strip. Cold-rolled strip is normally used for large alternators and transformers where the saving in lost power (and the problems of disposing of heat generated) outweigh the additional cost compared with hot rolled.

7.3.9 Hardened and tempered steels

At a content of carbon above about 0.35% (or less when alloying elements are present) useful increases in strength may be obtained by transformation. The most important class of steel to which this procedure is applied is the 'Hardened and Tempered Steels'. These will be chosen from AISI/SAE 1035–4310 and BS 970 080A32–945A40.

7.3.9.1 Heat treatment

The steel heat treatments, quenching and tempering, austempering, martempering, annealing and isothermal annealing can be described most simply by means of the isothermal diagram (Figure 7.20). (There are other heat-treatment procedures, notably ageing and controlled rolling.)

7.3.9.2 Quenching and tempering (Figure 7.24(a))

Steel quenched to martensite is hard and brittle due to the carbon being in unstable solid solution in a body-centred tetragonal lattice[15,16] and has high internal stresses. Heating (tempering) at 100°C causes separation of a transition phase, ϵ, iron carbide ($Fe_{2.2}C$) from the matrix, this being the first stage of tempering; slight hardening may occur initially. As the temperature is increased, relief of stress and softening occurs due to cementite formation and release of carbon from the matrix. The steel becomes significantly tougher.

Steels of suitable composition quenched fully to martensite and tempered at appropriate temperatures give the best combination of strength and toughness obtainable. There is a

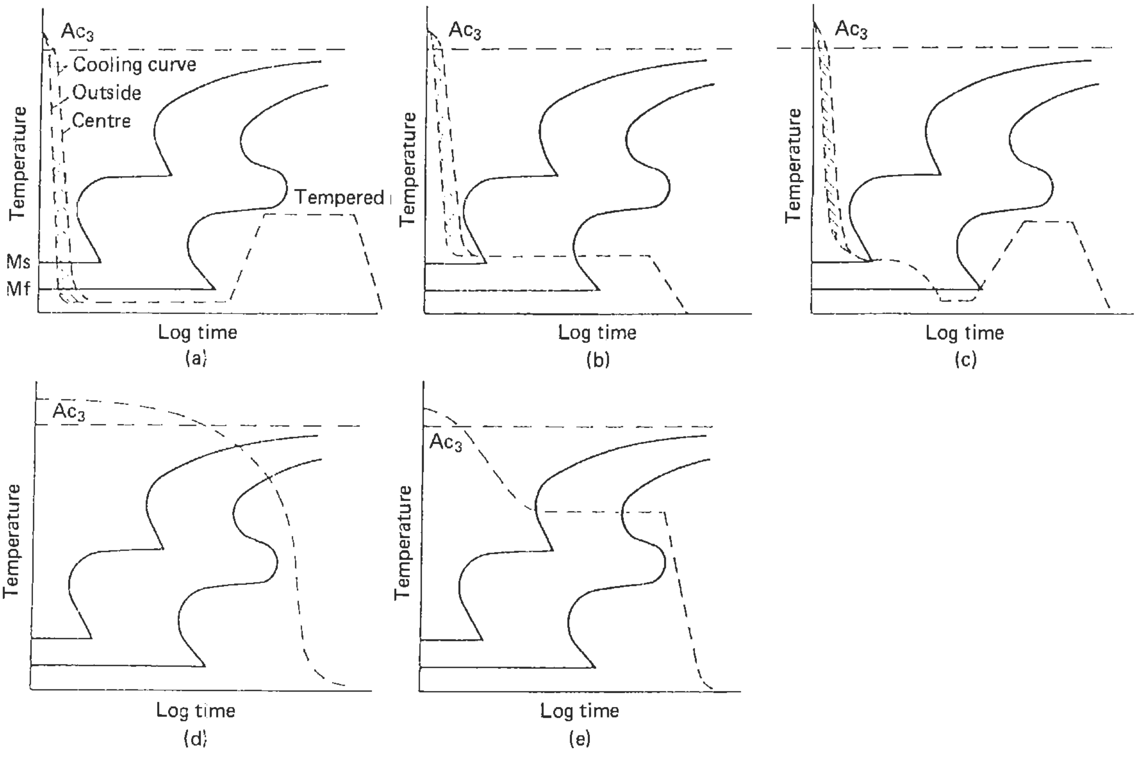

Figure 7.24 Isothermal diagrams showing heat treatment of steel. (a) Quenching and tempering. Product tempered martensite; (b) Austempering. Product lower bainite; (c) Martempering. Product tempered martensite; (d) Annealing. Product ferrite and pearlite; (e) Isothermal annealing. Product ferrite and pearlite

tendency, varying with different steels, for a degree of embrittlement to occur when tempering within the range 250–450°C, so steels are either tempered below 250°C for maximum tensile strength or above about 550°C for a combination of strength, ductility and toughness due to increasing coalescence of carbides.[17]

7.3.9.3 Austempering (Figure 7.24(b))

The purpose of this treatment is to produce bainite from isothermal treatment; lower bainite is generally more ductile than tempered martensite at the same tensile strength but lower in toughness. The main advantage of austempering is that the risk of cracking, present when quenching out to martensite, is eliminated and bainitic steels are therefore used for heavy-section pressure vessels.

7.3.9.4 Martempering (Figure 7.24(c))

The risk of cracking inherent in quenching to martensite can be reduced considerably while retaining transformation to martensite by quenching into a salt bath which is at a temperature slightly above that at which martensite starts to form, and then, after soaking, allowing the steel to air cool to room temperature. Distortion in quenching is a problem in pieces of non-uniform section and this is also considerably reduced by martempering.

7.3.9.5 Annealing (Figure 7.24(d))

Maximum softness is attained by annealing, involving slow cooling through the ferrite–pearlite field. The pearlitic structure developed provides optimum machinability in medium-carbon steels.

7.3.9.6 Isothermal annealing (Figure 7.24(e))

This treatment is used to produce a soft ferrite–pearlite structure. Its advantage over annealing is that, with appropriate steels and temperatures, it takes less total time because cooling down both to and from the isothermal treatment temperature may be done at any suitable rate, provided the material is not too bulky or being treated in large batches.

7.3.9.7 Hardenability of steel

Hardenability in this context refers to the depth of hardening, not the intensity. Hardening intensity in a quench is dependent on the carbon content. Plain-carbon steels show relatively shallow hardening; they are said to have low hardenability. Alloy steels show deep hardening characteristics to an extent depending primarily on the alloying elements and the austenitic grain size.

Hardenability is a significant factor in the application of steels for engineering purposes. Most engineering steels for bar or forgings are used in the oil-quenched and tempered condition to achieve optimum properties of strength and toughness based on tempered martensite. It is in this connection that hardenability is important; in general, forgings are required to develop the desired mechanical properties through the full section thickness.

Since the cooling rate in a quench must be slower at the centre of a section than at the surface, the alloy content must be such as to induce sluggishness in the austenite transformation sufficient to inhibit the ferrite–pearlite transformation at the cooling rate obtaining at the centre of the section. It follows that, for a given steel composition and quenching medium, there will be a maximum thickness above which the centre of the section will not cool sufficiently quickly except in those steels which have sufficient alloy content to induce transformation to martensite in air cooling (air-hardening steels). The practical usefulness of engineering steels, ignoring differences in toughness, can therefore be compared on the basis of this maximum thickness of cooling section which must be taken into account when considering selection of steel for any specific application.

A method for determining hardenability is to cool a bar of standard diameter and length by water jet applied to one end only. The cooling rate at any position along the bar will progressively decrease as the distance from the water sprayed end increases. The hardness is determined on flats ground on the bar surface located at 180°. The greater the hardenability, the further along the bar is a fully martensitic structure developed. This method of assessment is known as the Jominy end-quench test (for full details, see BS 3337).

Typical end quench (Jominy) curves for steels of medium and high hardenability are shown in Figure 7.25. A relationship between end-quench hardenability curves and the diameter of oil-quenched bars is shown in Figure 7.26. This can be used to choose a size of bar which will harden fully.

Jominy curves are provided by the SAE/AISI for steels to which the letter 'H' is added to the specification number and to BS 970 steels with the letter 'H' in the specification. Alternatively, a steel which will through-harden to the required yield stress at the design diameter may be selected from Table 7.6.

7.3.9.8 The function of alloying elements in engineering alloy steels

Apart from specialized functions – corrosion resistance, abrasion resistance, etc. – alloying elements are most widely used in engineering alloy steels with carbon in the range 0.25–0.55% or less than 0.15% for case hardening. Their function is to improve the mechanical properties compared with carbon steel and, in particular, to make possible the attainment of these properties at section thicknesses which preclude the use of shallow-hardening carbon steels, water quenched. They increase hardenability and thereby allow a lower carbon content to be used than would be required in a carbon steel and a softer quenching medium (e.g. oil). This substantially reduces quench cracking risks.

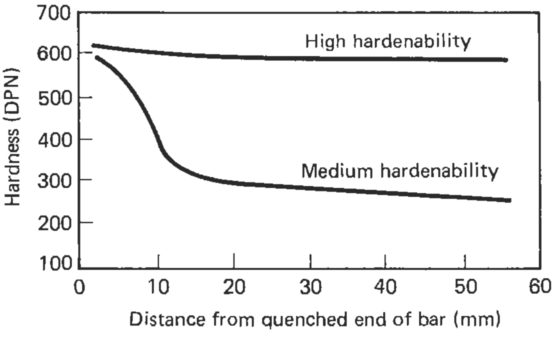

Figure 7.25 End-quench (Jominy Curves for steels of medium and high hardenability)

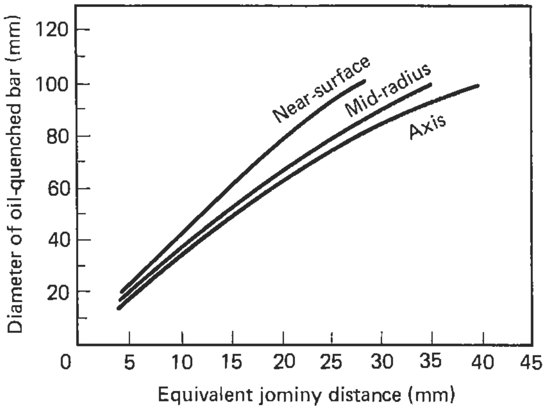

Figure 7.26 Relationship between end-quench hardenability curves and oil-quenched bars

The alloying elements are Mn, Ni, Cr, Mo, V and Al (as grain-refining element). An important function of alloying elements, by rendering austenite transformations sluggish, is to make possible treatments which depend on an arrested quench followed by a timed hold at somewhat elevated temperature (austempering, martempering) which reduce internal stress and minimize distortion and cracking risks.

For full effectiveness in increasing hardenability, the alloy elements should be completely dissolved in the austenite before quenching. This is no problem with Mn and Ni but Cr, Mo and V form carbides which, in the annealed steel prior to quenching, may be of comparatively large size and, owing to a slower solution rate than cementite, are more difficult to dissolve. Solution temperatures may therefore be increased and/or times increased.

The effect of alloying elements when tempering is important.[18] In general, they retard the rate of softening during tempering compared with carbon steel but the effect, in this respect, of the carbide formers (Cr, Mo, V) is much greater than that of the other elements. They increase the tempering temperatures required for a given degree of softening, which is beneficial for ductility and toughness. Mo and V, at higher levels, confer an increase in hardness at higher tempering temperatures due to alloy carbide precipitation; this is 'secondary hardening' and is the basis of hardness in heat treatment of alloy tool steels. The effect of individual elements on the properties of steel is given in Table 7.7.

7.3.10 Free-cutting steels

Most free-cutting steels and those with the largest number of (and the most important) applications are carbon/carbon manganese steels. Some hardened and tempered and a few stainless steels are also free cutting. AISI/SAE free-cutting carbon/carbon manganese steels have 11 or 12 as the first two digits instead of 10 and the BS 970 designations have as the first digit a 2 while the second and third figures indicate the mean, or the maximum, sulphur content.

Free-cutting steels are really composites with additions which form a soft particulate second phase which acts as a 'chip breaker' during machining. This reduces tool wear, greatly diminishes the time and cost of machining and makes it easier to obtain a good finish.

The addition is usually sulphur in amounts between 0.1% and 0.33%. These steels were formerly manufactured by using a less effective sulphur-removing slag but present procedure is to resulphurize and the additional processing stage results in a slightly higher price for free-cutting steels. There is no systematic nomenclature for direct-hardening resulphurized alloy steels.

Additions of lead in amounts between 0.15% and 0.35% in addition to sulphur make steel even easier to machine. Specifications indicate leaded steels by inserting an L as an additional third letter in AISI/SAE grade numbers or adding Pb to BS 970 grade designations.

Free-cutting austenitic steels are limited to 303 or 303 Se which are standard 18/8 304 steels with sulphur or selenium additions. Free-cutting versions of 13% chromium steels are available to BS 970 416 S21, 416 S29 and 416 S37.

The particulate phase in free-cutting steels reduces their resistance to fatigue and may introduce other drawbacks. Free-cutting steels may be safely used in low-duty applications in non-aggressive environments for components which are not to be welded. It is essential, however, to ensure that components for severe duties are not made from them. This is of great importance when ordering components from a machining firm which will supply components made from free-cutting steel wherever possible to reduce costs. In particular, the designation 18/8 should not be used when ordering a steel as the supplier can supply 303 *or* 304. The AISI number should always be specified.

7.3.11 Case-hardening steels

Case hardening produces a very hard wear- and fatigue-resisting surface on a core which is usually softer but strong and tougher than that of a hardened and tempered steel. Besides its obvious advantages, case hardening usually improves fatigue endurance, partly because of the compressive stress induced at the surface. There are at least five different processes:

Surface hardening
Carburizing
Carbonitriding
Nitriding
Ion implantation

7.3.11.1 Surface hardening

Surface hardening is achieved by austenitizing only the surface of the steel by applying a high heat flux by electrical induction or by direct flame impingement, and then quenching in moving air, water or oil. Any steel of high enough carbon content may be surface hardened. Those most usually employed are carbon and free-cutting steels with 0.45–0.65% and hardened and tempered steels with 0.35–0.55% carbon.

The properties of the core are those to which the steel has originally been heat treated while hardnesses of from 50 to 65 Rockwell C are produced on the case. These hardnesses are lower than those available from other case-hardening processes but surface hardening is very versatile.

The depth of case produced by induction hardening may be varied by varying frequency from 0.64 mm at 600 kHz to 5 mm at 1 kHz. This is a much thicker case than can be produced by any other method and very valuable for combating abrasive wear.

In flame hardening the surface is heated by one or more gas burners before quenching. The process can be applied to workpieces whose shape and size precludes other methods of case hardening.

7.3.11.2 Carburizing

Any carbon, free-cutting or direct-hardening alloy steel with 0.23% or less carbon is suitable for carburizing. The steel should be chosen according to the properties desired in the core. BS 960 and SAE publish lists of carburizing steels with hardenability data. Core strengths between 500 and 1310 MPa are available and Charpy impact toughness up to 55J (68 with 5 Ni 0.15 Mo steel). Case hardnesses of 64 Rockwell C for low-hardenability steels and 60 Rockwell C for high-hardenability steels can be obtained and the case, which contains a proportion of cementite, is hard wearing.

Carburizing is achieved by exposing the surface of the steel to a gas or liquid with a high carburizing potential at a temperature up to 925°C. Surfaces not required to be carburized should be masked, possibly by copper plating or, better, the carburized layer should be machined off before it has been hardened. There are three processes.

In pack carburizing the component(s) are placed in a heat-resisting box surrounded by a carburizing powder consisting basically of coke or charcoal particles and barium carbonate. The coke and barium carbonate react to produce carbon monoxide from which carbon diffuses into the steel. The process is simple, of low capital cost and produces low distortion, but it is wasteful of heat. It is also labour intensive because the boxes have to be packed and later emptied before heat treatment.

In liquid carburizing the component is suspended in a molten salt bath containing not less than 23% sodium cyanide with barium chloride, sodium chloride and accelerators. The case depth (which is proportional to time) is 0.3 mm in 1 hour at 815°C and 0.6 mm in 1 hour at 925°C. The process is efficient and the core can be refined in (and the component hardened from) the salt bath, but the process uses very poisonous salts, produces poisonous vapours and maintenance is required.

In gas carburizing, hydrocarbon gas is circulated around the workpiece at between 870° and 925°C. The relationship between case depth temperature and time is the same as for liquid carburizing. The process is clean, easy to control, suited to mass production and can be combined with heat treatment but the capital cost of the equipment is high.

7.3.11.3 Carbonitriding

Carbonitriding is achieved by heating the steel in a bath similar to a liquid carburizing bath but containing 30/40% sodium cyanide which has been allowed to react with air at 870°C (liquid carbonitriding) or in a mixture of ammonia and hydrocarbon (gas carbonitriding) at a lower temperature than is used for gas carburizing. The case produced is harder and more wear and temper resistant than a carburized case but is thinner. Case depths of 0.1–0.75 mm can be produced in 1 hour at 760°C and 6 hours at 840°C, respectively.

Steels which are carburized can also be carbonitrided, but because the case is thinner there is a tendency to use steels of slightly higher carbon and alloy content so that the harder core offers more support to the thinner case. A significant advantage of carbonitriding is that the nitrogen in the case significantly increases hardenability so that a hard case may be obtained by quenching in oil which can significantly reduce

1. In each block, the three sub-columns denote:
   1st Present designation of the steel in BS 970. The 'M' in the designation indicates that the steel is to be ordered to specific mechanical property requirements. However. many steels may be ordered to analysis only, when the letter becomes 'A'. or to analysis and hardenability (end-quench) specifications, when the letter becomes 'H'. The first three figures indicate the broad analysis classification, the last two the carbon content.
   2nd Type of steel by broad analysis. These do not give full analyses. only the medium content of the leading element and a list of other alloying elements. For the straight carbon steels, the carbon content is repeated here, but for the alloy steels the carbon content can be inferred from the designation.
   3rd Yield stress range available for the steel at the specified equivalent diameter.

2. Steels marked with an asterisk are free-machining qualities.

3. Steels with first three digits 905 have high aluminium contents and are specifically intended for surface-hardening by nitriding. However. steels 722M24 and 897M39 are also suitable for nitriding, as well as for general purposes.

4. As a general rule, steels quoted in any one block can be tempered down to the next lower tensile range. Equally, where a tensile range is quoted up to a certain maximum diameter, the properties can be attained on smaller diameters, but in practice this may be wasteful of the alloy content, and a cheaper steel may be satisfactory.

5. All steels below the dashed line in the 10″ diameter blocks refer to heavy forgings as specified in BS 4670, but all steels may be used as smaller section forgings as well as rolled bar or billet.

6. This table is based on the 1970 edition of BS 970 and the 1971 edition of BS 4670 except that steels in italics have been eliminated from the 1983 edition of BS 970.

Table 7.7 Influence of added (and adventitious) elements in steel

Element	*Dominant characteristic*	*Influence in ferritic steel*	*Influence in austenitic steel*
Carbon	Strong austenite former	Strongly increases strength and hardenability Decreases ductility	Causes weld decay unless stabilized Stabilizes austenite
Nitrogen	Strong austenite former	Increases strength Decreases toughness	Increases strength Stabilizes austenite
Manganese	Austenite former	Strongly increases strength Increases hardenability Increases tendency to quench cracking Neutralizes harmful effect of sulphur	Stabilizes austenite
Nickel	Austenite former	Refines grain Increases toughness Increases hardenability Slightly increases strength	Stabilizes austenite Stress corrosion cracking peaks at content of 17%
Chromium	Ferrite former Carbide former	Improves corrosion and scaling resistance Improves hardenability Slightly increases strength Retards softening in tempering	Improves corrosion and scaling resistance Destabilizes austenite In high concentration forms brittle 'sigma' phase with iron
Molybdenum	Ferrite former Carbide former	Strongly increases hardenability Moderately increases strength Retards softening on tempering Strongly increases strength at high temperature Alleviates temper embrittlement	Improves corrosion resistance Strongly increases strength at high temperatures
Vanadium	Ferrite former Carbide former	Strongly increases hardenability Moderately increases strength Strongly increases high-temperature strength Increases toughness Alleviates embrittlement by nitrogen	
Silicon	Deoxidizer	Improves scaling resistance Increases hardenability Reduces toughness Increases resistivity Promotes decarburization	Improves scaling resistance
Niobium	Strong carbide former	Increases strength of carbon steel by age hardening	Stabilizes against weld decay Increases strength at high temperature
Titanium	Strong carbide former		Stabilizes against weld decay Increases strength at high temperature
	(with aluminium)	Strongly increases strength by age hardening	Very strongly increases strength by age hardening
Aluminium	Deoxidizer	Increases toughness by combining with nitrogen. Increases sealing resistance. Renders steel suitable for gas nitriding	
Boron		In small amounts greatly increases hardenability. Improves strength at high temperatures	Greatly improves creep and rupture strength
Sulphur	Impurity except when added to improve machinability	Reduces cleanliness Reduces ductility ~0.3% added to improve machinability	Reduces cleanliness Reduces ductility ~0.3% improves machinability

Table 7.7 *(continued)*

Element	*Dominant characteristic*	*Influence in ferritic steel*	*Influence in austenitic steel*
Lead	Improves machinability	Added to improve machinability	
Selenium	Improves machinability		Added to improve surface finish on machining
Phosphorus	Impurity	Reduces ductility and cleanliness Can improve strength of carbon steel	Reduces ductility and cleanliness
Copper	Normally impurity	Improves corrosion resistance May improve strength but reduces ductility by ageing	Improves corrosion resistance Can increase strength at high temperature
Sn, Sb, As, Bi	Tramp element Impurities	Strongly reduces ductility Promotes temper embrittlement	Fortunately seldom encountered
Hydrogen	Impurity Decarburizer	Strongly promotes rupture and fracture	Fortunately seldom encountered

distortion in heat treatment. Case hardnesses of 65 Rockwell C may be produced with the same range of core strengths as by carburizing.

7.3.11.4 Nitriding

Nitriding may be achieved by heating steel in a cyanide bath or an atmosphere of gaseous nitrogen at 510–565°C. The steel component is heat treated and finish machined before nitriding.

Liquid nitriding uses a bath of sodium and potassium cyanides, or sodium cyanide and sodium carbonate. The bath is pre-aged for a week to convert about a third of the cyanide into cyanate. Two variants of the process are liquid pressure nitriding in which liquid anhydrous ammonia is piped into the bath under a pressure of 1–30 atm, and aerated bath nitriding in which measured amounts of air are pumped through the molten bath. All the processes provide excellent results, depth and hardness of case being the same as obtained from gas nitriding. Unlike gas nitriding, carbon steels can be liquid nitrided and the case produced on tool steels is tougher and lower in nitrogen than a gas-nitrided case. On the other hand, liquid nitriding uses a highly poisonous liquid bath at a high temperature and the process may take as long as 72 hours. It is really only suitable for small components.

Gas nitriding is achieved by introducing nitrogen into the surface of a steel by holding the metal at between 510°C and 565°C in contact with a nitrogenous gas, usually ammonia. A brittle nitrogen-rich surface layer known as the 'white nitride layer' which may have to be removed by grinding or lapping is produced. There are two processes: single- and double-stage nitriding.

In the single-stage process a temperature between 496°C and 524°C is used and about 22% of the ammonia dissociates. This process produces a brittle white layer at the surface. The first stage of the double-stage process is the same as the single stage but, following this, the ammonia is catalytically dissociated to about 80% and the temperature increased above 524°C. Less ammonia is used in the double-stage compared with the single-stage process and the brittle white layer is reduced in depth and is softer and more ductile. Process times are in the order of 72 hours.

Gas nitriding can only be used if the steel contains an alloying element such as aluminium, chromium, vanadium or molybdenum that forms a stable nitride at nitriding temperatures. The film produced by nitriding carbon steels is extremely brittle and spalls readily. In general, stainless steels, hot-work die steels containing 5% chromium and medium-carbon chromium containing low-alloy steels have been gas nitrided. High-speed steels have been liquid nitrided.

There are also a number of steels listed in AISI/SAE or BS 970 (or having the name 'Nitralloy') to which 1% aluminium has been added to make the steel suited for gas nitriding. AISI 7140 (BS 970 905 M39) is typical.

Nitriding can produce case hardnesses up to 75 Rockwell C depending on the steel. This hardness persists for about 0.125 mm but depths of case with hardness above 60 Rockwell of 0.8 mm may be produced.

The relatively thin case compared with other methods of case hardening make it customary to use fairly strong core material. For ferritic steels a UTS between 850 and 1400 MPa is usual. Typical components nitrided are gears, bushings, seals, camshaft journals and other bearings, and dies – in fact all components which are subject to wear. In spite of their relatively low hardness, austenitic stainless steel components are nitrided to prevent seizure and wear, particularly at high temperatures. Two considerations apply.

First, stainless steels must be depassivated by mechanical or chemical removal of the chromic oxide film before nitriding. Second, nitriding decreases corrosion resistance by replacing the chromic oxide film by a chromium nitride film and should not be employed when corrosion resistance is of paramount importance.

Ion implantation is achieved by bombarding the surface of a steel with charged ions, usually nitrogen when the object is to harden the surface. The cost is high, the quantity of nitrogen implanted small, and it can only be carried out by a laboratory which has an accelerator such as AERE. It is used for special applications which will probably increase in number.

7.3.12 Stainless steels

The addition of strong oxide-forming elements (aluminium silicon and chromium) replaces the oxide on the surface of iron by a tenacious film, which confers corrosion and oxidation resistance.[19] Alloys of iron with substantial proportions of aluminium and silicon have undesirable properties so that chromium additions which in progressively increasing quanti-

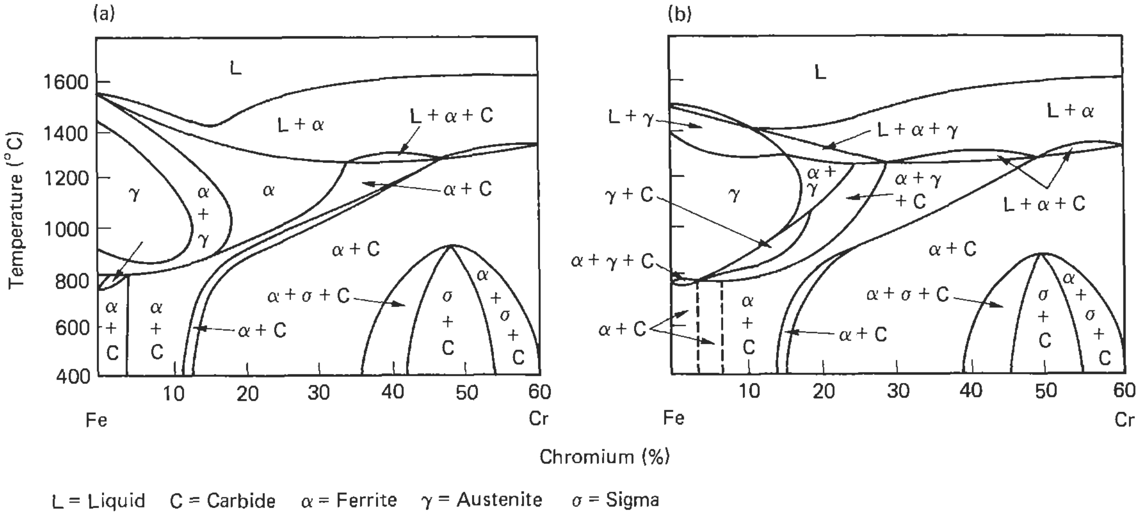

Figure 7.27 Iron–chromium–carbon phase diagrams (a) at 0.10% carbon, (b) at 0.50% carbon

ties change the oxide film first to a spinel and then to chromium tri-oxide must be employed. Stainless steels are alloys with a minimum of 50% iron and a minimum of 12% chromium.

7.3.12.1 Metallurgy of stainless steels

Iron forms a complete series of solid solutions with nickel and with chromium; the alpha or delta form (ferrite) will form solid solutions with chromium up to 100% of the alloying element but will dissolve only a limited amount of nickel and the gamma form (austenite) will dissolve up to 100% of nickel without a new phase appearing but can dissolve only limited amounts of chromium.

The above comments are reflected in the phase diagram for the Fe–Cr system (Figure 7.27). Of particular significance is the small austenite field known as the gamma loop; alloys to the right of this loop are ferritic and undergo no allotropic changes in heating or cooling, consequently grain refinement by such changes is not possible. The amount of chromium which closes this loop if no other element is present is 12.8%. Above this figure pure Fe–Cr alloys are ferritic and subject to grain growth as temperatures are raised to the liquidus. Addition of austenite formers enlarges the gamma loop so that, in the limit, the austenitic phase is stable over the entire range of temperature. Varying the proportions of chromium and nickel (and manganese and nitrogen) produces the several types of stainless steel.

Ferritic stainless steels contain betwen 11 and 30% of chromium, a minimum of austenite formers (see Table 7.7) such as carbon whose influence on the extent of the gamma loop is shown in Figure 7.27 and often some other ferrite formers so that they always retain a ferritic structure.

The standard ferritic (and martensitic) stainless steels have '400' series AISI and BS 970 numbers. These numbers increase with the chromium content, low numbers (e.g. 403) denoting 12% chromium. Other things being equal, therefore, a higher-numbered steel will have a better resistance to general corrosion than a lower-numbered one. The following numbers indicate a ferritic steel: 405, 409, 430, 434, 436. The non-standard steels include Carpenter 182 FM and four aluminium-containing steels Armco 18 SR, and BSC Sichromal 9, 10 and 12.

Ferritic stainless steels are marketed only in the form of plate and strip and all have similar mechanical properties: UTS 415–460 MPa, yield strength 275–550 MPa, elongation 10–25% depending on thickness of plate. They require no heat treatment beyond an anneal at about 800°C followed by air or furnace cooling. The steels are easily drawn and pressed and their machinability is good, 430 FSe being naturally the best. They are prone to grain growth particularly during welding and this impairs toughness and ductility.

The steels are virtually immune to chloride-induced stress corrosion cracking at the relatively low temperatures at which they are used and have good resistance to scaling at elevated temperatures, the aluminium containing varieties (e.g. the Sichromals being some of the best available materials in this respect). They are significantly cheaper than austenitic steels and are used for chemical plant components, domestic and catering equipment, automobile trim, domestic and industrial heater parts, exhaust systems and fasteners. The higher numbers, which have greater resistance to general corrosion, are used for the more demanding applications.

'Low Interstitial' grades characterized by carbon and nitrogen contents below 0.03%, chromium contents between 17 and 30% usually with molybdenum and other additions are recently developed ferritic stainless steels. These include one standard steel, 444 (with, in spite of its high number, only 18.5% Cr) and non-standard steels Alleghenny Ludlum 'E Brite 261' 'A129.4.4' and 'A294C', Nyby Uddeholm 'Monit', Crucible 'Seacure/SCI' and Thyssen 'Superferrit'.

These steels, particularly the versions which contain 28% Cr and 4% or more percentage Mo are claimed to have exceptional resistance to general, stress and pitting corrosions and to be suitable for the most aggressive environments obtaining in chemical plant and elsewhere.

Martensitic stainless steels contain 11–18% of chromium and some austenite formers (see Table 7.7) such as carbon (see Figure 7.27) so that they can be hardened by cooling through the gamma/alpha phase transformation.

The US martensitic stainless steels also have 400 series numbers, 403^B, 410^B, 414^B, 416^B, 420^B, 422, 431^B and 440 (the affix B indicates a BS 970 version) with chromium contents increasing with specification number from 12% to 17% (the highest chromium content at which a steel can have a fully martensitic structure). They have therefore less general corrosion resistance than the ferritic stainless steels but have fair resistance to stress corrosion. The steels can be hardened by quenching from above 950°C to form a hard and brittle structure which must be tempered. Tempering at 150–370°C improves ductility with little loss of strength but above 500°C the strength falls off rapidly. Holding at temperatures between 370°C and 600°C causes temper embrittlement which reduces impact resistance and must be avoided.

The martensitic high carbon grades are difficult to form and weld. They are particularly suited for operations requiring resistance to wear and manufacture of a cutting edge and their applications include valves, tools, cutlery, scissors, turbine blades, coalmining equipment and surgical instruments. The most widely used (and therefore most easily available) martensitic and ferritic stainless steels are listed in Table 7.8.

Austenitic stainless steels contain 15–27% Cr and, in the case of the '300' series 8–35% Ni. In the '200' series for which there is no BS 970 equivalent some of the nickel is replaced by Mn and N, which cost less than nickel. These steels can be cold worked to higher strengths than the '300' series steels.

[a] Depending on size. [b] BSC Trade Name.

Austenitic materials with much more than 30% nickel are 'Nickel Alloys'. If they contain age hardening Al,Ti additions they are iron (or Nickel) Superalloys. The mechanical properties of austenitic steels range between UTS 490–680 MPa, Yield Strength 205–575 MPa, elongation 30–60%.

Some of the AISI specification numbers are followed by letters, and these letters (and where applicable to BS 970 numerical codes) are:

H: (BS Code 49). These steels contain 0.006B and 0.15Nb (except 347, which already has a higher Nb content) and have creep-resisting properties.

Se: This steel contains 0.15% Se and is free machining.

L (BS Code 11): These steels contain a maximum of 0.03% C.

N (BS Code 6X): These steels contain 0.2% nitrogen and therefore have proof stresses from 50 to 130 MPa higher than the non-nitrogen-containing steels.

Ti or Cb (BS Code 40): These steels contain Ti or Nb to combine with the carbon and thereby prevent weld decay.

There are over 50 standard AISI and slightly less BS 970 austenitic stainless steels. Table 7.9 lists those most commonly used and therefore most readily available. (Steels suitable for use at elevated temperatures are listed in Table 7.10.)

There are, in addition, a very large number of non-standard austenitic steels of which the following list is a small selection:

- Alleghhenny Ludlum 'A286': Really a superalloy but used also as a stainless steel because of its high yield strength.
- Armco 'Nitronic' high-nitrogen steel also with high yield strength.
- Avesta 254 and 654 'SMO': High-molybdenum-containing steel with exceptional resistance to pitting corrosion.
- Carpenter '20Cb3': Really a nickel alloy but generally known as a stainless steel, has a high resistance to sulphuric acid attack.
- BSC 'Esshete 1250': Steel with exceptional creep resistance and high yield.

Austenitic stainless steels are chosen on account of their resistance to general corrosion which is superior to that of a ferritic steel of similar chromium content and also because of the high ductility of the face-centred gamma structure which confers high hot and cold formability and high toughness down to cryogenic temperatures.

It is not possible to state exactly where the limits of stability of austenite steel lie at room temperature because transformation can be too sluggish to permit precise delineation of the phase fields and is influenced by further alloy addition such as Mo, Si and N. The austenite should ideally be 'Persistent', that is, it should not transform under the temperature or working conditions encountered in fabrication and service. The range of compositions with 'Persistent' austenite at room temperature is shown in Figure 7.28 (labelled 'A').

Austenite stability is increased by increasing nickel, manganese, carbon and nitrogen. Partial transformation will cause the steel to lose its non-magnetic character, impair its deep drawing characteristics and reduce notch toughness at cryogenic temperatures. There may be other drawbacks but service performance is not usually impaired.

Two substantial advantages are conferred by the presence of a proportion of ferrite: the prevention of fissuring on solidification and resistance to intergranular corrosion. Except in the case of welding (see Section 7.3.17.1) these advantages apply to cast rather than wrought austenitic steels.

Many austenitic stainless steels (including 304, typically 18.8 grade) are partially transformed by cold work and work harden appreciably. Steels such as these are air cooled in thin section but thicker sections are water quenched. Besides promoting stability this retains carbide in solution.

7.3.12.2 Duplex stainless steels

Duplex stainless steels contain 18–27% Cr, 4–7% Ni, 2–4% Mo with copper and nitrogen in proportions which ensure that they have a mixed ferritic austenite structure that is not heat treatable (see Figure 7.28). Their mechanical properties range between UTS 600–900 MPa, Yield Strength 410–850 MPa, Elongation 16–48%. The one standard duplex stainless steel is AISI 329, but there are, in addition, BSC 'SF22/5', Langley Alloys 'Ferralium 255', Sandvik '2RE60' and 'SAF2205/AF22' and Sumitomo 'DP3'.

The duplex stainless steels have outstanding properties. Their resistance to stress corrosion cracking is superior to that of comparable austenitic steels and they have good resistance to pitting corrosion. They have better toughness than ferritic steels and are easily welded. Those containing nitrogen can be cold worked to higher strengths than ferritic or austenitic steels, and are highly weldable provided that a welding consumable that will ensure the presence of ferrite in the weld metal is employed.

They have so far been used for tube plates, for marine applications, for sour gas pipeline and acetic acid production. When they are better known and more widely available they should become used in preference to austenitic steels for the more demanding applications.

Precipitation-hardening stainless steels contain 12–28% Cr, 4–7% Ni, Al and Ti to give a structure of austenite and martensite which can be precipitation hardened. The mechanical properties of these steels range between UTS 895–1100 MPa, Yield Strength 276–1000 MPa, Elongation 10–35%.

No precipitation-hardening stainless steels are standardized by AISI or in BS 970 but Firth Vickers 'FV 520' is covered by BS 1501 460552 for plate and BS Specification S143, 144 and 145 for bars, billets and forgings. Non-standard steels include Armco '15–5PH', '17–4 PH' and '17–7 PM' and Carpenter 'Custom 450' and 'Custom 435'.

Their excellent mechanical properties and corrosion resistance has caused precipitation-hardened stainless steels to be used for gears, fasteners, cutlery and aircraft and steam turbine parts. They can be machined to finished size in the soft condition and precipitation hardened later. Their most significant drawback is the complex heat treatment required which, if not properly carried out, may result in extreme brittleness.

7.3.13 Corrosion resistance of stainless steels

Corrosion resistance of stainless steels depends on surface passivity arising from the formation of a chromium-containing oxide film which is insoluble, non-porous and, under suitable conditions, self-healing if damaged. Passivity of stainless steel is not a constant condition but it prevails under certain environmental conditions. The environment should be oxidizing in character. Other factors affecting corrosion resistance include composition, heat treatment, initial surface condition, variation in corrosion conditions, stress, welding and service temperature.

7.3.13.1 Composition

Those ferritic and martensitic steels with roughly 13% Cr are rust resisting only and may be used for conditions where corrosion is relatively light (e.g. atmospheric, steam and oxidation resistance up to 500°C). Applications include cutlery, oil-cracking, turbine blades, surgical instruments, automobile exhausts, etc. 17% Cr (ferritic and martensitic) steels are corrosion and light acid resisting. They have improved general corrosion resistance compared with 13% Cr steels. Applications for the ferritic grade include domestic and catering equipment, automobile trim, and industrial heater parts. The martensitic grade is used in general engineering, for pump and valve parts in contact with non-ferrous metals or graphitic packings.

The addition of molybdenum significantly improves the integrity of the oxide film. The ferritic 434 and 436 grades can withstand more severe corrosive conditions and the martensitic, 440 grades are used where wear and acid resistance is required such as in valve seats.

Table 7.10 Steels suitable for use at elevated temperatures showing 0.2% proof and creep rupture strengths near the top of their useful temperature ranges.

BS 1501, 2 or 3 designation	*AISI equivalent*	*Type of steel*	*Min. 0.2% PS at temperature* (MPa)	*10^5 h rupture strength at temperature* (MPa)	*Note*

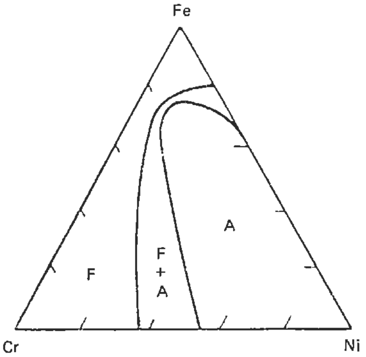

Figure 7.28 Iron–nickel–chromium phase diagram at room temperature showing persistent austenite (A) and duplex ferrite austenite (F+A) phase fields

Additional amounts of nickel above 8% to form an austenitic structure in the '300' steels further improve resistance to corrosion and acid attack. Applications include domestic, shop and office fittings, food, dairy, brewery, chemical and fertilizer industries.

The stainless steels with the highest corrosion resistance are those with even higher chromium contents such as 310 with 25% Cr and the low interstitial steels with up to 30% Cr. The addition of molybdenum up to 6% is also highly beneficial. The resistance to sulphuric acid attack of Carpenter 20 Cb-3 which contains 3.5% Cu as well as 2.5% Mo has already been mentioned.

Note that to ensure an austenitic structure, the nickel content of the Mo-bearing steels increases above 8% as the content of Mo and other ferrite-stabilizing elements (Ti, Nb, etc.) increases. The 4.5% Mo alloy 317 LM is used in sodium chlorite bleaching baths and other very severe environments in the textile industry.

7.3.13.2 Heat treatment

Heat treatment has a significant influence on corrosion resistance. Maximum resistance is offered when the carbon is completely dissolved in a homogeneous single-phase structure. The 12–14% Cr steels are heat treated to desired combinations of strength, ductility and toughness and because of their low carbon content are generally satisfactory unless tempered in the range 500–600°C.

Austenitic steels (18/8) are most resistant when quenched from 1050°C to 1100°C, their normal condition of supply. A steel chosen for welded fabrications should be Ti or Nb stabilized (AISI, 'Ti' or 'Cb', BSI '40') or, better, an extra-low carbon (AISI 'L' or BSI 11) grade. Quenching after welding is usually impracticable.

7.3.13.3 Surface condition

For maximum resistance to corrosion the passive film must be properly formed; this is ensured by removing all scale, embedded grit, metal pick-up from tools and other surface contaminants. Polishing improves resistance. Passivating in oxidizing acid (10–20% NHO_3 by weight) solution at 25°C for 10–30 min confers maximum resistance to austenitic steels. The ferritic–martensitic grades are passivated in nitric acid–potassium dichromate solution (0.5% nitric acid + 0.5% potassium dichromate at 60°C for 30 min).

7.3.13.4 Variation in corrosion conditions

In the absence of experience, samples of the proposed steels should be tested in the condition in which they will be used (i.e. welded, if fabricated) in the intended environment taking full note of any possible variation in service conditions. The effect of welding on corrosion resistance is considered in Section 7.3.17.

7.3.13.5 Service temperature

Because stainless steels (other than those with very low carbon) which are unstabilized or partly stabilized with Ti or Nb may show chromium carbide precipitation when subjected to service temperatures above 350°C (see Section 7.3.17) this should be the upper limit for service in corrosive environments. Fully stabilized steels are not restricted in this manner.

7.3.13.6 Localized corrosion of stainless steels

The considerations discussed in Sections 7.3.13.1–5 apply principally to general corrosion which progressively reduces the thickness of a component until it is completely dissolved or its strength is so reduced that it can no longer withstand imposed stress. More insidious attack mechanisms on stainless steels are the five varieties of localized corrosion, galvanic, crevice, pitting, stress corrosion and intergranular penetration. These are confined to isolated areas or lines on the surface but penetrate through the thickness of a component to destroy its integrity without materially affecting its dimensions. Their incidence is less predictable and their onset more difficult to predict than general corrosion but their effect may be catastrophic.

Crevice and galvanic corrosion must be countered by designing to eliminate crevices and the juxtaposition of metals of different solution potential. Intergranular penetration will be discussed in the section dealing with welding. Pitting and stress corrosion are composition dependent.

Pitting occurs in conducting aqueous liquid environments (usually halide solutions) when local penetration of the oxide film creates stagnant locations in which diffusion generates strongly acid environments which rapidly penetrate a component. Figures 7.29(a) and (b) show, respectively, a pit in an early and in a very late stage. Resistance to pitting in low interstitial ferritic steels increases with a rise in chromium content from 18% to 29% and molybdenum from 1% to 4% while austenitic steels require at least 20% chromium and between 4.5% and 6% Mo. Typical austenitic steels with very high resistance are Alleghenny Ludlum 'A16 × M', Avesta '254 and 654 SMO' and Weir Material Services Zenon 100, all of which are claimed not to pit in stagnant seawater. These steels are also claimed to resist crevice corrosion should this not have been eliminated by design. The best standard austenitic stainless steel is 317 LM.

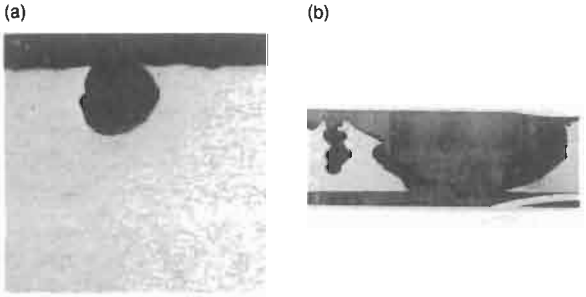

Figure 7.29 Pits, at (a) an early and (b) a late (penetrating) stage

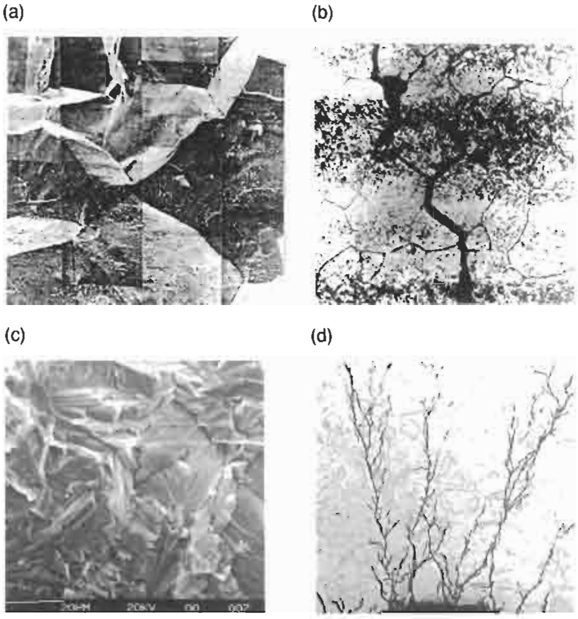

Figure 7.30 Stress corrosion cracks. (a) and (b) Intergranular; (c) and (d) transgranular

Stress corrosion cracking occurs when a material is stressed in tension in an aggressive aqueous environment, usually an alkali metal halide or hydroxide solution. Cracks may be transgranular as in Figure 7.30(a) and (b) or intergranular as in Figure 7.30(c) and (d). The tendency to stress corrosion cracking of a material is measured by its K_{1scc} value, which is the lowest value of stress intensity in $MNm^{-3/2}$ at which a crack will propagate in a specific medium at a specific temperature.

The growth rate of stress corrosion cracks is highly temperature dependent, increasing about 500 times with a rise in temperature from 20°C to 100°C. Most austenitic steels are resistant at ambient temperature but if temperature rises above about 40°C in a saline environment a change should be made to a high-molybdenum steel, a duplex steel, a nickel-free ferritic steel or a nickel alloy, depending on the severity of the conditions.

Materials are tested for resistance to stress corrosion by exposure to stress in a boiling aqueous solution of 42% $MgCl_2$. Very few materials will withstand this for long.

7.3.14 Heat-resisting steels

The range of operating temperature of carbon steels is limited to about 400°C by decrease in resistance to deformation, and in oxidizing atmospheres to about 500°C by diffusion of oxygen through the oxide film. Operation above these temperatures is achieved by the addition of alloying elements such as

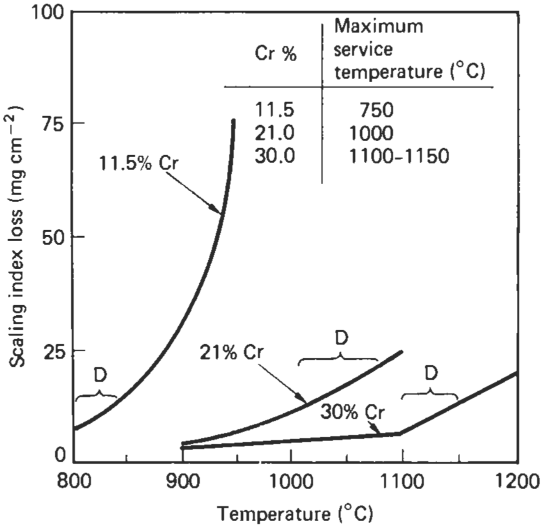

Figure 7.31 Relationship between scaling loss, temperature and chromium content of chromium steels

chromium, aluminium and silicon which render the oxide film more tenacious and limit diffusion (see Figure 7.31) and chromium, molybdenum, vanadium and niobium which, in solid solution or as carbides, impart stability and increase resistance to deformation.

The scope for providing high-temperature yield and creep strength in ferritic steels is limited, therefore for service above about 550°C, austenitic steels are used. Steels for use at high temperature must, in addition, be stable and capable of fabrication to the design shape. Material requirements vary with application.

Steam power plant materials, with minor exceptions, operate below 650°C and in atmospheres which are only a little more aggressive than air. But they must last for at least 10^5 hours and preferably two or three times that figure.

Chemical and refinery plant may be required to operate over a wider temperature range in very varied environments but they have shorter lives (usually about 2–4 × 10^4 hours). Aircraft propulsion turbines require materials to withstand high stresses at very high temperatures but component operating lives are seldom above 10^3 to 10^4 hours.

The materials used to meet these requirements are basically as follows. For components which must resist oxidation but are not stressed, ferritic chromium steels, preferably also containing silicon and aluminium, may be chosen. The choice will depend on cost, temperature, aggressiveness of environment and ability to fabricate from 405, 409 (the cheapest weldable stainless steel), 446 and BS Sichromal '9', '10' and '12'. For stressed components operating at high temperatures a choice may be made from the steels listed in Table 7.10. This table gives only a few out of many alternatives but provides at least one steel that may be selected with confidence to operate over any part of the temperature range.

At temperatures below 450°C silicon-killed carbon or carbon manganese steels are used except for heavy pressure vessels, where bainitic steels such as BS 1501 271 or 281 which have a high proof stress in the normalized condition are used.

Time-dependent deformation becomes more important than yield at temperatures above 400°C and the design criterion changes from a factor of the proof stress to a factor of the creep rupture stress at the design life of the component. As temperature increases above 400/450°C carbon steels start to give place to chromium–molybdenum bainitic or martensitic steels. In power plant, strength rather than corrosion resistance is the critical parameter and the lower chromium steels are preferred.

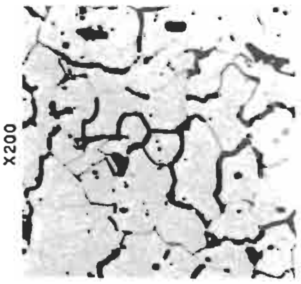

Figure 7.32 Micro fissures caused by hydrogen in steel

In chemical or refining plant the environment may be hydrogenous and higher chromium contents are essential to prevent hydrogen which diffuses into the steel, combining with carbon to cause internal ruptures (see Figure 7.32).

Increase in temperature beyond 550°C requires the higher creep resistance of an austenitic steel. One of the steels designated 'H' by AISI or coded 44 by BS 970 should be selected. These are stabilized by niobium and their creep rupture strengths and ductilities improved by the addition of 0.006% boron.

Standard steels are satisfactory up to about 600°C but non-standard steels such as BS 'Esshete 1250' have an increased temperature range and allow the use of thinner sections. In critical locations the very high scaling resistance of 310 may be used as the corrosion-resistant face of a laminated structure backed with Esshete 1250. For the higher temperatures and higher stresses in aircraft gas-turbine engine blades or disks recourse must be had to superalloys such as Allegheny Ludlum 'A286' or 'Discoloy'. Where high temperature strengths of these are inadequate recourse must be had to nickel alloys (see Section 7.4.5). Scaling resistance of aircraft gas-turbine blade materials is provided by coating with aluminium.

7.3.14.1 Structural stability

Stainless steels heated to above 600°C in fabrication or operation are subject to embrittlement mechanisms which have, in the past, given rise to severe problems. These mechanisms are listed and the compositions over which they may occur are indicated in Figure 7.33. The better understanding of the problems has resulted in a method of avoidance or the appreciation that they are not so serious as was originally considered.

Embrittlement due to carbide precipitation is avoided by using a low-carbon or a stabilized steel (AISI 'L' or 'H' or BS 970 Code '11' or '44'). Straight chromium steels with chromium contents less than 27% Cr are not subject to sigma-phase embrittlement (precipitation of an intermetallic FeCr phase). Steels with more than 27% Cr should not be employed within the temperature range 520–700°C at which sigma-phase embrittlement occurs. The sigma phase is dissolved by heating to 820°C.

Straight chromium steels with more than 15% Cr suffer from '475°C' embrittlement if held in (or slowly cooled through) the range 525–425°C.

Austenitic steels, particularly 310 with silicon in excess of 1.5%, develop sigma phase when heated in the range

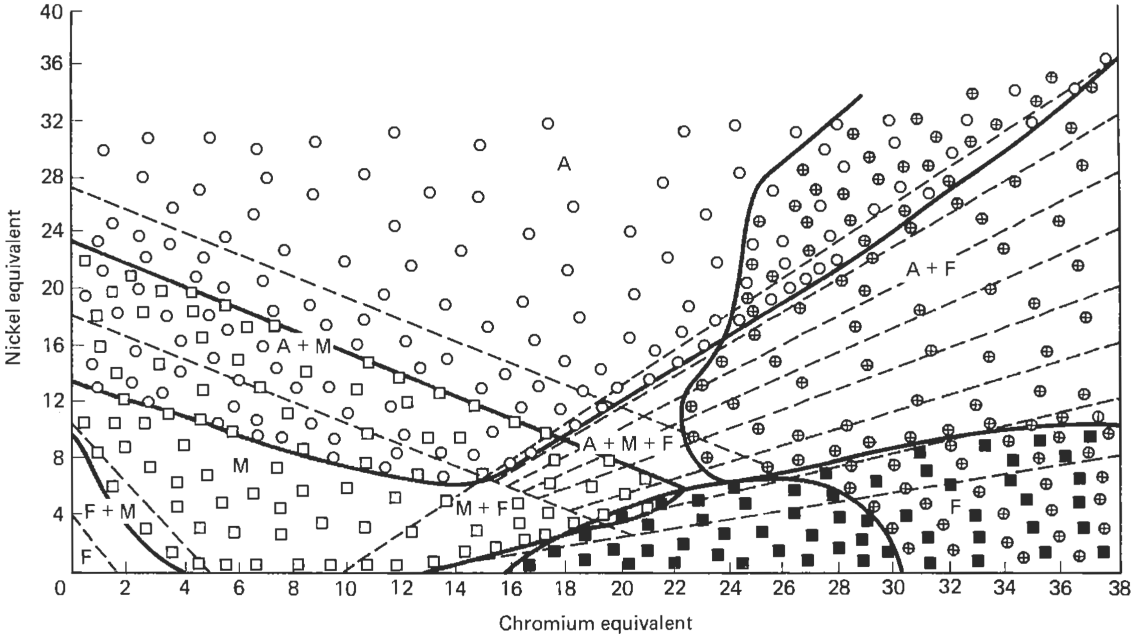

Figure 7.33 Embrittlement mechanisms in stainless steels related to composition (□) Martensitic cracking between 0 and 290°C; (○) hot cracking above 1250°C; (⊕) σ phase embrittlement after heat treatment or service at 500–900°C; (■) cold brittleness after gain growth due to high temperatures (>1150°C)—ductile above 400°C. Where symbols overlap, the material shows the characteristics of both mechanisms

590–925°C but, provided local stressing by differential expansion is prevented by design, the embrittlement has little effect on service performance even though the steel has zero room temperature ductility.

Austenite transformation to ferrite may be avoided by ensuring that the composition of the steel is such as to produce persistent austenite. There is little evidence of the transformation leading to problems in service even when this condition has not been met.

7.3.14.2 Valve steels

Internal combustion engine valves operate under severe conditions of fatigue, impact, high-temperature corrosion and wear. In the USA the SAE lists a special category which includes all types of steel which are used for valves (see the *SAE Handbook*[11]).

In the UK five steel types classified as stainless steels in BS 970 are described as Valve Steels. They are:

1. Grade 401 S45; 3% Si, 8% Cr (strictly, not a stainless steel), martensitic steel used for inlet valves in petrol engines and exhaust valves in medium-duty diesels. Limiting temperature 700°C
2. Grade 382 S34; 21% Cr, 12% Ni. Austenitic steel used for diesel exhaust valves, must be hard faced above 700°C.
3. Grade 443 S62; 2% Si, 20% Cr. Martensitic steel used for exhaust valves in petrol engines. Limiting temperature 750°C.
4. Grades 331 S40 and 331 S42 (KE965)*: 14% Cr, 14% Ni-Si-W. Austenitic steel suitable (with hard-faced seats) for temperatures up to 800°C.
5. Grades 349 S52, 349 S54, 352 S52 and 352 S54 (the S54 types are free cutting with sulphur additions). Scaling resistance to 900°C. Used for petrol engine exhaust valves.

7.3.15 Toughness in steels

Toughness is the property that prevents failure of a material when a load is either rapidly applied or generates a high stress intensity at the root of a discontinuity. It is defined as the critical stress intensity resulting in fracture K_{Ic}, $MNm^{-3/2}$ or Charpy Impact Energy J. In the case of metals with a body-centred-cubic structure (ferritic steels) or a hexagonal structure (magnesium), which decline sharply in toughness over a narrow temperature range, Impact Transition Temperature (f.a.t.t.°C) is also used. These parameters are discussed in Chapter 8, Section 8.3. This section is confined to a description of materials which meet requirements for specific applications.

Other things being equal, fracture toughness bears an inverse relationship to tensile strength, grain size, and carbon content of a steel. Martensitic structures are tougher than bainitic which are themselves tougher than pearlitic structures with the same hardness.

Toughness is reduced by increase in the content of hydrogen, oxygen, nitrogen and sulphur and the so-called tramp elements, phosphorus, antimony, arsenic and tin, which cause 'temper embrittlement'. It is increased by a rise in content of nickel, manganese and appropriate amounts of aluminium, vanadium, niobium and molybdenum which specifically reduces temper embrittlement. The face-centred-cubic austenitic steels do not suffer from a ductile/brittle transition at low temperature.

Two examples of failures which were eliminated by a change to a tougher material are:

- Failures in the original welded ships which, in some cases, split in half. These failures all occurred at low temperature. In one specific case failure occurred at a weld start strake at 2°C in a steel with a ductile brittle transition temperature of 30°C and a Charpy energy at failure temperature of 11J. Failures were eliminated by deoxidizing steel with 0.15–0.3% Si and 0.02–0.05% Al which refines grain size and combines with nitrogen. Ship plate is now specified to have a Charpy V notch J value of 20 at 4°C, a figure which is well within the capability of modern steels low in hydrogen, oxygen, sulphur and phosphorus.

---

*Common (or trade) name.

- Failures in heavy-section turbogenerator forgings, which operated at relatively low temperature, due to embrittlement by hydrogen combined with temper embrittlement. Hydrogen has been eliminated by vacuum treatment of the molten steel. 'Lower nose' temper embrittlement is associated with the migration of 'tramp' elements such as phosphorus, arsenic, antimony and tin, which are taken in solution at the tempering temperature and reprecipitate at grain boundaries at temperatures around 500°C. The migration is promoted by carbon, silicon, nickel and manganese but retarded by molybdenum. The embrittlement could be avoided by quenching the steel from its tempering temperature but the internal stresses so produced would be worse than the temper embrittlement. Temper embrittlement is minimized by reducing the content of tramp elements and by using carbon vacuum deoxidation which obviates the need for silicon.

Figure 7.34 and Table 7.11 show the properties available in modern large forgings in a 3.5 NiCr V steel.

Control of embrittlement is also important to avoid the risk of failure in light water pressure vessels made from ASTM 533B MnMoNi and 508 NiCrMo steels and is achieved by a specification with limits of: Cu, 0.10; P, 0.012; S, 0.015 and V, 0.05% which guarantees a K_{1c} value of 176 $\text{MNm}^{-3/2}$ at room temperature.

7.3.15.1 Cryogenic applications

Care must be taken when choosing steels for cryogenic applications for which, as a result of their ductile/brittle transition, the normal ferritic steels are unacceptably brittle. All the common standard austenitic stainless steels have excellent toughness at temperatures down to −240°C, measured by Charpy impact values usually between 140 and 150. Tensile and 0.2% proof stress increase as the temperature is lowered to around 1500 and 456 MPa, respectively, and elongations decrease slightly but remain adequate at 40–50%. The 0.2% nitrogen grades (typically, 316N, H (316 S66)) have higher proof stresses and are particularly suited to cryogenic applications, because the nitrogen ensures that the austenite is persistent. There is some evidence that the endurance limit of austenitic steels increases as temperature decreases.

If a non-stainless steel is preferred there are the French 'Afnor' specification steels, 3.5% Ni, 5% Ni and 9% Ni whose low-temperature properties improve with increasing nickel content. If high strength combined with high toughness at cryogenic temperatures is required, a maraging steel should be specified.

7.3.16 Maraging steels

Maraging steels are supplied to ASTM A579. They are high-nickel steels which are hardened by precipitation of an aluminium titanium compound on ageing at 500°C. They have a number of advantages including high strengths, normally ranging between 1100 and 1930 MPa (but a steel with a proof stress of 2400 and a UTS of 2450 MPa is available), excellent toughness even at −196°C and good resistance to stress corrosion cracking.

Their greatest advantage is, however, ease of fabrication. They can be machined at their low-solution-treated hardness of 300 VPN and then aged to their optimum hardness at 500°C with minimal distortion and no risk of cracking. They have good weldability, needing no preheat and their properties may be restored after welding by ageing.

Their main disadvantage is their high cost and the fact that, to obtain optimum toughness, they should be made by ESR or vacuum arc melting. Also, because of the absence of hard carbides, they are inferior in wear properties to hardened and tempered steels.

7.3.17 Weldability of steels

Steels may be welded by almost all varieties of electric arc welding methods, including gas-shielded MIG and TIG with and without filler, flux shielded manual metal arc, submerged arc, electro slag, spot, projection and flash butt. Other fusion methods include the more recently developed electron beam and laser, and relatively old-fashioned gas welding. Solid-phase methods, forge, diffusion, friction and explosive welding may also be used. Many of these procedures are concerned with relatively thin sections or special design and applications.

7.3.17.1 Weldability of non-stainless steels

'Weldability' of steels usually implies the ability to make long runs in fairly large sections either by manual metal or submerged arc and is governed in ferritic steels by the 'Carbon Equivalent':

‡ Embrittled: step cooled.

$$CE = C\% + N\% + \frac{Cr\% + Mo\%}{5} + \frac{V\% + Ni\% + Cu\%}{15}$$

(Boron is not taken account of in this equation but has a great influence on hardenability and therefore on weldability.) Steels with carbon equivalent below 0.14% are readily welded without special precautions in a wide range of thicknesses.

Steels with carbon equivalent between 0.14% and 0.45% require the following precautions, depending on the value of carbon equivalent and section size to prevent the formation of austempered martensite cracking aggravated by hydrogen.

Specification of low-hydrogen electrodes This is always desirable but requires operator skill to compensate for the more sluggish metal and slag flows compared with other electrodes.

Use of preheat before welding The preheat temperature required depends on the CE and the metal thickness; for a carbon equivalent of 0.2, 40°C and 110°C are advisable for respective metal thicknesses of 25 and 225 mm, while for a carbon equivalent of 0.45, 170°C and 260°C are advisable for the same thicknesses.

Control of heat input Other things being equal, a higher heat input gives less risk of formation of austempered martensite than a lower heat input but care must be taken to limit distortion and the introduction of stress.

Use of post-heat after welding This is seldom required for CEs below about 0.35%, but high-duty components with restrained welds should be post-weld heat treated at between 600°C and 650°C for one hour per 25 mm thickness. Besides preventing immediate cracking (or making it obvious during inspection) post-weld heating improves dimensional stability.

It is essential when welding thick and complex structures to post-heat-treat one weld before commencing to weld a cross seam.

Steels with carbon equivalent above 0.45 These present very severe problems in welding. Very high preheats ranging up to 340°C for carbon equivalent 0.6 and 225 mm thickness, low-hydrogen electrodes (preferably lower in carbon equivalent than the parent material) and immediate post-heat-treatment at temperatures around 800°C are essential. Sample test welds are advisable.

Maraging steels With carbon contents around 0.03% these have a soft martensite matrix and are highly weldable with no risk of decarburization, distortion or cracking. They should be used where very high strength combined with weldability is required.

7.3.17.2 Welding of stainless steels

Welding is the normal method of fabricating stainless steel vessels. The heat-affected zones are raised to incipient fusion temperature but time at temperature varies with different welding processes. Argon arc and spot welding are most satisfactory in heating for minimum time; metal arc welding, inert-gas metal arc and submerged arc are less so in that order from this point of view.

The problems associated with welding stainless steels fall into two categories. The first, associated with carbide precipitation, includes 'Weld Decay' and 'Knife Line Attack' and affects mainly corrosion behaviour. The second includes those phenomena which may be assessed by means of the Schaeffler Diagram (see Figure 7.33).

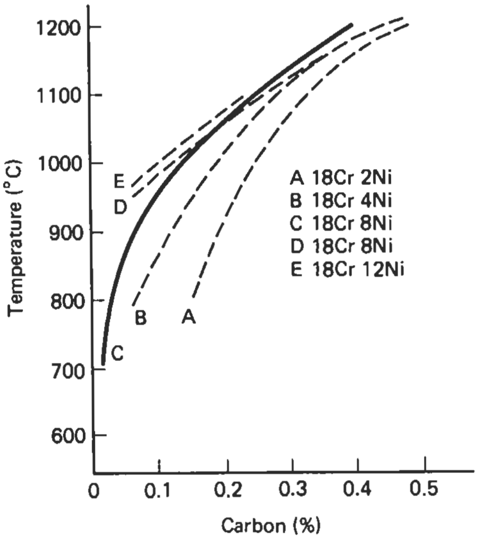

Figure 7.35 Variation of solubility of carbon in 18% chromium steels with temperature and nickel content

7.3.17.3 *Carbide solution and precipitation*

The solubility of chromium carbide in austenite decreases with decreasing temperature and increasing nickel content (Figure 7.35). At room temperature the solubility in 18% Cr 8% austenite (solid line) is approximately 0.03%. If an 18% Cr 8% Ni alloy containing, say, 0.06% C is annealed at 1050–1100°C all chromium carbide is in solution and remains in unstable solution after quenching to room temperature. If the alloy is heated to an intermediate temperature excess carbide is precipitated.

The mode of precipitation of carbide is dependent upon whether or not the austenite has been worked. If the quenched but unworked alloy is heated in the temperature range 450–750°C chromium carbide is precipitated at the grain boundaries; the lower the temperature, the longer the time required. Thus at around 450°C the time taken for precipitation can be about two years whereas at 700°C it is a matter of minutes.

Precipitation is effected by diffusion of carbon atoms to the grain boundaries where they each combine with approximately four times the number of chromium atoms. Diffusion of carbon is relatively fast at these temperatures but that of chromium extremely slow. Consequently, the chromium atoms are almost entirely supplied by the grain boundaries so that the grain boundary chromium content is substantially lowered. This local depletion of chromium causes loss of passivity in acid corrodants with consequent attack along grain boundaries.

7.3.17.4 *Weld decay*

The resultant 'Intergranular Penetration' in a casting or, if the heating has been caused by welding, 'Weld Decay' (see Figure 7.36) can completely disintegrate the material. Precipitation in cold-worked material takes place along slip planes as well as grain boundaries, consequently the distance that the chromium atoms must diffuse is small. Hence, although the same amount of chromium is removed as carbide, the depletion is more uniformly distributed with a consequential lowering of general corrosion resistance but a lower tendency to intergranular failure.

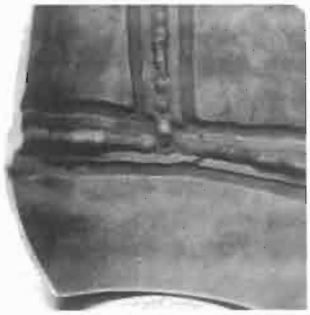

Figure 7.36 Example of 'weld decay' in an austenitic steel

There are two alternative approaches to the problem of preventing intergranular corrosion. Either the carbon content of the steel is limited, by using an AISI 'L' or BS 970 Code '11' steel, to 0.03% at which precipitation of carbide in sufficient quantity to cause trouble is impossible, or an element such as titanium or niobium, which has a stronger affinity for carbon than chromium, is added to form the appropriate carbide by using an AISI 'Nb' or 'Ti' or BS 970 Code '40' steel. The theoretical amounts required to ensure that all carbon in excess of 0.02% is combined are titanium = 4 × excess carbon, niobium = 8 × excess carbon. In practice, allowance must be made for nitrogen combining with the added element (particularly Ti) and for the efficiency of combination – carbon levels below 0.06% requiring a higher titanium or niobium to carbon ratio for complete combination than those above 0.08%.

7.3.17.5 *Knife-line attack*

Furthermore, when a stabilized (Ti or Nb treated) steel is heated to successively higher temperatures above 950°C up to 1250°C the carbide enters solution and is broken down into its constituent elements to an increasing extent so that above 1100°C a relatively small amount of carbon remains combined. The free carbon is then available to form chromium carbide on subsequent re-heating in the 450–750°C range. Combination of carbon with titanium occurs in the 850–950°C range given adequate time. The whole question of stabilization is concerned with time, temperature and amount of free carbon.

Time at temperature affects the extent of re-solution of the titanium and niobium carbides present in stabilized steels; titanium carbide dissolves more rapidly than niobium carbide. Re-solution takes place at temperatures in excess of approximately 1200°C under welding conditions. The extent depends on carbide particle size as well as time at temperature. If reheated within the sensitization temperature range (around 650°C) this narrow zone immediately adjacent to the weld metal precipitates intergranular chromium carbide, because combination of Ti or Nb with C cannot occur at this temperature.

Thus, although the stabilized steels will not precipitate chromium carbide in the region of the heat-affected zone raised to 650°C by welding, there is the possibility, in conditions where the edge of the weld metal is reheated to 650°C, that intergranular attack can occur. The existence of such conditions depends on the welding practice but in most fabricated articles, as distinct from samples with single-run

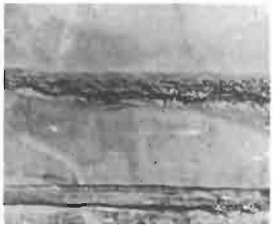

Figure 7.37 Example of 'knife-line' attack on stainless steel weld

welds, positions must arise at weld junctions where these conditions will obtain; welded samples should therefore always have crossed welds.

This particular type of intergranular attack at the weld metal edges is known as 'knife-line' attack (see Figure 7.37). It is most likely to be seen in boiling dilute nitric acid solutions. The composition of the steel affects its incidence; steels with lower nickel-to-chromium ratio, which produce a greater amount of delta ferrite in the knife-line zone, are less susceptible. Fully austenitic Ti stabilized grades appear to be more susceptible than fully austenitic Nb stabilized.

Where corrosion conditions are known to offer a knife-line hazard, treatment of the fabrication at 870°C will promote precipitation of the carbon as titanium of niobium carbide with consequent resistance to attack. The unstabilized 431 and 434 grades are susceptible to intergranular attack after welding. This can be prevented by heat treating for 2 hours at 600–800°C which coalesces the carbide films.

7.3.17.6 Weld problems which may be assessed by means of the Schaeffler Diagram

Fully austenitic weld metal tends to crack on solidification because of inherent weaknesses at the boundaries of columnar grains. The composition of the filler metal is therefore adjusted to ensure that all the molten zone contains a small proportion of ferrite (that is, it lies on the A + F side of the A/A + F line in Figure 7.33) and also to ensure that its strength is not excessive compared with the parent metal.

As long as the weld metal composition is maintained within the zone in which ferrite and austenite co-exist austenitic steels have excellent weldability. Ferritic stainless steels are weldable but suffer from the brittleness and grain growth problems described in Section 7.3.12. Martensitic stainless steels suffer from the same brittleness problems as carbon and quenched and tempered steels unless the carbon content is below 0.12%.

Both precipitation hardening and duplex stainless steels (the compositions of which can be roughly estimated from Figure 7.28) are fully weldable without preheat, and the precipitation-hardening steels may be hardened by precipitation after welding. Brief summary notes on corrosion and welding aspects of stainless steels are given in Table 7.12. This is also referred to in Section 7.9 where for the convenience of the reader some of the figures in Sections 7.3.13 and 7.3.17 have been repeated.

7.3.18 Tool steels

The name tool steels (BS 4659: 1971 and AISI/SAE 'Tool Steels') covers a wide variety of steels used for forming and cutting materials which have as essential properties high hardness, resistance to wear and abrasion and adequate toughness. There are (or have been) some 82 AISI standard steels, 25 BS steels and many non-standard steels, but it should be possible to meet almost all requirements from the nine steels listed here.

Carbon steels are used for hand tools and other applications where high levels of toughness are required and where some distortion in heat treatment can be tolerated. Recommended steels are:

AISI 109; BS 4659 BW1A; 0.9%C steel with good combination of hardness and toughness, good general-purpose steel
AISI 210; BS 4659, BW2; 1%C, 0.25%V. Retains a sharp edge and withstands shock better than BW1A.

A carbon tool steel should be quenched in water or brine and tempered as soon as its temperature has been quenched to 'hand warm'. Carbon tool steels will soften and lose their edge if appreciable heat is generated by the cutting action.

Table 7.12 Corrosion resistance and weldability of stainless steels

AISI No.	*Nominal composition*					*Corrosion notes*
	C	*Cr*	*Ni*	*Mo*	*Other*	
410	0.08–0.4	12–14	—	—	—	Rust resisting. Higher-carbon grades for engineering applications, turbine blades, cutlery, etc.
465	0.08 max.	13	—	—	Al	Weldable grade.
430	0.1 max.	16.5	—	—	—	Resists mild acids. Special feature is resistance to nitric acid. May require heat treatment after welding (600–800°C) to avoid intergranular attack. Forming of sheets up to 3 mm at room temperature; greater thickness at 200–350°C.
430Ti	0.1 max.	17.5	—	—	Ti	Weldable grade not requiring heat treatment. Argon arc (gives minimum grain growth) preferred. Both grades, if welded, should not be applied under conditions of shock loading or vibration.
304	0.08 max.	18	10	—	—	Rust and acid resistant. Suitable for welding in certain applications.
304L	0.03 max.	18	10	—	—	Extra low carbon. Very resistant to intergranular corrosion. Weldable for practically all applications.
309Cb 321	0.1 max.	18	10.5	—	Nb or Ti	Not susceptible to intergranular attack (but see reference to knife-line attack in text). Applicable above 300°C. Weldable.
316	0.07 max.	17.5	11	2.2	—	Resistance to chemical attack better than 18/8 (e.g. severe acid attack). Resists intergranular attack up to 6 mm thickness. Applicable below 300°C. Weldable for most applications.
316L	0.03 max.	17.5	11	2.2	—	Superior resistance to intergranular corrosion, suitable for thicknesses greater than 6 mm.
316Cb 316Ti	0.1 max.	17.5	11.5	2.2	Nb or Ti	Not susceptible to intergranular attack (but see knife-line attack). Applicable above 300°C. Suitable for strong acids at elevated temperatures. Weldable.
317	0.07 max.	17.5	12	2.8	—	Resists intergranular attack up to 6 mm thickness. Applicable below 300°C. Corrosion resistance superior to 2% Mo alloys. Weldable for most applications.
317Cb 317Ti	0.1 max	17.5	12.5	2.8	Nb or Ti	For strong acids at high temperatures. Applicable above 300°C. Weldable.
317LM	0.03 max.	17	13.5	4.5	—	Resistance to strong organic acids at elevated temperatures. Increased resistance to pitting. Applicable below 300°C. Resists intergranular attack. Weldable for most applications.

High-speed steels have a high content of carbide forming elements W, V and Cr and therefore retain their hardness at high temperatures (i.e. they have good 'red hardness'). Recommended steels are:

AISI M2; BS 4659 BM2 for normal duty;
AISI T4; BS 4659 BT4 for faster cutting and increased output;
AISI M42; BS 4659 BM42 for cutting hard materials.

'T' steels are tungsten steels and 'M' steels molybdenum steels which are cheaper but slightly more difficult to heat treat. Heating must be carried out in atmosphere-controlled furnaces to prevent decarburization; slowly to 825°C then quickly to the manufacturer's recommended temperature around 1300°C, followed by quenching in air blast, oil or salt bath at 525°C and air cooling. After an optional refrigeration treatment the steel must be tempered (secondary hardened) two or three times at about 545°C, again in controlled atmosphere.

For many purposes high-speed steels are being replaced by sintered carbides or ceramics such as sialons (see Section 7.5) which have exceptional wear and heat resistance even though they may not be as tough as high-speed steels.

Hot-work steels are used for forming (not cutting) hot materials. They must not soften at temperature and must have good wear resistance. They must also be able to resist thermal fatigue when heated and cooled (sometimes by water jets). Their metallurgy is similar to that of high-speed steels. Recommended steel is:

AISI H13; BS 4659 BH13. This steel has the highest and deepest hardness of the hot work steels.

Cold-work steels are used for forming cold materials and resistance to abrasive wear is of highest importance. In addition, they may have to be machined to very complex shapes and must therefore have very high dimensional stability during heat treatment.

Recommended steels are:

AISI 01; BS 4659 B01; 0.95CW,W.V. Steel for light duties, simple to heat treat.
AISI D2; BS 4659 BD2; 1.5C, 12Cr, MoV. Martensitic stainless steel with very high hardness and wear resistance for general application.

Shock-resisting steels are used for tools which are subject to heavy vibration or hammering; they must be hard but also have reasonable toughness to avoid failure by brittle fracture. Recommended steel is:

AISI, S1, BS 4659 BS1; 0.5C SiMnCrW. Metallurgy is relatively uncomplicated and heat treatment straightforward.

7.3.19 Steels for springs

There are three different types of spring steel. 'Patented' and cold-drawn carbon steel wire is used for small coil springs. 'Patenting' consists of heating the billet to roughly 1000°C to develop a coarse grain size so that after slow cooling the steel has a coarse pearlite/bainite structure which is readily drawn into wire.

The steels used and the properties of the wire are covered by BS 5216 and ASTM A227 and 228 specifications. They have carbon contents varying between:

- 0.65% for 'Hard drawn spring wire' which has the largest diameter (up to 9 mm), the poorest surface finish and the lowest tensile strength (less than 940 MPa); and
- 0.85% for 'Piano or Music wire', which has the smallest diameter (0.1 mm minimum), the best surface finish and the highest tensile strength (up to 3780 MPa).

Many ranges of tensile strength are available. Springs are cold coiled from the wire. Carbon and alloy spring steels are made to specifications in BS 970: Part 5.1972 and corresponding AISI/SAE grades.

Coil springs are usually made from hot-rolled and ground bar of the diameter required for the final spring. The bar is heated to a temperature within the hardening temperature range, coiled on a mandrel, slipped off the mandrel, quenched and tempered to a tensile strength around 1650 MPa. Carbon steels are used for springs up to 13 mm diameter, more highly alloyed steels for higher diameters, the maximum around 80 mm diameter being made from BS 925 A60 SiMnMo steel.

The purchase specification must strictly limit decarburization of the surface (to which silico manganese steel, which is popular for springs, is particularly prone) because fatigue cracking, which will propagate across the spring, may start in a soft decarburized surface layer. The surfaces of all but the smallest springs are conditioned by shot peening which induces a compressive surface stress and increases fatigue strength by 25–30%. 'Scragging', which overloads the spring in the direction it will be used in service, produces residual stresses which oppose service stresses in the surface layers and therefore improves endurance.

Rust is harmful to spring performance and, to prevent it, a spring should be protected immediately after peening.

Corrosion-resistant steel springs are covered by an old British Standard (BS 2056: 1953) which uses the EN designations. In practice, stainless steel wire for springs is usually supplied to AISI number.

Martensitic steels are usually supplied softened and lightly cold drawn to a UTS between 620 and 850 MPa. They are hardened and tempered after forming. Austenitic steels are cold drawn to UTS between 1800 and 2000 MPa for diameters below 2 mm and 1000 MPa for diameters up to 10 mm. One precipitation-hardening stainless steel DTD5086 can be supplied for forming in the softened condition and can then be precipitation hardened to 1800 MPa.

7.3.20 Cast steel

All the types of steel described earlier in this section can, in principle, be produced as castings. In practice, the steel grades listed in BS and the several US standards authorities are confined to a limited number of types given in Table 7.13. This includes:

- BS specifications
- ASTM grades for carbon steels and for steels with alloy content up to 8% and UTS between 482 and 827 MPa
- ACI (Alloy Castings Institute of the USA) grades for Heat Resistant and Corrosion Resistant Steel Castings.

While each grade in a Steel Castings Specification is the equivalent of a grade in BS 970 or SAE/AISI they differ in important aspects. For example, a foundry is less likely to be equipped for carbon vacuum deoxidation than is a large steelworks. To allow for this, the silicon content of steel castings is usually set at a higher level than for the corresponding wrought steel and the very low carbon grades are not included. This may require the content of other alloying additions to be adjusted. Also, an austenitic steel casting often contains more ferrite than the corresponding wrought steel to prevent fissuring during solidification (both in casting and welding) and to resist intergranular penetration. A designer is advised therefore when ordering a casting to specify the BS 1504, BS 3100 or ACI grade rather than the BS 970 or AISI grade number for the corresponding wrought steel.

If a compelling reason exists for specifying a steel not listed in a standard casting specification the casting will almost

Table 7.13 Standards for steel castings

Most grades are covered by ASTM A743 and A744.

[a] US alloying practice does not correspond with British, so ASTM designations do not correspond exactly with BS. Other ASTM specifications include: A567, A128, A487, A216, A217, A757, A352, and A747.

[b] The figures indicate carbon content.

certainly be more expensive because the foundry may have to make experimental castings and will not be able to recycle scrap directly. Also, it may be more difficult to obtain a guarantee of quality.

Design of castings is too complex a subject for detailed consideration here. The essential criterion is to make absolutely sure that nowhere within the casting exists a point where, through a local increase in section, metal is left to solidify surrounded by metal that has already solidified. Walls should be of as uniform thickness as possible, corners radiused, multiple junctions eliminated, changes of section tapered and where large sections are inevitable they should be so placed that they solidify progressively towards a feeding head. Where isolated large increases in section are unavoidable chills may be used. (See *The ASM Metals Handbook*, 1961 edition, pp. 122–146.)

In principle, the properties of a casting should be identical to those of a forging of the similar composition, and in practice castings are available with UTS to match any forgings up to 827 MPa UTS and corresponding yield strengths are available. There are, however, significant differences in the cast and wrought structure, particularly in alloys with more than one phase present.

Castings have a 'cast structure' which is effectively a skeleton of intermetallics that tend to limit and restrict slip. In a correctly worked wrought alloy this skeleton is broken up so that it becomes effectively a dispersion of fine particles rather than a network. Working refines the grain and renders the alloy more susceptible to heat treatment, and has two effects which are significant in design. Ductility is increased and creep strength decreased.

The reduction in ductility of castings compared with wrought steel has a negligible effect on design with steels with UTS around 500 MPa. However, with strengths of 800 MPa and above, the fracture toughness of cast material is lower and more variable and the fatigue endurance limit about 20% lower than that of wrought material. In addition, the continuous-casting process for manufacturing ingots from which wrought material is forged has much superior feeding and segregation characteristics than is possible in a large sand casting so that the material is inherently superior. Furthermore, forging, correctly programmed, can be made to align the grain (and any discontinuities) in the principal stress direction and thus make the component more resistant both to brittle fracture and fatigue. On the other hand, the transverse properties of a casting should be superior, and thorough inspection will reduce or eliminate dangerous defects.

The improved creep resistance of the cast structure is of considerable value in the case of large turbine castings, while the creep properties of the small lost wax castings (listed in BS 3146) could not be obtained in forgings. Even higher creep properties could be obtained by directional solidification but this is used for the more highly creep-resistant nickel alloys rather than steels.

7.3.21 Cast iron: general

Cast iron is an alloy of iron with carbon in the range between 1.7% (the eutectic composition) and 4.5%. There are two basic types, one of which is a composite of steel and graphite while the other, white cast iron, consists of cementite in a matrix of steel.

White Cast Iron, Low Alloy White Cast Iron, Martensitic White Cast Iron and High-Chromium White Cast Iron have special wear and environmental resistant properties. The graphite-containing cast irons which include the Flake Graphite, Nodular Graphite and Malleable grades have been regarded as a cheap and brittle substitute for other engineering materials, but have in addition to their relatively low cost very definite technological advantages. These are particularly evident in the case of the newly developed Austempered Ductile Irons.

The several grades of cast iron, with the permission of BCIRA, are given according to BS specification in Table 7.14, which lists all (with the possible exception of damping capacity) relevant physical and mechanical properties.

7.3.22 Grey cast iron

Grey cast iron (Flake Graphite Iron) can be 'non-alloyed', 'low alloy' or acicular. Design stresses etc. given in Table 7.14 (BS 1452 and ASTM A48 Class 20–60) are for non-alloyed grey cast iron with carbon contents varying from 3.65% to 2.7%, silicon from 2.5% to 1.35%, phosphorus from 0.5% to 0.09% and manganese around 0.6%.

This is the cheapest engineering metal, not only because the raw materials – pig iron, cast iron and steel scrap, limestone, coke and air – are all relatively inexpensive but also because melting costs in a cupola are relatively low. Casting is very easy because cast iron is more fluid, has a narrower solidification range and a lower in-mould shrinkage than steel. Machinability is excellent because graphite acts as both a chip breaker and a tool lubricant.

Grey cast iron has good dry-bearing qualities and its freedom from scuffing makes it a good material for automobile cylinder walls. Its wear resistance is assisted by slight chilling and a hard network of phosphide eutectic. It has also excellent damping capacity, particularly in the lower (higher-carbon) grades and is particularly suitable for machine-tool bases and frames. On the other hand, it is brittle because the graphite flakes reduce strength, the maximum recommended tensile design stress is only 25% and the fatigue loading limit between 11% and 16% of the tensile strength. (It should be remembered that tensile stress is measured by bend – see Section 7.1.)

There are (or were) two variants with better fatigue properties. Compacted graphite iron or meehanite is made by inoculating an iron which would otherwise solidify white.

Haematite high-carbon low-phosphorus iron was originally made from haematite pig iron. Its low phosphorus content improves its fatigue properties (while reducing fluidity).

Low-alloy and Acicular Cast Irons made by adding Ni, Cu, Cr, Mo, V or Sn (and in the case of acicular cast iron reducing the phosphorus content) enable grey cast iron to be used in higher-duty applications without redesign or technological change.

7.3.23 Nodular graphite ('SG') iron

Nodular or spheroidal graphite, 'SG' cast irons are available in grades corresponding to those of grey cast iron but are produced by inoculation of the melt with nickel, magnesium and caesium compounds which change the form of the graphite to near-spheroidal nodules (see Figure 7.38). This produces material which has strength, ductility and thermal shock resistance more typical of steel but castability, damping capacity and machinability more typical of cast iron.

The recommended, design, tensile and fatigue stresses are a much higher proportion of the UTS than is the case with cast iron. Steel castings, fabrications and sometimes forgings may be replaced with considerable economic advantages. Matrix structures can be varied by changing cooling rate or alloying, between ferrite, pearlitic carbide and acicular structures for higher-duty applications.

The development of nodular and other higher-duty irons detailed here has accelerated the trend to modern melting

practice. Casting from a cupola is not amenable to the precise composition control which is possible with an electric or gas furnace. Even where a cupola is used for the actual melting, final control of composition requires a holding furnace.

7.3.23.1 Austempered ductile iron

Austempered ductile iron is SG iron with added alloying elements, (usually Mo, Ni and/or Cu) sufficient for a bainitic structure, usually with retained austenite, to be produced in the section size by austempering. Such material can have yield strength and UTS up to 1150 and 1400 MPa with elongations of 6% and fatigue limit up to 33% of the UTS. Wear resistance because of the graphite and retained austenite is superior to steel of the same hardness and components such as gears are quieter in operation. The potential of austempered ductile iron, which is substantially cheaper than forged steel and can be cast closer to shape than steel is usually forged, exceeds that of any other recently developed material.

Obtaining the required properties requires dedication to process control in foundries and heat-treatment departments. The most economically rewarding application for austempered ductile iron is as a material for gears which can be made quieter, lighter and cheaper than the equivalent steel gears. One disadvantage, for the highest-rated gears, is the lower fatigue strength of austempered ductile iron compared with that of steel, but this is being overcome by shot peening the teeth of the gears. Austempered ductile iron has been used successfully for tracks for off-the-road vehicles, pump bodies, agricultural equipment, friction blocks and drive shafts.

7.3.24 Malleable iron

Malleable iron is cast with a white cementite structure which is converted to a steel–graphite composite by annealing. The requirement for the as-cast structure to be graphite-free limits the maximum section to about 38 mm and the general run of castings weigh under 5 kg and have a maximum section of 25 mm. There are three varieties:

1. Whiteheart Malleable has a carbon content of about 3.5% which improves castability compared with the other varieties. Other alloying elements are Si 0.6%, Mn 0.25%, $S < 0.3$, $P < 0.1$. It is heat treated for 5–6 days at 875°C packed in an oxidizing medium to produce spidery graphite aggregates in a pearlite/ferrite matrix. This long heat treatment increases cost, limits rate of production and decarburizes the surface layer.
2. Blackheat Malleable has compositions varying between C 2–2.65%, Si 0.9–1.65%, Mn 0.25–0.55%, $S < 0.05$–0.18 and $P < 0.18$. It is heat treated in a neutral atmosphere for 40–60 hours at 860°C, cooled to 690°C, held for 4–5°C per hour and air cooled. It has graphite aggregates in a ferrite matrix (no decarburization) and, although not so easy to cast as whiteheart has rather better properties and the best combination of machinability and strength of any ferrous material. There are two ASTM A47 grades, 32510 and 35018 and one A197 'Cupola' grade of lower quality.
3. Pearlitic Malleable has usually a higher manganese content, varying from 0.25% to 1.25% and may be cooled rapidly after annealing. It has higher strength than the other malleables and, unlike them, has good wear resistance and is difficult to weld.

Because of their low cost and excellent shock resistance the malleable irons have been used extensively in the power train, frame, suspension and wheels of motor vehicles, rail, agricultural and electrical equipment but the market for them has contracted except for galvanized pipe fittings.

7.3.25 Austenitic cast irons

Austenitic cast irons have an austenitic matrix containing either flake or nodular graphite. They are non-magnetic, have thermal expansion coefficients similar to low-expansion aluminium alloys (with which they can be used as wear- and thermal fatigue-resistant inserts for pistons) and are available in a wide range of grades including:

- Ni-resist 14–32% Ni, 20% Cr for resistance to medium concentration acids and
- Nirosilal; Ni + Si for resistance to high-temperature oxidation and growth up to 950°C.

High-nickel nodular irons have excellent ductility and are suitable for cryogenic applications.

7.3.26 High-silicon cast irons

High-silicon cast irons, composition 10–17% Si, Mo $< 3.5\%$, have a silico ferritic solid solution matrix with dispersed graphite, exceptional corrosion resistance to mineral-oxidizing acids and, although extremely brittle, are used as pipes, stills and vats where strength is not needed. The 4% Si, 0.5% Mo grade has good resistance to oxidation and acids and better strength than the high-silicon grades.

7.3.27 White cast iron (abrasion-resisting white iron)

There are four types of White Cast Iron; unalloyed, low-alloy, martensitic and high-chromium.

Unalloyed White Cast Iron has a reduced content of silicon so that on fairly rapid cooling after casting no graphite is formed and the carbon is in the form of cementite or pearlite. Chill in white cast iron is increased by raising the content of carbon and manganese but reduced by increasing sulphur and phosphorus.

White irons with carbon content above 3.5% can have Brinell hardness of up to 600. However increased carbon decreases transverse breaking strength and causes brittleness. Low-alloy white irons have added elements (usually Cr and Ni) that increase chill and improve toughness and wear resistance (but are insufficient to produce a martensitic structure).

Martensitic white cast iron (e.g. Nihard) has sufficient alloying elements (usually Cr and Ni) to produce a cementite/martensite structure with higher hardness (up to 90 schleroscope) and toughness than other cast irons and is also stable at temperatures up to 550°C. Martensitic white cast iron should preferably be stress relieved.

The white cast irons can be machined only with difficulty using carbide tools and should be cast as nearly to size as possible. They have higher solidification shrinkage than other cast irons and require careful running and feeding. They are used for grinding and ore crushing equipment, mill liners, tables, rollers and balls and other applications requiring wear resistance.

The selection of the correct wear-resistant material for any application depends on relative life and relative cost. Martensitic white irons cost more than low-alloy which cost more than unalloyed, but, depending on the application, the life in wear of the most expensive material may be between 50% and 400% longer than the cheapest. Also, the more ductile, more expensive material should be less prone to fracture, but this may depend more on the events in the mill or on the technique of the supplying foundry. It is advisable to carry out comparative trials on different materials including, where appropriate, forged martensitic steel and deposited carbides and to standardize on that material which proves to be most economical for the specific application.

7.3.28 High-chromium iron

Irons of chromium content 15–35% have a partially austenitic structure with higher toughness and strength than Ni-based and high corrosion and oxidation resistance. They have a higher resistance to strong acids than silicon cast irons and can be used for heat-treatment equipment, melting pots for lead, zinc and aluminium, other parts exposed to corrosion at high temperature and for wet-grinding operations.

7.4 Non-ferrous metals

7.4.1 Copper and its alloys

7.4.1.1 General

Copper is basically more expensive than iron but has important advantages for special applications, the most significant of which is conduction.[20] Its electrical conductivity when pure is superior on a volume basis to all metals other than silver, and on a weight (and specific cost) basis to all metals other than aluminium. The same relationships apply to its thermal conductivity. Both properties are reduced by alloying, but the conductivities of copper alloys are superior to those of steels.

Copper's second most important characteristic is its resistance to natural environments. Where iron rusts, copper remains bright or develops an attractive patina, and this characteristic is improved by appropriate alloying. In marine environments the toxicity of copper prevents fouling. There is, however, a temperature limitation on the use of copper alloys compared with steels.

Copper and a high proportion of its alloys are highly ductile so that they are eminently suited to forming operations. Some, particularly the leaded brasses, are also highly machinable so that the finished cost of a brass component may well be competitive with that of any other material when allowance is made for the value and easy recovery of scrap.

The mechanical properties of copper, tensile and fatigue strength and creep resistance can be improved by alloying, without, however, achieving the strengths of steels or approaching the specific strengths of the light metals. The good mechanical properties are retained at cryogenic temperatures but are inferior to steels at elevated temperatures.[21,22] Other properties also benefit from alloying. The influence of specific additions is indicated in Table 7.15.

Copper alloys are by no means the easiest to cast or weld and their toxicity, although having useful biocidal applications, prohibits contact with foodstuffs. They are divided into classes, the main classes having traditional names. The main classifications together with their BS designations are listed in Table 7.16. The British Standards for product forms are given in Table 7.17 and the material condition codes in Table 7.18.

7.4.1.2 Copper

'Copper' is an alloy of copper and oxygen. The oxygen content of the conductivity grades is not such as to affect their electrical conductivity, but unless an 'Oxygen-Free' grade is used, would cause problems in welding[23] and also when heated in a reducing atmosphere. Non-conductivity grades are deoxi-

Table 7.15 Influence on copper of alloying additions

Improved property	*Alloying addition*
Strength	Aluminium, beryllium, chromium, zirconium, zinc, tin, phosphorus, silicon, nickel, manganese, iron
Corrosion resistance	Nickel, aluminium, silicon, tin, arsenic, manganese, iron
Wear resistance	Tin, cadmium, silicon, aluminium, silver
Bearing properties	Lead
Colour	Zinc, tin, nickel
Cost	Zinc
Machinability	Lead, tellurium, sulphur, zinc
Castability	Zinc
Resistance to annealing (conductivity not impaired)	Silver

dized, usually with phosphorus which reduces electrical conductivity.

The suitability of copper for electrical conductors depends on its high conductivity combined with a high resistance to atmospheric corrosion and ease of drawing and fabrication. Material for conductors should be selected from grades C100–104 or 110, all of which have electrical conductivities of at least 101 IACS annealed, 97 IACS cold drawn (100 IACS = 0.019 $\mu\Omega$m). If the conductor is to be heated in a reducing atmosphere the oxygen-free grade C103 should be used. The high-conductivity grades have UTS 385 and proof stress 325 MPa hard and 220 and 60 MPa annealed.

Additions of silver between 0.02% and 0.14% improve creep strength and resistance to annealing without impairing conductivity and should be used for rotating machinery or where a component must be heated during manufacture.

For general engineering and building operations where conductivity is not significant any of the grades C101–107 may be used. Arsenical grades have slightly better strength at high temperature, phosphorus deoxidized grades are better to braze or weld.

7.4.1.3 High-conductivity copper alloys

There are a number of alloys containing a high percentage of copper which balance the minimum possible reduction in conductivity against some other desirable property, machinability (C109, 110) strength (CB101) wear resistance (C108) or strength at high temperature (CC101, 102). Strengths range from 495 to 1346 MPa and conductivities from 90 to 20 IACS. Several of these alloys are available in cast form.

7.4.1.4 Brass

The range of composition of copper–zinc alloys is illustrated in Figure 7.39. There are two classes, α brasses containing between 24% and 37% zinc and duplex brasses with 40–47% zinc.

All brasses can be hot worked; α brasses are readily cold worked and cast but duplex brasses are significantly more workable at elevated temperatures and can be extruded and forged into complex sections and shapes. This formability has the result that brasses are available in a very wide range of shapes. They are intrinsically easy to machine and machinability is improved even more by the addition of low percentage of lead. Brasses have a very useful strength range (330–810 MPa), are resistant to atmospheric and natural water corrosion and the incorporation of zinc lowers their cost appreciably compared with copper.[23]

The most suitable alloy for high-speed machining is the leaded CZ1214 PB and for hot stamping CZ122. These alloys

Table 7.16 Classes of copper alloy

Common name	*Description*	*British Standard Wrought*	*British Standard and ASTM Cast*	*ASTM designation Wrought*
Copper	Alloy of copper and oxygen. Sometimes accompanied by deoxidant. Sometimes contains silver	C100–107, 110	HCC1 (BS 4577 A1/1)	OF ETP OLP
High-conductivity copper alloy	Alloy of copper with additions which improve strength at a minimum loss in conductivity	C108, 110, 111–113 CB101, CC101/2	A2/1–4/2

BS 2870	B248	Copper and copper alloys – sheet, strip and foil
BS 2871	B251	Copper and copper alloys – tubes (3 Parts)
BS 2872	B124	Copper and copper alloys – forging stock and forgings
BS 2873	B250	Copper and copper alloys – wire
BS 2874	B249	Copper and copper alloys – rods and sections (other than forging stock)
BS 2875	B248	Copper and copper alloys – plate
BS 1432		Copper for electrical purposes – strip with drawn or rolled edges
BS 1433		Copper for electrical purposes – rod and bar
BS 1434		Copper for electrical purposes – commutator bars
BS 1977		High-conductivity copper tubes for electrical purposes
BS 4109		Wire for general electrical purposes and for insulated cables and flexible cords
BS 4608		Copper for electrical purposes – rolled sheet, strip and foil

[a] These are a selection of ASTM standards, many of which refer to particular material applications.

Table 7.18 Material condition coding for copper alloys

0	Annealed
$\frac{1}{4}$H, $\frac{1}{2}$H, H, EH	Harder tempers produced by cold working (or part annealing)
SH, ESH	'Spring hard' tempers produced by cold rolling thin material
M	'As manufactured'
W	Solution treated. Will precipitation harden
W($\frac{1}{4}$H), W($\frac{1}{2}$H), W(H)	Material solution treated and then cold worked to progressively harder tempers
WP	Solution and precipitation treated
W($\frac{1}{4}$H)P, W($\frac{1}{2}$H)P, W(H)P	Material solution treated, cold worked to progressively harder tempers and then precipitation treated

have ultimate tensile strengths of 450 MPa and they are, because of their high zinc content, the least expensive of the wrought brasses.

Where a higher tensile strength is required there are a number of high-tensile brasses, with additions which include aluminium, iron, manganese and silicon. The wrought alloys CZ114–116 and 135 have tensile strengths between 430 and 770 MPa, the cast alloys between 470 and 810 MPa. Corrosion resistance may be improved by adding tin, aluminium, arsenic and nickel.

Two important considerations must be observed when introducing brass components into service in aqueous environments:

1. In some potable, marine or industrial waters containing sulphur compounds many brasses, particularly duplex, are prone to 'dezincification' – the preferential dissolution of zinc leaving a weak copper sponge. This can usually be prevented by choosing an alpha brass inhibited with arsenic, and recently a duplex alloy CZ132 has been developed which, when correctly heat treated, is claimed to resist potable waters (see 'dezincification-resistant brass, Figure 7.39(a)).
2. Stress corrosion may be caused by ammonia derived from organic refuse, by chlorine or by mercury. Brass which may be exposed to these environments should be given a stress-relief heat treatment.

Where there is a possibility that either of these phenomena will occur, trials should be made of the behaviour of the brass in the chosen environment. Alternatively, a bronze or aluminium bronze (but *not* manganese bronze) should be used.

7.4.1.5 Bronze and gunmetal

Brasses all contain zinc but the parallel does not apply to bronzes, which traditionally are copper–tin alloys. 'Aluminium Bronze', 'Silicon Bronze' and 'Lead Bronze' contain no tin and 'Manganese Bronze' is a brass.

The true wrought bronzes contain up to 8% tin and are deoxidized with phosphorus. They have a single-phase solid solution structure at the annealing temperature but the solubility of tin falls with decreasing temperature (see Figure 7.39(b)). Cold working the resultant supersaturated solution gives them excellent elastic properties to which, coupled with a high resistance to corrosion, they owe the majority of their applications.

The phosphor bronze most generally used is PB102 containing 5% tin but higher and lower tin contents with UTS ranging between 590 and 680 MPa hard and 320 and 380 MPa annealed are available. They are used for springs, instrument components and bearings.

Cast phosphor bronzes PB1, 2 and 4 contain 10% tin, more than the wrought alloys and are also used for bearings with hardened steel where load-carrying capacity at low speed is required. Gunmetals (single-phase alloys of copper, tin and zinc) G1, also with lead LG1, 2 and 4, which combine modest strength (UTS ranging between 180 and 440 MPa) with good corrosion resistance are more widely used because of their better castability. Applications include pumps, valves, bearings and statuary.

Also used for bearings are the leaded bronzes LB1–LB5 which have better plasticity and are particularly suitable for mating with soft-steel journals which would be scored by

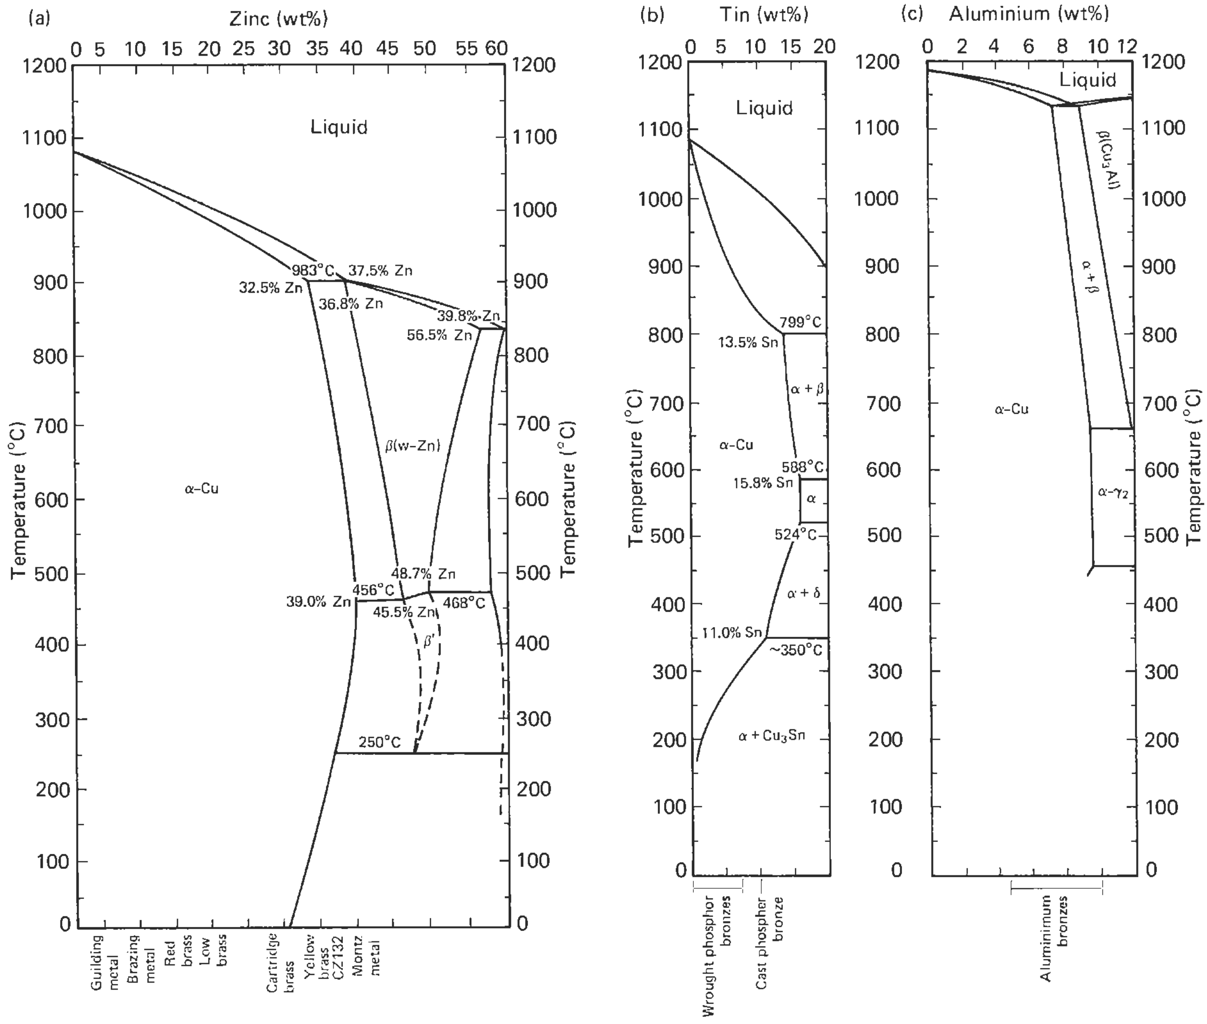

Figure 7.39 Partial phase diagrams. (a) The copper–zinc alloys; (b) The copper–tin alloys; (c) The copper–aluminium alloys

harder materials. The addition of lead (which does not dissolve in solid or liquid copper but forms a composite) confers machinability and very considerably improves bearing characteristics.

7.4.1.6 Aluminium bronze

Aluminium bronzes CA102 and 104–7 and AB1–3 contain between 6% and 10% aluminium together with iron, nickel or silicon (see Figure 7.39(c)). They all have excellent corrosion-resistant properties, due basically to the combination of the electrochemical properties of copper with the tenacious oxide film of aluminium, and good mechanical properties (ultimate tensile strengths ranging from 430 to 820 MPa wrought and from 460 to 700 MPa cast).

Aluminium bronzes can be used in a very wide range of environments including dilute acids with the exception of nitric. They are particularly suited to marine environments where, unlike most steels, they resist pitting and crevice corrosion and because of the biocidal nature of copper are not subject to biodeterioration. The alloys with higher aluminium contents (see Figure 7.39(c)) have a duplex structure of α solid solution and β Cu_3Al and develop high strengths when worked.

Although aluminium bronzes have quite good wear resistance they should not be used in applications which involve relative movement in contact with other metals because the oxide film causes galling, fretting and seizure. This restriction apart, aluminium bronze has a very high potential as an engineering material which has yet to be realized fully.

7.4.1.7 Silicon bronze

There is one silicon bronze CS101 (CuSi3Mn) used mainly as wire for marine fasteners.

7.4.1.8 Copper–nickel alloys

The copper–nickel alloys CN101, 2, 4, 5 and 7 wrought and CN1 and 2 cast have even better corrosion resistance than the aluminium bronzes. They have moderate strengths, UTS ranging from 300 to 390 MPa annealed and from 360 to 650 MPa hard. They may be used with confidence in the most severe conditions of marine pollution and corrosion. However, no copper alloy is completely resistant to corrosion/erosion. Where, as is the case with those marine condenser tubing installations from which sand or silt cannot be excluded, corrosion erosion is the principal cause of failure, titanium or a pitting-resistant stainless steel performs better.

7.4.1.9 Nickel–silvers

Nickel–silvers NS102–6 are copper alloys with 10–25% Ni and 18–28% Zn. They have good corrosion resistance and attractive colour and are available as strip and wire with proof stress between 600 and 620 MPa, which makes them very suitable for relay springs at ambient and moderately elevated temperatures. Leaded nickel–silvers NS1OI and NS111, which have improved machinability, are available also as bar.

7.4.1.10 Miscellaneous alloys

Copper alloys with between 20% and 45% lead are used for bearings whose loadings are too high for white metals. They were originally cast into a steel backing but are now usually made by powder metallurgy techniques to improve consistency and produce a more favourable structure.

Alloys of copper with manganese and aluminium or manganese and nickel can have very small temperature coefficients of electrical resistance. They are used in instruments and are usually supplied as annealed wire. Other copper manganese alloys have high damping capacities.

Typical compositions and mechanical properties of these alloys (which are not covered by British Standards) are listed in Table 7.19.

Alloys of copper with zinc 12–40% and aluminium 2–8% are capable of existing in two distinct configurations above and below a critical temperature which may be selected to lie between −100°C and +100°C. This 'Shape Memory' characteristic enables the manufacture of a component that will generate a force 200 times that which can be obtained from a bimetallic strip of similar size and is used for controlling temperature.

7.4.1.11 Selection of copper alloys

Choice of the alloy of copper that will most satisfactorily fulfil most appropriate engineering applications may be made by consulting Tables 7.20–7.23.

Table 7.19 Some miscellaneous copper alloys

(a) Copper–lead alloys for bearings (lead bronzes)

	Composition (wt %)					*Tensile strength* (MN/m^2)	
Type	*Cu*	*Pb*	*Sn*	*Ag*	*Others*		*Characteristics*
80/20 Cu–Pb	78	20	—	—	1.2–5 Ni	140	Bonded to steel shells for bearings. Alloys up to 45% lead are in use
74/24 Cu–Pb	74	24	2	—	—	140	Good conductivity
70/30 Cu–Pb	69	30	—	0.6	—	140	Withstands 'pounding'
60/40 Cu–Pb	59	40	—	1	—	—	Lead distribution improved by powder metallurgical processing
55/45 Cu–Pb	55	45	1			120	

(b) Copper–manganese alloys

	Composition (%)					*Tensile properties*		
Type	*Cu*	*Mn*	*Al*	*Ni*	*Condition*	*Strength* (MN/m^2)	*Elongation* (%)	*Characteristics*
Cu-Mn-Ni ('Manganin')	Balance	12	—	2–4	Drawn – Soft	420	30	High specific resistance alloys with low temperature coefficient of electrical resistance
Cu-Mn-Al	Balance	13	2	—	Drawn – Soft	430	30	
					– Hard	680	10	
General-purpose high-damping alloy ('Incramute')[a]	58	40	2	—	Hot and cold worked			High capacity for vibration damping and good corrosion resistance. Good casting and hot and cold forming properties, but difficult to machine. Costly
Marine high-damping alloy ('Sonoston')[b]	63.5	30	4	2.5	Cast			High capacity for vibration damping and good marine corrosion resistance. Casting requires skill. Poor machinability. Costly. High strength suitable for springs
	60	20	—	20	Heat treated

7.4.2 Aluminium and its alloys

7.4.2.1 General

Although aluminium has been used commercially for little more than a hundred years it has become, on a volume basis, the most widely used non-ferrous metal. It has the essential characteristic of high corrosion resistance in normal atmospheres and conditions and its cost per unit volume is usually lower than that of any other metal except steel.[24] One of the most important characteristics of pure aluminium is its high electrical conductivity, 61 IACS on a volume basis, but because of its low specific gravity, aluminium conductors are usually cheaper than copper conductors.

A most important point to consider in the selection of aluminium is the cyclic price variation. The supply of aluminium is inelastic because furnace capacity cannot be expanded quickly. While therefore aluminium components cost less than copper or magnesium components when supply exceeds demand, magnesium components and occasionally even copper conductors may become superior economically when aluminium is in short supply. In extreme cases a correct choice made when a component is designed may prove to be incorrect when it comes to be manufactured.

Aluminium is ductile and easily fabricated and, although its mechanical properties are not outstanding, the specific strength and modulus of its alloys are excelled only by titanium and magnesium among common engineering metals because of its low specific gravity (2.7).

The tensile properties of aluminium improve with reduction in temperature and, because it has a face-centred-cubic structure, it does not embrittle at cryogenic temperatures. It is therefore suitable for components for operation at cryogenic temperatures.

The casting and fabrication of aluminium are easy due to its low melting point and high ductility. Because of this, and because of its wide usage, aluminium is readily available in all wrought forms, shapes and finishes, and all varieties of castings. BS specifications covering aluminium alloys are listed in Table 7.24.

Most wrought alloys can be hardened by cold working and are available in a variety of tempers. Some alloys, both cast and wrought, are amenable to heat treatment by solution treatment and ageing. The several heat treatments and conditions are denoted by letter and number codes which are listed in Table 7.25. All except some heat-treated alloys are very easy to weld.

Aluminium is easily machined and, in spite of its ductility, capable of a good finish. It is non-sparking and non-magnetic.

Drawbacks are poor fatigue and elevated temperature properties. Aluminium has no endurance limit, the fatigue strength of the pure metal at 10^8 cycles is only about 60% of its tensile strength and this ratio is lower, the higher the tensile strength of the alloy.[25] Because of its low melting point, high-temperature capability is very limited and the tensile strength of wrought alloys falls very sharply above 220°C and that of cast alloys above 270°C.

Although corrosion resistance in normal atmospheres is good, aluminium is prone to galvanic corrosion when coupled to most engineering metals (except magnesium and zinc) and certain alloys in high heat-treatment conditions are prone to localized corrosion.

7.2.4.2 Wrought aluminium alloys (see Table 7.26)

All aluminium alloys are collectively known as 'aluminium'.[26] 'Pure aluminium' is an alloy of aluminium, iron and silicon derived from the reduction process, in contents varying according to grade up to 1% with minor quantities of other metals. 'Bright Trim' grades have slightly higher impurity contents and small additions of magnesium. In 'Super Pure' aluminium, which is double refined, the impurities Cu, Si and Fe total less than 0.01%.

The tensile strengths of the pure aluminium grades vary from about 55 MPa (temper designation 'O') annealed to about 160 MPa Strain Hardened Full Hard (temper designation 'H.8'). Increases in strength are obtained by alloy additions. Manganese and magnesium in amounts up to 1.25% Mn and 4.5% Mg increase the UTS up to about 300 MPa annealed and 375 strain hardened half-hard.

None of these alloys owes its tensile properties to heat treatment, and corrosion resistance is reduced only marginally compared with that of pure aluminium. All of the alloys are readily welded.

Table 7.24 British Standard specifications covering aluminium alloys

BS 1490:1970	*Aluminium and aluminium alloy ingots and castings*
	Applications
BS 1470:1985	Wrought aluminium and aluminium alloys for general engineering purposes – plate, sheet and strip
1471	Drawn tube
1472	Forging stock and forgings
1473	Rivet, bolt and screw stock
1474	Bars, extruded round tubes and sections
1475	Wire
BS 3087:1974	Anodic oxide coatings on wrought aluminium for external architectural applications
BS 1615:1972	Anodic oxidation coatings on aluminium
BS 5762:1979	Methods for crack opening displacement (COD) testing
BS 8118:1985	Code of practice for the design of aluminium structures

See also BS L series and DTD specifications for defence materials.

Table 7.25 Codes for aluminium product forms and conditions used by BS

Wrought material
Prefixes indicating product form

B = bolt and screw stock
C = clad
J = longitudinally welded tube
R = rivet stock
E = bars, extruded round tube and sections
F = forging stock and forgings
G = wire
S = plate, sheet and strip
T = drawn tube

Suffixes indicating condition

F = as fabricated
O = annealed
H = strain hardened (i.e. strengthened by cold working – not heat-treatable materials)
H2 = approximately equivalent to previous BS designation 1/4H
H6 = approximately equivalent to 1/2H
H8 = approximately equivalent to 3/4H

Heat treatable:

T4 = solution treated and naturally aged (formerly TB or W)
T3 = solution treated, cold worked and naturally aged (formerly TD or WD)
T5 = precipitation treated (formerly P or TE)
T8 = solution treated, cold worked and precipitation treated (formerly TH or WDP)
T6 = solution treated and precipitation treated (formerly TF or WP)

A special suffix E indicates an electrical grade of material.

Cast material
Code indicating heat treatment

M = as cast
TB = solution heat treated and naturally aged (formerly W)
TB7 = solution heat treated and stabilized (W special)
TE = precipitation treated (P)
TF = solution heat treated and precipitation treated (WP)
TF7 = solution heat treated, precipitation treated and stabilized (WP special)
TS = thermally stress relieved

Ingot materials have the same designations as castings but no code letters for condition.

The lower-strength alloys of this group are used for domestic and culinary equipment and automobile trim; the medium-strength alloys for architectural, marine and commercial road vehicles; and the higher-strength alloys for marine, welded structural applications and aircraft tubing.

Higher strengths are obtained by quenching suitable alloys from elevated temperatures and then ageing by reheating at lower temperatures. There are several groups:

1. Alloys containing amounts of Mg and Si in the ratio of the compound Mg_2Si with Mn or Cr. These have UTS up to 330 MPa without any real deterioration in corrosion resistance. They are used for applications similar to those of the non-heat-treated alloys but requiring slightly higher strength.
2. Alloys containing Cu as well as Mg_2Si with one or more of Mn, Fe, Ni, Cr, Ti, Zr and Nb may age harden at room temperature after quenching or may require precipitation heat treatment to give UTS up to 450 MPa. The corrosion resistance of these alloys is impaired so that they must be protected from weathering. These alloys may be used for aircraft structures, other miscellaneous structural applications, and in some cases forged aircraft engine parts, including forged pistons.
3. Alloys containing Zn + Mg + sometimes Cr, some of which give UTS around 450 MPa while others range up to 600 MPa. Alloys heat treated to the higher levels may have their fracture toughness as well as their resistance to stress corrosion impaired. These are mainly used for aircraft structural applications but other structural applications are becoming important.
4. The addition of lithium in amounts around 2.5% to CuMgZr alloys gives an increase in modulus and a decrease in specific gravity of 10% in alloys with 0.2% PS and UTS of 500 and 420 MPa, elongations around 7%, and plane strain fracture toughness values around 35, which are to be compared with the properties of 2324 or 2014 for which the lithium alloys might be substituted. Fatigue crack growth rates also appear comparable or better than the standard alloys, as does the range of general corrosion. These alloys are, however, prone to stress corrosion. Samples of these alloys have been flying for several years and qualifying tests for major usage are proceeding.[27–29]

7.4.2.3 *Aluminium casting alloys* (see Table 7.27)

The alloying additions for casting alloys differ significantly from those for wrought because of the role of silicon in improving castability and reducing thermal expansion. The coefficient of thermal expansion is reduced by 33% for a silicon content of 23% and proportionately for other contents – an effect which can be important in components such as pistons. All aluminium casting alloys contain approximately 0.2% titanium as a grain refiner. In addition, aluminium silicon alloys must be 'modified', that is, the acicular silicon phase in the aluminium silicon eutectic must be converted to a fine spheroidal particle by the addition of sodium, either as a metal or as a fluoride compound, if the alloy is to have a reasonable ductility. The eutectic composition of modified silicon aluminium is approximately 12.6%. If, to reduce the coefficient of thermal expansion, the silicon content is raised above this value, the elongation will become very low because of the presence of hyper eutectoid silicon.

Five major casting alloy groups can be identified:

1. In castings additions of manganese or up to 12% silicon increase the UTS up to 170 MPa without heat treatment. The straight aluminium silicon alloys are used where castability is essential but only moderate strength is required.
2. Moderate increases in tensile strength without heat treatment are obtained by additions of copper sometimes accompanied by iron, magnesium or zinc to the basic silicon alloys. These alloys are used where good casting characteristics, weldability and pressure tightness are required with moderate strength. Applications include mani-

folds, valve bodies, ornamental grills and general-purpose castings.

3. Heat-treated alloys, either AlSiMg or AlSiCu, may have UTS ranging up to 310 MPa but ductility is low with elongations values ranging around 1% or less, particularly with the higher silicon-content materials. They are used for automobile and diesel pistons and pulleys.
4. UTS ranging up to 300 MPa with elongation between 4 and 10 may be obtained by heat treating aluminium magnesium, aluminium copper, aluminium zinc magnesium or more complex alloys of low silicon content. These are used for more highly stressed components such as aircraft fittings, internal combustion engine pistons and cylinder heads where higher strength and hot strength are important but castability is not so critical.
5. There is one, silver containing, casting alloy Al4.5 Cu, 0.7 Ag, 0.34 Mg, 0.10 Si, 0.14 Fe, 0.4 Mn, 0.4 Cr not in any standard which, when manufactured by a high-technology casting process, may be heat treated to UTS 450 MPa elongation 10%, equivalent to many forging alloys. It is expensive and unlikely to have a high resistance to corrosion but it offers great advantages for complex highly stressed components such as may be used in fighter aircraft.

7.4.2.4 Fabrication of aluminium and its alloys

Aluminium has a face-centred-cubic structure and its consequent ductility combined with its relatively low melting point make it easy to cast and work. It is available in the form of sand, gravity and pressure die castings, a very wide range of shapes and sizes of extruded sections, forgings, plate, sheet and strip, many sheet metal products, rod, wire and tube. Most of its alloys can be welded by inert gas shielded metal arc or electric resistance processes. Powder processes have been developed, principally for producing composites usually of an alumina or other ceramic in an aluminium matrix.

High-quality aluminium components depend on the production of a fine-grained defect-free casting. Aluminium has no allotropic modification and cannot be refined by heat treatment. While aluminium alloys can be recrystallized after working, their fatigue characteristics depend on the production of an inherently fine-grained casting with a very fine dispersion of intermetallic particles. Further, because of the high solidification contraction, aluminium alloys depend for their soundness on very efficient feeding during solidification. These problems are compounded by the tendency of molten aluminium to absorb hydrogen which is evolved to form cavities in the metal on solidification and by the tenacious oxide film which forms on the surface of the molten (as of the solid) metal, and may be carried under the surface of the casting by turbulence to form discontinuities and interrupt feeding.

Hydrogen must be minimized by melting practice and eliminated by fluxing shortly before pouring. A fine cast structure and satisfactory feeding of ingots for mechanical working can be achieved by continuous casting and this process is amenable to smooth liquid metal transfers which minimize or eliminate oxide inclusions.

The production of high-quality conventional sand and gravity die castings has, in the past, depended to a very large extent on the experience and skill of the foundry. Recent developments in the technique, both of sand and die casting, have gone far to ensure rapid and efficiently fed solidification of a melt free from oxide inclusions. The most modern techniques of sand and die casting consist of causing molten alloy to rise from the centre of the melt into a superimposed die or mould. The liquid metal (which has therefore no oxide skin) rises with an unbroken surface during all stages of filling with metal, transferred in non-turbulent conditions, from a large quiescent enclosed bath of molten alloy. The pressure head developed to raise liquid smoothly into the mould is maintained to feed the casting during solidification. The more even flow of metal itself increases the chilling effect of the mould on the solidifying metal but this effect is augmented by using mould materials with greater heat capacity.

Cosworth Foundry, whose casting unit is represented diagrammatically in Figure 7.40, uses zircon sand which, besides producing a greater chill, has a lower thermal expansion than silica sand and significantly improves accuracy. The newly developed casting processes improve tensile and fatigue strength by about 30% and double elongation compared with conventional sand casting.[30]

7.4.2.5 Identification and standards of aluminium alloys

Wrought products The BSI, the US Government and the standards organizations of many countries use the four-digit system of the Aluminum Association of the US to identify

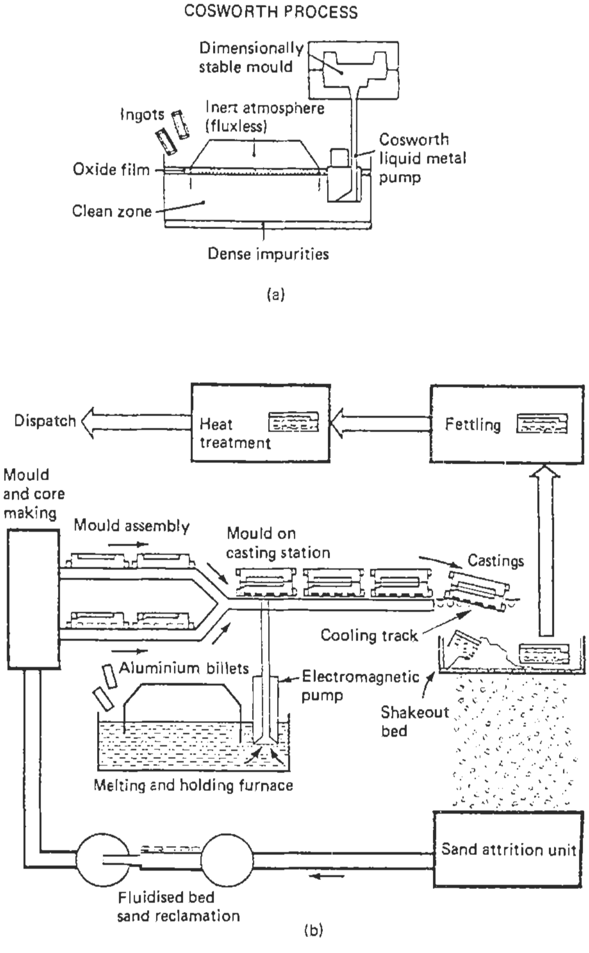

Figure 7.40 The Cosworth casting process. (a) The casting unit; (b) flow diagram of the Cosworth process. (Reproduced by permission of *Metals and Materials*) *Note*: For the convenience of the reader this figure is also reproduced in section 16.5.44

wrought aluminium alloys as listed in Table 7.26. In most cases the BS numbers are identical with those of the USA, but a few British alloys, for which there is not always a US equivalent, retain the old L system of numbering and a few newer alloys are so far covered only by DTD specifications.

Castings Casting alloy numbers have not been homologized. Most BS alloys have 'LM' numbers but a few 'L' numbers survive and some alloys are covered by DTD specification. At least three distinct number classifications are used in the USA. Aluminum Association casting alloy numbers and BS Product Specifications are listed in Table 7.24 and condition codes in Table 7.25.

7.4.2.6 Design using aluminium

The attention of the design engineer is called to three matters which are of great importance in the design and operation of aluminium components. Creep buckling in compressed struts and sheets can occur under loads far smaller than those calculated from the normal Euler formula using the modulus of elasticity.[31]

Creep buckling is not unique to aluminium alloys but the loading conditions in aircraft struts are often such that it is critical.

When a typical aluminium alloy is compared with a steel the fatigue crack growth rate per cycle da/dN for the aluminium alloy is forty times that for the steel. When compared with a titanium alloy of twice the yield stress, dA/dn for the aluminium alloy is twenty times that of the titanium alloy. K_{Ic} for the aluminium alloy is typically 20 $MNm^{-3/2}$ compared with 160 $MNm^{-3/2}$ for the steel and 60 $MNm^{-3/2}$ for the titanium alloy (see Chapter 8, Section 8.3). This is, to some extent, offset by the lower stresses used in design with aluminium. Even so, fatigue crack growth calculations play a much more significant part in the design process for aluminium alloys than for medium-strength steels.

The fatigue crack growth versus stress intensity curve shows less tendency to turn down to the vertical with aluminium alloys than with steel. Therefore aluminium alloys do not have a well-defined endurance limit. This is not so serious as it might seem, because aluminium alloy components are seldom designed to withstand cyclic loading in the region of 10^8 cycles. It should be noted that the endurance limits normally quoted for sand castings refer to those produced by conventional methods and not the high-technology methods described in Section 7.4.2.4.

The choice of alloy to meet specific requirements will be assisted by reference to Table 7.28 for resistance to environmental corrosion, Table 7.29 for resistance to aqueous corrosion, Table 7.30 for resistance of castings, Table 7.31 for wrought products to stress at room temperature, and Table 7.32 for resistance to stress at elevated temperatures.

7.4.3 Titanium and its alloys

7.4.3.1 General

The importance of titanium as an engineering material depends on specific strengths which (except beryllium, which is costly and toxic) are greater than those of any other metal

Table 7.28 Guide to exposure of aluminium alloys to rural, marine and industrial environments

Castings (BS 1490)	*Wrought (BS 1470–75)*	*Notes*
Group 1		
LM5-M LM10-TB LM6M, LM9-TE and TF LM18-M, LM20-M	1060, 1050, 1200 3103, 3105 5005, 5251, 5154, 5454 5083 6060-T4, 6061-T4, 6082-T4, 6463-T4, 2014C-T4, 2024C-T4	Weathers to pleasant grey colour, deepens to black in industrial atmospheres Superficial pitting occurs initially and gradually ceases Seldom needs painting except for decoration May be anodized for appearance but some alloys (e.g. LM6) give dark films
Group 2		
LM4-M, LM2-M LM16-TF, LM13-M LM21-M, LM22-TB, LM24-M LM27-M, LM31-M LM20-M	6060-T6, 6061-T6, 6065-T6, 6082-T6, 6463-T6	Weathers as above Is normally painted in severe industrial environments and for marine service May be anodized as above
Group 3		
LM12-TF	2014-T4 2024-T4 and T6	Painting needed in marine and industrial atmospheres, but coatings need only infrequent renewals Sprayed aluminium coatings, or cladding, give excellent protection Seldom anodized

Aluminium retains its initial appearance if it is washed periodically at 3- to 12-month intervals, depending on the severity of the pollution in the air. For many applications the weathered surface is satisfactory but anodizing is often undertaken, particularly for architectural items, to preserve a smooth appearance but periodic washing is desirable, especially when the anodic film is coloured. Anodizing should be in accordance with the relevant British Standards BS 1615:1972 and BS 3987:1974.

alloys. It has excellent creep resistance up to 600°C and exceptional corrosion resistance to oxidizing media. The high specific strengths derive from alloys with tensile and yield strengths up to 1380 and 1230 MPa, respectively, and a specific gravity pure of 4.51 rising to a maximum of 4.85 alloyed, roughly half that of steel. The corrosion and oxidation resistance is due to a tenacious oxide film on a metal above silver and nickel and below only Hastelloy and Monel in the electrochemical series for structural metals in sea water. One research programme on coupled specimens in sea water indicated titanium to be the most noble of structural metals. Titanium alloys are very resistant to cavitation erosion.

These advantages are reinforced by a high fatigue resistance, (endurance limits are roughly half of UTS) and a thermal expansion ($8–10 \times 10^{-6}$°C^{-1} between 0°C and 500°C), roughly half that of austenitic stainless steels and aluminium

and two thirds that of ferritic steels. Most titanium alloys may be welded using gas-shielded or diffusion methods, and some are capable of superplastic forming.

The main disadvantage of titanium is its cost.[32] Ore separation and reduction to metal is expensive and the metal reacts readily when hot with oxygen and nitrogen so that melting and casting must be done *in vacuo* and welding under a protective atmosphere. Further features are a modulus 105–125 GN m^{-2}, compared with 180 GN m^{-2} for steel and 65 GN m^{-2} for aluminium alloys, and low electrical and thermal conductivities (only about 4% of that of copper). (The higher modulus compared with aluminium can have advantages for springs, ultrasonic devices, surgical implants, etc.) Also, in spite of its generally excellent performance, the corrosion reactions of titanium with very strongly oxidizing media can be catastrophic and it is attacked by uninhibited reducing media.

There are essentially six major groups of engineering applications of titanium:

- Roofing and cladding
- Process plant and flue lining
- Marine condenser tubing
- Electrochemical fitments
- Aerospace frames
- Aero engines

The most exciting applications lie in the compressors (and other components) of aircraft turbine engines. The development of these engines has depended on the parallel development of alloys, with progressively improved creep resistance without sacrificing fatigue resistance. The development of titanium alloys has kept pace with these requirements as is illustrated diagrammatically in Figure 7.41.

7.4.3.2 *Titanium metal and alloy structure*

The structure of titanium metal is transformed from the low-temperature close-packed hexagonal α-phase to the higher-temperature body-centred β-phase on heating above 850°C. Alloying elements influence the properties of one or both phases, and their relative stability.

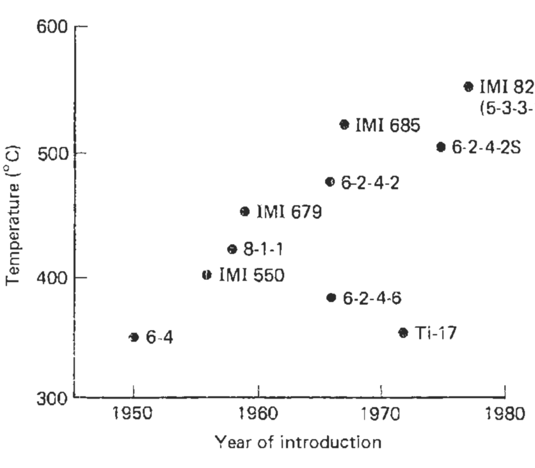

Figure 7.41 High-temperature alloys of titanium at present in production aero engines: year of development and temperature capability under optimum stress conditions. (Reproduced by permission of IMI Titanium Ltd)

Titanium with α-stabilizing and strengthening elements Zirconium and tin are two additions that strengthen the α-phase considerably, particularly at high temperature. Unfortunately, they also raise the density. Oxygen and nitrogen which may be introduced during reduction and processing stabilize the α-phase and increase strength at the expense of toughness. Their content must therefore be limited. The addition of small quantities of palladium (IMI Grade 260, 262) markedly improves resistance to reducing environments and the addition of Mo and Ni (ASTM Grade 12) is a cheaper but less effective attempt to obtain a similar result.

Aluminium stabilizes the α-phase and also reduces density. The alloy Ti 5 Al-2.5 Sn (ASTM Grade 6) has useful tensile properties up to 300°C and is weldable but difficult to cold form. Unfortunately, attempts to increase strength still further by increasing the alloy content resulted in embrittlement due to ordering and formation of Ti_3 Al which led to the rule

$$\mathrm{Al} + \frac{\mathrm{Sn}}{3} + \frac{\mathrm{Zr}}{6} + 10 \times \mathrm{O}_2 < 9\ \mathrm{w\%}$$

Titanium with β-stabilizing and strengthening elements Mn, Fe, Cu, Cr, V and Mo additions tend to stabilize the β-phase. The most favourable elements are those that do not have a peritectic reaction (see Figure 7.42).

Very high strengths (up to 1500 MPa) can be achieved in metastable β-alloys but although alloys such as Ti 8 Mn (which was processed in the $\alpha + \beta$-phase region) and Ti 13V-11Cr 3Al (which was strengthened by precipitation of the α-phase) have ben developed. the alloys can embrittle on heating above about 300°C and none have found high-temperature applications in aero engines.

Titanium with both α- and β-stabilizing and strengthening elements Titanium alloys with added elements that stabilize both the α- and β-phases simultaneously provide significantly increased room and high-temperature strengths. Ti-6Al-4V is rated up to 350°C and has found widespread application. The addition of Si significantly increases creep strength and Ti-4Al-2Sn-4Mo-0.5Si (IMI550) not only is 10% stronger than Ti-6Al-4V but, in addition, can be operated up to 400°C. (It has been later found that the optimum benefit of silicon additions occurs at a lower level of addition to near-α-titanium alloys (see Figure 7.43).

$\alpha + \beta$ alloys have also been developed to have high strength for moderate-temperature applications (up to about 400°C). These include Ti-2.1/4 Al-11 Sn-4 Mo-0.2 Si (IMI680) and Ti-6Al-5Zr-4 Mo-1Cu-0.2 Si (IMI700) and in the USA Ti-6Al-2 Sn-4 Zr-6 Mo and Ti-5Al-2Sn-2Zr-4 Mo-4Cr.

Near-α-titanium alloys The near-α-titanium alloys have the maximum amount of α-stabilizers with β-stabilizing elements high enough to give medium-strength levels but low enough to avoid problems in welding and embrittlement in creep at high temperature. Ti-11Sn-2.1/4 Al-5 Zr-1 Mo-0.2 Si (IMI679) can be operated up to 450°C and the American alloy Ti-8Al-1V-1Mo up to 400°C, although it suffers from ordering embrittlement and needs careful control in processing. Ti-6Al-2Sn-4Zr-2Mo ('6.2.4.2') was developed to have a temperature capability of about 470°C and has been widely used in the USA.

All these alloys had previously been worked and heat treated in the $\alpha + \beta$-phase region. β-heat treatment significantly improved creep strength but reduced tensile ductility to an unacceptably low level. This problem was overcome by the development of near-α Ti-6Al-5Zr-0.5 Mo-0.25 Si (IMI685) which is β heat treated to produce an acicular microstructure and in this temper has creep capability up to 520°C (see Figure 7.44).

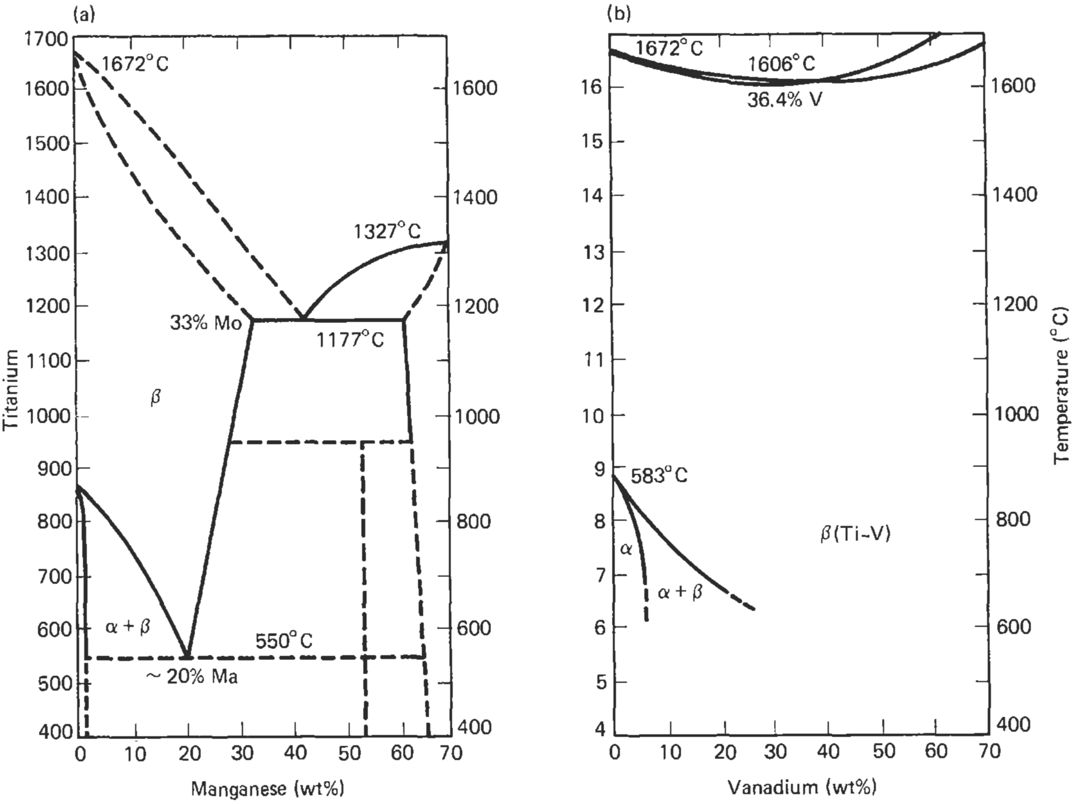

Figure 7.42 Partial phase diagrams of β-stabilizing additions to titanium. (a) Unfavourable structure of manganese alloys showing peritectic; (b) favourable simpler structure of vanadium alloys

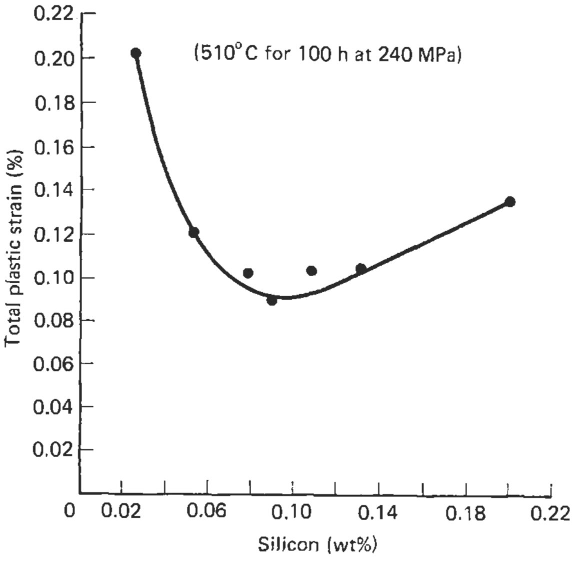

Figure 7.43 Effect of silicon on the creep strain in 6-2-4-2. (Reproduced by permission of IMI Titanium Ltd)

β heat treatment by itself may not be sufficient to maximize creep resistance. Cooling rate is also critical and an example of this is shown in Figure 7.45.

Fracture toughness and fatigue crack growth rate are improved by changing from α + β to β heat treatment. This is illustrated in Figure 7.46. Unfortunately, room-temperature tensile ductility and fatigue crack initiation are worsened. The effective initiation unit is the prior β grain or the α colony which, in a β-treated structure, can be from 0.5 to 2 mm in size compared with 10–15 μm in an α + β structure.

Reduction in size of structural features while retaining an acicular structure can be achieved by utilizing thermomechanical processing using multi-recrystallization stages, and by alloy development. This procedure has resulted in β grain sizes between 0.5 and 0.75 mm in an alloy Ti-5.6Al-3.5Sn-3Zr-Nb 0.3Mo-0.3Si (IMI829). Improvements have also been carried out in the USA on Ti6Al-2Sn-4Zr-2Mo.

The best creep properties (see Figure 7.44) together with an acceptable fatigue crack growth rate are available in Ti-5.8 Al, 4.4 Sn-3.5 Zr -0.7 Nb-0.5 Mo-0.35 Si-0.06C (IMI834). This alloy is characterized by a more gradual change in α-phase content with heat-treatment temperature as in the comparison of β transus approach curves for this alloy and 829 shown in Figure 7.47. This allows the alloy to be heat treated in the high α field for optimum creep and crack propagation resistance but with β grain size controlled to about 0.19 mm for improved fatigue performance.

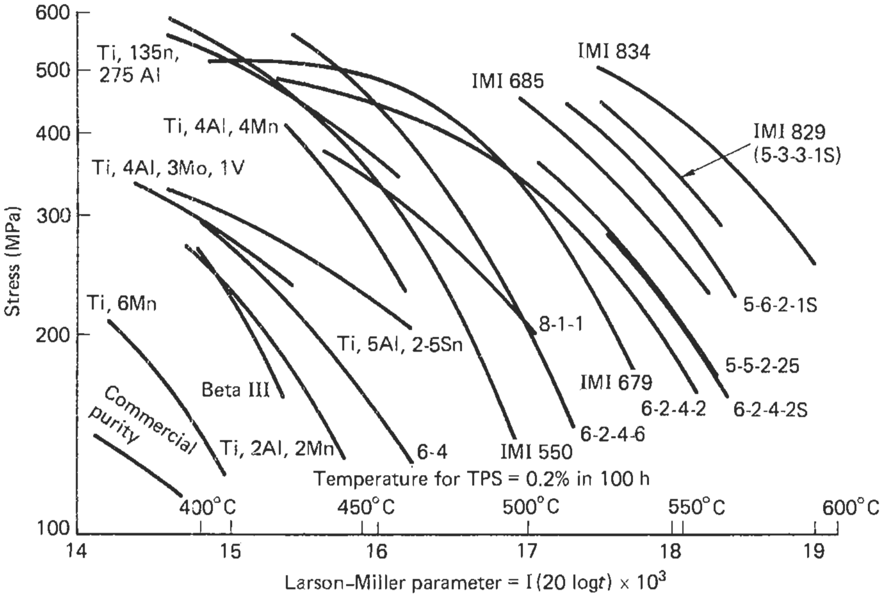

Figure 7.44 Creep-resistant alloy development. Larson-Miller plot showing improvements over the last 30 years. (Reproduced by permission of IMI Titanium Ltd)

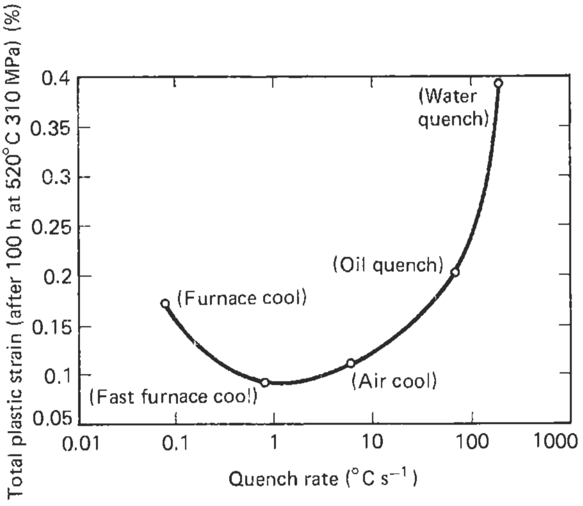

Figure 7.45 Effect of cooling rate on the creep strain in IMI 685. (Reproduced by permission of IMI Titanium Ltd)

The relationship between heat-treatment temperature and the balance of creep and fatigue properties is illustrated schematically in Figure 7.48. The optimum balance can be adjusted for a particular application.

7.4.3.3 Nomenclature and standards

The chemical composition, nomenclature (where available), UK and US specification numbers, tensile properties and weldability are listed in Table 7.33. In Europe titanium alloys

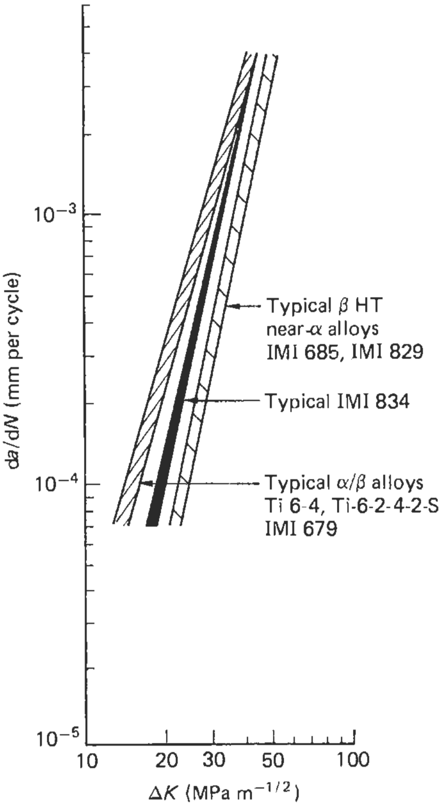

Figure 7.46 Crack-propagation data of high-temperature alloys. (Reproduced by permission of IMI Titanium Ltd)

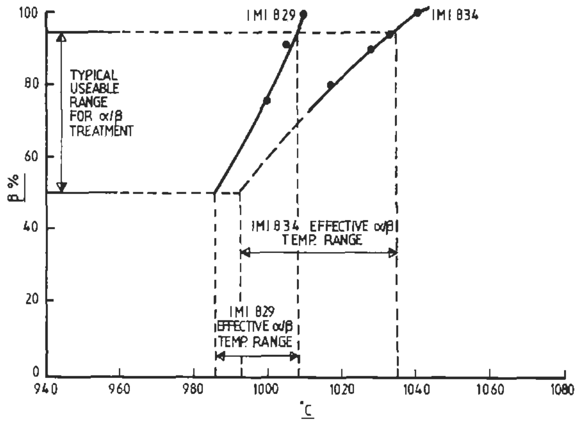

Figure 7.47 β transus approach curves

are often referred to by their IMI number. Some of the more recent titanium alloys had not, at the time of writing, appeared in national material specifications. The properties of the more attractive of these (IMI 829 and 834) are therefore listed in Table 7.34.

Such is the pace of titanium alloy development that designers are recommended to approach the manufacturer for information on materials available at the time before finalizing their designs.

7.4.3.4 *Fabrication*

Titanium and (where appropriate) alloying metals are compacted and welded into electrodes for vacuum arc consumable electrode furnaces and double or triple melted to ensure homogeneity. The resulting ingot is forged and then rolled. Bar, rod, wire, sheet, plate, seam-welded tube and bored or extruded and drawn seamless tube are available commercially.

Almost all titanium alloys can be forged. One technique which can produce near to size components is isothermal press forging, in which the metal and dies are heated to the same temperature between 900°C and 950°C. Some fine-grained duplex alloys, including IMI 318, 550 and 6242, have high strain rate sensitivity at temperatures between 900°C and 950°C and will deform superplastically at low strain rates to strains of over 1000%.

Titanium will dissolve its own oxide and can therefore be diffusion bonded, and this process can be combined with superplastic forming to make a variety of hollow components economically. Most titanium alloys are weldable by electron beam, inert gas-shielded arc, resistance, flash butt, pressure or friction welding and, even in those alloys which are considered to deteriorate when welded, the properties can usually be augmented by heat treatment. Titanium alloys IMI 110–160, 260, 262, 318, 685 and 829 can be centrifugally cast in rammed graphite or investment moulds using a consumable electrode or skull melting furnace.

Tensile and yield strengths are about 5% below those of forgings and dimensional tolerances vary from 0.6% to 2%, depending on process and size. It is becoming increasingly common for castings to be hot isostatically pressed to give properties comparable to those of forgings.

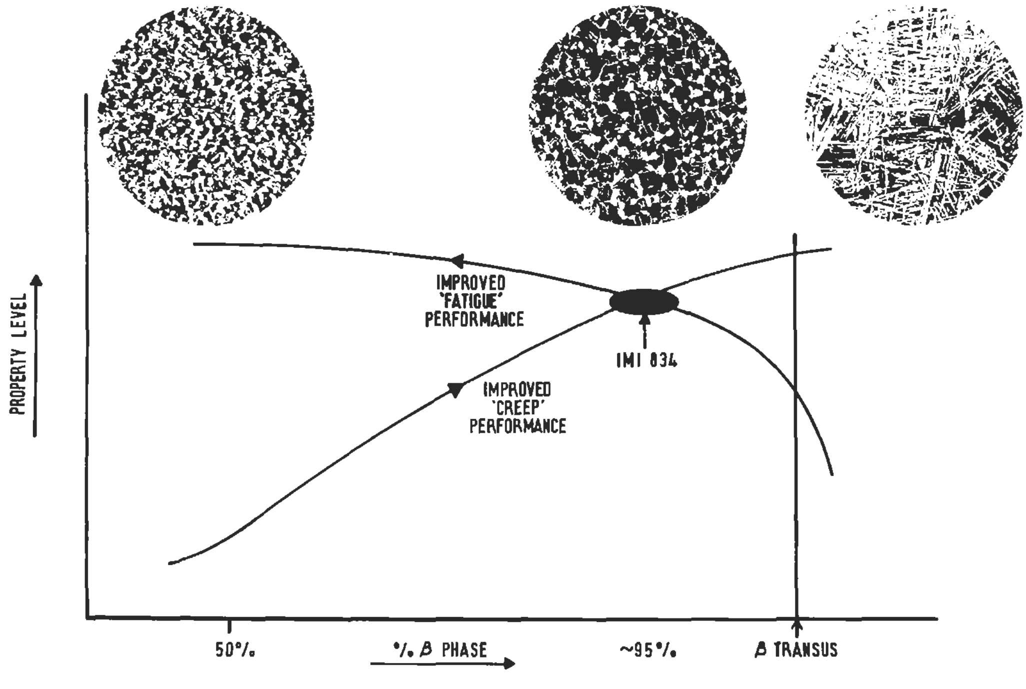

Figure 7.48 Effect of α/β phase proportions on creep and fatigue properties (schematic). (Reproduced by permission of IMI Titanium Ltd)

7.4.3.5 Applications

So-called 'commercially pure' titanium (IMI 110–160) is primarily a chemical plant vessel and piping material, resisting sea water, halogen compounds, oxidizing and organic acids and many gaseous environments. It is also used for non-consumable anodes, sometimes coated with precious metal, and fitments for metal finishing and other electrochemical operations. IMI 260 or 262 may be substituted if there is any possibility that the environment may become reducing in nature. A coarse-grain faceted structure can be produced which can be selectively anodized and used for decorative and jewellery products. The ultimate tensile strengths of these alloys range up to 650 MPa so that they can be used for less highly stressed aircraft components. Aircraft engine casings and bypass ducts require stronger and more creep-resistant material, and for these the higher-strength more creep-resistant readily formed and welded alpha-strengthened IMI 230 or, if there is no severe forming operation involved ASTM Grade 5 (IMI 318) may be used. $\alpha + \beta$ alloys (for example, IMI 550) have much higher tensile and fatigue strengths (which are exceeded only by the less stable β-strengthened alloys) and are used for discs, blades and highly stressed airframe components.

The creep properties of the near-α alloys have already been described. They are used for the higher-temperature compressor discs, rings, blades and impellers at temperatures approaching 600°C. Above this temperature the limitation for titanium appears to be in the field of oxidation rather than strength. Oxidation-resistant noble metal ion plated coatings and Ti-Al and Ti-Nb-Al alloys or compounds are showing promise.

7.4.4 Magnesium and its alloys

7.4.4.1 Introduction

Magnesium is the least dense of the engineering alloys and, because of this, the specific strengths of its alloys are superior to those of aluminium and medium-strength steels.[33,34] More important, although the specific rigidities $E\rho^{-1}$ of the alloys differ little from those of aluminium and steel, the stiffness in bending of a section of equal weight (which is related to $E\rho^{-3}$) is far superior.

Substantial savings in weight are possible for designs for which rigidity is a significant criterion. A further advantage of magnesium is its high damping capacity which helps to minimize vibration fatigue. Further scope for weight reduction in comparison with aluminium arises from the excellent castability of some alloys for components where section thickness is determined by casting considerations. Die casting benefits from the fact that dies are not attacked by molten magnesium as they are by molten aluminium. Magnesium is readily extruded and forged at elevated temperatures. It is highly machinable but suffers from a risk of fire and even explosion unless precautions are taken to prevent accumulation of swarf.

These advantages are (or have in the past been) offset by three major drawbacks. The major one compared with aluminium is the less protective nature of the oxide. The early magnesium alloys had very poor corrosion resistance, and although this disability has to a large extent extent been overcome in more recently developed alloys, the liability to galvanic corrosion has not been lessened and care must be taken to prevent it. A second drawback arises from the hexagonal structure of the magnesium crystal, which prevents fabrication by cold working. A third was the higher price of magnesium compared with aluminium which, even allowing for the lower specific gravity, confined its use to applications in which weight reduction is at a premium. These include aerospace, components for high-performance automobiles, materials handling, portable tools, high-speed machinery and high-value portable consumer goods. Recently, however, the relative costs of the two metals have reversed and magnesium components may cost less than aluminium.

7.4.4.2 Alloy designation and standards

Magnesium alloys are usually referred to by their ASTM designations which, together with their temper designations, are given in a four-part code. The alloy designation consists, first, of *letters* which identify the major alloying elements, given in order of decreasing concentration. The letters are followed by *numbers* which give, to the nearest percentage, the weight percentage of the alloying elements. The code which relates the letters to alloying elements is as follows:

A	aluminium
B	bismuth
C	copper
D	cadmium
E	rare earth
F	iron
H	thorium
K	zirconium
L	lithium
M	manganese
N	nickel
P	lead
Q	silver
R	chromium
S	silicon
T	tin
W	yttrium
Y	antimony
Z	zinc

In the ASTM system only the *two most concentrated* alloying elements are designated. Thus MEL alloy ZCM711, which contains 6.5 wt% Zn–1.2 wt% Cu–0.7 Mn has the ASTM designation ZC71. The *third* part of the alloy designation consists of a letter which refers to a standard alloy within the broader composition range specified by the first two parts of the designation. The *temper* designation, which is separated from the first two or three parts of the code by a hyphen, is the same as that adopted for aluminium alloys. This is given in full in ASTM specification B296-67. Thus a complete designation might read as

QH21A-T6

The alloy contains approximately 2 wt% silver and 1 wt% thorium; its exact composition is covered by the specification for the 'A' version of the alloy; and it is in the solution-treated and artificially aged condition. The alloy designation is given in full in ASTM specification B275. ASTM specification numbers comprise:

- B92 magnesium ingot
- B93 magnesium alloy ingot
- B94 die castings
- B50 sand castings
- B199 permanent mould castings
- B403 investment castings
- B90 sheet and plate
- B91 forgings
- B107 extruded bar shapes and tubes

BS 2970 lists alloys, cast and wrought and has a code for conditions similar to ASTM with the addition of M for as-cast. The designations of the major British supplier, Magnesium Electron, are roughly similar to those of the ASTM. Tables 7.35 and 7.36, respectively, list the cast and wrought alloys with their magnesium electron designations, British and ASTM specifications, principal mechanical properties and characteristics.

7.4.4.3 Development

The first magnesium alloys contained aluminium up to 10% and sometimes also up to 6%. These alloying additions increase strength and give precipitation-hardening properties. The addition of manganese reduced iron pick-up and so improved corrosion resistance. Further development was aimed at improving creep and corrosion resistance, both of which were very poor in the earlier alloys.

Addition of zirconium refines the grain structure and improves the strength and ductility, both hot and cold. About 0.5% of this alloying addition together with additions of thorium, rare-earth metals, silver and/or copper provide a combination of strength, castability and high-temperature tensile and creep strengths comparable with the high-temperature aluminium alloys.

Improvements in corrosion resistance have resulted from an understanding of the effect of heavy-metal impurities. Aluminium- and zinc-containing casting alloys are now produced with the following impurity limits: $\text{Fe} < 0.005\%$, $\text{Ni} < 0.001\%$, $\text{Cu} < 0.015\%$ with $0.15\% < \text{Mn} < 0.25\%$ to suppress iron pick-up. As a result, the high-purity versions, ASTM designations AZ1D and AM60B, have corrosion rates in salt solution only about 2% of those of the original alloys. Alloy WE54 is unique among the creep-resisting alloys in that its corrosion resistance is excellent and on a par with that of the high-temperature aluminium casting alloys.

7.4.4.4 Casting of magnesium alloys

A major problem in the manufacture of magnesium castings has been the prevention of oxidation of the molten metal which has, in the past, been prevented by melting under a layer of flux. It has always been difficult to prevent entrainment of flux, and the possibility of flux inclusions in castings has worsened the problems arising from corrosion. New techniques of fluxless melting and stirring have been developed and the introduction of low-pressure casting as used for aluminium alloys should bring further improvements.[35]

7.4.4.5 High-temperature strength of magnesium alloys

The stress to produce 0.2% total strain at 1000 hours is shown in Table 7.37 and the variation of ultimate tensile and proof stress of the creep resisting cast alloys of magnesium in Figure 7.49. These properties are adequate for many aerospace and automobile engine components.[36] A creep-resistant forging alloy ZT is available but its application is restricted compared with that of castings.

Table 7.37 Stress to produce 0.2% total strain in 1000 hours in creep-resisting cast magnesium alloys

7.4.4.6 Corrosion

The improved corrosion-resistant alloys of magnesium have been referred to in Section 7.4.4.3. The high-purity casting alloys have performed at least as well as high-temperature aluminium alloys in salt fog corrosion tests. Painted diecast high-purity AZ91D has shown negligible scribe corrosion creepages and excellent stone chip resistance.

Unfortunately, the galvanic corrosion of magnesium is not affected, and great care must be taken in design not to place magnesium in electrical contact with a metal with a significantly more positive electrode potential. Where juxtaposition is unavoidable for service in a corrosive atmosphere, reliable insulation should be inserted between the two components, or the magnesium component should be protected in some other way. This applies particularly to riveted joints. Because of the limitation on ductility imposed by the hexagonal crystal structure, magnesium cannot be used for rivets. Rivets of aluminium which has a relatively small positive electrode potential to magnesium are used. Steel or copper rivets must not be employed.

7.4.4.7 Applications

Improvements in high-temperature and corrosion resistance have increased the possible applications of cast magnesium alloys in automobile, aerospace and other applications where reduction in weight is significant. These include helicopter gearboxes, aircraft engine casings, high-performance car and motorcycle components (including wheels), computer parts, military equipment and video and conventional cameras. The applications of wrought alloys are more restricted because of the problems of cold forming and riveting, but include railings, ladders, brackets and cans for 'magnox' reactors.[37,38]

7.4.5 Nickel and its alloys

7.4.5.1 General

Although the major proportion of nickel mined is used as an alloying agent for ferrous metals, nickel as a major constituent

The tensile properties quoted are the specification minima for the first specification listed for that alloy and condition. The ranges given are the specified minima; values in parentheses are for information only.

[a] The values quoted are for separately cast test bars and may not be realized in certain portions of castings.

[b] Elongation values are based on a gauge length of 5.65$\sqrt{A}$ except in the case of thin material where a gauge length of 50 mm may be used (see BS 2 L.500, 3370 and 3373). With the latter gauge length, elongation requirements for sheet and plate depend on thickness and a range of minima is quoted.

[c] Endurance values for 50×10^6 reversals in rotating bending-type tests; semi-circular notch, radius 1.2 mm; SCF approx. 2.0. Reversed bending for sheet.

Larger sizes than those shown above are available: when required, property levels will be by agreement.

[a] The tensile properties quoted are the specification minima for the first specification listed for that alloy and condition. Where a range is quoted the specification requirements depend on sheet thickness. Bracketed values are for information only.

[b] Elongation values are based on a gauge length of $5.65\sqrt{A}$ except in the case of thin material where a gauge length of 50 mm may be used (see BS 2 L.500, 3370 and 3373). With the latter gauge length, elongation requirements for sheet and plate depend on thickness and a range of minima is quoted.

forms many alloys which have a very wide range of outstanding properties.

The face-centred-cubic lattice of nickel persists without allotropic change from very low temperatures to its melting point. This confers ductility down to cryogenic temperatures and strength up to 70% of the melting point, which makes nickel an outstanding base for creep-resistant materials.

Pure nickel has excellent corrosion resistance to non-oxidizing media, and this property is enhanced by the addition of copper, chromium and molybdenum. Oxidation and scaling resistance is conferred by the addition of chromium and adherence of the chromic oxide surface layer is improved by rare-earth additions.

The range of properties available in nickel alloys includes very low thermal expansion coefficients and almost constant elastic moduli over limited ranges of temperature. Other alloys have a wide range of electrical resistance and in some this is almost constant over a range of temperature. Excellent magnetic properties are available but only at low magnetic induction.

The major drawback of nickel alloys is their cost. Nickel is not widely distributed and some of the more abundant deposits are expensive to process. The cost of the metal is augmented by that of some of the alloying additions. The embrittling action of some impurities requires their content to be kept very low. This complicates the refining and scrap-segregation procedures and further increases cost.

The manufacturing cost of components from nickel alloys is high, partly because of their poor castability, partly because of their high resistance to deformation at elevated temperatures and partly because of their high rate of work hardening. Very powerful equipment operating at high temperatures is required to work nickel alloys and they are hard to machine. The resistance of nickel to oxidizing gases is poor and the action of sulphidizing gases catastrophic.

There are six main groups of nickel alloys. These comprise: corrosion-resistant, high-temperature, electric, magnetic, controlled physical property and hard-facing alloys. There are also a few miscellaneous types.

7.4.5.2 Nomenclature and standards

Some of the more important alloys are covered by national specifications, but among engineers they are normally referred to by the designation given by their supplier, usually a subsidiary of the International Nickel Corporation. Sometimes the identical material is available from another supplier, and in this case it is usually referred to by the same number but without the trade name (e.g. 'Alloy 800' instead of 'Incoloy 800').

Most wrought alloys are provided in all the semi-finished forms and may also be available as castings. Cast alloys are usually available only in that form. Such British and ASTM standards as exist are listed in Table 7.38.

Table 7.38 British and ASTM standards for nickel and nickel alloys

Refined nickel, principally cathodes, briquettes and pellets.
BS 375: five grades (99.5–99.95) of refined nickel
ASTM B39: 99.8% refined nickel
Depending on grade, nickel may contain from 0.005% to 1.5% Co, 0.05% to 0.1%C and 0.002% to 0.15% Cu. Minor impurities are restricted to values between 0.00002% and 0.002%.

Nickel alloy castings:
BS 3071 Nickel–copper (~30%) castings
ASTM 494 Chemical composition and tensile requirements for 11 casting alloys

Wrought nickel alloys:

BS 3072	Nickel and nickel alloy sheet and plate
BS 3073	Nickel and nickel alloy strip
BS 3074	Nickel and nickel alloy seamless tube
BS 3075	Nickel and nickel alloy wire
BS 3076	Nickel and nickel alloy bar
ASTM B564	Nickel alloy forgings
ASTM B161	Nickel seamless pipe and tube
ASTM B162	Nickel plate sheet and strip
ASTM B168	Nickel chromium iron alloys plate sheet and strip
ASTM B69	Welded nickel alloy pipe
ASTM B670	Precipitation hardening nickel alloy plate sheet and strip
ASTM B335	Nickel molybdenum alloy rod

7.4.5.3 *Corrosion-resistant alloys*

The corrosion-resistant alloys include:

- 'Nickel', a name which covers a range of general-purpose corrosion-resistant materials.
- 'Monels', essentially nickel alloys with 30% copper which have exceptional resistance to aqueous environments.
- 'Hastelloys' (a Cabot Corporation trade name), nickel–molybdenum alloys which have excellent resistance to acids at high temperature.
- 'Iliums', nickel–chromium–molybdenum copper alloys which resist sulphuric acid.
- 'Inconels', nickel–chromium–iron alloys and 'Incoloys', nickel–chromium–molybdenum alloys, which are really high-temperature alloys but inconel 625 and incoloy 800 have exceptional resistance to stress corrosion and incoloy 825, with additional copper resists strong mineral acid.

The corrosion-resistant alloys are listed, with their standard designations, tensile strengths and dominant characteristics in Table 7.39.

7.4.5.4 *High-temperature alloys*

The high-temperature alloys of nickel (with the exception of the dispersion-strengthened composites 'SDO') can be regarded either as based on Nimonic 75 (80/20 nickel chrome) or as an extension of the austenitic steels with progressively reducing contents of iron and progressively increasing strengthening additions. There are two classes:

(1) *High-temperature corrosion-resistant alloys*: these have relatively low hot strength (for a nickel alloy) but good scaling resistance (see Table 7.39). They include:
    (a) Nimonic 75 (originally developed as Brightray wire) but available in other forms;
    (b) Inconel 600 and 601 with higher scaling resistance are similar to Brightray but contain some iron;
    (c) 50/50 nickel chrome available as castings or as a cladding material (Incoclad) and IN657 (with niobium) available as castings are the materials with the highest resistance to fuel ash corrosion (except for precious metals).

(2) *Creep and corrosion-resistant alloys (nickel superalloys)*: these are alloys of nickel and chromium, or nickel, chromium and iron with strengthening additions. They are employed anywhere that strength and oxidation resistance are required at high temperature but their development as materials to withstand progressively more severe conditions in gas turbine engine components has stimulated research both in alloy composition and in manufacturing technique. The progress and results of this development are summarized in the following section. The relative rupture strengths of the several alloys produced in different ways are shown in Figure 7.54.

7.4.5.5 *Nickel alloys for gas turbines*[39]

Materials for forged blades[40–42] The original nickel alloy turbine blades were forged and their creep and creep rupture strengths were improved by increasing the proportion of ordered precipitating phase γ' ($NiAl_3$) and solid solution strengthening additions, chromium, cobalt, molybdenum, tungsten and tantalum. These elements also dissolve in the γ' phase and may have a twofold hardening effect. The compositions must be optimized to obtain the most favourable balance of creep and thermal fatigue strength and oxidation resistance. Unfortunately, increasing content of γ' has to be balanced by a reduction in chromium (which reduces the solubility of aluminium and titanium) but the effect of this on scaling resistance is offset to some extent by the increase in aluminium. At the highest temperatures oxidation resistance is obtained by coating with aluminium.

The increased temperature capacity of the improving forged nimonic alloys is apparent from Figure 7.50 and from the following list:

Nimonic alloys Basic grade(s)	*Improved corrosion resistant grade(s)*	*Operating temperature °C*
80 A	81	815
90. Inconel 750	91	920
105		940
115		1010

Increase in γ' content reduces the range of temperature available for hot working between softening and incipient melting. This can be offset to some extent by the addition of cobalt which increases the solvus temperature. Even so, the small margin between maximum preheating temperature (1100°C) and minimum working temperature (1050°C) of Nimonic 115 indicates that this is likely to remain the forged alloy with the best high-temperature properties.

Cast blades Vacuum casting provided an alternative manufacturing route. Problems met in the earlier alloys included cracking due to the separation of massive carbides on solidification and the formation of σ-like intermetallic compounds. However, in one specific alloy, IN100 up to 70% γ' fraction can be achieved. This had the immediate effect of eliminating the need for solid solution strengthening so that a low-density high creep-resistant material became available. Early casts of IN100 embrittled after prolonged exposure at 850°C due to the formation of intermetallic compounds σ, μ, X, π or Laves phases had to be avoided by computerized phase control (Phacomp) techniques.[43,44]

The achievement of yet higher-temperature capability required the addition of a high melting point solid solution strengthener such as tungsten. The further addition of 2% hafnium improved ductility and minimized cracking by increasing the amount of low melting point eutectic in (Martin Marietta) MarM002. This and the alloy IN138 which, although it lacks the best creep rupture properties, is extremely well suited to coating with aluminium and is therefore used where the maximum creep resistance is not essential, were standardized.

The structure of the grain boundaries is important. Too little strengthening impairs creep resistance, too much impairs creep ductility and therefore thermal fatigue. The grain boundary structure is controlled through precipitation of carbides, usually chromium carbides (but substituted with other carbides) and by boron and zirconium additions. Compositions of wrought and cast superalloys are listed in Table 7.40.

Directional solidification[45–48] The next improvement in temperature capability came with directionally solidified blades made in a plant of the type shown in Figure 7.51. The mould is enclosed within a hot zone and the heat extracted through a chill plate. The blade consists effectively of a bundle of crystals each with the (100) direction longitudinal and having random rotational orientations transverse to this direction.

This structure has little effect on creep but, because there are no transverse grain boundaries, very significantly increases rupture ductility, particularly in the highly creep-resistant

alloys such as Mar M200 (see Figure 7.52). This produces greatly increased thermal fatigue life, which is further enhanced by a low elasticity modulus in the longitudinal (100) direction. This allows a greater elastic extension in a thermal stress cycle and reduces $\Delta\epsilon_p$ (see Chapter 8, Section 8.4).

Single crystals Even greater improvements accrue from casting blades as single crystals either by restricting the cross section of the solidifying metal in advance of the moulded blade (see Figure 7.53) or by using a seeding crystal. There are

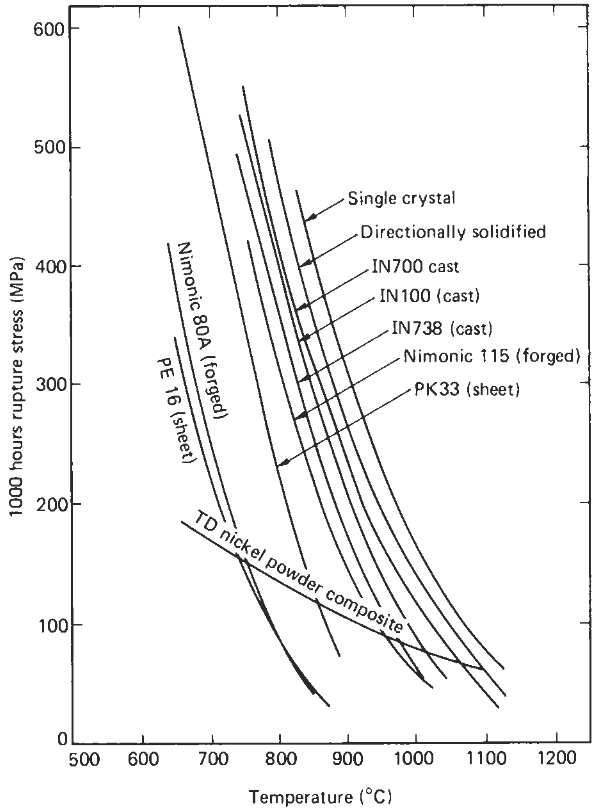

Figure 7.54 Comparative 1000 h to rupture strengths of nickel alloy gas turbine blading materials produced by a variety of techniques

no grain boundaries in a single crystal, consequently elements introduced to strengthen grain boundaries such as carbon, boron, zirconium and hafnium may be omitted. Higher-solution treatment temperatures can therefore be used and stronger more uniform γ' precipitates produced. Thus, in the UK SRR99 will replace MarM002, low-density RR2,000 will replace IN100 and RR 2060 will be used for nozzle guide vanes.

The kind of performance that may be expected from directionally solidified and single-crystal materials is indicated in Figure 7.54. The compositions of superalloys that are suitable for directional solidification are listed in Table 7.41. Any significant further advance in gas-turbine blade materials must come from the use of composites.

Composite blades Composites can be produced by casting eutectic alloys in directionally solidifying furnaces or by powder techniques. Directionally cast eutectics normally have a laminar structure but can, theoretically, be seeded to produce fibre reinforcement in a matrix. Typical compositions are listed in Table 7.42. Unfortunately, some directionally solidified eutectics have limited oxidation resistance, some delaminate on thermal cycling and some have uneconomically long production times. None have so far been exploited commercially.

Dispersion-strengthened (ODS) alloys resist creep at very high temperatures (see TD Nickel, Figure 7.54) but it is extremely difficult to produce a material with high strength at lower temperatures. One such alloy MA6000 (see Table 7.40) is said to be strong enough for stubby tapered unshrouded blades which can be run at higher temperatures than other nickel base-alloy blades.

Turbine disk materials Turbine disk materials require good tensile strength (to prevent bursting in the event of an overspeed) and good low-cycle fatigue life (to withstand the changes of stress undergone in the flight cycle) rather than

creep resistance at high temperatures. The alloys adopted, Astroloy, Waspaloy and Nimonic 901 (see Table 7.40) are similar in composition to turbine blade alloys but are given low-temperature thermomechanical treatments which generate a homogeneous dislocation structure, improve tensile strength by up to 40% and produce a fine-grained microstructure which has good fatigue properties.

Ingots cast from more highly alloyed disk materials are prone to segregation and difficult to forge. It should be possible to overcome this by powder processing but, so far, the presence of defects too small to be detected by NDT has prevented the application of powder techniques to turbine disks. The mechanically alloyed powder API (Table 7.40) is an example of this type of alloy.

Casing materials Sheet materials have compositions similar to blade materials but their creep resistance is usually lower, partly because it is not needed, partly because the high-technology casting procedures are not applicable to sheet and partly because they usually have to be welded. The creep rupture properties of two sheet materials, PE16 and PK33, which span the available range are indicated in Figure 7.54. The compositions of a selection of available (and potential) nickel gas-turbine alloys are listed in Tables 7.40–7.42.

This account has been based on experience at Rolls-Royce but similar developments, using alloys of marginally different compositions tailored to meet specific design requirements, have been achieved at General Electric and United Technologies.

7.4.5.6 *Electrical alloys*

Nickel and nickel alloys are used, usually in the form of wire or strip, because of their individual characteristics of resistivity, electron emission, thermoelectric properties or corrosion resistance. Table 7.43 lists these materials, giving composition, supplier, tensile strength, and property of major interest. They are usually supplied in the form of annealed bar for drawing into wire or strip.

7.4.5.7 *Magnetic alloys*

The magnetic alloys of nickel are principally those with high magnetic permeability in low- or medium-strength magnetic

fields or some special form of magnetic hysteresis loop. They are used mainly in the form of tapes or sheet, or as powder for cores for electronic equipment. Very careful control is needed in production. Pure nickel or nickel-rich cobalt alloys are used as magnetostriction transducers. Compositions, tensile strengths and an indication of magnetic characteristics are listed in Table 7.44. They may be obtained from Telcon Metals, ITT (Harlow) and International Nickel.

7.4.5.8 Alloys with special dimensional and elastic properties

Certain alloys of nickel have minimal or controlled coefficients of expansion over certain ranges of temperature. Alloys with minimal expansion coefficients are used in instruments and those with controlled coefficients for sealing to glass or ceramics in vacuum devices. Alloys with small positive temperature coefficients are used for temperature-insensitive vibrating instrument devices. There is also a low-temperature shape memory alloy Nitinol. The compositions, ultimate tensile strengths and an indication of the characteristic properties of nickel alloys with dimensional property applications are listed in Table 7.45.

7.4.5.9 Hard-facing materials[57,58]

A large number of commercial hard-facing alloys depend on a nickel matrix, usually containing a dispersion of chromium and chromium carbide, boron and sometimes molybdenum and silicon. Hardness of the deposited material varies according to composition between 300 and 720 VPN, and wear resistances can be obtained superior to other materials at room temperature but inferior to cobalt alloys at high temperature or in resistance to aqueous environments.

7.4.6 Zinc and its alloys

7.4.6.1 Introduction and standards

Zinc owes its commercial applications to three characteristics:

1. Zinc components are essentially low priced. The metal requires less energy to produce and to cast than any of its competitors and is cheap to machine.
2. It has quite exceptional corrosion properties. Only aluminium, magnesium and the alkali metals are anodic to it so that it will protect all other metals sacrificially and can be

[b] Nitinol is the designation of the Naval Ordnance Laboratory, Washington, DC, USA.

used as the anode in an electrolytic cell, but in normal atmospheres it forms a protective film which is penetrated only about 0.01 mm/yr in the worst industrial atmospheres.

3. Its low melting point makes it exceptionally suited as a material for die casting. Its drawbacks are that it is relatively soft and weak, has poor creep resistance and its hexagonal structure makes it brittle at room temperature.

Zinc's major uses are:

- As a coating to protect steel
- As a base for casting alloys
- As a sheet material for battery cases and roofing.

Standards covering zinc metal include:

BS 1004 and ASTM B669. Zinc alloys for casting
BS 3436 Ingot zinc and ASTM B6 Zinc
BS 5338 Code of practice for zinc alloy pressure die casting
ASTM B69 Rolled zinc
ASTM B 418 Cast and wrought galvanic zinc anodes for use in saline electrolytics

7.4.6.2 *Zinc-based casting alloys*[49,50]

Zinc-base alloys may be used for all types of sand, investment, gravity and pressure die casting. Melting is clean and easy, casting is less sensitive to problems of oxide inclusions, misruns and voids, finish is superior, wall thicknesses can be thinner, detail sharper, and shapes more complex than with such competitive materials as aluminium and copper alloys and cast irons. Zinc alloys have excellent machinability and less machining is required than with castings in other metals. Complex shapes can therefore be produced more cheaply in them than in any other metallic material. A further advantage of the zinc alloys is that for those low-speed bearing applications for which copper alloys have traditionally been used there are indications that zinc casting alloys perform better than leaded gunmetal.

Casting alloys, which usually have aluminium as their main alloying element, are commonly known by their 'ZA' numbers.[51,52] Their composition and properties are listed together with those of competitive materials in Table 7.46.

7.4.6.3 *Alloy development*

Zinc-base alloys early developed a poor reputation because some castings disintegrated in service and electroplate sometimes showed poor adherence. The cause of disintegration was traced to the presence of heavy metals, iron, lead, cadmium and tin, which are held strictly to acceptable limits in modern high-purity zinc and research on plating eliminated the problems of adherence.

Alloys ZA3 and ZA5 are very suitable for hot-chamber high-pressure die casting because the molten metal has a very low affinity for iron and there is very little wear on the dies. Castings in these alloys are therefore inexpensive to produce and very suitable for complex lowly stressed components.

Increase in aluminium content very significantly increases strength but also increases aggressiveness to iron so that above 8% (the aluminium content of ZA8) the alloys cannot be hot-chamber die cast. Although more expensive in the form of components, the higher aluminium casting alloys are more than competitive with cast iron, copper and aluminium alloys in situations where their low hot strength is not detrimental. ZA12 should not be considered for stressed applications at or above 120°C but the ASME boiler code design stress for ZA27 at 150°C (which is the stress required to produce a secondary creep of 1% in 100 000 hours) is 69 MPa. As long as these limitations are observed, ZA12 and ZA27 have a potential market for components for mass-produced cars equivalent to that of magnesium alloys for high-performance sports cars.[53]

7.4.6.4 *Wrought zinc alloys*

Zinc is available in the form of sheet, extrusions (and forgings) and wire. Sheet zinc is used mainly for roofing and as anode cans in the common dry cell. Roofing zinc can be pure, or the more creep-resistant zinc copper or zinc titanium alloys which are an economic replacement for copper or lead. Zinc strip for battery cases contains approximately 0.5% lead and zinc plate for photo-engraving (an important application), 0.2% lead and 0.2% cadmium. Seventy-eight per cent zinc, 22% aluminium sheet can be made superplastic and drawn and stretched into shapes that require a very high degree of deformation.

Extruded zinc is available as the copper–titanium alloy. These alloys are used for architectural purposes in conjunction with roofing or walling sheet, but their applications have been largely superseded by plastics. A major remaining application for pure extruded (or sheet) zinc is as sacrificial anodes to protect steel ships or buried pipes.

Zinc wire is largely used for spray metallizing but is available for nails, hooks, gauze and similar wire products and for solder.

7.4.6.5 *Zinc coating for corrosion protection*

The major use for zinc is as a coating on steel for corrosion protection. Zinc operates in two ways. Its room-temperature oxidation product is adherent (as opposed to that of steel in moist conditions) but after it has eventually been penetrated it protects the underlying metal electrochemically. It makes an excellent base for paint. There are three types of zinc coating:

- 'Hot dip galvanizing' is achieved by immersing the steel in a bath of molten zinc. The zinc and steel form an alloy at the interface.
- 'Electrogalvanizing' is achieved by electroplating zinc through an aqueous electrolyte. The thickness of coating is more uniform but usually thinner than that produced by other methods.
- 'Sherardizing' (heating the component to 370°C in zinc powder) produces a layer of uniform thickness.

'Zalutite' (a trademark of BSC), 55% aluminium, 43.5% zinc and 1.5% silicon coated steel, combines the protection of zinc and aluminium and, in many environments, is superior to galvanized.

7.4.7 Lead, tin and their alloys

7.4.7.1 *Introduction*

Lead and tin are soft metals with low melting points. Lead is used pure or strengthened by alloying with antimony for roofing, cable sheathing, radiation shielding, battery electrode and chemical plant materials. Both lead and tin alloys are used for bearings.

Alloys of lead and tin have melting points lower than those of either metal and may be further alloyed with antimony and bismuth to reduce the melting point still more or to confer other properties. Tin is used for coating steel and may be alloyed with lead for this purpose.[54]

[a] Preliminary data.

7.4.7.2 *Nomenclature and standards*

Chemical lead: BS 334: Type A: Pure lead
Type B1: Copper lead
Type B2: Copper tellurium lead
Type C: Antimonial lead
ASTM B 29: Pig lead

White metal-bearing alloys (Babbitt metal): BS 3332 and ASTM B23
Solder metal: ASTM B 32
Tinplate: BS 2920

7.4.7.3 *Lead in corrosion service*

Lead forms adherent corrosion products which may be sulphate, oxide, carbonate, chromate or more complex compounds. These coatings protect the base alloy and have led to its use for roofing, underground pipes and contact with sulphuric, sulphurous, chromic and phosphoric acids. The two main drawbacks of lead are its toxicity, which has caused its withdrawal from all applications associated with potable liquids and its low creep strength.

Antimony additions increase both the UTS and the creep strength of lead. The tensile strength of pure lead is about 15 MPa and the stress to cause 1% creep per year at 30°C about 2.1 MPa. Lead containing 8% antimony has a tensile strength of 60 MPa and a stress to cause 1% creep per year at 30°C of 2.7 MPa.

7.4.7.4 *Bearing metals (babbitts)*

'Babbitt'-bearing metals contain up to 90% tin with antimony, copper and in some cases lead, or up to 90% lead with antimony and tin. Their important characteristics are 'anti-seizure' properties and 'fatigue resistance'.

Anti-seizure properties imply that the material is readily wetted with oil, but that, should the oil film break down, the material will not adhere to a steel journal but flow out of the way locally and embed and cover any hard particle which may have gained access. Both lead and tin have these characteristics.

Fatigue resistance in a bearing implies that the material will, when the bearing is subjected to an alternating load, resist the formation of cracks that initiate at right angles to the bearing surface, propagate almost to the backing and then turn at right angles to form 'loose tiles' that will erode away. Traditional tin-base babbitts were considered to have greater fatigue resistance than lead base but it is now appreciated that lead is superior if is made thin enough, preferably down to a thickness of 0.125 mm.

Both tin- and lead-base babbitts are easy to cast, easy to bond to the backing and easy to machine. They are useful for low-duty bearings made in short production runs. They have, however, been supplemented by other types of bearing for high-duty service and mass production. Often a very thin layer of pure lead bonded to the surface of a stronger support material is used.

7.4.7.5 *Low melting-point alloys*

Solders are alloys of tin and lead in varying proportions (for example, 38 Pb 62 Sn for tinman's solder and 66 Pb 34 Sn for plumber's solder). There are a number of lead–tin alloys with bismuth or antimony whose applications depend on their low melting points. The most important are the type metals which contain from 12% to 30% antimony. Antimony expands on solidification and an alloy containing between 20% and 30% of this metal has a negligible contraction and produces a clear typeface.

Tin and terneplate Electrolytic or immersion tinplate has been used to protect steel sheet used mainly in the food industry. For other than food products, terneplate (which contains 10–25% tin, remainder lead) is supplanting tinplate, largely on a cost basis but also because the lubricity of lead assists drawing and forming operations.

7.4.8 Cobalt and its alloys

7.4.8.1 *Introduction*[55,56]

Cobalt is a soft, silvery metal readily corroded by aggressive environments but properties developed by alloying include a high coercive force, exceptional resistance to corroding and oxidizing environments at ambient and elevated temperatures, exceptional hardness and wear resistance and high hot strength. It can also be transmuted by irradiation with neutrons to Co-60 which emits 7×10^6 eV γ-rays and is used for high-penetration radiography.

Its major drawbacks are its high cost and the distribution of its ores which are found in politically unstable countries. Also, its alloys compare unfavourably in high-temperature strength to those of nickel (see below).

7.4.8.2 *Applications of cobalt alloys*

The major application of cobalt is as a permanent magnet material. Alnico 5, 24% Co, 14% Ni, 8% Ai, 3% La, 51% Fe has, for example, retentivity B_r 12 500 Gauss and coercive force H_c 550 Oersteds. Cobalt is also a constituent of high-permeability magnets. Permendur has saturation induction B_s 24 500 Gauss and coercive force H_c 2 Oersteds.

The next most important group of applications are those which depend on strength, hardness and corrosion resistance at room and elevated temperatures. These include gas-turbine materials, furnace hardware and wear-resistant and spring alloys. Almost all of these materials are based on an alloy containing between 20% and 30% chromium to which are added other constituents conferring specific mechanical properties.

Because cobalt is a high melting-point metal with no allotropic modifications its prospects as a high creep-strength material for aircraft turbines would appear highly favourable. Unfortunately, no strengthening mechanism comparable with the γ'-precipitation process in nickel has been found. This deficiency might be overcome by the development of a creep-resisting composite but there is little incentive to develop such a material on a base whose supply might fail in an emergency. Nickel has therefore supplanted cobalt as a gas-turbine material. The deformation, corrosion and oxidation resistant characteristics of the cobalt superalloys, LG05, HS188, UMCo50 and stellite 250 have led to their extensive application as furnace hardware.

There are a number of dental and prosthetic alloys specified in ANSI/ASTM F75–76 for cast alloys and ANSI/ASTM F90–76, F562–78, and ASTM F563–78 for wrought alloys. BS 3561: Part 2: 1980 includes both cast and wrought.

Cobalt alloys are superior for dental purposes to gold because of their higher strength and lower specific gravity. The decision as to which cobalt alloy to use for prosthetic purposes, or whether to use surgical stainless steel, titanium or tantalum instead depends on the preference of the surgeon.

Cobalt-based wear-resistant products are, in effect, alloys of cobalt/20% chromium with tungsten carbide. They are available to a number of designations depending on the wear and other characteristics required and in forms which include castings, forgings, powder for compaction and hard-facing consumables (see References). The most comprehensive classification is that of the Australian Welding Research Association (AWRA).

Cobalt is also the basis for a number of alloys for springs ('Elgiloy' or 'Cobenium'), low-expansion corrosion-resistant alloy ('Stainless Invar') and alloys with low-temperature coefficients of modulus of elasticity.

7.4.9 Other non-ferrous metals

There are some 28 non-ferrous metals not considered individually. Many of them are used as alloying additions to the metals described in Sections 7.3.1–7.3.7. Only those which form the major constituents of alloys will be considered here.[57–59]

7.4.9.1 *Metals used for alloying steels*

Tungsten has the highest melting point (3410°C) of any metal and the highest strength at elevated temperatures. The UTS (of 1 mm dia. wire) is approximately 2600 MPa at room temperature and 30 MPa at 2800°C. It has good corrosion resistance but oxidizes in air at temperatures over 500°C.

Tungsten is normally fabricated by powder metallurgical techniques but can be cast by vacuum arc or electron beam. Its applications depend on its high-temperature properties in protective atmospheres and include:

- Electric light filaments. These are made by a powder metallurgy technique incorporating an oxide which restricts grain growth so that the filament consists of a bundle of single crystals each of which is continuous along the length of the filament.
- Electrodes in electron tubes.
- Electrodes for inert gas welding. For this and the previous application, thorium oxide may be incorporated to promote ionization and the smooth striking of an arc.
- Electrical contact materials for highly repetitive and continuous arcing applications. Tungsten has outstanding resistance to arcing, welding or sticking. It has, however, a tendency for the positive terminal to oxidize, which can be prevented by substituting palladium or platinum for this terminal only.

Molybdenum[60] has many of the high-temperature characteristics of tungsten but its melting point (2610°C) is lower and its high-temperature strength, although good, does not compare with that of tungsten. Like tungsten, it oxidizes in air above 500°C unless protected. It is, however, more ductile and more easily fabricated. It is highly resistant to liquid media including glasses and molten metals, but is attacked by oxidizing agents. It is fabricated by consumable arc melting. Molybdenum's applications include:

- Electrical and electronic parts.
- High-temperature furnace parts (particularly for vacuum furnaces).
- Glass-melting furnaces.
- Hot-working tools.
- Dies and cores for die casting.

Chromium[61] is a light, silvery metal which is highly resistant to oxidation and to many corroding media, but not to hydrochloric acid. It is, however, extremely brittle (the production of ductile chromium has been reported but not followed up) and this restricts its use. Applications are:

- Mirrors.
- X-ray targets.
- Decorative and wear resistant electroplate.

The hardness of electroplated chromium depends on its hydrogen content and may be up to 1200 VPH as-plated reducing to 70 VPH annealed. Chromium has a low coefficient of friction; 0.12 sliding, 0.14 static and can be plated in a porous form to retain oil.

Tantalum and *niobium* have excellent fabricability, high hot strength and a low ductile brittle transition but oxidize in air above 300°C. Tantalum is used for chemical plant liners, surgical implants and, because of the electrical properties of its oxide film, for rectifiers and capacitors.

7.4.9.2 *Precious metals*

The precious metals have very high resistance to oxidation and corrosion. They include:

- The platinum group metals: platinum, palladium, iridium, rhodium, osmium and ruthenium, which have high melting points, (1760–3050°C), high strengths and excellent dimensional stability at elevated temperatures; and
- Gold and silver, which have low melting points (1063°C and 961°C, respectively) and are soft and ductile.

Precious metals are specified for applications which demand extreme reliability or absolute freedom from corrosion and those in which high recovery value and long trouble-free service offset a high original cost. Applications of specific precious metals include:

- *Silver*
  Electrical conductors which, unlike copper, do not oxidize at elevated temperatures and contacts.
  Corrosion-resistant containers for food processing (now largely superseded by stainless steels).
  Bearings.
  Ornaments and jewellery (sometimes as plates).
  High melting-point solder.
- *Gold*
  Instruments requiring corrosion resistance.
  Conductors for transistor circuitry.
  Dentistry.
  High melting-point solder.
  Coinage, jewellery and ornamental uses.
- *Platinum* (and, to a lesser extent, *palladium*)
  Catalyst, particularly for automobile exhaust systems and chemical synthesis.
  Furnace windings.
  Laboratory crucibles and containers.
  Resistance thermometers and thermocouples.
  Linings for optical glass and fluoride process plant.
  Electrical contacts.

Iridium and rhodium are used mainly as alloying agents for platinum, but pure iridium has been used for the manufacture of high-quality glass and rhodium as an electroplate having even more resistance than platinum. Osmium and its alloys have very high hardness (approximately 800 VPH), resistance to wear and corrosion and moduli. They are used for fountain-pen nibs, record-player needles, instrument pivots and electrical contacts.

7.4.9.3 *Nuclear metals*

Nuclear metals are divided into 'fissile', fertile', 'canning' and 'control' materials. Fissile metals undergo fission when irradiated by neutrons, disintegrating into two major fission products, a number of neutrons which serve to carry on the chain reaction, other particles and energy including γ-radiation. Fissile materials include U-235 (a constituent of natural uranium), U-233 (a product of neutron capture by thorium) and *plutonium* (a product of neutron capture by U-238, the major constituent of natural uranium). They constitute the fuel in nuclear reactors. 'Fertile' metals include U-238 and *thorium*. They are incorporated into nuclear reactor fuel or used separately in 'blankets' to absorb neutrons and produce additional fissile material. 'Canning' metals are used to contain nuclear fuel in a reactor, maintain its integrity and dimensions, protect it from attack by the coolant, retain fission products so that they do not contaminate the coolant (and, through it, the environment), transfer the heat produced efficiently and absorb a minimum proportion of neutrons. Canning and core structural materials now in use include *stainless steel* for sodium-cooled and high-temperature gas-cooled reactors, *magnesium alloy* for the original 'magnox' reactors, *zirconium* for pressurized water and boiling water-cooled power reactors and *aluminium* for water-cooled research reactors.

Zirconium[62] occurs naturally together with *hafnium*, which has high neutron-absorbing properties. These must be separated by a complex chemical process before they can be used in water reactors: zirconium as a core structural material, hafnium as a control rod material. Both have excellent resistance to pressurized water attack if they are suitably alloyed and satisfactorily pure.

Beryllium combines a very low nuclear capture cross section with good strength and hardness at moderately high temperatures. It appeared to have great promise as a canning and core structural material but the promise has not been fulfilled mainly because of its lack of ductility and resistance to environmental attack and partly because of doubts concerning the effect of helium, which is produced when beryllium is irradiated by neutrons. The applications of alloys based on beryllium are confined to those such as spacecraft, where its high specific strength outweighs its high cost and hazard to health. (Its oxide causes 'beryllicosis', similar to silicosis but more virulent when ingested by breathing.)

7.4.9.4 Metals used in integrated circuits

Silicon and *germanium*, which when pure are very poor electronic conductors of electricity, can be transformed by 'doping'. Introducing into the lattice pentavalent elements, phosphorus, arsenic or antimony creates free electrons and gives rise to negative or *n*-type conductivity. Introducing trivalent elements boron or aluminium reduces the number of electrons to form 'holes' and gives rise to positive or *p*-type conductivity.

Junctions between regions of these two conductivity types are called *p-n* junctions. These are at the heart of most semiconductor devices: diodes, transistors, solar cells, thyristors, light-emitting diodes, semiconducting, lasers, etc. By taking a slice of highly pure single-crystal silicon, diffusing into it *p*- and *n*-type atoms in a geometrical pattern controlled photographically and then insulating or interconnecting regions by metallization, circuits with millions of components can be formed on one silicon chip.

Highly pure, zone-refined single-crystal silicon has completely superseded germanium for the manufacture of transistors and silicon integrated circuits. The quantity used is small, amounting only to tens of tons per annum, but its technological importance is enormous.

7.5 Composites

7.5.1 Introduction

A composite is a combination of two or more constituents to form a material with one or more significant properties superior to those of its components. Combination is on a *macroscopic* scale in distinction to alloys or compounds which are *microscopic* combinations of metals, polymers or ceramics. Those properties that may be improved include:

Specific gravity
Elasticity and/or rigidity modulus
Yield and ultimate strength and, in the cases of ceramics and concrete, toughness
Fatigue strength
Creep strength
Environmental resistance
Hardness and wear resistance
Thermal conductivity or thermal insulation
Damping capacity and acoustical insulation
Electrical conductivity
Aesthetics (attractiveness to sight, touch or hearing)
Cost

Not all these properties can (or should) be improved at the same time, but the consideration which governs the choice of a composite is that a critical property has been adequately improved, while deterioration in other properties has not been significant.

Usually (but not invariably) a composite consists of a matrix which is relatively soft and ductile containing a filler which is harder but may have low tensile ductility. The use of composites has persisted ever since tools of wood or bone (which are naturally occurring composites) were used by primitive humans. The earliest human-made composite was probably straw-reinforced mud for building. The Egyptians invented plywood, an early example of the improvement (which continues to the present day) of the natural composite, wood.

There are two ways of classifying composites: according to either the material of the matrix or the geometrical distribution of the components. Composites classified according to geometry include:

Particulate composites which are distributions of powder in a matrix;
Laminar composites which comprise layers of two or more materials;
Fibrous composites which comprise a matrix that is usually relatively soft and ductile surrounding a network of fibres which are usually stronger but may be brittle relative to the matrix. The fibres may be short and their orientation effectively random or they may be long and carefully aligned. Composites with long fibre reinforcement are known as 'Filamentary Composites' and the fibres may be aligned on one, two or three directions.

Composites classified according to matrix include:

Fibre-reinforced or powder-filled polymers
Concrete, reinforced concrete and prestressed concrete
Wood and resin-impregnated wood
Metal matrix composites
Fibre-reinforced ceramics and glasses
Carbon fibre-reinforced carbon

Of these, reinforced concrete probably has the greatest industrial importance but fibre-reinforced polymers have the greatest technological and engineering interest and the major part of this section will be devoted to them. Some other classes of composite will be described briefly and their properties and applications outlined.

7.5.2 Reinforcing fibres

Reinforcing fibres may be long (even continuous) and carefully aligned, or short with only the limited degree of alignment that is produced by flow during fabrication. The ability to control directional properties by the use of long fibres has opened up new fields in design, particularly for aerospace. Fibre material may be glass, ceramic, high-modulus polymer, carbon, boron or metal. Most types of fibre are manufactured and used in long lengths but the cheaper materials may be used in short lengths. In the case of glass the fibres are manufactured long but may be chopped. Some ceramic fibres, notably alumina, can be produced short or long depending on the technique of manufacture.

The most widely used glass fibres are 'E glass', a non-alkaline alumino borosilicate of average composition SiO_2, 54; Al_2O_3, 14; B_2O_5, 8.5; CaO, 18.5; MgO, 4; rare earth oxide, 0.8. This material was originally developed for electrical insulation and represents a compromise between mechanical property considerations and ability to form fibres from the melt. Fibres are made by feeding the liquid glass through a multitude of orifices to form up to 4000 filaments approx. 20 μm dia. in one strand of roving. E-glass fibres have a specific gravity of 2.5 and a breaking strength of 2.6 GPa, higher than that of massive glass probably because discontinuities are less severe. However, their modulus of 86 GPa is low and this makes it difficult to utilize the high tensile strength in design because of the danger of buckling and the high elastic deformation.

Glasses with higher strength and slightly higher modulus are available but it is more difficult to manufacture fibre from them. Quartz fibres have excellent high-temperature strength but must be drawn individually from heated rod, and are therefore expensive.

E-glass cannot be used to reinforce concrete because it is attacked by alkali. Glass in which the alumina is replaced by zirconia is more difficult to convert to fibre, but retains its strength much better in concrete and is marketed by Pilkington under the name of 'Cemfil', as a substitute for asbestos, which may no longer be used. The specific gravity of Cemfil is 2.5, its UTS 3.6 GPa and its elastic modulus 75 GPa.

The most extensively used oxide fibre is alumina prepared by spinning or extruding an aqueous solution of a precursor, aluminium hydroxide/chloride, with a slurry of alumina in suspension. Spinning produces relatively short staple fibre 2–4 cm long in blanket form; extrusion produces continuous filament. Small amounts of silica may be present. The spun or extruded fibre is converted into alumina by heating and may have UTS up to 1.8 GPa and elastic modulus up to 380 GPa. Alumina fibres have no application for resin matrix composites but their high-temperature strength makes them an attractive constituent of metal matrix composites and they have been used both in the staple form and as whiskers.

Carbon and graphite fibres are made by spinning a precursor filament, usually polyacrylonitride (PAN), which is then heat treated while being subjected to tensile stress. The heat treatments include stabilization, oxidation, pyrolysis and graphitization at temperatures increasing from around 200 to 3000°C. Fibres with tensile properties ranging between 3.4 GPa UTS, 235 GPa elastic modulus and a breaking strain of 1.5% (for Courtauld's Graphil AXS) and 2.5 GPa UTS, 340 GPa elastic modulus with a breaking strain of 0.6% (for Graphil HMS) may be obtained in the more expensive grades by varying the temperatures and stress applied. The production of carbon fibres is illustrated schematically in Figure 7.55. Cheaper grades are available with inferior properties. Cheaper precursors for carbon fibre include cellulose and pitch of high-aromatic low-impurity content.

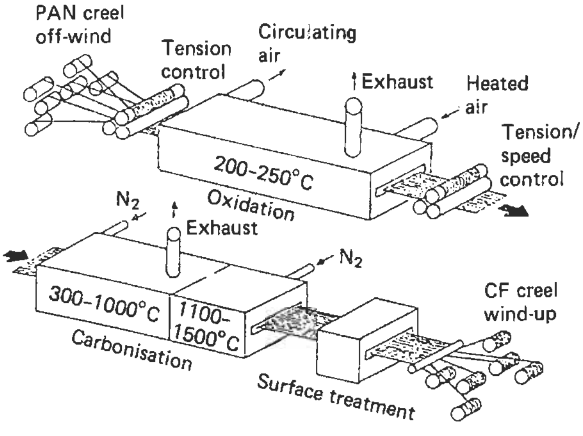

Figure 7.55 Schematic production of carbon fibre. (Reproduced by courtesy of North-Holland Publishing Company)

Boron filaments B/W Fibres 95–200 μm diameter are manufactured by the chemical deposition of boron from a gaseous mixture of boron trichloride and hydrogen at betwen 1000 and 1300°C on a 12.5 μm diameter tungsten wire. B/C fibres have been made experimentally by deposition on carbon filaments. The tensile strength of B/W fibres range from 3.4 to 3.9 GPa, their elastic modulus is 390 GPa and their specific gravity 2.5. Although the ductile properties of boron fibres are no better than those of a ceramic they do not suffer long-time loss of strength and their creep properties are superior to those of tungsten. They are the strongest and stiffest fibres at present used for composite reinforcement.

Silicon carbide fibres are manufactured by spinning high molecular weight polycarbon silane fibres at between 200°C and 300°C, curing in air at 200°C and heat treating at 1250°. Depending on the grade of precursor, fibres 10 μm diameter may have UTS between 2 and 3 GPa and elastic moduli between 150 and 200 GPa. They have excellent high-temperature strength and useful electrical properties.

Para-orientated aromatic polyamide (Aramid) fibres are manufactured by spinning a liquid crystalline solution (or 'dope') of their sulphuric acid ester to form highly ordered domains of extended polymer chains. This structure confers a much higher modulus than is common in polymers and is the basis of the commercial exploitation of polyparaphenylene teraphthalamide (Kevlar) fibres. After spinning, the 'dope' is spun into fibres, coagulated in an aqueous bath at low temperature, stretched, washed, dried and heat treated at temperatures between 250°C and 550°C. The resultant fibres have specific gravities around 1.45, UTS 2.64 GPa, moduli between 59 GPa and 127 GPa and breaking strains between 2.8 and 4.0%.

Fibres with moduli up to 60 GPa can be made from polyolefins and polyoxymethylene. Metal-reinforcing fibres include carbon, alloy and stainless steels, tungsten, niobium and tantalum. The characteristics and properties of these materials are described in Section 7.3. The properties of fibres and whiskers appropriate for use in composites are listed in Table 7.47.

7.5.3 Polymer matrices

The essential qualities of a matrix material are the ability to infiltrate among and bond strongly to reinforcing fibres. After

Steel	High tensile		7860	200	2 000	0.25	3.1	3	Concrete matrix
	Stainless		7860	160	1 700	0.22	2.5	3.5	Polymer matrix

these criteria have been met it should set as quickly as possible to a strong and heat- and environment-resisting solid. Polymers share with concretes the advantage over other possible matrix materials that they fulfil these requirements at a relatively low processing temperature. There are two classes: thermosetting and thermoplastic polymers (see Section 7.4). Thermosetting resins compounded with a hardener may be infiltrated between fibres while liquid and allowed to harden at room or elevated temperature. They include unsaturated polyesters, which are relatively cheap and easy to work but do not bond well to fibres and have a relatively high shrinkage. These are used for large and comparatively low-duty composites, usually with glass reinforcement.

Epoxide resins are the most extensively used matrix materials for high-duty carbon, boron and aramid fibres. They perform excellently at temperatures up to the region of 160–200°C.

Thermosetting resins which have been used as matrices operating at higher temperatures include phenolics, phenol arakyls and the recently developed polyphenylene quinoxialine. Resins which are beginning to replace epoxides for high-temperature service with carbon reinforcement are bismaleides (BMI) and polyimides (PI) which have continuous service capabilities of 200°C and 300°C respectively. (Some polyimides have survived short exposures to 760°C.) These polymers are, however, difficult to handle and polyimides in particular are expensive and require high cure temperatures.

Thermoplastic matrix materials are tougher than thermosets, have an indefinite shelf life, the semi-finished composite can be hot formed and in some cases have better high-temperature and solvent resistance. However, the molten polymer has a higher viscosity than an uncured thermoset, fabrication temperatures are high and some are expensive.

Many thermoplastics have been used, ranging from the cheapest (nylon) to the highly expensive polyamide imide (PAI) and polyether-ether ketone PEEK. PEEK composites have a maximum service temperature of 250°C, a work of fracture up to thirteen times that of epoxide composites and significantly better fatigue resistance, but are expensive.

7.5.4 Manufacturing procedures for filamentary polymer composites

Filamentary composites are manufactured by 'lay-up', a term used for positioning the fibres and matrix to form the shape of the final component. Lay-up may be accomplished by 'pultrusion', 'winding' or 'laying', 'tow', 'tape', 'cloth' or 'mat'. In none of these forms are the fibres twisted to form a yarn. All forms of sub-assemblies can be obtained as 'prepregs' saturated with the resin which is later to form the matrix.

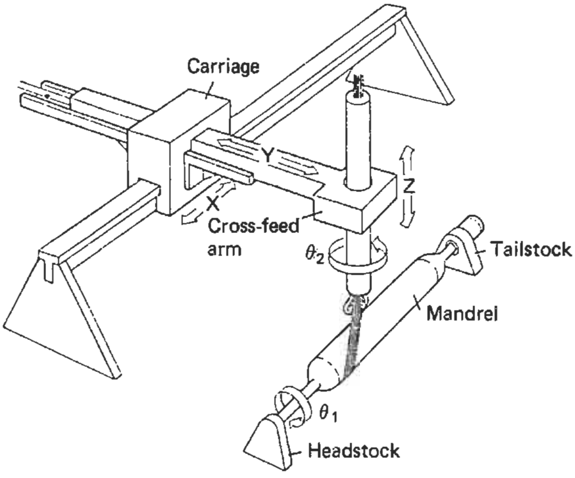

Figure 7.57 Gantry type five-axis filament winding machine. (Reproduced by permission of *Metals and Materials*)

In *pultrusion* (see Figure 7.56) the reinforcing fibres are used to pull the material through a die.

In *winding*, impregnated single filaments, rovings or tapes are wound onto a former or mandrel. Figure 7.57 shows a winding machine which may be computer controlled to produce any convex shape from which the mandrel can be removed. Filaments may be orientated according to the pattern of stresses that are to be withstood.

Cloth winding or laying utilizes pre-impregnated cloth which is deposited in the desired form and orientation. The bidirectionality and convolutions of the fibres in cloth make for lower precision in strength and stiffness. Cloth laying is therefore often used for filling where strength and stiffness are not critical. *Moulding* can start with a deposition of pre-cut layers of prepreg fibres which are compressed at elevated temperature to form the final laminate. *Continuous lamination* is the application of pressure by rolling to bond layers of prepreg cloth or mats.

7.5.5 Properties of filamentary polymer composites

Filamentary polymer composites consist, in principle, of 'laminae' which are assembled into 'laminates'. A 'lamina' is a flat or curved assembly of unidirectional fibres in a matrix. It is

highly anisotropic, having low stiffness and strength transversely (see Table 7.48).

Laminae of varying orientations are therefore superimposed in a stack to form a 'laminate' with directional properties tailored to match the stress. Laminates are therefore essentially two-dimensional structures (the 'dimensions' may be curved when the component is a cylinder or sphere) and the mechanical properties in any of the principal directions of a laminate are inferior to those in the principal direction of one of the constituent laminae. Additionally, the thermal stresses which arise on cooling from the curing temperature may impair strength.

Three-dimensional reinforcement such as is employed in carbon/carbon composites (see Sections 7.5.8 and 7.5.11) is not normally applied to laminated plastics and shear and transverse tensile stresses can result in delamination.

The matrix supports, protects, distributes load among and transmits load between the fibres. If a fibre should break the matrix, stressed in shear, transmits load from one broken end to the other and to adjacent fibres. Because boron or graphite fibres in a polymer matrix provide by far the greater proportion of strength and stiffness, composites with these fibres can, in most cases, be considered to be linear elastic materials. In composites with glass or aramid fibres the lower modulus results in the matrix bearing a higher proportion of the load and the stress strain relation may depart from linearity. Elastic and physical properties may, in the case of high-strength composites, be calculated from classical theory.[63] Strengths are more difficult to calculate because the secondary stresses induced in a composite may exceed the transverse shear strengths and may themselves cause failure.

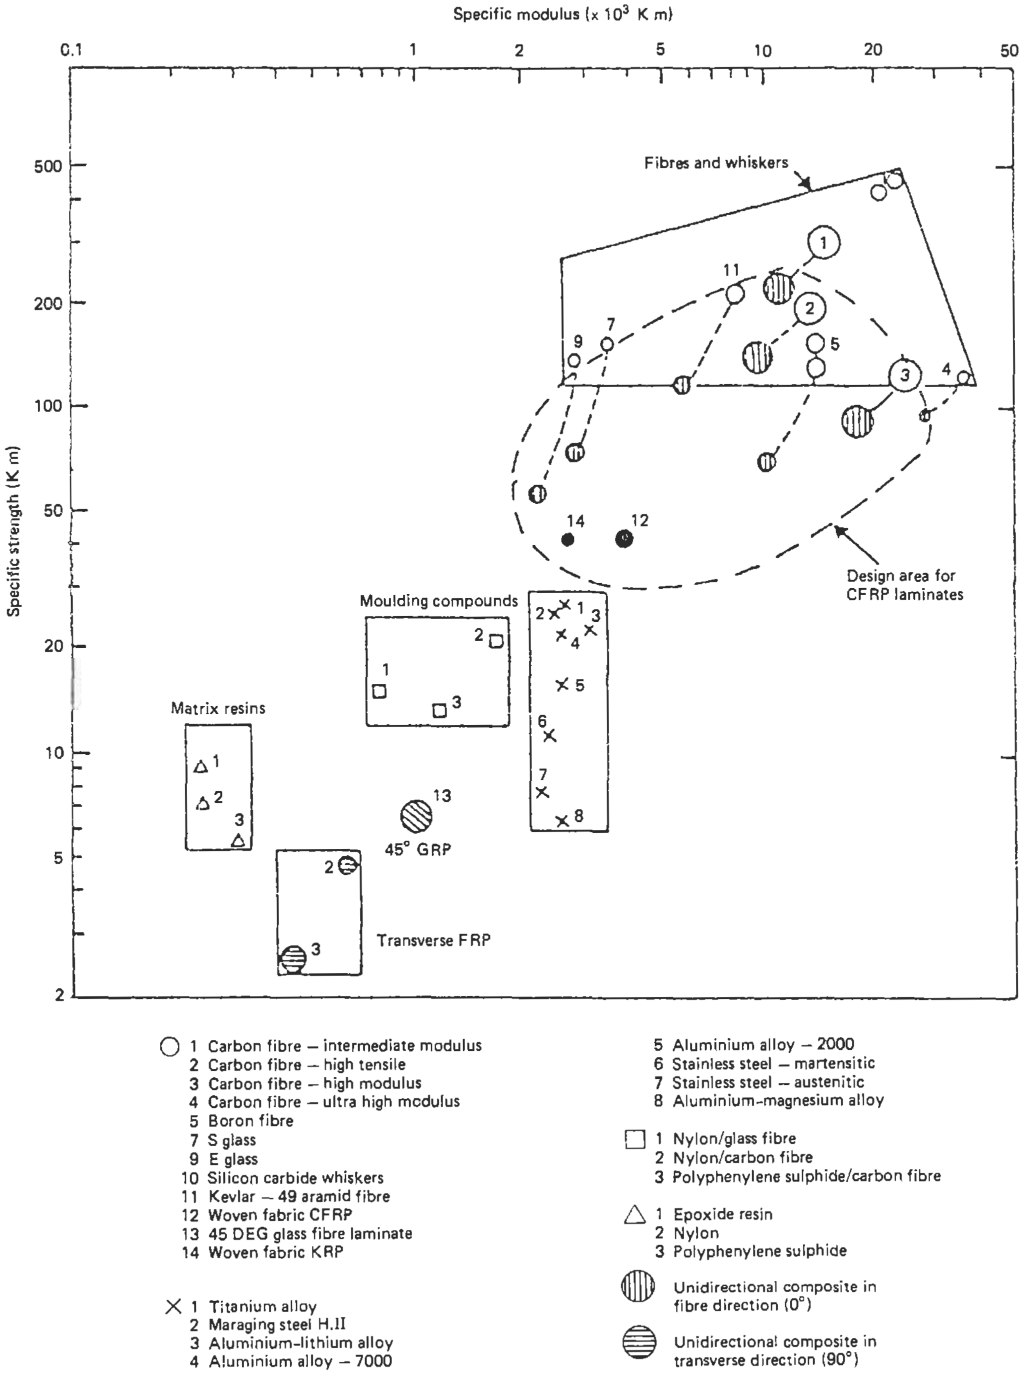
The parameters which must be taken into account in design include:

1. *Elastic properties*: Longitudinal Stiffness E_{11}, Transverse Stiffness E_{22}, In-Plane Shear Modulus G_{12}, Poisson's ratio ν_{12}.
2. *Strength properties*: Longitudinal Tensile Strength $\sigma_{1,T}$, Transverse Tensile Strength σ_{xr}, Longitudinal Compressive Strength $\sigma_{1,c}$, Transverse Compressive Strength $\sigma_{2,c}$, Yield Strength σ_y, In-plane Shear Strength $T_{1,2}$.
3. *Physical properties*: Specific Gravity SG, Longitudinal Thermal Expansion Coefficient α_1, Transverse Thermal Expansion Coefficient α_2, Longitudinal Thermal Conductivity k_1, Transverse Thermal Conductivity k_2.

The Specific Strengths and Moduli of Fibrous Composites and other engineering materials are illustrated diagramatically in Figure 7.58. (In this figure specific properties are derived by dividing the modulus or strength by the density and a gravitational term of 9.81.)

The fatigue processes which occur in composites differ fundamentally from those in metals, and, providing that they are well understood, offer very significant advantages to the designer. High-modulus fibres such as carbon and boron confer excellent tension/tension fatigue properties, the fatigue stress at 10^7 cycles of longitudinal boron epoxy being only 15% less than the tensile stress. This is because the high-modulus fibres limit the stress in the lower-modulus matrix and so protect it from fatigue damage.

However, in those plies in which fibres are orientated transverse to the principal cycle stress the matrix is subjected to transverse tensile and shear stresses which cause cracking



(Average values only – check individual value at source)

parallel to the plies and delamination. The effect of fibre orientation on CFRP laminates is shown in Figure 7.59.

Only glass composites have a steep *S-N* slope, presumably caused by the diffusion of moisture which causes cracks to initiate in the glass fibres. Even so, the *specific* fatigue resistance of longitudinal fibreglass is far superior to that of any metal.

A further advantage of composites subjected to fatigue is that, whereas in metal fatigue there is, during the greater part of the life of a component, no superficial evidence of deterioration, there is in filamentary reinforced plastics a slow and progressive deterioration revealed at an early stage by a decrease in modulus or an increase in cracking in specific plies which is easily detectable by non-destructive examination. This reduction in modulus could, if allowed to continue, lead to failure by buckling, but both because of the higher specific fatigue strength and because of the more obvious incidence of failure, catastrophic fatigue failures in filamentary composites are much less likely than in metals.

The assessment of the influences of impact on filamentary composites is more complex than metals because of their anisotropy and large number of failure mechanisms. Where, for example, in a jet engine a titanium blade will shear undamaged through the body of an intruding bird, a composite blade of equivalent strength will shatter. It can be stated that, in terms of impact strength, for composites the common fibres may be ranked in order of superiority:

1. Kevlar 29, Glass
2. Kevlar 49, boron
3. High-tensile carbon
4. High-modulus carbon

The resistance to attack of polymers depends on the specific polymer and its environment. Traditional matrices based on polyesters, vinyl esters and epoxides perform very successfully in atmosphere, soil and many items of chemical plant. Protection may, however, be needed against degradation by ultraviolet radiation from sunlight. Some polymers, including fluoroplastics PTFE and PDF and polyether ether ketone PEEK have exceptional resistance to radiation damage and may be used as matrices and as coatings.

7.5.6 Applications of filamentary polymer composites

The cost of GFRP is of a similar order to steel and aluminium or timber and where its lightness and corrosion resistance are advantageous, and its fabrication methods suitable for the specific component, it is used. Applications include small boats (and not so small minesweepers), roofing and cladding for buildings and many components for road and rail transport.

Other uses of GFRP are promoted by one or more specific property parameters. It is, for example, displacing steel for vehicle leaf springs on account of its lightness and fatigue resistance. It is replacing porcelain and glass for electrically insulating components on account of its strength and insulating properties. It is replacing steel for aqueous liquid vats, tanks and pipes because of its lightness, strength and corrosion resistance.

High-performance composites are used in aerospace or sport, where the requirement for the specific stiffness and/or specific strength justifies the increased cost. The aerospace applications of CFRP include the basic structures of spacecraft and commenced with ancillary fittings, floors and furniture of aircraft, but is now extending to major structural items such as stabilizers, tailplanes and fins. Future fighter aircraft will probably contain a high proportion of CFRP and will benefit from a reduced sensitivity to radar.

High-performance sports goods are also increasingly made of CFRP because the reward of coming first in a race (or a fishing contest) far outweighs the additional cost of a CFRP racing-car skin or a CFRP fishing rod compared with any conceivable alternative material, except possibly boron-fibre (BF) reinforced composites.

The combination of a specific tensile strength around 0.8 and modulus around 105 GPa m^3 kg^{-1} can only be obtained from BF-reinforced plastics. Boron fibres may be used by themselves or as a hybrid composite, part BF, part CF for horizontal and vertical stabilizers, control surfaces, wing skins, flaps, slats, tail surfaces, spars, stringers, fuselage-reinforcement tubes, spoilers, airhole flaps, doors, hatches, landing-gear struts, helicopter rotor shafts and blades for military and civil airplanes and space shuttles. The use of such materials (including aluminium matrix composites) can reduce weight by from 12% to 45%, almost double service life, and decrease fuel usage and maintenance by about 10%. BF-reinforced composites are also used for the pickup arms for high-fi record-playing decks where specific stiffness is paramount.

The relative cost of glass, carbon, hybrid and boron-reinforced plastics is 1, 10, 20 and 30, but the cost of the high-strength high-modulus fibres is reducing with time.

The use of 'aramid' para-orientated aromatic polyamids fibres has been restricted because their relatively low moduli (58.9–127.5 GPa) makes it difficult to take advantage of their high UTS, (up to 2.64 GPa) in designs which may be buckling critical. They have been used for golf shafts, tennis racquets and boat hulls, Kevlar T950 for tyres and Kevlar T956 for other rubber components.

7.5.7 Discontinuous fibre-reinforced polymer composites

7.5.7.1 General

Discontinuous fibres of an average length in the region of 380 μm may be incorporated in proportions up to about 25% by volume in mouldable polymers to enhance their stiffness, strength, dimensional stability and elevated temperature performance. Reinforced thermoplastic materials (RTP) may be shaped by melt fabrication techniques, injection moulding, extrusion, blow moulding and thermoforming. The material is melted or plasticized by heating, shaped in the plasticized condition and cooled to resolidify. Reinforced thermosets may be made to flow in the pre-cured state and cured or cross linked to an infusible mass in the hot mould.

'Commodity' thermoplastics, polyolefins, polystyrene, polyvinyl chloride, etc. are utilized mainly in the non-reinforced form but are marketed in the fibre-reinforced form. A much higher proportion of engineering thermoplastics, polyamides, polyacetyls and thermoplastic polyesters are reinforced, usually with short glass fibre and the specialized high-performance thermoplastics such as polysulphones are also reinforced, often with short carbon fibre. Short glass-fibre reinforcement is used for thermosets such as phenolic, amino and melamine formaldehyde resins which may be injection moulded, although the curing time lengthens the manufacturing cycle.

An important class of composite are the long fibre-reinforced sheet-moulding compounds (SMC) and the dough-moulding compounds (DMC) based on unsaturated polyester, vinyl ester and epoxide resins. These materials are normally compression moulded (see Figure 7.60) and have to compete with steel pressings. Similar composites are based on the thermoplastics which are produced as sheets that are heated and then pressed between cold dies.

Two materials are used for discontinuous fibre reinforcement: short and long staple glass fibre, and short staple carbon fibre. Aramid fibres have the required properties but polymers compounded with them are not yet obtainable commercially. Discontinuous fibre-reinforced plastics cost less to fabricate than the corresponding filamentary reinforced materials but their mechanical properties are significantly inferior. This is because the rule of mixture that is obeyed precisely so far as modulus is concerned, and approximately so far as yield strength and UTS is concerned, for high-modulus continuous fibres is no longer obeyed for discontinuous fibres. The strength of short fibre-reinforced polymers is controlled by a complex series of interactions between the fibres and the matrix.

The fibre/matrix interface is usually the weakest link. In aligned fibres the end becomes debonded at quite low loads and the debonding spreads along the fibre as the load increases. Debonding reduces the stiffening efficiency of the fibre and constitutes a microcrack which may extend into the matrix.

The mechanical strengths of typical short and woven fibre-reinforced thermosets are listed in Table 7.49. Table 7.50 details the mechanical properties of short fibre-reinforced

thermoplastics which includes some carbon fibre-reinforced materials. The superiority of filamentary reinforcement is evident. Short fibre reinforcement shows to even less advantage in fatigue, creep and impact loading and is not to be recommended for highly stressed parts. Short fibre reinforcement is, however, much cheaper than filamentary reinforcement and is used extensively for a great variety of domestic, architectural, engineering, electrical and automotive components.

7.5.8 Carbon–carbon composites

Carbon–carbon composites retain their strength to a higher temperature than any competitive material (see Figure 7.61). They are unique in that the matrix is identical in composition to that of the reinforcing fibres. They differ from the polymer composites already described in that the matrix which can exist in any number of quasi-crystalline forms from 'glassy' or amorphous carbon to graphite has low strength and negligible ductility. While, therefore, single and bidirectionally reinforced carbon–carbon composites are manufactured the need to avoid delamination has promoted three-directional reinforcement.

Complex weaving equipment has been developed to achieve multilayer locking by means of structures such as are shown in Figure 7.62. Even more complex patterns are employed.

As an alternative to three- (or eleven-) directional weaving, the directional reinforcement may be produced by fabric piercing. Arrays of layers of two-directional fabric are pierced with metal rods or needles. The metal needles are withdrawn and replaced by yarns or by pre-cured resin yarn rods. Fabric piercing is versatile and can produce a higher overall fibre volume and a higher preform density than weaving.

Other techniques for producing multi-directional structures involve the assembly of rods consisting of yarns pre-rigidized with phenolic resins by pultrusion. These can be used to form '4D' tetrahedral structures or by incorporating a filament winding operation into a cylindrical structure. Densification of the structure with carbon is achieved by impregnation with pitch, a thermosetting phenol or furfural type resin or by depositing carbon from a hydrocarbon (CVD process).

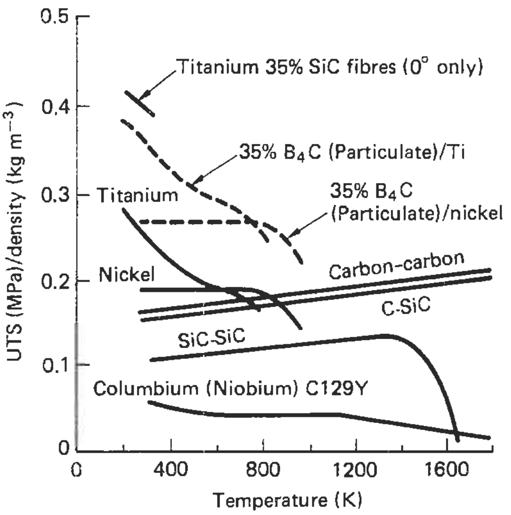

Figure 7.61 Strength-to-density ratio for several classes of high temperature materials with respect to temperature. (Reproduced by permission of *Metals and Materials*)

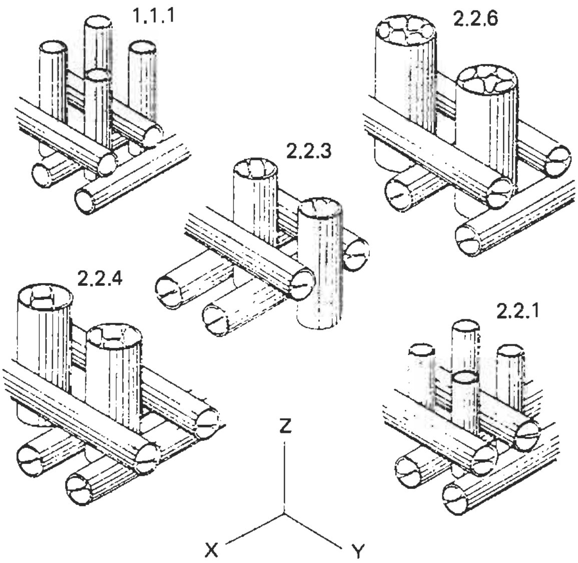

Figure 7.62 Three-dimensional orthogonal weaves for carbon carbon composites. (Reproduced by courtesy of North-Holland Publishing Company)

The preform may be impregnated with liquid by a vacuum process, carbonized at 650–1100°C at low pressure and then graphitized within the range 2000–2750°C. The cycle is repeated until the desired density is achieved. Alternatively, the preform may be impregnated with pitch, carbonized and then graphitized at high pressure in a HIPIC furnace; and the cycle repeated as required. In this process the workpiece must be isolated from the pressure vessel in a furnace of the type shown in Figure 7.63.

Impregnation by carbon by the CVD process is carried out by feeding hydrocarbon gas through and into the pores of the preform, isothermally, under a thermal gradient or under differential pressure. Carbon is deposited at 1100°C and in this case, as in impregnation with a thermosetting resin, a carbon rather than a graphite matrix is formed. The tensile properties of carbon–carbon composites with various matrices are listed in Table 7.51.

The application of carbon–carbon composites has so far been restricted by high cost and their susceptibility to oxidation at temperatures above 400°C. Coatings to protect against oxidation are under development. Their most important application has been as rocket nozzles, thrust chambers, ramjet combustion lines and heat shields for space vehicles. They are used commercially for aircraft brake systems for Concorde and military aircraft as well as for hot pressing moulds. They can also be employed for very high-temperature heat shields and elements for vacuum furnaces. Their high-temperature strength will favour a large number of uses if their cost is reduced.

7.5.9 Fibre-reinforced metals

The potential of fibre-reinforced metals is so great that they have been declared a strategic material in the United States.

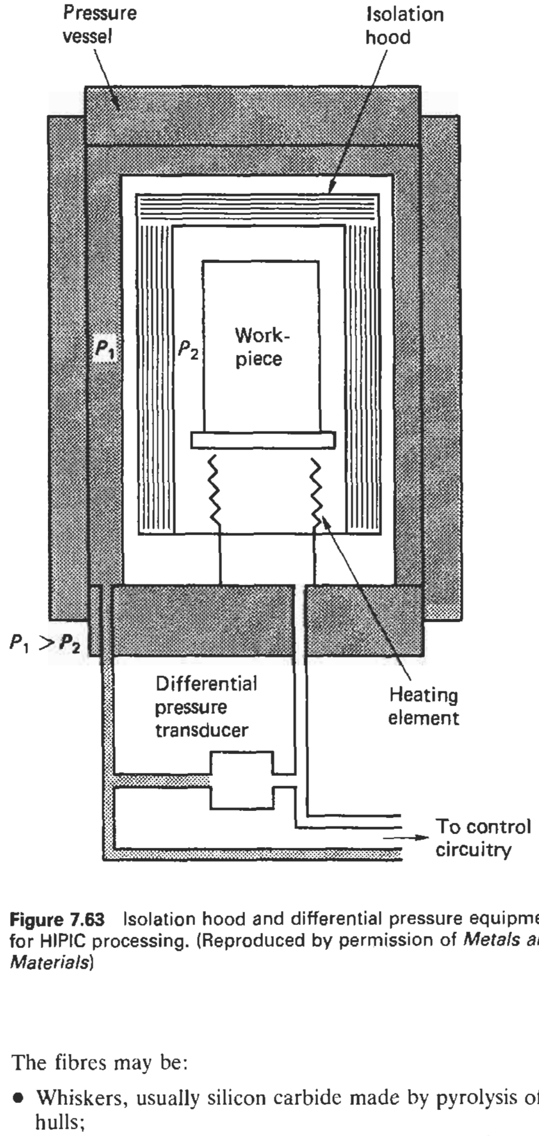

Figure 7.63 Isolation hood and differential pressure equipment for HIPIC processing. (Reproduced by permission of *Metals and Materials*)

The fibres may be:

- Whiskers, usually silicon carbide made by pyrolysis of rice hulls;
- Discontinuous fibres, alumina and alumina silica often felted together as insulation blankets;
- Continuous fibres, boron, silicon, carbide, alumina, graphite, tungsten, niobium zinc and niobium titanium.

Most engineering metals could be used as a matrix for a composite. Matrices of titanium, magnesium, copper and superalloys are the subject of investigation but almost all the applications so far recorded have used an aluminium matrix.

Typical properties of metal-matrix composites so far investigated are shown in Table 7.52. The fabrication techniques used include conventional and squeeze casting, powder methods including hot moulding and isostatic pressing, diffusion bonding and vapour deposition. A major problem is to prevent damage or dissolution of the fibres during the manufacturing process while producing a good metallurgical bond with the matrix. Surface treatments are sometimes employed to promote one or both of these objectives.

Silicon carbide particles and whiskers are given a special surface treatment which promotes wetting by aluminium. After casting, the composite may be worked by any of the conventional methods.

Powder metallurgy techniques are best suited to the manufacture of particle-filled composites but, provided the pressing operation is designed to avoid damage to the fibres either by carefully controlled direction of the pressure or by hot hydrostatic pressing, it can be used to make fibrous metal-matrix composites.

In 'Squeeze casting' pressure is used to force molten metal into the interstices of fibre preforms which have preferably been evacuated. Production of a piston by this process is illustrated in Figure 7.64.

Defusion bonding has been used to fabricate boron fibre-reinforced aluminium by the process illustrated in Figure 7.65 but it can also be used for magnesium or titanium. Fibres of silicon carbide or aluminium may be coated with aluminium by vapour diffusion or by passing through molten aluminium, and bundles of coated files may then be compacted by rolling, swaging or hot hydrostatic pressing.

Almost all the manufacturing processes for metal-matrix filament composites are expensive and most of the applications have so far been limited to space technology. The aluminium boron composite described earlier has been used for tubular spars for the space shuttle. An antenna boom is being built for the NASA space telescope from graphite fibre-reinforced aluminium which has the advantage of a very small thermal expansion coefficient and a good thermal conductivity.

A commercial application is the manufacture of the pistons illustrated in Figure 7.64 with fibrous alumina reinforcement in the region of the top ring groove and the crown. The piston outperforms the previous marque of piston which had niresist inserts and is cheaper.

7.5.10 Fibre-reinforced glasses and ceramics

The advantages which would accrue from conferring increased toughness to a material such as a ceramic which has high hardness, high temperature strength and chemical inertness has stimulated investigations into the manufacture and properties of fibre-reinforced ceramics and glasses. Enhanced toughness properties have been achieved in composites which include:

- Graphite fibre/lithium alumino silicate matrix. These had fracture strengths ranging up to about 10^3 MPA and work of fracture γ_F* about 10^4 Jm^{-2} compared with 10 Jm^{-2} for the majority of ceramics.
- Silicon carbide fibre/silica glass matrix. These had fracture strengths ranging up to 600 MPa and work of fracture γ_F up to 600 Jm^{-2}.
- Silicon carbide fibre/silicon nitride matrix. These had fracture strengths between 55 and 127 MPa and work of fracture γ_F between 200 and 900 Jm^{-2}.

These materials are very costly to produce and, in the case of glass matrix composites, the glass tends to attack the fibres at temperatures above 400°C. Also, for reasons too complex to be detailed here, low fibre/matrix bond strengths produce higher toughness values (but lower strengths) than high bond strength composites. For these reasons, the only composite of this class to have achieved significant commercial application has been glass reinforced with steel wire mesh which continues to present a barrier after the glass has been shattered. Further information on the principles and technique of fibre reinforcement of ceramics is to be found in references 64 and 65.

7.5.11 Reinforced concrete

Concrete and mortar constitute, in terms of volume, the most important matrix materials for human-made composites. They are particulate composites. 'Concrete' comprises a matrix of hydrated Portland cement (other cements have been used) surrounding mineral particles, usually silica in the form of sand and aggregates. 'Fine' aggregates are limited in size to 5 mm, 'coarse' aggregates to between 5 and 20 mm. 'Mortar' is hydrated Portland cement and sand.

---

*The work of fracture γ_F is the integrated area below the load-deflection curve divided by twice the specimen cross-sectional area.

Portland cement should conform to BS 12. The sampling and testing of aggregates is described in BS 812 in conjunction with BS 882.

The maximum compressive strength of concrete structures has over 30 years increased from 40 to over 100 MPa provided that Norwegian codes are worked to. This has been achieved by: reducing the water required (and therefore the voidage) to provide workability during pouring and compaction by adding super plasticizers and water reducing agents; adding silica fume which forms an extremely dense matrix with Portland cement; and partially replacing cement by p.f.a and g.g.b.s. which react more slowly than cement and achieve the same strength without a damaging temperature rise. This development has been retarded in the EC by the limitation in BS 8100 of the design shear stress to a value based on strength of 40 MPa.

The tensile strength of concrete is affected by slow crack growth and must therefore be assessed by the Weibull techniques referred to in Section 7.6: 5 MPa is a reasonable working estimate. A material, 'macro defect-free (MDF) cement', has been made by removing macroscopic flaws during preparation of cement paste having flexural strengths between 60 and 70 MPa and compressive strengths greater than 200 MPa.[66]

The addition of polymers further improves concrete. There are two types: polymer-impregnated and polymer-added concrete. Polymer-impregnated concretes (PICs) are made by drying and vacuum/pressure impregnating hardened concrete with a liquid monomer such as methylmethacrylate to fill the voids and then polymerizing the monomer by radiation, thermal or promoter catalysis. The strength of PIC is about four times that of normal concrete, 200 MPa compressive and 20 MPa tensile being obtained. However, the material is more prone to brittle failure. Water permeability, water absorption and chemical attack are also reduced, but PIC is expensive and its commercial application is therefore limited. Polymer-added concrete is prepared by the addition of a polymer or monomer during the mixing stage. The increases in strength are not as great as those of PIC, compressive strengths being limited to about 100 MPa while tensile strengths up to 18 MPa are reported. Polymer-added concretes have increased resistance to abrasion and chemical attack and bond well to existing concrete. Since the increase in cost is only the cost of the materials they have extensive applications for items such as floors subject to heavy wear.

Concrete, like carbon, is a brittle material and benefits from three-dimensional reinforcement by both short and long fibres, as is shown (for both concrete and mortar) in Table 7.53. Chopped steel, glass and polypropylene have been used for precast concrete sections and steel for *in-situ* concrete. Flexural reinforcement can be achieved by adding 2% of random steel fibre to concrete.

The main problem is to obtain an adequate dispersion of this concentration. The mix must contain 50% of fines and, if vibration compacting is used, care must be taken to avoid unacceptable fibre alignment. 0.44% polypropylene has been used successfully for pile sections.

Glass fibre and steel bar and wire are used for filamentary reinforcement. Concrete pipes are manufactured with 1% wound glass fibre concentrated at the inner and outer sections. Reinforced concrete contains a three-dimensional network of steel bar and/or wire aligned to resist tensile stress. Compression stresses are resisted by the concrete, but those regions of the concrete near to a steel bar which is stressed in tension are subjected to tensile stress during operation.

The versatility of reinforced concrete is illustrated by its use in the Thorpe railway suspension bridge. This bridge actually contained more steel than would have been used in a steel girder bridge, but it was cheaper steel, and does not require to be painted.

In prestressed concrete steel tendons may be stressed, while the concrete is poured over them, and released to compress the concrete after it has cured. More frequently they pass through channels or holes in the concrete and are stretched, and the ends secured after the concrete has cured. In correctly designed structures of prestressed concrete the whole of the concrete should be in compression. Prestressed concrete structures can be designed to have much lighter sections than reinforced concrete.

Corrosion of the steel reinforcement can be a serious problem with both reinforced and prestressed concrete. A sound layer of concrete 25 mm thick will protect steel from corrosion but cracks which may form under either tensile or compressive loading may allow water, which is very likely to contain salt, to gain access to the steel reinforcement. If the steel rusts it will increase in volume and eventually cause disintegration of the concrete.

The techniques for improving the fracture strength of concrete discussed earlier should prove extremely beneficial, not only in preventing failure due to corrosion but also, by alloying reinforced and prestressed concrete structures to be designed to higher stresses, in opening up new applications in the field of mechanical as well as civil engineering. Evidence is accumulating as a result of studies on biomechanics[67] that comparatively high values of modulus and toughness can be

Table 7.53 Fracture strengths and work of fracture of cement/mortar composites

achieved in such materials as nacre (mother of pearl) and antler by geometrical arrangements of calcium carbonate and small quantities of organic material. It is conceivable that high modulus, high strength and high toughness might be achieved at relatively low cost by combining high-strength high-modulus fibres, an MDF cement matrix and a thin tough, flexible polymer or elastomer interlayer which would bond to both the fibres and the matrix.

7.5.12 Particulate composites

The most important metal-matrix particulate composites are cemented carbides or hard metals. These are cermets, consisting of finely divided hard particles of carbide of tungsten, usually accompanied by carbides of titanium or tantalum, in a matrix, usually cobalt, but occasionally nickel and iron.

Hard metals have the high elastic moduli, low thermal expansions and low specific heats of ceramics combined with the high electrical and thermal conductivities of metals. They have high abrasive wear and corrosion resistance, good resistance to galling and good friction properties and they are, compared with ceramics, ductile, having fracture strengths about 1000 MPa and work of fracture γ_F about 250 Jm^{-2}.

Hard metal dies and tools are manufactured by a powder route. A 'green' or partially sintered compact is machined into shape and then sintered in a hydrogen atmosphere at a temperature approaching (or even reaching) the melting point of the matrix metal. After sintering (or solidification) cobalt occupies the interstices between the grains as an almost pure metal with its original ductility. If nickel or iron are used as a binder they tend to dissolve more tungsten carbide than does cobalt and the ductility of the resulting composite is impaired. Increasing the percentage of cobalt increases ductility but decreases hardness, modulus, resistance to wear, galling and crater formation.

Cemented carbides with 3% cobalt have a hardness (HV 500 g) above 1900, a flexural strength of 2200 MPa and an elasticity modulus of 675 GPa. Increasing the cobalt percentage to 25 decreases hardness to 950 and the modulus to 462 GPa but increases flexural strength to 3200 MPa.

In general, high-carbide versions, particularly those with added titanium carbide, are used for finishing cuts. Medium-carbide content materials are used for roughing cuts and low carbide content materials for high-impact die applications. Tantalum carbides are used for applications involving heat.

Tungsten carbides may be used in oxidizing conditions up to about 550°C and in non-oxidizing conditions up to about 850°C. Titanium carbides can be employed at temperatures up to about 1100°C.

The application of hard metals for wear-resistant cutting tools is now being challenged (in the absence of shock) by ceramics such as alumina and sialon. British standards for hard metals include:

BS 3821:	1974	Hard metal dies and associated hard metal tools
BS 4193:	1980	Hard metal insert tooling
BS 4276:	1968	Hard metal for wire, bar and tube drawing dies

A new and important development in metal-matrix particulate composites is the reinforcement of aluminium by silicon carbide particles. Forty volume per cent of silicon carbide in aluminium doubles the modulus, halves the coefficient of thermal expansion, increases tensile strength and greatly reduces frictional wear. This composite is available as sheet, extrusions, forgings and castings.

The field of metal in metal particulate composites is, by comparison, restricted. Examples are the additions of lead to steel to promote machinability and to copper to produce a bearing material. These applications are both giving place to other materials. In particular, bearings are made of porous sintered bronze impregnated with PTFE.

7.5.13 Laminar composites

The number of laminar composites is vast and defies classification. Metal/metal laminates usually comprise a substrate that provides strength but reduces cost with a surface material that resists environment or improves marketability. Examples include rolled gold, Sheffield and electroplate, tinplate, galvanized iron or titanium-sheathed steel. Alternatively, the core may be ductile and the surface hard enough to provide a cutting edge (e.g. a damascus sword blade).

Wrought iron consists of layers of iron and slag which confers corrosion resistance (and solid-phase weldability). Glass is laminated with transparent plastic for automobile windscreens.

A most important class of laminar composite is the sandwich (lightweight) structure which comprises two high-strength skins which may be metal, wood, plastic or cardboard separated by a core that may be basically lightweight such as balsawood or foam or of honeycomb construction.

7.5.14 Wood and resin-impregnated wood

Wood is a natural composite and is one of (if not the) oldest composite used by humans. It is reinforced by a system of parallel tubes constructed of cellulose fibres which confer longitudinal properties such as those shown in Table 7.54. This structure has developed by natural selection in such a way as to ensure that failure of one element does not interact with an adjacent element is such a way as to lead to progressive failure. The low specific gravity of wood gives it specific strengths comparable with steel. Its transverse properties are very poor and it very easily splits longitudinally. Provided, however, that this is allowed for in design, timber structures, such as the Lantern Tower at Ely Cathedral, may be designed to support heavy loads for many centuries.

Elastic modulus	(GPa)	14	14.3	2.06

[a] Parallel to grain.

Plywood was developed by the ancient Egyptians to provide strength in two directions and to prevent warping. The next advance was to impregnate laminated wood with resin. This can be achieved in two ways:

1. Veneers of softwoods such as Douglas Fir are impregnated with epoxy resin, laid up in a female mould and cured under a vacuum bag. Figure 7.66 shows a section near the root end of an aerogenerator blade made by joining two half-sections made in this way. Design allowables (based on wooden propellor blade experience) are given in Table 7.55. Tests on prototype aerogenerator blades have indicated that the mechanical properties are adequate and in series production the blades would be cheaper than any other material (with the possible exception of prestressed concrete).
2. Compressed impregnated wood (as manufactured by Permali, Gloucester) involves laying up birch or beech veneers interleaved with phenolic resin and bonding at high temperature and pressure. This product is a highly weather-resistant electrical insulating material with mechanical properties as listed in Table 7.56 and a substantially flat S-N curve with fatigue strength better than 90 MPa at 10^9 cycles.

7.6 Polymers

7.6.1 Introduction

A 'polymer' is, strictly, any molecule which consists of two or more molecules of another chemical compound which is known as its 'monomer'. Polystyrene $(C_5H_8)_n$, which is a glassy solid, is formed by the polymerization of its monomer styrene or phenylethylene into a long-chain compound (see Figure 7.67). This occurs on standing but is accelerated by

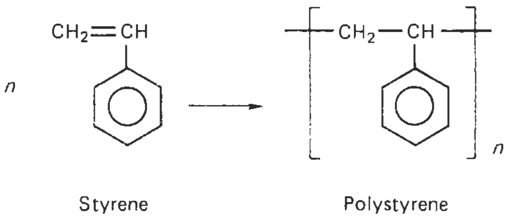

Figure 7.67 Styrene becomes polystyrene by the conversion of a double bond into two links

heat or the additions of an accelerator (for example, benzoil peroxide).

True polymerization requires the presence in the monomer of a double bond as in styrene or of a molecular structure which can be broken to provide links to other molecules. The name 'polymer' has, however, been extended, first, to include products of high molecular weight formed by 'condensation polymerization', which occurs by the elimination of a small molecule (usually water at each polymerization step), and, second, the formation of a large molecule from equal numbers of two different molecules. A typical example of these processes is the formation of polyamide 'Nylon' by the action of heat on adipic acid and hexamethylene diamine to form a chain which contains a repeating unit (see Figure 7.68).

The term 'polymer' (or 'elastomer') is now used for all synthetic resins, compounds of carbon or silicon with one or more of hydrogen, oxygen, nitrogen, chlorine, fluorine and sulphur, which contain large numbers of repeating units grouped in long chains or in cross-linked structures. An elastomer differs from a polymer in having a comparatively low modulus and in being capable of elastic extension of several hundred per cent. Elastomers are more closely related to natural products because a large number of them are rubbers and the compositions of many synthetic elastomers are similar in composition to rubber.

There are natural polymers. Amber or the adhesive mentioned in the Bible as the binder for straw-reinforced bricks are among the oldest materials used by humans.

The great technological importance of polymers and elastomers arises because they can be compounded with additives, fillers and reinforcing agents (see Table 7.57) to become plastics, fibres, coatings, fluids, rubbers or composites from which useful artefacts or engineering structures may be manufactured. Plastics are generally less stiff and weaker than metals but their ease of processing, low density, attractive appearance, resistance to environment, usually lower cost and potential for recycling often render them the preferred raw material.

Polymers are usually purchased from the manufacturer or supplier in the form of plastics. It often happens that manufacturers have given names to the plastics which they supply that differ from those of the polymers which are their most important constituents. To avoid confusion, this section refers to the materials which it describes by the name of the polymer or elastomer. Where the manufacturer's name has obtained very wide currency it is also mentioned, together with the name of the manufacturer. All commercially available polymers, their US supplier and trade names are listed in *The Plastics Encyclopaedia*[68] published by Modern Plastics and the UK suppliers are listed in *Kompas UK*[69] published by Reed Information Services in association with the CBI. Both these are published annually and, in case of difficulty in obtaining a specific plastic, the reader is recommended to consult them.

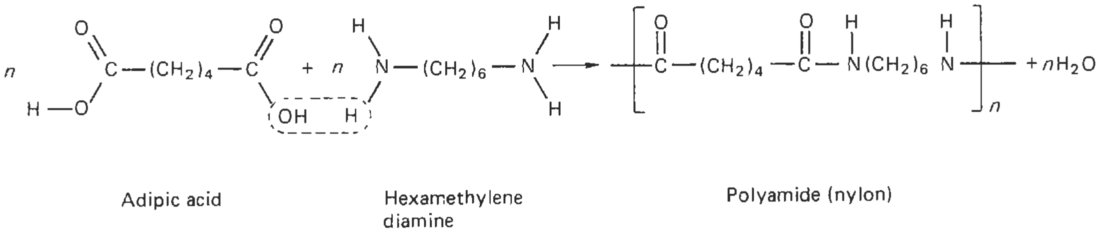

Figure 7.68 Formation of polyamide (nylon 66) from molecules of adipic acid and hexamethylene diamine with elimination of water

Table 7.57 Fillers and reinforcement for polymers

Type	*Function*	*Type of material*	*Example of material*
(a) Additive fillers			
Inert filler	Reduce cost. Reduce tackiness Improve electrical insulation Reduce distortion on moulding Reduce die swell on extrusion Reduce wear	Inert and insoluble mineral	Calcium carbonate China clay Talc Barium sulphate Carbon black
Coupling agent	Promote adhesion between polymer and filler	Adhesive	γ Mercaptopropyl-tri methoxysilane
Plasticizer	Lower melt viscosity (therefore facilitating processing)	Non-volatile solvent (high molecular weight)	Di-n-butyl phthalate metallic soap
Extender	Cheap replacement for properties of plasticizer	Compatible with plasticizer	Chlorinated paraffin wax
Lubricant	Prevent sticking of compound to processing equipment	Limited compatibility with compound	Lead or calcium stearate or stearic acid
Impact improver	Improve toughness of rigid amorphous thermoplastics	Synthetic rubber	Ethylene-propropylene rubber in polypropylene ABS and polystyrene
Stabilizer	Prevent ageing due to (a) Oxidation (b) Ultraviolet light	Chain breaking antioxidant Converts UV radiation to heat Shielding material	Substituted phenol (Benzo triazole) Carbon black
Colorant	Mass coloration	Pigment or die	
Cross linking agent	Produce cross links in linear polymers	Vulcanizing agent in rubber Accelerators in thermosets	Sulphur in rubber Aminos in epoxide resins Peroxides
Friction reducer	Reduce friction between plastic used as a bearing and (usually metal) shaft or plate	Material with low inherent friction	Graphite PTFE PTFE fibre Molybdenum disulphide
Nucleating agent	Promote rapid freezing, refine crystallization, improve clarity and reduce voids	Polymer of similar cohesive energy density but higher melting point	Nylon 66 in Nylon 6 Fine silica
Antistatic additive	Prevent generation of static electricity during service	Conducting compound which will migrate to the surface	Quaternary ammonium compound Glycol alkyl ester
Conducting additive	Confer some conductivity to the plastic	Conducting powder or flake that forms a network through the plastic	Silver, carbon black, graphite
Flame retardant	Resist the propagation of fire in and along a plastic		Trichloroethyl phosphate Antimony trioxide
Blowing agent	Produce cellular plastic	Substance which generates gas during processing	Azocarbonamide Water Fluorocarbon (obsolete)
Density reducer	Increase volume but not weight	Hollow spheres	Glass spheres
Photo-degradant	Renders polymer from photo-degradable by ultraviolet light	Ultraviolet light absorber which generates reactive chemical intermediates	Iron di-thio-carbonate.

Table 7.57 *(continued)*

Type	*Function*	*Type of material*	*Example of material*
Biodegradant	Render plastic degradable by biological action	Constituent which can be acted upon by naturally occurring enzyme	Cellulose or urea derivative
(b) Reinforcing fillers			
Reinforcing particle	Increase hardness, wear resistance and tensile strength mainly in the case of elastomers	Inert particle, to which the polymer will bond sometimes assisted by coupling agent	Carbon black Also silica, aluminium hydroxide, zinc oxide and calcium silicate
Reinforcing fibres	Increase modulus and tensile and impact strength usually in specific direction	(a) Generally used fibrous material	Wood flour and shaped wood particles, cotton flock, macerated fabric and synthetic organic fibre (nylon)
		(b) Cut fibre, usually of uniform length oriented to reinforce in specific direction	Glass, aramid and carbon Recently whiskers
		(c) Fibres running the full component length. (See section 7.5 Composites)	Glass, aramid and carbon

7.6.2 Classification of polymers

Polymers are classified into three categories: 'thermoplastics', 'elastomers' and 'thermosets'.

7.6.2.1 Structure of thermoplastics

The structures of thermoplastics (and elastomers) are essentially long single-chain molecules but chain branching occurs either with the production of relatively short and well-defined spur groups or (sometimes unintentionally) the chain may bifurcate into two long branches. The backbone of the chain consists, in the simpler cases, of carbon atoms but other atoms such as nitrogen and oxygen may substitute for carbon atoms at regular (or intentionally irregular) intervals; and in the case of silicones, the backbone consists of alternating silicon and oxygen atoms.

Each carbon atom can, in principle, link with four atoms, two to continue the chain and two to link with other atoms. The natural angle between two carbon bonds is 109°28′, therefore a carbon chain would naturally assume a zig-zag pattern, but these angles are flexible and can, under certain conditions, permit rotation of one carbon atom with its attached groups relative to the next atom. The chains can therefore, in principle, bend to make way for other chains and to accommodate bulky side groups attached to the chain.

In the case of some polymers the link betwen two adjacent carbon atoms is made by two bonds (see Figure 7.69). Double bonds prevent rotation (although they may facilitate rotation round the next single bond in the chain), restrict bending and leave only one link free for hydrogen or a side group to be attached to each of the two carbon atoms on either side of the double bond.

An important characteristic of double bonds both in the main chain or in a side group is that they may be broken to leave two carbon atoms free to link with a side group or to cross link to another chain. This is important in the case of elastomers and thermosets where chains are linked together. Some polymer chains contain cyclic groups and have therefore two strands at intervals along their length. A chain is inflexible (and bulky) at these points. Flexibility is further reduced when two adjacent cyclic groups are linked at two points (see Figure 7.70). The structure of the chain controls the characteristics of the polymer and therefore the plastic derived from it.

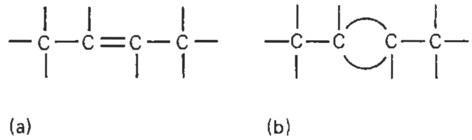

Figure 7.69 Double bond in carbon chain. (a) Chemical representation; (b) representation illustrating strain in bond

7.6.2.2 Influence of chain structure and length on properties of thermoplastics

Phase diagrams of thermoplastics There are two types of long-chain thermoplastic: amorphous and crystalline, depend-

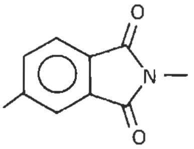

Figure 7.70 Phenyl group linked at two points to imide group

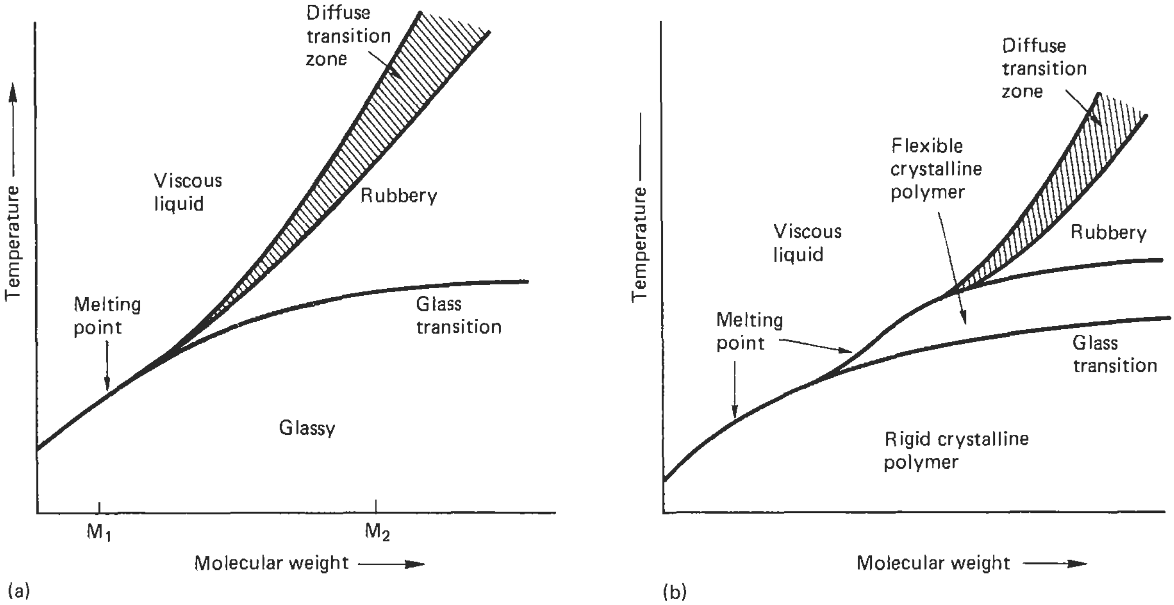

Figure 7.71 Temperature molecular weight diagram (a) of amorphous thermoplastics, (b) of crystalline thermoplastics

ing on the structure of the chain. Simple regular configurations promote packing and favour crystallization. Bulky side radicals or irregularly spaced blocks inhibit crystallization and favour amorphous polymers. The temperature, molecular weight diagrams of both types are shown in Figure 7.71. For high molecular weight polymers there is usually a liquid phase which, in cooling, transforms at the melting point, T_m, to a rubbery phase. On further cooling the rubbery phase transforms in the case of an amorphous polymer to a glassy phase at the glass transition temperature. In the case of a crystalline polymer the rubbery phase transforms to a flexible crystalline phase which itself transforms to a rigid crystalline phase at the glass transition temperature.

Properties of the liquid phase In the liquid phase the molecules of a thermoplastic polymer have sufficient energy to move independently of each other and the polymer is capable of viscous flow. The melting-point temperature depends on the stiffness of the chain – the stiffer the chain, the higher the melting point. With very stiff-chain polymers the liquid phase may be absent. The viscosity of the liquid depends on the length of the chain – the longer the chain, the higher the viscosity.

The preferred fabrication process for thermoplastics ('melt processing') is carried out in the liquid phase. A high melting point and viscosity require high pressures and fabricating equipment strong enough to withstand these pressures at high temperatures. In the limit the fabricating temperature may exceed that at which the polymer boils or decomposes so that the polymer cannot be melt processed. Certain very high molecular weight thermoplastics require to have the chains broken up into smaller lengths by a masticating process before they can be melt fabricated.

Properties of the 'rubbery' state Below T_m (which for high melting-point polymers is not sharp but is a diffuse transition) a thermoplastic enters a rubbery state. A simple (but not universally accepted) concept is that in the rubbery state molecular rotation about single bonds in the chain can occur within a short time scale. The molecules are highly coiled, and uncoil on the application of a tensile stress and will accommodate reversible elongations as high as 1200%.

Influence of the glass transition (T_g) of amorphous thermoplastics Below the glass transition temperature T_g an amorphous polymer changes from a rubbery to a glass-like state. If this occurs below ambient temperature the polymer is an 'elastomer' and is capable of large extensions when stressed in tension. In natural and synthetic rubbers the highly flexible polymer molecules must be lightly cross linked to prevent them slipping past one another when stressed and in the rubber industry diene rubbers are 'vulcanized' with sulphur. When the glass transition temperature is above ambient the polymer is a transparent glass-like thermoplastic.

Properties of crystalline thermoplastics Thermoplastics with highly regular structures such as PTFE, polyethylene, nylon and aliphatic polyester are able to crystallize and this makes the glass transition temperature less definite. In high molecular weight polymers a flexible crystalline phase appears between the rubbery phase and the glass transition temperature. The rigid crystalline phase is less transparent (highly crystalline polymers may be opaque) and generally less ductile than the glass phase of amorphous thermoplastics. Polymers may also show shrinkage for long periods while they crystallize, but this may be avoided by annealing at a temperature where crystallization takes place rapidly.

The ability of a polymer to crystallize may be controlled or eliminated by introducing irregularities into the chain. One very effective way is by copolymerization, which can introduce two quite different groups at random (or controlled) intervals along the chain:

1. *Fibre-forming thermoplastics*: these include polyamides (nylon 66) and polyethylene terephthalate (Terylene). Most amorphous polymers have yield strengths around 55 MPa. Crystalline polymers may vary between 14 MPa (polyethylene) and 83 MPa (nylon). When, however, a crystalline polymer is stretched in the flexible crystalline phase (room temperature for nylon 66 and above 67°C for Terylene) it can develop strengths approaching 700 MPa, many times greater than unorientated polymers. High strengths can also be induced in films and sheet by two-way stretching. Besides high strength, biaxially stretched films of Melinex (polyethylene terephthalate), Saran (polyvinylidene chloride) and polypropylene have excellent clarity because the biaxial orientation of the crystallites does not affect the transmission of light waves.
2. *Liquid crystal polymers*: Even higher tensile strengths can be achieved in the so-called 'liquid crystal polymers' which consist of rod-like molecules that tend to orientate in the direction of shear when stretched (see Section 7.6.5). Tensile strengths up to 3.8 GPa, which (except for a lower modulus) is equivalent to steel or carbon for composite reinforcement, are available in poly-*p*-phenylenediamine ('Kevlar': Dupont).

Other properties of thermoplastics dependent on structure

1. *Creep strength*: Creep of a thermoplastic is thermally activated sliding of the chains relative to each other. This is hindered by a number of factors – spatial interference, chain stiffness and electrical and chemical interactions between the constituents of chains. A special case is hydrogen bonding, where the hydrogen of one chain is shared with oxygen or nitrogen at a nearby location on an adjacent chain. Most creep-resisting thermoplastics contain phenyl groups with sulphone, ether, ketone or imide links or a combination of all three. A high melting point does not by any means imply high resistance to creep.
2. *Density*: Density both of thermoplastics and thermosets depends mainly on the individual atoms present. Hydrocarbons do not contain heavy atoms and have specific gravities of 0.86–1.05. Where chlorine or fluorine are present specific gravities can range up to 2.2. Crystallization implies closer packing and therefore increases density.
3. *Electrical properties*: Electrical properties of thermoplastics and thermosets depend on the presence within the molecule of dipoles, pairs of atoms with contrasting values of electronegativity (see Table 7.58). The greater the difference in the electronegativity of the atoms bonded together, the greater the polarity of the bond. Where this difference is greater than 2, electrovalent bonds are commonly formed. Where it is less than 2, the bond is usually covalent but it may also be polar. Thus a carbon fluorine bond is more polar than a carbon hydrogen bond. The influence of dipoles is only felt if they are unsymmetric. In the case of symmetrical molecules or groups such as carbon tetrachloride, phenyl groups, polyethylene and polyisobutylene the polar effects neutralize each other, therefore any electrical property is controlled solely by electron displacement. Such compounds and non-polar polymers have high-volume resistivities of the order of 10^{19}–10^{20} Ωm, high dielectric strengths (180–320 kV cm^{-1}), low dielectric constants (2–2.5) and low power factors (loss tangents less than 0.0003). On the other hand, polymers containing unbalanced dipoles, such as cellulose nitrate, have volume resistivities down to 10^{13} Ωm, dielectric strengths down to 120 kV cm^{-1}, dielectric constants as high as 7 and loss tangents as high as 0.06. Loss factor and dielectric constant are frequency related. At low frequencies the polar molecules are able to vibrate in-phase with the electric field and losses are low. They are unable to do this at higher frequencies and losses reach a maximum but become smaller at higher frequencies still because the dipoles cannot respond quickly enough. The effects are complex and the reader is recommended to consult reference 88.

Table 7.58 Electronegativity values of some common elements

Element	*Electronegativity*	*Element*	*Electronegativity*
Caesium	0.7	Iodine	2.4
Potassium	0.8	Carbon	2.5
Sodium	0.9	Sulphur	2.5
Lithium	1.0	Bromine	2.8
Aluminium	1.5	Nitrogen	3.0
Silicon	1.8	Chlorine	3.0
Hydrogen	2.1	Oxygen	3.5
Phosphorus	2.1	Fluorine	4.0

7.6.2.3 Structure and properties of thermosets

Thermosetting polymers are, compared to thermoplastics, relatively small molecules, either branched or straight chains which each contain at least three reactive groups that can link with reactive groups in other molecules. These groups can be caused to interact by heat, by the addition of a hardener or accelerator, or by the action of all three. The result is a rigid cross-linked polymer which is chemically stable, does not melt and cannot be subjected to significant deformation. Such a polymer cannot be fabricated by any conventional process and must be processed in the low molecular weight form known as the 'A'-stage resin. The fabricated shape is then cross linked to form the 'C'-stage resin.

7.6.3 Polymer processing

7.6.3.1 Melt processing

Melt processing is the most important, most economical way of shaping plastics. It can be used for those thermoplastics with melting point and viscosity low enough not to subject die materials to excessive temperatures and stresses.

Melt processing of thermoplastics The raw material to be processed is usually supplied in the form of regular shape and even-size granules, because this makes quantity metering easier and quicker and leads to more uniform and predictable heating. One technique which has been developed recently is to pultrude impregnated continuous-fibre rovings to produce a lace which is chopped into 10 mm lengths (Verton: ICI). This produces a 10 mm fibre reinforcement which has greatly improved properties compared with normal short-fibre reinforcement. Whatever form of raw material is used, it is essential that it should be dried thoroughly before use.

The most important processing procedures involve the use of a screw pump.[70] The equipment used for 'injection moulding' is shown in Figure 7.72(a). The granules are fed into a heated cylinder by a screw which first recedes to provide space for the material and then advances to inject it into a relatively cool mould in which it sets. When the plastic has set the mould is opened and the moulding removed. Figure 7.72(b) shows an 'extruder' which will produce rod, tube or filament that can be

quenched and drawn, sheet or strip in conjunction with a casting drum or three-roll stack (see Figure 7.72(c)) or coated wire.

Bottles may be produced by 'extrusion blow moulding' (see Figure 7.73(a)) in which a rod is extruded against a 'blow pin spigot'. After extrusion a mould is closed on the extruded parison which is still above softening point and the bottle is blown.

Procedures which do not involve extrusion are:

1. *Calenderizing*: flattening material out to sheet between rolls (Figure 7.73(b)). (This process is used extensively for plasticized PVC because problems have arisen in extrusion.)

2. *Centrifugal casting*: this involves filling a mould with (preferably) powder, spinning, heating to melt the powder, cooling slowly and removing the hollow casting.
3. *Compression moulding*: this process is more usually employed for thermosetting plastics but it can be used for thermoplastics, preferably in the form of powder. The compression moulding cycle involves compacting the polymer in the mould, heating above melting point and then applying a heating compression/relaxation technique; typically, 3.5 MPa for one minute, release, then 7 MPa for one minute, release, then 14 MPa for 10 minutes and cool at 40°/minute to removed included air.

Melt processing of thermosets Because a fully cross-linked thermoset will not melt, melt processing must be carried out on an 'A'-stage resin, a low molecular weight cross-linkable polymer which may be compounded with a hardener and/or accelerator. Cross linking is normally initiated by the heat of the mould and shaping must be completed before cross linking has occurred to such an extent that it prevents flow. This clearly raises problems in extrusion or injection moulding, because any material remaining in the extruder will set and become difficult to remove. Extrusion of thermosets must therefore be a discontinuous process in which a high-pressure reciprocating ram forces the thermoset through the die.

The most commonly used process is compression moulding, illustrated in Figure 7.74. The mould is heated to approximately 170°C and the material softens and flows to fill the mould before casting. The moulding material may be powder, a dough-moulding compound (DMC), a sheet-moulding compound (SMC) or a preform moulding.

Alternative processing methods There are a variety of alternatives to melt processing, some of which are used as a matter of convenience while others may be employed for materials which cannot be melt processed. PTFE, which cannot be melt processed, is formed by powder compression and sintering. Solution processing – dissolving the thermoplastic in a solution which is later allowed to diffuse out – may be used for

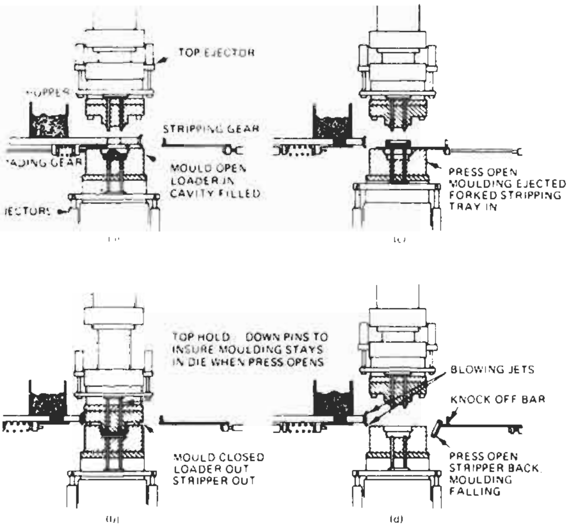

Figure 7.74 Typical process for the compression moulding of thermosetting plastics. (a) Load; (b) mould; (c) eject, stripper in; (d) strip

other difficult thermoplastics. This process may also be employed for casting, film casting and fibre spinning.

Suspension processing is important because many polymers occur in latex form, i.e. as polymer particles of diameter of the order of 1 μm suspended in a liquid, usually an aqueous medium. The suspension is formed to shape by dipping, spraying or some other means of deposition and then coagulated by means of an acid. Other suspensions include particles of PVC suspended in a plasticizer.

Polymerization casting can be used for both thermoplastics and thermosets. A liquid monomer or the low molecular weight polymer is poured into a mould and polymerizes *in situ*. This process is mainly used for small sections to avoid problems associated with the heat involved during polymerization. A most important application is the encapsulation of small electrical or electronic components by epoxide resins. Other materials suitable for casting are acrylics, nylon and polyester resin.

Reaction injection moulding (RIM) is a form of polymerization casting which can produce components with foam cores and a non-porous skin as well as solid components. The components of the polymer are mixed with a liquid blowing agent in a reaction vessel and transferred to a mould. The heat of reaction volatilizes the blowing agent (which has in the past been a fluorocarbon but can be water) in the core but not at the surface of the component, where it is cooled by the mould. RIM is used for thermoplastic polyurethane elastomers.

Processing in the rubbery state is used where (as is the case with PTFE, high molecular weight polyethylene and cast polymethyl methacrylate) the polymer cannot be melt processed or where processing from sheet is the most convenient and economical means of manufacture. PTFE and polymethyl methacrylate are warm coined.

The forming of sheet is usually carried out by a vacuum-forming process (Figure 7.75) but polymers which are more difficult to deform such as polymethyl methacrylate and unplasticized PVC may require mechanical pressure or positive air pressure (Figures 7.75(d) and (e)).

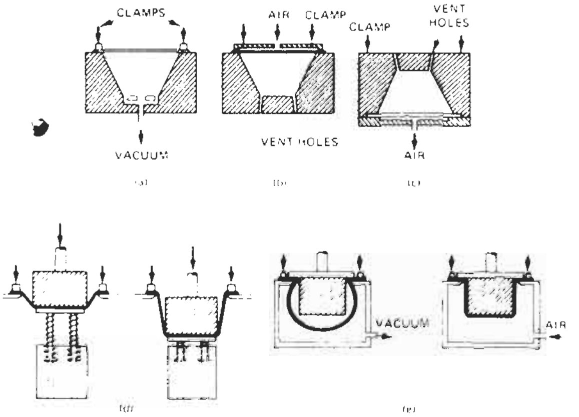

Figure 7.75 Shaping of sheet in the rubbery phase. (a) Application of vacuum; (b) and (c) air pressure; (d) mechanical pressure; (e) combination of methods (vacuum snapback)

There are, in addition to the processes described in this section, a variety of procedures for the fabrication of composites. These are described in Section 7.6.5.

7.6.4 Design of plastic components

When choosing a plastic material for a new or existing component the designer must be satisfied that the material can be fabricated to the required shape at an economic cost; will withstand environmental and stressing conditions which it will undergo during service and any emergencies that may arise; will satisfy any electrical, optical or aesthetic conditions that may be inherent in its operation; and will under no circumstances give rise to any safety or toxicity hazard. The tables associated with each class of polymer in Section 7.6.5 will provide the information required to satisfy many of these requirements. Answers to other questions may be obtained from fabricators and material suppliers or impartial authorities such as RAPRA[71] and the BPF.[72]

There exist, for all plastics, limiting minimum wall thicknesses that it is unwise to venture below. These are shown in Table 7.59. Wall thicknesses should be as even as possible because sudden changes in thickness in thermoplastics can lead to residual stresses and distortion and moulding faults such as sinks and voids. Corners should be radiused to reduce stress concentration. The effect of the radius of a fillet upon the stress concentration is shown in Figure 7.76. There is little benefit in increasing the fillet radius to thickness ratio above about 0.6.

The rigidity of plates or walls can be increased by the use of ribs which may be used as part of the runner system in injection moulding. Rib dimensions may be calculated by the standard strength of materials formulae provided that the plastic stiffness data used are appropriate to the temperature and loading conditions of service. Sinks or voids at the junction of the rib and wall are minimized by making the section of the rib less than that of the wall.

Detailed descriptions of the design of ribs, bosses, inserts, undercuts and general mould design are available in the literature.[73–76] Information on mould design for specific plastics may be obtained from the supplier.

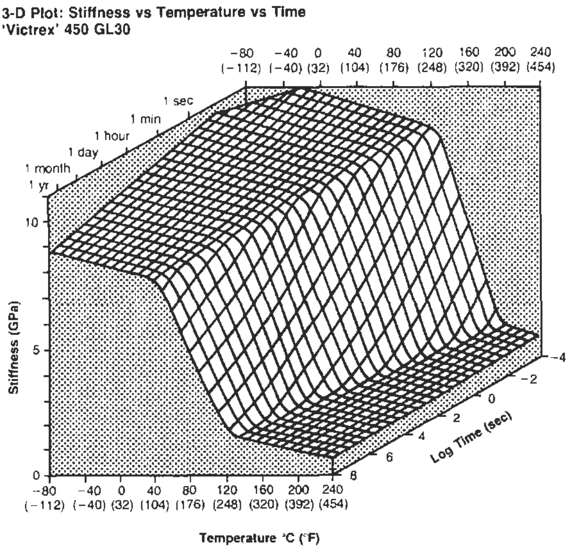

Figure 7.77 Stiffness versus temperature versus time for Victrex PEEK 450 GL30 (three-dimensional plot)

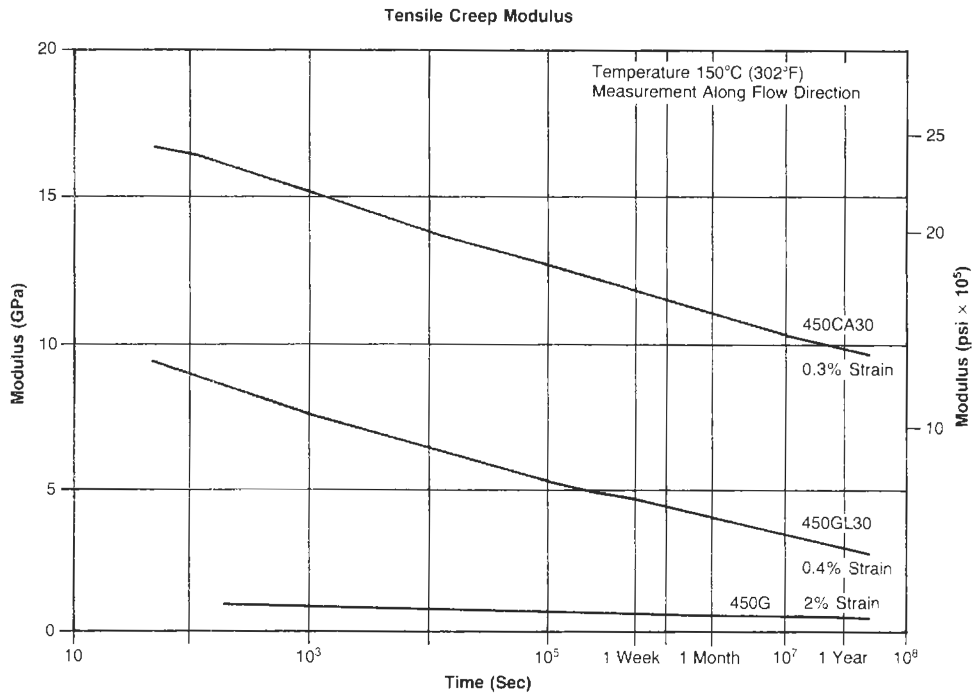
7.6.4.1 *Designing for stiffness*

The properties of a plastic depend on time and temperature, on any fibre reinforcement which may have been incorporated and on the fibre orientation. A typical three-dimensional plot of stiffness versus temperature versus time is shown in Figure 7.77. The influence of the glass transition temperature of 143° is evident.

The data to be used are supplied by the supplier of the plastic (in this case, ICI) as plots of tensile creep modulus against time at a series of temperatures (see Figure 7.78). The influence of anisotropy is taken into consideration by providing data measured along and transverse to the flow direction. Every attempt should be made to align the flow in the direction of the principal stress.



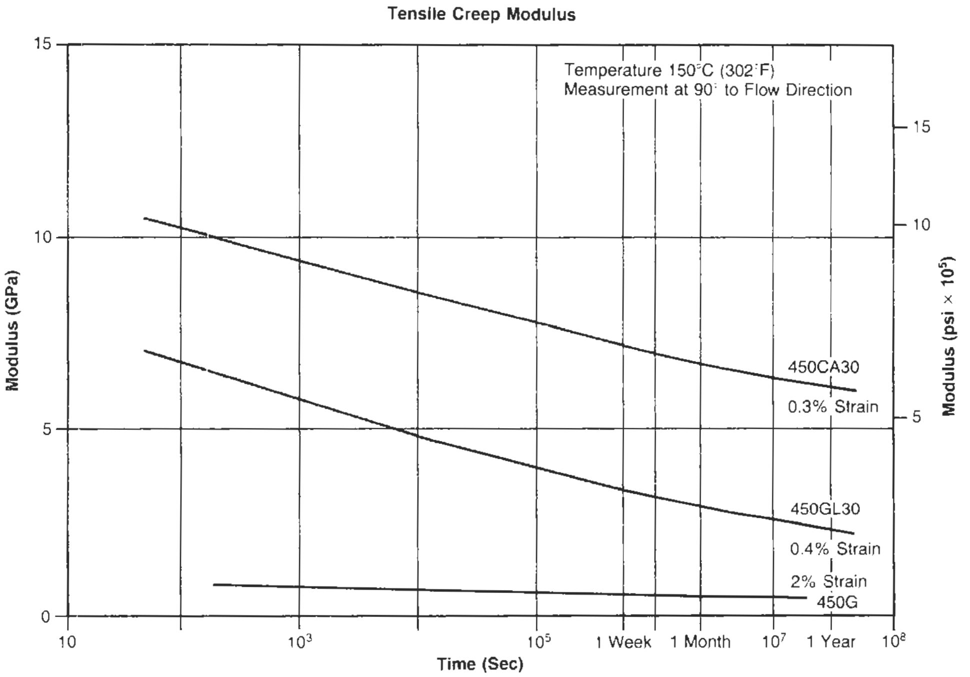


Figure 7.78 Plots of tensile creep modulus against time for three grades of Victrex PEEK in flow direction and transverse to flow direction (courtesy of ICI)

It is reasonable to assume that creep moduli in compression and tension are similar. The ratio between creep modulus in tension and in shear is approximately 2.9. A more precise value can be obtained from the supplier for each material. Tensile creep rupture data (see Figure 7.79) are also provided by the supplier.

It is first necessary to decide how much distortion of a component is allowable over its design life. The dimensions (thickness) of the component are then calculated from normal elastic formula using a value of *E* obtained from the tensile creep modulus at the appropriate temperature and design lifetime. When the dimensions have been decided the maximum stress can be calculated by elastic formulae. If this stress is not more than 60% of the creep rupture stress at the design lifetime the design is safe. A worked example of this procedure is provided in the appendix to this section.

Collapse of plastic structures may be avoided by substituting the value of the stress in the stress rupture curve into the von Mises yield criteria. Fatigue characteristics for plastics are presented as maximum stress versus cycles to failure (*SN*) curves (see Figure 7.80).

The values may be frequency sensitive because of the generation of heat at discontinuities at high frequencies. The values obtained should not be expected to compare with the fatigue strengths of continuously reinforced composites.

7.6.5 Polymer characteristics, properties and applications

7.6.5.1 Thermoplastics

Thermoplastics fall naturally into three classes: commodity thermoplastics, which are inexpensive and have relatively low strength and temperature resistance; engineering thermoplastics, which are stronger but rather more expensive; and high-temperature thermoplastics, which can have properties equal to or better than thermosets and compete for some applications with metals.

Commodity thermoplastics Properties of typical commodity thermoplastics are listed in Table 7.60.

- *Polyethylene*: This is the simplest polymer, essentially a long-chain aliphatic hydrocarbon (Figure 7.81). Its advantages are low cost and easy processability, it is an excellent electrical insulator and is tough and flexible. Its disadvantages are a low softening point and tensile strength and very poor creep resistance. The low-density form (LDPE) is used mainly for packaging and piping. The high-density form (HDPE) is fabricated by injection into domestic articles and by blow moulding into household bottles.
- *Polypropylene*: This is essentially polyethylene with an $R(CH_3)$ group replacing one hydrogen molecule attached to every other carbon atom in the chain (Figure 7.82). Commercial polypropylene is essentially 'isotactic', that is, the methyl groups are all disposed on one side of the chain. Compared with polyethylene, polypropylene has a lower density, a higher softening point and therefore a higher service temperature and appears to be free from environmental stress cracking. On the other hand, it has a higher brittle point and is more susceptible to oxidation. It is used in preference to polyethylene, where its slightly higher stiffness and higher service temperature are advantages and also where its great resistance to fatigue in flexure (such as is required in integral hinges) is an advantage.
- *Polyvinyl chloride*: This is essentially polyethylene with a chlorine atom replacing a hydrogen atom bonded to every other carbon atom in the chain (Figure 7.83). The polymer itself is unstable, and in order to allow it to be processed a stabilizer (white lead for non-food applications) or a metallic soap must be added. Polyvinyl chloride is a rigid plastic but the addition of plasticizers such as di-isoethyl phthalate imparts flexibility and extensibility to produce materials with a wide range of properties. This, assisted by a very reasonable price, has resulted in very extensive application. PVC will also form pastes and latexes with plasticizers which extend its applications to coatings and rotationally moulded hollow articles. Further chlorination of vinyl chloride results in chlorinated polyvinyl chloride (Figures 7.84 and 7.85).

$$n\mathrm{CH_2{=}CCl_2} \longrightarrow \left(-\mathrm{CH_2}-\mathrm{CCl_2}-\right)_n$$

Figure 7.85 Structure of polyvinylidine chloride

- *Polystyrene*: This is essentially polyethylene with a phenyl group replacing a hydrogen group bonded to every other carbon atom in the chain (see Figure 7.67). The effect of the benzene ring which, in contrast to the methyl group in polyethylene, can be attached in any direction, is to make the polymer stiff and brittle but amorphous, and it has poor chemical resistance. It is used for applications mainly promoted by its low cost. The impact strength of polystyrene can be improved by alloying, progressively with a rubber (styrene butadiene or polybutadiene) or with acrylonitrile to form SAN and with both butadiene rubber and acronitrile to produce ABS. The improved toughness greatly increases the applications and ABS competes propertywise with engineering plastics at a significantly lower cost.
- *Polymethyl pentene* (*TPX*): This is an ethylene chain thermoplastic with a rather bulky and knobbly side chain. TPX has a very low density, very high transparency and a continuous service temperature of 134°C. This promotes applications for lamp covers, electrical equipment which has to withstand soldering and encapsulation and for transparent sterilizable equipment in spite of relatively high cost, low impact strength and poor ageing properties. TPX was developed by ICI but is now marketed by Mitsui.

- *Acrylics*: Acrylic plastics are a further example of an ethylene chain. They are produced by the polymerization of ethyl methacrylate or, more usually, methyl methacrylate. They are hard, transparent materials. The applications of polymethyl methacrylate stem from its good light transmission and outdoor weathering properties. It is used mainly for covers of light signs.
- *Cellulosic polymers*: 'Celluloid' (cellulose nitrate plasticized with camphor and cellulose acetate, made respectively by the nitration and acetylation of cotton linters or wood pulp) was among the earliest plastics but most of the applications have been discontinued in favour of vinyl plastics. Cellulose nitrate is still used for knife handles, spectacle frames and table-tennis balls. Cellulose acetate, because of its clarity, is used for films and sheeting. Its application for mouldings and extrusion is being displaced by styrene polymers and polyolefins.

Engineering thermoplastics Engineering thermoplastics combine reasonable strength, stiffness and toughness. Their raw material cost varies from at least twice to several times that of the commodity thermoplastics. The properties of typical engineering thermoplastics are listed in Table 7.61.

- *Polyamides* (*nylons*): (Aliphatic) polyamides differ from polyethylene-type polymers by having polar CONH groups spaced out at regular intervals along the aliphatic chain. The polar groups cause the polymers to crystallize with a high molecular interaction while the intervening aliphatic chain segments provide flexibility in the amorphous region. In principle, polyamides are formed by the condensation of a diamine with a dicarboxylic acid (Figure 7.86). Nylons are classified by numbers according to the number of carbon atoms ($m + 2, p$) in the material or materials from which they are formed. Thus nylon 6 which is formed from caprolactum, which contains six carbon atoms, has the formula shown in Figure 7.87. The number(s) provide a measure of the spacing of the CONH groups in the chain. The closer the CONH groups, the higher the melting point and heat deflection temperature and the higher the tensile strength, rigidity, hardness, resistance to creep and hydrocarbons and the water absorption.

  Nylon 6 and nylon 66, which have relatively closely spaced CONH groups (Figures 7.87 and 7.88), are very suited to fibre production which takes betwen 80% and 85% of their production. This gives these two grades an economy of scale advantage so that the other grades are only used where nylon 6 and nylon 66 are unsuitable, usually because of their high water absorption. Nylon 6 and nylon 66 plastics are used mainly for engineering applications where their good bearing qualities are advantageous, but recently acetal resins, which are superior in everything except toughness (the toughness of nylon is enhanced by water absorption), are giving nylons increasing competition. Nylon 11 and nylon 12 are used for electrical insulation where water absorption may be critical. Glass-filled nylons such as ICI Verton, which has aligned long fibres, are taking an increasing share of the market.

- *Aromatic polyamides*: These, derived from aliphatic amines and terephthalic acid, are, not surprisingly, amorphous, more rigid, harder, have lower water absorption, lower expansion coefficient, better heat and moisture resistance, better insulation properties than nylon and are transparent. They compete with polymethyl methacrylate, polycarbonate, polysulphone and ABS in toughness but have not the heat resistance of polysulphone and ABS (Figure 7.89).
- *Aramid fibres*: There is a special class of aromatic polyamide fibre defined by the US Federal Trade Commission as 'aramid fibres' for which the fibre-forming substance is a long-chain synthetic polyamide in which at least 85% of the amide linkages are attached directly to two aromatic rings. Two such liquid-crystal fibres, poly-*p*-phenylene terephthalimide (Kevlar), and poly-*m*-phenylene isophthalimide (Nomex), are marketed by Dupont (Figure 7.90). Kevlar has exceptional strength (up to 3.8 GPa) and is used for reinforcement. It is equivalent in strength but inferior in modulus to steel or carbon.

Figure 7.92 End sealing of acetal chain

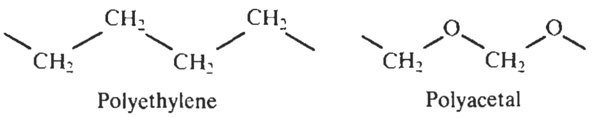

Figure 7.93 Polyethylene and acetal chains compared

- *Acetal resins*: Very pure formaldehyde can be persuaded to polymerize into a linear polymer as shown in Figure 7.91. In contrast to the polymers already described, however, the chain is unstable unless the ends are esterified, as shown in Figure 7.92. The –C–O– bond is shorter than the CH_2–CH_2 bond in the polyethylenes and the polyacetals pack more closely. The resultant polymer is therefore harder, more dense and has a higher melting point and a higher crystallinity (Figure 7.93). Compared with the nylons, acetal resins have better stiffness, fatigue endurance, creep resistance and water resistance and a lower coefficient of friction against steel but are less ductile. Acetals are available blended with PTFE to give a very high operating value of pressure–velocity product above 15 000 against a steel shaft, and blended with polyurethane to give high toughness.
- *Polycarbonates*: These are esters of dibasic alcohols with carbonic acid H_2CO_3. In practice, the market is dominated by bisphenol carbonate, but other polymers are being developed (Figure 7.94). This polymer has rigidity, extremely good toughness up to 140°C, transparency, good insulating properties and is self-extinguishing. It has a very wide application where two or more of these attributes are required and its production capacity has doubled in seven years. Its major application is in electronic and electrical engineering. Its disadvantages are special care needed in processing, limitations in chemical and ultraviolet light resistance, moderate electrical tracking resistance and notch sensitivity.

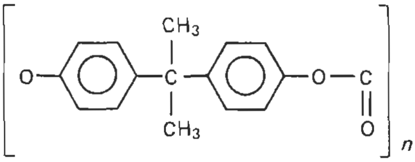

Figure 7.94 Structure of bisphenol carbonate

- *Polyesters*: Linear polymers with very varied structure and properties may be obtained from esters of dihydroxy alcohols and dicarboxylic acids. The possibilities of variation of the polyesters are almost infinite. The principal types are: polyethylene terephthalate (PETP), well known as a fibre (Terylene), as a film (which is stabilized and crystallized by two-way stretching and annealing), as a reinforced and nucleated moulding material and again by two-way stretching as a bottle material in this case gas permeability is reduced by coating with vinylidene chloride base copolymers and polybutylene terephthalate (*PBT*): This has a lower processing temperature but also lower values of T_m and T_g. PBT has better processability than PETP and has therefore a wider range of application for moulded equipment. Other polyesters marketed include polyarylates with high mechanical strength and low notch sensitivity and oxybenzoyl polyesters which have continuous-use temperatures up to 300°C. They are both highly expensive, as are the liquid-crystal polyesters which have excellent mechanical properties and ductility.
- *Modified polyphenylene oxide* (*Noryl*: *GEC*): Polyphenylene ether, whose structure consists of benzene rings linked by oxygen atoms, would be expected to have high thermal and dimensional stability. Such a material with 2.6 methyl side groups was found to form and polymerize very easily and is marketed by GE under the (incorrect) name polyphenylene oxide. It is a rigid, heat resistant, more or less self-extinguishing polymer with good electrical and chemical resistance, low water absorption and very good dimensional stability. Unfortunately, its price is too high to justify more than very limited application and GE therefore introduced a series of blends with polystyrene-type plastics. They are available in combinations of self-extinguishing and non-self-extinguishing and glass-reinforced and non-reinforced grades. They go some way to bridging the gap between the engineering thermoplastics and the more recently developed high-temperature thermoplastics.
- *Polyphenylene sulphides*: These present a problem in classification. They have rather more heat resistance than standard engineering polymers such as polycarbonates but not enough to bring them into the classification of high-temperature polymers. They are, in principle, thermoplastic but can be cross linked by air ageing. Their advantages are:

  Heat resistance better than polycarbonate
  Flame resistance UL temperature index 240, Oxygen Index 53%

Chemical resistance next to PTFE
Good electrical insulant but not as good as PTFE and polyethylene.

Their disadvantages are:

Brittleness
High mould temperature
High cost (compared with polycarbonate).

High-temperature thermoplastics The properties of typical high-temperature thermoplastics are listed in Table 7.62. High-temperature thermoplastics combine good oxidative stability with high-temperature strength. They compare in resistance to environments at high temperature with fluorocarbons but in most cases cost less and are easier to process. They can be melt processed as thermoplastics and compete for most applications with thermosets and for many applications with metals.

Commercially available high-temperature thermoplastics include polysulphone (Udel: Union Carbide), polyether sulphones (Victrex and Astrel: ICI and Carborundum, and Radel: Union Carbide); polyether ketones (PEEK and PEK: ICI), polyetherimide (Ultem: GE), polyimide (Kapton: Dupont) and polyamide-imide (Torlon: Amoco).

- *Polysulphone*: The simplest polysulphone (polyphenylene sulphone) is not thermoplastic and decomposes as it melts. The material marketed as a sulphone, Udel (Union Carbide), supplements the sulphone linkage with other linkages and an isopropyledene group which provides flexibility, imparting toughness and improving processability. The glass-transformation temperature T_g is 150°C.
- *Polyether sulphones*: In polyether sulphone Victrex (ICI) the ether group allows mobility of the chain in the melt phase while the sulphone group gives high-temperature performance. The glass transformation temperature is 230°C. So-called polyarylsulphone Astrel (Minnesota Mining and Manufacturing) has a glass transformation temperature of 285°C. Polyether sulphone Radel (Union Carbide, now marketed by Amoco) is tougher. The polyether sulphones have good tensile and creep strength and impact resistance at both high and ambient temperatures. They have good resistance to attack by petrol, oil and acids, resist burning, produce very little smoke and can be sterilized. They are excellent insulators with a high dielectric constant. They can be melt processed. Their application can be recommended where their superior performance at high temperature as compared with polycarbonate justifies their higher cost. Blends of polysulphone with ABS such as Mindel (marketed by Amoco) are cheaper, easier to process and have higher impact strengths but lower glass-transformation temperature than the unblended homopolymer. They may be used at lower temperatures.
- *Polyether ketones*: Victrex PEEK (ICI), whose structure is illustrated in Figure 7.95, is an outstanding heat-resisting thermoplastic because it has a very high oxidative stability (Underwriters Laboratory temperature index of 240°C), very low flammability without the need for additives, the lowest toxic gas and smoke emission of any thermoplastic (see Figure 7.96) and a high softening point. In addition, it is tough, has excellent fatigue resistance, outstanding hydrolytic stability, low moisture absorption and good radiation resistance. It is easily processed but at high melt temperatures. It can be recommended for use where its outstanding high-temperature properties (its glass-transformation temperature is 144°C) justify its high cost. Its most important application is as an insulator for electrical wiring in locations where its resistance to fire makes it pre-eminent. Polyether ketone (PEK: BASF Hoescht and ICI) has the structure illustrated in Figure 7.97. PEK has

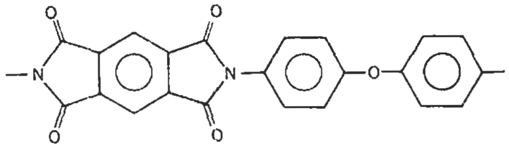

Figure 7.98 Structure of thermoplastic polyimide Kapton

the excellent attributes of PEEK but a superior heat-deformation resistance.

- *Polyimide*: Polyimides such as Kapton (Dupont), whose structure is illustrated in Figure 7.98, have excellent electrical properties, solvent resistance, flame resistance, outstanding abrasion resistance and exceptional heat resistance. The limited tractability of the polymer makes it almost impossible to process by conventional thermoplastic methods and it is very expensive. It may, however, be made into laminates by dissolving a precursor in acetone, impregnating the glass or carbon-fibre reinforcement and curing. The main application is for seals for jet engines and similar rubbing applications where the very high cost is justified. Polyimides may, however, crack in water or steam at 100°C.
- *Polyamide-imide*: Introducing an amide link NHOC in series with the imide group produces a polyamide-imide such as Torlon (Amoco), whose structure is illustrated in Figure 7.99. The polyamide grouping provides sufficient flexibility to allow compression and injection moulding but still retain many of the high-temperature characteristics of polyimides. Polyamide-imides may be used where high-temperature stiffness and creep resistance is required but their main use is for high-temperature bearings. For this purpose they are usually blended with PTFE and graphite.
- *Polyetherimide Ultem* (GE): Ultem, a polyetherimide introduced in 1982, has ether linkages in series with the polyimide linkages. The ether linkages give sufficient flexibility to permit melt processing albeit at high temperatures and the material retains many of the high-temperature properties of the polyimides (Figure 7.100). The material is claimed to have high temperature strength, high softening point, high UL temperature index, high flame resistance, low smoke emission and excellent hydrolytic stability at a price competitive with that of polycarbonates.
- *Fluoroplastics*: The fluoroplastics may be regarded as derived from the polyethylenes—polypropylenes by the substitution of fluorine for hydrogen. The carbon fluorine bond is very stable, having a bond strength up to 504 kJ while fluorine oxygen has a very low bond strength and the polymers are therefore very stable and resistant to attack by a wide range of chemicals. The properties of typical fluoroplastics are listed in Table 7.63.

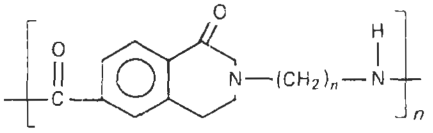

Figure 7.99 Structure of polyamide-imide Torlon

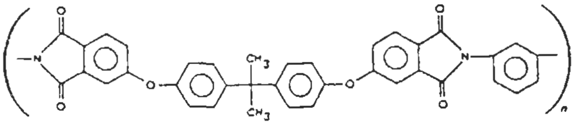

Figure 7.100 Structure of polyetherimide Ulten

Polytetrafluoroethylene (PTFE): PTFE lacks flexibility and has a high melting point. It cannot therefore be melt processed and must be fabricated by powder techniques, pressing and sintering, free sintering or a form of very slow 'extrusion', in which the powder is fed cold into a long heated sintering die. However, the intermolecular attraction between PTFE chains is very small and, as a result, the bulk polymer lacks rigidity and tensile strength and its creep resistance is very low (Figure 7.101). PTFE is also relatively expensive. It has, however, the advantages of inertness, is even more resistant than PEEK, is very resistant to weathering, resists ignition and, if burned by sustained flame from other sources, produces very little smoke. It has excellent electrical characteristics, is non-adhesive and has the lowest coefficient of friction of any material. It is used mainly for coatings and anti-friction additions to other plastics.

Other fluorine-containing polymers: The desirable properties of PTFE have promoted the development of fluorine-containing polymers that can be melt processed. The properties of PTFE are very closely approached by tetra fluoroethylene-hexa fluoropropylene, Teflon FEP (Dupont), which has a lower maximum service temperature and tetra fluoroethylene–ethylene copolymer Tefzel ETFE (Dupont), whose maximum service temperature is still lower. The best processable alternative to PTFE is probably a copolymer of tetrafluoroethylene and perfluoropropyl vinyl ether, Teflon PFA (Dupont). This material has a higher melting point than Teflon FEP, easier processability and improved high-temperature mechanical properties. All these polymers are costly even compared with PTFE and the only fluoroplastics to have gained a significant market share are polyvinyl fluoride, PVF Tedlar (Dupont) which is supplied as a weather-resistant glazing film and polyvinylidine fluoride which has piezo and pyroelastic properties and forms the basis for many fluoro rubbers.

- *Silicones* (*thermoplastics*) The silicon atom is more electropositive than carbon. Therefore although silicon will form compounds analogous to the lower molecular weight hydrocarbons the mutual repulsion between the silicon atoms limits their maximum number in a chain to six. Silicon has, however, a great affinity for oxygen. Silicone polymer chains have therefore a backbone structure of alternate silicon and oxygen atoms as shown in Figure 7.102, where R is normally hydrocarbon ($CH_3C_2H_5$) but may be halide, hydroxyl group or another oxygen-linked silicon radical (siloxane). The most important thermoplastic silicones are silicone fluids, most of which are dimethyl siloxane chains as in Figure 7.103. (Some specialized fluids have branched chains.) They are colourless, odourless, of low volatility, non-toxic and stable at temperatures below 150°C. Their physical properties are summarized in Table 7.64. For linear silicones at 25°C the viscosity (η) in centistokes and the number n of dimethyl siloxy groups are connected by the relationship

$$\log \eta = 0.1\sqrt{n} + 1.1$$

Silicones are used as polish additives, release agents for rubber moulding, lubricants, greases and anti-foaming agents.

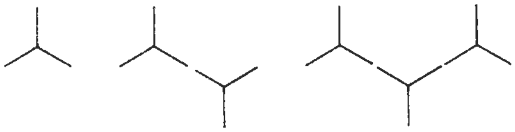

Figure 7.104 Proliferation of reactive groups as thermosets cross link

7.6.5.2 Thermosets

Consider a monomer with at least three reactive points where linkage can occur. A dimer formed by linkage of two of these molecules will have four reactive groups and a trimer will have five. In general, an *n*-mer will have $n + 2$ reactive groups (Figure 7.104).

Linkage from an 'A'-stage resin may therefore start fairly slowly but it accelerates rapidly in the later stages, forming large cross-linked molecules of 'C'-stage resin. Polymers which form these large cross-linked molecules are known as thermosets. They can be made to polymerize by heating, by the addition of a hardener and/or an accelerator or by a combination of both. Polymers cannot be melt processed in the 'C' stage and processing must be carried out before or in the early stages (the 'A' stage) of polymerization.

Thermosets are rigid at room temperature and have markedly greater resistance to distortion or creep at elevated temperature and higher resistance to abrasion than thermoplastics. A consideration which is growing in importance is that, unlike thermoplastics, they cannot be recycled. Although there is no commonly accepted division into commodity and engineering thermosets such a distinction will, for convenience, be made in this section.

'Commodity' thermosets The properties of 'commodity' thermosets are listed in Table 7.65.

- *Phenolics*: The phenolic resins were the first to be produced commercially from compounds of low atomic weight. They are produced by the action of formaldehyde (in the form of formalin, a roughly 37% aqueous solution) on phenol. Novolaks are prepared by reaction of phenol with formaldehyde in the ratio 1:08 under acid conditions (Figure 7.105). They cannot be hardened by heating alone but require the addition of a hardener, usually hexamine tetramine prepared by the action of gaseous amonia on, a formaldehyde solution. Resols are prepared by reacting phenol with an excess of formaldehyde under basic conditions. They will cross link without a hardener if the pH is adjusted (Figure 7.106). A phenol formaldehyde moulding powder will con-

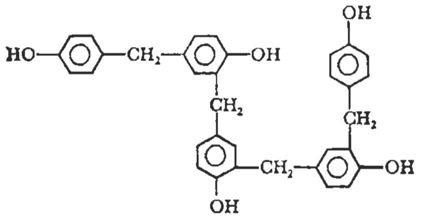

Figure 7.105 Structure of phenolic novolak

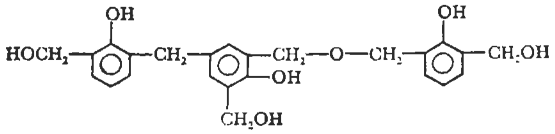

Figure 7.106 Structure of phenolic resol

tain: resin, hardener, (if novolak), accelerator (lime or magnesium oxide), filler, (woodflour, mica, cotton flock, chopped fabric, or twisted cord), lubricant, pigment and (optionally) plasticizers. The filler is essential to combat shrinkage because of the high heat evolution during curing. Phenolics can be moulded at 100–110°C and are cured at 170°C. They are used for domestic and industrial hardware. A large range of phenolic laminates are manufactured. Although they are being replaced by thermoplastics for many applications, a process that is being accelerated by environmental considerations, the general increase in living standards has maintained the overall demand for them.

- *Aminos*: The most widely produced aminos are the urea and melamine formaldehyde resins. Both depend, in a somewhat complicated way, on reactions between methylene groups, between methylene and amino groups and on the elimination of ether linkages, as shown in Figure 7.107. The advantages of urea formaldehyde over phenol-formaldehyde are low cost, high mechanical strength and wear resistance, freedom from taste and odours, the ability to self-extinguish, good electrical properties and a wide colour range. On the other hand, aminos must be filled for successful moulding, have a poor long-term oxidation resistance, poor impact properties, cannot be used above 77°C and have a high moulding shrinkage. The moulding powders are used for bottle caps and electrical fittings and urea formaldehyde adhesives have a large application in the manufacture of chipboard. Melamine reacts with formaldehyde to form trimethylol melamine and hexamethyl melamine, as shown in Figure 7.108. The melamine derivatives have, respectively, three and six reactive groups and will condense to form very hard plastics which have a good colour range, good heat resistance and excellent electrical properties. They are used for tableware and laminates for decorative and electrical applications.

'Engineering' thermosets

- Unsaturated polyester resins:
  Unsaturated polyesters are esters, usually of polyhydric alcohols with unsaturated acids. The resins considered here include: laminating resins, moulding compounds, allylics and alkyds.

  (*a*) *Moulding and laminating polyester resins*
  Moulding compounds are usually maleic acid (or its trans-isomer fumaric acid) esters of 1, 2 propylene glycol as in Figure 7.109. Since any COOH group can react with any OH group it is clear that there is scope for ester molecules with several points where cross linking can occur. In practice, a proportion of saturated acid is added to space out the double bonds and reduce the density of cross linking. Phthalic acid is used in the form of its anhydride because it provides an inflexible link which maintains rigidity in the cured resin and is cheap. The use of isophthalic acid instead of phthalic anhydride gives higher heat-distortion temperatures and flexural modulus and better craze resistance. Styrene is added as a reactive copolymer diluent and because more can be added to isophthalate resins the water and alkali resistance of these can be made better than that of the terephthalates. These resins are used, cured with benzoylperoxides, for high-temperature curing or methyl ethyl ketone peroxide or cyclohexanone

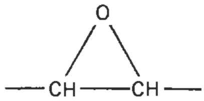

Figure 7.111 Structure of epoxide group

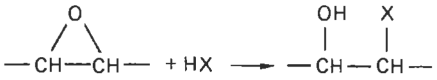

Figure 7.112 Cross linking reaction of epoxide group

peroxide with a cobalt compound as an accelerator for room-temperature curing. They are used to make laminates.

(*b*) *Polyester moulding compounds*

Dough moulding compounds (DMC) are blends of polyester resin reinforcing fibre, mineral filler, pigment, catalyst (usually benzoyl peroxide) and lubricant. They are usually press moulded. Problems have in the past been experienced with DMC but most of these are being overcome by incorporating thermoplastic acrylic/styrene polymers. The problem of damage to fibres is overcome by substituting a sheet moulding compound (SMC) which is made via a system of rolls which produce sheet sandwiched between polythene films. SMC can be moulded and cured to produce many designs for which DMC otherwise have to be used. The polyesters are inferior in strength, adhesiveness and resistance to environments to the epoxide resins, but are much less expensive, and this has ensured their application for all but the most demanding engineering purposes. Developments in thermoplastic resins and their fabrication techniques, and, even more important, the environmental benefit which accrues from their recycling capacity (which the thermosets lack) is enhancing the competition which polyesters have to face.

(*c*) *Alkyds*

Alkyd moulding compounds are polyesters blended with such fillers as cellulose pulp, mineral fillers, lubricants, pigments and peroxide curing agents mixed on hot rolls and powdered. The name 'Alkyd' is also employed for polyester-type surface coatings. In this case the unsaturated acids are derived from natural oils such as linseed oil, soya bean oil and tung oil and they form glycerides with phthalic acid. The coating resins are effectively thermoplastic when applied as a thin coating but air oxidation causes them to cross link so that they harden and set.

(*d*) *Allylics*

Allylic resins are polyesters of vinyl alcohol, which is unsaturated, with phthalic acid. There are two versions, diallyl phthalate (DAP) and diallyl isophthalate (DAIP), as shown in Figure 7.110. The DAP resins are superior for use as electrical insulators to phenolic resins and alkyds in tracking resistance at elevated temperature. The DAIP resins are more expensive and are claimed to withstand 220°C for long periods. Allylics are available in a wide range of colours. They have the drawback of a high shrinkage on cure and, where this is important, epoxide moulding compounds should be used instead. Diallyl glycol carbonate, also an unsaturated glycol ester of dibasic acids, is transparent, hard, has excellent optical properties and is used for spectacle lenses and coatings.

- *Epoxide resins*: These are characterized by the possession of at least two highly strained and therefore highly reactive epoxide groups (see Figure 7.111). These groups react particularly with substances which provide hydrogen ions (Figure 7.112). Since there are at least two epoxide groups per molecule cross linking occurs very easily. As there is no elimination of water, epoxies exhibit a lower curing shrinkage than many other thermosets. Eighty to ninety per cent of epoxide resins are produced by reacting bisphenol A and epichlorhydrin to produce a compound or polymer with the structure shown in Figure 7.113. These will link not only by the epoxy groups but also by the hydroxyl group(s) but other forms include cyclic aliphatic, acrylic, aliphatic and other glycidyl ether resins. There is not only a variety of monomers but also a choice of hardening systems. These include amines of which primary and secondary amines enter themselves into the cross linking while tertiary amines are catalytic, acids, and acid anhydrides. Anhydrides are preferred to acids because they release less water on cure, and are in other respects equivalent. Amines give a more rapid cure and the polymer has greater resistance to alkalis but precautions must be taken to protect the skin of the operator from attack. Acids are less skin sensitive and give higher heat-distortion temperatures. That of amine-cured resin seldom exceeds 100°C, that of phthalic anhydride is about 120°C while methylnadic anhydride gives 202°C. Other additions include diluents and flexibilizers.

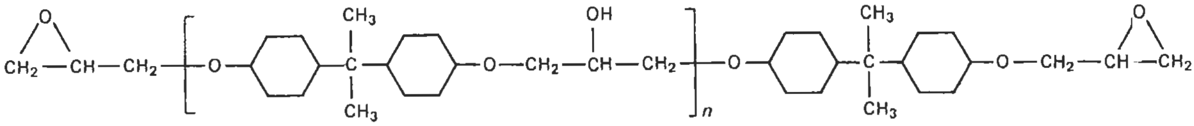

Figure 7.113 Glycidal ether epoxy resin

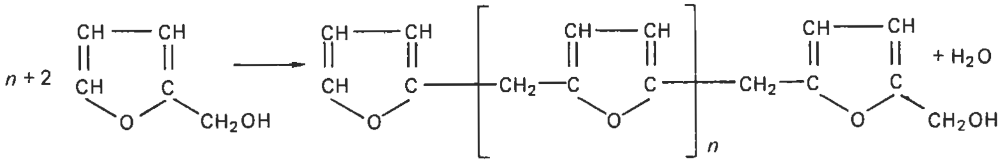

Figure 7.114 Suggested mechanism of furan resin formation

In general, epoxide resins have almost unequalled adhesion, low shrinkage on cure, freedom from volatile solvents, very high chemical resistance, high tensile strength and creep resistance. This combination of properties has ensured their application in spite of their relatively high cost. Their major application is for surface coatings. Another important use is for adhesives.

Liquid resins are used to encapsulate electrical and electronic circuit components. There is a small production of moulding powders. The most significant technological application of epoxide resins is as a matrix for composites. These have outstanding value where a high strength/weight ratio is paramount.

- *Thermosetting polyimides*: These have similar structural features and properties to thermoplastic polyimide but have the advantage that they can be processed in the monomer form and then hardened. They are used mainly for high-temperature bearings reinforced and filled with graphite or PTFE or both. Their properties are listed in Table 7.66 along with thermoplastic polyimides.
- *Furan resin, Quacorr RP100A (Quaker Oats Co)*: Furan resin is a condensation product of furfural alcohol (which itself is prepared from oat husks by digesting and hydrogenating – see Figure 7.114). When hardened by, for example, the addition of 4% of toluene *p*-sulphonic acid the chains cross link as shown in Figure 7.115. The cross linked molecules are rigid and inflexible and therefore have a high deformation temperature, and chemical and water resistance better than phenolics, polyesters and epoxides. Furan resins are used for lining of tanks, vats and piping in chemical plants and as laminates to resist organic fluids, particularly at high temperature.
- *Silicone resins (thermosetting)*: Silicone resins which contain OH groups (usually produced by the action of water on chlorosilanes) cross link by condensation (Figure 7.116). Clearly, an increase in the proportion of hydroxyl (–OH) groups to methyl groups (CH_3) attached to the silicon atoms in the chain would provide additional cross linkage and a 1:1 ratio of methyl to silicon would be brittle when hardened. Methyl/silicon ratios between 1.2 and 1.6 are used in practice. Phenyl groups C_6H_5 can be substituted for a proportion of the methyl groups. Methyl-phenylsilicone resins are used mainly for glass cloth laminates for electrical applications at high temperature. They are cured, initially by heating and finally by a catalyst such as triothanolamine zinc octoate or dibutylin octoate. Compression-moulding compounds may be used for high-temperature electrical applications but are even more expensive than PTFE.

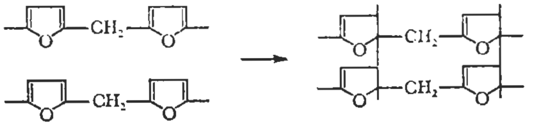

Figure 7.115 Cross-linking reaction of furan resin

Appendix: Worked examples of design of plastic components

Cantilever beam

A rectangular cantilever beam of length 20 cm is required to support an end load of 5 N at a temperature of 150°C. At the end of its useful life of 1 year the end deflection should be no more than 3 mm. Select an appropriate grade and beam dimension.

[a] Approximate mid-1991 prices, £ per kilo per tonne.

From Strength of Materials formula

(1) $Y_{max} = \frac{WL^3}{3EI}$

Hence $\frac{WL^3}{3EI} = 3 \times 10^{-3}$m

(2) $I = \frac{bd^3}{12}$

Assume the bar is moulded from the end and hence along-the-flow data can be used.
Try the carbon reinforced grade 450 CA30.
From the graph of Tensile Creep Modulus versus Time at 150°C

$E \sim= 10$ GPa

From (1)

$$3 \times 10^{-3} = \frac{5 \times 0.2^3}{3 \times 10 \times 10^9 \times 1}$$

Therefore $I = 4.44 \times 10^{-10}$ m^4

From (2)

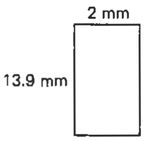
$$\frac{bd^3}{12} = 4.44 \times 10^{-10} \text{ m}^4$$

The most economical use of material will be with b as thin as feasible, say 2 mm. Therefore

$$444.4 \times 10^{-12} = \frac{2 \times 10^3 \times d^3}{12}$$

and $d = 13.9$ mm

In 450 CA30 the beam dimensions will be



Check stress level

$$\frac{M}{I} = \frac{\sigma}{y}$$

$M = 5 \times 0.2 = 1$ Nm

$I = 4.44 \times 10^{-10}$

$$y = \frac{d}{2}$$
$$= 6.95 \times 10^{-3}\text{m}$$

$$\text{Therefore } \sigma = \frac{1 \times 6.95 \times 10^{-3}}{4.44 \times 10^{-10}}$$

$= 15.6$ MPa

From the tensile creep rupture curve this is seen to be well on the safe side.

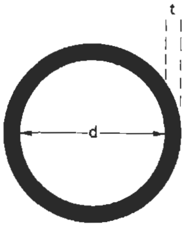
Key to symbols:
Y_{max} = maximum deflection
I = moment of inertia
y = distance from neutral axis
L = length of bean
W = load
b = breadth of beam
d = depth of beam
E = modulus
M = bending moment
σ = stress

Thin-walled tube

A thin-walled tube of 10 mm internal diameter is required to carry hot gas under a pressure of 30 bar. The tube will operate at 100°C. Calculate the wall thickness required in PEEK 450G.
Thin cylinder assumption is valid if $t/d \leqslant 0.1$.

Circumferential (hoop) stress $\sigma_c = \frac{pd}{2t}$

Longitudinal stress $\sigma_L = \frac{pd}{4t}$



From the graph of Tensile Creep Modulus versus Time at 100°C E for 450G at long times and 100°C = 2.5 GPa.
This is valid up to a 2% strain.

$$\sigma_c = 2.5 \times 10^9 \times 0.015$$
$$= 37.5 \text{ MPa}$$

Assume a design strain level of 1.5%.

$$\frac{pd}{2t} = \frac{30 \times 10^5 \times 0.01}{2 \times t}$$

$$\text{Therefore, wall thickness } t = \frac{30 \times 10^5 \times 0.01}{2 \times 37.5 \times 10^6} \text{ metres}$$
$$= 0.4 \text{ mm}$$

$$\text{Check thin wall assumption } t/d = \frac{0.4}{10}$$
$$= 0.04$$

This is less than 0.1 and therefore the assumption is valid.

Key to symbols:
t = wall thickness
σ_L = longitudinal stress
d = internal diameter
p = pressure
σ_c = circumferential (hoop) stress
E = modulus

7.7 Elastomers

7.7.1 Introduction

Elastomers, or rubbers, have been used in engineering for a little over one hundred years. For the first half of this time there was no practical alternative to the natural material; the fact that examples have survived to present times shows that components made with elastomers can perform useful functions after long periods. Today elastomers are a large and growing class of materials. At one end of the spectrum, natural rubber (NR) and synthetics such as chloroprene rubber (CR) are soft materials which have the ability to undergo extensions of many hundreds of per cent yet return rapidly to their original shape when the deforming force is removed; at the other extreme lie some of the thermoplastic elastomers (TPEs) which are harder and less elastic. The compliance of rubbers in shear and extension combined with their near-incompressibility means that particular techniques are often necessary for stress analysis with these materials.

Natural rubber (NR) was used in the ancient civilizations of Central and South America. It was not possible to exploit fully its elastic characteristics for mechanical applications until Charles Goodyear discovered in 1839 that the addition of sulphur, followed by heating, changed the rubber into a truly elastic material. This process, known as vulcanization (or curing), results in cross links being formed between the long molecular chains of the base polymer.

In the 1920s synthetic elastomers began to appear. Today there are over 20 types of synthetic elastomer produced commercially, each with its own characteristics. Advances have also been made in the vulcanizing systems, antidegradants, fillers and oils used with the elastomer in the formulation of an engineering material. With modern formulation methods, elastomers are available to cater for a wide range of mechanical requirements, service temperatures and environmental conditions, singly or as blends.

The mechanical properties of NR epitomize those of a strong, fully rubbery material, and it is these attributes, together with its competitive price, which account for the continued widespread use of NR in vehicle suspension springs, for example. Where excellent resistance to weathering and high temperatures is required with a good degree of elasticity, synthetic elastomers such as ethylene propylene rubber (EPM/EPDM) are used. A relatively new set of additions to the family of elastomers are the thermoplastic elastomers (TPEs). These are materials with properties intermediate between elastomers and thermoplastics. It is sometimes possible to redesign rubber-based components, replacing the elastomer with a TPE and achieving cost and/or weight reductions.

7.7.2 Vulcanization, compounding and moulding

During vulcanization or 'curing' the polymer chains of a base elastomer are chemically cross linked (Figure 7.117). Unvulcanized natural rubber was used for rubber balls, erasers and macintoshes, but vulcanization resulted in an altogether stronger, more environmentally resistant material and paved the way to the use of rubber in mechanically demanding applications.

The original curing process used sulphur and high temperatures (hence the name 'vulcanization'). The majority of cross-linking processes for natural and other rubbers still involve the use of sulphur and elevated temperatures. However, vulcanization conditions can vary a great deal from high-temperature (up to 200°C) cures lasting only a few seconds, through 'normal' cures typically lasting about 15 min at 150°C, to room-temperature vulcanization taking place over days or longer. The properties of the vulcanized rubber (or 'vulcanizate') are influenced by the number of cross links and their type: the properties can also be affected by other molecular modifications to the elastomer which occur during the vulcanization process. Vulcanizing systems with relatively high loads of sulphur are termed 'conventionally accelerated', those with low sulphur levels are called 'EV' (efficient vulcanization) systems. EV systems produce NR and styrene–butadiene (SBR) vulcanizates with more stable properties at high temperature and lower creep (see Section 7.7.3.2). For NR, EV leads to a reduction in fatigue resistance but in SBR fatigue resistance is maintained.

The term 'compounding' in rubber technology refers to the mixing of various ingredients into rubber. Mixing of solid rubber is performed on open two-roll mills and in closed mixers. The high shear forces produced are used to disperse ingredients and can also be used to break down the molecular weight or 'masticate' certain rubbers. In addition to the vulcanizing chemicals, the ingredients usually include particulate fillers. These can be non-reinforcing (clay, chalk and some carbon blacks, finely divided carbon powders fall into this category) or reinforcing (carbon black or fine silica powder). Non-reinforcing fillers, added to harden or cheapen a rubber, generally have a neutral or negative effect on strength properties. Reinforcing fillers, in contrast, tend to have a positive effect on strength properties. This is particularly true for some of the synthetics, a number of which are weak without reinforcing fillers. Silicone rubber is an example of an elastomer the strength properties of which benefit greatly from the presence of an appropriate silica filler. Fillers can also markedly increase the damping and the stiffness of the elastomer – particularly at small strains – and can lead to complex history-dependent behaviour.

Rubber compounds routinely include some oil or other diluent added to aid processing of the rubber prior to vulcanization and/or to influence the properties of the vulcan-

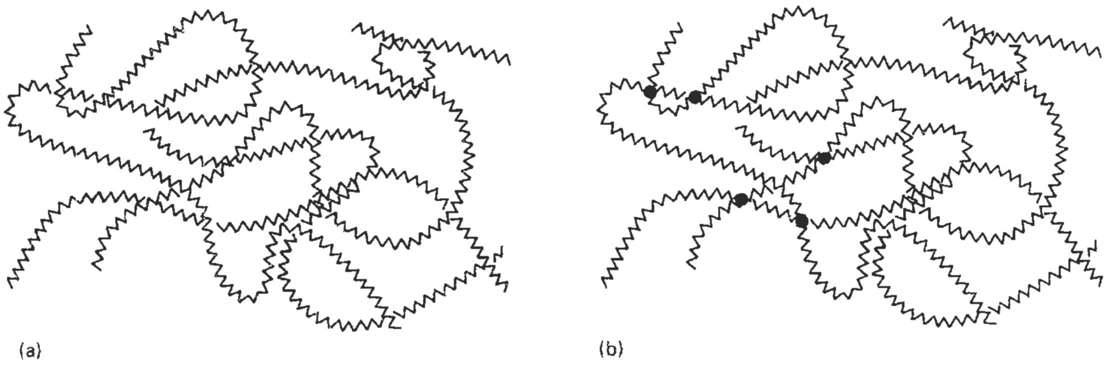


Figure 7.117 Cross linking of elastomer chains. (a) Elastomer chains kinked, coiled and entangled prior to vulcanization; (b) elastomer chains cross linked (●) together

izate – notably stiffness or low-temperature resistance. Many elastomers have anti-degradants of various kinds added during compounding to improve the resistance of the final vulcanizate (to attack, for example, by oxygen or ozone). Natural, butadiene and styrene–butadiene rubbers (NR, BR and SBR) are examples of elastomers whose environmental resistance is greatly improved by the presence of appropriate anti-degradants.

Vulcanized elastomeric products can be given their final shape in a number of ways. Machining of vulcanized rubber is relatively rare, except for trimming; but calendering of unvulcanized sheet, coating of fabric from rubber solution, extrusion and moulding are all common.

Broadly, there are three types of moulding. In compression moulding a quantity of unvulcanized material is placed in a single-cavity mould (or mould area) with a closing lid or plunger. The mould is then pressed between heated platens of a press whereupon the elastomer is shaped and vulcanized. Transfer moulding is also widely used and here the plunger is located in the first cavity; when the moulding is under the press the rubber is forced through transfer ports into the second, shaping, cavity. Compression or transfer moulding time is normally not less than 5 min although there is considerable variation depending on size of component, rubber formulation and temperature. It should be realized that conventional thermosetting elastomers such as NR, EPM/EPDM, BR, SBR, chloroprene rubber (CR) and nitrile (NBR) behave as complex non-linear viscoelastic materials during the moulding process, and that it is only under high pressures that they can be made to flow at a satisfactory rate. Injection moulding of a thin-walled elastomeric component typically takes less than 1 min for conventional elastomers. With conventionally moulded elastomers it is not unusual for products to be heated in an oven after removal from a hot mould; this process, termed 'post-cure', is particularly common for certain speciality rubbers (e.g. fluorinated types). Post-cure can improve elastic recovery in the vulcanizate and reduce the tendency to creep without the need for long and expensive moulding cycles.

Steam autoclaves and molten-salt baths are two further methods for the cure of rubber articles, although previous shaping is necessary in such low-pressure curing. Millable polyurethanes are processed as conventional elastomers but castable polyurethanes flow more easily so lighter moulds can be used. Although castable elastomers are not processed/vulcanized in the same way as conventional elastomers, a form of chemical cross-linking does normally take place during and after moulding.

For thermoplastic elastomers (TPE), however, chemical cross-linking does not take place during moulding. Instead, within the TPE, thermoplastic areas, molten during and solid after moulding, take the place of chemical cross-links. Because there is no cure time, very rapid injection moulding is possible for TPEs, and the temperature of the mould itself needs to be lower. There are two main classes of TPE; the block co-polymers and the physical blends, although there are also materials with thermally labile (reformable) cross-links (e.g. ionomeric polymers, which can be classed as TPEs). Physically blended TPEs are prepared from thermoplastic and rubbery polymers which generally remain distinguishable in the final material. The molecular chain structure of block polymer TPEs consists of alternate blocks of hard, amorphous or crystalline, polymer and soft rubbery polymer.

Block co-polymer TPEs are composed of alternate blocks of hard polymer (high glass-transition temperature or crystalline) and soft rubbery polymer (low glass-transition temperature) on a molecular scale. At high temperatures the 'hard' segments are sufficiently soft to allow flow into shape to take place. However, at low and moderate operating temperatures the hard segments link the soft segments together and have a similar function to chemical cross-links and reinforcing filler in a conventional vulcanized and filled rubber. Styrene–butadiene–styrene (SBS) block co-polymers are an early example: the glassy polystyrene blocks link the rubbery polybutadiene blocks. Polyether–polyester block copolymer rubbers first became commercially available a decade after SBS, but now, together with polyurethane and polyether–polyamide materials, epitomize the high, mechanical performance TPEs. In polyether–polyester TPEs most of the polyester (hard) material is crystalline at operating temperature but some is in the amorphous phase with the polyether. This interlinked morphology makes for a strong material. Polyurethane TPEs consist of urethane-sparse (soft) and urethane-rich (hard) segments; their morphology is broadly similar to that of polyether–polyester TPEs. Polyether–polyamide block copolymer TPEs consist of soft (polyether) and hard (polyamide) segments.

TPOs, TPVs and TPEAs are all essentially physical blends between rubbers such as EPM/EPDM, NR or NBR and polyolefin thermoplastics – typically polypropylene but sometimes polyethylene. Depending on the proportions present, method of preparation and other factors, the elastomer and thermoplastic or the thermoplastic alone form continuous phases. Materials with more rubbery properties can be obtained by vulcanization of the rubber phase during blending with the thermoplastic; these dynamically vulcanized materials are sometimes called 'thermoplastic elastomer alloys'. The addition of fillers and liquid diluents is normally made at the production stage of TPE materials.

7.7.3 Basic elastomer properties

7.7.3.1 Elasticity

Natural rubber (NR) was the first elastomer and its mechanical properties set a standard by which other elastomers are judged. NR when compounded without filler (gum NR) can have a very low shear modulus (~0.3 MNm^{-2}) depending on the degree of cross-linking, and can undergo deformation of several hundred per cent without failure or significant permanent deformation (Table 7.67). Some insight into the mechanical properties of NR can be gained by considering its molecular structure (Figure 7.118). NR consists principally of chains of *cis*-1,4 polyisoprene units. These polymer chains consist typically of 20 000 repeat units. The IV–I carbon–carbon bonds permit easy rotation between adjacent isoprene units. Thus it is possible for a polymer chain to have a relatively straight configuration (low entropy) or a very twisted configuration (high entropy). It is these *entropic* changes which are primarily responsible for the mechanical behaviour of gum NR up to strains of several hundred per cent. This is in sharp contrast to many other materials for which distortion of interatomic bonds is of prime importance; the fact that the tension in a section of stretched gum NR *increases* when it is heated emphasizes this difference. In crude terms the shear modulus of vulcanized gum NR is about 0.4 MNm^{-2} whereas the bulk modulus is around 2000 MNm^{-2}.

Elastomers are sometimes specified in terms of their hardness, on the IRHD (international rubber hardness) or Shore A scales. However, it should be realized that a given percentage hardness tolerance typically corresponds to a much wider percentage tolerance of modulus. Filled elastomers have non-linear stress–strain characteristics, particularly at small strains, and hardness indentation produces non-uniform strain within the elastomer; this combination leads to uncertainty in the

[a] Gum vulcanizate containing cross-linking ingredients only.

[b] Vulcanizate containing approx. 50 parts of a reinforcing carbon black per 100 parts, by weight, of natural rubber.

[c] GN (sulphur modified) type plus 44 parts of a reinforcing carbon black per 100 parts, by weight of chloroprene rubber.

[d] Estimated value.

[e] Hardness range is zero (e.g. liquid) to 100 (e.g. glass).

[f] W type.

[g] GN type.

[h] Calculated using original unstrained cross-sectional area; when the cross section just before break is used the value can be up to 200 MNm^{-2}.

[i] For isotropic materials, at small strains, E is related to G, K and ν by $E = 2G(1 + \nu) = 3K(1 - 2\nu)$.

[j] Plane compression waves in medium of large extent.

[k] Depends on filler type and concentration, etc. High values obtainable by replacing carbon black by silica. Values under 10 Ωm achievable by using specially conductive carbon blacks.

relationship between hardness and modulus, with hardness often corresponding best with shear moduli measured at about 5% strain.[77]

When strains are large the equations of classical elasticity are no longer strictly applicable; so deformations in gum elastomer are often described in terms of extension ratios (λ_1, λ_2, λ_3) of final length (l) to original length (l_0) in the three principal directions:

$$\lambda_1 = l/l_0$$

For elastomers it is usually appropriate to consider true stresses, based on current areas, rather than engineering stresses, based on original areas. In rubber elasticity theory, also known as hyperelasticity and finite strain theory, widespread use is made of the three invariants:

$$I_1 = \lambda_1^2 + \lambda_2^2 + \lambda_3^2$$

$$I_2 = \lambda_1^2\lambda_2^2 + \lambda_2^2\lambda_3^2 + \lambda_3^2\lambda_1^2$$

$$I_3 = \lambda_1^2\lambda_2^2\lambda_3^2$$

which are independent of the directions of the axes chosen. Provided that energy dissipation processes can be ignored, the mechanical behaviour of the elastomer can be predicted from the strain energy density, or stored free energy, W. (In

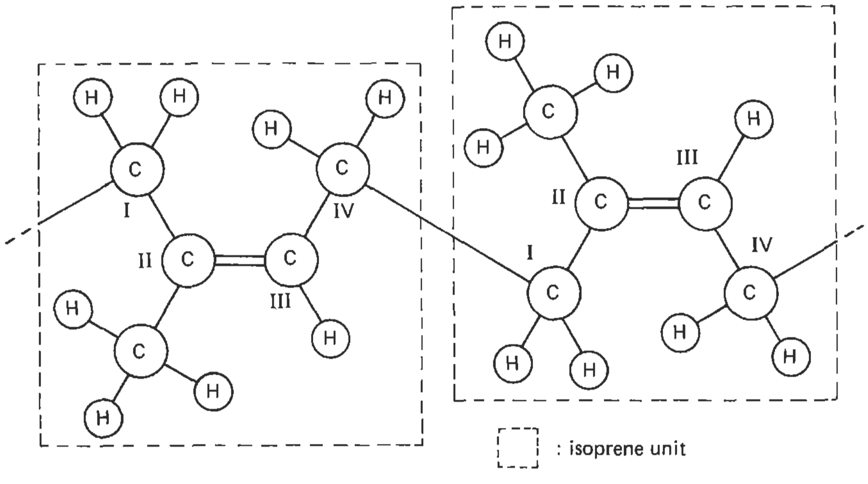

Figure 7.118 Molecular structure of *cis*-1,4-polyisoprene

practice, this is applicable to a well-vulcanized gum, unfilled, elastomer operating well above its glass-transition temperature, T_g.) The principal (true) stress in direction 1, for example, is given by

$$\sigma_1 = \frac{1}{\lambda_2\lambda_3}\frac{\partial W}{\partial \lambda_1}(I_1, I_2, I_3)$$

The simplest hyperelastic strain energy density function is given by the statistical (mechanics) theory, which assumes incompressibility and therefore independence of W from I_3:[78]

$$W = \tfrac{1}{2}G(I_1 - 3)$$

The statistical theory is capable of giving approximate values in stress calculations and provides some useful insights into the way that elastomers behave. If an element of elastomer is subjected to a simple shear, γ (Figure 7.119), it can be shown that $I_1 - 3$ is γ^2, so that statistical theory predicts

$$W = \tfrac{1}{2}G\gamma^2$$

and the shear stress

$$\sigma_{xy} = \frac{dW}{d\gamma} = G\gamma$$

indicating that shear stress is proportioned to shear. This behaviour is observed for *unfilled* vulcanization up to quite high deformations ($\gamma \sim 1$). However, such simple linear relationships are not predicted for other modes of deformation. For homogeneous compression as in a tensile test, the principal extension ratios are:

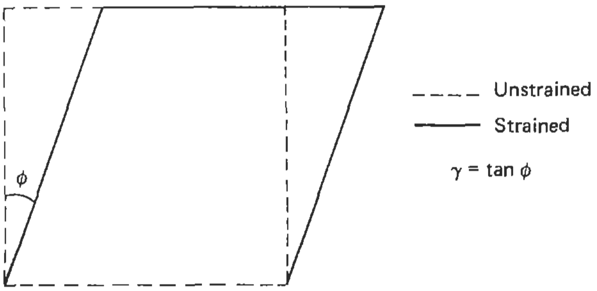

Figure 7.119 Simple shear

$$\lambda_1 = \lambda \text{ and } \lambda_2 = \lambda_3 = \lambda^{-1/2}$$

The extension or compression stress given by statistical theory is

$$\sigma_1 = G\left(\lambda^2 - \frac{1}{\lambda}\right)$$

where it has been assumed that $\sigma_2 = \sigma_3 = 0$. Note, too, that the stress given is the *true* stress – based on *final* cross-sectional area; the corresponding engineering stress based on the original cross section is

$$\sigma_E = G\left(\lambda - \frac{1}{\lambda^2}\right)$$

This result can be seen to coincide with the classical result for infinitesimal longitudinal strains ($\epsilon = \lambda - 1$) if Poisson's ratio is taken as $\frac{1}{2}$:

$$\sigma_E = E\epsilon = 2(1 + \nu)G\epsilon = 3G\epsilon$$

The Mooney–Rivlin equation for W is sometimes used as an improvement on the statistical theory:

$$W = C_1(I_1 - 3) + C_2(I_2 - 3)$$

This equation gives the true stress for homogeneous elongation or compression as:

$$\sigma_1 = 2C_1\left(\lambda^2 - \frac{1}{\lambda}\right) + 2C_2\left(\lambda - \frac{1}{\lambda^2}\right)$$

Once again the side stresses σ_2 and σ_3 have been taken to be zero. The Mooney–Rivlin equation is the first two terms of the more general expression for the strain energy density function:[79]

$$W = \sum_{i,j=1}^{N} C_{ij}(I_i - 3)^i\,(I_j - 3)^j$$

In principle, by taking a sufficient number of terms in this or other series, strain energy density functions can be represented to a high degree of accuracy. However, there are problems which remain. When elastomer is confined it cannot be assumed incompressible. Compressibility is sometimes allowed for by adding terms in (powers of) $(I_3 - 1)$ or $(I_3^{1/2} - 1)^2$ to the strain energy power series.

The stress–strain curves for filled elastomers often exhibit sharp changes of slope – especially for small strain amplitude deformations. This can lead to computational difficulties with the power series representation of the strain energy density function. A related and more fundamental problem is that when filled elastomer is deformed not all the work done is stored – some is lost from the mechanical system in the form of heat. The stress is therefore no longer simply a function of the state of strain: it also depends on how that state of strain was arrived at.

7.7.3.2 Creep and stress relaxation

A well-vulcanized gum elastomer, such as polybutadiene (BR) or natural rubber (NR), operating well above its T_g has low creep. Stress relaxation ($\dot{S}$) and creep ($\dot{C}$) rates are defined:[80]

$$\dot{S} = -\frac{1}{\sigma}\frac{\partial\sigma}{\partial t}\bigg|_{\epsilon}, \quad \dot{C} = \frac{1}{\epsilon}\frac{\partial\epsilon}{\partial t}\bigg|_{\sigma}$$

So their interrelationship is:

$$\dot{C} = \frac{\sigma}{\epsilon}\frac{\dot{S}}{(\partial\sigma/\partial\epsilon)_t}$$

showing that for a given stress relaxation rate and secant modulus, creep is lowest for stiffening spring and highest for softening spring behaviour. The theory of linear viscoelasticity holds reasonably well for gum elastomers, especially in shear, so that time, physical stress relaxation, and the mechanical loss tangent (tan δ) are interrelated:

$$t\dot{S} \approx \frac{2}{\pi}\tan\delta$$

Therefore unfilled elastomers with high mechanical damping such as nitrile (NBR) have relatively high creep and stress relaxation rates. For filled materials based on low-damping elastomers, damping is largely non-viscoelastic and the previous equation substantially overestimates $\dot{S}$.

Plots of deformation during creep or stress during relaxation against log t are approximately linear. The rate of stress relaxation is generally reported as a percentage (of the stress 1 min after the displacement was applied) per decade (tenfold increase in time); creep is similarly reported in percentage per decade. As an indication, stress relaxation for a normal gum NR vulcanizate is about 1.5% per decade, while for a heavily filled NR vulcanization about 5% per decade can be expected. After long periods, stress relaxation may largely be caused by chemical changes in the elastomer rather than by viscoelastic or other physical processes. The 'chemical' relaxation rate is approximately independent of time and has a different dependence on temperature than does physical relaxation. For a typical NR-based material at 10°C, the anaerobic chemical relaxation rate is about 0.5% of initial stress per annum. In sustained cold conditions, some elastomers crystallize, also resulting in stress relaxation; these effects, in contrast to other physical and chemical relaxation processes, can be reversed by sufficient warming.

7.7.3.3 Effects of filler

It can be seen in Figure 7.118 that each isoprene unit in *cis*-1, 4-polyisoprene contains a double bond between carbon atoms II and III: the polymer chain's backbone is said to be 'unsaturated'. The prevalence of these double bonds in NR renders it vulnerable to oxidative attack by diatomic oxygen, ozone or ultraviolet radiation, for example. There are similar potential problems for other unsaturated elastomers such as styrene–butadiene (SBR). However, replacement of carbon atoms II or III by an atom of high electropotential and/or large radius can provide some protection by stabilization of the double bond by electron sharing and/or by the blocking effect of the large atom; the chlorine atom in chloroprene rubber performs these roles. Vulnerable elastomers can also be protected from diatomic oxygen and ozone by the inclusion into the rubber compound of anti-degradant chemicals which impede the oxidation process. Wax included in the elastomer formulation diffuses to the surface after moulding and can form an effective barrier against ozone in some applications. Addition of even a small amount of carbon black powder gives protection against ultraviolet radiation.

When NR is subjected to very large strains, highly ordered regions of polyisoprene are formed. (A corresponding process occurs in other elastomers – notably chloroprene rubber.) This process of strain crystallization, which is quickly reversed once the strains are reduced, gives NR a good measure of resistance to fatigue crack propagation – even when the elastomer contains little or no filler. In contrast, many other elastomers, notably EPM/EPDM and styrene–butadiene (SBR), normally require substantial loadings of reinforcing filler to give adequate fatigue life.

Inclusion of filler in a rubber compound can also modify processing properties and harden the vulcanized material. However, the presence of significant amounts of reinforcing filler in a rubber compound leads to appreciable levels of mechanical damping, particularly at strain amplitudes around 3%. The filled material can be much stiffer at small strains than at large strains and the mechanical properties depend on strain history to a marked extent. Overall, the effect of a substantial filler loading on an elastomer is to create a material which is of great practical use but whose detailed mechanical behaviour is difficult to model with accuracy. Filled elastomer mechanical behaviour includes:

1. Non-elliptical force deformation loops;
2. High damping without strong frequency dependence of modulus;
3. Strain and history dependence of properties.

The 'triboelastic' model for filled elastomers has recently been developed to incorporate some aspects of (1)–(3) above; notable for its relative simplicity it is based on combinations of spring and frictional elements.[81] Fractional calculus offers another approach to modelling the weak frequency dependence of modulus in high-damping filled elastomers.[82] However, modelling the dynamic behaviour of filled elastomers remains a research area.

7.7.4 Thermoplastic elastomers

Thermoplastics elastomers (TPEs) are materials which have mechanical properties intermediate between conventional elastomers and normal thermoplastics. TPEs share the advantages of normal thermoplastics: rapid moulding, re-usable scrap and the potential to combine a number of parts in a single moulded unit. Where a metal or thermoplastic component is replaced by a TPE, machining costs can sometimes be reduced because dimensional tolerances are less critical for the TPE as it is more deformable. Environmental and fluid resistance is often higher for TPEs than for the rubber which they seek to replace. The high ozone resistance of TPEs can lead to very high fatigue lives at low strain amplitudes. (Often it is ozone cracking which initiates failure in vulnerable elastomers operating at low strain amplitudes.)

In general, TPEs show less complete recovery immediately after deformation than do many conventional elastomers. Chemical creep and relaxation rates, dominant at long times, tend to be lower for TPEs although physical, shorter-term, relaxation is generally higher. In components moulded from TPE, residual stress can be significant and further study of the effects of this on long-term performance would be beneficial.

Higher modulus materials, with Young's moduli up to hundreds of MNm^{-2} can be obtained with TPEs than is normal for conventional elastomers; however, the yield strains of these high-modulus TPEs is correspondingly small (typically 10%) when judged by the standards of other elastomers. The relatively high moduli of some TPEs means that weight savings can be achieved compared with conventional elastomers where a particular stiffness is a prime requirement in the product. However, the lower extensibility of hard and moderately hard TPEs means that redesign is often necessary.

7.7.5 Design of elastomeric components

Frequently, an elastomeric component is required to have a particular stiffness and to be able to support a given load safely. For dynamic applications a damping level over a particular frequency range may also be specified. (Dynamic stiffness and damping may also interact significantly with temperature effects (see Section 7.7.7.2).)

Approximate design of elastomeric components to a stiffness is relatively straightforward for simple geometries. However, some account must generally be made of the history-dependent non-linear behaviour of the material and the state of cure of various parts of the component. The qualifying geometries are limited to the high aspect-ratio bonded pad and a few others. For these, analytical small-strain formulae are available.[83–86] In the case of a circular bonded pad of diameter, d, and thickness, t, the shape factor, S, is given by

$$S = \frac{d}{4t}$$

If $2.5 < S < 7$ and G is the shear modulus of the elastomer, the translational shear stiffness (k_s), the torsional shear stiffness (T_s), the compressive stiffness (k_c) and the tilting stiffness (T_c) are given (Figure 7.120), to a reasonable approximation, by:

$$k_s = \pi d^2 G/4t, \quad T_s = \pi d^4 G/32t$$

$$k_c = 3\pi d^2 G S^2/2t, \quad T_c = \pi d^4 G S^2/32t$$

Also, if the pad is compressed by an amount d, the shear strains produced in the elastomers are typically $\sqrt{6}\,Sd/t$ rising to a maximum of $6Sd/t$ at the edges of the bonds. Note also that the horizontal stiffness of a multiple layer pad may be significantly reduced because of tilting of the layers.

For more complex geometries, in the past a combination of approximate formulae, experience, intuition, trial and error and rubber compound adjustments have been needed to obtain a component of a given stiffness. Today, finite-element analysis (FEA) is increasingly being used to calculate the force–deformation behaviour of (and stresses within) elastomeric components. For unfilled elastomers, there is little difficulty in describing the material properties needed for either small- or large-strain programs (see Section 7.7.3). Small-strain linear programs may be adequate in many cases where the strains are approximately 30% or less since the relative error will be of the order of the prevailing strain. The near-incompressibility of elastomers does, however, present a difficulty for many FE packages. The small-strain non-linearity of filled elastomers can present a serious difficulty for small- or large-strain FE programs and prediction of the dynamic behaviour of components made with highly filled elastomer remains a research area. Finite element analysis is, however, very useful for gaining insight into the behaviour of components of complex shape (Figure 7.121).

7.7.6 Elastomeric composites

A widely used type of elastomeric composite consists of layers which are virtually rigid alternating with (and bonded to) layers of elastomer. The rigid layers are often made from steel and are commonly referred to as 'reinforcements'. As shown by the formulae in Section 7.7.5, the stiffness in a direction perpendicular to the planes of the reinforcements can be made much greater than the in-plane stiffness. Many components, such as laminated earthquake isolation bearings and the suspension springs for some lorries, do have simple planar reinforcements. However, in other units the reinforcement layers can be V-shaped, as in suspension springs for some trains, or two-dimensional curves, as in certain helicopter rotor bearings.

Elastomeric composites are also made in which the bonded reinforcement layers are woven fibres of glass. These reinforcements are relatively inextensible and such pads have been used widely as expansion bearings in bridges in California. Another subtly different type of composite pad consists of alternate layers of nylon fabric with some extensibility and cork-filled elastomer. Such bearings are used widely in Britain for vibration isolation. Although the shape factors are high in many of the types of composite listed above, in most cases their compliance derives principally from the filled rubber layers: in a further commercially available type of composite a significant amount of compliance is provided, initially at least, by the non-elastomer layers. In this case the elastomer layers are hundreds of times thinner than the plan dimensions of the pad and the non-elastomer layers are woven textile fibre.

Most elastomeric composite springs in use are of compact design. Their forte is the support of large loads – especially those acting perpendicular to the plane of reinforcements; furthermore, the translational stiffnesses in all three directions can be adjusted independently of one another by judicious choice of reinforcement, shape and spacing. Such 'conventional' elastomeric springs do have their limitations, however: one is that the maximum repeated deflection is limited to about the minimum dimension of the spring. Larger deflections can be achieved by combining the rubber unit with a lever. In one novel rubber spring under development the elastomer is sandwiched between relatively flexible but inextensible layers; the spring operates in flexure so that large deflections can be achieved but, unlike a normal beam, the ends remain parallel.[87] Other types of elastomer-based composites under development include short-fibre-reinforced elastomers.

In general, reinforcement of elastomers by short discontinuous fibres gives a composite having a performance lying between high-structure carbon black reinforced rubber and continuous fibre rubber composites. The aim of short-fibre elastomer composites is to maintain flexibility while exploiting the high moduli of reinforcing materials such as fibres of carbon, glass or polymers. Detailed properties depend on the fibre and matrix materials; adhesion between the two; and on dispersion, orientation and aspect ratio of the fibres. Aspect, length to width, ratios of 1000:1 are usual; dimensions are at the micrometre level.

The properties that short-fibre reinforcement produce are highly anisotropic unless special procedures are adopted in processing. Appreciable increases in modulus are achievable, relative to the matrix elastomer, and high compressive loads can be applied to the composite material, which retains some recoverable flexibility and extensibility. Abrasion resistance and high-temperature properties are frequently improved. These results can often be achieved with short-fibre reinforced elastomers by processes which are less laborious than those, such as laminating, required for continuous fibres.

Short-fibre reinforcement has been shown to be particularly effective in improving dimensional stability for blended, unvulcanized, TPEs because of cross-interface location of the fibres. Aramid fibres increase the heat-distortion temperature of polyester TPEs from 80° to 200°C and wear life is improved four hundredfold. Silk fibre has been shown to raise the longitudinal tensile strength of TPEs by a factor of two.

High-modulus short fibres can be effective only if forces are transferred to them. However, force transfer is limited as fibre levels must be kept relatively low if some degree of elastomeric behaviour is to be retained; this constrains their use in elastomers as compared to thermosetting plastics. In order to be fully effective, and to avoid premature failure in moulded components, the reinforcing fibres must be fully dispersed and wetted by the matrix elastomer; attainment of these objectives requires continuing development of process methods.

For continuous fibre reinforced materials it is often assumed that the strains in the matrix and reinforcement materials are equal. This assumption is not entirely valid for elastomer composites with relatively low levels of short fibres when stressed in the longitudinal direction.

'Stress quenching' mechanisms of fibre pull-out can occur during impact and improve impact resistance for plastic-fibre composites; these mechanisms are not helpful in fibre-reinforced elastomers, for which good bonding is essential.

With particulate filler in the elastomer matrix, fibre dispersion is improved, and the strains in the matrix and fibre are less dissimilar when the composite is under load. Under these circumstances the minimum length for the reinforcements to be effective (L_c) can be estimated from the fibre radius (R), the interfacial shear strength (τ_i) and the tensile breaking stress of the fibres (σ_c):

$$L_c \approx R\sigma_c/\tau_i$$

However, in practice, processing does not give ideal alignment of the fibres and this makes analysis difficult.

7.7.7 Elastomers in use – further properties

7.7.7.1 Crack growth and fatigue

The fact that the stiffness of an elastomer originates largely from configurational changes in the polymer chains rather than from distortions in interatomic bonds accounts for the low elastic (shear) moduli that can be obtained with these materials – down to about 0.3 $\mathrm{MNm^{-2}}$. Their strength, however, does depend on interatomic bonds; thus the failure stress even for soft vulcanizates, such as unfilled or lightly filled natural rubber, is about 25 $\mathrm{MNm^{-2}}$ in tension – comparable to that for thermoplastics such as high-density polyethylene and nylon 66 (Table 7.67). For practical purposes, failure and the elastic limit are coincident in conventional elastomers; similar fracture mechanics theory is applied to elastomers as to other materials but with the proviso that the strains are orders of magnitude larger.

According to fracture mechanics, the propagation rate of a crack into an elastomer is governed by $\boldsymbol{T}$:

$$\boldsymbol{T} = -\left.\frac{\partial U}{\partial A}\right|_{l}$$

where U is the total elastic energy and A is the area of one fracture surface; the partial derivative is evaluated with boundaries of the elastomer a fixed distance l apart so that the external forces do no work. $\boldsymbol{T}$ (also written as $\boldsymbol{G}$) is known as the 'strain energy release rate', although 'rate' here refers to changes in strain energy as a function of crack size rather than of time.

If $\boldsymbol{T}$ is less than a threshold value $\boldsymbol{T}_0$, the crack will propagate only by ozone attack for susceptible elastomeric materials (Tables 7.68 and 7.69). $\boldsymbol{T}_0$ is ~50 $\mathrm{Jm^{-2}}$, but there are significant differences between elastomers, while compounding details such as cross-link density and filler loading also have an effect.

The existence of a threshold value for $\boldsymbol{T}$ implies indefinite life for components (in the absence of attack by ozone, etc.) if the deformation is kept below a threshold level. Deformation

Table 7.68 Selection guide: common elastomers

Name	*Symbol*[a]	*Operational temperature range*[b] (°C)	*Tolerance*[c]			*Comments*
			Ozone	*Water* (20°C)	*Mineral oil* (20°C)	
Natural	NR	−60/+80	P	G	P	Excellent tear strength properties unfilled or filled. Can give low hardness and low mechanical damping. Properties relatively insensitive to temperature and frequency. Good tolerance of gamma radiation. Low-temperature crystallization stiffening most rapid at about −25°C. $T_g \approx -70$°C.
Synthetic polyisoprene	IR	−60/+80	P	G	P	Strength properties best for highest *cis* types. Properties can be similar to NR's; creep rate and strength generally slightly lower for IR.
Butadiene	BR	−70/+80	P	G	P	As is the case for many elastomers in this and Table 7.69, a generic title covering many structural variations. Damping and temperature/frequency dependence of modulus can be even lower than for NR because of low T_g (about −90°C).
Butyl Halobutyl	IIR, CIIR BIIR	−60/+120	F	G	P	Very good strength properties when filled, although unfilled generally inferior to NR. High damping over a wide temperature range but frequency sensitive. Lower gas permeability than most elastomers ($T_g \approx -65$°C) but some flexibility retained even at cryogenic temperatures. Cure of IIR is sluggish: halogenated butyls are faster, thus more suitable for covulcanization with other elastomers.
Chloroprene	CR	−30/+100	F	F	F	Excellent tear strength properties unfilled or filled. Self-extinguishing because of halogen in chemical structure but evolved halogen compounds may cause problems. Excellent fire resistance with appropriate additives. Particular formulations may be required for prolonged contact with water. $T_g \approx -40$°C.
Ethylene-propylene		−40/+130	G	G	P	Standard high-temperature non-oil-resistant elastomer. Large amounts of filler and oil can be added to modify properties. Acceptable strength properties when filled but no match for NR when strength/fatigue properties and low heat build-up due to mechanical working are paramount.
Copolymers	EPM					
Terpolymers	EPDM					
Nitrile	NBR	−30/+100	P	G	G	NBR is a standard oil-resistant elastomer. Properties depend on acrylonitrile content of copolymer. Brittleness temperature, oil and high temperature resistance all increase and rubberiness decreases with increasing acrylonitrile. $T_g \approx -45$ to −15°C depending on acrylonitrile content. Acceptable strength properties only when filled. High mechanical damping and low gas permeability. XNBR has better strength and abrasion properties than NBR. HNBR has better mechanical properties and higher resistance to heat and to oxidized fuels (sour gasolines) than NBR.
Hydrogenated	HNBR[d]	−30/+140	F	G	G	
Carboxylated	XNBR[d]	−30/+120	P	F	G	
Styrene butadiene	SBR	−40/+80	P	G	P	A generic title covering many structural variations. The styrene content greatly influences final properties. Good strength properties and abrasion resistance when filled.
Urethane						Wide range of hardness available – hardest have high strength but low deformability before yield. Range of damping available through the hardness range. Creep relaxation generally higher than for NR. Very good resistance to gamma radiation. Continuous contact with hot water should often be avoided.
Polyester	AU	−30/+80	G	F	G	
Polyether	EU		G	G	G	

---

[a] Unless otherwise indicated ASTM D1418 or ISO 1629 symbols are used.

[b] Indications only of typical long-term continuous operating temperatures: formulation details are often important. See also ASTM D2000.

[c] Intrinsic level: G, good; F, fair; P, poor. Additives can improve tolerance. F means either intrinsic resistance moderate or special care needed in formulation. See also ASTM D2000 and ISO TR 7620.

[d] Not an ASTM/ISO symbol.

Table 7.69 Selection guide: special-purpose elastomers

Name	*Symbol*[a]	*Operational temperature range*[b] (°C)	*Tolerance*[c]			*Comments*
			Ozone	*Water* (20°C)	*Mineral oil* (20°C)	
Chlorinated polyethylene	CM	−20/+140	G	G	G	Good environmental resistance but not a very 'rubbery' elastomer.
Chlorosulphonated polyethylene	CSM	−20/+130	G	G	G	Temperature range and other properties depend on degree of chlorosulphonation. Elasticity and strength properties do not match those of NR. Brilliant white vulcanizates available.
Epichlorhydrin						
Homopolymers	CO	−10/+140	G	P	G	Fair strength properties. ECO can give relatively low mechanical damping. Gas permeability for CO can be significantly lower than for IIR.
Copolymers	ECO	−20/+140	G	F	G	
Epoxidized natural	ENR[d]	−20/+80	P	G	F–G	Degree of oil resistance and other properties depends on degree of epoxidation. Strain crystallizes to give excellent tear strength filled or unfilled. High damping and low gas permeability obtainable.
Ethylene-methylacrylate	AEM (EACM[d])	−40/+150	G	G	F	Strength properties fair. High damping over a wide temperature range. Can accept substantial quantities of filler – e.g. fire retardant.
Ethylene-vinylacetate copolymers	EVA[d]	−40/+120	G	G	F	Properties depend on proportion of vinylacetate-when above about 1/3, essentially elastomeric. Substantial quantities of filler accepted.
Fluorinated hydrocarbon (fluoroelastomers)	FKM (FPM)	−20/+230	G	G	G	Vulcanizates quite hard. Relatively low extensibility.
Fluorosilicone	FVMQ	−90/+230	G	G	F	See silicone.
Perfluorinated	FFKM	−20/+260	G	G	G	As FKM but tolerant of a wider range of fluids.
Polyacrylics	ACM	−10/+140	G	P	G	Vulcanizates relatively hard. Moderate strength properties.
Polynorbornene	PNR[d]	−40/+80	P	G	P	These elastomers are highly plasticized polynorbornene – properties can depend on the plasticizing oil. Very soft vulcanizates available with acceptable strength and elasticity.
Polypropylene oxide	GPO	−50/+130	G	F	F	Lower mechanical damping possible than for most. Moderate strength properties.
Polysulphide	TM	−40/+80	G	G	G	Excellent tolerance to wide range of organic fluids at moderate temperatures. Rather weak.
Silicone	MQ, VMQ, PMQ, PVMQ	−90/+240	G	G	P	Poor strength properties at room temperature can be improved by silica filler – to a point. Strength properties decline only gradually with increasing temperature. High permeability to gases.
Tetrafluoroethylene–propylene copolymers	TFE/P[d]	−20/+200	G	G	G	As FKM but resistant to a wider range of fluids.

[d] Not an ASTM/ISO symbol.

in simple extension provides an illustration. For an edge crack in a tensile test piece of an elastomer with Young's modulus E, small-strain theory gives

$$T \approx 3E\epsilon^2 c$$

where ϵ is the tensile strain and c is the crack length. For a high-quality well-mixed elastomeric material $c = 25\ \mu\text{m}$ is representative of flaw size so, for typical values of $E = 3\ \text{MNm}^{-2}$ and $T_0 = 50\ \text{Jm}^{-2}$, indefinite life is predicted if the strain is kept below about 50%. This does occur in the absence of ozone cracking.

If T exceeds T_0, mechanical crack growth proceeds at a rate which depends on T. The progress of a crack may be slowed by rate-dependent energy-dissipation processes, particularly in high glass-transition temperature elastomers such as nitrile rubber (NBR). In strain-crystallizing elastomers such as NR or chloroprene rubber (CR) even at quite high values of T crack growth can be disrupted by the formation of crystallites at the crack tip. In many circumstances, then, when a constant stress is applied to a piece of NR or CR a crack will not grow; the crack advances only each time the stress is released and restored and by an amount which depends on the maximum T during the stress cycle; if the stress is only partially released, the crack growth per cycle is reduced by an amount depending on the minimum stress level. For a strain-crystallizing elastomer it is only when T exceeds the threshold value by orders of magnitude that a component of any bulk will fail during a single application of stress. Elastomers such as nitrile (NBR) which do not strain crystallize suffer mechanical crack growth even under non-cyclic conditions; this is termed 'time-dependent' crack growth. For susceptible elastomeric materials time-dependent crack growth is again a function of T; under cyclic conditions there is an extra contribution to crack growth. The presence of reinforcing fillers in the formulation can impede time-dependent crack growth in susceptible elastomers but, at high concentrations, they may produce side-effects which are not required. Thus NR or CR are frequently chosen for components which support substantial static loads. Nevertheless, under some conditions even strain-crystallizing elastomers may require significant amounts of reinforcing filler to improve their fatigue resistance.

It should be emphasized that fatigue in elastomers is a complex area. Elastomers vary in their fatigue resistance ranking according to the mechanical severity of the application and the mode of deformation.

7.7.7.2 *Temperature, frequency and damping*

For sinusoidal strain cycling of amplitude ϵ_0 and radian frequency ω

$$\epsilon = \text{real or imaginary part of } [\epsilon_0 e^{j\omega t}]$$

In general, the steady-state, cyclic stress response (σ) of an elastomer component is non-sinusoidal but can be described by a Fourier series:

$$\sigma = \text{Re or Im}\left[\epsilon_0 \sum_{n=0}^{\infty} A_n^* e^{jn\omega t}\right]$$
$$= \text{Re or Im}\left[\epsilon_0 \sum_{n=0}^{\infty} |A_n^*| e^{j(n\omega t+\phi_n)}\right]$$

where $A_n^* = A_n' + jA_n''$. If the component and material are symmetrical about $\epsilon = 0$, all even terms will be zero; when only the $i = 1$ term is non-zero this corresponds to the linear viscoelastic case:

$$\sigma = \text{Re or Im}[\epsilon_0 A_1^* e^{j\omega t}]$$
$$= \text{Re or Im}[\epsilon_0 |A_1^*| e^{j(\omega t + \phi_1)}]$$

ϕ_1 is the mechanical energy loss angle and is usually written as δ. Because of the orthogonality of terms in the Fourier series, δ is an accurate measure of mechanical energy dissipation even when there are higher harmonics in the stress response. For simple shear:

$$A_1^* = G^* = |G^*|e^{j\delta} = G' + jG''$$

where G^*, G', and G'' are the complex storage and loss shear moduli, respectively. (Even for heavily filled NR the third harmonic contribution to the stress response is unlikely to be more than ~3% of the fundamental up to shear-strain amplitudes of 100%.)

An elastomer's damping is often quoted in terms of rebound resilience (R). This is the fraction (or percentage) of mechanical energy remaining after a collision between two very dissimilar masses. The fractional resilience is related to the loss factor ($\tan\delta$):

$$R \approx e^{-\pi \tan\delta}$$

However, caution needs to be exercised as $\tan\delta$ can depend both on strain amplitude and on frequency – hence on the duration of the collision. The damping ratio (ζ or u%), relative to critical, of a damped spring-mass system is given by

$$\zeta \approx \tfrac{1}{2}\tan\delta$$

at the natural frequency. The approximation is very good for $\delta \leqslant 10°$.

According to linear viscoelasticity theory, the loss tangent of elastomers implies frequency dependence in the storage modulus:[88]
