Originally in the early 1960s packaged boilers were designed to be as compact as possible, resulting in some inherent faults. Since then design criteria have greatly improved and the present packaged boiler is constructed to acceptable commercial standards.

15.3.4.7 Evaporation

This is the quantity of steam produced by the boiler at temperature and pressure. It may be stated as equivalent evaporation 'from and at 100°C', usually expressed 'F&A 100°C', or 'actual evaporation'.

Evaporation F&A 100°C is a figure taken for design purposes and is based on the amount of heat required to convert water at 100°C to steam at the same temperature. Actual evaporation is the amount of steam passing the crown valve of the boiler. As boilers operate with differing working pressures and feed-water temperatures the above may be compared by using the 'factor of evaporation'.

15.3.4.8 Factor of evaporation

This is the figure obtained by dividing the total heat of steam at working condition by the latent heat of steam at atmospheric condition (i.e. 2256 $kJ\ kg^{-1}$). Then

$$\text{Factor of evaporation} = \frac{H - T}{2256}$$

where

H = total heat in 1 kg of steam at working pressure above 0°C taken from steam tables ($kJ\ kg^{-1}$)
T = heat in feed water ($kJ\ kg^{-1}$)
2256 = the latent heat of steam at atmospheric conditions.

15.3.4.9 Availability

This is the period of time that a boiler may be expected or required to operate before being shut down for cleaning or maintenance. It will vary with the type of boiler, the fuel being used and the operating load on the boiler.

15.3.4.10 Priming

This is when the water surface in the boiler shell becomes unstable. Vigorous surging will occur and this may cause the boiler to go to low water and cut out or possibly lock out. This, in turn, will exacerbate the condition.

There are two possible causes. The first could be incorrect control of water treatment and blowdown. This can result in excessive levels of suspended solids in the boiler water, organic matter in the boiler water or high alkalinity. The second can be mechanical.

If the boiler is operated below its designed working pressure it will increase the efflux velocity of the steam leaving the water surface area to a point where it may lift the water surface and drop the water level. It is important therefore to give due consideration to the steam load required from the boiler.

15.3.4.11 Thermal storage

A method of supplying a steam load in excess of the maximum continuous rating of the boiler for limited periods.

15.3.4.12 Cavitation

This is a condition which occurs when the feed-water pump is unable to deliver feed water to the boiler although the feed tank has water available. The temperature of the feed water coupled with the possible suction effect from the feed-water pump in the line between the feed tank and the pump effectively drops the pressure, causing the feed water to flash to steam. The pump then loses its water supply. In most cases this condition may be avoided by arranging a sufficient head of water and by correct sizing of the feed-water pipework.

15.3.4.13 Turndown

Turndown, or modulation range, refers to the firing range of the combustion appliance and therefore the output of the boiler. It is the range between the maximum continuous firing rate (MCR) and cut-out to on/off operation. It may be restricted by either the design of the combustion appliance or the boiler. For example, the combustion gas exit temperature from the boiler should not be below steam saturation temperature or fall into dewpoint areas.

15.3.5 Waste-heat boilers

A waste-heat boiler will always be designed to suit its particular installation. Occasionally it may be possible to offer a standard boiler shell for certain applications, but this will only be after careful appraisal by the boiler designer and manufacturer. The sources of waste gases vary widely and could be furnaces, incinerators, gas turbines, diesel exhausts and process plants such as cement or chemical works.

The prime requirement is that the waste gases must contain sufficient useful heat to produce steam or hot water at the condition required. In most processes there is a practical limit on the minimum gas temperature from the waste-heat boiler in order to prevent dewpoint occurring with its associated corrosion problems.

Waste-heat boilers may be horizontal or vertical shell or water tube type. The limitations between shell and water tube are similar to those indicated in Figure 15.132 although now it is also necessary to take account of the mass flow of the gases. These may produce a velocity too high for a shell-type boiler although it is within its evaporative and pressure range.

Shell waste-heat boilers will normally be of single- or two-pass design with one or two banks of tubes. This is acceptable with most gases up to 1200°C. If the waste gas temperature exceeds this, as it may from incineration, then an additional pass similar to a combustion tube will be incorporated to reduce the gas temperature before it enters the tube bank.

Supplementary firing equipment may also be included if a standby heat load is to be met and the waste gas source is intermittent. Waste-heat boilers may be designed to use either radiant or convected heat sources. In some cases problems may arise due to the source of waste heat and due consideration must be taken of this. Examples are plastic content in waste being burned in incinerators, carry-over from some type of furnaces causing strongly bonded deposits and carbon from heavy oil-fired engines. Some may be dealt with by maintaining gas exit temperatures at a predetermined level to prevent dewpoint being reached and others by soot blowing. Currently there is a strong interest in small combined heat and power (CHP) stations and these will normally incorporate a waste-heat boiler.

15.3.6 Economizers

Economizers are installed in the exhaust gas flow from the boiler. They take heat from the flue gases which they transfer via extended surface elements to the feed water immediately prior to the water entering the boiler. They therefore increase the efficiency of the boiler and have the added advantage of reducing thermal shock.

In water-tube boilers they may be incorporated within the structure of the boiler or supplied as a free-standing unit. With shell boilers they will be separate units fitted between the boiler flue gas outlet and the chimney.

Figure 15.133 is a schematic illustration of such a unit. It is desirable for each boiler to have its own economizer. Where one economizer is installed to take the exhaust gases from more than one boiler special considerations must be taken into account. These will include gastight isolation dampers, consideration of flue gas pressures at varying loads, maximum and minimum combined heat load to match economizer and a pumped feed-water ring-main. Economizers may be used for both forced- and induced-draught boilers and in both cases the pressure drop through the economizer must be taken into account when sizing the fans.

Economizers are fitted to most water-tube boilers, an exception being on a waste-heat application. Here it may be desirable due to the nature of the products being burned to maintain a relatively high gas outlet temperature to prevent corrosive damage to the boiler outlet, ductwork and chimney.

With water-tube boilers economizers may be used when burning coal, oil or gas. The material for the economizer will depend on the fuel. They may be all steel, all cast iron or cast iron protected steel. An all-steel construction would be used for non-corrosive fuel gases from the burning of natural gas, light oil and coal. Cast iron may be used where the feed-water condition is uncertain and may attack the tube bore. Fuels may be heavy fuel oil or coal and there is a likelihood of metal temperatures falling below the acid dewpoint. Cast iron protected steel is used when heavy fuel oil or solid fuel firing is required and feed-water conditions are suitably controlled. As cast iron can withstand a degree of acid attack these units have the advantage of being able to operate without a gas bypass where interruptible natural gas supplies are used with oil as standby.

With shell boilers, economizers will generally only be fitted if natural gas is used as main fuel, and then only on larger units. It would be unlikely that a reasonable economic case could be made for boilers of less than 4000 kg h^{-1} F&A 100°C evaporative capacity. The economizer will incorporate a flue-gas bypass with isolating dampers to cover for periods when oil is used and for maintenance. The dampers require electric interlocks to the selected fuel.

As the majority of shell boilers operate in the pressure range 7–10 bar the flue gas outlet temperature will be in the range of 190–250°C. It may be appreciated from this that the boiler needs to operate at 50–100% of its maximum continuous rating for most of the working day to produce an economic return.

Where an economizer is installed it is essential to have water passing through the unit at all times when the burners are firing to prevent boiling. Therefore boilers fitted with economizers will have modulating feed-water control. Even then it is possible that the water flow requirement can become out of

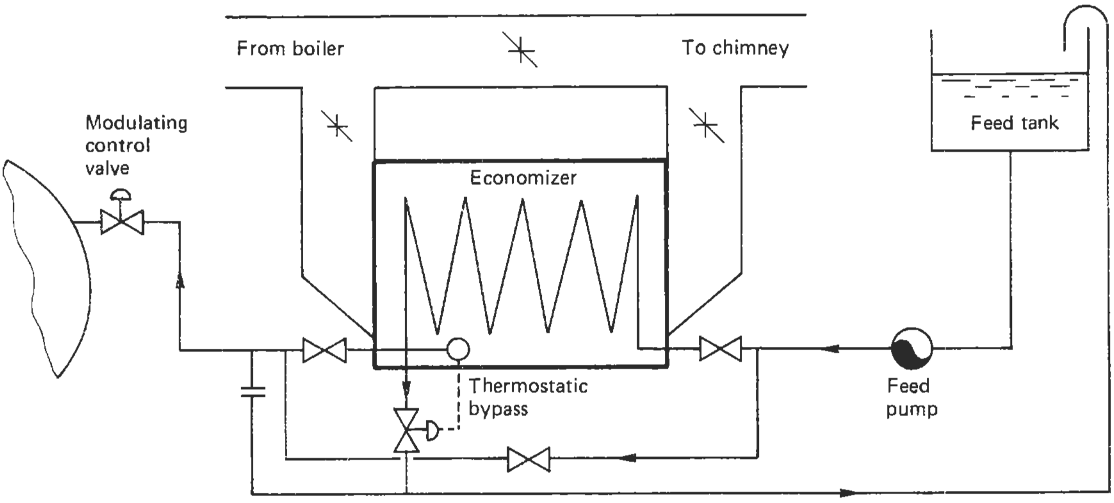

Figure 15.133 Schematic illustration of an installed economizer

phase with the burner firing rate. To prevent damage, a temperature-controlled valve allows a spillage of water back to the feed-water tank thus maintaining a flow of water through the unit. Each economizer will be fitted with a pressure-relief safety valve.

Due to the amount of water vapour produced when natural gas is burned it is important not to allow the exhaust gas temperature to fall below 80°C otherwise the water dewpoint will be reached. Not only the economizer but also the ductwork and chimney must be considered and provision incorporated for drainage.

In the event of a separate use for low-grade hot water being required it is sometimes practical to install a secondary condensing economizer. With this the material of which the economizer is constructed allows for condensate to form and drain away without excessive attack from corrosion.

A recent development in heat recovery has been the heat tube. This is a sealed metal tube which has been evacuated of air and which contains a small quantity of liquid which for boiler applications could be water. When heat from the flue gases is applied to one end of the heat pipes the water in the tube boils, turns to steam, and absorbs the latent heat of evaporation. The steam travels to the opposite end of the tube which is surrounded by water where it gives up its latent heat, condenses and returns to the heated end of the tube. Batteries of these tubes can be arranged to form units usually as a water jacket around a section of flue.

15.3.7 Superheaters

Steam produced from a boiler is referred to as dry saturated and its temperature will correspond with the working pressure of the boiler. In some instances, particularly with shell boilers, this is perfectly acceptable. There are occasions, however, where it is desirable to increase the temperature of the steam without increasing the pressure. This function is performed by a superheater.

Superheated steam may be required where steam-distribution pipework in a plant is over extended distances resulting in a loss of heat and an increase in wetness of the steam. Another case may be where a process requires a temperature above the working pressure of the plant. The third case is where steam is used for turbines. Here it improves the performance of the turbine where for every 6°C increase in steam temperature it can produce about a 1% reduction in steam consumption.

Steam from the drum or shell of the boiler is passed through a bank of tubes whose external surfaces are exposed to the combustion gases, thus heating the steam while not increasing the pressure. Where a superheater is fitted the boiler working pressure must be increased to allow for the pressure drop through the elements. This will be between 0.3 and 1.0 bar.

In a water-tube boiler the superheater is a separate bank of tubes or elements installed in the area at the rear or outlet of the combustion chamber. Saturated steam temperature may be increased by 200°C with final steam temperature of up to 540°C.

For shell boilers superheaters may be one of three types depending upon the degree of superheat required. The first and simplest is the pendant superheater installed in the front smokebox. The maximum degree of superheat available from this would be around 45°C. The second pattern is again installed in the front smokebox but with this the elements are horizontal 'U' tubes which extend into the boiler smoketubes. The degree of superheat from this pattern is around 55°C. Third, a superheater may be installed in the reversal chamber of the boiler. A wet-back chamber presents problems with lack of space and therefore either a semi-wet-back, dry-back or water-cooled wall chamber may be considered. Maximum degree of superheat would be around 100°C.

Superheater elements are connected to inlet and outlet headers. The inlet header receives dry saturated steam from the steam drum of a water-tube boiler or the shell of a horizontal boiler. This steam passes through the elements where its temperature is raised and to the outlet header which is connected to the services. A thermometer or temperature recorder is fitted to the outlet header.

It should be appreciated that a steam flow must be maintained through the elements at all times to prevent them burning away. If a single boiler is used then provision to flood the superheater during start-up periods may be required.

Superheaters may also be supplied as independently fired units. These may be used when either the amount of superheated steam required is much less than the boiler evaporation or is required only on an intermittent basis.

15.3.8 Steam storage

Most boilers built now together with their combustion equipment are quick to respond to load fluctuations. Occasionally where very rapid load changes occur, the firing rate of a gas or oil burner can be virtually instantaneous by the use of special control equipment. This control will have to work in conjunction with the boiler and therefore the boiler should have adequate steam space and water surface area to help accommodate the rapid changes in steam demand. Good water treatment is especially important here in order to reduce the risk of priming during peak draw-off periods. A boiler with a large shell will have an advantage over one with a smaller shell, assuming equal heating surfaces, but it will give no more than a slight buffer against severe loads.

Most boiler plants can be installed using one or more boilers which can accommodate minimum to maximum loads. Occasionally heavy peak loads occur for only relatively short periods and here there may be an advantage, on economic running grounds, to install boilers whose firing rate will not meet these peaks. In these cases there are two methods which may be used. One is thermal storage and the other is an accumulator.

15.3.8.1 Thermal storage

The principle is based on a special feed-water control system which allows a volume of water already at temperature and pressure within the shell to convert to steam to meet a load in excess of the maximum firing rate. Conversely, during periods of low steam demand the control system allows the water level to re-establish itself. This is achieved using a constant burner firing rate which should match the average steam demand, thus allowing maximum efficiency. It is claimed that it is possible with this system to control the limits of boiler working pressure to within ±0.07 bar.

15.3.8.2 The accumulator

Unlike thermal storage, this depends upon differential pressures. It is suited to a situation where both high- and low-pressure steam systems are required (for example, 17 bar and 7 bar). Alternatively, if no high-pressure steam is needed then the boilers must be designed to operate at a higher pressure with all steam supplies going to the process through a pressure-reducing station. Any high-pressure surplus then goes to the accumulator to help meet peak loads. Figure 15.134 shows the diagrammatic layout of an accumulator.

The storage vessel is filled to around 90% of its volume with water. The overflow valve is controlled by the pressure of the boilers. On rising steam pressure indicating that the boilers are producing more steam than the process requires a signal to the overflow valve allows all surplus high-pressure steam to flow into the accumulator via a non-return valve and internal distribution header. Here it is condensed and its thermal energy stored. If a peak load develops on the high-pressure system then controls will close the overflow valve and allow steam to discharge from the accumulator through the pressure-reducing valve set to meet the low-pressure steam requirement. Similarly, if the peak develops on the low-pressure system then high-pressure steam may pass directly to the pressure-reducing set to supplement steam from the accumulator.

Every accumulator will be designed to meet its specified duty. It will be appreciated that the greater the differential pressure, the smaller the vessel will need to be.

15.3.9 Water-level control

Water-level controls continuously monitor the level of water in a steam boiler in order to control the flow of feed water into the boiler and to protect against a low-water condition which may expose the heating surfaces with consequent damage. The controls may be either float operated or conductivity probes.

With water tube boilers the control of the water level needs to be precise and sensitive to fluctuating loads due to the high evaporative rates and relatively small steam drums and small water content. Control will be within ±10 mm on the working water level and will be two- or three-element control. Two-element control will comprise modulating feed-water control with the first low-water alarm and high–low control with

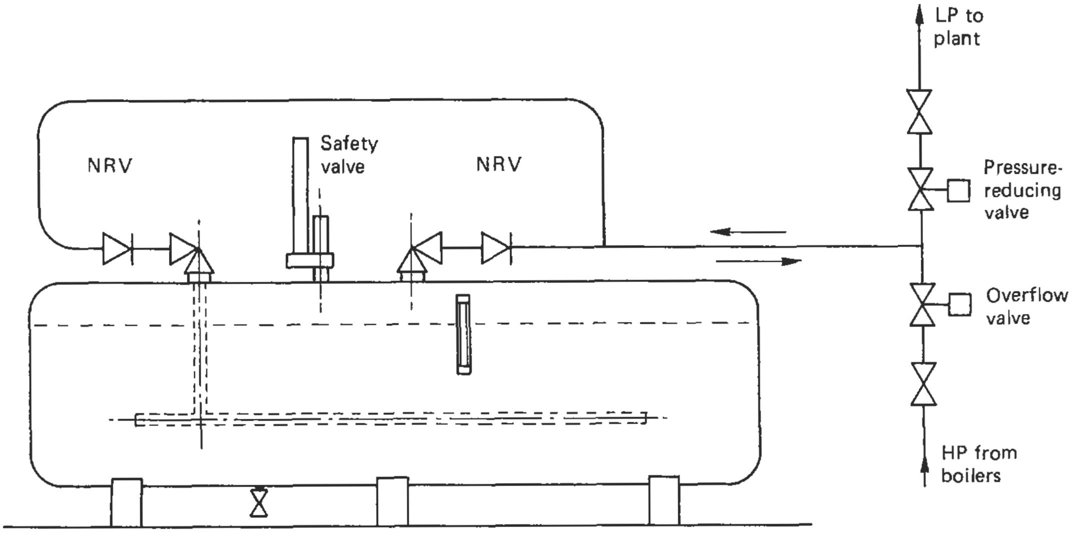

Figure 15.134 Diagrammatic layout of a steam accumulator

low-water cut-out and alarm. The second element will be monitoring of the steam flow to give early indication of any increase in steam demand. This signal may then be linked to the firing rate of the burners and the feed-water modulating valve. The third element senses a drop in feed-water demand which would signal the firing rate of the burners to modulate down.

Shell boilers will have two external level controls each independently attached to the shell. Boilers up to about 9000 kg h^{-1} F&A 100°C will have a dual control and either a single or high–low control. The dual control instigates the feed-water pump which operates on an on–off cycle over a water-level band of ±15 mm and also operates the first low-water alarm. The single or high–low control will incorporate a second low-water alarm with burner lock-out, and with the high–low control also an indication of high water which may be linked to shut down the feed-water pump with automatic restart when the water level drops to normal.

Boilers of larger evaporations will have modulating and high–low control. The modulating level control monitors the working water level in the shell and operates a control valve in the feed-water line allowing water to enter the boiler from a continuously running feed pump. It will also incorporate the first low-water alarm. The high–low control operates as before.

The advantage of modulating control is that it maintains a constant working water level and therefore the boiler is always in its best condition to supply steam for peak loading. These controls may also be fitted to boilers below 9000 kg h^{-1} F&A 100°C if severe loads are present or when the working pressure is above 10 bar.

With water-level controls it is important to check that they are functioning correctly and that they will be operated daily to simulate low-water condition. Shell boilers will also be subject to a weekly evaporation test to prove low-water controls. Blowdown of external level controls is invariably manual but may be motorized on water tube boilers.

Shell boilers may alternatively be fitted with internal level controls. These will have an electronic testing facility operating automatically and arranged to take the boiler to lock-out in the event of a fault.

For fully automatic unstaffed operation three independent level controls are required. These will be first low water and burner cut-out, second low water and burner lock-out and the third level control will be for the feed-water pump and high-water alarm.

With external level controls the sequencing blowdown valve will be motorized and for internal level controls they will be subject to continuous electronic monitoring.

Comprehensive information on Automatically Controlled Steam and Hot Water Boilers is given in the Health and Safety Executive Guidance Note PM5 (Automatically Controlled Steam and Hot Water Boilers).

15.3.10 Automatic control

15.3.10.1 Automatic control of boilers

Whether the boiler is fired on oil, gas or solid fuel, it may be expected to operate automatically. When boiler plant is not run continuously initial start-up may be manual, time clock or through an energy-management system. Manual attendance may be limited to maintenance functions dictated by the size and type of plant.

Automatic controls will cover combustion appliance, water level and blowdown. Requirements to comply are detailed in the Health and Safety Executive Guidance Note PM5. Any degree of automation to the boiler plant should be implemented only after consultation with the covering insurance company.

15.3.10.2 Automatic boiler start

In order to control the operating times of a boiler it is a simple matter to fit each with time-clock control. Alternatively, they may be controlled through a central energy-management system. Either way, a boiler or boilers may be shut down at the end of each day and programmed to restart the following day or when required. Special considerations need to be made if standing periods are extended allowing a boiler to go cold.

With hot-water units time-clock control can operate satisfactorily as automatic bypass valves built into the distribution system will help the heater to achieve its working temperature quickly. With steam boilers it is important that the boiler achieves a reasonable working pressure before steam is allowed into the distribution system.

For example, if boilers are left open to a system for an extended length of time while not firing they will quickly lose their pressure. This is not only wasteful of energy but eventually creates a problem on start-up. To start a boiler on a zero pressure system with all valves open will undoubtedly cause the boiler to prime and go to lock-out condition but not before condensate has, at least in part, flooded the system. Therefore where a time clock is incorporated it is recommended that the crown valve(s) be closed at the end of each working day and opened only after the boiler has reached working pressure the next time it is required. This operation can be automated by the use of motorized or similar valves.

These valves may be fitted to each steam supply line from a manifold adjacent to the boilers and providing adequate safeguards are incorporated to protect the boilers the on-line boiler(s) may be left open to the manifold. Alternatively, each boiler may have its own automatic motorized start-up valve.

Each valve would have a control panel incorporating a timer. This may initially be set to a 'crack' position timed to open after the boiler has started to fire and is already building up pressure. This will allow gentle warm-up of the system while allowing the boiler to achieve working pressure. After this the valve may be set to open in timed adjustable steps to its fully open position. At the end of a timed period, coinciding with the time clock fitted to the boiler, the valve automatically closes at the end of the working cycle.

Where multiple valves are used their control may be incorporated into a single panel or, alternatively, become part of an energy-management system.

15.3.10.3 The automatic boiler house

As described in Section 15.3.10.1, the boiler will operate automatically and may be programmed to operate to suit various cycles (Section 15.3.10.2). There are, however, other areas within the boiler house which still require consideration. The first of these would be the feed-water pump. Each boiler may be fitted with duplicate pumps and these can be arranged for automatic changeover in the event of a failure of one pump by use of a pressure switch and motorized valves. Other areas would be oil-circulating pumps, gas boosters and water-treatment plant and pumps.

There must be an economic limit as to the extent of duplication and on a multi-boiler installation it would be expected to have a degree of reserve capacity if even for a limited period. An energy-management system would probably form part of the automatic boiler house and as such would have the facility to bring on any standby capacity.

15.3.11 Feed-water requirements

Poor or unsuitable water can be a major factor where failure in a boiler occurs. There are four problem areas for which feed water needs suitable treatment and control. These are sludge, foam, scale and corrosion.

Boiler feed water may be from various supplies. If it is from a mains water supply further filtering prior to treatment is unlikely but for other supplies such as boreholes, lakes, rivers and canals filters may be required. Impurities in water may be classed as dissolved solids, dissolved gases and suspended matter and suitable treatment is required.

Table 15.24 indicates the recommended water characteristics for shell boilers and Table 15.25 the water quality guidelines for industrial water tube boilers. Due to the wide parameters encountered in the quality of feed water it is not possible to be specific and define which treatment suits a particular type and size of boiler. The quality of make-up and percentage of condensate returns in a system will both have to be taken into consideration.

For some small boilers it may be possible to supply internal dosing subject to a suitable water supply and other conditions being favourable. However, for anything other than very small installations external treatment is recommended. For shell boiler installations a simplex or duplex base exchange system with suitable dosing is usual, although on larger installations or if the water is excessively hard and there is little condensate return then a de-alkalization plant may be used.

Table 15.24 Recommended water characteristics for shell boilers

For pressures up to 25 bar[a]			
Total hardness in feed water, mg/l in terms of $CaCo_3$ max.	2	20	40
Feed water			
pH value	7.5–9.5	7.5–9.5	7.5–9.5
Oxygen	b	b	b
Total solids, alkalinity, silica	b	b	b
Organic matter	b	b	b
Boiler water			
Total hardness, mg/l in terms of $CaCO_3$ max.	ND[c]	ND	ND
Sodium phosphate, mg/l as Na_3PO_4[d]	50–100	50–100	50–100
Caustic alkalinity, mg/l in terms of $CaCO_3$ min.	350	300	200
Total alkalinity, mg/l in terms of $CaCO_3$ max.	1200	700	700
Silica, mg/l as SiO_2 max.	Less than 0.4 of the caustic alkalinity.		
Sodium sulphite, mg/l as Na_2SO_3	30–70	30–70	30–70
or			
Hydrazine, mg/l as N_2H_4	0.1–1.0	0.1–1.0	0.1–1.0
Suspended solids, mg/l max.	50	200	300
Dissolved solids, mg/l max.	3500	3000	2000

[a] 1 bar = 10^5 N/m^2 = 100 kPa = 14.5 lb/in^2.

[b] Numerical values depend upon circumstances but the comments are relevant.

[c] ND: not detectable.

[d] Phosphate is usually added as sodium phosphate but determined as phosphate (PO_4^{3}): $Na_3PO_4 = 1.73 \times PO_4^{3}$.

Based on Table 2 of BS 2486: 1978 by permission of BSI.

Table 15.25 Water-quality guidelines recommended for reliable, continuous operation of modern industrial water tube boilers

Boiler feed water			
Drum pressure (psig)	*Iron* (*ppm Fe*)	*Copper* (*ppm Cu*)	*Total hardness,* (*ppm $CaCo_3$*)
0–300	0.100	0.050	0.300
301–450	0.050	0.025	0.300
451–600	0.030	0.020	0.200
601–750	0.025	0.020	0.200
751–900	0.020	0.015	0.100
901–1000	0.020	0.015	0.050
1001–1500	0.010	0.010	ND[d]
1501–2000	0.010	0.010	ND[d]

Boiler water			
Drum pressure (*psig*)	*Silica* (*ppm SiO_2*)	*Total alkalinity*[a] (*ppm $CaCO_3$*)	*Specific conductance,* (*μmho/cm*)
0–300	150	350[b]	3500
301–450	90	300[b]	3000
451–600	40	250[b]	2500
601–750	30	200[b]	2000
751–900	20	150[b]	1500
901–1000	8	100[b]	1000
1001–1500	2	NS[c]	150
1501–2000	1	NS[c]	100

[a] Minimum level of hydroxide alkalinity in boilers below 1000 psi must be individually specified with regard to silica solubility and other components of internal treatment.

[b] Maximum total alkalinity consistent with acceptable steam purity. If necessary, the limitation on total alkalinity should override conductance as the control parameter. If make-up is demineralized water at 600–1000 psig, boiler water alkalinity and conductance should be shown in the table for the 1001–1500 psig range.

[c] NS (not specified) in these cases refers to free sodium- or potassium-hydroxide alkalinity. Some small variable amount of total alkalinity will be present and measurable with the assumed congruent control or volatile treatment employed at these high-pressure ranges.

[d] None detectable.

For water tube boilers base exchange or de-alkalization may be used providing the water quality is suitable and the boilers are not operating at pressures in excess of 30–35 bar. With modern water tube boilers demineralized water is recommended. Where boilers are operating at high pressures or are used for power generation it is essential to use demineralized water in order to prevent build-up of deposits, particularly silica, on turbine blades.

With hot-water installations it is equally important that water suitably treated for hardness and corrosion should be used. Even when cleaning or flushing a new or modified system care must be taken to prevent premature corrosion occurring by the addition of a suitable treatment. Few (if any) hot-water systems are completely sealed and provision should be designed into the system to treat all make-up water. Draw-off of hot water directly from the system should never be done and a calorifier always used. Analysis of the water in the boiler and system should be carried out at least monthly and more frequently during the commissioning period of a new installation or where an existing system has ben refilled.

Where steam or hot-water boilers are not required to operate for a period of time it is important that suitable measures are taken to prevent waterside corrosion. For periods of a few days the water may be left at its normal level but daily testing must be carried out as if the boiler were in use and corrective treatment added as necessary. If the period is for several months then the boiler should be fully flooded to exclude all air and the water treated. Regular testing of this water should be carried out and corrective treatment used. For longer periods boilers should be drained completely and thoroughly dried out. The boiler may then either be left vented with the addition of a small electric heater inside or sealed and trays of moisture absorbing chemicals such as hydrated lime or silica gel laid inside. In potentially humid atmospheres such as near sea coasts the dry method is preferred, as keeping the boiler full of cold water will cause condensation to be continuously present on the fireside, giving rise to surface corrosion.

15.3.12 Blowdown requirements control and tanks

In order to maintain the level of dissolved and suspended solids within the boiler as recommended in Section 15.3.11 it is necessary for the boiler to be blown down. This is an operation where a quantity of water is drained from the boiler while the boiler is operating at pressure. This may be achieved by various methods.

The simplest, and that applied to small boilers, is for the main bottom blowdown valve to be opened for a set period of time at regular intervals (e.g. 20 seconds every 8 hours). This method may also extend to larger boilers where conditions are such that there is little build-up of solids. Such conditions could be high-condense returns and good-quality make-up feed water.

The second method could be automatic intermittent blowdown. With this a timer-controlled valve is installed at the bottom of the boiler prior to the main blowdown valve. A programme is then designed to operate this valve in short bursts which disperses any sludge and controls the levels of solids. This method is preferred for boilers having internal treatment.

The third method would be continuous blowdown through a regulating or micrometer valve. The take-off position for this should preferably be about 250 mm below the working water level and may either be on the side of the shell or on the crown with a dip pipe down to the correct level. If a connection is not available it is possible to install the valve on the bottom connection prior to the main blowdown valve.

All these methods will require careful monitoring initially to set up and determine the correct rate of blowdown once the plant is operating. In order to take the necessary sample from the boiler the boiler(s) should be fitted with a sample cooler. To automate the continuous blowdown a conductivity-controlled system may be installed. Here a controller continuously compares the boiler water electrical conductivity with a value set in the controller. Depending if this is above or below the set rate it will automatically adjust the blowdown flow rate.

While the above methods control the level of dissolved and suspended solids in the boiler it will still be an insurance requirement to operate the main blowdown valve periodically.

The minimum amount of blowdown may be calculated as a percentage of the evaporation rate by the following formula:

$$\text{Blowdown rate} = \frac{F}{B - F} \times 100\%$$

where F = the total dissolved solids content of the feed in parts per million allowing for the mixture of make-up and condensate plus any chemical treatment and B = the maximum recommended solids content for boiler water in parts per million.

While vitally necessary, blowdown can be expensive in terms of lost heat. Therefore a point will be reached when it is economical to install a blowdown heat-recovery system. Generally, the heat content in the blowdown water for a shell boiler will represent only about 25% of the heat content in the same percentage of steam. Therefore if a blowdown rate of 10% is required this represents an approximate heat loss of 2.5% from the boiler capacity. This differential reduces and eventually becomes insignificant on high-pressure water tube boilers. The blowdown from the boiler(s) will be run to a flash steam vessel mounted adjacent to the feed tank. Flash steam will be introduced into the feed tank through a dip pipe terminating in a distribution manifold. The drain from the flash vessel may then be taken to a residual blowdown heat exchanger. Any remaining heat is then transferred to the make-up water to the tank before the blowdown runs to drain.

Blowdown from the boiler(s) should always be taken to either a blowdown sump or blowdown vessel before discharging into drains. Both should be adequately sized to give cooling by dilution and be fitted with vent pipes to dissipate pressure safely. The boiler(s) should have independent drain lines for the main manually operated blowdown valve and the drains from a continuous blowdown system. This is set out in Clause 8.7 (Boiler Blowdown and Drain Mountings) in BS 2790: 1989.

15.3.13 Clean Air Act requirement for chimneys and flue designs

15.3.13.1 Introduction

The function of a chimney is to discharge in a manner to give adequate dispersal to the products of combustion in accordance with the third edition of the 1956 Clean Air Act Memorandum on Chimney Heights. The scope of the memorandum is as follows:

1. The publication provides for the use of local authorities, industry and others who may need to determine the height appropriate for certain new chimneys a relatively simple method of calculating the appropriate height desirable in normal circumstances.
2. Heights determined by these methods should be regarded as a guide rather than as a mathematically precise decision on chimney height. The conclusions may need to be modified in the light of particular local circumstances such as valleys, hills and other topographical features.
3. The advice given is applicable only to chimneys of fuel burning plant with a gross heat input of between 0.15 MW and 150 MW, including stationary diesel generators. It does not deal with direct-fired heating systems which discharge into the space being heated, gas turbines or incinerators (which require separate treatment, depending on the pollutants emitted).
4. The main changes from the second edition are the inclusion of a method dealing with very low-sulphur fuel, the extension of the method for taking into account the height of nearby buildings and the extension of the range of the size of furnace included.

15.3.13.2 Gas velocity

In order to maximize the chimney height the efflux velocity of the gases leaving the chimney should be designed on 12 m s^{-1} at maximum continuous rating (MCR) of the boiler. On some very small boilers this may be impractical to achieve but a target velocity of not less than 6 m s^{-1} at MCR should be attempted. With boilers at the top end of the range a velocity of 15 m s^{-1} at MCR is required. Some inner-city authorities may stipulate higher efflux velocities and some plants have been installed with gas velocities of 22 m s^{-1}.

15.3.13.3 Chimney height

Originally the height of the chimney was designed to produce a draught sufficient to produce induced-draught air for combustion. With modern boiler plant forced-draught and/or induced-draught fans are used. This allows for the greater degree of control of the air to be designed into the combustion appliance. The chimney is therefore required only to disperse the gases.

When using gaseous fuel it is normally sufficient to terminate the chimney 3 m above the boiler house roof level subject to there being no higher buildings adjacent to the boiler house. In such cases these buildings may need to be considered.

On medium-size boiler plant where gas is to be the main fuel it may have oil as a secondary standby fuel. In this case the chimney height must be based on the grade of fuel oil capable of being burned.

The methods of calculating proposed chimney height are clearly laid out in the Clean Air Act Memorandum and will be based on:

1. Quantity of fuel burned
2. Sulphur content of fuel burned
3. District Category
4. Adjacent buildings
5. Any adjacent existing emissions.

Application for approval of the proposed chimney height should be made to the appropriate authority at an early stage of a project in order to ascertain their approval or other height they may require. Failure to do this can result in an embarrassing situation where insufficient finance has been allocated due to their requiring a larger chimney than was included in the planned costings.

Where waste products are being incinerated special consideration may have to be given to the resulting flue gases. This may involve having to arrive at a chimney height in conjunction with HM Inspectorate of Factories for Pollution.

15.3.13.4 Grit and dust emissions

Solids emissions from solid and liquid fuel-fired plant are covered in the HMSO publication *Grit and Dust – The measurement of emissions from boiler and furnace chimneys*. This states levels of emissions which should be achieved in existing plant and which should be specified for new plant. Suitable sampling connections should be incorporated into the flue ducting for the use of test equipment if permanent monitoring is not installed.

15.3.14 Energy conservation

Energy conservation in the boiler house can be considered in two areas. One is the selection and installation of suitable equipment and the second is good operation and management.

15.3.14.1 Plant installation

The boiler, flues and chimney, pipework and hotwell where installed should all be insulated to adequate standards and finish. Valves should be enclosed in insulated boxes, although on small installations this can prove disproportionately expensive. The boilers may be fitted with either inlet or outlet air-sealing dampers. These will prevent the flow of ambient air through the boiler during off-load and standby periods thus helping to maintain the heat already in the boiler.

Economizers may be installed particularly if gas is the main fuel. It is unlikely that an economic case can be made for a single boiler if less than 4000 kg h^{-1} evaporation. An economizer can produce fuel savings of 4–5% but it must be remembered that this will be at MCR and if the load factor of the installation is lower then the savings will also be proportionately lower.

Combustion controls such as oxygen trim help to maintain optimum operating conditions especially on gaseous fuels. Instrumentation can give continuous visual and recorded information of selected boiler and plant functions. To be effective, it must be maintained, the data assessed and any required action taken before the information is stored.

Energy-management systems will form an important part of a multiboiler installation whether on steam or hot water. Boiler(s) for base load will be selected and further boilers brought on-line or taken off-line as required. The important feature of these systems is that the selection of boilers coming either on- or off-line will be ahead of the load and programmed to anticipate rising or falling demands.

Computer monitoring and control systems have been recently introduced. These are designed to operate in place of conventional instrumentation. Using intelligent interface outstations connected to a desktop computer, many plant functions may be programmed into the computer and controlled centrally.

15.3.14.2 Operation and maintenance

As most boiler plants installed today are designed for unattended operation it is even more important that early action is taken in the event of the boiler requiring adjustment of combustion or other maintenance. If full instrumentation is not installed then a portable test kit should be used and the plant checked and logged daily or weekly. Perhaps the most obvious waste to look for after steam leaks is a rise in the flue-gas outlet temperature. The boiler will progressively have deposits adhere to its heating surfaces but at an increase in temperature of no more than 16°C above its design outlet temperature it should be cleaned. The time period between cleaning will vary according to the type of fuel and operational load.

15.3.15 Design Standards for pressure vessels, pipes and flanges

BS 779	Cast Iron Boilers for Central Heating and Indirect Hot Water Supply (44 kW and above)
BS 855	Welded Steel Boilers for Central Heating and Indirect Hot Water Supply (44 kW to 3 MW)
BS 2790	Design and Manufacture for Shell Type Boilers
BS 1113	Design and Manufacture for Water Tube Steam Generators (Including superheaters, reheaters, and steel tube economizers)
BS 5500	Design and Manufacture for Unfired Fusion Welded Pressure Vessels
BS 3601	Specification for Carbon Steel Pipe and Tube
BS 3602	Specification for Seamless and ERW Steel Tubes
BS 4504	Circular Flanges for Pipe, Valves and Fittings
BS 4882	Bolting for Flanges and Pressure Containing Purposes

ASME 1989 Part 1	Power Boilers
ASME 1989 Part 2	Material Specification
ASME 1989 Part 8	Pressure Vessel Division 1 Design Code

15.4 Heating, ventilation and air conditioning

15.4.1 Heating

15.4.1.1 Statutory heating regulations

Except for some defined types of accommodation, the use of fuel or electricity to heat premises above a temperature of 19°C is prohibited by the Fuel and Electricity (Heating) (Control) Order 1980. The current Order is an amendment to an earlier Regulation, which limited the temperature to a maximum of 20°C, and although 19°C is generally taken to refer to air temperature the Order does not specify this. The minimum temperature was laid down in the Factories Act 1961 and should be reached one hour after the commencement of occupation.

15.4.1.2 Building regulations

Unfortunately, the optimum results in cutting down space heating energy usage can often be obtained only when a building is at the design stage. Insulation, draught exclusion and the best possible heating system can then be built in at minimum cost. It is usually more expensive to add to (or modify) an existing building. Space heating is probably the largest usage of energy in buildings, so this section considers what can be done to improve insulation and other thermal properties. When energy was relatively cheap, little thought was given to conservation, and these omissions now have to be rectified.

In 1957 the Thermal Insulation (Industrial Buildings) Act laid down standards of insulation for roofs of new buildings. In 1978, Amendments to the Building Regulations specified standards for walls and windows. At this point it is necessary to define the term '*U* value', or the insulation characteristic of the building material. This measures the rate at which energy flows through the material when there is a temperature difference of 1°C between the inside and outside faces, and this value is measured in watts (the unit of energy) per square metre of surface area, i.e. W/m^2 °C or W/m^2 K.

Symbol 'K' = °C temperature difference.

The amendments can briefly be summarized in Table 15.26.

Table 15.26

Industrial and commercial buildings
External walls of building enclosing heated spaces, internal walls exposed to unheated ventilated spaces, floors where the undersurface is exposed to outside air or an unheated ventilated space, and roofs over heated spaces (including the cases of ceilings with an unheated ventilated space above them).

Maximum average U value
For factories and storage buildings, such as warehouses, the *U* value is laid down to be 0.7. For shops, offices, institutional buildings and places of assembly, such as meeting halls, theatres, etc., the maximum average *U* value is to be 0.6.

The *U* values for walls, roofs and floor are intended as average figures, so it is permissible to have some areas of the structure underinsulated (i.e. with higher *U* values) providing other areas have sufficient extra insulation to bring the average of all areas down to (or below) the Regulation values.

Limits are also imposed on window areas and apply to all buildings above 30 m^2 floor area. For the first group, industrial and commercial buildings, these limits apply both to rooflights and to windows in the walls. These percentages for windows or rooflights assume single glazing, and somewhat larger values can be used if double or triple glazing is to be fitted. However, calculations must be produced to show that the total heat loss from such units would be no greater than the single-glazed unit complying with the set limits (Table 15.27).

In most single- and two-storey buildings the largest proportion of heat loss from the building structure is usually through the roof. (In buildings of three storeys or more the losses through walls and windows may overtake the roof loss.)

New Building Regulations for the Conservation of Fuel and Power for England and Wales came into operation on 1 April 1990. The new maximum *U* values of the elements (W/m^2 K) are shown in Table 15.29.

Table 15.28 gives some of the insulation properties for various building materials. The property given is for the rate at which energy would pass through a unit area of the material. In the standard units it becomes the number of watts that would be transferred through a square metre of the material of normal thickness in the form it would be used, if the air at either side of the material shows a temperature difference of 1°C. In SI units this becomes W/m^2 °C, which, in this case, is commonly known as the *U* value. The larger the *U* value, the more energy it will transfer, so the worse are its insulation properties.

The *U* values are given in W/m^2 °C for various building material under normal weather conditions. There will always be slight variations around these values, dependent on particular manufacturers of the materials. With any insulation which is being fitted, advice should be sought regarding the fire risk and condensation problems.

15.4.1.3 Estimation of heat losses from buildings

The normal procedure in estimating the heat loss from any building is as follows:

1. Decide upon the internal air temperature to be maintained at the given external air temperature.

Table 15.27

Type of building	*Maximum permitted glazed area*	
	In walls as percentage of wall area	As rooflights as percentage of roof area
Factories and storage	15	20
Offices, shops and places of assembly	35	20
Institutional, including residential	25	20

Note: Where figures for both rooflights and windows in walls are given, these really apply as a combined total. If the full wall window allowance is not used the balance can be reallocated to rooflight areas and vice versa. For example, a factory with only 10% of wall area as windows could add the other 5% of wall area as an increase to the permitted 20% of roof area that could be rooflights.

Table 15.28 *U* values

Roofs	
Pitched covered with slates or tiles, roofing felt underlay, foil-backed plasterboard ceiling	1.5
Pitched covered with slates or tiles and roofing felt underlay, foil-backed plasterboard ceiling with 100 mm glass-fibre insulation between joists	0.35
Corrugated steel or asbestos cement roofing sheets	6.1–6.7
Corrugated steel or asbestos cement cladding with 75 mm fibreglass lightweight liner	0.38
Corrugated steel or asbestos cement roofing sheets with cavity and aluminium foil-backed 10 mm plasterboard lining	1.9–2.0
Corrugated double-skin asbestos cement sheeting with 25 mm glass-fibre insulation between with cavity and aluminium foil-backed 10 mm plasterboard lining; ventilated air space	0.8
Steel or asbestos cement roofing sheets, no lining with rigid insulating lining board 75 mm	0.4
Asphalt 19 mm thick or felt/bitumen layer on solid concrete 150 mm thick	3.5
Asphalt 19 mm thick or felt/bitumen layer on 150 mm autoclaved aerated concrete roof slabs	0.9
Flat roof, three layers of felt on chipboard or plasterboard	1.54
Flat roof, three layers of felt on rigid insulating board 100 mm thick	0.29
Timber roof with zinc or lead covering and 25 mm plaster ceiling	0.96
Walls	
Steel or asbestos cement cladding	5.3–5.7
Steel or asbestos cement cladding 75 mm fibre glass lightweight liner	0.37
Steel or asbestos cement cladding with plasterboard lining and 100 mm fibre insulating roll	0.4
Solid brick wall unplastered 105 mm	3.3
Solid brick wall unplastered 335 mm	1.7
Solid brick wall 220 mm thick with 16 mm lightweight plaster on inside face	1.9
Brick/cavity/brick (260 mm total thickness)	1.4
260 mm brick/mineral fibre-filled cavity/brick	0.5
260 mm brick/cavity/load-density block	1.0–1.1
Brick/expanded polystyrene board in cavity/ low-density block/inside face plastered	0.5
Weather boarding on timber framing with 10 mm plasterboard lining, 50 mm glass-fibre insulation in the cavity and building paper behind the boarding	0.62

Glazing		
Single glazing	Wood frame	4.3
	Metal frame	5.6
Double glazing	Wood frame	2.5
	Metal frame	3.2
Triple glazing		2.0
Roof skylights		6.6

Floors	
20 mm intermediate wood floor on 100 mm × 50 mm joists 10 mm plasterboard ceiling allowed for 10% bridging by joists	1.5
150 mm concrete intermediate floor with 150 mm screed and 20 mm wood flooring	1.8

Table 15.28 *(cont'd)*

The heat loss through floors in contact with the earth is dependent upon the size of the floor and the amount of edge insulation. Insulating the edge of a floor to a depth of 1 m can reduce the *U* value by 35%. Following are some typical *U* values for ground floors. Effectively, most of the heat loss is around the perimeter of the floor.

Solid floor in contact with the earth with four exposed edges:

150 m × 50 m	0.11
60 m × 60 m	0.15
15 m × 60 m	0.32
15 m × 15 m	0.45
7.5 m × 15 m	0.62
3 m × 3 m	1.47

Suspended timber floors directly above ground. Bare or with linoleum, plastic or rubber tiles:

150 m × 60 m	0.14
60 m × 60 m	0.16
15 m × 60 m	0.37
15 m × 15 m	0.45
7.5 m × 15 m	0.61
3 m × 3 m	1.05

Suspended timber floors directly above ground with carpet or cork tiles:

150 m × 60 m	0.14
60 m × 60 m	0.16
15 m × 60 m	0.34
15 m × 15 m	0.44
7.5 m × 15 m	0.59
3 m × 3 m	0.99

Table 15.29

Building type	*Ground floors*	*Exposed walls and floors*	*Semi-exposed walls and floors*	*Roofs*
Industrial storage and other buildings, excluding dwellings	0.45	0.45	0.60	0.45

Note: An exposed element is exposed to the outside air; a semi-exposed element separates a heated space from a space having one or more elements which are not insulated to the levels in the table.

Maximum window areas for single glazing in buildings other than dwellings will be unchanged.

2. Decide the heat transmission coefficient (*U* values) for the outside walls and glass, roof and bottom floor, and the inside walls, ceilings, or of heated spaces adjacent to non-heated spaces.
3. Measure up the area of each type of surface and compute the loss through each surface by multiplying the transmission coefficient by the measured area by the difference between the inside and the outside temperatures.
4. Calculate the cubic contents of each room and, using the appropriate air change rate, the amount of heat required

to warm the air to the desired temperature by multiplying the volume of air by the difference between the inside and outside temperatures and the specific heat of air.

The above calculations will give the heat losses after the building has been heated. Under conditions in which the heating system will operate continuously, satisfactory results will be obtained if the heating system is designed to provide heat equivalent to the amount calculated above. Suitable allowance must be made for losses from mains.

When, however, operation is intermittent, safety margins are necessary. These are, of course, speculative, but the following suggestion has frequently proved satisfactory. When it is necessary to operate after a long period of vacancy, as may happen in certain types of substantially built buildings, it is necessary to add up to 30% to the 'steady state' heat transmissions. In buildings of light construction this margin may be reduced.

In selecting the appropriate U values we must pay due regard to the exposure and aspect of the room. It appears reasonable to make allowance for the height of a room, bearing in mind that warm air rises towards the ceiling. Thus in a room designed to keep a comfortable temperature in the lower $1\frac{1}{2}$ or 2 m, a higher temperature must exist nearer the ceiling, which will inevitably cause greater losses through the upper parts of windows, walls and roof. This effect is greatest with a convective system, i.e. one which relies on the warming of the air in the room for the conveyance of heat. This would occur in the case of conventional radiators, convectors and warm air systems. In the case of radiant heated rooms, this does not occur, and a much more uniform temperature exists from floor to ceiling.

15.4.1.4 Allowance for height of space

In heat loss calculations a uniform temperature throughout the height of the heated space is assumed, although certain modes of heating cause vertical temperature gradients which lead to increased heat losses, particularly through the roof. These gradients need to be taken into account when sizing appliances. Attention is also drawn to the means of reducing the effect of temperature stratification, discussed in Section 15.4.1.9.

15.4.1.5 Characteristics of heat emitters

Designers will need to decide whether it is necessary to add a margin to the output of heat emitters. During the warm-up cycle with intermittently operated heating systems, emitter output will be higher than design because space temperatures are lower. Also, boost system temperatures may be used to provide an emission margin during warm-up. The need for heat emitter margins to meet extreme weather conditions will depend on the design parameters used in determining heat losses.

In summary, although the addition of a modest margin to heat emitter output would add little to the overall system cost and a margin on the heat generator or boiler output can only be utilized if the appropriate emitter capacity is available, the decision should be based on careful discrimination rather than using an arbitrary percentage allowance. In general, for buildings of traditional construction and for the incidence of design weather in normal winters in the UK an emitter margin in excess of, say, 5% or 10% is unlikely to be justified. However, for well-insulated buildings the heat loss reduces in significance relative to the heat stored in or needed to warm up the structure. For such applications a larger heating system margin is required, and the emitter margin provided would need to be considered accordingly.

15.4.1.6 Central plant size

In estimating the required duty of a central plant for a building it should be remembered that the total net infiltration of outdoor air is about half the sum of the rates for the separate rooms. This is because, at any one time, infiltration of outdoor air takes place only on the windward part of the building, the flow in the remainder being *outwards*.

When intermittent heating is to be practised the pre-heating periods for all rooms in a building will generally be coincident. The central plant rating is then the sum of the individual room heat demands, modified to take account of the *net* infiltration.

If heating is to be continuous some diversity between the several room heating loads can be expected. When mechanical ventilation is combined with heating, the heating and the ventilation plant may have different hours of use, and the peak loads on the two sections of the plant will often occur at different times.

The central plant may also be required to provide a domestic hot water supply and/or heat for process purposes. These loads may have to be added to the net heating load to arrive at the necessary plant duty, but careful design may avoid the occurrence of simultaneous peaks. In large installations the construction of boiler curves may indicate whether savings in boiler rating can be made. In many cases little or no extra capacity may be needed for the hot water supply, its demands being met by 'robbing' the heating circuits for short periods.

15.4.1.7 Selective systems

In some cases the various rooms of a building do not all require heating at the same time of day and here a so-called 'selective system' may be used. The supply of heat is restricted to different parts of the building at different times of the day; the whole building cannot be heated at one time. A typical application is in dwellings where the demands for heat in living spaces and bedrooms do not normally coincide.

In a selective system the individual room appliances must be sized as indicated above, to provide the appropriate output according to heat loss, gains and intermittency. The central plant need only be capable of meeting the greatest simultaneous demands of those room units which are in use at the same time. This will generally lead to a large power being available to meet the demands of those units which form the lesser part of the load. These units may then be operated with a high degree of intermittency.

15.4.1.8 Multiple-boiler installations

Load variation throughout the season is clearly large, and consideration should be given to the number of boilers required in the system. Operation at low loads leads to corrosion and loss in efficiency and should be avoided. On the other hand, a number of smaller boilers gives an increase in capital costs.

It has been shown that when boilers are chosen which have a fairly constant and good efficiency over a working range of 30–100%, then the effects on overall costs (running + capital) of varying the number and relative sizes of boilers in the system is less than 5%. The optimum number depends on the frequency of occurrence of low loads.

Under these circumstances the engineer is free to choose the number of boilers in the system based on practical rather than economic considerations.

Table 15.30 Design water temperatures for warm and hot water heating systems

Category	*System design water temperatures* (°C)
Warm	40–70
LTHW	70–100
MTHW	100–120
HTHW	Over 120

Note: Account must be taken of the margin necessary between the maximum system operating temperature and saturation temperature at the system operating pressure.

15.4.1.9 Heating systems

Warm and hot water heating systems Warm water or low-, medium- or high-temperature hot water systems are categorized in Table 15.30. Warm water systems may use heat pumps, fully condensing boilers or similar generators, or reclaimed heat. In many cases the system design may incorporate an alternative heat generator for standby purposes or for extreme weather operation. Under such circumstances the system may continue to function at warm water temperatures or could operate at more conventional LTHW ones.

LTHW systems are usually under a pressure of static head only, with an open expansion tank, in which case the design operating temperature should not exceed 83°C. Where MTHW systems operating above 110°C are pressurized by means of a head tank, an expansion vessel should be incorporated into the feed and expansion pipe. This vessel should be adequately sized to take the volume of expansion of the whole system so that boiling will not occur in the upper part of the feed pipe. On no account should an open vent be provided for this type of system.

MTHW and HTHW systems require pressurization such that the saturation temperature at operating pressure at all points in the circuit exceeds the maximum system flow temperature required. A margin of 17 K (minimum) is recommended and is based on the use of conventional automatic boiler plant and includes an allowance for tolerances on temperature set points for the automatic control of heat-generation output. A check must be made on actual tolerance used in the design of a control system to ensure that this allowance is adequate.

When selecting the operating pressure, allowance must be made for the effect of static head reduction at the highest point of the system and velocity head reduction at the circulating pump section, to ensure that all parts of the system are above saturation pressure within an adequate anti-flash temperature margin. Additionally, the margin on the set point of the high-temperature cut-out control should be 6 K, except for boilers fired with solid fuel automatic stokers, where it should be at least 10 K.

Medium- and high-temperature systems should be fully pressurized before the operating temperature is achieved and remain fully pressurized until the temperature has dropped to a safe level. In all systems the heat generator or boiler must be mechanically suitable to withstand the temperature differentials, and the return temperature to the boiler must be kept high enough to minimize corrosion. Automatic controls may be used to achieve this.

Design water flow temperature For low-temperature heating systems using natural convective or radiant appliances the normal design water flow temperature to the system is 83°C (see also Table 15.30). Boost temperatures may be used on modulated-temperature systems because of the changes in heat output characteristics with varying temperatures. Additionally, comfort aspects must be borne in mind, as forced convective emitters operating on modulated temperature systems can deliver airstreams at unacceptably low temperatures.

For MTHW and HTHW systems heat emitters may be as for LTHW systems, except that, for safety reasons, units with accessible surfaces at water temperature would not normally be employed. Embedded panel coils may be used in conjunction with a MTHW or HTHW distribution system, with insulating sleeves around the coil piping to reduce the heat flow. Alternatively, the coils can be operated as reduced temperature secondary systems by allowing only a small, carefully controlled proportion of flow temperature water to be mixed with the water circulating in the coils. Design arrangements for reduced-temperature secondary systems (sometimes referred to as injection circuits) include fixed provisions for minimum dilution rates. Conventional system-balancing devices with three-port automatic modulating valves to regulate mixed water temperatures and, hence, heat output are used. Automatic safety controls must prevent excessive temperatures occurring in the coil circuits, as floor fabrics or finishes could be damaged very rapidly.

Maximum water velocity The maximum water velocity in pipework systems is limited by noise generation and erosion/corrosion considerations. Noise is caused by the free air present in the water, sudden pressure drops (which, in turn, cause cavitation or the flashing of water into steam), turbulence or a combination of these. Noise will therefore be generated at valves and fittings where turbulence and local velocities are high, rather than in straight pipe lengths.

A particular noise problem can arise where branch circuits are close to a pump and where the regulating valve used for flow-rate balancing may give rise to considerable pressure differences. Oversizing regulating valves should be avoided, as this will result in poor regulation characteristics; the valve operating in an almost shut position and creating a very high local velocity.

High water velocities can result in erosion or corrosion due to the abrasive action of particles in the water and the breakdown of the protective film which normally forms on the inside surface of the pipe. Erosion can also result from the formation of flash steam and from cavitation caused by turbulence.

Minimum water velocity Minimum water velocities should be maintained in the upper floors of high-rise buildings where air may tend to come out of solution because of reduced pressures. High velocities should be used in down-return mains feeding into air-separation units located at a low level in the system.

System temperature drop British practice on LTHW systems uses a typical system temperature drop of 11 K and a maximum system temperature of 17 K. Continental practice has tended to use higher drops (up to 40 K). An advantage of a higher system temperature drop is the reduction in water flow rates. This will result in reduced pipe sizes with savings in capital cost and distribution heat losses and a reduced pump duty, with savings in running costs. A disadvantage of higher system temperature drops is the need for larger and consequently more expensive heat emitters. However, if it is possible to raise the system flow temperature so that the mean water temperature remains the same, then with certain types of emitter only a small increase in size is required. With large system temperature drops the average water temperature in a radiator tends to fall below the mean of flow and return temperature and, thus, a larger surface is needed. Furthermore, on one-pipe circuits the progressive reduction in temperature around the circuit may lead to excessively large heat emitters.

Higher system temperature drops can be used with MHTW and HTHW systems since the mean temperature of the heat emitters will be correspondingly higher. Additionally, these media are well suited to use for primary distribution systems, conveying heat over long distances.

Precautions should be taken to prevent the danger of injury from contact with hot surfaces. The safe temperature for prolonged contact is relatively low and reference should be made to BS 4086 and other sources.

Use of temperature-limiting valves on emitters On some group and district heating schemes, outlet limiting valves which permit flow only when the water temperature has dropped to a specified low level are used. This procedure minimizes the water quantity to be pumped and permits indicative heat metering by water quantity alone. In such cases care must be taken to size emitters to suit the available water temperatures. The effect of low water velocities through the emitter must also be taken into consideration, since the heat output of some convective appliances is greatly reduced under such conditions.

Miscellaneous components Data regarding relief valves, feed and expansion cisterns are available in Table 15.31.

Distribution system design The design of pipework distribution systems must allow for the following:

1. Future extensions, where required, by the provision of valved, plugged or capped tee connections.
2. Provision for isolation for maintenance. Where it is necessary to carry out maintenance on a 'live' system, valves must be lockable and may need to be installed in tandem.
3. Thermal expansion.
4. Provision for distribution flow rate balancing for initial commissioning or rebalancing to meet changed operational requirements. Typical provisions for balancing comprise the following:
   (a) A measuring station – which may be an orifice plate, a venturi, an orifice valve or other proprietary device – provided with a pair of tappings to permit the measurement of upstream and downstream system dynamic pressures.
   (b) An associated regulating valve – preferably a double-regulating valve or other arrangement which permits the required setting to remain undisturbed by closure.
5. Provision for drainage, including drainage after pre-commission flushing; water circulation during flushing must be in excess of design flow rates and, in order to discharge the flushing effluent effectively, drainage connections must be full diameter.
6. Removal of air from the system by provision of:
   (a) Air separators, one form of which uses the principle of centrifugal force to separate the heavier constituent (water) from the lighter one (non-condensable gases). Best results are achieved by locating the separator at the highest temperature point of the system where air has a greater tendency to come out of solution. The velocity of the medium requires to be above the minimum stated by the manufacturer (usually about 0.25 m/s).
   (b) Automatic air vents for systems operating at temperatures below atmospheric boiling point.
   (c) Air bottles with manually operated needle valves to release accumulated air, for systems operating at temperatures in excess of atmospheric boiling point.
7. Provision of test points for sensing temperature and pressure at selected locations.

Sealed heating systems Pressurization of medium- and high-temperature hot water sealed heating systems referred to above may take the following forms:

1. *Pressurization by expansion of water* The simplest form of pressurization uses the expansion of the water content of the system to create a sufficient pressure in an expansion vessel to provide an anti-flash margin of, say, 17°C at the lowest pressure (highest point) of the system. The main disadvantage of a naturally pressurized expansion vessel is the ability of water to absorb air and the consequent risk of oxygen corrosion.

   A diaphragm expansion vessel is divided into two compartments by a special membrane or diaphragm of rubber or rubber composition which prevents the water coming into contact with the air. On one side of the diaphragm the vessel is filled with air or nitrogen at the required pressure. The other section of the vessel is connected directly to the water system. A correctly positioned air separator will assist in de-aerating the water in the system.
2. *Pressurization of elevated header tanks* Given very careful attention to design, installation and commissioning, MTHW systems may be operated with the necessary system pressure provided by an elevated feed and expansion tank. Where the system operating temperature exceeds 110°C an expansion vessel should be sized to absorb the volume of expansion for the complete system, thus preventing water at operating temperatures entering the feed and expansion tank and causing boiling. On no account should an open vent be provided for this type of system.
3. *Gas pressurization with spill tank* This form consists of a pressure cylinder maintained partly filled with water and partly with gas (usually nitrogen) which is topped up from pressure bottles. Water expansion is usually arranged to discharge from the system through a pressure-control valve into a spill tank open to atmosphere or to a closed cylinder lightly pressurized with nitrogen. A pump is provided to take water from the spill tank and return it under pressure to the system as cooling-down results in a pressure drop. The pump operation is regulated by a system presure sensor.
4. *Hydraulic pressurization with spill tank* In this form the pressure is maintained by a continuously running centrifugal pump. A second pump under the control of a pressure switch is provided to come into operation at a predetermined pressure differential and as an automatic standby to the duty pump. Surplus water is delivered to or taken from a spill tank or cylinder as described previously.
5. *Example of pressure differential*

Assume system flow temperature of 120°C	
Allow 17 K anti-flash margin – 137°C	
Corresponding absolute pressure	3.4 bar
Assume static absolute pressure on system	2.0 bar
Minimum absolute pressure at cylinder	5.4 bar
Allow operating differential on pressure cylinder, say –	0.5 bar
Minimum operating absolute pressure of system	5.9 bar

6. *Example of water expansion*

Assume water capacity of system		200 000 l
Assume ambient temperature of 10°C		
Assume system maximum flow temperature of 120°C		
Assume system minimum return temperature of 65°C		
Increase in volume from 10°C to 65°C		
$200\,000\,\dfrac{(999.7 - 980.5)}{980.5}$	=	3916 l
Increase in volume from 65°C to 120°C		
$200\,000\,\dfrac{(980.5 - 943.1)}{943.1}$	=	7931 l
Total increase in volume	=	11 847 l

Maintenance of water heating systems A common practice in many hot water heating installations is to drain the complete system during summer months. This practice, involving a complete change of raw water every year, is to be deprecated. It introduces additional hardness salts and oxygen to the system, resulting in very significant increases in scaling and corrosion. Where it is necessary to drain the boiler or heat generator or other parts of the system for inspection or maintenance purposes, isolating valves or other arrangements should be used to ensure that the section drained is kept to a minimum.

Steam heating systems These are designed to use the latent heat of steam at the heat emitter. Control of heat output is generally by variation of the steam saturation pressure within the emitter. For heating applications with emitters in occupied areas low absolute pressures may be necessary in order to reduce the saturation temperature to safe levels.

The presence of non-condensable gases in steam systems (e.g. air and CO_2) will reduce the partial pressure of the steam, and hence its temperature, thus affecting the output of the appliance. A further adverse effect is the presence of a non-condensable gas at the inside surface of a heat emitter. This impedes condensation and, hence, heat output. It is therefore imperative that suitable means are provided to prevent formation of CO_2 and to evacuate all gases from the system.

Superheat, which must be dissipated before condensation occurs, can be used to reduce condensation in the distribution mains.

On–off control of steam systems can result in the formation of a partial vacuum, leading to condensate locking or back feeding, and infiltration of air which subsequently reduces the heat transfer.

When using modulating valves for steam, heat emitter output must be based on the steam pressure downstream of the valve, which often has a high-pressure drop across it, even when fully open.

Steam traps must be sized to cope with the maximum rate of condensation (which may be on start-up) but must perform effectively over the whole operational range, minimizing the escape of live steam.

Partial waterlogging of heater batteries can lead to early failure due to differential thermal expansion. Steam trap selection should take account of this.

Where high temperatures are required (e.g. for process work) and lower temperatures for space heating, it is desirable to use flash steam recovery from the high-temperature condensate to feed into the low-temperature system, augmented as required by reduced pressure live steam.

Steam as a medium for heating is now seldom used. Hot water, with its flexibility to meet variable weather conditions and its simplicity, has supplanted it in new commercial buildings. Steam is, however, often used for the heating of industrial buildings where steam-raising plant occurs for process or other purposes. It is also employed as a primary conveyor of heat to calorifiers such as in hospitals, where again steam boiler plant may be required for sundry duties such as in kitchens, laundry and for sterilizing. Heating is then by hot water served from calorifiers.

High-temperature thermal fluid systems Where high operating temperatures are required, high-temperature thermal fluid systems may be used instead of pressurized water or steam systems. These systems operate at atmospheric pressure using non-toxic media such as petroleum oil for temperatures up to 300°C or synthetic chemical mixtures where temperatures in excess of this are required (up to 400°C). Some advantages and disadvantages of thermal fluid or heat transfer oil systems are listed below.

Advantages

No corrosion problems.
Statutory inspections of boilers/pressure vessels not required.
No scale deposits.
No need for frost protection of system.
Cost of heat exchangers/heat emitters less, as only atmospheric pressures are involved.
Better energy efficiency than steam systems.
Operating temperature can be increased subsequent to design without increasing operating pressure.

Disadvantages

Medium more expensive than water (but no treatment costs).
Medium is flammable under certain conditions.
Heat transfer coefficient is inferior to that of water.
Care necessary in commissioning and in heat-up rates due to viscosity changes in medium.
Circulating pump necessary (not required for steam systems).
Air must be excluded from the system.
In the event of leakage the medium presents more problems than water.

Warm air heating systems These may be provided with electric or indirect oil- or gas-fired heaters or with a hot water heater or steam battery supplied from a central source. Because the radiant heat output of warm-air systems is negligible, the space air temperature will generally need to be higher for equivalent comfort standards than for a system with some radiant output. This will increase energy use, and legislative standards for limiting space temperatures should be considered. Attention is drawn to the vertical temperature gradient with convective systems and, when used for cellular accommodation, the likelihood of some spaces being overheated due to the difficulty of controlling such systems on a room-by-room basis.

With the advent of natural gas, direct-fired warm air systems are used where the heat and products of combustion, diluted by fresh air introduced into the system, are distributed to the heated spaces. In designing such installations account must be taken of the requirements of the Building Regulations 1985, Part J, and of the Regional Gas Authority. Care must also be taken in design and application to ensure that the moisture in the products of combustion will not create condensation problems. Direct-fired systems are more suited to large, single-space low-occupancy applications such as warehouses and hangars and should not be used to serve sleeping accommodation.

Reducing the effect of temperature stratification As with all convective systems, warm air heating installations produce large temperature gradients in the spaces they serve. This results in the inefficient use of heat and high heat losses from roofs and upper wall areas. To improve the energy efficiency of warm air systems, pendant-type punkah fans or similar devices may be installed at roof level in the heated space. During the operational hours of the heating system these fans work either continuously or under the control of a roof-level thermostat and return the stratified warm air down to occupied levels.

The energy effectiveness of these fans should be assessed, taking into account the cost of the electricity used to operate them. The following factors should also be borne in mind:

1. The necessary mounting height of fans to minimize draughts;
2. The effect of the spacing of fans and the distance of the impeller from the roof soffit;
3. Any risk to occupants from stroboscopic effects of blade movements;
4. The availability of multi- or variable-speed units.

Punkah fans may also be operated during summer months to provide air movement and offer a measure of convective cooling for occupants.

High-temperature high-velocity warm air heating systems These systems, best suited to heating large, single spaces, may use indirect heating by gas or oil or direct gas heating. Relatively small volumes of air are distributed at high temperature (up to 235°C) and high velocity (30–42.5 m/s from heater unit) through a system of well-insulated conventional ductwork. Air outlets are in the form of truncated conical nozzles discharging from the primary ductwork system into purpose-designed diffuser ducts. The high-velocity discharge induces large volumes of secondary air to boost the outlet volume and reduces the outlet temperature delivered to the space, thereby reducing stratification. Most of the ductwork thermal expansion is absorbed by allowing free movement and long, drop-rod hangers are used for this purpose. Light, flexible, axial-bellows with very low thrust loads can also be employed where free expansion movement is not possible. System design and installation is generally handled as a package deal by specialist manufacturers.

15.4.1.10 Heating equipment – attributes and applications

Water system heating equipment The range of heat emitters may be divided into three generic groups:

1. Radiant
2. Natural convective
3. Forced convective

Table 15.31 lists the principal types of appliance in each group, together with descriptive notes. Typical emission ranges are quoted for each type over its normal span of working temperatures. These are intended as a guide only and manufacturers' catalogues should be consulted for detailed performance values.

Electric heating equipment Where electric heating equipment is installed within the space to be heated the total electrical input is converted into useful heat. There are two categories of electric heating equipment, direct acting and storage heating. The two types of electric heating can be used independently or to complement one another to meet particular heating requirements.

Gas- and oil-fired heating equipment Where gas or oil appliances are used for heating and installed within the heated space, between 70% and 90% of the total energy content of the fuel input will be converted into useful heat.

15.4.2 Ventilation

15.4.2.1 Introduction

Ventilation systems are defined as systems providing air movement through a space without artificially heating or cooling the air. It must be said, however, that, in practice, there is often a large degree of overlap, since office ventilation systems often provide heating in winter and complex ducted ventilation systems share much equipment and design procedures with air-conditioning systems.

This section is intended to provide guidance towards defining needs, assessing whether ventilation is the correct solution and selecting equipment and systems to match these requirements in as economic a manner as possible.

Reasons for ventilation Ventilation is used to maintain a satisfactory environment within enclosed spaces. The environmental criteria controlled may be:

Temperature – relief from overheating
Humidity – prevention of condensation or fogging
Odour – dilution of odour from smoking, body odour, processes, etc.
Contamination – dilution or removal of dangerous or unpleasant fumes and dust

The required values for these criteria will depend upon the reason the space is being ventilated. It may be for the benefit of people, processes, equipment, materials, livestock, horticulture, building preservation or any combination of these. Guidance on selection of these values is provided by CIBSE[30] and ASHRAE.[33]

Definitions

Aerodynamic area – The effective theoretical open area of an opening. It is related to the measured area by the coefficient of entry or discharge (C_d).
Air-handling unit – A self-contained package incorporating all equipment needed to move and treat air, requiring only connection to ductwork and services to provide a complete ventilation system.
Coefficient (entry or discharge) – The ratio of aerodynamic (effective) area to the measured area of an opening. The value for a square-edged hole of 0.61 is used for most building openings.
Capture velocity – The air velocity needed to capture a contaminant at source, overcoming any opposing air currents.
Automatic fire ventilation – See *Smoke ventilation*.
Dilution ventilation – A ventilation strategy whereby contaminants are allowed to escape into the ventilated space and are then diluted to an acceptable level by means of the ventilation system.
Industrial ventilation – A term used to cover any ventilation system designed to remove contaminants. Its use is sometimes restricted to local extract systems.
Maximum Exposure Limit (MEL) – Maximum limits of concentration of airborne toxic contaminants, listed by the Health and Safety Executive[47] which must not be exceeded.
Occupational Exposure Standards (OES) – Limits of concentration of airborne toxic contaminants, listed by the Health and Safety Executive[47] which are regarded as safe for prolonged exposure for 8 hours per day.

Table 15.31 Characteristics of water system heating equipment

Type	*Advantages*	*Disadvantages*	*Emission range*
Radiant			
Radiant panel	No moving parts, hence little maintenance required; may be mounted at considerable height or, in low-temperature applications, set flush into building structure.	Slow response to control; must be mounted high enough to avoid local high intensities of radiation (e.g. onto head).	350 W/m^2 to 15 kW/m^2 of which up to 60% may be radiant.
Radiant strip	No moving parts, hence little maintenance required; may be mounted at considerable height or, in low-temperature applications, set flush into building structure.	Slow response to control; must be mounted high enough to avoid local high intensities of radiation (e.g. onto head).	150 W/m to 5 kW/m of which radiant emission may be up to 65% of total.
Natural convective			
Radiators	Cheap to install; little maintenance required.	Fairly slow response to control. With steel panel radiators there is a risk of corrosive attack in areas having aggressive water, which may be accentuated by copper swarf left in the radiator. This leads to rapid failure unless a suitable inhibitor is used. Not suitable for high-temperature water or steam.	450–750 W/m^2.
Natural convectors	May be used on high-temperature hot water or low-pressure steam without casing temperature becoming dangerously high: fairly rapid response to control.	Take up more floor space than radiators. Likelihood of fairly high-temperature gradients when using high-temperature heating media.	200 W to 20 kW.
Continuous convectors	Take up relatively little space; give even distribution of heat in room. May be used with medium-temperature hot water or low-pressure steam without casing temperatures becoming dangerously high. Return pipework may be concealed within casing.	May produce large temperature gradients on high-temperature heating media if poorly sited.	500 W/m to 4 kW/m.
Skirting heating	May be used on water or low-pressure steam. Gives low-temperature gradients in the room. All pipework concealed.	Relatively low output per metre of wall. More work involved when installing in existing building as existing skirting has to be removed.	300 W/m to 1.3 kW/m.
Forced convective			
Far convectors	Rapid response to control by individual thermostat. By use of variable speed motors rapid warm-up available in intermittent systems; filtered fresh air inlet facility.	Electric supply required to each individual unit.	2 to 25 kW.
Unit heaters	Rapid response to control by individual thermostat; by use of multi-speed motors rapid warm-up available on intermittent systems; filtered fresh air inlet facility.	Electric supply required for each individual unit.	3 to 300 kW.

Infiltration – Movement of air through a space with no specific ventilation openings by natural forces.
Local extract – A ventilation strategy whereby heat, steam or contaminants are captured at source and ducted to discharge outside the space.
Mechanical ventilation – See *Powered ventilation*.
Natural ventilation – A ventilation system in which air movement is produced through purpose-designed openings by natural forces (wind and thermal buoyancy).
Powered ventilation – A ventilation system in which air movement is induced by mechanical means – almost invariably a fan.
Smoke logging – The filling of a space with smoke in the event of fire.
Smoke ventilation – A ventilation system designed to remove smoke and heat in the event of fire to prevent or delay smoke logging allowing personnel to escape and firefighters to attack the fire.
Spot cooling – A ventilation strategy whereby the space temperature is allowed to rise and air movement is induced locally to provide comfort conditions within a limited area.
Threshold Limit Value (TLV) – Maximum values of concentrations of airborne toxic contaminants, listed by the American Conference of Governmental Industrial Hygienists[34] (ACGIH), regarded to be safe for 8 hours per day exposure.
Transport velocity – The air velocity required in a duct to transport a contaminant without it falling out of suspension.

15.4.2.2 Ventilation systems and controls

How natural ventilation works Natural ventilation operates by means of airflows generated by pressure differences across the fabric of the building. An airflow will occur wherever there is a crack, hole or porous surface and a pressure difference.

For the relatively large openings in which we are interested the flow rate can be found from the velocity or airflow generated through the aerodynamic area of the opening from the formulae:

$$V = \sqrt{\frac{2\Delta P}{\rho}} \qquad (15.38)$$

where V = velocity (m/s),
ΔP = pressure difference (Pa),
ρ = density (kg/m^3).

Then flow rate:

$$\dot{V} = AC_dV \qquad (15.39)$$

where $\dot{V}$ = volumetric flow rate (m^3/s),
A = measured area of opening (m^2),
C_d = coefficient of opening.

For purpose-built ventilators the manufacturer will be able to provide values of C_d. For other openings it is conventional to use the value for a sharp-edged square orifice of 0.61.

The pressure can be generated by three mechanisms:

1. Powered ventilation equipment;
2. Buoyancy (temperature difference);
3. Wind.

In still air conditions the source of pressure difference to drive ventilation is buoyancy due to the decrease in density of heated air. In any occupied building there will be a higher temperature inside than outside due to heat gains from people, plant and solar radiation. The lighter heated air will try to rise, causing an increase in internal pressure at high level and a reduction at low level with a neutral plane between the two conditions. Any opening above the neutral plane will therefore exhaust air and any opening below the neutral plane will provide inlet air. Under steady heat load conditions a balance will be achieved with a throughput of air dependent upon the heat load and the size and location of the openings. Conditions at this balance point can be readily calculated using one of the following formulae:

For more than one opening (inlets all at one height, exhausts all at one height)

$$\dot{V} = A_eC_e\sqrt{\frac{2gH\Delta t}{\bar{T}}} \qquad (15.40)$$

For a single opening

$$\dot{V} = \frac{AC_d}{3}\sqrt{\frac{gh\Delta t}{\bar{T}}} \qquad (15.41)$$

where g = acceleration due to gravity (m/s^2),
H = height between centre lines of inlet and outlet openings (m),
Δt = temperature difference between inside and outside (°C),
$\bar{T}$ = average of inside and outside temperatures (absolute) (K),
h = height of single opening (m),
C_eA_e = overall effective opening size calculated from

$$\frac{1}{(C_eA_e)^2} = \frac{1}{(\Sigma\, C_iA_i)^2} + \frac{1}{(\Sigma\, C_vA_v)^2}$$

(subscript i denotes inlet opening, subscript v exhaust opening).

Under wind conditions a complex system of pressures is set up on the external surfaces of the building which will vary with wind speed and direction. Pressure coefficients C_p[35,36] define the relationship according to the formula:

$$\dot{V} = A_eC_eU_r\sqrt{(\Delta C_p)} \qquad (15.42)$$

where U_r = reference wind speed,
ΔC_p = difference between coefficients at ventilation openings.

The coefficients C_p will vary across each surface of the building and, except for very simple shapes, can only be found by model or full-scale test. Since the coefficients will change with wind direction, complete calculation of wind-induced ventilation is very unwieldy, needing computer analysis.

When both wind and temperature difference act on ventilation openings the result is very complex, but a reasonable approximation of flow rate is made by taking the higher of the two individual flow rates. This means that we can, for ventilation design purposes, generally ignore wind effects and design on temperature difference only, since wind effects can be assumed only to increase the ventilation rate.

Advantages and disadvantages

Advantages	*Disadvantages*
Quiet	Variable flow rate and direction dependent upon wind conditions
Virtually no running cost	Filtration is generally impractical
Self-regulation (flow rate increases with heat load)	Limited ducting can be tolerated
Low maintenance cost	Effectiveness depends on height and temperature difference
Provides daylight when open (roof vent)	
Psychological appeal of clear sky (roof vent)	
Easy installation	

When to use natural ventilation Natural ventilation is used in a number of situations:

1. Shallow-plan offices – by opening windows to remove heat and odour;
2. Large single-storey spaces (factories, warehouses, sports halls, etc.) – by roof and wall ventilators – to remove heat, contaminants, smoke, steam;
3. Plant rooms.

It is not suitable in situations where:

1. Dust, toxic or noxious contaminants must be removed at source;
2. Unfavourable external conditions exist requiring treatment to incoming air – e.g. noise, dust, pollution;
3. A steady controlled flow rate is required – e.g. hospitals, commercial kitchens;
4. Existing mechanical ventilation will affect the flow adversely;
5. Abnormal wind effects can be anticipated due to surrounding higher buildings;
6. The space is enclosed so as to have no suitable source of inlet air.

In many of these situations a system of natural inlet/powered exhaust or powered inlet/natural exhaust will be the best option.

Control Low-level ventilation openings, whether windows, doors or ventilators, are generally manually operated for simplicity and economy, allowing personnel to control their own environment. High-level openings can also be manually controlled by means of rod or cable operation, although this has generally lost favour (except in the case of simple windows) and automatic operation is preferred.

Automatic operation may be by means of compressed air, operating a pneumatic cylinder, or electricity. Pneumatics are generally favoured for industrial applications and electricity for commercial premises. Economy of installation is normally the deciding factor, since running costs are low for either system.

Automatic control allows a number of options to be considered to provide the best form of control for the circumstances. Generally available controls offer the following features:

1. Local control by personnel;
2. Automatic thermostatic control (single or multiple stage);
3. Fire override to open ventilators automatically by means of a connection to the fire-detection system or fireman's switch. This normally overrides all other control settings;
4. Timeswitch control to shut ventilators during unoccupied periods;
5. Weather override to close ventilators during rain or snow;
6. Wind override to shut high-level exhaust ventilators on windward walls (mainly used for smoke ventilation).

How powered (mechanical) ventilation works[38] By definition, a powered ventilation system includes a mechanical means of inducing an airflow using an external power source. This is invariably an electrically driven fan. When a fan blade rotates it does work on the air around it, creating both a static pressure increase (P_s) and an airflow across the fan. The airflow has a velocity pressure associated with it, defined as $P_V = \frac{1}{2}\rho V^2$, and the fan can be described as producing a total pressure $P_T = P_s + P_V$. The pressure generated is used to overcome pressure losses (resistances) within the ventilation system.

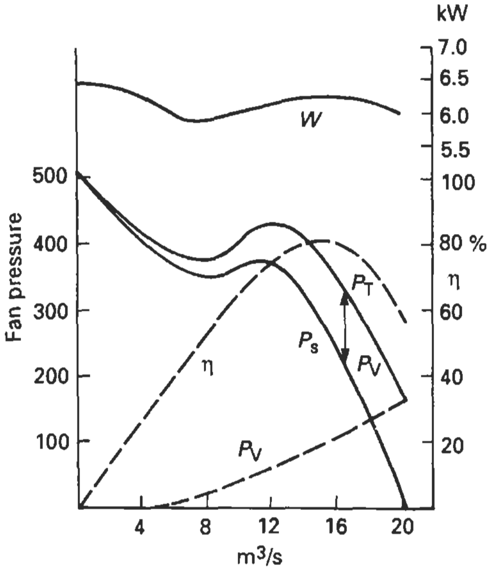

Figure 15.135 Typical fan curve for an axial fan

Each fan has a unique set of characteristics which are normally defined by means of a fan curve produced by the manufacturer which specifies the relationship between airflow, pressure generation, power input, efficiency and noise level (see Figure 15.135). For geometrically similar fans the performance can be predicted for other sizes, speeds, gas densities, etc. from one fan curve using the 'fan laws' set out below.

For a given size of fan and fluid density:

1. $\frac{\dot{V}_1}{\dot{V}_2} = \frac{N_1}{N_2}$ Volume flow is directly proportional to fan speed
2. $\frac{P_1}{P_2} = \left(\frac{N_1}{N_2}\right)^2$ Total pressure and static pressure are directly proportional to the square of the fan speed
3. $\frac{W_1}{W_2} = \left(\frac{N_1}{N_2}\right)^3$ Air power and impeller power are directly proportional to the cube of the fan speed

For changes in density:

4. $\frac{P_1}{P_2} = \frac{W_1}{W_2} = \frac{\rho_1}{\rho_2}$ Pressure and power are directly proportional to density and therefore for a given gas are inversely proportional to absolute temperature

For geometrically similar fans operating at constant speed and efficiency with constant fluid density:

5. $\frac{\dot{V}_1}{\dot{V}_2} = \left(\frac{D_1}{D_2}\right)^3$ Volume flow is directly proportional to the cube of fan size
6. $\frac{P_1}{P_2} = \left(\frac{D_1}{D_2}\right)^2$ Total pressure and static pressure are directly proportional to the square of fan size
7. $\frac{W_1}{W_2} = \left(\frac{D_1}{D_2}\right)^5$ Air power and impeller power are directly proportional to the fifth power of fan size

where

$\dot{V}$ = volumetric flow (m^3/s),
P = pressure (kN/m^2),
W = power (W),
D = size parameter (diameter) (mm).

In passing through the fans gases are compressed slightly due to the increase in pressure. For absolute accuracy note should be taken of this effect using the gas compressibility factor which will affect flow rate, static and total pressure and power. However, in most fan systems the effect is very small, since the pressure increase through the fan is insignificant compared to atmospheric pressure. By convention, compressibility effects are therefore normally ignored.

Since the pressure generated by most fans is far in excess of pressure differences due to buoyancy and wind, the performance of a powered ventilation system is effectively independent of these, and flow rates and directions can be confidently predicted and will be constant regardless of conditions. The high-pressure generation also allows resistive components such as heater batteries, filters and attenuators to be used within the system. Advantages and disadvantages are:

Advantages	*Disadvantages*
Weatherproof	Fixed air flow – not self-regulating
Predictable constant performance	Running costs (electrical and maintenance)
Air treatment can be incorporated	Noise
Fresh air can be delivered at optimum volume, velocity and temperature	

When to use powered ventilation Powered ventilation is essential in some instances:

1. Local extract;
2. When pre-treatment of incoming air is required;
3. When a steady controlled airflow is required;
4. When there are no suitable external walls or roof for natural ventilation;
5. In deep-plan offices or large industrial spaces to provide positive air movement in central zones.

It can also be used in any situation where natural ventilation is suitable, generally becoming more economic as the roof height lowers, subject to noise levels being acceptable.

Control Simple systems are normally controlled by a starter or contactor with manual push-button or thermostatic operation to start and stop the fan. More complex systems incorporating other components needing control or monitoring are normally operated from purpose-built central control panels. The most common functions provided are fan motor stop, start and speed control, damper control, filter-condition indication and heater battery control. For optimum control the system should be automatically controlled from thermostats or other sensors and a timeswitch.

15.4.2.3 Powered ventilation equipment

This falls into two basic groupings: supply air systems and extract systems. The equipment used for both is similar, comprising, as a minimum, a fan and weather-proof cowl, plus ducting, air-treatment equipment and grilles as required.

Fans Five main types of fan are used in ventilation systems as described below.

1. *Centrifugal* The airflow changes direction through 90°, which can make this type of fan difficult to use within a ducted system. Two blade types are used, backward curved providing high-pressure at low volume flow and forward curved providing medium-pressure and volume flow. Typical static efficiencies are 70–75% and 80–85%, respectively.
2. *Axial* Duties are usually high- to medium-volume flow rates at medium to low pressures. In its simplest form there is an impeller and its drive motor only mounted within the cylindrical casing, and the discharge flow usually contains a fairly pronounced element of rotational swirl which may, if not corrected, materially increase the resistance of the downstream part of the system. More sophisticated versions include either downstream or upstream guide vanes to correct the swirl. Typical static efficiencies are 60–65% or 70–75% with guide vanes.
3. *Propeller* This is really a simple form of axial fan but with its impeller mounted in a ring or diaphragm which permits it to discharge air with both axial and radial components. Duties covered are high volume and low pressure. Static efficiency is normally under 40%.
4. *Mixed flow* This is a fan in which the air path through the impeller is intermediate between the axial and centrifugal types giving the benefit of increased pressures but capable of being constructed to provide either axial or radial discharge. Static efficiency is typically 70–75%.
5. *Cross flow* This type normally has a long cylindrical impeller having a relatively large number of shallow forward-curved blades. Due to the shape of the casing surrounding this impeller, air enters all along one side of the cylindrical surface of the impeller and leaves on another side. Static efficiency is typically 40–50%.

In general, axial fans are used for roof extract units and small ducted systems and centrifugal fans for large-ducted systems.

Roof extract units These are the most commonly used powered ventilators in large open buildings such as factories, warehouses and sports halls. Mounted directly onto the roof or wall, they comprise an axial fan, a safety grille and a weatherproof casing. Two forms are normally available, the vertical-discharge type which tends to have a complex casing arrangement but which throws the exhaust clear of the building, and the low-discharge type which has a simple casing but directs the exhaust onto the roof of the building. Vertical discharge is essential when smoke or fumes are being exhausted.

These ventilators can normally be used with limited ducting or accessories. A variation, fitted with a centrifugal fan, is available for more extensive ducting and is often used for duties such as toilet extract in commercial buildings.

Roof inlet units This specialized form of supply air system is often used in large open industrial spaces. It comprises a modular system of components which can be built up into simple systems. A typical system might have a roof inlet cowl, a recirculation damper, a heater battery, a fan, one or two outlet grilles and short sections of connecting ductwork, and would handle airflows up to 3–4 m^3/s, depending on size. A number of individual systems would be used to provide the total airflow required in the space (Figure 15.136). Systems are normally manufactured with aluminium casings to reduce the roof load.

Ducted systems[39,40] Larger ducted ventilation systems, as used in offices and commercial premises using a central air-handling unit and fabricated distribution ductwork, are

Figure 15.136 Roof inlet system

akin to air-conditioning systems but with less treatment to the air at the AHU (see Section 15.4.3).

Local extract systems[41] Local extract systems are designed specifically to remove fumes, dust, mists, heat, etc. at source from machinery and fume cupboards. The main design considerations are capture of the contaminant which will normally involve special hoods or cabins, and extract at sufficient velocity to satisfactorily transport the contaminant. Ductwork must be manufactured to resist abrasion or corrosion and sufficiently well sealed to prevent leakage. Welded ductwork is often needed. The fan may also need protection and the motor may need to be flameproof or out of airstream if the contaminant is flammable or corrosive. Treatment of the exhaust may be required to reduce pollution and nuisance and to comply with legislation.

Air cleaners A wide range of types of air cleaners are available to match the number of contaminants needing removal from air. Figure 15.137 shows typical particle size ranges and the range of operation of each type of air cleaner.

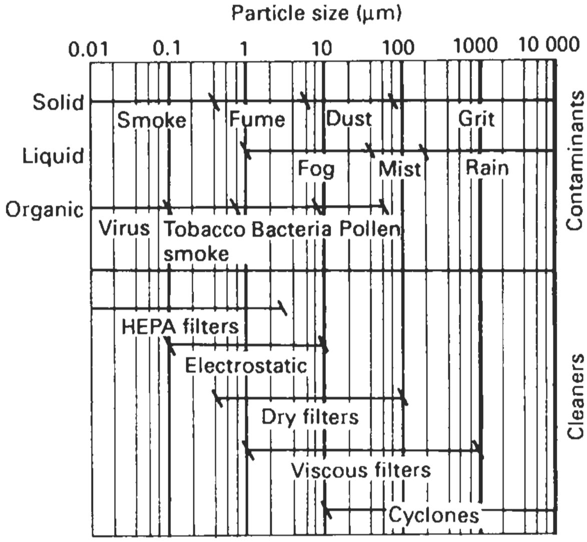

Figure 15.137 Typical particle sizes

15.4.2.4 Natural ventilation equipment

The natural ventilation equipment commercially available can be split into two basic groups, fixed and controllable. The fixed ventilation, normally a weathered louvre system, is used in applications where ventilation is constantly needed, winter and summer, with no need for control to maintain human comfort conditions. Typical examples are plant rooms and building block drying rooms. Louvre systems are also often used for inlet or exhaust to powered ventilation or air-conditioning systems and for architectural cladding. Controllable ventilation, which may be weatherproof if required, is used in buildings which are normally occupied and where waste process heat is not sufficient to heat a ventilated building in winter (i.e. most buildings).

Fixed ventilation Fixed ventilation has to be weatherproof to some degree. If it were not, then a simple hole in the wall or roof would be sufficient. The normal form of fixed ventilator is the louvre panel. At its simplest, this may be a number of slats of wood mounted at 45–60° in a door or wall opening, and at its most sophisticated an aerodynamically designed two- or three-bank 'chevron' of roll-formed or extruded aluminium.

With all louvres there is a balance between their weatherproofing qualities and their airflow, and it is important to select a louvre with the correct balance for each application. No louvre can be guaranteed to be 100% waterproof under all conditions, but the best ones approach this standard under normal flow and wind conditions. A bird or insect guard (as applicable) is normally mounted behind the louvre.

Controllable ventilation Controllable ventilation is normally provided by one of three types of ventilator: louvred, opening flap and weathered. The most common is the louvred ventilator which has a number of centre hinged louvre blades controlled from a pneumatic ram or electric actuator which can be fully opened when ventilation is needed and fully closed to a weatherproof condition when it is not. These may normally be roof or wall mounted.

Opening flap ventilators have one or two hinged flaps (opaque or glazed) which are normally held closed but which may be opened to between 45° and 90°, depending upon design. Control is normally pneumatic or electric. Specific designs are available for roof or wall mounting.

Weathered ventilators need to have a complex air path in order to prevent rain entry so they therefore provide a restricted airflow. To overcome this, multifunctional ventilators are often used providing a direct airpath during dry weather and a restricted one during rainfall. These ventilators are normally only roof mounted.

Most ventilators are powered in one direction with spring return. Thus a pneumatic ventilator might be described as 'pressure to open' or 'pressure to close'. With the pressure to open type the ventilator will fail to the closed position under the influence of the return spring, ensuring the building remains weatherproof. Where ventilators are installed mainly as smoke ventilators it is important that they fail to the open position, so pressure to close ventilators should be used. A fusible link is normally fitted into the controls so that in the event of fire, affected ventilators will open automatically to release smoke and heat.

A limited range of accessories may be provided, normally bird guard, insect guard or attenuators, but since airflow through the ventilators is driven by very small pressure differences (perhaps 5 Pa), great care has to be taken to ensure the ventilation remains effective.

15.4.2.5 System design

Overheating Overheating can be due to a number of causes, but is usually from solar gain and machinery heat losses. If ventilating to provide thermal comfort in a space for humans or animals there are a number of considerations apart from simply air temperature:

1. Air temperature
2. Mean radiant temperature
3. Radiant temperature asymmetry
4. Air velocity
5. Humidity

Thus someone working near a window will receive hot solar radiation through the window in summer and cold radiation from the cold window surface in winter, causing uncomfortable radiant asymmetry even if the room temperature is perfect for personnel working away from the window. Ventilation will not be the correct solution for this problem – sun shading and double glazing would be more effective.

It is therefore important when considering ventilation design to consider the whole thermal environment and not to simply assume that reduction of air temperature to 20–22°C will cure all problems.

Fume dilution Dilution of fumes in factories, warehouses, etc. is generally required for one of two reasons: either to reduce the level of harmful (toxic or irritant) fumes to a safe level, normally below the OES[47] (Occupational Exposure Standard) or to dilute offensive odours. Care must be taken with the latter to ensure that the problem is not merely passed on to neighbours. If it is, then a local extract with air-cleaning equipment will be preferred if it is practical. Indeed, a local extract system is always preferable, since it removes the problem at source, resulting in a cleaner environment within the building, and may be mandatory (see 15.4.2.6).

The starting point for design of a dilution ventilation scheme is normally a hygiene survey in which levels of pollutants and the ventilation rate are measured under worst conditions.

The ventilation should be designed so that airflow is directed from clean to dirty areas to keep the majority of the building as clean as possible. However, this form of ventilation does little for operatives working at the source of contamination.

Normal ventilation equipment can be used unless the fumes are corrosive or flammable. Powered equipment is normally employed to ensure that a steady airflow is provided.

Since the ventilation will be needed both summer and winter, there will be an energy penalty for the high level of airflow, and either the inlet airflow must be pre-heated or additional space heating will be required.

In offices and public spaces fume dilution is normally required to reduce body odour and tobacco odours. CIBSE[30] gives current UK recommendations for fresh air requirements for various rooms to overcome these, varying from 5 to 25 l/s per person. These figures give a balance between energy loss and air purity, and higher levels of ventilation may be needed if a clean atmosphere is of overriding importance.

In most older offices the natural ventilation achieved by infiltration is sufficient to provide reasonable conditions, but areas of high occupancy such as conference rooms, theatres, bars and restaurants normally require mechanical ventilation. Sufficient ventilation must be provided to match the highest demand, whether for odour dilution or summer overheating.

An alternative to ventilation to clear tobacco smoke is the use of electrostatic air cleaners which clean and recirculate air within a room. These provide smoke dilution without the energy penalty of extra ventilation but require frequent cleaning to keep operating at maximum efficiency.

Prevention of condensation Condensation occurs whenever moist air comes into contact with a surface which is colder than the 'dewpoint' of the air. The dewpoint is the minimum temperature at which the air can contain the amount of moisture within it, and it will vary with moisture content. Condensation can also occur in the air when warm moist air meets cold air, when it is known as 'fogging'.

Condensation will appear on the inside surface of porous or impervious materials, forming first on the worst-insulated surfaces (normally glazing or steelwork). On porous surfaces condensation can occur within the material or at an internal boundary. This is known as interstitial condensation, and it is especially dangerous, since it is often not known about until it has caused noticeable damage.

Condensation can be avoided or reduced by insulation, reduction of moisture emission, ventilation or dehumidification. Calculation for condensation problems is complex but is covered in the CIBSE Guide[30] in some depth.

Local extract Local extract is used to remove contaminants directly from a process to the exterior without passing through personnel breathing zones. It thus provides a high degree of safety and because small volumes of air are extracted relative to a dilution ventilation system it is energy efficient.

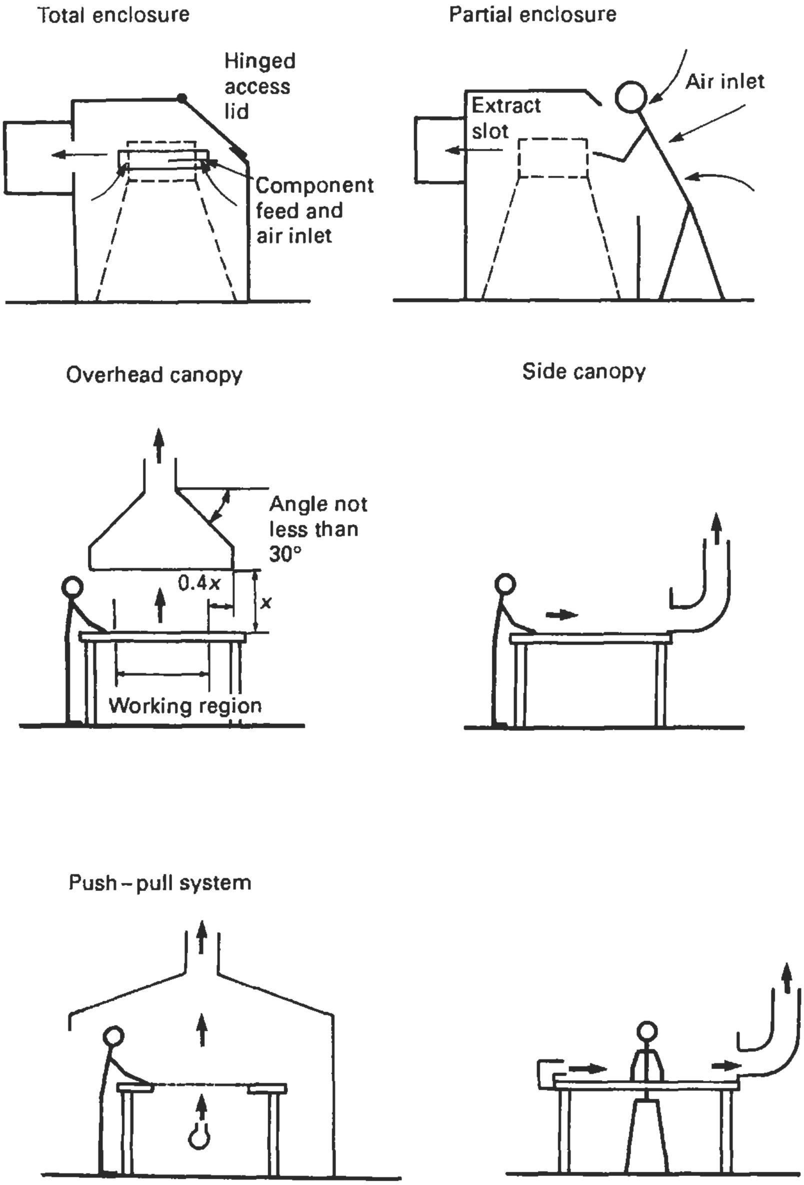
Where dusts, grits, sawdust or other large particles are being extracted it is normally mandatory to include an air-cleaning device before the air is exhausted. Unless they are controlled under the Environmental Protection Act, fumes can normally be exhausted into the atmosphere at a suitable location well away from anywhere with normal personnel access.

The design of a system can be broken into three main areas: capture, transport and cleansing. Capture of the contaminant is of paramount importance. Depending upon the source of the contaminant, capture may be via a hood, slot, booth or enclosure, with the airflow designed to take the contaminant from the source into the duct system without passing through the operatives' breathing zone. Some typical examples of good design are shown in Figure 15.138. To capture the contaminant, a minimum air velocity, referred to as the 'capture velocity', is needed at the source. Full guidance in the design of capture systems is given by the ACGIH.[41]

Once captured, the contaminant has to be carried along a duct system. If the duct velocity is too low, particles will tend to drop out of suspension and collect in or fall back down the duct. It is therefore essential that a suitable minimum duct velocity, referred to as the transport velocity, is maintained. Nothing is gained by velocities far in excess of the recommended transport velocity, and in some cases as much is lost, since abrasion of particles on the duct can cause premature erosion and failure.

Removal of particles from the airstream is generally carried out in a cyclone, positioned outside the building and taking particles from all sources in the building. Care should be taken to position cyclones away from noise-sensitive areas since both ducts and cyclones can be noisy, especially if grits or chips are being carried.

Selection of fans and ducting for local extract must be more rigorous than for other systems. The fan must be capable of



Total enclosure
Hinged access lid
Component feed and air inlet
Partial enclosure
Extract slot
Air inlet
Overhead canopy
Angle not less than 30°
0.4x
x
Working region
Side canopy
Push – pull system

Figure 15.138 Typical local extract hoods and enclosures

withstanding abrasion or corrosion from the contaminants, and if they are flammable must have a flameproof or out-of-airstream motor. The ducting also must be able to withstand abrasion or corrosion and must be fully sealed to prevent escape of contaminants within the building. For specialist applications such as fume cupboard extract, ducting and fans are often of plastic construction.

Smoke ventilation Smoke-ventilation systems are designed to clear smoke and heat from a building in the event of fire. In large open spaces it is impossible to 'smother' a fire (as is often recommended in domestic situations) by closing doors and windows. The aim of smoke ventilation is to minimize damage due to smoke staining and heat and to assist evacuation and firefighting by providing a layer of clear air below the smoke. Without smoke ventilation a space can become 'smoke logged' from ceiling to floor in only a few minutes.

The actual design of a smoke-ventilation system is very complex, and although much published guidance is available[43–46] it should be left to experts.

In discussing design or vetting tenders, there are a number of important points to consider:

1. *Design fire size* – An accurate assessment is needed of the maximum size of fire which is likely and which can be designed for. Since the whole design is based upon this value it is essential that this be carefully considered.
2. *Interaction with sprinklers* – The likely size of fire will be smaller in sprinklered buildings and the temperature of the smoke produced will be lower since the smoke is cooled by the sprinkler flow.
3. *Fire detection* – For efficient operation, control of the ventilation must be linked to a fire-detection system or sprinkler flow switch to ensure that the ventilators are operated as early as possible. Natural ventilators must incorporate a fusible link or bulk as a back-up fail-safe device, but this should not be considered as the main form of emergency operation.
4. *Fire resistance* – Fans, motors, cabling and controls which are expected to operate under fire conditions must be suitably rated for the temperature expected.
5. *Air inlet* – A suitable low-level inlet ventilation area must be provided for the expected air flow rate. Where personnel escape routes will be used for inlet, the inlet velocity must be low enough not to impede progress.

Smoke ventilation is not intended to replace other forms of fire prevention and control but to work as an important component in an overall scheme.

15.4.2.6 Legislation and codes of practice

Legislation Most legislation regarding ventilation has been aimed at controlling the environment within the workplace, and until very recently there was a plethora of assorted and outdated regulations in force. Most of these have now been repealed under COSHH.

Legislation regarding the state of the air exhausted into the external environment is limited, the Environmental Protection Act being the main Act in force. The major pieces of existing legislation are discussed briefly below:

1. *Health and Safety at Work etc. Act 1974 (HASAWA)* This does not directly relate to ventilation but places duties upon employers and employees regarding health and safety and is an enabling Act for further Regulations.
2. *Control of Substances Hazardous to Health Regulations 1988 (COSHH)* Enabled under HASAWA, these Regulations provide a requirement for adequate control of hazardous substances and therefore directly cover use of ventilation to keep the atmosphere clean within the workplace. Ventilation equipment installed to comply with COSHH must be regularly inspected and tested at no more than 14-month intervals, and monitoring may be required to ensure its continued effectiveness.
3. *Workplace (Health, Safety and Welfare) Regulations 1992* Regulations 6 and 7 require effective and suitable ventilation in enclosed workplaces and the temperature in all workplaces inside buildings during working hours to be reasonable.
4. *Highly Flammable Liquids and Liquefied Petroleum Gases Regulations 1972* These require mechanical ventilation to be provided, preferably by local extract from cabinets or enclosures, to avoid dangerous concentrations of vapours occurring in workrooms.
5. *Woodworking Machines Regulations 1974* These Regulations require local extract to be provided at designated machines to remove sawdust, chips, etc. and for all solid particles collected to be discharged into suitable receptacles.
6. *Environmental Protection Act 1990* This controls emission of pollutants from premises in two ways. HMIP control emissions of prescribed substances and from prescribed processes under the Integrated Pollution Control mechanism – the scope of this is steadily widening. Other emissions are controlled as statutory nuisances by local council environmental health departments.
7. *Control of Pollution Act 1974* This Act allows local authorities to require the occupier of any premises to provide estimates or other information as specified concerning emission of pollutants.

Note: These synopses are the author's interpretation only. Neither the author nor the publishers can take any responsibility for any result of any actions taken as a result of reference to this section.

Codes of Practice

1. *BS 5925: 1980: Design of buildings: ventilation principles and designing for natural ventilation* This British Standard gives recommendations on the principles which should be observed when designing natural ventilation of buildings for human occupation and provides a basis for choice between natural and powered systems.
2. *BS 5720: 1979: Code of Practice for mechanical ventilation and air conditioning in buildings* This deals with design, planning, installation, testing and maintenance of systems.
3. *BS 6540: Part 1: 1985: Methods of test for atmospheric dust spot efficiency and synthetic dust weight arrestance* This gives standard test methods for filters used in ventilation and air-conditioning systems.
4. *ISO 7730: Moderate thermal environments – determination of the PMV and PPD indices and specification of the conditions for thermal comfort* This gives a method of measuring and evaluating moderate thermal environments to which people are exposed.
5. *EH22 (Revised May 1988): Ventilation of the workplace* This Health and Safety Executive Guidance Note provides information on standards of general ventilation and fresh air requirements in the workplace.
6. *EH40/93: Occupational Exposure Limits 1993* This gives advice on limits to which exposure to airborne substances

hazardous to health should be controlled in workplaces. It is revised annually.

15.4.2.7 *After installation*

Commissioning and testing Once any system has been installed it is important that it is properly commissioned to ensure that everything is working satisfactorily and to specification. A guide to commissioning ducted systems is available from BSRIA. Commissioning of other systems should be in accordance with the manufacturers' recommendations.

Maintenance Most simple ventilation systems require only annual maintenance unless some form of air cleaning or filtration is incorporated, although where systems are pneumatically operated the compressor will need weekly checking. Air cleaners or filters will need regular emptying, cleaning or replacement to maintain efficiency and prevent clogging up. This can either be carried out on a regular schedule (based on the manufacturer's guidance and site experience) or when indicated by a pressure differential gauge or alarm. The cost of a gauge is easily repaid by savings in maintenance costs by maximizing intervals between cleaning or replacement. The task of maintenance can be made easier by taking care in design to provide good access.

Compressors will need a weekly oil level and receiver auto drain check and oil changes and filter cleaning at (typically) 500-hour intervals, although for compressors used only to operate ventilation this can be only an annual task due to the limited usage. Manufacturers' recommendations should be followed.

Running costs Running costs of ventilation systems can be broken down into three main areas:

1. *Maintenance costs* Regular service checks such as filter cleaning and compressor oil level are normally carried out in-house and time can be allocated for these tasks once some experience has ben gathered. Annual maintenance may be carried out in-house or by specialist service engineers employed either by manufacturers or HVAC service companies. A service contract can often include breakdown cover, which has the advantage of reducing risk of unexpected bills and ensuring that prompt repairs are effected at the cost of a higher annual premium.
2. *Electrical costs* The only significant electrical cost involved in ventilation systems is operation of fans. Other electrical equipment such as dampers, compressors, etc. generally run for such short periods that costs are negligible.

   Electrical costs for fans can be estimated from the following formula:

   $$C = V \times \phi \times A \times \text{fuel cost} \times \text{hours run} \qquad (15.43)$$

   where C = cost per annum (£),
   V = motor voltage per phase (V),
   ϕ = number of phases,
   A = operating current (A),
   Fuel cost = cost of electricity (in £/k Wh),
   Hours run = total running hours per annum.
3. *Heat loss* Where a ventilation system is required to run during periods when heating is provided then there is an energy cost associated with the heated air being exhausted from the building. This is related to the extra heat input needed from the heating system to balance the heat loss through the extra ventilation. A calculation method is available in section B18 of the CIBSE Guide.[31]

15.4.3 Air conditioning

15.4.3.1 *Basic principles and terms*

Abbreviations In addition to the abbreviations used in SI, the following are employed in air conditioning work:

db	Dry bulb temperature
wb	Wet bulb temperature
dp	Dewpoint temperature
rh	Relative humidity
kg/kg	Kilograms water vapour per kilogram dry air (absolute moisture content)
TH	Total heat
SH	Sensible heat
LH	Latent heat
SHR	Sensible heat ratio
ON OFF	The condition of air or water entering or leaving a coil or heat exchanger
TR	Tons of refrigeration capacity
TRE	Tons of refrigeration capacity extracted
TRR	Tons refrigeration rejected (at final cooler)
HP	High pressure (refrigerant)
LP	Low pressure (refrigerant)
DX	Direct expansion cooling
ΔT	Temperature difference
ach	Air changes (room volumes) per hour
ahu	Air-handling unit
swg	Static water gauge
NR	Noise rating. One of a series of curves relating noise level and frequency to speech inteference
NC	Noise criteria. Similar to NR, but differing, particularly at the low-frequency end

Terms

1. *Mechanical ventilation* The movement of air by fan, conveying outside air into the room or expelling air or both. Filtration, heating and control of the distribution pattern may be included. It is not cooling in the sense of temperature reduction but can be used to limit temperature rise when the outside air is below that of the space being treated.
2. *Full air conditioning* This necessitates plant capable of control of temperature by being able to add or subtract heat from the air and control of humidity by being able to add or subtract moisture. The system also comprises fan(s), filtration, a distribution system and may include noise control. Other terms such as 'cooling' or 'comfort cooling' may be met and these can be taken to mean an ability to lower the temperature of the air by refrigeration but without full control of humidity. Moisture may be removed as an incidental characteristic of the cooling coil. The term 'air conditioning' is sometimes used where control of humidity is not included. It is essential to employ clear specifications of performance.
3. *Air* Atmospheric air is a mixture of gases, mainly nitrogen and oxygen together with water vapour. It normally carries many millions of dust particles per cubic metre.
4. *Temperature* A measure of the average energy of the molecules of a substance. The heat intensity.
5. *Heat* A form of energy which, when given to a body, raises its temperature or changes its state from solid to liquid or liquid to gas.
6. *Heat flow* Heat flows from a body at one temperature to a body at a lower temperature. Materials have the property of resistance to the rate of heat flow. It differs from material to material.

7. *Sensible heat* The heat energy causing a change in temperature, as in raising a kettle of water from cold to boiling point.
8. *Latent heat* The heat necessary to change the state of a substance from solid to liquid or from liquid to gas, or the heat given up during the reverse process. There is no change in temperature during these processes. For example, continuing to boil a kettle of water previously raised to 100°C to steam requires the addition of latent heat, but there is no change in temperature if the pressure remains constant.
9. *Total heat* The sensible heat plus latent heat in such a mixture as moist air. In air-conditioning work it is referred to a base a little below 0°C, not absolute zero.
10. *Sensible heat ratio* Sensible heat flow divided by the total heat flow.
11. *Enthalpy* The heat content of a substance per unit mass.
12. *Dry bulb temperature* The temperature of air as indicated by a dry sensing element such as a mercury-in-glass thermometer.
13. *Psychrometrics* The study of moist air. The psychrometric chart shows the relationship between the various properties of moist air in graphical form and can be used for the solution of problems.
14. *Wet bulb temperature* The temperature of air as indicated by a thermometer when its bulb is enclosed by a water-wet wick. If the surrounding air is not saturated water will evaporate, taking the necessary latent heat from the thermometer bulb which then gives a lower reading than a dry bulb in the same air. The depression in wet bulb temperature is proportional to the amount of moisture in the air. Normal practice is to arrange a flow of air over the wick by using a sling (whirling) or fan-assisted instrument. If the thermometer is stationary an area of higher saturation builds up around the wick but the reading may be referred to tables for screen instead of sling readings.
15. *Partial pressure* The contribution by each constituent gas to the total air pressure. Standard air pressure is 1013 mbar.
16. *Vapour* A gas which is below its critical temperature and which can therefore be turned to liquid by an increase in pressure.
17. *Saturation* There is a limit to the amount of water vapour air can hold. It is higher at higher dry bulb temperatures. At the limit, air is said to be saturated.
18. *Relative humidity* This compares the amount of moisture in a sample of air with the amount it would contain if saturated. More accurately, relative humidty is the partial pressure of vapour present divided by saturation vapour pressure × 100%. Saturation = 100% relative humidity.
19. *Dewpoint* The temperature to which a sample of air has to be reduced to bring it to saturation. It is fixed by the moisture content of the air sample.
20. *Absolute humidity* This measures the quantity of water in a sample of air in kg moisture per kg air. The relative humidity then depends on the air dry bulb temperature. Air at 25°C containing 0.01 kg/kg is at 50% relative humidity (rh). If now cooled to 14°C the air would be at its dewpoint (i.e. saturated). If cooled further, moisture is condensed out, the sample remaining saturated as it cools. If now reheated back to 25°C its rh would be lower than 50%. If cooling had not been continued to condense moisture its rh would return to 50% at 25°C.
21. *System resistance* The resistance to air flow which causes a static pressure drop. It is similar to electrical resistance and voltage drop (see Section 15.4.3.4). The term 'resistance' is often used erroneously when pressure drop is meant.
22. *Upstream, downstream* Used to denote positions earlier or later in the system relative to the direction of air flow.
23. *Condensing unit* A refrigeration compressor and condenser on one chassis complete with controls.
24. *Split system* As above but with a remote condenser.
25. *Chiller* A compressor, water-chilling evaporator and condenser on one chassis.

The plant These divide broadly into two types:

1. The direct expansion plant where the air-cooling coil is fed with cold refrigerant;
2. The chilled water plant where the cold refrigerant first chills water (or other liquid) which is fed to the air-cooling coil.

A block diagram of the DX system is shown in Figure 15.139. It has two main circuits – the air circuit and the refrigerant circuit. In the chilled-water system there are additional circuits:

1. Of chilled water between the refrigerant and the air-cooling coil;
2. Of water carrying heat from the refrigerant to the heat-rejecting device.

Figure 15.140 shows a block diagram of the system.

A temperature difference must exist betwen each stage to cause a heat flow from one to the other. The air and refrigeration side are described in further detail below.

The air-handling plant The plant may comprise one or more complete factory-made units or may be built up on-site from sub-assemblies. There can be variations from the arrangements discussed below and shown in Figure 15.141. The condition or quantity of air input to the conditioned space (referred to below as the room) must be varied such that after it has gained or lost heat or moisture by the applied load its condition and therefore the room condition is as specified.

1. *Outside air intake* The quantity is discussed in Section 15.4.3.2. Its purpose is to keep the room fresh and to pressurize it against the ingress of unconditioned air. Its psychrometric condition during most of the year will differ from that required. It can be introduced into a chamber, mixing it for treatment with return air from the room. Alternatively, it can be treated in a separate plant before being introduced to the system, but care then has to be exercised in design, since the sometimes small quantity of air has to control the full humidity load. An advantage is that corrosive wet processes are kept out of the main plant.
2. *Mixing chamber* This is where the outside air intake and recirculated air are brought together before proceeding to the next stage of treatment. As shown in Figure 15.141, it is a low-pressure area which will induce outside air without the use of another fan if the route has low resistance.

When two samples of air are brought together the condition of the mixture may be arrived at arithmetically by adding the heat flow of each and dividing by the total

mass flow; and similarly for the moisture flow. Alternatively, plot the condition of each onto a psychrometric chart. The mixed condition lies on a straight line between the two in a position proportional to the two quantities.

3. *Pre-filter* Where a high degree of cleanliness is not required it could be the only filter in the system. The subject is covered in more detail in Section 15.4.3.6.
4. *The cooling coil* This is the exchanger where heat flows from the room return or mixed air to cold refrigerant or to chilled water. It is an arrangement of finned tubes normally of aluminium fins on copper tubes, but copper fins can be specified for corrosive atmosphere. Performance characteristics are controlled by fin and tube spacing. If the room rh is high, dehumidification may be brought into use by operating the coil or one of a number of parallel coils at a low temperature. If the room's sensible heat load is low reheat must be allowed to operate at the same time. Dehumidification can be achieved by partially bypassing the coil such that the remaining air travels through the coil at low velocity. This can also be inherent in the full-load design operation of the coil.
5. *Heater battery* This is used when (1) the room needs heating instead of cooling or (2) for reheat as described above. It is vital in close control systems that its capacity is sufficient to maintain room temperature under these conditions, otherwise the system may fall into a loop, with the controls continuing to see high rh due to low temperature. Using only part of the cooling coil for dehumidification will alleviate this situation. A heater capacity of the sensible heat extracted during dehumidification plus half the peak winter fabric loss is recommended where the room load could be nil in winter such as a start-up situation. Separate reheat batteries may be placed in branch ducts where one plant supplies both a main area calling for cooling and an auxiliary room without heat load. Correct rh in the auxiliary rooms results (only) if it is correctly controlled in the main room and they require the same dry bulb temperature. While wasteful of energy, it simplifies the plant design and may be found to use less resources.
6. *The fan* This drives the air around the system against its resistance (see Section 15.4.3.5).
7. *Humidifier* The humidifier is a means of increasing the absolute humidity of the air although usually controlled from a relative humidity sensor. It should be positioned where shown so that it can correct any over-dehumidification by the cooling coil (see Section 15.4.3.7).
8. *Air flow* The quantity supplied must be matched to the load on the plant (see Section 15.4.3.2). After leaving the plant it is distributed to match loads of the rooms or zones to be served.

The refrigeration plant The basic circuit is shown in Figure 15.142 and the principal items are described below:

1. *Evaporator* This is the device where the air or water being cooled gives up its heat to provide the latent heat of evaporation to the refrigerant. Superheat is also added to the refrigerant at this point to prevent damaging liquid forming on the way to the compressor.
2. *Compressor* A compressor circulates the refrigerant around the system, raising its pressure such that the refrigerant can be condensed by removal of latent heat. It may also be considered as raising the temperature of the refrigerant above that of the final cooling medium to which heat is rejected. Lubricating oil is contained in the crankcase but, being miscible in the refrigerant, is carried around the system and returned.
3. *Condenser* This is the vessel where the refrigerant rejects its heat to waste or reclaim, turning back to liquid in the process. Sub-cooling is practised by the removal of further heat. This prevents liquid flashing back to vapour on return to the evaporator.
4. *Expansion valve* A reduction in pressure and hence in temperature takes place across this item before the refrigerant re-enters the cooling coil via distributor pipes.

Controls

1. *Room condition*
   (a) *Dry bulb temperature* This is sensed by a thermostat in the conditioned space or in the return duct. Where underfloor air return is practised it is strongly recommended that the sensor be placed close under a return grille to prevent changes of condition occurring

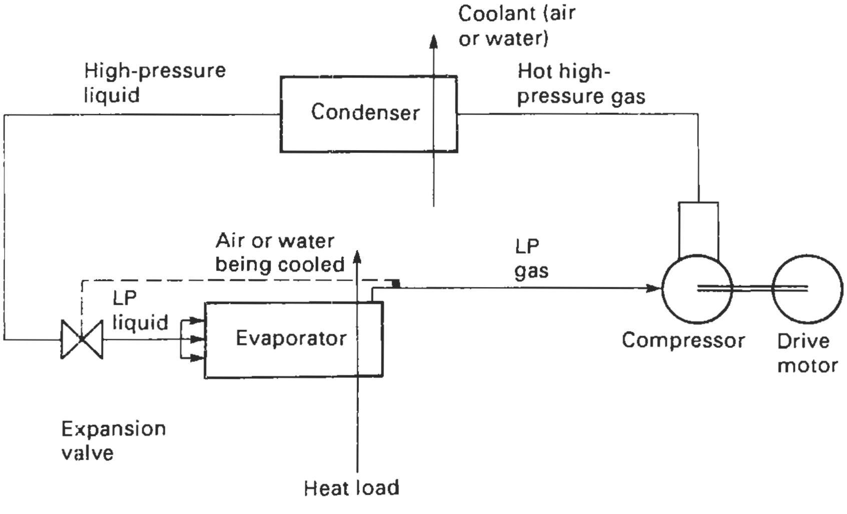

Figure 15.142 Refrigerant flow path in a cooling system

between the room and the sensing position. In large rooms separate thermostats can be arranged to give an average signal but individual zones of control each separately treated are much better. Dry bulb sensors may be bi-metal strips, thermistors or refrigerant-filled phials or bellows responding to pressure differences caused by temperature change. These, in turn, provide an electrical or mechanical signal. The mechanical items are used to alter the value of potentiometers or make-or-break contacts. The signals are transmitted to amplifiers which respond to the degree of error. An important feature is the proportional band of temperature over which the controls call for up to full plant capacity.

   (b) *Humidity* Humidity sensors may be animal or plastic skins varying in length with changes in rh or lithium chloride coating changing in electrical resistance. The former are prone to lose calibration. Other comments above apply equally to rh control.
   (c) *Control at the evaporator* A phial senses the temperature of the outlet sunction line to the compressor and controls the expansion valve opening to maintain a constant temperature in the coil.

2. *Control at chilled water coil* A three-way motorized valve is modulated between full flow to the coil and full bypass to satisfy the room thermostat.
3. *Control of water-chilling compressors* Being large multi-cylinder machines, the chilling capacity is controlled in steps by rendering cylinder valves inoperative. Control is initiated by sensing water temperature in a storage buffer tank or by sensing return water temperature from the air-cooling coil. Small (DX) compressors are run on a start–stop basis on call from the room thermostat. Safety devices associated with compressors include:

   High (gas) pressure cut-out;
   Low (gas) pressure cut-out;
   Oil differential cut-out (oil feed pressure to be above the crankcase pressure);
   Freeze thermostat (low water temperature limit);
   Single-phase protection (preventing attempts to start with loss of one phase of a three-phase electrical supply);
   Time out (preventing too-frequent starting and motor burn).

   Until all the switches in the interlock train are satisfied and closed the compressor will not start or will not continue to run.

The load on the plant The unit of heat is the watt. However, the imperial unit should be understood as it will still be met, particularly outside Europe. The ton of refrigeration is derived from an ability to remove sufficient heat from a short ton (2000 lb) of water at 32°F to turn it to ice at the same temperature in the course of 24 h. This amounts to a heat extraction rate of 3.517 kW.

The load presented by the room is first transmitted to the room air which, in turn, passes it to the cooling coil. Other gains will occur as detailed below. The total load is best considered in two parts – sensible and latent.

Machine heat All electrical energy fed to the room will appear as heat. This presents a load to the plant unless power is conveyed out of the room by cable or hot items are physically removed. Parts of some large computers are cooled by a direct supply of chilled water presenting a load on the refrigeration plant but reducing the load on the air side. Cold outside conditions will result in some of the internal load being met by fabric loss.

Fabric losses or gains In winter in cold climates heat will be lost through fabric of the building. This will be advantageous at times of high internal load but will need to be considered as a heater battery duty at times of low internal load. In winter there can be considerable loads for humidifiers if the structure is not adequately vapour sealed. Weather-tightness is insufficient. For example, a computer room in the UK held at normal conditions may experience up to 100 mm water gauge vapour pressure difference, forcing moisture out. During high summer in temperate and hot climates the external water vapour pressure will be higher than in the conditioned space.

Personnel People give off both sensible and latent heat. During light work such as in a computer suite or laboratory they emit 110 W sensible 30 W latent and while seated, 90 W sensible 20 W latent.

Air ducts A duct carrying cool air through a warm space such as a loft will gain heat before entering the conditioned room, contributing to the load on the plant. Ducts passing through the conditioned space do not add to the load. Similarly, there will be losses in winter if they carry warm air through cold spaces and moisture gains and losses if leaky. Insulation and vapour-tight joints are necessary.

Fan heat The power fed to the fan shaft (or the total electrical power fed to the motor if within the duct) appears as sensible heat in the system. During a heating cycle this is useful. As a rule of thumb, fan shaft power is 17 × flow m^3 × mm swg watts. This commonly lies between 2% of the cooling duty for small systems to 10% for large systems.

Compressor heat Friction (or, if within the refrigerant path, as in hermetically sealed or semi-hermetic machines, the whole of the input to the motor) increases the amount of heat to be rejected by the final cooler or available for heat recovery. It is uneconomic to operate refrigeration plant at unnecessarily high temperatures in order to assist heat recovery.

Pump heat In chilled-water systems pump shaft power adds to the heat of the circulating water. Similarly, if the chiller has a water-cooled condenser pump heat is added to that handled by the final cooler. Power is proportional to the flow and pressure:

$$\frac{102 \times \text{l/s} \times \text{metres head}}{\text{Efficiency}} \text{ watts}$$

Efficiency can vary between 35% for very small pumps and 80% for large ones, and may be found to lie between 3% for small heating circuits and 10% of the heat conveyed for large systems.

15.4.3.2 The air quantity required

Air change rate Change rates (room volumes per hour) can be used to calculate the quantity to be supplied or extracted by a mechanical ventilation system. These figures also apply to parts of an air-conditioning system where stale air must not be recirculated. This is discussed in Section 15.4.2.

Volume to be supplied For the design of close control systems or where large amounts of heat are to be removed the mass flow to be employed must be calculated. Use is made of the specific heat of air which for normal room conditions may be taken as 1.02 kJ/kg°C. 1.02 kW raises a flow of 1 kg/s by 1°C and pro rata. The volume of a given mass of air varies with change in temperature but supply volume is often more convenient to consider. Taking the specific volume to be 0.82 m^3/kg then 0.1 m^3/s will convey 1 kW with a temperature rise of 8°C and pro rata. A subsequent fall of 8°C across the cooling coil is suitable for areas controlled to 21°C 50% rh. A smaller air quantity would be too close to the limiting temperature to hold the necessary moisture when leaving the coil. Greater temperature differences may be used if the rh is to be controlled to a lower level or not controlled at all. A maximum temperature difference of 10°C supply to room is recommended where occupants are close to supply points. For comfort, larger volumes are preferable to low temperature.

In ventilation systems the temperature rise calculated on the basis of specific heat alone will be pessimistic by one or two degrees because of the effect of building mass. Unless an extract is specifically designed to remove heat from hot spots or lights, the extract and room temperature can be taken to be the same.

Outside air intake When temperature limitation is more important than close control of conditions, a considerable economy of refrigeration plant operation results from arranging to draw in outside air when it is sufficiently cool and rejecting this back to outside after having gained heat from the room. However, where close control of temperature and humidity is required accuracy and economy ensue from minimizing the outside air intake. The quantity may be based on the number of occupants using 0.008 m^3/s minimum per person. Alternatively, if larger, use 0.002 $m^3/s/m^2$ floor area, which is sufficient in a good quality building to keep the room pressurized to one or two mm swg. Because air loss is a function of the building surface, this is preferred to the basis of a proportion of the supply air volume, which is a function of load. If the latter is used for applications such as computer rooms it is seldom necessary to use more than 2.5%.

General considerations Outlets should not be provided in constantly recirculating systems, particularly where close control of humidity is required. The overpressure developed is far less than that exerted by the wind, and for this reason any system which does have both intake and discharge ducts should have them on the same face of the building. While care is necessary to prevent short-circuiting, this alleviates problems arising from the considerable wind pressure difference that can develop on opposite sides of a building.

Air-lock entries should be used where close control of conditions is required and for clean rooms, but conventional doors with close fit and self-closures are sufficient.

Fire authorities may stipulate pressurization of certain areas such as stairways and may require smoke-extract systems to be brought into operation automatically in the event of a fire. They should be consulted at an early stage of the design.

15.4.3.3 Heat losses and gains

Heat losses Heat transfer through a partition is a function of resistance to heat flow, the temperature difference driving the heat through and the surface area. The function of heating systems is to provide the heat lost in maintaining the temperature difference. Thus

Heat flow (watts) is $U \times$ TD × area

where U is a coefficient for the partition in watts per m^2°C. For each room served the loss through each wall, ceiling and floor should be calculated and for each part of those surfaces where differences occur, such as windows in walls or cantilevered structures of upper floors.

The U values of many partitions or composite constructions can be found in standard references but others may have to be calculated where no data are available or changes are contemplated. The resistivity (r) of each element of the partition encountered by the heat in passing through must be found and multiplied by the thickness in metres. Manufacturers are usually able to give resistivities. The sum (R total) of all the elements, including the inner and outer surface resistances and the resistance of any interleaf air gap, is found. The U value is the reciprocal of R total. For example, for a wall:

Outer surface (normal exposure)	0.055
112 mm brick skin 0.12 × 0.112	0.01344
50 mm uninsulated air gap	0.180
150 mm lightweight block skin 5.88 × 0.15	0.882
15 mm rendering 2.5 × 0.015	0.0375
Inner surface	0.123
R total =	1.29094
$U = 1/R$ =	0.775

If this is insufficient for the purpose (e.g. the external wall of a dwelling house) the problem could be reworked using insulation in the interleaf gap.

The temperature at any intermediate point is proportional to the R total to that point. This may be used to decide whether that point is above or below the dewpoint of penetrating air.

In maritime climates such as the UK the lowest external temperatures are not sustained for long periods. The mass of the structure has a slugging effect, and it is safe to use a relatively high external design temperature (e.g. −1°C in the south of the UK and −4°C in the north). These figures do not apply to an outside air intake where the full effect of low temperature is felt immediately nor to lightweight structures. When choosing a design temperature difference, one must take into account that adjacent rooms may not always be heated to their design temperature. Heat bridges, which are weak points in the insulation, must also be considered in proportion to their areas.

Cold outside air introduced to the system by infiltration or by design of the plant will require heat to be added by the plant or directly in the room to maintain the room temperature. The heat required is

kg/s × 1.02 × °C TD kW

For infiltration it is convenient to use m^3/h × 0.33 × °C TD watts, but where air conditioning is employed infiltration should not be allowed. Air lost from the space by pressurization carries heat away but this is not an additional load beyond that mentioned above.

The available heating capacity should exceed the calculated figure, this being sufficient only to balance the losses under steady conditions. A 25–50% excess capacity is recommended to provide warm-up from cold and good response to controls but without excess overshoot. It is important in close control air-conditioning design to have sufficient heating capacity to raise the room temperature from cold following plant stoppage. If the room is cold the controls will see high rh and call for dehumidification upon restarting. Unless this is countered by sufficient reheat the control of conditions will not recover automatically.

Internal gains Any heat liberated within the room reduces the heating effort required by the plant. At any time these gains exceed the loss more than marginally, cooling is required. Heat sources are:

1. The total electrical input to the room unless power is carried away by cable or heat by pipe. This includes lighting and it should be remembered that the input to fluorescent fittings is greater than the tube ratings. Some luminaires are designed as air-extract fittings, in which case their heat is a load on cooling plant, but does not contribute to room heating unless the plant is in a non-cooling recycling mode;
2. Heat from other processes unless carried away by pipe or items are taken out of the room;
3. Heat from personnel (see above);
4. There should be no space heating within air-conditioned rooms but some gains may arise from hot water pipes passing through to other areas;
5. Gains from adjacent spaces held at a higher temperature;
6. Heat gains into ducts where these pass through warm areas *en route*;
7. The shaft power of fans will appear in the system as heat. Where the drive motor is in the airstream the whole of the motor input will appear as heat.

Heat gains The calculation of heat gains through the building fabric is more complicated than for heat losses, taking into account the gains from both the air-temperature difference and from solar intensity. The gain varies during the day with the movement of the sun and changes in air temperature. Heavily glazed buildings are susceptible to large gains from low sun elevations at all times of year and here building orientation can have a considerable effect on plant loads.

A structure with a large mass will result in the peak gain appearing on the inside some hours after the external peak, and the gain will be attenuated since the outside condition will be reduced before that time. The time of peak gain will differ for each of the enclosing surfaces, so it is necessary to calculate each for several hours to find the peak for one room and to repeat this for each room to find the peak load on a plant serving several rooms. Computer packages of varying merit are available to undertake this laborious task.

To avoid temperature shock and for economy, the control of comfort air conditioning may be allowed to drift with extremes of external temperature. However, where the design is to maintain specified internal conditions under virtually all external conditions data may need to be adjusted upwards.

Heat of outside air intake In close control air conditioning the condition of the outside air is rarely as required for passing forward to the controlled space. Therefore it contributes to the cooling, heating, humidification or dehumidification loads on the plant. Whether computer rooms, laboratories, etc. with their sparse population are considered or auditoria where there is a larger ventilation requirement, the peak latent heat load caused by treating the outside air is greater than that from the personnel. The heat from personnel is given above.

The calculation of the heat of intake air is in two parts:

Mass flow kg/s × change in latent heat kJ/kg (from tables or psychrometric chart) (kW); plus
Mass flow kg/s × change in sensible heat kJ/kg (kW).

15.4.3.4 Air distribution and system resistance

Duct sizing Ducts convey conditioning air from point to point at a variety of speeds. Slow speeds result in large ducts, costly in themselves and in building space. High speeds result in noise and the need for high fan powers. A good basis for air conditioning is 6–7 m/s adjacent to the plant but, as discussed below, less at distant points.

When we refer here to static pressure we mean the difference between internal and external pressure causing air to tend to flow into or out of ducts. Velocity pressure is that due to the air's forward movement. The sum of the two is total pressure.

Duct design Simple runs of a few metres may be designed for a constant velocity. A supply duct is thus reduced in steps at each outlet or a return or exhaust duct similarly increased in section in the direction of flow.

A large system with branches, several inlets or outlets and some tens of metres long will be more easily controlled at the end distant from the plant if velocities are reduced as we progress down the length of the duct. If air is slowed in a controlled way with the duct sides diverging at not more than 15° included angle its velocity pressure will reduce and (ideally, without loss) its static pressure will rise to maintain a constant total head to compensate for pressure loss as the air progresses down the duct. However, at least by manual methods, design for static regain is laborious and the duct shape unconventional. It is seldom practised.

A method commonly used is that of equal surface friction per unit run. If rectangular ducts are being considered their equivalent circular diameter must be found. This may be obtained by

$$1.3 \times [(w \times d)^{.625}]/[(w + d^{.25})]$$

Here w and d are width and depth and the units may be metres or millimetres. Alternatively, the diameter may be found from published charts.

Where practicable, the large surface area of wide shallow ducts should be avoided to keep pressure gradients to a minimum. There can be no hard-and-fast rule, 4:1 being a suggested limit. The system may, of course, be designed to use only round-section ducts.

System pressure drop The point of interest is the path of highest pressure drop or index leg. Other parallel branches can be designed of appropriate size to pass the required amount of air, those of lower resistance than the index leg being throttled by dampers. The pressure drop is the sum of the drops caused by the following and is calculated to determine the pressure against which the fan must operate:

Surface friction of duct as discussed above (Pa/m × length);
Changes in section;
Bends;
Branches;
Obstructions;
Grilles, meshes, etc.

Plant resistance

In the design of tailor-made plant is is necessary to calculate the above as they occur within the plant and add the pressure drop of all other items such as air filters at their dirty conditions, coils, etc. In the case of proprietary units it is normal for the manufacturers to quote an external pressure against which they will deliver the specified air quantity.

Duct resistance

The basis of good duct design is to arrange gradual changes to section and direction. It is sometimes necessary to construct a 90° elbow with no inside radius. The pressure drop and noise generation can be greatly reduced by incorporating turn vanes which split the air into a number of near-parallel paths.

Ventilated ceilings A ventilated ceiling is an alternative to ducts, diffusers and grilles as a means of distributing air within a room. It is suspended below the structural ceiling forming a shallow void. One type consists of perforated metal trays or tiles. Each is supplied with a bagged acoustic pad which is removed from those trays or tiles which are to ventilate. Another consists of tiles with single-row slot openings at intervals between runs of tiles, the openings being controlled by dampers integral with the slots. Any type of tile which can shed dust or is combustible should be avoided. Rising hot air and descending cold air mix a few hundred millimetres below the ceiling, giving a near-uniform condition in the occupied levels. The availability of very small areas of control can be advantageous where electronic apparatus with mild chimney effect would have its natural cooling upset by strong downdraughts, by confining air supply to gangways.

The method is useful where large quantities of air are to be introduced without draughts; where the distribution of heat load is unknown at the time of design or is likely to alter; and where, as a measure of reliability, it is required to redistribute the remaining air in the original proportions in the event of partial failure of the plant.

15.4.3.5 Fans

Fan selection Fans propel the air through the system, and must be chosen to be capable of delivering the required volume flow against the calculated system static pressure, advisedly with a small margin.

Individual fans are capable of operating over a range of volumes and pressures which are interrelated, the performance being shown in manufacturers' tables and curves. Venturing outside the recommended area of operation may, depending on the type of fan, result in motor overload, motor undercooling, vibration or stall. Selection should be made for minimum power input, which is also likely to be the quietest fan for the duty. Performance is usually quoted for a standard condition of 1.2 m^3/kg. Calculations of system resistance are best carried out at the same condition. The user may find only the static pressure quoted. If total or velocity pressure are also quoted or the outlet velocity can be calculated the designer can calculate how much pressure can be recovered after the exit. Any mismatch due to difficulty in calculating system resistance will cause the volume to rise or fall, to settle on the fan characteristic curve.

Types The broad range of types used in air conditioning is:

1. Centrifugal
2. Axial
3. Propeller
4. Mixed Flow

These are discussed in Section 15.4.2.3.

Multiple arrangements Fans may be operated in parallel but are best of similar characteristic to avoid stalling. In the event of failure of one the effect of reduced pressure drop in the system is to give a flow of about two thirds that of two. Non-return dampers should be fitted.

Fans may also be operated in series. Axial-flow fans are available having two (contra-rotating) impellers and motors in the one casing. Further staging may be arranged. If one stage fails or is switched off it will idle round with loss, but since similar losses in centrifugal fans are much higher, these are not usually operated in series. However, supply and extract fans in a recirculating system effectively in series, may differ.

Fan laws See Section 15.4.2.2.

Volume regulation This falls under two headings:

1. Where a permanent change is found to be needed during commissioning or change of duty. The volume may be changed:
   (a) By variation of system resistance by damper action. Care is needed to prevent axial fan motors overheating or reaching the stall point;
   (b) By changing the speed of the drive. In centrifugal fans the common practice is to change or adjust belt drive pulleys, taking care not to exceed the power capability of the motor. In axial fans the pitch of the blades may be adjustable by swivel mountings on the hub.
2. Where frequent change is required in the normal operation of the plant:
   (a) By switching motors in multi-stage fans;
   (b) By speed control of motors electrically (e.g. by pole changing), varying the circuit resistance of wound rotor motors, or thyristor part-cycle disconnection;
   (c) By damper modulation;
   (d) By bypass (fan recirculation) dampers;
   (e) By axial fans with pitch variable while running.

Mounting It is common practice to support the fan on anti-vibration mountings and connect the fan casing to the duct by short lengths of flexible non-combustible material. Care should be taken during installation to see that these are aligned to prevent entry turbulence and noise generation.

15.4.3.6 Dust control and filtration

Dust control Dust is continually being introduced to the conditioned space by clothing fibres, skin particles, shoe dirt, room processes and the outside air make-up. Dust particle sizes range from 1 μm to 75 μm, smaller particles being described as smoke. In an apparently clean office there may be as many as 30 million particles per cubic metre.

Control is by filtration in the plant but smoke can be removed by local recirculation through fan filter units.

For Clean Rooms (rooms of a very high standard) dust count per unit volume will be specified, but other specifications for room cleanliness are usually in terms of filtration performance against a standard test dust. Other important features are resistance to air flow and dust-holding capacity, leading to the fan energy required and filter life.

By number count the great majority of particles in the outside air are likely to be less than 1 μm. By weight these small particles will account for a very small proportion of the sample. A filter with a high efficiency measured by weight of particles trapped may be almost transparent to the small ones. Very high counts can be found in rural areas from pollen or agricultural activities.

Where a high cleaning efficiency is required it is sound practice to install a filter of lower performance upstream to trap the larger particles and prolong the life of the more expensive High Efficiency Particulate (HEPA) Air Filter. Two filters of equal merit placed in series will not be materially more efficient than one.

The action of most filters is mechanical. These are normally scrapped when fully loaded but may, for lower efficiencies, be washable. Another type uses electrostatic charges.

Filter life Filter life varies with make and type, and may be limited by the ability of the fan to operate against pressure drop. It is a function of the dirtiness of the air and the amount of material packed into the filter bank. Life may be quoted in terms of dust held in g/m^2 face area. For fan selection a knowledge of pressure drop is required. Typically, a panel filter might be quoted as operating from, say, 75 Pa initially at 2.5 m/s face velocity to 250 Pa when loaded and a HEPA might operate up to 700 Pa. The pressure drop across a bank of filters is kept within bounds by changing a proportion in rotation.

15.4.3.7 Humidification

The ability to add moisture to the air to raise humidity is an essential part of close control air conditioning. The need may be brought about by a change in the condition of the outside air, fabric losses or a change in the gains within the room or in plant operation.

Humidifier capacity The humidifier is sized to meet the load of the outside air intake quantity. It is necessary to know the rh to be achieved, outside air intake rate (kg/s) and its lowest winter moisture content (kg/kg). This can be taken as 0.0027 kg/kg in the south UK and 0.002 for the north, corresponding to −4° and −7°C saturated, respectively. Since the capacity will be reduced by blowdown time, allowance is necessary for control, and there will be leaks from the plant and building fabric, an addition of about 30% above the calculated value is recommended.

Types of humidifier These may be Direct (i.e. installed within the conditioned room) or Indirect (i.e. installed in the conditioning plant). Water may be introduced (a) as a spray or mist or (b) as steam generated separately or by a device within the plant.

In most air-conditioning work the humidifier will be indirect. The psychrometric operation of various types is described below.

Pan humidifier The steam is generated in a pan of water by electric elements. High-temperature hot water or steam coils could also be used. About 30% of the input appears as waste sensible heat, giving a sensible heat ratio of 0.3.

Where the pan is in the airstream the condition downstream of the pan has an increased moisture content (kg/kg) found from the air flow and moisture input. On a psychrometric chart this will lie on a line of sensible-to-total heat ratio of 0.3. Thus the psychrometric plot shows a steep rise in moisture content with a small rise in dry bulb temperature. The latter is a disadvantage when cooling is required. Regular blowdown is needed, preferably controlled by a timer, to prevent furring when mains water is used, and open pans should not be utilized where the conditioned space is to be dust controlled. A small water volume is an aid to quick response.

Steam jet Where it is available the source can be a separate boiler plant, but common practice is to employ purpose-made electrode boilers within or adjacent to the plant. The latter reduces sensible gains to the plant but, being essentially saturated steam, condensate return pipes are required. In addition to the rise in moisture content of the air (kg/kg) being dependent on air-flow and steam-injection rates, there is a very small increase in dry bulb temperature by the cooling of the vapour to the air temperature. The rise in total heat is: total heat of steam (kJ/kg) × quantity supplied per kg air.

Proprietary units are supplied with automatic blowdown cycles and can be matched to the broad water analysis. Cylinders have a limited life.

Spray humidifiers Water is injected into the airstream in a fine mist by pumped jets or spinning disk. For practical purposes, the psychrometric plot follows a wet bulb line. The air provides the latent heat of evaporation, resulting in a fall in dry bulb temperature. If water were to be supplied at up to 100°C the humidified condition would be at a correspondingly higher total heat of 420 kJ per kg water supplied.

Where dust control is important the system should only be used with a supply of demineralized water to avoid solids being passed into the conditioned space. The temperature of the air must be sufficient to hold the quantity of moisture being supplied, any excess being deposited in the duct. Unless drained away, this can give rise to corrosion and to incorrect control by re-evaporation when the humidifier is switched off under control.

Air washers Banks of sprays discharge water into the airstream with the object of achieving saturation of the whole air flow. Excess water falls into the base tank of the washer from which it is pumped back to the sprays. Downstream eliminator plates entrap any remaining free moisture, acting best within a specified velocity range. Cleanliness is essential to avoid bacterial growth. A constant bleed and make-up is normally arranged to control the accumulation of waterborne solids, but this, in turn, dilutes bacteriocides and inhibitors. The washer does not fully wash the air in the normal sense but does have the cleaning efficiency of a low-grade filter.

If the temperature of the water is not controlled it will come to the wet bulb temperature of the air passing through. Ignoring pump heat, the process is adiabatic. The psychrometric plot follows a wet bulb line.

If heat is added to the water the condition for 100% saturation takes the new wet bulb temperature of the incoming air.

If the water is chilled, cooling of the supply air takes place together with control of dewpoint and hence humidity of the room treated. Saturation efficiency is given by:

$$\frac{\text{Entering air db} - \text{leaving air db}}{\text{Entering air db} - \text{entering air wb}} \times 100\%$$

Due to bypass, a single bank of sprays might achieve 60% saturation and a capillary washer (one where the air passes through a wetted mat) might achieve 95%.

Humidifier run time Humidification is an expensive process and it is useful to be able to assess energy costs when considering its inclusion in a plant. It is possible from meteorological records for any particular area to find the time in hours per year and extent to which the external moisture content is, on average, at or below a required absolute value. As an example, in the southern UK humidification would be required in varying degrees for 6700 h per year if 21°C 50% rh was to be maintained. If the characteristic of cooling coils is to dehumidify when only sensible cooling is required then the humidifier load will be greater.

15.5 Refrigeration

Two basic types of refrigerator are considered here: the 'vapour compression refrigerator' and the 'gas refrigerator'. The former consists of a compressor followed by a condenser where the refrigerant is liquefied at high pressure. It is then expanded in a 'throttle valve' to a lower pressure and temperature and finally evaporated in an 'evaporator' before re-entry into the compressor. The cycle is similar to the Rankine cycle in reverse.

The gas cycle is the reverse of a closed gas-turbine cycle, i.e. the constant pressure or Joule cycle.

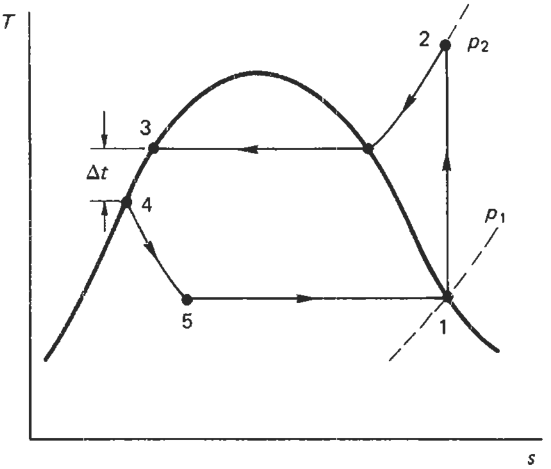

Figure 15.143 Vapour compression cycle

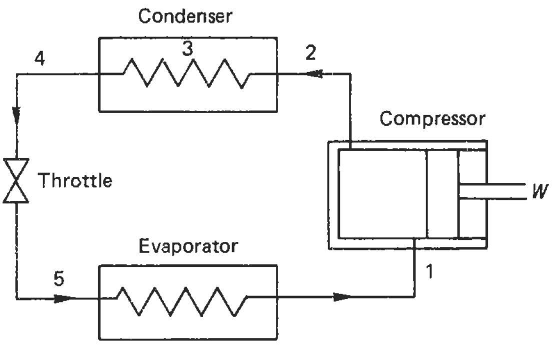

Figure 15.144 Vapour compression refrigerator

15.5.1 Vapour compression cycle

The process can be shown on the temperature entropy (T–s) chart (see Figures 15.143 and 15.144) for the appropriate refrigerant, e.g. ammonia, Freon 12, etc.

1. *Compression* Work in $W = h_2 - h_1$
   where $h_1 = h_g$ at p_1, h_2 = enthalpy at p_2
   $s_2 = s_1$ (since isentropic compression)
2. *Condensation at constant pressure* p_2
3. *Under-cooling* from T_3 (= T_s at p_2) to T_4
   degree of undercooling $\Delta T = T_3 - T_4$
4. *Throttling* from 4 to 5
   therefore $h_5 = h_4$ and $h_4 = h_f$ at T_4
5. *Evaporation* at pressure p_1
   Refrigeration effect $RE = h_1 - h_5$
   Work in $W = h_2 - h_1$
   Coefficient of performance COP = RE/W
   Heat removed $Q = \dot{m}\ RE$, where m = mass flow rate of refrigerant.

15.5.2 Pressure–enthalpy chart

The pressure–enthalpy chart (Figure 15.145) is a more convenient way of showing refrigeration cycles. Work in and refrigeration effect can be measured off directly as the length of a line.

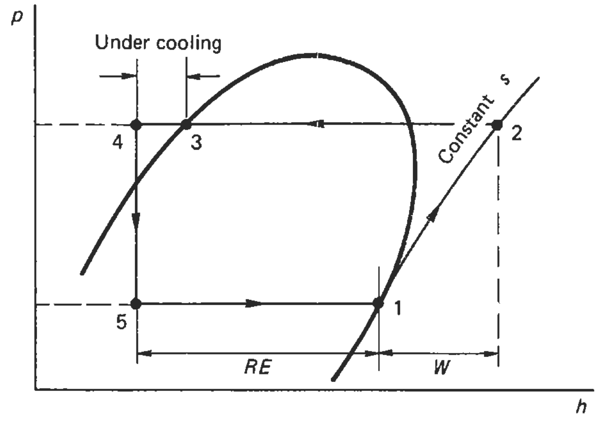

Figure 15.145 Pressure–entropy diagram for a refrigerator

If p_1, p_2 and the undercooling temperature T_4 are known, the diagram can be easily drawn and RE and W scaled off as shown.

15.5.3 Gas refrigeration cycle

Referring to the T–s diagram (Figures 15.146 and 15.147):

Refrigeration effect $RE = c_p(T_1 - T_3) + c_p\eta_t(T_3 - T_4)$

Work in $W = c_p\dfrac{(T_2 - T_1)}{\eta_c} - c_p\eta_t(T_3 - T_4)$

Coefficient of performance COP = RE/W

where: $\dfrac{T_1}{T_2} = \dfrac{T_4}{T_3} = \left(\dfrac{p_1}{p_2}\right)\left(\dfrac{\gamma - 1}{\gamma}\right)$ an index should be:

$$\left(\frac{p_1}{p_2}\right)^{\left(\frac{\gamma - 1}{\gamma}\right)}$$

and η_t = turbine isentropic efficiency
η_c = compressor isentropic efficiency

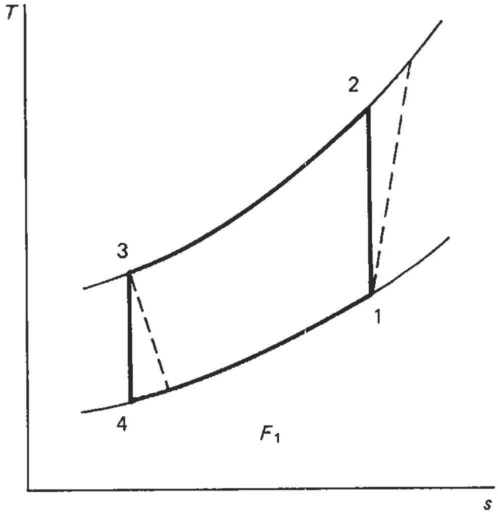

Figure 15.146 Gas refrigeration cycle

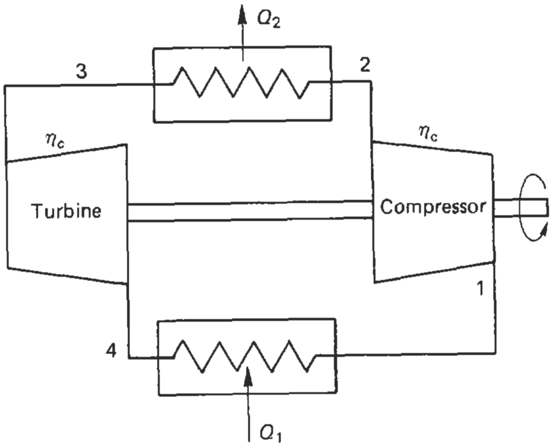

Figure 15.147 Gas refrigeration plant

15.6 Energy management

15.6.1 The energy manager

In 1973 the price of oil increased considerably. At this time about 50% of the UK primary fuel use was oil with 40% coal and 10% gas. One direct result of this price increase was to focus attention on the cost of energy to industry and the concept of an energy manager within a company became established. This is not to suggest that no company was aware of the cost of energy before 1973 but that the serious effects on price inflation were soon apparent and action was needed to contain the problem. In many traditional industries a general knowledge of the amount of energy used was available but the detail of the breakdown of use in particular processes was probably unknown and a knowledge of whether a process was the most energy efficient was certainly not. This latter statement is still true in many situations.

In general terms, we waste about half the energy we obtain from fossil fuels. Much of this waste is due to the widespread use of electricity which is generated at about 35% efficiency and individual companies are not in control of this waste except that they can minimize their consumption of electricity and hence their costs. Other serious causes of waste are poor combustion in boilers, inadequate insulation and poor building environment control, all of which are within individual company control.

It is the duty of an energy manager to know how and why energy is being used within the company and to organize the use of the most cost-effective supply. The nature of this task requires contact with a range of energy users, including both management and workforce, and will require enthusiasm, tact, persuasiveness and patience as well as expert knowledge. It is an ongoing situation in which all changes in energy use due to change of product, new buildings, new equipment, etc. need to be monitored. One key weapon in the manager's armoury is that if everything else remains constant a cut in the energy bill will mean a rise in wages or profits. If this can be achieved with little or no capital cost, but merely by good housekeeping or a change in working practices, then he or she will be in an unassailable position. The energy manager must therefore generate the cooperation of management, unions, shopfloor managers and all the users of energy in the factory, users in the office and users outside in the delivery and sales vehicles. The manager must be able to communicate at all levels.

Energy management is encouraged by government in at least four ways:

1. Information – the government provides information in the form of free pamphlets, books[48] and newspapers[54] which focus attention on particular aspects of energy use and advise on efficiency. Energy managers should be aware of these valuable sources of information.
2. Grants – from time to time, grants for specific purposes are available. Initially these were mainly for simple one-day surveys by outside consultants who would bring an experienced, impartial eye to look broadly at the way energy was being used and produce a short report with recommended further actions. The availability of grants may change and the Department of Energy should be consulted for current information.
3. Legislation – the government ensures, through the Building Regulations, that adequate insulation standards are applied to buildings, hot fluid pipes and hot fluid stores, that window areas are not excessive and that thermostat control is fitted to heating systems. These regulations are not normally retrospective but they are progressively improved and the energy manager may well see economic sense in applying some to existing situations. The government also sets statutory maximum and minimum temperatures for heated buildings.
4. Audits of industries – detailed analyses have been made of a number of energy-intensive industries. In the present context the Audit of the Engineering Industries[49] is particularly relevant but the other surveys may contain useful information and the energy manager would be well advised to examine the whole series.

The energy manager needs a small library to form a database to assist in the task. Because of the interest in this field in the post-1973 years there is a considerable volume of literature which would take some time to read. Apart from the government publications mentioned above, the books and journals in references 50–53 should enable many questions to be answered.

15.6.2 Energy surveys and audits

It is quite clear that an energy manager must know how energy is being used before any attempt at management is possible. Obviously, the manager must have access to historical information in the form of bills for electricity, gas, coal, oil, petrol, etc. and possibly in daily rates of production. These will show how much was spent and made in any particular period but they will not tell a great deal without further detail. Some points are highlighted below:

1. Unless the firm is very small the bills will not show where the energy was actually used.
2. The bills will not show the total cost of energy. For example, coal and oil are often stored requiring a proportion of the rates, capital value of land and buildings, capital value of the stored fuel and depreciation in quality of some stored fuels, etc.
3. The bills will not show whether the methods of purchase of fuel are the optimum for the business. Contracts for liquid and solid fuels may be renegotiated, gas may be purchased on long-term contract. If electricity is considered as an expensive fuel (only because of the generation efficiency which ensures that it costs about three to four times as much as the raw fossil energy used in the power station) there are a number of tariffs available, depending on how

the electricity is supplied and used. Important considerations for electricity are:

(a) If the electricity is supplied and metered at high voltage to the consumer's own substation or if it is supplied and metered at low voltage;
(b) The amount consumed;
(c) The consumer's power factor;
(d) The consumer's maximum demand, especially in winter when each kilowatt of maximum demand can cost forty times the summer rate.

The supply method is dependent on the capital cost of a substation and decisions will require consultation with the electricity supplier. The supplier may also advise on 'off-peak' electricity. The other three items are within the energy manager's field.[48] The principles to contain these costs are avoiding waste which leads to an excessive consumption, ensuring that the power factor does not fall below 0.9 by fitting power factor-correcting capacitors to plant with inherently low power factors (such as induction motors used for driving machine tools, welders and induction furnaces, etc.) and ensuring that everyone concerned with electrical driven devices understands the maximum demand penalties. The maximum demand charge is related to the generating capacity that has to be available to meet the greatest national demand. The charge is based on twice the maximum number of units of electricity supplied in any single half-hour in the particular month. To avoid maximum demand charges it must be clear that random switching on or off of high-consumption electrical devices (plating plant, furnaces, etc.) must be eliminated. This is a task which requires a *control system* and user cooperation. Ideal control means that the loads are arranged so that the continuous demand is equal to the maximum demand which gives a *load factor* of unity. Computer-controlled demand (Figure 15.148) is one solution but there may well be a need for special intervention in circumstances where a computer power cut to avoid demand charges could cost more in damaged product than is saved.

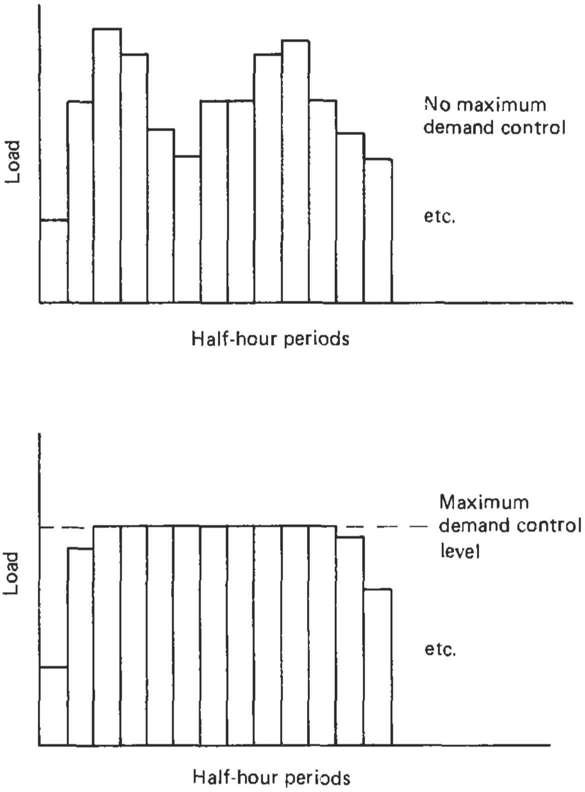

Figure 15.148 In the upper diagram there is no maximum demand control and the maximum demand charge will be 25% higher than that in the lower diagram, where the control has rephased some loads to fit into periods where there is spare capacity. The total consumption in the thirteen periods shown is the same in both diagrams

The bills will not relate to external happenings, which do not appear on them. Common examples are special production needs to meet a time penalty or excessively cold weather. The former information may be available internally and the latter in the form of weather statistics. These are published for different areas of the UK as degree days both as a twenty-year average and for the past two years updated monthly in a free Department of Energy publication.[54] The degree days (for heating) in a particular month is the mean number of degrees by which the outside temperature on a given day is less than 15.5°C added up for all the days in the month. Degree days will vary from year to year. For example, in February 1986 Southeast England had 467 degree days rather than the 376 in February 1985, so that to maintain the same internal temperature the energy input would have needed to be about 1.24 times greater in 1986 than in 1985. Although weather is outside the energy managers' control they still face higher electricity bills as both consumption and maximum demand will rise.

The bills will not show the efficiency of the plant. However, if all the gas goes to one boiler it may tell the manager something about that piece of plant. Other problems of historical information could be listed but it must be clear that bills are an inadequate method of energy management without further information. A complete and ongoing audit system is required.[48] This can be built up starting with a simple survey of the energy needs of all equipment that uses energy. Later it might be desirable to fit individual metering to each piece of equipment and to note consumption, time in operation and goods produced. Between these extremes there could be a compromise. The more instrumentation used, the more complete the picture and the more the use of energy can be controlled either by humans, who are unreliable due to memory lapses, lack of interest, etc., or by computers which are only as succesful as their programs permit.

When an audit has been made the information should tell how, why, when and where energy is being used. This should enable analysis to make sense of the results, detect waste and indicate where savings may be made. Plans can then be made for short-, medium- and long-term actions to minimize energy use. In the short term it might be that boiler efficiency, heat exchanger effectiveness, good housekeeping (closing doors and windows, turning off lights, etc.), lighting levels, draught proofing and stopping leaks of steam or air would pay dividends. In the medium term, insulation, instrumentation, controls and power factor correction might feature and in the long term new boilers, process changes, building use and heat recovery schemes might be considered. Table 15.32 shows possible audit layouts for environment and production energy.

Table 15.32 Simple initial energy audit tables

ENVIRONMENTAL ENERGY AUDIT FOR 19

	Building A	*Building B*	*etc.*
Space heating	kWh	kWh	
Heating ratio	$\frac{\text{kWh}}{\text{m}^2}$	$\frac{\text{kWh}}{\text{m}^2}$	
Lighting	kWh	kWh	
Lighting ratio	$\frac{\text{kWh}}{\text{m}^2}$	$\frac{\text{kWh}}{\text{m}^2}$	
Domestic hot water, etc.	kWh	kWh	
Energy cost total	£	£	

Notes

(1) Heating and lighting will vary from month to month with the seasons.
(2) Holidays etc. must be allowed for.
(3) Note the use of the kWh (or any other unit) for *all* cases to enable simple comparisons.

PRODUCTION ENERGY AUDIT FOR 19

	Workshop A	*Workshop B*	*etc.*
Electricity	kWh	kWh	
Gas	kWh	kWh	
Other fuels (oil, coal, etc.)	kWh	kWh	
Total energy	kWh	kWh	
Energy cost total	£	£	
Production quantity	units	units	
Cost per unit	£/unit or $\frac{\text{kWh}}{\text{unit}}$	£/unit or $\frac{\text{kWh}}{\text{unit}}$	

Notes

(1) It would be preferable to break down the use of electricity into machine tools, paint drying, air compressors, etc.
(2) The environmental cost of the above table may also be included in the production costs if so desired.
(3) Again note the use of kWh in all cases.

Concurrent with any analysis, long or short term, must be an assessment of the cost of implementing energy-saving measures. This is best determined in terms of the payback period – the time taken to recover the capital cost needed to achieve the savings. Once this period is passed, profits or wages increase. The determination of cost effectiveness when the payback period is lengthy is complex, depending on the accounting system used and will require judgement of the likely long-term benefit. Payback periods of up to three years can enable simple decisions, but beyond this period a decision needs a knowledge of the product stability and the marketing situation. The energy manager can only present findings to the accountancy department who will have conflicting claims for capital expenditure. In the end it is no good being energy efficient if you have no buyer for your product.

Even if a firm does not feel that it wishes to pursue detailed energy management, a person delegated to walk around once a month can save money by monitoring leaks, broken windows, dirty windows and lighting, machine motors idling during lunch periods, vehicle entrances wide open in cold weather, etc. Over a period of time this would lead to noticeable savings in the annual energy expenditure.

15.6.3 Applications

The Audit of the Engineering Industries[49] gives a breakdown of the total primary energy requirement of a range of producers. The word 'primary' implies that the electrical energy purchased has been divided by 0.3 to take generation efficiency into account so that the figures are closer to actual energy costs in financial terms. By averaging the figures listed it is possible to estimate some data which might be considered typical of a very diverse industrial scene. The information is tabulated below and may be seen to fall into three classes:

Building energy	
Space heating	50%
Lighting	7%
Production energy	
Driving machinery, welding and plating	23%
Heat treatment	10%
Compressed air	2%
Miscellaneous energy	
Transport, computing, packing, etc.	8%

Some of these aspects are considered in more detail below.

15.6.3.1 Space heating

Since the average above shows that 50% of industrial energy costs are associated with space heating this is an important area for examination by the energy manager. The buildings in use will have probably been built at various times and may well presently be used for purposes for which they were not originally intended. They will consist of large open-space workshops, possibly with high roofs which allow warm air to convect away from the workforce at floor level, office spaces, controlled environments for inspection or computers, etc. each of which will present different problems. The UK climate is also capricious by nature, presenting quite rapid variations in external conditions which require expensive extra capacity to deal with extremes of heat or cold that may only obtain for a few days each year. Comfort for people (and for computers) is based on both temperature and humidity and it is necessary to ventilate all spaces at an appropriate rate or even air condition, depending on the activity within the space considered. Human beings radiate energy at various rates when working. A seated person at rest radiates at about 115 W and heavy work increases energy release to 440 W. All machines supplied with electrical energy eventually dissipate this energy into the work space as heat so that a machine shop on a hot summer's day is being heated by the motors driving the tools and the operators. Conversely, many spaces have delivery bays for lorries and smaller openings for internal transfers by forklift trucks which may allow considerable ingress or egress of cold or hot air to or from the workplace.

All spaces should be audited to determine the energy balance within them in the worst summer conditions and the worst winter ones. This will allow the largest cooling and heating loads to be determined. The audit should also reveal the heating and cooling methods used and the associated costs, the efficiency of boilers and heaters, the amount of insulation fitted, the building materials in the space, the glazing state, the draughtproofing state, the ventilation rate, the humidity state, the control system used, etc. There will be regulations concerning ventilation, temperature levels and any other health and safety aspects of the particular situation. Fire regulations may also be involved.

A very important consideration for the determination of steady-state heat losses or gains through the building fabric are the U-values of the structural materials. A U-value is a transmittance or overall heat transfer coefficient through a particular wall structure in air measured in $\mathrm{Wm^{-2}\,K^{-1}}$. Thus the heat transfer through a wall is given by

$$\dot{Q} = UA\theta$$

where $\dot{Q}$ is the heat transfer (W), A is the area ($\mathrm{m^2}$) and θ is the temperature difference between the inside air and the outside air (K). (*Note*: a temperature *difference* in K is numerically equal to a temperature *difference* in °C.) The U-value may be found by the addition of the resistances of the air layers inside and outside the wall and of the wall itself. If R is resistance ($\mathrm{m^2\,KW^{-1}}$) then

$$U = \frac{1}{\Sigma R}$$

For small heat losses or gains U should be small. This is achieved by suitable *insulation thickness* (Figure 15.149). Tables of data may be found in references 48, 51 and 55. U-values are also used to find heat losses from pipes carrying hot fluids and heat gains to pipes carrying cold fluids, heating effects from room heaters, etc. Examples of the benefits of insulation can be found in a Fuel Efficiency Booklet 16,[48] one of which shows that a 1000 $\mathrm{m^2}$ corrugated steel roof which is uninsulated and has a U-value of 6.7 $\mathrm{Wm^{-2}K^{-1}}$ can, with relatively simple insulation, reduce the U-value to 0.7 $\mathrm{Wm^{-2}\,K^{-1}}$ which should save almost £6000 per year in a Midlands situation. This example does not show the cost of the insulation installed but does illustrate a 90% reduction in heat loss costs. There is a danger of overestimating savings since insulation tends to increase inside temperature, and the heating system needs to be adequately controlled to achieve the full benefit.

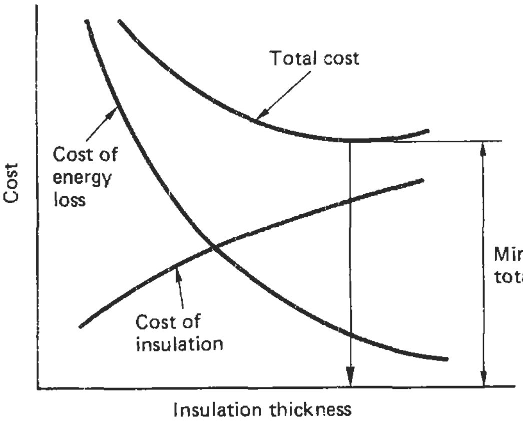

Figure 15.149 This diagram shows how an economic thickness for insulation may be determined. It must be realized that this is drawn for a chosen payback period since the energy loss cost is continuous but the insulation cost is a single occurrence

The methods used to ensure that buildings are heated to the appropriate condition before the workforce arrives and, conversely, that they are not overheated after the workforce leaves also need study. Heating and cooling in these situations are transient problems. Buildings with thick walls store energy within their fabric when the inside air is hot (or due to solar heating) and release it when the inside (or outside) air is cold. The time for a building to warm up or cool down will vary for different structures. A building with thick walls may need to be heated earlier in the morning than a thin-walled structure and the heating may be turned off earlier to compensate.[55]

Overheating a building above the *necessary* temperature, which will lie between the statutory limits, is wasteful. Every degree of excess temperature costs about 5% more in fuel costs and, similarly, every hour of non-essential heating due to the transient effects discussed above may cost about 10% more in an 8-hour day.

Inefficient use of fuel for heating is a waste; a modern boiler should operate with an efficency in excess of 75% at all loads at which it is intended to be used. 'Efficiency' is an imprecise word and should be clearly defined in any discussion. The boiler efficiency has two components: combustion efficiency and heat transfer efficiency, the latter representing the process of transferring energy from the combustion products to the water. This is not perfect, since the exhaust gases carry considerable energy to the atmosphere. This loss is unavoidable, since lowering the exhaust temperature has acid-forming effects. Some modern plant does have lower exhaust temperatures as a design feature. Combustion efficiency is maximized by ensuring that the best air–fuel ratio is used by constant monitoring of the exhaust gas composition (usually CO_2 or O_2 content). Burner nozzles also need cleaning to ensure good combustion. Heat transfer efficiency is maximized by regular blowdown to remove impurities fouling the boiler tubes (blowdown is also necesary to maintain steam quality). Boilers operate best at high loadings, and it may well be economic to have both a summer and a winter boiler to operate effectively. Clearly, the efficient operation of boiler plant is worthwhile.

Space heating and environment control is a complex problem which may well need professional advice to achieve satisfactory results in a modest-sized company, although help can be found in journals[53] and books.[48,50,52,56] Advice is essential when modifying building use or when a new building is being designed. The checklist below may be used but cannot show all considerations in all situations:

Buildings
Structure
Size
Insulation
U-values
Glazing
Draughtproofing
Ventilation
Energy outputs from occupants, machines, lighting, kitchens, furnaces, etc.
Statutory regulations

External environment
Temperature variation (annual and diurnal)
Solar gains
Wind exposure
Dampness
Degree days of location

Internal environment
Statutory regulations
Heating (convective, radiative)
Boilers, fuels and efficiency

Heat pumps
Humidity
Air conditioning

Control
Thermostats
Computers
Climate control
Building management systems

It must be emphasized that, because of the high cost of space heating, all energy managers should regularly monitor temperature levels, heating methods, insulation standards, boiler maintenance, door and window states, the timing of heating systems as the seasons change and the introduction of new machinery which alters loads and of new local heating devices without the energy manager's advice. This should be regarded as prudent housekeeping and should not be an expensive operation.

15.6.3.2 Lighting

Although lighting represents an average of only 7% of industrial energy use it is well worth consideration, because correct illumination is essential to efficient work in both offices and workshops. Savings may be achieved in other costs by better work or less time loss due to sickness as well as in energy costs. The unit by which illumination is measured is the lux (1 lux = 1 lumen m^{-2}). The definition of a lux is that a radiating source of 1 candela at the centre of a sphere of 1 m radius gives an illumination of 1 lux at the surface of the sphere. There are recommended illuminance figures for various grades of work.[48] Some examples are shown below to illustrate the range of levels involved. The symbol for lux is lx and for lumen is lm:

Outdoor stores	30 lx
Corridors	100 lx
Rough bench or machine work	300 lx
Drawing office	750 lx
Fine bench and machine work	1000 lx
Very fine work	1500 lx
Minute detail, engraving	2000 lx

A lighting analysis should decide the level of illumination required and the installation design will require a knowledge of the output of the lamps available. To be energy efficient the lumens per watt of electricity input, known as the lamp efficacy, should be used.[48] Lamp life is also valid information since the lighting system has to be maintained. Typical value of these data are shown below:[48]

Tungsten filament	8–18 lm.W^{-1}	1000–2000 h
Low pressure mercury discharge (tubular fluorescent)	37–90 lm.W^{-1}	5000–10 000 h
High pressure sodium discharge	67–121 lm.W^{-1}	6000–12 000 h
Low pressure sodium discharge	101–175 lm.W^{-1}	6000–12 000 h

There are other lamps available.

From this table it is clear that the most energy-efficient lighting would be sodium lamps, but lamp choice cannot be made solely by lamp efficacy since not all lamps produce the same colour light. For example, the low-pressure sodium lamp produces a monochromatic yellow light so that all colours except yellow appear brown or black. In general, tungsten lamps should be replaced by:

1. Low-pressure mercury types when good colour rendering is required for which there is a choice of type, with differing emphasis on both light colour and quality. Rotating machinery may pose problems as some lamps may cause a flicker effect which could mask rotation at certain speeds. Expert advice is needed for this problem.
2. High-pressure sodium lamps in areas requiring general lighting such as walkways, large workshops, etc.

The design of a lighting installation requires special knowledge[57,58] for the choice and positioning of luminaires is important. When the total load to give the required illumination has been determined it is essential to ensure that it is correctly distributed over the illuminated horizontal, inclined and vertical surfaces without reflection, glare or claustrophobic effects. The positions of windows and the decoration of the spaces also needs to be considered. Window areas may be increased but extra heating cost may result.

The cost of replacing a lighting system is usually recouped within two to three years because the running cost of high-efficiency lamps is about six times the total cost of installation, equipment and maintenance over the lamp life.[52] Once the cost has been recovered the ongoing running costs of the new system should be about a quarter of a tungsten-based system. To be cost effective, a lighting system needs a planned maintenance routine involving cleaning after perhaps 3000 h (including windows) and lamp replacement after 6000 h. By slight overdesign (10–15%) this is found to be cheaper than exact design and lamp replacement on failure[48] (3000 h is 10 h a day, 6 days a week for 50 weeks). Thus even though lighting is a relatively small item in engineering energy costs it can be considerably reduced in many situations.

Even with a good system energy can be wasted by poor use. In a sensible lighting installation attention is paid to switching arrangements. If it is not clear and simple, whole blocks of lamps will be switched on in order to illuminate a single lamp. Individual switching may lead to savings. It is also clear that humans will turn lights on when required but not off when they are not, so that some system of automatic control may be advisable. Time switches or photo-electric devices may be used. Control of lighting for early-morning cleaning, watchmen's rounds and other activities during 'off' periods can also be economic.

The final factors to include in any lighting calculations are:

1. All electricity inputs to lighting systems contribute to the building heating.
2. Lighting loads must be considered in the calculation of maximum demand costs in winter and in the overall power factor considerations in electricity charges.

15.6.3.3 Manufacture

The energy directly consumed by manufacture (i.e. excluding the costs of material, space heating, lighting, etc.) will depend on a number of factors, including:

1. The design of the component
2. The planning of the manufacture
3. The control of the plant used

If energy is considered at all these stages then some changes in the design philosophy, manufacturing processes, working traditions and habits and the plant in use may be considered possible and should be evaluated for their suitability, acceptability and payback time. Some general considerations are discussed below but most industries will have their own particular facets which should appear at the audit stage.

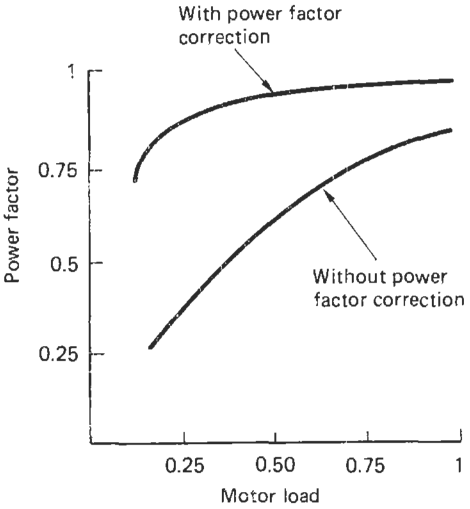

Figure 15.150 The effect of fitting power factor correction to an induction motor is very marked at part-load operation which occurs for a considerable percentage of the motor use

15.6.3.4 Driving machinery, welding and other processes using electricity

Machine tools used for a variety of metal cutting and forming processes are driven by electric motors. Most of these are induction motors which have a poor power factor and in order to achieve their best should run close to their rated power outputs. Induction motors must be fitted with *power factor correction* capacitors (or other devices) which must increase the power factor to more than 0.9 over a wide range of motor loadings. This is particularly valid (Figure 15.150) at part-load running where the power factor is worst in uncorrected motors. The energy audit[49] produced some data showing the distribution of cutting machine loads as working 28%, idling 52% and off 20%.

During cutting the motors operated at 50–80% of their rated power and during idling at 25% of their rated power, the overall result being that 42% of the energy consumed was in idling. It is obvious that there must be idling time between operations but this percentage is high and production planning, including the movement of parts and materials, should be arranged to minimize this waste. In winter a portion of this energy would be useful space heating but in summer it may need cooling plant to remove the excess energy, and even in winter, space heating by idling electric motors is an expensive technique. The planning should include both a time and a power estimation for roughing cuts and finishing cuts in any large-scale repetitive situation, since the energy consumed will depend on both the duration and the rate of consumption of the operation. Reference 49 describes a *measured* range of operating situations for a particular milling machine and a particular lathe. It clearly illustrates that in situations where the power for a machine varies between 23% and 130% of the rated motor power it would be difficult to predict the *maximum demand* in a machine shop. Some control might be possible for heavy power-consuming machines and some statistical data might be used to estimate likely demand in a quasi-steady production environment. A control system to stop some automatic start-up of non-essential plant when the maximum demand is near the limit could save much expensive idling. Air-compression plant might fall in the category of controlled plant or indeed heating systems.

15.6.3.5 Welding equipment

Welding equipment fed by an a.c. transformer has a very low power factor and such plant must be fitted with *power factor correction*. Design of welded components should minimize the amount of filler required since the electricity consumed is directly proportional to the amount of filler used. Some data are given in reference 49. Pre- and post-heating should, as far as is possible, be localized to avoid waste. Similarly, stress-relieving processes should be considered by choice of method to avoid waste.[49]

15.6.3.6 Heat treatment

Processes such as hardening, tempering and annealing use more energy than any other manufacturing process, and the choice of process and the design of the component will therefore have a marked effect on the cost of the product. Reference 49 shows the relative energy costs for surface hardening of crankshafts (the electrical energy was divided by 0.3 to allow for the cost effect of generation efficiency). It shows that *induction heating* is the most energy efficient method. This technique does not, however, produce the best fatigue resistance nor the hardest surfaces as the other methods, so the design should take account of the proposed production method to be used. Induction heating may be employed for other heat treatment processes such as annealing and normalizing, where it is again found energy efficient.

When furnaces are used for heat treatment, combustion control is important. For example, if a reducing atmosphere is required no oxygen should be present in the gases. Furnaces should be well insulated since the processes are often lengthy, but extra insulation should not be added without consulting the manufacturer, as it may lead to overheating or other unwelcome side-effects. Linings in furnaces should have a low thermal mass to reduce the energy absorbed and wasted on cooling, but this needs analysis of the intended use since low thermal mass ceramic fibre linings are more expensive than traditional refractory bricks. Heat-recovery techniques should be considered for the exhaust gases.

When vats are used for degreasing, cleaning or pickling at elevated temperature there can be considerable loss of heat from the sides of the vat and by evaporation from the liquid surface in the vat. These may be minimized by the vat design, insulation and the use of floating plastic balls on the liquid surface. Other losses due to heating of the work and liquid solvent on the work surfaces are less easily controlled. There will also be an energy loss if the solvent is toxic and the fumes have to be removed by a ventilation system. The design of such a system should minimize the amount of warm room air removed and may include a heat-recovery system.

Paint drying and moisture-evaporation processes should be closely examined to see if the commonly used convection heaters could be replaced by radiant heating which avoids the 'ventilation' losses associated with convective designs. However, the ventilation may be vital with toxic solvents and heat recovery may be possible. It is also possible that the different effects of radiant and convective heating may require some design modifications since radiation penetrates the surface with a different drying effect and may also result in higher product temperature during the process.

15.6.3.7 Compressed air

Many users do not consider the cost of compressed air because, like water, air is erroneously considered to be free. Air-driven equipment should be assessed and the compressor matched to the minimum pressure required. Excess pressure is expensive. Similarly, the compressor should be matched to the demand so that it is running close to the rated output. The electric motor will then be operating at a high power factor. Air is often stored in a receiver and the compressor will operate at times when the receiver dictates. Careful management of the on–off cycle is essential and, if possible, the compressor should recharge the receiver at times chosen to use up spare maximum demand in any half-hour. Any compressor (or other machine) automatically switching on in a high-load half-hour will produce very expensive compressed air (or other product). Matching the compressor to the demand and on–off control are not the only ways to assure energy efficient compressed air supplies. Others include:[48]

1. Avoid leaks by regular inspection of the pipelines and the tools using the air;
2. Compressing air generates heat and both the compressor and the air produced are cooled, therefore an energy-recovery system may be economic;
3. Where tools exhaust air that is still above atmospheric pressure some other use or recycling of the air may be possible;
4. For large installations the use of two-stage compressors with intercooling between the stages will result in lower running costs;
5. Clean filtered *cool* outside air should be compressed rather than warm inside air which increases the energy use for a given delivery amount;
6. Choose the correct pipe sizes to minimize friction loss;
7. Maintain the machinery in accordance with the schedule.

15.6.3.8 Miscellaneous energy use

In any company there will be energy uses specific to the product. It is not possible to cover every aspect here but some comments on the more common, but perhaps unconsidered, peripheral energy uses are given below. *Audits should reveal more.*

15.6.3.9 Transport

Transport embraces a variety of modes: internal movements by battery-powered trucks, road transport of goods, road transport for sales and service staff, other car users, rail transport, sea transport, air freight, etc. The costs of transport may also include any special packaging or containers demanded by the mode. Many factors will decide which method of transport is best. If vehicles are required it is still possible to buy, hire, lease or even to subcontract the work. In spite of all these possibilities, most companies will still own and operate vehicles, and these may be audited to assess their cost and efficiency.

Since vehicles are driven over different routes with different drivers and different loads it will be possible to make comparisons and hence to be able to set reasonable targets in terms of fuel consumption per tonne-km for a particular type of delivery vehicle or litres per 100 km for sales or service duty, and over a period of time to build a picture of what may be reasonably expected. Economy may only be achieved with the cooperation of the workforce and this must also apply to salesforce and management to achieve harmony. If a car is part of the emoluments of the user this should not be debited to the transport bill but to the appropriate fund.

Having established the audit bounds and obtained some ongoing data it should be possible to look for measures to improve the use of energy (fuel). The following list is not exhaustive but indicates fields which might prove to be worth examination:

- Routes should be planned to avoid problems (roadworks, congestion, etc.).
- Telephones may be cheaper than personal visits.
- Loads should use the full vehicle capacity.
- Diesel vehicles are more economic than petrol vehicles.
- Vehicles may no longer be the ideal for their use (too large or too small).
- Speed controllers may be fitted.
- Aerodynamics can be improved with deflectors or load covers.
- Trailers can improve cost effectiveness.
- Vehicle servicing is important, particularly cooling controls for optimum engine temperature, binding brakes, idling speeds, rack or carburettor settings, injectors, ignition, plugs, tyre pressures, wheel alignment, balance, etc.

Multiple small inefficiencies can cost a great deal if vehicles spend most of their time transporting goods and persons. This is what they should be doing, of course, and if vehicles spend excessive time in parking lots then they are not required and hire or contract should prove economic.

15.6.3.10 Refrigeration

Refrigeration may be required for some processes (see also Section 15.5). A refrigerator takes energy from the material being cooled and rejects it to a coolant at a higher temperature. This process requires the input of energy and thus the total energy rejected in the refrigerator condenser is equal to the sum of the energy extracted from the cooled material and the driving energy input. This is likely to be contained in cooling water at a temperature between 20°C and 45°C, depending on the mode of operation of the plant. There is scope for heat recovery here if the plant is large.

15.6.3.11 Computing

The electrical energy supplied to a computer has to be dissipated to avoid overheating. In small installations this energy would be a constituent in the heat input to the space in which the computer is sited. In very large installations there will be a need for air conditioning and associated refrigeration plant from which energy recovery may be possible.

15.6.3.12 Storage, stock, packaging

Space allocated to storage of material for future use, finished product and packaging needs to be heated and lighted (and costs in rates). Careful calculations of stock levels may reduce the energy service cost of this facet of factory operation.

15.6.4 Waste-heat recovery

Waste-heat recovery or energy recovery has been mentioned in various places in this section. The critical factor in the value of waste heat is the temperature at which this energy is available. If the temperature is relatively high then it is not difficult to envisage useful applications of such energy, but it should be realized that each transfer of enegy requires a 10 K temperature difference to drive the heat transfer so that the energy is degraded in value at each transfer. At lower temperatures waste heat is also useful if the quantity is large enough to justify the use of a heat pump. The use of waste heat therefore requires the investigation of heat exchangers[59,60] and heat pumps.[61]

The first consideration for any waste heat must be to decide if it can be used directly. For example, uncontaminated hot water may be used for heating a building in a radiator system. If direct use is not possible due to contamination, toxic effects, etc. then a heat exchanger will be needed to transfer the energy to a suitable medium. Common types of heat exchanger include shell and tube, plate, run-around coils, recuperators and regenerators. The choice will depend on application and the fluids involved.[51]

Three other types of heat-recovery equipment are the rotary regenerator, the heat pump and the heat pipe. Conventional regenerators are cyclic in operation but the rotary design provides continuous recovery. This is achieved by slow rotation of a drum-shaped matrix which transfers the energy gained from the hot waste gas to the cold gas (Figure 15.151). Each of these gases passes continuously through a sector of the rotating matrix. The heat pump (Figure 15.152) is identical in concept to the refrigerator except that the objective is to absorb *low-temperature* waste heat in the evaporator and, by the energy input in the compressor, to deliver the waste heat and the compressor energy input at a *higher temperature*. The heat pipe is a device based on the evaporation of a liquid at one end of the pipe by the waste heat and the recovery of this energy by condensing the vapour at the other end of the pipe (Figure 15.153). Heat pipes may be used to remove energy from small or awkward situations and transmit the energy over distances varying from a few centimetres to a few metres.[60]

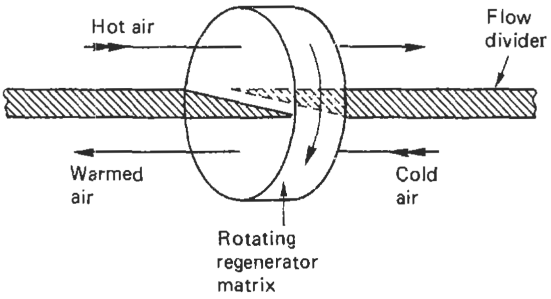

Figure 15.151 The rotary regenerator in which a cold air stream is *continuously* warmed by the waste hot air stream

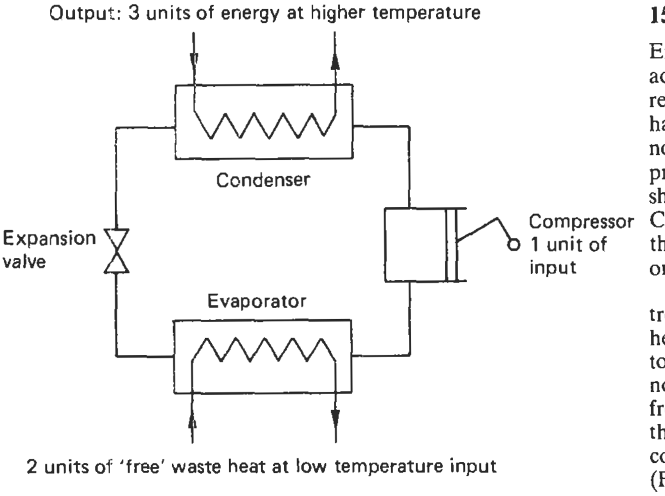

Output: 3 units of energy at higher temperature
Condenser
Expansion valve
Compressor 1 unit of input
Evaporator
2 units of 'free' waste heat at low temperature input

Figure 15.152 A heap pump with a coefficient of performance of 3, which means that for each one unit of 'paid for' energy input to the compressor three units of useful energy are delivered

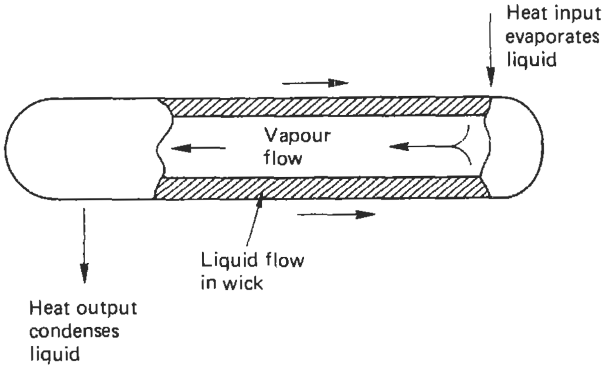

Figure 15.153 The heat pipe in which the energy input evaporates the liquid inside the pipe. At the other end of the pipe the energy is released as the vapour condenses. Various fluids are used inside a heat pipe ranging from nitrogen evaporating at −196°C to lithium evaporating at 1340°C

Common sources of waste heat include energy in flue gases from driers, boilers and furnaces, condenser coolants, air compressors, refrigerators, engine coolants, process liquids, condensate, flash steam, blowdown, etc.

It is possible to install a plant to produce both electric power and process heat. This combined heat and power plant (CHP) is an energy-efficient way of meeting two demands both on a large scale or as a top-up system in winter when both heat and power needs will probably rise. Maximum demand charges may then be avoided. It is also possible to supply excess electrical output to the grid in some situations. Expert advice should be sought for such schemes.

15.6.5 Control systems

Energy management control systems have made significant advances in recent years. Such systems are essential in any realistic scheme because of the unpredictable, forgetful and habit-forming nature of human beings. Control systems are not inherently perfect but, provided that they have been set or programmed correctly and are adequately maintained, they should continue to operate satisfactorily and save energy. Controls are considered so important that they form part of the Building Regulations and are *mandatory* in new buildings or extensions of appropriate size.

Simple open-loop controls have no feedback of the controlled parameter so that, for example, a control may switch a heater on in a room but without feedback the room is unable to inform the control that it is hot enough and the heater will not be turned off. The addition of a thermostat feedback link from the room will enable the heater to be turned on and off as the temperature falls below or rises above preset limits. The control system is now an energy efficient closed-loop system (Figure 15.154).

From this simple example control systems can be made progressively more complex until we have a Building Automation System[52] where computer-controlled continuous *data*

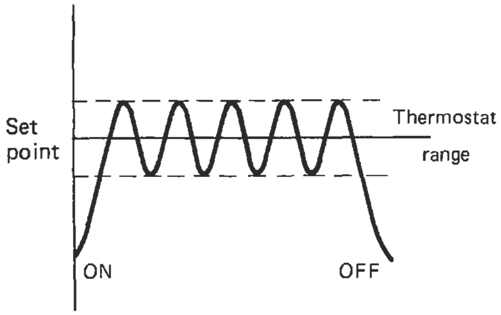

Figure 15.154 Simple thermostat control

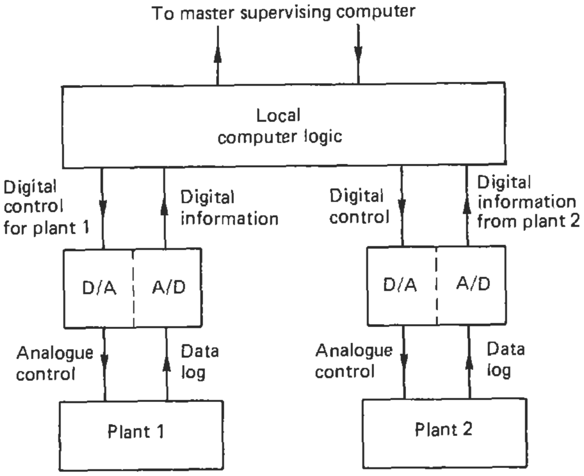

Figure 15.155 A computer control system in which only two plant stations are shown although there will normally be many more. The local computer may control a number of local pieces of plant and there will be several local computers controlling local energy tactics. All the local computers will be supervised by the master computer, which is in charge of the overall energy strategy

logging, assessment and management of the complete building energy demands are achieved (Figure 15.155). This will include heating, cooling, humidity, lighting, ventilation, etc. Other control systems to organize the total electrical load in the whole plant will be interactive with the Building Automation System to ensure that excessive demand is avoided and to make the electrical load factor approach unity. The installation of such complex systems needs expert advice and considerable monitoring at the commissioning stage to ensure that the system cannot cause catastrophic effects due to load shedding to cut demand.

The actuators in a computer-controlled system need regular maintenance. A computer can only data log and issue commands based on the installed program. If the actuators are worn or faulty the system response will be inadequate, leading to incorrect or inefficient operation.

No energy manager can afford to ignore the rapid development of control systems for both large and small factories. Any system that is over 5 years old should be assessed for updating on a basis of a payback period for possible improvements.

15.6.6 Summary

Key considerations for the energy manager are as follows:

- Building Regulations, Health and Safety, attitude of workforce and management
- Available grants, use of experts
- Audits, instrumentation to give data
- Good housekeeping, insulation, power factor, maximum demand
- Waste-heat recovery
- Control systems
- Continuous assessment of energy consumption against targets

15.7 Condition monitoring

In managing mechanical resources there are various options to deal with the inevitable problem of mechanical breakdown. The first decision is whether to maintain the machine or operate it on a run-to-break basis. Run-to-break is now rarely considered viable in industrial applications as machines are becoming increasingly larger, more complex and expensive. The consequences of mechanical failure at unpredicted times can be catastrophic in terms of finance, loss of production and safety. Run-to-break should thus only be considered in the case of small items of plant (pumps, motor, etc.) where spare parts are available off the shelf and where failure will not damage other components and will be readily noticed. In most machinery some form of preventive maintenance will be required.

15.7.1 Preventive maintenance

There are two available options for preventive maintenance: periodic maintenance or predictive maintenance. Periodic maintenance is outside the scope of this section but, briefly, relies on a statistical background. It is based on the concept that machines will be more likely to fail, the more hours they have operated. While theoretically sound, this assumption does not take into account such factors as load conditions and machine speeds nor, more importantly, production tolerances of the machine, etc.

If high reliability is required (as in machines which will result in expensive downtime if failure occurs) the time interval between services will have to be reduced to well below the shortest time between predicted failures. This, in turn, means a high percentage downtime of the machine and the need to carry large stocks of spares (thus tying up capital). In addition, the increased overhaul frequency leads to greater opportunities for failure caused by human error (due to fault in reassembly, etc.). Also, it may not be practical to prevent failure, by planned maintenance, of certain components which have a relatively long life and are difficult to examine visually at maintenance periods (the inside of roller bearings, for instance).

15.7.2 Predictive preventive maintenance

With the arrival of modern technology, including cheap computer systems, the ideal solution may be found in predictive preventive maintenance. This system involves monitoring the condition of machinery, setting ideal operating limits and dealing with problems that result in these limits being breached. In addition, the method usually allows for diagnostics to be carried out, thus avoiding major strips down. The method has the advantage of much shorter downtime periods and obviously the need to carry large stocks of spare parts. The method is usually capable of predicting failure for some considerable time before it actually occurs. This lends itself to the maintenance being carried out at favourable times (for instance, at periods of minimum production) thus avoiding, as far as possible, production interruption.

15.7.3 Condition monitoring

The benefits of condition monitoring extend beyond maintenance and can be summarized as follows:

Maintenance
Enables repair to be planned, therefore, cheaper labour, part costs, and reduced need to stock excessive amounts of spares
Safety – increased operator safety
Secondary damage – avoided

Production
Reduction in machine downtime
Assured productivity
Improved machine throughput
Reduced scrap levels

Quality Assurance
Early indication of deterioration in machine leads to increase in the quality of the product

Machinery planning
Condition monitoring can be used to assess new machinery prior to it being brought into use

15.7.4 The parameters

The following parameters can be measured and contribute to a condition monitoring system:

Vibration
Bearing temperature
Coolant temperature
Lubricant pressure
Oil and hydraulic fluid analysis (for foreign particles)
Lubricant flow
Electrical parameters (volts and amps)

Vibration is the primary indicator of failure in rotating machinery and all others are secondary indicators. Condition monitoring systems are built up around measuring systems of varying complexity. The most simple system may involve the use of a hand-held vibration meter and moveable accelerometers held manually against the machine. This system will usually involve only overall vibration levels. In order to determine the likely time of failure with the highest order of accuracy this system will not be adequate. Some form of vibration frequency analysis will be necessary – this may have the added benefit of being able to identify the component that is due to fail.

In the case of very large machines, or those which have dangerous rotating components in the areas of interest, it may not be possible to use the simple hand-held meter approach. It is more likely that fixed accelerometers will be installed and cabled to one central data processing point. If a central point approach is chosen more than one input parameter can be analysed simultaneously. This gives advantages in fault diagnosis.

Vibration is perhaps the most costly parameter to measure. In the case of simple machines vibration measurements may not be cost effective, and one of the other parameters may be used. If this is the case it is likely that some combination of planned and predictive preventive maintenance is likely to have to be adopted. For example, bearing temperature may indicate worn or damaged bearings but will not indicate out-of-balance shafts.

Apart from vibration, the only test for worn or damaged gears in gearboxes is by oil analysis (in itself a complicated procedure). This method can be used to diagnose which part of the assembly has failed (if the materials have distinct characteristics) by the use of spectroscopic techniques. This is a very costly procedure and only suitable for the most expensive machinery and then only on an intermittent basis.

Oil pressure or flow may be used to assess the state of journal bearings but will not be suitable for deciding the state of rolling element bearings. Electrical parameters may be used to indicate excessive loadings on motors, etc. (perhaps due to tight bearings) as well as possible electrical insulation breakdown.

15.7.5 Vibration monitoring for machine condition

The reader is referred to the section of this book on vibration control (Section 15.8) in order that some understanding of the basics of vibration theory and measurement may be gained. This will be necessary in order to fully understand the information that follows.

As previously stated, it is rarely sufficient to measure vibration merely in terms of overall level (RMS). In order to obtain sufficient 'early warning' much more sophisticated techniques will have to be adopted. In describing the various analysis techniques it is first useful to discuss the characteristics of the vibration in a typical device. A gearbox is considered, as it exhibits many types of vibration effects.

15.7.5.1 Low-frequency range

Low-frequency vibration is caused by imbalance, misalignments, bent shafts, etc. and occurs at the shaft rotational speed. Harmonics (i.e. multiples) of this frequency will also be present.

Journal bearings can produce vibration at frequencies below the shaft frequency. This vibration is caused by the centre of gravity of the shaft moving around within the clearance of the bearing. The vibration is caused by 'oil whirl' and seems to depend on the surface of the shaft and the bearing. Typical frequencies are between 40% and 49% of the rotational speed.

Another type of shaft vibration is known as hysteresis whirl. As the shaft passes through a critical frequency the hysteresis whirl will build up and remain at the critical frequency independent of shaft speed.

Mechanical looseness in a system will also be observed. Typically, this may produce interharmonic and subharmonic components (e.g. half-harmonic, one and a half harmonic, etc.).

15.7.5.2 Medium-frequency range

Tooth-meshing frequency will be the next frequency of vibration to be encountered. The frequency of this vibration will depend on the shaft speed multiplied by the number of teeth on the gear. The gear will also produce harmonics of this fundamental gear tooth frequency. Wear on gears produces higher levels at the harmonics (due to an increase in the sliding action of worn gear teeth) rather than a simple increase at the fundamental. General wear can thus be detected by the increase in these harmonics.

A single damaged tooth, on the other hand, produces quite different effects. This will result in a series of pulses in the time-domain signal from the gearbox and will create a line spectrum with each line spaced with the repetition frequency.

Thus damage to a single tooth will show up on the overall spectrum as an increase in the sidebands spaced with rotational speed above as well as below the tooth-meshing frequency. It may be difficult to see this signal as below the tooth-meshing frequency there will be all the low-frequency components (as already discussed) and above it the tooth mesh harmonics will have much more energy. It may, however, just be possible to detect this signal between the tooth meshing harmonics. If more than one tooth is damaged the effect will tend towards an amplitude modulation of the overall time signal. This will result in high-amplitude sidebands around the tooth meshing frequency (and its harmonics) spaced at the rotational frequency.

Another interesting source of gear vibration is 'ghosting'. This arises from errors in the machining of the gear when first produced.

Gears are produced by mounting blanks on a table which is rotated by an index wheel during machining. Inevitably, this index wheel will not itself be perfect and errors will be introduced into the gear being produced. The frequency of vibration produced by the gear in service will correspond to the number of teeth on the index wheel (times the rotational speed of the gear). This ghost frequency will thus be at an integer of the rotational speed of the gear but will not correspond to any tooth meshing frequency of the gearbox. As the gear gradually 'wears-in', the ghost component will gradually disappear (this is one way of determining that the vibration is due to a ghost). Also, the ghost will not be so affected by loading as the main tooth meshing frequency.

15.7.5.3 High-frequency range

At higher frequencies the primary source of vibration is rolling element bearings. Faulty bearings produce a pulse of vibration which repeats periodically dependent upon the shaft speed and the geometry of the bearing. There are four main frequencies associated with a rolling element bearing:

1. Ball-passing frequency outer-race (BPFO) – caused by a fault on the outer race.
2. Ball-passing frequency inner-race (BPFI) – similarly corresponds to the frequency of a ball passing a fault on the inner race.
3. The ball-spin frequency (BSF) – caused by a fault on the rolling element.
4. The fundamental train frequency (FTF) – caused by a fault on the bearing cage.

These frequencies can be determined by:

$$\text{BPFO } (H_z) = \frac{n}{2} f_r \left(1 - \frac{\text{BD}}{\text{PD}} \cos\beta\right)$$

$$\text{BPFI } (H_z) = \frac{n}{2} f_r \left(1 + \frac{\text{BD}}{\text{PD}} \cos\beta\right)$$

$$\text{BSF } (H_z) = \frac{\text{PD}}{\text{BD}} f_r \left[1 - \left(\frac{\text{BD}}{\text{PD}} \cos\beta\right)^2\right]$$

$$\text{FTF } (H_z) = \frac{1}{2} f_r \left(1 - \frac{\text{BD}}{\text{PD}} \cos\beta\right)$$

where

n = number of balls or rollers and f_r = relative rev/s between inner and outer races (see Figure 15.156).

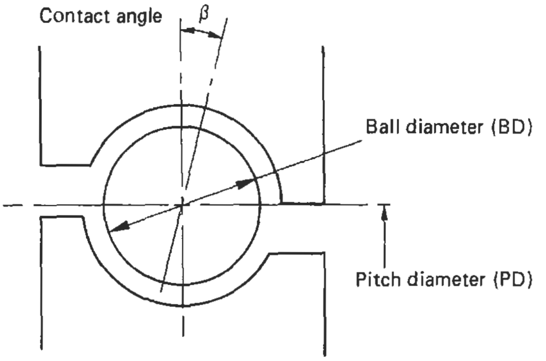

Figure 15.156

In practice, it may be difficult to isolate this ball-passing frequency due to interference from other effects. The pulse of energy transmitted into the race of the bearing will, however, cause it to resonate at its natural frequency. This will typically be at higher frequencies (between 1 kHz and 20 kHz) and will be easier to measure since other sources (as discussed previously) typically occur much lower down the frequency spectrum.

15.7.6 Vibration analysis techniques

15.7.6.1 Overall (RMS) levels

The overall (RMS) level can be measured simply by a portable (hand-held) meter and accelerometer system. This can be carried by an engineer and used on a regular basis to monitor machines. The actual level of vibration measured can be compared with previous readings (at the same location) so that trends in vibration levels may be plotted. In order that a high level of reproducibility is obtained it may be considered necessary to attach special metal disks to the parts of the machine to be monitored and use a magnetically mounted accelerometer. For one-off readings it is possible to gain some insight into machine condition by comparing the reading with ISO standards (ISO 2372/3 and 3945). These give levels of vibration for various classes of machine (in terms of power ratings of machines). The vibration levels are assessed into four bands (good, allowable, just tolerable, not permissible). An increase of 8 dB indicates a change of band. An increase of 20 dB shows that vibration levels have reached the 'danger' zone.

The main disadvantage with using overall (RMS) levels is that the reading is influenced (on the whole) by the single highest frequency 'spike'. In order to influence the overall level a fault signal has to exceed this level. As explained earlier, it is quite possible for a machine to produce high vibration energy at low frequency (perhaps due to slightly out-of-line shafts) and yet operate satisfactorily. Vibration produced by an incipient fault in a bearing will not be detected until its level rises sufficiently to overcome the low-frequency energy, by which time catastrophic failure may be imminent.

The main advantages may thus be classified as follows:

Simple
Cheap
Robust
Portable
Adaptable

Disadvantages are:

Insensitive
Diagnostics not possible

15.7.6.2 *Crest Factor*

Simple vibration meters often have the facility to measure peak level as well as RMS. The use of this facility, together with the overall (RMS) level, can be used to gain some further insight into the nature of a probable fault.

A typical use for this method is in the detection of faulty rolling element bearings. It may be useful to first filter the signal so as to leave only the range between 1 kHz and 10 kHz. As a bearing operates normally the peak level will remain at a constant figure above the RMS level. As a fault develops, however, the short burst of energy produced by a ball passing a fault increases the peak but does not significantly alter the RMS. The ratio of peak to RMS value therefore increases. This factor is known as the Crest Factor.

As the faults in the bearing progress, more spikes will be produced which will ultimately increase the RMS level. Therefore, towards the end of the bearing life the Crest Factor will fall (perhaps to its original value) while both peak and RMS will be elevated. By observing trends in these data (perhaps by plotting both RMS and peak level on a time graph and obtaining the Crest Factor as the difference between the two curves) the life of a bearing may be predicted.

Advantages and disadvantages are that this technique is very similar to the overall measurement method but it does allow for some diagnostics/trending.

15.7.6.3 *Constant percentage bandwidth spectrum comparison*

By frequency analysing the signals, using an FFT analyser, an overall 'picture' of the vibration signals is obtained. In order to display the full spectrum it is usual to display the frequency axis in terms of constant percentage bandwidth (i.e. log). A display from 0 Hz to 20 kHz can thus be conveniently displayed on one screen.

Spectrum comparison can be carried out by controlling the FFT analyser with a computer and software package. The computer compares the current displayed spectra with one taken when the machine was in a known 'healthy' condition.

So that small variations in spectra do not trigger alarms a reference 'mask' has to be created around the reference spectra. The mask is created by widening the bands of the reference spectrum, to allow for small speed variations, and increased in height to allow for permissible increases in vibration levels. It is possible to have several 'alarm' levels. Commonly, the maximum permissible increase would be 10× the reference mask. At twice the reference mask it is usual for the software to start to plot the trend in change of level. These trend data can be used in conjunction with data obtained previously to predict the time at which the fault will reach the trend limit (i.e. the 10× level), at which point the machine must be shut down.

These trend data may be used to safely predict that, while a fault has occurred on a particular machine, it will not become terminal before the next available convenient time for shutdown. In practice, it has been found that machines can exceed this suggested trend limit by more than a factor of two before breakdown occurs (see Figure 15.157).

The actual setting of the thresholds will, of course, have to be determined by experience with the actual process, and the above figures should only be used as guides.

As mentioned above, the software should be capable of making compensation for speed changes. If the machine only operates with minor excursions from one set speed, the actual spectral shape may not change significantly, but merely be shifted along the frequency axis. The software will be capable of tracking one characteristic frequency 'spike'. If the machine operates over a wide range of speeds the frequency characteristics may be quite different at the extremes of operating conditions. In this case it will be necessary to break up the operating range into several speed bands and record one reference spectrum (and hence create a mask) for each band. The software will track the signal within one band (as above) but when the speed range goes outside that band it will automatically switch to the next reference spectrum in the memory. This process will repeat depending upon how many separate reference spectra are considered necessary.

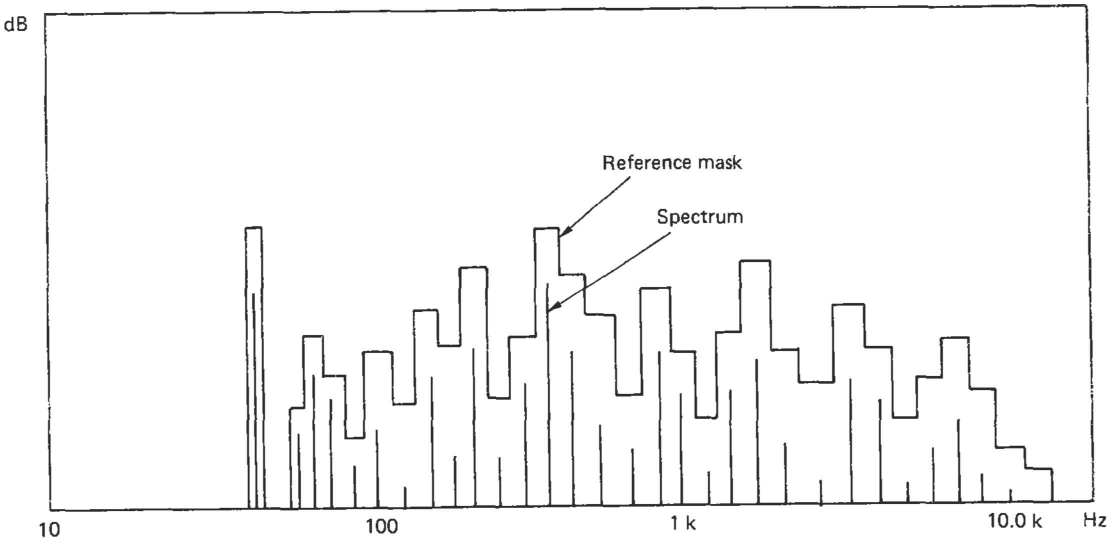

Figure 15.157 Typical reference spectrum and associated mask

15.7.6.4 Narrow band analysis

In order to study a spectrum in more detail it is usual to have the facility to magnify (or zoom) it. The frequency axis is usually expressed as constant bandwidth (as opposed to constant percentage bandwidth).

Narrow band analysis is used as a diagnostic tool (perhaps after an exceeding of a reference mask as in the previous system) and is sensitive enough to isolate the ball passing frequencies of bearings (or perhaps the higher-order harmonics if the fundamental is lost in the background noise 'floor'). This method would be used to analyse sideband build-up as would be necessary in gearbox fault diagnosis (as previously discussed).

15.7.6.5 Envelope analysis

If it is not possible to isolate a fault (in a bearing, for instance) because of interference from other sources this technique can be employed. For example, the bearing passing frequency of a rolling element bearing may be lost in the background noise. The high-frequency element (i.e. the resonance of the bearing race) will contain information concerning the repetition rate of the impacts that cause this resonance. By filtering the time signal so that only the bearing race resonant frequencies remain, the signal will be made clearer. This filtering may be carried out by the use of a high-pass filter or by the analyser's zoom facility. We are thus left with a time signal that contains the resonant frequency amplitude modulated by the impulses in the signal. If we rectify and smooth this signal we will be left with the envelope of the system still containing the impulses. This signal can then be passed through the frequency analyser to display the peak at the fault impact rate and can be identified as being one of fundamental frequencies of the bearing (i.e. BPFO, BPFI, BSF or FTF).

15.7.6.6 Cepstrum analysis

The cepstrum is a spectrum of a logarithmic spectrum (i.e. log amplitude but constant bandwidth frequency). It has the advantage of displaying periodicity in the spectrum. Families of harmonics will be well displayed on a cepstrum and random vibrations will not be displayed.

A spectrum is derived from the time domain signal by a Fourier transform which 'counts' the periodicity. i.e. a signal at 1000 cycles per second in the time domain is represented as a single line at 1 kHz on the spectrum with the amplitude being equal to the RMS time signal amplitude. In the same way, the cepstrum is a Fourier transform of the spectrum and looks for periodicity, i.e. a signal at 100, 200, 300 Hz, etc. (a harmonic series) and represents this as a single line on the frequency scale (the y-axis of the cepstrum). This technique can be very useful in gearbox and turbine fault diagnostics.

In the gearbox, for example, several faults are possible, including eccentricity of gears, single or several tooth faults or general tooth wear. Eccentricity produces an amplitude modulation of the normal tooth meshing frequency with the envelope period corresponding to the rotational frequency. At the same time, the varying contact pressure can give rise to rotational speed fluctuations (shown as frequency modulation of the tooth meshing frequency). This will give rise to a family of sidebands either side of the tooth meshing frequency with a spacing equal to the modulating frequency (i.e. the rotational frequency). Similar sidebands will occur around the harmonics of the tooth meshing frequency.

A single tooth fault will produce a fundamental at the fault rotational frequency and also the harmonics of this frequency (these will all typically be at much lower frequencies than the tooth meshing frequency). General tooth wear will show up as amplitude modulation of the signal (in the same way as eccentricity) and will produce sidebands around the tooth meshing frequencies.

In practice, several of these effects can occur at once and many spikes will be noticed on the spectra. It can thus be almost impossible to locate periodicity by eye alone.

Cepstra can be easily interpreted, as they give a single line corresponding to each sideband spacing with a height equivalent to the average sideband height. The cepstrum is achieved in practice by taking a frequency analysis of a time signal and processing it so as to concentrate on the frequencies of interest (perhaps by the use of the zoom facility). This spectrum is then fed to a personal computer equipped with a specialized software package which controls the frequency analyser. The computer then feeds the spectrum back into the analyser as if it were a time signal. The analyser then produces a further spectrum (which is now the cepstrum of the original signal).

Cepstrum analysis can thus be used as a diagnostic tool and, in addition, may be employed for condition monitoring (by the use of a mask in the same way as spectral comparison). This may be particularly useful if the signal is particularly complex and the component to be monitored is suitable (i.e. one that is likely to produce increased harmonics or sidebands in the event of faults).

15.7.6.7 Phase between transducers

If transducers are mounted on more than one bearing housing along a shaft the phase between the vibrations can give a useful aid to the diagnostics of various faults. Static imbalance produces in-phase vibration at both ends of the shaft (Figure 15.158) and 180° out of phase is likely to be caused by a dynamic imbalance of the shaft (Figure 15.159). By placing accelerometers in more than one plane, further information can be obtained (Figure 15.160). This situation would indicate

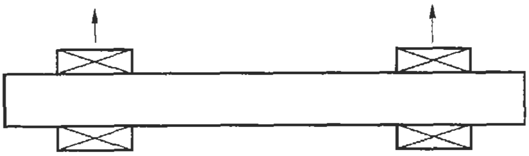

Figure 15.158

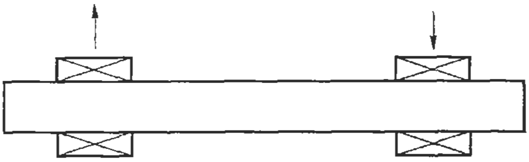

Figure 15.159

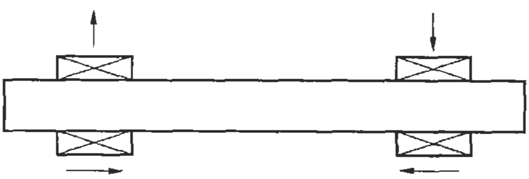

Figure 15.160

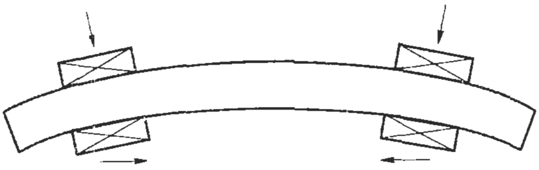

Figure 15.161

a rocking movement of the shaft (which must be caused by an external force) while the above situation would be caused by a bent shaft (Figure 15.161).

15.7.6.8 Synchronous averaging of the time domain signal

In the normal frequency analysis procedure the analyser produces the spectra of the time signal and then averages those to produce a display. The averaging time can be set by the user.

If we imagine a time signal with just two main frequencies (say, 10 Hz and 35 Hz) and their families of harmonics we may wish to analyse just one part without interference from the other. This could be achieved by synchronous time averaging. In this procedure the signals are averaged in the time domain before frequency analysis. If we took the sample rate at 10 Hz, all the 10 Hz signals would be in phase with the sampling rate and would be displayed normally. The 35 Hz signals would, however, progressively come into phase and go completely out of phase with the sample rate and would thus be averaged out to zero.

This procedure can be very useful when analysing the signals from gearboxes with multiple shafts. By choosing the right averaging period the analyser can eliminate most of the signals from the rest of the shafts and focus on the one of interest. In the case of variable-speed devices the triggering of the time domain averaging is done with the use of a trigger attached to the shaft (this can be in the form of an optical device).

If it is not possible to access the shaft in question, it may be possible to access another (perhaps the output shaft) which will be turning at a fixed ratio to the shaft in question. The optical trigger can then be attached to this shaft and fed through a device known as a multiplier. This can be set with the speed ratio of the output shaft to the shaft under examination and produces a signal synchronous with the shaft that is inaccessible.

15.7.6.9 Trending results

Trending of the increase in vibration levels may be a useful indicator in certain cases. The primary use is to predict the time to failure of rolling element bearings and wear on machines in general. Trending may also be applied to changes in oil pressure and other simple indicators, but may not be useful in the case of machines which are subject to one-off (sudden) failures (e.g. compressor turbines losing blades from fans). It may be possible to carry out trending manually; however, by far the most common procedure is to use the computer that is controlling the FFT analyser. If a computer is employed it is usual to trigger the trending procedure when a reference mask is exceeded by a pre-set limit.

The computer generates a line graph (as in Figure 15.162) and 'fits' the points to this line. The correlation (or fit) is expressed as an overall correlation (1.0 = perfect fit to the line). This trend line can then be projected onto the failure point and the lead time derived.

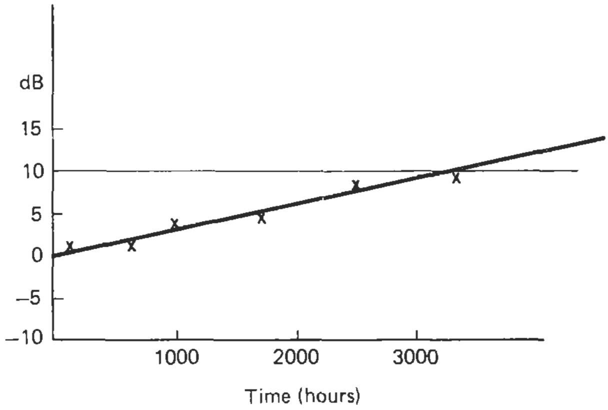

Figure 15.162 Trend curve

The lead time can only be derived accurately if a significant amount of previous testing has been conducted on other machines which have been allowed to fail while being monitored. Even then, it must be remembered that the procedure will allow a degree of statistical error (due to the nature of the actual failure perhaps being slightly different to all other recorded data). A degree of 'safety' must therefore be allowed, and it would be normal to set a shutdown level at perhaps 20 dB above normal running level.

Further information on condition monitoring can be found in references 62 and 63.

15.8 Vibration isolation and limits

15.8.1 Introduction

Vibration may be defined as the oscillatory movement of a mechanical system, and it may be sinusoidal or non-sinusoidal (also known as complex). Vibration can occur in many modes, and the simplest is the single degree of freedom system. If the mass were deflected from its rest position and released the resulting movement would be sinusoidal and decaying with time (as a result of the action of the damper). The actual frequency of vibration will depend on the undamped resonant frequency and the degree of the damping. If no damping is present the mass will always vibrate at the resonant frequency of the system. This frequency is determined by the stiffness of the spring and the mass put on it:

$$f_r = \frac{1}{2\pi}\sqrt{\frac{k}{m}}$$

where

f_r = resonant frequency (Hz)
k = spring stiffness (Nm^{-1})
m = mass (kg)
g = acceleration due to gravity

f_r can also be derived from the amount, d, that the spring is compressed when the weight is put on it (the static deflection) from the following equation:

$$f_r = \frac{1}{2\pi}\sqrt{\frac{g}{d}}$$

The displacement of the object from its rest position can be derived from

$x = x_{\text{peak}} \operatorname{Sin}(\omega t)$

where x = displacement at time t
x_{peak} = peak displacement
ω = angular velocity ($2\pi f$)

Vibration may be expressed in terms of three factors:

Displacement (m)
Velocity (m s^{-1})
Acceleration (m s^{-2})

The relationship between these factors can be expressed by the equation:

$$A_{\text{peak}} = +\omega\, V_{\text{peak}} = -\omega^2\, x_{\text{peak}}$$

For linear systems this can also be expressed as:

$$V(t) = \frac{dx}{dt} \text{ and } A(t) = \frac{d^2x}{dt^2}$$

For sinusoidal vibrations we can therefore conveniently change between displacement, velocity or acceleration units at will, either by the use of a nomograph or, more conveniently, using an integrator fitted to the measurement accelerometer (see below).

There is a phase angle of 90° between displacement and velocity and a further 90° between velocity and acceleration. Vibration may also be expressed in terms of decibels and the standard reference levels used are:

10^{-8} m s^{-1} for velocity
10^{-5} m s^{-2} for acceleration

15.8.2 Damping

The natural resonant frequency of a system is modified by the presence of damping. The damped frequency is

$$f_d = \frac{1}{2\pi}\sqrt{\frac{k}{m} - \frac{(c)^2}{(2m)}}$$

where c = damping force. This can be related to the undamped natural frequency by the following equation:

$$f_d = f_r\sqrt{1 - \frac{(C)^2}{C_c}}$$

where C_c = damping force for critical damping.

15.8.2.1 Critical damping

If the damping force is very high harmonic motion is not possible. Any displacement of the mass from rest will result in it returning exponentially to its rest position. It may be shown that this situation will occur where:

$$\frac{(C)^2}{(2m)} > \frac{k}{m}$$

This is known as supercritical damping. If

$$\frac{(C)^2}{(2m)} < \frac{k}{m}$$

and the mass is displaced and released it will oscillate at the damped natural frequency (see above) and the oscillation will decrease in magnitude with time (decaying more quickly at higher damping rates).

The effect of damping may be shown by Figure 15.163, where

$$\text{Dynamic magnification factor} = \frac{\text{disp. mass}}{\text{disp. base}}$$

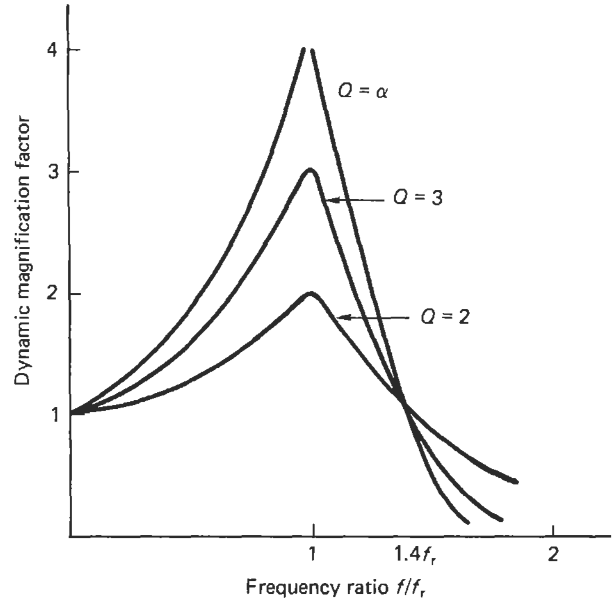

Figure 15.163 Response of damped system (f_r = natural resonant frequency of system)

The Q-factor (the dynamic magnification at resonance) is often used as a measure of damping, i.e. for no damping $Q = \alpha$.

In practice, all mass/spring systems have some natural damping (dependent upon the nature of the spring) and this will tend to reduce the theoretical infinite excursions at resonance.

15.8.3 Multi-degree of freedom systems

Until now we have only concerned ourselves with one mass/spring system. In practice, it is more usual to find multi-degree of freedom systems. These may be considered in terms of Figure 15.164. At low frequencies all the masses will remain coupled as there is low inertia in the system. If the base drives the system all of the masses will move as one with all motion lost in k. As the driving frequency increases to f_{r1} (the resonant frequency of m_1) the masses will vibrate violently again as one. At frequencies above f_{r1}, the masses will be isolated from the base. As f_{r2} approaches (the resonant frequency of m_2) m_2 will oscillate violently and will impose some of its motion on m_1 (dependent on the ratio of masses m_2 to m_1). The graph showing transmissivity will, therefore, be modified by the effect of m_2 and m_3 and dips or bumps in the main transmissivity curve will occur at f_{r2} and f_{r3} (the resonant frequencies of m_2 and m_3).

15.8.4 Vibration isolation

As can be seen from Figure 15.163, above 1.4 × f_r the motion of the suspended mass is less than the motion of the base. The mass is, therefore, said to be vibration isolated.

In practice, isolation systems are chosen so that the forging frequency is between eight to ten times the resonant frequency of the mounted system. Such a simple system may be suitable for constant-speed machines (which vibrate at a constant frequency). Unfortunately, it is more normal for machines (particularly those involving rotating shafts) to start from a

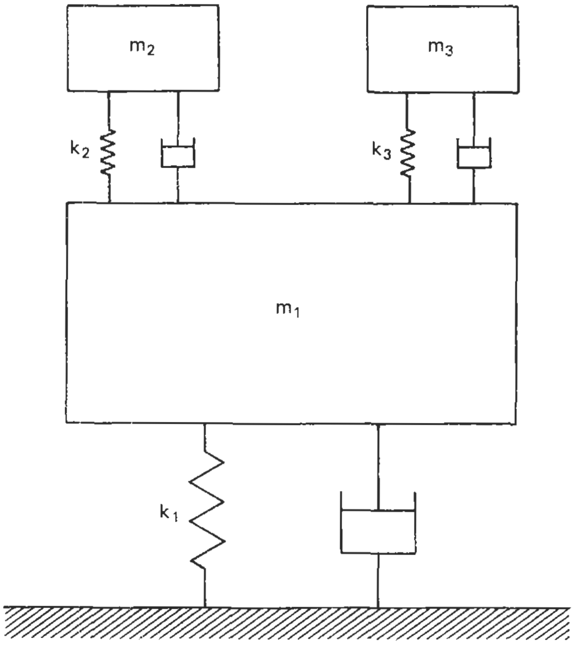

Figure 15.164 Compound mass spring damper system

standstill and accelerate to the normal running speed. For a period, therefore, the machine is likely to be vibrating at the resonant frequency of the system. The excursions of the machine mass may then become unacceptably large. If this were to be the case, damping would have to be applied to reduce the resonance. Unfortunately, this has the side effect of reducing the isolation of the mount under the normal operating conditions.

It may be that the machine will accelerate very rapidly through the resonant frequency and, in this case, the dangerous oscillations may not have sufficient time to build up. The damping could, therefore, be decreased or eliminated altogether (as most spring systems have, at least, some degree of natural damping).

15.8.4.1 Worked example of the vibration isolator selection procedure

Problem A machine has a mass of 20 kg and vibrates predominantly at frequencies between 150 Hz to 1 kHz. This machine is to be isolated from the building by four mounts attached to the four lower corners of the machine.

Solution In order to isolate frequencies greater than 150 Hz the resonant frequency should be chosen as one-tenth of the driving frequency, i.e. 15 Hz. The stiffness of the mounts required to give this resonant frequency can be determined from the formula:

$$k \approx 40 \times m \times (f_r)^2 \text{ N m}^{-1}$$

If four mounts are used the mass on each mount is 5 kg, thus

$$k = 40 \times 5 \times (15)^2 \text{ N m}^{-1}$$
$$k = 45 \times 10^3 \text{ N m}^{-1}$$

Manufacturers specify mounts in terms of the deflection at the maximum permissible imposed weight. The stiffness can be derived from

$$k = \frac{10m}{d} \text{ (N m}^{-1}\text{)}$$

where m = maximum permissible load (kg) and d = static deflection at maximum permissible load (m).

15.8.4.2 Siting of isolators

It should be remembered that a machine mounted on four springs will exhibit more than one degree of freedom of movement. It is normal to consider six degrees of freedom in such a system (three linear directions and three rotational planes). In order to simplify the calculations and to reduce rocking effects the centre of gravity of the machine must be kept as low as possible. In addition, the mounts must be placed so that they are equidistant from the centre of gravity (they will thus all carry the same load). If this is not possible due to the configuration of the machine two solutions exist.

In the first case a sub-frame is made to fit the machine and this is in turn mounted on the isolators (which may now be mounted symmetrically about the centre of gravity). If this is not an alternative, and different loads have to be carried by each mount, the stiffness of each mount is chosen to be of a different value such that the static deflection of each mount is the same when the weight of the machine is imposed on it.

If the machine is light in weight or the centre of gravity is high, unacceptable excursions may occur. In this case the solution is again to use a sub-frame, but this should incorporate a large mass which will lower the centre of gravity and increase the stiffness of the isolators for a given resonant frequency.

15.8.4.3 Compound vibration isolation

By the use of compound systems (see Figure 15.165) it is possible to increase the attenuation of the system above that possible with simple systems. These systems may also be used where vibration problems exist at one discrete frequency. An example of this type is the inertia damper. In this type the superimposed mass (m_2) is chosen to resonate at the troublesome frequency. This vibration is out of phase with the main machine and will tend to cancel out the energy of the troublesome vibration. The calculation of the exact effect of compound vibration isolation systems is beyond the scope of this work and readers are advised to consult specialist textbooks such as reference 64.

15.8.5 Shock isolation

Shock isolation has many similarities to vibration isolation but there are some key differences and it is necessary to appreciate these prior to designing a shock isolation system.

A shock may be defined as the transmission of kinetic energy to a system which takes place in a relatively short time (compared to the resonant frequency of the system). In order to study shock isolation it is necessary to appreciate the time history of the shock pulse.

Shock pulses may have different time histories and may be explained by Figure 15.166. Frequency analysis of these shocks would reveal that they contain energy spread over all frequencies from zero to infinity, with no distinct frequency 'spikes'. It may thus be seen that the isolator design techniques used for vibration isolators (which depend on frequency measurement) will not be suitable for shock isolators. If the

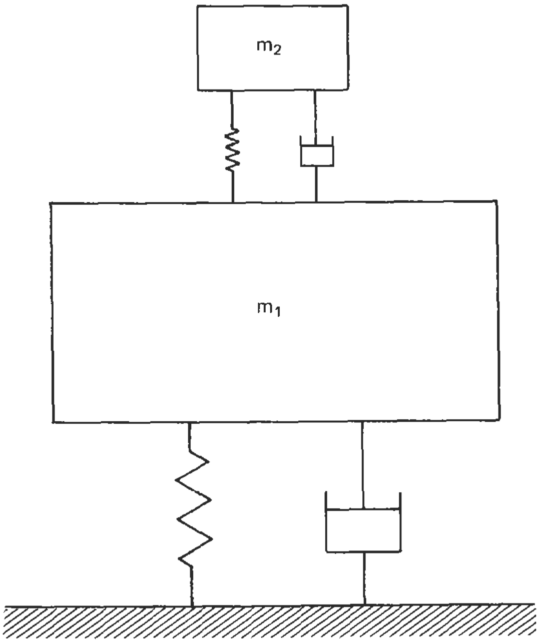

Figure 15.165 Compound system

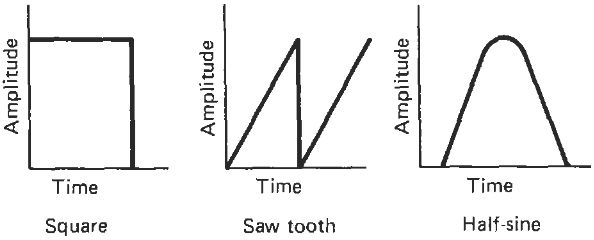

Figure 15.166 Shock pulse time histograms

time of the shock pulse is short compared to the natural frequency of the system the area of the shock pulse (i.e. the area under the amplitude/time graph) is the most important characteristic. Graphs are available for different types of pulse patterns which indicate the shock response spectra.

Knowing the resonant frequency of the system and the force acting on a body the transmitted force may be calculated. The 'force response' is therefore calculated as a fraction of the applied force. This force response will be lower with an increase in the natural period of the system compared with the time duration of the shock pulse. Shock isolation systems should, therefore, be designed with resonant frequency (rad. s^{-1}) in the order of $0.1T$. The maximum displacement of the mass can be calculated from $x = F/k$, where F = force response (N) and k = stiffness of spring (N m^{-1}) (see Figure 15.167). Similarly, velocity and acceleration may be determined from the standard relation equations:

$$V = 2\pi f_{\text{res}} \frac{F}{k}$$

$$a = 4\pi^2 f_{\text{res}}{}^2 \frac{F}{k}$$

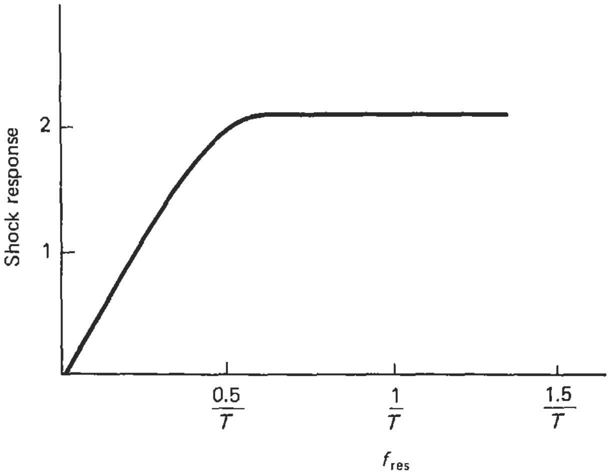

Figure 15.167 Typical shock-response curve

In practice, it may not be easy to assess the likely shock forces on a system mathematically. In this case we may have to resort to the measurement of a test system (see Section 15.8.7) and then produce a 'real' system once the experimental data have been manipulated.

15.8.6 Vibration attenuation

As in noise control, vibration reduction can follow three distinct phases:

1. Reduction of vibration at source
2. Interruption of transmission
3. Protection of affected persons/machines, etc.

15.8.6.1 Reduction of vibration at source

Vibrations may be produced acoustically by out-of-balance forces on rotating components, electrical forces, worn bearings, poor gear meshing and numerous other causes. In the first instance, reduction at source should be considered. This may have the added advantage of improving the efficiency and life of the machine in question. Frequency analysis techniques may be used to isolate the precise source of the vibration (see Section 15.7). Worn or defective components can be dealt with as the first stage of vibration reduction. Out-of-balance forces may be investigated and, if found to be excessive, shafts, etc. should be balanced.

If resonance is found to be a problem, machine rotational speed may be altered in order to take exciting forces away from the resonant frequency range (this is unlikely to be suitable in many cases). This method may be adopted for fans, etc. The flow volume may be maintained by changing the pitch of blades, etc. Finally, damping of the structure may be considered; either by adopting inertia weights (in the form of adhesive backed lead mats, bolt-on weights, etc.) or by stick-on damper materials (felts and rubbers, etc.)

15.8.6.2 Interruption of transmission pathway

This is by far the most common approach to vibration isolation. If all reduction at source has been pursued, the vibrating device can be mounted on vibration isolators. Care should be taken that no 'bridging' occurs or that all services (e.g. power supplies, etc.) are mounted in such a way that they can flex as the machine moves and do not unduly restrict the movement of the machine on the mounts. The nature of the flexible connection should be such as to resist fracture of the service element.

The machine should be sufficiently far from fixed objects so that no collision can occur as the machine deflects on the mounts. Machines may be mounted on a variety of materials and their individual properties are described below.

15.8.6.3 Vibration isolation materials

Steel springs These are suitable for all frequency ranges (as the stiffness may be easily tailored to suit loadings and hence the required resonant frequency). They are, however, most suitable at low frequency. They have the disadvantage of having low internal damping and hence readily transmit high frequencies.

High-frequency transmission is usually overcome by mounting the spring with rubber washers at each end. The steel spring has the advantage of being easy to produce at the required stiffness and is not subject to degradation by oils, etc. It is also tolerant of relatively high temperatures. It is, therefore, the first choice for anti-vibration mounts. Damping is achieved by the use of external damper elements. Steel springs are available as helical compression, helical tension or leaf springs. Leaf springs have the advantage of having higher internal damping. All steel springs can be constructed so as to have a non-linear action.

Rubber mounts Although termed 'rubber' mounts, these are often composed of synthetic rubbers which are not so readily attacked by oils and can operate over a much wider temperature range. The rubber is usually mounted onto a steel base (although it may be used in simple 'mat' form) and may be in compression, shear, or shear-compression (depending upon the configuration of the mount).

Different frequencies may be catered for by changing the hardness of the rubber, but the usual use for rubber mounts is for high-frequency isolation. Damping is better than steel springs but decreases with an increase in the hardness of the rubber.

Mats Machines, etc. may be simply mounted on mats of isolation material and common materials are rubber, cork, foam or felt. These have the disadvantage of having a low static deflection (and hence are only capable of high-frequency attenuation on relatively light machines).

A development of the simple mat is the ribbed rubber mat. In this version higher static deflections are possible and hence lower-frequency control. All mats have the disadvantage of having to be placed under the machine and are hence liable to degradation from oils, etc.

15.8.6.4 Isolation of structures

If it is not possible to mount the machine directly on suspension type mounts the building may be treated as a whole. The isolation of the pathway may start at the machine and continue through isolation of the machine foundations (perhaps by isolating the concrete slab with resilient material) up to complete isolation of a building housing vibrating machines. It is obviously most cost effective to deal with the vibration at the most practicable point near to the machine (as there is less mass to be isolated).

15.8.6.5 Protection of affected persons/machines, etc.

Another approach to vibration isolation is to isolate the affected persons/machines. This will only be practicable if a limited number of positions have to be protected. This method may prove cost effective if the only other alternative would be major structural isolation (if machine isolation was not practical).

Examples of this approach are the suspension in the driver's seat of heavy lorries right up to 'floating' noise refuges in press shops. The vibration isolation principles are exactly the same as vibration source isolation, and similar isolation materials are used.

15.8.7 Measurement of vibration

Vibration measurements are almost universally carried out by the use of accelerometers (these measure acceleration). Other types of vibration transducer are available but are not as adaptable as the accelerometer (at one time it was common to use velocity-sensitive devices). If velocity or displacement measurements are needed it is usual to carry this out electrically on the acceleration signal by means of an integrator.

15.8.7.1 The accelerometer

The majority of accelerometers marketed are of the piezoelectric type. The construction is essentially as shown in Figure 15.168. In this type of accelerometer two disks of piezoelectrical material are trapped between the base of the device and a heavy mass (which is located in position by a spring). When the device is subjected to a vibration the mass exerts a variable force on the disks and generates an electrical output (proportional to the force on the disks). The output is, therefore, proportional to the acceleration of the mass.

The mass will have a resonant frequency which will depend on the weight of the mass and the stiffness of the mounting system. It can be shown that below this resonant frequency (which is commonly in the order of 10–100 kHz) the output of the device will be linear when plotted against frequency.

The actual output (in terms of milli-volts/g) will depend upon several factors, including the piezoelectric properties of the disks and the size of the mass. For a given disk material the output will be primarily governed by the size of the mass (the largest masses giving the largest output).

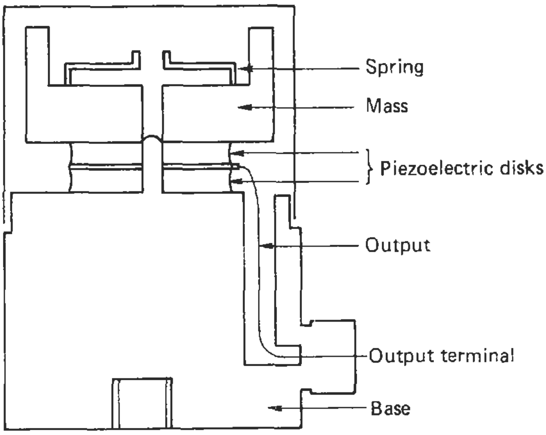

Figure 15.168 Schematic drawing of a piezoelectric accelerometer

Unfortunately, the disadvantage of a high mass transducer may outweigh the voltage gains, as the device may affect the performance of the system to which it is attached (a fundamental design feature of any transducer is that it should not significantly affect the system which it purports to measure). Also the resonant frequency of the accelerometer will be reduced as the mass increases (although this may not be significant at the frequencies we are interested in). Manufacturers supply calibration certificates for each transducer they sell which will give the sensitivity and the frequency at which resonance occurs (usually in graphical as well as numerical form). Graphs are also available so that one may choose the most suitable type of accelerometer for a particular test. An example of such a graph is given in Figure 15.169.

Other factors to consider in choice of accelerometer are:

1. Transverse sensitivity
2. Operating temperature range
3. Acoustic environment
4. Long-term stability

15.8.7.2 Transverse sensitivity

The sensitivity of the accelerometer to vibrations in planes other than in line with the main axis of the device is known as transverse sensitivity. Measurements of this factor are usually carried out perpendicular to the main axis. A good accelerometer should have a low response to this test (one manufacturer quotes less than 3% of the main axial response at low frequencies).

15.8.7.3 Temperature range

Normal operating temperature ranges are up to 250°C and a good-quality device should operate satisfactorily at this temperature (and remain sealed to prevent the ingress of water vapour). Special devices are obtainable which will allow higher operating temperatures (up to 400°C). Temperatures down to −100°C are no problem (except that voltage sensitivity increases slightly).

15.8.7.4 Acoustic environment

It is inevitable that acoustic noise will be present adjacent to all vibrating bodies. The effects of this noise on the device must be considered. Specifications may be given in terms of v/bar. A typical acoustic interference figure may be 1 mV at 140 dB compared to the output at, say, 50 mV g^{-1}). At low vibration levels allowance may have to be made for this effect.

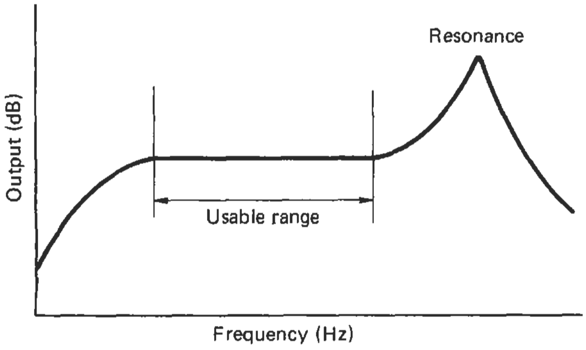

Figure 15.169 Frequency response of an accelerometer

15.8.7.5 Other vibration measurement devices

Devices other than the accelerometer may be used for special applications. These include:

Velocity pick-ups
Displacement transducers
Strain gauges

Velocity pick-ups These are commonly used at low vibration levels at low frequencies. The accelerometer may be at a disadvantage here if information is needed in terms of velocity or displacement as the electronic integration of low-level signals may not be possible. Velocity pick-ups usually operate on either the moving coil or moving magnet principles and have output as high as 350 V m s^{-1}.

Displacement transducers There are two general types: the non-contacting or the contacting. The non-contacting (or proximity sensor) type usually work by capacitive or inductive means. The sensor is brought near to the vibrating object and, as the distance between it and the sensor changes, the capacitance (or inductance) changes and this can be measured electrically. The contacting types actually touch the object which is vibrating and operate an electrical device directly. This type have the disadvantage of damping the object in question and also require very accurate manufacture if they are not to fail early.

Strain gauges A strain gauge measures displacement between two points on the surface of an object (i.e. how much it stretches). The other types of transducer are not suitable for this measurement. These gauges are important in assessing the likely failure of materials when subject to stress. In these devices the active element is stretched by the motion, causing electrical resistance of the material to change. This is measured by 'bridge' amplifiers (which can also be fitted with compensation links to cancel out such effects as temperature change).

15.8.7.6 The measurement system

In vibration assessment it is often important to determine not only the level of the vibration but also the frequency characteristics. The most simple systems consist of a sensing device (often the accelerometer), an amplifier and some form of display (the meter). This system gives no frequency information and is therefore of little use for general application (although it may have specific uses – for example, in machine condition monitoring).

A more practical system involves the use of an analyser (either of the octave/third octave or narrow band type). Such a system can be represented by the schematic shown in Figure 15.170.

For vibration application it is particularly important to study the manufacturer's specifications so that inaccuracies are not introduced. The selection of suitable matching equipment may be made simpler by choosing all equipment from one supplier only. Phase and impedance effects are so crucial at low frequency that the writer would advise all but the most experienced that this is, perhaps, the most significant point to note in all vibration work.

15.8.7.7 Amplifiers

The factors likely to be considered in amplifier choice are:

1. *Frequency response* The response should be linear over the range at which measurements are to be performed.

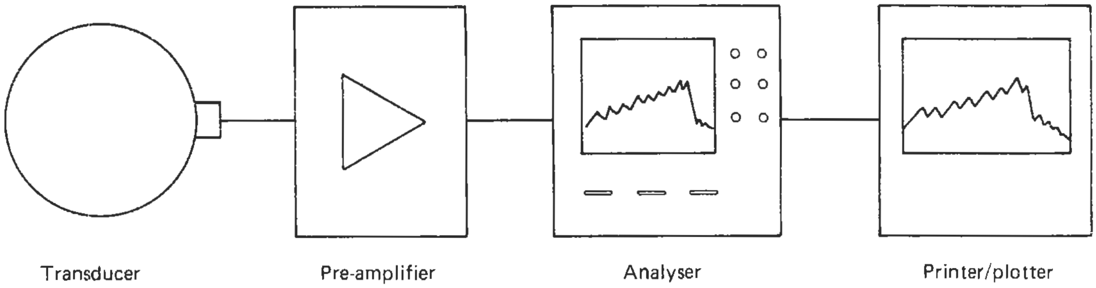

Figure 15.170 Schematic vibration analysis system

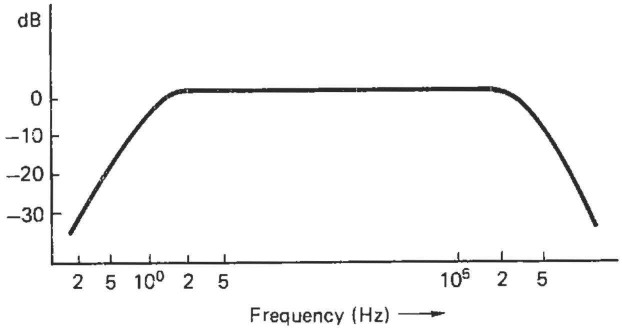

Figure 15.171 Typical amplifier frequency-response curve

The specification may either be given numerically in terms of a 3 dB change in output (e.g. 2 Hz to 200 kHz) or may be displayed as a response graph (Figure 15.171).

2. *Phase* All amplifiers distort phase to a greater or less extent; with complex signals this phase change will cause signal distortion. The phase relationship of periodic sine waves leads to the characteristic shape of the signal (e.g. square wave, saw tooth, etc.) being modified. If the phase of the high- or low-frequency components is changed as compared to the middle frequencies the characteristic shape will be distorted.

15.8.7.8 Harmonic distortion

Amplifiers have a tendency to introduce harmonic distortion (i.e. the generation of multiples or sub-multiples of the original signal). In the case of vibration measurement we may be trying to measure actual frequency harmonics (as in the case of out-of-balance shafts). If these are masked by electronically generated harmonics then actual vibration harmonics may be swamped. Amplifiers with low harmonic distortion should be specified for vibration work and they must never be overloaded.

15.8.7.9 Dynamic range

The dynamic range of an amplifier is the ratio of the lowest to the highest inputs which may be accepted without changing ranges on the controls. The higher the dynamic range, the better, as range-changing may not be possible with rapidly fluctuating signals. Dynamic range should be compared to harmonic distortion figures as high harmonic distortion occurs when overloading (or clipping) occurs. Pure sine waves will be changed to a flat top (or square wave) shape and extra harmonics rapidly produced.

As a general rule, the ideal operating range of an amplifier (if phase change effects are to be avoided) is ten times the lower-frequency −3 dB point to one-tenth of the high-frequency 3 dB cut-off point.

15.8.7.10 Transient distortion

Transient distortion is that produced when the rise time of the signal is too great for the amplifier to cope with. Again, overload type effects occur and (depending on the level of the signal) distortion or reduction in the response takes place.

15.8.7.11 Frequency analysis

Vibration limits are usually expressed graphically as it is the frequency of the vibration that is often as important as its actual level. It is therefore important that some knowledge of the frequency of the signal is gained. The same frequency analysis equipment as is used for work on acoustic noise is employed, but some special characteristics have to be considered.

The most important point is the likely frequency range to be used. Machinery vibration, in the past, was often at low frequency (perhaps 100 Hz or below) but with modern high-speed machines it is now important to have the ability to measure up to, say, 5 kHz. It is most important, however, that the lower frequencies are accurately measured as it is these that are likely to contain the most energy.

15.8.7.12 Octave analysis

In order to perform octave analysis the signal has to be passed through a series of filters, one at a time. The audible frequency spectrum is divided up into ten bands whose centre frequencies and bandwidths are agreed by international standards. These band centre frequencies are:

32.5, 63, 125, 250, 500, 1k, 2k, 4k, 8k, 16k (Hz)

It should be noted that the centre frequency of each band is twice that of the one below it. Similarly, the upper frequency of each band is twice its lower frequency. The upper and lower frequency of each band can be found from:

Lower frequency $= 1/\sqrt{2} \times$ centre frequency
Upper frequency $= \sqrt{2} \times$ centre frequency

Therefore the band centred on 1 kHz stretches from 707 Hz to 1414 Hz. The 2 kHz band stretches from 1414 Hz to 2828 Hz.

The disadvantage in using octave filters for vibration frequency analysis is that the bandwidth is often too wide for any really useful analysis. Also, the filters have to be used sequentially; this may be of no use when transients are involved as the signal may be 'missed' by one filter. The only option here would be to tape record the signal (onto a precision FM tape recorder) and play the tape back through each filter in turn.

15.8.7.13 One-third octave filters

A development of the octave filter set is the one-third octave filter set. In this progression each centre frequency is

$\sqrt[3]{2} \times$ previous centre frequency
Upper frequency $= \sqrt[6]{2} \times$ centre frequency
Lower frequency $= 1/\sqrt[6]{2} \times$ centre frequency

Therefore the band centre on 1 kHz extends from 891 to 1122 Hz.

The third octave filters go some way towards overcoming the limitations of the octave filter set in terms of bandwidth but they exacerbate the problem of having to sequentially filter the signal. The answer to these problems is the use of a frequency analyser.

15.8.7.14 The FFT frequency analyser

A more detailed description of the FFT (Fast Fourier Transform) analyser will be found in Section 15.9.19, but it should be noted that for vibration work this instrument has many advantages compared to the use of filter sets.

The FFT analyser is usually supplied as a self-contained unit or as an add-on unit to a personal computer. It is normal for the machine to operate in the time (as well as the frequency) domain. It is therefore relatively simple to track a time-domain graph to the point of interest (perhaps a transient) and then perform a frequency analysis at this point. This task would be almost impossible without this machine. The FFT analyser may be capable of operating in narrow bands, one-third octaves and octaves at the touch of a switch. All filters are accessed in parallel and hence no sequence is necessary. The results may be either printed as numerical data or plotted graphically.

15.8.8 Vibration limits

Vibration limits are set in order to protect personnel, equipment and buildings from the deleterious effects of the vibration. Numerous sources may be researched for criteria. These include ISO (International Standards Organization),[65,66] DIN (German standards) and scientific journals. The effects of vibrations and some suggested limits are detailed below.

15.8.8.1 Effects of vibration on people

The effect of vibrations on people can be further divided into

1. Vibration-induced noise effects
2. Vibration-induced nuisance
3. Ill health or poor performance caused by vibration

Noise effects Vibration may be transmitted over large distances by structures or objects and then re-radiated as noise at a structure/air interface. The noise limits given in the section on Noise Control then become applicable. Noise reduction is usually achieved by vibration reduction at source or isolation of the transmission pathway.

Vibration-induced nuisance There are no defined limits as to the level of vibration that is likely to constitute a nuisance and very little case law exists. It should be noted, however, that nuisance levels are probably very little above perceptible levels in the domestic environment. Early work on the effects of vibration on people has led to a set of curves being accepted as reasonably representative of the response of the average person (Figure 15.172).

Ill health or poor performance The body is a complex structure that, when subject to vibration and shock, may exhibit physical and psychological effects. Physical effects may be caused by structural resonance within the body:

At 3–6 Hz the thorax/abdomen system resonates
At 20–30 Hz the head/neck system resonates
At 60–90 Hz the eyeballs resonate
At 100–200 Hz the lower jaw resonates
The skull itself has internal resonances between 300 and 900 Hz.

Apart from physical damage to the body these vibrations cause psychological effects. Again, data is rather limited but some research has been carried out to determine perception, discomfort and pain threshold.

ISO curves are available which give acceptable time periods at differing acceleration levels (Figure 15.173). These curves give the 'fatigue decreased proficiency boundary', i.e. the maximum allowable acceleration with no noticeable decrease in performance. The suggested maximum exposure limits are twice (6 dB upwards) these levels. Perception would be at one-third of these levels.

15.8.8.2 Effects of vibration on machinery

The most common defect in machines caused by excessive vibration is the mechanical failure of a part caused by fatigue. Other failures may be caused by electrical failures due to contacts failing in switches or similar devices, or by physical damage caused by two components being forced into contact with one another.

Stress cracks form in materials which are subject to excessive vibration levels. The exact degree of damage caused will depend on numerous factors but these will include a factor which will depend on the nature of the material, the number of stress reversals and the strain placed upon the material.

If a number of similar samples are subject to the same fatiguing experiments all will not fail at the same time. Some will fail early, some will fail very late, but the majority will fail between these two limits. The actual failure of one sample can be predicted statistically within confidence limits by this experimental process. Other failures of machines can be predicted by experimental or calculus means,[67] although the former method will still be subject to the statistical failure effect.

Failure due to collision of components may be easier to predict and may occur more precisely at the predicted vibration levels (particularly if structural resonance is involved). If complex modes of vibration are encountered it may be possible to model the situation with the use of computer programs.

While on the subject of machine vibration it should be noted that ISO standards exist which grade various types of rotating shaft according to their precision of balance.

15.8.8.3 Effects of vibration on buildings

In order to produce damage to buildings vibration levels will have to be very high compared to nuisance levels. The actual degree and nature of the damage produced will depend upon the building structure – both its type and condition.

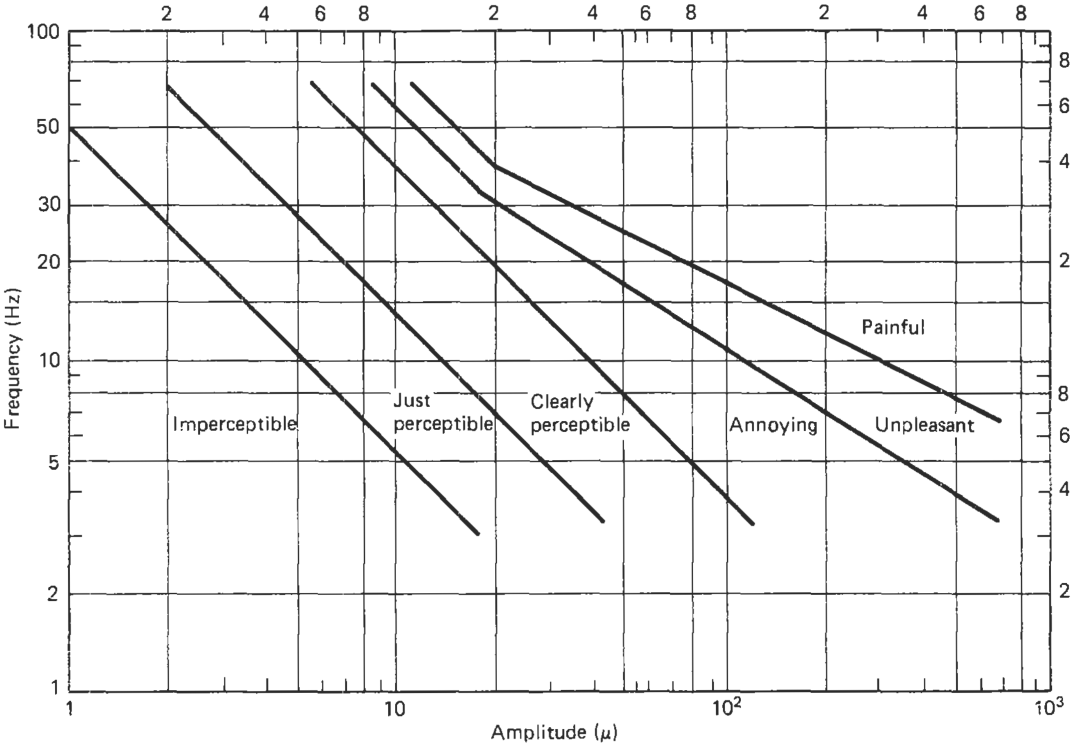

Figure 15.172 Human sensitivity: Reiher–Meister scale (vertical vibration)

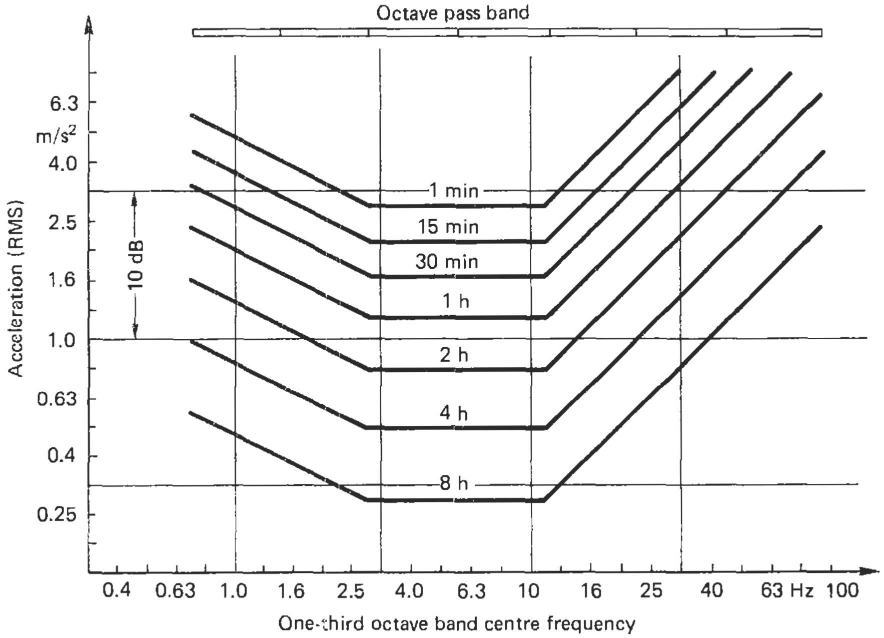

Figure 15.173 ISO vibration criteria for a person in a vertical position

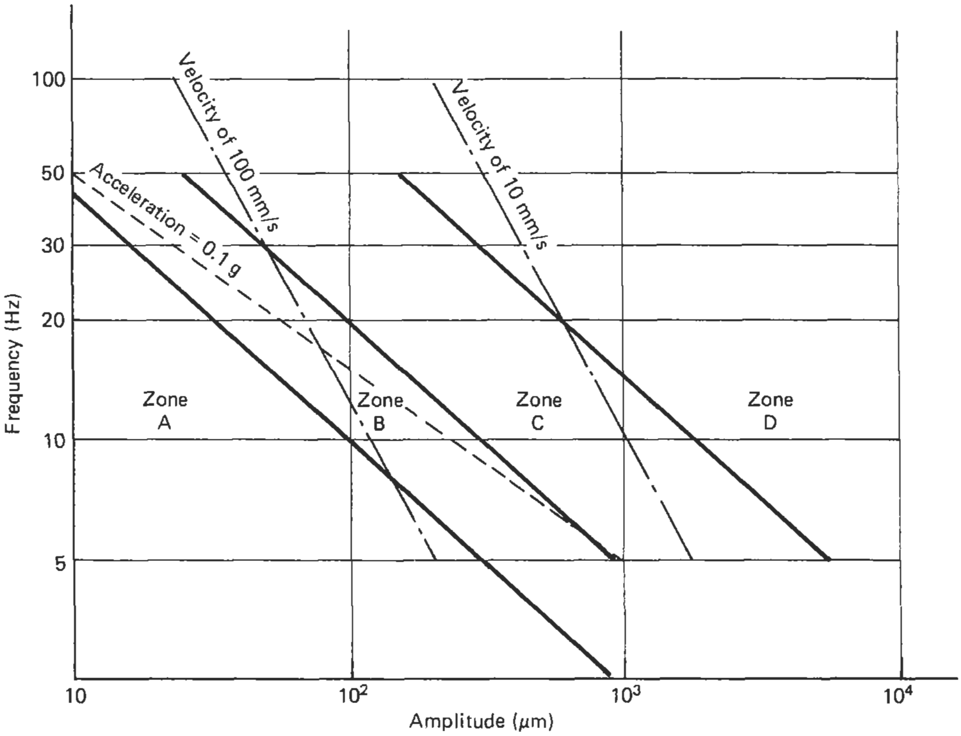

Figure 15.174 Building damage criteria. Zone A – no damage, zone B – plaster cracking possible, zone C – damage to structure, zone D – total destruction

At relatively low vibration levels cracks can occur in plaster (particularly around windows). At higher levels, structural members may crack and ultimately fail. These two types of damage may be easily attributed to mechanical vibration.

Another type of damage may result from building settlement caused by ground-borne vibrations compacting the ground differentially beneath buildings. This type of damage is indistinguishable from settlement caused by other occurrences. Specifications for maximum permissible vibrations may be found in DIN standards which are given in terms of maximum velocity (in mm s^{-1}) which is allowable for different classes of buildings from ruins and historical buildings up to reinforced concrete structures. More accurate criteria may be found in the technical press and HMSO publications. One such type of drawing is shown in Figure 15.174.

15.9 Acoustic noise

15.9.1 Introduction – basic acoustics

Sound can be defined as the sensation in the ear caused by pressure variations in the air. For a pressure variation to be known as sound it must occur much more rapidly than barometric pressure variations. The degree of variation is much less than atmospheric pressure.

Audible sound has a frequency range of approximately 20 Hz to 20 kHz and the pressure ranges from 20×10^{-6} N m^{-2} to 200 N m^{-2}. A pure tone produces the simplest type of wave form, that of a sine wave (Figure 15.175). The average pressure fluctuation is zero. Measurements are thus made in terms of the root mean square of the pressure variation (abbreviated to RMS). For the sine wave the RMS is 0.707 times the peak value.

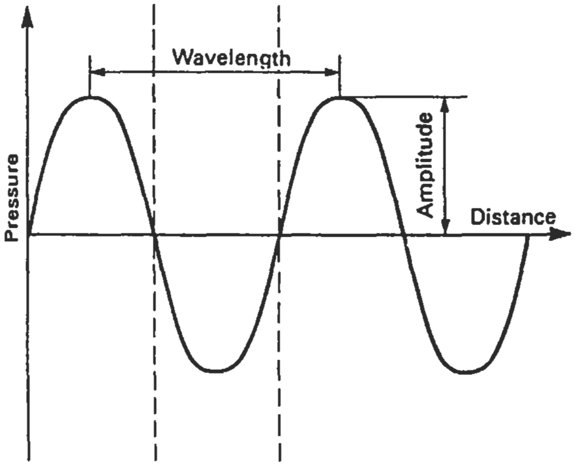

Figure 15.175 Sine wave

Since RMS pressure variations have to be measured in the range 20×10^{-6} N m^{-2} to 200 N m^{-2} (a range of 10^7) it can be seen that an inconveniently large scale would have to be used if linear measurements were adopted. Additionally, it has been found that the ear responds to the intensity of a sound ($\propto p^2$) in a logarithmic fashion. The unit that has been adopted takes these factors into account and relates the measured sound to a reference level. For convenience, this is taken as the minimum audible sound (i.e. 20×10^{-6} N m^{-2}) at 1 kHz.

The logarithm (to the base 10) of the ratio of the perceived pressure (squared) to the reference pressure (squared) is known as the Bell, i.e.

$$B = \text{Log}_{10} \frac{P^2}{P_{\text{ref}}^2}$$

Since this would give an inconveniently small scale (it would range from approximately 0 to 14 for human response), the Bell is divided numerically by 10 to give the decibel. The equation therefore becomes:

$$\text{dB} = 10 \log_{10} \frac{P^2}{P_{\text{ref}}^2} \equiv 20 \log_{10} \frac{P}{P_{\text{ref}}}$$

15.9.2 Sound intensity

Sound intensity, I, is a measure of energy and its units are watts per metre. Intensity is proportional to the square of pressure. Sound intensity level (SIL) is defined in a similar manner to sound pressure level. In this case the equation is

$$\text{dB (sound intensity level)} = 10 \log_{10}, \frac{I}{I_{\text{ref}}}$$

15.9.3 Sound power

Similarly, the power of a source (measured in watts) can be expressed in terms of decibels (in this case called the sound power level (SWL))

$$\text{dB (sound power level)} = 10 \log_{10}, \frac{W}{W_{\text{ref}}}$$

W_{ref} is taken as 10^{-12}.

It can thus be seen that it is important not only to express the unit but also to state sound pressure level (SPL), sound intensity level (SIL) or sound power level (SWL).

15.9.4 Addition and subtraction of decibels

For coherent sound waves addition of values is possible. It will be apparent that as the scale is logarithmic, values cannot merely be added to one another. Intensities can, however, be added and thus the equation becomes

$$\text{SIL (total)} = 10 \log_{10} \frac{I_1 + I_2}{I_{\text{ref}}}$$

i.e. 70 dB + 73 dB

$$70 = 10 \log_{10} \frac{I_1}{I_{\text{ref}}}$$

$$I_1 = \frac{\text{antilog } 7}{I_{\text{ref}}}$$

$$73 = 10 \log_{10} \frac{I_2}{I_{\text{ref}}}$$

$$I_2 = \frac{\text{antilog } 7.3}{I_{\text{ref}}}$$

$$\begin{aligned} \text{SIL (total)} &= 10 \log (\text{antilog } 7 + \text{antilog } 7.3) \\ &= 10 \log (2.99526 \times 10^7) \\ &= 74.76 \text{ dB} \end{aligned}$$

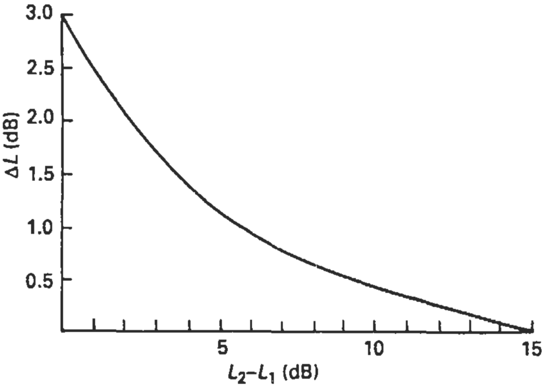

Figure 15.176 Noise-level addition graph

The square of individual pressures must be added and thus the equation in this case must utilize

$$P(\text{total}) = \sqrt{(P_1^2 + P_2^2)}$$

15.9.5 Addition of decibels: graph method

It is possible to use a graph to calculate the addition of decibels, even in the case of multiple additions (Figure 15.176). The graph is used in the following way:

1. In the case of the addition of two levels – the difference between the higher and lower levels is plotted on the lower scale of the graph. The correction is then read from the vertical scale by projecting a horizontal line across to this scale from the point on the graph. The correction is added to the highest original level to give the total level.
2. In the case of subtraction of levels – the difference between the total sound level and the one to be subtracted is plotted onto the graph and the correction obtained as above. In this case the correction is subtracted from the total level to give the remaining sound level.
3. In the case of multiple additions – if there are more levels to be added the first two levels are added using the graph and then the third is added to the resultant using the same method.

15.9.6 The relationship between SPL, SIL and SWL

The total acoustic power of a source can be related to the sound pressure level at a distance r by the following equation (assuming spherical propagation):

$$W = P^2/(\rho c 4\pi r^2)$$

where ρ = density of the medium and c = velocity of sound in that medium. By substituting this back into the SPL equation we obtain

SPL = SWL − 20 $\log_{10} r$ − 11 (spherical propagation)

It is also possible to derive equations for other common situations, i.e.

Point source on a hard reflecting plane
Line source radiating into space
Line source on a hard reflecting plane

These equations are:

SPL = SWL − 20 $\log_{10} r$ − 8 (hemispherical propagation)
SPL = SWL − 10 $\log_{10} r$ − 8 (line source in space)

$$\text{SPL} = \text{SWL} - 10 \log_{10} r - 5 \text{ (line source radiating on a plane)}$$

These equations are useful for calculating distance attenuation effects.

If the sound pressure level at distance r_0 is known it is possible to calculate the sound pressure level at position r_1 quite easily:

$$\text{SPL}_0 - \text{SPL}_1 = 20 \log_{10} r_1 - 20 \log_{10} r_0$$

$$\text{SPL}_0 - \text{SPL}_1 = 20 \log_{10} \frac{r_1}{r_0} \text{ dB}$$

If r_1 is double r_0 it will be seen that the SPL will be approximately equal to 6 dB ($20_{10} \log 2$). This gives us the principle of a decrease in level by 6 dB per doubling of distance (inverse square law). For the line source the same calculation produces a difference of only 3 dB per doubling of distance.

15.9.7 Frequency weighting and the human response to sound

In practice, noises are not composed of one single pure tone but are usually very complex in nature. It is essential that more than the overall noise level (in dB) is known in order to appreciate the loudness of a noise, as the ear does not respond uniformly to all frequencies.

As previously stated, the ear can respond from 20 Hz to 20 kHz and the response can be demonstrated by equal-loudness contours (Figure 15.177). It can be seen in Figure 15.177 that there is a loss in sensitivity (compared to 2 kHz) of approximately 60 dB at the low-frequency end of the chart. It will also be seen that all the curves are approximately parallel, but there is a tendency to linearity at the higher noise levels.

In order to produce meaningful readings it is therefore important to state the sound pressure level in dB and the frequency of the noise. A weighting can be imposed on noise readings which corresponds to the inverse of the equal-loudness contours. If this weighting is used all readings which are numerically equal will sound equally loud, regardless of frequency.

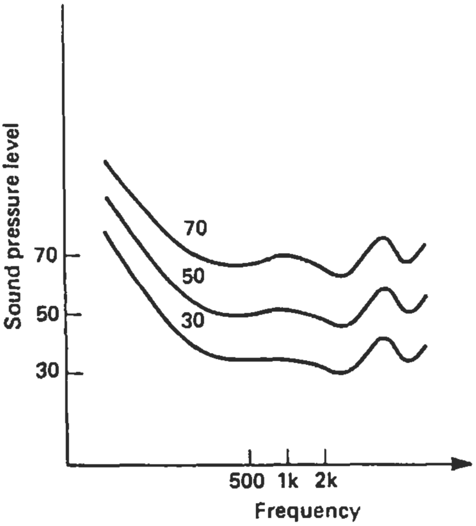

Figure 15.177 Equal-loudness contours

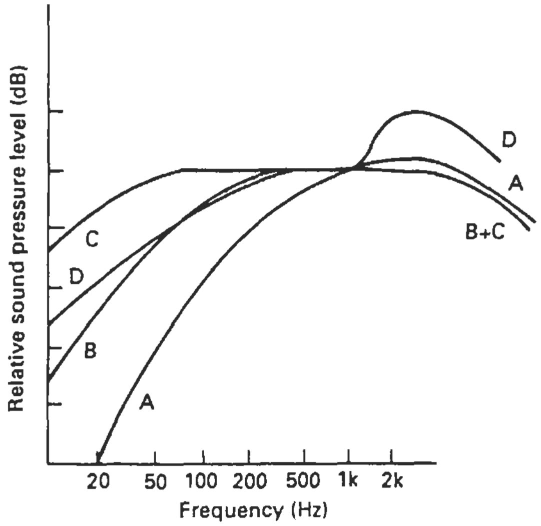

Figure 15.178 Weighting networks

Originally, three networks were proposed (A, B and C) and it was suggested that these be used for low, medium and high noise levels, respectively. It was proved, in practice, that this introduced numerous difficulties particularly with rapidly changing noise levels when a change of filter network was necessary. It was also found that the 'A'-weighting network corresponded very well to annoyance levels at all noise levels (Figure 15.178). It was therefore decided that the 'A' weighting would be used as the norm for noise readings concerning human response. There is another weighting network (the 'D' network) that is used for aircraft noise measurement.

If it is necessary for engineering purposes to know the tonal make-up of a noise, several approaches are possible. The noise can be processed by a bandpass filter. The most common filters are octave band filters and the agreed centre frequencies are as follows

31 63 125 250 500 1k 2k 4k 8k 16k (Hz)

If further resolution is necessary, one-third octave filters can be used, but the number of measurements that are required to be taken is most unwieldy. It may be necessary to record the noise onto tape loops for the repeated re-analysis that is necessary. One-third octave filters are commonly used for building acoustics.

Narrow band real-time analysis can be employed. This is the fastest of the methods and most suitable for transient noise. Narrow band analysis uses a visual display screen to show the graphical results of the fast Fourier transform (FFT) and can also provide octave or one-third octave bar-graph displays.

15.9.8 Noise indices

All the previous discussions have concerned steady-state noise. It will, however, be apparent that most noises change in level with time. It may therefore be necessary to derive indices which describe how noise changes with time. The commonest of these are the percentiles and equivalent continuous noise levels.

Percentiles are expressed as the percentage of time (for the stated period) during which the stated noise level was exceeded, i.e. a 5-minute $L90$ of 80 dB(A) means that for the

5-minute period of measurement for 90% of the time the noise level exceeded 80 dB(A). Therefore *L*0 is the maximum noise level during any period and *L*100 is the minimum.

The variation of noise levels within a discrete period of time can best be described by a set of *Ln* results (the more results available, the greater the representation of the noise event). Sound-level meters commonly measure *Ln*'s at seven points (commonly, *L*1, *L*2, *L*10, *L*50, *L*90, *L*95, *L*99). More sophisticated modern machines are capable of being adapted by the user and non-standard *Ln*'s are available.

*L*eq (the equivalent continuous noise level) is defined as the continuous steady noise level which would contain the same total acoustic energy as the actual fluctuating noise, measured over the same period of time. This concept may be understood by considering electrical power consumption. If a machine uses

4 kW for 1 hour
2 kW for 2 hours
1.5 kW for 4 hours
1 kW for 1 hour

the total usage of power is 15 kW h^{-1}. The equivalent power for the 8-hour period would be 1.875 kW.

If two events are to be added together and the *L*eq derived we must first convert to intensity units. Addition may then take place directly using the equation:

$$Ieq = \frac{1}{T}(I_1t_1 + I_2t_2 + I_3t_3 \ldots)$$

where T = total time, I_1 = intensity for the first event, t_1 = time for the first event, I_2 = intensity for the second event, t_2 = time for the second event, etc. The total intensity is then converted back to decibel units by

$$\text{dB(A)} = 10 \log_{10} \frac{I}{I_{\text{ref}}}$$

where I_{ref} = reference intensity. However we usually know the levels in terms of dB(A) rather than intensities, therefore by substitution

$$Leq = 10 \log \frac{1}{T}(t_1 \times 10^{L_1/10} + t_2 \times 10^{L_2/10} + t_3 \times 10^{L_3/10})$$

where L_1 = level 1 in decibels, etc. As noise is often measured on the 'A'-weighted scale *L*eq is usually expressed in this way. In this case the nomenclature becomes *L*Aeq.

A further derivation of equivalent continuous level is the single-event level (SEL), also known as sound-exposure level or *L*ax. This a special type of *L*eq used for transient events such as the passage of aircraft, gunshots, etc. The SEL is a one-second *L*eq and can be defined as the steady level which over one second would contain the same 'A'-weighted energy as the actual event (regardless of its duration). Thus

$$Leq = 10 \log \frac{1}{T}(t_1 \times 10^{L_1/10} + t_2 \times 10^{L_2/10} + \ldots \text{etc.})$$

$$\text{SEL} = 10 \log (t_1 \times 10^{L_1/10} + t_2 \times 10^{L_2/10} + \ldots \text{etc.})$$

where $t_1 + t_2$ etc. are the durations of levels L_1, L_2, etc. in seconds.

15.9.9 Noise-rating curves

These are a set of graphs that are commonly used as a specification for noise from machinery. They are similar to Noise Criteria Curves (used in the USA to specify noise from ventilation systems). The rating of a noise under investigation is the value of the highest noise-rating curve penetrated by the readings when plotted on the graphs (Figure 15.179).

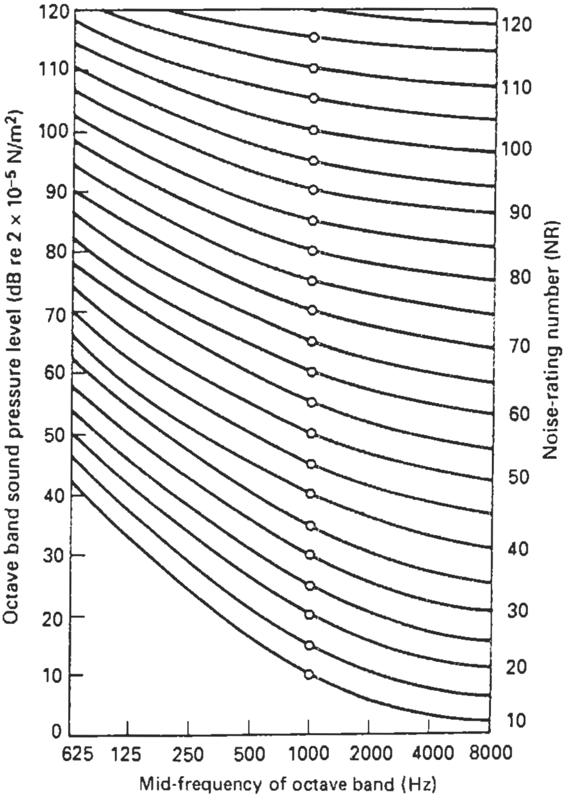

Figure 15.179 Noise-rating curves

15.9.10 Community noise units

Noise has been defined as unwanted sound. To quantify noise is therefore much more complicated than to quantify sound itself (which is what we have previously considered). Units have to be derived from these purely acoustic measurements by assessment of experimental psycho-acoustic data. It has been found that the response to different types of aural stimulation cannot be described by one single measurement, and hence a number of different noise measures are used. We now have three distinct classes of measurement:

1. Noise Units – these are the basic physical measurements of sound (i.e. decibel).
2. Noise Scales – these are composed of a combination of physical measurements (usually sound level, time, etc.) (i.e. *Ln*'s, *L*eq, SEL).
3. Noise Indices – here other factors are used to modify the noise scales in order to more closely relate the noise scale to other factors (annoyance, for instance)

A criterion is a noise index value which is used to describe the reaction of a given percentage of the population.

15.9.11 Road traffic

Road traffic is assessed by an 18-hour *L*10. This is not the percentile for 18 hours but rather the arithmetic average of the

18 one-hour $L10$'s between 6 a.m. and midnight on a normal working day.

15.9.12 Air traffic

It has been found that annoyance caused by aircraft flyovers is related to the average value of the maximum perceived noise levels and the number of events. The index is known as NNI (noise and number index) and is obtained from:

$$\text{NNI} = Lpn(\text{max}) + 15\log(10N) - 80$$

where $Lpn(\text{max})$ is the logarithmic average of the maxima of the flyovers and N is the number of flyovers.

15.9.13 Railway noise

Railway noise is assessed in *L*eq units. 65 dB(A) *L*eq is the usual criterion at which double-glazing is fitted where new housing is built near to railway lines.

15.9.14 Noise from demolition and construction sites

Hourly *L*eq is used as the index.

15.9.15 Noise from industrial premises

British Standard 4142: 1990 is described in detail in Section 15.9.25 and is derived from the noise measured in *L*eq compared to a background level measured in *Ln*.

15.9.16 Measurement of noise

The simplest sound-level meter consists of a microphone, an amplifier and a meter of some type. Sound-level meters are graded according to British and international standards. For most precision work a Type 1 (precision) sound-level meter is used. This has an accuracy of approximately ±1 dB(A). Type 0 meters (laboratory) grade are rarely encountered. Type 2 (industrial) grade sound meters may be suitable for some initial survey work but may not be sufficiently accurate to comply with legislative requirements at all frequencies. In particular, the lower grade of instruments have poor performance above 10 kHz (the human ear responds to noise at least up to 16 kHz).

15.9.17 Microphones

The microphone is a device for converting pressure fluctuations in the air into an electrical signal. For precision work two types may be chosen. The polarized condensor microphone consists of a very thin metal diaphragm stretched in close proximity to a back plate. This diaphragm is charged to a polarization voltage of 200 V (some are lower). The diaphragm thus forms a condensor with the back plate. Sound causes the diaphragm to move in relation to the back plate, thus changing the charge on the condensor. This can be sensed electrically and used to measure the sound.

The pre-polarized (or electret) microphone is a development of the polarized microphone, the main difference being that the charge across the diaphragm is permanent (or almost) and no polarization is needed (which simplifies the electronics of the pre-amplifiers). The disadvantage of the polarized microphone is that it is very moisture sensitive. Condensation on the diaphragm may result in electrical breakdown which causes sparks. These damage the diaphragm, thus ruining the microphone. The pre-polarized microphone has the disadvantage of slightly reduced long-term stability (although this has now been largely overcome). Other types of microphone have been used – notably the piezoelectric type – but these are not suitable for anything more than the most basic noise 'survey' meters.

Microphones should be capable of measuring the pressure changes in the air without altering the pressure waves they are trying to measure. This may seem to be a fairly fundamental point but, unfortunately, this is not physically possible. The diagphragm must have sufficient frontal area in order to capture the pressure wave and hence produce a reasonably sensitive output. Some reflections will occur at the diaphragm and hence produce addition and/or cancellation effects with incoming pressure waves. This effect will differ depending upon the angle of incidence of the sound on the diaphragm and the frequency of the pressure fluctuations.

In the past it was necessary to have 25 mm diameter diaphragms in order to get a sensitive response and reflection errors were a significant problem. It is now common to employ 12 mm diameter microphones and these problems are now reduced. There are, however, still many specialized microphones produced but they fall broadly into three types:

1. *Pressure microphones* – used for measuring sound in ducts, etc.;
2. *Free field* – used for measuring sound (usually out of doors) in which the angle of incidence is at 0° to the centre line of the microphone; and
3. *Random incidence* – used for measuring sound (usually indoors) in a reverberant field where the angle of incidence is more random.

Note that most precision sound-level meters are fitted with a switch which can change electronically the response between free field and random response.

For infra-sound (sound below the normal audible range) measurement special microphones may have to be used. Although some ordinary microphones are capable of operating at low frequency, great care has to be exercised in impedance matching if low-frequency cut-off is to be avoided.

15.9.18 The sound-level meter

The precision sound-level meter incorporates the pre-amplifier in the nose of the meter (usually in the stem that the microphone fixes on to). The main amplifier is contained within the body of the meter and may either be auto ranging or may have one or more user-adjusted ranges. In older instruments the range had to be adjusted in 10 dB steps (which was very awkward to use with rapidly changing noise levels). Simple sound-level meters merely display the output of this amplifier onto an analogue meter (Figure 15.180).

Modern sound-level meters are equipped with internal filters and intergrating circuits and can produce outputs in terms of percentiles, *L*eq and frequency spectra. Some sound-level meters have a computer-controlled circuitry that is addressable from a ROM cartridge which is inserted to load a program and then removed. These sound-level meters can then perform many functions as several cartridges are available. The sound-level meter thereby becomes dedicated to one particular type of task.

Memory power of sound-level meters is increasing daily and it is now common to hold many sets of data (for instance, percentiles) in the sound-level meter memory and download later (perhaps in a kinder environment) either to a printer directly or to a personal computer. If the PC option is chosen the data can be introduced to a graphics program and results displayed in a chosen graphics format which can produce elegant displays.

Digital outputs are available on most sound-level meters which will enable connection to portable computers if much

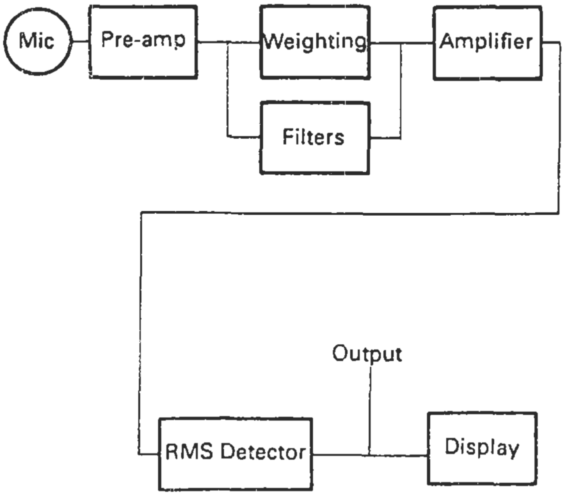

Figure 15.180 Schematic diagram of a sound-level meter

greater memory is required (or if on-site processing is chosen). Sound-level meters are also equipped with a.c. or d.c. outputs which will enable the connection of tape recorders, etc.

Ruggedized sound-level meters are available which are designed for leaving out of doors. These devices (often referred to as environmental noise analysers) are fitted into steel weathertight cases and have a large battery capacity (and the provision for external battery connection). They are fitted with their own printers. Battery and paper life is in the order of six days. Longer life may be obtained by the use of external batteries and minimizing the amount of data being printed to the paper roll.

15.9.19 Digital signal analysis

While analogue filtering of signals may be of some use, as previously described, if detailed information is needed inevitably digital processing is called for. The principle of frequency analysis is known as Fourier Analysis. The Fourier series states that any complex signal can be represented as a series of sine waves of various frequencies, magnitudes and relative phase angles.

An example of this is the square wave. This signal may be represented by the series of sine waves composed of the fundamental frequency – a sine wave at three times the fundamental and one-third of the amplitude, a sine wave at five times the frequency and one-fifth the amplitude, etc., with the progression carrying on to infinity. Electrically, this process is known as FFT (Fast Fourier Transform) analysis. The narrow band FFT analyser displays this signal graphically (as a display with frequency on the x-axis and amplitude on the y-axis).

Octave or one-third octave analysers usually employ digital filters which are arranged such that real-time analysis is possible (where the whole of a signal is analysed rather than merely a snapshot). The sophistication of the machine and the required upper frequency will determine whether real-time operation is possible or not. Both types of analyser have digital outputs which will enable downloading to larger computers for further manipulation or to allow long-term storage.

It is now possible to obtain add-on hardware and software systems for existing personal computers which will enable them to be used both as statistical (*Ln* and *L*eq, etc.) and frequency analysers (both narrow and octave band, etc.). These units are now available in laptop computers. They are not, at present, being produced by the major instrumentation companies, who continue with their dedicated machinery. It has to be said, however, that the add-on units are not as fully developed as they might be.

Current developments include the provision of amplifiers and power supplies to enable microphone connection directly, and if these prove successful the end of the dedicated sound-level meter may be in sight.

15.9.20 Noise control

Noise is capable of causing psychological, physiological and pathological reactions as well as physical damage to plant, machinery and building structures. The need for the control of noise is recognized in many statutes for the protection of both workers and members of the public in their homes.

15.9.21 Noise nuisance

Section 80 of the Environmental Protection Act 1990 gives local authorities the power to serve a notice where certain classes of nuisance have occurred or may occur. The expression 'nuisance' is not defined in the Act or indeed in any other. The use of the expression 'nuisance' can be traced back to legal action as far as the thirteenth century and its meaning is now well understood.

Nuisance describes anti-social un-neighbourly behaviour, and has been taken to mean the interference with one's neighbours in their day-to-day-activities. Noise nuisance can therefore be a statutory nuisance (by virtue of the Environmental Protection Act), a private nuisance (actionable at common law as a tort) or a public nuisance (a crime). For a noise to be a statutory nuisance it must also be a common law nuisance and hence a private or public nuisance.

The concept of private nuisance is now well developed. Private nuisance is a land owner's tort and is a complaint that the use or enjoyment of his or her land has been interfered with. The nuisance only applies to the occupier of the land and not his or her family or sub-tenants.

There are two types of private nuisance. The first concerns rights attached to land (for instance, right of way) and the second to enjoyment of the land (which does have relevance to noise control). This class of nuisance is described as 'where a person is unlawfully annoyed, prejudiced or disturbed in the enjoyment of land or with his health, comfort or convenience as an occupier'. The interference must be substantial and the duration, nature and level of the noise must be considered. A single event may not therefore constitute a nuisance.

The area affected by the nuisance must therefore be considered. One often-quoted remark is taken from the case of *Sturgess* v. *Bridgam* (1879), in which Theiseger, L. J., said 'What would be a nuisance in Belgrave Square would not necessarily be so in Bermondsey'. However, care must be taken if it is to be assumed that because an area is already noisy extra noise will not constitute a nuisance. In one case another printing press in Fleet Street proved to be a nuisance (1907).

Two other legal precedents should be considered at this stage. The first concerns sensitivity. In the case of *Walter* v. *Selfe* (1851) the expression 'ought this inconvenience to be considered – not merely according to elegant or dainty modes of habit or living, but according to plain and sober and simple notions amongst the English people' was quoted. This forms a cornerstone of nuisance law and gives rise to the question of reasonableness of a nuisance. Special sensitivities are not therefore to be considered when the question of nuisance arises. This may have relevance to shift workers, for instance, who while they might expect their daytime sleep to be protected by law, may be disappointed to find that the law will only protect their property against noise that would affect the enjoyment of the average person (i.e. one who is not sleeping during the day). The second precedent concerns the case of the aggrieved person who moves next to a noise source and hence suffers a nuisance.

The law of prescription concerns private nuisances (but not public) and states that if things are done which affect your neighbour (with his or her knowledge) and continue for 20 years, you obtain the right to continue. However, this does not translate well to noise nuisance. If, for example, the noise has continued for more than 20 years but no one has been affected by it, there has been no noise nuisance and hence there can be no prescriptive right.

This can be illustrated by the case of *Sturgess* v. *Bridgman* (1879). The plaintiff was a doctor who built a consulting room at the bottom of his garden against a neighbouring property and was affected by the noise of machinery from that property. The judge ruled that as the doctor had not known about the noise until he built his consulting room no prescriptive right accrued. Therefore in the common case of a complainant moving next door to a factory the normal rules of nuisance will apply, despite the factory occupier's insistence that 'they were there first'.

15.9.22 Health effects

Exposure to noise has been shown (in clinical experiments) to cause nausea, headache, irritability, instability, argumenativeness, reduction in sexual drive, anxiety, nervousness, insomnia, abnormal somnolence, and loss of appetite, as well as the more well-known hearing loss. Generally these health effects were shown to occur at noise levels greater than 85 dB(A).

In the case of hearing damage, numerous experiments have been conducted with the aim of arriving at a safe exposure to noise. It has been found that some individuals are much more susceptible to hearing damage than others. Some people may suffer permanent damage over a few months' exposure while others may take years to develop the same damage (at the same noise levels).

Physical injury occurs at sound pressure levels in excess of 140 dB (at this level there is a risk of rupture of the tympanic membrane) while levels greater than 130 dB result in acute pain. Statistical studies on workers exposed to noise levels between 75 dB(A) and 95 dB(A) lead to the following conclusions:

1. For a 40-year working life a daily *L*eq of less than 75 dB(A) will lead to negligible risk.
2. The experimental data would indicate that for higher noise levels, and corresponding shorter time periods, the risk to hearing damage is the same. For example, 78 dB(A) for an 8-hour period is the same as 81 dB(A) for a 4-hour period.
3. Above 75 dB(A) 8-hour *L*eq the risk of hearing damage increases proportionately with the rise in levels.
4. Most countries have legislation which restricts noise levels to 85 dB(A) ±5 dB(A) with a tendency to reducing acceptable levels. It should be noted that at the UK's limit of 90 dB(A) there is some risk of hearing damage.
5. Infra-sound (sound below the normal human audible range) is capable of causing health effects. More recent research indicates an effect similar to excess alcohol consumption and indeed a synergistic effect with alcohol has been noted. It may be that in certain cases infra-sound is capable of causing an increase in accident rates. High infra-sound levels are noted in the foundry industry and in drivers' cabs in large vehicles.

15.9.23 Damage to plant/machinery/building structures

Noise can lead to damage in two ways:

1. Directly – as a result of induced vibrations
2. Indirectly – as a result of interference with the operative's normal function

Direct damage includes vibration fractures of electrical components (particularly switch contacts), structural panels, etc. Damage to buildings occurs particularly around windows (infra-sound is particularly troublesome in this effect).

Indirect damage is probably the greatest effect of noise levels. Operator performance is affected by fatigue and also the inability to hear potential problems with the machine (that might ordinarily be attended to with no significant damage resulting). In addition, the inability to hear shouted warnings may result in accidents and further plant damage.

15.9.24 Legislation concerning the control of noise

15.9.24.1 Environmental Protection Act 1990, Section 80

A notice may be served where a nuisance has occurred or the Local Authority think a nuisance may occur. Noise nuisance is not defined as such, but includes vibration. The notice may not be specific and may merely require the abatement of the nuisance. A notice may, however, require the carrying out of works or specify permissible noise levels. The time period for compliance is not specified in the Act, but must be reasonable.

Appeals against a Section 80 notice must be made to the magistrate's court within 21 days of the serving of the notice. The grounds of appeal are given in the Statutory Nuisance (Appeals) Regulations 1990 and are as follows:

1. That the notice is not justified by the terms of Section 80. The most common reason for this defence is that the nuisance had not already occurred, and that the Local Authority did not have reasonable grounds to believe that the nuisance was likely to occur.
2. That there had been some informality, defect or error in, or in connection with, the notice. It may be that the notice was addressed to the wrong person or contained other faulty wording.
3. That the Authority have refused unreasonably to accept compliance with alternative requirements, or that the requirements of the notice are otherwise unreasonable in character or extent, or are unnecessary. This defence is self-explanatory.

   The Local Authority are only permitted to ask for works that will abate the noise nuisance. Other works (perhaps to comply with other legislation) should not be specified in the notice. They may, however, be contained in a letter separate from the notice. An example of this would be where food hygiene requirements were breached by the fitting of acoustic enclosures to food-manufacturing machines. Readily cleanable enclosures may be a requirement of the Food Hygiene Regulations, but it should not be contained in a Section 80 Environmental Protection Act notice.
4. That the time (or, where more than one time is specified, any of the times) within which the requirements of the notice are to be complied with is not reasonably sufficient for the purpose.
5. Where the noise to which the notice relates is that caused by carrying out a trade or business, that the best practicable means have been used for preventing or for counteracting the effects of the noise. 'Best practicable means'

incorporates both technical and financial possibility. The latter may be related to the turnover of a company. Therefore a solution that may be the best practicable means for one company may not be so for another.

6. That the requirements imposed by the notice are more onerous than those for the time being in force in relation to the noise to which the notice relates of
   (a) Any notice under Sections 60 or 66 of the Control of Pollution Act 1974, or
   (b) Any consent given under Sections 61 or 65, or
   (c) Any determination made under Section 67.

   Section 60 relates to a construction site notice. Section 61 is a consent for construction works. Sections 65–67 relate to noise-abatement zones (see below).
7. That the notice might lawfully have been served on some person instead of the appellant, being the person responsible for the noise.
8. That the notice might lawfully have been served on some person instead of, or in addition to, the appellant, being the owner or occupier of the premises from which the noise is emitted or would be emitted, and that it would have been equitable for it to have been so served.
9. That the notice might lawfully have been served on some person in addition to the appellant, being a person also responsible for the noise, and that it would have been equitable for it to have been so served.

15.9.25 British Standard 4142: 1990

This British Standard is a revision of a standard first published in 1967 and was revised in 1975, 1980, 1982 and 1990. The standard purports to rate noises of an industrial nature affecting persons living in the vicinity. It gives a method of determining a noise level, together with procedures for assessing whether the noise in question is likely to give rise to complaints. It does make the point that while there is a correlation between the incidence of complaints and general community annoyance, quantitive assessment of the latter is beyond the scope of the document, as is the assessment of nuisance.

The previous document has been used extensively as a guide to the assessment of nuisance in various circumstances (certainly outside the scope of the document) and has gained a status that outweighs its original intention. Unfortunately, the early document was very flawed in its methodology (as is the current one) and resulted in numerous difficult legal decisions when it was produced in court as the definitive guide to noise nuisance. In particular, the old BS 4142 had a method for obtaining a 'notional background level' where the actual background level (i.e. that level which exists when the noise in question was suppressed) could not be measured, which was widely discredited as being grossly inaccurate.

The new BS 4142 rates noise in terms of *L*eq over a measured time interval (one hour in the daytime and 5 minutes at night) and compares this level with a background measured in terms of the *L*90 of the ambient. If a noise has a duration shorter than the measurement period in question, an 'on-time' correction is applied by the use of the following equation:

$$L\text{Aeq}\ T_r = L\text{Aeq}\ T_m + 10 \log_{10} \frac{T_{on}}{T_r}$$

where

$L\text{Aeq}\ T_r$ = Leq for reference period
$L\text{Aeq}\ T_m$ = measured Leq for the event
T_{on} = time on
T_r = reference time period (5 or 60 minutes)

Table 15.33 Corrections to noise level readings

Noise level reading LA*eq* T *minus background* LA*90,* T (dB)	*Correction subtract from noise level reading* (dB)
6–9	1
4–5	2
3	3
<3	Make measurements closer to source and back-calculate theoretical noise level in isolation from background

A further correction may need to be applied if the specific noise does not exceed the background by more than 10 dB. A simplified correction table is used (Table 15.33).

Finally a correction is applied dependent upon the nature of the noise. If the noise contains a distinguishable, discrete, continuous note (whine, hiss, screech, hum, etc.) or if there are distinct impulses in the noise (bangs, clicks, clatters or thumps), or if the noise is irregular in character enough to attract attention, add 5 dB to the specific noise level to obtain the rating level. The assessment for complaint purposes is then made by comparing this rating level with the background noise level. If the rating level exceeds the background by 5 dB the standard states that the result is marginal, and if the rated level exceeds the background by 10 dB or more, complaints are 'likely'.

This background noise level is one of the main criticisms of the document as it is intended to include any existing noise sources in the area. The new noise source is therefore compared against the existing noise climate, even if most of this is produced by the same factory. The example given in the British Standard further reinforces this point by considering premises which produce 40 dB(A) at the nearest house when operating normally and yet the ambient falls to 29 dB(A) during a factory shutdown. Thus the existing contribution is already 11 dB. A new source is assessed which adds 4 dB to the existing (40 dB) ambient, and the result is determined to be marginal! If this situation were to continue the background sound level (as defined in the standard) would 'creep' upwards – obviously an undesirable situation and one that is addressed in a planning circular (Circular 10/73) that deals with planning and noise. This circular particularly addresses creeping ambients and states that 'the introduction of a new noise source into an area is liable to result in a creeping growth of ambient noise level, and consequent deterioration in the quality of the environment, even though each of the new sources, considered separately, would not be liable to give rise to complaints'. This point alone is sufficient for the method to be discredited by Environmental Health Officers when investigating nuisances, and the standard is unlikely to be used by them as a definitive guide. Consequently, operators of industrial premises should not use the information given in this British Standard as evidence when arguing (in legal situations) that they are not causing a statutory nuisance.

Further, this British Standard takes very poor account of the effects of discrete frequency components. It is quite possible for a narrow band component to cause a serious nuisance while being almost unmeasurable on an 'A'-weighted scale. Consequently, more detailed narrow band analysis would be necessary and it is essential to compare the actual noise with the background noise within that narrow band (usually octave or one-third octave). The British Standard makes no mention of such a situation.

15.9.26 Noise-abatement zones

Local Authorities are empowered by the Control of Pollution Act 1974 to designate areas as noise-abatement zones. Within these areas noise levels are measured and entered onto a register. It is an offence to increase noise levels beyond register levels unless a consent is obtained. If the Local Authority are of the opinion that existing noise levels are too high, noise-reduction notices can be served.

In the case of new premises the Local Authority will determine noise levels which it considers acceptable, and these will be entered into the noise level register. Appeals against notices or decisions are made to the Secretary of State.

15.9.27 Planning application conditions

Local Authorities are empowered to impose conditions on planning applications to protect environmental amenities of neighbours. Noise is commonly controlled by conditions. Local Authorities may ask for more onerous controls on planning conditions than the mere avoidance of nuisance. Planning conditions are designed to avoid reduction in amenity of neighbours. This may mean that a process has to be almost inaudible (particularly in the case of Light Industrial Consents). Appeals against planning conditions are made to the Secretary of State.

15.9.28 The Health and Safety at Work etc. Act 1974

Section 2 of this Act imposes a general duty on employers to ensure, so far as is reasonably practicable, the health, safety and welfare at work of all his or her employees. This general section will include the acoustic environment. It should be noted that there are specific regulations made under this Act (The Noise at Work Regulations 1989 – dealt with later) that control noise (primarily to protect hearing) but they do not completely satisfy the overall requirements of Section 2. For instance, if high noise levels mask an audible alarm such that a risk of injury is caused, a breach of Section 2 would be likely (despite the fact that the noise levels in The Noise at Work Regulations have not been exceeded). Section 3 of the Act deals with an employer's duties to non-employees and again imposes a duty of care.

The Noise at Work Regulations have no relevance to members of the public as they apply only to persons at work. Section 3 of the Act would, therefore, control noise exposure to non-employees who would be likely to suffer risks to health and safety. Noise nuisance is controlled by other legislation (The Environmental Protection Act 1990 and others).

Section 4 of the Act imposes the general duty on employers to care for the health and safety of persons, who not being his or her employees, nevertheless have resort to premises under his or her control. This duty is designed to protect subcontractors, etc.

Section 6 concerns articles manufactured for use at work and will control the acoustic output of machines, etc. The control of the manufacture of noisy machines is carried further by The Noise at Work Regulations.

15.9.29 The Noise at Work Regulations 1989

These Regulations came into force on 1 January 1990 and control the exposure to noise of persons at work. They establish three noise levels known as the first, second and peak action levels. Different regulations are applicable as each action level is exceeded. The unit of measurement is known as equivalent continuous sound level and may be defined as 'that notional continuous steady level which would have the same 'A'-weighted acoustic energy as the real fluctuating noise measured over the same period of time'. For the purposes of the Regulations an 8-hour time period is used and the 8-hour equivalent continuous sound level is abbreviated to L_{EP}, d:

The first action level is 85 dB(A) L_{EP},d
The second action level is 90 dB(A) L_{EP},d
The peak action level is 200 Pascals (equivalent to 140 dB)

Damage to the hair cells in the inner ear is proportional to the noise energy received. This is a dose concept comprising the product of noise level and exposure duration. It follows, therefore, that the same amount of deafness will follow from the exposure to a very intense sound for a short period as to a lower level for a proportionally longer period.

It has been shown that the exposure time has to be halved for each 3 dB(A) increase in the noise levels. 3 dB(A) represents a doubling of sound energy, hence this rule has become known as the equal energy damage risk criterion. It follows that 93 dB(A) for 4 hours is also 100% of the permitted exposure for a day; similarly, 2 hours at 93 dB(A) would be 50% of the permitted exposure. Where an employee is likely to be exposed to above the first action level the employer shall ensure that a competent person makes an assessment of the noise levels which is adequate for the purposes:

1. Of identifying which of his or her employees are so exposed, and
2. Of providing him or her with such information with regard to the noise to which those employees may be exposed as will facilitate compliance with his or her duties under the Regulations, specifically:
    (a) Reduction of noise exposure
    (b) Ear protection
    (c) Ear protection zones
    (d) Provision of information to employees

15.9.29.1 The requirements of the Regulations

An employer must:

1. Carry out an assessment when an L_{EP},d of 85 dB(A) is likely to be exceeded.
2. Review the assessment if changes necessitate this.
3. Record the exposure and keep records.
4. Reduce the risk of damage to hearing to the lowest level reasonably practicable.
5. Every employer shall, when any of his or her employees is likely to be exposed to the second action level or above or to the peak action level or above, reduce, so far as is reasonably practicable (other than by the provision of personal ear protectors) the exposure to noise of that employee.
6. If an employee is exposed to greater than the first action level and less than the second action level the employer shall provide hearing protection if so required by the employee.
7. If an employee is exposed to greater than the second action level or greater than the peak action level the employer shall provide hearing protection which, when properly worn, will reduce the risk of hearing damage to below that arising from exposure to the second action level or, as the case may be, to the peak action level.
8. Ear-protection zones (i.e. areas where the second action level is likely to be exceeded) shall be established. Employees must wear ear protection in this zone. The employer shall erect suitable signs.
9. Information, instruction and training shall be provided for employees where exposure is likely to exceed the first

action level or the peak action level. This information shall include:

(a) The risk of damage to an employee's hearing that such exposure may cause;
(b) What steps an employee can take to minimize that risk;
(c) The steps that an employee must take in order to obtain the personal ear protectors which the employer must provide.
(d) The employer's obligation under the Regulations.

15.9.30 Noise control engineering

Before attempting noise control it is important to consider the nature of the problem. The first (and usually the most cost-effective) approach is to silence the noise at source. In order to appreciate likely noise sources and the methods used to reduce their emission, we will consider the ordinary reciprocating piston engine.

The first source is the crankcase wall 'ringing' under the reciprocating forces of the combustion. Excess noise will be produced if the frequency of the combustion pulses is at the resonant frequency of part of the engine. The solution is to de-tune the block by stiffening (which may have an added mass-law effect) or by the addition of damping materials.

The next source to consider is the crankshaft and bearings. Most shafts will be out of balance to some degree and will have a resonant point. A well-designed engine should not run at this resonant frequency. Bearings are two main types – sliding (or plain) bearings and roller. Excess clearance can give rise to bearing knock and the solution here is to replace bearings. Poorly designed systems can give rise to bearing knock if the shaft has a bending mode within the engine's operating range.

Plain (oilite) type bearings can produce screech on start-up from cold (these bearings are used in electric motors, starter motors and alternators, etc.). Replacement may make matters better.

Roller bearings are generally quieter than plain bearings but can produce considerable noise if damaged. Frequency analysis of the noise can be used to assess the source but there are many modes involved in a bearing 'click'. Again the solution is replacement, with care being taken to locate the new bearing without causing damage (by only inserting the bearing with force on the outer race) and by careful checks of the dimensions of the bearing housing.

Gearboxes give rise to noise as teeth contact each other. If excess clearance (and/or poor lubrication) is present, noise will be exacerbated. Again, frequency analysis can help to locate the source of trouble by comparing the dominant frequency of the noise with the gear teeth meshing frequencies. It should also be noted that gears themselves can ring (particularly if they are free and not cast as part of a layshaft, etc.). The dominant frequency may be at the damaged gear's resonant frequency.

Finally, hydraulics can give rise to noise due to the intermittent force pulses produced by pumps. The solution would be to introduce some flexibility into the receiver system to damp out the very high intermittent pressures produced by the incompressibility of the fluid.

Other examples of machines which lend themselves to noise reduction at source are:

1. Presses – is the degree of impact necessary? Can it be adjusted? Can the press operate by pressure alone?
2. Air discharge – use of air tools and nozzles. The turbulence in the boundary layer of air between the rapidly moving airstream and the atmosphere is heard as noise. Can the airstream be diffused (silencers fitted to the exhaust)? Nozzles used for cleaning can have devices fitted which give a gradual transition from the rapidly moving air to atmosphere by the use of an annular ring of small nozzles round the central nozzle. These silence with very little loss in efficiency.
3. Reciprocating compressors – these give rise to very high noise levels at low frequency (below 250 Hz typically). These low-frequency noises are very difficult to attenuate. The most popular solution is to use rotary (vane type) compressors instead. These are inherently quieter and have the further advantage that the noise they generate is at high frequency (typically above 1 kHz) and is, therefore, easy to attenuate.
4. Cutting machines – modifications to the method of restraining material being cut to reduce 'ringing'. Reducing free length of material.

If reduction of noise at source is not possible (or does not provide sufficient reduction) the transmission pathway must be considered:

Source of sound energy → Transmission pathway → Receiver

15.9.31 Noise-reduction principles

There are many thousands of noise control devices. All, however, rely on one or more of the three basic noise control principles. These are: insulation, absorption and isolation.

15.9.31.1 Insulation

The simplest insulator is a sheet of material placed in the sound-transmission pathways. Sound energy reaches the surface in the form of a pressure wave. Some energy passes into the partition and the rest is reflected.

Energy that passes into a partition may be partially absorbed and transformed into heat. This is likely to be very small in a plain partition. The remainder of the energy will then pass through the partition by displacement of molecules and pass as sound in the same way that sound travels in air. This can then pass to the edge of the partition and be re-radiated as sound from other elements of the structure – this is known as flanking transmission. By far the greatest amount of energy, in a thin partition, will pass through the partition by actually causing the partition to vibrate in sympathy with the incident sound and, hence, re-radiating the sound on the opposite side. The amount of sound transmitted through a partition is represented by the ratio of the incident energy to the transmitted energy. This factor when expressed as decibels is known as the sound-reduction index:

$$\mathrm{SRI} = 10 \log_{10} \frac{1}{\text{Transmission coefficient}} \ (\mathrm{dB})$$

The movement of the panel (and hence its resistance to the passage of sound) is controlled by a number of factors:

1. The surface mass affects the inertia of the panel. Greater mass causes a corresponding greater inertia and hence more resistance to movement. At high frequencies this becomes even more significant. The mass law can be expressed:

   $\mathrm{SRI} = 20 \log_{10} mf - 43$ dB

   where m is the superficial weight (kg m^{-2}) and f is the frequency (Hz).
2. Stiffness – at very low frequencies the movement of the panel will be controlled by the stiffness, as inertia is a dynamic force and cannot come into effect until the panel has measurable velocity. Stiffness controls the perfor-

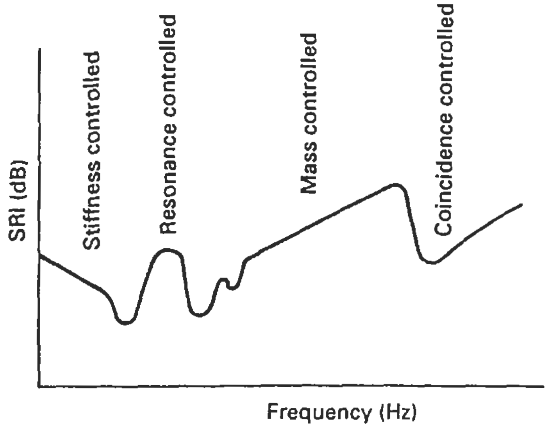

Figure 15.181 Typical insulation characteristics of a partition

mance of the panel at low freqencies until resonance occurs. As the driving frequency increases, the resonance zone is passed and we enter the mass-controlled area. The increase in sound-reduction index with frequency is approximately linear at this point and can be represented by Figure 15.181.

3. Coincidence – a panel will have a bending mode when a wave travels along the length of the sheet of material. The frequency of this bending mode is known as the critical frequency. This mode of bending will be introduced by sound incident at angles greater than 0°. At the critical frequency coincidence will only occur for a sound wave with a grazing incidence (90°). At greater frequencies the partition will still be driven, but in this case by progressively lower angles of incidence. The coincidence dip is not, therefore, a single dip but will result in a loss of sound-reduction index at progressively higher frequencies. The desirable insulation panel will, therefore, be massive but will not be stiff.

15.9.32 Absorbers

15.9.32.1 Porous absorbers

As sound passes through a porous material, energy is lost by friction within the material. The material is usually employed by fixing it to the surfaces in a room. The absorber will have the highest efficiency when positioned where the air molecules are moving the fastest (and hence more energy is absorbed). At the wall surface the molecules are stationary. If we plot a single-frequency graph we find that the maximum particulate velocity occurs at $\lambda/4$ (one-quarter wavelength) from the surface. In practice, incident sound is rarely of single frequency. But the principle can be observed that the absorber must be one-quarter of the wavelength away from the wall (for the frequency of the sound to be absorbed). This can be arranged either by having a thickness greater than $\lambda/4$ for the lowest frequency to be absorbed or, alternatively, to mount the absorber on a frame some distance away from the wall such that the centre of the absorber is at $\lambda/4$ for the frequency to be absorbed.

15.9.32.2 Resonant absorbers

The simplest resonant absorber is known as the Helmholtz resonator. This device consists of a chamber connected to the duct (or whatever area is to be controlled) by a narrow neck. The volume of air in the chamber will resonate at a frequency, F_{res}, determined by the volume of the chamber, the length of the neck and the cross-sectional area of the neck.

$$F_{res} = 55 \frac{S}{lV} \text{ (Hz)}$$

where S = cross-sectional area (m^2), l = length of neck (m) and V = volume of enclosure (m^3). As the chamber resonates, air is forced through the narrow neck and hence energy is absorbed in overcoming the resistance.

The degree of attenuation at the critical frequency can be very large, but this type of silencer has a very narrow bandwidth. This device may be suitable when the machine being dealt with emits sound predominantly of a single wavelength. The absorption bandwidth of a Helmholtz resonator can be expanded by lining the chamber with absorbers but this has the effect of reducing the efficiency.

The perforated absorber which forms the basis of many acoustic enclosures and silencers is a development of the resonator principle. As stated previously, the bandwidth may be broadened by packing the chamber with an absorber, but this lowers efficiency. This may be overcome by using multiple absorbers in the sound path. It can be arranged by placing a perforated sheet some distance away from the rigid outer wall of the enclosure and filling the cavity with absorber. It is not necessary to use cross-walls between the 'chambers' so formed. In this case the equation becomes:

$$F_{res} = 5000 \frac{P}{l\,(t + 0.8d)} \text{ (Hz)}$$

where

l is the depth of airspace (mm)
t = thickness of panel (mm)
d = diameter of holes (mm)
p = percentage open area of panel

15.9.32.3 Panel absorber

This absorber is basically a panel attached to the structural wall which is designed to absorb energy. It is therefore frequency dependent and has an absorption peak at its resonant frequency. This type of absorber is not commonly used.

15.9.33 Vibration isolation

Vibration in machinery or plant can be induced in a number of ways, including:

- Out-of-balance forces on shafts
- Magnetic forces in electrical apparatus
- Frictional forces in sliding objects

The first course of action in vibration isolation is the reduction at source. This may be achieved by balancer shafts in engines, stiffer coils in electrical apparatus or better lubrication between adjacent sliding surfaces.

When all possible vibration reduction has been achieved the machine must be isolated from the structure by some form of spring mounting. Spring mounts have a resonant frequency depending upon the stiffness of the spring and the weight of the object placed upon it. It will be apparent that the static deflection of the spring will also be proportional to the resonant frequency.

As the driving force of the mass/spring increases from zero up to the resonant frequency the amount of transmission of the vibration increases until resonance is reached and the

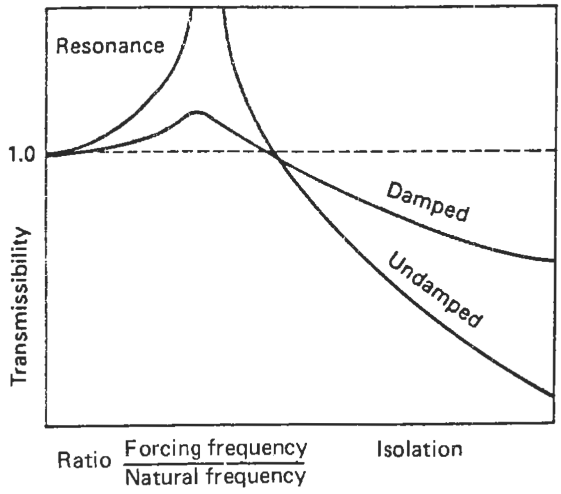

Figure 15.182 Performance of anti-vibration mounting

transmission becomes infinitely large. As the resonant point is passed, the transmission begins to reduce until at some point the transmissibility falls below one (see Figure 15.182), i.e. isolation occurs.

In practice, however, spring systems have some inbuilt damping and this will have the effect of reducing the amplitude of the resonance below infinity. This is very necessary in real systems to avoid excessive excursions of mounted machinery. A damped mounting will follow the second curve in Figure 15.182 and it will be noted that the vibration isolation at high-frequency ratios is less than that for undamped systems. It is important, therefore, to use the lowest degree of damping that is necessary.

15.9.34 Practical applications

15.9.34.1 Acoustic enclosures

Panels of multi-resonator material are made from perforated plate sandwiched with solid plate with an intermediate absorber layer. These panels can be built up into enclosures taking care to seal all junctions adequately. Typically, these enclosures are made to surround small machines (e.g. compressors). They may be fitted together with spring catches to allow for dismantling for maintenance purposes.

Ventilation may be a problem but can be dealt with in several ways:

1. Acoustic louvres – louvres are constructed of the absorbent panel material (suitable for small degree of noise reduction only);
2. Silencer fitted to ventilation duct (see later);
3. Baffled enclosures to ventilation duct.

15.9.34.2 Building insulation

Single-panel insulators have been described earlier. In building insulation it is usual to provide double insulation. In theory, if the insulation panels have no interconnection it should be possible to arithmetically add the sound reduction of the two elements of the structure. In practice, it will be found that there is bridging, either by the structure, wall ties or flanking transmission or by the air between the two elements acting as a spring. If the two elements of the wall were in rigid connection the insulation would be 3 dB more than the single element alone (mass law) and if totally separated it would be the sum of the figures. In practice, a cavity wall with ties and a 50 mm cavity gives approximately 10 dB more reduction compared to a single-skin wall of half the surface mass.

Double-glazed windows work on the same principle. It is important to avoid the coincidence of the resonant frequencies of the two elements and hence it is usual to arrange for the glazing panels to have different thicknesses (and hence a different resonant frequency). This is not necessary if one element is subdivided by glazing bars to give different size panes from its opposing element. The reveals of a double-glazed window should be lined with acoustically absorbent material to damp the sound within the cavity. The width of the cavity should not be less than 150 mm.

If insulation panels are not of uniform construction, as in the case of a wall containing a window, the average sound-insulation value has to be derived for use in calculations. The total transmission coefficient for the composite panel will equal the sum of the individual coefficients multiplied by their respective areas and divided by the total area. Thus:

$$t_{av} = \frac{t_1 s_1 + t_2 s_2 + t_3 s_3 + \ldots \text{ etc.}}{s_{tot}}$$

and the SRI of the total panel derived from

$$\text{SRI} = 10 \log_{10} \left(\frac{1}{t_{av}}\right) \text{ (dB)}$$

15.9.34.3 Control of noise in ducts

Fans produce the least noise when operating at their maximum efficiency. It is, therefore, important to select the correct fan for the airflow and pressure characteristics required. It is also important to remember the noise generated within the system (as opposed to at the fan) depends on the air velocity, and, hence, for a required airflow rate, a larger cross-section duct (with a correspondingly lower velocity) will give quieter results. It will also give other advantages when it comes to providing extra noise attenuation and fitting of silencers.

It is most important in the design of systems to eliminate as much turbulence as possible. To achieve this, the fans should be mounted some distance away from bends (at least one and a half duct diameters). Junctions between pipes and connectors should present a smooth internal profile and inlets to systems should be tapered and not plain. Outlet grilles should be of larger diameter than ducts and have aerodynamically smooth profiles where possible.

If it is necessary to add extra attenuation to a duct it is essential to decide on the required amount. If only a relatively small degree of absorption is required the first course of action is to line part of the duct with absorber. The length of duct to be lined will be determined by the degree of attenuation required and the thickness will be determined by the frequency of the noise. The data for these factors are available from many sources and are usually published as tables by manufacturers. For further attenuation it is necessary to provide a centre-pod type attenuator (Figure 15.183). This increases the area of the absorber and also aids low-frequency attenuation. For further low-frequency attenuation an in-line splitter silencer is employed (Figure 15.184).

These are capable of providing a high degree of attenuation, depending on the width between the elements. The smaller the gap, the higher the attenuation. Again, tables of performance are published by the major manufacturers. It is necessary, in order to decide on the design of the silencer to be

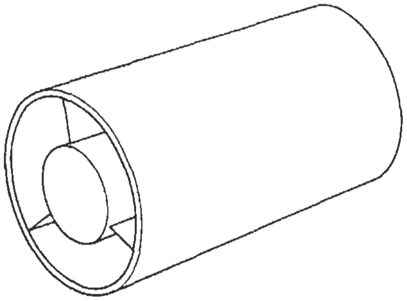

Figure 15.183 Centre-pod silencer

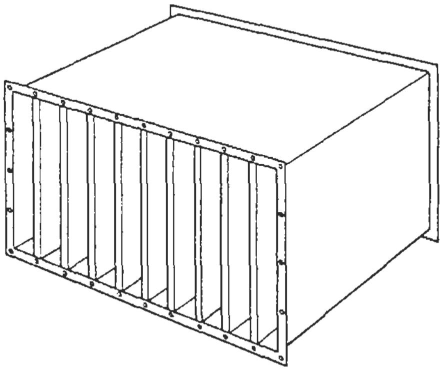

Figure 15.184 Splitter silencer

installed, to know the required attenuation (and something about the frequency/noise level profile) and the permitted pressure loss in the system.

Manufacturers' data can then be consulted. Splitter silencers are also available, made into bent shapes, and these can provide even higher degrees of attenuation as well as aiding installation. Silencers should ideally be fitted in systems as near to the noise source as possible to avoid noise break-out from the duct. Other obstructions in the duct must be considered, however, as they may generate further aerodynamic noise which, if it occurs after the silencer, will not be attenuated.

15.9.34.4 Anti-vibration machinery mounts – in practice

Again, the characteristics of the system need to be considered. The weight of the machine and the frequency will determine the static and dynamic deflections of the mounts and hence the material of which the mount is to be constructed. At very high frequencies, mats may be placed under machinery. These may consist of rubber, cork or foam. At middle frequencies it is usual to use rubber in-shear mounts. At low frequencies metal spring mounts are used.

15.9.34.5 Mats

Anti-vibration mats are very useful for frequencies about 25 Hz. They have the disadvantage of being liable to attack by oils and if they become saturated or deteriorated they will compress and lose their efficiency.

15.9.34.6 Rubber mounts

Although these are loosely termed 'rubber' mounts, they are often composed of synthetic rubbers which are not readily attacked by oils and can operate over a much wider temperature range. Typical maximum static deflections are 12.5 mm.

15.9.34.7 Steel spring mounts

Steel springs have the disadvantage of transmitting the high frequencies along the length of the spring. It is usual to mount the spring with a rubber or neoprene washer under its base. Steel spring mounts are also most vulnerable to resonance problems, and the solution is to build in a damper device. This has the disadvantage of reducing the isolator's efficiency.

15.9.34.8 Positioning of anti-vibration mounts

Machinery must be positioned so that all mounts are equally loaded, and failure to do so will result in the possibility of a rocking motion developing. This may require mounting the machine on a subframe. If this is not possible the load should be assessed at each mounting point and mounts of different stiffness used.

15.9.34.9 Installation

Mounts should be installed so that the whole machine is isolated from the structure. Services (e.g. power, hydraulics, etc.), should be mounted flexibly. Bridging is the most common fault when providing vibration isolation to machines and building structures, and should be carefully avoided. Services should be designed to withstand the degree of movement permitted by the anti-vibration mounts without suffering damage.

Further information on acoustic noise and its control can be found in references 68–70.

16.1 Large-chip metal removal

16.1.1 Large-chip processes

All the large-chip processes use cutting tools of defined geometry which are applied in a controlled manner to remove metal at a predetermined rate. The processes could be classified in many ways, but it is convenient to consider them in terms of the kinematics of the machine tools. With this in mind, they have been separated into four main machine groups:

1. Turning (rotating work)
2. Shaping (reciprocating tool or work)
3. Milling (rotating tool)
4. Drilling and boring (rotating tool)

Turning machines embrace the wide variety of lathes and vertical boring machines which can be controlled manually or automatically. Automatic control can be achieved using cams, sequential controllers, hydraulic copying devices or numerical programming. All machines in this group are capable of performing six basic operations as shown in Figure 16.1. In addition, copying lathes and numerically controlled lathes can generate non-parallel forms by traversing the tool simultaneously in two planes.

Most turning processes use tools with a single cutting edge where the cutting action is characterized by a relatively uniform section of material being presented to the cutting zone, resulting in a continuous chip when cutting ductile materials or a repetitive form of short discontinuous chips when cutting brittle materials. Although the production of continuous chips indicates an efficient cutting action the chip streamer itself presents disposal problems, frequently wrapping itself round the workpiece, the cutter or parts of the machine tool, creating a hazard to both the process and the operator.

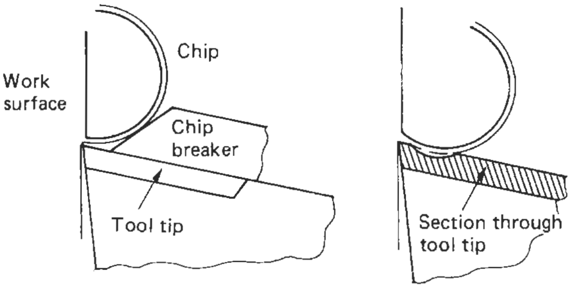
Figure 16.1 Basic lathe operations

Chip breakers are extensively used to induce continuous chips to break into short lengths which are relatively safe and can be easily disposed of. These push against the underside of the chip and cause it to curl into a tight spiral, the free end of which strikes against the tool, and the resulting bending stress causes fracture. The earliest form of chip breaker, still extensively used with flat-top tools, consists of a hard wedge-shaped block of sintered carbide clamped to the rake face of the tool about 2 or 3 mm from the cutting edge (Figure 16.2(a)). The introduction of disposable sintered carbide inserts has allowed more complicated rake-face geometries to be used which act as built-in chip breakers (Figure 16.2(b)). Effective chip breaking is largely a matter of trial and error, being influenced by the feed, tool bluntness and cutting speed as well as by the material being machined.

The development of new and improved cutting materials has enabled a hundredfold reduction in cutting time to be achieved since the beginning of the twentieth century. Unfortunately, the reduction in idle time, caused by the need for tool adjustment, and in the tool approach and retraction times before and after cutting has not been of a comparable order. In achieving lower production costs the emphasis has now rightly moved away from further reducing cutting time to attacking the disproportionately large amount of non-cutting time.

Disposable sintered cutting inserts are made to a high level of precision which allows them to be indexed or replaced in tool holders in a few seconds, usually without the need for sizing cuts. When all the cutting edges are worn the inserts are discarded, obviating the need for time-consuming regrinding which is common practice when using high-speed steel tools. When resetting lathes between work batches a substantial time saving can now be achieved by using preset tools mounted in holders which can be replaced as cartridges in the tool post. No doubt further improvements will be achieved in the development of cutting tool materials, but reduction of manufacturing time in future will be determined mainly by reducing idle time, both by better tool changing mechanisms and by improved machine tool design to facilitate chip disposal and to reduce the tool approach and retraction times.

The shaping group of machine tools produce chips by a relative linear motion between the cutting tool and the work. It includes shaping machines, planing machines and slotting machines, all of which are used mainly for tool manufacture or maintenance work and have little application in modern production. They operate on a reciprocating principle, cutting



(a)

(b)

Figure 16.2 Chip breakers: (a) clamped, (b) built-in

on the forward stroke and idling on the return stroke. Although they have quick-return mechanisms the cutting time is only in the order of half the reciprocating cycle time. Swarf disposal is usually no great problem due to the intermittent nature of the cut. Figure 16.3 shows typical configurations of these three machine types, which have changed little in recent years.

Other machines in the shaping group are gear shapers and gear planers, outlines of which are shown in Figure 16.4. In gear shaping the cutter resembles a side-relieved spur gear, the involute profile being generated by rapid reciprocation of the cutter while slowly revolving the cutter and gear blank in synchronism. Helical gears can be generated using a cutter with helical teeth and applying an appropriate helical motion to the spindles. Gear shaping is used for producing gears when hobbing would be impossible due, for instance, to a turned shoulder close to the involute profile. Gear planers have little modern use, particularly in a production environment. The cutter is in the form of a straight-tooth rack, suitably relieved, and the gear is generated by reciprocating the cutter and moving the gear blank and the cutter at a constant speed. To enable a short rack to be used it can be removed from the cut and indexed back at intervals.

Broaching machines also belong to the shaping group, but these produce the required form in a single pass. Internal broaching is for opening circular holes to produce non-circular forms. The cutter is a broach which has a number of cutting edges along its length and which is usually drawn (but sometimes pushed) through the hole by means of hydraulic pressure. Each cutting edge is larger than its predecessor by about 0.05–0.08 mm, so the number of cutting teeth is determined by the form to be produced.

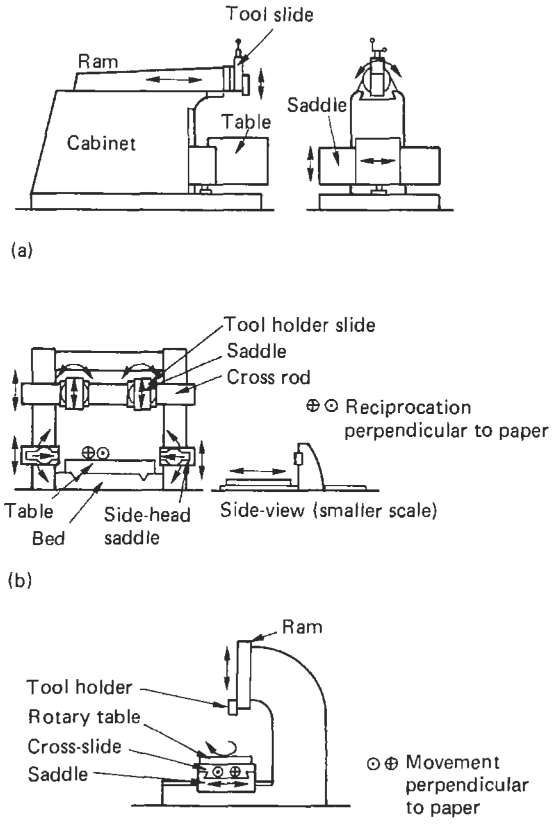


Figure 16.3 Outlines of reciprocating machines: (a) shaping, (b) planing, (c) slotting

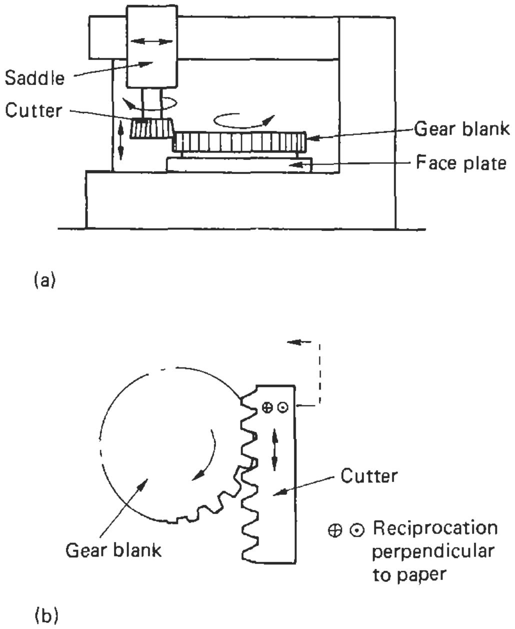

Figure 16.4 Kinematics of gear-generating machines: (a) gear shaper, (b) gear planer

Push broaching is limited to broaches with a small number of teeth which have a low length/cross-section ratio and which would not buckle under compression. Surface broaching is of more recent introduction, and is used as an alternative to milling for the production of external surfaces. Surface broaches are rigidly clamped to a machine slide and traversed against the component being machined, producing a surface in a shorter time than is required for milling, and usually giving a superior finish. Whereas internal broaching is usually the only feasible method for producing the desired shapes, surface broaching is an alternative to milling and is usually justified only if the quantities required are sufficient to absorb the high equipment and tooling costs.

The milling group comprises a large range of manually operated or numerically controlled machines, many of which can perform operations such as drilling, reaming and boring as well as the accepted milling operations. Milling cutters generate surfaces either by means of cutting edges on the periphery or the face of the cutter. Peripheral milling is now seldom used for generating large plane surfaces, its main use being for machining slots or profiles. Although peripheral cutters can be fitted with carbide cutting edges the majority are of high-speed steel and, except when used for machining the more exotic hard materials, will probably continue to be so in the foreseeable future. Frequently they also have shallow teeth on the cutter face, although these teeth usually contribute little to the total metal removed. A range of typical peripheral cutters is shown in Figure 16.5.

Face milling cutters are essentially for generating plane surfaces. They are fastened to the end of stub arbors in the machine spindle and their configuration makes them suited to the use of specially designed carbide inserts (Figure 16.6). The cutting edges of both peripheral and face milling cutters are in contact with the uncut part of the component for, at most, half

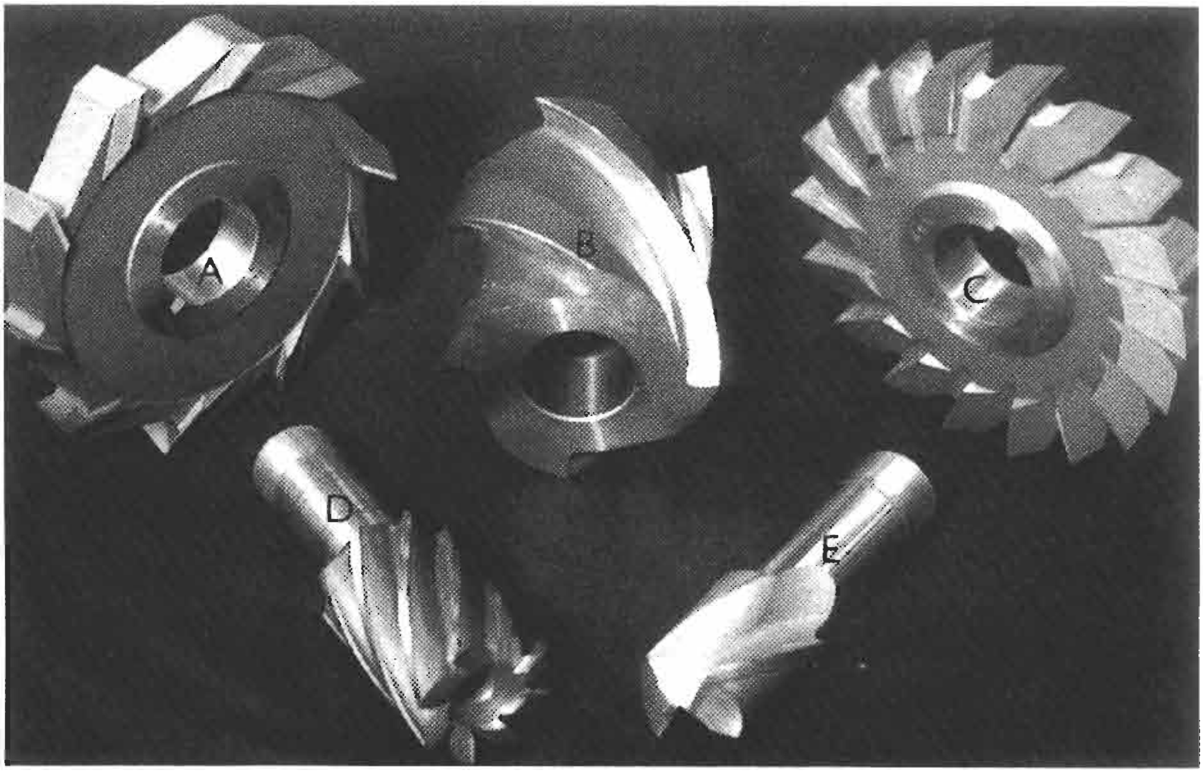

Figure 16.5 Peripheral cutters: (A) high radial rake cutter, (B) helical cutter, (C) side and face cutter, (D) end milling cutter, (E) slot drill

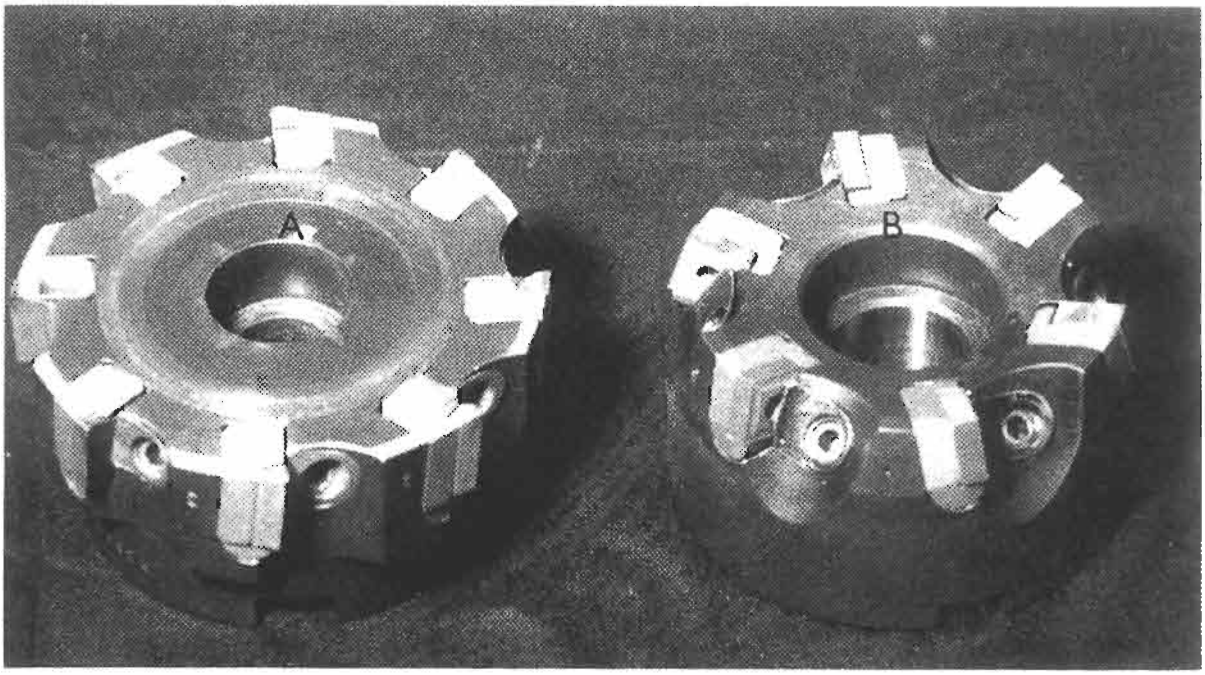

Figure 16.6 Face milling cutters: (A) zero corner angle, (B) 15° corner angle

a revolution. Since the chip length is in the order of one third of the length of the uncut surface the chips have a maximum length approximating to the cutter radius, so chip breaking poses few problems.

Gear hobbing machines also belong to the milling group. Hobs are in the form of a screw with a straight side rack-form thread, gashed to give cutting edges and relieved to provide cutting clearance. Gears are generated by rotating the blank and the hob in synchronism and the hob is fed parallel to the axis of the arbor on which the blank is mounted. When a number of identical gears are required, several blanks can be fitted to the same arbor and machined at a single pass.

The machines in the drilling and boring group can be sub-divided into drill presses, radial drilling machines, jig-boring machines and horizontal boring machines. They have rotating spindles which hold drills, stepped cutters, taps, reamers or single-point boring tools, and the cut is applied by feeding either the spindle or the work table. Typical configurations within this group are shown in Figure 16.7.

Increased metal-removal rates, made possible by the development of new cutting materials, have forced machine-tool manufacturers to design new machines capable of large ranges of spindle speeds and feeds. This has necessitated more powerful motors and structures having high rigidity to resist the increased cutting forces and to reduce the likelihood of self-induced vibrations, giving rise to chatter.

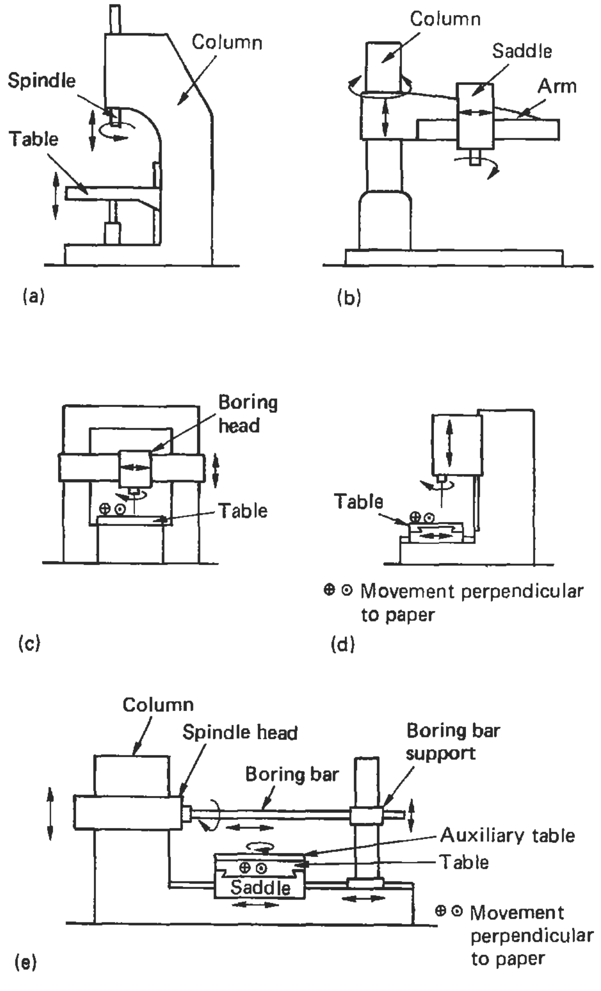

Figure 16.7 Machines in the drilling and boring group: (a) single-spindle drill press, (b) radial drilling machine, (c) gantry-type jig-boring machine, (e) horizontal boring machine

With increased rates of metal removal the problem of swarf disposal has become more acute. The magnitude of this problem can be visualized when it is realized that swarf occupies about one hundred times the volume of the metal removed, so a 10 kW motor running at full power can generate about 1 m^3 of mild steel swarf or about 3 m^3 of aluminium swarf per hour.

Modern high-production metal-cutting machines commonly cost in excess of £100 000. If they are amortized over a period of 5 years the depreciation cost of such a machine when used continuously on a double-shift basis is more than £5 per hour. It follows that such plant requires high utilization, efficient programming to produce at optimal metal-removal rates, an effective system of tool management to reduce non-cutting time and intelligent application of terotechnology to minimize lost time due to maintenance.

Where large-scale production justifies continuous or large-batch manufacture the achievement of these objectives becomes a feasible possibility. Unfortunately, few products are marketed in such large quantities and a large-batch approach usually results in uneconomically high stocks. British manufacturing industry in the 1970s became notorious for its inflexibility and for the disproportionately high stocks which pursuit of large-batch policies entailed. Present policies are directed towards small batches, and this manufacturing philosophy has highlighted the need for rapid change-overs and for manufacturing systems accommodating large numbers of tools which can be called into use in response to the demands of small batches.

16.1.2 Cutting-tool geometry

Most of the research into chip formation has been based on orthogonal cutting, a simplified situation which is seldom met in practice. The tool approaches the work with its cutting edge parallel to the uncut work surface and at right angles to the direction of cutting. To prevent end effects the tool is wider than the work, as shown in Figure 16.8. Orthogonal cutting can be achieved only in a planing or shaping operation, although a close approximation can be obtained when turning on the end of a thin-walled tube.

In practice, the cutting tools usually approach the work obliquely and have rake angles in both directions on the rake face together with a nose radius at the end of the cutting edge. The direction in which the chip flows across the tool surface is determined by this complicated geometry. British Standard 1296: 1972 defines the angles on single-point cutting tools in terms of the normal rake system (Figure 16.9), based on two coordinate rake angles.[1] The back rake or cutting edge inclination λ_s is measured parallel to the cutting edge in the vertical plane and the normal rake γ_n is measured in a plane at right angles to the cutting edge and perpendicular to the rake face. ψ_r is the tool approach angle and κ_r' is the horizontal clearance angle, or the tool minor cutting edge angle. In addition, the tool is relieved to give vertical clearance angles of about 5°.

Other systems of tool nomeclature relate the rake angles to the coordinate axes of the tool shank, or to the cutting edge, measuring the angles in each case in the vertical plane. Although these systems are conceptually simpler, they are of little use in deducing the direction of chip flow. The British Standard relates to single-point tools but it can also be applied to multi-point tools and is generally preferable to the other systems.

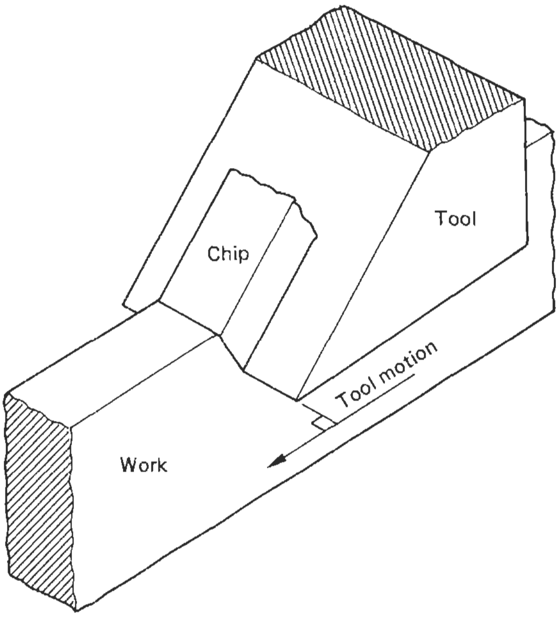

Figure 16.8 Orthogonal machining

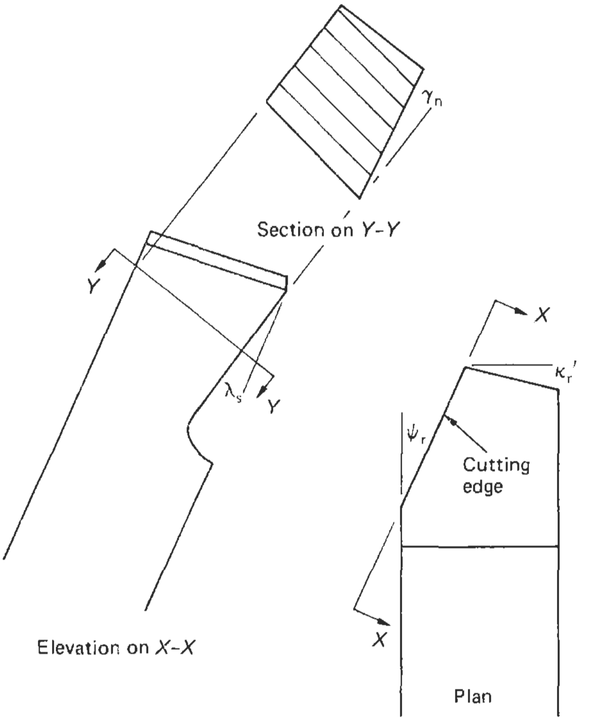

Figure 16.9 Angles in the Normal rake system

16.1.3 Cutting-tool materials

The variety of cutting-tool materials has increased rapidly in recent years due to the development of more difficult-to-machine materials and to the insistent demand for higher productivity. Any attempt to summarize these materials is unlikely to be completely successful due to the rate at which improvements and innovations are occurring. However, this is no excuse for ignoring the published state of the art at the time of writing.

When selecting a tool material for a particular application it is necessary to measure its rating against the following list of properties, some of which are mutually opposed. For instance, in most cases hardness and impact resistance of competing tools tend to be inversely related. The essential properties are:

1. High hardness at elevated temperatures
2. High compressive strength
3. Adequate impact resistance
4. Insusceptibility to violent local temperature variation
5. Chemical inertness at working temperatures
6. Low interface friction
7. Good abrasion resistance

Temperatures at the chip/tool interface can be about 1000°C when machining steel, and considerably higher when machining some of the more exotic materials, particularly if heat is applied to help soften the work material. Since cutting temperature is largely dependent on cutting speed, it follows that pursuit of higher productivity creates increasing demands on the high-temperature properties of the tool materials.

16.1.3.1 High-speed steel

High-speed steels (HSS) are likely to continue to be used in the foreseeable future for many applications such as drilling, reaming, tapping and dieing, forming, broaching and milling due to the ease with which they can be shaped in both the soft and hardened state. Typically, they consist of carbon steel alloyed with tungsten or molybdenum, together with percentages of chromium, vanadium and cobalt. The alloying elements raise the temperature at which tempering occurs, allowing HSS to be used at temperatures up to about 650°C. Their hardness is limited to 750 HV, adequate for machining most of the common metals, including alloy steels in their unhardened forms.

Cutting speeds are necessarily limited to prevent excessive rise in temperature. When machining mild steel, cutting speeds of about 1.5 m/s are possible if a plentiful supply of coolant is provided. A recent development is the coating of HSS drills with a deposit of about 3–5 μm of titanium nitride which allows rotational speeds to be increased, resulting in a 50% increase in penetration rate and longer tool life. With a few exceptions of this sort it is unlikely that HSS will ever again pose a threat to the supremacy of sintered carbides for heavy-metal removal.

Despite their relatively low hardness and susceptibility to softening at high temperatures, high-speed steel tools are tougher than most of the competing materials, enabling them to be used for interrupted cuts without fear of fracture. They can also be reground, giving a number of cutting lives before they must be finally discarded.

16.1.3.2 Cast non-ferrous alloys

These alloys, consisting of cobalt, chromium, tungsten and carbon, although less versatile than high-speed steels, enable cutting to be performed at higher temperatures. Their main use is for drilling, where their superior hardness at elevated temperatures is an advantage when the application of fluids is frequently a problem. Their cutting performance is generally superior to high-speed steel but inferior to sintered carbides, so they are unlikely to grow in popularity.

16.1.3.3 Sintered carbides

The introduction of sintered carbides for cutting has been the most important single contribution to increased productivity during the past 50 years. They are essentially cermets, which consist of hard carbide ceramic particles embedded in a metal matrix. Early carbide tools were usually of tungsten carbide and cobalt. Their brittleness encouraged the use of negative rakes to promote compressive stresses and restricted their use to continuous cutting. Subsequent improvements in the sintering process, and the introduction of alternative ceramic and metallic components, has enabled a range of carbide tools to be produced which withstand the rigours of thermal and mechanical shock, making them suitable for interrupted cutting in turning and milling.

The first generation of carbide tools consisted of sintered tips brazed to steel shanks. This provided a fairly rigid cutting system and the tools could be reground when blunt. More recently, the brazed tip has been almost completely superseded by disposable tips which are mechanically clamped into steel tool holders. These tips are polygonal, with three or more cutting edges which can be indexed when worn to expose new edges. The negative rake varieties can be inverted to double the number of edges. They are a throwaway concept, regrinding being uneconomic. Their introduction has forced a reappraisal of metal-cutting economics, making tool lives in the order of 15 min a desirable objective. Practical cutting speeds are about three times as great as could be achieved with high-speed steel, 5 m/s being a typical maximum when machining mild steel.

16.1.3.4 Ceramics

Sintered ceramic tools based on aluminium oxide (Al_2O_3) have been available for more than 30 years. Their brittleness and poor thermal shock resistance can be improved by additions of zirconium oxide and titanium carbide, but they are generally unsuited to interrupted cutting. They are suitable for machining hardened steels and chilled cast irons, and are similarly suitable for heat-assisted machining of hard materials such as the nimonic alloys and Stellite. However, their brittle behaviour has proved a severe limitation for general-purpose machining of steels, an area in which their high metal-removal potential would have been an advantage.

Mixed ceramics, based on carboxides with dispersed titanium carbide, have achieved better impact resistance without significant loss of hardness. They can be used at high cutting speeds in the order of 15–20 m/s when operated at low feeds, making them suitable for finish turning and finish milling hard materials.

A recent addition to the range of commercially available ceramic cutting tools uses silicon nitride (Si_3N_4) with differing levels of aluminium and oxygen substitution. The silicon nitride ceramics have good resistance to thermal and mechanical shock, enabling them to be used for discontinuous cutting. They can be operated at higher cutting speeds than carbides together with higher feeds than other types of ceramics. Their main applications to date are for rough turning and rough milling grey cast iron and for turning nickel-alloy steels. Due to their high thermal shock resistance they can be used to cut dry or with coolant, the latter method being inadvisable with other ceramics. Chemical action occurs at cutting temperatures, causing rapid wear when machining most steels, so at present there is little likelihood of silicon nitride supplanting carbides in this important area of manufacture.

16.1.3.5 Cubic boron nitride (CBN)

Polycrystalline cubic boron nitride is another comparatively recently introduced addition to the range of metal-cutting materials. It has a hardness considerably in excess of ceramic tools and retains this hardness at temperatures well in excess of 1000°C. The main application is for machining hard ferrous materials at very high cutting speeds, giving a surface finish comparable to grinding. It has relatively good impact resistance, allowing it to be used for interrupted cutting. It is also of use for hot machining of refractory metals such as Stellite, where a 90% reduction of machining time compared with carbide has been claimed. Due to the high cost of CBN tools, the manufacturers do not claim great cost savings, but the time saving is very significant.

16.1.3.6 Diamonds

Diamond is the hardest material known to humans and it has found a limited cutting application where this is an important attribute. Natural diamonds, brazed to steel holders, have been used for many years for producing fine finishes on copper and aluminium. Being monocrystalline, natural diamonds have planes of weakness which render them unsuitable for anything but fine finishing cuts.

The production of polycrystalline synthetic diamonds (PCD) has extended the usefulness of diamonds by improving their impact reistance. PCD cutting tools are now extensively used to machine abrasive aluminium–silicon alloys, fused silica, and reinforced plastics. They are chemically reactive at high temperatures, so they are of little use for machining ferrous materials.

16.1.3.7 Limitations imposed by machine tools

Industry has, until recently, been very reluctant to replace machine tools while they continue to perform the function for which they were purchased. Machine-tool manufacturers market machines which adequately utilize the cutting tools available at the time of purchase. Inevitably, with the rapid development of new cutting materials, the existing machine tools cease to provide a service which uses the cutting tools in an economic manner.

Self-induced vibration, giving rise to chatter, is undesirable in any cutting operation. It is particularly undesirable when using brittle cutting tools where catastrophic failure can become a very real possibility. The problem of self-induced vibration becomes more acute as metal-removal rates increase at high cutting speeds. Ideally, resonant frequencies should be as high as possible, but this requires high structural stiffness and low mass. Unfortunately, dynamic stiffness tends to be directly related to mass, so a simple scale-related solution does little to reduce chatter. The solution, if it exists, lies in structural redesign to enhance stiffness without a proportional increase in mass.

Optimal cutting speeds using modern cutting tools require a large increase in the rotational speed of spindles and a corresponding increase in input power. Manufacturers of machine tools recognize this need, which is reflected in their latest designs, together with improved provision for handling the greater volumes of swarf which are produced.

16.1.4 Cutting fluids

Cutting fluids are used for three main purposes: as a lubricant at low cutting speeds, to cool the tool and work, and to assist in clearing the swarf. At cutting speeds in excess of about 0.7 m/s there is little noticeable lubricating effect. Below this speed extreme pressure (EP) mineral oils containing sulphur or chlorine additives can be used to reduce friction in the latter stages of chip/tool contact due to the formation of low-shear-strength sulphides or chlorides. The balance of the cutting forces is affected, giving rise to a larger shear angle and reduced contact length, and encouraging the thinner chip to curl, making for more effective chip breaking. High compressive stresses near the tool point prevent lubricant penetrating in this area, so the lubricating effect is limited to the latter part of the chip/tool interface where sliding friction occurs. The chemical reaction giving rise to low-strength compounds is both temperature and time dependent. Hence, at higher cutting speeds the lubricant rapidly loses its effectiveness.

High-speed steel cutting tools start to soften at temperatures above about 650°C. When using these materials the cooling effect of cutting fluids enables the tools to be operated at higher cutting speeds than would be possible when cutting dry. Water-soluble oils, having high specific heat and good metal-wetting properties are better coolants than the mineral oils used as lubricants. With carbides and ceramics the poor resistance to thermal shock makes the use of cutting fluids inadvisable except in special circumstances. Fortunately, these materials can be used satisfactorily at high temperatures, and coolants are therefore not usually required.

The purely mechanical function of using cutting fluid to assist swarf disposal is sometimes of prime importance. An example of this application is in deep-hole drilling, where cutting fluid is pumped to the cutting edges at high pressures of about 6 N/mm^2.

16.1.5 Forces and power in metal cutting

Most lathes and milling machines lack the power to exploit the cutting tools in an economic manner. This shortcoming is usually aggravated by a natural trepidation on the part of operators to run machine tools near their power limits for fear of stalling the drive motor. It is surprising that few machine tools are fitted with wattmeters, so operators usually have no idea how near they are to causing an overload.

Among the more sophisticated numerically controlled machines, very few are fitted with adaptive control devices which cause feed or cutting speed to respond to excessive power demands. The vast majority operate from a predetermined program which has been based on safety considerations where the power requirements are well within the rated output of the motors.

There is an ill-founded belief that the cutting forces, and hence the power required, increase significantly as the tools wear, increases of 40% sometimes being quoted. In fact, cutting power seldom increases by more than 10% over the life of the tools.

At rated power, transmission losses usually account for about 30% of the input power, with a correspondingly greater percentage loss when operating at lower energy levels. Transmission losses are higher when the machine tool is cold, and drop significantly over the first half-hour of operation. It is desirable, therefore, to record the transmission power over the full range of cutting speeds and feeds on a machine tool in both the cold and warmed-up conditions. Only then is it possible to know the available power which can be used for cutting.

16.1.5.1 Forces in turning processes

Although a knowledge of cutting forces is desirable to prevent excessive structural loads, the main reason for wishing to know is as a basis for estimating power. The power in watts is simply the product of the peripheral speed in metres per second and the tangential cutting force measured in newtons.

Due to the formation of a built-up edge when cutting steel at low speeds, forces on the tool vary in an unpredictable manner, but above about 2.5 m/s become relatively constant when built-up edge ceases to have a significant effect. At cutting speeds below about 0.7 m/s the lubricating effect of cutting fluids can do much to inhibit build-up, and on the rare occasions when such low speeds are used the cutting force can often be reduced by this means. When using sintered tools it is usually possible to operate at cutting speeds high enough for the forces to be considered constant.

16.1.5.2 Forces and power in milling operations

Peripheral milling removes metal by means of teeth on the circumference of the cutter. It is seldom used to produce large flat surfaces, which are more effectively generated by face milling. Mostly, peripheral milling cutters are used for end milling slots or for producing slots or stepped surfaces by using one or more horizontally mounted side and face cutters or helical slab milling cutters.

End milling seldom requires the rated power of the drive motor. The limiting factor is usually the maximum recommended feed per cutting tooth which will prevent damage to the cutter. Horizontal peripheral milling, however, can be limited by the power of the drive motor, and it is useful to consider the way in which the cutting parameters affect the power required.

Peripheral cutting can be performed in either the upcut or climb mode (Figure 16.10). In upcut milling the cutting edge must penetrate the previously cut surface before chip generation commences. This causes a high radial force at the commencement of the cut which does not happen with climb milling. Cutters with large radial rakes have a weak tooth form which results in rapid wear when subjected to the high radial forces associated with upcut milling. Radial forces experi-

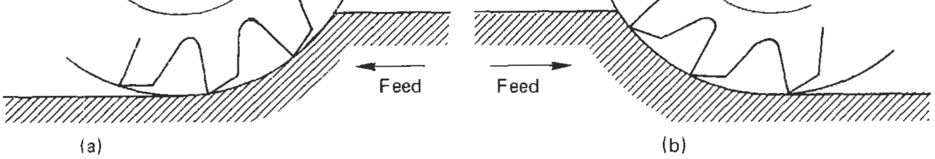

Figure 16.10 Climb and upcut milling: (a) climb, (b) upcut

enced in climb milling are much lower and wear is usually not a severe problem.

Summarizing, the most economic performance in terms of specific power can be achieved when climb milling with a high radial rake cutter operated at large feeds. It is preferable to operate at high feeds rather than high cutting speeds since the index of feed in the cutting power equation is less than unity whereas power is directly proportional to cutting speed.

16.1.5.3 Hot machining

Some work materials pose machining problems which cannot readily be solved by conventional methods. These include the nimonic alloys and Stellite cast alloys. To give some idea of the problems which are encountered, some of the nimonic alloys when machined with carbide tools on a 100 mm diameter bar necessitate cutting speeds as low as 0.15 m/s and tool failure commonly occurs after machining a 100 mm length of the bar. When the surface of the bar is preheated with a gas tungsten arc or a transferred plasma arc struck between the electrode and the work surface and using ceramic or CBN tools, cutting speeds of about 2.5 m/s are possible, and the tools remain serviceable after machining a considerable length of bar.

This technique is not one which would be advised if alternatives are possible, but with some of the more refractory metals now in use the hot-machining process is frequently the only practical solution. The surface preheat temperature is about 600°C, giving such high interface temperatures that carbide tools cannot be used.

16.1.6 Surface-finish considerations

Built-up edge is one of the main factors contributing to poor surface finish. When machining most materials this can be reduced (if not eliminated) by operating at high cutting speeds. Where finish cuts are required, the uncut chip area is relatively small so the cutting power is never likely to be an important consideration, even at very high cutting speeds. If ceramic tools are used the speed limitation is usually that imposed by the available spindle speeds, but when using carbides or high-speed steels the speed constraint is usually that imposed by tool wear.

The theoretical surface roughness in turning is determined by tool plan geometry, a pointed tool operated at a given feed producing a rougher surface than one having a nose radius.

The surface generated by a peripheral milling cutter is directional in property. In the direction of feed the theoretical surface is geometrically similar to that for a turned surface, the cusps having a radius equal to that of the cutter, and the pitch between cusps being equal to the feed per cutting tooth. Due to the almost inevitable lack of straightness of the arbor on a horizontal milling machine, the contour generated by the cutter teeth varies as some teeth take a greater depth of cut than others. In severe cases one tooth may take such a disproportionately deep cut that the surface generated has a periodicity corresponding to the feed per revolution rather than the feed per tooth, and the cusps are correspondingly deeper.

Face milling usually produces a finish superior to that generated by peripheral cutters. The geometry of the cutter is specially designed so that the combination of corner angle, end cutting-edge angle and nose radius produce very flat cusps. In addition, due to the use of carbide cutters, cutting speeds are much higher than those achievable using HSS peripheral cutters.

16.1.7 Tool-life assessment

It is fortunate that, with few exceptions, tool wear occurs in a predictable manner. Although it takes different forms, each is associated with a known cause which happens within particular ranges of feed and cutting speed. The most usual causes are associated with crumbling of the cutting edge, cratering of tungsten carbide, plastic deformation of the tool, thermal and mechanical shock, or attritive wear on the clearance face.

16.1.8 Economics of metal cutting

The main financial objective of a manufacturing company is maximization of return on capital. This implies a knowledge of profitability which, in turn, requires a knowledge of cost and selling price. Production engineers are concerned with the processes needed to make components which are eventually assembled into finished products. Selling price, therefore, is not usually a very useful statistic for the process planner. He or she must settle for sub-objectives such as minimum cost or, sometimes, maximum output which, although not synonymous with profitability, at least contribute to its achievement. When discussing manufacturing economics these are the objectives to which we must address ourselves.

Metal cutting is an intrinsically wasteful operation, involving the removal of large quantities of material. Although there are no reliable figures to support this contention, it is probable that only about 70% of the material purchased is contained in finished parts, the balance being expensively converted to swarf which has a very low resale value. Intelligent design can do much to increase material utilization but material wastage will always be a significant proportion of the total component cost. In spite of the attractiveness of contending production options such as metal forming, it is inevitable that cutting processes will continue to be extensively used. The subsequent analysis assumes that due cognizance has been taken at the design stage of the importance of material utilization, and the cost factors include only the direct cost of manufacture and its associated overhead. The operating cost, taking account of direct labour, machine depreciation and factory overhead, may well be in the order of £20 per hour.

16.1.8.1 Minimum-cost production

The cost of manufacture per component, K, can be divided into five parts:

1. Set-up and idle time cost per component, K_1
2. Machining cost per component, K_2
3. Tool-changing cost per component, K_3
4. Tool-depreciation cost per component, K_4
5. Tool regrinding cost per component, K_5

where $K = K_1 + K_2 + K_3 + K_4 + K_5$. Assuming that disposable inserts are used, there is no regrinding cost, so K_5 can be ignored.

The setting cost can be substantially reduced by using preset tooling. However, with the current trend towards small batch sizes, the setting cost ascribed to each component will increase proportionately. The idle time per cutting cycle is composed of loading and unloading time in addition to the tool approach and tool retraction times before and after machining has taken place. Set-up and idle time can therefore contribute significantly to production cost, and its reduction is frequently the largest single factor in cost minimization.

Machining cost is directly related to cutting time which, in turn, is dependent on cutting speed and feed. The use of large feeds and high cutting speeds reduces machining cost but decreases tool life and, consequently, increases both the unit tool depreciation and unit tool changing costs. It is therefore the minimization of the total of these three costs which determines minimum production cost for any given set-up.

Figure 16.11 illustrates by way of a carpet plot how K typically varies with both feed, f, and cutting speed, v. The main point worth noting is that within the broad range of feeds and cutting speeds selected the minimum cost occurs inside the speed range and at the maximum value of feed.

16.1.8.2 The influence of chatter

A great deal of research has been published on the stability boundary between width of cut and spindle speed.[8] The boundary envelopes vary with the machine tool and the process parameters, but a typical boundary is shown in Figure 16.12, where the maximum width of cut under stable machining conditions decreases as the spindle speed increases. A large tool approach angle and nose radius increase the effective length of the cutting edge, which is tantamount to increasing the width of cut and decreasing the uncut chip thickness. If chatter is likely to occur it is obvious that tool approach angle and nose radius should be kept as small as possible, a recommendation which conflicts with recommendations as regards tool life.

The influence of feed on the stability boundary is more significant, but this does not appear to have received the attention it deserves. *Figure 16.13* shows how the critical width of cut increases as feed increases, making the case for using large feeds to oppose the onset of chatter.[9]

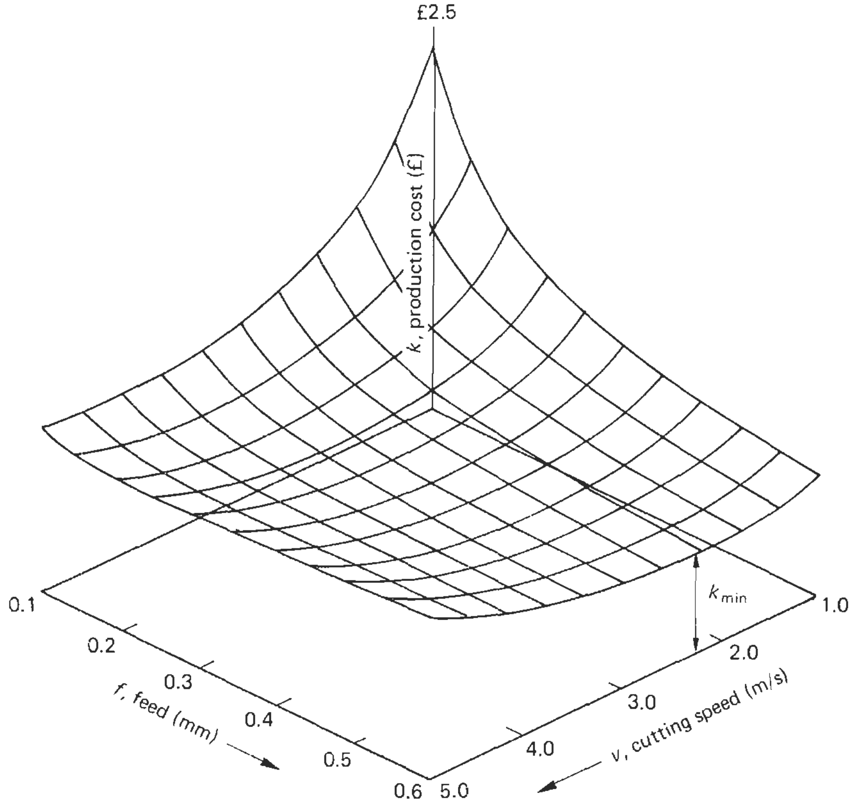

Figure 16.11 Production cost related to cutting speed and feed

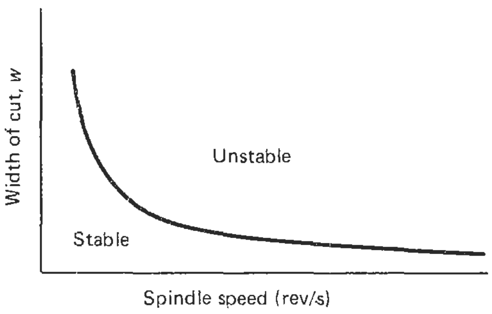

gure 16.12 Variation of stability threshold with spindle speed

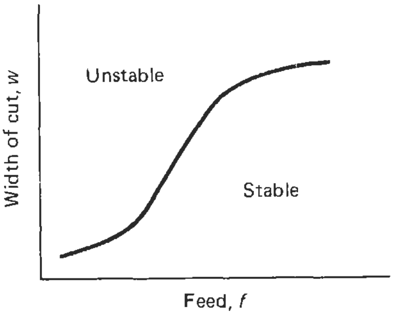

Figure 16.13 Variation of stability threshold with feed

In conclusion, it is pertinent to stress again the importance of large feeds in achieving not only chatter-free performance but also low specific cutting power and minimum-cost machining.

16.2 Metal forming

16.2.1 Introduction

Metal forming, i.e. changing the shape of the material without actually removing any part of it, was practised at least 3000 years ago in Egypt, where hammer forging to produce gold sheet, cut subsequently to make wire, is recorded in the Bible to have taken place. Rolling in wooden mills was employed to manufacture papyrus. Manual swaging and wire drawing were well established in the Middle Ages but, naturally, were limited in scope by the power available. It was only with the advent of the Industrial Revolution that progress was made and processes like extrusion and cross and longitudinal rolling became available. But even here, the restrictions imposed by the low quality of tool materials, lubrication problems and the lack of understanding of the basic precepts of plasticity impeded progress until, in some cases, well into the twentieth century.

The ever-increasing demand for high quality products—often of sophisticated shape in difficult to process materials—economically produced, fabricated or semi-fabricated, combined with the rising cost of metallic engineering alloys has focused attention on metal-forming processes and techniques.

The emphasis here lies on the 'chipless' approach to shaping. This provides an economical, direct means of converting a cast ingot to slab, plate, billet or bloom and then—in another chipless operation—of changing these basic shapes into profiled finished or semi-finished products. The avoidance of the removal of the material during a forming operation enhances the economics of the process by reducing wastage associated with the swarf-producing machining. Whereas the latter has, of course, a very considerable and necessary role to play in the range of manufacturing activities, its indiscriminate use (a feature of the early years of plentiful supply of cheap labour and materials) is no longer acceptable when high tonnage of accurately manufactured product can be obtained at a much lower cost.

In the most simplistic terms, the desired change in shape is effected either in the cold, warm or hot state (the latter below the melting point of the material) by the application of external forces, pressures or torques of sufficient magnitude to induce plastic flow, and thus a permanent set, of the material through the forming pass. Depending on the operation, the material is forced to flow between driven rolls, through (or into) open or closed dies, or between sets of dies and rolls. Solid or hollow sections are thus produced from the initially solid blocks of metal.

The *standard* basic operations are:

1. rolling (flat, oblique or longitudinal),
2. extrusion (axisymmetrical or asymmetrical),
3. drawing (solid or hollow components),
4. sheet forming (deep drawing, bending, pressing or bulging),
5. forging (solid and hollow sections), and
6. cropping (shearing and piercing).

Within the compass of any of these operations, a number of variants exists which reflects not only a variety of manufacturing routes and subroutes, but also the nature, properties and characteristic responses of the processed materials. Modern metal-forming technology makes use of solid and semi-solid ('mashy' state), and superplastic, as well as explosively pre-welded metallic composites and dynamically compacted particulate matter. Mixtures of metallic and/or ceramic and polymeric materials are formed to manufacture composites of very specific properties. The problem of forming these into desirable shapes presents the engineer with new and often difficult situations to solve. Selection of the appropriate forming process, the tool design, the effects of the pass geometry on the final physical and mechanical properties of the product, the dimensional accuracy, and the achievement of the as near as possible final shape in the minimum of operational stages have to be faced.

The apparently simple sequence of ingot–slab–semifabricate–finished product becomes complex unless there is good understanding of the basic characteristics of the individual processes and an appreciation of the principles of the theory of plasticity, as well as that of the concepts of tool and process design. The bases for and fundamentals of the major processes and technological developments are discussed in the following sections, but detailed treatment of the individual topics is only indicated by reference to the appropriate literature.

16.2.2 Classification of processes

For a given application, the selection of the correct process necessitates the introduction of a criterion of process classification. Since hot working homogenizes and refines the crystallographic structure of the material and thus, ultimately, improves its strength and toughness, whereas cold working increases strength, hardness, dimensional tolerances and improves surface finish, these temperature-induced effects are often used to differentiate between the various manufacturing methods.

Important as the processing temperature is, in some circumstances other criteria of classifying metal-forming processes may well be more appropriate. From a purely manufacturing point of view, quantity and shape may have to be considered, while the likely response of the processed material to the level and/or rate of stressing, as well as the manner of application of the forming load system, may offer a better clue to the desirability or otherwise of using a particular technique or operation.

The parameters that characterize forming operations give rise to the following possible classification systems:

1. operational temperature (hot, warm or cold forming),
2. shape effect (bulk or sheet forming),
3. operational stress system,
4. operational strain rate,
5. starting material (ingot, slab, billet, bloom, slurry, or powder).

16.2.2.1 Operational-temperature criterion

The idea behind the subdivision into hot, warm and cold processing of materials is not only to indicate the nature of the operation, but also to draw attention to the plant and ancillary equipment needed, to the level of force parameters required, and to the likely metallurgical response of the processed material.

An outline of this classification scheme, including only the basic operations, is given in Table 16.1.

Starting with a cast ingot, the primary hot operations of flat, billet and slab rolling, and slab forging will produce the starting stage for the secondary, further processing of the slab into plate, billet or a large forging. These, in turn, will form the first step in the manufacturing route of a more sophisti-

Table 16.1 Classification of dynamic regimes

Characteristic time (s) *Strain rate* (s^{-1})	10^{6} 10^{6} 10^{-8} 10^{-6}	10^{2} 10^{0} 10^{-4} 10^{-2}	10^{-2} 10^{-4} 10^{0} 10^{2}	10^{-6} 10^{4}	10^{-8} 10^{6}
	Creep rates	*Quasi-static rates*	*Intermediate strain rates*	*High strain rates*	*Very high strain rates*
Primary load environment	High or moderate temperatures	Slow deformation rates	Rapid loading or low velocity impact	High velocity impact or loading	Very high velocity or hypervelocity impact
Usual method of loading	Constant load or constant stress machines	Conventional hydraulic or mechanical machines	Fast-acting hydraulic or pneumatic machines, cam plastometers, low impact devices	High velocity impact devices, expanding-ring technique, high-speed metal cutting	Light gas gun or explosively accelerated plate or projectile impact
Dynamic considerations in testing	Strain versus time	Constant-strain-rate test	Machine stiffness wave effects in specimen and testing machine	Elastic–plastic wave propagation	Shock wave propagation, fluid-like behaviour
	← Isothermal →		← Adiabatic →		
	← Inertia forces neglected →		← Inertia forces important →		

cated, profiled product. Hot operations are carried out at elevated temperatures exceeding annealing and normalizing ranges and, consequently, yield a hot-finished product showing a relatively low level of flow stress. However, the force parameters required match the mechanical properties of the material and are also relatively low. It follows that the rate of wear of the tooling can be kept at an economical level especially if the lubrication problems are well under control.

To improve the mechanical properties of the product, while at the same time keeping the loading at a moderate level, warm processing is used. Here, the temperatures are well above ambient but, equally, well below the hot-processing range, and usually slightly less than for recrystallization. The increased material ductility is sufficient to reduce the power requirement of the plant. Cold-working conditions are confined to ambient temperature and are characterized by a high energy requirement—necessitated by large operational forces and/or torques—but result in very high quality final product displaying both good dimensional tolerances and mechanical properties.

A rough guide to the temperature ranges can be obtained by considering the operational temperature/melting point ratio. On this scale, hot working takes place when the ratio is >0.6, warm working when the ratio is 0.3–0.5 (the latter corresponds to recrystallization conditions), and cold when the ratio is <0.3.

16.2.2.2 Shape-effect criterion

The effect of shape reflects the geometry of both the initial and final component and, consequently, the nature of the change imposed on it by the forming operation.

A process in which a component of a relatively small initial surface area/thickness ratio is deformed in such a way that the ratio is increased, is often classed as a 'bulk deformation operation'. On the other hand, the component of an initially high surface area/thickness ratio, shaped in a process which does not impose any change in the thickness but effects shape changes only, is said to be 'sheet formed'. Any change in the thickness of such a component can easily lead to tensile plastic instability and incipient, localized yielding.

Bulk processes are those of rolling, extrusion, forging and solid- and/or hollow-section drawing. Bending, pressing, deep drawing, spinning and shearing are the main sheet-forming operations.

16.2.2.3 Operational-stress system

Because of the inherent severity of many forming processes, particularly the rotary ones, a consideration of the type and property of the induced stress field is of primary importance. The success of the operation may well depend on its compatibility with the properties of the processed material.

The presence of tensile and compressive stress fields results in the appearance of shearing stresses which, in turn, lead to the sliding of molecular planes and, eventually, to the yielding and plastic flow of the metal. Stress systems containing these components are most likely to give rise to plastic flow which, if it is controlled, will produce the desired amount of deformation.

Purely compressive or tensile systems create conditions of hydrostatic pressure in a triaxial field (absence of shear), or produce shearing stresses in uni- and bi-axial conditions. Clearly, since it is the configuration of the individual stress system that is indicative of the type of deformation which can be expected, its assessment prior to choosing a forming system is imperative. These various possibilities are illustrated, diagrammatically in Figure 16.14.

As an indication of the incidence of any of the stress systems, the following, non-exhaustive, list can be considered:

Tensile–compressive systems
Biaxial tension/uniaxial compression:

1. under a roll of a two-roll piercer,
2. under a roll of a two- and three-roll piercer, and
3. under a roll in the helical rolling process.

2. bulging.

16.2.2.4 Operational strain rate

A number of engineering alloys and even some practically 'pure' materials, e.g. commercially pure aluminium, are susceptible to the changes in the rate of straining. Modern technological techniques have either 'speeded up' conventional processes—for instance, wire can be drawn at some 120 m min^{-1} —or have introduced new ones that operate in truly dynamic conditions. Impact extrusion, explosive forming, welding and compaction, and mechanically and electrically induced discharges of energy producing high strain rates, have all combined to introduce an entirely new field of high-energy rate fabrication, known commonly as HERF.

The range of possibilities arising in this context are listed in Table 16.2 which provides a detailed insight into the effect of different strain rates and the means of producing them in an industrial environment.

Table 16.2 Mass-velocity relationship contributing to total kinetic energy

Forming system	*Mass contribution* (kg)	*Velocity contribution* (m s^{-1})	*Velocity/mass*
Drop hammer	144	122	0.84
Trapper rubber	144	122	0.84
Floating piston	4.54	3050	672
Explosive in gas	0.004	2.75×10^6	687×10^6
Explosive in liquid	0.008	1.52×10^6	190×10^6
Electric discharge	0.008	1.52×10^6	190×10^6

16.2.2.5 Starting material

Since some modern processes do not require bulk solids as starting materials, but utilize particular matter and semi-solid substances, a classification based on the initial physical state of the material offers an interesting alternative to the more conventional approach.

Typical examples of unconventional starting materials are: 'mashy' state processing, leading to conventional rolling of composite sandwich components; the Conform-type extrusion, starting with a powder or granulated material, or an explosive compaction of powders.

16.2.3 Characteristics of the basic groups of processes

Of the major processes listed in Section 16.2.1, forging is the most diverse and cannot therefore be described in more general terms. For this reason, the basic characteristics of only four groups of processes are indicated here and those of forging, sheet forming, cropping, etc., are discussed later.

All rolling processes rely on the forces transmitted through the rolls to the material to effect deformation and on the rigidity of the roll system for the dimensional accuracy of the product.

Sheet and plate are initially obtained from a slab by rolling the slab in a relatively simple system (Figure 16.15). Driven rolls introduce the material into the roll gap, or working zone of the pass, and reduce the thickness. The success of any further processing to obtain strip rather than a sheet or large area of plate, depends on the ability of the system to maintain a constant width of the processed metal and on reduction of the thickness (this being equivalent to the reduction in the cross-sectional area). These requirements call for a plane strain operation which is possible only if the lubrication of the pass is very efficient. Processing in this mode can proceed in either cold or hot conditions.

A much more complex rolling system is that of longitudinal rolling, which is employed in the production of axisymmetrical billets, bars and hollows (Figure 16.16). A train of suitably shaped rolls, mounted on stands (either in pairs or in three-roll configurations) inclined at right angles (between the successive stands) is used, as shown diagrammatically in Figure 16.16(a). A gradual reduction in the cross-sectional area of the material takes place (Figure 16.16(b)) as the specimen moves axially forward through the sets of driven rolls. While fully engaged in the train, the processed material experiences, additionally, axial tensions resulting from a differential distribution of successive stand velocities. The ovality of the early passes is slowly reduced along the train until the last stand is reached. Here, the final, circular cross-section is expected to be achieved.

An alternative to longitudinal rolling is offered by the oblique-rolling system in which a single set of two or three driven rolls produces tractive, frictional forces which propel the specimen axially while, at the same time, causing it to rotate. The motion of an element of the worked material is thus forward, but helical.

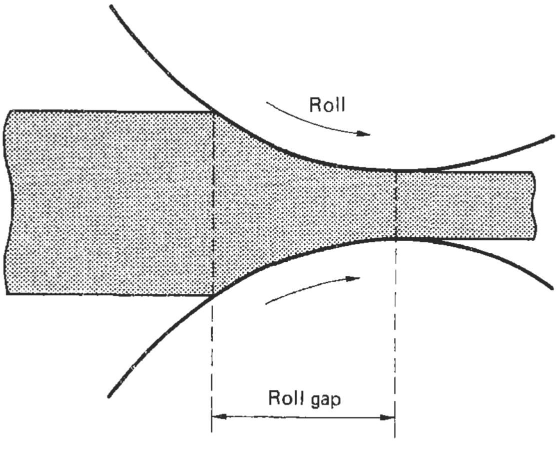

Figure 16.15 The principle of sheet and plate rolling

Figure 16.17 illustrates, using an example of tube rolling, the basic principle involved. In this case, three profiled, driven rolls, disposed at 120° to each other, and inclined at an angle α (the feed angle) to the horizontal mill axis, and an angle β (the cone angle) in the vertical plane, introduce the bloom (supported internally in the bore by a mandrel) into the forming pass. The bloom is 'sunk' onto the mandrel in the zone AB and has its wall thickness reduced on the roll 'hump' BC. Slight elastic recovery takes place along DE. The bloom is thus elongated and its wall is thinned. The amount of deformation imposed depends on the size of the inter-roll opening or the 'gorge'.

These basic characteristics of oblique rolling operations (the variants of which are discussed later) are common to all operations, as indicated, for instance, in Figure 16.18. This shows, diagrammatically, the operation of the so-called 'secondary piercing', or 'oblique plug rolling' of a tube—a process in which a long cylindrical mandrel is replaced by a short profiled plug.

On the other hand, processes of profiling by rolling can take various forms, one of which is indicated in Figure 16.19 where a stepped shaft, required to acquire a series of specific profiles, can be manufactured by oblique rolling in a single three-roll stand. An operation in which the billet is rotated and fed through a system of driven rolls produces this effect. In another variant of oblique rolling, a two-roll system of helically ribbed rolls (Figure 16.20) will produce metal balls out of a solid cylindrical billet.

These few examples illustrate the versatility of rolling operations, a more detailed discussion of which is given in Section 16.2.4.

When the initial shape of the work piece has been imposed on it by one of the processes described above, there often arises the problem of how to achieve a degree of further deformation leading, possibly, to the final product. Drawing processes answer this need by providing a means of producing either solid (bar, rod or wire) or hollow tubular sections, either circular or non-circular in shape. The drawing operation is carried out in a die—or a set of consecutive dies forming a tandem drawing system—into which the work piece, with a swaged leading end, is introduced (Figure 16.21). An axial force is applied through a gripping device (as indicated by the arrow in Figure 16.21) and the work piece is pulled through the die. In the case of a solid specimen, the outer dimension only is reduced, whereas with a hollow section there is also a change in the wall thickness. Lubrication of the working zone of the pass (the part of the die surface along which the deformation is effected) is of importance from the point of view of the magnitude of both the drawing load and the induced drawing stress, and in view of the surface finish.

Similar results can be obtained in extrusion, a process in which the starting billet (sometimes referred to as the 'slug') is inserted into a cylindrical container and is then pushed mechanically through a suitably profiled die (Figure 16.22). There is a number of variants of this process (see Section 16.2.6), but the two basic operations are those of forward (or direct) and inverse (or backward) extrusion. In the forward extrusion a solid moving ram is brought into direct contact with the billet and activates the latter by moving it axially forward through the die. In inverse extrusion a hollow ram is in contact with a movable die which bears onto the billet, firmly held in the container. When the pressure exerted by the tooling is sufficiently high to exceed the yield stress of the material, plastic flow is initiated and backward extrusion into and through the hollow ram takes place.

Considerable control over the dimensional accuracy can be exercised in such systems but, again, solution of the lubrica-

tion problem is of importance. In this latter context, hydrostatic extrusion (to be described later) provides an important alternative to the conventional arrangements indicated here.

A large group of 'unorthodox', dynamic processes introduces a number of new elements and opens new operational possibilities of using materials which are sometimes difficult to process and of reducing manufacturing costs by dispensing with heavy plant and equipment.

The high-energy-rate processes stem essentially from the usually overlooked fact that the working of metal requires energy and not merely the application of force, and that, in addition, the rate of dissipation of energy is of importance. A simple consideration of the basic equation for kinetic energy shows that a comparatively small change in the velocity of a body will have a more pronounced effect than will a change in its mass. A typical conventional system approaching the conditions of high-energy forming, i.e. drop-hammer forming, is limited in its usefulness by the necessity of using large masses and, therefore, unwieldy and costly equipment.

The sources of energy used in the high-velocity systems are chemical explosives, electrostatic and magnetic fields, and pneumatic–mechanical devices. The basic processes are those of forming (shaping), welding and powder/particulate-matter compaction. A variety of forming systems exists, each displaying specific characteristics associated with either sheet or tube forming, for which it is intended.

16.2.4 Rolling processes and products

16.2.4.1 Classification of processes

With the exception of special steels and/or profiled sections rolling processes follow one of two main routes:

1. production of plate and strip; or
2. production of billets, bars, rod, sheet, tube or sections.

Traditionally, both routes start with a cast ingot (Figure 16.23) which is then rolled down to slabs (route 1) by cogging. In route 2, cogging again leads to the production of a bloom (a product of over 10 cm^2, or equivalent, in cross-section), and then to either a variety of small flats or large rounds or, through a billet mill, to a billet (a product of cross-sectional area less than 10 cm^2). However, very satisfactory developments in the area of continuous casting have led to the introduction of casting machines into these cycles. In the new, fully automated and computer-controlled, high-productivity works, continuous casting of slabs has to a great extent eliminated the cast ingot.

In route 2, in a modern mill the stress is on the use of continuous billet casters (in preference to bloom casters), thus eliminating one stage of the production line. Where blooms are still required, normal practice is to employ two or three strands of material which are then rolled in two or three passes to produce blooms. With smaller sizes of billet, up to six strands can be cast.

It is clear from *Figure 16.23* that the manufacture of a wide range of either semifabricates or finished products calls for a variety of mills and plant settings. A very brief review of these is provided here but, again, detailed information can only be obtained from the Further Reading at the end of this chapter.

Basically, the process, whether hot or cold, begins with the preparation of stock such as an ingot (in older plant) or continuously cast bloom or billet. In hot operations this is followed by heating in a strictly controlled atmosphere and temperature, and then rolling proper. Finishing of the work piece includes a number of operations such as cutting, cooling and, very often, straightening. In cold operations, which are used to enhance the mechanical properties of the material and improve dimensional accuracy, the ancillary equipment consists of furnaces for heat treatment and plant for surface finishing. Whereas modern plant comprise not only the rolling mill(s) proper, but also a number of pieces of ancillary equipment concerned with the preparation of the material prior to and post rolling, interest centres mainly on the actual mill since the dimensional quality of the product will depend mainly on its performance.

According to their actual functions, rolling mills are subdivided into the following classes:

1. cogging mills (production of blooms, billets and slabs from ingots, where these are still used);

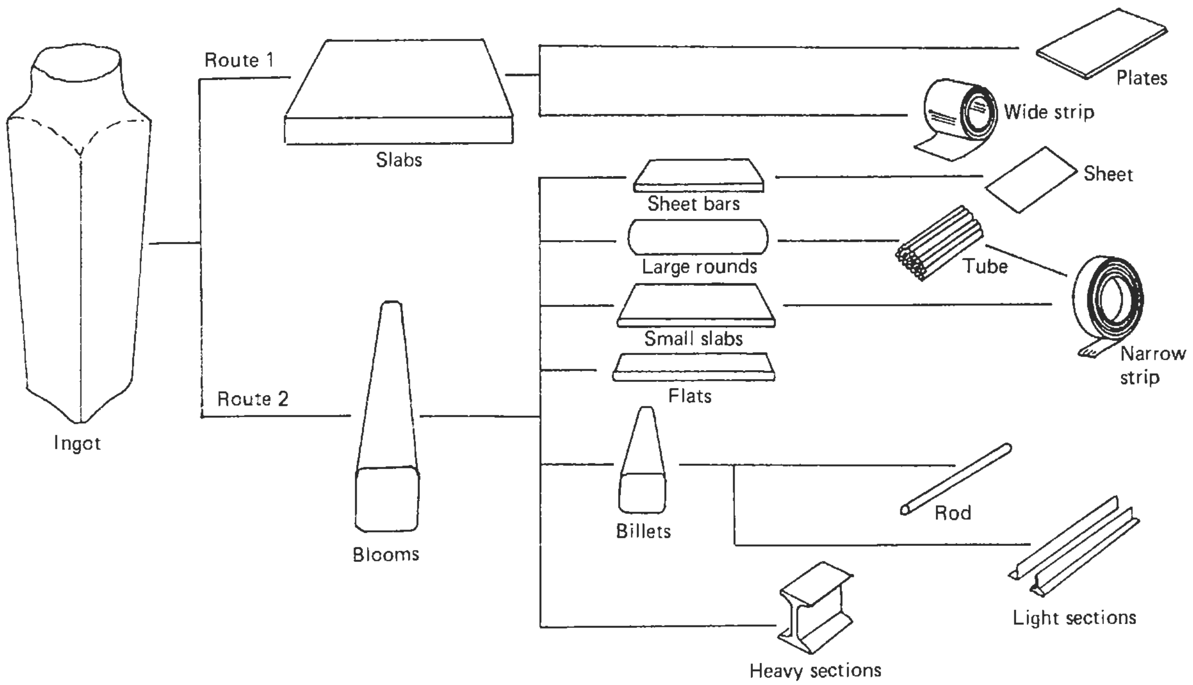

Figure 16.23 Schematic, simplified representation of the sequences of the basic rolling processes. Route 1 leads to the production of plate and wide strip. Route 2 results in sheet, narrow strip, tube and sections

2. plate, strip and sheet mills;
3. tube mills (longitudinal rolling and cross-rolling);
4. section mills (production of profiled sections, rounds, flats and strip); and
5. special mills (production of machine parts).

An individual mill is characterized by the function for which it is intended and also by the type, position and number of rolls. These are located in stands, which in some cases are incorporated in a stand train. Depending on the position of the stands, mills can be further classified as linear (where the stands are in a line and there may be one or two lines driven by a single motor), or continuous (where a number of stands is placed in tandem and, at any given time, rolling takes place in more than one stand).

In each stand the number of rolls involved defines the stiffness of the structure and, therefore, reflects on the dimensional accuracy of the product, whereas the disposition of the rolls specifies the function of the system. Irrespective of the complexity or otherwise of the roll arrangement, the actual work of deformation is normally performed by a pair (or a set) of innermost rolls which are backed up (for the mentioned structural stiffness) by a number of other usually larger diameter sets of rolls. The number of these gives rise to the name of the mill which is described as *n*-high.

A selection of basic arrangements for flat, horizontal rolling is given in Figure 16.24. With reference to the figure, the following types of mill can be distinguished.

1. *Two-high*—either (i) reversing or (ii) non-reversing.
   (i) Used for slabbing, large rail, profiled sections and thick plate rolling.
   (ii) Used for continuous rolling of billets, rods, rounds and plate, linear rolling of sheet, and for dimensional calibration of the product.
2. *Double duo*—used mainly in older mills for rolling small and medium-sized rods, strip and profiled sections.
3. *Three high*—used for rolling medium and large billets, rails, rods and profiled sections.
4. *Three-high with the middle roll oscillating between the two outer rolls*—all the rolls are driven; used for blooming or slabbing of ingots of around 3.5 ton in weight.
5. *Three-high Lauth, with an idle middle roll*—used for rolling thick plate and as a first stage in linear hot rolling of thin sheet.
6. *Four-high*—either (i) reversing or (ii) non-reversing.
   (i) Used for cold rolling thin strip and hot rolling thin and thick plate.
   (ii) Used for continuous hot rolling strip and plate and cold rolling strip.
7. *HC rolling mill (Hitachi)*—used mainly for cold rolling plate and strip.
8. *Taylor mill*—used for precision rolling of thin sheet and strip.
9. *Six-high*—used for cold rolling thin sheet and foil.
10. *Sendzimir twelve-high mill*—used for cold rolling thin sheet and foil.
11. *Twenty-high, planetary Sendzimir mill*—used for cold rolling thin sheet and foil.

The quality of product in terms of material properties depends considerably on whether processing takes place at an elevated or at ambient temperature. Rolling hot is not only intended to minimize the forces and torques necessary to effect deformation, but also to improve the structure through recrystallization. Unless recrystallization takes place, strain hardening (produced by deformation) will adversely alter the structural characteristics of the metal, even at temperatures much higher than ambient. The processing temperature should, therefore, lie above that of recrystallization, in order

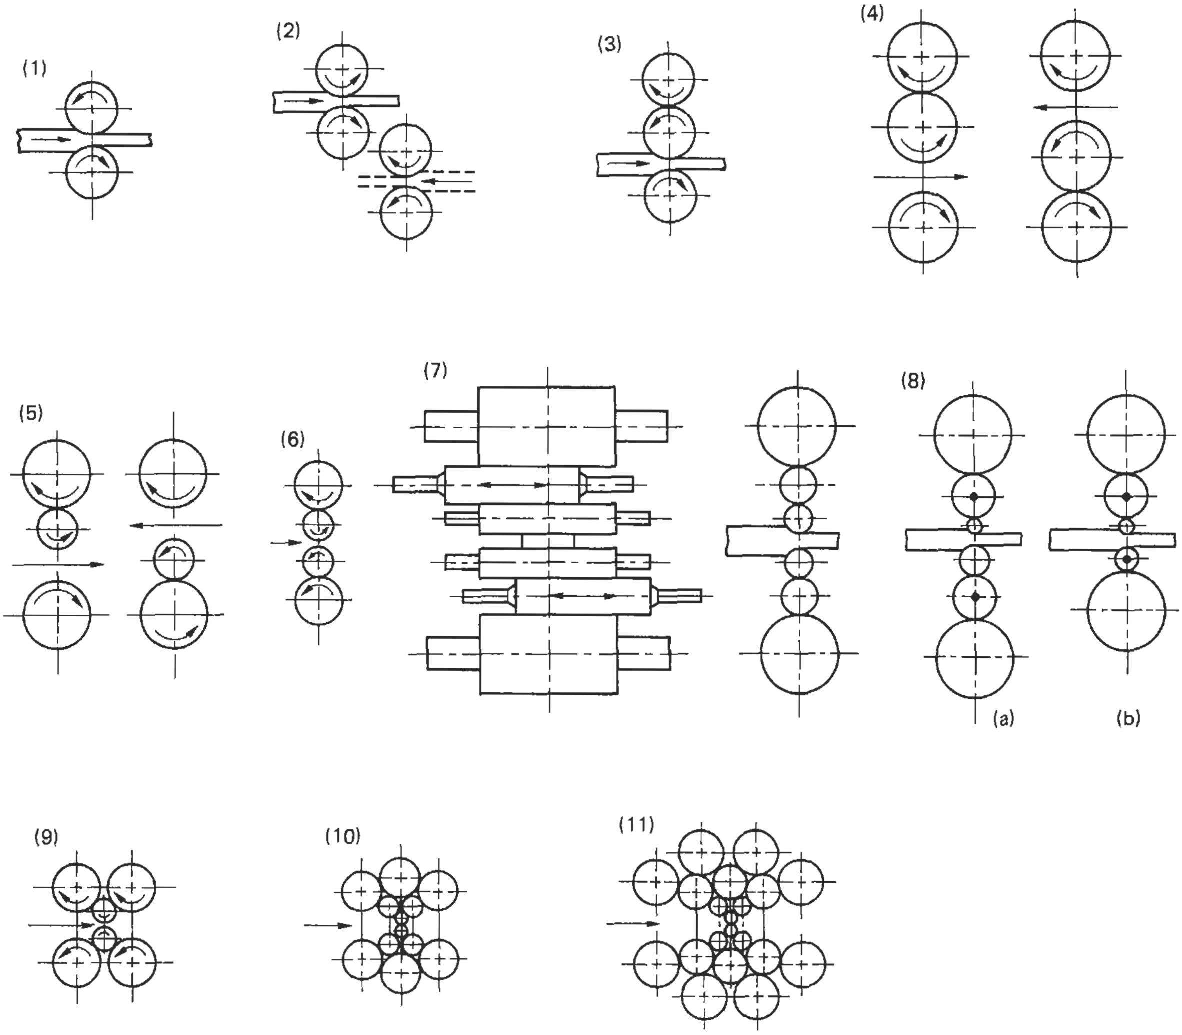

Figure 16.24 Flat rolling: scheme to show the position of horizontal roll systems. For a description of (1) to (11), see text

to produce new, small grains (Figure 16.25), but below the value at which oxidation takes place and affects the surface of the product.

The main function of cold rolling, as already mentioned, is to improve the mechanical properties of the alloy, to impart a surface finish suitable for the future use of the product, and to enable the manufacture of dimensionally accurate very thin sheet, strip and foil (0.001–0.2 mm thick) and 'medium' thick sheet (1.0–1.5 mm thick). Depending on the quality of the surface, the rolled sheet can be used for stamping when the material displays fine-grain finish, for plating when the surface is smooth, or for further artificial surface coating when the surface is dull.

16.2.4.2 Rolling of plate, strip and sheet

The definition of each of these products is somewhat vague, but it is usually taken that, in hot processes, a rolled item is referred to as 'plate' when its thickness is in the range 4–160 mm and its width is 600–3800 mm. Sheet that is 4–50 mm thick and 200–1500 mm wide is also sometimes called 'universal', whereas 'thin sheet' or 'thin strip' is material

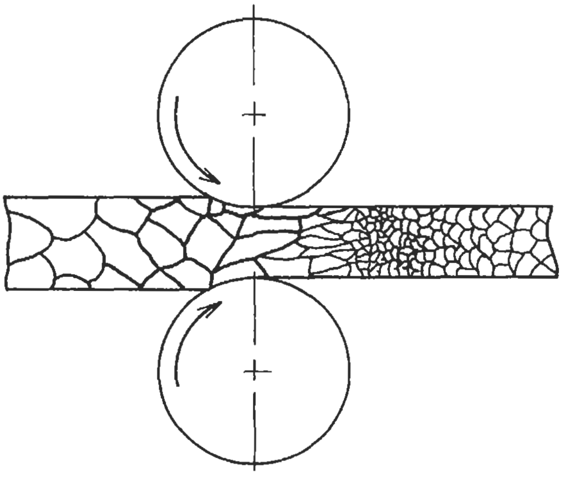

Figure 16.25 Recrystallization in hot rolling

of thickness 0.2 to <4 mm with a width of 600–2400 mm. 'Plate', intended as a constructional material for bridge structures, general building purposes, boilers, ship hulls, car and railway rolling stock bodies, etc., is rolled up to a length of some 36 m, depending on the final use of the product. Rolling is done either from slabs or flat billets. Thicker plates are usually produced in linear, two-stand, two-high reversing systems ((1) in Figure 16.24) followed by a train of four-high finishing stands. Typically, thinner plates may be rolled from slabs in a single stand, Lauth linear system ((5) in Figure 16.24) or, for greater accuracy, in a planetary mill.

More recently, thick and thin products have been rolled in semi-continuous systems employing two universal stands in tandem, followed by a continuous mill arrangement.

Strip and medium heavy sheet are produced in lengths of 4–20 m on either linear or planetary mills; with the latter, in particular, high thickness reductions of up to 95% are obtained.

Thin sheet, intended as structural material, is often rolled, as separate items, to a length of approximately 1800 mm, or alternatively in long lengths in continuous mills and is then coiled. The car and electronic industries, in particular, make considerable use of steel and aluminium alloy sheets and strips coated with thin layers of plastic material. The metallic product used in such applications varies in thickness from some 0.3 to 2 mm.

Cold rolling operations have a two-fold objective: to improve the mechanical properties and dimensional accuracy of the product and to enhance the economic feasibility of the operation (hot rolling of materials to less than about 2 mm thickness is uneconomical). Due to economic considerations hot-rolled strip or sheet is further processed in a variety of mills (very similar to those shown in Figure 16.24), but particularly in planetary or cluster mills if very thin material is required. A typical arrangement employed in the latter case is shown in Figure 16.26. The usual working sequence consists of pickling the hot-rolled material, rolling to the required size, followed, where necessary, by heat treatment and, finally, by general finishing operations.

The range of thicknesses that can be obtained depends, to a degree, on the properties of the starting material, since the roll forces and torques required can be very high. It is often because of this that cluster mills, characterized by their high rigidity, are used. Low carbon steel can be rolled down to a thickness of about 0.2–0.4 mm. Similar strip thicknesses are obtained in Inconel, Monel, nimonic and bimetallic combinations, rolled in Sendzimir mills which use rolls of 450–1300 mm in length. Consecutive rolling operations are employed to produce very thin foils.

16.2.4.3 Rolling of structural sections

Semifinished or hot-finished structural sections are rolled in semicontinuous, continuous, Universal, linear, or H mills. Although a variety of shapes and components can be made on such mills, of particular engineering interest is the rolling of medium and heavy sections. Depending on the actual sizes and weight per length run, these comprise channels, I- and T-beams, rails and angular sections, as well as semiproducts intended for further processing, such as rounds, squares and flats. Without being specific about the type of mill, it is generally understood that 'bar mills' are used for rolling heavy sections and 'rod mills' for light sections.

Channels (50–450 mm high, designated as heavy sections when the height exceeds 200 mm) are usually processed in continuous mills, as are T-sections (30–220 mm high). The method of manufacture of I-beams is less uniform. Smaller sizes (below, say, 200 mm in height) are produced in continuous mills, whereas heavy sections (up to 600 mm and, occasionally, up to 1 m in height, with flanges of 200–400 mm in width) are rolled in universal-type mills. The method of rolling steel rails depends on the weight per metre run. In general, sizes range from 8 to 75 kg m^{-1}, the 40–75 kg m^{-1} sizes representing heavy sections.

In most cases, two-line, two- or three-high, two- to seven-stand linear systems are used but, more recently, special universal and H-type mills have been introduced.

The semifabricates (rounds 6–200 mm in diameter; square sections 8–200 mm side) are produced on semicontinuous and continuous mills, as are rods (5–8 mm in diameter) intended for wire manufacture. These products are rolled in up to 39 stands.

16.2.4.4 Rolling of seamless tubing

Seamless tubing is produced by either longitudinal or cross (oblique) rolling of hot finished rounds. Both manufacturing routes start with pickling, dressing, heating and piercing the billet to provide a roughly made tube which can then be further hot and, if necessary, cold processed. The latter stages are intended to give dimensional tolerances to the product and, in the case of cold processing, to impart both better mechanical properties and, often, better surface finish.

The two routes comprise the following intermediate processes:

1. *Longitudinal rolling* consists of rotary or punch piercing, plug or mandrel rolling. It occasionally may incorporate the Erhardt or push-bench process, followed by the finishing sequences of sinking and stretch reducing.

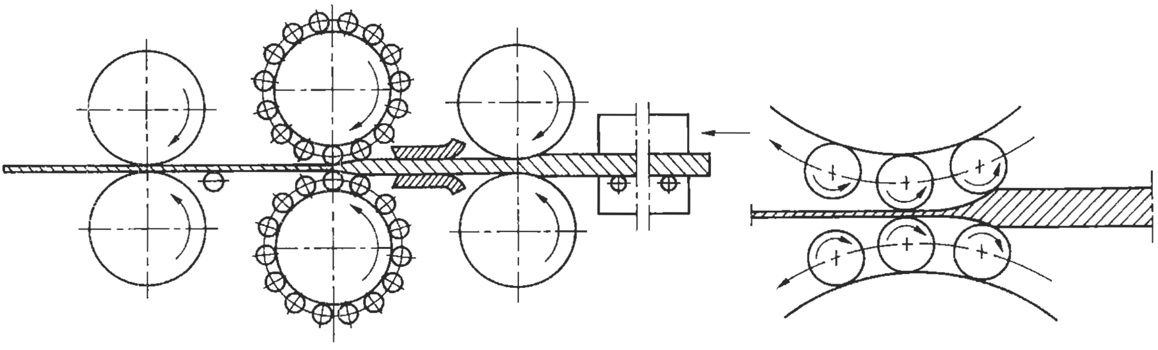

Figure 16.26 System incorporating a planetary mill for cold strip rolling

2. *Cross-rolling* involves rotary piercing. Assel elongating (possibly a combined piercing–elongating process) or Diescher elongating.

Irrespective of the route followed, the piercing stage precedes further operations and consists either of rotary piercing of a solid round or hydraulic punch piercing of a square billet.

Of these two methods, cross-rolling (Figure 16.27) is carried out in a two- or three-roll system in which the rolls are inclined at an angle (feed angle α) to the central axis of the mill, and a plug (situated on a long bar) is inserted between the rolls. The plug bar can either be free to rotate or driven.

With the rolls set obliquely to each other, the billet is drawn into the pass by frictional tractive forces, the axial component of the forces being responsible for the forward movement and the tangential component for the rotation. The physical conditions that develop in the pass are equivalent first to oblique rolling and then to cross-rolling. The cross-rolling zone extends from the plug nose to the exit from the pass, and the billet is worked between the roll and plug surfaces.

The process is not continuous, in the sense that the successive arcs of the billet circumference come, in turn, into contact with the rolls. The set-up clearly tends to develop ovality in the billet, unless horseshoe-type adjustable guides are introduced between the rolls. Up to a point, these guides rectify this undesirable condition and help to preserve circularity of the tube.

Longitudinal rolling The main elongation of the bloom, to produce a hot finished hollow, is carried out in either a plug or a mandrel (continuous) mill and is then completed in one or two finishing stages.

In the plug-mill system, the plug, a short cylindrical, detachable tool, is maintained in position by a plug bar, an arrangement similar to that in the rotary piercing plant, and controls the dimensions of the bore of the hollow. The work piece passes through grooved, oval rolls that are usually positioned in two stands and maintained at 90° to each other. The mill is generally used as a breaking-down stage and operates on tubing of 3–40 mm wall thickness and 20–400 mm diameter.

In the mandrel-mill system the hollow bloom is threaded on a long mandrel and is fed into a continuous train of 7–10 pairs of rolls arranged in tandem. The tube is rolled out on the mandrel without interruption to approximately the finished thickness. The axes of the rolls are alternately at right angles to one another. The earlier breaking-down passes have considerable ovality. The finishing passes are designed to leave the tube loose on the mandrel and more or less circular so that no reeler is required to enable the mandrel to be withdrawn.

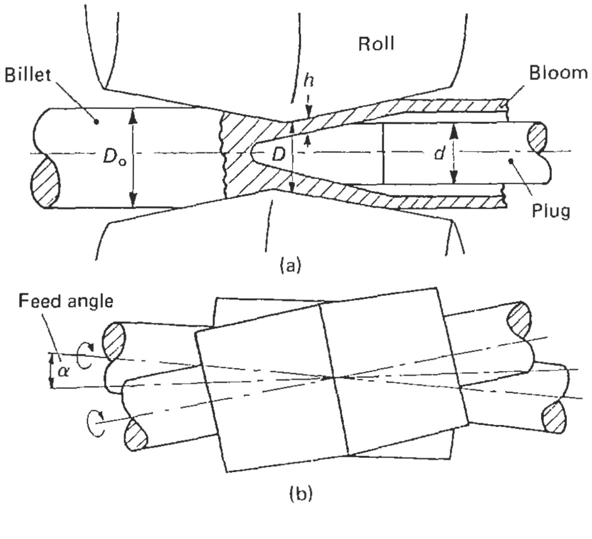

Figure 16.27 Rotary piercing of rounds

The method is no more continuous than any other seamless process which starts with a billet of finite length and rolls it into tube. The continuous mill is outstanding for producing long lengths of all thickness at a very high rate of output.

The final rolling stage uses a sizing or reducing mill to give the tube its final outside diameter with, preferably, little change in wall thickness. Reducing mills fall into three broad categories:

1. sizing,
2. stretch reducing, and
3. sinking.

Sizing mills are used to produce an accurately sized finished tube without appreciably reducing the outer diameter. They are usually equipped with three to seven stands, each containing two rolls, and are normally designed for an overall diameter reduction of 3–8%. In general, the diameter reduction is accompanied by a thickening of the tube wall.

Sizing mills are usually installed in plants designed to produce the larger tube-size range, but can be used with advantage in the manufacture of smaller tubes when following main seamless processes that are reasonably flexible in the sizes that they can produce.

Reducing sinking mills comprise a continuous train of passes designed to reduce a larger tube to a smaller one without a mandrel or plug to support the bore. The amount of reduction per pass is usually 3–5% according to the type of mill.

A reducing mill is usually employed in conjunction with a main unit to improve the performance of the latter. This may be done by:

1. reducing the number of size changes to be made in the mill;
2. increasing the weight of the billet worked by the mill and, therefore, the rate of output; and
3. increasing the maximum length available, and decreasing the available minimum diameter.

In obtaining these advantages the following disadvantages must be taken into account:

1. a reheating furnace is necessary;
2. an additional process is thus introduced increasing costs of fuel, power, labour and tenance;
3. tubes become thicker during reduction and, therefore, the mill must roll thinner gauge; and
4. the quality of the bore of the tube deteriorates for various reasons and this limits the amount of reduction possible.

These mills are usually designed with up to about 24 two-roll stands, and are capable of overall diameter reductions of up to 55%. The stands are driven through bevel gear boxes from common line shafts, and the behaviour of the tube-wall thickness depends on the relationship between the gearbox reductions. It is normal for sinking mills to operate with no axial tension between the stands so that the wall thickens freely. If, however, some tension is applied, wall thickening can be restricted to about half of that which would occur without tension.

Stretch reducing mills are primarily used for the economic production of small diameter thin-walled tubes. As the name implies, the wall thickness is reduced in the process and, to achieve this condition, considerable tension must be applied between the stands (Figure 16.28).

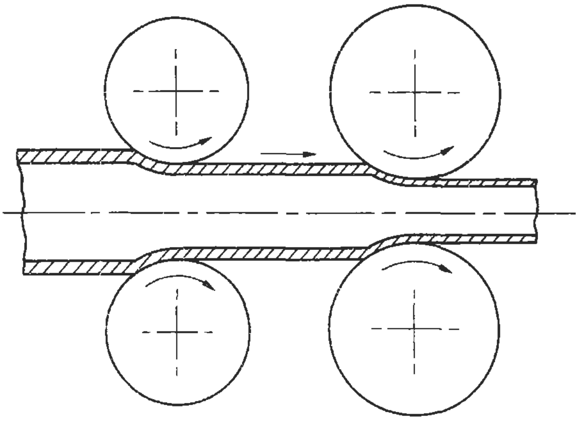

Figure 16.28 Rolling with interstand tension in a stretch-reducing mill

The mills are designed with up to 22 stands, each with two or three rolls, and are capable of overall diameter reductions of more than 75%, and wall reductions of up to 40%. To obtain the control required over the interstand tensions, the mills are designed with either d.c. motor drives to each stand or hydraulically regulated drives.

As the ends of the tube cannot be subjected to full tension in the mill, they are inevitably heavy walled and of a length that is proportional to the elongation, stand spacing and percentage wall reduction. The end crop can have a significant effect on the yield and, therefore, it is necessary to put the longest possible length into the mill to minimize the percentage loss.

In addition to the essential change in the outer diameter of the tube in the reducing operation, there is always some change in wall thickness. The thickness change plays a vital role in the design and operation of reducing mills and depends on the rolling condition.

No-stretch conditions prevail when a tube passes through a single stand, so that its diameter is reduced without any external axial forces being applied to it; the thickness also increases. In this case, where the change in wall thickness occurs purely as a result of the compressive action of rolls on the tube, the reduction is said to take place under the 'no-stretch condition'.

In a mill consisting of a number of stands that are all reducing the tube simultaneously, this condition can arise providing that the roll speeds in successive stands are set such that there is no tension or compression in the length of tube between each pass. Since there is always an increase in the linear speed of a tube as it is reduced, the roll speeds in successive stands must be increased in relation to the elongation that occurs. It follows that if a tube is being continuously processed through a number of reducing mill stands, the volume of flow must be constant. The cross-sectional areas multiplied by the linear speed must, therefore, be the same at all points in the mill, and as the tube area is reduced its speed must correspondingly increase.

Under no-stretch conditions, the whole tube thickens uniformly throughout its length, the amount of thickening being dependent on the diameter to thickness ratio of the in-going tube and the total diameter reduction given. It is unaffected by the reduction given in each stand or by the number of stands working on the tube at any time.

Conversely, in no-stretch conditions, if tension occurs between the stands, wall thickening can be partly or fully compensated for, or the wall thickness can be reduced. Tension is applied by arranging for each pass to run at a higher speed, relative to the preceding pass, than is required for no-stretch conditions.

With *stretch conditions*, not only is the thickness reduced between the stands but the diameter is also reduced so that the actual reduction in diameter brought about by the compressive action of the rolls is slightly less than that which takes place with no stretch, resulting in slightly less thickening of the tube wall between the rolls. Stretching can occur only on a section of tubing which is between two passes. Consequently, the extreme ends of the tube can never be subjected to stretch nor can an appreciable length at the ends suffer the full stretching action. Therefore, a mill that is designed to stretch or in which stretching occurs produces a tube that is thinner in the centre than at the ends, the thickness at the extreme ends being that which would arise under no-stretch conditions and the centre thickness being that arising from the stretching action. The thickness change is not abrupt but gradual and there is normally an appreciable length of uniform thickness between the thickened ends.

The push-bench process (Figure 16.29) forms an alternative to the above routes. The standard push-bench system incorporates punch-piercing of the hot billet, while retaining a solid base on the leading end, elongating on the bench proper and hot-reducing on an appropriate mill. To retain a reasonable degree of concentricity, the depth of penetration of the piercing punch must not exceed seven times the punch diameter. The 'bottle' which is fed into the bench is relatively short and the process may not be fully economical.

Modern developments have led to the introduction of roller-type dies (the Manfred–Weiss process) and, even more recently, to the incorporation of an elongator in the cycle. The elongator increases the depth of penetration to nine times the punch diameter while retaining good concentricity through the medium of equalization of the wall thickness. Since the elongator will also reduce the diameter of the bottle, the amount of deformation to be obtained on the bench is lower and the quality of the manufactured tube is higher.

Some of the advantages of the elongator are, however, offset by the fact that the gauge correction cannot be carried out at the ends of the bottle and that some reduction in output must therefore be expected.

When the elongator forms an integral part of the cycle, reheating of the bottle, after punch piercing, will be necessary and will, of course, add to the cost of the operation.

The modern push-bench is normally used for the manufacture of tubing of outer diameter of 6–15 cm. Thin-walled tubing can be obtained in lengths of up to 10 m when an elongator is used, and in lengths of up to 6 m without the elongator.

The advantage of the modern roller-die beds of the bench proper over the old ring-die system lies in the reduction of thrust required by about 30%, and a reduction in the size of the die bed by about 25%. Although the provision of three or four rolls in a cluster is more expensive than the installation

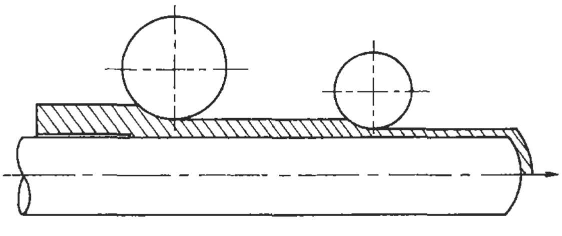

Figure 16.29 Push-bench process

and maintenance of ring dies, the considerable increase in speed of the working cycle, resulting from the possibility of using more passes on a given bed, and from the actual increase in the axial speed of the operation, offsets the apparent economic disadvantage. High speeds of operation are, in fact, required in the case of alloy steels which harden rapidly with a drop in temperature.

Cross rolling The two major rotary production processes employed are those of Mannesmann and Assel. In the Mannesmann cycle a cold centred round billet is heated in a roller-type furnace, pierced in an oblique rotary mill, possibly repierced on another rotary piercer, hot forged, reheated in a continuous furnace and stretch reduced. The piercing and repiercing operations are of primary importance from the point of view of the incidence of redundancy.

In the Assel cycle (Figure 16.30), the billet is heated in a roller-type or rotary-hearth furnace, pierced in an oblique rotary mill, elongated in the Assel mill, reheated in a continuous furnace, and then either sized or sunk on a longitudinal rolling mill. The first two stages, i.e. piercing and elongating, account for most of the redundant shears induced in the worked material.

To increase the range of possible deformations, it is occasionally necessary to follow the piercing stage by a repiercing or secondary piercing operation in which the bore of the pierced bloom is increased while its wall thickness is reduced. A purely elongating operation in which the bore remains unchanged and the wall is further deformed will follow. Secondary piercing operations have been developed from the basic Assel elongating technique and are considered in that context.

An Assel mill is shown diagrammatically in Figure 16.17. In this process, the previously pierced tube, with a cylindrical floating mandrel inserted in the bore, is drawn by frictional forces into the pass defined by the setting of the rolls. In the entry zone of the pass, the diameter of the tube is slightly reduced. The hump of the roll then reduces the wall thickness, and a smoothing operation takes place in the reeling zone of the pass to remove the triangulation of the vertical section of the tube. Final rounding of the tube proceeds in the exit zone of the roll. Elongation occurs primarily as a result of wall thinning, but it is also slightly influenced by the reduction in tube diameter.

Of special interest in tube making is the production of stainless-steel tubing. This, as will be seen later, is generally manufactured in extrusion, but rotary processes are also used, since the rate of yield is likely to be higher.

The production routes used in this case are somewhat complex and reflect both the cost of the material and basic processing difficulties. The main process lines are:

1. punch piercing, Calmes elongator, rotary hot forging;
2. punch piercer, push-bench, polishing mill;
3. disk rotary piercer, plug mill; and
4. Mannesmann rotary piercer, hydraulic push elongator, rotary hot forging.

A possible alternative to asseling is offered by the Diescher elongator. This mill incorporates two oblique barrel rolls and two disks (set at right-angles to the rolls) which replace the horseshoe guides necessary (see piercing) to correct the ovality of the tube. Elongation is carried out between the rolls and a bore-supporting mandrel. The mill improves concentricity of the tube and, by effecting elongation in both forward and backward directions relative to the gorge, imparts a burnishing finish to the tube.

16.2.4.5 Flow forming

Practical difficulties of producing large diameter, thin-walled long tubing in a variety of materials, including stainless steel, has introduced a new approach because the ordinary manufacturing techniques could not always cope with the sizes and materials involved and, even where this was possible, the cost of production was very high.

A solution to this problem was first proposed, on a modest scale, in the early 1950s when the horizontal flow-turning lathe was introduced. This was followed by a vertical cold 'floturning' machine in which three stands, carrying five rollers each, were introduced. In this, short thick-walled bloom is supported in the bore by a solid cylinder of hardened tool steel machined to the exact tolerances and to the degree of surface

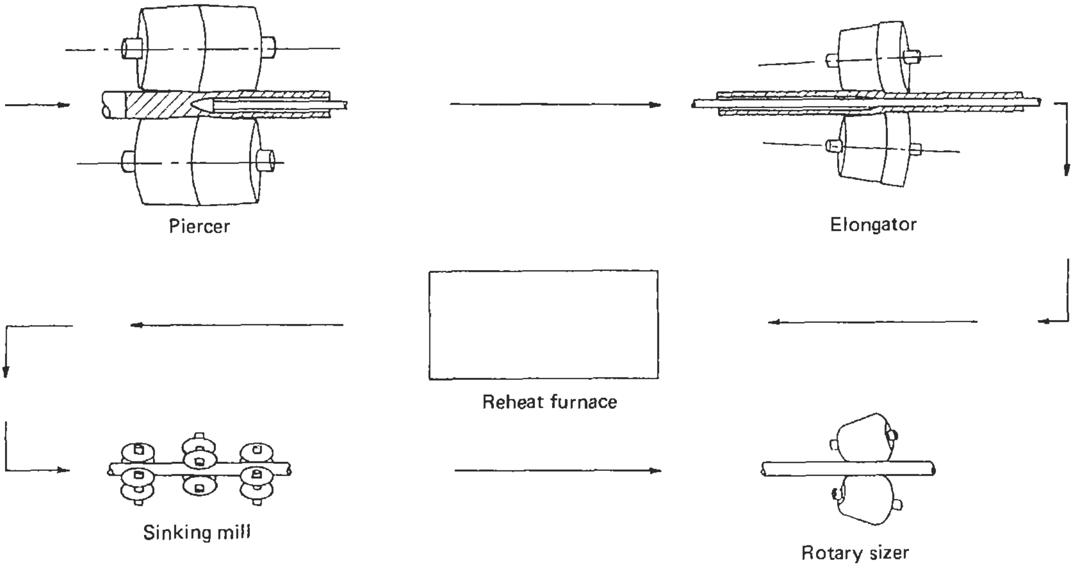

Figure 16.30 The Assel cycle

finish which is required of the bore. Each station, capable of angular adjustment to obtain optimum forming conditions, is powered hydraulically. Rollers are advanced into the forming positions and retracted at the end of the cycle. The wall thickness of the bloom is easily reduced by one-sixth of the total reduction by each roller. As an example of the possibilities, in one pass a steel cylinder of 1.25 m outer diameter, 1.25 mm thickness and 3.5 m in length can be formed from a hollow of 8 mm thickness and about 0.75 m in length. In effect, therefore, the machine reduces the wall thickness of the hollow, elongates the work piece between the rollers, but retains the original diameter of the bore. The control of the mechanical properties of the material can be maintained throughout annealing, and that of the surface finish can be maintained throughout the finish of the roller surfaces.

Some limitations on the length of the tubing obtained on a vertical machine can be expected and this appears to be the reason for a parallel development of horizontal 'floturning' equipment. The floturn process does, in fact, utilize, in general, the horizontal-type machine.

The development of horizontal machines was initially stimulated by the demand for large diameter, long tubing required for the boosters on space vehicles. The equipment designed for this purpose is capable of turning out precise tubing of up to 635 mm in outer diameter and of 30 m length in alloy steels, titanium, Monel, aluminium and stainless steel.

Essentially, the process consists of reducing the diameter of an initially thick-walled, short hollow by threading and clamping the latter on a rotating mandrel, and driving a carriage with the forming rolls along the work piece. The carriage contains three rollers located at 120° to each other which, when driven slowly over the surface of the hollow, will reduce its thickness. This particular process, known as 'par-forming', can retain wall-thickness tolerances to within ±0.51 mm on, say, a 655 mm outer diameter, 2.95 mm thick and 13 m long aluminium tube, and on a 508 mm outer diameter and 2.15 mm thick stainless steel component.

To achieve these high tolerances, a certain amount of preparatory dressing of the hollow is necessary. Initially, the hollow is turned, faced and machined in the bore. The bore is usually honed to remove tool marks and to impose the required tolerances. The tube should fit the mandrel to within 200 μm and, for the final tube sizes stipulated above, it should be about 1.5 m long. Mandrels are made of high quality chromium–molybdenum–tungsten steels and are ground to give tolerances of the order of 51 μm.

The actual forming operation takes place in two stages. Again, for the sizes discussed, something of the order of five passes of the forming rolls over the hollow will be needed, these will be followed by annealing and, finally, by two further finishing passes.

Machines of this type are fully capable of forming tubular components with shoulders, tapers and partial or full closures. The range of tube sizes varies from about 75 to 700 mm in outer diameter, the range of wall thickness being 0.38–3.8 mm. Surface finish can be controlled to within 380 μm on the bore and 760 μm on the outer surface.

Floturning machines are often incorporated in mechanized plant and this facilitates cleaning of tubing prior to adhesive bonding, where required, of two dissimilar metallic components. Cleaning sequences depend on the material processed but, in general, will include emulsion, water and alkaline cleaning for non-ferrous materials (e.g. aluminium) and pickling in nitric hydrofluoric acid for, say, stainless steels.

The capital cost of the equipment involved in these operations is obviously high, as is the cost of hollow dressing, and the cost increases with the increase in the outer diameter of the tube. Clearly, the existing industrial units serve very specific purposes and are not necessarily intended for ordinary commercial purposes. In their own field of application, i.e. large diameters, thin walls, and substantial lengths, they are well advanced compared with other methods.

The possibility, however, of using the same principle for processing small diameter tubing has not been neglected. One of the main problems arising here is that of buckling. In the nose forming of steel tubes, where the components are compressed on a mandrel by conical rollers, the effect of wall thickness on the stability and formability of the tube is noticeable.

16.2.4.6 *Rolling of machine parts*

Although developed primarily for tube manufacture, cross-rolling processes are now often employed, for reasons of economy, in the production of a variety of machine parts.

These range from a three-roll, oblique rotary grooved shaping of a shaft (Figure 16.19) to the helically two-roll manufactured special hubs (Figure 16.31). Three-roll (inclined at 120° to each other) finned-roll systems are used in the production of finned tubing of high dimensional accuracy, whereas grooved two-roll mills are used to produce ball bearings (Figure 16.20). Bevel and spur gears, as well as bearing races and similar components are manufactured by cross-rolling with a very substantial saving in material as compared with many machining production routes in a variety of rolling systems.

16.2.4.7 *Sheet roll bending*

An interesting development in the area of cold-rolling is that of using especially profiled rolls to bend metal sheet (usually aluminium, but also hot or cold rolled steel) into simple or even complex shapes that serve as structural components in the car and aircraft industries.

Bending is carried out in machines incorporating roll trains of driven and idle tools, which can produce long length (up to 30 m) suitably profiled components, without changing the initial thickness of the sheet.

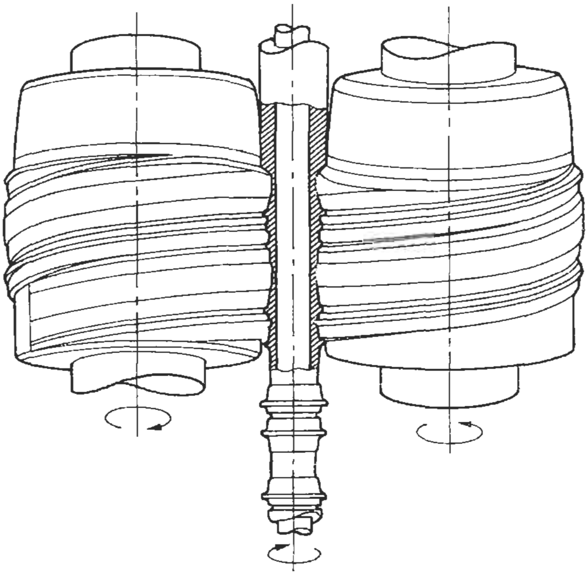

Figure 16.31 Cross-rolling shaped-hub manufacture

16.2.5 Forging operations

16.2.5.1 Basic concepts

Forging, one of the oldest known metal-forming operations, relies entirely on the application of compressive forces to effect the change of shape. In its simplest form, forging is used to preform a billet by changing its dimensions (preparatory to further shaping), and in its more sophisticated form it produces complex shapes to a very high degree of accuracy. Depending on whether the operation is carried out hot, warm or cold, forging affects the structure and properties of the forged component to varying degrees.

Whilst being essentially simple in concept, forging processes, in their many varied forms, are in fact extremely complex. By far the most common group of processes is concerned with the forging of ferrous alloys and a breakdown of the costs involved in producing the average ferrous forging illustrates the reason for the introduction of new methods, techniques and ideas. The cost can be apportioned as follows:

Material in final forging	35%
Material wasted in forging	15%
Labour	10%
Overheads	30%
Tools	10%

It is clear from these figures that material usage is an area in which savings should be introduced and, consequently, innovative preforming processes of powder forging, transverse rolling and cast preform forging, aimed specifically at reducing material usage, must be considered in addition to the standard techniques normally employed. In this context, the idea of forging is of particular interest.

In the hot forging process, the work piece preheat temperature is usually chosen to be as high as possible, consistent with the production of a sound forging, thus exploiting the benefit of minimum flow stress. Any accompanying consideration of economic and technical feasibility must make reference to the work piece preheating costs, corresponding handling costs and the effects of surface oxidation and decarburization. Cold forging of steel, on the other hand, is conducted at room temperature with a consequent saving in heating costs and material wastage, but against this must be set the higher tooling costs. The fact that some work hardening usually takes place is only infrequently exploited.

It is not surprising, therefore, that the possibility of forging at intermediate warm temperatures is advocated in order to obtain the benefits of both hot and cold forging. In this connection, two approaches are adopted.

The first seeks to improve the accuracy of the hot forging process by selecting preheat temperatures high in the spectrum between hot and cold forging. If, for a typical mild (low carbon) steel a forging temperature of, say, 800°C is chosen, then oxidation will be reduced, thus permitting a lower machining allowance and benefit will be gained from the low flow stress. Tolerances of ±0.25 mm are claimed for warm forging in this temperature region. In addition, the small amount of strain-hardening which occurs may be beneficial in some cases. It is important, however, to realize that the heating and attendant costs are still present. As the temperature is reduced further, the flow stress begins to increase rapidly and the process becomes less attractive.

The second approach is from the cold-working end of the spectrum. Due to strain-hardening and strain-ageing effects, lower grade steels may be taken to higher final strengths. This is also in competition with heat treatment over which it has the advantage of being more controllable. A further refinement is to start the process with a quenched and tempered structure on top of which warm forging will produce even more strength and ductility.

In its classical form, forging is of three main types:

1. open die,
2. impression die, and
3. closed die.

In addition, the already mentioned modern developments have given rise to a whole series of processes of hot and cold rotary forging (including tube making), orbital forging, high-energy-rate (dynamic) forging of both shapes and particulate matter, and cast-preform forging.

The objective of the 'standard' operations is to produce, in stages, machine parts and components such as gears, wheels, compressor and turbine disks, crankshafts and connecting rods, small tooling, screws and bolt heads, and coins and medals, and to assist in the conduct of other operations by providing simple preforms. Punch piercing of billets is a typical example of the latter application of forging.

16.2.5.2 An outline of open-, impression- and closed-die operations

Open-die forging, also known as 'upsetting', is concerned mainly with reducing the height of a cylindrical billet. This is generally done between two flat dies, although the dies can be profiled in a simple manner to impart a specific shape to the ends of the upset specimen.

The outcome of an upsetting operation, in terms of the shape of the preform, depends on the frictional effects that develop between the dies and the faces of the billet. With efficient lubrication, the reduction in height produced by the application of compressive forces is accompanied by an increase in the diameter of the billet, but with the billet retaining its original sharp edges. In an unlubricated or poorly lubricated operation, the deformation becomes inhomogenous and barrelling occurs. The amount of barrelling depends on the value of the width/height (d/h) ratio and the reduction in height r (Figure 16.32).

Although open-die forging offers a simple and relatively inexpensive means of producing small components, it calls for a high degree of manipulative skill on the part of the operator, since acquisition of the basic shape can only be achieved by turning the work piece to different positions between successive blows. The deforming forces are applied either mechanically by means of powered hammers or manually. In either case, the rate of yield of the component is low and the process is unsuitable for mass production. The additional difficulty, which has an additional cost associated with it, is the requirement to machine the specimen in order to obtain both the desired final shape and the required dimensional tolerances, neither of which is likely to result from the forging operation on its own. The machining stage naturally introduces an element of wastage of material and an additional labour requirement.

To introduce a high degree of dimensional accuracy and better material usage, impression and closed-die forging operations are used. These operations are shown in their most basic form in Figure 16.33. The fundamental requirement is that the die cavity, whether that of an impression die (Figure 16.33(a)) or a closed die (Figure 16.33(b)), is completely filled with the forged material and, most importantly, that the material remains structurally sound. The more complex the shape to be forged, the more involved the production line becomes since, clearly, it is impossible to convert a starting cylindrical or square billet to the desired shape in a single blow. Not only are preforming operations required, but several actual forging stages may also be needed.

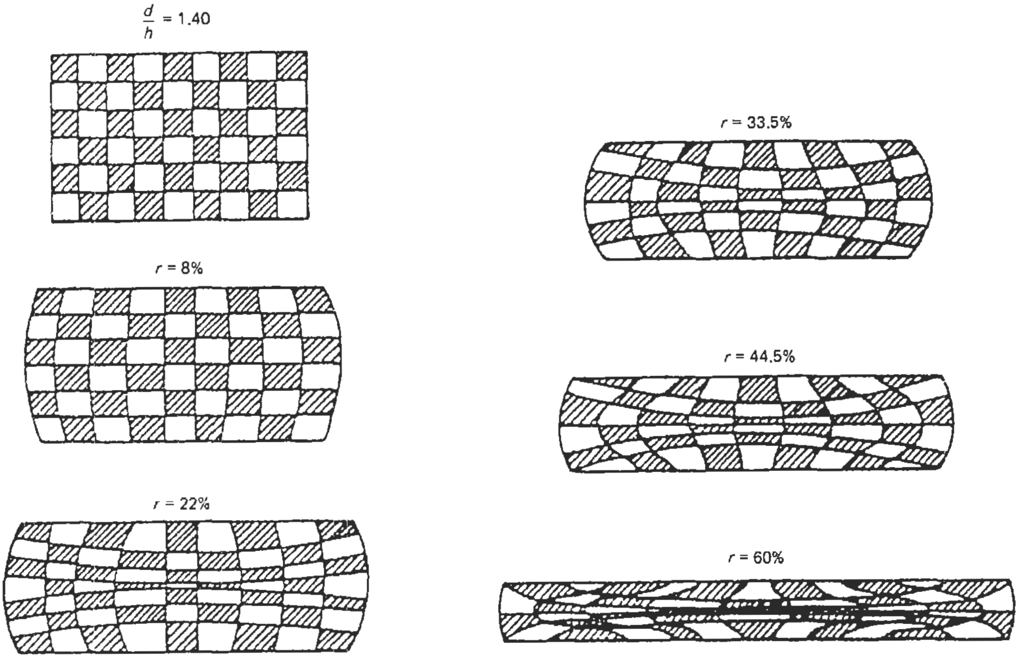

Figure 16.32 Barrelling in unlubricated, open-die forging

The basic characteristics of impression dies is the fact that, when activated by a mechanical hammer or hydraulic press, they do not close completely, and thus some metal is allowed to escape and forms a flash (Figure 16.33(a)) between the flat surfaces. The presence and magnitude of the flash are of considerable importance in impression-die forging because they influence the mechanics of the operation. By the nature of its geometry, the flash is subjected to high pressures and, consequently, it experiences a high degree of frictional resistance as it propagates radially outwards. This constrains the tendency of the bulk of the material to flow between the dies and, therefore, creates better conditions for the filling of the die cavity. This action is further assisted by rapid cooling of the flash (as compared with the cooling of the material in the die), which results in a further increase in the resistance to flow. These characteristics form the basis of die design.

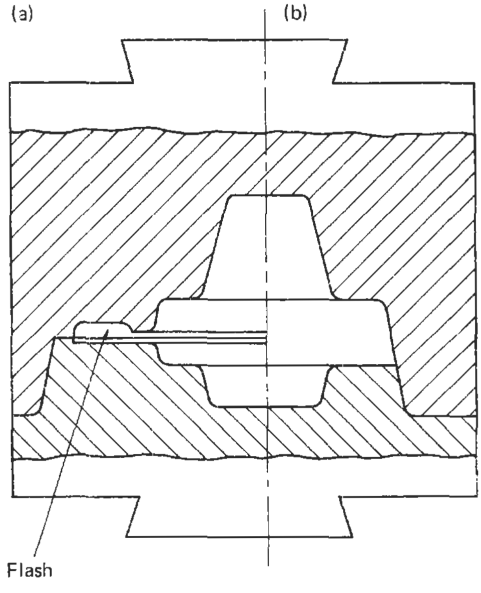

Figure 16.33 (a) Impression-die and (b) closed-die forging

In the normal sequence of operations, preforming will be necessary and may consist of the following operations:

1. simple upsetting,
2. blocking, and
3. rolling.

Upsetting and blocking in blocker dies are the more usual routines, although rolling (see previous sections) of profiled shapes is also used.

A blocker die belongs to the impression-die group, but provides only a general outline of the work piece. The final stage is not achieved using a blocker die, but the material is distributed in a way that ensures a more acceptable uniformity. On trimming the flash, the work piece can undergo further processing in a finishing die that will impart to it its final shape.

A set of impression dies will produce a parting line in the specimen and, unless the die design takes into account the most likely response of the material, in terms of its pattern of flow and formation of fibres in its structure, problems may arise because, on trimming, the fibres are severed.

To facilitate the removal of the forging on completion of the operation, dies are provided with draft angles (a situation similar to that in casting).

Reduction in height, piercing and bulging are the basic operations associated with impression-die forging. However, their sequence and intensity depend on the required shape of the forging. Figure 16.34 illustrates a selection of the possibilities arising in these operations. If the required forging is of simple shape, the arrangement shown in Figure 16.34(a) may

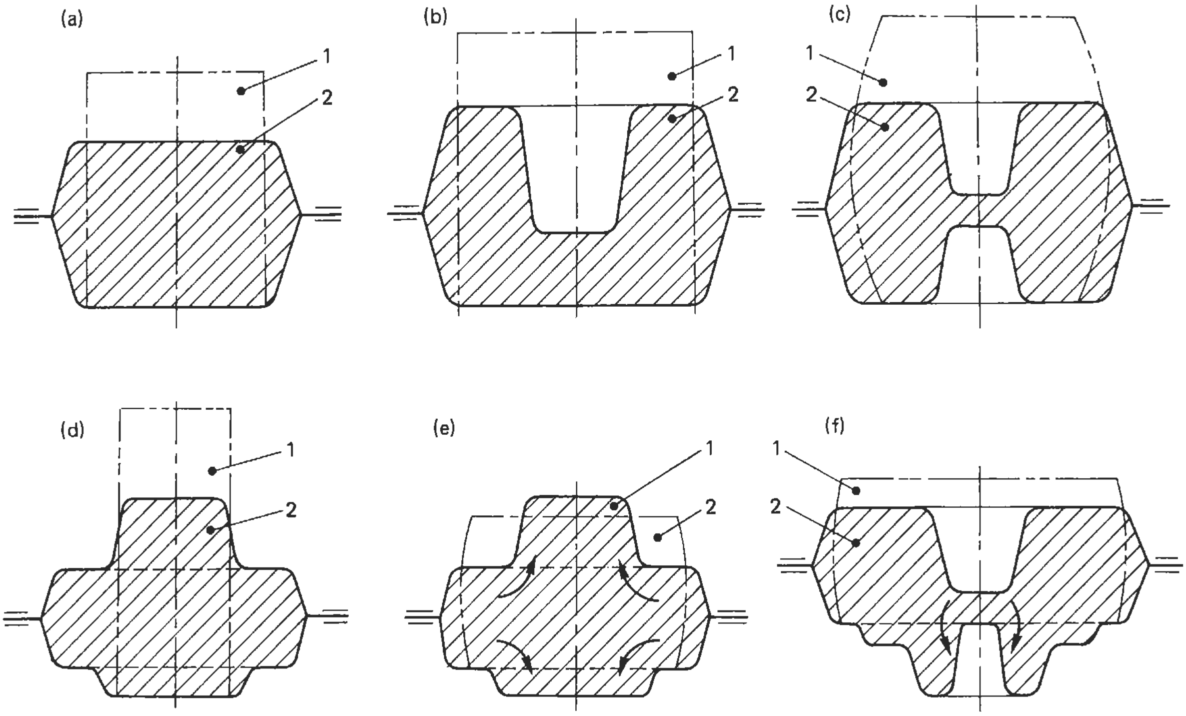

Figure 16.34 Different routes of filling the cavity of a finishing die: 1, starting shape; 2, final shape of forging

be sufficient. If one- or two-sided indentations are needed (Figure 16.34(b) and (c)), the final shape is obtained by height reduction and piercing in the die. Formation of more complex shapes with side bulges, etc., depends on the dimensions of the starting material. If the diameter of the billet is less than that of the elongated part of the axisymmetric forging, then the cavity is filled simply by reducing the billet height (Figure 16.34(d)). On the other hand, when the starting diameter is larger than that of the forging, height reduction and flow into the die cavities are required (Figure 16.34(e)). A more complex operation is required (Figure 16.34(f)) when the forging has both indentations and side bulges, and the starting billet diameter is larger than that of the side of the forging. Height reduction, piercing and bulging must occur to give the final impression.

In true closed-die forging, the operation produces a completely flashless forging (Figure 16.33(b)). To achieve this highly desirable situation, the die/billet relationship must be carefully worked out, since incorrect dimensions of the billet lead to either incomplete filling of the die cavity or damage to the dies and punches. If the forging system is correctly designed and the die (or dies) and the punch are machined to the required degree of accuracy, a precision, or near-net-shaped forging will be obtained.

16.2.5.3 Special applications of closed-die forging

A number of special operations associated with closed-die forging are carried out cold, i.e. at a temperature below the recrystallization temperature of the metal in question. However, some difficulty is experienced in the case of steels, since these alloys recrystallize at temperatures above 600–700°C, temperatures that are too high to be called 'cold'. Consequently, forging at room temperature is often referred to as 'cold', and forging at elevated, but below recrystallization, temperatures is called 'warm'. Generally, the purpose of cold forging is to produce a finished part with high dimensional accuracy.

Highly ductile materials, such as aluminium, lead and tin, have been cold forged for a long time, mainly in the form of extrudates, but 'proper' cold forging is normally limited to either small parts in low and medium carbon steels (such as bolts and nuts) or larger parts of up to 10 kg in mass which require good dimensional tolerances.

Of the better known applications in this area are the coining and embossing operations (Figure 16.35) used for the production of coins and medals, and for the improvement in dimensional accuracy of other preforms. The coining operation is one that is actually carried out in a closed-die system, sometimes with embossing forming, a stage that includes an open-die system. In these processes, three-dimensional details are reproduced in the material giving not only a faithful impression of the punch and/or die surface, but also good surface finish. It is not surprising that the forging loads used are high. The design of the dies is critical since lubrication cannot be

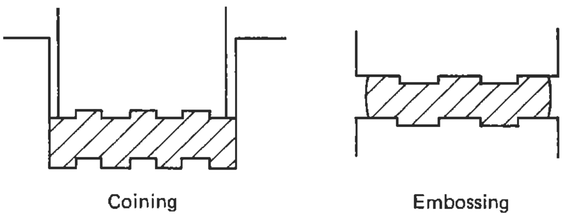

Figure 16.35 Coining and embossing

used in coining operations because of the danger of entrapment and the consequent damage of the forging.

A completely different type of application of closed-die hot forging is that of powder forming, also known as 'sinter forging'. This process, an offshoot of conventional powder metallurgy processes, involves the following sequence of operations. Cold powder is compacted in a press to produce a powder preform. The preform is subsequently sintered in a controlled-atmosphere furnace but, instead of being allowed to cool in that atmosphere (as in conventional powder metallurgy processes), the preform is removed from the furnace whilst still hot and forged in closed dies to produce the final shape. Since only the exact amount of powder required to make the final shape is actually used, there is an obvious elimination of waste.

The same final shape could also be made in the first compaction operation, but the introduction of the forging stage produces a superior product. Improvements in strength, ductility and density are expected, with accuracy increasing to some 0.025 mm. Against these advantages must be balanced the drawbacks of additional processing and the possibility of deleterious oxidation occurring immediately before and after the forging operation.

Commercial applications of powder forging range from forged-powder connecting rods, through material properties approaching those of commercial forged steels, to valve spring cage components. In the latter, for instance, the density (as compared with normally sintered material) increases by some 30%, the elongation quadruples, and the ultimate tensile strength almost trebles.

More recently, the process has been extended to the cold forging of polymeric powders which, although they show some post-forging elastic recovery, can be quite successfully compacted in this way.

16.2.5.4 *Subsidiary forging operations*

These operations are often associated with preforming and comprise:

1. cogging,
2. fullering,
3. heading, and
4. hubbing.

Cogging or drawing (Figure 16.36) of a rectangular section specimen involves reduction in height by successive blows or bites, leading to a gradual elongation of the original blank. The successive bites reduce the force requirement, but they must be grouped closely together to produce an even surface. The operation will not cause plastic deformation of the bulk material to occur, unless bites of sufficient length are initiated. To avoid possible buckling of the specimen, the height/width (h/w) ratio should be kept below 2.5.

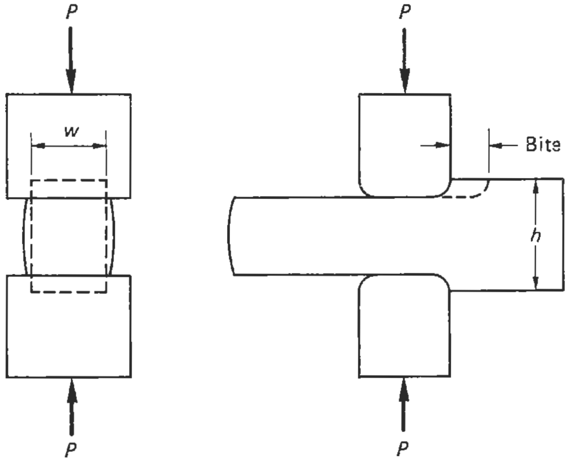

Figure 16.36 Cogging of a rectangular specimen

Fullering (Figure 16.37) is another preform operation in which the original bar is shaped by profiled open dies into an outline suitable for more detailed, further forging. Thus the basic function of fullering is to redistribute the bar material along its length, prior to cropping of the individual preforms.

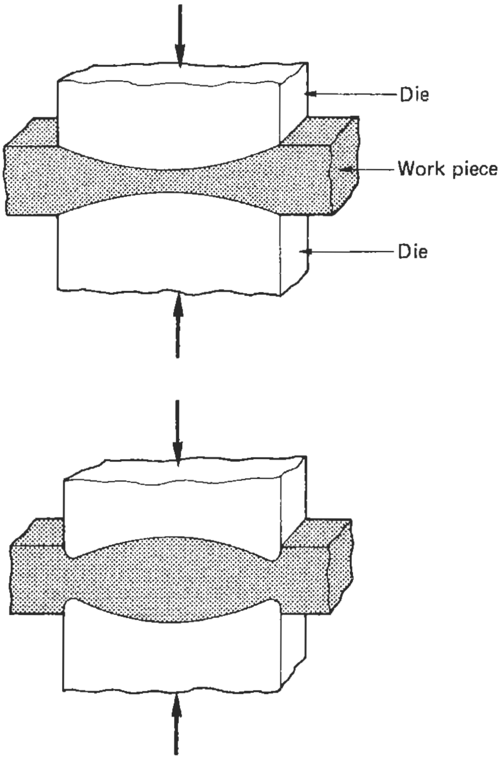

Figure 16.37 Fullering

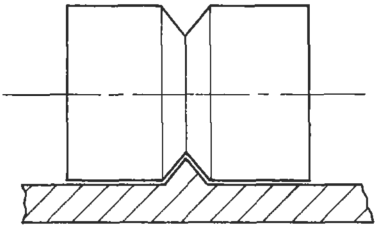
Heading is an operation that combines forging and extrusion. In the forging part an upsetting operation carried out between flat dies will flatten (by bulging) the end of a cylindrical billet, thus forming a bolt head. The remaining portion of the billet can then be extruded to form the bolt.

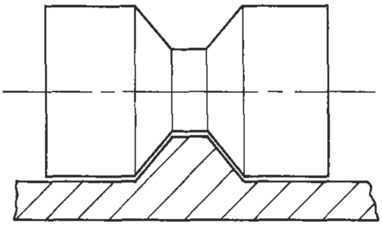
Hubbing is used as a means of forming die cavities by indenting the material of the blank with suitably profiled punch heads. The operation is thus very similar to in-die punch piercing (discussed above). It generally calls for punch pressures of about three times the flow stress of the material to be forged.

16.2.5.5 *Rotary forging*

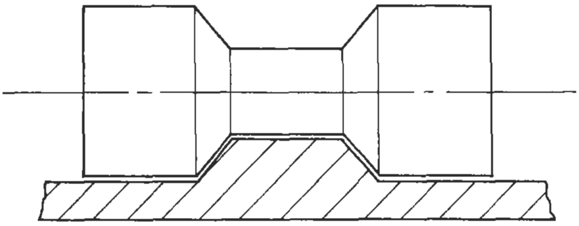
Rotary forging, also known as 'transverse rolling', is used as a preform operation in which profiled tools are positioned on driven rolls (see Figure 16.38).



Reduction at position 1



Reduction at position 2



Reduction at position 3

Figure 16.38 An example of transverse roll forging

The bar stock is located transversely between three rolls. The rolls make one revolution and the bar makes several. The wedge impressions on the roll surface (Figure 16.39) are then progressively imparted to the work piece to give the required preform shape. Subsequent flash discards of 15–20% are usually expected.

16.2.5.6 Rotary tube forging

Of very considerable industrial importance is the use of the rotary-forging concept in hot and cold seamless tube manufacture. The operation is carried out on a pilger mill.

In hot pilgering, the already rotary-pierced bloom is threaded onto a cylindrical floating mandrel and is steadily advanced forward and retracted in a reciprocating motion in which the forward stroke always exceeds the length of the backward one (hence the name of the operation, which is derived from the movement of the chorus of pilgrims in an opera) and is executed by two profiled, driven rolls. Each successive movement is accompanied by a 90° turn of the tube–mandrel assembly.

Figure 16.40 shows a sequence of successive 'bites' culminating in a finished tube. Irrespective of whether the working roll surfaces are parabolic, hyperbolic or form logarithmic each roll (being basically a cam) is characterized by three distinct zones. The working zone AB consists of the reducing portion that produces the highest degree of wall reduction. It is this deformation which, in turn, converts a bloom to a tube and is accomplished by a change in roll radius. The finishing zone BC imparts the required dimensions to the tube; the roll radius remaining constant along this part of the profile. The third zone is the idle intercept CA during which reciprocating and rotational motions of the tube–mandrel assembly are performed. To obtain the final geometry of the tube up to six passes may be required, with each successive bite reducing the wall thickness of the bloom further.

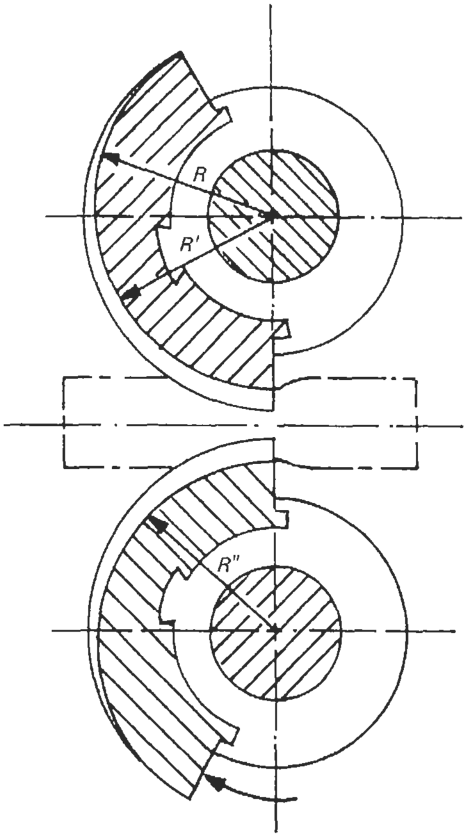


Figure 16.39 Profiled roll system in rotary forging

To obtain even thinner walled seamless tubing displaying high dimensional accuracy and good mechanical properties, cold pilgering (also known as 'cold reducing') is employed. The cold-reducing process is a step-by-step operation which uses tapered grooved rolls (Figure 16.41). Several dissimilarities exist between hot and cold pilgering. The most obvious of which is that, whilst in the hot process the rolls revolve completely and continuously, in cold reducing they rotate backwards and forwards through approximately 180°. In the hot process the rolls are mounted on a fixed stand, and the work piece reciprocates, whilst in cold reducing the roll stand reciprocates and the work piece remains stationary.

The machine operates as follows. Each time the saddle is at the end of the stroke, so that the large ends of the die grooves are presented to the in-going hollow, the cross-head pushes the hollow forward by a fixed amount (or the feed). The dies then roll the material thus inserted down the cone, simulta-

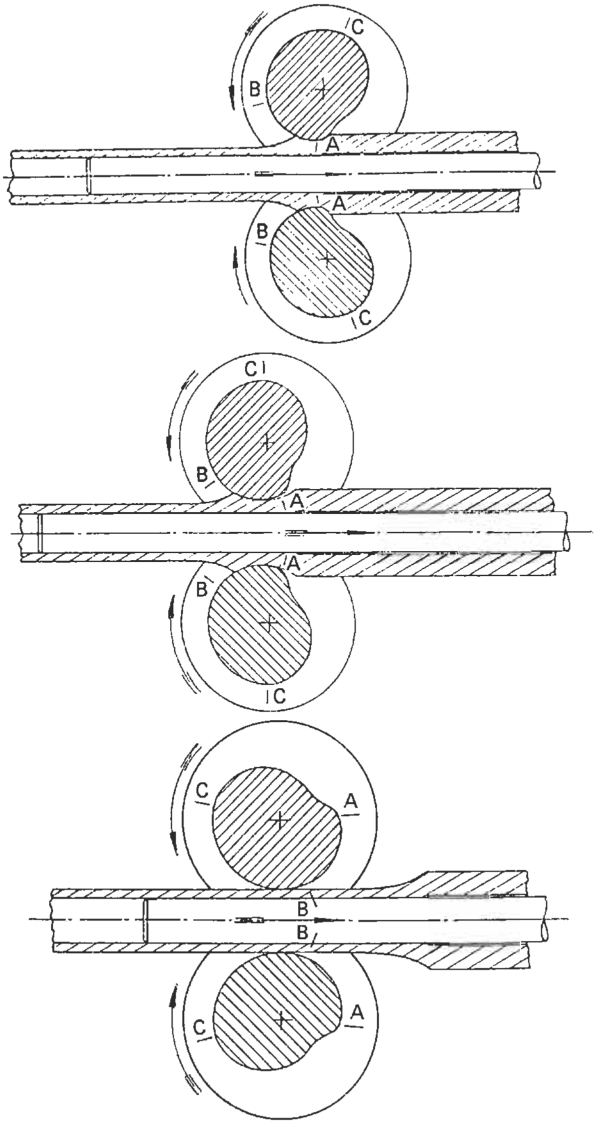

Figure 16.40 Sequence of events in hot pilgering of a seamless tube. AB, working zone; BC, finishing zone; CA, idle zone

neously thinning the wall and reducing the diameter, with the consequent elongation of the tube. At the far end of the saddle stroke, the tube and mandrel are rotated through approximately 60°, and the saddle returns. This is repeated at frequencies of 1–2 Hz, depending on the size and type of machine.

At each end of the saddle stroke, because of the clearance in the dies and also because the rolls turn through slightly more than 180°, there is a short period of time when the dies are not in contact with the tube being rolled. It is during this time that feed has to occur at one end of the stroke and turning of the tube at the other.

In general, this cold forging process is associated with deformation of tubing in the 10–230 mm wall thickness range, and is employed whenever the specified wall-thickness tolerances of the finished product are required to be below ±10%, and the quality of the tubing, with regard to surface or structure, calls for cold deformation. Tube obtained in this manner can either be used directly, in industrial applications, or can form an intermediate stage of production requiring a cold-drawing operation.

16.2.5.7 Orbital forging

The orbital forging process is intended to allow smaller machines to be used for suitable forging operations. This process is based on the simple concept that the axial force required to effect a desired deforming zone between the platens is confined to a small region. The plastic zone is then moved through the work piece, thus resulting in progressive deformation.

The plastically deforming region is formed by initially indenting with a conical platen into the work piece which is supported by a lower platen capable of axial movement only. The plastic region is then moved through the material by the upper conical platen which is capable of rotation about the central axis of the machine and, also, about its own geometric axis. In order to produce a flat top surface on the work piece, the geometric axis of the upper conical platen is inclined to the central axis of the machine.

The process, known also as 'Rotaform', can be applied successfully to the hot, warm and cold forging of a wide range of materials and axisymmetric shapes. The Rotaform is a completely automatic machine provided with automatic feeder and ejection equipment. Figure 16.42 illustrates the principle involved.

The die uses a pair of cooperating dies, one of which is adapted to perform a wobbling motion, relative to the other, about a centre at or near the axial centre-line of the dies. The wobbling die, which has a circular rocking motion without actual rotation about its axis, is actuated at high frequency. The complementary half-die is secured to a hydraulic ram which conveys the work piece to, and presses against, the wobbling die. The cycle of operations commences with the introduction of a billet into the receiving station of the automatic feeder which places the billet accurately into the non-wobbling die. The hydraulic ram raises the non-wobbling die at a speed programmed for the most suitable deformation rate throughout the forging stroke. When the forging has assumed its final shape, the ram retracts rapidly and the forging is automatically ejected and blown clear of the dies.

The cycle time is very short and outputs of 15 forgings per minute have been achieved.

16.2.5.8 Cast-preform forging

The material of all metal components usually originates from a cast and subsequently undergoes a considerable degree of processing before being finally transformed by, say, forging into a component. Since all the intermediate mechanical working improves the properties of the structure, this improvement, to a level necessary for most components, can be achieved by cast-preform forging.

From a technological point of view, the structure of a reasonably homogeneous casting can be transformed to a forged structure by quite small amounts of hot working, amounts which could quite easily be achieved in the forging process itself. Internal cavities can be closed up and welded, providing they are located in regions of high deformation. Due to oxidation, however, cavities extending to the surface are likely to remain as faults. The economics of such a process require some consideration, but it becomes obvious that the operation is viable when the casting can be produced without a lot of waste material in the form of runners and risers. In

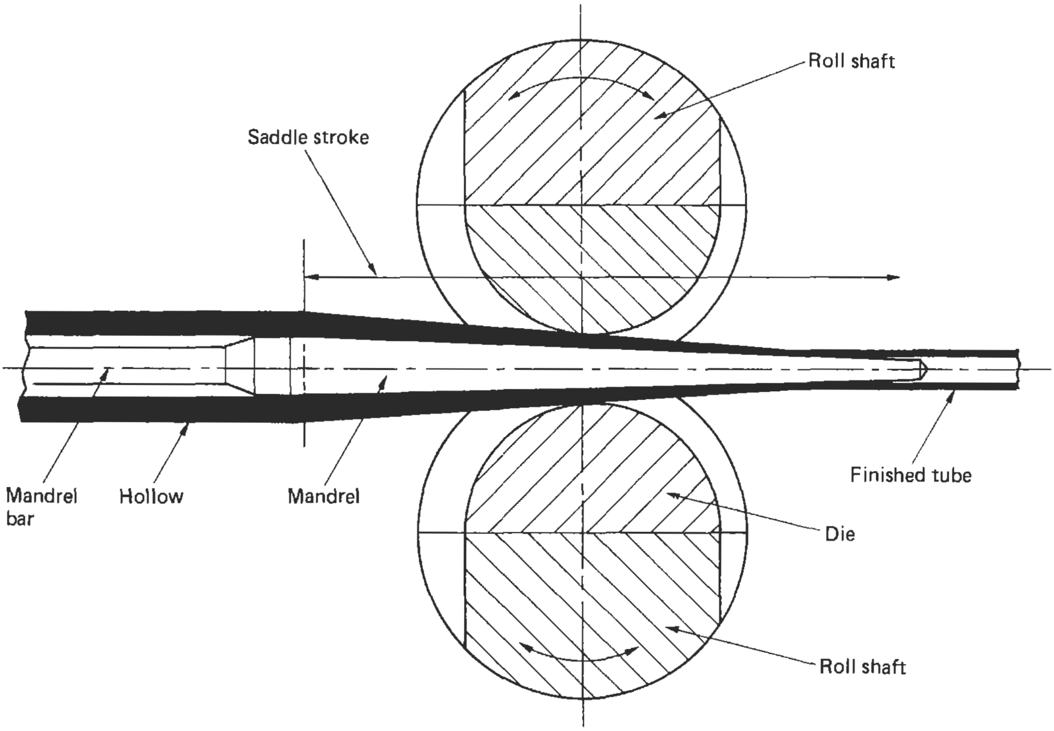

Figure 16.41 Cold pilgering (reducing) tube forging process

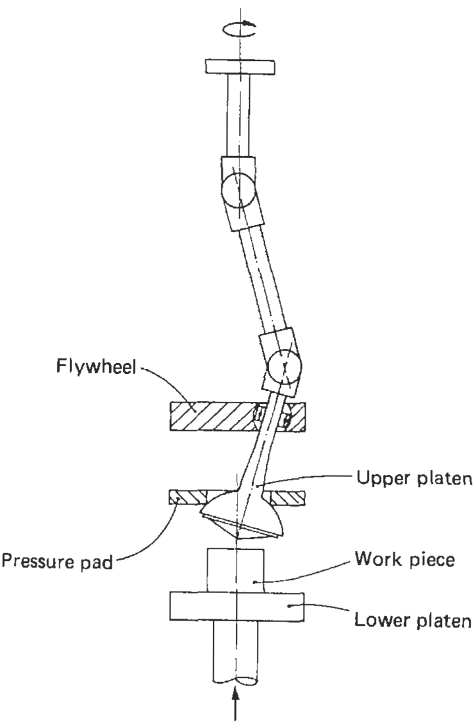

Figure 16.42 Orbital forging arrangement

addition, shapes normally forged from a cropped billet in single impression dies, where material usage is high, are not amenable to this process.

Major economic advantages can be gained if the casting and forging operations are combined. Several techniques are available for this; for example, a conventional steel-casting plant is situated alongside the forging press and reheating is done between the two operations. This technique has been developed as the 'Auto-forge' process which consists of a rotary table with a number of stations at which the various operations are performed. Casting is carried out at the first station and the moulds are water cooled while the table rotates to the next station where the forging operation is performed. The work piece then rotates to the clipping station. Another type of process, the 'Auto Forcast', consists of a melting plant coupled with a continuous casting plant. The various sections of cast steel produced are straightened and hot cropped into billets before being fed into the forging press.

16.2.5.9 Isothermal forging

A more expensive and complicated process is that of isothermal forging in which the dies are heated to the temperature of the blank prior to the operation itself.

The advantages of this technique include low stress fields and, consequently, improved flow of the material which, combined with the absence of a temperature gradient at the tool–work piece interface, reduces the inherent difference in the bulk forging material.

16.2.6 Extrusion

16.2.6.1 General concepts

One of the very widely used metal-forming processes is that of extrusion. In its basic form, the operation involves preparation of a, generally, cylindrical billet (sometimes referred to as the 'slug'), insertion of it into a container (which holds a suitably profiled die), and applying pressure (by means of a punch or a ram) to the trailing end of the billet. The billet is thus pushed, or extruded, through the die.

Since extrusion normally constitutes a more or less direct step from the billet to the finished product, tool design (including its material) and lubrication are of primary importance.

The term 'extrusion' is sometimes applied to forging operations that involve elongation of the product, but it is used here only for the case of 'pure' extrusion described above.

The extrusion process is used in the manufacture of round or profiled bars and tubes, profiled sections, simple and shaped containers, finned or ribbed components and, more recently, spur gears.

Actual extrusion operations are carried out using either mechanical or hydraulic presses; the former being of the vertical type and the latter, as a rule, of the horizontal type. These machines provide extrusion ratios (initial to final cross-section ratios) varying from 10 to 100, with punch speeds of up to 500 mm s^{-1}. Slower speeds are used for most of the lighter non-ferrous alloys of aluminium, magnesium and copper, and higher velocities of deformation are needed when processing ferrous alloys, refractory metals and titanium.

Mechanical presses show a slight advantage over hydraulic machines in terms of speed. The speed of operation precludes almost completely the possibility of using glass as a lubricant which plays an important role in extrusion of stainless steels. Consequently, the process becomes more severe and the billet to hollow ouput can be slightly lower than that for hydraulic presses. A further disadvantage of mechanical presses lies in the fact that the punch velocity varies during the working stroke, and so very considerable difficulties can be created when processing alloys suceptible to strain-rate variations.

In addition, the maximum length of the product is limited by the length of the crankshaft. Hydraulic presses remove these difficulties because the speed of extrusion is controllable and can be maintained almost constant while the length of the extrudate depends on the load capacity of the press and not on its mechanical characteristics.

A distinct, additional and practical advantage of this type of press is the ease of removal of long tubing, or other extrudate, as opposed to the vertical, mechanical presses where a provision for, say, a pit must be made.

It is, however, advisable to remember that, in general, alignment is better on vertical presses than on horizontal ones, and that loading conditions are less severe on the former.

With the great advantages of glass as a lubricant, the number of horizontal presses has inevitably increased, being at present about three times that of vertical presses.

Because of its very wide range of application, the extrusion process is looked upon in a variety of ways that reflect the particular use to which it is put in any specific circumstance. As a consequence of this, the classification of extrusion operations follows diverse courses.

The most basic classification recognizes four extruding techniques:

1. forward or direct extrusion,
2. backward or inverse extrusion,
3. side extrusion, and
4. continuous extrusion.

However, depending on the shape of the product, a further subdivision is often used:

1. solid (circular or non-circular rod) extrusion,
2. hollow (tubular) extrusion, and
3. can extrusion.

In view of the importance of die design and, therefore, the die profile, the process is sometimes classified with reference to the tooling:

1. square (flat faced) die extrusion,
2. conical (linearly converging) die extrusion, and
3. profiled die extrusion.

Naturally, extrusion processes can be carried out at elevated temperatures (hot extrusion), or below the recrystallization temperature of the alloy (warm or cold extrusion).

Square-die processing is used normally in the hot extrusion or profiled light metal (aluminium or copper alloys) components. Continuous profile dies are mainly used for lubricated cold or warm extrusion to enhance material properties and improve surface finish. Streamlined dies are employed because of the higher degree of homogeneity of flow that can be obtained.

Depending on the properties of the starting material and the complexity of the shape of the extrudate, cold extrusion processes (which clearly require high extrusion pressures) involve three distinct techniques which, under specific conditions, ameliorate to some degree their severity:

1. conventional extrusion,
2. impact extrusion, and
3. hydrostatic extrusion.

As in other cold-forming operations, the mechanical properties of the metal are considerably improved if, of course, the increase in temperature associated with the operation does not exceed the temperature of recrystallization. Dimensional tolerances are of a very high order and, as already mentioned, efficient lubrication gives good surface finish, which is also made possible by the absence of oxidizing effects that are present in hot working conditions.

16.2.6.2 Basic extrusion operations

The three most basic extrusion operations of forward, backward and side flow are shown in Figure 16.43. Although, as shown in the figure, these operations refer to axisymmetric solid or hollow components of circular cross-section, profiled or asymmetric shapes can also be obtained in this way. Again, the techniques are equally applicable to hot, warm or cold conventional processing.

In a forward extruding operation involving the manufacture of a solid rod or hollow tube (Figure 16.43(a),(b)) the previously prepared billet is placed in the container and is either directly extruded to form the rod or, if prepierced, it is threaded onto a cylindrical mandrel which supports its bore and is then extruded. The deformation of the tube results in the thinning of its wall and the consequent elongation of the extrudate. If there is no prepiercing, a piercing punch is positioned in the container to provide, on the one hand, the initial hole and, on the other, to act as a mandrel.

In the extrusion of a can (Figure 16.43(a)), a counterpunch in the container acts as a die by causing the material to flow between the container walls and its own outer surface. At the conclusion of the operation and retraction of the punch an ejector removes the formed can from the container.

In the backward extrusion of a rod (Figure 16.43(d)), the billet is placed in the bottom of the container and a hollow punch, of bore diameter corresponding to the outer diameter of the rod to be extruded, is forced into the material, causing it to flow upwards.

A similar arrangement is used when extruding tubular components (Figure 16.43(e)), but here either a prepierced hollow is used or piercing in the container forms the first stage which is followed by extrusion. Again, an ejector is necessary to remove the product.

When extruding a can (Figure 16.43(f)), a reverse of the forward process is effected. The billet is placed in the die and a solid punch is moved axially into the metal. An ejector is necessary to remove the can.

Side extrusion, either one- or two-sided, is limited to rod (Figure 16.43(g)) or tube (Figure 16.43(h)) manufacture. In the first case, the die is situated in the side of the container with the billet positioned at right angles to it, but supported at its lower end. The punch moves axially downwards forcing the metal to flow through the die. When making a tube, the billet must be pierced first, inserted into the container and the

mandrel threaded through it. It is only then that the punch can be actuated and cause plastic flow to commence.

As in other forming processes, extrusion, in any form, produces a number of material defects which are associated either with the characteristics of the process itself, or with the selected geometry of the forming pass. In more general terms, these can be summarized in the form given in Figure 16.44. Defective items in extrusion may reach a proportion as high as 10–15% of the total volume of the product and, although inspection of extrudates can prevent the use of defective components, rejection of parts increases production costs since, in addition to the expense of full processing, the inspection itself is expensive.

Defects that may occur are usually due to any, or a number, of the following:

1. defective billets,
2. defective or unsuitable tooling, and/or
3. processing technique.

Irrespective of their origin, all these defects can be reduced or even eliminated by correct design of the extrusion tooling.

A very characteristic feature of extrusion, especially when using flat dies, is the phenomenon of the 'dead-metal zone'.

It can be seen from Figure 16.45 that in flat dies (90° die semi-angle) part of the billet material becomes trapped in the corner of the die/container space and does not participate in extrusion. The bulk of the material moving through the die shears past the trapped annular ring of stationary metal which thus effectively forms a new, curved die surface that merges with the proper die.

Depending on the point of view adopted, the formation of a dead-metal zone can be regarded either as a defect or as a desirable phenomenon which may enable the material to adopt the optimal flow path.

16.2.6.3 Conventional tube extrusion

One of the most important applications of the extrusion process is the manufacture of seamless tubing and, in particular, the manufacture of the stainless-steel variety. This is because rotary, longitudinal rolling processes often give unsatisfactory results, and operations such as Assel elongating fail altogether. The importance of extrusion becomes obvious in these circumstances, and its applicability to the processing of ferrous alloys cannot be stressed too strongly.

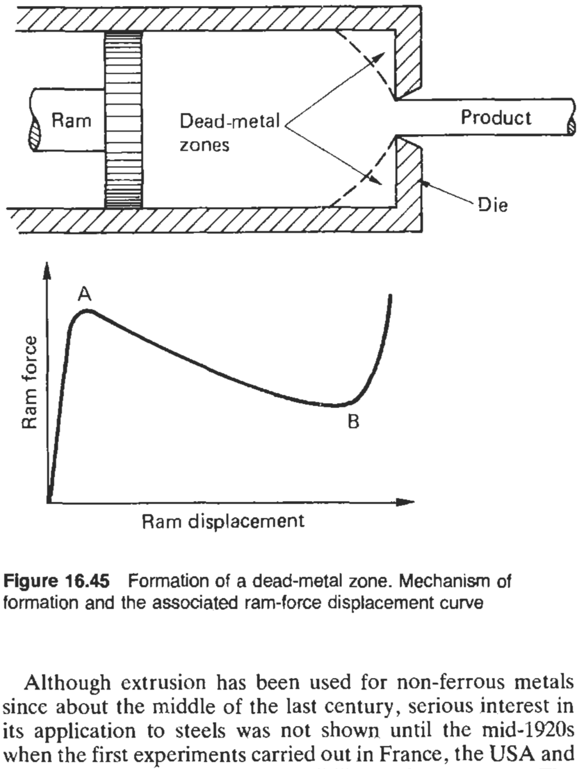

Figure 16.45 Formation of a dead-metal zone. Mechanism of formation and the associated ram-force displacement curve

Although extrusion has been used for non-ferrous metals since about the middle of the last century, serious interest in its application to steels was not shown until the mid-1920s when the first experiments carried out in France, the USA and Germany showed the distinct feasibility of the operation. The problem encountered was the high rate of tool wear, in particular of the dies. The slow development of tool materials and manufacturing techniques prohibited any extensive use of extrusion until almost the outbreak of World War II, but rapid progress was then made in Germany and the USA, whereas in France, Sejournet continued the development of his glass lubricating technique, which became widely accepted in the 1950s.

Since the extrusion of stainless steel offers wide scope for discussion, these materials are used in the following as the basis for a review of techniques and practices.

The current practice of extruding stainless-steel as tubing and sections, either by direct or reverse methods, is based on the following sequence of operations:

1. preparation of billet,
2. heating,
3. lubricating,
4. providing a pilot hole,
5. reheating and relubricating,
6. extruding,
7. removing the lubricant, and
8. straightening whenever required.

Reheating and relubricating (5) are not necessary in some processes.

In general, four main variants of the process are in operation. These involve the following techniques:

1. prepiercing, extruding;
2. drilling the billet, expanding, extruding;
3. drilling the billet, extruding; and
4. staving (dumping) the billet, piercing, extruding.

The choice and application of a given technique are examined in the following detailed discussion of the general sequence of operations.

Preparation of billet Irrespective of the process involved, all billets are faced at least on one end. Furthermore, they are normally machined, or sometimes ground, since the surface finish of the billet determines to a great extent the surface quality of the hollow. A surface finish of about 7.5 μm is often required, thus increasing considerably the cost of production.

In the case of direct extrusion (using drilling as the means of providing the pilot hole), billets are drilled centrally at this stage. Holes of up to 50 mm in diameter are machined out on twist drilling and vertical boring machines. Larger holes are made by trepanning. Trepanning is also used on smaller size holes in an effort to increase the initial length of billets.

Invariably, billets are either radiused or chamfered externally at the leading ends to offset the tendency to cracking in this region during extrusion.

Heating Heating of billets is of great importance, not only from the point of view of the time involved, but also in terms of the economics of the possible descaling operation.

The general trend appears to be towards the low frequency inert gas atmosphere heating of billets. Theoretically, the economic use of a low frequency induction furnace puts severe limitations on the use of smaller diameter billets below, say, 100 mm diameter; the range above 150 mm being considered economical. The advantage of obtaining a scale-free billet may sometimes outweigh the disadvantage of higher heating costs and, consequently, the intermediate range between 100 and 150 mm is occasionally used.

When using induction furnaces, the general practice is towards preheating billets to about 1020°C followed by further induction heating to about 1200°C for staving and prepiercing, and expanding processes.

Other techniques are also in use, e.g. preheating to about 820°C in a gas-fired furnace to avoid heavy scaling, followed by heating in a salt bath to extrusion temperature. A practice widely adopted in the USA consists of preheating in a Selas radiant heat slot furnace to about 1200°C, followed by heating in a barium or sodium chloride bath (to dissolve scale) to extrusion temperature.

A new heating system that makes use of dual fuel furnaces is also in use. In this system, steel is preheated to 900°C in a gas-fired furnace and is brought rapidly to 1250°C in an induction furnace. Scaling appears to be negligible.

In the case of billet drilled for direct extrusion, heating is usually carried out in a salt bath, with the exception of the revolving Balestra type furnace. The latter combines the heating and lubricating operations, being a drum type furnace in which the refractory lining is coated with a thick layer of molten glass. Prior to heating, glass wool is inserted into each end of the hole drilled in the billet in order to prevent oxidation. Equiverse type furnaces, which have proven very successful in the case of low carbon steels, are not often used for stainless steels.

Essentially, the final heating operation is carried out either in an induction- or salt-type furnace. Each of these processes has distinct advantages and disadvantages.

Lubrication The inherent difficulty in extruding steels, and particularly stainless steels, requires more efficient and, to a certain extent, more sophisticated lubricating methods than those used for the processing of ordinary engineering alloys. Originally, graphite type lubricants were widely used mainly because of the possibility of lubricating the mandrel when extruding small-bore hollows. The Ugine–Sejournet process, using glass as lubricant, has changed this situation significantly.

The innovation consists not only in using glass, but also in introducing the novel idea (in hot working) of lubricating only the work piece and not the tools.

However, the possibility of increasing the range of extrudable materials and the amount of deformation in a given operation when using glass can be predicted from a theoretical analysis of the process.

Glass is applied by means of pads of fibre, cloth or pressed powder. The only disadvantage of glass is the slight difficulty in removing it from the extrudate. In a properly controlled process, however, the layer of glass is very thin and on cooling there is a tendency for iron oxides to form. These dissolve glass slightly and facilitate its removal.

Providing a pilot hole An initial hole is made either by drilling or machining, or by hot piercing. Drilling and machining, followed directly by extrusion, are used where the finished bore is small (usually up to about 30 mm). The cost of the waste material and labour involved is considerable, but the lack of eccentricity in the finished tube outweighs to a certain extent this distinct disadvantage. This technique is also used whenever the formed metal is difficult to hot pierce.

To obtain bore sizes of 32–115 mm, small pilot holes are drilled and then expanded. Pilot holes for this operation are 20–25 mm in diameter. For bore sizes larger than 115 mm in diameter, hot piercing followed by extrusion is employed.

Extrusion The techiques of extrusion are discussed in Section 16.2.6.2 but, in the case of stainless steel and the Ugine–Sejournet process, tube sizes and the corresponding required press capacities need careful assessment.

The inherent weakness in the extrusion process lies in the production of discard associated with the formation of the dead-metal zone which, naturally, represents the total loss of material. With the high cost of stainless steels, the problem of discard is more serious than for other materials. The weight of discard is approximately proportional to the cube of the mandrel diameter. The weight is not affected by the introduced variations in the diameter of the die. Although a reduction in the die angle gives some improvement, this is small in comparison with the improvement achieved by completing the piercing–extruding operation in two stages. In this operation, the billet is first pierced against a solid plate which temporarily replaces the die. On completion of piercing, the plate is removed and the extruding die is introduced into its place.

The advantage of reducing the weight of the discard in this way must be set against the cost of the labour involved and the provision of back-plates which, obviously, can be damaged easily.

Removal of lubricant Graphite-based lubricants are easily removable by conventional methods. When glass is used as lubricant, techniques vary slightly but, essentially, they all depend on the application of some type of pickling bath. Thus, glass is removed by pickling in a mixture of 4% hydrofluoric acid and 14% nitric acid, or in a mixture of hydrofluoric acid and sodium sulphate.

Small amounts of the mixture of partly decomposed glass and scale are sometimes removed by sand blasting.

The increase in the use of the extrusion process in the last 25 years has been due partly to economical and partly to technical considerations. Extrusion becomes economical and competitive with rolling processes for a range of sizes of up to 150 mm outside diameter, and for comparatively short lengths and runs. The cost of plant required for the production of bigger hollows, both in terms of presses and ancillary equipment, increases rapidly when this limit is exceeded without there being, at the same time, any possibility of increasing the length. At present, the intermediate range (say, 150–250 mm outer diameter) is manufactured using extrusion presses but the process becomes rather expensive owing to considerable tool wear and increased rate of scrap. The additional, inherent disadvantage of the process is its comparative slowness with, on average, 50–60 extrusions per hour.

A more important reason for the use of extrusion is the fact that, from the point of view of formability, the process is capable of dealing with very difficult materials. This is possible due to the lower incidence of redundant strains than in rotary processes, and the consequent reduction in the severity of the operation.

16.2.6.4 Cold extrusion processes

Conventional cold extrusion operations are based on the same three basic systems of forward, backward and side operations (see Figure 16.43). The range of materials usefully employable in engineering applications is limited to steels and aluminium and copper alloys. Although easily extrudable, materials like tin, lead and magnesium show no benefit from strain hardening and, in any case, are of no great industrial importance.

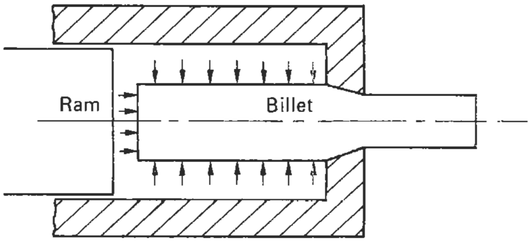
Although hollow sections are produced by extrusion in non-ferrous alloys, the bulk of the products consists of profiled sections (particularly in aluminium) used extensively in the car and aircraft industries, as well as in domestic situations.

Very high extrusion pressures, combined with extensive frictional effects that occur in the container and in the die, make conventional extrusion unsuitable for processing less ductile materials or composites. Although the individual demand for either is not yet very high, developments in modern technology make it imperative that processes capable of coping with such materials be developed. Two processes fulfilling the demand are hydrostatic and impact extrusion. Both of these rely on high pressure, but reduced friction, forming.

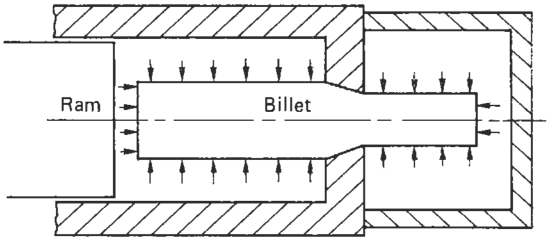
The process of hydrostatic extrusion differs from conventional extrusion in that it employs a pressurized liquid instead of an extrusion ram. A diagram of the type of hydrostatic extrusion systems available is shown in Figure 16.46. The extrusion die has, in this case, a relatively small cone angle, but the high bursting stresses associated with this are offset by the fact that the fluid pressure acts as a containing element around the die circumference.

In practice, this operation has a number of advantages over conventional extrusion, most of which are related to the fact that there is no contact between the billet and the extrusion container wall. This results in:

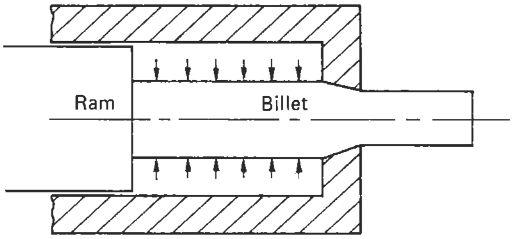
1. lower extrusion pressure,
2. improved lubrication from the pressurizing liquid,
3. a reduction in redundant work since smaller die angles can be used, and
4. the extrusion of longer billets—the limit being the length of the container.



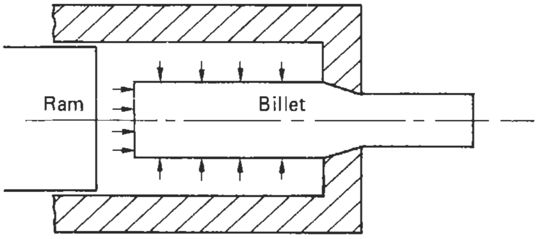
(a) Basic hydrostatic extrusion



(b) Differential extrusion



(c) Billet augmented extrusion



(d) Product augmented extrusion

Figure 16.46 Different hydrostatic extrusion systems

A further advantage of hydrostatic extrusion is associated with the improvement in ductility which most materials undergo when deformed under hydrostatic pressure. In practice, this means that the extrudability of materials is improved when the hydrostatic pressure component is present and under such conditions many nominally brittle materials have been satisfactorily cold extruded.

As in other processes, it is found that for a given amount of deformation and specific frictional conditions, there is an optimum die angle which gives the best balance between friction and inhomogeneous strain and, hence, there is a minimum extrusion pressure.

In spite of considerable research and development work on hydrostatic extrusion, the process has not been as widely accepted as an important industrial process as was originally expected.

Away from the conventional operations, including hydrostatic extrusion, it is the high-energy-rate operations that are steadily finding application in specialized industrial areas, and extrusion is no exception to this development.

Impact extrusion can be employed in the case of either bar or tube forming. The forming energy is supplied through the medium of a ram which, in turn, is actuated by a sudden expansion of gas produced by, say, an explosive charge or a pneumatic–mechanical system.

In the forward extrusion of bar (Figure 16.47), immediately after impact the ram and billet travel together at high speed with the extrusion of the billet taking place in the die. Relatively high strain rates can be attained and in some alloys these will lead to a substantial increase in the value of the yield stress Y, combined with a reduction in the strain to fracture. This is particularly noticeable towards the end of the operation when a high degree of deceleration is reached. It is also at this stage that high tensile stresses are reached at the base of the extruded bar and result in either the necking or breaking off of the product.

The maximum possible deformation depends mainly on the ability of the tool materials to withstand shock conditions.

Impact extrusion of tubular components is more conveniently carried out in a reverse system (Figure 16.48). This employs a ram of either flat or contoured face and a means of applying additional carefully controlled external pressure p to the walls of the extruded product. Pressure p is required to minimize the effect of two major faults which characterize the operation, i.e. cavitation and fish skin. Fish skin occurs throughout the operation and is equivalent to the appearance of circumferential tearing of the surface. Cavitation is associated with the flow of the material upwards, leaving the corners of the container unfilled. Rounded instead of sharp edges are thus produced. The practical usefulness of this particular process depends, to a considerable degree, on whether the incidence of faults such as break-offs in a bar or cavitation and fish skin in, say, tubular bottle manufacture, can be avoided.

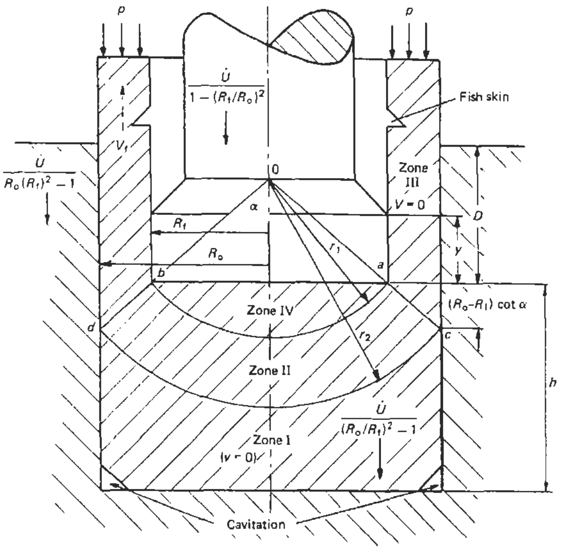


Figure 16.48 Reverse impact tube extrusion

16.2.6.5 *Continuous extrusion*

Continuous extrusion processes have been explored in some depth, but it appears that, at present, the Conform process is the only one that is used extensively.

The process relies on frictional forces generated between the billet and container. These are sufficiently high to effect

extrusion through the die. The operational system is illustrated in Figure 16.49. The product can be delivered either axially or radially (as in side extrusion) as shown in Figure 16.50(a).

The tooling consists of a rotating wheel with a circumferential groove, a shoe which overlaps a portion of the wheel surface and includes a grip segment and an abutment containing the die.

Solid and tubular sections can be extruded in aluminium and copper through single- or twin-port dies (Figure 16.50(b)). Both solid and particulate matter can be used as starting material, but very high extrusion ratios of up to 200 produce temperatures of up to 500°C and die pressures of up to 1000 MPa. Consequently, good tool materials must be used and the system must be cooled efficiently. With the groove of the wheel undergoing cyclic thermal stressing, the possibility of fatigue must be considered when designing this part.

16.2.6.6 Section and sheet extrusion

Although interest often centres on the extrusion of rod and wire, a large proportion of extrudates in light-metal alloys is manufactured as profiled sections ranging from simple curtain rails to very complex structural shapes a selection of which is shown in Figure 16.51.

In such cases the flow of metal during the operation is far from uniform and the incidence and level of redundancy can be high unless die profiles are designed correctly.

The requirements of modern industry demand more and more composite bi- or tri-metallic components which possess sufficiently good mechanical and physical properties to be suitable for forming to specific shapes. Examples of such applications involve the use of bimetallic sheets in the chemical industry where, say, a thin layer of stainless steel on a low carbon steel base will provide both structural strength and anticorrosive properties, and can be used in the fabrication of containers and pressure vessels, or in the electrical industry for the manufacture of bimetallic strip conductors.

Bimetallic strip is often produced by rolling but, more recently, an extrusion method has been developed for small width and thickness strip in which billets of different metals are extruded simultaneously from two or more containers to form a composite strip.

This manufacturing method provides a means of obtaining good dimensional tolerances and results locally in sufficiently high stresses to produce pressure welding. High deformations exceeding 50% are needed for this to occur.

Extrusion pressures, experienced by the metals, are only slightly higher than the corresponding pressures occurring with similar extrusion ratios in circular sections.

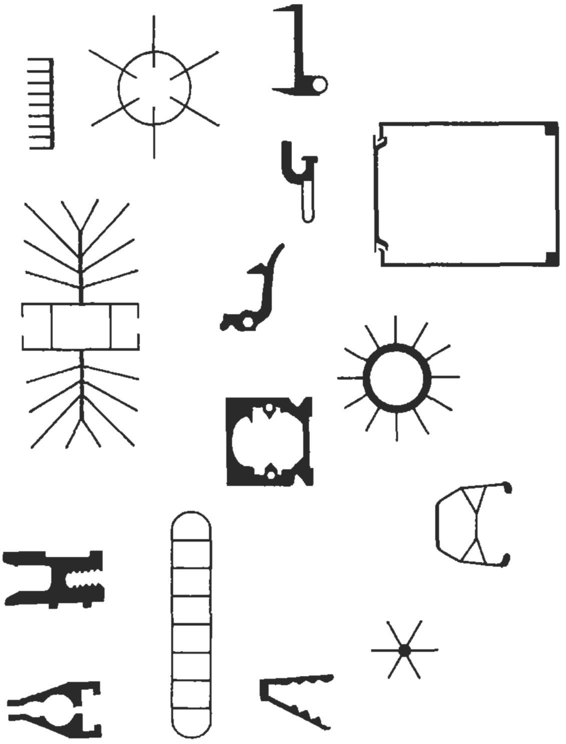

Figure 16.51 A selection of profiled sections extruded in light-metal alloys

16.2.6.7 Die materials

For the hot extrusion of aluminium and similar light alloys, H13 steel dies are normally used. α/β brass extrusions require H10A and H21 steel dies or stellites and cobalt-based alloys. Copper components are extruded through Nimonic 90, or other nickel based alloy dies, whereas steels are usually processed in H13 and H21 steel dies, or in TZM molybdenum alloy. Nickel alloys are invariably extruded through Nimonic 90 dies, and titanium alloys through hot-work refractory oxide coated steel tools.

16.2.7 Cold drawing of wire and tube

16.2.7.1 Introduction

As pointed out earlier, hot processing normally produces low-strength materials and uneven dimensional properties of the product. If high-quality fabricates are required, cold processing must follow the preliminary hot method of shape acquisition. In axisymmetric components, such as wire (rod) and seamless tubing, this is achieved by cold drawing the hot-finished product through a die (or a series of dies). This treatment imparts good mechanical properties and effectively regulates dimensional tolerances.

Basically, a nozzled (in the case of a tube) specimen is inserted in the die and is then gripped by a suitable device which can pull it forward on a mechanical or hydraulic bench. A reduction in the diameter (solid specimens) and wall thickness (tubular specimens) results. Multi-die drawing is necessary in wire production, whereas single-die processing is more usual in the case of a tube although, for special reasons, tandem drawing is sometimes employed.

Coiled rod, obtained in a hot-rolling or extruding process, forms the starting stage of wire drawing, whereas a hot-finished tube is used for a cold-drawing operation.

There are a number of variants of wire-drawing processes. Processes are usually based on the method of lubrication adopted, but the four major routes are:

1. conventional dry or wet drawing,
2. hydrodynamic lubrication system,
3. hydrostatic lubrication system, and
4. ultrasonic vibration system.

The main operational tube drawing processes are:

1. sinking,
2. floating plug,
3. stationary plug,
4. mandrel, and
5. ultrasonic vibration.

The main characteristics of some of these operational systems are shown diagrammatically in Figure 16.52. In a sinking operation, the tube is drawn without any internal support of the bore and, therefore, the change in wall thickness cannot be controlled. Because of the bending and unbending that the wall undergoes in its passage through the die, thinning or thickening of up to 4–11% can take place. The process is generally used only as a preliminary operation to further manipulation.

The normally adopted route is that of drawing over a cylindrical plug. Either a stationary or a floating tool can be used. In the former case the tool is positioned in the die throat and is held there by a rigid plug bar. The tube, of a bore slightly larger than the plug diameter, is pulled over the plug and the plug bar. Initially the tube is 'sunk' onto the plug and is then drawn in what is known as 'close pass' or 'pure draft'. Both the diameter and the wall thickness of the tube are reduced in a controlled manner.

For the drawing of long, small bore, small diameter, thin-walled tubes, floating plug or semi-floating 'captive' processes are used. Here, an initially hot-processed or cold-annealed tube is inserted into a die which contains, in one case, an unsupported conical free plug. The tube is drawn over the plug and is then coiled on a drum for ease of storage and transportation. In the other variant of the operation, a conical plug that is free to float is prevented from moving in one direction by a bar.

The older method of drawing over a long mandrel, which supports the bore, is now seldom used, mainly because the tube drawn in this way clamps tightly onto the mandrel. Thus, to remove the tube after drawing, the tube and mandrel may have to be reeled in a cross-rolling reeler which expands the tube and thus frees it from the mandrel. The reeling operation can impart helical markings to the outer surface of the tube, thus necessitating another drawing operation, and is also likely to affect the uniformity of dimensions along the whole length of the tube. In some cases, where highly polished and dimensionally accurate, but relatively short tubing is needed, mandrel drawing can be used if withdrawal of the tool is possible without reeling. This is the case for tubing with sufficient wall thickness that buckling does not occur when the tube is freed by pulling the mandrel/tube assembly through a 'gate' of a diameter only fractionally larger than that of the mandrel. This results in a stripping operation.

In ultrasonic vibratory systems, used either in wire or tube drawing, the die is vibrated at an appropriate frequency to increase the efficiency of the process by affecting the rate of feed of lubricant and the mechanics of the drawing.

The techniques described above are equally applicable to the manufacture of ferrous and non-ferrous tubing, but con-

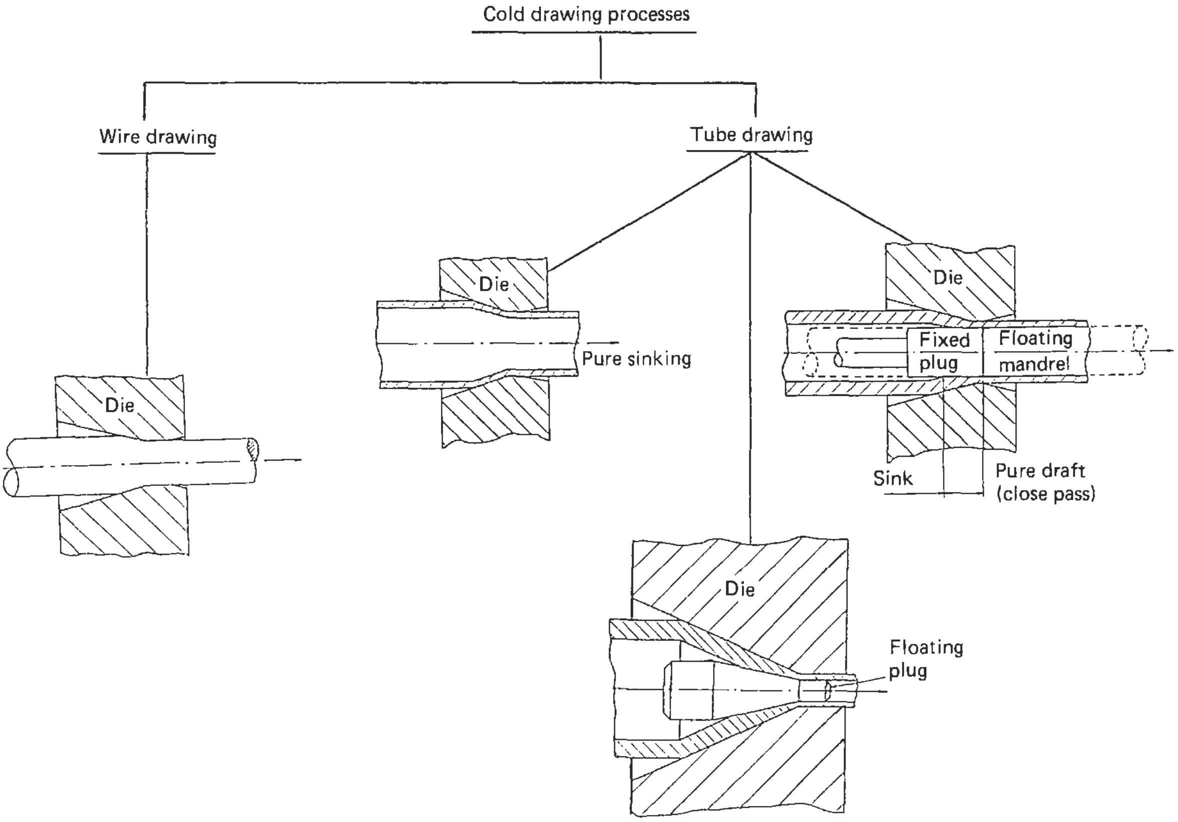

Figure 16.52 Cold drawing of wire and tube

ventional cold and warm drawing of stainless steels and cold drawing of square sections are of particular interest.

In the case of stainless steel, an increase in temperature to about 300°C reduces drawing forces by up to 35% and increases the attainable deformation by about 55%. Warm drawing thus constitutes an important development in this type of processing.

The development of the floating-plug technique, with its saving in tool material, better carry-through of lubricant, and saving of space when coil drawing, has been rapid and, in some cases, has overtaken the use of more conventional fixed-plug operations. Again of particular interest is the ever-increasing use of this process in the coil drawing of stainless and carbon steels. Irrespective of the material being drawn, the rate of production is increased; some 40% saving in time is possible when, for example, coil drawing on 0.9 m diameter drums.

Although the spring back or the final diameter of the drawn coil depends on the material processed, it is easily assessable for aluminium, brass, copper and alloy steels.

Wire drawing, often thought of only in terms of steel and copper, is in fact used to produce satisfactory lengths of rods and wires in a number of more exotic metals and alloys. On the single-metal side, brittle materials such as molybdenum and beryllium can be drawn, whilst tungsten wires must be manufactured at high temperature in order to counteract the unfavourable mechanical properties of this material. Bimetallic wires are manufactured by coaxial drawing of solid cores surrounded by hollow tubular sheaths, including ultrafine composites of niobium and copper, and copper and aluminium. Transformation-induced-plasticity steel has been processed, as has ausformed silicon–chromium steel.

Clearly, the range of application of cold drawing is large and it continues to increase bringing in non-circular section rods and wires.

16.2.7.2 Basic concepts of wire drawing

Although it is customary when considering theoretical aspects of wire drawing to refer to a single pass, it must be made clear that drawing from a coiled rod to the finished product must be carried out in a multistage, normally automated, machine or draw bench. Successive passes call for the correct design of dies and the provision of suitable lubricating conditions. Die design requires minimization of the degree of redundancy and size of the drawing load, leading to the choice of the optimum (for the given conditions) effective die angle, while at the same time allowing a protective lubricating film to develop and be maintained constantly throughout the operation. Failure in lubrication results in impaired quality of the surface finish and an increase in the rate of wear of the die. The cost of remachining or replacement of the tool is then added to the cost due to the loss of dimensional accuracy of the product.

Since successive drawing passes are not able to rectify original surface faults or the presence of scale created by annealing the rod, the preparation of the rod is all important. Here, either 'dry' or 'wet' processing is adopted.

In a typical 'dry' in-line system for rod drawing, the specimen undergoes the following sequence of operations:

1. grit blasting by three or four sets of guns at, say, 90° to each other;
2. grit extraction through filters in a chamber;
3. air blasting to remove the dust;
4. lubricating in an enclosed chamber; and
5. drawing.

A dry blasting operation results in pitting of the surface or, at least, a matt finish, either of which assists in trapping the lubricant and creating local conditions of hydrostatic lubrication. This, in turn, promotes the possibility of applying single heavy passes. Various alloys, including stainless steels, can be treated in this way without any additional surface preparation.

The 'wet' descaling processes include the well-established acid pickling, improved, and sometimes accelerated by, the passage of an electric current of some 7 A cm^{-2} and ultrasonic vibration, both of which help to dislodge and precipitate the scale.

However, environmental considerations weigh against the atmospheric and effluent pollution associated with the use of acids and, therefore, attention has been focused on reducing the original amount of scale and on using molten salt bath heating in place of acid pickling.

A controlled carbon oxide atmosphere is suitable for high-speed, low-scale-forming annealing, and is sometimes preferable to vacuum annealing which may cause strand welding. Depending on the alloy processed, resistance heating can be used for, say, brass annealing, or fluidized beds can be used to reduce the time of operation and the amount of scale.

Electrochemical lubrication, resulting from the use of suitable molten salts of, for instance, potassium and lithium chlorides is the direct result of descaling in a non-acidic environment. Descaled and cleaned rods are then coiled and fed into drawing machines. Drawing of the wire itself is carried out at speeds ranging from 30 to 2500 m min^{-1}, depending on the material, with resulting reductions in cross-sectional area of 15–25% in the case of narrow diameter wires and 20–45% for coarser wires.

The two basic techniques employed are, again, the 'wet' and 'dry' processes. In the former, the entire production line is usually immersed in the lubricating liquid, whereas in the latter the wire 'picks up' the lubricant on passing through a container.

Copper and copper alloy, some aluminium, and very fine diameter wires are normally processed in the wet condition, while ferrous alloys and all other materials tend to be drawn dry.

In consequence, a wide range of lubricants is employed. The lubricant used must account for not only the specific material requirements, but also for the effects of cooling that are now recognized as being of major importance.

For most ferrous materials, the preferred method of lubrication is that of precoating the wire. Ordinary carbon steels are phosphate coated, but stainless steels require either oxalate compounds or borax as a lubricant. Although oxides protect the surface from die damage during drawing, they do not necessarily act as lubricants and so two-stage lubrication is still, reluctantly, used. In addition to oxide films, crystalline lubricants are required, and chlorine and sulphur type additives are used.

Electrochemical deposition of lubricants is still in the development stage but, if proven sufficiently economical, it will provide a relatively easy answer to standard processing lubrication problems in that the deposition and removal (combined with temperature control) of substances such as molybdenum sulphide is relatively simple by this means.

The removal, and possibly re-use (for reasons of economy), of lubricant is of importance. Cleanliness of the lubricant as achieved by, say, filtration of debris, can be high and will thus affect the 'brightness' of the surface when the wire undergoes the final series of passes. When drawing very fine wires, ultrasonic cleaning is necessary.

16.2.7.3 Non-standard wire-drawing techniques

These techniques include principally hydrodynamic lubrication systems and ultrasonic drawing. The basic idea behind hydrodynamic lubrication is to provide a continuous, but sufficiently thick, layer of pressurized lubricant that will separate the tool from the wire. In this way tool wear is considerably reduced.

An effective technique of achieving these conditions is that of drawing through a sealed tube containing oil as lubricant (although occasionally soap can be employed) and terminating in a constriction or nozzle and, eventually, in a die. As the speed of drawing increases (and high speeds are necessary) so does the oil pressure until, theoretically, it reaches the value of the yield stress of the processed material. The difficulties experienced in operating the system are related to the problems of sealing at high pressures and velocities, and to those of precision nozzle design which is 'adjustable' to materials and conditions.

Copper and aluminium wires can be drawn, but the pressures required for 'harder materials' such as, for example, steels, are too high to maintain successfully over a period of time. Nevertheless, since very good lubrication is generated with, consequently, low friction and tool wear, the technique should be considered where economy of operation is important.

In an ultrasonic multidie system, one or more dies when vibrated in the direction of drawing create conditions of back-pull which, in turn, alter the force requirement and directly affect its magnitude. As a result of die vibration, an oscillatory force is induced in the wires, between the consecutive dies and, eventually, the coiler drum. In consequence, greater reductions in cross-sectional area are achievable without either an increase in the degree of plasticity of the material or any decrease in interface friction. The level of this reduction depends on the value of the back-pull exerted and increases with decreasing back-pull factor. The surface finish and mechanical properties of the drawn wire remain unaffected by the oscillatory nature of the force system.

16.2.7.4 Special tube-drawing operations

Two completely diverse drawing systems now in operation are: ultrasonic drawing of ferrous and non-ferrous alloys; and fixed-plug drawing of explosively prewelded bi- or tri-metallic tubing.

Ultrasonic drawing is based on either the volume or surface effects produced by the oscillatory vibration of tools. The volume effect is subdivided into:

1. the superposition mechanism,
2. metallurgical effects, and
3. the swaging effect

The surface effects comprise:

1. the change in friction between the tool and the work piece, and
2. the friction vector.

If only the plug is vibrated at about 20 kHz, friction is reduced by surface effects, i.e. by a thickening of the film of lubricant between the tools and the work piece. This reduces the drawing load and/or eliminates pick-up and chatter. However, practical difficulties are experienced in designing the plug and plug bar that will give the required resonance.

If, however, the die is vibrated ultrasonically in the radial direction, rather than remain stationary as in a conventional drawing operation, a swaging effect is produced in the tube which, although conforming to the subdivision listed above, indicates that, industrially, the division between volume and surface effects is not all that important.

Again, the details of the design of suitable equipment cannot be reproduced here, but information is available in the publications listed in the Further Reading at the end of this chapter.

The process has the following basic characteristics:

1. the reduction in the drawing stress increases with increasing ultrasonic energy density,
2. a reduction in area of more than 54% is achievable,
3. the ultrasonic energy density can be increased by reducing the speed of drawing rather than by increasing the energy input,
4. surface finish is improved when radial die oscillations are used, and
5. pick-up and chatter are low or absent.

The high degree of sophistication required in the rapidly developing technology of the manufacture of petrochemicals, electronic devices (particularly cybernetics, cryogenic systems, and of atomic pile and toxic metals remote control systems) calls for the development of a new range of engineering, tubular composites. Some of these cannot be produced by conventional techniques alone or can only be manufactured at high cost. A typical example of the first group is a multilayer, multimetallic cylindrical pressure vessel, whereas an example of the second is a semiconductor system enclosed permanently in a protective tubular metal sheath. In between these extremes there is a wide range of components such as special bi- or multi-metallic heat exchangers, that combine structural strength with anticorrosive properties and ensure a rate of heat flow as good as that shown by the individual metals of the composite.

Conventional codrawing or coextruding of such assemblies gives less satisfactory results, because even with a high degree of process control it is practically impossible to ensure that no lubricant or debris is trapped on the surfaces. Furthermore, lack of cohesion between the original components of the assembly is likely to lead to very high differential deformation and the associated in-built shearing stress.

Many of these limitations can be eradicated if the integrity of the component is assured *a priori* by, say, explosive welding. In this respect, the manufacture of duplex or triplex, bimetallic or multimetallic cylindrical pressure containers is of practical importance and this has been accomplished successfully. Because of the technical problems involved when long composite cylinders are explosively welded, the usual technique is to weld short, large diameter combinations, and then to obtain the required dimensions by means of cold-plug drawing.

The characteristic features of drawing are the changes effected in the distribution of hardness across the tube section, and in the quality of the weld. While the former simply reflects the effect of strain hardening of the composite associated with the imparted deformation, the latter represents the effect of shearing at interfaces. Unlike hydrostatic extrusion, discussed earlier, where the adhesion of implosively welded elements is improved, in drawing weakening and even failure of the weld can occur. Of course, the failure, often only local, of the weld does not reduce the strength or tightness of the cylinder, since the function of the weld is only to promote more 'homogeneous' drawing conditions.

16.2.8 Sheet-metal forming

16.2.8.1 Forming processes

The considerable success and continuous expansion of the sheet-forming industry are due to a number of unrelated but important developments.

The introduction of the continuous tandem rolling mill has made it possible to produce wide strip which can either be coiled or cut to suitable operational sizes. At the same time, cold forming of sheet ensures greater resistance of the formed section to corrosion, since the preformed material has good surface finish due to treatments such as pickling. Surfaces cleaned in this way form suitable bases for the application of protective layers of, for instance, paint or plastic coating and, furthermore, they can be galvanized and then rolled or drawn.

The good dimensional qualities of preformed sheet make it a good starting material for operations such as bending, piercing, dimpling and drawing, by ensuring general uniformity of thickness. The exception here is the change in sheet thickness on transition sections where thinning is likely to occur. However, in a cold operation, strain hardening accompanied by changes in thickness will tend to counteract the effect of the actual variation in thickness.

The five basic processes effecting a change in shape are:

1. shearing,
2. bending,
3. spinning,
4. stretching, and
5. drawing.

A wide range of sections and shapes, and a varied range of products for industrial, domestic or general use can be produced.

Industrial applications are found in the following areas:

1. computer, nuclear and space industries;
2. the chemical industry;
3. the aircraft industry;
4. the car industry; and
5. the food industry.

Cold-formed sections are used industrially as components, plant, equipment, containers, panels, radiators, body parts, chassis, frames, racks, stiffeners, etc.

Domestic applications include, among others:

1. components,
2. cookers,
3. panels,
4. refrigerator bodies,
5. washing machines, and
6. shower cabinets.

General applications range from building constructions and components through structural elements, to rail and road transport, civil and highway engineering, agricultural machinery and equipment, and architectural and shop fittings. A major part of the output is intended for the electrical heating and ventilating applications represented by conduits, casings, cable supports, electrical appliances, heating panels, and dust-extraction equipment.

16.2.8.2 Shearing operations

The shearing operation constitutes the first stage of any forming process by producing either the starting material (cutting out of a sheet) or preparing an existing work piece by punching a hole or a series of holes before forming.

Basically, the operation involves placing the material between the edges of a shearing tool, which serve as supports, and separating a part of it by the action of a punch. Purely shearing stresses are generated, but the quality of the separating cut depends on the clearance between the tool and the specimen. If the clearance is too small, the cracks produced by the tool do not coalesce and tearing occurs. At the other extreme, too large a clearance results in considerable plastic flow which inhibits formation of the cracks and produces a burr at the upper edge.

16.2.8.3 Bending

Bending is executed either by pushing the strip into a die of the desired profile or, more often, by cold-roll bending (see Section 16.2.4.7). Either method can be used to produce a variety of shapes, a selection of which is shown in Figure 16.53.

Since the final quality depends on the material used, it may well be that the phenomenon limiting the degree of bending allowable in any given case will not be simply that of fracture or instability, but also one that produces an unsatisfactory finish. A selection of possible limiting factors, including the basic fracture and necking, is given in Figure 16.54. The maximum deformation may be limited by indentation caused by the die edges, galling, wrinkling and crease forming.

In addition to actual sheet bending, the operation is often extended to tube or blank flanging. Severe compressive stresses are imposed in these processes and may lead to buckling in a tube.

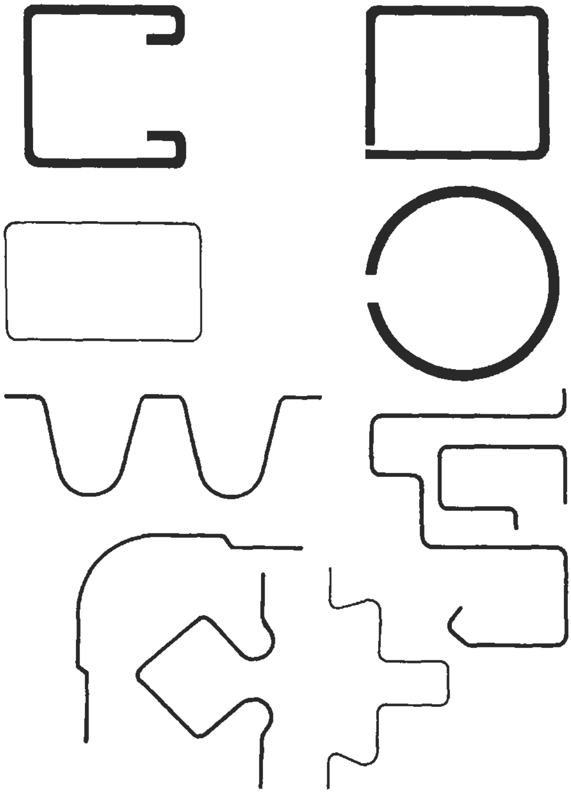

Figure 16.53 A selection of sheet sections obtained in bending

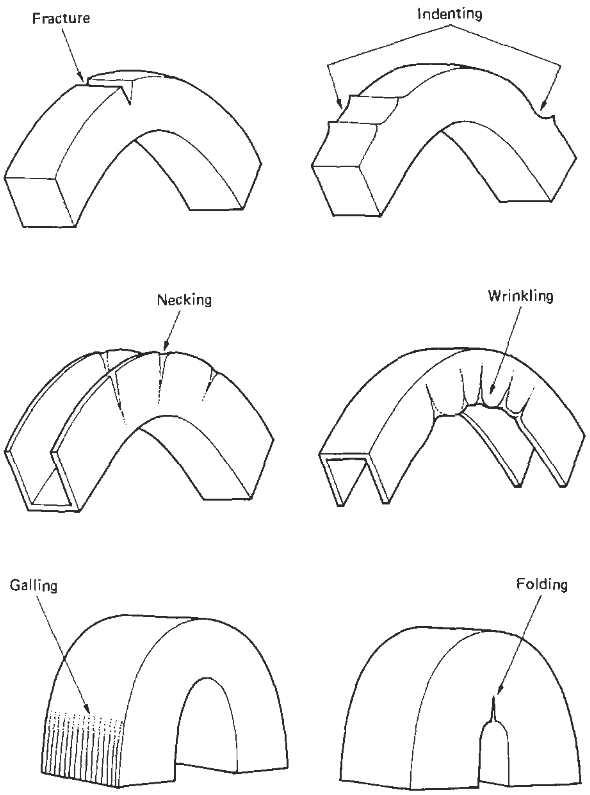

Figure 16.54 Sheet bending limiting product-quality phenomena

16.2.8.4 Spinning

Sheet forming by spinning is applicable to axisymmetric shapes only. The operation involves a driven, rotating system to which the male forming die is attached. The sheet to be formed is held against the die. Either manual or power, cold or hot spinning operations are used. The limit of formability is imposed by the ductility of the material and can be assessed from a simple tensile test.

16.2.8.5 Stretch forming

Stretch forming is often used to produce either simple components, comparable to cylindrical cups, or more complicated pressing-type shapes. Basically, stretch-forming operations depend on the use of conventional punch and die systems or a dieless-punch system. In either case, the rim of the blank is clamped (Figure 16.55) and the stretching, with consequent thinning of the material, can proceed on loading the punch. The thinning is particularly pronounced on the radiused rim of the supporting die or anvil. Instability can set in and lead to failure through localized necking.

Dynamic or explosive stretch forming is also used (see Section 16.2.9.3).

16.2.8.6 Deep drawing

Deep drawing is normally associated with the manufacture of cups, cans and similar containers. The operation is usually divided into two main groups: first-stage drawing, in which a flat circular metal blank is made into a cup; and a redrawing

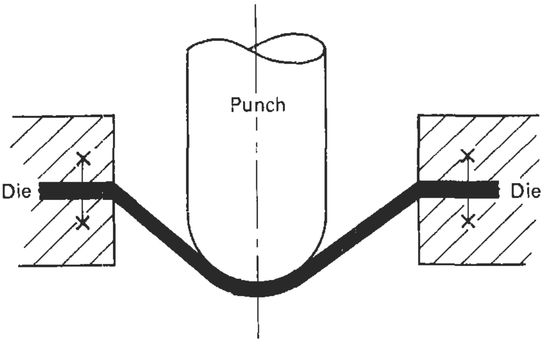

Figure 16.55 Conventional stretch forming

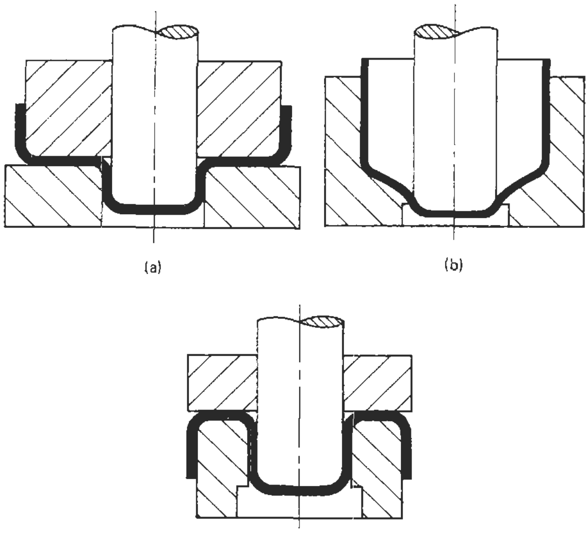
stage (or stages) in which the cup reaches its final size. The latter operation is necessary because first-stage drawing cannot normally produce a higher degree of deformation than that defined by the ratio of the diameter of the blank and the die throat (drawing ratio) of about 2.2, or a cup height/diameter ratio of about 1.

The sequence of operation is as follows. Initially, the specimen held in position by a blank holder, is partly in contact with the die, partly with either the die or punch, and partly with the punch only. The downward movement of the punch initiates drawing. The outer rim of the blank is then subjected to pure radial drawing (i.e. drawing towards the vertical axis of the system) between the die and blank holder. A part of the material bends and slides over the die and is further stretched between the punch and the die, whereas the material initially in the vicinity of the punch head and actually in contact with it bends and slides over the radiused part of the punch and stretches over the punch head.

The redrawing systems often used are shown in Figure 16.56. Parts (a) and (b) in the figure show direct redrawing systems with and without blank holders, respectively, while a reverse system is shown in (c). In (a), the wall of the cup undergoes double bending and unbending, the severity of which is expected to be high because the respective directions of deformation are at right angles to each other. System (b) shows less severity because of the tapered wall support, although double bending is involved. This system can be used only for relatively low cup diameter/wall thickness ratios which do not require the use of a blank holder. In comparison with the direct methods, system (c), having a generously radiused die profile, tends to reduce the degree of (or with a semicircular profile to eliminate completely) one bending and unbending effect. Whether there is significant advantage to using any system depends on the balance between the reduction in redundancy and practical production considerations.



(a)
(b)
(c)

Figure 16.56 Direct cup redrawing with (a) and without (b) a blank holder. (c) Reverse drawing

The definition of 'redundancy' in deep drawing is not easy since redundancy is not necessarily associated with the effects of macroshear. The nature of the processes is such that portions of the blank material undergo some phases of deformation which in themselves induce redundant effects and yet are physically unavoidable if the process is to be completed. It is therefore the degree of severity imposed rather than the avoidance of a certain phase of the operation that matters. In this respect, the process differs significantly from the bulk forming operations discussed previously.

The three main sources of unnecessary strain in and/or distortion of the blank or cup material are flange wrinkling, the already discussed bending and unbending, and, partly, ironing. The latter is used to eliminate the increase in cup wall thickness which can be as much as 30% in the first stage of drawing. If this is followed by a further substantial rise in successive processing stages and is accompanied by wrinkling, an additional drawing operation becomes necessary. As far as redundancy is concerned, ironing is the only operation that brings back the 'standard' features of shearing.

The formability of a material depends on the blank-holder pressure and, consequently, the deep drawing ratio $R = D/d$ may be limited either by wrinkling of the flange, tearing of the cup bottom, or by galling. Figure 16.57 shows diagrammatically the boundaries of these conditions and indicates the presence of a 'safe window' within which deep drawing is likely to be successful.

In determining the drawability, the criterion to be adopted is that relating to the first incidence of any fault.

16.2.8.7 Hydroforming and hydromechanical forming

To increase the depth of the draw, while reducing local stress concentrations, the techniques of fluid-backed or fluid-mechanically augmented processing have been introduced.

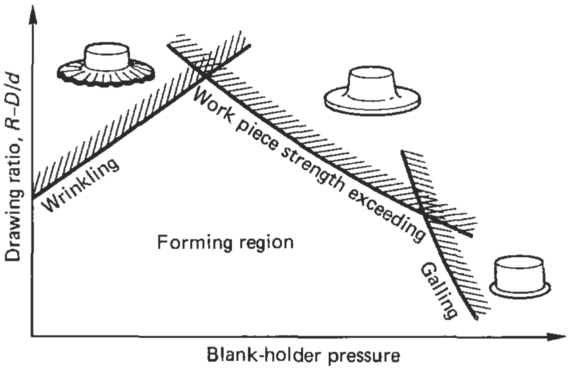


Figure 16.57 The effect of blank-holder pressure on the cup drawability

In a pure hydroforming operation (Figure 16.58(a)), a rubber diaphragm pressurized by the fluid acts as both a blank holder and a flexible tool. The only rigid tool is the punch. Since hydraulic pressure is exerted on the blank, the stressing is uniform and is accurately controlled. With reduced sheet thinning and considerable suppresion of cracks, high draw ratios (up to $R = 3$) are possible. The method is suitable for the forming of both jet-engine components (some 1 m × 1 m in size) and a variety of car components, including side and roof panels. A selection of parts so formed is shown in Figure 16.58((b)–(e)).

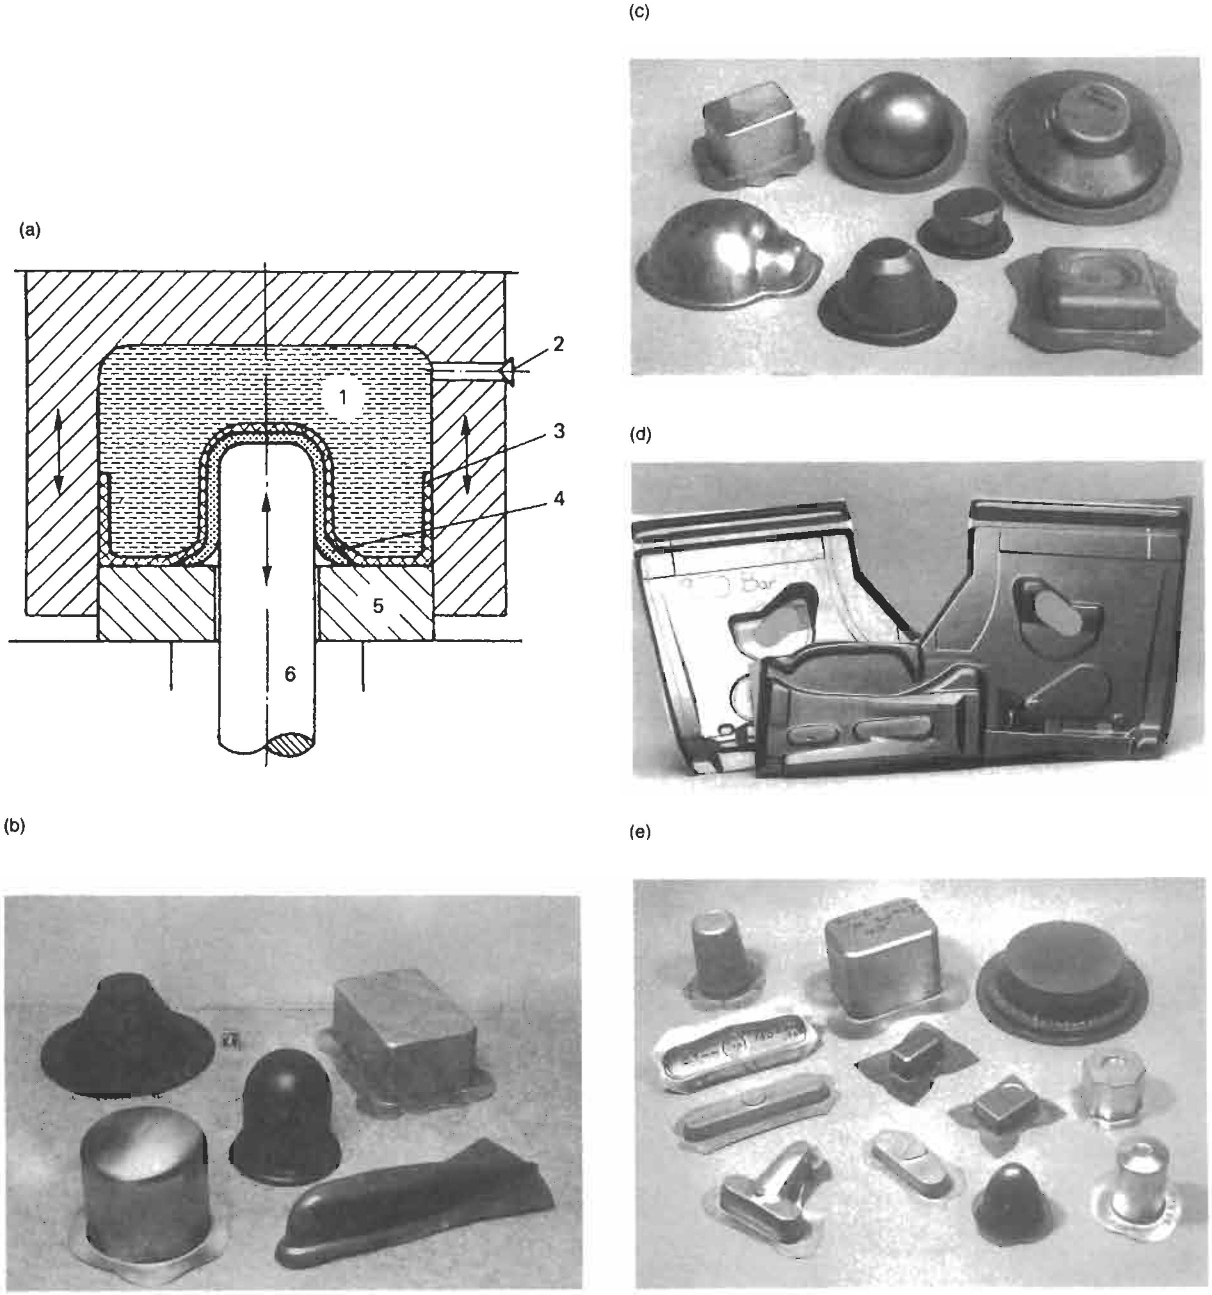

Figure 16.58 (a) Pure hydroforming operation: 1, hydraulic cushion; 2, pressure regulator; 3, cup diaphragm; 4, blank material; 5, pressure pad; 6, punch. (b, c) A range of jet engine and aircraft components. (d) Side panel of a car body. (e) Car parts. (Parts (b) to (e) courtesy of Saab-Scania AB Car Division, Sweden)

In the Hydromec, or mechanically augmented system (Figure 16.59), the sealing diaphragm is omitted and the blank comes into direct contact with the fluid. The sealing of the fluid is effected through the use of sealing rings. The blank is pressed firmly against the punch and thus possible bulging between the die ring and punch is avoided; a feature of the process that is of particular importance in the deep drawing of parabolic components. Complex parts can be drawn in a single operation, thus reducing operational costs. Sizing tools are claimed to be unnecessary.

16.2.9 High-energy-rate operations

16.2.9.1 Introduction

The last three decades have seen the development of industrial forming techniques based on the utilization of high-energy-rate dissipation. The dynamic aspects and mechanisms of these operations make it possible to manufacture, usually fairly economically, either large components, such as radar dishes, rocket nose cones and pressure vessels, or to produce smaller semifabricates (in sheet or tubular form) to be processed further in conventional operations. Some examples of this approach were given in Sections 16.2.6 and 16.2.7.

The usual sources of energy available are:

1. chemical explosives,
2. electrostatic fields (hydroelectric forming), and
3. magnetic fields (magnetic forming).

These sources of energy are used in:

1. forming (sheet and tube),
2. welding (sheet sandwich semifabricates, and multimetallic tubular components),
3. powder compaction (to form prefabricates),
4. forging, and
5. hardening.

The potential use of any of these operations is conditional on the formability of the given metal in the dynamic condition. An indication of this, based on 1100-0 Al as standard, is given in Figure 16.60.

16.2.9.2 Sources of energy

Explosives The proper utilization of the energy evolved when an explosive charge is detonated depends on the degree of understanding of both the properties of explosives and of the detonation phenomena.

From a practical point of view, commercial chemical explosives will generally fulfil the requirements of the welding, forming and compacting processes. On detonation, the detonating front travels through the explosive converting its mass to a high temperature, high pressure gas which is then used in the generation of a stress wave and, depending on the conditions, in the appearance of shock and release waves.

Chemical explosives are subdivided into 'high' and 'low' (deflagrating) materials. High explosives are characterized by very high detonation pressures and high rates of reaction. Because of this, high explosives are subdivided further into two groups.

1. Primary or detonating explosives which are sensitive and may be detonated by slight impact, flame, static electric charge, or simple ignition. They are normally used in detonators, but seldom as a source of energy in metal working.

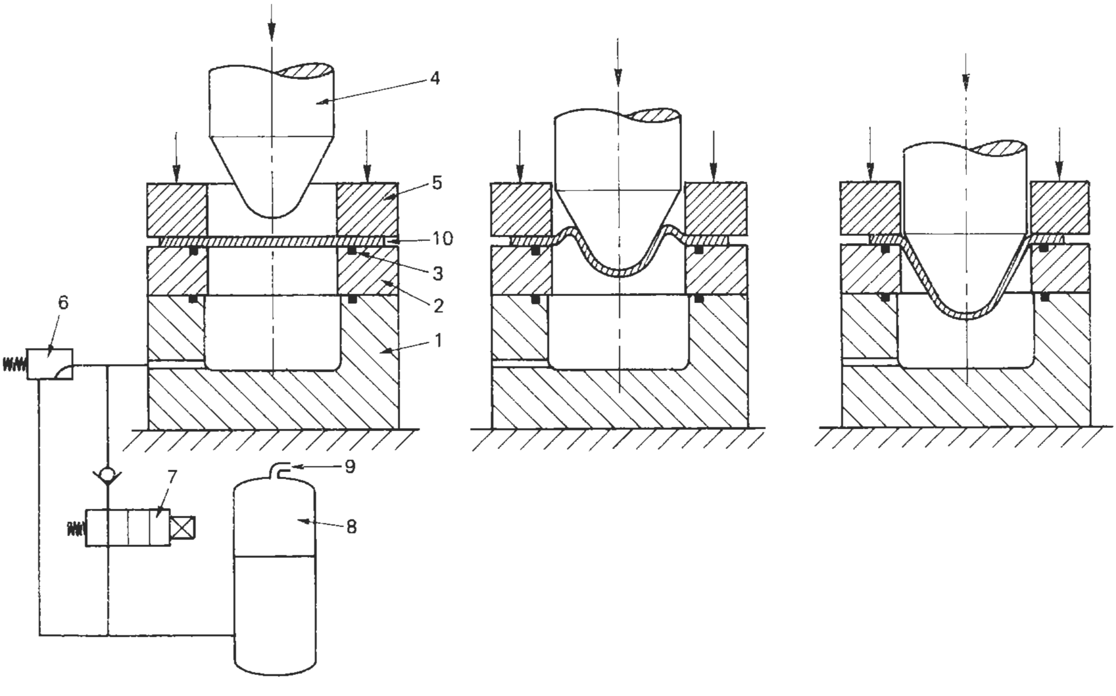

Figure 16.59 Hydromechanical deep drawing (the Hydromec process). 1, Container for hydraulic cushion; 2, die ring; 3, die ring seal; 4, punch; 5, blank holder; 6, pressure regulator; 7, electromagnetic control valve; 8, fluid container; 9, compressed air supply; 10, circular blank

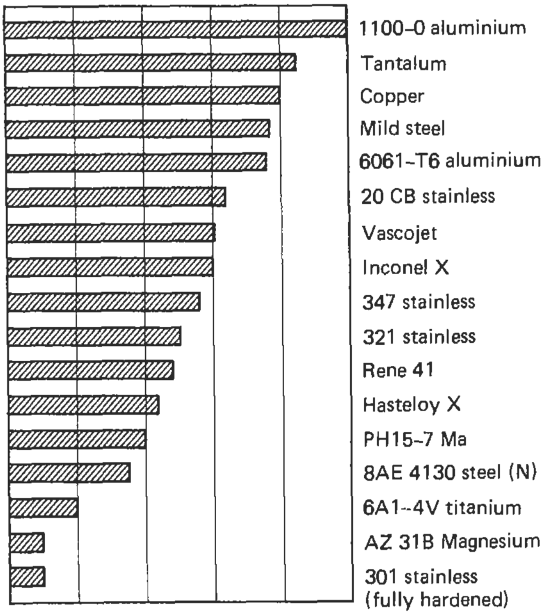

Figure 16.60 An assessment of the formability of metals

2. Secondary high explosives are used mainly in metal working and other industrial applications. They require a detonator to initiate the reaction and sometimes a booster charge to reinforce the detonation wave. They have a higher energy content than primary explosives.

Deflagrating or low explosives burn rather than detonate when the reaction is initiated and produce much lower pressures. They usually contain their own oxygen supply and, therefore, burn easily, but in some materials the reaction is difficult to initiate. Their low rate of burning makes them excellent propellants, but fire risk is considerable when handling such chemicals.

The charges are initiated by detonators. Electric detonators are widely used and are safe to handle if reasonable precautions are taken. Commercial detonators normally consist of a thin metallic container protecting the contents of an initiating primary high explosive, and a small amount (about 1 g) of a sensitive secondary explosive, e.g. PETN or tetryl. Initiation is achieved electrically, using an exploding bridge wire. Some types contain a slow-burning material to provide a time delay when many charges are fired at different time intervals.

The following explosives are commercially available and are used in industrial applications.

Primary high explosives
1. mercury fulminate,
2. lead azide,
3. diazodinitrophenol,
4. lead styphnate, and
5. nitromannite.

Secondary high explosives
1. TNT (trinitrotoluene),
2. tetryl (trinitrophenylmethylnitramine),
3. RDX (cyclotrimethylenetrinitramine),
4. PETN (pentaerythritol tetranitrate),
5. ammonium picrate,
6. picric acid
7. ammonium nitrate,
8. DNT (dinitrotoluene),
9. EDNA (ethylenediaminedinitrate),
10. NG (nitroglycerine), and
11. nitro starch.

Low explosives
1. smokeless powder;
2. nitrocotton;
3. black powder (potassium nitrate, sulphur, charcoal); and
4. DNT (dinitrotoluene ingredient).

Explosive materials are available in different forms and some of them in more than one. Many of them can be melted allowing other explosives to be added in the form of slurries. Powdered, granular, solid, liquid and plastic explosives can be used. One of the most useful types is so-called ‘Datasheet’ or ‘Metabel’, which is essentially a PETN explosive combined with other ingredients to form a tough, flexible waterproof sheet that can be cut and shaped to the required size for contact and stand-off operations. It is available in different thicknesses and can be glued together or used as shaping back-up material if a shape charge is required. Another very useful type is powder explosive, particularly various mixtures of TNT with aluminium powder, which can fill a container of any form and then be compacted to attain higher densities. Sealed containers are not required, thus offering an advantage over liquid explosives. Cord explosives, e.g. Cordtex, are also available. These consist of a flexible cord containing a core of explosive. Cords are very useful when continuous long charges are needed and give reasonable accuracy in a number of forming operations.

The effectiveness of a charge depends on the characteristics of the explosive, as reflected by the pressure–time function, velocity of detonation, explosive/specimen mass ratio, stand-off distance and the transmitting medium.

‘Detonation’ is a term used to describe the process in which an explosive charge undergoes a chemical reaction accompanied by a characteristic type of shock wave (or detonation wave). Depending on the properties and type of the explosive material, the velocity and intensity of the characteristic shock wave varies, but remains constant for a given type of explosive and for a charge of uniform geometry and density. This simplifies the mathematical solution of the hydrodynamic theory which applies to the process. The general behaviour of a primary explosive during reaction is characterized by a slow combustion process at the beginning, and then by deflagration, up to a point of sudden transition to detonation. The whole process is completed in a few microseconds. However, the rate of build up of the reaction and the transfer to detonation when a secondary explosive is detonated without a detonator is much slower and burning before detonation may occur.

Low explosives are characteriized by the absence of the transition period. They react at rates which are proportional to the build-up pressure which, in turn, increases as the chemical reaction speeds up. This cycle leads to explosion within a fraction of a second, but the rate of reaction is usually much slower than 1% of that in detonation, and peak pressures are also lower. However, energy comparable with that obtained from high explosives can be generated by low explosives when they are adequately confined or used in sufficient quantity, and pressure distribution is easily controllable.

As far as metal-working processes are concerned, the most important parameters of the detonation process are:

1. the energy released by the detonation.
2. the detonation velocity (i.e the velocity of propagation of the detonation front), and
3. the pressure exerted by the gaseous products of detonation on the specimen.

Other aspects of the process, such as the thermal stability and sensitivity of the explosive, the temperature, the heat generation and the ionization phenomena in the gaseous products, as well as their composition, are of no importance.

To carry out a successful metal-working operation the optimum strain rate for the metal must be ascertained, and the amount of energy dissipated must be adjusted to give the desired rate.

The adjustment of the amount of energy available for a given operation depends on the source used and the method of application. Regardless of the type of source used, the energy can be delivered in one of two ways: through a transmitting medium, or directly to the metal. Apart from some special applications, delivery through a transmitting medium is more usual.

Hydroelectric forming The principle of operation is based on the rapid dissipation and transmission of energy evolved when an electrostatic field is suddenly discharged. Two different techniques of using the energy stored in a bank of condensers are employed: underwater discharge, and exploding wire. In the former case, the discharge across two submerged electrodes produces a shock wave in the transmitting medium, accompanied by heating and vaporizing of the adjacent layers of the medium. The plasma created by the spark expands as a gas bubble, transmitting the force of explosion to the work piece. The efficiency of the operation depends on the conductor material, losses of energy in the circuit, and the geometry and surface conditions of the electrodes.

The second method consists of connecting submerged electrodes with an initiating wire. The transmitted energy vaporizes the wire and converts it into plasma, creating a pressure wave. The increase in volume of the vaporized wire is of the order of 25 000 times its original volume. The exploding-wire method possesses certain distinct advantages over the spark-discharge method in that the process can be more rigidly controlled. The shape of the shock wave can be determined by the shape of the wire, and a long arc discharge can be obtained as opposed to a point source one. The amount of energy can be controlled by the dimensions and material of the wire. For instance, tungsten produces more energy than tantalum, niobium, molybdenum, titanium, nickel or aluminium (in that order).

Electromagnetic forming The principle of electromagnetic forming is, basically, the same as that of an electrohydraulic operation. The energy stored in a bank of condensers is rapidly discharged through a magnetic coil, which surrounds, is placed inside, or is in the proximity of the work piece (Figure 16.61). A high intensity magnetic field is thus created and, providing that the material of the work piece is conductive, electric current is induced in the specimen. The current interacts with the coil field and produces high transient forces. The specimen thus acts as a secondary short-circuited coil. The energy level produced by the magnetic field depends on the conductive properties of the formed metal, its shape and mass and the duration of the initial current pulse. These factors can quite easily be controlled by suitable choice of the materials and geometry of the coils. Materials of low conductivity are sometimes lightly coated with copper. The shape of the impulse wave can be modified by using 'field shapers' which consist of shaped beryllium–copper pieces inserted in the coils. Electrically, shapers help to depress or concentrate the intensity of the magnetic flux in those sections of the work piece which may require a lower or higher degree of deformation.

The life of a coil depends on the magnitude of the force to which it is subjected. This being equal to the force generated on the surface of the work piece, the pressures can be very high. The usual practice consists, therefore, of using one-shot disposable coils for more complicated operations involving only a few parts, and of limiting the pressures to the value of the compressive strength of the coil material for mass-produced parts.

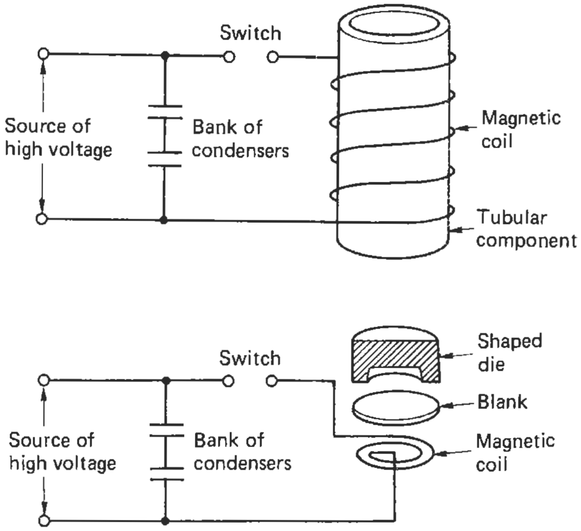

Figure 16.61 Some circuits used for magnetic forming

16.2.9.3 Forming systems

Explosive forming Explosives are used primarily for shaping sheet, plate and tubes, and for sizing and flanging, all these operations being of the stand-off type. Close-contact operations are used to a lesser extent and for more sophisticated processes such as extruding, cladding (welding), powder compaction and controlled surface hardening of Hadfield steels. The particular applicability of explosives to forming arises from the fact that virtually any shape in any size can be obtained without recourse to plant or machinery. The forming tool consists of a die which is comparatively light and does not require any foundations since the inertia of the tool mass is sufficient to counteract the applied force. It is essential, however, to realize that explosive forming is not economically viable when a very large number of components is required. Its advantage over the conventional methods lies in the possibility of producing complex parts very accurately and with very little or no machining, but in small quantities. The saving is due to the fact that there is no capital cost of presses, tooling, etc. The dies for stand-off operations are very often made from cheap cast materials such as epoxy or concrete.

The range of metals successfully worked includes: aluminium and its alloys, stainless steels, magnesium and some of its alloys, titanium and its alloys with aluminium, vanadium and manganese, refractory metals, copper and its alloys, and special alloys such as stellite, iron–nickel, nickel–copper, chromium–nickel and cobalt–iron. Carbon and low-alloy steels are less often used because of their low formability in dynamic conditions.

Three essential types of techniques characterize the stand-off operations: (i) free forming (cups, flanging and deep drawing), (ii) cylinder forming, and (iii) bulkhead forming (sheet and plate). These techniques are shown diagrammatically in Figure 16.62. Cylinder shaping is done in an open system using high explosives. A transmitting medium other than air is used to sustain the pressure for a longer period, thus increasing the impulse delivered to the work piece. In general, the forming of metals can be carried out either in a tank sunk in the ground and filled with water as the transmitting medium, or in an empty tank with the water being contained in a polythene bag (in the case of a cylindrical component) or in any suitable, disposable container. The first method is used for large components that require large charges, where the confinement of explosion within a large volume of water serves both as a safety measure and as a means of reducing noise. In such a case, the space between the undeformed metal and the die must be sealed-off and evacuated to enable full deformation to take place. In the second case, it may not be necessary to evacuate the air, providing that the die is fitted with a suitable system of ventilating holes.

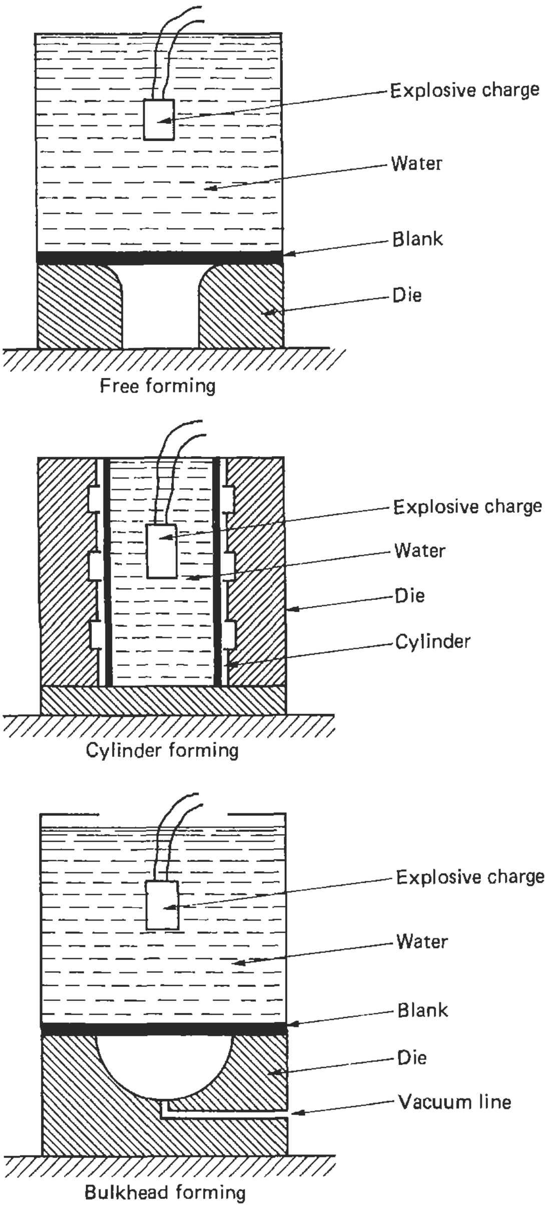

Figure 16.62 Basic explosive forming systems

A very important aspect of this method of forming is correct die design. The near absence of spring-back depends on the proper balance of tool profile, avoidance of sharp edges and deep narrow grooves and the provision of reasonably smooth transition sections.

Bulk forming of sheet is carried out by using either a single blank subjected, possibly, to a series of shots until the die is filled completely, or by using a mechanically shaped preform which is then given its final accurate dimensions in an explosive operation (Figure 16.63).

Forming without a die is also possible when relatively simple shapes are required, e.g. an impeller. An initially circular specimen can be formed to the shapes shown in Figure 16.64.

Although explosive forming cannot be regarded as a substitute for existing processes, it is an extension of the techniques now in use in the sense that it enables a number of difficult materials to be formed to a high degree of accuracy and at low cost. In the general field of metal shaping, the process is very advantageous when large parts are formed, often in a single operation, as costly heat treatment, tooling and machining are not required. The process is not competitive when parts can be produced in bulk using conventional equipment in a small number of operations. The use of explosives requires special precautions when storing and handling, and for safety reasons forming cannot be done in a congested enclosed area.

Hydroelectric forming In the application of this controlled and repeatable electrical force, the most obvious difference from explosive forming is the design of the forming apparatus. The dies are completely enclosed, since the volume of plasma generated is very small compared with the gas bubble created by a chemical explosive. By closing the die, full advantage can be taken of the pressure wave and, in the case of tubular parts, the shock wave is reflected from the ends, thus giving rise to additional energy. Each die has its own set of electrodes. In either technique the discharge takes place in a matter of microseconds, and is repeatable within 30 s. Operations can be automated and, unlike explosive forming, are eminently suited for mass production. Industrial forming machines are commercially available that have a basic output of, for example, 15 kJ, the amount of energy sufficient to form

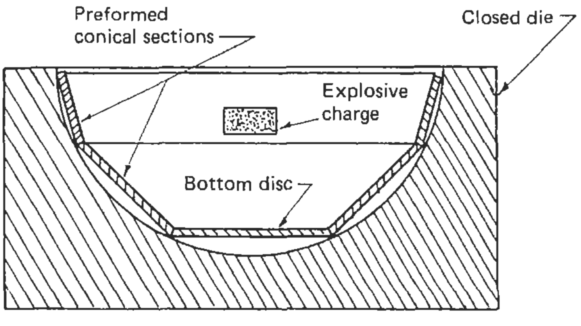

Figure 16.63 Preform bulk forming

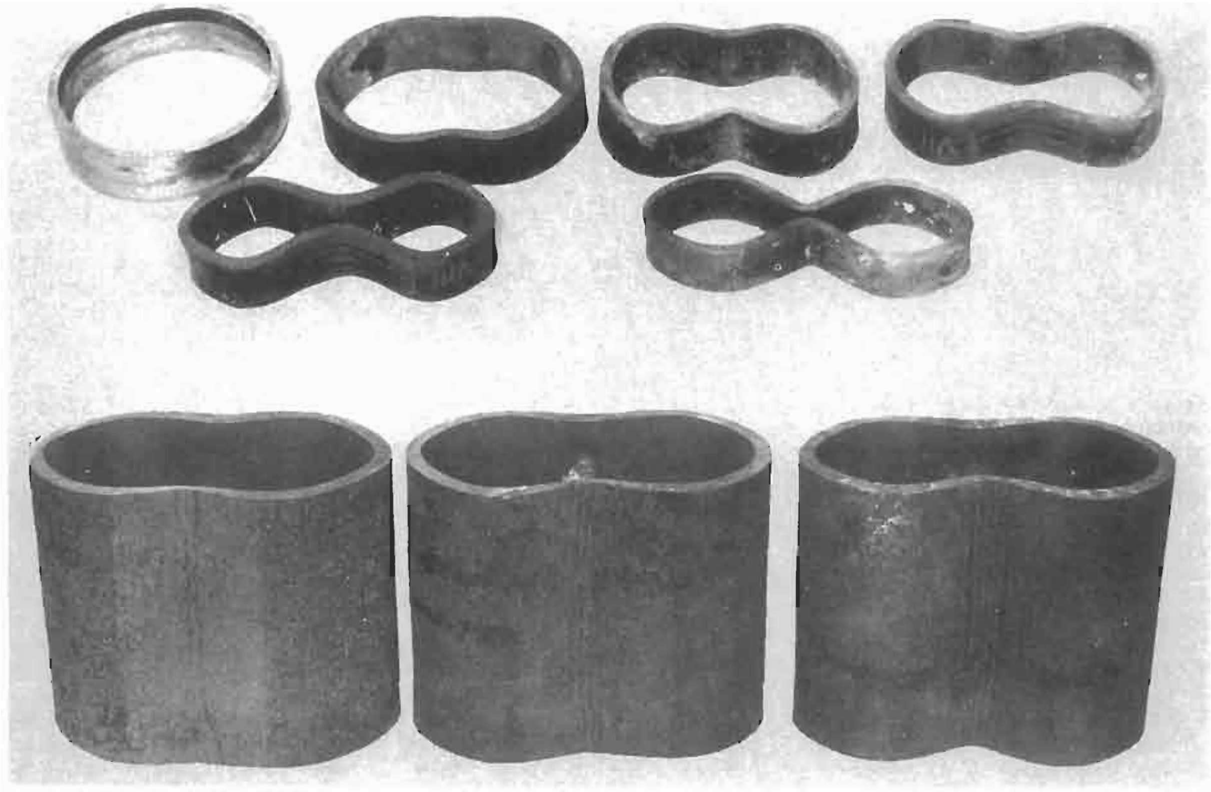

Figure 16.64 Steel impellers formed without using a die

ordinary commercial materials using blanks of 12–100 mm diameter and wall thicknesses of 0.2–2.5 mm. The output can be increased to 60 kJ.

For most purposes, dies used in hydroelectric forming are made of aluminium or cheap castable materials. The serious disadvantage of this technique is the comparatively high cost of the electrical equipment needed.

Electromagnetic forming The dies used in this process are made from cheap materials and, in some cases, are not required at all since the magnetic fields produce uniform pressures sufficient to expand cylindrical parts. The technique is very suitable for shaping sheet and tubular parts, swaging and the production of finned components. The process can be fully automated and forming machines are available. These are capable of producing magnetic flux densities of the order of 3×10^5 G, corresponding to pressures of over 340 MPa. The duration of the pulse is short, because of the permeability of metals, and is usually limited to 10 ms. Magnetic fields are quite sufficient for forming copper, aluminium and similar materials, but for metals like tungsten and for large parts, fields of the order of 5×10^5 to 5×10^6 G are needed.

The major disadvantage of the process is, again, the relatively high cost of the electrical equipment, but this is offset to some extent by the very high reliability, repeatability, speed of production and accuracy obtainable.

16.2.9.4 Explosive welding

The use of explosives for welding is now a well-established practice and provides a means of joining either flat or curved (tubular) surfaces of metallic alloys which are either incompatible (from the point of view of conventional welding) or impossible to join because of the geometry involved.

Explosive welding is a pressure operation in which two initially separate elements are joined together as a result of the metal jetting action which originates at the point of contact between them. The contact is achieved by detonating a charge covering the surface of one component (the flyer) which then gradually collapses onto the other (the base) component. The latter may be rigidly supported on an anvil. The shearing stresses generated at the point or line of contact are too high for either material to sustain and liquefaction takes place. A jet containing the elements of the flyer and the base is created and is propagated along the surface of the base. Since the detonation of the charge continues in a finite, albeit a short, time of microseconds, the flyer collapses in stages, creating new points of contact with the base and thus giving rise to further jetting. An indenting wave is produced (Figure 16.65) which, in addition to molecular welding, also creates a mechanical bond between the two surfaces. Elements welded in this way are usually made of the materials listed in Table 16.3, but more 'exotic' combinations can be produced easily.

Explosive welding is used to produce large sandwich (multimetallic) plates which can then be processed further by rolling, shearing, bending and/or deep drawing, and to manufacture duplex or triplex cylinders, assemblies of rods and tubes which can be further cold drawn or hydrostatically extruded.

Special welding–forming operations and processes are employed and range from the manufacture of honeycomb panels to multilayered foil cylinders. The latter can be used as light but strong pressure vessels and are made either from layered foils or, if required, can be reinforced by metallic mesh interleaved with foil.

16.2.9.5 *Powder compaction*

Various dynamic powder-compaction techniques involving the use of chemical explosives, high pressure gas guns, or electromagnetic or mechanical pneumatic power sources are used to compact metallic powders into semifabricates and finished machine parts. Either cold or preheated powders are used and the products, produced at pressures of 100–1000 kbars, amount to many thousands of tonnes annually. Like explosive-welding operations, explosive powder compacting is an exact and very complex process which requires detailed in depth study.

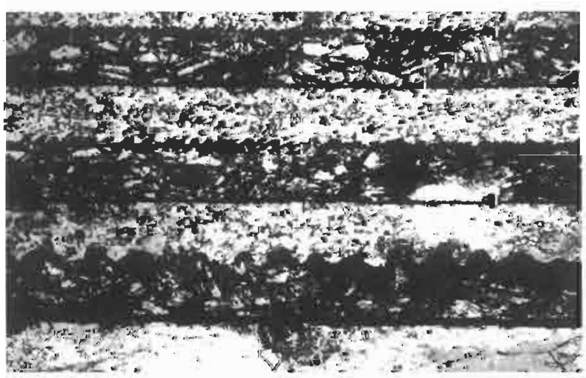

Figure 16.66 Cross-section of an explosively welded and formed multilayer copper/brass foil cylinder. Magnification ×110

16.2.10 Superplastic and mashy state forming

16.2.10.1 *Superplasticity*

The definition of the term 'superplasticity' is related to the fact that 'normal' alloys rarely show a greater degree of elongation than, at most, 60% when cold worked and only very occasionally exceed 100% when hot worked. In a few cases metallic alloys elongate at elevated temperatures to as much as ten times their original length—these are called 'superplastic' materials.

A number of alloys behave superplastically at temperatures ranging from ambient to 500°C but, because they are prone to corrosion and have poor creep properties, their industrial application is extremely limited. Tin/lead alloys are typical examples of this group.

The introduction of modern manufacturing techniques, e.g. diffusion bonding, enables the production of materials characterized by high strength (e.g. the titanium alloy Ti, 6% Al, 4%V) which are of considerable practical interest, although they require temperatures of up to 900°C.

Although welcome in general terms, the ability of a material to extend by several hundred per cent may not be acceptable from the point of view of the quality of the final product, since it could imply considerable thinning. Consequently, practical considerations limit the extent to which the superplastic tendency of a material can be utilized.

A practical guide defines a desirable material as one that will deform at very low stress, with a high rate sensitivity and freedom from damage, up to an elongation of some 100%.

The usefulness of these materials depends on the grain-growth response to strain rate, because only fine-grain structure is acceptable. Practically acceptable superplastic alloys should, therefore, display the following characteristics:

1. they must be stable at high temperatures (0.3–0.5 T_m);
2. the grain growth must be limited at high strain rates;
3. the flow stresses must be lower than the corresponding stresses in the same, but coarse grain, alloy; and
4. the acceptable properties must be obtainable at normal operational strain rates of up to $10^{-2}\ s^{-1}$.

Since superplastic materials can be formed at low stresses, they are ideal for first-step operations in which blanks are preformed to non-uniform thickness, but are subsequently formed to the required shape exhibiting a very high degree of thickness uniformity.

16.2.10.2 *Mashy state operations*

When a metal is heated to a temperature higher than its solidus temperature, its structure changes and consists of both solid and liquid elements, the latter generated by partial melting. The 'mashy state' is thus created the properties of which enable easy processing of the material in both the conventional forming processes and composite manufacturing techniques.

In the mashy state, the liquid component is normally present at grain boundaries and separates the solid component consisting of the incompletely melted grains (Figure 16.67). The properties of mashy state metals are as follows:

1. low flow stresses;
2. behaviour like that of a slurry when the solid fraction φ is less than 65%;
3. when φ is low a mashy state metal can be mixed with other metals; and
4. two different mashy state materials can be bonded together.

Solid component
Liquid component

Figure 16.67 Diagrammatic representation of the mashy state

The following operations can be carried out on mashy state metals:

1. extrusion,
2. rolling of sheet metal,
3. production of particle-reinforced metals,
4. production of particle-reinforced cladding metals, and
5. the manufacture of composite sheet.

Extrusion Extrusion of wires, bars and tubes is carried out in a conventional manner by using an electric furnace and an extrusion press. Billets are heated to the required temperature to obtain solid fractions of at least 70–80% and are extruded using preheated tools.

The characteristics of mashy state extrusion are:

1. a low extrusion pressure (20–25% of that used in hot extrusion),
2. a high extrusion ratio obtainable in a single pass,
3. the liquid component provides lubrication, and
4. complex sections are easy to extrude.

Rolling of sheet metal The success of this operation depends on steady flow and homogeneous deformation, which can only be achieved if the state of hydrostatic pressure is maintained along the pass. The process has the advantage of enabling metals with complex internal structures to be processed, where a conventional cold- or hot-rolling operation is inappropriate.

A diagrammatic representation of the forming system is given in Figure 16.68. The liquid component is cooled by the rolls, solidifies and is forced into the roll gap, whereas the grains of the solid component are compressed, deformed and then drawn into the gap. In the gap each grain is deformed and elongated.

The manufacture of particle-reinforced metals Since additives, in the form of particulate matter, can be mixed effectively with a mashy metal, composites of different metals, or metals and ceramics, can be made and these are particle-reinforced structures. These can then be processed conventionally by extrusion and rolling to produce the desired shapes and dimensions.

Two possible production routes and applications are shown in Figure 16.69. A metallic matrix and, say, reinforcing ceramic particles can be stirred and mixed together and then be extruded directly to form bars, wires or tubes, or be rolled to form sheet. On the other hand, on cooling the metal matrix gradually during stirring, metal powder is obtained. This can then be mixed with reinforcing particulate matter, formed into billets and then be extruded. Both routes are indicated in Figure 16.69.

Particle-reinforced cladding metals Although particle-reinforced metals possess good hardness and antiwear properties, they are basically brittle and so have low formability. To compensate for this disadvantage, particle-reinforced cladding metals obtained in the mashy state can be used. The particle-reinforced cladding metal consists of a layer of particle-

reinforced material and a metal base which provides the required ductility. The bonding between the two layers is obtained in mashy state forging.

The various manufacturing routes used are shown in Figure 16.70, which shows the possibilities of preforming the reinforcement to sheet followed by forging, cold forming following by forging, or starting with a mixture of powders taken directly to mashy forging.

The manufacture of composite sheet Either metal/ceramic-fibre reinforced or metal/metal combinations can be produced. An example of the adopted practice is given in Figure 16.71 which refers to the manufacture of a particle- or fibre-reinforced cladding sheet. The new manufacturing processes, briefly outlined here, are beginning to be used in normal industrial routines but, naturally, a great deal of further development work is still necessary.

16.3 Welding, soldering and brazing

16.3.1 Welding

Welding is used for joining metals so that the physical and mechanical properties of the parent metal are reproduced in the joint. The integrity of a welded component, which has metallurgical continuity across the joint, is also characterized by properties such as pressure tightness or heat and corrosion resistance. These properties have contributed to the rapid development, both technical and economic, in all fields including nuclear power, chemical engineering, bridge building, offshore engineering, shipbuilding and the manufacture of cars, railway locomotives and rolling stock, aero engines, domestic appliances, and military hardware from small arms to main battle tanks.

Metallurgical continuity across a joint can cause problems compared with bolted or riveted connections. For example, under certain conditions, cracks originating from fatigue or brittle failure can propagate across welded seams whereas they are arrested by mechanical joints. Nevertheless, extensive research has been carried out over many years on the factors controlling fatigue and brittle failure and guidelines are available in the literature and in various codes of practice which are effective in avoiding cracking problems during the service life of welded structures and components.

A weld is, in effect, a miniature casting and some of the defects that can occur in castings may also be present in welds. The heat affected zone adjacent to a weld is heated to high temperatures during welding and cools rapidly as heat is conducted into the body of the component. This area may be heated again to lower temperatures when more weld metal is deposited on the top of the first weld to build up the joint. The sequence of heating, cooling rapidly, and reheating to a lower temperature is similar to the heat treatment of steel by quenching and tempering.

Some welding processes involve substantial plastic deformation of metal adjacent to the interface between the parts being welded, which is similar in many respects to the forging process used to form metal parts. Thus welding encompasses the whole field of metallurgy, albeit on a small scale, and the application of metallurgical science has successfully solved the major welding problems such as cracking of weld metal or parent plate, porosity and slag inclusions in welds, as well as those that may occur in service such as cracking due to fatigue, brittle fracture or creep, and wear or corrosion.

It will be readily understood that welding technology has developed into a discipline in its own right and this section can only refer to important aspects. However, the engineer must know what methods are available for joining the materials used because the most economical manufacturing route in many cases depends on selection of the most appropriate welding procedure that will produce welded joints having the minimum level of quality fit for their intended purpose. This will require decisions to be taken by an experienced welding engineer who will generally have a professional qualification, but to understand the logic of the welding engineer's decisions a brief knowledge of welding technology is advantageous for any engineer. The purpose of this sub-section is to provide basic information on the principal methods of welding, brazing and soldering and their fields of application. For more detailed information the references at the end of the chapter should be consulted.

16.3.1.1 Types of joint

The types of joint used and their associated weld types are described in detail in BS 499.[10] The commonest joint types are butt, T, corner and lap.

Butt joints These are joints between parts that are generally in line. If two plates are placed in contact (a close square butt joint) they can be welded with full penetration by one run of weld metal deposited by a manual welding process from each side provided that the plate thickness does not exceed approximately 8 mm (Figure 16.72). However, plate above 6 mm thickness is generally bevelled and the Vee edge preparation formed is filled by depositing a number of runs of weld metal. If high-current mechanized welding processes are used penetration of the weld may be at least double the above dimensions and for electron beam welding may be many times as high.

T joints and corner joints The parts may be joined by fillet welds or butt welds made by an arc welding process (Figure 16.73).

Lap joints These are commonly used for sheet metal up to about 3 mm thick in which one sheet is overlapped by another. This type of joint is used for soldering, brazing, resistance spot or seam welding, and for arc spot welding, plug welding, as well as for adhesive bonding. For material of 3 mm or thicker (even up to 10 mm) lap joints are occasionally used and fillet welds are deposited at the plate edges by arc welding.

16.3.1.2 Welding processes

The various welding processes can be used to join the majority of metallic materials, whether in cast or wrought form, in thickness from 1 mm or less up to I m or more. A simple classification of welding processes is shown in Figure 16.74. For a complete classification and for definitions of the processes BS 499: Pt 1[10] should be referred to.

A description of the welding processes is as follows.

16.3.1.3 Manual metal arc welding

Manual metal arc welding (referred to in the USA as shielded metal arc welding) is the most widely used process and accounts for approximately 50% of all the welding in the world today. With this process, welding is carried out with flux-coated electrodes which are connected via an electrode holder and length of cable to one terminal of a welding power source, such as an a.c. transformer or a d.c. generator (Figure 16.75). The other terminal of the power source is connected to the work piece via the earth return or the ground cable, so that when the end of the electrode is placed in contact with the work piece, electric current flows through the circuit. By withdrawing the tip of the electrode to about 3 mm from the work piece an arc will be struck and current will continue to flow in the circuit and pass through the arc which is electrically conductive.

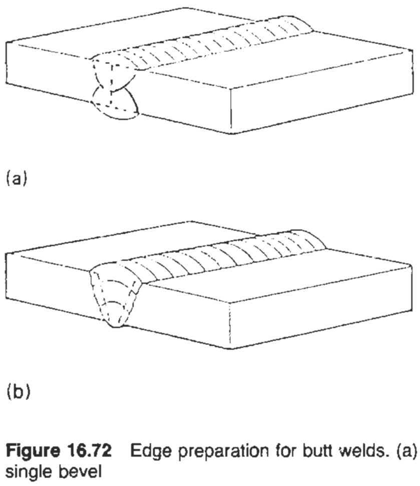

Figure 16.72 Edge preparation for butt welds. (a) Square edge; (b) single bevel

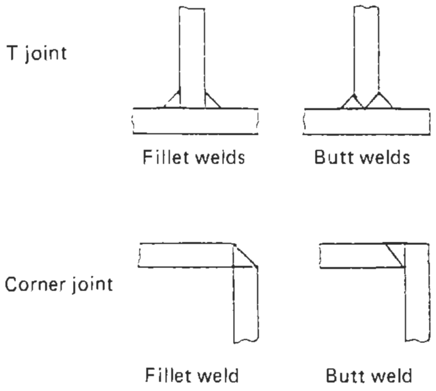

Figure 16.73 Examples of welded joints

If an arc is maintained between a rod-type electrode and plates to be welded together the tip of the rod becomes molten and so does a portion of the plates (the fusion zone). Gravity causes drops of molten metal to drip onto the plate and form a weld (Figure 16.76).

Apart from gravity, other forces caused by electromagnetic effects propel molten metal globules across the arc and these forces always transfer metal from the rod to the plate, whether a.c. or d.c. is used and whether the polarity is electrode positive or negative. They will also transfer the metal against the force of gravity, so that vertical or overhead welding is possible.

Electrodes These have core wire diameters from 2.4 mm to 10 mm and are 300–450 mm in length. The deposition rate of weld metal, which governs the overall rate of welding, increases with the current and has a maximum value for each electrode length and diameter. Exceeding the maximum current causes overheating of the electrode core wire by resistance heating, which can damage the electrode coating. Welding currents vary from 60 A for the smallest electrodes up to 450 A for the largest. The highest currents and deposition rates can only be used when welding downhand, i.e. in the flat position. Vertical and overhead welding can be used with electrodes having diameters up to 5 mm with maximum currents of approximately 170 A.

A bare wire can be used for welding, but the arc is mechanically unstable and the surface appearance of the weld is rough. The molten weld metal combines with nitrogen and oxygen from the air, resulting in poor mechanical properties.

The above problems can be overcome by coating wires with suitable fluxes and the principal purposes of this are:

1. To facilitate the initiation or striking of an arc and to stabilize it so that it can be easily maintained.
2. To provide a gas shield which protects the molten metal

3. To provide a slag which protects the hot, solidifying metal from oxidation. The characteristics of the slag (e.g. melting point, surface tension and viscosity) determine the shape of the weld bead and the suitability of the electrode for positional welding.
4. To supply alloying elements to the weld metal; this means that an inexpensive rimming steel core wire can be used for many different weld metal compositions.

The constituents of the flux covering are mixed together in dry powder form and then binding agents are added. The flux paste is pressed into the form of slugs and loaded into machines which extrude the covering round electrode core wires as they pass at high speed through a die of appropriate size. The electrodes are then dried as they pass through ovens and are stamped with identification marks before being packed.

The classification of flux coverings The development of flux coverings, consisting of mixtures of various minerals, has followed fairly well-defined lines with slight variations between different manufacturers and in different countries. Electrodes can be classified according to their coating types and for a full description BS 639: 1986[11] and the American standard AWS A5.1–81[12] should be consulted.

Steel electrode types are designated by letters in BS 639 and the main characteristics of the different electrodes are as follows:

1. *R (rutile)*: Rutile coverings containing a high proportion of titanium dioxide in the form of the mineral rutile or ilmenite. The electrodes are easy to use but produce weld metal having high hydrogen contents which can cause cracking of the weld or parent metal heat affected zone in heavily restrained joints.
2. *RR (rutile, heavy coated)*: The thick covering enables the electrodes to be used as contact electrodes which can be

held in contact with the parent plate and dragged along the joint at high welding speed. Iron powder is often added to the coating to increase the deposition rate, and the RR type electrodes are not suitable for welding in the vertical and overhead position.

3. *B (basic)*: A basic covering usually has a high content of limestone (calcium carbonate) and fluorspar (calcium fluoride). Basic covered electrodes are often referred to as low hydrogen because they were developed to produce weld metal having a low hydrogen content which reduces any tendency to hydrogen-induced cracking. This covering decomposes to give a gas shield containing a large proportion of carbon dioxide. These electrodes are used extensively because of their ability to weld medium- and high-tensile steels as well as high-sulphur (free-cutting) steels without solidification cracking of the weld metal and also because, by suitable drying treatment, the moisture content of the flux covering can be reduced so that the weld metal hydrogen content will be correspondingly low. This gives insurance against hydrogen-induced cracking of both the weld metal and the heat-affected zone (HAZ). Properly designed basic covered electrodes produce weld metal which has the highest fracture toughness properties, and they have the advantage over other types of electrodes in that high fracture toughness is maintained in all welding positions.
4. *BB (basic, high efficiency)*: These are similar to basic covered electrodes but have iron powder added to the coating so that the quantity of weld metal deposited is at least 130% of the weight of the core wire. The high deposition rates make these electrodes unsuitable for welding in the vertical and overhead positions.
5. *C (cellulosic)*: This designation indicates a covering which has a high content of cellulosic material. These electrodes operate at a high arc voltage, which gives a deep penetrating arc and rapid burn-off. The covering forms a voluminous gas shield, consisting chiefly of carbon monoxide and hydrogen, and a small volume of slag which facilitates work involving changes in welding position such as pipe welding for which these electrodes are particularly suitable. They can also be used for the fast, vertical down welding of vertical seams in storage tanks up to about 12 mm thick. Because of the excellent penetration the root does not require gouging before making a sealing run on the reverse side. In pipe welding the close control of penetration is necessary because the deposition of a sealing run on the inside is generally impossible.

Power sources There are basically three types of power source:

1. A.C. generators
2. D.C. rotary generators
3. D.C. solid state

The choice of power source is described by John and Ellis.[13]

A fourth type of power source of recent development is based on an invertor which is used to convert the mains frequency from 50 Hz to between 5 and 25 kHz. Transformers for currents operating at these high frequencies are much lighter than those used in conventional a.c. generators. In the invertor type power source the a.c. mains input is rectified to give d.c. which is then fed to an invertor which converts it back to a high-frequency a.c. The power is then reduced to the welding voltage by a lightweight transformer and it is rectified again to d.c. for welding.

In Britain transformers have traditionally been the most widely used type of power source for manual metal arc welding because of their relative cheapness, reliability and long life. The development of d.c. solid-state power sources has eliminated the moving parts and maintenance costs associated with rotary generators and has also reduced the capital costs. Therefore the use of d.c. welding is likely to increase in future, particularly in view of the fact that welding is easier because of the more stable arc and ability of d.c. to weld non-ferrous alloys and to produce the highest quality welds in stainless steel.

For use in repair work (for example, in the garage trade and for the DIY market) a number of low-power welding sets are available which operate from the single-phase 220/240 V supply. These power sources can be used with electrodes up to 3.25 mm diameter and both a.c. and d.c. units are available. For the home market, video instruction is available.[14]

Applications The main reasons for the popularity of manual metal arc welding are its versatity, simplicity of operation and the relatively low cost of equipment. The process can be used with equal facility in a workshop or on-site. To weld on a remote part of a structure it is possible, within reason, to lengthen the cables from the power source and when the limits of the extended cables are reached the power sources are readily transported by crane or motor vehicle or by manhandling on level sites. Movement of the power sources is facilitated by their simplicity and robustness.

The range of thicknesses welded varies from less than 2 mm in the fabrication of sheet metal ventilation ducting to 75 mm and above in the production of nuclear containment pressure vessels. These two examples are indicative of the wide range of quality standards that may be required, from general sheet metal work up to the highest possible standards of radiographic soundness and mechanical properties.

Metals that are most commonly fabricated by manual metal arc welding are carbon and carbon manganese steels, low-alloy steels and stainless steels of both the corrosion- and heat-resisting types. By selection of suitable electrodes described in various standards[11, 15–18] the mechanical properties of the weld metal in respect of strength, ductility and toughness match those of the parent plate at ambient temperature and also at elevated or subzero temperatures as required. References to American Welding Society (AWS) specifications are included because of their worldwide use in the oil and petrochemical industries.

Non-ferrous metals such as nickel, copper and aluminium and their alloys are welded much more extensively with the gas shielded processes, although nickel and nickel alloys are readily welded by the manual metal arc process and a wide range of electrodes are available.[19–21] Some tin–bronze (copper–tin), and aluminium–bronze (copper–aluminium) electrodes are manufactured, but their main use is for repair work, particularly of castings (e.g. marine propellers). These can also be used for welding pure copper, because the high conductivity of copper has prevented the successful production of a copper electrode. Pure copper is generally used for its high thermal or electrical conductivity, and therefore the application of copper alloy electrodes is strictly limited to those circumstances where weld metal, having low thermal or electrical conductivity, is satisfactory. Some non-ferrous electrodes based on nickel, nickel–iron or nickel–copper alloys are used for welding the cast irons.[22]

A wide range of electrodes is available for hard-surfacing components to increase their wear resistance under conditions of abrasion, impact, heat or corrosion or various combinations of these factors. Electrodes for hard surfacing are manufactured from core wires of mild steel, carbon and alloy steels, stainless and heat-resisting steels, nickel–chromium and cobalt–tungsten–chromium alloys, and are also made from steel tubes containing granules of refractory metal carbides such as tungsten and chromium carbides.[23]

16.3.1.4 Gravity welding

This is a semi-mechanized welding process which is used principally in shipyards for fillet welding stiffeners to horizontal plates. Covered electrodes of the contact type, typically 600 mm long, are supported by an electrode holder which slides down one arm of a tripod. The other end of the electrode is positioned in the corner of a T-joint to be welded and when the current is switched on an arc is initiated and the electrode moves along the joint line as the electrode holder slides down the arm of the tripod under the force of gravity. One person can operate three gravity welding units simultaneously, thus trebling the rate of manual welding.

16.3.1.5 Open-arc automatic welding

Although no longer used, it is appropriate to mention a mechanized welding process which was employed extensively in the 1950s up to the 1970s in ship building and bridge building. The engineer may find the process referred to in periodic inspection reports of these types of welded structures.

Mechanized welding with covered electrodes was carried out with a continuous coiled electrode having a core wire from 4 to 8 mm diameter. The core wire was wrapped helically with two thin wires about 1 mm diameter, which anchored the extruded flux in place and also acted as a means of conducting electrical current from the jaws of the welding head to the core wire.

Automatic open-arc welding with continuous covered electrodes has now been superseded by the submerged-arc process.

16.3.1.6 Submerged-arc welding

This is the most widely used mechanized welding process (Figure 16.77). A bare wire (1.6–6.3 mm diameter but usually 3.25 or 4 mm) is fed from a coil and an arc is maintained between the end of the wire and the parent metal. As the electrode wire is melted, it is fed into the arc by a servo-controlled motor which matches the wire feed rate to the burn-off rate so that a constant arc length is maintained.

The region of the joint is covered with a layer of granular flux approximately 25 mm thick, fed from a hopper mounted above the welding head. The arc operates beneath this layer of flux (hence the name 'submerged arc'). Some of the flux melts to provide a protective blanket over the weld pool and the unmelted flux is collected and re-used. The electrode wire, welding head, wire drive assembly and flux hopper are mounted on a traverse system which moves along the work piece as the weld metal is deposited.

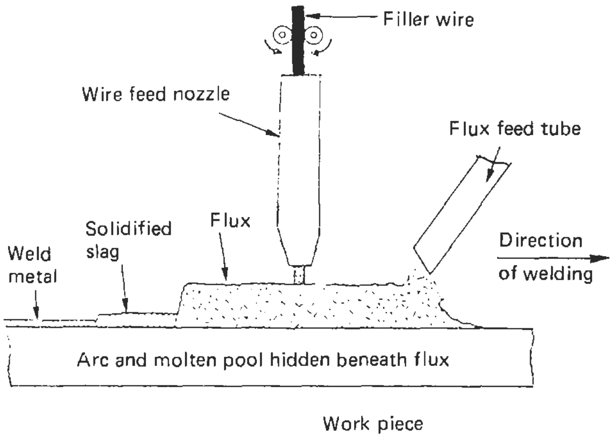

Figure 16.77 Submerged-arc welding

The traverse system may consist of a carriage mounted on a boom or it may be a motorized tractor either on rails or running freely with manual adjustment to follow the weld seam. Alternatively, the welding head can remain stationary while the work piece is moved. This method is used for welding the circumferential seams of a pressure vessel while it is rotated under the welding head.

Electrode wires The electrode for submerged-arc welding is a bare wire in coil form usually copper coated. Two types are available – solid wire or tubular wire. The solid wire is widely used for general fabrication of mild and low-alloy steels, stainless steels and non-ferrous metals. For welding mild and low-alloy steels it is either a low-carbon ultra-low-silicon steel or a silicon-killed steel with manganese addition and sometimes low-alloy additions, the selection of either type depending upon the type of flux to be used with it (i.e. a flux with manganese or manganese and alloy additions or a neutral flux, respectively). The tubular wire (made by forming narrow strip into a tube) carries alloy powders which permit the economical production of a wider range of weld compositions than is possible by using the solid wire type. Tubular wires are widely used for hard-facing. Wire compositions for welding carbon steel and medium tensile steel are listed in BS 4165.[25]

With coated manual electrodes, wire and coating are one unit so that such electrodes can be classified according to the type of coating and its effect on weld mechanical properties. In submerged-arc welding, any wire may be used with a number of different fluxes with substantially different results in respect of weld quality and mechanical properties. Consequently, BS 4165 grades wire flux combinations according to the tensile and impact strengths obtained in the weld metal.

A number of tubular wires are available, particularly for surfacing and hard-facing. These contain alloy powders which produce weld metals consisting of low-alloy steels, martensitic and austenitic stainless steels, chromium and tungsten carbides, and various cobalt- and nickel-based heat- and corrosion-resistant alloys. Some corrosion-resistant alloys, including stainless steel, are available in the form of coiled strips from 100 mm to 150 mm wide, 0.5 mm thick for high deposition rate surfacing by a submerged-arc welding process known as strip cladding.

Fluxes Two main types of fluxes are available: fused and agglomerated. Fused fluxes are manufactured by fusing together a mixture of finely ground minerals, followed by solidifying, crushing and sieving the particles to the required grain size. Fused fluxes do not deteriorate during transportation and storage and do not absorb moisture. Agglomerated fluxes are manufactured by mixing finely ground raw materials with bonding agents such as sodium or potassium silicates followed by baking to remove moisture. This type of flux is sensitive to moisture absorption and may require drying before use. Agglomerated fluxes are more prone to mechanical damage which can cause segregation of some of the constituents.

Fluxes are classified as acid, neutral, or basic, the last being subdivided into semi-basic or highly basic. The main characteristics of the fluxes are as follows:

1. *Acid fluxes*: High content of oxides such as silica or alumina. Suitable for high welding currents and fast travel speeds. Resistant to porosity when welding rusty plate. Low notch toughness. Not suitable for multipass welding of thick material.

2. *Neutral fluxes*: High content of calcium silicate or alumina-rutile. Suitable for fairly high welding currents and travel speeds and also for multipass welding.
3. *Basic fluxes*: High content of chemically basic compounds such as calcium oxide, magnesium oxide and calcium fluoride. Highest weld metal quality in respect of radiographic soundness and impact strength. Lower welding currents and travel speeds are suitable for multipass welding of thick sections. For further information on fluxes references 25 and 26 should be consulted.

Power sources Either d.c. or a.c. may be used. D.C. may be supplied either by a motor generator or by a rectifier, either of which can have flat or sloping current voltage characteristics. These are referred to as constant voltage or constant current types. Generators will deliver up to about 650 A continuous output, rectifiers up to about 1200 A at 100% duty cycle. A.C. is supplied by welding transformers which are designed to give a drooping characteristic. Transformer output may range up to 2000 A.

Power sources are of rugged construction and are designed for the 100% duty cycle. With the constant current type the arc voltage determines the wire feed rate which varies to maintain a constant arc length. The constant voltage type of power source produces a self-adjusting arc in which an increase in arc length or arc voltage causes a decrease in current and burn-off rate so that the original arc length is rapidly obtained. A decrease in arc length increases the current and burn-off rate and this self-adjusting effect occurs with a constant wire feed rate.

Application As the process operates with a continuous coil of electrode wire, butt welds in the flat position requiring multiple runs to fill the joint can be made with minimal stops and starts. Thus circumferential joints in cylindrical bodies such as pressure vessels, pipes, etc. can be made with one stop and start per revolution of the work piece, this stop being necessary to reset the position of the welding head. Consequently, the possibility of stop and start defects is minimized; a most important consideration when reliability in costing is required. Although most widely applied to welding of joints in mild steel, low-alloy high-tensile steel, creep-resisting steels and, to a lesser extent, stainless steels, it is also widely used for building-up work, either for reclamation or replacement of defective parent metal or for hard-surfacing.

Submerged-arc welding is suitable for welding material from 5 mm to 300 mm and even thicker but plates less than about 10 mm thick are generally welded by the gas shielded or flux cored arc welding process. A semi-automatic variant of the process is available in which the welder manually manipulates a welding gun on which is mounted a small hopper containing the flux. Electrode wire is fed to the gun from a coil by a wire feed unit. This process, which is used only to a limited extent, is sometimes referred to as 'squirt' welding.

Other variations of the submerged-arc welding process are mainly concerned with increasing deposition rates and therefore welding speed and productivity. These include:

1. Increasing the electrode extension or stick-out by up to 150 mm by using an insulated guide tube. The resistance of the wire increases the burn-off rate by the I^2R heating effect.[27]
2. Addition of iron powder to the joint which increases the weld volume.
3. The use of multiple wire techniques in which two or more wires are used with two or three separate power sources.[27]
4. Narrow gap welding of plates more than 100 mm thick in which a parallel gap of 14–20 mm between the square edges of the plates is used instead of a V or U groove. The saving in quantity of weld metal used is considerable, with consequent increase in productivity.[28]

16.3.1.7 Electro-slag welding

Electro-slag welding is an automatic process for welding material 18 mm or thicker in the vertical position. Square edge plate preparation is used and joints are limited to butts and T-butts. Heat for fusion is obtained by the current in the consumable electrode wire which passes through the molten slag formed by melting of a flux formulated to have high electrical resistance in the molten state.

The joint is set up with a wide gap (approximately 25–36 mm, depending on plate thickness), the very large weld pool being contained in the joint by water-cooled copper shoes. One, two or three wires are fed into the joint with or without a reciprocating motion to ensure uniform heat generation, the plate thickness determining the number of wires. One welding head with three wires can weld plate 450 mm thick. The copper shoes rise up the joint to prevent spilling of metal and slag and these shoes form part of the welding head.

A variation of the electro-slag process is known as consumable guide welding. Here the welding head remains stationary and feeds one or more wires down a tube which melts into the pool. The equipment is substantially cheaper than the conventional slag welding machines.

The consumable guide process, while theoretically suitable for very thick sections, is more usually applied to metal up to, say, 50 mm because it is more manageable in these thicknesses. The equipment needed is much simpler than for the conventional process consisting of a constant potential generator, rectifier or transformer with a flat characteristic and a wire feed unit. These are also the essential ingredients of submerged-arc equipment and, by slight modification, they can be adapted for consumable guide welding.

The ultra-slow cooling rate of an electro-slag or consumable guide weld minimizes hydrogen cracking susceptibility in the parent steel and weld metal but produces a large grain size weld. This tends to give a comparatively poor notch impact strength as determined by conventional tests. Consequently, for pressure vessel application, current codes require normalizing after welding.

Fluxes Electro-slag welding fluxes produce complex silicate slags containing SiO_2, MnO, CaO, MgO and Al_2O_3. Calcium fluoride is added to increase electrical conductivity and lower slag viscosity. Slags based on CaF_2–CaO have a strong desulphurizing action which assists the welding of steels higher in carbon than 0.25% without solidification cracking in the weld metal. Fluxes must be kept dry.

Economics of the process On heavy steel plate, for pressure vessels, boiler drums, etc. the actual welding speed (rate of filling the joint) is about twice as fast in 40 mm plate, four times in 90 mm and eight times in 150 mm compared with multi-run submerged arc welding. Welding speed is 1–1.7 m per hour. Plate-edge preparation by bevelling is also avoided. On this evidence it would seem highly attractive economically. However, 'setting up' the machine and selecting the correct welding parameters is a a matter of experience or tests. Therefore the 'setting-up' time must also be considered and the cost of determining the correct procedure included in the cost estimate.

Thus the process gives full economic benefit on repetitive work where set parameters can be used based on experience. An example is the wide use of the process for the longitudinal seams of boiler drums in steel 125–150 mm thick. On one-off applications involving plate thicker than 150 mm the process is economical on each joint and, providing sufficient work of a suitable type is available, the high capital cost is recovered within a reasonable time.

Mechanical properties The weld metal mechanical properties are determined to a considerable degree by the composition and cleanliness of the parent steel. However, proper selection of wire and flux and suitable parent metal confer strength and ductility equal to or better than the parent metal.

In the as-welded condition degradation of notched impact properties in the heat-affected zone results in values lower than the weld metal. Where notched impact requirements must be met, it is necessary to normalize the completed joints. In general, electro-slag welding is an acceptable and economic method of welding thick steel. It finds application for ships' hulls, boiler drums, press frames, nuclear reactors, turbine shafts, rolling mill housings and similar heavy fabrications.

16.3.1.8 Gas-shielded metal arc welding

This general term covers a group of welding processes in which no added flux is used. The molten weld pool is protected by a gas shield which is delivered to the welding gun through a flexible tube at a controlled rate, either from a gas bottle or from a bulk supply. The shielding gas may be inert (e.g. argon or helium or mixtures of these gases) or it may be active (e.g. carbon dioxide (CO_2) or mixtures of CO_2 with other gases such as argon). Sometimes small additions of oxygen or hydrogen are included in the shielding gas.

The wide variety of shielding gases which may be completely inert or non-reactive or may be active (i.e. slightly oxidizing or reducing) has led to the use of the terms MIG (metal inert gas) and MAG (metal active gas) to describe the principal gas-shielded metal arc welding processes.

MIG and MAG welding In MIG or MAG welding, referred to in the USA as gas metal arc welding (GMAW) (Figure 16.78) a small-diameter (0.6–1.6 mm) wire is fed from a coil by a wire feed unit which contains an electric motor, gearbox and grooved drive rolls. The wire is fed to a welding gun that has a trigger which operates the wire feed drive, the current and the flow of shielding gas.

An arc is struck when the wire contacts the work and the arc length depends on the voltage, which is preset by adjustment of a knob on the power source. Welding current is picked up by the wire from a copper contact tube through which the wire passes. The distance between the contact tube where current enters the wire and the end of the wire is usually a maximum of 25 mm, compared with 300–450 mm for a covered electrode. Therefore overheading is not a problem, particularly as there is no flux coating. Higher currents can be used than those normally employed for manual metal arc welding (e.g. 120–450 A for 1.6 mm diameter wire). Therefore deposition rates are generally higher than for manual metal arc welding. Another advantage of MIG/MAG welding is that the arc is automatically maintained at a length that depends on the arc voltage, which means that the welder has to move the welding gun only along the joint line holding the nozzle of the gun at approximately the same distance from the joint. This is because the arc is self-adjusting because the voltage current characteristic of a MIG/MAG power source is flat or only slightly drooping.

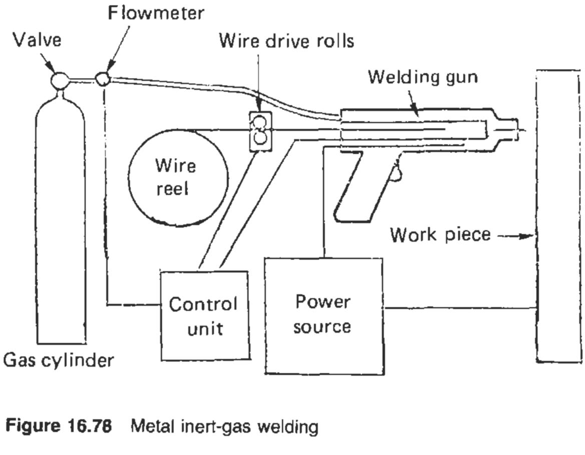

Figure 16.78 Metal inert-gas welding

If the welding gun is moved away from the joint the arc length and the arc voltage increase slightly. With a flat or slightly drooping characteristic a small increase in voltage will cause a large decrease in welding current and the wire will burn off at a lower rate. The original arc length will be rapidly attained at which voltage the burn-off rate will once again match the wire feed speed. Similar self-adjustment in the opposite sense will occur when the welding gun is moved towards the work piece.

Filler wires The commonest filler wires are 1.0, 1.2, and 1.6 mm in diameter with 0.6 and 0.8 mm less frequently used. Because of the wide range of current that can be used with each wire it is necessary to stock only one or two diameters. This is in contrast with manual metal arc welding, where a number of different diameters of electrodes and possibly two or more coating types may be required just for welding a single type of material such as carbon–manganese steel.

However, a disadvantage of solid filler wires is the limited range of compositions available because it would be too expensive for a steel maker to produce small quantities of low-alloy or stainless steel wires. Small batches of covered electrodes can readily be produced by introducing alloys in powder form through the coating. This situation is reflected by the number of electrodes and filler wires for welding low-alloy and stainless steels listed in British Standards, which are:

	Low alloy steels	*Stainless steels*
Covered electrodes	30	39
Solid wires	6	16

Any deoxidizing elements such as silicon or aluminium required to refine or degas the weld pool are contained in the solid wire and compositions of wires available are listed in BS 2901: Parts 1–5[29] for ferritic steels, austenitic stainless steels, copper and copper alloys, aluminium and aluminium alloys and magnesium alloys, and nickel and nickel alloys.

Modes of metal transfer In MIG or MAG welding the operating conditions in terms of current and voltage determine the type of metal transfer which must be suitable for the application. There are four modes of metal transfer.

Short circuiting (dip transfer) This occurs when a low voltage and current are used which causes metal to be transferred from the end of the wire to the work piece by frequent short circuiting of the wire to the weld pool. This technique produces low heat input and a small controllable weld pool essential for welding steel sheet in all positions and thicker steel sections in the vertical and overhead positions. A disadvantage of the process is the production of spatter in the form of globules of metal expelled from the weld pool when each short circuit is broken. Spatter particles which adhere to the work piece can be reduced by fine tuning of the inductance of the power source.

Globular transfer (semi-shorting) This occurs when somewhat higher currents and voltages are used than for dip transfer welding of steel, but metal transfer still occurs by short circuiting of the filler wire to the weld pool. Because of the large droplet size and the larger weld pool, this mode of welding is not suitable for vertical or overhead welding. The production of spatter still occurs.

Spray transfer Free flight of metal droplets occurs with no short circuiting when the current and voltage are sufficiently high. This give maximum deposition rates and deep penetration welding suitable for flat-position welds in medium and heavy steel plate and for horizontal–vertical fillet welding (e.g. between a vertical and a horizontal plate). Spray transfer is used for welding aluminium and aluminium alloys in all positions because the spray transfer of droplets occurs at much lower welding currents than with other metals. Therefore small weld beads can be deposited which solidify rapidly and enable welding to be carried out in the vertical and overhead positions.

Pulsed transfer This was developed to produce spray transfer at all current levels so that welding of all metal thicknesses in all welding positions could be carried out without the formation of spatter. In pulsed transfer the welding current is switched from a high pulse current to a low background current at a typical frequency of 50 Hz. The background current is sufficient to sustain the arc but it is insufficient for metal transfer. The pulse current is set above the critical level to produce sufficient electromagnetic force with each pulse to transfer one metal droplet from the tip of tthe wire. With the first pulsed arc power supplies the pulse frequency had to be a multiple of mains frequency and setting up welding conditions was difficult to the extent that it hindered the use of the process in industry. The average current, which depended on the background current, the pulse current and the frequency, had to produce a usable burn-off rate at a constant arc length. The process was also sensitive to electrode stick-out (the electrode extension beyond the contact tube) which could disrupt the balance between pulse energy and metal transfer, causing arc extinction and spatter. The full advantages of the pulsed MIG process, including stable low mean current operation particularly when welding aluminium alloys or stainless steel and positional welding capabilities of all metal thicknesses, were made readily available with the development of transistorized power sources referred to in the next subsection.

Power sources MIG and MAG welding are always carried out with d.c. and the principal types of power sources are transformer rectifiers with constant potential or controlled-slope characteristics and motor generators which are used for site work (e.g. welding pipeline). Invertor type power sources, described in the section on manual metal arc welding, are also used for MIG and MAG welding. The main advantage of invertors is the considerable decrease in size and weight compared with conventional transformer rectifiers.

Electronic power control has had a considerable and beneficial influence on MIG/MAG welding, enabling the process parameters to be pre-programmed which eliminates the complicated setting-up operation and enables 'one-knob' control to be achieved. Programmed control for both dip and spray transfer was originally developed in the late 1960s. The relationship between wire feed speed and voltage for any filler wire type and diameter could be programmed into the power source and a single control could be used to vary mean current continuously. The equipment contained preset resistors to store the fixed parameters but microprocessor-controlled units are now available.

A number of different electronic control systems have been developed for MIG/MAG welding in both the dip and spray transfer modes of operation, which overcome the setting-up difficulties mentioned above. These setting-up difficulties were particularly acute with the pulsed arc mode of operation, but they have been overcome by the so-called synergic control technique used in conjunction with a transistorized power source. With synergic control, precise independent regulation of the pulse shape, pulse current time, pulse frequency and background current is obtained. The electronic power source can produce continuously variable 25–250 Hz pulse frequencies. With variable-frequency pulsing the correlation between pulse energy, burn-off rate and arc characteristics can coincide with all electrode wire feed speeds to provide one metal drop transfer per pulse.[30]

With synergic control all the pulse parameters are preprogrammed for a wide range of wire feed speeds. During welding the wire feed rate and pulse frequency automatically adjust together to produce one metal droplet transfer at a constant arc length. The welder only needs to adjust one control – average current.

Modern power supplies have control systems based on microprocessor technology. Memory chips in the control unit store process data and produce the optimum operating parameters if the user presses the appropriate switches to specify the types of filler wire and shielding gas. In some power sources users can load their own operating programs into the control unit. For further information references 31 and 32 should be consulted.

As in manual metal arc welding, there are a number of 'hobby' sets on the market which can be used on the 13 A mains. These have a limited number of current settings for use with 0.6 or 0.8 mm diameter wire and can be used to weld carbon steel, stainless steel and aluminium in thicknesses up to 6 mm. Tuition by video is available.[33]

Applications MIG and MAG welding with the various modes of metal transfer can be used for applications similar to those fabricated by MMA welding. In addition, they are more suitable for welding some of the non-ferrous alloys such as aluminium and copper alloys and are probably equally suitable for welding stainless steel and nickel alloys. For sheet metal thicknesses which are welded by a single run of weld metal, MIG and MAG welding are generally up to 50% faster than MMA welding. In thicker materials, MIG/MAG welding and MMA welding used with the same duty cycle, i.e. the proportion of arcing time to total time, will have approximately the same overall welding rate, provided that full use is made of positioners to enable a large proportion of the welding to be carried out in the flat or horizontal–vertical positions. Claims made in the literature or in suppliers' brochures about the superiority of one process over the other in respect of productivity and economic advantages should be treated with caution, because they may only be valid for a specific application. One great advantage of MIG/MAG welding over MMA welding is the ease with which the process can be mechanized either by fitting the welding gun to a traverse unit or by moving the work piece under a stationary gun either by linear motion or rotation.

Robotic and automated MIG/MAG welding has advanced with the developments in microcomputers and electronic power sources, the latter providing very stable arcing conditions in spite of mains voltage fluctuations. Automated MIG/MAG welding utilizes seam-tracking devices which are necessary to compensate for inaccuracies of the component parts or distortion during welding.

Seam-tracking devices contain contact-type sensors such as probes or guide wheels or the non-contact types such as electromagnetic, ultrasonic or video systems. For further information on robotic or automated welding references 34–36 should be consulted.

16.3.1.9 Flux-cored arc welding

Flux-cored arc welding is similar in many respects to MIG/MAG welding except that in one version of the process no shielding gas is added. In this case the gas shield originates from the decomposition of minerals contained in the tubular core electrode and this version of the process is sometimes referred to as self-shielded welding.

Cored electrodes in coiled form are manufactured from steel strip which is first bent into a U-section as it passes through forming rolls. The U-shaped strip is then filled with a metered quantity of flux and metal powders and the strip is passed through dies to form it into a circular cross-section from 0.9 to 3.2 mm diameter.

Tubular cored electrodes Tubular cored electrodes may be gas shielded with CO_2 or Ar/CO_2 mixtures or they may be self-shielded. Cored electrodes are classified according to the constituents contained in the core which influences the characteristics of the electrode.

For full descriptions of the different carbon and carbon–manganese steel types, BS 7084: 1989,[37] AWS A5.20–79[38] and AWS A5.29–86[39] should be consulted. Many higher-tensile and low-alloy steels can be welded with flux-cored wires having matching strengths. Stainless steel cored wires are available for use either with or without shielding gas and many different types of cored wires are used for hard-facing applications in which a coating is applied to a steel base to confer resistance to wear, corrosion or heat.

Application Flux-cored arc welding is used for applications similar to manual metal arc or MIG/MAG welding and, like MIG/MAG welding, the process can be mechanized. Tubular cored electrodes are available in a wider range of compositions than solid wires because of the ease of introducing alloying elements in powder form. Flux-cored wires, particularly the gas-shielded types, meet the mechanical property requirements of a range of applications and some grades give good low-temperature impact properties. The mechanical properties attainable with self-shielded cored wires is more limited, with maximum weld metal strengths of 700 N mm^{-2}.

Self-shielded wires are particularly useful for site work because unwieldy bottles of shielding gases are not required. Another advantage on-site is that there is no externally added shielding gas which is susceptible to disruption by wind. Flux-cored wires can be used at higher maximum currents than solid wires, resulting in high deposition rates.

16.3.1.10 Gas-shielding tungsten arc (TIG) welding

In this process an arc is established between a tungsten electrode and the parent metal, forming a weld pool into which filler rod is fed, generally by hand (Figure 16.79). Mechanized systems which feed the filler wire are available and movement of the welding head along the joint line can also be mechanized. The tungsten electrode is non-consumable and contamination of the weld pool by air is prevented by an inert shielding gas such as argon, helium or mixtures of these gases. A high level of skill is required by the welder, who can control penetration with great precision. This makes the process particularly suitable for the welding of thin sections and for the deposition of root runs in pipe.

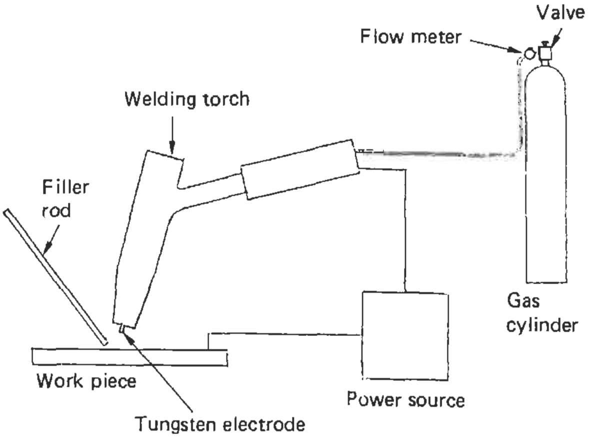

Figure 16.79 Tungsten inert-gas welding

Electrodes and filler rods Pure tungsten electrodes can be used but improved arc initiation and stability are obtained by the use of electrodes containing additions of either thoria (thorium oxide) or zirconia (zirconium oxide). Thoriated electrodes are preferred for d.c. welding and zirconiated electrodes are used for a.c. Electrode diameters vary from 1.2 to 4.8 mm depending on the welding currents used, which can range from 75 to 450 A for thoriated electrodes and from 50 to 200 A for the zirconiated types.

Filler rods which are specified in BS 2981: Parts 1–5[29] have diameters of 1.2–5.0 mm and are available in a wide range of compositions suitable for welding carbon and low-alloy steels, stainless steels, copper and copper alloys, nickel and nickel alloys, aluminium and aluminium alloys, titanium and zirconium.

Power sources An a.c. or d.c. power source with standard generators, rectifiers or transformers is used. For stable operation the power source must have a 'drooping characteristic', so that when variations occur in voltage or arc length the current remains substantially constant. When changes occur in the arc length when the welding torch is manually guided along the joint line the power input remains within ±8% of the preset value.

If the arc is initiated by touching the tungsten electrode onto the parent metal the electrode becomes contaminated and to avoid this, a high-frequency oscillator is incorporated into the power source. Alternatively, a spark starter using a high-voltage coil similar to that in a car-ignition circuit can be used. When the gas in the gap between the electrode and the parent plate is ionized by either the high frequency or the spark discharge the full welding current flows. With d.c. the high frequency is normally turned off automatically after arc initiation but with a.c. it is operated continuously to maintain ionization of the arc path when the arc voltage passes through zero.

Power sources are available for pulsed arc welding which enables a stable arc to be maintained at low currents down to 10 A. In pulsed TIG welding the pulse frequency varies from 10 per second to 1 per second, and each pulse forms a molten pool which solidifies before the next pulse. Pulsed TIG welding can be used to control penetration in thin sheet and in the root runs of pipes and positional welds in plate.

Applications TIG welding is particularly suited to welding light-gauge carbon, alloy and stainless steels and all non-ferrous metals and alloys. A clear, clean weld pool is formed with precise control of heat input and the ability to weld with or without filler metal in all positions makes the process attractive for critical applications where exceptionally high quality is essential. Examples are stainless steel piping for nuclear applications and the wide range of piping compositions used in chemical plant. For such critical applications, fully mechanized orbital welding equipment has been developed in which the welding torch and wire-feeding mechanism rotates round the pipe joint. Thin- and thick-section pipes can be welded with a narrow gap joint preparation and *in-situ* fabrication of nuclear and chemical plant is now possible. Other specialized TIG welding equipment is used for the mechanized welding of tubes to tube plates.

16.3.1.11 Plasma arc welding and cutting

Plasma arc welding was developed from TIG welding by placing a narrow orifice round the arc and supplying a small flow of argon through the orifice (Figure 16.80). The constricted arc dissociates the argon gas into positive and negatively charged electrons to form a plasma. When the plasma gas flows away from the arc column it forms neutral atoms again and gives up its energy in the form of heat.

A low-current pilot arc is initiated between the tungsten electrode and the water-cooled copper orifice. The argon gas flowing through the orifice is ionized and initiates the primary arc between the tungsten electrode and the parent metal when the current is increased. The arc and the weld zone are shielded by a gas flowing through an outer nozzle. The shielding gas consists of argon, helium or gas mixtures of argon with either hydrogen or helium.

A normal tungsten arc has a temperature of approximately 11 000°C but the constricted arc of a plasma torch can reach 20 000°C. The high-temperature ionized gas jet gives up its energy when it contacts the parent metal and thus increases the energy of the tungsten arc. This produces a deep penetration weld with a high depth-to-width ratio with minimum distortion of the parent metal. The term 'keyhole' is used to describe the shape of the hole formed in the parent metal when a close square edge butt joint is welded. As the torch is moved along the joint, molten metal flows round the edges of the hole and solidifies at the rear of the hole. The molten metal at the sides of the hole is held in place by surface tension and the pressure of metal vapour in the hole.

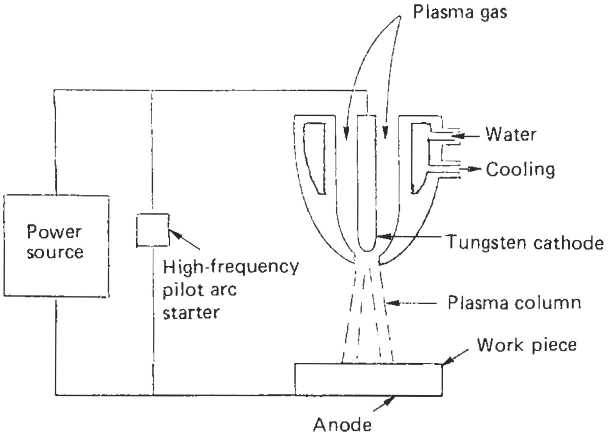

Figure 16.80 Plasma arc welding

The keyholing welding technique can be used on carbon, low-alloy steels and stainless steels in thicknesses of 2.5–10 mm and in aluminium alloys up to 20 mm. Welding speeds are generally 50–150% higher than those possible with TIG welding.

A low-current version of the process is micro-plasma arc welding, which is used for precision welding of thin sheet from 0.025 to 1.5 mm thick at currents of 0.1–10 A. The plasma arc is much more stable than a TIG arc, which tends to wander from the joint line at low currents.

Plasma cutting If the current and gas flows are increased sufficiently the molten metal formed round the keyhole is ejected at the bottom of the hole and as the plasma torch is traversed along the work piece a cut is formed. Plasma cutting is especially suitable for cutting non-ferrous metals, such as aluminium, copper and nickel, and their alloys which are not easily cut by oxy-fuel gas flames. Most non-ferrous metals are cut using nitrogen, nitrogen–hydrogen mixtures or argon–hydrogen mixtures as the plasma gas. A secondary shielding gas delivered through a nozzle that encircles the plasma gas nozzle is selected according to the material being cut. For mild steel and stainless steel it can be CO_2 and for aluminium it is an argon–hydrogen mixture. Sometimes water is used instead of the ancillary shielding gas and in another variety of the process water is injected round the end of the plasma gas nozzle, which has the effect of concentrating the plasma flame and allowing higher cutting speeds.

Plasma cutting can be used for plate edge preparation (i.e. bevelling) and for shape cutting. The process can be used manually or the torch can be mounted on mechanized cutting equipment identical to that used for oxy-fuel gas cutting. For metal thicknesses up to 75 mm carbon steels can be cut faster by plasma cutting than by oxy-fuel gas, and up to 25 mm thick the cutting speeds can be five times as fast.

An important variation of the process is the use of compressed air for the plasma gas without the provision of any additional shielding gas. The use of compressed air instead of water for cooling enables the torch to be of simplified construction.

Small manual air plasma torches are available which find increasing applications in sheet metal cutting (e.g. motor repair shops). For further information reference 40 should be consulted.

16.3.1.12 Gas welding and cutting

Gas welding is carried out by a flame produced by burning approximately equal volumes of oxygen and acetylene which are delivered at equal pressures from gas bottles to a welding torch. The flame temperature is approximately 3100°C, which is high enough to melt steel and other metals. Filler metal, if required, is added by manually feeding a rod into the front edge of the weld pool while the torch is moved along the joint. The products of combustion provide sufficient protection from the atmosphere when welding steel. When welding other metals such as cast iron, stainless steel, aluminium alloys and copper alloys, fluxes are used to clean and protect the metal from oxidation.

Equipment The welding torch has two knurled control knobs which regulate the flow rates of oxygen and acetylene so that a neutral or slightly oxidizing or reducing flame is obtained, depending on the application. The torch has a screw-in nozzle from a set of nozzles having different diameter holes which produce the appropriate size of flame and therefore the required heat input for the particular metal and thickness to be welded. The oxygen and fuel gas hoses are connected between the welding torch and the gas bottles, the gases passing through flashback arresters and pressure regulators. Flashback arresters are safety devices that prevent a flame from travelling back into the cylinders in the case of a backfire. For workshop use the gas bottles are generally mounted in pairs on a trolley which can be moved to where it is required.

Filler metal and fluxes Chemical compositions of filler metals are specified in BS 1453: 1972 and include ferritic steels, cast iron, austenitic stainless steels, copper and copper alloys and aluminium alloys. Ferritic steels do not require the use of a flux but proprietary fluxes are available for other materials.

Applications Gas welding is used mainly for repair and maintenance work, particularly in the repair of car bodies and agricultural implements, although it is slowly being replaced by small TIG and MIG welding equipment. Gas welding is used, to a certain extent, for sheet metal work (i.e. heating and ventilating ducting) and is still employed for making the root runs in pipes, where it is particularly useful for bridging gaps.

Two applications where gas welding has distinct advantages over other processes are in the welding and repair of grey iron casting and in hard-facing with expensive alloys. Grey iron castings can be successfully welded by the use of high preheating temperatures of up to 600°C and gas welding with cast iron filler rods. The deposition of high-cost wear-resistant alloys such as the cobalt–chromium tungsten types or those based on chromium or tungsten carbides can be carried out with minimum melting of the parent metal, so that dilution of the deposited alloy and the consequent decrease in wear resistance is avoided. Gas welding is also successfully applied in jewellery manufacturing with miniature torches and small gas bottles.

Acetylene is the only fuel gas suitable for gas welding because of its favourable flame characteristics of both high temperature and high propagation rates. Other fuel gases, such as propane, propylene or natural gas, produce insufficient heat input for welding but are used for cutting, torch brazing and soldering. They are also used for flame straightening of distorted components and for preheating before welding and post-heating after welding.

Gas cutting Gas cutting, sometimes referred to as flame cutting or oxygen cutting, involves an active exothermic oxidation of the steel being cut when the material has been preheated by an oxy-fuel gas flame to the ignition temperature of around 900°C. The equipment for gas cutting is the same as for welding except that a special cutting nozzle is required. The nozzle has an outer ring of holes through which the preheating gas mixture is delivered and a central hole through which the oxygen jet flows. The exothermic reaction of oxidation of steel forms a fluid slag of iron oxide and after a few seconds, depending on the metal thickness, the section is pierced. Iron oxide and molten metal are expelled from the cut by the oxygen stream. Movement of the cutting torch across the work piece produces a continuous cutting action and the torch can be operated manually or by a motorized carriage. Steel up to 300 mm thick can be cut by this process.

Oxidation-resistant steels such as stainless steel may be cut by specialized methods, including the introduction of iron powder or other proprietary powders into the oxygen stream. These powders react with the refractory chromium oxides and reduce their melting points and increase their fluidity, enabling cutting to take place. For further information reference 40 should be consulted.

Stainless steels and non-ferrous metals and alloys are usually cut by the plasma cutting process, which does not rely on an exothermic reaction.

Manual gas cutting is possible and the accuracy of cutting can be improved by the use of a small wheel mounted on the cutting torch. The wheel may be free-running or motorized. For general cutting and profiling (including cutting bevels on plate edges) mechanized cutting is normally used. For mechanized cutting electronic tracing devices are common and consist of a photoelectric cell that follows the outline of a drawing and guides the cutting nozzle by means of driving motors which regulate the movement of a carriage and cross-arm to which the torch is attached.

Numerically controlled cutting machines are available which use programs stored or punched on magnetic tape which send appropriate signals to the drive motors.

16.3.1.13 Welding and cutting with power beams

Electron beam welding and laser welding utilize high-energy beams which are focused onto a spot of about 0.2 mm diameter on the work piece surface. This intense heat source, which releases its kinetic energy when the beam hits the surface, is radically different from arc welding, in which the arc melts an area of about 5–20 mm in diameter, depending on the welding conditions.

When the power density of an electron or a laser beam at the focused spot is 10 kW mm^{-2} or greater, energy is delivered at a faster rate than can be conducted away in the form of heat in the work piece and the progressive vaporization of metal through the section thickness forms a hole. If the beam is then traversed along the work piece, molten metal flows around the sides of the hole and solidifies at the rear of the hole. Molten metal at the sides of the hole is held in place by surface tension and the presence of metal vapour in the hole in the same manner as that described as the keyholding technique in Section 16.3.1.11.

As with plasma welding, a deep penetration weld with a high depth-to-width ratio is formed with minimum distortion of the parent metal. Maximum penetration depths in steel are approximately 280 mm for electron beam welding and 12 mm for laser welding, although developments in the latter process are likely to increase this to 25 mm or more.

Electron beam welding In this process a finely focused beam of electrons passes from a cathode and travels through a hole in an anode and is focused onto a spot on the work piece 0.2–1 mm diameter by means of a magnetic lens. Deflection coils are used to cause the beam to move in a circular pattern to increase the width of the weld, so that fusing two mating surfaces together in a close square butt joint is possible. The cathode in the electron gun is maintained at a negative potential of 60–150 kV and the gun is contained in a vacuum of 5×10^{-5} torr. In the work chamber a pressure of 5×18^{-3} torr is suitable for welding most metals and for some applications a pressure of 10^{-1} torr or less is used with the advantage of much shorter chamber excavation times, resulting in increased production rates.

High-vacuum welding High-vacuum welding, in which the work chamber is maintained at a pressure of 10^{-3} to 10^{-5} torr depending on the application, has the following features:

1. Maximum weld penetration and minimum weld width and shrinkage, enabling all thicknesses to be welded in a single pass.
2. The highest purity weld metal is produced because of the absence of any contaminating gases such as oxygen or nitrogen.

3. A high vacuum allows a long distance to be maintained between the gun and the work piece, which facilitates observation of the welding process.
4. The pump downtime is lengthy, up to an hour or more depending on the size of the chamber, which would lower the production rate of small jobs with shallow welds but would be insignificant when welds in plate 50 mm or thicker are made with a single pass.

Welding speeds for steel are shown in Table 16.4.

Table 16.4 Penetration depth and welding rates

Welding power (kW)	*Plate thickness* (mm)	*Welding speed* (mm/min)
0.25	1	1500
2.0	10	750
4.5	10	750
15	50	150
75	280	50

Medium-vacuum welding In medium-vacuum welding the working chamber is maintained at a pressure generally within the range of 10^{-3} to 10^{-1} torr, although pressures of up to 25 torr are reported in the literature[41] and correspondingly short pump downtimes of a few seconds.

Medium-vacuum welding with small working chambers is used extensively for small repetitive work such as welding of finish machined geartrains and similar high-volume mass-production applications for the motor industry. Many high-precision semi-finished or fully machined components for aircraft engines are also welded by the electron beam process.

Medium-vacuum electron beam welding is not suitable for welding reactive metals and alloys such as titanium and zirconium, which require the high-vacuum process to obtain sound welds.

Out-of-vacuum electron beam welding Provided that the gun-to-work distance is less than about 35 mm to allow for the greater dispersion of the electron beam compared with working in a vacuum, it is possible to weld many materials out of vacuum. With 60 kW non-vacuum equipment single-pass welds can be made in metal thicknesses up to 25 mm. Metals welded out of vacuum include carbon and low-alloy steels, and copper and aluminium alloys. Because of the presence of air, which can cause contamination of the weld metal, it is usually necessary to provide an inert shielding gas to cover the weld zone.

Laser welding and cutting Two types of lasers are used for welding and cutting: the solid-state YAG (yttrium–aluminium–garnet) and the carbon dioxide (CO_2) laser. The term 'laser' is an acronym for Light Amplification by Stimulated Emission of Radiation and a laser is a device for producing monochromatic (single-wavelength) light that is coherent (i.e. all the waves are in the same phase). A laser beam can be transmitted over many metres and can be focused to produce the high-energy density required for welding or cutting.

The solid-state YAG laser The solid-state laser is stimulated to emit coherent radiation by means of the light from one or more powerful flash tubes and the output is in the infrared region around 1.06 μm. Both input and output are generally pulsed and the power output is a maximum of 500 W.

Pulsed laser welding is extensively used in the electronics industry where miniaturization requires very precise positioning of small welds. Typical examples are encapsulation of microelectronic packages and the joining of fire wires by butt, lapped or cross-wire joints. Spot welds can be made between overlapping sheets and seam welds formed by a series of overlapping spot welds. Most metal can be welded, including steel, copper, nickel, aluminium, titanium, niobium, tantalum, and their alloys. Solid-state lasers are also used for precision drilling of holes with very small diameters.

The carbon dioxide laser In the carbon dioxide laser the lasing medium is a gaseous mixture of carbon dioxide, nitrogen and helium at a reduced pressure of 2–50 torr. The output of the carbon dioxide laser is in the mid-infrared (10.6 μm) and CO_2 lasers are available with powers of up to 20 kW. The high power density produced (10^4 W mm^{-2} or more) forms a cavity or keyhole in the work piece which enables a deep penetration weld to be produced similar in appearance to an electron beam weld.

Penetration is less than for an electron beam operating at the same power because of plasma gas formed in the keyhole. The plasma gas escapes from the keyhole and interacts with the laser beam, restricting penetration to approximately 12 mm in mild steel. Methods have been developed for overcoming this problem[41] by the use of either a pulsed output from the laser with pulses of shorter time than that required to generate the plasma or a high-velocity jet of helium to disrupt the plasma above the weld. Such developments are likely to increase the thicknesses that can be laser welded to 25 mm or more.

Carbon dioxide lasers are used in production in some automotive and aerospace applications, particularly for titanium and nickel alloys. The advantage of laser welding over elctron beam welding is that a vacuum is not required, which simplifies the welding operation. Other materials that can be welded by the carbon dioxide laser are steels, copper alloys, zirconium and refractory metals, but aluminium alloys are not readily weldable with the CO_2 laser because of their reflectivity of the laser beam.

Laser cutting Cutting with the CO_2 laser is carried out by a combination of melting and vaporization with an auxiliary jet of gas to blow the molten metal from the cut. Various gases are used for this purpose, including oxygen, compressed air, inert gases and carbon dioxide.

Oxygen produces an exothermic reaction with ferrous metals which increases the efficiency of cutting. The inert gases produce clean unoxidized surfaces – important features when cutting readily oxidized metals such as aluminium and titanium.

16.3.1.14 Resistance welding

Spot, seam and projection welding Spot, seam and projection welding are carried out by electric resistance heating two overlapping metal parts which are pressed together by copper or copper alloy electrodes. Local melting occurs at the faying surfaces and an internal weld nugget is formed. The welding cycle, comprising current, pressure and time, is readily controlled automatically, giving the following advantages:

1. Little skill is required in operation.
2. Welding can readily be built into production lines.
3. Welding can be associated with automatic loading, unloading and transferring of components so that resistance welding is the simplest process for automation or robotic welding.
4. Welding times are short so that output is high.
5. No filler wires or fluxes are used.

6. Distortion is a minimum as heating is confined to a small area.

The high currents required for resistance welding are generally obtained from a single-phase a.c. transformer having a primary winding of several hundred turns. The secondary winding consists of one or two turns of thick copper which may be water cooled. The voltage is stepped down to a value between 4 and 20 V.

Three-phase welding machines are available which are more expensive but they have a better power factor. A three-phase transformer is sometimes used with a d.c. rectifier to carry out resistance welding with d.c. For further information on power sources reference 41 should be consulted.

Spot welding Spot welding (Figure 16.81) is used for the fabrication of sheet metal from 0.6 to 3 mm thick to produce lap joints intermittently welded and therefore not pressure-tight. Typical applications are low-carbon steel components for car bodies, cabinets and general sheet metalwork. Spot welding is also applicable to stainless steel, aluminium and aluminium alloys, and copper alloys.

Because of high electrical conductivity, pure aluminium is difficult to spot weld and its softness results in heavy indentation by the electrodes. The high electrical conductivity of copper makes it unsuitable for spot welding. Stainless and heat-resisting steels are spot welded for aircraft and gas turbine engines.

Seam welding Seam welding (Figure 16.82) is similar in principle to spot welding and uses rotating wheel electrodes which roll the overlapping components between them. The welding current passes intermittently through the electrodes, forming a series of welds that overlap one another. The electrode wheels rotate continuously and at least one is power-driven to move the component along, in addition to carrying the welding current.

Pressure-tight seams can readily be made and the process is faster than spot welding. However, machines are heavier and more costly than spot welding machines. Seam welding is primarily suited to making long straight welds, although curved welds can be made (for example, welds which may occur at the corners when joining two half pressings together to form a fuel tank). Typical applications are pressure-tight seams for oil drums and refrigerator parts.

Projection welding In this process the current is concentrated by the shape of the components themselves, small dimples being formed on one of the sheets to be joined as shown diagrammatically in Figure 16.83. The electrodes are of relatively large area compared with spot welding electrodes and can therefore be made of a hard material having a comparatively high electrical resistance, such as a copper–tungsten alloy. As several welds can be made at the same time, the welding machine has to be of high electrical capacity and must also be capable of applying the high total mechanical load to the components during welding. Three projections welded simultaneously give the best results, and up to five projections are common. Applications involving larger numbers of projections are known, but as the number increases it becomes increasingly difficult to ensure uniform and adequate welding of all the projections. The process can also be used for attaching studs, nuts and disks to flat plates.

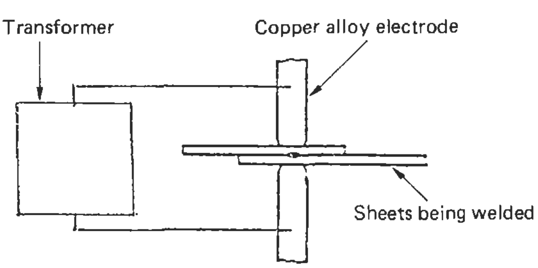

Figure 16.81 Resistance spot welding

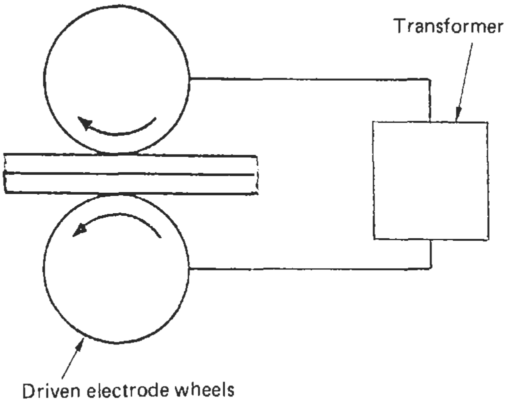

Figure 16.82 Resistance seam welding

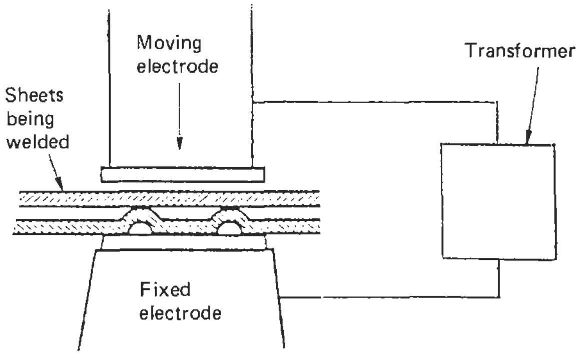

Figure 16.83 Projection welding

The main features of the process are as follows:

1. Several welds can be made simultaneously in the time it would take to make a single spot weld.
2. Electrodes have longer lives between dressings compared with spot welding electrodes because of the relatively low current densities.
3. Welds are generally of better external appearance than spot welds due to the absence of indentations.
4. T-joints may be made as well as lap joints.
5. Machines are generally more costly than spot welding machines.
6. The cost of preparing components is greater because of the necessity of forming projections.

16.3.1.15 Resistance butt and flash welding

Resistance butt welding The two ends of the parts to be joined are brought into contact and current is passed across

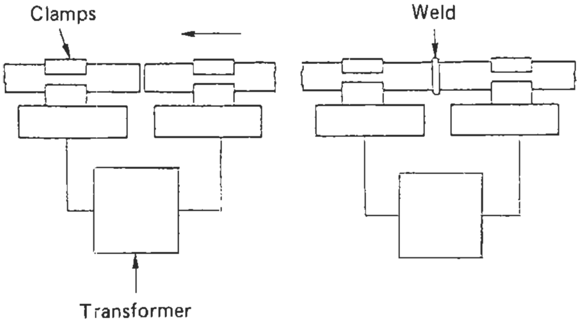

Figure 16.84 Resistance butt welding

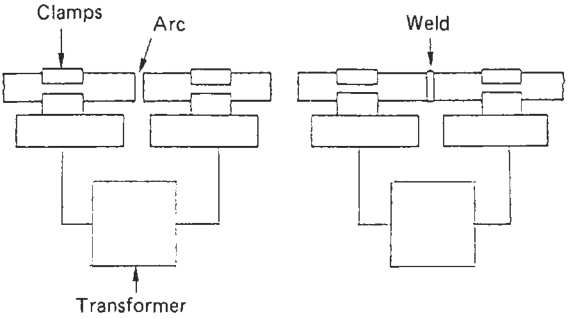

Figure 16.85 Flash welding

the joint while a moderate mechanical force is applied to the components (Figure 16.84). As the joint heats by electrical resistance the material softens and welding takes place. The finished joint shows a thickening or upsetting of the components in the joint area, and for some distance away from the joint. Resistance butt welding is essentially a solid-state welding process in which no melting occurs.

Recrystallization of the metal takes place across the faying surfaces and the upsetting action has the effect of removing oxides from the joint. The process has two main applications:

1. Joining two components of the same cross-section end to end (e.g. wire, rod, bar or tubing). Used in rod and wire mills for joining the ends of coils for continuous processing.
2. Continuous welding of longitudinal seams in pipe or tubing formed from flat plate.

The process is applicable to the welding of carbon, alloy and stainless steel, aluminium alloys, copper alloys, nickel alloys, and electrical resistance alloys.

Resistance butt welding machines are generally designed to weld a particular family of alloys because the current densities and pressures as well as the rate of application of the pressure differ widely between, for example, steels and aluminium alloys. The cross-sectional areas to be joined also determine the current capacity of the welding transformer.

The welding machine has two platens on which are mounted clamping dies which grip the components. One platen is stationary and the other moves to produce the pressure required.

Flash welding Flash welding was developed from resistance butt welding and the principle is shown in Figure 16.85. The currrent is switched on before the ends of the components are in contact, with the result that small volumes of metal melt explosively at the points where contact is first made. This process continues as the two components are moved towards one another, causing a large amount of flashing and removal of metal while, at the same time, heating the areas in contact and the material immediately behind. Once suitable temperature conditions have been established, the two ends of the components are forced together by a sudden increase in the load applied and the current is switched off. The effect of this sudden load is to squeeze out from the joint all the overheated and oxidized metal and to form a high-quality pressure weld. The fin or flash of upset metal surrounding the joint is normally removed before the component is put into service.

Typical applications of flash welding are the production of continuous welded railway track, motor-car wheel rims formed from flat steel stock and mitre joints in door and window frames. The materials welded are similar to those that can be resistance butt welded.

16.3.1.16 Friction welding

Friction welding is a solid-state joining process, i.e. there is no fused metal involved. The heat to make a forge weld is produced by moving one component relative to a mating component under pressure. The motion is usually rotational, although the linear relative motion can be used and is under development. A friction weld is similar in appearance to a resistance butt or a flash weld with upset metal or flash which is generally removed after welding by a machining operation.

Butt welds can be made in rods or tubes, and rods or tubes can be welded to plates. One of the components is generally circular in cross-section although square rods can be joined by friction welding. A wide range of sizes can be friction welded from small-diameter wires used in the electronics industry up to 150 mm diameter aluminium bus bars.

Typical applications are found where high production rates are required (e.g. the motor industry). Examples are axles, drive shafts, steering shafts and valves where a high-alloy heat-resisting head is welded to a cheaper carbon steel shank. Bar stock can be welded to plates to produce parts that would normally be forged.

Most metals and alloys, with the notable exception of cast iron, can be friction welded. Dissimilar metals can also be welded without the formation of a brittle zone that often occurs with arc welding (e.g. aluminium can be welded to steel).

Friction surfacing is an important development in which a corrosion- or wear-resistant alloy rod is rotated rapidly under pressure against a surface to be clad with the alloy. Under carefully controlled conditions a friction weld can be deposited over the surface and the weld metal is unchanged in composition because there is no dilution of the weld caused by melting of the parent metal as occurs in surfacing by arc welding. For further information on friction welding reference 41 should be consulted.

16.3.2 Soldering and brazing

Brazing and soldering are carried out at temperatures below the melting points of the metals being joined. Brazing filler metals have melting points above 450°C and solders melt below this temperature. In both processes the molten filler metal flows by capillary action between closely fitted surfaces of the parts to be joined.

Unlike welding, soldering and brazing do not generally produce joints having mechanical properties matching those of the parent metal. Typical applications, such as car radiators and electrical connections, require leak-tightness and electrical conductivity, respectively. If high strength or ductility is required correct alloy selection and joint design are essential and for further guidance references 42 and 43 should be consulted.

The low temperatures involved in soldering and brazing have two beneficial effects compared with welding: (1) parent metal properties are less affected, especially by soldering; (2) residual stresses and distortion are lower. For successful joining, the following procedures are required:

1. For wetting of the present metal by the solder or brazing alloy the surfaces must be chemically clean. Degreasing and mechanical cleaning or pickling may be necessary.
2. During the joining operation a flux is generally used to remove surface oxides and to prevent them from reforming. In some brazing processes a reducing or neutral atmosphere or a vacuum is used.
3. Heating of the parent metal must be carefully controlled so that both the mating surfaces reach the melting temperature of the filler metal before it is applied to the joint. When the filler metal is pre-placed in the joint the same requirement applies because the molten filler metal will not wet the surface unless that surface is hot enough.
4. All traces of flux residues which might lead to corrosion must be removed after soldering or brazing.

16.3.2.1 Soldering

Solders The normal range of soft solders are listed in BS 219: 1977[44] which also indicates typical uses. The commonest solders are the tin–lead alloys, some of which have antimony added. These solders are used in various applications, depending on the composition, including manufacture of food-handling equipment, tin-plated cans, domestic utensils, electronic assemblies, heat exchangers and general engineering work. Tin–antimony solder is used for higher service temperatures (e.g. above 100°C) and in applications for joining stainless steels where lead contamination must be avoided. The alloy is also used for plumbing and refrigeration applications. Tin–silver solder is used for fine instrument work and food applications while tin–lead–silver solder is used for service above 100°C and also below −60°C.

Soldering methods Many sources of heat can be used for soldering, including the following: heated iron, flame or torch, hot-plate or oven, HF induction, electric resistance, hot gas, as well as dip, wave or flow methods involving molten solder baths. For further information on both manual and mechanized soldering techniques references 43, 45 and 46 should be consulted.

Manual soldering methods using a soldering iron or a torch are fairly slow and require a reasonable degree of skill, although repetitive work carried out by an experienced operator can give high production rates. Dip soldering is faster and the electronics industry uses specially designed equipment for wave soldering of printed circuit boards.

16.3.2.2 Brazing

Brazing alloys are specified in BS 1845[47] under eight groups based on aluminium, silver, copper–phosphorus, copper, copper–zinc, nickel, palladium and gold. The choice of brazing alloy for a particular parent metal can be fairly wide and a decision may be based on metallurgical considerations, including corrosion resistance, maximum temperature to which the parent metal can be heated to avoid deterioration in properties or melting of previously applied brazing alloys. For further information references 42, 48 and 49 should be consulted. A brief summary of the uses of the eight main groups of brazing alloys is given in Table 16.5.

Brazing alloys are available in the form of wires, rods, powders and inserts of various shapes for pre-placing in the joint.

Table 16.5 Main uses of brazing alloys

Brazing alloy	*Materials suitable for brazing*
Aluminium	Pure aluminium and some aluminium alloys
Silver	Most ferrous and non-ferrous metals and alloys except aluminium, magnesium and refractory metals and their alloys
Copper–phosphorus	Copper and copper alloys
Copper	Ferrous materials in a protective atmosphere or in a vacuum
Copper–zinc	Stainless steel and other heat- and corrosion-resistant alloys in a protective atmosphere or in a vacuum
Nickel	Stainless steel and nickel–chromium heat-resisting alloys for high-temperature service
Palladium and gold	Metallized ceramics, copper, nickel and ferrous alloys in a protective atmosphere or in a vacuum

Heating methods A full description of the various heating methods and their advantages and disadvantages are described in BS 1723: Part 2: 1986.[48] The methods comprise hand-torch brazing, mechanized flame brazing, induction brazing, furnace brazing (including protective atmosphere), vacuum and open-furnace brazing, and immersion brazing, including flux bath, dip bath and salt-bath brazing. Special processes referred to are infrared brazing and laser brazing. Reference 48 also contains details of design and location methods for brazing.

Applications Brazing is applicable to cast irons, steels, galvanized steel, aluminium, copper, magnesium, nickel and their alloys, stainless and heat-resisting steels, titanium, zirconium, ceramics and refractory metals and to dissimilar metal joints. It is selected in preference to other joining processes for the following reasons:

1. Where heating must be restricted to avoid melting or distortion of one of the parts to be joined.
2. Where strength or dimensional accuracy of the assembly would be impaired by heating to a high temperature.
3. Where a soft soldered joint would not be strong enough.
4. Where parts cannot be welded because of the properties of the parent materials involved (e.g. ceramics, refractory metals).
5. Where a number of joints have to be made in a small complicated assembly.
6. Where joints would be inaccessible to the welding processes.

16.3.3 Productivity and welding economics

Productivity, in the broadest sense, is what determines profit. Unfortunately, the cost of welding is one of the least-documented topics in the whole field of welded fabrication. When a company decides to review its fabrication methods there is often a lack of understanding of the principles involved and only limited knowledge of the alternatives available. Reliance may be placed on equipment salespersons who may be fair and have an excellent product to sell but, quite naturally, may be biased in their approach.

There is a lack of information compared with that readily available on machine tools (e.g. cutting speeds, depth of cut which can enable a machine to be integrated into a manufacturing system to give a high utilization or duty cycle and therefore maximize productivity). The same objective should be applied to welding as part of the manufacturing system.

The first task in reviewing fabrication methods is a simple one and concerns design. In the case of arc welding, fabrications should be designed to have the minimum amount of weld metal that will meet the service requirements of the components in terms of mechanical properties.[50] The total quantity of weld metal in a fabrication is, of course, only a very small proportion of the total weight (perhaps 2% or less) but, nevertheless, it is sensible to use the minimum amount necessary. This requires close attention to detail design, shopfloor supervision and inspection to ensure that welded joints are not overdesigned and weld metal is not being wasted.

Sometimes partial-penetration butt joints will be adequate and intermittent fillet welds can replace continuous ones. Fillet weld profiles should not be excessively convex because any weld metal in excess of a mitre fillet does not contribute to the strength of a joint.

For butt joints the plates are usually cut with bevel angles of 30° to given an included angle of 60° when the plates are placed together. With a gap at the root of 1–3 mm this is the optimum edge preparation to give full penetration and room to manipulate a covered electrode or MIG welding gun. If the included angle is increased to 70° the weld volume is increased by 20%, which represents 20% waste. If a fillet weld having a size or leg length of 6 mm is adequate, then a leg length of 8 mm will result in 57% wasted weld metal because of the amount of overwelding. The increase in the cost of wasted consumables may be small but the cost of depositing excess weld metal includes labour costs and overheads, which can increase the overall cost by a considerable amount.

Having ensured that the optimum welded detail design is employed, there may be a desire to increase productivity still further. The next point to consider is the deposition rate, which depends on the welding current whichever arc welding process is used. As a simple example, in manual metal arc welding if the electrode size is increased from 4 mm to 5 mm diameter and the current increased accordingly the cost of welding can be reduced by approximately 25%. A similar increase in welding current has the same effect in other processes such as MIG or submerged-arc welding. The above simple example relates to a particular job where the duty cycle was 30% (the duty cycle being the ratio of arcing time to total elapsed time for the welding operation). A welder is obviously not welding for 100% of the time and typical activities for a manual welder in various industries are shown in Table 16.6.

Table 16.6 Observed MMA welder activities (percentage breakdown in time)

Industry	*Pressure vessel*	*Site pipework*	*Engineering Light*	*Engineering Heavy*
Activity:				
Arcing (duty cycle)	42	36	62	35
Deslagging, setting up, etc.	22	30	25	32
Other activities: waiting/using crane instructions, etc.	14	23	5	14
Idle	22	21	8	19

Duty cycles may be considerably lower than those shown in the table. For example, in repair work where defects have to be laboriously removed by mechanical means, the welding duty cycle may be less than 10%. In contrast, the duty cycle of a robot MIG welding parts of car bodies may have to be 70% or higher to justify the capital investment.

Returning to the manual welder who increases the deposition rate by changing to a larger electrode and increasing the current, this gives a worthwhile cost saving provided that the duty cycle is at least approximately 20%. If the welder only deposits weld metal for 10% of the time, then even if the deposition rate is doubled it will have only a slight effect on productivity. The duty cycle may be low because the welder has to fetch and carry components and set them up for welding. If a labourer is employed to deliver components and set them up at a second workstation or in a second jig the welder can possibly double or treble the duty cycle and take full advantage of optimizing the deposition rate of the welding process that is being used. It is necessary to carry out an exercise in method study to reveal the true cost of welding and to indicate how improvements in productivity may be accomplished with the equipment currently in use. Costing methods for arc welding must take account of the costs of consumables, weight or volume of weld metal, deposition rates and duty cycles, labour costs and overheads and amortization of equipment. For further information on the calculation of welding costs, references 51–53 should be consulted.

A further important point to consider in economic surveys of welding operations is the welding position. Deposition rates can be maximized by welding in the flat position because a large molten pool of weld metal can be maintained, whereas in the vertical or overhead welding positions the size of the weld pool has to be restricted. Therefore the provision of a welding manipulator or turning rolls can enable work to be rotated so that welding can be carried out in the flat position with maximum deposition rates. In some cases, depending on the shape and size of component, the rate of welding can be doubled or trebled by suitable manipulation of the work piece.

When a welding engineer has considered all the elementary principles of welding engineering and has determined the possible increase in productivity at minimum cost, the next question to be asked is whether this is satisfactory for the company. Management decisions are required on the rate of production required at present and in the foreseeable future, and any plans for the manufacture of different products. New product lines may raise the question of what is technically required in respect of quality of welded joints (for example, static or fatigue strength, fracture toughness, corrosion or wear resistance). With this information, a choice can be made on the most appropriate welding processes, equipment and consumables capable of achieving the quality and production rates required. If a welding engineer is available he or she will obviously be expected to make recommendations on the choice of welding processes and equipment. Otherwise, the company may have to contact outside sources such as equipment suppliers, national advisory bodies or a consultant. In any of these circumstances it is advisable that the manager making investment decisions should have some basic knowledge of welding technology if only to be able to ensure that all the possible alternatives have been considered.

For further information on the choice of manual, mechanized or robotic welding processes coupled with economic considerations, references 36 and 54–56 should be consulted.

16.4 Adhesives

16.4.1 General comments

Adhesives can offer substantial economic advantages over conventional methods of joining. Indeed, it was for this reason that the application of adhesives to metal fabrication, in common with many other technological innovations, was pioneered by the aircraft industry. A realization of the advantages of adhesive bonding over other methods of joining materials has led to a rapid growth of the adhesives industry. This has been accompanied by advances in the science and technology of adhesion and adhesives, with an emphasis on high-performance synthetic products for the mechanical engineering sector. Adhesive bonding, either alone or in combination with other methods of fastening, represents a key enabling technology for the exploitation of new materials and for the development of novel concepts and structural configurations.

The strength of an adhesive bonded joint is determined by the strength of its weakest element; this is not necessarily the adhesive! The correct choice of adhesive and an appreciation of appropriate process procedures are necessary for the satisfactory fabrication of bonded assemblies. Load-bearing joints require proper design. Thus the engineer requires at least a qualitatively correct overall picture of the various factors influencing adhesion and controlling joint performance. This section seeks to present a balanced overview of these factors.

16.4.2 Definitions and terms

16.4.2.1 Adhesives

An adhesive may be defined as any material which, when applied to surfaces, can join them together and resist their separation. Thus adhesive is the general term and may include cement, glue, gum, paste, etc. There are several, largely synthetic, generic groups of adhesives of value to the engineer embracing numerous subgroups, individual formulations and generic combinations.

The adhesive is involved with wetting, adsorption and interdiffusion reactions with the substrate surface before solidification. A schematic cross-section through a bonded interface is given in Figure 16.86.

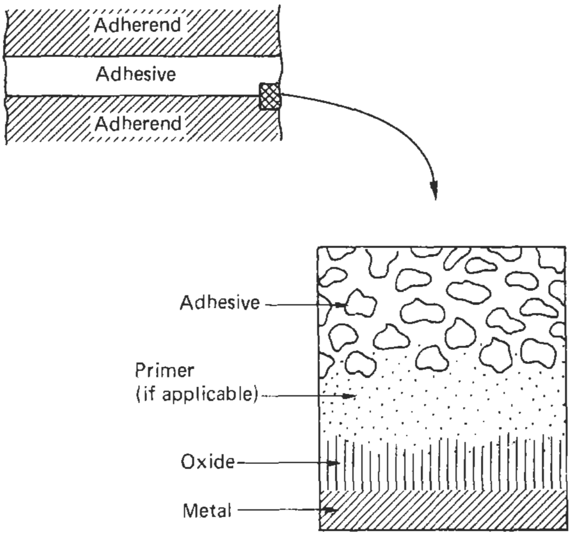

Figure 16.86 Elements of a metal adherend/adhesive interface

16.4.2.2 Adhesion

Adhesives join materials primarily by attaching to their surfaces within a layer of molecular dimensions. The term 'adhesion' refers to the attraction between substances whereby, when they are brought into contact, work must be done in order to separate them. Thus adhesion is associated with intermolecular forces acting across an interface, and involves a consideration of surface energies and interfacial tensions.

16.4.2.3 Adherends or substrates

The materials being joined are usually referred to as the adherends or substrates.

16.4.2.4 Adhesive bonding

Bonding means the uniting of similar or dissimilar adherend surfaces with a relatively low modulus interlayer of adhesive material. The resultant properties of the composite made are a function of the bonding, the materials involved and their interaction by stress patterns.

16.4.2.5 Advantages and limitations of adhesive bonding

The main advantages and limitations of adhesive bonding as compared with welding or mechanical fastening are given in Table 16.7. The relative importance of individual items naturally depends upon the perspective of different users.

16.4.2.6 Requirements for a satisfactory bonded joint

1. Selection of a suitable adhesive
2. Adequate preparation of the adherend surface
3. Appropriate design of the joint
4. Controlled fabrication of the joint itself
5. Post-bonding quality assurance

16.4.3 Adhesives

16.4.3.1 Introduction

Adhesives may be classified as either organic or inorganic materials in a number of different ways – for example, by origin, by method of bonding, by end-use or by chemical composition. Some classifications employ more than one criterion, such as that offered in Table 16.8.

Natural adhesives such as starch, animal glues and plant resins have been used for centuries, and are still used widely today for packaging and for joining wood. Rubber-based adhesives were introduced in the shoe and tyre industries towards the end of the nineteenth century, but the birth of modern structural adhesives is generally dated from the early twentieth century with the introduction of phenol-formaldehyde resins. Over the past four or five decades the natural adhesives have been improved, and there has been an intense development of synthetic adhesives to meet more technically demanding applications. These synthetic adhesives include thermoplastic and thermosetting types. Thermoplastic adhesives may be softened by heating and rehardened on cooling, and included in this group are relatively low-performance materials such as acrylic polymers, 'hot-melts' and products based upon polyvinyl acetates (PVAs). Thermosetting materials represent thermally stable highly cross-linked

Table 16.7 Advantages and limitations of adhesive bonding

Advantages	*Limitations*
Ability to join dissimilar materials	Surface pretreatments normally required, particularly with a view to maximum joint strength and durability
Ability to joint thin sheet material efficiently	Fairly long curing times frequently involved
More uniform stress distribution in joints which imparts enhanced fatigue resistance	Poor resistance to elevated temperature and fire
Weight savings over mechanical fastening	Structural joints require proper design
Smooth external surfaces are obtained	Brittleness of some products, especially at low temperatures
Corrosion between dissimilar metals may be prevented or reduced	Poor creep resistance of flexible products
Glueline acts as a sealing membrane	Poor creep resistance of all products at elevated temperatures
No need for naked flames or high-energy input during joint fabrication	Toxicity and flammability problems with some adhesives
Capital and/or labour costs are often reduced	Equipment and jigging costs may be high
	Long-term durability, especially under severe service conditions, is often uncertain

Table 16.8 Adhesive classification (reprinted from *Polymeric Building Materials* by Feldman, 1989)

Occurrence	*Origin*	*Adhesive*
(1) Natural	(a) Animal	Albumen, casein, animal glue, shellac
	(b) Vegetable	Resin: gum arabic, tragacanth, colophony, Canada balsam, natural rubber Oils: linseed oil Waxes: carnauba wax Proteins: soya bean Polysaccharides: starch, dextrine
	(c) Mineral	Waxes: paraffin Resins: copal, amber Other materials: silicates, phosphates, sulphur, magnesia, litharge, bitumen
(2) Synthetic	(a) Thermoplastic	Vinyl polymers and copolymers: poly(vinyl acetate), poly(vinyl alcohol), poly(vinyl acetal)s, polystyrene Acrylic polymers: polyacrylates, polymethacrylates, polyacrylamides, poly(cyanoacrylate)s polyamides and saturated polyesters polyurethanes Cellulose derivatives: Cellulose acetate, cellulose nitrate, cellulose acetate–butyrate, methyl cellulose, hydroxy ethyl cellulose, carboxy ethyl cellulose, and others
	(b) Thermosetting	Phenolic resins: phenol–formaldehydes, resorcinol formaldehydes Amino plastics: urea–formaldehydes, melamine formaldehydes Polyepoxides and derivatives: polyepoxides, epoxy–polyamide, epoxy–bitumen, epoxy–polysulphide, etc. Unsaturated polyesters Polyaromatics: Polybenzimidazole, polyimide, polybenzothiazole

linked structures, and may be regarded as structural adhesives. Included in this group are epoxides and phenolics.

16.4.3.2 Application and setting

During the bonding operation the adhesive must be applied to the substrate in a fluid form, to wet the surface and penetrate its surface irregularities without leaving air voids. The adhesive must then set by changing from a liquid to a solid. The solidification mechanisms used are:

1. Solvent evaporation
2. Cooling from above melting point
3. Chemical reaction

Mechanisms (1) and (2) generally apply to low-performance, thermoplastic, materials while (3) applies to most thermosetting engineering adhesives. The rate of chemical reaction is increased considerably by exposure to heat, and as a rule of thumb is approximately doubled for every 8°C rise in temperature.

16.4.3.3 Selection criteria

Lees[57] states that there exist twelve major family groups of adhesives likely to be of value to the engineer. This poses a major problem in weighing up the pros and cons of different systems for particular applications. However, some computerized processes do exist, and are excellent for newcomers to the technology because they enable the user to gain valuable insight into the criteria which limit selection. Current UK proprietary software includes CATS (Centre for Adhesive Technology), EASeL (Design Council), PAL (Permabond Adhesives) and STICK (Lucas).

The major considerations governing the process of adhesive selection are:

1. Strength requirements (shear, tension, compression, impact, etc.)
2. Deformation characteristics (modulus, strain to failure, creep)
3. Sealing requirements
4. Joint geometry
5. Nature of adherend(s) (mechanical and chemical characteristics)
6. Production processes (method of application, speed of cure, pretreatments, etc.)
7. Service conditions (exposure to heat, moisture, stress)

In general, it will be appreciated that flexible or thin sheet materials should be bonded with relatively flexible adhesives with a high strain to failure, whereas thick sections should be united with a relatively stiff adhesive in order to make a load-bearing joint.

16.4.3.4 Types

It is useful to identify engineering adhesives with four main groups:

1. Epoxy (and toughened variants)
2. Polyurethane
3. Phenolic/resorcinolic
4. Acrylic (including anaerobic, cyanoacrylate and toughened acrylic and tape variants).

Commercial formulations are, in general, complex and sophisticated blends of many components. Fillers, toughening agents, plasticizers, diluents, surfactants and anti-oxidants are among the components which may be added to a 'basic' formulation.

Epoxy Known to most engineers and designers, epoxies represent a group of very strong adhesives. The adhesive comprises an epoxide resin and one of many reactive hardeners. Numerous cold, warm and hot-cured formulations are available to meet particular requirements, and the adhesive can be supplied in paste, film, powder or liquid form. Although often supplied as two components, 'single-part' formulations are also available in which the latent hardener is released for reaction polymerization at temperatures above 100°C. These adhesives may also be toughened by the inclusion of a dispersed rubbery phase to improve peel and impact strength.

Uses are frequently on large components, and where gap-filling, high strength, creep, moisture and heat resistance are required. Many applications in civil engineering (using heavily filled cold-cure formulations), metal plate fabrication, structural engineering, vehicle and general product assembly.

Polyurethane The polyurethane adhesives represent a group of very versatile cold- or warm-cure adhesives, and many formulations are possible. The very active reacting group of the resin is an isocyanate, which is combined with hardeners often similar in nature to those used in epoxies. They may be supplied in paste or liquid form, either as two components or as 'single-part' formulations; moisture is generally the catalyst in the latter case. Unlike epoxies, these materials can harden extremely quickly. However, polyurethanes are generally weaker and more susceptible to moisture attack than other structural adhesives, so that environmental operating conditions must be considered carefully.

Uses are frequently in thin-film form for bonding large sandwich panel assemblies and/or where plastics and timber represent adherend materials. Many applications in vehicle, general product assembly, car repairs, etc., where gap-filling and relatively light-duty connections prevail.

Phenolic/resorcinolic This group represents phenol-formaldehyde and resorcinol-formaldehyde resins, numbered among the earliest structural adhesives to be developed. They are rarely found outside the aircraft or timber and laminating industries. Although good adhesives, they are difficult to use because water is liberated as a by-product of the curing reaction. Heated presses or autoclaves are required to hold the components being bonded together under high pressures, while excess water escapes as steam. They possess outstanding environmental durability.

Uses are in thin-film form for bonding timber components, laminated assemblies and large metal components in the aircraft industry. Their continued use stems from their ability to maintain structural integrity under severe environmental conditions.

Acrylic This group comprises several important cold-curing subgroups, all of which depend upon the activity of the acrylic group for polymerization reactions. The structure of the acrylic backbone is adjusted according to the preferred curing mechanism. Generally, they are used in thin-film form:

1. *Anaerobic*: Sometimes known as sealants and locking compounds, these may be supplied in liquid or paste form. They are single-part adhesives that set characteristically in the presence of metal ions and the absence of atmospheric oxygen; under solely anaerobic conditions the rate of cure is very slow. This cure mechanism is very useful in assembly since hardening of the adhesive occurs only when the joint is closed. Various levels of 'strength' are available, together with toughened variants which enable them to function as true adhesives.

Uses are locking, sealing and retaining closely fitting metal parts – particularly co-axial assemblies. High-viscosity variants are used as gasketing materials.

2. *Cyanoacrylate*: These highly reactive single-component adhesives harden only in thin-film form because surface moisture is used to catalyse them. Traces of (slightly basic) moisture are found on most surfaces, and this slight alkalinity is sufficient to cause polymerization within seconds. Acidic surfaces tend to inhibit curing. Moisture resistance is poor, and there is no gap-filling capability.
   Uses are bonding of small plastic and rubber parts, and even human tissue.
3. *Toughened acrylic*: These represent very versatile two-component adhesives for use in thin-film form. The resin is applied to one surface and an initiator to the other. When the joint is closed the initiator diffuses quickly through the resin and polymerization is complete within minutes – although several hours may be required to achieve full cure. These adhesives bond extremely well to most substrates, and the inclusion of a dispersed rubbery phase confers excellent peel and impact resistance. Recent acrylic derivatives, developed to fill gaps, are true two-part systems similar in nature to epoxy adhesives.
   Uses are bonding of sheet metal, coated metal, plastic parts and some rubbers. Reasonably large structures can be bonded with confidence, especially where surface treatment is minimal.

16.4.3.5 Mechanical characteristics

In general, the properties of adhesive polymers are determined by their internal structure, although the blend of components in many commercial formulations prevents simple chemico-physical relationships being drawn. The types of adhesives of greatest interest to the mechanical engineer range from ductile polyurethane and acrylic formulations through the stiffer epoxides to some stiff (and brittle) anaerobic adhesives. Some stiffer materials still are based upon imide chemistry, and are used in advanced weapons and aerospace structures. The basic property trade-offs for single-phase thermosetting adhesives have been described by Bolger[58] (e.g. Figure 16.87) and it can be seen that high strength is obtained for the price of reduced ductility and toughness. However, the incorporation of rubber toughening into adhesive polymers has meant that reasonably high strength can now be obtained in addition to toughness, at least in acrylates and epoxides. A comparison of the stress/strain characteristics of different adhesives is given in Figure 16.88, showing the range of properties available.

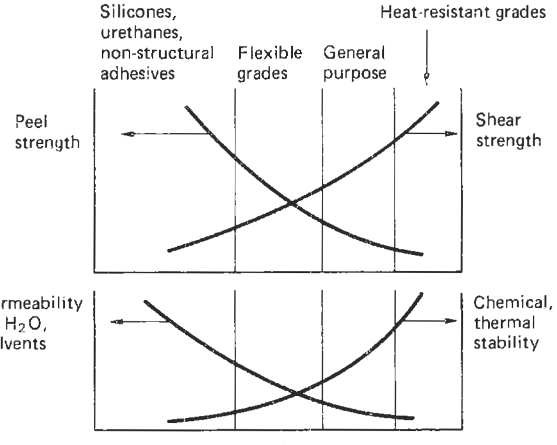

Figure 16.87 Property trade-offs for single-phase thermosetting adhesives. (Reproduced from reference 58, copyright Marcel Dekker)

The modulus of polymers arises from the forces required to move molecules with respect to each other. Adhesives therefore possess a relatively low modulus which decreases with increasing temperature. For epoxies, Young's modulus E is typically between 1 and 6 G Nm^{-2}, while the modulus of acrylics and polyurethanes may be a tenth, or even a hundredth, of such values. Variations in temperature can transform materials which are tough and strong at 20°C to ones which are soft and weak at 100°C. The glass transition temperature, T_g, denotes a marked change in the mechanical properties of a polymer. Above T_g the material will be rubbery, and below, glass-like and stiff (see Figure 16.89). The T_g's of sealants are around −140°C, whereas those of room-temperature curing adhesives are around 40–50°C. By warm- or heat-curing adhesives their T_g's are increased, and epoxides cured between 150°C and 200°C will have T_g's in excess of 120°C.

Organic polymers all absorb moisture and one effect is to plasticize the adhesive itself. This modifies its response to mechanical deformation in a manner analogous to a lowering of the T_g. Such effects are, however, reversible, depending upon proximity to moisture – in liquid or vapour form. Thus water and heat have similar effects, and this is illustrated in Figure 16.90 for the case of a cold-cure epoxy formulation.

Finally, adhesive polymers are visco-elastic and the time-dependent component of polymer response is of great importance to the use of adhesives required to sustain either permanent or transient loads; this can be a major determinant of the fatigue life of a bonded joint. Thus low-frequency load cycling and, to a lesser extent, elevated temperatures are very important considerations in adhesive selection.

16.4.3.6 Summary of adhesive considerations

There are a number of sources listing the factors involved in adhesive selection and the performance properties to consider.[57–62] Reference 62 offers a checklist of considerations within the epoxy group, upon which Table 16.9 is based. The choice is clearly a matter of swings and roundabouts.

16.4.4 Adhesion and surface pretreatment

16.4.4.1 Adhesion, or how adhesives stick

Concepts The basic requirements for good adhesion are very simple:

1. Intimate contact between adhesive and substrate
2. Absence of weak layers or contamination at the interface

Adhesives join materials primarily by attaching to their surfaces within a layer of molecular dimensions, i.e. of the order of 0.1–0.5 nm. In joints involving metallic substrates, the adhesive sticks to the surface oxide layer and not to the solid itself. Being liquid, adhesives flow over and into the surface irregularities of a solid, coming into contact with it and, as a result, interact with its atomic forces. The adhesive then solidifies to form the joint.

Interfacial contact Adhesive bonding involves a liquid 'wetting' a solid surface, which implies the formation of a thin film of liquid spreading uniformly without breaking into droplets

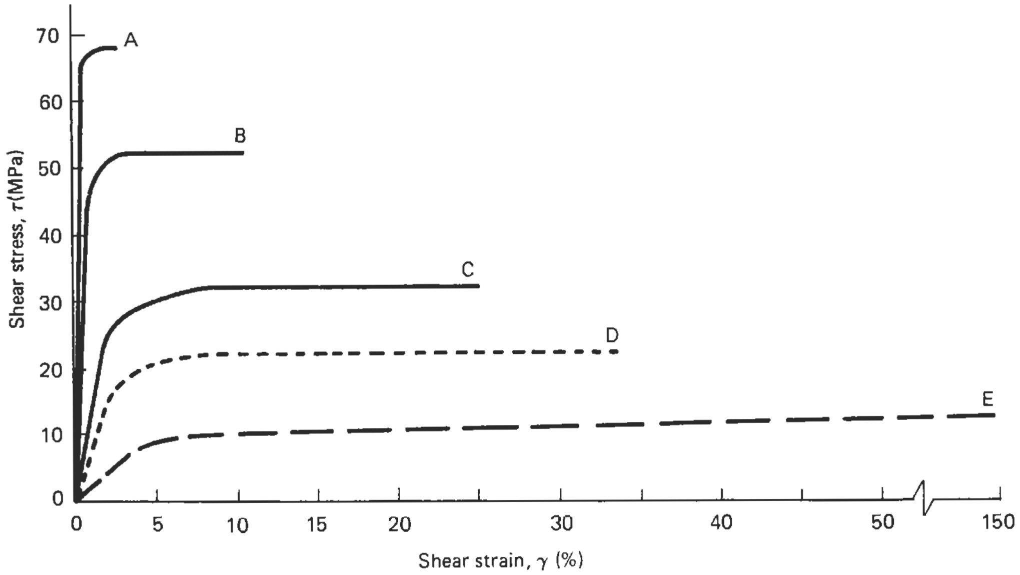

Figure 16.88 Typical stress–strain characteristics of adhesives used for structural and mechanical engineering assembly. (Based upon reference 57, copyright Permabond Adhesives Limited.) A1 – 1 Stiff, heat-resisting, brittle epoxy; B1 – 1 tough, stiff, head-cured, single-part epoxy; C1 – 1 tough, cold-cured, two-part-epoxy; D1 – 1 stiff, cold-cured, polyurethane; E1 – 1 tough, cold-cured ductile acrylic

(b)

Figure 16.90 Schematic representation of the effects of temperature and moisture on the mechanical behaviour of an unmodified cold-curing epoxy adhesive. (a) Shear response; (b) tensile response

Table 16.9 Checklist of epoxy adhesive selection considerations

Strength requirements	
Shear	Unlikely to be limiting, but if so use a suitably modified epoxy
Cleavage/tension	Sacrifice shear strength for high toughness and good peel strength with flexibilized or toughened epoxy
Impact	High toughness derived from toughened epoxy; good peel resistance conferred by flexible materials such as epoxy-polysulphide formulations
Deformation characteristics	
Modulus	High for unmodified epoxy
Creep	Use adhesive with T_g well above service temperature; best resistance with unmodified epoxides
Service conditions	
Moisture/temperature	Best resistance with unmodified epoxides and formulations with high T_g's
Stress	Modified, flexibilized and toughened grades to suit function

(Figure 16.91); the water break-free test is the simplest qualitative visual method of assessment. Since adhesion involves intimate contact of two surfaces, it is convenient to think in terms of the free energies of the surfaces involved. Just as liquids have surface tensions or surface energy, so do solid surfaces by virtue of the fact that they are surfaces. However, surface tension of solids tends to go unnoticed because solids are usually too rigid to be visibly distorted by the interatomic, rather than intermolecular, forces holding them together.

Zisman[63] introduced the useful distinction between high- and low-energy surfaces. Most plastics and liquids have surface-free energies below 100 mJ m^{-2}, with organic adhesives such as epoxides having low surface-free energies – usually <50 mJ m^{-2}. Hard solids such as metals and metal oxides, *when atomically clean*, have high surface-free energies typically in excess of 500 mJ m^{-2}. Some important values of surface-free energies are collected in Table 16.10.

An energetic surface will make a wetting liquid spread on it, rather than remain as a discrete drop, so that adhesives should readily spread and wet the oxide layers of metals. There will, however, be a problem with bonding plastics such as polyethylene and polypropylene whose surface-free energies are *less* than those of most organic adhesives. However, the problem with high-energy surfaces is that atmospheric contaminants and moisture are readily adsorbed on them, converting them to surfaces with a free energy barely greater than that of adhesives. This often gives rise to the need for special precautions to be taken with surface pretreatment and process control.

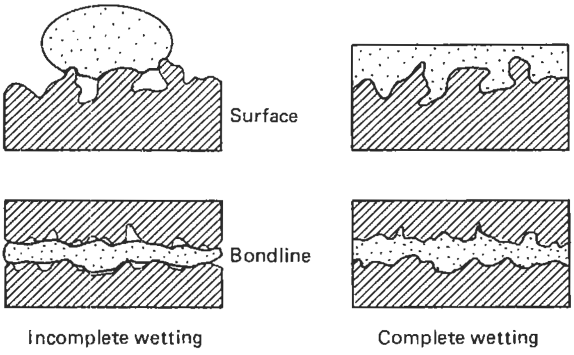

Figure 16.91 Wetting

In summary, the ideal conditions for establishing interfacial contact are that the:

1. Surface-free energy of the adherend should be higher than that of the liquid adhesive;
2. Liquid adhesive should exhibit a near-zero contact angle with the adherend(s);
3. Adhesive's viscosity should be relatively low at some time during the bonding operation;
4. Joint should be closed carefully to assist air displacement.

Mechanisms of adhesion Once interfacial contact has been established, the adhesive cures in order to be able to transmit stress. There is some debate regarding the basic nature of the forces then acting across interfaces which prevent them from separating under an applied load. The four main theories of adhesion which have been proposed are: mechanical interlocking, adsorption, diffusion and electrostatic attraction.[63–65] However, the *adsorption* mechanism is generally favoured, with *mechanical keying* also playing an important role. Whichever mechanism or combination of mechanisms are operating, the important surface characteristics are:

1. Surface energy
2. Surface chemistry
3. Surface micro- and macro-morphology

The adsorption theory proposes that adhesive macromolecules are physically adsorbed onto the substrate surface because of the forces acting between the atoms in the two surfaces. In effect, the polar nature of the adhesive molecules acts like a weak magnet and they are attracted toward polar adherend surfaces. The most common interfacial forces are van der Waals' forces, referred to as secondary bonds, although hydrogen bonding and primary bonding are involved in some cases.

Mechanical keying or interlocking of the adhesive into the irregularities or pores of the substrate underlies the instinctive procedure of roughening surfaces to improve adhesion. On porous or fibrous materials, the adhesive certainly flows into

Table 16.10 Values of surface-free energies

Surface	*Surface-free energy, γ, in vacuo* (mJ m^{-2})	*Young's modulus, E* (G Nm^{-2})	*Material class*
High-energy surfaces			
C (diamond)	5140	1200	Diamond
Fe_2O_3 (ferric oxide or red haematite)	1357	210	Metals
Al_2O_3 (alumina or aluminium oxide)	638	70

Silicones	25		Elastomers
PTFE	15.5		

[a] Large polar component, γ^p

the structure of the material and is keyed in place. The penetration of adhesive into the *microstructure* of high-alloy metal oxide layers is important, and this micromechanical interlocking at a molecular scale aids the retention of adhesion under severe environmental conditions[64,65] (e.g. Figure 16.92).

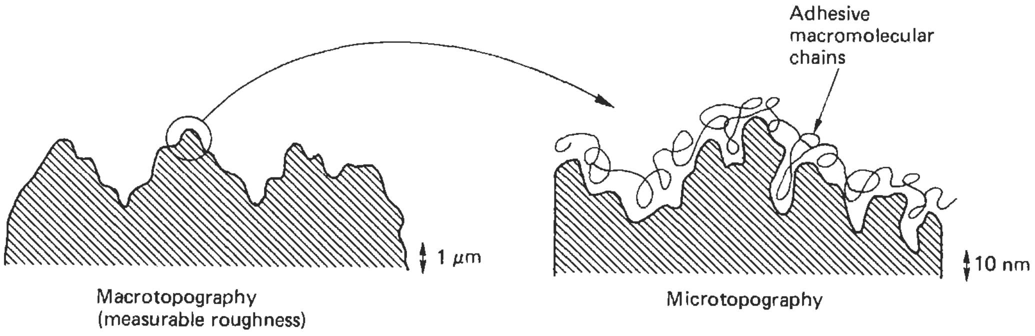
16.4.4.2 *Surface pretreatment*

Adhesives are quite often blamed for 'not sticking', but the general source of the trouble lies with the surface preparation. Surface pretreatments, while greatly affecting bond durability, generally have less effect on initial strength. Inadequate surface pretreatment is usually the main cause of durability problems and of joints failing in service.[66] While adhesives are available which can absorb oily films and a certain amount of surface contamination, some form of pretreatment is generally recommended. The degree of surface pretreatment required depends upon the nature of the adherends (e.g. Table 16.11), and some effects are summarized in Table 16.12. Surface pretreatment generally involves:

1. Cleaning
2. Removal of weak surface layers
3. Re-cleaning

It can be appreciated from Table 16.12 that surfaces can be made to be very much more 'receptive' towards adhesives in terms of altering the adherend's surface chemistry, energy and morphology. A detailed literature exists giving practical information on pretreatment procedures for a wide range of substrates,[57,60,61,67–71] while a number of surface analytical and optical techniques have been devised for examining surfaces before and after treatment.[65,68] Electron microscopy has been found to be particularly valuable (e.g. Figures 16.92 and 16.93).

The main methods of surface pretreatment fall into four groups:



Adhesive macromolecular chains
1 μm
10 nm
Macrotopography (measurable roughness)
Microtopography

Figure 16.92 Schematic topography of solid surfaces

Table 16.11 Pretreatment requirements

Material	*Suitability for bonding*	*Pretreatment required*
Cast iron	*****	Cursory
Steel	****	Straightforward
Stainless steel	***	Quite demanding
Zinc	***	
Aluminium	***	
Concrete	****	Straightforward
GRP	****	
CFRP	***	
PVC	**	Rigorous
Polyolefin	*	Complex

Table 16.12 Effects of surface pretreatments

Treatment	*Possible effects on surface*	*Substrate*
Solvent etch	Remove weak boundary layer	M, P
	Weaken surface region by plasticization	P
	Increase surface roughness	P
Mechanical	Remove weak boundary layer	M, P
	Increase surface roughness	M, P
Chemical	Remove weak boundary layer	M, P
	Increase, or decrease, surface roughness	M, P
	Alter surface chemistry with consequent changes in the rate and degree of wetting	M, P
Physical (e.g. flame, plasma, corona discharge)	Remove weak boundary layer	M, P
	Weaken surface region by plasticization	P
	Alter surface chemistry	M, P

Substrate abbreviations: M, metal; P, plastic

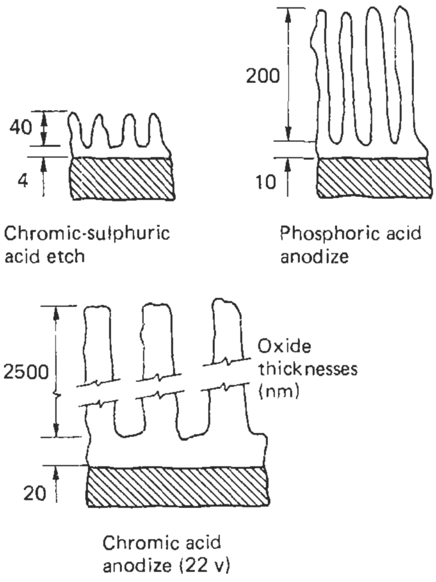


Figure 16.93 Oxide morphology on aluminium alloy following chemical treatments

1. Solvent degreasing – wiping, brushing, dipping or vapour degreasing in organic solvents such as acetone or trichloroethylene. Wiping with MEK or IPA may be suitable for plastics and rubbers. Alkaline cleaners and/or detergent solutions can also be used for metallic substrates.
2. Mechanical abrasion – action of wire brushes, sand and emery papers, abrasive pads, gritblasting, etc. Dust must be removed prior to bonding. The effects on adhesion of such (obvious) roughening are often complex.
3. Chemical treatments – numerous chemical treatment and rinsing procedures exist. Very complex surface changes are brought about in terms of cleaning, altering surface chemistry and morphology (e.g. Figure 16.93).
4. Physical methods – use of ionic bombardment or flaming action to clean and oxidize surfaces. Useful on low-energy thermoplastic materials.

A further possibility lies with the application of an adhesive-compatible primer coating. Generally, the advantages to be gained such as 'pre-wetting' of the substrate surfaces outweigh the disadvantages. Often a more reproducible surface is created and, with the application of some primers (e.g. coupling agents such as silanes), a water-stable interface may result. In the future, it may become commonplace to employ pre-coated metals ready for bonding.

16.4.5 Joint design

Load-bearing bonded joints must be designed properly. It is, for instance, not sufficient simply to substitute adhesive bonding for welding, bolting or riveting. The adhesive, which can be likened to plastic material, represents a low-modulus interlayer and is likely to be the weakest link in a joint, unless very weak or thin-sheet adherends are present. Design considerations generally involve the geometry of the bond, selection of an adhesive, knowledge of the properties of the adhesive and adherend, and analysis of the stresses to which the joint will be subjected.

Adhesive bonded joints should be designed to provide, as far as possible:

1. A large bond area
2. A uniformly thin and continuous bondline
3. Shear (and, ideally, compression) loading on the adhesive
4. Minimum peel loading and avoidance of stress concentrations
5. Self-jigging features to locate and hold the assembly during curing.

It is important to design an assembly correctly to incorporate adhesive bonding. Adhesives generally have good shear strengths but poor peel and cleavage properties, and the joint design should be arranged to eliminate these weak modes of loading – for example, by the use of additional mechanical support (Figures 16.94 and 16.95). Bonds are therefore designed to place the adhesive in shear or, ideally, compression! Other common engineering joints and joint designs are depicted in Figure 16.96.

16.4.5.1 Joint behaviour

The lapped joint is one of the most commonly occurring joints in practice, and is therefore both the most studied and the configuration most often used for testing adhesives.[61,62] However, lapped joints, however fastened, support most of the applied load as stress concentrations at the two ends of the joint. As shown in Figure 16.94(a), the problem is that the loads are not linear, and this causes the joint to rotate. In consequence, the adhesive layer is subjected to shear and tearing stresses at the ends of the joint; the adherends, too, are subjected to shearing, stretching and bending. Double-lap

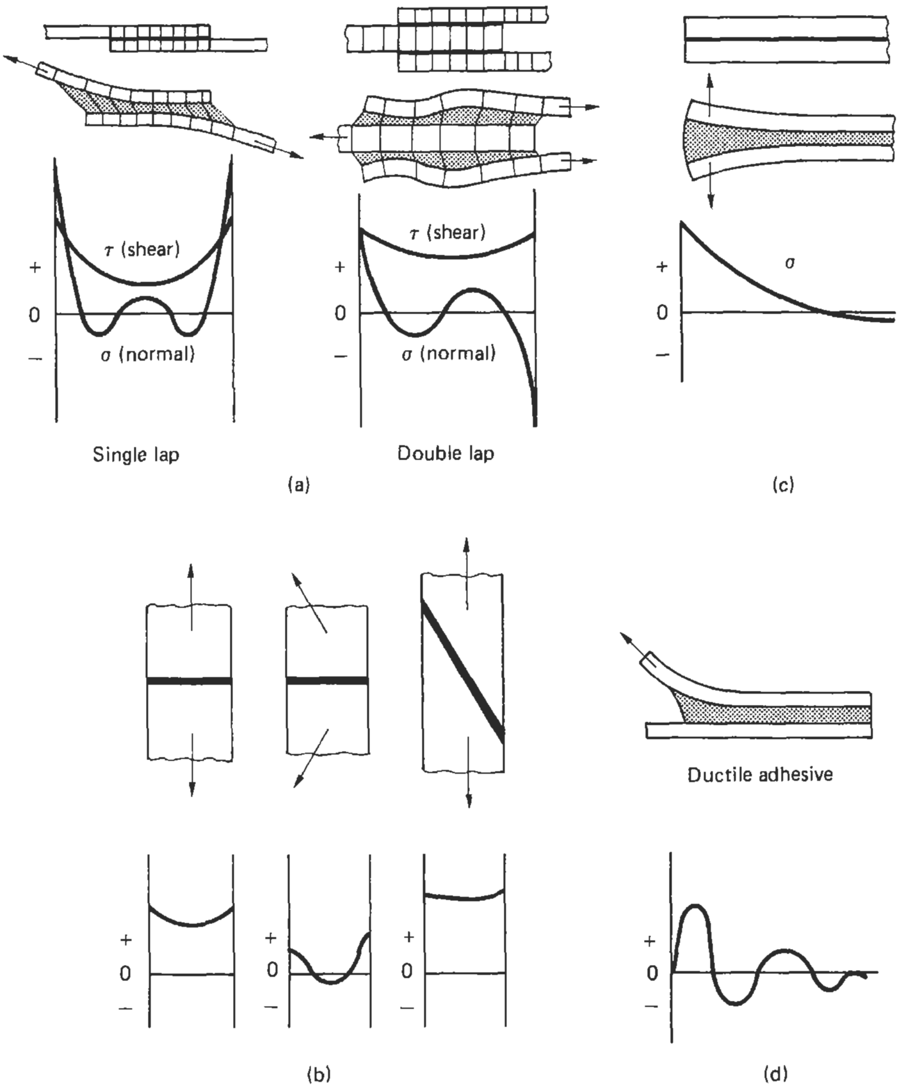

Figure 16.94 Elastic stress distributions in various kinds of bonded joints. (a) Lap shear; (b) butt-tensile and scarf; (c) cleavage; (d) peel

joints, while eliminating gross joint rotation, simply represent a back-to-back arrangement of two single-lap joints and significant tearing stresses still exist.

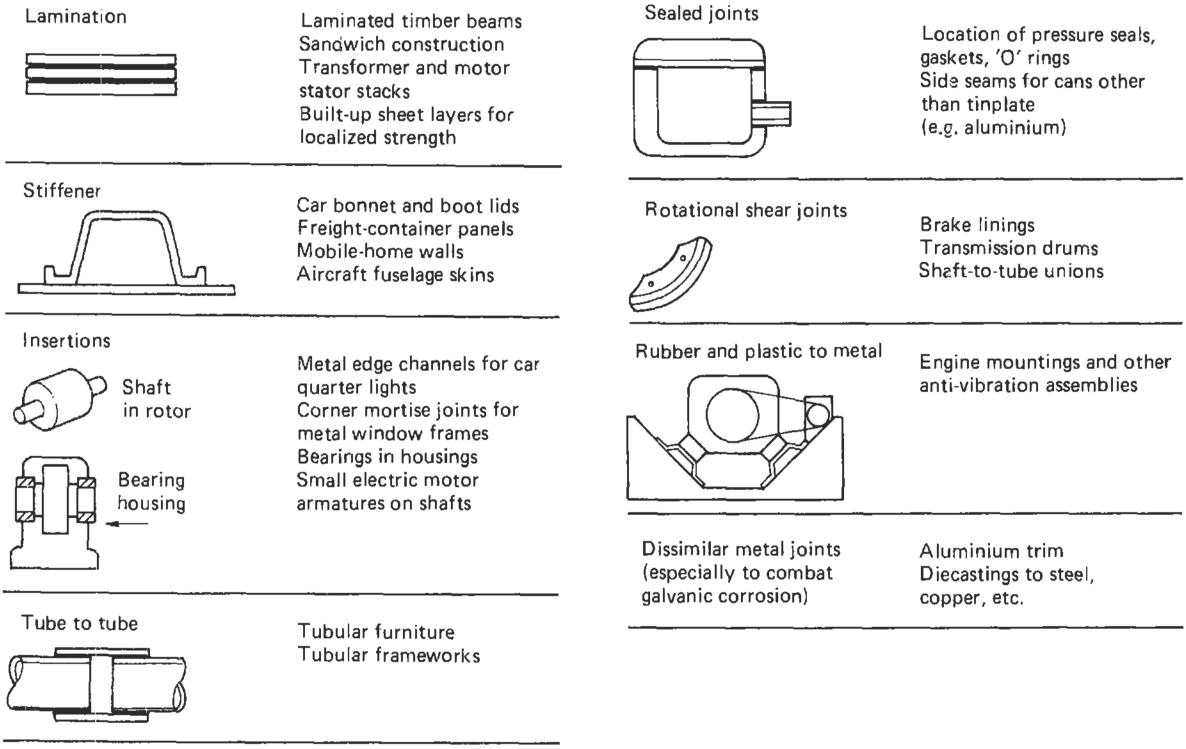
The stress peaks arising in most forms of bonded joints are at a minimum when stiff adherends and/or flexible adhesives are involved (e.g. acrylics), but can become very large when more flexible substrates or rigid adhesives (e.g. stiff epoxides) are present (Figure 16.97). The factors influencing these peaks are:

1. Adhesive shear modulus, G_a
2. Overlap length, l
3. Adherend moluli, E
4. Adherend thickness(es), h
5. Adhesive layer thickness, t
6. Plastic strain capacity of adhesive

The stress concentration in elastic theory can be described in simple terms by the coefficient $G_a l^2/Eht$. It may therefore be appreciated that lap joint strength depends generally on joint width, and not overlap length (Figure 16.98). However, on the positive side, real bonded joints are inevitably formed with spew fillets of adhesive at their extremities and this generally has the effect of reducing stress concentrations at the end of the overlap length.[62]

Since the strength of structural adhesive joints bonded with relatively stiff adhesives is so determined by the stress peaks induced under load, many design modifications have been introduced to improve stress distribution uniformity by adherend scarfing, tapering, stiffening, and so on (see Figure 16.96). Simple butt joints are often formed with adhesives, but better designs utilize co-axial and rebated concepts in order to subdue large stress peaks caused by adherend deformations (Figure 16.99).

Where very flexible adherends are concerned, flexible adhesives must be used in combination with a joint design that minimizes peel and cleavage stresses in the adhesive. Combi-



Lamination
Laminated timber beams
Sandwich construction

nations of mechanical fastening and adhesive bonding are also popular to overcome some of the problems of adhesive bonded-only joints. Thus bolts and rivets can be used to subdue peeling or cleavage forces in the adhesive. Clinching and patent mechanical locking arrangements are also popular, as is spot-welding through the adhesive. These hybrid assemblies are sometimes referred to by the terms 'riv-bond', 'clinch-bond' and 'weld-bond'.

16.4.5.2 Design approaches

Structural adhesive joints are generally designed to be loaded in shear, so that most of the analytical tools so far developed are confined to load transfer through the adhesive in shear. Simple analyses allow only for elastic behaviour, while more sophisticated developments enable plastic behaviour (of both the adhesive and adherends) to be modelled.

All the theoretical models for predicting joint strength require:

1. Adherend tensile modulus (E) and Poisson's ratio (ν)
2. Adhesive shear (G_a) and tensile (E_a) moduli, and Poisson's ratio (ν_a)
3. Ultimate strength properties.

Analyses which allow for adhesive non-linear behaviour require data on ductility such as:

4. Yield stress (strain) and ultimate stress (strain), in shear or tension, or both.

Some very sophisticated analyses require information on the adhesive's coefficients of thermal, and even hygroscopic, expansion.

The empirical approach to the design of simple overlap joints was to construct a correlation diagram between failure load and the joint geometrical ratio, h/l, for a particular set of test conditions. Mathematical treatments of joint analysis, employing differential equations to describe stress (strain) fields, have been developed from the early work of Volkersen and of Goland and Reissner. Sophisticated solutions allowing for gross adherend deformations have been produced by Renton and Vinson, Allman, Hart-Smith, and Grant. These approaches are documented by Adams and Wake[62] and have been adapted and formulated into various software packages (see Section 16.4.5.4).

It is now accepted that non-linear analysis is the key to predicting failure of structural adhesive bonded joints. It is also apparent that joint strength is determined largely by the ultimate stress or the ultimate strain capability of the adhesive in tension. Finite element methods are recognized as being the most useful techniques for analysing real joints, particularly where large non-linearities and/or geometrical complexities can be modelled.[62]

In recent years a fracture mechanics approach to joint failure has been taken, at least for test methods.[65,72,73] The fracture energy (strain energy release rate), G_c, or the critical stress-intensity factor (adhesive fracture toughness), K_c, in tensile Mode I opening (see Figure 16.100) represents the most critical situation in bonded joints. G_c or K_c may be related to a critical crack length in a bonded assembly, such that cracks which are shorter are safe and cracks which are longer are self-propagating and potentially catastrophic. Naturally, the use of rubber-toughened adhesives which inhibit crack propagation is an attractive option.

16.4.5.3 Test procedures

Bulk adhesive and/or bonded joint tests may be used for reasons such as:

1. Comparing the mechanical properties of a group of adhesives
2. As a quality check for a batch of adhesive
3. Checking the effectiveness of surface pretreatment(s)
4. Measurement of environmental effects
5. Determining quantitative mechanical and physical data on adhesives for structural design and analysis
6. Analysis of fracture mechanisms.

A large number of parameters are involved in the fabrication and testing of bulk adhesive specimens and adhesive joints; these must be controlled if meaningful experimental data are to be obtained. Bulk adhesive tests are useful for determining quantitative mechanical and physical properties. Data from joint tests usually reflect the mechanical properties of the adhesive as well as the degree of adhesion and the effectiveness of surface treatments. Many standard test procedures are listed by ASTM, BSI,[74] DIN and other official bodies, and some joint test methods are listed in Table 16.13. Useful commentaries on the relative merits of such methods, and an interpretation of the data generated, are presented by many authors.[61,62,65,75]

Comparative data on adhesive performance is commonly obtained from single-lap shear testing to BS 5350 and/or ASTM D1002. Adhesive formulators generally quote data from such tests, and an enormous data bank now exists worldwide. As discussed previously, the adhesive is subjected to cleavage as well as to shear, in a ratio dependent upon various joint stiffness factors. Nevertheless, comparative properties of different bonding systems and surface treatments may be evaluated over a range of environmental conditions. Cylindrical pin-and-collar assemblies are often used for testing low-viscosity adhesives such as anaerobics. Peel tests are generally employed where flexible substrates are involved, or where a test of adhesion is required.

Quantitative data on adhesive mechanical properties such as moduli, Poisson's ratio, stress and strain to failure, and glass transition temperature are difficult to determine. Bulk tests (e.g. tensile dumb-bells, blocks for compression, strips for torsion pendulum and water sorption experiments) may be conducted on carefully cast specimens. Suitable joint tests include torsional shear or thick adherend shear test methods using appropriate strain measurement. It is usual to conduct such tests over a range of temperatures. A discussion of such methods and procedures is given by the Engineering Sciences Data Unit in London.[76]

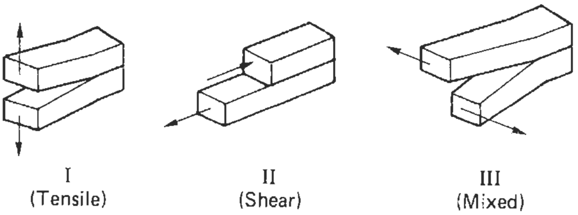

Figure 16.100 Principal fracture modes

Tests for adhesion and surface treatment effects should subject the bonded interface to tensile stresses. Lap shear, peel and cleavage (fracture energy) tests are therefore common. These should be used in conjunction with the results of surface analytical studies to assess surface energy, chemistry and morphology.

Fracture energy tests are usually conducted in tension (Mode I) and/or shear (Mode II). Parallel or tapered cantilever beam configurations are common for investigating G_{IC} and K_{IC}. A thin parallel cantilever beam geometry is used in the 'Boeing Wedge Test' derivative for assessing surface treatments – where crack propagation is monitored along the adherend/adhesive interface, as opposed to extending cohesively within the adhesive layer. Ironically, 'toughened' adhesives can be awkward to test!

Environmental testing Durability assessment represents a very important aspect of adhesive bonding technology. Most test methods are required to provide accelerated ageing. Since the major environmental factors influencing joint degradation are moisture, heat and applied stress, accelerated ageing methods seek to combine some or all of these factors. Suitable test configurations involve small bonded areas and include simple lap joints (sometimes perforated to accelerate moisture accession), peel tests, tensile butt-joints and wedge cleavage specimens. All such joints may be exposed to various natural or aggressive laboratory environments, either unstressed or stressed. Fatigue loading may even be included. Obviously, it is important to note, or monitor, the locus of failure; interfacial failure indicates an unstable surface. A detailed treatment of failure mechanisms and of methods of testing and assessment is given by Kinloch.[66]

Test joints versus real joints Real joints do not consist of simple, separate, elastic materials with a clear mathematical geometry. The adherend surface is often rough, and the thickness and properties of the primer (if applied) and adhesive layer are often difficult to determine. There also remains some debate as to whether the in-bondline, or thin-film form, properties of the adhesive are the same as they are in bulk. In service, the applied loads will generally be much lower than those applied in the laboratory.

There remains a need for the development of appropriate, cheap, simple and quantitative test methods for general engineering applications of adhesives. The test coupon approach to design and quality control has been reviewed by many

Table 16.13 Some standard test methods for adhesive-bonded joints

Test	*Standard*	*Remarks*
Definitions	ASTM D907-82(85)	Standard definitions of terms relating to adhesives
Axially loaded butt joints	BS 5350: Part C3: 1978	
	ASTM D897-78 (83)	
	ASTM D2094-69 (80) and D2095-72 (83)	Specifically for bar- and rod-shaped specimens
	BS 5350: Part C6: 1981	Bond strength in direct tension in sandwich panels
Lap joints loaded in tension	BS 5350: Part C5: 1976	Single- or double-lap joint test
	ASTM D1002-72 (83)	Basic metal-to-metal single lap joint test
	ASTM D3528-76 (81)	Double-lap joint test
	ASTM D3163-73 (84) and D3164-73 (84)	Specifically for polymeric substrates
	ASTM D2295-72 (83)	Single-lap joint test for metal-to-metal joints at elevated temperatures
	ASTM D2557-72 (83)	As above but at low temperatures
	ASTM D905(86), D906 (82) D2339-82 and D3535-79 (84)	Specifically for wooden joints
	ASTM D3983-81 (91) DIN E 54451-77	Thick substrates used; shear modulus and strength of adhesive determined
Peel joints	BS 5350: Part C9: 1978 and ASTM D3167-76 (81)	Floating-roller test
	BS 5350: Part C10: 1979 and BS 5350: Part C14: 1979	90° peel test
	BS 5350: Part C11: 1979 and ASTM D903-49 (83)	180° peel test
	BS 5350: Part C12: 1979 and ASTM D 1986-72 (83)	'T' peel test for flexible-to-flexible assemblies

	ASTM D3762-79(83)	Wedge cleavage test (for aluminium adherends)
Fatigue strength	ASTM D3166-73(79)	Single-lap joint loaded in tension
Flexural strength	ASTM D1184-69(86)	Laminated assemblies
Torque strength	ASTM E229-70(81)	For determining pure-shear strength and shear modulus of structural adhesives (napkin-ring specimen)
	ASTM D3658-78(84)	Specifically for ultraviolet light-cured glass–metal joints
	BS 5350: Part G1: 1987	Anaerobic adhesives on threaded fasteners

Test	*Standard*	*Remarks*
Impact resistance	ASTM D3807-79(84)	Plastics-to-plastics joints
	ASTM D950-82 BS 5350: Part C4: 1986	Block shear specimen
Creep resistance	BS 5350: Part C7: 1976	Various test geometries permitted
	ASTM D1780-72(83) and ASTM D2294-69(80)	Single-lap joint loaded in tension
	ASTM D2293-69(80)	Single-lap joint, having long overlap, and loaded in compression
Environmental resistance	ASTM D2918-71(81)	Subjected to stress, moisture and temperature; uses peel joint
	ASTM D2919-84	As above, but uses single-lap shear joint loaded in tension
	ASTM D3762-79(83)	As above but uses a wedge test
	ASTM D1151-84	Exposure to moisture and temperature
	ASTM D1183-70(81)	Exposure to cyclic laboratory ageing conditions
	ASTM D904-57(82)	Exposure to artificial and natural light
	ASTM D896-84	Exposure to chemical reagents
	ASTM D3632-77(82)	Exposure to oxygen
	ASTM D1828-70(81)	Natural weathering
	ASTM D1879-70(81)	Exposure to high-energy irradiation

authors.[77] A common observation is that problems which are likely to arise in the 'real' structure simply do not arise in the test coupon.

16.4.5.4 The way forward in design

The use of structural adhesives requires both essential choices between the many types available, as well as a considered decision on the design approach appropriate to structures assembled with them. A balance of material requirements and an understanding of their interaction must be achieved for optimum performance. The simplest way forward currently could involve the following steps:

1. Adhesive selection and usage considerations from literature sources and/or proprietary software such as CATS (Centre for Adhesive Technology), EASel (Design Council), PAL (Permabond Adhesives), STICK (Lucas).
2. Structural design using stress analysis programs, e.g. BISEPS and CADEPT (Harwell Laboratory), CATS, ESDU suites,[78,79] PAL, STICK, and software from PERA International. Appropriate factors of safety should be included to allow for adhesive material uncertainties and changes with response to environmental conditions.
3. Experimental work to investigate joint strength and durability, particularly with respect to the range of likely operating conditions.

16.4.6 Fabrication and assembly

Education and training of the personnel involved is essential. They must possess a qualitatively correct overall picture of the importance of the different stages of the bonding operation, and of the health and safety considerations. Control of the working environment (temperature, humidity) may also be important, particularly with regard to cleanliness.

16.4.6.1 Production processes

The adhesive bonding production process generally involves:

1. Surface preparation of the components
2. Application of a primer (if used)
3. Mixing, dispensing and application of the adhesive
4. Curing or setting of the adhesive.

These processes are determined by joint parameters such as the geometry and component fit-up, the materials involved, bond quality and reliability, and production rate. The procedures that need to be followed to ensure high-integrity structural joints can become very expensive in time and equipment.

As indicated in Section 16.4.4, some form of surface pretreatment is recommended – particularly to enhance interfacial stability. This is particularly important where cold-curing epoxy formulations are involved, or where joints will be subjected to hot moist and/or stressed conditions in service. Some adhesives can absorb oily films, but solvent cleaning is very effective in improving joint quality. Depending upon the substrate, mechanical abrasion, chemical etching or physical treatments may additionally be necessary. Such procedures must be well defined.

The time elapsed between surface pretreatment and application of the adhesive should be kept to a minimum in order to minimize subsequent contamination. Priming of the surfaces involved can serve the purposes of protection and sealing (of porous surfaces), as well as providing a more reliable and reproducible surface ready for bonding. Priming may be conducted with, what are essentially, dilute solutions of adhesives themselves, chromate/phosphate solutions, or with chemical coupling agents such as silanes.[80]

Adhesive mixing, dispensing and application must be controlled carefully. The techniques involved should be considered alongside the component design, production rate and adhesive employed. Single-component adhesives can be applied by spraying, brushing, roller-coating, or direct extrusion (for paste-like materials). Two-component systems must be carefully measured and mixed before dispensing, either manually or automatically. In recent years there has been a revolution in adhesive packaging so that weighing or measurement is not required, minimizing errors and mess. For high-volume applications equipment is available for automatic metering, mixing and dispensing, even by robots, of adhesives with a wide range of viscosities and mixing ratios.

Insufficient adhesive will result in joint performance and durability problems, while a gross excess will hamper assembly and necessitate clean-up and extra finishing operations. Joints should also be closed carefully to minimize the inclusion of air. With close-fitting parts over large bonded areas a means of air escape should be provided. A good joint design will assist the positioning and location of the joint parts, but jigs or permanent mechanical fixings may also be required to hold the components while the adhesive cures. Bondline thickness control is required both to confer a uniform design thickness as well as to prevent displacement of the adhesive under pressure from clamps or jigs. It is often desirable to leave fillets of adhesive around the perimeter of a bonded joint, and these can be tooled when the joint has been closed.

Once the adhesive has been applied, the curing and hardening process must take place. This may be within a matter of seconds for some acrylate adhesives or several hours for cold-curing epoxy formulations. The various curing systems employed were discussed in Section 16.4.3, from which it is clear that provision may sometimes have to be made for moisture or solvent evaporation, conversely for providing moisture for polyurethanes or, perhaps, ultraviolet light for some acrylic formulations. The time of reaction can be shortened considerably by the application of heat, and a typical time–temperature curing profile for a single-part epoxy is depicted in Figure 16.101. Ovens, infrared lamps, induction-, radiant- and resistance-heating systems are among the methods for achieving faster curing rates.

16.4.6.2 *Health and safety*

Safety aspects should partner the measures practised within a quality system. The history of adhesive bonding has shown that accident and health problems associated with the technology are rare. Commonsense precautions such as the use of skin and eye protection are sufficient for many applications. Concentration and duration of exposure to hazardous materials generally governs any risks.

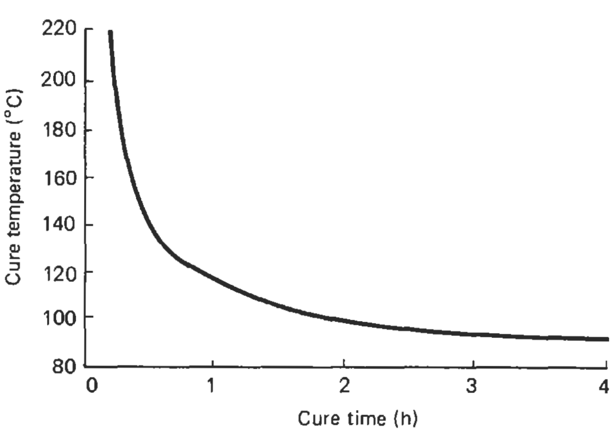

Figure 16.101 Typical time–temperature cure profile for single-part epoxy adhesive in an air circulating overn. (Based upon reference 57, copyright Permabond Adhesives Limited)

Legislation requires the adhesive supplier to label and classify products, as well as including standard risk phrases and safety procedures. Production information sheets must also be supplied in accordance with the Health and Safety at Work Act. Useful guidelines for users of adhesives are documented by the British Adhesives and Sealants Association.[81]

Most engineering adhesives contain no organic solvents and therefore problems such as solvent abuse are not present. However, solvents are sometimes used in considerable volume for surface degreasing processes as well as for cleaning-up operations. Some surface treatment processes utilize acids and other chemicals, for which a hazard is presented both in handling the liquids as well as with disposal of the residues. Mechanical abrasion techniques carry an obvious, albeit limited, risk.

When comparing the risks inherent in other joining processes such as brazing or welding the use of adhesives can significantly improve safety.

16.4.7 Quality control and non-destructive testing

16.4.7.1 *Quality control*

Test methods for the control of fabrication procedures and non-destructive testing (NDT) are basic requirements for the formation of structural adhesive joints. There are two essential but different quality aspects to be considered. These are the:

1. Adhesion between the adhesive and substrate
2. Cohesive strength and integrity of the cured adhesive layer.

A measurement of potential adhesion only is possible, restricting (1) to an assessment of the adherend surface characteristics prior to bonding through visual inspection, wettability tests, or surface potential difference techniques (for monitoring contamination). Appropriate post-bonding mechanical tests of adhesion include assessments of peel, tension and cleavage.

The quality of the cured adhesive layer can depend on many factors. Adhesive materials may be assessed in the fresh uncured state (e.g. by measurements of viscosity, sag, pot-life, etc.) as well as in their hardened state. In the latter case mechanical measurements and NDT techniques may be used.

Quality variations in the cured adhesive layer may be due to the presence of air voids (trapped during joint assembly), local areas of uncured material, insufficient curing or cracking due to shrinkage on cure. The presence of such defects may or may not be important, depending on their extent, location and so on. In many joints such defects are unimportant unless around the joint perimeter and/or in regions of high stress transfer (e.g. at the ends of a bonded overlap). The nature and significance of defects is reviewed by Adams and Wake.[62]

16.4.7.2 *Non-destructive testing (NDT)*

NDT represents a large and diverse field in which a number of review papers exist.[62,82,83] The NDT methods available are essentially void detectors, although claims are made that information can additionally be obtained on the density and thickness of the adhesive, and even on the overall structural stiffness of a bonded assembly. Numbered among the techniques are:

1. Sonic methods, such as coin-tapping
2. Ultrasonic methods
3. Acoustic emission

4. Thermography
5. Radiography
6. Holography.

Methods using ultrasound (2), heat (4) and X-rays (5) have been developed quite successfully for monitoring density variations and disbonds in bonded structures, particularly in sandwich panels. Advances in such techniques have been spurred on mainly by aircraft industry requirements for production control and regular inspection of airframe integrity.

16.5 Casting and foundry practice

16.5.1 Introduction

Casting has significant advantages compared with other methods of component manufacture. Castings are generally cheaper than components made in other ways. The casting process in one or other of its forms provides the designer with an unrestricted choice of shape made in a single stage. A casting can usually be made much closer to the chosen design, which provides savings in both material and finishing processes compared with other methods of manufacture. In addition, the cast structure has the highest resistance to deformation at elevated temperatures so that castings have higher creep strengths than wrought and fabricated components. This advantage can be enhanced by modifying and aligning solidification to produce highly creep-resistant structures such as bundles of crystals with one crystallographic axis oriented lengthwise or single crystals (see Chapter 7, Section 7.4 non-ferrous metals). Cast metal may also have superior wear resistance than the equivalent forged metal. These advantages have combined to ensure that casting has become the most important process for the manufacture of components in metals (and in some other materials).

Castings may be cast in one of a variety of 'sand' moulds formed around a pattern and classified as 'sand castings'; in one of a variety of moulds formed around a fusible wax pattern and classified as 'precision' or 'lost wax' castings; in a metal mould and classified as 'die castings'; or they may be formed by centrifugal force and classified as 'centrifugal castings'. 'Splat' casting produces material with the optimum mechanical properties in the form of small flakes.

Even when casting has not been adopted to generate the shape of a component it may well have entered into the process of manufacture at an earlier state having been used to produce the stock for mechanical working, forging, rolling or extrusion by a process such as 'ingot', 'billet', 'continuous' or 'semi-continuous' casting.

The advantages of castings have, in the past, been offset by significant disadvantages compared with wrought products. Castings are considered to be less ductile than the equivalent wrought product, and they have a less consistent performance in fatigue and inferior integrity. The difference in ductility may be more apparent than real. A forged or rolled component may have a higher ductility than a casting in the direction of forging or rolling but a significantly lower transverse ductility. This is a distinct advantage if the longitudinal direction has to resist the principal stress but it is not necessarily a sign of inferiority of the casting.

However, some of the problems concerned with brittleness, lack of integrity and an inferior and less consistent performance under fatigue loading stem from fundamental difficulties in the casting process. These problems will be highlighted and analysed and the way in which modern developments ameliorate and eliminate them will be indicated in the accounts of individual techniques.

16.5.2 Problems inherent in casting technology

The problems inherent in casting technology may be classified under the headings 'Shrinkage', 'Gas' (originating from metal and mould), 'Coarse structure and segregation', 'Inclusions' (originating from metal and mould) and such defects as 'Cold shuts' where metal streams meet but do not unite, or dimensional errors which arise from movement of cores.

16.5.2.1 Shrinkage and contraction

Metals (with the exception of some alloys of antimony, tin and bismuth) contract in volume when they solidify and continue to contract as they cool to room temperature. If, therefore, a substantial body of metal is located alongside thinner sections which solidify earlier so that it cannot be fed from them that body will shrink by forming external sinks, internal shrinkage cavities or possibly interdendritic voids which may communicate through the walls. The influence of shrinkage cavities on the UTS of A357 alloy is shown in Figure 16.102.[84] If the body is constrained excessively by the mould or by the rest of the casting while its metal is in a hot short condition it will crack. (An alloy is 'hot short' when it comprises solid islands or dendrites surrounded by thin bands of molten metal and therefore has no strength or ductility.) If it has reached a temperature at which it is ductile, it will distort and perhaps fail to clean up during subsequent machining.

Design of components to be cast should therefore, wherever possible, avoid the introduction of isolated relatively heavy sections. Where it has not proved possible to achieve this, casting design should ensure either that such sections are heavily chilled and the flow of metal arranged so that they solidify at the same time as the rest of the casting, or that adequate arrangements are made to feed them by liquid metal channelled to them for this purpose. Interdendritic shrinkage cavities may be present even in cast material which may be considered to have been fed satisfactorily.

Cores should, as far as possible, be made weak enough to give against the contraction stresses imposed by the cast metal and should be removed from the casting as soon as possible after the metal has solidified.

16.5.2.2 Gas

The effect of gas varies with the metal cast. Hydrogen dissolved in molten aluminium may generate cavities of its own but generally increases the size of shrinkage cavities. In steel, hydrogen causes a number of very dangerous effects described in Chapter 7, Section 7.3 (Corrosion). The requirement for good-quality castings demands its complete removal from both metals. Fortunately, hydrogen is reasonably easy to remove from molten metal, in the case of aluminium by bubbling gas through the melt before casting. Figure 16.103

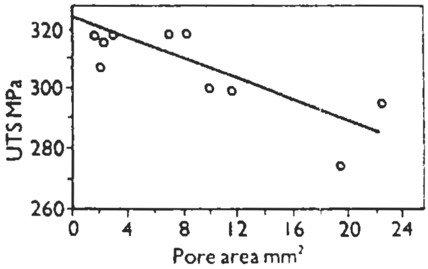

Figure 16.102 Strength of fully heat treateed A357 alloy as a function of maximum observed pore size on the fracture surface

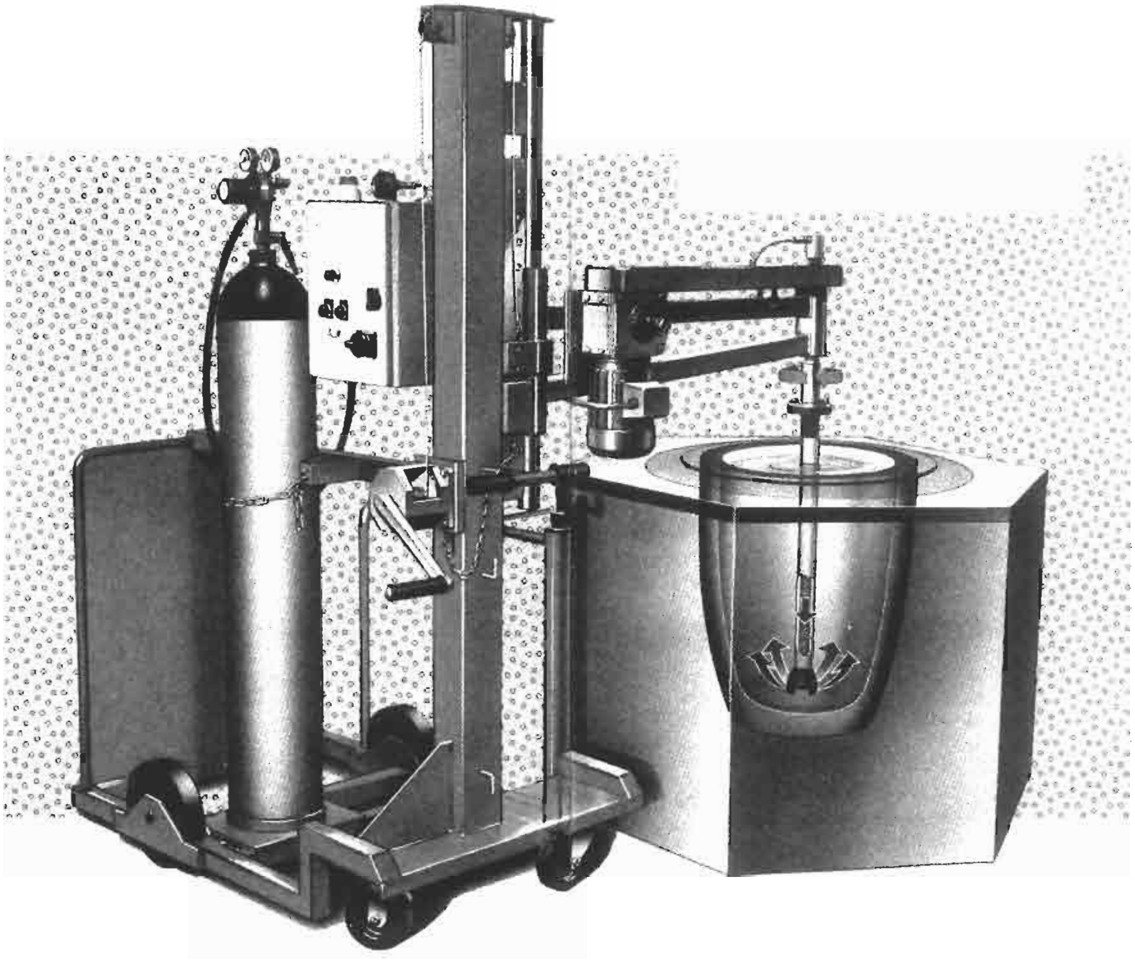

Figure 16.103 Spinning rotor argon lance system for degassing molten aluminium (courtesy of Foseco plc)

shows the arrangement of a spinning rotor argon lance system which, it is claimed, will approximately halve the quantity of hydrogen in 250 kg of molten aluminium in 10 min. Hydrogen is removed from steel by vacuum treatment of the metal in the molten state (see Chapter 7, Section 7.3, Ferrous metals).

Oxygen is removed from molten steel by 'killing' with silicon and/or aluminium. In the case of ingot casting of unkilled or 'rimming' steel advantage is taken of the effect of the bubbles of oxygen evolved when this steel solidifies to neutralize the solidification contraction and eliminate the pipe on the top surface. It therefore becomes possible to forge and roll the whole of the ingot, and not go to the expense of discarding the top 30%, as would have to be done with killed steel.

16.5.2.3 Coarse structure and segregation

Slow cooling of solidifying metal generates a columnar structure of coarse dendrites growing perpendicular to the cooled surface which have (in an alloy with a margin between liquidus and solidus) a lower solute content than the melt. The space between and in advance of the dendrites is therefore enriched in solute (in the case of steel this includes carbon and other alloying agents) and the result is a coarse segregrated structure. The result of variation of cooling rate on tensile properties of A357 alloy is illustrated in Table 16.14[84] and the effect of structural variations on fracture toughness in Figure 16.104.[84] The cooling rate should be the maximum consistent with good feeding and is compared diagrammatically for a selection of casting processes in Table 16.15.

16.5.2.4 Inclusions

Inclusions can originate from oxide formed on the metal surface from slag, flux, from the melting crucible or from the mould and can have just as great an effect on metal properties as pores (see Figure 16.105[84]). Clearly, all possible precautions must be taken during melting to provide as clean a metal as possible. In addition, weirs that trap inclusions should be provided in the runner of the casting and filters which are now available for all types of cast metal can be inserted in the metal stream. Filters not only remove entrained oxide and nonmetallics but will, if strategically placed, eliminate turbulence, the flowing metal on the downstream side emerging as a

Cosworth	242	312	9.8

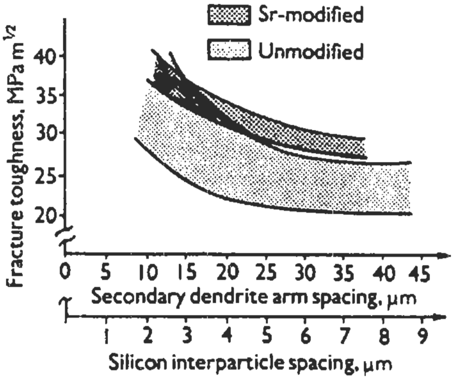

Figure 16.104 Fracture toughness of A357 alloy in castings solidified over a range of cooling rates with and without Sr modification

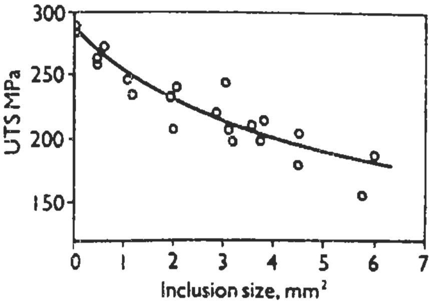

Figure 16.105 Fracture strength of a porosity-free magnesium alloy as a function of inclusion size

smooth coherent flow (see Figure 16.106). Filters restrict metal flows, a filter 50 × 50 × 22 mm gives a flow rate of 6 kg s^{-1} of grey cast iron at 300 mm head. Impingement against the mould wall and consequent entrapment of mould material are avoided.

Upward pouring, as in the low-pressure die casting and Cosworth processes, is a very good solution to this problem because it allows metal to be transferred upwards from below its surface without turbulence, thus minimizing inclusions. Once the casting has been formed the molten metal head is maintained until all parts of the casting have been fed, thus maintaining a reservoir of hot metal as long as required. With top-pouring methods, on the other hand, the top of the feeders may solidify as soon as the casting.

16.5.2.5 *Cold shuts*

'Cold shuts', i.e. locations where two metal streams meet without uniting, must be avoided by good casting design.

16.5.2.6 *Core movement*

Cores are normally of lower density than the surrounding metal and may float when submerged or be displaced by the metal flow. Core prints must be accurate in dimensions and adequate in size. Where necessary, core prints may be provided with steel bushes which fit in corresponding bushes in the mould.

16.5.2.7 *General*

The problems described above have been long appreciated and techniques are being developed which will completely overcome them. These techniques are not necessarily applicable to all metals or to every size and shape of casting, but where they can be applied they will produce castings with consistency in fatigue behaviour adequate for any requirement.

The following sections describe the techniques used to produce castings and stock for mechanical working with particular emphasis on the most recent developments and most advanced processes which provide the highest quality products in the most efficient way. Not every difficulty has been eliminated with every metal and alloy cast, but this account will indicate how castings which will perform fully as well as forgings (and, in some cases, better) can be produced in an increasing proportion of materials.

It is not possible in an account of this length to detail the very large number of variations in casting process which are and have been employed. Where a selection has had to be made the process or variation described is, as far as possible, the most efficient, the most modern, and produces a product

of the highest material quality, mechanical properties, dimensional accuracy and surface finish.

16.5.3 Ingot, billet and slab casting

16.5.3.1 Conventional casting of steel

For many years stock for mechanical working was made by top pouring individual ingots or billets typical of which are the square steel ingots shown in Figure 16.107.[85] During this period great advances have been made in metal treating and handling techniques. Cleaner steelmaking technology, better deoxidation control and secondary steel making in the ladle and the arc furnace have been introduced and furnaces have been designed (for steel and also for aluminium) which yield metal free from both surface and bottom oxides and slag. Hydrogen can be removed from molten steel by vacuum treatment, and from molten aluminium as described above. New types of refractory stoppers, both vertical and sliding, have made it possible to start, stop and control the rate of flow of the casting stream.

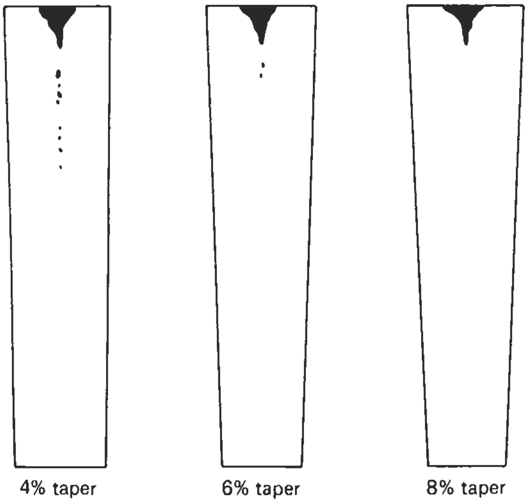

Figure 16.107 Segregation and bridging in typical steel ingots

However good the metal quality, however carefully the dimensions, shape and casting parameters of the ingot were chosen, and however well the ingot was fed (and however effective the measures taken to keep the top of the ingot hot) ingots formed from killed steel developed a pipe (which sometimes bridged) in which was located considerable segregation (see Figures 16.107 and 16.108[85]). There was also usually segregation in a band round the ingot where the columnar crystals which advanced from the surface gave way to the equiaxed structure. Segregation also developed if cracks appeared between the columnar crystals at the surface and material of a higher solute concentration bled out of the cracks. (This formation of blebs enriched in impurity elements also occurred in aluminium ingots.) To avoid vertically orientated surface cracks the perimeter section of large ingot moulds consists of a series of arcs intersecting at cusps.

In a top-poured ingot the metal has to fall to the base of the mould from a height at least equal to that of the top of the mould. The resultant splashing caused surface defects which were so serious that stainless steel ingots, where surface quality is paramount, used to be bottom poured in spite of the increase in pipe and segregation which resulted. The combined effects of pipe, segregation surface defects and cracking of individually cast ingots resulted in a substantial proportion of metal being discarded. The introduction of continuous (and semi-continuous) casting proved so effective in overcoming these defects that this process is rapidly displacing individual casting in steel (see Figure 16.109[86]) and other metals.

16.5.3.2 Continuous casting of steel

Billets, blooms, slabs, thin slabs and strip may be continuously cast. Continuous casting eliminates longitudinal segregation and for billet and bloom casting horizontal segregation may be reduced or eliminated by electromagnetic stirring of liquid steel in the mould (M-EMS), in the strand (S-EMS) and/or in the final stage of solidification (F-EMS). (Centreline segregation may, however, be a problem in slab where electromagnetic stirring is difficult to apply.) Defects in quality are therefore restricted to surface defects, including cracking, possible internal cracks and inclusions derived from nonmetallic particles carried in the molten metal.

The practices and techniques devised to improve the efficiency of a continuous slab casting machine may be described with reference to Figure 16.110,[87] which shows a continuous slab casting machine with hot connection facility. Reoxidation of the steel stream from ladle to tundish and from tundish to mould is prevented by using a ladle shroud, a submerged entry nozzle, and by flooding with argon. Flow from the tundish to the mould is controlled by replaceable stoppers. The tundish design (Figure 16.111[87]) has been improved to give longer residence time, to incorporate weirs and dams and to allow bubbling of inert gas through porous plugs located at the bottom to improve flotation and removal of inclusions. Tundish level control has been made automatic and the tundish can be heated for start-up.

Flow control from ladle to tundish and from tundish to mould has been integrated and automated, and level in the mould controlled by a duplex electromagnetic/radioactive system. The metal in the mould is protected and the metal mould interface lubricated by a 50 mm layer of 'black powder'.[88] This is the name given to a series of proprietary fluxes probably containing calcium silicate and fluoride and more than one variety of carbon. The geometry of the particles and

the distribution of their constituents is more critical to performance than their composition. Hollow sphere granules with carbon concentrated on the exterior maintain good insulation until the granules melt and then the flux lubricates the mould/strand interface.

Figure 16.112 shows a flux feeder with automatic gravity feeding. The mould is oscillated vertically to prevent the strand shell sticking to the copper mould and causing breakout. Oscillation is controlled hydraulically to give a downstroke synchronized with the strand's downward velocity and an up-stroke giving low 'negative strip' time, thus saving powder consumption and improving lubrication. This gives good surface quality and requires low maintenance. The width of the mould can be changed remotely during slab casting

without impairing surface quality so that a whole variety of product widths may be cast in one stream. Further operational flexibility is obtained by 'link casting', which allows small batches of differing steel grades to be cast without restranding. When a ladle of one grade has been cast a fabricated metal link is partially immersed in the liquid steel and the exposed part becomes enveloped by the steel of another grade from the following ladle.

Additional flexibility is provided by multi-strand casting. Either dividers are fixed in a single-slab mould or individual slab moulds are mounted within one slab machine. The first stage of solidification takes place in the water-cooled copper mould. Air-mist cooling, in which compressed air has been used to atomize spray water to fine droplets, is becoming increasingly adopted, first for slab and more recently for bloom casting. This has the advantage of greater uniformity, higher heat transfer coefficient, less risk of blockage because of the larger outlet orifice, much higher turndown ratio and greater facility for automatic control than water only.

The principles of computer software for dynamic spray control of secondary cooling devised by one manufacturer are shown diagrammatically in Figure 16.113.[87] The same manufacturer has developed a system of quality assurance in real time that assigns quality values to segments of the strand during casting and enables selection of those slabs suitable for direct rolling from those which have to be cooled for inspection and rectification.

In a machine such as that illustrated in Figure 16.110 slabs are bent, straightened and soft reduced while metal in the

interior of the strand is still molten. Complex stresses introduced in these processes may result in problems associated with centreline and spot segregation caused by solute enrichment in certain steels for 'offshore-structural' and 'resistance to hydrogen-induced cracking' plate. These problems are overcome by 'continuous straightening', which applies a constant bending moment over the straightening zone, and special roll design and optimized cooling during soft reduction.[89]

There are two further developments. Direct rolling eliminates a reheating furnace, saves energy, reduces scaling and therefore increases yield and, if it can be automated, may save labour. On the other hand, the rolling mill must be sited near the caster, the slab must be transferred rapidly, edge heating is required and scheduling of production is highly complex. Direct rolling is already practised[90] in certain plants but the compromise procedure, hot linking, in which the slab is cut hot into appropriate lengths, insulated and reheated for rolling before it has fully cooled, is more widespread and provides moderate savings in energy and cost.

Low-head casting will enable a continuous casting machine to be sited in an old ingot casting shop, the low ferrostatic head will reduce bulging strains which lead to internal defects and the smaller machine size will reduce weight and therefore cost.

Near-net shape (15–25 mm thick) and final thickness (1–3 mm thick) strip casting have been the subject of considerable study and processes which may include moving-belt moulds and moving casting belts may be realized in the medium or long term.

16.5.3.3 Continuous casting of aluminium

When continuous casting of aluminium alloys was first introduced it provided a very significant improvement in soundness and fineness of structure compared with the 'can cast' method of ingot production, which was the best previously available. A very large number of systems – some vertical, some horizontal, some utilizing fixed moulds while some depend on casting wheels, bands, segmented moulds or rolls – are summarized in Table 16.16.[91]

Table 16.17[91] places the systems in approximate order of cooling rate and the fineness of structure of the material they produce. The twin-roll and stationary mould strip casters will produce 3–7 m dendritic structures in 12.5 mm thick strip.

16.5.3.4 Continuous casting of other metals

Gold, silver with palladium, copper, bronzes, brasses, zirconium copper, chromium copper, platinum, platinum rhodium nickel, solders, cadmium and cobalt are continuously cast in the following size ranges:

Solid rod 2–300 mm dia.
Strip 1.6 mm thick and up to 1000 m wide
Pipe, bore 30 mm (min), OD 350 mm (max), wall 12 mm min

Throughputs 1000–2800 kg h^{-1} (dependent on diameter) can be achieved.

The casting techniques used are those introduced by Propergi, Haslett, Southwire and Ontokampi. Typical examples of plant are shown in Figure 16.114, which illustrates a Technics Guss or Wertli systems caster for strip 2 cm thick and 60 cm wide, and Figure 16.115, a Rautomead RT650 caster for small-diameter copper and alloy rod. casters and both utilize a graphite tundish or crucible from a hole in the bottom or side of which the molten alloy flows into a high-density polished graphite mould. A protective atmosphere, usually nitrogen, may be maintained around both. Heat is extracted from the mould by a water-cooled copper cooler and the rod or strip is withdrawn intermittently. The key to success is precise control of molten metal temperature, die cooling and withdrawal cycle. Although, unlike in continuous casting of steel, the die is stationary instead of oscillatory, movement of the strand relative to the die is similar, consisting of a rapid pull alternating with a relatively long hold. In the case of the strip caster a pull of 1 cm in 1–2 s alternates with a hold of 2–4 s and overall strip production is 10–15 cm per minute.

Higher casting speeds are possible with the quick withdrawals which can be obtained with a pneumatic-activated pulsed movement via a 'sprag clutch' to feed rolls (see Figure 16.116[92]) and a supercooler heat sink (see Figure 16.117[92]). It is not possible in an account of this length to discuss cooler/strand relationships but Figure 16.118[92,93] gives some idea of the variations in cooling rate. Secondary cooling after the mould may be used to avoid solid-state reactions such as precipitation in alloys where this may occur.

16.5.3.5 Semi-continuous casting

Semi-continuous casting processes ('vacuum arc remelting' and 'electroslag remelting') are employed to produce very high quality stock for mechanical working. In both, one or more cast or forged billets are made into one electrode (where three parallel electrodes are employed three-phase current may be used). The electrode(s) are fed downwards and as they melt, the metal melted by the arc (or by the heat generated by the resistance of a bath of slag) is transferred downwards to the other electrode which is located in a cylindrical water-cooled copper vessel.

In vacuum arc remelting (see Figure 16.119) the arc is contained in a vacuum and the consumable electrode is fed downwards through a seal which retains the vacuum. In electroslag remelting (see Figure 16.120) a bath of fused slag is retained above the other electrode in the copper vessel. In both cases, after the start continuous casting and cooling and feeding conditions exist in the bath of metal which is formed, and climbs continuously up inside the vessel. The resulting billet which is fed and rapidly cooled during solidification is the best stock that can be produced for mechanical working.

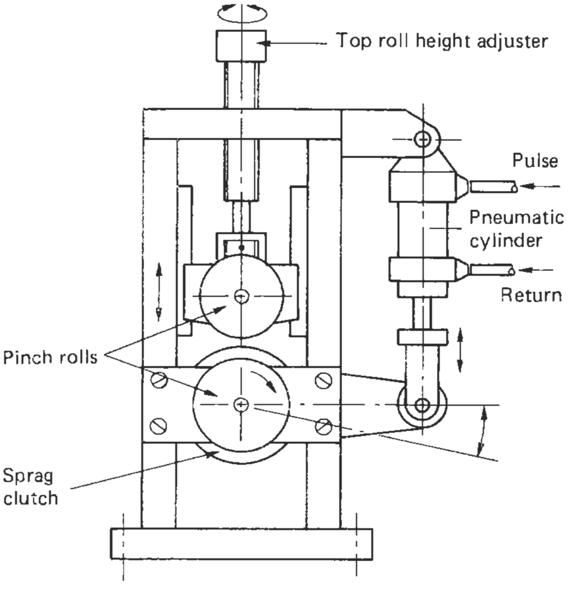

Figure 16.116 Runtomead quick pneumatic withdrawal mechanism providing square/box curve withdrawal

Electroslag remelting refines the metal by dissolving such non-metallics as alumina in the flux. Vacuum arc remelting breaks and disperses non-metallic inclusions but does not remove them completely. It does, however, completely remove gaseous impurities such as hydrogen and oxygen from steel.

In general, electroslag remelting is used for steel and nickel and cobalt alloys, vacuum arc remelting for refractory metals, titanium, zirconium, tantalum and molybdenum, but it is also used for steel and nickel alloys.

16.5.4 Sand casting

In sand casting, of which there are many variants, molten metal is poured into a sand 'mould' which defines the exterior shape (including any re-entrant surfaces) of the component. 'Cores' also formed of sand define the interior.

The components of the mould of which there are usually two, the 'cope' and the 'drag', are moulded in sand around 'patterns' and the cores are made in 'core boxes'. Very simple examples of patterns and core box which might be used for hand moulding of the pipe connection (Figure 16.121(a)) are shown in Figures 16.121(b) and (c). Usually each section of the pattern is mounted on a 'moulding board' as shown in Figure 16.122(a). In the moulding board are drilled two holes which register with corresponding holes in the other pattern section assembly and with 'moulding flasks' also shown in Figure 16.122(a). Alignment of the moulding board and pattern is maintained with the flask by means of 'moulding pins' which fit the holes accurately. The flask is filled with moulding sand, which is compacted and levelled off with the top of the flask, which is then turned over to form the 'drag' or bottom section of the mould. The pattern is lifted out vertically and the core, which has been made of sand blown into the core box and hardened, is placed in the mould supported in 'core prints' which are formed by the extensions to the pattern shown in Figure 16.121(b).

The 'cope', the other section of the mould which has been prepared in the same way, is placed on top of the drag and aligned by means of moulding pins. Molten metal is introduced into the mould by means of channels (described later).

After the metal has solidified, the casting is removed from the mould, shaken and brushed to remove sand (which if it should have stuck to the casting must be scraped or ground off) and runners, risers and feeders appended to it for the purposes of casting 'fettled' off. The procedure described imposes certain geometrical constraints on the shape which can be cast.

16.5.4.1 Geometrical considerations

The pattern must be capable of being withdrawn vertically from the mould. Each nominally vertical surface must therefore be given a draft to facilitate this withdrawal and, if a two-part mould only is to be used, no pattern can contain an overhang.

When, as is the case with the three-arm flanged connection shown in Figure 16.123, the design provides for an overhanging flange, whichever way the component is moulded one of the flanges will prevent withdrawal of the pattern. The problem may be overcome by blocking off the overhanging part of

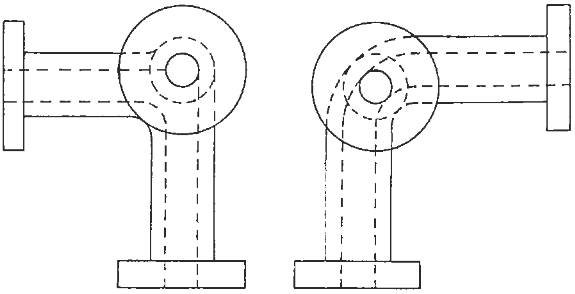

Figure 16.123 Pipe connection elbow with three arms at right angles so that one of the flanges will give difficulty in moulding

the pattern with a 'core print' (see Figure 16.124(a)) and making a core which forms the shape blocked off and itself fits into this core print.

Although simple and neat, this is not a perfect solution. Some draft for which permission must be obtained from the designer must be allowed on the vertical arm of the connection and, as the position stands, with a flat top to the core the top flange will form a sharp angle with the pipe. Such a sharp edge will constitute a stress concentration in operation but, more seriously, may cause cracking or shrinkage cavities as the casting solidifies.

There are other ways of overcoming overhangs including:

1. The use of a three-part pattern and mould.
2. The use of a cover core (Figure 16.125(b)). These methods are to be avoided if possible because they are difficult to mechanize.
3. The incorporation into the pattern of segmented loose pieces (Figure 16.125(c)).

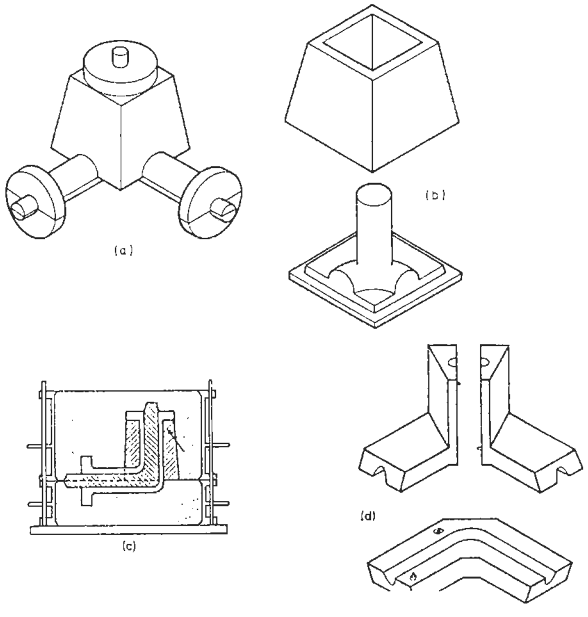

Figure 16.124 Using a core. (a) Pattern with a case joint to overcome difficulty in moulding the flange. (b) Two parts of a simple core box to produce the core. (c) Arrangement of mould and core box. (d) Core box for centre core

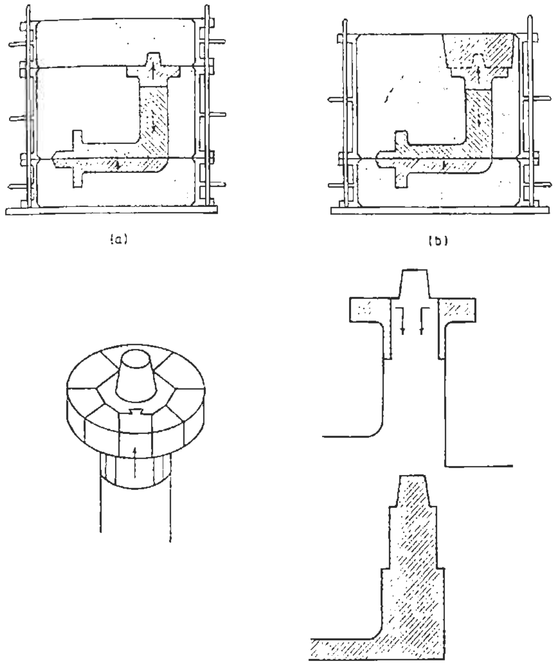

Figure 16.125 (a) Three-part pattern and mould. The arrows show the direction of pattern part removal. (b) Three-part pattern and two-part mould. Arrows again indicate the direction of removal and the broken lines where the cover core will be replaced

This method introduces a significant amount of hand work into what should be a simple mechanized process. Also, sand compaction under the overhang may be inadequate and the act of removing segments may damage the mould. A much more satisfactory procedure is to modify the design of the casting to eliminate overhangs. The pipe connection in Figure 16.123 might have been designed as a T to align all the flanges in one plane. Some other examples[94] are shown in Figures 16.126 and 16.127.

The need to provide for pattern withdrawal is not the only constraint in casting design. Cores are subjected to flow and buoyancy forces imposed by the molten metal, and the design of the casting must be such that it is possible to support them. Figure 16.128 gives examples of designs which respectively make it difficult and easy to provide such support. Design (b) also makes it easier to provide for the escape of gas evolved during casting.

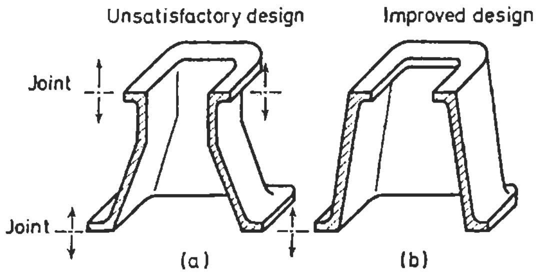

Figure 16.126 Design modification to eliminate a joint

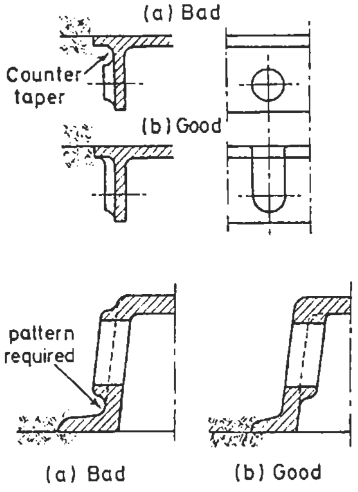

Figure 16.127 Modifications to simplify moulding of small projecting bosses

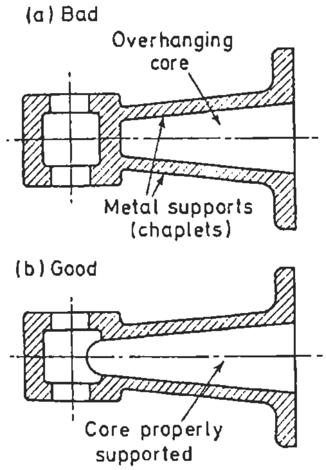

Figure 16.128 Alteration to the design not only gives more support to the core but also improves core venting

16.5.4.2 Running and feeding

In conventional sand casting metal is poured into a 'pouring basin' and enters the casting via a 'sprue' or 'downgate', a runner bar and a number of 'ingates' (see Figure 16.129). The objective is to introduce metal as smoothly and as free from turbulence as possible, so that it fills up and then solidifies uniformly and simultaneously upwards from the bottom of the casting over as wide an area as possible thus minimizing differential contractions. It solidifies last in the feeding heads which therefore contain all the shrinkage cavities. The 'pouring basin' helps to equalize the flow into the downgate and, it is hoped, traps slag or dross.

The 'sprue' or 'downgate' is a component of the runner system necessary to connect the pouring basin (which must be at the top of the cope) to the runner bar (which must usually be at the level of the parting line). It may be tapered from the top to the bottom to allow for the effect of gravity increasing

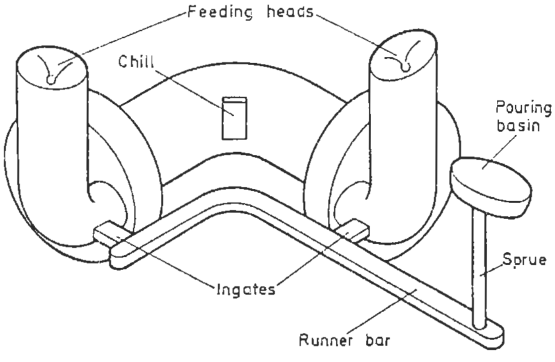

Figure 16.129 Components of a running and feeding system

the rate of flow downwards. Pouring basin and sprue are milled into the mould after moulding is completed.

The 'runner bar' is usually moulded into the face of the cope and the drag, and should extend almost all the way round the casting. It is both larger in section than the sprue (to promote a smooth flow) and the total section of the ingates (to ensure as far as possible that metal flows through them all at the same time). Filters, weirs and spinners are provided for preference between the sprue and the start of the runner bar to trap slag and dross. The correct size and position of the ingates is vital to the success of the casting and may vary according to the metal cast. A recommended design for magnesium is shown in Figure 16.130[94]. This metal has a low heat capacity and solidifies quickly. For this reason, the rule that the cross-section of the ingates is less than that of the runner does not hold for this metal. Filling must be rapid enough to ensure that the casting fills while the metal is molten without resorting to unreasonably high temperature.

Ideally, for all materials (with the exception of a few alloys, which include tin bronze) the aim is to get the whole of the casting to fill with metal while it is liquid. It will then solidify progressively from the thin sections remote from the feeders and the metal will remain liquid last in the feeder heads at the top.

This can be achieved best by placing the ingates into or next to the base of the feeder heads (as in Figure 16.129). If a flange has been placed in between a feeder and an intermediate section its roots should be chamfered. Otherwise a well of liquid metal heated from the other side of the flange will persist until the metal round it has solidified to form a shrinkage cavity. Feeder heads should be larger than the sections they have to feed, and if they are internal to the mould they should be equipped with exothermic devices to keep them hot.

The majority of castings are poured from small solidification range alloys which tend to form skins of solid metal and shrinkage cavities which have to be 'chased' into the feeders. Those alloys which have large solidification ranges form dispersed porosity. This must be overcome by modifying the temperature gradient by control of the casting temperature, by gating and by the use of chills to produce directional solidification.

However, with some alloys (including tin bronzes) the skin of the casting solidifies with such a steep temperature gradient that it is free from shrinkage, and the microporosity goes to the centre of the section and cannot be chased into a feeder. In this case the foundry worker avoids directional solidification which might concentrate porosity in one part of the casting and encourages an even rate of solidification throughout the casting. In all other cases the design engineer should do his or her best to assist the foundry worker to achieve directional solidification. If possible, section thickness should increase smoothly to some point (probably a flange) which is conveniently fed. Thick sections, isolated in the centre of thinner sections, will cause difficulties. Sharp corners and re-entrant angles will cause shrinkage, puncturing and cracks, and this is accentuated by variation in section.

The way in which various types of junction give rise to increases in mass is illustrated in Figure 16.131,[95] and the way in which they can be lightened and made more flexible by staggering is shown in Figure 16.132.[95] The development of

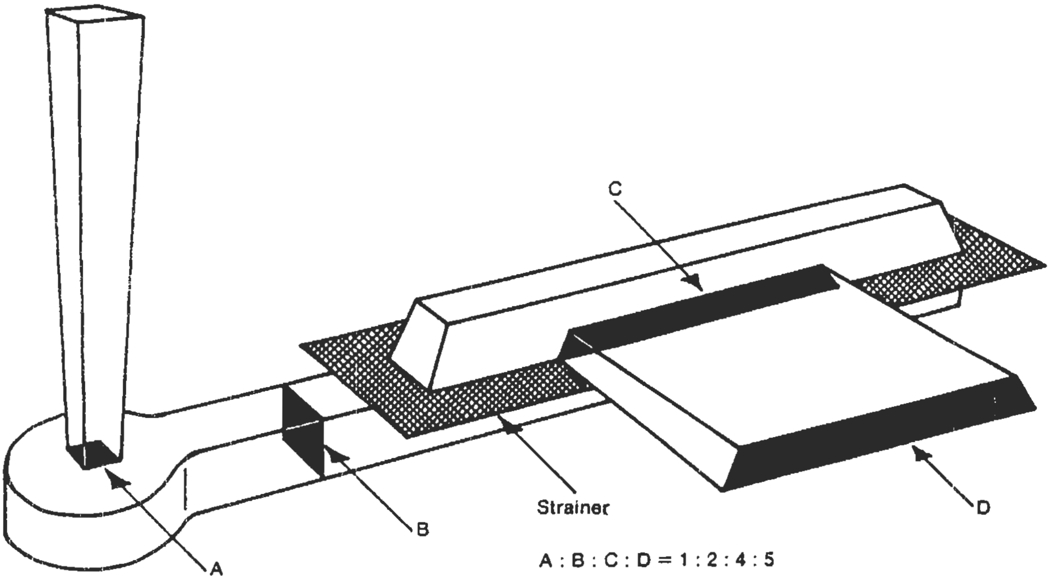

Figure 16.130 Design of gating system for magnesium

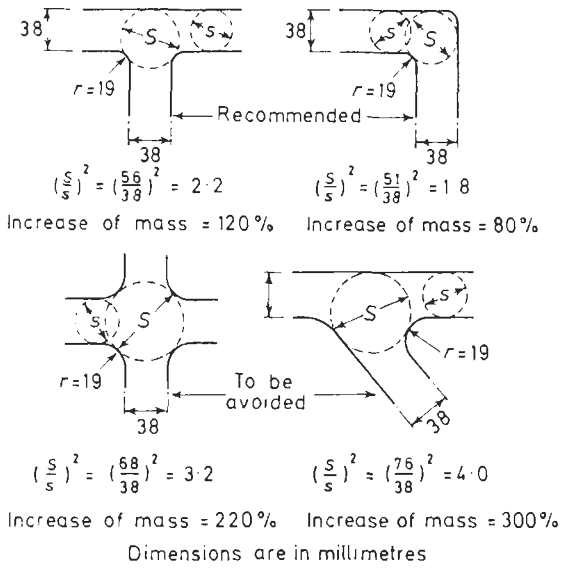

Figure 16.131 Increase in mass at various types of junction

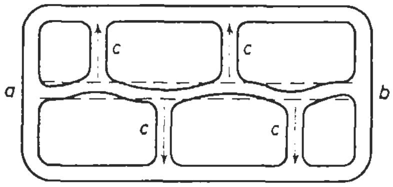

Figure 16.132 Staggering of ribs prevents the increase of section at junctions, reducing shrinkage problems, and also allows easier deformation to reduce the tendency to crack

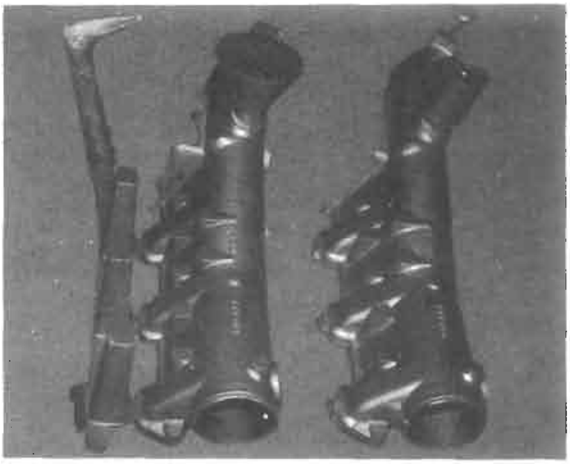

Figure 16.133 Sand cast aluminium alloy inlet manifold. The casting on the left requires a 3 kg running system and a 2 kg riser. On the right the same casting passed through a Dypur unit has a 1 kg riser and needs no running system

the type of filter shown in Figure 16.106 has raised the possibility that the entire gating system may be dispensed with. It is claimed that if a ceramic foam system is placed in a convenient riser as close as possible to the mould cavity, gravity, die and sand castings in aluminium, magnesium and some copper alloys may be direct poured to produce higher-quality casting and save substantial quantities of metal. Figure 16.133 compares an aluminium alloy manifold poured through a conventional running system and through a 'Dypur' filter unit.

16.5.4.3 Modern sand handling and moulding procedures

The traditional mould material for sand casting has been silica sand possibly with a natural binder – new for the facing sand, and recycled to form the backing sand. This is not a well-controlled material and optimum moulding and core-making performance requires precise control of grain size, binder and, where appropriate, water content.

Sand reclamation The precision material required by a modern foundry requires a reclamation plant that will return pure, dry, uncoated, dust-free particles for mixing and moulding. There are two basic processes: one attrites the sand and burns off residual binders; the other relies on dynamic impulses, grain against grain, that rub off binder coatings and remove them as dust (see Figure 16.134). In either case, 1% of sand only is lost.

The small usage of sand allows an alternative to silica sand to be used. Zircon sand with 99% reclamation gives lower cost than silica sand used conventionally. The heat capacity of the zircon sand produces a finer cast structure giving solidification rates in aluminium equivalent to those in permanent moulds. Zircon sand is more satisfactory for service with higher melting point materials. The thermal expansion of zircon sand is (see Figure 16.135) smaller and more consistent than that of silica, and the lower tolerances which result promote savings in weight of casting and finished component. Metred amounts of various kinds of binder (see below) are added.

Moulding The processes used for sand moulding include squeeze, jolt, jolt squeeze and sand sling. A method which is claimed to give the most uniform and accurate compaction is the air impact process (see Figure 16.136). This process takes a metered quantity of sand to which bentonite clay has been added.

Modern core-making processes Core-making differs from moulding because the core must be transferred into the mould, and must therefore be strong enough to be free standing while this process is carried out. (Typical cores are shown in Figure 16.137.)

Originally, cores were of silica sand bonded with molasses and linseed oil with bentonite to provide green strength for handling. Cores were packed in sand and baked to develop dry strength and to remove gases which would be evolved in heating.

The most modern development is to use a small precise addition of resin binder to recovered sand. Figure 16.138 illustrates a typical plant arrangement. A metered quantity of mixed sand is blown into a core box, the two halves of which are clamped together hydraulically. After filling, the binder is cured either by heat from a hot core box or by introducing an

amine gas accelerator. Both processes are rapid. Up to 80 cores an hour can be made by the cold process on a machine of the type illustrated and the tolerances of the finished castings are the most precise that can be achieved by sand casting (see below). Cores may be located into the moulds either by a steel pin and bush system or by engineered sand to sand locations.

Dressings for mould and core The size of the grains of a moulding sand is a compromise. A large grain size is desirable so that gases evolved near the mould surface are able to diffuse away and not cause blowholes in the casting. A small grain size is required to produce a good surface finish. Where these objectives are incompatible a dressing must be applied to the surface of the mould or core. This can consist essentially of a finer-grain version of the moulding sand but, where a high melting point metal is to be cast, the use of a highly refractory base such as zircon flour has the great advantage of preventing 'burn-on' of the mould onto the casting.

There are a number of proprietary dressings, mostly consisting of suspensions of refractory powders in liquid, which can

Figure 16.138 A typical core-making system suitable for hot or cold process (courtesy of George Fischer)

be sprayed or brushed onto the mould. It is essential to ensure that the mould is dried after the dressing has been applied.

A recently developed process which is claimed to give satisfactory results projects a dry powder based on zircon sand towards the mould surface by means of a gun. This charges the particles electrically by contact with its barrel and thereby ensures a uniform adherent coating by electrostatic charge.

16.5.4.4 Specific sand casting processes

Green sand casting Green sand casting uses a clay bonded sand as described above for the mould, with (where required) a dry sand core. The process is very versatile in the range of materials cast, size and shape of castings, and quantities required. It is also economical and production can start as soon as a pattern becomes available. The sand must be a compromise between the best possible finish, which requires a fine grade, and the possibility of gas evolved from the mould causing blowholes, which requires a relatively coarse grade (unless a mould dressing, which requires an additional, probably manual process, is used) – see above.

Core assembly processes The core assembly process is similar to green sand but the mould consists of one or more cores made as described above. The 'mould' is stronger and tolerates long, thin projections. There is less risk of gas evolution which may cause blowholes than from a green sand mould. However, a number of cores cost more to produce and assemble than a mould which consists only of a cope and drag and more parting line flash may result.

Cold set sand mould With the introduction of cold catalyst hardening resins the distinction between mould and core has vanished (except in the actual geometry of production). The tolerances which can be worked to are the smallest of any sand casting process. For aluminium cast in zircon sand tolerances are as low as

+0.15 mm up to 100 mm
+0.20 mm up to 300 mm
+0.25 mm up to 800 mm
+0.10 mm across each core joint.

These close tolerances permit much greater precision in design and make possible substantial savings in weight of finished component, in weight of metal cast and also in cost of finishing processes.

The Cosworth Process[96] The Cosworth Process, developed for aluminium but equally applicable to magnesium and zinc alloys, takes advantage of the close tolerances and high cooling rate conferred by zircon sand and cold setting resin mould and core systems. It uses them in conjunction with an upward pouring system (see Figure 16.139).

Molten metal is held in a large holding furnace which smooths out variations in temperature and analysis. Metal is degassed by bubbling through inert gas at the ingot charging station, and the metal is held under inert gas. Oxide particles and inclusions are separated by floating or sinking. The mould is filled from below by means of an electromagnetic pump. Metal enters the casting smoothly and without turbulence, and the pressure head is maintained during feeding. When feeding is complete, the pressure head is removed and the liquid metal, in what in a conventional casting would be the feeder head, runs back into the bath. This results in a greatly improved metal yield.

To summarize, the advantages claimed for the Cosworth Process compared with the conventional green sand casting process are:

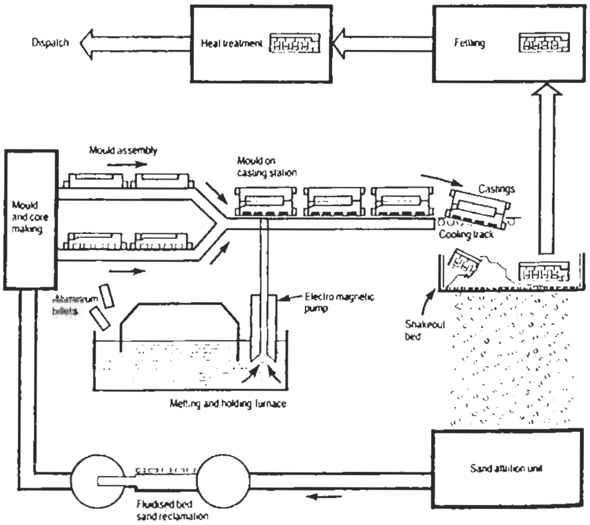

Figure 16.139 The casting unit of the Cosworth Process

- A finer metal structure with tensile strength improved by 30% and elongation almost doubled.
- Improved integrity, pressure-tightness and freedom from porosity inclusions and casting defects.
- Increased dimensional accuracy which results in saving metal, component weight and machining time.
- Additional saving in metal melted because metal in runners and feeders is saved.

Premium-quality castings It has been claimed that metal quality in aluminium castings may be further improved by varying the composition of the material of the mould (so that very high cooling rates are obtained locally) and by optimizing gating and feeding. By these means, castings have been produced with properties equivalent to those of forgings, but they are very expensive.

Other sand casting processes Green sand and core assembly processes produce the vast bulk of sand castings but there are a number of other processes which require mention because they have been, and in some cases still are, extensively used. They are:

1. *Dry sand moulding*: This process starts with a green sand mould which is baked in a stove (or by blowtorches) until it becomes hard. It was used in the past for moulds for very large castings in which the metal pressure might wash away green sand mould material. Drying also makes sure that moisture does not cause blowholes. Dry sand moulding has almost been superseded by the development of high-pressure moulding which confers the requisite strength on green sand.
2. *Loam moulding*: Loam moulding uses very moist green sand which, instead of being formed on a pattern which is relatively expensive and time consuming to manufacture, is formed to a profile against a 'strickle' which is rotated on a spindle. The mould is later dried to remove excess moisture.

Randupson process The Randupson process uses a mixture of sand with cement and water for larger sized castings. The moulds take about 24 hours to harden and the material can be crushed and re-used. However, this causes a substantial dust hazard.

Sodium silicate process This is a cold-hardening process which bonds the sand with sodium silicate that is hardened by passing CO_2 through the mould. The process is used for both moulds and cores and has been developed by adding hardening agents such as glyceryl acetate, cement, ferro-silicon and calcium silicate to the sand immediately before moulding. The process gives higher strength than green sand without the need for storing. Tolerances are better than for green sand, production rate is high and materials are cheap. Steel castings may tend to burn-on, cores are difficult to knock out and there is a problem with dust.

Fluid and castable sand process Sand with sodium silicate and a self-setting agent is suspended in a detergent foam poured around the pattern and allowed to set. No ramming or drying is necessary because of the low water content of the sand, but the process can only be used for simple shaped castings. The mould needs dressing to produce a satisfactory finish and a licence is required to operate the process.

16.5.4.5 Expendable pattern processes

A number of casting processes derive the shape of the finished casting not from a re-usable pattern but from a material which is removed by the action of heat before or during casting. This eliminates the limitations which arise from the need to withdraw a pattern. The mould (or shell, see below) can be made in one piece so that drafts can be eliminated (unless they are needed to make the pattern which may, however, be flexible). Parting-line mismatch and flash are eliminated, and undercuts are easier to deal with.

On the other hand, the operation of making the pattern occurs once for every casting instead of once per component design. This may be satisfactory for prototypes, or one-off castings, for which the expendable pattern may be cheap and easy to produce, and for large runs where the expendable pattern is mass produced. The additional operation may prove costly for intermediate quantities.

The full-mould expendable-pattern process This uses lightweight, foamed plastic patterns moulded or machined and, if required, assembled by cementing sections together. The pattern, incorporating runners and risers, is surrounded by any form of cold setting sand, or by dry unbonded sand, and is removed as a vapour by the heat of the incoming metal. This forms an interface with the evaporating plastic and prevents collapse of the mould even though the sand is unbonded.

16.5.4.6 Shell-moulding techniques

These utilize, instead of a solid mould, a shell a few millimetres thick. This may be either one-piece formed around an expendable pattern, or two-piece formed around a solid pattern.

In the 'Croning' process sand coated with a thermosetting resin is projected onto a metal pattern heated to 250°C. After removal from the pattern, the halves of the shell are fixed together, possibly backed with sand or steel shot, and the metal poured.

In the 'Shaw' process the pattern is dip-coated with a mixture of a fine refractory such as sillimanite and ethyl silicate. The bond produced by this mixture is rubbery when green, which makes stripping from the pattern easy. The mould is flash fired to remove alcohol, fired at 800–1000°C and poured.

Both these processes give good reproduction of details and exceptional accuracy of dimensions, so finishing operations are minimized. Patterns are, however, expensive; size of part is limited; and large runs in the order of 500 castings are needed to make them economic.

16.5.4.7 Casting processes incorporating both shell moulding and expendable patterns

'Investment', 'precision' or 'lost wax' casting[97,98] Lost wax casting is employed to produce components to any conceivable shape in nickel, copper, titanium and aluminium alloys, steel and precious metals. It is not limited by the need to withdraw a pattern. There are no mould parting lines and very fine detail may be reproduced. The surface smoothness of the casting is 1–3 μm rms and dimensioned tolerances as low as ISO 10 IT. For a casting process lost wax is expensive but the cost of a finished component (if indeed it can be made in any other way) is competitive.

The manufacture of weapons, tools and ornaments by lost wax casting continued, with only minor changes, for almost 5000 years up to the introduction, in 1932 by Austenal Laboratories Inc., of hydrolysed ethyl silicate binder for quartz dental moulds. Development was intensified early in the Second World War by the requirements for blades first for aircraft turbosuperchargers and later for aircraft turbines. The high creep strength alloys are difficult to forge and machine and cast blades with a structure of equiaxed crystals, columnar crystals with a preferred orientation, or one single crystal[97] have much superior creep resistance to forged blades.

The investment casting process employs a model or pattern of the object to be cast in wax (or an alternative material such as frozen mercury, a low melting point metal or a polymer) which can easily be removed from the mould which is formed round it. The wax pattern(s) may be made in robot moulding machines with up to 100 tonnes clamping pressure and assembled singly or in clusters with casting gates and/or runners and vents. They are next dipped repeatedly in coating materials consisting of refractory slurry and liquid binder.

There has been several variants of coating materials which use either alkaline silica sol or acidic alcoholic hydrolysed ethyl silicate air dried and ammonia set binders. In some processes these two methods are used for alternate coats. At the time of writing, however, the rapid ammonia set process has been most widely adapted. The filler is fine silica for the primary coat. Subsequent coatings have a higher ratio of liquid binder to solid refractory and the gradings become progressively coarser.

Moulds, typically 8 mm thick, are dried at room temperature and then plunged into furnace chambers at 1050°C. This melts the surface wax before the main body has time to expand and, after dewaxing, cures the ceramic mould.

Some aircraft turbine blades require to be cast hollow to permit the passage of cooling air. These are made by forming the wax round a core of strong ceramic the same shape as the cavity required in the cast component. The completed shell mould may be inserted free-standing in the casting furnace or may be supported by dry granular refractory.

The actual casting may be carried out in normal atmosphere, *in vacuo*, or in a protective atmosphere. The pouring and cooling can be varied according to the material structure required[98, 99] (see Chapter 7, Section 7.4). Centrifugal assistance (see Section 16.5.6.3), or mould heating, may be incorporated to give improved casting detail. The ceramic core of a hollow casting is removed by chemical leaching.

In the Middle Ages the lost wax process was used to cast equestrian statues greater than life size, but the great bulk of modern castings are measured in inches. However, integral turbine wheels and vane rings are now cast in one piece and large structural aerospace components can be made in titanium or nickel base alloys.

The 'Replicast 20, 21' ceramic shell process[100] The Replicast process resembles the full mould expendable pattern process in using an expanded polystyrene replica of the required article; and the precision casting process in using a ceramic shell. It has the flexibility of the lost wax process (including absence of parting lines, draft or tapers) but is claimed to be more suitable for larger castings because the patterns are light in weight, cheaper and less liable to distortion and fracture as size increases. In addition, the ceramic shells may be produced thinner (4–6 mm) and therefore cheaper because they are subjected to a much lower stress during removal of the polystyrene than is generated by the removal of wax. The shells are positioned on a box supported by loose sand, vibrated to fill all cavities, and then held under vacuum during casting. It is claimed that a casting can be made within 5 hours of the replica being removed from the die.

Dimensional tolerances and surface finish claimed for the Replicast process compared with other casting processes are illustrated in Figures 16.140 and 16.141. It is claimed that the reduction in casting wall section and the casting-in of the bolt holes of the casting shown in Figure 16.142 gave a weight saving in the castings delivered of 23%. Other benefits which derive from the Replicast process as compared with casting in a green sand mould are:

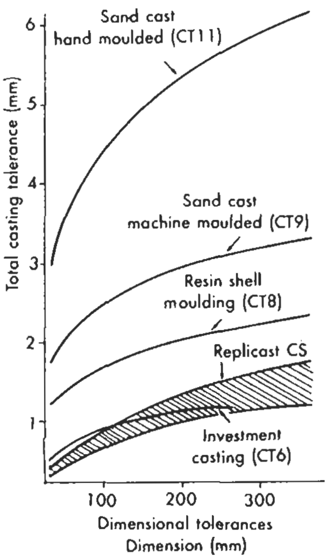

Figure 16.140 Dimensional tolerances achievable with the Replicast process compared with other processes

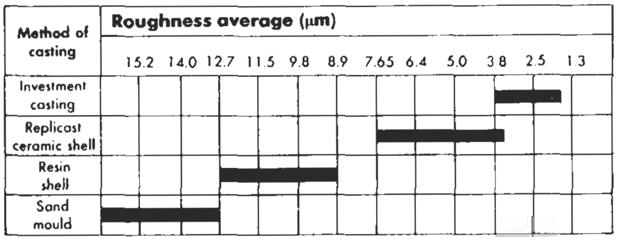

Figure 16.141 Surface finish achievable with the Replicast process compared with other processes

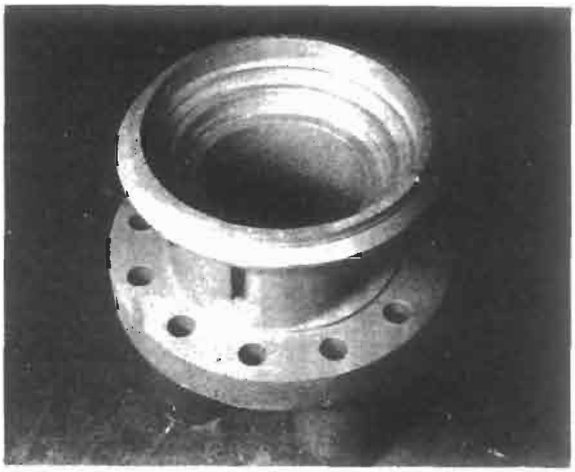

Figure 16.142 Replicast 8-inch ball valve body after shake-out from the mould and fine shot-blasting

1. Improved positioning of feeder heads is possible.
2. The chilling effect of the ceramic enhances feeding and is claimed to eliminate hot tears.
3. The strength and integrity of the ceramic are claimed to eliminate inclusion defects and gas evolution.

The major advantage claimed is, however, the reduction in fettling and machining compared with green sand casting. The limitations and drawbacks are problems in making parts in excess of 250 kg, high labour costs at front-end, higher die costs and a longer lead time for manufacture of new parts. As a consequence, Replicast is best suited to components of fairly complex geometry with stringent acceptance criteria and with a high machining content destined for high-duty applications. The Steel Castings Research and Trade Association (SCRATA) operate a demonstration foundry.

16.5.5 Permanent mould or 'die' casting

Die casting comprises the transfer of molten metal to a die which is a metal block, or assembly of blocks, containing a machined cavity which is the shape of the required casting together with a runner and feeder(s). There may be, inside the cavity, one or more metal or sand cores. Die casting imposes a quicker rate of cooling on the metal as it solidifies than sand casting and produces a finer structure with improved tensile and ductile properties. A dressing is usually applied to the die runner and riser. This may be based on a refractory such as alumina, silica or zirconia where a decreased chill is required, or graphite where a high chill is beneficial. In either case a binder which may be based on sodium silicate is required. The dimensional accuracy of die castings is generally superior to that of sand castings. This leads to savings in metal and machining costs. Most metal alloys can be die cast, but the bulk of die castings are made in metals of medium melting point, mainly alloys of aluminium, zinc and magnesium.

16.5.5.1 Gravity die casting

In gravity die casting molten metal is poured into a die, usually from a hand ladle. Moulds are usually two part split vertically and locked together during casting. Figure 16.143[101] shows one half of a typical die for casting magnesium alloy. The pouring gate is located in the parting line of the die. The junction between the down-sprue and the gate may house either a metal filter or a weir to trap inclusions. The die is filled from the runner and the metal flows in horizontally to the metal in the die cavity to achieve directional solidification. Note that most metals are more fluid than magnesium alloys and will normally require smaller section runners. The feasibility of direct-pouring gravity-lie castings down the feeder using a filter unit such as is shown in Figure 16.106 is worth consideration.

Good mechanical properties significantly superior to those of sand castings can be achieved in well-designed and carefully produced die castings in aluminium, magnesium and zinc. For example, the properties of 'Y alloy' are 275MPa UTS 1% elongation as compared with 220 MPa UTS 0.5% elongation sand cast, and 400MPa 15% elongation wrought.

Gravity die castings may also be made in low melting point alloys, copper alloys and cast iron. The process is not normally applied to steel.

Die castings can be made in weights from 150 g to 200 kg but the optimum is from 1 to 50 kg, section thickness from 3 to 50 mm, ISO dimensional tolerances IT12–14, machining allowance roughly 1 mm, and surface smoothness 2.5–25 μm r.m.s.

16.5.5.2 Low-pressure die casting

Low-pressure die casting bears the same relationship to gravity die castings as the Cosworth process does to conventional sand casting. It also has the same advantages. It was developed initially to improve the quality of gravity die casting in aluminium and zinc alloys, and it could be applied to many other metals. Figure 16.144 illustrates the principle of the process.

The mould or die is sited above a bath of molten metal in a gas-tight chamber. A riser tube extends from well below the surface of the metal to the base of the mould cavity. Metal is constrained to rise smoothly and without turbulence until it completely fills the mould by using the pressure of the atmosphere above the melt, usually less than 69 kNm^{-2}. Solidification contraction is fed from the reservoir of molten metal under pressures in the rider tube. The pressure is released when solidification is complete in the mould and the molten metal in the tube drains back into the furnace.

Figure 16.144 The principles of low-pressure die casting

Feeding is greatly improved compared with gravity die casting because of the improved thermal pattern, and this improves strength and pressure-tightness. The absence of turbulence and the metal source from below the surface reduce the chance of inclusions. Yield is very high (90–95%) because only a small butt of metal requires to be trimmed from the gate. This compares with 40–60% for gravity die casting. The process is very suitable for automation using, if required, multi-cavity moulds. The disadvantage compared with gravity die casting is the higher capital cost of the equipment.

16.5.5.3 High-pressure die casting

Alloys of the majority of metals can be high-pressure die cast. In its best-known form this process is known simply as 'die casting' and is used extensively for alloys of zinc, aluminium and magnesium. It is equally applicable to the low melting point metals tin, lead and cadmium.

The process has recently been extended to enable castings up to 3 kg in weight to be produced in carbon (up to 0.5%C) and stainless steels, copper and copper alloys, cobalt and air-melting grades of nickel alloys. There are three variants of the process: high-pressure cold chamber die casting; high-pressure hot chamber die casting; and the GKN 'Ferro Die' process for casting steel and other relatively high melting point metals.

There are two variants of cold chamber diecasting machine: the horizontal and the vertical, the working principles of which are illustrated in Figures 16.145 and 16.146.[101] In both variants, a metered quantity of metal is poured into the shot sleeve and injected into the die at 5–500 M Nm^{-2} pressure by a piston. When the metal has solidified, the die is opened and the casting ejected. It is desirable in the case of the horizontal machine that the piston should move in two stages; slowly at first to expel air, and quickly when the metal reaches the gate.

In hot chamber die casting (Figure 16.147) the shot tube is located below the surface of a reservoir of liquid metal and fills automatically when the plunger is withdrawn. This greatly increases the rate of production, and, presumably, reduces those defects caused by chill in the shot tube.

The hot chamber machine is simple, easy to operate and permits even higher production rates than the cold chamber machines. It operates at lower pressures and is particularly suitable for thin-walled castings in magnesium alloy and the lower aluminium content zinc alloys. Aluminium and the higher aluminium content zinc alloys attack the parts of the machine with which they come in contact so that they are not really suitable for hot chamber high-pressure die casting.

High-pressure die castings can be made in the weight range 0.1 g to 10 kg. They have an extremely good surface finish and a high dimensional accuracy (ISO tolerance IT 11–14). Smaller wall thicknesses may be cast (magnesium > 1.2 mm, aluminium > 0.7 mm, zinc > 0.2 mm) than by any other casting process. Pressure die castings require very little machining and their machining allowance may be as low as 0.25 mm.

Labour costs are low, but die costs and die preparation times high. Dies last up to 100 000 shots before failing (together with the shot tube and piston) by crazing. The process is only economic for large-scale production.

The most serious disadvantage of high-pressure die castings is the large amount of internal porosity. Castings have a so-called 'skin' 0.1–0.2 mm thick, formed by the rapid freezing of the first metal injected into the die cavity. Beneath this skin can be found spherical gas porosity, interdendritic porosity and 'flow line' porosity (see Figure 16.148[102]) which occurs between the skin and the central region of the casting.

The origin of these defects lies in the shot chamber where chilling of the metal can cause solidification to occur and large agglomerates of solid can cause blockages in the gate region. A chart which may be used to determine the possible causes of

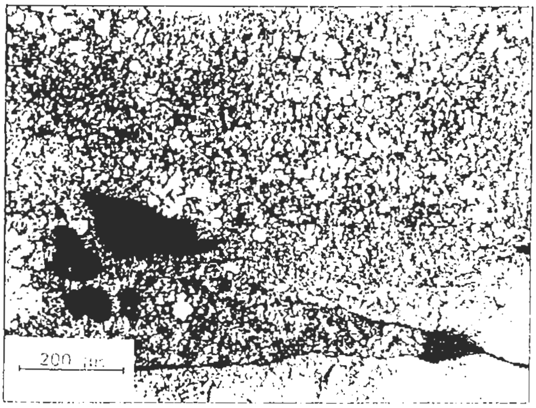

Figure 16.148 Flow line discontinuity with its associated porosity in aluminium alloy pressure die casting

specific defects in magnesium high-pressure die casting is shown in Figure 16.149.[102]

Better properties are achievable by other casting routes and this, and the porosity, limit the useful application of die castings to non-structural components. High-pressure aluminium alloy die castings cannot be heat treated or anodized because the porosity would cause blistering.

In general, high-pressure die castings are used in non-load-bearing situations such as zip fasteners, car door handles and carburettor bodies. Computer printer and other rapidly moving parts are die cast in magnesium alloys.

16.5.5.4 The GKN 'Ferro Die' process

The GKN 'Ferro Die' process is carried out on what is essentially a horizontal cold chamber machine modified by making the parts that come into contact with molten metal (including the die) of molybdenum. The ladle is replaced by a vertical tube furnace heated by an induction coil. A weighed slug of solid metal is placed in the furnace. As soon as the slug melts and falls into the shot tube it is injected into the die. The process is economic for the production of a minimum of 500 castings.

16.5.5.5 Squeeze casting

Squeeze casting gives (pending the development of rheocasting and thixocasting) the most favourable properties obtainable by any method of casting. Squeeze cast products bear comparison in properties with forgings. It has so far been applied to alloys of aluminium and magnesium to manufacture castings and also metal matrix composites.

In squeeze casting the metal being cast is solidified under pressure between metal dies. In 'direct' squeeze casting a metered quantity of molten metal (which must be clean, free from gas and preferably filtered) is poured into the female die casting or mould and the male die is driven into the metal at a controlled speed so that it forms the required shape in a non-turbulent manner. Pressures between 50 and 150 MPa are maintained on the metal while it solidifies. The dies are coated with a graphite coat and heated. The process is illustrated graphically in Figure 16.150.[103]

Direct squeeze casting has the following advantages over all casting processes described so far:

- The resulting casting is completely free from gas and shrinkage porosity.
- The very high cooling rate which the applied pressure facilitates favours control of microstructure by means of temperature control of mould and liquid metal. Very fine-grain structures may be produced without the use of grain-refining additions.
- No feeders or risers are required.

In the indirect squeeze casting process, metal is injected (as in pressure die casting) into the die cavity by a small-diameter piston. One process arrangement is illustrated in Figure 16.151[103], but other methods have been proposed. Unlike pressure die casting, the pressure remains on throughout solidification, which takes place progressively from the part of the casting away from the punch. Although it is more difficult to obtain such good properties as with the direct process, high quality automobile parts have been produced.

In both direct and indirect versions of squeeze casting there are no internal or external defects which require NDT. Mechanical properties are as good (or sometimes better) than those of forgings. The production cycle times for squeeze castings are less by as much as 66% of those for comparable die castings because of the high heat transfer coefficients.

Many aluminium alloys can be produced with very substantially improved properties by squeeze casting. Table 16.18[103] shows how the properties of 7010 alloy vary with squeezing pressure. The effect of grain size on the fracture toughness of this alloy is shown in Figure 16.152.[103]

Figure 16.153[103] shows how the consistency of the SN curve of 70/mm grain size 7010 compares with that of plate material and also the way in which the fatigue strength varies with the grain size.

Figure 16.150 Production of solid ingot and hollow shapes by 'direct' squeeze casting

Magnesium alloys can be fabricated by squeeze casting and Figure 16.154 gives a comparison between squeeze and other casting processes in A91 alloy. The squeeze cast properties are better, but in this and in other cases squeeze casting does not appear to provide an advantage comparable with that obtainable with aluminium alloys. More research is required before the full potential of squeeze casting is realized.

16.5.5.6 Rheo-casting and thixo-casting[104, 105]

In both rheo-casting and 'thixo-casting' a slurry (prepared by stirring an alloy while it is in the semi-solid condition between the solidus and liquidus) is cast. Dendrites which may have formed as the alloy is solidifying are broken up and the slurry flows as a thixotropic liquid whose viscosity decreases as it flows but recovers when it is allowed to stand so that the material stiffens.

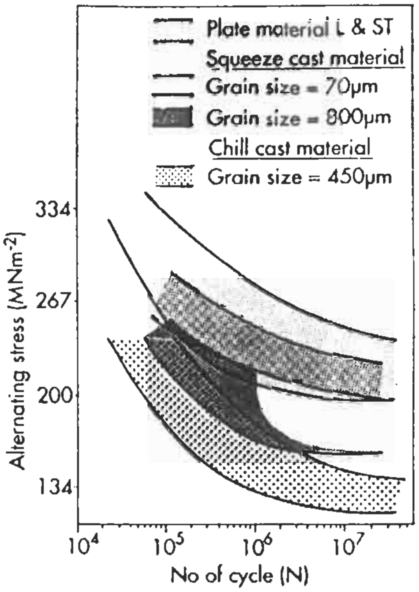

Figure 16.153 *S-N* curves for cast 7010 (peak aged) material and plate material

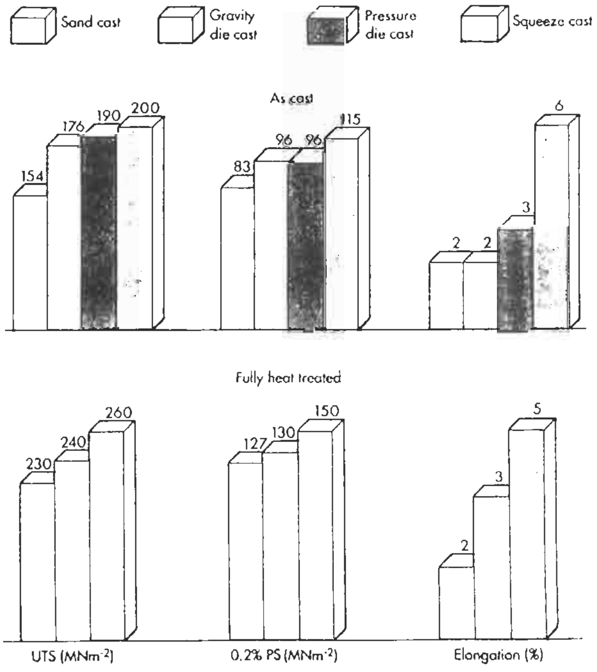

Figure 16.154 Comparison between properties produced by squeeze and other casting processes in A91 alloy

The first slurries produced, containing up to 60% of particles, were formed by mechanical stirring when the alloy had partially solidified. More recently it has been shown[106] that induction electromagnetic stirring will produce the necessary agitation. Slurries may also be prepared by a powder route in which elemental powders are mixed, cold pressed and then heated to a temperature at which an alloy (created by diffusion between the powders) melts. Intermittent stirring may then produce a structure in which spheroidal particles are contained within a liquid matrix.[107] Slurries may also be obtained by deformation, recrystallization and incipient melting and by gas atomizing a fine stream of metal in nitrogen or argon (as in the Osprey process). Whichever process is found to be suitable for the specific alloy will, if successful, produce a fine equiaxed structure which should lead to optimum properties in the resultant casting.

The casting processes are illustrated diagrammatically in Figure 16.155. In rheo-casting a metered quantity of the slurry may be poured directly into the shot chamber of a die-casting machine or into a squeeze casting die. In thixo-casting the slug is allowed to solidify as a billet which is cut up into unit charges. These are reheated to the inter-solidus/liquidus temperature and either die or squeeze cast. (The billet can, of course, be forged instead of cast, but thixo-forging is outside the scope of this section.)

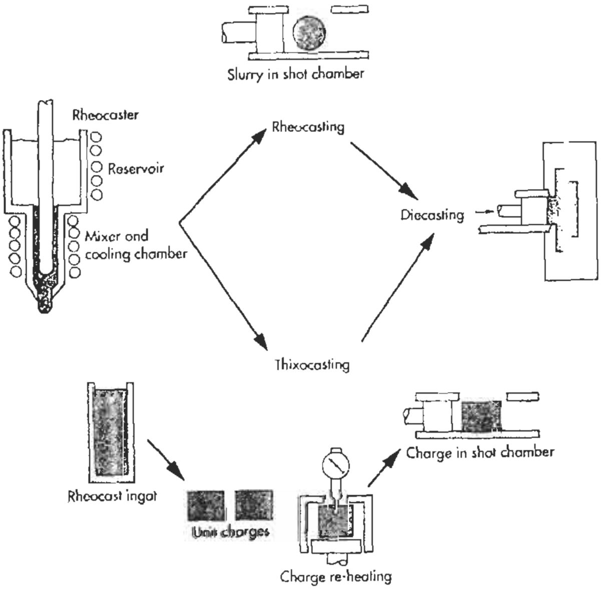

Figure 16.155 Rheo-casting and thixo-casting processes

These casting processes will normally lead to castings with properties significantly better than traditional casting techniques (particularly if thixo-casting is combined with squeeze casting), but there may be additional advantages.

If the powder route is used, the temperature to which the alloy must be heated is lower than if it is completely melted. This greatly eases the duties imposed on furnaces and refractories. This proved to be a great advantage in the manufacture of dental castings in titanium alloys where the temperatures required were about 1250°C as compared with 1650°C for complete melting. The properties of a series of alloys thixo- and conventional-cast are listed in Table 16.19.[108]

16.5.5.7 *Casting metal matrix composites*

Casting processes are among many which have been used for manufacturing metal matrix composites. Conventional casting is used to manufacture particulate alumina and silicon and tungsten carbides in aluminium, and short-fibre and whisker alumina, silicon carbide and carbon in aluminium. The volume fraction is limited to approximately 20% by the increase in viscosity of the molten metal.

Squeeze casting is used for the Toyota car piston[109] as described in Chapter 7, Section 7.6 (Composites). The main problem is the high pressure involved which limits the size and shape produced.

The liquid pressure forming (LPF) process may be used to produce composites with aluminium, magnesium and lead alloys and the reinforcing materials listed in Table 16.20.[109] The process is based on low-pressure die casting and uses gas pressure to force molten metal into a preform housed in a split steel die which has previously been evacuated (see Figure 16.156[109]).

16.5.6 Centrifugal casting processes

Three types of casting process rely on centrifugal force rather than gravity or pressure to impel molten metal into a mould or die. This has the advantage that a force which can be greater than gravity, and which may be increased or decreased at will, is available to run and feed the casting.

16.5.6.1 *Centrifugal casting*

Centrifugal casting produces hollow cylinders (generally of cast iron or steel) by pouring molten metal into a launder projecting into the end of a horizontally or vertically rotating cylinder. This is usually made of steel but sometimes of graphite or ceramic. The metal is held against the mould wall by centrifugal force. Feeding is good and dross tends to migrate to the bore where it can be machined off. Dimensional accuracy is good; production rate is rapid and dimensions range from very large pipes and cylinders to small 'pots' which can be machined to form cylinder liners and piston rings. The

casting shape is, however, limited to cylinders and the equipment is expensive.

16.5.6.2 Semi-centrifugal casting

Semi-centrifugal casting produces rotationally symmetric castings, the moulds for which can be stacked vertically and poured in the common axis while rotating. The centrifugal force available makes this very suitable for pulleys and gear blanks which require the best quality metal on the periphery. This process is very suitable for the production of gears and its use should increase.

16.5.6.3 Centrifugally assisted casting

In this process a number of moulds, often of the investment type, are located symmetrically round a crucible. When the metal has been melted the assembly is rotated at a controlled speed so that the metal runs smoothly into the moulds. When the moulds are filled the speed is increased so that detail is well reproduced and the castings are satisfactorily fed. The process is excellent for casting small articles of jewellery.

17.1 Trigonometric functions and general formulae

17.1.1 Mathematical signs and symbols

Sign, symbol	*Quantity*
$=$	equal to
$\neq$	not equal to
$\equiv$	identically equal to
Δ	corresponds to
$\approx$	approximately equal to
$\rightarrow$	approaches
$\simeq$	asymptotically equal to
$\sim$	proportional to
∞	infinity
$<$	smaller than
$>$	larger than
$\leq \leqslant \leqq$	smaller than or equal to
$\geq \geqslant \geqq$	larger than or equal to
$\ll$	much smaller than
$\gg$	much larger than
$+$	plus
$-$	minus
$\times$	multiplied by
$\frac{a}{b}$; a/b	a divided by b
$\lvert a \rvert$	magnitude of a
a^n	a raised to the power n
$a^{1/2}$; $\sqrt{a}$	square root of a
$a^{1/n}$; $\sqrt[n]{a}$	nth root of a
$\dot{a}\rvert$; $a\rangle$	mean value of a
$p!$	factorial p, $1 \times 2 \times 3 \times \ldots \times p$
$\binom{n}{p}$	*binomial coefficient,* $\frac{n(n-1)\ldots(n-p+1)}{1 \times 2 \times 3 \times \ldots \times p}$
Σ	sum
Π	product
$f(x)$	function f of the variable x
$[f(x)]_a^b$	$f(b)-f(a)$
$\lim\limits_{x \to a} f(x)$; $\lim_{x \to a} f(x)$	the limit to which $f(x)$ tends as x approaches a
Δx	delta x = finite increment of x
δx	delta x = variation of x
$\frac{df}{dx}$; df/dx; $f'(x)$	differential coefficient of $f(x)$ with respect to x
$\frac{d^n f}{dx^n}$; $f^{(n)}(x)$	differential coefficient of order n of $f(x)$
$\frac{\partial f(x,y,\ldots)}{\partial x}$; $\left(\frac{\partial f}{\partial x}\right)_{y\ldots}$	partial differential coefficient of $f(x,y,\ldots)$ with respect to x, when $y\ldots$ are held constant
df	the total differential of f
$\int f(x)dx$	indefinite integral of $f(x)$ with respect to x
$\int_a^b f(x)dx$	definite integral of $f(x)$ from $x=a$ to $x=b$
e	base of natural logarithms
e^x, $\exp x$	e raised to the power x
$\log_a x$	logarithm to the base a of x
$\lg x$; $\log x$; $\log_{10} x$	common (Briggsian) logarithm of x
$\mathrm{lb}\, x$; $\log_2 x$	binary logarithm of x
$\sin x$	sine of x
$\cos x$	cosine of x
$\tan x$; $\mathrm{tg}\, x$	tangent of x
$\cot x$; $\mathrm{ctg}\, x$	cotangent of x
$\sec x$	secant of x
$\mathrm{cosec}\, x$	cosecant of x
$\arcsin x$	arc sine of x
$\arccos x$	arc cosine of x
$\arctan x$, $\mathrm{arctg}\, x$	arc tangent of x
$\mathrm{arccot}\, x$, $\mathrm{arcctg}\, x$	arc cotangent of x
$\mathrm{arcsec}\, x$	arc secant of x
$\mathrm{arcosec}\, x$	arc cosecant of x
$\sinh x$	hyperbolic sine of x
$\cosh x$	hyperbolic cosine of x
$\tanh x$	hyperbolic tangent of x
$\coth x$	hyperbolic cotangent of x
$\mathrm{sech}\, x$	hyperbolic secant of x
$\mathrm{cosech}\, x$	hyperbolic cosecant of x
$\mathrm{arsinh}\, x$	inverse hyperbolic sine of x
$\mathrm{arcosh}\, x$	inverse hyperbolic cosine of x
$\mathrm{artanh}\, x$	inverse hyperbolic tangent of x
$\mathrm{arcoth}\, x$	inverse hyperbolic cotangent of x
$\mathrm{arsech}\, x$	inverse hyperbolic secant of x
$\mathrm{arcosech}\, x$	inverse hyperbolic cosecant of x
i, j	imaginary unity, $i^2 = -1$
$\mathrm{Re}\, z$	real part of z
$\mathrm{Im}\, z$	imaginary part of z
$\lvert z \rvert$	modulus of z
$\arg z$	argument of z
z^*	conjugate of z, complex conjugate of z
$\bar{\mathrm{A}}$, A', A^t	transpose of matrix A
A^*	complex conjugate matrix of matrix A
A^+	Hermitian conjugate matrix of matrix A
$\mathbf{A}$, $\mathbf{a}$	vector
$\lvert\mathbf{A}\rvert$, A	magnitude of vector
$\mathbf{A} \cdot \mathbf{B}$	scalar product
$\mathbf{A} \times \mathbf{B}$, $\mathbf{A} \wedge \mathbf{B}$	vector product
∇	differential vector operator
$\nabla\varphi$, grad φ	gradient of φ
$\nabla \cdot A$, div $\mathbf{A}$	divergence of $\mathbf{A}$
$\nabla\times \mathbf{A}$, $\nabla \wedge \mathbf{A}$ curl $\mathbf{A}$, rot $\mathbf{A}$	curl of $\mathbf{A}$
$\nabla^2\varphi$, $\Delta\varphi$	Laplacian of φ

12.1.2 Trigonometric formulae

$$\sin^2 A + \cos^2 A = \sin A \operatorname{cosec} A = 1$$

$$\sin A = \frac{\cos A}{\cot A} = \frac{1}{\operatorname{cosec} A} = (1 - \cos^2 A)^{1/2}$$

$$\cos A = \frac{\sin A}{\tan A} = \frac{1}{\sec A} = (1 - \sin^2 A)^{1/2}$$

$$\tan A = \frac{\sin A}{\cos A} = \frac{1}{\cot A}$$

$$1 + \tan^2 A = \sec^2 A$$

$$1 + \cot^2 A = \operatorname{cosec}^2 A$$

$$1 - \sin A = \operatorname{coversin} A$$

$$1 - \cos A = \operatorname{versin} A$$

$$\tan \tfrac{1}{2}\theta = t;\ \sin\theta = 2t/(1 + t^2);\ \cos\theta = (1 - t^2)/(1 + t^2)$$

$$\cot A = 1/\tan A$$

$$\sec A = 1/\cos A$$

$$\operatorname{cosec} A = 1/\sin A$$

$$\cos(A \pm B) = \cos A \cos B \mp \sin A \sin B$$

$$\sin(A \pm B) = \sin A \cos B \pm \cos A \sin B$$

$$\tan(A \pm B) = \frac{\tan A \pm \tan B}{1 \mp \tan A \tan B}$$

$$\cot(A \pm B) = \frac{\cot A \cot B \mp 1}{\cot B \pm \cot A}$$

$$\sin A \pm \sin B = 2 \sin \tfrac{1}{2}(A \pm B) \cos \tfrac{1}{2}(A \mp B)$$

$$\cos A + \cos B = 2 \cos \tfrac{1}{2}(A + B) \cos \tfrac{1}{2}(A - B)$$

$$\cos A - \cos B = 2 \sin \tfrac{1}{2}(A + B) \sin \tfrac{1}{2}(B - A)$$

$$\tan A \pm \tan B = \frac{\sin(A \pm B)}{\cos A \cos B}$$

$$\cot A \pm \cot B = \frac{\sin(B \pm A)}{\sin A \sin B}$$

$$\sin 2A = 2 \sin A \cos A$$

$$\cos 2A = \cos^2 A - \sin^2 A = 2\cos^2 A - 1 = 1 - 2\sin^2 A$$

$$\cos^2 A - \sin^2 B = \cos(A + B)\cos(A - B)$$

$$\tan 2A = 2 \tan A/(1 - \tan^2 A)$$

$$\sin \tfrac{1}{2} A = \pm \left(\frac{1 - \cos A}{2}\right)^{1/2}$$

$$\cos \tfrac{1}{2} A = \pm \left(\frac{1 + \cos A}{2}\right)^{1/2}$$

$$\tan \tfrac{1}{2} A = \frac{\sin A}{1 + \cos A}$$

$$\sin^2 A = \tfrac{1}{2}(1 - \cos 2A)$$

$$\cos^2 A = \tfrac{1}{2}(1 + \cos 2A)$$

$$\tan^2 A = \frac{1 - \cos 2A}{1 + \cos 2A}$$

$$\tan \tfrac{1}{2}(A \pm B) = \frac{\sin A \pm \sin B}{\cos A + \cos B}$$

$$\cot \tfrac{1}{2}(A \pm B) = \frac{\sin A \pm \sin B}{\cos B - \cos A}$$

17.1.3 Trigonometric values

Angle	*0°*	*30°*	*45°*	*60°*	*90°*	*180°*	*270°*	*360°*
Radians	0	$\pi/6$	$\pi/4$	$\pi/3$	$\pi/2$	π	$3\pi/2$	2π
Sine	0	$\tfrac{1}{2}$	$\tfrac{1}{2}\sqrt{2}$	$\tfrac{1}{2}\sqrt{3}$	1	0	−1	0
Cosine	1	$\tfrac{1}{2}\sqrt{3}$	$\tfrac{1}{2}\sqrt{2}$	$\tfrac{1}{2}$	0	−1	0	1
Tangent	0	$\tfrac{1}{3}\sqrt{3}$	1	$\sqrt{3}$	∞	0	∞	0

17.1.4 Approximations for small angles

$\sin\theta = \theta - \theta^3/6$; $\cos\theta = 1 - \theta^2/2$; $\tan\theta = \theta + \theta^3/3$; ($\theta$ in radians)

17.1.5 Solution of triangles

$$\frac{\sin A}{a} = \frac{\sin B}{b} = \frac{\sin C}{c};\ \cos A = \frac{b^2 + c^2 - a^2}{2bc}$$

$$\cos B = \frac{c^2 + a^2 - b^2}{2ca};\ \cos C = \frac{a^2 + b^2 - c^2}{2ab}$$

where A, B, C and a, b, c are shown in Figure 17.1. If $s = \tfrac{1}{2}(a + b + c)$

$$\sin\frac{A}{2} = \sqrt{\frac{(s - b)(s - c)}{bc}};\ \sin\frac{B}{2} = \sqrt{\frac{(s - c)(s - a)}{ca}}$$

$$\sin\frac{C}{2} = \sqrt{\frac{(s - a)(s - b)}{ab}}$$

$$\cos\frac{A}{2} = \sqrt{\frac{s(s - a)}{bc}};\ \cos\frac{B}{2} = \sqrt{\frac{(s - b)}{ca}}$$

$$\cos\frac{C}{2} = \sqrt{\frac{s(s - c)}{ab}}$$

$$\tan\frac{A}{2} = \sqrt{\frac{(s - b)(s - c)}{s(s - a)}};\ \tan\frac{B}{2} = \sqrt{\frac{(s - c)(s - a)}{s(s - b)}}$$

$$\tan\frac{C}{2} = \sqrt{\frac{(s - a)(s - b)}{s(s - c)}}$$

17.1.6 Spherical triangle

$$\frac{\sin A}{\sin a} = \frac{\sin B}{\sin b} = \frac{\sin C}{\sin c}$$

$$\cos a = \cos b \cos c + \sin b \sin c \cos A$$

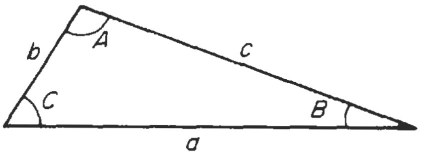

Figure 17.1 Triangle

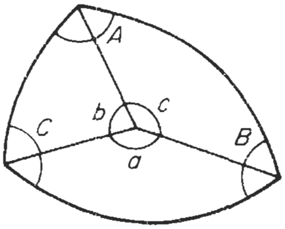

Figure 17.2 Spherical triange

$\cos b = \cos c \cos a + \sin c \sin a \cos B$

$\cos c = \cos a \cos b + \sin a \sin b \cos C$

where A, B, C and a, b, c are now as in Figure 17.2.

17.1.7 Exponential form

$$\sin\theta = \frac{e^{i\theta} - e^{-i\theta}}{2i} \quad \cos\theta = \frac{e^{i\theta} + e^{+i\theta}}{2}$$

$$e^{i\theta} = \cos\theta + i\sin\theta \quad e^{-i\theta} = \cos\theta - i\sin\theta$$

17.1.8 De Moivre's theorem

$$(\cos A + i\sin A)(\cos B + i\sin B) = \cos(A + B) + i\sin(A + B)$$

17.1.9 Euler's relation

$$(\cos\theta + i\sin\theta)^n = \cos n\theta + i\sin n\theta = e^{in\theta}$$

17.1.10 Hyperbolic functions

$\sinh x = (e^x - e^{-x})/2 \quad \cosh x = (e^x + e^{-x})/2$

$\tanh x = \sinh x \cosh x$

Relations between hyperbolic functions can be obtained from the corresponding relations between trigonometric functions by reversing the sign of any term containing the product or implied product of two sines, e.g.:

$\cosh^2 A - \sinh^2 A = 1$

$$\begin{aligned}\cosh 2A &= 2\cosh^2 A - 1 = 1 + 2\sinh^2 A \\ &= \cosh^2 A + \sinh^2 A\end{aligned}$$

$\cosh(A \pm B) = \cosh A \cosh B \pm \sinh A \sinh B$

$\sinh(A \pm B) = \sinh A \cosh B \pm \cosh A \sinh B$

$e^x = \cosh x + \sinh x \quad e^{-x} = \cosh x - \sinh x$

17.1.11 Complex variable

If $z = x + iy$, where x and y are real variables, z is a complex variable and is a function of x and y. z may be represented graphically in an Argand diagram (Figure 17.3).

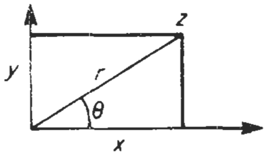

Figure 17.3 Argand diagram

Polar form:

$z = x + iy = |z|(\cos\theta + i\sin\theta)$

$x = r\cos\theta \quad y = r\sin\theta$

where $r = |z|$.

Complex arithmetic:

$z_1 = x_1 + iy_1;\ z_2 = x_2 + iy_2$

$z_1 \pm z_2 = (x_1 \pm x_2) + i(y_1 \pm y_2)$

$z_1 . z_2 = (x_1x_2 - y_1y_2) + i(x_1, y_2 + x_2, y_1)$

Conjugate:

$z^* = x - iy \quad z . z^* = x^2 + y^2 = |z|^2$

Function: another complex variable $w = u + iv$ may be related functionally to z by

$w = u + iv = f(x + iy) = f(z)$

which implies

$u = u(x,y) \quad v = v(x,y)$

e.g.,

$$\begin{aligned}\cosh z = \cosh(x + iy) &= \cosh x \cosh iy + \sinh x \sinh iy \\ &= \cosh x \cos y + i\sinh x \sin y\end{aligned}$$

$u = \cosh x \cos y \qquad v = \sinh x \sin y$

17.1.12 Cauchy–Riemann equations

If $u(x,y)$ and $v(x,y)$ are continuously differentiable with respect to x and y,

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y} \quad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}$$

$w = f(z)$ is continuously differentiable with respect to z and its derivative is

$$f'(z) = \frac{\partial u}{\partial x} + i\frac{\partial v}{\partial x} = \frac{\partial v}{\partial y} - i\frac{\partial u}{\partial y} = \frac{1}{i}\left(\frac{\partial u}{\partial y} + i\frac{\partial v}{\partial y}\right)$$

It is also easy to show that $\nabla^2 u = \nabla^2 v = 0$. Since the transformation from z to w is conformal, the curves u = constant and v = constant intersect each other at right angles, so that one set may be used as equipotentials and the other as field lines in a vector field.

17.1.13 Cauchy's theorem

If $f(z)$ is analytic everywhere inside a region bounded by C and a is a point within C

$$f(a) = \frac{1}{2\pi i}\int_C \frac{f(z)}{z - a}\,dz$$

This formula gives the value of a function at a point in the interior of a closed curve in terms of the values on that curve.

17.1.14 Zeros, poles and residues

If $f(z)$ vanishes at the point z_0 the Taylor series for z in the region of z_0 has its first two terms zero, and perhaps others also: $f(z)$ may then be written

$f(z) = (z - z_0)^n g(z)$

where $g(z_0) \neq 0$. Then $f(z)$ has a *zero* of order n at z_0. The reciprocal

$$q(z) = 1/f(z) = h(z)/(z - z_0)^n$$

where $h(z) = 1/g(z) \neq 0$ at z_0. $q(z)$ becomes infinite at $z = z_0$ and is said to have a *pole* of order n at z_0. $q(z)$ may be expanded in the form

$$q(z) = c_{-n}(z - z_0)^n + \ldots + c_{-1}(z - z_0)^{-1} + c_0 + \ldots$$

where c_{-1} is the *residue* of $q(z)$ at $z = z_0$. From Cauchy's theorem, it may be shown that if a function $f(z)$ is analytic throughout a region enclosed by a curve C except at a finite number of poles, the integral of the function around C has a value of $2\pi i$ times the sum of the residues of the function at its poles within C. This fact can be used to evaluate many definite integrals whose indefinite form cannot be found.

17.1.15 Some standard forms

$$\int_0^{2\pi} e^{\cos\theta} \cos(n\theta - \sin\theta)d\theta = 2\pi/n!$$

$$\int_0^{\infty} \frac{x^{a-1}}{1 + x} dx = \pi \operatorname{cosec} a\pi$$

$$\int_0^{\infty} \frac{\sin\theta}{\theta} d\theta = \frac{\pi}{2}$$

$$\int_0^{\infty} x \exp(-h^2x^2)dx = \frac{1}{2h^2}$$

$$\int_0^{\infty} \frac{x^{a-1}}{1 - x} dx = \pi \cot a\pi$$

$$\int_0^{\infty} \exp(-h^2x^2)dx = \frac{\sqrt{\pi}}{2h}$$

$$\int_0^{\infty} x^2 \exp(-h^2x^2)dx = \frac{\sqrt{\pi}}{4h^3}$$

17.1.16 Coordinate systems

The basic system is the rectangular Cartesian system (x,y,z) to which all other systems are referred. Two other commonly used systems are as follows.

17.1.16.1 Cylindrical coordinates

Coordinates of point P are (x,y,z) or (r,θ,z) (see Figure 17.4), where

$x = r\cos\theta \quad y = r\sin\theta \quad z = z$

In these coordinates the volume element is $r\, dr\, d\theta\, dz$.

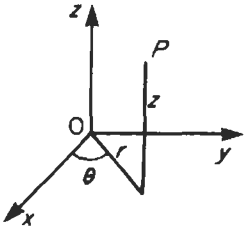

Figure 17.4 Cylindrical coordinates

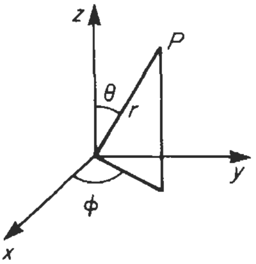

Figure 17.5 Spherical polar coordinates

17.1.16.2 Spherical polar coordinates

Coordinates of point P are (x,y,z) or (r,θ,φ) (see Figure 17.5) where

$x = r\sin\theta\cos\phi \quad y = r\sin\phi\sin\emptyset \quad z = r\cos\theta$

In these coordinates the volume element is $r^2 \sin\theta\, dr\, d\theta\, d\phi$.

17.1.17 Transformation of integrals

$$\iiint f(x,y,z)dx\, dy\, dz = \iiint \varphi(u,v,w)J du\, dv\, dw$$

where

$$J = \begin{vmatrix} \frac{\partial x}{\partial u} & \frac{\partial y}{\partial u} & \frac{\partial z}{\partial u} \\ \frac{\partial x}{\partial v} & \frac{\partial y}{\partial v} & \frac{\partial z}{\partial v} \\ \frac{\partial x}{\partial w} & \frac{\partial y}{\partial w} & \frac{\partial z}{\partial w} \end{vmatrix} = \frac{\partial(x,y,z)}{\partial(u,v,w)}$$

is the Jacobian of the transformation of coordinates. For Cartesian to cylindrical coordinates, $J = r$, and for Cartesian to spherical polars, it is $r^2 \sin\theta$.

17.1.18 Laplace's equation

The equation satisfied by the scalar potential from which a vector field may be derived by taking the gradient is Laplace's equation, written as:

$$\nabla^2\Phi = \frac{\partial^2\Phi}{\partial x^2} + \frac{\partial^2\Phi}{\partial y^2} + \frac{\partial^2\Phi}{\partial z^2} = 0$$

In cylindrical coordinates:

$$\nabla^2\Phi = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial\Phi}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2\Phi}{\partial\theta^2} + \frac{\partial^2\Phi}{\partial z^2}$$

In spherical polars:

$$\nabla^2\Phi = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial\Phi}{\partial r}\right) + \frac{1}{r^2\sin\theta}\frac{\partial\Phi}{\partial\theta} + \frac{1}{r^2\sin^2\theta}\frac{\partial^2\Phi}{\partial\Phi^2}$$

The equation is solved by setting

$$\Phi = U(u)V(u)W(w)$$

in the appropriate form of the equation, separating the variables and solving separately for the three functions, where (u,v,w) is the coordinate system in use.

In Cartesian coordinates, typically the functions are trigonometric, hyperbolic and exponential; in cylindrical coordinates the function of z is exponential, that of θ trigonometric and that of r is a Bessel function. In spherical polars, typically the function of r is a power of r, that of φ is trigonometric, and that of θ is a Legendre function of $\cos\theta$.

17.1.19 Solution of equations

17.1.19.1 Quadratic equation

$$ax^2 - bx + c = 0$$

$$x = -\frac{b}{2a} \pm \frac{\sqrt{b^2 - 4ac}}{2a}$$

In practical calculations if $b^2 > 4ac$, so that the roots are real and unequal, calculate the root of larger modulus first, using the same sign for both terms in the formula, then use the fact that $x_1 x_2 = c/a$ where x_1 and x_2 are the roots. This avoids the severe cancellation of significant digits which may otherwise occur in calculating the smaller root.

For polynomials other than quadratics, and for other functions, several methods of successive approximation are available.

17.1.19.2 Bisection method

By trial find x_0 and x_1 such that $f(x_0)$ and $f(x_1)$ have opposite signs (see Figure 17.6). Set $x_2 = (x_0 + x_1)/2$ and calculate $f(x_2)$. If $f(x_0)f(x_2)$ is positive, the root lies in the interval (x_1,x_2); if negative in the interval (x_0,x_2); and if zero, x_2 is the root. Continue if necessary using the new interval.

17.1.19.3 Regula falsi

By trial, find x_0 and x_1 as for the bisection method; these two values define two points $(x_0,f(x_0))$ and $(x_1,f(x_1))$. The straight line joining these two points cuts the x-axis at the point (see Figure 17.7)

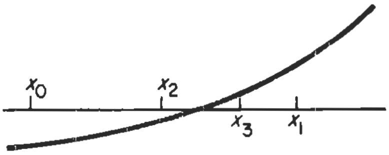

Figure 17.6 Bisection method

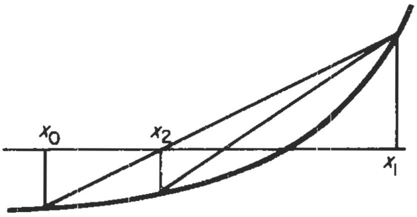

Figure 17.7 Regula falsi

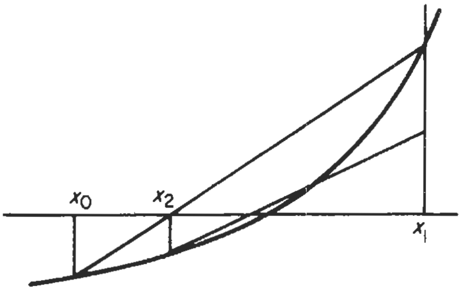

Figure 17.8 Accelerated method

$$x_2 = \frac{x_0 f(x_1) - x_1 f(x_0)}{f(x_1) - f(x_0)}$$

Evaluate $f(x_2)$ and repeat the process for whichever of the intervals (x_0,x_2) or (x_1,x_2) contains the root. This method can be accelerated by halving at each step the function value at the retained end of the interval, as shown in Figure 17.8.

17.1.19.4 Fixed-point iteration

Arrange the equation in the form

$$x = f(x)$$

Choose an initial value of x by trial, and calculate repetitively

$$x_{k+1} = f(x_k)$$

This process will not always converge.

17.1.19.5 Newton's method

Calculate repetitively (Figure 17.9)

$$x_{k+1} = x_k - f(x_k)/f'(x_k)$$

This method will converge unless: (a) x_k is near a point of inflexion of this function; or (b) x_k is near a local minimum; or (c) the root is multiple. If one of these cases arises, most of the trouble can be overcome by checking at each stage that

$$f(x_{k+1}) < f(x_k)$$

and, if not, halving the preceding value of $|x_{k+1} - x_k|$.

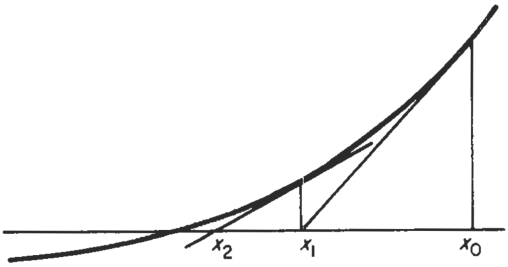

Figure 17.9 Newton's method

17.1.20 Method of least squares

To obtain the best fit between a straight line $ax + by = 1$ and several points (x_1,y_1), (x_2,y_2),..., (x_n,y_n) found by observation, the coefficients a and b are to be chosen so that the sum of the squares of the errors

$$e_i = ax_i + by_i - 1$$

is a minimum. To do this, first write the set of inconsistent equations

$$ax_1 + by_1 - 1 = 0$$

$$ax_2 + by_2 - 1 = 0$$

$$\vdots$$

$$ax_n + by_n - 1 = 0$$

Multiply each equation by the value of x it contains, and add, obtaining

$$a\sum_{i=1}^{n} x_i^2 + b\sum_{i=1}^{n} x_iy_i - \sum_{i=1}^{n} x_i = 0$$

Similarly multiply by y and add, obtaining

$$a\sum_{i=1}^{n} x_iy_i + b\sum_{i=1}^{n} y_i^2 - \sum_{i=1}^{n} y_i = 0$$

Lastly, solve these two equations for a and b, which will be the required values giving the least squares fit.

17.2 Calculus

17.2.1 Derivative

$$f'(x) = \lim_{\delta x \to 0} \frac{f(x + \delta x) - f(x)}{\delta x}$$

If u and v are functions of x,

$$(uv)' = u'v + uv'$$

$$\left(\frac{u}{v}\right)' = \frac{u'v - uv'}{v^2}$$

$$(uv)^n = u^{(n)}v + nu^{(n-1)}v^{(1)} + \ldots + {}^nC_p u^{(n-p)}v^{(p)} + \ldots + uv^{(n)}$$

where

$${}^nC_p = \frac{n!}{p!(n-p)!}$$

If $z = f(x)$ and $y = g(z)$, then

$$\frac{dy}{dx} = \frac{dy}{dz}\frac{dz}{dx}$$

17.2.2 Maxima and minima

$f(x)$ has a stationary point wherever $f'(x) = 0$: the point is a maximum, minimum or point of inflexion according as $f''(x) <, >$ or $= 0$.

$f(x,y)$ has a stationary point wherever

$$\frac{\partial f}{\partial x} = \frac{\partial f}{\partial y} = 0$$

Let (a,b) be such a point, and let

$$\frac{\partial^2 f}{\partial x^2} = A, \quad \frac{\partial^2 f}{\partial x \partial y} = H \quad \frac{\partial^2 f}{\partial y^2} = B$$

all at that point, then:

If $H^2 - AB > 0$, $f(x,y)$ has a saddle point at (a,b).
If $H^2 - AB < 0$ and if $A < 0$, $f(x,y)$ has a maximum at (a,b),
but if $A > 0$, $f(x,y)$ has a minimum at (a,b).
If $H^2 = AB$, higher derivatives need to be considered.

17.2.3 Integral

$$\int_b^a f(x)dx = \lim_{N\to\infty} \sum_{n=0}^{N-1} f\left(a + \frac{n(b-a)}{N}\right)\left(\frac{b-a}{N}\right)$$

$$= \lim_{N\to\infty} \sum_{n=1}^{N} f(a + (n-1)\,\delta x)\delta x$$

where $\delta x = (b - a)/N$.

If u and v are functions of x, then

$$\int uv'dx = uv - \int u'vdx \quad \text{(integration by parts)}$$

y	$\int ydx$

17.2.5 Standard substitutions

Integral a function of	*Substitute*
a^2-x^2	$x=a\sin\theta$ or $x=a\cos\theta$
a^2+x^2	$x=a\tan\theta$ or $x=a\sinh\theta$
x^2-a^2	$x=a\sec\theta$ or $x=a\cosh\theta$

17.2.6 Reduction formulae

$$\int\sin^m x\,dx=-\frac{1}{m}\sin^{m-1}x\cos x+\frac{m-1}{m}\int\sin^{m-2}x\,dx$$

$$\int\cos^m x\,dx=-\frac{1}{m}\cos^{m-1}x\sin x+\frac{m-1}{m}\int\cos^{m-2}x\,dx$$

$$\int\sin^m x\cos^n x\,dx=\frac{\sin^{m+1}x\cos^{n-1}x}{m+n}$$

$$+\frac{n-1}{m+n}\int\sin^m x\cos^{n-2}x\,dx$$

If the integrand is a rational function of $\sin x$ and/or $\cos x$, substitute $t=\tan\frac{1}{2}x$, then

$$\sin x=\frac{1}{1+t^2},\quad\cos x=\frac{1-t^2}{1+t^2},\quad dx=\frac{2dt}{1+t^2}$$

17.2.7 Numerical integration

17.2.7.1 Trapezoidal rule (Figure 17.10)

$$\int_{x_1}^{x_2}y\,dx=\tfrac{1}{2}h(y_1+y_2)+O(h^3)$$

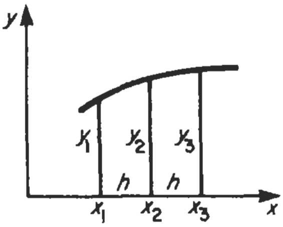

Figure 17.10 Numerical integration

17.2.7.2 Simpson's rule (Figure 17.10)

$$\int_{x_1}^{x_2} y\,\mathrm{d}x = 2h(y_1 + 4y_2 + y_3)/6 + \mathrm{O}(h^5)$$

17.2.7.3 Change of variable in double integral

$$\iint f(x,y)\mathrm{d}x\,\mathrm{d}y = \iint F(u,v)|J|\mathrm{d}u\,\mathrm{d}v$$

where

$$J = \frac{\partial(x,y)}{\partial(u,v)} = \begin{vmatrix} \dfrac{\partial x}{\partial u} & \dfrac{\partial x}{\partial v} \\ \dfrac{\partial y}{\partial u} & \dfrac{\partial y}{\partial v} \end{vmatrix} = \begin{vmatrix} \dfrac{\partial x}{\partial u} & \dfrac{\partial y}{\partial u} \\ \dfrac{\partial x}{\partial v} & \dfrac{\partial y}{\partial v} \end{vmatrix}$$

is the Jacobian of the transformation.

17.2.7.4 Differential mean value theorem

$$\frac{f(x+h) - f(x)}{h} = f'(x + \theta h)\ 0 < \theta < 1$$

17.2.7.5 Integral mean value theorem

$$\int_a^b f(x)g(x)\mathrm{d}x = g(a + \theta h)\int_a^b f(x)\mathrm{d}x$$

$h = b - a,\ 0 < \theta < 1$

17.2.8 Vector calculus

Let $s(x, y, z)$ be a scalar function of position and let $\mathbf{v}(x, y, z) = \mathbf{i}v_x(x, y, z) + \mathbf{j}v_y(x, y, z) + \mathbf{k}v_z(x, y, z)$ be a vector function of position. Define

$$\nabla = \mathbf{i}\frac{\partial}{\partial x} + \mathbf{j}\frac{\partial}{\partial y} + \mathbf{k}\frac{\partial}{\partial z}$$

so that

$$\nabla \,.\, \nabla = \nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

then

$$\text{grad } s = \nabla s = \mathbf{i}\frac{\partial s}{\partial x} + \mathbf{j}\frac{\partial s}{\partial y} + \mathbf{k}\frac{\partial s}{\partial z}$$

$$\text{div } \mathbf{v} = \nabla \,.\, \mathbf{v} = \frac{\partial v_x}{\partial x} + \frac{\partial v_y}{\partial y} + \frac{\partial v_z}{\partial z}$$

$$\text{curl } \mathbf{v} = \nabla \times \mathbf{v} = \mathbf{i}\left(\frac{\partial v_z}{\partial y} - \frac{\partial v_y}{\partial z}\right) + \mathbf{j}\left(\frac{\partial v_x}{\partial z} - \frac{\partial v_z}{\partial x}\right) + \mathbf{k}\left(\frac{\partial v_y}{\partial x} - \frac{\partial v_x}{\partial y}\right)$$

The following identities are then true:

$\text{div}(s\mathbf{v}) = s \text{ div } \mathbf{v} + (\text{grad } s) \,.\, \mathbf{v}$

$\text{curl}(s\mathbf{v}) = s \text{ curl } \mathbf{v} + (\text{grad } s) \times \mathbf{v}$

$\text{div}(\mathbf{u} \times \mathbf{v}) = \mathbf{v} \,.\, \text{curl } \mathbf{u} - \mathbf{u} \,.\, \text{curl } \mathbf{v}$

$\text{curl}(\mathbf{u} \times \mathbf{v}) = \mathbf{u} \text{ div } \mathbf{v} - \mathbf{v} \text{ div } \mathbf{u} + (\mathbf{v} \,.\, \nabla)\mathbf{u} - (\mathbf{u} \,.\, \nabla)\mathbf{v}$

$\text{div grad } s = \nabla^2 s$

$\text{div curl } \mathbf{v} = 0$

$\text{curl grad } s = 0$

$\text{curl curl } \mathbf{v} = \text{grad}(\text{div } \mathbf{v}) - \nabla^2\mathbf{v}$

where ∇^2 operates on each component of $\mathbf{v}$.

$\mathbf{v} \times \text{curl } \mathbf{v} + (\mathbf{v} \,.\, \nabla)\mathbf{v} = \text{grad } \tfrac{1}{2}\mathbf{v}^2$

potentials:

If curl $\mathbf{v} = 0$, $\mathbf{v} = \text{grad } \phi$ where ϕ is a scalar potential.
If div $\mathbf{v} = 0$, $\mathbf{v} = \text{curl } \mathbf{A}$ where $\mathbf{A}$ is a vector potential.

17.3 Series and transforms

17.3.1 Arithmetic series

Sum of n terms,

$$\begin{aligned} S_n &= a + (a + d) + (a + 2d) + \ldots + [a + (n - 1)d] \\ &= n[2a + (n - 1)d]/2 \\ &= n(a + l)/2 \end{aligned}$$

17.3.2 Geometric series

Sum of n terms,

$S_n = a + ar + ar^2 + \ldots + ar^{n-1} = a(1 - r^n)/(1 - r)$

$(|r| < 1)$

$S_\infty = a/(1 - r)$

17.3.3 Binomial series

$$(1 + x)^p = 1 + px + \frac{p(p-1)}{2!}x^2 + \frac{p(p-1)(p-2)}{3!}x^3 + \ldots$$

If p is a positive integer the series terminates with the term in x^p and is valid for all x; otherwise the series does not terminate, and is valid only for $-1 < x < 1$.

17.3.4 Taylor's series

Infinite form

$$f(x + h) = f(x) + hf'(x) + \frac{h^2}{2!}f''(x) + \ldots + \frac{h^n}{n!}f^{(n)}(x) + \ldots$$

Finite form

$$f(x + h) = f(x) + hf'(x) + \frac{h^2}{2!}f''(x) + \ldots + \frac{h^n}{n!}f^{(n)}(x) + \frac{h^{n+1}}{(n+1)!}f^{(n+1)}(x + \lambda h)$$

where $0 \leqslant \lambda \leqslant 1$.

17.3.5 Maclaurin's series

$$f(x) = f(0) + xf'(0) + \frac{x^2}{2!}f''(0) + \ldots + \frac{x^n}{n!}f^{(n)}(0) + \ldots$$

Neither of these series is necessarily convergent, but both usually are for appropriate ranges of values of h and x respectively.

17.3.6 Laurent's series

If a function $f(z)$ of a complex variable is analytic on and everywhere between two concentric circles centre a, then at any point in this region

$$f(z) = a_0 + a_1(z - a) + \ldots + b_1/(z - a) + b_2/(z - a)^2 + \ldots$$

This series is often applicable when Taylor's series is not.

17.3.7 Power series for real variables

	Math	*Comp*
$e^x = 1 + x + \frac{x^2}{2!} + \ldots$	all x	$\lvert x \rvert \leqslant 1$
$\ln(1 + x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \ldots$	$-1 < x \leqslant 1$	
$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \ldots$	all x	$\lvert x \rvert \leqslant 1$
$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \ldots$	all x	$\lvert x \rvert \leqslant 1$
$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{15} + \frac{17x^7}{315} + \ldots$		$\lvert x \rvert < \frac{\pi}{2}$
$\arctan x = x - \frac{x^3}{3} + \frac{x^5}{5} - \frac{x^7}{7} + \ldots$		$\lvert x \rvert \leqslant 1$
$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \ldots$	all x	$\lvert x \rvert \leqslant 1$
$\cosh x = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \ldots$	all x	$\lvert x \rvert \leqslant 1$

The column headed 'Math' contains the range of values of the variable x for which the series is convergent in the pure mathematical sense. In some cases a different range of values is given in the column headed 'Comp', to reduce the rounding errors which arise when computers are used.

17.3.8 Integer series

$$\sum_{n=1}^{N} n = 1 + 2 + 3 + 4 + \ldots + N = N(N + 1)/2$$

$$\sum_{n=1}^{N} n^2 = 1^2 + 2^2 + 3^2 + 4^2 + \ldots + N^2 = N(N + 1)(2N + 1)/6$$

$$\sum_{n=1}^{N} n^3 = 1^3 + 2^3 + 3^3 + 4^3 + \ldots + N^3 = N^2(N + 1)^2/4$$

$$\sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{n} = 1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \ldots = \ln(2)$$

(see $\ln(1 + x)$)

$$\sum_{n=1}^{\infty} \frac{(-1)^{n+1}}{2n - 1} = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \ldots = \frac{\pi}{4} \text{(see arctan } x\text{)}$$

$$\sum_{n=1}^{\infty} \frac{1}{n^2} = 1 + \frac{1}{4} + \frac{1}{9} + \frac{1}{16} + \ldots = \frac{\pi^2}{6}$$

$$\sum_{n=1}^{N} n(n + 1)(n + 2) \ldots (n + r)$$

$$= 1 \,.\, 2 \,.\, 3 \ldots + 2 \,.\, 3 \,.\, 4 \ldots + 3 \,.\, 4 \,.\, 5 \ldots + \ldots + N(N + 1)(N + 2) \ldots (N + r)$$

$$= \frac{N(N + 1)(N + 2) \ldots (N + r + 1)}{r + 2}$$

17.3.9 Fourier series

$$f(\theta) = \frac{1}{2} a_0 + \sum_{n=1}^{\infty} (a_n \cos n\theta + b_n \sin n\theta)$$

with

$$a_n = \frac{1}{\pi} \int_0^{2\pi} f(\Theta) \cos n\Theta \mathrm{d}\Theta$$

$$b_n = \frac{1}{\pi} \int_0^{2\pi} f(\Theta) \sin n\Theta \mathrm{d}\Theta$$

or

$$f(\theta) = \sum_{n=-\infty}^{\infty} c_n \exp(\mathrm{j}n\theta)$$

with

$$c_n = \frac{1}{2\pi} \int_0^{2\pi} f(\Theta) \exp(-\mathrm{j}n\Theta) \mathrm{d}\Theta = \begin{cases} \frac{1}{2}(a_n + \mathrm{j}b_n) & n < 0 \\ \frac{1}{2}(a_n - \mathrm{j}b_n) & n > 0 \end{cases}$$

The above expressions for Fourier series are valid for functions having at most a finite number of discontinuities within the period 0 to 2 of the variable of integration.

17.3.10 Rectified sine wave

$$f(\omega t) = \frac{1}{\pi} + \frac{1}{2} \cos \omega t + \frac{2}{\pi} \sum_{n=1}^{\infty} (-1)^{n+1} \frac{\cos 2n\omega t}{4n^2 - 1}$$

$$f(\omega t) = \frac{\sin(\pi/p)}{\pi/p} + \frac{2p}{\pi} \sin\left(\frac{\pi}{p}\right) \sum_{n=1}^{\infty} (-1)^{n+1} \frac{\cos np\omega t}{p^2n^2 - 1}$$

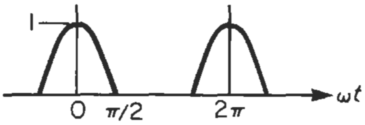

Figure 17.11 Half wave

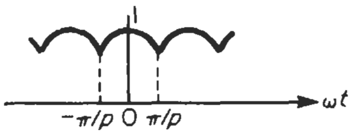

Figure 17.12 *p*-phase

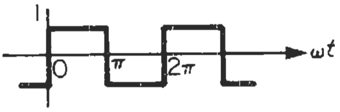

Figure 17.13 Square wave

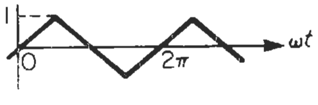

Figure 17.14 Triangular wave

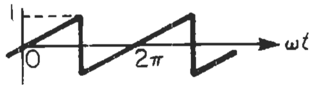

Figure 17.15 Sawtooth wave

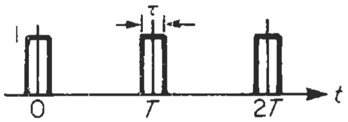

Figure 17.16 Pulse wave

17.3.11 Square wave

$$f(\omega t) = \frac{4}{\pi} \sum_{n=1}^{\infty} \frac{\sin(2n-1)\omega t}{(2n-1)}$$

17.3.12 Triangular wave

$$f(\omega t) = \frac{8}{\pi^2} \sum_{n=1}^{\infty} (-1)^{n+1} \frac{\sin(2n-1)\omega t}{(2n-1)^2}$$

17.3.13 Sawtooth wave

$$f(\omega t) = \frac{2}{\pi} \sum_{n=1}^{\infty} (-1)^{n+1} \frac{\sin n\omega t}{n}$$

17.3.14 Pulse wave

$$f(t) = \frac{\tau}{T} + \frac{2\tau}{T} \sum_{n=1}^{\infty} \frac{\sin(n\omega\tau/T)}{n\pi\tau/T} \cos\left(\frac{2n\pi t}{T}\right)$$

17.3.15 Fourier transforms

Among other applications, these are used for converting from the time domain to the frequency domain.

Basic formulae:

$$\int_{-\infty}^{\infty} U(f)\exp(\mathrm{j}2\pi ft)\mathrm{d}f = u(t) \leftrightarrows U(f) = \int_{-\infty}^{\infty} u(t)\exp(-\mathrm{j}2\pi ft)\mathrm{d}t$$

Change of sign and complex conjugates:

$u(-t) \leftrightarrows (U(-f),\ u^*(t) \leftrightarrows U^*(-f)$

Time and frequency shifts (τ and ϕ constant):

$u(t-\tau) \leftrightarrows U(f)\exp(-\mathrm{j}2\pi f\tau)\exp(\mathrm{j}2\pi\phi t)u(t) \leftrightarrows U(f-\phi)$

Scaling (T constant):

$u(t/T) \leftrightarrows TU(fT)$

Products and convolutions:

$u(t)^*v(t) \leftrightarrows U(f)V(f),\ u(t)v(t) \leftrightarrows U(f)^*V(f)$

Differentiation:

$u'(t) \leftrightarrows \mathrm{j}2\pi fU(f),\ -\mathrm{j}2\pi tu(t) \leftrightarrows U'(f)$

$\partial u(t,\alpha)/\partial\alpha \leftrightarrows \partial(U-f,\alpha)/\partial\alpha$

Integration ($U(0) = 0$, a and b real constants):

$$\int_{-\infty}^{t} u(\tau)\mathrm{d}\tau \leftrightarrows U(f)/\mathrm{j}2\pi f$$

$$\int_{a}^{b} v(t,\alpha)\mathrm{d}\alpha \leftrightarrows \int_{a}^{b} V(f,\alpha)\mathrm{d}\alpha$$

Interchange of functions:

$U(t) \leftrightarrows u(-f)$

Dirac delta functions:

$\delta(t) \leftrightarrows 1 \qquad \exp(\mathrm{j}2\pi f_0 t) \leftrightarrows \delta(f-f_0)$

Rect(t) (unit length, unit amplitude pulse, centred on $t = 0$):

$\mathrm{rect}(t) \leftrightarrows \sin \pi f/\pi f$

Gaussian distribution:

$\exp(-\pi t^2) \leftrightarrows \exp(-\pi f^2)$

Repeated and impulse (delta function) sampled waveforms:

$$\sum_{-\infty}^{\infty} u(t-nT) \leftrightarrows (1/T)U(f) \sum_{-\infty}^{\infty} \delta(f-n/T)$$

$$u(t) \sum_{-\infty}^{\infty} \delta(t-nT) \leftrightarrows (1/T) \sum_{-\infty}^{\infty} U(f-n/T)$$

Parseval's lemma:

$$\int_{-\infty}^{\infty} u(t)v^*(t)\mathrm{d}t = \int_{-\infty}^{\infty} U(f)V^*(f)\mathrm{d}f$$

$$\int_{-\infty}^{\infty} |u(t)|^2\mathrm{d}t = \int_{-\infty}^{\infty} |U(f)|^2\mathrm{d}f$$

17.3.16 Laplace transforms

$$\bar{x}_s = \int_{0}^{\infty} x(t)\exp(-st)$$

Function	*Transform*	*Remarks*
$e^{-\alpha t}$	$\dfrac{1}{s+\alpha}$	
$\sin \omega t$	$\dfrac{\omega}{s^2+\omega^2}$	
$\cos \omega t$	$\dfrac{s}{s^2+\omega^2}$	
$\sinh \omega t$	$\dfrac{\omega}{s^2-\omega^2}$	
$\cosh \omega t$	$\dfrac{s}{s^2-\omega^2}$	
t^n	$n!/s^{n+1}$	
$H(t)$	$1/s$	
$H(t-\tau)$	$\dfrac{1}{s}\exp(-s\tau)$	Heaviside step function
$x(t-\tau)H(t-\tau)$	$\exp(-s\tau)\bar{x}(s)$	Shift in t
$\delta(t-\tau)$	$\exp(-s\tau)$	Dirac delta function
$\exp(-\alpha t)x(t)$	$\bar{x}(s+\alpha)$	Shift in s
$\exp(-\alpha t)\sin \omega t$	$\dfrac{\omega}{(s+\alpha)^2+\omega^2}$	
$\exp(-\alpha t)\cos \omega t$	$\dfrac{(s+\alpha)}{(s+\alpha)^2+\omega^2}$	
$tx(t)$	$-\dfrac{d\bar{x}(s)}{ds}$	
$\dfrac{dx(t)}{dt} = x'(t)$	$s\bar{x}(s) - x(0)$	
$\dfrac{d^2x(t)}{dt^2} = x''(t)$	$s^2\bar{x}(s - sx(0) - x'(0)$	
$\dfrac{d^nx(t)}{dx^n} = x^{(n)}(t)$	$s^n\bar{x}(s) - s^{n-1}x(0) - s^{n-2}x'(0) \dots -sx^{(n-2)}(0) - x^{(n-1)}(0)$	

Convolution integral

$$\int_0^t x_1(\sigma)x_2(t-\sigma)d\sigma \rightarrow \bar{x}_1(s)\bar{x}_2(s)$$

17.4 Matrices and determinants

17.4.1 Linear simultaneous equations

The set of equations

$$a_{11}x_1 + a_{12}x_2 + \dots + a_{1n}x_n = b_1$$
$$a_{21}x_1 + a_{22}x_2 + \dots + a_{2n}x_n = b_1$$
$$\dots$$
$$a_{n1}x_1 + a_{n2}x_2 + \dots + a_{nn}x_n = b_n$$

may be written symbolically

$$\mathbf{Ax} = \mathbf{b}$$

in which $\mathbf{A}$ is the *matrix* of the coefficients a_{ij}, and $\mathbf{x}$ and $\mathbf{b}$ are the *column matrices* (or vectors) $(x_1 \dots x_n)$ and $(b_1 \dots b_n)$. In this case the matrix $\mathbf{A}$ is square ($n \times n$). The equations can be solved unless two or more of them are not independent, in which case

$$\det \mathbf{A} = |\mathbf{A}| = 0$$

and there then exist non-zero solutions x_i only if $\mathbf{b} = 0$. If $\det \mathbf{A} \neq 0$, there exist non-zero solutions only if $\mathbf{b} \neq 0$. When $\det \mathbf{A} = 0$, $\mathbf{A}$ is *singular*.

17.4.2 Matrix arithmetic

If $\mathbf{A}$ and $\mathbf{B}$ are both matrices of m rows and n columns they are *conformable*, and

$$\mathbf{A} \pm \mathbf{B} = \mathbf{C} \text{ where } C_{ij} = A_{ij} \pm B_{ij}$$

17.4.2.1 Product

If $\mathbf{A}$ is an $m \times n$ matrix and $\mathbf{B}$ an $n \times l$, the product $\mathbf{AB}$ is defined by

$$(\mathbf{AB})_{ij} = \sum_{k-1}^{n} (\mathbf{A})_{ik}(\mathbf{B})_{kj}$$

In this case, if $l \neq m$, the product $\mathbf{BA}$ will not exist.

17.4.2.2 Transpose

The transpose of $\mathbf{A}$ is written $\mathbf{A}'$ or $\mathbf{A}^t$ and is the matrix whose rows are the columns of $\mathbf{A}$, i.e.

$$(\mathbf{A}^t)_{ij} = (\mathbf{A})_{ji}$$

A square matrix may be equal to its transpose, and it is then said to be *symmetrical*. If the product $\mathbf{AB}$ exists, then

$$(\mathbf{AB})^t = \mathbf{B}^t\mathbf{A}^t$$

17.4.2.3 Adjoint

The *adjoint* of a square matrix $\mathbf{A}$ is defined as $\mathbf{B}$, where

$$(\mathbf{B})_{ij} = (A)_{ij}$$

and A_{ij} is the *cofactor* of a_{ji} in $\det \mathbf{A}$.

17.4.2.4 Inverse

If $\mathbf{A}$ is non-singular, the *inverse* $\mathbf{A}^{-1}$ is given by

$$\mathbf{A}^{-1} = \text{adj } \mathbf{A}/\det \mathbf{A} \text{ and } \mathbf{A}^{-1}\mathbf{A} = \mathbf{AA}^{-1} = 1$$

the *unit* matrix.

$$(\mathbf{AB})^{-1} = \mathbf{B}^{-1}\mathbf{A}^{-1}$$

if both inverses exist. The original equations $\mathbf{Ax} = \mathbf{b}$ have the solutions $\mathbf{x} = \mathbf{A}^{-1}\mathbf{b}$ if the inverse exists.

17.4.2.5 Orthogonality

A matrix $\mathbf{A}$ is orthogonal if $\mathbf{AA}^t = 1$. If $\mathbf{A}$ is the matrix of a coordinate transformation $\mathbf{X} = \mathbf{AY}$ from variables y_i to variables x_i, then if $\mathbf{A}$ is orthogonal $\mathbf{X}^t\mathbf{X} = \mathbf{Y}^t\mathbf{Y}$, or

$$\sum_{i=1}^{n} x_i^2 = \sum_{i=1}^{n} y_i^2$$

17.4.3 Eigenvalues and eigenvectors

The equation

$$\mathbf{A}\mathbf{x} = \lambda\mathbf{x}$$

where **A** is a square matrix, **x** a column vector and λ a number (in general complex) has at most n solutions $(\mathbf{x}, \lambda)$. The values of λ are *eigenvalues* and those of **x** *eigenvectors* of the matrix **A**. The relation may be written

$$(\mathbf{A} - \lambda\mathbf{I})\mathbf{x} = 0$$

so that if $\mathbf{x} \neq 0$, the equation $\mathbf{A} - \lambda\mathbf{I} = 0$ gives the eigenvalues. If **A** is symmetric and real, the eigenvalues are real. If **A** is symmetric, the eigenvectors are orthogonal. If **A** is not symmetric, the eigenvalues are complex and the eigenvectors are not orthogonal.

17.4.4 Coordinate transformation

Suppose **x** and **y** are two vectors related by the equation

$$\mathbf{y} = \mathbf{A}\mathbf{x}$$

when their components are expressed in one orthogonal system, and that a second orthogonal system has unit vectors $\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_n$ expressed in the first system. The components of **x** and **y** expressed in the new system will be $\mathbf{x}'$ and $\mathbf{y}'$, where

$$\mathbf{x}' = \mathbf{U}^t\mathbf{x}, \quad \mathbf{y}' = \mathbf{U}^t\mathbf{y}$$

and $\mathbf{U}^t$ is the orthogonal matrix whose rows are the unit vectors $\mathbf{u}_1^t$, $\mathbf{u}_2^t$, etc. Then

$$\mathbf{y}' = \mathbf{U}^t\mathbf{y} = \mathbf{U}^t\mathbf{A}\mathbf{x} = \mathbf{U}^t\mathbf{A}\mathbf{x} = \mathbf{U}^t\mathbf{A}\mathbf{U}\mathbf{x}'$$

or

$$\mathbf{y}' = \mathbf{A}'\mathbf{x}'$$

where

$$\mathbf{A}' = \mathbf{U}^t\mathbf{A}\mathbf{U}$$

Matrices **A** and **A**$'$ are *congruent.*

17.4.5 Determinants

The determinant

$$D = \begin{vmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{vmatrix}$$

is defined as follows. The first suffix in a_{rs} refers to the row, the second to the column which contains a_{rs}. Denote by M_{rs} the determinant left by deleting the rth row and sth column from D, then

$$D = \sum_{k=1}^{n} (-1)^{k+1} a_{1k} M_{1k}$$

gives the value of D in terms of determinants of order $n - 1$, hence by repeated application, of the determinant in terms of the elements a_{rs}.

17.4.6 Properties of determinants

If the rows of $|a_{rs}|$ are identical with the columns of $|b_{sr}|$, $a_{rs} = b_{sr}$ and

$$|a_{rs}| = |b_{sr}|$$

that is, the *transposed* determinant is equal to the original.

If two rows or two columns are interchanged, the numerical value of the determinant is unaltered, but the sign will be changed if the permutation of rows or columns is odd.

If two rows or two columns are identical, the determinant is zero.

If each element of one row or one column is multiplied by k, so is the value of the determinant.

If any row or column is zero, so is the determinant.

If each element of the pth row or column of the determinant c_{rs} is equal to the sum of the elements of the same row or column in determinants a_{rs} and b_{rs}, then

$$|c_{rs}| = |a_{rs}| + |b_{rs}|$$

The addition of any multiple of one row (or column) to another row (or column) does not alter the value of the determinant.

17.4.6.1 *Minor*

If row p and column q are deleted from $|a_{rs}|$, the remaining determinant M_{pq} is called the *minor* of a_{pq}.

17.4.6.2 *Cofactor*

The *cofactor* of a_{pq} is the minor of a_{pq} prefixed by the sign which the product $M_{pq}a_{pq}$ would have in the expansion of the determinant, and is denoted by A_{pq}:

$$A_{pq} = (-1)^{p+q} M_{pq}$$

A determinant a_{ij} in which $a_{ij} = a_{ji}$ for all i and j is called *symmetric*, whilst if $a_{ij} = -a_{ji}$ for all i and j, the determinant is *skew-symmetric*. It follows that $a_{ii} = 0$ for all i in a skew-symmetric determinant.

17.4.7 Numerical solution of linear equations

Evaluation of a determinant by direct expansion in terms of elements and cofactors is disastrously slow, and other methods are available, usually programmed on any existing computer system.

17.4.7.1 *Reduction of determinant or matrix to upper triangular or to diagonal form*

The system of equations may be written

$$\begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \vdots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{bmatrix} \begin{matrix} \\ x_1 \\ \vdots \\ \\ \end{matrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_n \end{bmatrix}$$

The variable x_1 is eliminated from the last $n - 1$ equations by adding a multiple $-a_{i1}/a_{11}$ of the first row to the ith, obtaining

$$\begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ 0 & a'_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & \cdots & a''_{nn} \end{bmatrix} \begin{matrix} \\ x_1 \\ \vdots \\ \\ \end{matrix} \begin{bmatrix} x_1 \\ x_2 \\ \\ x_n \end{bmatrix} = \begin{bmatrix} b_1 \\ b'_1 \\ \\ b''_n \end{bmatrix}$$

where primes indicate altered coefficients. This process may be continued by eliminating x_2 from rows 3 to n, and so on.

Eventually the form will become

$$\begin{bmatrix} a_{11} & a_{12} & \dots & a_{1n} \\ 0 & a'_{22} & \dots & a'_{2n} \\ \vdots & \vdots & \dots & \vdots \\ 0 & 0 & \dots & a''_{nn} \end{bmatrix} \begin{matrix} \\ x_1 \\ \vdots \\ \\ \end{matrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} = \begin{bmatrix} b_1 \\ b'_2 \\ \vdots \\ b''_n \end{bmatrix}$$

x_n can now be found from the nth equation, substituted in the $(n-1)$th to obtain x_{n-1} and so on.

Alternatively the process may be applied to the system of equations in the form

$$\mathbf{Ax} = \mathbf{Ib}$$

where $\mathbf{I}$ is the unit matrix, and the same operations carried out upon $\mathbf{I}$ as upon $\mathbf{A}$. If the process is continued after reaching the upper triangular form, the matrix $\mathbf{A}$ can eventually be reduced to diagonal form. Finally, each equation is divided by the corresponding diagonal element of $\mathbf{A}$, thus reducing $\mathbf{A}$ to the unit matrix. The system is now in the form

$$\mathbf{Ix} = \mathbf{Bb}$$

and evidently $\mathbf{B} = \mathbf{A}^{-1}$. The total number of operations required is $O(n^3)$.

17.5 Differential equations

A differential equation is an equation involving a *dependent* variable and its derivatives with respect to one or more *independent* variables. An *ordinary* differential equation is one in which there is only one independent variable – conventionally x or t. A *partial* differential equation is one in which there are several independent variables.

17.5.1 Notation and definitions

An ordinary differential equation with y as *dependent* variable and x as *independent* variable has the general form

$$f\left\{x; y, \frac{dy}{dx}, \frac{d^2y}{dx^2}, \dots\right\} = 0$$

where $f\{\ \}$ represents some specified function of the arguments. *Solving* a differential equation involves obtaining an explicit expression for y as a known function of x.

The *order* of a differential equation is the order of the highest derivative appearing in it. Thus

$$\frac{d^2y}{dx^2} + 3\frac{dy}{dx} + 6y = 6$$

is a second-order equation. A differential equation of order n has a *general* solution containing *n arbitrary constants*. Specified values of the *dependent* variable and/or its derivatives which allow these arbitrary constants to be determined are called *boundary conditions* or (when the independent variable is t and the values are given at $t = 0$) *initial conditions*. Boundary conditions in which the dependent variable or its derivatives are assigned zero values are called *homogeneous* boundary conditions. A solution in which the arbitrary constants take definite values is called a *particular* solution.

A *linear* differential equation is one which is linear in the *dependent* variable and its derivatives, having the general form

$$p_n(x)\frac{d^ny}{dx^n} + \dots + p_1(x)\frac{dy}{dx} + p_0(x)y = f(x) \qquad (17.1)$$

where $p_0(x) \dots p_n(x)$ and $f(x)$ are specified functions of x. If $f(x) \neq 0$ the differential equation is said to be *inhomogeneous*. If $f(x) = 0$, so that

$$p_n(x)\frac{d^ny}{dx^n} + \dots + p_1(x)\frac{dy}{dx} + p_0(x)y = 0 \qquad (17.2)$$

the differential equation is said to be *homogeneous*.

In a partial differential equation the independent variables are normally variables defining spatial position plus (possibly) time. A particular solution of a partial differential equation requires the definition of a *solution region* with a bounding curve or bounding surface, together with the specification of suitable boundary conditions on that curve or surface. A partial differential equation, like an ordinary differential equation, may be linear or non-linear, and a linear partial differential equation may be homogeneous or inhomogeneous. Boundary conditions, specifying values of the dependent variable and/or its derivatives, may also be homogeneous or inhomogeneous.

17.5.2 Ordinary differential equations: analytical solutions

Simple analytical solutions exist for first-order linear differential equations and for linear equations of higher order with constant coefficients.

17.5.2.1 First-order linear equations

A *first-order* linear differential equation has the general form $p_1(x)(dy/dx) + p_0(x)y = f(x)$, which can be written as

$$\frac{dy}{dx} + P(x)y = Q(x) \qquad (17.3)$$

This equation has the general solution

$$ye^{\int P(x)dx} = \int Q(x)e^{\int P(x)dx}dx + C \qquad (17.4)$$

where C is an arbitrary constant. The function $e^{\int P(x)dx}$ is known as the *integrating factor.*

17.5.2.2 Linear equations with constant coefficients

Homogeneous equations A second-order homogeneous linear differential equation with constant coefficients has the general form

$$a\frac{d^2y}{dx^2} + b\frac{dy}{dx} + cy = 0 \qquad (17.5)$$

The general solution is

$$y = C_1e^{\lambda_1x} + C_2e^{\lambda_2x} \qquad (17.6)$$

where λ_1, λ_2 are the roots of the *auxiliary equation* $a\lambda^2 + b\lambda + c = 0$ and C_1, C_2 are arbitrary constants.

If the roots of the auxiliary equation are complex, with values $\lambda_1 = \alpha + j\beta$, $\lambda_2 = \alpha - i\beta$, it is more convenient to write the general solution of the differential equation in the form

$$y = e^{\alpha x}(C_1 \cos \beta x + C_2 \sin \beta x) \qquad (17.7)$$

If the roots are equal, i.e. $\lambda_1 = \lambda_2 = \lambda$, say, then the general solution is

$$y = e^{\lambda x}(C_1 + C_2 x) \tag{17.8}$$

where again C_1, C_2 are arbitrary constants.

The solution of third- and higher-order homogeneous equations follows a similar pattern, the auxiliary equation being a polynomial equation in λ of appropriate degree.

Inhomogeneous equations A second-order inhomogeneous linear differential equation with constant coefficients has the general form

$$a\frac{d^2y}{dx^2} + b\frac{dy}{dx} + cy = f(x) \tag{17.9}$$

where $f(x)$ is a specified function. The general solution of equation (17.9) is the general solution of the homogeneous equation (17.5) containing two arbitrary constants (this solution is called the *complementary function*) plus a function (called the *particular integral*) which, when substituted into equation (17.9), gives the correct function $f(x)$ on the right-hand side.

For many simple right-hand sides the particular integral can be found by replacing y in the differential equation by a 'trial solution' containing one or more unknown parameters, here written as α, β, etc.

Right-hand side: $f(x)$	Trial solution: $y(x)$
constant	α
x^n (n integral)	$\alpha x^n + \beta x^{n-1} + \ldots$
e^{kx}	αe^{kx}
xe^{kx}	$(\alpha x + \beta)e^{kx}$
$x^n e^{kx}$	$(\alpha x^n + \beta x^{n-1} + \ldots)e^{kx}$
$\sin kx$ $\cos kx$	$\alpha \sin kx + \beta \cos kx$. (If only even differential coefficients occur in the differential equation then $\alpha \sin kx$ or $\beta \cos kx$ is sufficient.)
$e^{k_1x} \sin k_2x$ $e^{k_1x} \cos k_2x$	$e^{k_1x}(\alpha \sin k_2x + \beta \cos k_2x)$

Equating the coefficients of the functions on the two sides of the equation gives the values of the parameters. This technique can also be used to solve equations of third and higher orders.

If $f(x)$ has the same form as one of the terms in the complementary function then the substitution $y = uf(x)$ should be made, where u is an unknown function of x. This substitution generates a simple differential equation for $u(x)$.

Simultaneous linear differential equations The analysis of a linear mechanical or electrical system with several degrees of freedom may require the solution of a set of simultaneous linear differential equations, in which there is one independent variable (normally time) and several dependent variables. In cases where the equations have constant coefficients, as in the example

$$\frac{du}{dt} + 3\frac{dv}{dt} + u - v = t^2$$

$$2\frac{du}{dt} - \frac{dv}{dt} - 2u + 3v = 0$$

the equations can be solved by a procedure very similar to the elimination method for solving sets of linear algebraic equations. This procedure generates a linear differential equation (with order equal to the sum of the orders of the original equations) for one of the dependent variables: after solution of this equation the other dependent variables can be obtained by back-substitution.

Inserting the initial or boundary conditions A linear differential equation of order n has a general solution

$$y = \xi_0(x) + C_1\xi_1(x) + C_2\xi_2(x) + \ldots + C_n\xi_n(x) \tag{17.10}$$

where $\xi_0(x)$ is the *particular integral* and $C_1\xi_1(x) + C_2\xi_2(x) + \ldots + C_n\xi_n(x)$ is the *complementary function*. Once this general solution has been found, the values of the n constants $C_1, \ldots, C_n$ can be obtained by imposing n boundary or initial conditions, i.e. n values of y and/or its derivatives at particular values of x. If all the boundary conditions are specified at a single value of x the problem is referred to as a *one-point boundary-value* problem or, if the independent variable is t and the conditions are specified at $t = 0$, as an *initial-value* problem. Initial value problems can also be solved by the use of Laplace transforms (see Section 17.3.16). The Laplace transform method determines a particular solution of a differential equation, with the initial conditions inserted, rather than the general solution (17.10).

Impulse and frequency responses: the convolution integral The solution of the differential equation

$$a_n\frac{d^ny}{dt^n} + \ldots + a_1\frac{dy}{dt} + a_0y = f(t) \tag{17.11}$$

for a general function of time $f(t)$ with homogeneous initial conditions

$$\frac{d^{n-1}y}{dt^{n-1}} = \frac{d^{n-2}y}{dt^{n-2}} = \ldots = \frac{dy}{dt} = y = 0 \text{ at } t = 0$$

can be obtained from the *impulse response* $g(t)$, which is the solution of the differential equation with the same initial conditions when $f(t) = \delta(t)$. ($\delta(t)$ is the Dirac δ-function, defined by the equations

$$\int_{-\infty}^{\infty} \delta(t)dt = 1;\ \delta(t) = 0 \text{ if } t \neq 0.)$$

The impulse response can be obtained by solving the homogeneous equation

$$a_n\frac{d^ny}{dt^n} + \ldots + a_1\frac{dy}{dt} + a_0y = 0 \tag{17.12}$$

with initial conditions $(d^{n-1}y)/(dt^{n-1}) = 1/a_n$, $(d^{n-2})/(dt^{n-2}) = \ldots = dy/dt = y = 0$ at $t = 0$. Alternatively, it can be found by the use of Laplace transforms.

The solution of equation (17.11) for an arbitrary right-hand side $f(t)$ is given in terms of the impulse response $g(t)$ by the *convolution integral*

$$y(t) = \int_0^t g(\tau)f(t - \tau)d\tau \tag{17.13}$$

This integral is symmetric in the functions g and f, and can therefore be written in the alternative form

$$y(t) = \int_0^t f(\tau)g(t - \tau)d\tau \tag{17.14}$$

If $f(t) = e^{i\omega t}$ and equation (17.11) represents a stable system (i.e. the complementary function has no exponential terms with positive real part) then as $t \to \infty$ the solution tends to the 'steady state' form $y(t) = G(\omega)e^{i\omega t}$. The complex function

$G(\omega)$ is called the *frequency response* of the system. It may be obtained from the differential equation by substituting the trial solution $y = \alpha e^{i\omega t}$ or from the impulse response by the use of equation (17.13). The latter derivation gives the result

$$G(\omega) = \int_{-\infty}^{\infty} g(\tau) e^{-i\omega\tau} d\tau \tag{17.15}$$

This equation states that the frequency response $G(\omega)$ is the *Fourier transform* of the impulse response $g(t)$ (see Section 17.3.15).

17.5.2.3 Linear equations with variable coefficients

Second- and higher-order linear equations with variable coefficients do not, in general, have solutions which are expressible in terms of elementary functions. However, there are a number of second-order equations which occur frequently in applied mathematics and for which tables of solutions exist. Sub-routines for generating these solutions are available on most scientific computers. Two of the most important of these equations are

Bessel's equation: $$x^2 \frac{d^2y}{dx^2} + x\frac{dy}{dx} + (\lambda^2x^2 - n^2)y = 0 \tag{17.16}$$

Legendre's equation: $$(1 - x^2)\frac{d^2y}{dx^2} - 2x\frac{dy}{dx} + n(n + 1)y = 0 \tag{17.17}$$

In certain other cases an equation with variable coefficients can be converted into one with constant coefficients by means of a change of variable. In general, however, solutions of linear differential equations with variable coefficients can only be obtained by approximate methods.

17.5.3 Ordinary differential equations: approximate solutions

Approximate solutions of differential equations can be obtained by graphical, numerical or analytical methods.

17.5.3.1 A graphical method for first-order equations

A graphical solution of the general first-order equation $dy/dx = f(x,y)$ can be obtained as follows. A series of curves $f(x,y) = c_1, c_2, \ldots, c_i, \ldots$ (termed *isoclines*) are drawn in the x, y plane, where the c's are suitable constants. On each isocline line-segments are drawn with slope equal to the associated value of c_i: these segments give the direction of the solutions as they cross the isocline. The general form of these solutions can be obtained by joining up the segments to form continuous curves.

A simple example is shown in Figure 17.17, which illustrates the solution of the differential equation $dy/dx = -x/y$. The isoclines $-x/y = c_1, c_2, \ldots, c_i, \ldots$ are straight lines through the origin, and the segments which form part of the solutions are always perpendicular to the isoclines. It is clear from the figure that the solutions are circles centred on the origin: this is easily verified analytically.

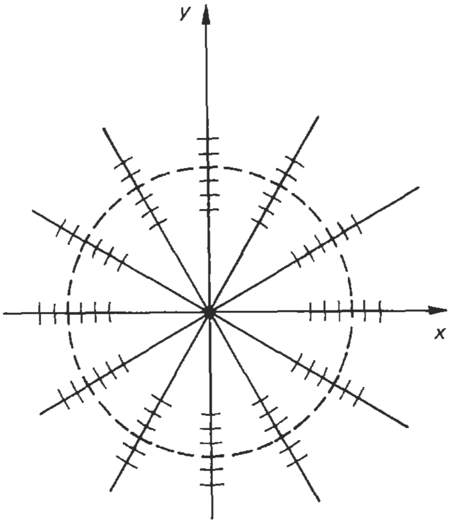

Figure 17.17 Isoclines for the differential equation $dy/dx = -x/y$

17.5.3.2 Approximate numerical methods

Derivatives and differences If a continuous function $y(x)$ is sampled at a series of equally spaced points $x_0, \ldots, x_n, \ldots, x_N$ to give a set of values $y_0, \ldots, y_n, \ldots, y_N$ then it follows from the definition of a differential coefficient that

$$\left(\frac{dy}{dx}\right)_{n+1/2} \approx (y_{n+1} - y_n)/h, \quad \left(\frac{dy}{dx}\right)_{n-1/2} \approx (y_n - y_{n-1})/h \tag{17.18}$$

or alternatively

$$\left(\frac{dy}{dx}\right)_n \approx (y_{n+1} - y_{n-1})/2h \tag{17.19}$$

where h is the sampling inverval, as shown in Figure 17.18. Taking the difference of the two equations (17.18) and dividing by h gives

$$\left(\frac{d^2y}{dx^2}\right)_n \approx (y_{n+1} - 2y_n + y_{n-1})/h^2 \tag{17.20}$$

and the process can be continued in a similar way to give approximations to $(d^3y/dx^3)_{n+1/2}$, etc. The quantities $(y_1 - y_0), \ldots (y_{n+1} - y_n), \ldots (y_N - y_{N-1})$ are termed the *first*

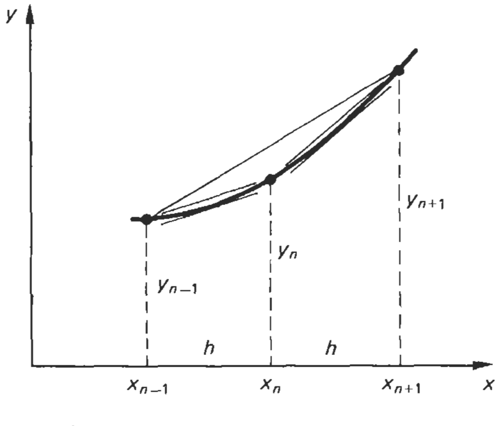

Figure 17.18 Approximate representations of dy/dx

differences of the set of values y_n, the quantities . . . $(y_{n+1} - 2y_n + y_{n-1})$, . . . the *second differences*, and so on. The role of differences in numerical analysis is similar to that of differential coefficients in calculus.

Two-point boundary-value problems An approximate solution of the second-order linear differential equation

$$p_2(x)\frac{d^2y}{dx^2} + p_1(x)\frac{dy}{dx} + p_0(x)y = f(x) \tag{17.21}$$

with boundary conditions $y = y_0$ at $x = 0$, $y = y_N$ at $x = a$ can be found by dividing the solution range $0 \leqslant x \leqslant a$ into N equal intervals and replacing the continuous function $y(x)$ by a set of $N + 1$ quantities $y_n = y(x_n)$, $(n = 0, \ldots, N)$, where $x_n = nh$ and $h = a/N$. Replacing the differential coefficients in equation (17.21) by the approximations (17.19) and (17.20) gives

$$\begin{aligned} &p_2(x_n)(y_{n+1} - 2y_n + y_{n-1}) + hp_1(x_n)(y_{n+1} - y_{n-1})/2 \\ &+ h^2p_0(x_n)y_n = f(x_n) \\ &(n = 1, \ldots, N - 1) \end{aligned} \tag{17.22}$$

Setting up an equation of this form at each of the points $x_1, \ldots, x_{N-1}$ produces a set of $n - 1$ simultaneous linear algebraic equations which can be solved for the unknown function values $y_1, \ldots, y_{N-1}$ (the values of y_0 and y_N which appear in these equations are known from the boundary conditions). Intermediate values of $y(x)$ can be found subsequently by interpolation.

Initial-value problems The general first-order differential equation

$$\frac{dy}{dt} = f(t,y) \tag{17.23}$$

with initial condition $y = y_0$ at $t = t_0$ can be solved by a step-by-step procedure in which approximate function values $y_1, y_2, \ldots$ are computed successively at $t = t_1, t_2, \ldots$ The simplest step-by-step procedure is due to Euler and involves the replacement of the differential equation (17.23) by the approximation

$$y_{n+1} = y_n + hf(t_n,y_n) \; (n = 0, 1, 2, \ldots) \tag{17.24}$$

where h is equal to the interval $t_{n+1} - t_n$. As shown in Figure 17.19 this procedure takes the tangent at each solution point as the solution over the next interval. The truncation error in a single step is $O(h^2)$. If the step-length h is kept constant over a given range $0 \leqslant t \leqslant T$ the number of steps is T/h, so that the traucation error over the range is $O(h)$. (The round-off error increases with the number of steps, so that there is an optimum value of h which minimizes the total error.)

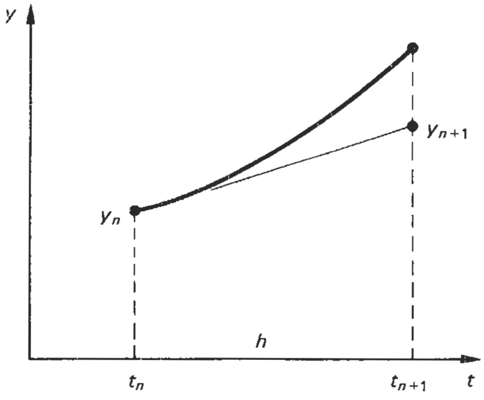

Figure 17.19 Euler's approximate integration procedure

The accuracy of the Euler procedure can be improved by using equation (17.24) as a 'predictor' to obtain an approximate value y^*_{n+1}, which is then inserted in a suitable 'corrector' formula to generate a more accurate value of y_{n+1}. A simple predictor/çorrector pair is

$$\begin{aligned} &\text{Predictor} \quad y^*_{n+1} = y_n + hf(t_n,y_n) \\ &\text{Corrector} \quad y_{n+1} = y_n + h\{f(t_n,y_n) + f(t_{n+1},y^*_{n+1})\}/2 \end{aligned} \tag{17.25}$$

One of the most popular predictor–corrector procedures is the Runge–Kutta. A single step of the procedure involves four evaluations of $f(t,y)$ in accordance with the formulae

$$\begin{aligned} &a_1 = hf(t_n,y_n), \qquad a_2 = hf(t_n + h/2, y_n + a_1/2) \\ &a_3 = hf(t_n + h/2, y_n + a_2/2), \; a_4 = hf(t_n + h, y_n + a_3) \end{aligned}$$

the final value of y_{n+1} being

$$y_{n+1} = y_n + \{a_1 + 2a_2 + 2a_3 + a_4\}/6 \tag{17.26}$$

The error per step is $O(h^5)$, so that the error over a given range of t is $O(h^4)$. A computer sub-routine for the Runge–Kutta procedure normally requires a user-supplied sub-routine to evaluate $f(t,y)$ for specified values of t and y.

An initial-value problem involving a differential equation of second or higher order can be solved by reducing the differential equation to a set of first-order equations. For example, the third-order non-linear equation

$$\frac{d^3y}{dt^3} + t\frac{d^2y}{dt^2} - 2t^2\left(\frac{dy}{dt}\right)^2 + y^2 = 10t$$

can be solved by introducing the additional variables u and v and writing the equation as

$$\frac{dy}{dt} = u; \; \frac{du}{dt} = v; \; \frac{dv}{dt} = 10t - tv + 2t^2u^2 - y^2$$

This set of first-order equations for the three variables u, v and y can be solved by any of the methods described above, the step-by-step procedure being carried forward simultaneously for each of the variables.

17.5.3.3 *Approximate analytical methods*

An approximate solution of a linear differential equation can also be obtained by choosing a set of M *basis functions* $B_m(x)$ and expressing the unknown solution $y(x)$ as

$$y(x) \approx c_1B_1(x) + \ldots + c_MB_M(x) = \sum_{m=1}^{M} c_mB_m(x) \tag{17.27}$$

There are a number of methods based on this approach. They may be classified according to the choice of basis functions $B_m(x)$ and the procedure used to find the constants c_m. The most important sets of basis functions are the integral powers of x (which generate power-series approximations) and the harmonic functions sin mx and cos mx (which generate Fourier approximations). In the following account the equation to be solved is written as

$$\mathscr{L}y = w(x) \tag{17.28}$$

where $\mathscr{L}$ represents a specified linear differential operator and $w(x)$ is a specified function of x. It is assumed that a solution is required in an interval $p \leqslant x \leqslant q$ and that sufficient homogeneous boundary conditions are specified at $x = p$ and $x = q$ to make the solution unique. It is further assumed that each of the approximating functions $B_1(x), \ldots, B_M(x)$ satisfies these boundary conditions.

In general the approximation (17.27) will not be capable of satisfying the differential equation (17.28) exactly, whatever values are assigned to the constants c_i: there will be an error function

$$\epsilon(x) = \mathcal{L}\left\{ \sum_{m=1}^{M} c_m B_m(x) \right\} - w(x)$$

which can be written in the form

$$\epsilon(x) = \sum_{m=1}^{M} c_m b_m(x) - w(x) \tag{17.29}$$

where $b_m(x) = \mathcal{L}\{B_m(x)\}$.

Two procedures for finding sets of constants which make the error $\epsilon(x)$ 'small' are *Collocation* and *Galerkin's method.* In the Collocation method the constants c_m are obtained by making $\epsilon(x)$ zero at a selected set of points x_k $(k = 1, \ldots, M)$ in the interval $p \leqslant x \leqslant q$. This generates a set of M simultaneous equations

$$\sum_{m-1}^{M} b_m(x_k)c_m = w(x_k) \quad (k = 1, \ldots, M) \tag{17.30}$$

which can be solved for the M constants. In Galerkin's method the constants c_m are obtained by making $\epsilon(x)$ orthogonal to the M basis functions $B(x)$,

$$\int_p^q B_k(x)\epsilon(x)\mathrm{d}x = \int_p^q B_k(x)\left\{ \sum_{m-1}^{M} c_m b_m(x) - w(x) \right\}\mathrm{d}x = 0$$

$(k = 1, \ldots, M)$

These equations can be written in the form

$$\sum_{m-1}^{M} \left\{ \int_p^q B_k(x) b_m(x)\mathrm{d}x \right\} c_m = \int_p^q B_k(x) w(x)\mathrm{d}x$$

$$(k = 1, \ldots, M) \tag{17.31}$$

Equation (17.31), like equation (17.30), represents a set of M linear algebraic equations for the unknown constants c_m. If the differential operator $\mathcal{L}$ is self-adjoint (a condition satisfied in most practical applications of the method) the coefficients

$$\int_p^q B_k(x) b_m(x)\mathrm{d}x$$

form a symmetric matrix. If, in addition, the functions $B_m(x)$ are chosen to be the normalized eigenfunctions of the differential operator $\mathcal{L}$, so that $\mathcal{L}\{B_m(x)\} = b_m(x) = \lambda_m B_m(x)$, then equation (17.31) takes the simpler form

$$c_k = \int_p^q B_k(x) w(x)\mathrm{d}x / \lambda_k \quad (k = 1, \ldots, M) \tag{17.32}$$

with each constant c_k depending only on the corresponding function $B_k(x)$.

17.5.4 Partial differential equations

Linear partial differential equations can be classified as elliptic, hyperbolic or parabolic. An elliptic differential equation is one in which the boundary conditions imposed on each segment of the boundary affect the solution at *all* points in the solution region or, conversely, one in which the solution at any point depends on the boundary conditions over the *whole* boundary, as shown in Figure 17.20(a). The commonest elliptic equation is Laplace's equation

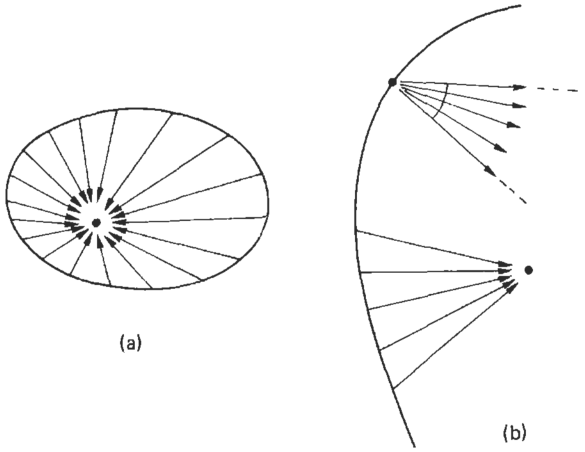

Figure 17.20 Partial differential equation types: (a) elliptic, (b) hyperbolic

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} + \frac{\partial^2\phi}{\partial z^2} = 0 \tag{17.33}$$

which is the equation governing gravitational fields in free space, steady heat and electrical conduction, seepage flow in soils, etc. The inhomogeneous form of Laplace's equation is Poisson's equation

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} + \frac{\partial^2\phi}{\partial z^2} = -\sigma \tag{17.34}$$

where σ is a known function of position. This equation governs gravitational fields in regions containing distributed matter, heat conduction in the presence of distributed heat sources, etc.

Another elliptic differential equation of interest to mechanical engineers is the bi-harmonic equation governing the bending of an initially flat plate:

$$\frac{\partial^4\phi}{\partial x^4} + 2\frac{\partial^4\phi}{\partial x^2\partial y^2} + \frac{\partial^4\phi}{\partial y^4} = -q/D \tag{17.35}$$

where ϕ is the transverse displacement of the plate, q is the known distribution of transverse load and D is a constant representing the stiffness of the plate.

Equations (17.33)–(17.35) can also be written in the more general form $\nabla^2\phi = 0$, $\nabla^2\phi = -\sigma$, $\nabla^4\phi = -q/D$, where ∇^2 is the Laplacian operator of vector calculus. This operator takes various forms, depending on the coordinate system (Cartesian, cylindrical polar, spherical polar, etc.) used to define the solution region.

A hyperbolic differential equation is one in which the boundary conditions on a segment of the boundary only affect a *part* of the solution region or, conversely, one in which the solution at any point only depends on the boundary conditions over *part* of the boundary, as shown in Figure 17.20(b). The commonest hyperbolic differential equation is the wave equation

$$\frac{\partial^2\phi}{\partial x^2} = \frac{1}{a}\frac{\partial^2\phi}{\partial t^2} \text{ or, more generally, } \nabla^2\phi = \frac{1}{a^2}\frac{\partial^2\phi}{\partial 7t^2} \tag{17.36}$$

which governs the propagation of sound and other waves in both fluids and solids.

Another common partial differential equation is the diffusion equation

$$\frac{\partial^2\phi}{\partial x^2} = \frac{1}{a^2}\frac{\partial\phi}{\partial t} \text{ or, more generally, } \nabla^2\phi = \frac{1}{a}\frac{\partial\phi}{\partial t} \qquad (17.37)$$

which governs, for example, the unsteady flow of heat in solids. The diffusion equation is an example of a parabolic differential equation. Such equations can be thought of as lying on the borderline between elliptic and hyperbolic forms.

17.5.4.1 *Analytical solutions: separation of variables*

Simple analytical solutions exist for linear partial differential equations with constant coefficients. For example, Laplace's equation in two dimensions is satisfied by both the real and imaginary parts of any analytic function $f(z)$, where z is the complex variable $x + jy$. This fact allows many two-dimensional field problems to be solved by a technique known as *conformal mapping*. Similarly, the one-dimensional wave equation

$$\frac{\partial^2\phi}{\partial x^2} = \frac{1}{a^2}\frac{\partial^2\phi}{\partial t^2}$$

has solutions of the form $f(x \pm at)$, where f is an arbitrary differentiable function. These solutions represent waves of arbitrary shape travelling along the x axis.

Analytical solutions of linear partial differential equations can be obtained by using the method of *separation of variables*. For a differential equation whose dependent variable is ϕ and whose independent variables are x and y this method involves assuming a solution of the form $\phi = X(x)Y(y)$, where X is an unknown function of x only and Y is an unknown function of y only. Substitution of this solution into the differential equation yields ordinary differential equations for the functions X and Y, which can be solved by methods described in Section 17.5.2.2.

Typical examples of separable solutions are the function

$$\phi = \begin{Bmatrix}\cos\\ \sin\end{Bmatrix}\lambda x \begin{Bmatrix}\cosh\\ \sinh\end{Bmatrix}\lambda y$$

which satisfies both the two-dimensional Laplace equation and the homogeneous plate bending equation and the function

$$\phi = e^{-a\lambda^2 t}\begin{Bmatrix}\cos\\ \sin\end{Bmatrix}\lambda x$$

which satisfies the one-dimensional diffusion equation.

Separable solutions always contain an arbitrary parameter λ called the *separation constant*. The imposition of boundary conditions on a solution may result in only certain values of λ being permissible. In such cases more general solutions can often be built up by combining a number of basic solutions involving these values of λ. For example, the solution of the one-dimensional diffusion equation given above implies the existence of a more general solution

$$\phi = \sum_{n=1}^{\infty} e^{-a\lambda_n^2 t}(A_n \cos\lambda_n x + B_n \sin\lambda_n x)$$

which can be made to fit a variety of boundary conditions by suitable choice of the constants A_n and B_n.

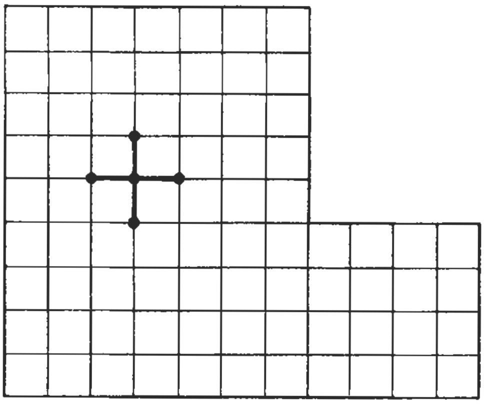

Figure 17.21 A finite-difference mesh

17.5.4.2 *Numerical solutions: the finite-difference method*

The finite-difference method for solving partial differential equations is similar to the numerical technique for solving ordinary differential equations with two-point boundary conditions described in Section 17.5.3.3. The following example shows how the method can be used to find the steady-state distribution of temperature within the L-shaped region shown in Figure 17.21 when the temperature variation on the boundary of the region is given. In this problem the temperature ϕ satisfies the two-dimensional Laplace equation

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} = 0$$

with appropriate values of ϕ specified on the boundary.

The region is first covered with a uniform grid of squares, as shown in the figure. The intersections of the grid lines within the solution region are called *nodal points* and the values of ϕ at these points are called *nodal values*: it is these values which are determined by the method. At each nodal point the partial derivatives which make up the differential equation are replaced by differences, using an appropriately amended version of equation (17.20). This operation converts the partial differential equation into a linear algebraic equation involving the nodal values at the chosen nodal point and its four nearest neighbours. If these points are labelled as shown in Figure 17.22 then the linear equation associated with the point p is

$$(\phi_q + \phi_r + \phi_s + \phi_t - 4\phi_p)/h^2 = 0 \qquad (17.38)$$

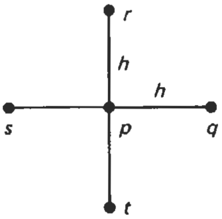

Figure 17.22 Nodal points associated with the difference equation for node p

A similar equation can be constructed for each nodal point within the solution region (it is not necessary to construct equations for nodal points on the boundary). For nodal points adjacent to the boundary at least one of the values $\phi_q, \ldots, \phi_t$ will be known.

This procedure converts the partial differential equation into a set of n simultaneous linear equations, where n is the number of nodal points within the solution region. In pre-computer days these equations were solved by an iterative process known as *relaxation*. Nowadays they are normally solved by a computer routine designed to take advantage of the sparse and banded nature of the coefficient matrix. Once the nodal values have been obtained, values of the solution at other points within the region can be found by interpolation.

17.5.4.3 Numerical solutions: the finite-element method

In recent years the finite-element method has largely replaced the finite-difference method as the standard numerical technique for solving problems of heat conduction and stress analysis in solid bodies. To assist in a comparison of the two approaches the following account considers the heat-conduction problem solved by finite differences in Section 17.5.4.2.

The finite-element method also begins with the construction of a 'mesh' covering the solution region. This mesh is commonly formed from triangles (the 'elements' of the method) although quadrilaterals can also be used. The mesh need not be uniform – indeed, it is standard practice to grade the mesh so that it is finer in regions where the solution is likely to vary rapidly, as shown in Figure 17.23.

The finite-element method, like the finite-difference method, changes the problem of solving a partial differential equation into that of solving a system of linear algebraic equations for a set of nodal values. However, in contrast to the finite-difference method, in which the value of the solution is only defined at the nodal points, the finite-element method replaces the actual solution by an approximation which is linear (or, more generally, a low-order polynomial) within each element.

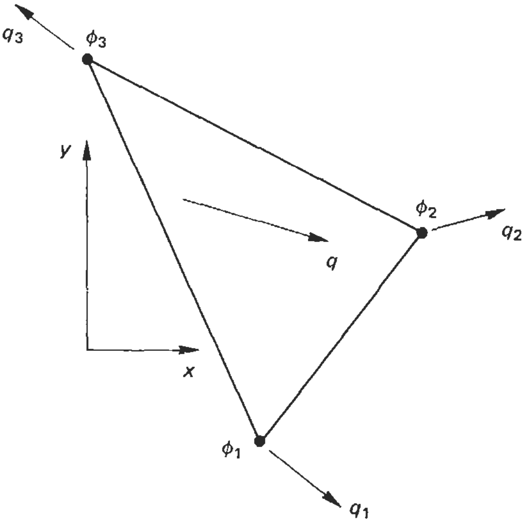

Figure 17.24 A typical finite element

The first stage of the solution procedure involves the determination of the properties of each individual element. A typical triangular element with nodal values ϕ_1, ϕ_2, ϕ_3 is shown in Figure 17.24. If the temperature ϕ within the element is assumed to vary linearly with position then it can be expressed in terms of the nodal values as

$$\phi = \phi_1 n_1(x,y) + \phi_2 n_2(x,y) + \phi_3 n_3(x,y) \qquad (17.39)$$

where n_1, n_2, n_3 are simple linear functions of x and y called *shape functions*. From this expression for ϕ it is straightforward to obtain the density of heat flow **q** (constant within the element) and the amount of heat flowing across each side of the triangle as linear functions of the nodal temperatures ϕ_1, ϕ_2, ϕ_3. In preparation for the next part of the procedure these distributed boundary flows are replaced by 'equivalent' concentrated flows q_1, q_2, q_3 at the vertices of the element, as shown in Figure 17.24, these concentrated flows being expressed as linear functions of the nodal temperatures ϕ_1, ϕ_2, ϕ_3.

The second stage of the solution procedure involves joining the elements together to form the solution region. This has two consequences. First, it imposes conditions of continuity on the temperature ϕ. If two elements have nodes p and q in common, as shown in Figure 17.25, then they share the same

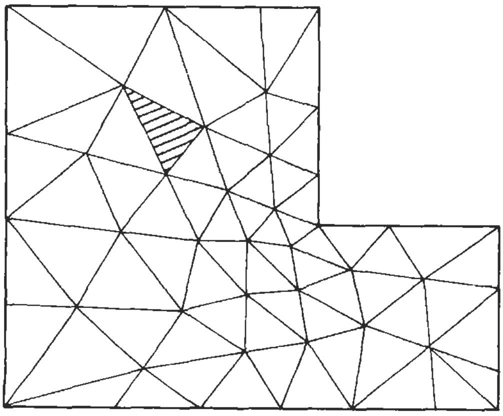

Figure 17.23 A finite-element mesh

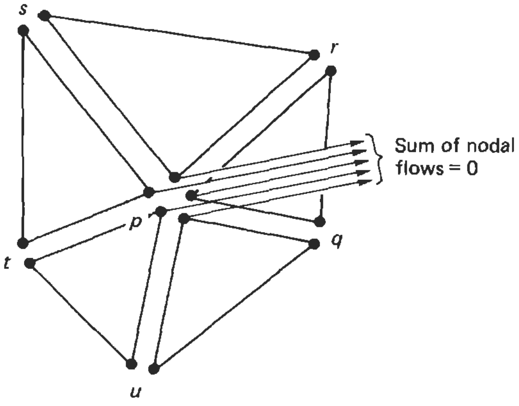

Figure 17.25 Adding up the nodal flows in a finite-element mesh

nodal values ϕ_p and ϕ_q. Furthermore, since ϕ is linear within each element, ϕ is also continuous on their common boundary pq. Second, it imposes conditions on the nodal heat flows. In the exact solution of a steady heat-flow problem the net outflow from any infinitesimal area within the solution region must be zero. In the finite-element method this condition is replaced by the condition that at each node within the solution region the equivalent concentrated nodal flows associated with the node must add up to zero. Since these nodal flows are known linear functions of the associated nodal values, this condition generates a linear equation which relates the nodal values at a group of neighbouring nodes. Thus for the elements shown in Figure 17.25 the condition of zero net outflow at node p generates a linear equation involving ϕ_p and $\phi_q, \ldots, \phi_u$. There is one such equation for each node within the solution region.

The final stage of the method is the solution of the nodal-flow equations for the nodal values. As with the finite-difference method, the coefficient matrix for these equations is both sparse and banded. After the equations have been solved, values of ϕ at points within elements can be found, if required, from equation (17.39).

This example has introduced the simplest form of finite element – the three-node triangle, within which the dependent variable varies *linearly*. Adding three additional nodes, one on each side of the triangle, allows a *quadratic* variation of the dependent variable within the triangle, giving improved accuracy. Four- and eight-noded quadrilaterals are also popular elements in the analysis of two-dimensional problems. In three-dimensional analyses the corresponding elements are tetrahedra, 'bricks' and 'wedges'. Nowadays it is common for applications of the method to involve meshes with tens of thousands of nodes.

The application of the finite-element method to stress analysis follows similar lines, with (vector) displacements replacing (scalar) temperatures and (tensor) stresses replacing (vector) heat flow densities. Many commercial computer programs are now available for solving a wide range of stress and thermal analaysis problems. The method can also be applied to fluid flow and electromagnetic field problems.

17.6 Statistics

17.6.1 Introduction

Data are available in vast quantities in all branches of engineering. This chapter presents the more commonly used techniques for presenting and manipulating data to obtain meaningful results.

17.6.2 Averages

17.6.2.1 Arithmetic mean

The arithmetic mean of n numbers $x_1, x_2, x_3, \ldots, x_n$ is given by

$$\bar{x} = \frac{x_1 + x_2 + x_3 + \ldots + x_n}{n}$$

or

$$\bar{x} = \frac{\sum_{r=1}^{n} x_r}{n} \tag{17.40}$$

The arithmetic mean is easy to calculate and it takes into account all the figures. Its disadvantages are that it is influenced unduly by extreme values and the final result may not be a whole number, which can be absurd at times, e.g. a mean of $2\frac{1}{2}$ people.

17.6.2.2 Median and mode

Median or 'middle on' is found by placing all the figures in order and choosing the one in the middle, or if there are an even number of items, the mean of the two central numbers. It is a useful technique for finding the average of items which cannot be expressed in figures, e.g. shades of a colour. It is also not influenced by extreme values. However, the median is not representative of all the figures.

The mode is the most 'fashionable' item, that is, the one which appears the most frequently.

17.6.2.3 Geometric mean

The geometric mean of n numbers $x_1, x_2, x_3, \ldots, x_n$ is given by

$$x_g = \sqrt[n]{(x_1 \times x_2 \times x_3 \times \ldots \times x_n)} \tag{17.41}$$

This technique is used to find the average of quantities which follow a geometric progression or exponential law, such as rates of changes. Its advantage is that it takes into account all the numbers, but is not unduly influenced by extreme values.

17.6.2.4 Harmonic mean

The harmonic mean of n numbers $x_1, x_2, x_3, \ldots, x_n$ is given by

$$x_h = \frac{n}{\sum_{r=1}^{n}(1/x_r)} \tag{17.42}$$

This averaging method is used when dealing with rates or speeds or prices. As a rule when dealing with items such as A per B, if the figures are for equal As then use the harmonic mean but if they are for equal Bs use the arithmetic mean. So if a plane flies over three equal distances at speeds of 5 m/s, 10 m/s and 15 m/s the mean speed is given by the harmonic mean as

$$\frac{3}{\frac{1}{5} + \frac{1}{10} + \frac{1}{15}} = 8.18 \text{ m/s}$$

If, however, the plane were to fly for three equal times, of say, 20 seconds at speeds of 5 m/s, 10 m/s and 15 m/s, then the mean speed would be given by the arithmetic mean as $(5 + 10 + 15)/3 = 10$ m/s.

17.6.3 Dispersion

17.6.3.1 Range and quartiles

The average represents the central figure of a series of numbers or items. It does not give any indication of the spread of the figures, in the series, from the average. Therefore, in Figure 17.26, both curves, A and B, have the same average but B has a wider deviation from the average than curve A.

There are several ways of stating by how much the individual numbers, in the series, differ from the average. The range is the difference between the smallest and largest values. The series can also be divided into four quartiles and the dispersion stated as the interquartile range, which is the difference between the first and third quartile numbers, or the quartile deviation which is half this value.

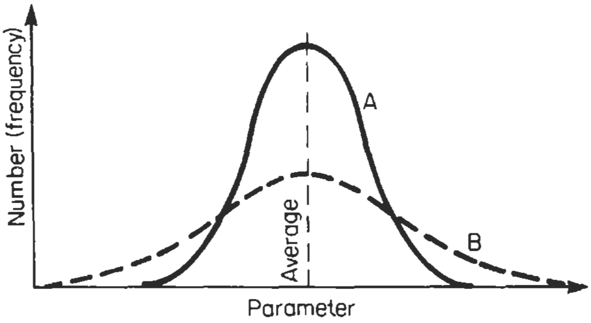

Figure 17.26 Illustration of deviation from the average

The quartile deviation is easy to use and is not influenced by extreme values. However, it gives no indication of distribution between quartiles and covers only half the values in a series.

17.6.3.2 *Mean deviation*

This is found by taking the mean of the differences between each individual number in the series and the arithmetic mean, or median, of the series. Negative signs are ignored.

For a series of n numbers $x_1, x_2, x_3, \ldots, x_n$ having an arithmetic mean of $\bar{x}$ the mean deviation of the series is given by

$$\frac{\Sigma_{r=1}^{n} \mid x_r - \bar{x} \mid}{n} \qquad (17.43)$$

The mean deviation takes into account all the items in the series. But it is not very suitable since it ignores signs.

17.6.3.3 *Standard deviation*

This is the most common measure of dispersion. For this the arithmetic mean must be used and not the median. It is calculated by squaring deviations from the mean, so eliminating their sign, adding the numbers together and then taking their mean and then the square root of the mean. Therefore, for the series in Section 17.6.3.2 the standard deviation is given by

$$\sigma = \left(\frac{\Sigma_{r=1}^{n}(x_r - \bar{x})^2}{n}\right)^{1/2} \qquad (17.44)$$

The unit of the standard deviation is that of the original series. So if the series consists of the heights of a group of children in metres, then the mean and standard deviation are in metres. To compare two series having different units, such as the height of children and their weights, the coefficient of variation is used, which is unitless:

$$\text{coefficient of variation} = \frac{\sigma}{\bar{x}} \times 100 \qquad (17.45)$$

17.6.4 Skewness

The distribution shown in Figure 17.26 is symmetrical since the mean, median and mode all coincide. Figure 17.27 shows a skewed distribution. It has positive skewness although if it bulges the other way, the skewness is said to be negative.

There are several mathematical ways for expressing skewness. They all give a measure of the deviation between the mean, median and mode and they are usually stated in relative terms, for ease of comparison between series of different units. The Pearson coefficient of skewness is given by

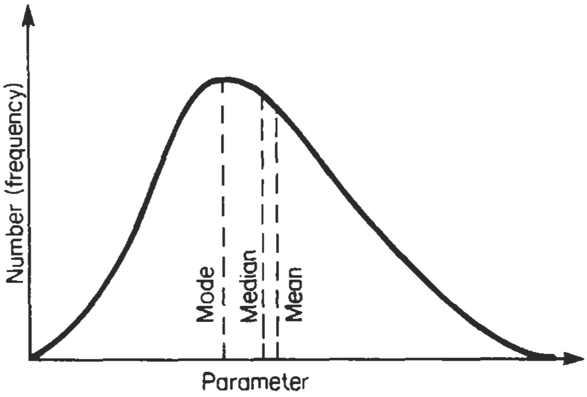

Figure 17.27 Illustration of skewness

$$P_k = \frac{\text{mean} - \text{mode}}{\text{standard deviation}} \qquad (17.46)$$

Since the mode is sometimes difficult to measure this can also be stated as

$$P_k = \frac{3(\text{mean} - \text{median})}{\text{standard deviation}} \qquad (17.47)$$

17.6.5 Combinations and permutations

17.6.5.1 *Combinations*

Combinations are the numbers of ways in which a proportion can be chosen from a group. Therefore the number of ways in which two letters can be chosen from a group of four letters A, B, C, D is equal to 6, i.e. AB, AC, AD, BC, BD, CD. This is written as

$${}^4C_2 = 6$$

The factorial expansion is frequently used in combination calculations where

$$n! = n \times (n - 1) \times (n - 2) \times \ldots \times 3 \times 2 \times 1$$

Using this the number of combinations of n items from a group of n is given by

$${}^nC_r = \frac{n!}{r!(n - r)!} \qquad (17.48)$$

17.6.5.2 *Permutations*

Combinations do not indicate any sequencing. When sequencing within each combination is involved the result is known as a permutation. Therefore the number of permutations of two letters out of four letters A, B, C, D is 12, i.e. AB, BA, AC, CA, AD, DA, BC, CB, BD, DB, CD, DC. The number of permutations of r items from a group of n is given by

$${}^nP_r = \frac{n!}{(n - r)!} \qquad (17.49)$$

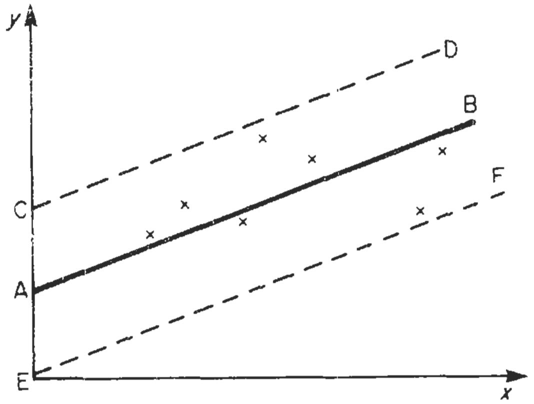

Figure 17.28 A scatter diagram

17.6.6 Regression and correlation

17.6.6.1 Regression

Regression is a method of establishing a mathematical relationship between two variables. Several equations may be used to establish this relationship, the most common being that of a straight line. Figure 17.28 shows the plot of seven readings. This is called a scatter diagram. The points can be seen to lie approximately on the straight line AB.

The equation of a straight line is given by

$$y = mx + c \tag{17.50}$$

where x is the independent variable, y the dependent variable, m is the slope of the line and c its interception on the y-axis. c is negative if the line intercepts the y-axis on its negative part and m is negative if the line slopes the other way to that shown in Figure 17.28.

The best straight line to fit a set of points is found by the method of least squares as

$$m = \frac{\Sigma xy - (\Sigma x \Sigma y)/n}{\Sigma x^2 - (\Sigma x)^2/n} \tag{17.51}$$

and

$$c = \frac{\Sigma x \Sigma xy - \Sigma y \Sigma x^2}{(\Sigma x)^2 - n\Sigma x^2} \tag{17.52}$$

where n is the number of points. The line passes through the mean values of x and y, i.e. $\bar{x}$ and $\bar{y}$.

17.6.6.2 Correlation

Correlation is a technique for establishing the strength of the relationship between variables. In Figure 17.28 the individual figures are scattered on either side of a straight line and although one can approximate them by a straight line it may be required to establish if there is correlation between the x- and y-readings.

Several correlation coefficients exist. The product moment correlation coefficient (r) is given by

$$r = \frac{\Sigma(x - \bar{x})(y - \bar{y})}{n\sigma_x\sigma_y} \tag{17.53}$$

or

$$r = \frac{\Sigma(x - \bar{x})(y - \bar{y})}{[\Sigma(x - \bar{x})^2\Sigma(y - \bar{y})^2]^{1/2}} \tag{17.54}$$

The value of r varies from +1, when all the points lie on a straight line and y increases with x, to −1, when all the points lie on a straight line but y decreases with x. When $r = 0$ the points are widely scattered and there is said to be no correlation between x and y.

The standard error of estimation in r is given by

$$S_y = \sigma_y(1 - r^2)^{1/2} \tag{17.55}$$

In about 95% of cases, the actual values will lie between plus or minus twice the standard error of estimated values given by the regression equation. This is shown by lines CD and EF in Figure 17.28. Almost all the values will be within plus or minus three times the standard error of estimated values.

It should be noted that σ_y is the variability of the y-values, whereas S_y is a measure of the variability of the y-values as they differ from the regression which exists between x and y. If there is no regression then $r = 0$ and $\sigma_y = S_y$.

It is often necessary to draw conclusions from the order in which items are ranked. For example, two judges may rank contestants in a contest and we need to know if there is any correlation between their rankings. This may be done by using the Rank correlation coefficient (R) given by

$$R = 1 - \frac{6\Sigma d^2}{n^3 - n} \tag{17.56}$$

where d is the difference between the two ranks for each item and n is the number of items. The value of R will vary from +1 when the two ranks are identical to −1 when they are exactly reversed.

17.6.7 Probability

If an event A occurs n times out of a total of m cases then the probability of occurrence is stated to be

$$P(\mathrm{A}) = n/m \tag{17.57}$$

Probability varies between 0 and 1. If $P(\mathrm{A})$ is the probability of occurrence then $1 - P(\mathrm{A})$ is the probability that event A will not occur and it can be written as $P(\bar{\mathrm{A}})$.

If A and B are two events then the probability that either may occur is given by

$$P(\mathrm{A\ or\ B}) = P(\mathrm{A}) + P(\mathrm{B}) - P(\mathrm{A\ and\ B}) \tag{17.58}$$

A special case of this probability law is when events are mutually exclusive, i.e. the occurrence of one event prevents the other from happening. Then

$$P(\mathrm{A\ or\ B}) = P(\mathrm{A}) + P(\mathrm{B}) \tag{17.59}$$

If A and B are two events then the probability that they may occur together is given by

$$P(\mathrm{A\ and\ B}) = P(\mathrm{A}) \times P(\mathrm{B}|\mathrm{A}) \tag{17.60}$$

or

$$P(\mathrm{A\ and\ B}) = P(\mathrm{B}) \times P(\mathrm{A}|\mathrm{B}) \tag{17.61}$$

$P(\mathrm{B}|\mathrm{A})$ is the probability that event B will occur assuming that event A has already occurred and $P(\mathrm{A}|\mathrm{B})$ is the probability that event A will occur assuming that event B has already occurred. A special case of this probability law is when A and B are independent events, i.e. the occurrence of one event has no influence on the probability of the other event occurring.

Then

$$P(\text{A and B}) = P(\text{A}) \times P(\text{B}) \tag{17.62}$$

Bayes' theorem on probability may be stated as

$$P(\text{A}|\text{B}) = \frac{P(\text{A})P(\text{B}|\text{A})}{P(\text{A})P(\text{B}|\text{A}) + P(\bar{\text{A}})P(\text{B}|\bar{\text{A}})} \tag{17.63}$$

As an example of the use of Bayes' theorem suppose that a company discovers that 80% of those who bought its product in a year had been on the company's training course. 30% of those who bought a competitor's product had also been on the same training course. During that year the company had 20% of the market. The company wishes to know what percentage of buyers actually went on its training course, in order to discover the effectiveness of this course.

If B denotes that a person bought the company's product and T that they went on the training course then the problem is to find $P(\text{B}|\text{T})$. From the data $P(\text{B}) = 0.2$, $P(\bar{\text{B}}) = 0.8$, $P(\text{T}|\text{B}) = 0.8$, $P(\text{T}|\bar{\text{B}}) = 0.3$. Then from equation (17.63)

$$P(\text{B}|\text{T}) = \frac{0.2 \times 0.8}{0.2 \times 0.8 + 0.8 \times 0.3} = 0.4$$

17.6.8 Probability distributions

There are several mathematical formulae with well-defined characteristics and these are known as probability distributions. If a problem can be made to fit one of these distributions then its solution is simplified. Distributions can be discrete when the characteristic can only take certain specific values, such as 0, 1, 2, etc., or they can be continuous where the characteristic can take any value.

17.6.8.1 Binomial distribution

The binomial probability distribution is given by

$$(p + q)^n = q^n + {}^nC_1pq^{n-1} + {}^nC_2p^2q^{n-2} + \ldots + {}^nC_xp^xq^{n-x} + \ldots + p^n \tag{17.64}$$

where p is the probability of an event occurring, $q(= 1 - p)$ is the probability of an event not occurring and n is the number of selections.

The probability of an event occurring m successive times is given by the binomial distribution as

$$p(m) = {}^nC_mp^mq^{n-m} \tag{17.65}$$

The binomial distribution is used for discrete events and is applicable if the probability of occurrence p of an event is constant on each trial. The mean of the distribution $B(M)$ and the standard deviation $B(S)$ are given by

$$B(M) = np \tag{17.66}$$

$$B(S) = (npq)^{1/2} \tag{17.67}$$

17.6.8.2 Poisson distribution

The Poisson distribution is used for discrete events and, like the binomial distribution, it applies to mutually independent events. It is used in cases where p and q cannot both be defined. For example, one can state the number of goals which were scored in a football match, but not the goals which were not scored.

The Poisson distribution may be considered to be the limiting case of the binomial when n is large and p is small.

The probability of an event occurring m successive times is given by the Poisson distribution as

$$p(m) = (np)^m \frac{\mathrm{e}^{-np}}{m!} \tag{17.68}$$

The mean $P(M)$ and standard deviation $P(S)$ of the Poisson distribution are given by

$$P(M) = np \tag{17.69}$$

$$P(S) = (np)^{1/2} \tag{17.70}$$

Poisson probability calculations can be done by the use of probability charts as shown in Figure 17.29. This shows the probability that an event will occur at least m times when the mean (or expected) value np is known.

17.6.8.3 Normal distribution

The normal distribution represents continuous events and is shown plotted in Figure 17.30. The x-axis gives the event and the y-axis the probability of the event occurring. The curve shows that most of the events occur close to the mean value and this is usually the case in nature. The equation of the normal curve is given by

$$y = \frac{1}{\sigma(2\pi)^{1/2}} \mathrm{e}^{-(x - \bar{x})^2/(2\sigma^2)} \tag{17.71}$$

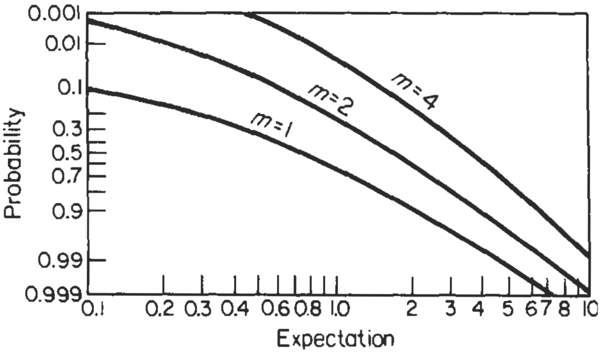

Figure 17.29 Poisson probability paper

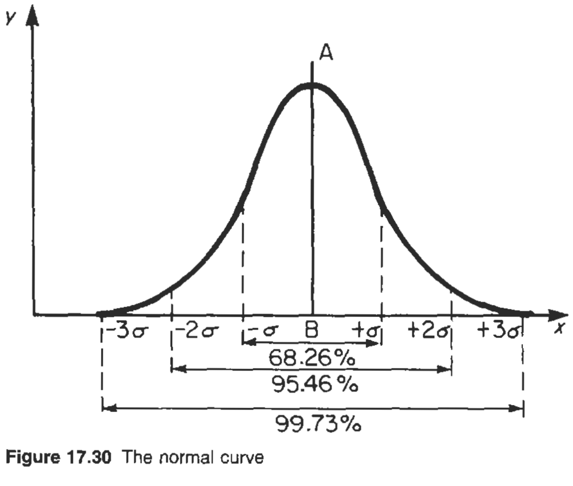

Figure 17.30 The normal curve

where $\bar{x}$ is the mean of the values making up the curve and σ is their standard deviation.

Different distributions will have varying mean and standard deviations but if they are distributed normally then their curves will all follow equation (17.71). These distributions can all be normalized to a standard form by moving the origin of their normal curve to their mean value, shown as B in Figure 17.30. The deviation from the mean is now represented on a new scale of units given by

$$\omega = \frac{x - \bar{x}}{\sigma} \tag{17.72}$$

The equation for the standardized normal curve now becomes

$$y = \frac{1}{(2\pi)^{1/2}} e^{-\omega^2/2} \tag{17.73}$$

The total area under the standardized normal curve is unity and the area between any two values of ω is the probability of an item from the distribution falling between these values. The normal curve extends infinitely in either direction but 68.26% of its values (area) fall between $\pm\sigma$, 95.46% between $\pm 2\sigma$, 99.73% between $\pm 3\sigma$ and 99.994% between $\pm 4\sigma$.

Table 17.1 gives the area under the normal curve for different values of ω. Since the normal curve is symmetrical the area from $+\ \omega$ to $+\infty$ is the same as from $-\omega$ to $-\infty$. As an example of the use of this table, suppose that 5000 street lamps have been installed in a city and that the lamps have a mean life of 1000 hours with a standard deviation of 100 hours. How many lamps will fail in the first 800 hours? from equation (17.72)

$$\omega = (800 - 1000)/100 = -2$$

Ignoring the negative sign, Table 17.1 gives the probability of lamps not failing as 0.977 so that the probability of failure is 1 − 0.977 or 0.023. Therefore 5000 × 0.023 or 115 lamps are expected to fail after 800 hours.

Table 17.1 Area under the normal curve from $-\infty$ to ω

17.6.8.4 *Exponential distribution*

The exponential probability distribution is a continuous distribution and is shown in Figure 17.31. It has the equation

$$y = \frac{1}{\bar{x}} e^{-x/\bar{x}} \tag{17.74}$$

where $\bar{x}$ is the mean of the distribution. Whereas in the normal distribution the mean value divides the population in half, for the exponential distribution 36.8% of the population is above the average and 63.2% below the average. Table 17.2 shows the area under the exponential curve for different values of the ratio $K = x/\bar{x}$, this area being shown shaded in Figure 17.31.

As an example suppose that the time between failures of a piece of equipment is found to vary exponentially. If results indicate that the mean time between failures is 1000 hours, then what is the probability that the equipment will work for 700 hours or more without a failure? Calculating K as 700/1000 = 0.7 then from Table 17.2 the area beyond 0.7 is 0.497 which is the probability that the equipment will still be working after 700 hours.

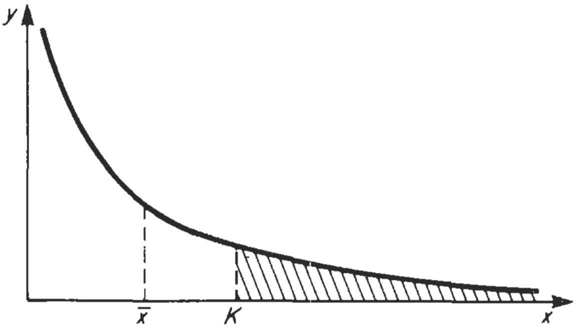

Figure 17.31 The exponential curve

Table 17.2 Area under the exponential curve from K to $+\infty$

K	0.00	0.02	0.04	0.06	0.08
0.0	1.000	0.980	0.961	0.942	0.923
0.1	0.905	0.886	0.869	0.852	0.835
0.2	0.819	0.803	0.787	0.771	0.776
0.3	0.741	0.726	0.712	0.698	0.684
0.4	0.670	0.657	0.644	0.631	0.619
0.5	0.607	0.595	0.583	0.571	0.560
0.6	0.549	0.538	0.527	0.517	0.507
0.7	0.497	0.487	0.477	0.468	0.458
0.8	0.449	0.440	0.432	0.423	0.415
0.9	0.407	0.399	0.391	0.383	0.375

Column 1 lists the ordinal values of ω or K and the corresponding values of area are presented in column 2. Interpolation between ordinal values can be achieved in steps of 0.02 by using the remaining 4 columns.

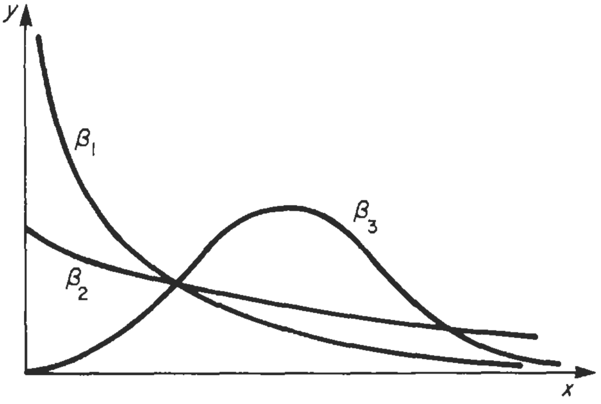

Figure 17.32 Weibull curves ($\alpha = 1$)

17.6.8.5 Weibull distribution

This is a continuous probability distribution and its equation is given by

$$y = \alpha\beta(x - \gamma)^{\beta - 1}e^{-\alpha(x-\gamma)^{\beta}} \tag{17.75}$$

where α is called the scale factor, β the shape factor and γ the location factor.

The shape of the Weibull curve varies depending on the value of its factors. β is the most important, as shown in Figure 17.32, and the Weibull curve varies from an exponential ($\beta = 1.0$) to a normal distribution ($\beta = 3.5$). In practice β varies from about $\frac{1}{3}$ to 5. Because the Weibull distribution can be made to fit a variety of different sets of data, it is popularly used for probability distributions.

Analytical calculations using the Weibull distribution are cumbersome. Usually predictions are made using Weibull probability paper. The data are plotted on this paper and the probability predictions read from the graph.

17.6.9 Sampling

A sample consists of a relatively small number of items drawn from a much larger population. This sample is analysed for certain attributes and it is then assumed that these attributes apply to the total population, within a certain tolerance of error.

Sampling is usually associated with the normal probability distribution and, based on this distribution, the errors which arise due to sampling can be estimated. Suppose a sample of n_s items is taken from a population of n_p items which are distributed normally. If the sample is found to have a mean of μ_s with a standard deviation of σ_s then the mean μ_p of the population can be estimated to be within a certain tolerance of μ_s. It is given by

$$\mu_p = \mu_s \pm \frac{\gamma\sigma_s}{n_s^{1/2}} \tag{17.76}$$

γ is found from the normal curve depending on the level of confidence we need in specifying μ_p. For $\gamma = 1$ this level is 68.26%; for $\gamma = 2$ it is 95.46% and for $\gamma = 3$ it is 99.73%.

The standard error of mean σ_e is often defined as

$$\sigma_e = \frac{\sigma_s}{n_s^{1/2}} \tag{17.77}$$

so equation (17.76) can be rewritten as

$$\mu_p = \mu_s \pm \gamma\sigma_e \tag{17.78}$$

As an example suppose that a sample of 100 items, selected at random from a much larger population, gives their mean weight as 20 kg with a standard deviation of 100 g. The standard error of the mean is therefore $100/(100)^{1/2} = 10$ g and one can say with 99.73% confidence that the mean value of the population lies between $20 \pm 3 \times 0.01$ or 20.03 kg and 19.97 kg.

If in a sample of n_s items the probability of occurrence of a particular attribute is p_s, then the standard error of probability p_e is defined as

$$p_e = \left(\frac{p_s q_s}{n_s}\right)^{1/2} \tag{17.79}$$

where $q_s = 1 - p_s$.

The probability of occurrence of the attribute in the population is then given by

$$p_p = p_s \pm \gamma p_e \tag{17.80}$$

where γ is again chosen to cover a certain confidence level.

As an example suppose a sample of 500 items shows that 50 are defective. Then the probability of occurrence of the defect in the sample is $50/500 = 0.1$. The standard error of probability is $(0.1 \times 0.9/500)^{1/2}$ or 0.0134. Therefore we can state with 95.46% confidence that the population from which the sample was drawn has a defect probability of $0.1 \pm 2 \times 0.0134$, i.e. 0.0732 to 0.1268; or we can state with 99.73% confidence that this value will lie between $0.1 \pm 3 \times 0.0134$, i.e. 0.0598 to 0.1402.

If two samples have been taken from the same population and these give standard deviations of σ_{s1} and σ_{s2} for sample sizes of n_{s1} and n_{s2} then equation (17.77) can be modified to give the standard error of the difference between means as

$$\sigma_{de} = \left(\frac{\sigma_{s1}^2}{n_{s1}} + \frac{\sigma_{s2}^2}{n_{s2}}\right)^{1/2} \tag{17.81}$$

Similarly equation (17.79) can be modified to give the standard error of the difference between probabilities of two samples from the same population as

$$p_{de} = \left(\frac{p_{s1}q_{s1}}{n_{s1}} + \frac{p_{s2}q_{s2}}{n_{s2}}\right)^{1/2} \tag{17.82}$$

17.6.10 Tests of significance

In taking samples we often obtain results which deviate from the expected. Tests of significance are then used to determine if this deviation is real or if it could have arisen due to sampling error.

17.6.10.1 Hypothesis testing

In this system a hypothesis is formulated and is then tested at a given confidence level. For example, suppose a coin is tossed 100 times and it comes up heads 60 times. Is the coin biased or is it likely that this falls within a reasonable sampling error? The hypothesis is set up that the coin is not biased. Therefore one would expect that the probability of heads is 0.5, i.e. $p_s = 0.5$. The probability of tails, q_s, is also 0.5. Using equation (17.79) the standard error of probability is given by $p_e = (0.5 \times 0.5/100)^{1/2}$ or 0.05. Therefore from equation (17.80) the population probability at the 95.45% confidence level of getting heads is $0.5 + 2 \times 0.05 = 0.6$. Therefore it is highly likely that the coin is not biased and the results are due to sampling error.

The results of any significance test are not conclusive. For example, is 95.45% too high a confidence level to require? The higher the confidence level the greater the risk of rejecting a true hypothesis, and the lower the level the greater the risk of accepting a false hypothesis.

Suppose now that a sample of 100 items of production shows that five are defective. A second sample of 100 items its taken from the same production a few months later and gives two defectives. Does this show that the production quality is improving? Using equation (17.82) the standard error of the difference between probabilities is given by $(0.5 \times 0.95/100 + 0.02 \times 0.98/100)^{1/2} = 0.0259$. This is less than twice the difference between the two probabilities, i.e. $0.05 - 0.02 = 0.03$, therefore the difference is very likely to have arisen due to sampling error and it does not necessarily indicate an improvement in quality.

17.6.10.2 Chi-square test

This is written as χ^2. If O is an observed result and E is the expected result then

$$\chi^2 = \sum \frac{(O - E)^2}{E} \qquad (17.83)$$

The χ^2 distribution is given by tables such as Table 17.3, from which the probability can be determined. The number of degrees of freedom is the number of classes whose frequency can be assigned independently. If the data are presented in the form of a table having V vertical columns and H horizontal rows then the degrees of freedom are usually found as $(V - 1)(H - 1)$.

Returning to the earlier example, suppose a coin is tossed 100 times and it comes up heads 60 times and tails 40 times. Is the coin biased? The expected values for heads and tails are 50 each so that

$$\chi^2 = \frac{(60 - 50)^2}{50} + \frac{(40 - 50)^2}{50} = 4$$

The number of degrees of freedom is one since once we have fixed the frequency for heads that for tails is defined. Therefore entering Table 17.3 with one degree of freedom the probability level for $\chi^2 = 4$ is seen to be above 0.025 (= 2.5%), i.e. there is a strong probability that the difference in the two results arose by chance and the coin is not biased.

Table 17.3 The chi-square distribution

Degrees of freedom	*Probability level*				
	0.100	0.050	0.025	0.010	0.005
1	2.71	3.84	5.02	6.63	7.88
2	4.61	5.99	7.38	9.21	10.60
3	6.25	7.81	9.35	11.34	12.84
4	7.78	9.49	11.14	13.28	14.86
5	9.24	11.07	12.83	15.09	16.75
6	10.64	12.59	14.45	16.81	18.55
7	12.02	14.07	16.01	18.48	20.28
8	13.36	15.51	17.53	20.09	21.96
9	14.68	16.92	19.02	21.67	23.59
10	15.99	18.31	20.48	23.21	25.19
12	18.55	21.03	23.34	26.22	28.30
14	21.06	23.68	26.12	29.14	31.32
16	23.54	26.30	28.85	32.00	34.27
18	25.99	28.87	31.53	34.81	37.16
20	28.41	31.41	34.17	37.57	40.00
30	40.26	43.77	46.98	50.89	53.67
40	51.81	55.76	59.34	63.69	66.77

Table 17.4 Frequency distribution of accidents in a factory during 24 hours

Time (24 hour clock)	*Number of accidents*
0–6	9
6–12	3
12–18	2
18–24	6

As a further example suppose that over a 24-hour period the average number of accidents which occur in a factory is seen to be as in Table 17.4. Does this indicate that most of the accidents occur during the late night and early morning periods? Applying the χ^2 tests, the expected value, (if there was no difference between the time periods) would be the mean of the number of accidents, i.e. 5. Therefore from equation (17.83)

$$\chi^2 = \frac{(9 - 5)^2}{5} + \frac{(3 - 5)^2}{5} + \frac{(2 - 5)^2}{5} + \frac{(6 - 5)^2}{5} = 6$$

There are three degrees of freedom, therefore from Table 17.3 the probability of occurrence of the result shown in Table 17.4 is seen to be greater than 10%. The conclusion would be that although there is a trend, as yet there are not enough data to show if this trend is significant or not. For example, if the number of accidents were each three times as large, i.e. 27, 9, 6, 18 respectively, then χ^2 would be calculated as 20.67 and from Table 17.3 it is seen that the results are highly significant since there is a very low probability, less than 0.5% that it can arise by chance.

17.6.10.3 Significance of correlation

The significance of the product moment correlation coefficient of equations (17.53) or (17.54) can be tested at any confidence level by means of the standard error of estimation given by equation (17.55). An alternative method is to use the Student t test of significance. This is given by

$$t = \frac{r(n - 2)^{1/2}}{(1 - r^2)^{1/2}} \qquad (17.84)$$

where r is the correlation coefficient and n the number of items. Tables are then used, similar to Table 17.3, which give the probability level for $(n - 2)$ degrees of freedom.

The Student t for the rank correlation coefficient is given by

$$t = R[(n - 2)/(1 - R^2)]^{1/2} \qquad (17.85)$$

and the same Student t tables are used to check the significance of R.

The regulations governing health and safety are surveyed in this chapter. Obviously, these regulations differ from country to country, but a general trend towards harmonization of European legislation through the European Community is bound to lead to more common legislation worldwide.

A brief section dealing with the legislation and administration of health and safety law in several countries follows. As a country with highly developed legislation and regulation, the UK has been chosen for the subsequent more detailed examination. This gives an illustration of various themes that run through the health and safety regulations of any country. The UK also has a system that is fairly similar to those of most European countries.

18.1 Health and safety in the European Community

The legislation and administrative organization of the European Community with respect to health and safety varies widely. At one extreme are countries like the UK and Denmark, who have highly developed legislation and, at the other, is Portugal, with no specific regulations.

18.1.1 Denmark

Health and safety in Denmark is controlled by the Health and Safety at Work Act 1985. Specific regulations are made under this enabling Act and are enforced by an inspectorate under the Minister of Labour. Safety committees have to be formed by companies with more than 20 employees.

18.1.2 Belgium

Health and safety is controlled in Belgium by File 2 of the General Regulations, for the protection of employment. These detail requirements including use of machinery, handling of materials, fire risks, hygiene of premises, temperature and sanitation. Safety officers have to be appointed by companies. Safety committees are necessary in companies employing more than 50 people. There is no government inspectorate but routine inspections are carried out by authorized private firms.

18.1.3 France

Labour codes control health and safety practices in France. Under labour code 236 companies employing more than 50 people are required to form safety committees:

Code 232-1 requires workplaces to be hygienic.
Code 233-1 protects workers against falls, collisions and suffocation.
Codes 231-6 and 231-7 list dangerous substances and control labelling and carrying instructions.

18.1.4 The Netherlands

Health and safety is controlled in the Netherland by the Working Conditions Act 1980. This Act, which was introduced in phases, requires employers to promote health and safety to employees. Employers are obliged to reveal to workers all information concerning risks to health and are required to assign tasks according to workers' physical and mental capacities.

There is an overriding obligation to organize activities to ensure the best possible working conditions and for companies with more than 100 employees there is a requirement to report annually on these conditions. Works councils must be set up to oversee and promote health and safety. For companies with more than 500 employees safety departments have to be organized and staffed by specialist personnel. The legislation is enforced by an inspectorate employed by the Labour Ministry.

18.1.5 Portugal

There is no formal legislation controlling health and safety in Portugal. Draft documents exist and these have been the subject of discussion since 1990. The regulations that do apply to factories are enforced by the Geneal Inspectorate of Labour. The Director General of Occupational Safety and Health advises on standards and carries out research.

18.1.6 Spain

Spanish codes of practice enforced by the labour inspectorate form the basis of legislative control. Firms employing more than 100 employees have to form health and safety committees. Staff representatives have a role to play in health and safety enforcement. If three-quarters of the safety representatives decide that there is a grave risk of an accident they are entitled to stop work at the premises. A ruling from the labour inspectorate is then made within 24 hours. Fines for breaches of regulations vary between £165 and £1650.

18.1.7 Germany

In Germany the Safety at Work Act 1973 controls health and safety. Inspection of premises is again entrusted to private authorized firms (for example, the Accident Prevention Institute). Employees have a duty to support these inspection agencies and companies must appoint a specialist safety officer if they have more than 20 employees.

18.1.8 Greece

Under safety law 1568/85 firms are required in Greece to form safety committees and a 'safety technician' has to be employed if there are more than 50 employees. A factory doctor is also required. Inspection of premises is carried out by a labour inspectorate under the Minister of Labour.

18.1.9 Irish Republic

Health and safety in the Irish Republic is controlled by the Health Safety and Welfare at Work Act 1989. This statute requires firms that employ more than 10 staff to produce a safety statement. If the statement reveals unsatisfactory situations the firms are obliged to deal with them. An inspectorate is employed which can inspect and require changes to be made to safety statements and, consequently, changes to work practices.

18.1.10 Italy

Under Article 2087 of the Civil Code companies in Italy are responsible for employees' physical and mental wellbeing. Article 41 deals with safety, freedom and human dignity in employment. Under Article 9 of the workers' statute workers have a collective right to verify measures to protect staff and prevent accidents and work-related diseases. Local health authorities can monitor situations with respect to space, light, cleanliness, toilet provision, protective clothing, etc. Regulations exist which control the employment of pregnant women.

18.2 Health and safety at work–law and administration in the USA

In the USA health and safety standards are set by the Occupational Safety and Health Administration (OSHA). During 1991 OSHA conducted 82 484 State and 42 113 Federal inspections and maximum penalties for breaches of legislation were increased by sevenfold during that year. A system of penalties for breaches of legislation is enacted by OSHA.

During 1991 a total of $9.7 million in federal penalties and $32.6 million in state penalties were imposed. Recently, OSHA introduced two new and three proposed standards. The new standards related to the construction industry and detailed safe practices in the use of the 'lift slab' construction method and one on the use of ladders and stairways in construction. The proposed new standards included:

1. A new limit value for formaldehyde
2. Indoor air quality
3. Cadmium

18.3 UK legislation and guidance

Health and safety at work in the UK is controlled by a large number of Statutory Instruments of varying importance and it is necessary to appreciate their individual significance and relationship to others.

The principal way that statute law is implemented is by Act of Parliament. The statute first passes through the House of Commons, after initial drafting and consultation phases, and then to the House of Lords. It passes again through the Commons where any amendments are considered. It will finally receive the Royal Seal of Approval and become an Act of Parliament.

Regulations may be made by persons (usually Ministers) authorized in Acts of Parliament (for instance, by Section 15 of The Health and Safety at Work etc. Act 1974). These Regulations do not pass through Parliament in the same way as an Act (although Parliament does maintain overall control). Regulations carry the same force of law as Acts of Parliament.

Approved Codes of Practice are also commonly employed in health and safety matters. These do not carry the same authority as Acts or Regulations but rather serve to amplify and add detail to requirements imposed by Acts or Regulations. Non-compliance with approved Codes of Practice is not (in itself) an offence, but is likely to result in an offence being committed under the enabling Act (or Regulations).

Guidance notes are also issued. These are of a technical nature and serve to give examples of good practice that will enable compliance with statutes. Again, non-compliance with a guidance note is not, in itself, an offence.

18.4 The Health and Safety at Work etc. Act 1974

This Act is intended to secure the health, safety and welfare of persons at work. In addition, the Act also protects persons (other than those at work) against risks to health and safety arising out of or in connection with the activities of persons at work. The Act also controls the keeping and use of explosives or highly flammable or otherwise dangerous substances and the emission into the atmosphere of noxious or offensive substances.

18.4.1 Duties of employers

Section 2 of the Act applies to employers and imposes a general duty to ensure the health, safety and welfare of all employees. This includes the provision and maintenance of safe plant, arrangements for handling and storage and transport of substances in a safe manner. The provision of instruction, information and training is also a requirement.

The work premises are required to be safe and without risks to health, including safe means of access and egress. The working environment shall similarly be safe and without risks to health, and adequate in facilities and arrangements for welfare at work. All these actions are required to be taken 'as far as is reasonably practicable' – an expression that involves both technical feasibility as well as an element of financial practicality.

Section 2 also requires the writing of safety policies (except as may be prescribed) which, currently, have to be prepared for companies with five or more employees. Statements must be reviewed at regular intervals and brought to the attention of employees.

18.4.2 Duties to others

Section 3 of the Act requires employers and the self-employed to take steps to protect persons not in their employment from work-related activities. In addition, this section requires employers and the self-employed (in prescribed circumstances) to provide certain information to persons who may be affected by their work activities concerning the way in which those work activities may affect those persons' health or safety. In addition, the self-employed have a duty of self-care concerning risks to their own health and safety.

18.4.3 Duties to non-employees on works premises

Persons having a control of premises (not including domestic) where persons (not being their employees) work or use plant or substances provided for their use have a duty of care to persons on their premises.

18.4.4 Duties of manufacturers

Persons who design, manufacture, import or supply articles for use at work have a duty of care to users such that the article is safe and without risks to health when properly used. For this purpose, they should carry out such tests and examinations as may be necessary. They must also make available to users adequate information about the use for which the article was designed and give information concerning any conditions necessary to ensure the safe use of that object.

18.4.5 Duties of employees

Employees (while at work) have a duty to take reasonable care of the health and safety of themselves and other persons who may be affected by their acts and omissions. In addition, they must cooperate with employers or other persons who have duties under this Act to ensure that that duty is performed or complied with.

18.4.6 Implementation of the Act

The Health and Safety Commission is the body that generates policies concerning health and safety. It consists of representatives from employers' and employees' organizations and is chaired by a person appointed by the Secretary of State. In addition, there may be representatives from Local Authority organizations and other professional bodies.

Enforcement of the Act falls to two Authorities (depending upon the nature of the use of the premises); the Health and Safety Executive and Local Authorities.

18.5 The Health and Safety Executive

The Health and Safety Executive has a dual role. One function is to generate guidance on aspects of health and safety, including guidance notes and liaison documents for Local Authorities. The second function is that of enforcement agency. Classes of premises are divided between the Health and Safety Executive and Local Authorities by the Allocation Regulations. Broadly, these Regulations allocate non-industrial premises (e.g. offices, warehouses, shops, places of entertainment) to Local Authorities and the rest falls to the Health and Safety Executive. Where more than one use takes place within one curtilage (for example, a cardboard carton-manufacturing factory which is within a large warehouse and only supplies that warehouse) several tests are applied concerning which use predominates. If the 'factory' use predominates, the Health and Safety Executive enforce, if the non-industrial use predominates, the Local Authority will enforce. Thus, for instance, a food warehouse with the cardboard carton-manufacturing plant used only for the purpose of boxing the food stored within the warehouse would be enforced by the Local Authority, whereas a large cardboard carton manufacturer who supplied other outlets and had a warehouse only to store its own cardboard boxes would be enforced by the Health and Safety Executive.

The test here is the prime purpose of the user. If the purpose is to manufacture and sell boxes the user is a factory (notwithstanding the fact that the warehouse may occupy a larger floor area than the box-manufacturing plant). The Health and Safety Executive is sub-divided into classes of inspectorate, as follows:

HM Factory Inspectorate
HM Agricultural Inspectorate
HM Explosives Inspectorate
HM Mines and Quarries Inspectorate
HM Nuclear Installations Inspectorate

The Health and Safety Executive operates from area offices located around the country, and, in addition, specialist offices are located in certain cities which deal with just one or two specialized industries (which may be prevalent in that particular area).

18.6 Local Authorities

Local Authorities appoint authorized officers to carry out their functions under The Health and Safety at Work etc. Act and these are usually Environmental Health Officers. Local Authority officers have exactly the same powers as the Health and Safety Executive enforcement officers and possess the same degree of expertise. As can be seen from the examples of allocations given above, the types of premises visited by Local Authorities may be essentially the same as those visited by the Health and Safety Executive. If, for instance, a large warehouse operation has an ancillary factory employing, say, one hundred operatives, the Local Authority would be responsible for enforcement, whereas the Health and Safety Executive would be responsible for a much smaller factory if the manufacturing use predominates.

18.7 Enforcement Notices

Breaches of the Health and Safety at Work etc. Act or its Regulations can be dealt with in one of three ways:

1. Improvement Notice
2. Prohibition Notice
3. Prosecution

18.7.1 Improvement Notice

This Notice may be served if the inspector believes that a contravention of one or more of the statutory provisions has taken place and that it is likely that the contravention will be repeated, or there is an ongoing breach of a statutory provision. In this case, the inspector may issue a Notice requiring works to be carried out. The time period for compliance is variable but should not be less than that allowed for appeal against the Notice (under Section 24).

18.7.2 Prohibition Notice

If the activities being carried out will involve a risk of serious personal injury the inspector may serve a Prohibition Notice. This may take immediate effect if the inspector feels that the risk of serious personal injury is imminent or may be deferred to a later date, if this is not the case.

18.7.3 Prosecution

An inspector may also prosecute any person who breaches a statutory provision in addition to (or instead of) the serving of a statutory notice.

18.7.4 Other powers

In addition to exercising the above powers an inspector may also physically render safe or seize any harmful substance or article. Inspectors have the power to enter premises (at any time if they believe that there is a dangerous situation), and may take a police officer with them if they have reason to believe that they will be obstructed. They may take photographs, samples, etc. and may order that premises be left undisturbed while investigations take place.

18.8 Control of Substances Hazardous to Health Regulations 1988

These Regulations (of which the majority came into force on 1 October 1989) lay down essential requirements for the control of hazardous substances and to protect persons exposed to them, and apply to the following:

1. Those substances that have been classified as being very toxic, toxic, harmful, corrosive or irritant under The Classification, Packaging and Labelling of Dangerous Substances Regulations 1984;
2. Those substances which have maximum exposure limits or occupational exposure standards (i.e. listed in HSE document EH/40);
3. Substances that have chronic or delayed effects, i.e. carcinogenic, mutagenic or teratogenic.

A substance should be regarded as hazardous to health if it is hazardous in the form in which it occurs in the work activity, whether or not its mode of action has been identified.

A substance hazardous to health is not just a single chemical compound but also includes mixtures of compounds, micro-oganisms, allergens, etc. When considering whether a substance is likely to be hazardous to health the following points are likely to be taken into account:

1. The form of the substance, i.e. particle size – respirable dust may be more hazardous than solid;
2. Impurities – contaminants in innocuous materials may render that material hazardous;
3. Fibres – fibrous form may be more hazardous;
4. Synergistic effects of more than one substance;
5. Microorganisms may arise from the work directly or indirectly (e.g. *legionella* – the causative organism of Legionnaires' disease which may be present in wet cooling towers).

18.8.1 Duties under the Regulations

The Regulations require employers to take steps to assess the risk to health arising from work with these hazardous substances and to decide on the precautions that are necessary. The employer then has to take the appropriate measures to prevent or control the risk (where it is not reasonably practicable to prevent it) and must then ensure that these control measures are used and that equipment is properly maintained and procedures observed.

Monitoring the health of workers is necessary in certain circumstances. Finally, instruction, training and the dissemination of information concerning the risks of working with the substances and the precautions to be taken are a requirement of the Act.

18.8.2 The assessment

The duty to carry out the assessment is placed on the employer, and it is acknowledged that the employer is likely to seek the services of an outside consultant (and this is most certainly the recommended course of action). However, the responsibility to make the actual assessment rests with the employer and cannot be delegated as such.

The Regulations require that after 1 January 1990 no work which is liable to expose anyone to substances hazardous to health shall be carried on unless an assessment has been made which need only relate to that part of the work liable to expose people to hazardous substances. If the conclusion is drawn that (while the substances covered are being used) there is no potential for exposure then no further assessment is needed.

The main points of the assessment are as follows:

1. Gather information.
2. Evaluate the risks.
3. Decide what precautions are necesssary.
4. Record the assessment.
5. Decide on the review period. (Review will also be necessary when there are any changes in the working practices or the substances used.)

18.8.3 Control measures

The Regulations require the prevention of exposure to the substance but acknowledge that this may not be reasonably practicable. In these cases the substance should be adequately controlled. The requirement is for adequate control, so far as is reasonably practicable, by means other than the provision of personal protective equipment. This means that engineering solutions, local exhaust ventilation, etc. should be the first considerations. If adequate control is not possible by these means then personal protective equipment should be used in addition to engineering solutions so that adequate control of the substance can be obtained.

18.9 Asbestos

Asbestos means any of the following minerals: crocidolite, amosite, chrysotile, fibrous actinolite, fibrous anthophyllite, fibrous tremolite and any mixture containing any of these minerals. There are various parts of legislation concerning the use, manufacture and removal of asbestos (or materials containing it) and reference must be made to these statutes prior to starting work:

The Asbestos (Licensing) Regulations 1983 prohibit work (subject to the Regulations) without a licence.
The Asbestos (Prohibition) Regulations 1985 (amended 1988), among other things, prohibit the application of asbestos by spraying, the use of asbestos materials for thermal and acoustic insulation, and the supply or application of any paint or varnish containing asbestos.
The Control of Asbestos at Work Regulations 1987 cover all work with asbestos.

18.10 Control of lead at work

The use of lead at work is controlled by The Control of Lead at Work Regulations 1980. An approved Code of Practice has been issued entitled Approved Code of Practice – Lead at Work (revised June 1985). The Regulations apply to work from which lead arises:

1. In the form of lead dust, fume or vapour which is liable to be inhaled;
2. In any form in which it is liable to be ingested (e.g. lead powder, dust, paint or paste);
3. In the form of lead compounds which are liable to be absorbed through the skin (e.g. concentrated lead alkyls).

The Regulations are thus not applicable to work with substances which, while containing lead, are not liable to be inhaled, ingested or absorbed by persons. An example of such a process given in the guidance notes is the handling of finished articles containing lead (e.g. pottery).

The extent to which the Regulations apply to a particular work activity is controlled by the probable nature and degree of exposure to lead and reference levels are set in the Regulations. A standard (known as the lead-in-air standard) is set at the following figures:

Lead (except for tetra-ethyl lead)	(as Pb)	0.15 mg/m^3 of air
Tetra-ethyl lead	(as Pb)	0.10 mg/m^3 of air

These limits are for 8-hour time-weighted average concentrations. The Regulations do allow some deviation from these standards as it is acknowledged that the absorption of lead is controlled by numerous factors including composition, solubility, particle size and period of exposure.

The degree of variance allowed is as follows:

The 8-hour time-weighted average concentration does not exceed three times the above figures.
The 40-hour time-weighted average does not exceed 0.15 mg/m^3 of air, if there is sufficient information available from biological test results to indicate that the degree of lead absorption is at an acceptable level.

The Regulations use the expression 'significant exposure' to apply or disapply certain Regulations. This is defined as:

1. An exposure of at least half the lead-in-air standard;
2. Where there is a significant risk of ingesting lead;
3. Where there is a risk of skin contact with concentrated lead alkyls.

Where biological monitoring is carried out as part of an assessment if the blood levels are greater than 40 μg per 100 ml or, in the case of workers exposed to lead alkyls, a urinary lead level of greater than 120 μg/l, the worker should be regarded as being significantly exposed to lead.

In the case of intermittent exposure (e.g. a few hours per week) if the lead-in-air standard is not exceeded and the weekly (i.e. 40-hour) average does not exceed one half of the 8-hour standard the exposure is not classed as significant. The main requirements of the Regulations are as follows:

Regulation 4 – where persons are exposed to lead the employer shall make an assessment.
Regulation 5 – employers shall ensure adequate information, instruction and training of their employees.
Regulation 6 – employers shall control the exposure of their employees to lead as far as is reasonably practicable otherwise than by the use of respiratory protective equipment. Control measures are considered adequate when they effectively control the exposure of employees to:

1. Lead-in-air concentrations not exceeding the lead-in-air standard;
2. Lead which can be ingested;
3. Lead which can be absorbed through the skin.

Regulation 7 – where it is not possible to control lead to the above standards the employer shall provide any employee liable to be exposed to airborne lead with respiratory protective equipment.
Regulation 8 – the employer shall provide protective clothing unless the exposure to lead is not 'significant' (see previous definition).
Regulation 9 – washing, changing and clothes storage facilities must be provided.
Regulation 10 – employers shall ensure that employees do not eat, drink or smoke in contaminated areas and that suitable areas are set aside for these activities.
Regulation 11 – the employer shall ensure the cleanliness of the workplace, etc.
Regulation 12 – the employer has a duty to ensure that contamination does not spread from the workplace so as to avoid exposure to persons not engaged in work with lead (e.g. the families of the lead workers).
Regulation 13 – control measures. If control measures (e.g. ventilation, respiratory protection, etc.) are necessary the employer shall ensure that they are properly used. The employer also has a duty under this section to properly use such facilities and to report any defects in such equipment, etc.
Regulation 14 – requires that employers shall adequately maintain control measures.
Regulation 15 – requires air monitoring to be carried out unless the exposure is not significant.
Regulation 16 – requires medical surveillance to be carried out if the exposure to lead is significant or if the Employment Medical Advisory Service-appointed doctor certifies that the employee should be under surveillance. The EMAS doctor can also require that an employer ceases to expose an employee to lead by way of a certificate that may also allow for some partial exposure (under specified circumstances).
Regulation 17 – requires the keeping of records of the assessments, maintenance, air tests and medical surveillance as required by previous Regulations.

18.11 The Electricity at Work Regulations 1989

The Electricity at Work Regulations came into force on 1 April 1990. These require precautions to be taken against the risk of death or personal injury from electricity in work activities. The Regulations apply to all electrical systems and equipment whenever manufactured, purchased or installed even if the use, etc. predates the Regulations.

18.11.1 The relationship to IEE Regulations

The Institution of Electrical Engineers Regulations are non-statutory Regulations and relate principally to the design, selection, erection, inspection and testing of electrical installations (whether permanent or temporary) in or about buildings generally and to agricultural and horticultural buildings, construction sites and caravans and their sites. There are thus many situations to which the IEE Regulations do not apply. In particular, they do not relate to systems operating at 1000 V a.c. or more. Compliance with IEE Regulations will mean that it is highly likely that a system will comply with The Electricity at Work Regulations.

18.11.2 The Regulations – definitions

The term 'system' is used to describe an electrical installation and is defined as including all the constituent parts of the system (e.g. conductors and electrical equipment) and is not a reference solely to the functional circuit as a whole. Where circuits are connected by inductance (e.g. in the windings of a transformer). Even if the circuits are galvanically separated, the two circuits are to be regarded as one system.

Some 'systems' may thus extend over a large geographical area if the circuits are connected in any way. Several persons may thus have control over one system. The Regulations require control over the system only insofar as they have control over the premises.

Electrical equipment is defined as every type of electrical equipment from a battery-powered torch up to a 400 kV overhead line. The Regulations apply where 'danger' may arise. Explosion risks are considered relevant. Thus low-voltage applicances (which present no danger of shock) may give rise to sparks which may present a danger.

Conductors mean any material capable of conducting electricity and include metals and other materials. The definition covers materials and structures not specifically designed for the transmission of electricity and may include, for example, salt water and ionized gases.

Circuit conductors are conductors whose normal function is to carry load currents or to be energized.

Danger is defined as the risk of injury.

Injury is defined as death or personal injury from electric shock, electric burn, electrical explosion or arcing or from fire or explosion initiated by electrical energy, where any such death or injury is associated with the generation, provision, transmission, tranformation, rectification, conversion, conduction, distribution, control, storage, measurement or use of electrical energy. The Regulations require that operatives prevent danger in some circumstances and prevent injury in others. This distinction is important. In some operations it is impossible to prevent danger (i.e. the risk of injury) but it is possible to prevent injury. Injury means death or injury caused by: electric shock, electric burn, fires of electrical origin, electric arcing and explosions initiated or caused by electricity.

Live – means that the conductor is at a voltage produced by a source of electricity.

Charged – means that the item has acquired a charge either because it is live or because is has become charged by static or induction charging.

18.11.3 The Regulations – requirements

The Regulations apply to employers and employees (including the self-employed). All systems shall be constructed so as to prevent danger (as far as is reasonably practicable). Every work activity should be carried out so as to avoid danger (again as far as is reasonably practicable).

The Regulations control both the way in which maintenance is carried out and the need for regular maintenance. The overriding preference for work on electrical systems is that they are made dead before work starts. Safe systems of work are considered most important in this case (particularly to avoid the system becoming inadvertently energized). The Regulations recognize that, under certain circumstances, it may not be possible to isolate circuits and particular requirements are made in terms of protective equipment which may need to be provided. The strength and capability of electrical systems is considered. Systems should take into account possible transient situations as well as normal conditions. Systems should be capable of operating without causing danger.

Adverse or hazardous environments are considered and it is a requirement that systems take account of mechanical damage, weather, wet, dirty or corrosive conditions as well as the presence of any flammable or explosive substances. The requirement again is to avoid danger.

Insulation is required to conductors which may give rise to danger or an alternative is permitted in that conductors may be made safe by position (this may also need the back-up of strictly controlled working practices). Earthing is required when conductors (other than circuit conductors) may become charged so as to cause danger. Alternative means of preventing this danger are also permitted (for instance, double insulation).

No device shall be placed in a reference conductor which is designed to connect to earth that might reasonably be expected to interrupt that conductor in such a way as may result in danger. Connections shall be mechanically and electrically suitable for use so as to prevent danger. Means for protecting from excess of current in any circuit are also to be provided. Where necesssary to prevent danger, a means of cutting off the supply and for isolation shall be supplied. Adequate precautions shall be taken to prevent equipment which has been made dead for the purposes of carrying out works from becoming electrically charged during work if danger may arise.

Work on or near live conductors, if liable to cause danger, is prohibited unless it is unreasonable in all the circumstances for it to be dead and it is reasonable in all the circumstances for the worker to be at work on or near it while it is live and suitable precautions (including, where necessary, the provision of suitable protective equipment) are taken to prevent injury. Working space, access and lighting are considered and the Regulations require that adequate means of access and lighting and adequate working space be provided when work is being carried out in circumstances which may give rise to danger. Regulation 17 of the Electricity (Factories Act) Special Regulations 1908 and 1944 gives dimensions for minimum passageways near switchboards, etc. and these are used as guidance for situations where circuit voltages do not exceed 3000 V.

Competent persons The Regulations require that all persons who work in any activity where technical knowledge or experience is necessary to prevent danger (or injury) are trained so as to possess that knowledge or experience unless under such a degree of supervision as appropriate considering the nature of the work.

Exemption certificates It is possible to obtain exemption from any of the Regulations by writing to the Health and Safety Executive. These exemptions will not be granted unless the HSE are satisfied that the health and safety of persons who are likely to be affected will not be prejudiced in consequence of it. The HSE may impose conditions or other requirements when granting exemption certificates. The HSE is also given the power to issue general exemptions or special exemptions. This power is written in to take account of unforeseen circumstances (as at the time of drafting) and is unlikely to be used in practice.

18.12 The Noise at Work Regulations 1989

These Regulations came into force on 1 January 1990 and control the exposure to noise of persons at work. They establish three noise levels, known as the first action level, the second action level and the peak action level. Different regulations are applicable as each action level is exceeded.

The unit of measurement is known as the equivalent continuous sound level and may be defined as 'that notional continuous steady level which would have the same weighted acoustic energy as the real fluctuating noise measured over the same period of time'. For the purposes of the Regulations an 8-hour time period is used and the 8-hour equivalent continuous sound level is abbreviated to L_{EP},d.

The first action level is 85 dB(A) L_{EP},d.
The second action level is 90 dB(A) L_{EP},d.
The peak action level is 200 Pascals (equivalent to 140 dB).

Damage to the hair cells in the inner ear is proportional to the noise energy received. This is a dose concept comprising the product of noise level and exposure duration. It follows, therefore, that the same amount of deafness will follow from the exposure to a very intense sound for a short period as to a lower level for a proportionally longer one.

It has been shown that the exposure time must be halved for each 3 dB(A) increase in the noise levels. 3 dB(A) represents a doubling of sound energy, hence this rule has become known as the equal energy damage risk criterion. It follows that 93 dB(A) for 4 hours is also 100% of the permitted exposure for a day. Similarly, 2 hours at 93 dB(a) would be 50% of the permitted exposure. Where an employee is likely to be exposed to above the first action level the employer shall ensure that a competent person makes an assessment of the noise levels which is adequate for the purposes:

1. Of identifying which employees are so exposed; and
2. Of providing the employer with such information with regard to the noise to which those employees may be exposed as will facilitate compliance with the employer's duties under the Regulations, specifically:
   (a) Reduction of noise exposure:
   (b) Ear protection;
   (c) Ear protection zones;
   (d) Provision of information to employees.

18.12.1 The requirements of the Regulations

An employer must:

1. Carry out an assessment when an L_{EP},d of 85 dB(A) is likely to be exceeded.
2. Review the assessment if changes necessitate this.
3. Record the exposure and keep records.
4. Reduce the risk of damage to hearing to the lowest level that is reasonably practicable.
5. Every employer shall, when any employee is likely to be exposed to the second action level or above or to the peak action level or above, reduce, so far as is reasonably practicable (other than by the provision of personal ear protectors) the exposure to noise of that employee.
6. If an employee is exposed to greater than the first action level and less than the second action level the employer shall provide hearing protection if so required by the employee.
7. If an employee is exposed to greater than the second action level or greater than the peak action level the employer shall provide hearing protection which, when properly worn, will reduce the risk of hearing damage to below that arising from exposure to the second action level or, as the case may be, to the peak action level.
8. Ear protection zones (i.e. areas where the second action level is likely to be exceeded) shall be established. Employees must wear ear protection in this zone. The employer shall erect suitable signs.
9. Information, instruction and training shall be provided for employees where exposure is likely to exceed the first action level or the peak action level. This information shall include:
    (a) The risk of damage to an employee's hearing that such exposure may cause;
    (b) What steps an employee can take to minimize that risk;
    (c) The steps that an employee must take in order to obtain the personal ear protectors which the employer must provide;
    (d) The employer's obligation under the Regulations.

18.13 Safety of machinery

18.13.1 Identification of hazard

It is first essential to consider all of the phases of a machine's life (i.e. construction through to dismantling). These will include:

Construction
Transport
Installation
Commissioning
Operation
Setting
Adjustment
Maintenance
Decommissioning

The hazard at each point of this list must be assessed. It may be that the most hazardous point will vary with the nature of the operation (i.e. tool setting may be more hazardous than actually operating the machine if the operation is carried out remotely).

18.13.2 Types of hazard

Machines injure in one or more of the following ways:

Entanglement
Trapping
Contact with machine or material in motion
Being struck by objects or parts of machine being ejected
Non-mechanical (electrical, chemical, heat, etc.)

18.13.3 Assessment

Two factors are normally considered, when carrying out risk assessment; the probability of injury and severity of injury produced. In assessing probability of injury the following points should be considered:

1. Frequency of access needed to danger areas;
2. What actions are likely when in danger areas.

An assessment of the two factors can lead to a measure of the proportion of these dangerous accesses likely to result in injury.

The nature of any likely injuries may be used when deciding on the degree of protection necessary. Clearly, an event capable of causing death requires the most stringent safety precautions, while a dangerous machine capable of, say, causing minor bruising might not warrant the same expenditure.

The overall risk is derived from consideration of the likelihood of injury and the probable outcome over all the phases of the machine's life.

18.13.4 Safety by design

Where possible, designers should ensure that new machines do not contain dangerous parts or that these are enclosed by the design of the machine. This is a much more desirable alternative to the fitting of guards to an established machine design. Designers should also pay serious attention to ergonomics. It is important particularly to avoid operator fatigue as much as possible.

The design of safeguards to prevent physical injury can also be used as an opportunity to protect the operator from other hazards – for instance, noise, heat, etc. Examples of typical construction details to reduce the risk of injury may include:

1. Avoidance of shear traps by filling gaps between static and moving parts of machines such that gaps are eliminated or reduced to such an extent that parts of the body cannot enter. Data are available which give information concerning dimensions suitable for the avoidance of trapping various parts of the 'typical' body. An alternative would be to widen a gap sufficiently to prevent body parts being trapped.
2. Drawing-in – consideration of surface roughness, in-running nips, speed or distance of movement, force, torque and inertia.

A consideration of all of the typical hazards to the body should be made and the design of the machine should be such as to eliminate them as far as is reasonably practicable.

If it is not possible to make the machine safe by design other considerations will have to be taken into account, concerning controls, proximity devices and guards. While on the subject of design, other factors to be considered should include:

1. Design of controls to avoid unexpected start-up and/or movement in unexpected directions;
2. Elimination of hazards due to failure of machinery (e.g.

falls of platerns due to hydraulic failure – trapping may be avoided by the use of scotches (props) which are only removed mechanically when guards are closed);
3. Stability – design such that stability is not prejudiced by, for instance, overloading material feed hoppers;
4. Lighting – one of several environmental considerations which are pertinent to risk elimination.

18.13.5 Guarding

If safety by design is not possible the next alternative must be guarding. Within this generic expression we may also include electrical and mechanical interlocking, proximity devices and two-hand switching, etc. There are two main classes of hazardous machinery to be considered:

1. Those involving hazardous parts to which access is not required during normal operation. Access may be needed during maintenance and some form of 'inching' device may be fitted;
2. Those machines to which access is required during normal operations.

The guards for the first type could include the following:

- Fixed enclosed guard;
- Fixed distance guard (barrier or tunnel of sufficient size/length to prevent parts of body from reaching danger area), interlocked guards;
- Trip device (e.g. photoelectric cells, pressure mats, etc.).

In the case of machines to which access is normally required, different types of guards may be necessary, and these would include:

- Interlocked guards (machine disconnected when guard not in position);
- Automatic guard (pushes operator away from danger area);
- Trip device (photocells, etc.);
- Adjustable guards – a poor option, but may be necessary in certain cases where the gap between guard and danger point cannot be completely eliminated (e.g. woodworking machines – these guards tend to be left in the widest gap position);
- Self-adjusting guards – the gap is adjusted by the workpiece itself, thereby reducing the risks of the adjustable guards;
- Two-hand control devices – the operator has to operate two on-switches which are situated to prevent spanning by one hand. The switches must be operated within 0.5 seconds of each other. This device will only protect one operator and is open to abuse if two persons use the machine;
- Hold-to run control – the control is placed out of the danger area and the operative must remain in contact with the switch all the time the machine is operating

18.13.5.1 Installation and practical considerations of guards

Hygiene Guards for use on food machines should be readily cleansable and completely removable from machines – hinged guards are difficult to clean. Removable guards should be adequately interlocked. If fixed guards are necessary they should be mounted on spacers away from the machine in order to permit cleaning, but gaps should not be sufficient to permit parts of the body to reach danger areas.

Corrosion The materials used should be suitable for any corrosive risk from the environment or cleaning materials used. Stainless steel is the most suitable for the food industry.

Visibility The guard should be designed, if necessary, so that the operative can see the moving parts of the machinery. The use of clear sheet, mesh or grills can be considered.

Strength and durability The materials used should be suitable for the use (or abuse!) to which the guard may be put.

Maintenance Guards should be subject to routine inspection. Routine replacement of moving parts should take place after the end of their design life, particular attention being given to interlock switches, hydraulic valves, etc. Testing of safeguards must be carried out only by properly trained personnel.

Operation without guards There are some circumstances in which machinery must be operated without guards (so as to lubricate, maintain or adjust). It is permissible to carry out these operations. However, they are controlled by The Factories Act 1961, Section 15 (where applicable), and operatives must be properly trained and operations must be specified in writing. Any other operations of machinery without guards is likely to result in a breach of The Health and Safety at Work etc. Act, which could result in the employee and/or the employer being prosecuted as well as the risk of injury.

18.14 Personal protective equipment

Personal protective equipment (PPE) can be defined as:

> all equipment designed to be worn or held by a person at work to protect him against one or more risks, and any addition or accessory designed to meet this objective, other than
> (a) ordinary working clothes and uniforms not specifically designed to protect the health and safety of the wearer;
> (b) personal protective equipment used for protection while travelling on a road within the meaning (in England and Wales) of section 192 (10 of The Road Traffic Act 1988, or (in Scotland) section 151 of The Roads (Scotland) Act 1984;
> (c) equipment used during the playing of competitive sports;
> (d) self defence or deterrent equipment;
> (e) portable devices for detecting and signalling risks and nuisances.

'Risk' means any risk to the health and safety of a person and includes wet or extreme temperature caused by adverse weather or otherwise. This definition is taken from a draft set of regulations published by the Health and Safety Commission. The regulations are intended to implement the requirements of The Health and Safety EC framework directive (which must be implemented by 31 December 1992).

18.14.1 Existing PPE legislation

Section 2, Health and Safety at Work etc. Act 1974
Construction (Head Protection) Regulations 1989
Control of Asbestos at Work Regulations 1987
Control of Lead at Work Regulations 1980
Control of Substances Hazardous to Health Regulations 1988
Ionizing Radiation Regulations 1985
Noise at Work Regulations 1989
Also various pre-Health and Safety at Work etc. Act Regulations.

18.14.2 The new Regulations

Section 2 of The Health and Safety at Work etc. Act 1974 is not sufficiently explicit to comply with the terms of the framework directive. Consequently, new Regulations will have to be made (and may be implemented by the time this book is published). They will be made under Section 15 of The Health and Safety at Work etc. Act and will cover all situations of work as yet not covered by existing Regulations.

Most pre-health and safety at work law concerning PPE is to be revoked as it is not considered 'consistent with modern practice or selection, use and maintenance of PPE'. Some older legislation will remain but will need alteration – primarily to take account of the new European approval method (in place of the old HSE approval). These are Section 30(6) of The Factories Act 1961. Regulations 50, 51 and 60 of The Ship Building and Ship Repairing Regulations 1960 and paragraph 24 to Regulation 18 of The Approval Code of Practice 'Safety in Docks'. These pieces of legislation deal with entry into confined spaces. The scope of the new Regulations would be that of The Health and Safety at Work etc. Act 1974 to include mining, quarrying and offshore work.

The use of PPE on means of transport would be dealt with by Regulations to be made by the Department of Transport (which is why it is specifically excluded from the definition of PPE). Guidance on the selection, maintenance and use of PPE is to be published along with the new Regulations. The Regulations will not apply to the areas covered by existing (post-HSW) Regulations (as listed above) but, rather, these Regulations will be modified so as to be in line with the new general Regulations.

The duty to provide PPE Existing legislation requires risks to be controlled at source and only stipulates the use of PPE if the risk cannot be adequately controlled. This duty is carried on in the new Regulations. The duty is placed on the self-employed as well as employers.

Suitability Regulation 4(3) of the new Regulations defines suitability. The overriding requirement is that the PPE is suitable for the degree of risk 'so far as is reasonably practicable'. After 30 June 1992 all PPE must carry the European mark of approval (the 'CE' mark). Regulations to be published by the DTI (which will implement the EC PPE Product Directive) will require manufacturers and suppliers of new PPE to ensure that their products comply with the basic safety requirements of those Regulations. HSE approvals would cease once the new Regulations apply. Any existing PPE can continue to be used if it complies with Regulation 4(3).

Assessment Regulation 5 requires the assessment of PPE, and this shall comprise:

1. An assessment of any risk or risks which have not been avoided by other means;
2. The definition of the characteristics which PPE must have in order to be effective against the risk referred to in (1) above, taking into account any risks which the equipment itself may create;
3. Comparison of the characteristics of the PPE available with the characteristics referred to in (2) above.

Accommodation for PPE Regulation 7 requires accommodation for PPE, and this is considered necessary to ensure proper maintenance and to enable equipment to be kept clean.

Use of PPE Regulation 9 requires that employers who provide PPE shall take all reasonable steps to ensure that it is properly used. In addition, there is a requirement on employees and the self-employed to make full and proper use of PPE provided under these Regulations and to take all reasonable steps to see that it is returned to the accommodation provided for it, after use.

Charging for the use of PPE An employer is not permitted to charge an employee for the use of PPE at work. There is a provision in the Regulations to allow an employer to charge for the private use (i.e. outside of work) of PPE by the employee. This charge must be reasonable and in line with the cost to the employer resulting from the use of the PPE outside of work. For the purpose of implementing this Regulation, Section 9 of The Health and Safety at Work etc. Act 1974, is disapplied (this section prohibited employers from making any charge) in cases subject to this Regulation.

18.15 Manual handling

More than a quarter of accidents reported to authorities each year are a result of manual handling. While it may be noted that fatalities are rare, major injuries (for instance, those involving major limb fractures) as a result of manual handling constituted 7% of those reported in 1988/1989.

The great majority of lost work days as a result of accidents involving handling were in connection with sprains or strains (approximately 64%). The most likely affected area is the back (40% of all 'over 3-day' injuries).

It should also be noted that it is not the traditional 'heavy' industries that result in the most accidents. The incidence of manual handling injury is widespread. For example, the incidence of manual handling injury in the construction industry is about 37% while that for the medical, veterinary and other health services is 51%.

The latest thinking in manual handling is known as the 'ergonomic approach'. This takes into account the nature of the task, the load, the working environment and the individual's capability. The old legislation approach of simple lifting-weight limits has now fallen into disfavour as being too simplistic and likely to lead to erroneous conclusions concerning an individual's capability.

Draft Regulations concerning manual handling have been proposed but have not yet been brought into force. It is suggested that the Regulations will require an assessment to be made of handling operations likely to result in injury.

In order to avoid carrying out assessments on all manual handling operations (which would be an impossible task), guidelines are given as to the area of manual handling that is not likely to result in injury. These guidelines are not intended to be rigid and detail lifting and lowering of weights. The maximum capability of a person to lift a given weight is represented by the use of a diagram. The greatest lifting power is for weights held close to the body and for those lifts which do not involve lifting above the shoulder or below the knee. As an example, 25 kg may be safely lifted closed to the body, between the upper thigh and the waist, while the capability of lifting a weight at arm's length from the shoulder to above the head is only 5 kg.

The guidelines for carrying are essentially similar to those for lifting with the proviso that no carrying will take place with weights lower than knuckle height. If weights are carried on the shoulder detailed assessment may show that greater weights may be carried.

The guideline for pushing and pulling is a load of 250 Newtons to start or stop the push and 100 Newtons continually.

If lifting from a seated position, the maximum that can be lifted (without further assessment) is 5 kg, if only lifted from waist height to shoulder height near to the body.

It should be noted that all of these weight limits are designed for safe lifting by 95% of all men and between one half and two-thirds of women. If the same degree of protection is required for 95% of women, the weight limits should be reduced by one-third.

In carrying out an assessment the following points should be considered:

The task
Reduce risk of injury
Improve layout
Use the body more effectively (e.g. no twisting)
Rest periods flexibly arranged
Posture
No handling while seated
The load
Make it lighter (subdivide packages)
Make it small
Easier to grasp
More stable
Less dangerous to hold (not oily, corrosive, dirty, etc.)
The working environment
Space constraints
Floors (condition and nature)
Working at different levels
Thermal environment
Lighting
Individual capabilities
Personal capability – injuries, pregnancy, back problems, etc.
Knowledge and training – as a complement to safe systems of work
Training to recognize loads which might cause injury – care with unfamiliar loads

19.1 SI units

The Système International d'Unités (SI) has been adopted and is defined by ISO 1000. Here the system is described and conversions to other commonly used systems are given.

SI comprises seven basic units from which a wide range of quantities can be derived in the form of products and quotients of these units which are shown in Table 19.1. The definitions of these units are as follows.

Metre (m). The metre is the length equal to 1 650 763.73 wavelengths in vacuum of the radiation corresponding to the transition between the levels $2p_{10}$ and $5d_5$ of the krypton-86 atom.
Kilogram (kg). The kilogram is the unit of mass; it is equal to the mass of the international prototype of the kilogram.
Second (s). The second is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the caesium-133 atom.
Ampere (A). The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section, and placed 1 m apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} newtons per metre of length.
Kelvin (K). The kelvin, unit of thermodynamic temperature, is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.
Candela (cd). The candela is the luminous intensity, in the perpendicular direction, of a surface of 1/600 000 m^2 of a black body at the temperature of freezing platinum under a pressure of 101 325 newtons per square metre.

The supplementary base units are defined as follows:

Plane angle (radian). The angle subtended at the centre of a circle of radius 1 m by an arc of length 1 m along the circumference.
Solid angle (steradian). The solid angle subtended at the centre of a sphere of radius 1 m by an area of 1 m^2 on the surface.
Mole (mol) is the amount of substance of a system which contains as many elementary entities as there are atoms in 0.012 kg of carbon-12. The elementary entities must be specified and can be atom molecules, ion electrons, other particles or specified groups of such particles.

19.1.1 Derived units

SI is a rationalized and coherent system because, for any one physical quantity, it admits of only one measurement unit with its entire structure derived from no more than seven arbitrarily defined basic units. It is coherent because the derived units are always the products or quotients of two or more of these basic units. Thus the SI unit for velocity is m s^{-1} (metre per second) and for acceleration is m s^{-2} (metre per second every second). Special names (Table 19.2) have been given to some derived units as an aid to communication.

Although SI is complete in itself, certain non-SI units are recognized for use in conjunction with it where, for traditional, commercial or practical purposes, it is difficult to discard them. For example, it is impracticable to disregard the minute (in SI 60 seconds) and the hour (in SI 3600 seconds) which are non-coherent units.

Table 19.1 Basic SI units

Quantity	*Name of unit*	*Unit symbol*
Length	metre	m
Mass	kilogram	kg
Time	second	s
Electric current	ampere	A
Thermodynamic temperature[a]	kelvin	K
Luminous intensity	candela	cd
Amount of substance	mole	mol

[a] Temperature difference is commonly expressed in degrees Celsius instead of degrees Kelvin. The unit of the temperature interval for these scales is the same: 0 K = −273.15°C; 273.15°K = 0°C.

Table 19.2 Derived units

Physical quantity	*SI unit*	*Unit symbol*
Force	newton	$N = kg\ ms^{-2}$
Work, energy quantity of heat	joule	$J = N\ m = kg\ m^2\ s^{-2}$
Power	watt	$W = J\ s^{-1} = kg\ m^2\ s^{-3}$
Electric charge	coulomb	$C = A\ s$
Electric potential	volt	$V = W\ A^{-1} = kg\ m^2\ A^{-1}\ s^{-3}$
Electric capacitance	farad	$F = A\ s\ V^{-1} = A^2 s^4\ kg^{-1}\ m^{-2}$
Electric resistance	ohm	$\Omega = V\ A^{-1} = kg\ m^2\ A^{-2}\ s^{-3}$
Frequency	hertz	$Hz = s^{-1}$
Magnetic flux	weber	$Wb = kg\ m^2\ A^{-1}{}_s{}^{-2}$
Magnetic flux density	tesla	$T = Wb\ m^{-2} = kg\ A^{-1}\ s^{-2}$
Inductance	henry	$H = kg\ m^2\ A^{-2}\ s^{-2}$
Luminous flux	lumen	$lm = cd\ sr^a$
Illumination	lux	$lx = lm\ m^{-2}$

[a] One steradian (sr) is the solid angle which, having its vertex at the centre of a sphere, cuts off an area of the surface of the sphere equal to that of a square with sides of length equal to the radius of the sphere.
The SI unit of electric dipole moment (A s m) is usually expressed as a coulomb metre (C m).

19.1.2 Gravitational and absolute systems

There may be some difficulty in understanding the difference between SI and the Metric Technical System of units which has been used principally in Europe. The main difference is that while mass is expressed in kg in both systems, weight (representing a force) is expressed as kgf (a gravitational unit) in the MKSA system and as N in SI. An absolute unit of force differs from a gravitational unit of force because it induces unit acceleration in a unit mass whereas a gravitational unit imparts gravitational acceleration to a unit mass.

A comparison of the more commonly known systems and SI is shown in Table 19.3. It should be noted in particular how all energy and power, whether from a mechanical, electrical or heat source, share a common derived unit in the SI.

19.1.3 Expressing magnitudes of SI units

To express magnitudes of a unit, decimal multiples and submultiples are formed using the prefixes shown in Table 19.4. This method of expressing magnitudes ensures complete adherence to a decimal system.

Table 19.3 Commonly used units of measurement

	SI (absolute)	*FPS (gravitational)*	*FPS (absolute)*	*cgs (absolute)*	*Metric technical units (gravitational)*
Length	metre (m)	ft	ft	cm	metre
Force	newton (N)	lbf	poundal (pdl)	dyne	kgf
Mass	kg	lb or slug	lb	gram	kg
Time	s	sec	sec	sec	sec
Temperature	°C K	°F	°F °R	°C K	°C K
Energy mech.	joule[a]	ft lbf	ft pdl	dyne cm = erg	kgf m
Energy heat		Btu	Btu	calorie	k cal.
Power mech.	watt	hp	hp	ergs	metric hp
Power elec.		watt	watt		watt
Electric current	amp	amp	amp	amp	amp
Pressure	N m^{-2}	lbf ft^{-2}	pdl ft^{-2}	dyne cm^{-2}	kgf cm^{-2}

[a] 1 joule = 1 newton metre or 1 watt second.

Table 19.4 The internationally agreed multiples and submultiples

Factor by which the unit is multiplied		*Prefix*	*Symbol*	*Common examples*
One million million	10^{12}	tera	T	
One thousand million	10^{9}	giga	G	gigahertz (GHz)
One million	10^{6}	mega	M	megawatt (MW)
One thousand	10^{3}	kilo	k	kilometre (km)
One hundred	10^{2}	hecto[a]	h	
Ten	10^{1}	deca[a]	da	decagram (dag)
UNITY	1			
One tenth	10^{-1}	deci[a]	d	decimetre (dm)
One hundredth	10^{-2}	centi[a]	c	centimetre (cm)
One thousandth	10^{-3}	milli	m	milligram (mg)
One millionth	10^{-6}	micro	μ	microsecond (μs)
One thousand millionth	10^{-9}	nano	n	nanosecond (ns)
One million millionth	10^{-12}	pico	p	picofarad (pF)
One thousand million millionth	10^{-15}	femto	f	
One million million millionth	10^{-18}	atto	a	

[a] To be avoided wherever possible.

19.1.4 Rules for use of SI units and the decimal multiples and submultiples

1. The SI units are preferred but it is impracticable to limit usage to these, therefore their decimal multiples and submultiples are also required. (For example, it is cumbersome to measure road distances or the breadth of a human hair in metres.)
2. In order to avoid errors in calculations it is preferable to use coherent units. Therefore, it is strongly recommended that in calculations only SI units themselves are used and not their decimal multiples and submultiples. (Example: use N m^{-2} × 10^6 not MN m^{-2} or N mm^{-2} in a calculation.)
3. The use of prefixes representing 10 raised to a power which is a multiple of 3 is especially recommended. (Example: for length, km . . . m . . . mm . . . μm. Thus hm; dam; dm; cm are non-preferred.)
4. When expressing a quantity by a numerical value of a unit it is helpful to use quantities resulting in numerical values between 0 and 1000. Examples:

   12 kN = 12 × 10^3 N instead of 12 000 N
   3.94 mm = 3.94 × 10^{-3} m instead of 0.00394 m
   14.01 kN m^{-2} = 14.01 × 10^3 N m^{-2} instead of 14 010 N m^{-2}

5. Compound prefixes are not used. (Example: write nm not mμm.) Where, however, a name has been given to a product or a quotient of a basic SI unit (for example, the bar (10^5 N m^{-2})) it is correct practice to apply the prefix to the name (for example, millibar (10^{-3} bar)).
6. In forming decimal multiples and submultiples of a derived SI unit preferably only one prefix is used. The prefix should be attached to the unit in the numerator. (Example: MW m^{-2} not W mm^{-2}.) The exception is stress, where BSI recommend the use of N mm^{-2}.
7. Multiplying prefixes are printed immediately adjacent to the SI unit symbol with which they are associated. The multiplication of symbols is usually indicated by leaving a small gap between them. (Example: mN = millinewton. If written as m N this would indicate a metre newton.)

19.1.5 SI quantities, units and symbols

Tables 19.5 to 19.13 contain lists of SI units used in certain fields together with other units or names of units which may be used and their values in SI units. The tables also show symbols typically used to describe quantities in the same fields.

The units shown in Tables 19.5 to 19.13 generally obey the above guide rules. However, it is expected that a practical attitude should prevail in the interpretation of these recommendations, particularly as certain countries still use Metric Technical Units which include such units as kgf cm^{-2}.

Table 19.5(a) Space and time: units

Quantity	*SI units*	*Conversion factors and remarks on non-SI units*
Plane angle[a]	radian (rad)	1° = 0.017 453 3 rad 1′ = $2.908\ 88 \times 10^{-4}$ rad 1″ = $4.848\ 14 \times 10^{-6}$ rad 1 right angle = *Π*/2 rad = 90°
Solid angle	steradian (sr)	
Length[b]	metre (m)	1 inch = 25.4 mm 1 foot = 0.3048 m 1 yard = 0.9144 m 1 mile = 1.609 344 km 1 UK nautical mile = 1.853 18 km 1 angstrom (Å) = 10^{-10} metre or 10^{-1} nm
Area	square metre (m^2)	1 sq. in = 645.16 mm^2 = 6.4516 cm^2 1 sq. ft = 0.092 903 m^2 1 sq. yd = 0.836 127 m^2 1 acre = 0.404 686 ha 1 sq. mile = 258.999 ha ha = hectare a = are
Volume[c]	cubic metre (m^3)	1 in^3 = 16.3871 cm^3 1 ft^3 = 0.028 3168 m^3 1 yd^3 = 0.764 555 m^3 1 UK fl. oz = 28.4131 mlitre 1 gal = 4.5461 litre
Time	second (s)	1 day = 7.344 Ms 1 hour = 3600 s 1 minute = 60 s
Angular velocity	radian per second (rad s^{-1})	rev min^{-1} = 0.104 720 rad s^{-1} rev s^{-1} = 6.283 19 rad s^{-1} 1 degree s^{-1} = 0.017 4533 rad s^{-1}
Velocity	metre per second (m s^{-1})	1 km h^{-1} = 0.277 778 m s^{-1} 1 ft s^{-1} = 0.3048 m s^{-1} 1 mile h^{-1} = 0.447 04 m s^{-1} or 1.609 34 km h^{-1} knot (kn) = 0.514 444 m s^{-1} 1 UK knot = 0.514 773 m s^{-1}
Acceleration	metre per second squared (m s^{-2})	1 ft s^{-2} = 0.3048 m s^{-2}
Angular acceleration	radian per second squared (rad s^{-2})	1 in s^{-2} = 0.0254 m s^{-2}

[a] *Plane angle*. The Sumerian division of the circle in 360° (hence degrees) is retained for geometry although dynamicists use the radian.

[b] *Length — the centimetre*. In many engineering disciplines the use of the centimetre is non-preferred. It has been adopted as the basic unit of measurement by primary schools and for commercial purposes. Sometimes the centimetre raised to a power (e.g. cm^2; cm^3; cm^4) is used to maintain a sensible range of numerical values in front of the unit. An instance of this concerns steel sections where the moduli of sections and moment of section may be given in steel tables of cm^3 and cm^4 respectively.

Where accuracy to the nearest millimetre is unwarranted, the centimetres can be used to imply a less precise dimension.

[c] *Volume and capacity – the litre*. Before 1964 the 1901 litre was equal to 1.000 028 dm^3. At the XII International CGPM meeting on units (1964) the litre was redefined to equate exactly to 1 cubic decimetre. The same conference agreed that the litre should not be used to express the results of precise measurements, so as to make sure that where high precision was involved (say, greater than 1 part in 20 000) the possibility of confusion between the former (1901) litre and the new (1964) litre would be eliminated.

It is recommended that the results of precise measurements of volume should be given only in terms of m^3, dm^3, cm^3, mm^3, etc. even though the millilitre (ex. cm^3) and litre (ex dm^3) will still be used for operational and commercial purposes.

Because of the possible confusion of the symbol for the litre 'l' with the figure '1', it is strongly recommended that the unit name be spelt in full.

Centilitre is sometimes used for arbitrary quantities implying a greater degree of tolerance.

Table 19.5(b) Space and time: symbols

Symbol	*Quantity*
θ (α, β, etc.)	plane angle
l	length
A	area
V	volume
t, T	time
ω	angular velocity
v, $\dot{s}$, ds/dt	velocity
a, $\ddot{s}$, d^2s/dt^2	acceleration
α, $\dot{\omega}$, $d\omega/dt$,	angular acceleration
s, x, y, z	distance or displacement

Table 19.6(a) Periodic and related phenomena: units

Quantity	*SI units*	*Units other than SI*	*Conversion factors and remarks on non-SI units*
Frequency	hertz (Hz)		1 c/s (or c.p.s.) = 1 Hz
Rotational frequency[a]	reciprocal second (s^{-1})	rev min^{-1}	1 rev min^{-1} = 0.016 667 s^{-1}
Wavelength	metre (m)	Å[b]	1 Å = 10^{-10} m

[a] *Rotational frequency (rev/min)*. The quantity rev/min is favoured for rotating machinery.

[b] Electromagnetic radiative wavelengths are often quoted in angstroms (Å).

Table 19.6(b) Periodic and related phenomena: symbols

Symbol	*Quantity*
T	periodic time
τ, (T)	time constant of an exponentially varying quantity
f, ν	frequency
η	rotational frequency
ω	angular frequency
λ	wavelength
$\sigma(\bar{\nu})$	wavenumber
k	circular wavenumber
$\log_e (A_1/A_2)'$	natural logarithm of the ratio of two amplitudes
$10 \log_{10}(P_1/P_2)$	ten times the common logarithm of the ratio of two powers
δ	damping coefficient
Λ	logarithmic decrement
α	attenuation coefficient
β	phase coefficient
γ	propagation coefficient

19.1.5.1 Mass and weight

Confusion sometimes arises over the measuring of the terms 'mass' and 'weight'. Commonly, and in many branches of engineering, it has been the custom to refer to quantities of mass as weights, e.g. weight of coal in kilograms.

Weight, however, is dependent upon the gravitational force acting upon the mass. Thus for a mass (M), weight (W) = Mg, where g is the local acceleration due to gravity which varies slightly from point to point on the earth's surface. For practical purposes, an approximated figure of 9.81 or 9.807 metres per second squared (m s^{-2}) is used for g.

The force unit in SI is the newton (N) and by using consistent units becomes the force applied to unit mass (kg) to

Table 19.7(a) Mechanics: units

Quantity	*SI units*	*Conversion factors and remarks on non-SI units*
Mass	kilogram (kg)	1 ton = 1016.05 kg or 1.016 05 tonne 1 cwt = 50.8023 kg 1 lb = 0.453 592 37 kg 1 oz = 28.3495 g (avoir)

Fuel consumption		1 gal/mile = 2.825 litre km^{-1} 1 mile/gal = 0.354 km litre^{-1}
Specific fuel consumption	kilogram per joule (kgJ^{-1}) cubic metre per joule (m^{3}J^{-1})	1 lb/hp h = 0.168 97 kg MJ^{-1} 1 pint/hp h = 0.211 68 litre MJ^{-1}

impart unit acceleration (m s^{-2}) to the mass (as distinct from gravitational acceleration, which equals 9.806 65 m s^{-2}). Thus it can be more readily understood by comparing the SI system with other systems for mass, weights and measures as shown in Table 19.8.

19.1.5.2 Megagram

The tonne and kilogram are generally accepted as replacement units for ton and pounds. In particular, most lifting equipment already marked in tons can be considered as adequate for lifting the same number of tonnes because of the small excess (1.6%) of the ton over the tonne.

However, in soil mechanics, the megagram (Mg) rather than the tonne is recommended. This is because with large masses involved in work on soil mechanics, confusion between the ton and the tonne could prove very expensive.

19.1.5.3 Pressure and stress

The SI derived unit for force per unit area is the newton per square metre (N m^{-2}), referred to as the pascal (Pa), and this unit with suitable multiples is favoured as the unit for stress. There are differences of opinion regarding the unit for pressure, but although some flexibility will have to be allowed in the expression of pressure values, the following practice should be adopted.

1. For the statement of stress property, use, without deviation, N m^{-2} and appropriate multiples of it (e.g. MN m^{-2}) or this, if preferred, expressed as N mm^{-2} or, if essential for non-metallic materials, kN m^{-2}.
2. For pressure statements use either N m^{-2} (and suitable multiples and submultiples of it) or bar or mbar. In such cases the conversion 1 bar = 10^5 N m^{-2} will always be quoted for reference.

Table 19.7(b) Mechanics: symbols

Symbol	*Quantity*
m	mass
e, ρ	density (mass density)
d	relative density
v	specific volume
p	momentum
b, p_0, p_θ	moment of momentum (angular momentum)
I, J	moment of inertia (dynamic moment of inertia)
F	force
$G(P, W)$	weight
γ	specific weight (weight density)
M	moment of force
M	bending moment
T	torque, moment of a couple
p	pressure
σ	normal stress
τ	shear stress
e,ε	linear strain (relative elongation)
γ	shear strain (shear angle)
$\Theta\theta$	volume strain (bulk strain)
μ, ν	Poisson's ratio Poisson's number
E	Young's modulus (modulus of elasticity)
G	shear modulus (modulus of rigidity)
K	bulk modulus (modulus of compression)
x, κ	compressibility (bulk compressibility)
I, I_a	second moment of area (second axial moment of area)
I_p, J	second polar moment of area
Z, $W\left(\frac{I}{v}\right)$	section modulus
$\mu(f)$	coefficient of friction (factor of friction)
$\eta(\mu)$	viscosity (dynamic viscosity)
γ	kinematic viscosity
$\sigma(\gamma)$	surface tension
A, W	work
E, W	energy
E_p, U, V, Φ	potential energy
E_k, K, T	kinetic energy
p	power

3. Pressures or pressure differences measured by manometer tube may often conveniently be expressed as a height of a column of fluid, the nature of the fluid being stated. Such readings must be converted to terms of N m^{-2} if they are to be used in calculations of flow, etc. On the other hand, manometers are sometimes used merely as indicators that a prescribed operating condition has been met. Judgement is therefore required as to when it can be of advantage to use mm H_2O, mm Hg, etc. or when it is of advantage to calibrate and read manometers in a suitable multiple of N m^{-2} or in mbar. It is understood that manometers calibrated in mbar are becoming increasingly available and it is recommended that pressures expressed as a height of a column of fluid should progressively give place to a suitable multiple of the SI unit or to the millibar.
4. Pressure units themselves are often not modified to indicate whether the pressure value is 'absolute' (i.e. above zero) or 'gauge' (i.e. above atmospheric pressure). If, therefore, the context leaves any doubt as to which is meant, the word 'pressure' must be qualified appropriately.

   e.g. '. . . at a gauge pressure of 12.5 bar'
   or '. . . at a gauge pressure of 1.25 MN m^{-2}'
   or '. . . at an absolute pressure of 2.34 bar'
   or '. . . at an absolute pressure of 234 kN m^{-2}'

Table 19.9 illustrates some of these practices. Note that this table works on a gauge pressure basis (atmosphere = 0), thus vacuum is shown measured in negative millibars. This continues the custom of associating the higher numerical readings with greater vacuum.

Notwithstanding previous practices of referring to pump performances in terms of pressure, the pump total head should be specified in linear measure (metres).

19.1.5.4 Viscosity

The recognized derived SI units for Dynamic and Kinematic Viscosity are Ns m^{-2} and $\mathrm{m}^2\,\mathrm{s}^{-1}$, respectively. However, the existing units, centipoise (cP) and centistoke (cSt) are so well established internationally, particularly for oils, that the operational use of these units will continue.

19.1.5.5 Energy

The choice of a suitable commercial energy unit common to all energy-producing concerns has still to be resolved. The SI unit is the joule and its multiples. However, electrical interests favour the adoption of the kWh (3.6 MJ = 1 kWh). The following are the probable commercial field quantities:

Coal	tonne
Electricity	kWh
Gas	100 MJ (the therm)
Oil	litre; m^3 kg; tonne

19.1.5.6 Hardness values

The hardness unit kgf is used to express the load applied by the indenter and this ensures that most hardness-testing machines and empirically based formulae are not made obsolete. Thus the Rockwell, Vickers and Brinell hardness numbers are used. This number is arbitrary and dimensionless and is dependent upon the resistance offered by the material under test to a definite load.

Table 19.11(a) Electricity and magnetism: units

$[Y]$	modulus of admittance (admittance)
B	susceptance
G	conductance
P	active power
$S, (P_s)$	apparent power
$Q, (P_q)$	reactive power

19.1.5.7 Concentration

Concentration should preferably be expressed on a mass/mass basis (i.e. kg kg^{-1}; mg kg^{-1}) or a volume/volume basis (i.e. m^3 m^{-3}; litre m^{-3}; millilitre m^{-3}). It may also be expressed in parts per million (ppm) or as a percentage 'by mass' or 'by volume', respectively.

ϕ	luminous flux
w	beamwidth

19.1.5.8 pH scale

This is a number based on the logarithm, to the base 10 of the reciprocal of the concentration of hydrogen ions in aqueous solution. It is used as a method of expressing small differences in the acidity or alkalinity of nearly neutral solutions in biological and electrolytic processes.

19.1.5.9 Quantities and units of light

The following definitions are based on the International Lighting Vocabulary.

Luminous flux (symbol ϕ): The light emitted by a source such as a lamp or received by a surface, irrespective of direction.
Lumen (abbreviation lm): The SI unit of luminous flux used in describing the total light emitted by a source or received by a surface. (A 100-watt incandescent lamp emits about 1200 lumens.)
Illumination: The process of lighting an object.
Illumination value (symbol E): The luminous flux incident on a surface, per unit area.
Lux (abbreviation lx): The SI unit of illumination value; it is equal to one lumen per square metre.
Lumen per square foot (abbreviation lm ft^{-2}): A non-metric unit of illumination value, equal to 10.76 lux. (Previously called the foot-candle, a term still used in some countries.)
Service value of illumination: The mean value of illumination throughout the life of an installation and averaged over the working area.
Initial value of illumination: The mean value of illumination averaged over the working area before depreciation has started, i.e. when the lamps and fittings are new and clean and when the room is freshly decorated.
Mean spherical illumination (scalar illumination): The average illumination over the surface of a small sphere centred at a given point; more precisely, it is the flux incident on the surface of the sphere divided by the area of the sphere. The

Quantity	*SI units*	*Conversion factors and remarks on non-SI units*
Sound intensity	watt per square metre (W m^{-2})	1 erg s^{-1} cm^{-2} = 10^{-3} W m^{-2}
Sound intensity (logarithmic)		1 decibel (dB) = 20 $\log_{10}(P/P_0)$ where P = measured sound pressure and P_0 = reference sound pressure of 2×10^{-5} N m^{-2}
Loudness		1 phon
Attenuation		neper per metre (np m^{-1})

Table 19.13(b) Sound: symbols

Symbol	*Quantity*
T	period, periodic time
f, ν	frequency, frequency interval
ω	angular frequency, circular frequency
λ	wavelength
k	circular wave number
ρ	density (mass density)
P_s	static pressure
p	(instantaneous) sound pressure
ε, (x)	(instantaneous) sound particle displacement
u, v	(instantaneous) sound particle velocity
a	(instantaneous) sound particle acceleration
q, U	(instantaneous) volume velocity
c	velocity of sound
E	sound energy density
P, (N, W)	sound energy flux, sound power
I, J	sound intensity
Z_s, (W)	specific acoustic impedance
Z_a, (Z)	acoustic impedance
Z_m, (w)	mechanical impedance
L_p, (L_N, L_w)	sound power level
L_p, (L)	sound pressure level
δ	damping coefficient
Λ	logarithmic decrement
α	attenuation coefficient
β	phase coefficient
γ	propagation coefficient
δ	dissipation coefficient
r, τ	reflection coefficient
γ	transmission coefficient
α, (α_a)	acoustic absorption coefficient
R	sound reduction index sound transmission loss
A	equivalent absorption area of a surface or object
T	reverberation time
L_N, (Λ)	loudness level
N	loudness

term 'scalar' illumination is the lux: care is needed to avoid confusing the unit with the illumination on a plane which is measured in the same unit.
Illumination vector: A term used to describe the flow of light. It has both magnitude and direction. The magnitude is defined as the maximum difference in the value of illumination at diametrically opposed surface elements of a small sphere centred at the point under consideration. The direction of the vector is that of the diameter joining the brighter to the darker element.
Luminous intensity: The quantity which describes the illuminating power of a source in a particular direction. More precisely, it is the luminous flux emitted within a very narrow cone containing that direction divided by the solid angle of the cone.
Candela (abbreviation cd): The SI unit of luminous intensity. The term 'candle power' designates a luminous intensity expressed in candelas.

19.2 Conversion of existing imperial terms

If it is necessary to convert existing imperial terms to a metric equivalent, care should be taken to ensure that the converted value implies the same degree of accuracy. The conversion factor must convey the same order of precision as the original value. Thus to translate 1 in as 25.4 mm or 1000 ft as 304.8 m conveys a tolerance which, in most cases, would be too precise.

Particular care is needed when converting machined tolerances. With a simple dimension such as 0.836 in, it is reasonable to assume that this dimension can be met because an imperial micrometer can measure to 0.001 in. The conversion factor for 0.836 in is 21.2344 mm. Thus 0.004 mm in our conversion represents an accuracy of 0.000 016 in, which is beyond the scope of most toolroom measuring devices. In such cases it should be borne in mind that a metric micrometer can measure to 0.01 mm and with a vernier attachment to 0.002 mm. Thus for the greatest possible accuracy our converted readings should be 21.234 mm. Table 19.14 gives some metric to other unit conversion factors.

19.3 Abbreviations

Table 19.15 gives an alphabetical list of commonly used abbreviations of units. Obsolete and rarely found units are also included. For definitions of these units see Tables 19.5–19.13 and other reference works listed at the end of this chapter.

rps	revolutions per second
s	second (time)
S	Siemen
S St	stokes
sb	stilb
sn	sthéne
sr	steradian
T	tesla
t	tonne
th	thermie
V	volt
VA	volt ampere
W	watt
Wb	weber
yd	yard

19.4 Physical and chemical constants

The following tables provide physcial and chemical constants most of use in engineering disciplines. Table 19.16 lists universal constants. Table 19.17 is a table of elements. Table 19.18 presents the principal elements in order of valency. Table 19.19 gives the surface tension of some common metals, and Table 19.20 lists specific heats, melting points and densities of selected elements. Table 19.21 reports the sectional properties of metals.

For further information on the properties of engineering materials, including common metals and alloys, see Chapter 7.

19.4.1 Atomic number

Radon has an atomic number of 86 (International Atomic Weights Commission). Isotopes of radon will have the same atomic number but different atomic weights.

19.4.2 Atomic weight

Weights are related to an arbitrary reference value of 16 for oxygen. Atomic weights vary because of natural variation in composition (different isotopes in mixture affect the weight average) and because of relativistic effects.

Table 19.16 Universal constants

Constant	*Symbol*	*Numerical value*	*SI unit*
Speed of light in vacuum	c	2.997 925(1)	10^8 m s^{-1}
Gravitational constant	G	6.670(5)	10^{-11} N m^2 kg^2
Elementary charge	e	1.602 10(2)	10^{-19} C
Avogadro constant	N_A	6.022 52(9)	10^{26} $kmol^{-1}$
Mass unit	u	1.660 43(2)	10^{-27} kg
Electron rest mass	m_e	9.109 08(13)	10^{-31} kg
		5.485 97(3)	10^{-44} u
Proton rest mass	m_p	1.672 52(3)	10^{-27} kg
		1.007 276 63(8)	u
Neutron rest mass	m_n	1.674 82(3)	10^{-27} kg
		1.008 665 4(4)	u
Faraday constant	F	9.684 70(5)	10^4 C mol^{-1}
Planck constant	h	6.625 59(16)	10^{-34} J s
	$h/2\pi$	1.054 494(25)	10^{-34} J s
Fine-structure constant	α	7.297 20(3)	10^{-3}
	$1/\alpha$	137.038 8(6)	
Charge-to-mass ratio for electron	e/m_e	1.758 796(6)	10^{11} C kg^{-1}
Quantum of magnetic flux	hc/e	4.135 56(4)	10^{-11} Wb
Rydberg constant	R_∞	1.097 373 1(1)	10^7 m^{-1}
Bohr radius	a_0	5.291 67(2)	10^{-11} m
Compton wavelength of electron	h/m_ec	2.426 21(2)	10^{-12} m
	$\lambda C/2\pi$	3.861 44(3)	10^{-13} m
Electron radius	$e^2/m_ec^2 = r_e$	2.817 77(4)	10^{-15} m
Thomson cross-section	$8\pi r_e^2/3$	6.651 6(2)	10^{-29} m^2
Compton wavelength of proton	$\lambda_{C,p}$	1.321 398(13)	10^{-15} m
	$\lambda_{C,p}/2\pi$	2.103 07(2)	10^{-16} m
Gyromagnetic ratio of proton	γ	2.675 192(7)	10^8 rad (s $T)^{-1}$
	$\gamma/2\pi$	4.257 70(1)	10^7 Hz T^{-1}
(uncorrected for diamagnetism of H_2O)	γ'	2.675 123(7)	10^8 rad (s $T)^{-1}$
	$\gamma'/2\pi$	4.257 59(1)	10^7 Hz T^{-1}
Bohr magneton	μ_B	9.273 2(2)	10^{-24} J T^{-1}
Nuclear magneton	μ_N	5.050 50(13)	10^{-27} J T^{-1}
Proton magnetic moment	μ_p	1.410 49(4)	10^{-26} J T^{-1}
	μ_p/μ_N	2.792 76(2)	
(uncorrected for diamagnetism in H_2O sample)	μ_p'/μ_N	2.792 68(2)	
Gas constant	R_0	8.314 34(35)	J K^{-1} mol
Boltzmann constant	k	1.380 54(6)	10^{-23} J K^{-1}
First radiation constant ($2\pi hc^2$)	c_1	3.741 50(9)	10^{-16} W m^{-2}
Second radiation constant (hc/k)	c_2	1.438 79(6)	10^{-2} m K
Stefan–Boltzmann constant	σ	5.669 7(10)	10^{-8} W m^{-2} K^4

Ytterbium	Yb	70	173.04	6 900	824	—	—	27.7
Yttrium	Y	39	88.905	5 509	1 482	—	—	80
Zinc	Zn	30	65.38	7 142	419.5	30	112	5.5
Zirconium	Zr	40	91.22	6 366	1 850	6.3	—	41

Table 19.18 Table of principal elements arranged in order of valency

Valency	*Name*	*Symbol*	*Atomic weight*
1 ((Monovalent)	Bromine	Br	79.9
	Chlorine	Cl	35.457
	Fluorine	Fl	19.00
	Hydrogen	H	1.008 1
	Iodine	I	126.92
	Potassium	K	39.096
	Silver	Ag	107.88
	Sodium	Na	22.997
2 (Divalent)	Barium	Ba	137.34
	Cadmium	Cd	112.40
	Calcium	Ca	40.08
	Copper	Cu	63.54
	Magnesium	Mg	54.93
	Mercury	Hg	200.61
	Oxygen	O	16.000
	Zinc	Zn	65.38
3 (Trivalent)	Aluminium	Al	26.98
	Bismuth	Bi	209.00
	Boron	B	10.81
	Cobalt	Co	58.94
	Gold	Au	197.20
	Iron	Fe	55.84
	Nickel	Ni	58.70
4 (Tetravalent)	Lead	Pb	207.21
	Platinum	Pt	195.23
	Silicon	Si	28.08
	Tin	Sn	118.70
5 (Pentavalent)	Antimony	Sb	121.75
	Arsenic	As	74.92
	Nitrogen	N	14.008
	Phosphorus	P	31.02
6 (Hexavalent)	Chromium	Cr	52.01
	Manganese	Mn	54.93
	Sulphur	S	32.06

Table 19.19 Surface tension of some common metals

Metal	*Temperature* (°C)	*Surface tension* (mN m^{-1})
Antimony	640	350
Bismuth	269	378
Cadmium	320	630
Copper	1131	1103
Gold	1120	1128
Iron (acc. to C content)	1300–1420	1150–1500
Lead	327	452
Mercury	20	465
Silver	998	923
Tin	232	526
Zinc	419	758

Surface tension of water is 78.5 mN m^{-1} at 0°C and decreases by 0.152 mN m^{-1} for each degree rise of.temperature.

Table 19.20 Specific heats, melting points and densities

Material	*Specific heat* (kJ kg^{-1} °C^{-1})	*Melting point* (°C)	*Density* (kg m^{-3}) *(approx.)*
Air (20°C)	0.996 8	—	1.2
Aluminium	0.914 9	657	2 700
Brass	0.395 3	850–950	8 400
Carbon	0.854 3	—	2 220
Cobalt	0.448	1 480	8 904
Copper	0.393 6	1 083	8 941
German silver	0.398	—	8 400
Graphite	0.837 4	—	2 300
Iron, cast	0.46–0.67	1 200	7 000
Lead (solid)	0.131 3	327.4	11 320
Lead (liquid)	0.197 2	—	—
Mercury	0.134	−38.9	13 540
Molybdenum	0.275 9	2 620	10 190
Nickel	0.454	1 452	8 915
Paraffin (solid)	2.6–2.9	38–56	900
Paraffin (liquid)	29.7	—	800
Pitch	—	—	1 100
Platinum	0.138 1	1 774	21 420
Silver	0.232 7	960.8	10 520
Solder	—	205–185	8 300
Tin (solid)	0.234 5	232	7 308
Tin (liquid)	0.268	—	—
Tungsten	0.146 6	3 370	19 320
Type metal	0.163 3	—	—
Water (20°C)	4.186 8	—	—
Zinc (cast)	0.39–0.50	419.5	7 142

Table 19.21 Sectional properties of metals

Substance	*E* (MN m^{-2})	*G* (MN m^{-2})	σ	*K* (MN m^{-2})	*Tensile strength* (MN m^{-2})
Aluminium	70 300	26 100	0.345	75 500	90–150
Brass	101 000	37 300	0.350	111 800	280–730
Copper	129 800	48 300	0.343	137 800	120–400
Iron (cast)	152 000	60 000	0.270	109 000	100–230
Iron (Wrought)	211 400	81 000	0.293	170 000	260–450
Lead	16 100	5 600	0.440	45 700	12–17
Magnesium	44 700	17 000	0.291	25 600	60–190
Silver	82 700	30 200	0.366	103 600	300
Platinum	168 000	61 000	0.377	228 000	330–370
Tantalum	185 700	69 200	0.342	196 300	800–1 100
Tin	49 900	18 400	0.357	58 200	20–35
Tungsten	411 000	160 000	0.280	311 500	1 500–3 500
Steel (mild)	211 900	82 200	0.291	169 200	430–690
Steel (hardened)	210 400	77 800	0.295	165 200	1 800–2 300

Notes: *E* is known as Young's modulus or longitudinal elasticity; *G* is known as Shear or Rigidity modulus; σ is known as Poisson's ratio; *K* is known as Bulk modulus.

19.4.3 Density

Values are taken at 293 K.

19.4.4 Melting point

Values are for 1 atm pressure (1.01325×10^5 Pa).

19.4.5 Linear coefficient of expansion

This is commonly known as the α value. It is worked out as a mm expansion over 100 m length using the equation $L = l(1 + \alpha t)$ for expansion and $l = L/(1 + \alpha t)$ for a contraction; where l = increase or decrease in length, L = original length, t = temperature change and α = linear coefficient of expansion.

19.4.6 Heat conductivity

This is sometimes called 'thermal conductivity' and is known as the k factor. Values are taken at 293 K.

19.4.7 Electrical resistivity

Values are given at 293 K.

MECHANICAL ENGINEERING

Mechanical Engineer's
REFERENCE BOOK

Edited by **Dr E H Smith**
University of Central Lancashire, UK

In 1946, the *Newnes Engineer's Reference Book* set a new standard of high quality for works of reference for professional engineers. This twelfth edition of the classic volume continues the tradition and is now available in paperback, making it accessible to every practising or student engineer.

Since publication of the eleventh edition, the book has been completely rewritten incorporating all subjects of importance to mechanical engineers. Experts from academia and industry have contributed sections on their areas of expertise to provide one of the most comprehensive sources of information for engineers. Among the many subjects covered for the first time are tribology, nuclear and offshore engineering, health and safety and the many applications of computers in engineering. The wide range of subjects covered, the concise but readable style, the large number of illustrations and the extensive reference lists make this book one of the most valuable volumes available on mechanical engineering.

'An excellent resource' CHOICE

'The presentation of the book is good - the text is clear and easy to read and the illustrations and the diagrams are very good indeed. The span of subjects is comprehensive and I can honestly say that I would like to have this one on the shelf at home.'

MECHANICAL INCORPORATED ENGINEER

'...incorporate(s) all subjects of importance to mechanical engineers.'

THE ENGINEER'S JOURNAL

CONTENTS: Mechanical engineering principles, electrical and electronic principles; Microprocessors, instrumentation and control; Digital computers and software; Computer integrated engineering systems; Design standards; Materials, properties and selection; Mechanics of solids; Tribology; Power units and power transmission; Fuels and combustion; Alternative energy sources; Nuclear engineering; Offshore engineering; Plant engineering; Manufacturing methods; Engineering mathematics; Health and safety; Units, physical constants and properties.
