$$\frac{\text{dln}[G'(\omega)]}{\text{dln}(\omega)} \approx \frac{2}{\pi}\tan\delta$$

The equation is mainly applicable to vulcanizates which obtain their damping from the base elastomer rather than filler effects; it indicates that high-damping elastomers will have moduli which increase strongly with increasing frequency. The low intrinsic damping at ambient temperatures of elastomers such as butadiene rubber (BR), natural and synthetic polyisoprene (NR, IR), and polypropylene oxide (GPO) is associated with a weak dependence of modulus on frequency. Frequency-insensitivity of modulus can be an advantage in some circumstances: increases in $|G^*|$ of $\leqslant$ 10% per hundredfold increase in frequency are typical for lightly filled NR, while for heavily filled NR the corresponding increase can be about 25% – depending on strain amplitude. Quite high levels of damping can nevertheless be obtained from materials such as filled NR – δ up to ~20° at low strain amplitudes even at frequencies around 1 Hz. (δ peaks at about 3% strain.) In contrast, the loss angle of unfilled or lightly filled NR is ~1.5° under similar conditions.

As in other glass-forming materials, the mechanical properties of elastomers exhibit a particularly strong temperature dependence as the temperature is reduced towards the glass-transition temperature T_g. G' rises towards the glassy value (about a thousand times the rubbery value); G'' also rises, but passes through a maximum just above T_g.

In the range T_g to T_g + 100°C the effects of temperature and frequency are interrelated, inversely, in a manner which holds for a wide variety of polymers. For a given elastomer, the frequency dependence of the viscoelastic properties can be estimated from their temperature dependence over a restricted frequency range and vice versa. The formula most widely used for time–temperature superposition in elastomers is the WLF (Williams, Landel, Ferry) equation. According to the WLF transform, the storage moduli and loss angles measured at temperature and frequency (T_1, f_1) and at (T_2, f_2) are the same if:

$$\frac{1}{A}\log_{10}\frac{f_2}{f_1} = \frac{T_2 - T_s}{B + T_2 - T_s} - \frac{T_1 - T_s}{B + T_1 - T_s}$$

For a given material, constants A, B and the reference temperature T_s should be determined from the data; however, they may be estimated from the following:

$A \simeq 8.86$, $B \simeq 101.6$, $T_s \simeq T_g + 50°\mathrm{C}$

Sometimes, before the transform operation, storage moduli, G', measured at an absolute temperature, T, are 'reduced' or 'normalized' relative to a chosen temperature, T_r, by an equation of the form

$$G'_n = \frac{\rho_r T_r G'}{\rho T}$$

where ρ and ρ_r are the densities at T and T_r, respectively.

The WLF and other transform equations are particularly useful because it can be difficult to obtain accurate dynamic data for elastomers at frequencies approaching 1 kHz and above. However, such transform equations should be used with caution as they can sometimes give misleading results. One conclusion is inescapable, though: choice of a high T_g elastomer, such as many nitriles (NBR), to achieve high damping, results in strong temperature and frequency sensitivity.

It should be noted that the effect of T_g-related damping in elastomers is to produce a decrease in modulus with increase in temperature whereas for a low-damping elastomer the statistical theory, supported by experiment, predicts the opposite effect.

It is not only the modulus of an elastomer which changes with temperature. Short-term effects of elevated temperature can include reduction in tear strength to unacceptably low values.

Long-term effects of high temperature include progressive breakdown of molecular bonds and/or progressive cross-linking reactions which soften and harden the vulcanizate respectively; an appropriately chosen cure system for high-temperature service can balance hardening and softening processes – producing little change in modulus with time. Strength properties show a more rapid deterioration at high temperatures.

7.7.7.3 *Effects of liquids*

Both equilibrium and time-dependent effects can be important when an elastomer is exposed to a liquid. Solubility is an equilibrium parameter of key importance when the elastomeric component is small in section or when immersion is continuous. In the absence of chemical cross-links susceptible elastomers can be dissolved in appropriate solvents. (Crepe rubber soles and diesel fuel is an example.) Well-vulcanized elastomers do not dissolve but can still be swollen and weakened considerably. The degree of swelling depends on the degree of chemical compatibility between the elastomeric material and the fluid concerned. The mineral (petroleum-based) oil compatibility of some hydrocarbon based elastomers such as natural (NR) and styrene–butadiene (SBR) is high and they can absorb large amounts. Other elastomers such as acrylonitrile–butadiene ('nitrile' NBR) have much lower mutual solubility with mineral oil and are therefore classed as oil resistant. Elastomers containing large numbers of chlorine or fluorine atoms have low compatibility with mineral oil. However, the presence of such strongly electronegative atoms can increase compatibility with water. The degree of compatibility of a liquid can also depend on non-rubbers in the vulcanized material. Polyisoprene has low compatibility with water but absorption can be increased by hydrophilic substances (e.g. protein) present in natural rubber (NR) but removed in deproteinized natural rubber.

When an elastomeric component is immersed in a soluble fluid the fluid does not saturate the elastomer instantaneously; in many cases the non-equilibrium concentration (c) is governed by the diffusion equation:

$$\frac{\partial c}{\partial t} = \mathrm{div}(D\,\mathrm{grad}c)$$

If D, the diffusion coefficient or diffusivity, is independent of the concentration the following results:

$$\frac{\partial c}{\partial t} = D\nabla^2 c$$

Analysis is complicated by the large amount of swelling that can occur, but the above equation indicates that the time required for a liquid to penetrate to a particular depth is roughly proportional to the square of the depth.

The diffusivity of a fluid in an elastomer depends, inversely, on the mechanical damping of the unfilled elastomer and strongly on the viscosity of the fluid (η). The diffusion coefficient of mineral oil is considerably lower in chloroprene rubber (CR) than in NR; in butyl rubber (IIR) and most nitriles (NBR) the diffusion coefficients are lower still. Whereas the penetration into NR of low- and moderate-viscosity petroleum-based oils is rapid it can take months for a viscous oil ($\eta \sim 0.3\ \mathrm{Nsm^{-2}}$) to penetrate much more than about 1 mm. It is this type of time-dependence which enables elastomers which are classified as non-oil-resistant to be used in circumstances where they are exposed to oil periodically.

7.7.7.4 *Heat transfer*

The diffusion equations given in Section 7.7.7.3 are also applicable to non-equilibrium thermal conditions. In this case temperature (T) is the relevant 'concentration'; the thermal 'diffusivity' is calculated from the thermal conductivity (k), the density (ρ) and the specific heat (s) of the elastomer.

$$D = k/\rho s$$

The thermal conductivity of many elastomeric materials is low in the absence of high carbon black loadings ($\sim 0.2\ \mathrm{Wm^{-1}\,°C^{-1}}$) and the specific heat is relatively high ($\sim 2000\ \mathrm{Jkg^{-1}°C^{-1}}$) while the density is $\sim 1000\ \mathrm{kgm^{-3}}$ giving a value of $D \sim 10^{-7}\mathrm{m^2s^{-1}}$. The low thermal diffusivity of elastomers means that although these materials can be vulnerable to sustained high temperatures, thick sections are resistant to high-temperature exposure of short duration. The relatively low thermal conductivity of elastomers can, however, be a disadvantage where there is significant mechanical energy dissipation in large components as heat build-up can result in damaging temperature levels.

7.7.8 Elastomer selection – some guidelines

In elastomer selection it is usual to categorize the properties of elastomeric materials into mechanical aspects such as modulus, damping or fatigue behaviour and into the elastomer's tolerance to environmental factors such as high or low temperature, exposure to oils, ozone, or ionizing radiation. The balance between the importance of mechanical properties and the degree of hostility of the environment, considered with the design of the component, will help determine whether an elastomer is suitable for a particular function. Simplified tables and guides to the performance of different elastomers may sometimes be misleading, as environmental factors can interact with each other and with mechanical conditions.

Although indications are given here of some of the complications, the main purpose is to give broad indications of the behaviour of various elastomer types (Tables 7.68 and 7.69).

The fact that some elastomers such as natural rubber (NR) and certain grades of chloroprene rubber (CR) and synthetic polyisoprene (IR) crystallize significantly when subjected to high strain gives these materials inherent advantages in strength and resistance to fatigue. Non-strain-crystallizing elastomers such as silicone rubber and most styrene–butadiene rubbers (SBR) require reinforcing fillers such as finely divided carbon black or silica powder to give them the strength properties required for many applications. Some elastomers, such as ethylene–propylene rubber (EPM/EPDM) and silicon rubber, have high innate resistance to degradation by ozone and diatomic oxygen whereas others, notably nitrile (NBR) and fluoroelastomers (fluorinated hydrocarbon rubbers), are relatively unaffected by many mineral (petroleum-based) oils.

Component geometry can have a profound effect on performance with regard to fatigue or environmental attack: fatigue life can be greatly extended by the avoidance of stress concentrations, while thick sections of 'non-resistant' rubber can often function adequately despite oil splashes or ozone attack.

A number of elastomers capable of withstanding high temperatures for long periods without deterioration are significantly weaker at the elevated temperature. Other elastomers can sometimes be used successfully above their normal operating limit; what constitutes an acceptably long life varies according to the application from hours, or less, to tens of years. It should also be remembered that the properties for a given elastomer type can vary widely depending on 'compounding' ingredients, and processing details (Section 7.7.2). Furthermore, elastomers are frequently blended with each other to influence performance or processing behaviour.

When high extensibility combined with strength and elasticity are the main requirements an elastomeric material rich in NR is often selected – especially so when the component is bulky. One reason that NR is favoured in these circumstances is that a low surface/volume ratio tends to protect the component against failure produced by surface degradation. A further advantage of NR for bulky components is that lower mechanical damping is obtainable with the natural material than with most other elastomers; it follows that problems of heat build-up are less when NR is used in components subjected to repeated deformation. (Similar comments apply to certain grades of synthetic polyisoprene, IR.) NR is, however, unsuitable for heavy exposure to mineral oils of anything but the highest viscosity; because of this and its inability to tolerate sustained temperatures much above 100°C NR is classified as a 'general-purpose' elastomer. Natural rubber is, however, resistant to a surprisingly wide range of liquids. The vulnerability of NR, and other elastomers such as SBR, to oxidative ageing and ozone attack can be overcome in many circumstances by incorporating anti-degradants into the formulation.

A typical temperature range for components made from NR is −60°C to +80°C for continuous operation. However, time-dependent stiffening due to crystallization can occur at temperatures well above −60°C. The maximum crystallization rate occurs in the region of −25°C. Although such stiffening is reversed by moderate strains or warming, the use of crystallization-resistant compounds (conventional sulphur vulcanization) is advisable in some applications.

The general-purpose (GP) base elastomers are competitive in price – natural rubber being least expensive. Although the price of ethylene–propylene base elastomers is currently four to five times that of NR this is offset by the fact that EPM/EPDM can accept large quantities of diluent oil of similar price to NR. The base elastomers of chloroprene rubber materials (CR) are also several (about five) times more expensive than NR. However, CR possesses a useful balance of mechanical and environmental characteristics which ensures it is widely used – although not in such quantities as the GP materials (Table 7.68). Chlorine compounds evolved on combustion give CR a level of fire retardancy but, in some circumstances, can pose problems. (Similar comments apply to other elastomers which contain chlorine or fluorine.) Improved fire resistance can be obtained with appropriate additives. Special formulations may be required for prolonged contact with water. Crystallization-resistant grades of CR are available, but in other grades quite rapid low-temperature crystallization-induced stiffening can take place – especially at temperatures around −10°C. Plasticizers can be used to depress the T_g of −40°C but care needs to be exercised, as this can sometimes increase the rate of stiffening caused by low-temperature crystallization.

Acrylonitrile–butadiene elastomers (NBR), commonly known as 'nitriles', are widely used because of their oil-resistant properties and the moderate price of the base elastomers (about four times that of NR). Typically, nitriles are significantly less rubbery than NR or CR. Increasing acrylonitrile content increases T_g, minimum usable temperature and oil resistance while reducing elasticity. (For 50%, 40% and 28% acrylonitrile content in NBR the approximate T_g are −15°C, −20°C and −45°C, respectively.) Nitrile is attacked by ozone, and polyvinylchloride (PVC) is sometimes blended in to improve resistance.

Isobutyl–isoprene elastomers (IIR), referred to as 'butyls', are similar in price to nitriles. In spite of their low T_g (about −65°C) unfilled gum butyl elastomers can give quite high levels of damping over a fairly wide range of temperatures. Other useful attributes of IIRs include low gas permeability and quite good tolerance to ozone.

Urethane elastomers (polyurethanes) can be formulated to give a particularly wide range of properties. It is this versatility coupled with convenient processing characteristics which accounts for the widespread use of urethane elastomers. Among this class of elastomers are materials with higher strengths and with moduli two orders of magnitude greater than conventional elastomers. High and low damping grades of urethane elastomers are available over a wide hardness range – although low damping grades have loss angles several times the lowest available for NR vulcanizates. Creep rates are generally significantly higher for urethane rubber than for NR vulcanizates. Some types of urethane elastomers have very good abrasion resistance. Urethane rubber is generally tolerant of oxygen and mineral oils, but polyester types (AU) are vulnerable to degradation by moisture (hydrolysis) in hot conditions, and to subsequent microbial/fungal attack. Polyether type urethanes (EU) are much more resistant to aqueous fluids but continuous use in water at over 80°C is not recommended and contact with strongly acidic or alkaline solutions should be avoided. On combustion, polyurethanes can produce highly toxic fumes so flame retardancy can be particularly necessary; this can be provided by additives or by polymer design. Urethane elastomers have good resistance to gamma radiation compared to most other elastomers. (The tolerance of NR is also good but halogen-containing elastomers have poor resistance to radiation.)

A number of special-purpose elastomers are available which can withstand chemical environments at temperatures around 150°C higher than those tolerated by general-purpose and other widely used elastomers such as chloroprene, nitriles and urethanes (Table 7.69). However, a high price must be paid for these remarkable elastomers. Fluorinated hydrocarbon elastomers (fluoroelastomers FKM/FPM) are currently about

Table 7.70 Typical properties of thermoplastic elastomers

50 times as expensive as general-purpose elastomers. Moreover, elastomers such as FKM can be more difficult to process and they produce vulcanizates which are harder and less elastic than the general-purpose materials. A useful attribute of silicone elastomers is that their strength properties decrease only gradually with increasing temperature.

Thermoplastic elastomers (TPEs) are available with a broad range of properties (Table 7.70). Styrenic (styrene–butadiene–styrene block copolymer) TPEs alone can have shear moduli as low as 0.3 MNm^{-2} or as high as several hundred MNm^{-2}. Although for harder types of TPE the elastic limit may be only about 10%, many of them yield before failure, making them tough materials. Hard, strong materials are available: the polyether–polyester block copolymers or block polyesters (YPBO); the polyurethane, or urethane TPEs; and the polyether–polyamide block copolymers or block polyamides. The chemical/environmental resistance of the YPBOs is also generally excellent – although at high temperatures additives may be required to give protection against attack by aqueous media. Environmental/chemical tolerance of urethane TPEs is generally good although there is some susceptibility to hydrolysis (attack by aqueous fluids) – especially for polyester-based materials at high temperatures. Resistance to water is better for polyether-based urethane TPEs and for harder grades.

The properties of thermoplastic elastomer blends vary widely according to the type of elastomer and thermoplastic and according to their composition and method of preparation. Many have higher resistance to ozone and diatomic oxygen than their rubbery component alone possesses, but their tolerance to mineral oils is generally not good unless an oil-resistant elastomer, such as nitrile, is used. Thermoplastic elastomer blends cannot withstand such high stresses as the urethane block polyamide and block polyester types. Short-term creep rates at ambient temperature for blends based on comparable contents of NR, EPDM and IIR are around 2.5%, 3% and 4% per decade, respectively (see also Section 7.7.3). However, at low (around −40°C) and high temperatures (about 100°C) EPDM-based TPEs can have lower creep rates than those based on the natural materials. The fact that short-term, physical, creep and stress-relaxation rates are relatively high for TPEs is offset by their long-term, chemical, creep rates being relatively low.

7.7.9 Example applications

By definition, elastomers are soft materials able to undergo large strains and remain within their elastic limit; often these characteristics make them natural materials for springs for vibration 'isolation' or energy absorption. Elastomeric springs are used for the reduction of dynamic force transmission (isolation) as major components in the suspension systems of trucks and rail vehicles. Often, these are elastomer–steel laminates giving different force–deflection characteristics in different directions. Usually an elastomer with good mechanical strength and low damping is used, such as natural rubber, to avoid excessive heat build-up in these large components. Damping, if required, is supplied by a separate damper. Although damping is detrimental to isolation performance well away from resonance, in many practical vibration sources such as bumpy roads or piston engines, a very wide range of frequencies occur: some near-resonant behaviour then becomes inevitable and a measure of damping can be beneficial. Where heat build-up is not a problem a high-damping elastomeric material, such as one based on butyl rubber, is therefore sometimes used. However, natural rubber continues to be used very extensively in engine mounts in spite of the high ambient temperatures under the bonnets of many contemporary cars.

One difficulty with plain elastomer engine mounts is that they tend to have low damping and stiffness at low frequencies and high displacement amplitudes and high damping and stiffness at high frequencies and low displacement amplitudes. The ideal characteristics are the reverse: high stiffness and damping to restrain engine movement at idling speed and low stiffness and damping to provide vibration isolation at running speed. These ideal requirements are now met to a large degree by fluid-filled mounts encased in elastomer. A subtle but important aspect of vibration isolation which is sometimes overlooked arises from the fact that any real 'isolation' spring has mass: vibration waves can therefore travel through it, greatly reducing the effectiveness of isolation at audio frequencies. Springs based on elastomers are much less susceptible to these 'wave effects' than are those made from materials with very low damping such as steel. Moreover, the high-frequency transmissibility of steel springs can be reduced by using elastomeric elements in series. Elastomers perform these and similar force reduction functions in many parts of an automobile; it should not be forgotten that the tyres themselves are an important part of the suspension system (Figure 7.122).

The mechanical properties of elastomers, particularly natural and chloroprene, are widely exploited in other areas for vibration isolation. Notable examples include the suspension of underground rail track on elastomeric springs or matting to reduce the transmission of groundborne noise to nearby buildings; conversely, the buildings themselves, or parts of them, can be supported on isolation springs. The same principles of groundborne noise/vibration/shock isolation are applicable to situations ranging from the operation of a large steam-hammer to that of an electron microscope; frequently isolation of the source or the receiver is accomplished with the assistance of elastomers. Recently, important buildings in earthquake-prone areas have begun to be built on elastomeric-steel mounts for earthquake protection;[89] even in areas of relatively low seismicity potentially hazardous plant must now be earthquake resistant – seismic isolation mounts can be used towards this end.

Elastomers are capable of absorbing large amounts of mechanical energy per unit volume and returning to their original shape: their capacity is orders of magnitude greater than that of steel, for example. This property has led to the widespread application of elastomers in devices to reduce forces occurring in collisions which are a regular occurrence; particular examples are: dock and other types of fenders, bump-stops and snubbers, and playground surfaces. In accordance with Newton's second law, collision impulse reduced if rebound does not occur, thus high damping can be an advantage. However, other factors such as (fatigue) strength also need to be taken into consideration. For a given travel, forces are minimized if they are near the average value throughout; this type of characteristic is frequently obtained for rubber springs by designing them to buckle under design loads. Such buckling constructions include matched pairs of columns, tubes and also cellular elastomers.

Low-damping elastomers, such as unfilled or lightly filled natural rubber, can be used effectively to store mechanical energy. Many devices to exploit this attribute have been considered over the years but, apart from toys, the only widespread application is in small harpoon guns. However, this is a position that could change in a future dominated by rising energy costs.

The low moduli of elastomers enable them to conform well to surface roughness and accounts for their good grip. The high friction of rubbery materials is used in a large number of devices: belt drives, conveyor belts, solid and pneumatic tyres are just a few examples – many are multifunction devices. The highest friction is obtained with very soft vulcanizates; often these are highly oil-extended – as in racing-car 'slicks', for example. Contrary to popular belief, friction coefficients in excess of 1 are possible. Conversely, much lower friction can be obtained by means of formulation additives or by using fluoroelastomers.

The use of elastomers in joints and bearings can pay rich dividends in terms of: reduction of complexity, avoidance of stick-slip behaviour and of backlash problems, low mainte-

stick-slip behaviour and of backlash problems, low maintenance, and weight saving. Elastomer-based bearings can be used to allow for thermal expansion of structures. They are widely employed to accommodate misalignment and relative movement in shaft couplings where they also give force reduction for shock loadings. Other related applications include helicopter rotor bearings and track pads in tracked vehicles.

Elastomers find another range of applications in the containment, piping or sealing of fluids where flexibility is required. In many cases less than full rubbery behaviour is tolerable. This is fortunate, since some of the most widely used mineral-oil-resistant elastomers are not very rubbery. Ethylene–propylene is generally used for radiator hose and for seals in these and other hot water systems. There are potential uses for some of the thermoplastic elastomers in these applications. One aspect of fluid sealing where fully elastic behaviour is beneficial is where reciprocating and rotary sliding occurs; such seals are often designed to allow slight leakage to lubricate the seal. In addition to being extensively employed in fluid containment – especially where flexibility is a requirement – elastomers are widely used for corrosion and abrasion-resistant surfaces. For abrasion-resistant coatings the choice between elastomer types and between elastomers and other materials such as ceramics depends on the details of the application.

Applications of short-fibre reinforced elastomer and TPE composites include: diaphragms, hose, static seals, conveyor belting and belt drives. These composites are also used as 'bead' and 'chafer' materials in off-the-road types.

The promise of TPEs in mainstream mechanical engineering design has been demonstrated in a number of applications including bicycle wheels and tyres, hose, car bumpers and hinges. However, the potential of TPEs remains to be fully exploited by industry.

7.7.10 Conclusions

Many aspects of contemporary life such as road transport would be much more difficult and noisy and less comfortable without elastomers. Nevertheless, elastomers remain under-exploited. This under-use can be partly explained by difficulties in modelling the mechanical behaviour of elastomers – particularly when filled. Also, frequently, elastomers are inadequately or inappropriately characterized. Too often, elastomers are regarded as fringe materials. In reality, elastomers are natural materials to consider in many situations where a spring, joint or bearing is required. The expanding range of mechanical and environmental properties available from elastomers offers designers a valuable resource and a worthy challenge to their ingenuity.

7.8 Engineering ceramics and glasses

7.8.1 Introduction

Ceramics are inorganic crystalline materials, low in ductility and high in melting point which are usually fabricated not by melting but by processes involving powder compacting and sintering at very high temperatures. They are usually compounds of metals with non-metals and they owe their high temperature resistance to deformation to directed covalent or electronic bonds between the constituent atoms which do not permit plastic flow at operating temperatures too low for diffusion to occur.

Glasses have analogous compositions to ceramics but have lower melting points and retain their amorphous liquid structure on cooling. They have, instead of a melting point, a glass-transformation temperature above which their viscosity is low so that they can be melt formed, and below which the viscosity is high so that they have effective shape retention equivalent to a solid. *Glass ceramics* or melt-formed ceramics can be melt formed as glasses but crystallize on a micron or sub-micron scale at a lower temperature. *Single-crystal materials* are special products with a uniform structure.

Machinable ceramics fall into two types. One type has platey structures which can be readily cleaved and the other consists of particles that are only weakly bonded together so that they can be readily chipped apart. These, unlike other ceramics that have to be ground with an abrasive, can be machined with conventional tools.

7.8.2 Standards

Most national standards are highly oriented to testing or application. Only in the field of electrical insulation has any systematic classification been attempted in IEC 672 1980 which is to be the basis for BS 6045. So far as is possible, the IEC classification will be followed in this section.

7.8.3 Clay-based ceramics

Technical porcelains are ceramics based on clay and other silicates with added alumina. Fine-grain versions IEC 1XX, 2XX and 4XX are used primarily for electrical purposes but coarser grain size chemical stoneware and kiln furniture are also included. These are well vitrified and therefore non-porous.

IEC Class C110, Porcelains with <30% alumina, consist of quartz grains and massive mullite surrounded by a matrix of glassy feldspar, and the shrinkage of the quartz on transformation at 530°C leads to microcracking. They have low strengths (50–100 MPa) and the lowest thermal conductivities (1.7–2.1 $\mathrm{Wm^{-1}\ K^{-1}}$). They are good insulators at ambient temperature but resistivity falls off as temperature increases. They are cheap and used for internal and external insulators.

IEC Class C111, Pressed porcelains with <30% alumina, are similar in composition to Class 110 but because the pressing process, which is carried out with a clay containing less water, allows trapping of air between the granules, pressed porcelains are more porous and have lower strengths. They must be glazed for outdoor applications and cannot be used at high voltages.

IEC Class C112, Crystobalite porcelains, contain crystobalite instead of quartz but are otherwise similar to Class 110.

IEC Class C120, Aluminous porcelains with 30–50% alumina: most or all of the quartz in Class 110 is replaced with alumina giving improved strength (*ca* 100 MPa).

IEC Class C130, Aluminous porcelains with 75% alumina: feldspar porcelains in which all the quartz has been replaced by alumina improving modulus and strength (up to 200 MPa).

IEC Class C2XX, Steatite and forsterite ceramics replace the quartz or alumina in class 1XX with enstatite or forsterite talc. These materials comprise:

- IEC Class C210, Low-voltage steatites. These are porcelains with 80–90% talc, 5–10% plastic clay and 5–10% feldspar. They have low strength (50–100 MPa) and because they have about 0.5% open porosity are limited to low-voltage insulation.
- IEC Class C220, Normal steatites. In these the electric losses of the glassy phase are reduced by the substitution of barium or calcium carbonate for the feldspar and the

addition of magnesia and zirconia. Class C220 has higher strength, resistivity and lower dielectric dissipation than Class C210.

- IEC Class C221, Low-loss steatites. Alkali levels are lower than those of Class C220 to reduce dielectric loss by minimizing the glassy phase.
- IEC Class C230, Porous steatites. These are low-loss steatites with *ca* 30% open porosity which improves machinability and thermal shock resistance but limits the material to low-voltage applications.
- IEC Classes C0240, Porous forsterites, and C0250, Dense forsterites. In forsterites the magnesia level is raised so that forsterite is formed instead of steatite to give a coefficient of expansion *ca* $10 \times 10^{-6}\ K^{-1}$ which matches titanium and some nickel–iron alloys for ceramic to metal assemblies in high-frequency power devices and microwave tubes.
- IEC Class C410, Dense cordierite. Cordierite is a magnesium aluminium silicate which is made synthetically from clay, talc and sillimanite and has a low coefficient of thermal expansion. Ceramics consisting of this material with 5% vitrifying feldspar are readily fired and can be made dense. Although their strength is only 50–100 MPa their low thermal expansions *ca* $3 \times 10^{-6}\ K^{-1}$ confer shock resistance.
- IEC Class C420, Dense Celsian and Zircon Porcelains (unclassified) are little used.

Porous ceramics (*IEC Classification C5XX*) may be based on clay, cordierite or alumina up to about 80%. (Porous ceramics with higher alumina contents are included under high aluminas, Class C7XX.) They are used primarily as electrical heating and thermocouple insulations where their porosity confers resistance to thermal shock and machinability. These ceramics are compounded from fine aggregates for electrical applications, but coarse aggregates may be used for crucibles and tubing for high-temperature processing.

IEC Class C510, Porous aluminosilicates: these are manufactured primarily from refractory clays with additions of quartz, sillimanite or alumina to increase refractoriness. They contain very little fluxing material and their 30% porosity gives them the thermal shock resistance required for such applications as gas fire radiants.

IEC Classes C511, 512, 520, Porous magnesium aluminosilicates: these are developed from Class C510 by the addition of magnesia-containing minerals to produce cordierite which greatly enhances shock resistance and the distinctions between the classes are based on performance. The highest-performance C520 Class will stand severe thermal cycling and are used for experimental heat exchangers and automobile exhaust catalyst supports.

IEC Class C530, Porous aluminous materials: these ceramics have alumina contents up to 80% and are more refractory but less shock resistant than the other classes of porous ceramic.

Impermeable aluminosilicate and mullite ceramics, IEC Class 6XX, are impermeable fine grain materials with high strength (100–200 MPa) and high dielectric strength. They are used for gastight tubing and high-temperature electrical insulation and are classed according to alumina content.

IEC Class C610, 50/60% alumina ceramics: these are made from clay and alumina (or aluminosilicates) and consist of mullite in a silicous glassy phase.

IEC Class C620, 60–80% Alumina ceramics: this specification covers materials with a wide range of properties and crystalline compositions because mullite, which is 71.8% Al_2O_3 and 28.2% SiO, is highly refractory and compositions containing more Al_2O_3 are also highly refractory (and require a high firing temperature). Compositions with more silica than mullite are less refractory and the addition of other oxides such as CaO reduces refractoriness considerably. If a highly refractory material is required this must be specified closely. However, all materials in this class are fine grained with no open porosity and have fair shock resistance.

7.8.4 Oxide-based ceramics

Oxide-based ceramics, IEC classification C3XX, C7XX and C8XX and non-classified materials consist of synthetic oxides together with bonding materials which sometimes form a glassy phase. The amount and composition of the glass has a significant influence on the engineering properties. In general, a low glass content gives a high refractoriness, a large grain size, high electrical resistance and low dielectric loss. On the other hand, strength and wear resistance are favoured by a low grain size which requires more glass to reduce the firing temperature.

IEC Classification 7XX, High alumina ceramics: in these ceramics the second two digits denote the minimum percentage of alumina. This degree of classification is presumably adequate for electrical purposes but not for all applications.

IEC Class C799, High-purity aluminas (>99.9% Al_2O_3): these are single-phase ceramics which may be sintered to give a large grain size or hot pressed to give low porosity and a small grain size. If sintered in a reducing atmosphere they can be made translucent or transparent and may be used, for example, for sodium vapour lamp envelopes.

Aluminas with over 99.7% Al_2O_3 may be made from relatively lower-purity aluminas or may have added magnesium oxide which restricts grain growth. The magnesia-free products are more refractory but weaker (100–200 MPa tensile strength) while those containing magnesia have tensile strengths of 2–400 MPa and are more suitable for thin-walled tubing or small diameter rods. Aluminas with 99–99.7% Al_2O_3 have usually small amounts of glassy phase which facilitates sintering and controls electrical properties.

These are the most widely used of the alumina ceramics for engineering and electrical purposes, those with fine grains having strengths up to 400 MPa while those with coarse grains are used for electrical insulation.

IEC Class C795: These aluminas all have a deliberately formulated glassy phase which facilitates metallizing by manganese/molybdenum.

IEC Class C786: this is a somewhat heterogeneous class, some having a glassy phase while others have additions of manganese and titanium dioxides which impair electrical properties and refractoriness. Those with lower alumina contents are non-refractory and are used for low-temperature electrical insulators and mechanical components.

IEC Class C780: there are two types of material in this class, one is refractory consisting of mullite and silica, the other non-refractory and limited to low temperatures and non-critical uses.

There are also aluminas which do not fall within the IEC classification. Porous alumina ceramics are available in the same composition ranges with high resistance to corrosion or slag attack. Unlike the non-porous materials, these can be machined (or rather chipped) by hard metal tools. The addition of 10–20% of zirconia to alumina ceramics enhances strength to over 400 MPa, making them suitable for cutting tool tips. The addition of 20–40% TiC also increases strength and stiffness for similar applications. The addition of TiO (a high-permittivity material) significantly increases the dielectric constant of alumina ceramics where this is desirable.

Synthetic alumina crystals such as sapphire and ruby are used for high temperatures and scratch-resistant windows and for bearings and laser elements.

IEC Class C830, Zirconia ceramics: zirconia is more refractory than alumina, it can be machined readily to give a low coefficient of friction against metals and it is a useful oxygen ion conductor above about 700°C. It is, however, more expensive than alumina, which is therefore used preferentially where either will suffice and its use is complicated by phase instability. Pure zirconia is monoclinic at room temperature, transforms to tetragonal form at about 1200°C and to a cubic form at about 2370°C. Its use as a ceramic depends on stabilization of the cubic phase, of a fine tetragonal phase within cubic crystals or of an all-tetragonal material.

Truly stable zirconia would be very strong (above 400 MPa) and highly refractory. Development is proceeding and, if manufacturers' claims are fully justified, zirconia ceramics have wide applications. Meanwhile they are used for oxygen probes, small crucibles, dishes, etc. and heating elements for operation in air at high temperature.

IEC Class C3XX, Titania ceramics: ceramics based on TiO_2 have been used for applications requiring high permittivity and clay-bonded sub-stoichiometric materials are used for thread guides in the textile industry because they are semiconducting and discharge static electricity.

IEC Class C820, Magnesia ceramics: magnesia possesses few advantages over alumina as a ceramic but, considered as a refractory, has a higher thermal conductivity, greater refractoriness and greater resistance to basic slags. Magnesia ceramics are therefore used in applications requiring resistance to corrosion at high temperatures and, specifically, for electrical purposes as an insulator in mineral insulated cabling.

IEC Class C810, Beryllia ceramics: beryllia is much more expensive than alumina and highly toxic. However, it has a thermal conductivity at room temperature of 500 $Wm^{-1} K^{-1}$, an order of magnitude greater than other electrical insulating material, and it is therefore used for some electronic devices. Its widely heralded future as a nuclear material has not yet been realized.

Other oxide ceramics not in the IEC classification include lime, thoria, uranium dioxide (used as a nuclear fuel), ferrites (which have very extensive magnetic applications) and titanates.

Ferrites, compounds of Fe_2O_3 with other oxides such as ZnO, are available with very high magnetic permeability and can be made in the powder form to have very low losses so that they may be used for cores for high-frequency inductors. Certain ferrites will form strong permanent magnets.

Titanates are used for their electrical properties. Some (usually barium titanates) have permittivities up to 5500 and are used as dielectrics for electronic circuitry. Magnesium titanates have permittivity-compensating properties. Lead zirconate–titanates have strongly piezoelectric properties.

7.8.5 Non-oxide ceramics

Non-oxide ceramics differ essentially from oxide ceramics in that they oxidize at high temperatures in air and cannot therefore be fabricated by a conventional oxide-sintering process. They must therefore be fabricated by the alternative routes listed in Section 7.8.11 and their compositions and microstructures are adjusted accordingly. The most important are carbides, silicides, borides and carbons.

7.8.5.1 Silicon carbide (carborundum)

This owes its application to its high hardness, very high refractoriness, high thermal conductivity and its semiconducting properties. Its electrical conductivity is low at low temperature and low currents, but increases by orders of magnitude at high temperatures and high currents. Although silicon carbide is oxidized in air at high temperature many of the commercial materials form a protective layer of silica.

The name 'silicon carbide' comprises a number of products manufactured in different ways. The conventional method of manufacture is the reduction of silica sand by carbon in the arc furnace which produces the high-temperature stable α-phase. The phase is produced by low-temperature gas reactions and is converted to the β-phase by heating above 2000°C. Commercial products include:

1. Clay-bonded silicon carbide containing 10–15% clay which bonds chemically to the surface film of silica on sintering;
2. Other additives which enhance sintering, but permit a higher proportion of silicon carbide than is possible with clay bonding, have been used with reported success;
3. Very high-temperature sintering of prime silicon carbide produces a coarse-grained, porous and highly refractory product;
4. Hot-pressed silicon carbide requires the addition of a secondary material, usually about 2% alumina. It is very strong (above 400 MPa), fine-grained and non-porous but very expensive;
5. Reaction-bonded silicon carbide is made by two distinct processes. In one type a compact of silicon carbide, carbon and an organic binder is infiltrated by liquid silicon which bonds the particles by the formation of additional silicon carbide. The free silicon remaining may, if required, be leached out with acid to leave an open porous refractory. The other process achieves the same object by firing a compact of silicon carbide and silicon in nitrogen to produce a silicon nitride bond.
6. Coatings or thin-walled components of pyrolytic silicon carbide can be produced by decomposing a gas mixture containing both silicon and a carbon on a heated substrate. This process found an important application in the manufacture of fuel elements for high-temperature gas-cooled reactors. In these fuel elements a silicon carbide shell contains fission products produced in small spheres of fissile material;
7. Graphite can be 'case hardened' with silicon carbide produced from solid (or gaseous) silicon.

The original application of silicon carbide was as an abrasive for grinding steel, but it has been replaced for this purpose by fused alumina and its use as an abrasive is now restricted to shaping materials of lower tensile strength. It is used extensively for refractories, particularly where the shock resistance conferred by its high thermal conductivity is an asset both in vacuum or reducing conditions and in air. A major use is in electrical resistance heating elements and it is also employed for susceptors in high-frequency induction fields. Its high hardness makes it suitable for abrasion-resistant components, particularly for non-lubricated bearings.

7.8.5.2 Silicon nitride-based materials

Silicon nitride and its derivatives have properties which augur a great engineering potential because of its high hardness, high strength, refractoriness, low coefficient of thermal expansion which confers thermal shock resistance and its resistance to oxidation which, like that of silicon carbide, is due to the formation on its surface of a silica film.

The applications of silicon nitride ceramics has, however, been hindered by fabrication difficulties. Like silicon carbide, it cannot be readily sintered, tending to dissociate at above 1850°C and alternative methods of manufacture are difficult to control or expensive. Two products are available:

1. *Reaction-bonded silicon nitride*: This can be produced by converting a silicon powder compact to nitride by sintering in a nitrogen atmosphere. The resulting compact is porous and the product variable.
2. *Hot-pressed silicon nitride*: This requires the addition of an oxide (typically 1–5% MgO) which provides a liquid phase at the sintering temperature. This produces a fine, strong product but limits the temperature at which the high strength is retained. Hot pressing is expensive and the shapes which can be produced are limited.

The applications of silicon nitride have so far been limited to high-temperature industrial applications. It is extremely valuable for such components and operations as furnace supports, heating tubes, jigs and printer's saggars, silver soldering and vacuum and copper brazing.

7.8.5.3 Sialons

The difficulties experienced with silicon nitride have, to a large extent, been overcome by the partial substitution in the molecule of aluminium for silicon and oxygen for nitrogen. The resulting sialons can be hot pressed from mixtures of silicon nitride, alumina, silica and aluminium nitride or, if additional densifying constituents are added, they can be sintered. These materials merit and have received considerable study and, as a result, porosities as low as those in hot pressings and strengths above 400 MPa may be achieved with sintered materials.

An alternative route to sintering is the nitriding (and subsequent high-temperature sintering) of a mixture of oxides and silicon. Sialons and related products are finding wide and increasing applications in manufacturing processes where resistance to heat and abrasion are required.

7.8.5.4 Boron carbide

Boron carbide is one of the hardest ceramic materials available and can be hot pressed to achieve tensile strengths above 400 MPa. It is used for very abrasive conditions (e.g. shot-blast nozzles and for ballistic armour). Its main drawback is its cost, which is high. The sintered product is more porous and has a coarser grain size.

7.8.5.5 Boror nitrides

Boron nitride in its most commonly available form differs from the ceramics already considered in that it has a laminar structure and is therefore soft and machinable. The properties of the boron nitride crystal are highly anisotropic and shapes deposited pyrolytically on a substrate have thermal and electrical conductivities and coefficients of thermal expansion which may be up to a hundred times greater parallel to the substrate than perpendicular to it. This property and the fact that many molten metals do not wet boron nitride has led to its use for crucibles for metal melting. There is also a cubic form made under high pressure which is used as an abrasive.

7.8.6 Carbons and graphites

Three allotropic modifications give rise to a very wide range of carbons and graphites with a correspondingly large range of applications:

1. Diamond is a cubic crystalline material with a very stable structure. It is the hardest substance known, highly refractive and highly transparent and very expensive when pure. It can, with difficulty, be manufactured but the manufactured product, which can be used as an abrasive, is barely competitive with the mined material.
2. Graphite has a laminar hexagonal ring structure. Each ring is strongly bonded to six other rings in approximately the same plane but the bonding betwen planes is weak. Graphite has therefore excellent lubricating properties, is highly refractory and, if the layers of hexagonal rings are continuous and aligned, very high specific strength and specific elasticity modulus in a direction in the plane of the rings.
3. Amorphous carbon is, as its name implies, amorphous to X-rays but this structure is probably a large-scale statistical phenomenon rather than a true liquid type structure. The available amorphous carbons are probably random assemblies of graphite platelets, the size and distribution of which govern the properties.

Solid carbon and graphite products are usually made from a mixture of graphite (which occurs naturally) or carbon particles (usually derived from coal or oil cokes) pressed with a carbonaceous binder to form a solid block. The mass is converted to carbon on firing. Very high-temperature firing graphitizes both the amorphous carbon and the carbon derived from the binder.

Both industrial carbons and graphites are highly refractory materials which must be protected from oxidation at high temperatures with strengths around 45 MPa and electrical resistivities around 30 Ωm. The thermal conductivity of graphite is higher than that of carbon. Carbons may be impregnated with resin to improve strength and soundnes or with metals.

Carbons and graphites manufactured by polymer carbonization are assuming great technical importance. They include:

1. Carbon fibres, made by carbonizing polymer fibres which are subjected to tension during carbonization and graphitization. They are highly oriented graphite fibres with high specific tensile strengths and specific moduli exceeded only by boron fibre. They are used for manufacture of composites described in Section 7.6. Carbon/carbon fibre combines the refractory and electrical conducting properties of graphite with high specific strength.
2. Vitreous carbon, produced by controlled carbonization of a cross-linked polymer, is glassy in appearance, and has no open porosity. It is available in plate, dish and crucible form and, according to grade, will withstand temperatures of 1000–2500°C in inert atmospheres.
3. Graphite foam and graphite or carbon felts are produced by carbonization or graphitization of the appropriate polymer foam or mat.

The refractoriness, electrical conductivity, lubricity and (in the form of fibre) high mechanical properties of carbon and graphites together with their reasonable cost render them suitable for many and varied engineering and consumer applications.

7.8.7 Miscellaneous ceramics

A number of other ceramics have specific applications. They include refractory metal, usually tungsten or titanium, carbides which are used extensively for cutting or forming tools. These are usually bonded with cobalt, nickel or nickel molybdenum and are described in Section 7.6.

7.8.8 Glasses

All commercial glasses are based on silica (SiO_2) to which may be added other oxides which progressively reduce softening point, increase thermal expansion and impact other characteristics. 99.8% silica glasses include:

- Fused silica, which contains small bubbles, and is used for applications that require good thermal shock and corrosion resistance;
- Fused quartz which is transparent and used for high-quality tubing; and
- Vitreous silica which is used for high-equality optical components.

Aluminosilicate glasses have service temperatures next to silica glasses and are resistant to alkalis. They are used for high-performance electronic applications and other industrial applications. Borosilicate glasses have lower softening temperatures than aluminosilicate glasses and, because of the lower cost of fabrication, have more widespread applications. Soda lime silicate glasses have still lower softening temperatures and higher coefficients of expansion. They are widely used for windows and other domestic applications because of their relatively low cost. Alkali-lead silicate glasses have, besides the lowest softening points commonly available, refractive indices and dispersive power which makes them useful for optical and similar applications. Other glasses include photochromic glasses, semiconducting glasses, solder glasses for glass–metal seals and ophthalmic glasses.

7.8.9 Glass ceramics

The properties of glass ceramics can be tailored to have specific properties to fit the desired application. These include:

- Thermal expansion, which can be made to match that of the material to which the glass ceramic is to be fused, or possibly to approach zero;
- Refractoriness;
- Transmission of light;
- Colour, or
- Machinability.

Where an application is foreseen, manufacturers or specialists should be consulted for advice on manufacturing procedure and practicability.

7.8.10 Mechanical properties

The applications of ceramics are strongly influenced by differences in mechanical behaviour compared with metals.

7.8.10.1 Elastic properties

The elastic properties of ceramics are influenced by the level of porosity and also by the proportion of different phases present. The effect of small, closed, randomly distributed spherical pores on the modulus of a material of Poisson's ratio $\nu = 0.3$ has been shown to be approximately:

$$E = E_0(1 - 1.9\nu + 0.9\nu^2)$$

where E_0 is the modulus of the non-porous material.

Each phase in a multiphase material contributes, to a first approximation, according to its volume fraction. Where, as is common in engineering ceramics, a high-modulus major phase is bonded by a low-modulus minor phase, the modulus reduces rapidly with increase in the content of the minor phase. Usually modulus decreases with increasing temperature but glasses and complex ceramics are available with moduli which increase with increasing temperature (over a limited range). The range of moduli for ceramics is indicated in Table 7.71.

Table 7.71 Typical room temperature elastic moduli of glasses and ceramics

Material	*Young's modulus* (GNm^{-2})	*Note*
Glass	63–73	
Glass ceramics	78–120	
Carbons and graphites	9–13	
Porous ceramics	54	
Porcelains	69–138	
Oxides	132–155	
Zirconias	230–580	
Aluminas $\nless$ 99%	280–350	
Silicon carbide	385–470	
Boron nitride	44–104	Anisotropic
Silicon nitride	160–310	
Sialon	280	
Boron carbide	440	

7.8.10.2 Strength and ductility

The tensile strength values for ceramics quoted in this section and elsewhere are not comparable with those quoted for metals. In a metal the strength of the material obtained from a simple mechanical test adjusted by a safety factor chosen on the basis of previous experience may be used to determine a safe loading stress. In ceramics and other brittle materials measurements on nominally identical materials will show scatter in strength results with standard deviations around 20% of the mean strengths. Catastrophic failure occurs by rapid propagation of a crack as soon as the stress at the most severe flaw reaches a critical value. (For more detailed discussion of this see references 90 and 91.) The consequences of this are:

1. Since specimens contain critical flaws of varying severity nominally identical specimens exhibit scatter in strength.
2. Large components and components with larger surface areas are, on average, weaker than smaller ones because there is a higher chance of finding a flaw of given severity. (It is also likely that a manufacturing method will produce a larger flaw in a larger component, but this is secondary to the argument.)
3. Because a severe flaw at a stress less than the maximum stress in a component may reach a critical value for fracture before a less severe flaw subjected to the maximum stress, a component will not necessarily fail at the point of maximum stress. A thorough stress analysis of a component must therefore be carried out.

There is therefore no single measure of strength applicable both to a test specimen and a component, and no absolute guarantee can be given that a component will not fail under its design load. Design must be based on a probabilistic approach which will keep the frequency of failure below an acceptable figure, depending on the seriousness of the consequences.

7.8.10.3 Methods of testing

The standard uniaxial tensile and compression tests used for metals are not applicable to ceramics because of the difficulties of gripping the specimen and of aligning it axially. The tests used apply specific parts of the specimen to tensile stress by loading other parts in compression. A number of tests have been devised[92] and the most straightforward method is the

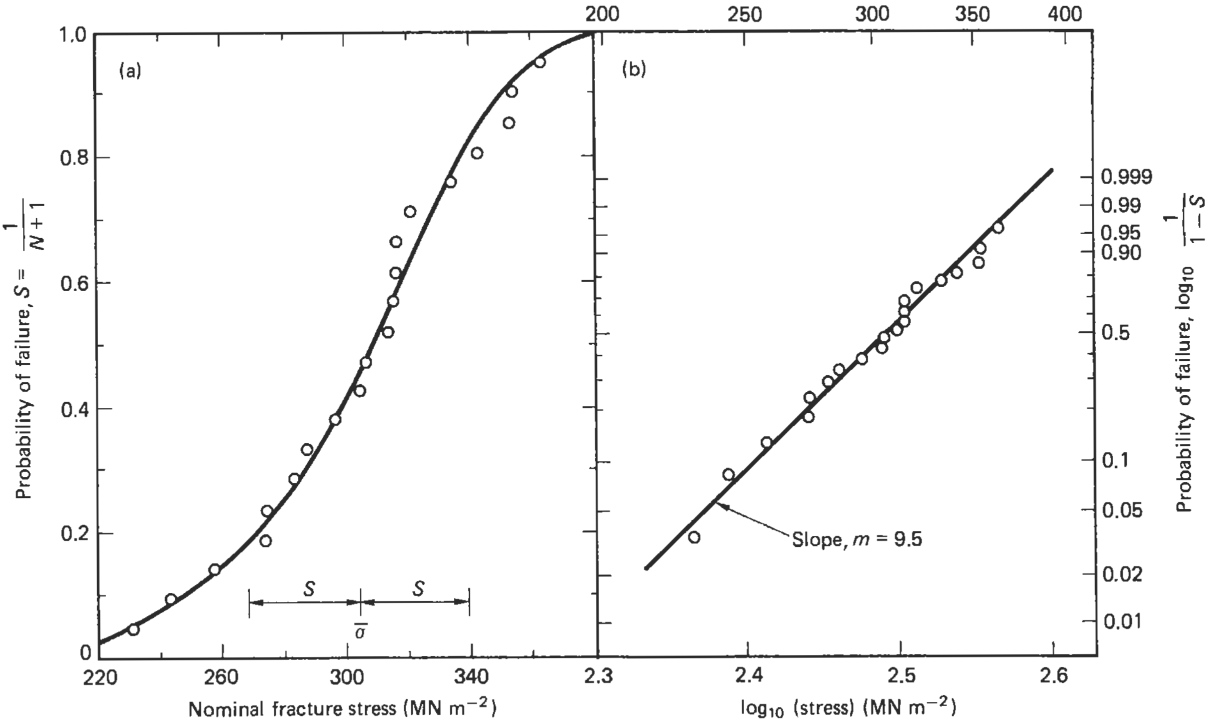

Figure 7.123 The fracture strengths of a batch of 95% alumina specimens tested in four-point bending at room temperature with a 320 grit ground surface finish are plotted (a) as a cumulative distribution and (b) as a Weibull plot to get a straight-line fit to the points. Using the Weibull parameters calculated the solid line in (a) represents the Weibull distribution calculated. The slope m of the straight line is the Weibull modulus. (Reproduced by courtesy of Dr R. Morrel[90])

three-point bend test, in which the tensile stress rises to a maximum on a line on one surface of the specimen.

There is no recognized international standard for the testing technique, specimen size, surface finish and shaping procedure, therefore small differences in strength quoted by a number of manufacturers should not be regarded as sigificant where it is desired to select the strongest. Procedures have been developed for determining the load which may be applied to a component to give a specific probability of failure in the short term.

It is necessary to undertake a programme of tests on at least 20 specimens from which a statistical distribution known as the 'Weibull modulus', m, which gives an estimate of the degree of scatter of the data (see Figure 7.123) may be determined. From the value of m and the effective volume or surface of the component the probability of failure at a given load may be calculated. Working stresses for a 10^{-4} failure probability may be of the order of 25–50% of the mean bend stress. The procedures are described in detail in references 90 and 93.

7.8.10.4 Long-term strength

The long-term strengths of many ceramics, particularly silicate-bonded materials, are lower than the short-term strength. This phenomenon has been described (usually referring to the behaviour of glasses) as 'static fatigue' but is more correctly termed 'slow crack growth'. The crack-like defects present in all ceramics (except whiskers) extend by a thermally activated atomic process, driven by the applied stress, influenced by the environment at the crack tip and strongly dependent on temperature: In oxide ceramics OH ions can break metal-oxide bonds, therefore clay bonded materials may have lower long-term strengths in high-humidity atmospheres and particularly in alkaline environments. With most non-oxide ceramics, water vapour has little influence, so that little effect may be observed at stresses well below the fracture stress.

Most ceramic components are subjected to low values of tensile stress in service but where a guarantee of survival for a specific period at stresses in excess of 10% of the nominal breaking stress is required the only solution is a short-term overload proof stress which rejects components in the low-strength tail of the distribution.[92]

7.8.10.5 Fatigue under cyclic loading

Little systematic work has been carried out on the effect of cyclic loading on ceramics. If cyclic loading cannot be avoided the effect may best be estimated by integrating the varying stress intensity factor raised to a power n (obtained from the reference to the previous paragraph) with time.

7.8.10.6 Strength at elevated temperatures

As described in Section 7.8.10.4, slow crack growth increases with increasing temperature, consequently increasing temperature may initially reduce long-term strengths. However, further increase in temperatures may result in flaw rounding, which increases strength to a maximum. Strength is reduced by creep and creep rupture at still higher temperatures. Few

Table 7.72 Approximate temperatures at which ceramics and glasses are suitable for long-term operation under load

Type of ceramic	*Temperature* (°C)	*Notes*
Soda-lime glass	300	
Silicon glass	800	
High-purity alumina	1400	
Silicon nitride	1600	Oxidizes in air above 900°C
Graphite	>1500	Oxidizes in air above 400°C

data are available beyond statements on 'upper use temperature' usually under no-load conditions, which implies suitability for short-term use without disastrous changes in microstructure. Temperatures at which ceramics are suitable for long-term use under load are indicated in Table 7.72.

7.8.11 Manufacturing procedures

The manufacture of ceramics includes shaping with or without the application of pressure and consolidation by firing. The characteristics of the ceramic and its cost depend on the process which must be used. The simplest (and cheapest) is compaction and sintering.

Compaction may be carried out by a variety of processes which may involve the addition of a binder or lubricant or may include the application of pressure. 'Sintering', in its pure sense, implies the densification of an assembly of particles at high temperatures by solid-state diffusion processes. This process is relatively slow, needs very high temperatures and a dense impervious body is achieved only with difficulty. Ceramics other than oxides may require a protective atmosphere.

Vitrification (or liquid-phase sintering) is achieved by incorporating a component which melts to a viscous liquid during sintering and solidifies (in the case of a clay-based ceramic) to a glassy phase. The term 'well vitrified' indicates that a dense impervious body has been achieved.

'Reaction bonding' is achieved by arranging for two or more components of a compacted body to react to form both a desired phase and a bond between particles. The reacting components may all be solid or one of them may be gaseous or liquid and introduced during the sintering process. 'Self-bonding' is bonding the major constituent of a ceramic with its constituents formed by reaction during sintering.

'Hot pressing' is achieved by the application of pressure during sintering. There are two variants. Hot pressing as commonly understood consists in applying pressure unidirectionally by a plunger acting on material in a rigid container. Hot hydrostatic pressing consists in submitting the material contained in a membrane to hydrostatic pressure during heating. Both processes produce material of a higher density and superior quality more quickly than can be achieved by sintering but they are substantially more expensive and component shape is restricted.

'Pyrolysis' is the process whereby a ceramic is deposited from a gaseous environment onto a (usually) heated substrate. This process is usually employed to deposit coatings or produce thin-walled components of graphite or silicon carbide from carbon or silicon-containing gas.

7.8.12 The future prospects of engineering ceramics

Ceramics and glasses have a wide range of applications in manufacturing technology and even wider applications in domestic use. If they are to achieve the really widespread engineering application that their properties appear to merit they must find this in some field such as the automotive industry.

Some components, including oxygen sensors, catalyst supports, diesel glow plugs, rocker arm pads, pre-combustion chambers and turbocharger rotors have already been standardized, usually for high efficiency and military engines. Tables 7.73 and 7.74 and Figure 7.124 list the properties and applications of the ceramics at present available for the required breakthrough into the mass market.

The major problem is that, depending on fabrication procedure, the cost of a ceramic component is from five to fifteen times that of the presently used steel component so that a substantial improvement in performance or a marked reduction in cost is required to justify the use of the ceramic. The potential advantage of materials such as sialons, which combine excellent properties and a relatively inexpensive manufacturing route (sintering) is evident.

7.9 Corrosion

7.9.1 Introduction

Corrosion is the term used to describe any effect which results in the impairment of the service performance of a material component by the action of another entity, usually its environment. It is usually envisaged to be the reduction in size or weakening of a component by removal of material, but deterioration in performance can occur in a number of ways which include increase in volume of the component or contamination of contained material.

Corrosive effects can be classified according to the substrate (the material subjected to corrosion), the corrodant (the

entity, usually a material the presence of which causes the attack), the mechanism of the attacking process or the resultant effects. An understanding of corrosion mechanisms enables the correct choice of material and conditions of operation to be made and therefore minimizes cost and enhances safety.

Cost includes not only the manufactured cost of a material component but also the cost of inspecting, replacing and servicing and the cost of outages arising from failure. A component must not fail in a manner which generates a hazard to operating personnel or to the public. Corrosion science and technology involves not only the correct choice of a material, its working environment and any protective techniques adopted to eliminate or postpone failure, but also the elucidation of the cause of failure.

7.9.2 Corrosion of metals in air or water

7.9.2.1 Oxidation

Thermodynamics The corrosion process is usually one of several reactions often forming a metal oxide (or hydroxide).[129] This reaction involves the oxidation (loss of electrons) of the metal to form an ion:

$$M - ne^- = M^{n+}$$

and the reduction of the oxygen to form an oxygen ion:

$$O_2 + 4e^- = 2O^{--}$$

The driving force for this reaction to occur is a reduction in free energy, G. For all metals, with the exception of gold, the change in free energy of the reaction

$$M + O_n = = MO_n - n\Delta G$$

is negative. The greater the decrease in free energy, the stronger the tendency to react.

Kinetics Reactions are normally activation energy controlled, and therefore, provided that the change of temperature does not change, the mechanism

$$d \log K/dt = -E/RT^2$$

where K is the rate of corrosion, E the heat of activation and T the absolute temperature. With the values of E which occur in most aqueous and oxidation types of corrosion, it can usually be taken with sufficient accuracy for most practical purposes that an increase in temperature of 10°C will double the rate of reaction.

Effect of film formation A metal surface reacts with oxygen extremely rapidly but, if an adherent film of oxide forms, subsequent oxidation depends upon oxygen or metal ions diffusing through the film. While the process of diffusion proceeds at an equilibrium rate the rate of increase of thickness is governed by the equation

$$y^2 = K_0 \exp(-Q/RT)t$$

where y is the thickness of the oxide film,
K_0 is a constant,
Q is the activation energy of diffusion through the film,
R the gas constant,
T is the temperature (K), and
t is the time.

With metals forming strong stable films the parabolic rate is never approached and the rate decreases asymptotically. With metals where diffusion through the film is more rapid the parabolic rate may, after a period, give place to a quasi-straight-line relationship. Corrosion after this event is known as 'catastrophic' or 'breakaway' corrosion and usually results in failure of the component.

Electrochemical corrosion Metals can be oxidized by aqueous environments but the dominant mechanism in conducting electrolytes is electrochemical. This requires both anodic and cathodic sites to exist on the surface of the metal exposed to the electrolyte. The metal is oxidized at an anodic site forming an ion in solution:

$$M - e = M^+$$

and liberating hydrogen gas or reducing dissolved oxygen

$$2H^+ + 2e^- = H_2$$

$$O_2 + 4e^- + 2H_2O = 4OH^-$$

at the cathodes. There must clearly be a complete electrical circuit between the anode(s) and the cathode(s) to permit electrons to flow through the electrolyte and the metal.

If the reaction products are soluble, the metal dissolves progressively and this process is termed 'general corrosion'. The reaction may be slowed or terminated by an insoluble layer. When this occurs, circumstances may arise in which the protective layer fails at points or lines so that the component is weakened or fractured, although its overall dimensions remain substantially unchanged. This form of corrosion is termed 'localized' corrosion.

The potential differences betwen two areas of substrate which lead to electrochemical corrosion may arise in a number of ways. These include externally applied potential (sometimes arising from stray currents), differences in temperature, local differences in concentration of the electrolyte (such as differences in oxygen concentration) and, most important, differences in composition of the substrate. The last may arise from the structure of the metal or from the presence of two different metals in electrical contact and exposed to the corroding solution. In this latter case the anodic or least-noble metal is corroded and the cathodic or most-noble metal protected. The effect is enhanced as difference in reactivity of the metals increases and depends on the relative area of the two metals. A smaller area of one metal compared with a larger area of the other suffers more intense corrosion or receives enhanced protection.

The order of reactivity in which the metals can be placed differs from one corroding solution to another. A typical order is shown in Table 7.75.

As a general rule, resistance to corrosion may be obtained by the choice of a metal or alloy which is high in the galvanic series or which forms a protective coating under the expected corroding conditions, or in which these two characteristics are combined. Resistance to the various types of corrosion classified according to specific metals and alloys is described in other sections. The following sub-section describes the specific types of corrosion in air and aqueous electrolytes and indicates how metals react to them.

7.9.3 Resistance of metals to specific corrosion mechanisms

7.9.3.1 General corrosion in air

All metals from zinc upwards in the galvanic series in Table 7.75 can be used unprotected at low temperatures. Care must be taken in marine and industrial atmospheres. At high temperatures stainless steel and nickel alloys in which diffusion through the oxide film is reduced (or eliminated) must be used.

Corroded (anodic or least-noble metal)

Order of increasing reactivity ↓

[a] Where it is feared that there is a danger of localized pitting or stress corrosion the common austenitic stainless steels should be placed much lower in the table, perhaps adjacent to brass.

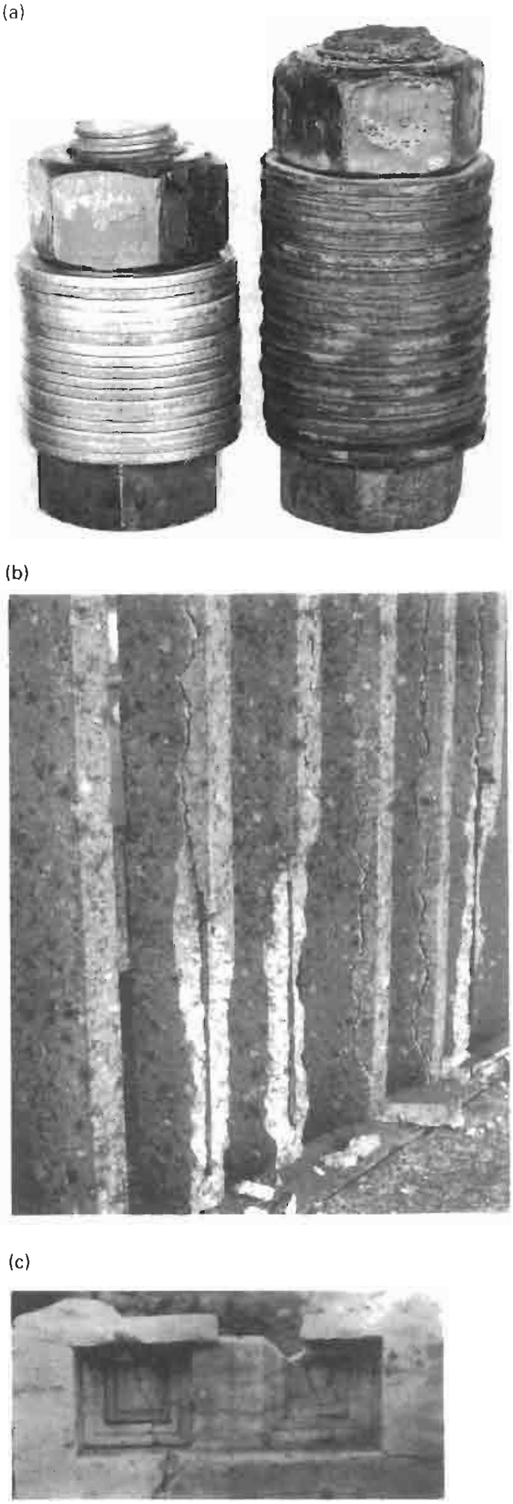

Figure 7.125 Typical examples of corrosion jacking. (a) Bolts, typical of those in magnet reactors before and after stretching because of washers corroding; (b) spalling of reinforced concrete (c) damage caused by Belano's repairs to Propylaea using mild steel supports.

7.9.3.2 General corrosion in aqueous solutions

All metals from aluminium upwards in the galvanic series can be used in pure water. More aggressive electrolytes in chemical process plant (and pure chemicals that must not be contaminated) require progressively more resistant stainless steels, nickel alloys, hastelloys and titanium.

Both water (including steam) and air oxidize steel but provided that the section is adequate and moderate increase in dimensions can be tolerated (see below) carbon steels give satisfactory service up to 350°C. Above this temperature progressively increasing proportions of chromium must be added.

Corrosion jacking This is a consequence of general corrosion in which a restraining or enveloping component is distorted or ruptured by an increase in volume of a metal, usually iron or steel. The phenomenon received its greatest publicity when bolts in the Magnox reactors were stretched and broken by oxide growing on the faces of washers (see Figure 7.125(a)) which had been made from low-silicon rimming steel. The problem was cured by reducing the operating temperatures of existing reactors and by using a steel of higher resistance to oxidation in the later ones. It has been a very serious problem in reinforced concrete road bridges where sometimes brackish water permeated through the concrete (Figure 7.125(b)). The cure is to maintain an adequately thick covering (*ca* 1 inch) of impervious concrete.

The problem was understood by the original builders of the Parthenon in Athens, who cast lead round their wrought-iron reinforcing bars. Later repairers (e.g. Belano) sometimes ignored the problem, usually with disastrous results (Figure

7.125(c)). Belano's steel is now being removed and titanium substituted.

7.9.3.3 Galvanic corrosion

'Galvanic corrosion' is homogeneous corrosion accelerated locally by an electric potential difference. It usually occurs when two metals fairly far apart in the galvanic series are in electrical contact and exposed to the same corroding solution. Figure 7.126 shows typical instances of galvanic corrosion. Other examples have occurred when copper and iron water-pipe fittings are used, when aluminium and stainless steel were employed together in an aircraft fuselage and when uninsulated steel bolts were used to assemble magnesium alloy castings. One way of producing galvanic corrosion (and, incidentally, protection) is to connect two pieces of identical metal in the same solution in series with a source of potential (this may be caused accidentally by a stray current). The effect is exaggerated when the areas of the two metals differ. The corrosive (or protective) action is enhanced at the surface which has the smaller area.

The influence of the galvanic effect is not uniformly disadvantageous. It may be used to protect a component by connecting to it one or more electrodes (or a coating) of a more electronegative metal (for example zinc) immersed in the corroding solution. Alternatively, the same 'cathodic protection' may be afforded by means of a resistant (for example, platinized titanium) electrode which is maintained at an appropriate negative potential by an EMF connected in series.

7.9.3.4 Galvanic corrosion: selective leaching

'Selective leaching' is a form of galvanic corrosion in which the two metals form part of the structure of the alloy corroded. Two examples are typical. A cast iron sea-water condenser has been known to have all the iron leached away in certain parts, leaving a friable graphite skeleton. Brass exposed to industrial atmospheres has the whole of the zinc leached away, leaving a sponge of copper having the original dimensions of the component but negligible strength.

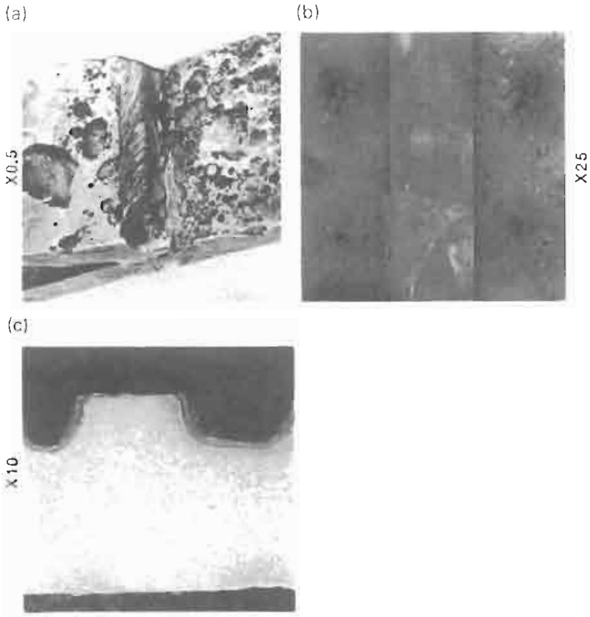

Figure 7.126 Typical instances of galvanic corrosion. (a) Characteristic appearance of galvanic corrosion caused by welding an austenitic steel gauze onto a 403 steel plate; (b) local pitting caused by deposit of tin on steel surface; (c) micro section through pits in (b)

The most common examples of selective leaching of zinc arise from the use of brass where bronze has (or should have) been specified. The result can be disastrous when (as has occurred) the component is a steeplejack's attachment ferrule. The situation is complicated by the fact that some materials with the trade name 'bronze' are in fact brasses prone to selective leaching. Brasses which are claimed to resist selective leaching have, however, been developed recently. Where there is any possible doubt a qualified corrosion expert must be consulted.

7.9.3.5 Homogeneous corrosion erosion

When corrosion and erosion occur simultaneously their effects are mutually reinforced because erosion removes any protective film that might otherwise impede corrosion. Steam/water mixtures may corrode/erode plant, as is shown in Figure 7.127. The cure here is to eliminate crevices through which the expanding steam/water mixture can flow. Cavitation (an example of which is shown in Figure 7.128) can also initiate corrosion. In cases where erosion and pitting both occur pitting-resistant stainless steels are replacing titanium for condenser tubing.

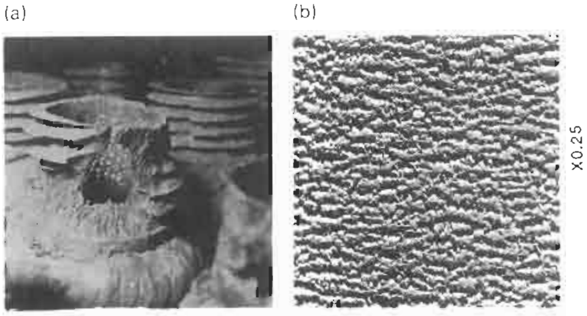

Figure 7.127 Typical instances of homogeneous corrosion/erosion, (a) Hot water seeping along threads and evaporating erodes/corrodes carbon steel bolts and sockets; (b) very high velocity steam at evaporation zone of once through boiler causes rippled magnetite which impedes flow and therefore reduces power

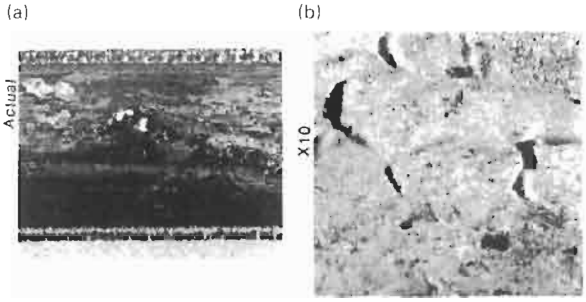

Figure 7.129 Heterogeneous erosion/corrosion of a condenser tube. (a) Actual size; (b) magnified ten times

7.9.3.6 *Heterogeneous erosion corrosion*

Where solid materials are transported by a corrosive solution or gas or where materials handling is carried out in the presence of corrosive liquids the impingement of solid particles causes erosion which mutually reinforces corrosion. Typical examples are shown in Figure 7.129. The best way of reducing this effect is to design to minimize impingement. If this cannot be achieved the material at the points of maximum impingement should be coated or replaced by a hard, corrosion-resistant material such as stellite (see Section 7.1).

7.9.3.7 *Localized corrosion*

Ionic concentration This occurs where a corrosive solution contains an anion which forms a hydrolysable salt with the substrate or another cation. It can lead to the local concentration of quite strong acids, which attack what are normally protective films. The typical processes of attack are:

1. *Crevice corrosion*: This type of corrosion frequently occurs with stainless steel. Strong acids form in crevices particularly where oxygen is reduced compared with the main body of the solution. The cure is to eliminate crevices by design. If this is not possible and the corroded material is a stainless steel a more resistant stainless steel (see Section 7.1) may be tried. Figure 7.130 shows the effects of crevice corrosion on a titanium tube plate.
2. *Pitting corrosion*: This is crevice corrosion in which the corrosion mechanism has formed its own crevice. Figure 7.131 illustrates the way development of a pit can lead to failure by perforation. Any material which depends on an oxide film for resistance to corrosion can suffer from pitting corrosion but it occurs mainly in austenitic steels in aggressive aqueous environments, including stagnant sea water and marine condenser tubes. It is easier to cure than is crevice corrosion. Filtration to remove particulate matter and avoidance of organic growths is sometimes successful. Austenitic stainless steels have been developed which are claimed not to pit in stagnant sea water.

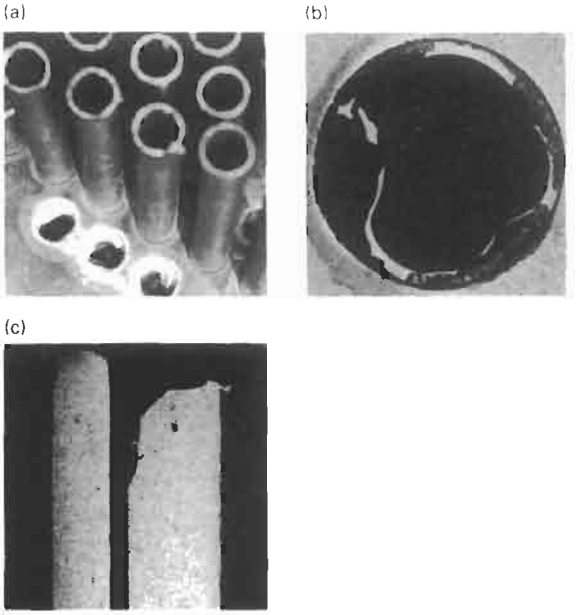

Figure 7.130 Three views of crevice corrosion of a titanium tube plate. (a) Heavy corrosion confined to crevices; (b) end view of corroded weld; (c) side view of corroded weld

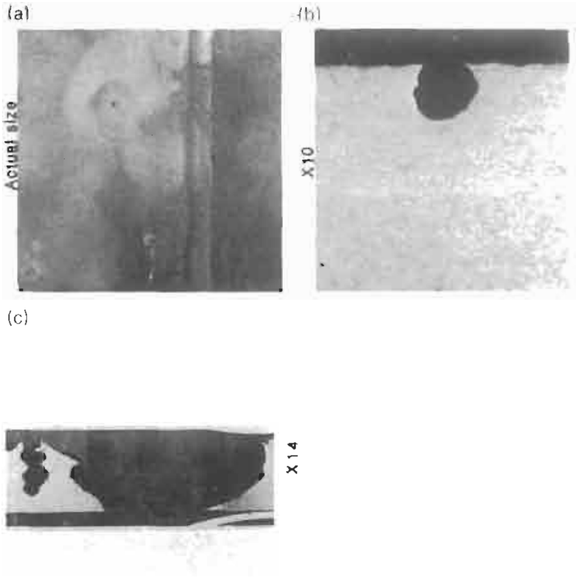

Figure 7.131 Failure develops from pitting corrosion. (a) Appearance of pit on surface; (b) section through pit; (c) section through pit which has penetrated wall

3. *'On-load' pitting corrosion*: This is a form of corrosion limited to steam generator tubes. Pressure, temperature, and heat rating of steam plant advanced more quickly than technological capability. As a result, pits of the type illustrated in Figure 7.132 developed in boiler tubes in ships and power stations. The pits occurred where debris collected in the tubes at positions of high heat flow or where the flow of water was reduced by faults in design or manufacture. Water containing chlorides and oxygen flowed towards the tube wall and steam flowed away from the wall, leaving behind impurities, and strong acids developed. 'On-load' pitting corrosion has been almost completely eliminated by improving:

- Overall boiler design to eliminate hot spots and points of reduced flow;

---

*For the convenience of the reader some of the figures in sections 7.3.13 and 7.3.17 are repeated here.

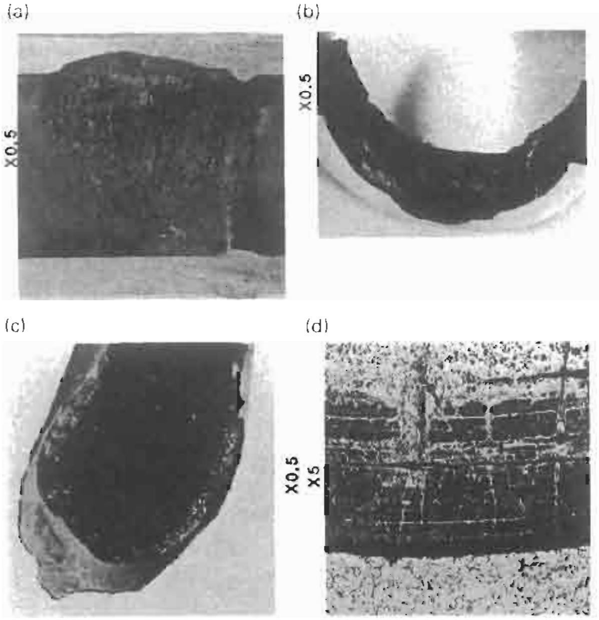

Figure 7.132 Characteristic appearance of 'on load' pitting corrosion. (a) Early stage of pit; (b) pit about to penetrate wall; (c) pit has caused hydrogen degenerated metal behind it to fracture; (d) structure of layered magnetite in pit and hydrogen degeneration in metal

- Construction to eliminate irregularities (e.g. weld protrusions) which caused local stagnant areas;
- Feedwater purity to eliminate inpurities such as oxygen and chlorides.

Penetration cracking corrosion processes There are a number of corrosion mechanisms which leave a substantial part of the substrate material intact but destroy its integrity by penetrating specific localities either as trenches or cracks. Some mechanisms depend for propagation on a combination of applied tensile stress and an aggressive environment, but in other cases the environment attacks specific structures in the absence of stress.

1. *Intergranular penetration*. This is corrosive attack by aqueous solutions, usually chlorides, along the grain boundaries of austenitic steels containing above 0.02% carbon which have been 'sensitized' by heating within the range 425–500°C. This precipitates chromium carbide at the grain boundaries (see Figure 7.133) and locally reduces the concentration of chromium and therefore the corrosion resistance. Intergranular penetration may be recognized by the presence of a multiple system of cracks which are orientated at random (see Figure 7.134). It can be prevented by:
    - Using a steel with a carbon content below 0.02%;
    - Incorporating into the steel stabilizing elements Nb, Ti, Mo, which are strong carbide formers;
    - Subjecting the steel to a desensitizing heat treatment above 870°C followed by rapid cooling.
2. *Intergranular corrosion in a gaseous environment*. Gaseous intergranular corrosion can arise in a number of ways. Typical is attack on nickel alloys by flue gas containing reducing sulphur which forms a nickel sulphide eutectic at the grain boundaries. The only cure is to avoid using this combination of materials in environments where this type of attack is known to occur.

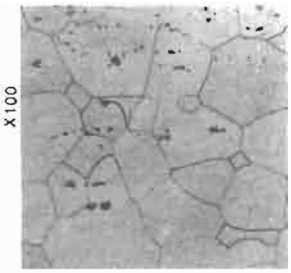

Figure 7.133 Structure of sensitized stainless steel showing chromium carbide precipitation

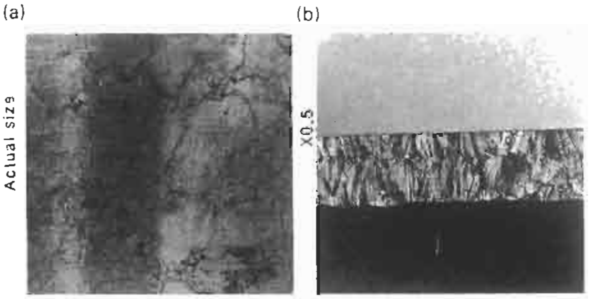

Figure 7.134 Characteristics of penetration cracking of sensitized austenitic steel. (a) Multiple crack system oriented at random (i.e. not aligned transverse to tensile stress); (b) appearance of fracture

3. *Weld decay*. This is a form of intergranular penetration of austenitic steel specific to the heat-affected zones of welds. An example of this (which can proceed until the weld drops out of the component) is shown in Figure 7.136. The cure is identical to that for intergranular penetration.
4. *Knife-line attack*. If the heating during welding is sufficiently prolonged and intense, stabilization of austentic stainless steels by additions of Nb and Ti will not prevent attack. Under these conditions corrosive attack is concentrated at the edges of welds (Figure 7.137). The cure is to

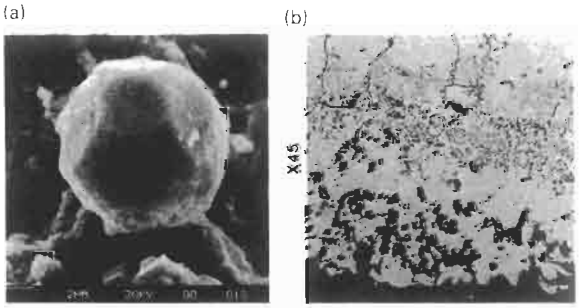

Figure 7.135 Intergranular corrosion of nickel alloy by furnace gas containing sulphur. (a) Nickel sulphide in scale; (b) sub-surface penetration by nickel sulphide

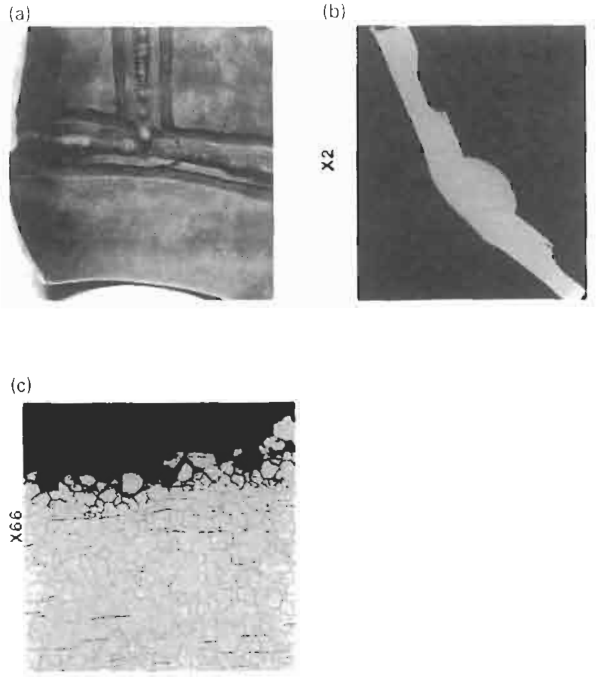

Figure 7.136 Characteristic appearance of weld decay. (a) Surface appearance showing trenches at side of welds; (b) section showing form of trenches; (c) intergranular attack at sides and base of trenches

adopt welding procedures which do not impose prolonged and intense heating. If this cannot be avoided the weld must be post-solution treated.

5. *Stress corrosion.* Stress corrosion cracking depends on the co-existence at a surface of an aggressive environment and a tensile stress. It has very great importance in materials technology because almost every known material is prone to stress corrosion by some environment and the two main constituents which lead to stress corrosion in metals (water and halides) are very widely distributed. Stress corrosion in metals can also be caused by liquid metals (see below) in polymers by organic solvents (see Section 7.5) and in ceramics by water vapour (see Section 7.7). Increase in temperature and stress intensity promotes initiation and accelerates propagation of stress corrosive cracks. The numerical relationships between these parameters are now being evaluated (see Section 7.1) but they are statistical in nature and one specimen may survive long periods in apparently arduous conditions while an apparently similar specimen may fail rapidly in relatively easy conditions. A component may last for a long period apparently undamaged then fail completely in a short time. Stress corrosion cracks in metals are seldom discrete but usually form a network of branching cracks which propagate in a direction normal to stress. The crack starts at a small defect which generates, with the stress, a stress intensity above a threshold value.

   Stress corrosion of austenitic stainless steels by chloride is often *transgranular* and the cracks are transverse to the tensile stress but change direction where they intersect grain boundaries (see Figure 7.138(a)). The appearance of the fracture as studied by SEM (Figure 7.138(b) and (c)) and the microstructure (Figure 7.138(d)) are very charac-

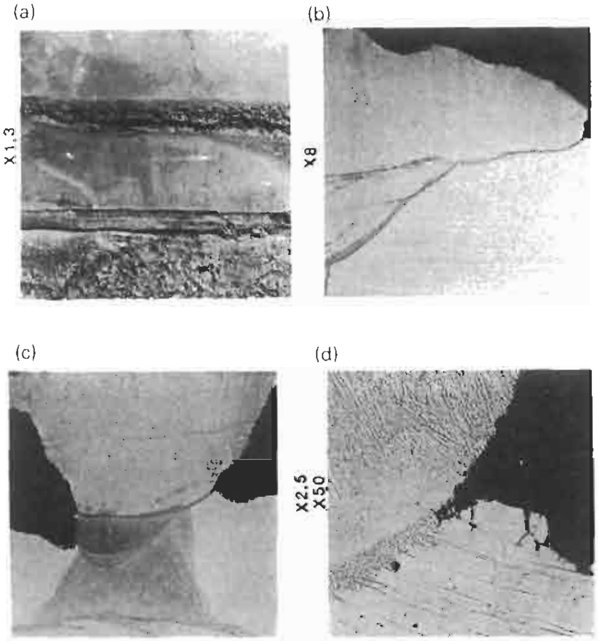

Figure 7.137 Characteristic appearance of knife-line attack. (a) Appearance of surface; (b) section at early stage; (c) section at late stage; (d) intergranular nature of attack

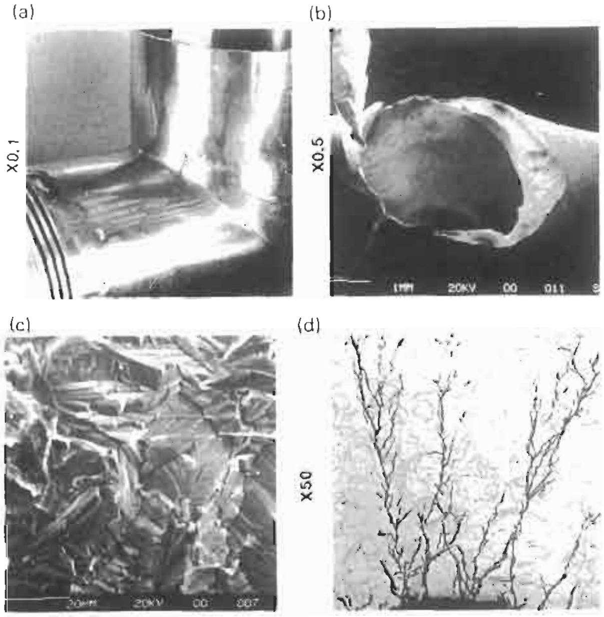

Figure 7.138 Characteristic appearance of transgranular stress corrosion. (a) Surface at low magnification. Multiple crack system roughly transverse to tensile stress but changing direction where they intersect grains. No deformation of metal. (b) Fracture at low magnification. Stress corrosion crack gives way to ductile tear. (c) Fracture at high magnification. Very characteristic appearance. (d) Micro section. Multiple branching thin transgranular cracks may be filled with corrosion products

teristic. However, fracture has been known to change from trans- to intergranular and back in a short distance along the crack.

Most forms of stress corrosion cracking are *intergranular* and, in the case of metals, require the presence of liquid water before they will propagate (chloride stress corrosion also requires the presence of oxygen). Stress corrosion can therefore be prevented by elimination of water and aggressive agents such as hydroxides, chlorides and thyonic acids. Component finish should be improved, stress reduced and (for austenitic steels) sensitization avoided. The appearance of intergranular stress corrosion can be seen in Figure 7.139. Data on stress corrosion of stainless steels are provided in Section 7.3.

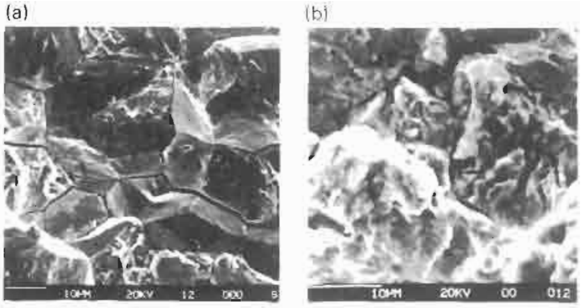

Figure 7.140 Two manifestations of hydrogen cracking. (a) Intergranular. Resembles SCC but hydrogen crack will not contain corrosion product. (b) Quasi-cleavage. Can only be hydrogen cracking

6. *Hydrogen cracking* (*usually of steel*). Hydrogen can be introduced into metals in a variety of ways, including the extraction process, pickling, plating, welding, exposure to an environment such as H_2S or holding in a hydrogen environment and will promote cracking where, for example, a steel of UTS greater than 930 MNm^{-1} is stressed in tension. Hydrogen cracking may be intergranular (see Figure 7.140(a)) when it resembles and may indeed co-exist with stress corrosion. It can be distinguished from stress corrosion by a characteristic quasi-cleavage appearance (Figure 7.140(b)) and, unlike stress corrosion, it does not necessarily start from a surface. Hydrogen cracking may be avoided by preventing ingress of hydrogen into the metal at all stages of manufacture, processing and operation.
7. *Hydrogen degradation*. When the quantity of hydrogen absorbed by a metal such as steel, zirconium, titanium or aluminium greatly exceeds the amount associated with hydrogen cracking it may lead to 'hydrogen degradation'. There are several manifestations. Hydrogen produced in steel making or by low-temperature aqueous corrosion migrates to inclusions or discontinuities, collects as molecular hydrogen or methane and, because neither can be re-absorbed, generates very high pressures which cause 'fish eyes' (see Figure 7.141) or blisters which disrupt the steel and may cause brittle fracture. Hydrogen absorbed at high temperature from 'on-load corrosion' or from hydrocarbon in a refinery first decarburizes the steel and then forms a grain boundary network (see Figure 7.142) which leads to crumbling of the steel. The remedies recommended for hydrogen penetration will also cure hydrogen degradation. In refinery service additions of chromium to the steel, increasing with increasing service temperature,

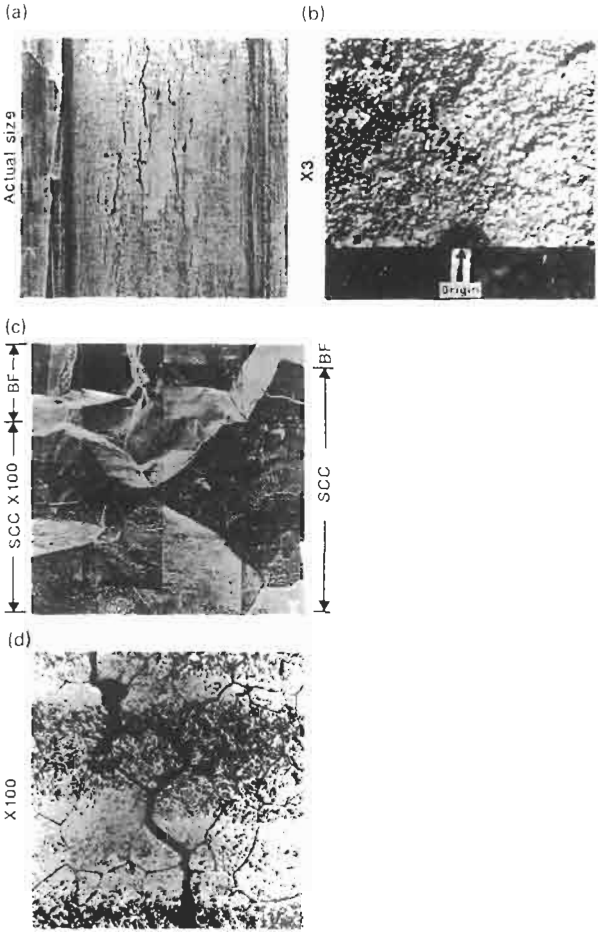

Figure 7.139 Characteristic appearance of intergranular stress corrosion. (a) Surface at low magnification. Multiple crack system roughly transverse to tensile stress but changing direction at corners of grains. No transverse strain. (b) Fracture at low magnification. SCC crack darker and covered with corrosion product gives way to intergranular brittle fracture. (c) Higher magnification at interface with brittle fracture shows continuous wall. (d) Network of cracks at grain boundaries may be filled with corrosion product

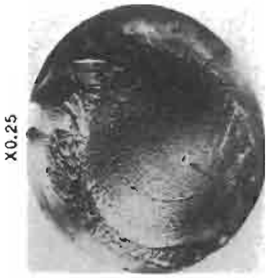

Figure 7.141 Fish-eye appearance typical of hydrogen degradation

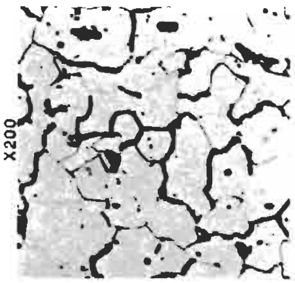

Figure 7.142 Microstructure of hydrogen-degraded steel showing microfissures where hydrogen (or methane) was trapped and decombines atom

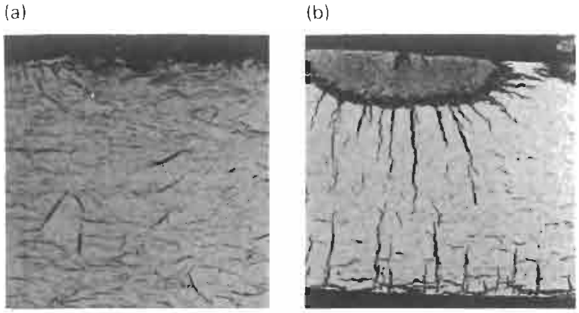

Figure 7.143 Hydride degradation in titanium and zirconium. (a) Hydride platelets in a titanium alloy; (b) 'sunburst' fracture aggravated by hydride in a leaking zirconium canned fuel element

prevent hydrogen degradation. Zirconium alloys in pressurized water reactors have suffered hydrogen degradation when the incorrect alloy has been used or when the alloy has been contaminated by nitrogen during fabrication. Hydride platelets are found in specific metallographic directions in both zirconium and titanium (see Figure 7.143(a)) and the failures may be spectacular (Figure 7.143(b)). Modern alloys and fabrication techniques have eliminated this problem.

8. *Corrosion fatigue.* Corrosion may initiate, accelerate, retard or prevent fatigue cracking. Corrosion *initiates* fatigue when a fatigue crack is initiated by a cyclic stress below the endurance limit of the material because the environment has attacked it at that point. Often, as in the case shown in Figure 7.144, the fatigue cracking starts away from the most highly stressed area of the specimen, and the main body of the fracture shows typical fatigue striations.

   Corrosion may *accelerate* fatigue when the corrosive environment diffuses along the fatigue crack and increases the rate of propagation. The appearance of the fracture is similar to that of fatigue but the surfaces are corroded (see Figure 7.145(a) and (b)), the striations blurred (Figure 7.145(c)) and the crack may be filled with corrosion product (Figure 7.145(d)). Instances have occurred when an apparently aggressive environment such as oxygenated seawater has *prevented* the initiation or *retarded* or *stopped* the propagation of a fatigue crack at a stress at which fatigue failure would have occurred in air. Corrosion fatigue is avoided by removing the aggressive agent in the environment or affording protection from it and/or by reducing cyclic and tensile stress.

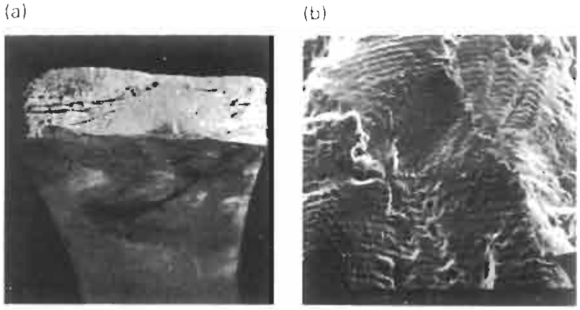

Figure 7.144 Characteristic features of corrosion-initiated fatigue. (a) In this instance fatigue initiated not at the point of highest loading, but at a point where crevice corrosion had occurred; (b) The crack showed striations typical of fatigue, with no blurring or corrosion product

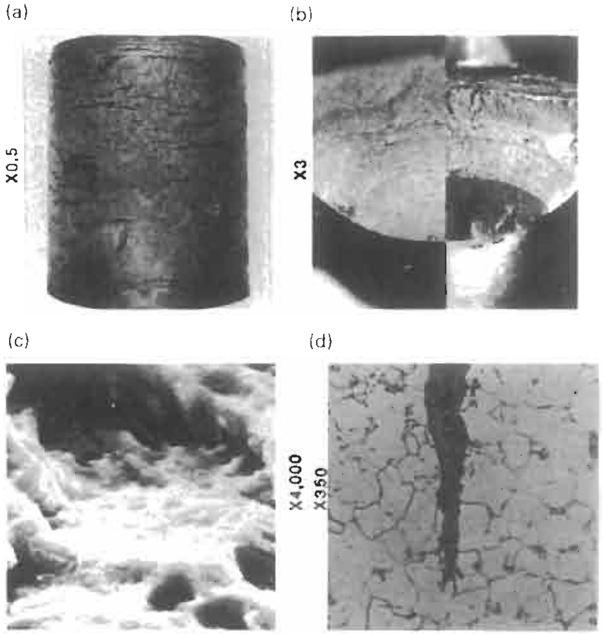

Figure 7.145 Characteristics of corrosion-accelerated fatigue. (a) Surface covered with corrosion product. Many parallel fatigue cracks; (b) fracture covered with corrosion product. Before and after cleaning; (c) striations blurred; (d) crack filled with corrosion product

7.9.3.8 Corrodants of metals other than water or air

Metals may be corroded by many agents besides aqueous and atmospheric environments. These include solid and liquid metals, furnace slags, glasses and gases.

Corrosion by solid metals

- *Fretting corrosion.* The most important solid/solid corrosion of metals is 'fretting corrosion', which occurs when vibration causes low-displacement slippage between two surfaces pressed together. It is caused either by repeated welding and separating of high spots or by abrasion by oxide layers.

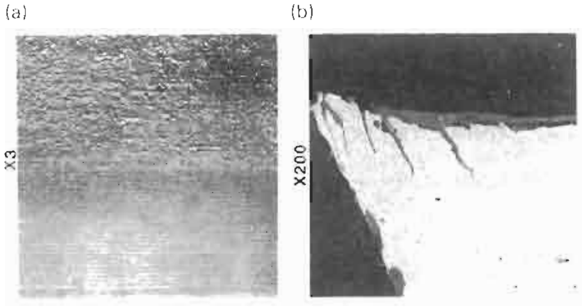

Figure 7.146 Characteristics of fretting corrosion. (a) Roughened pitted surface; (b) fatigue cracks developed from fretted surface

Most material combinations are prone to fretting corrosion but the presence of oxide films aggravates it, especially when oxygen is present. Failure occurs by accumulation of oxide debris, seizing, galling or loss of tolerance. Fatigue may initiate at fretted parts (see Figure 7.146) caused by small displacements but large displacements tend to 'rub out' the initiating fatigue cracks. Fretting corrosion is eliminated by stopping relative motion and alleviated by lubrication, using harder materials, fitting a gasket or by increasing relative motion.

- *Solid-state diffusion.* Almost any two metals that will form an alloy can, in theory, corrode each other. A typical example was the corrosion penetration of the prototype aluminium cans of the first uranium metal reactors. On heating at temperatures simulating reactor conditions the uranium alloyed locally with the aluminium can to form UAl_3 pyramids which penetrated the can, allowing ingress of oxygen. This destroyed the fuel element by oxide jacking. Inserting an uranium oxide/graphite layer between uranium and can prevented failure by this mechanism in the reactor.

7.9.3.9 Liquid metal corrosion

General liquid metal corrosion Any liquid metal that comes into contact with a solid metal with which it will form an alloy (for example, molten aluminium in a steel melting pot) is liable to corrode it away. The effect is enhanced if the liquid metal forms a circuit operating between a range of temperature. For example, molten bismuth corrodes steel slowly (if at all) but if it is used in a heat-transfer circuit the steel is dissolved at the higher temperature and deposited at the lower.

Liquid metal penetrations Far more potentially dangerous is liquid metal penetration, a form of stress corrosion in which the aggressive agent is a liquid metal which can penetrate rapidly along the grain boundaries of a metal stressed in tension and cause cracking. Many metals, including lead, bismuth, tin and zinc (cracking from which caused the Foxborough disaster), will cause penetration cracking in steel. One example was the failure of an overheated shaft (see Figure 7.147) caused by penetration of copper from brazing metal into the steel of the shaft which resulted in cracking.

7.9.4 Biodeterioration

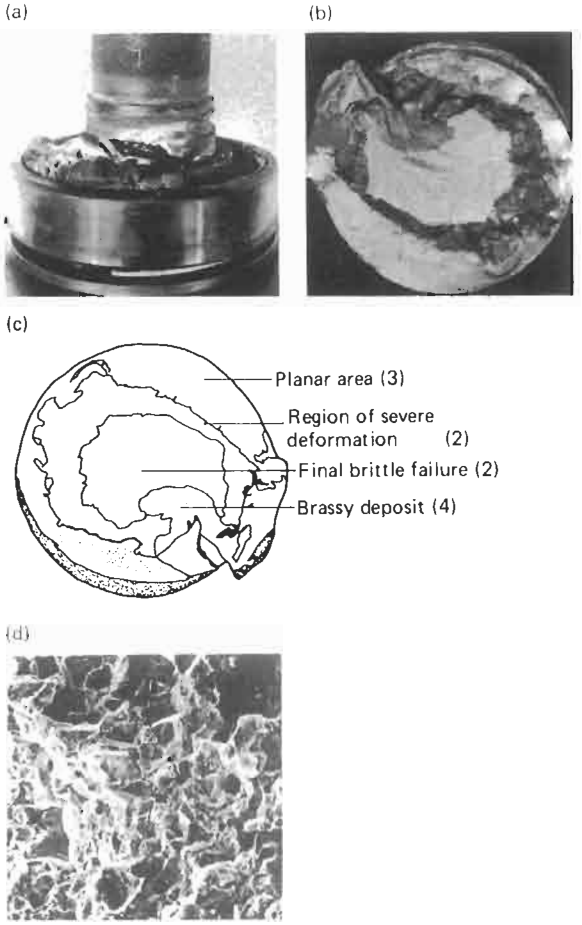

Figure 7.147 An example of penetration of liquid copper from brazing metal into the steel of an overheated shaft which resulted in failure by stress corrosion. (a) Appearance of failed shaft; (b) appearance of fracture showing copper deposit; (c) key to (b); (d) intergranular cracking and copper deposit

Biodeterioration is, with few exceptions, corrosion promoted and aggravated by biological action. It affects all classes of materials but the corrosive effects always require the presence of moisture.

7.9.4.1 Biodeterioration of metals

The most important biological effect in metal corrosion is pitting caused by the formulation of a differential aeration cell by a colony of bacteria or plants on the metal surface. Cast iron, carbon and low-alloy steel pit in fresh water and some stainless steels in seawater. Frequent changes of water help, but infected systems must be disinfected by a biocide such as chlorine.

Some organisms can produce organic acids (for example, *Cladisporum Rejinae*, which attacks aluminium at kerosene/water interfaces in aircraft fuel tanks). Sulphate-reducing bacteria can produce sulphides which corrode iron pipes, piles and the hulls of ships berthed in estuaries. This is very difficult to cure completely but pipelines may be surrounded by sand or chalk (with a biocide added) and piles and ships' hulls painted or cathodically protected.

Thiobacilli can produce sulphuric acid which attacks metals in mines or sewers. The cure is to use lime as an inhibitor in buried metals, to aerate sewers and to use acid resisting stainless steel in mines.

7.9.4.2 Biodeteriation of building materials

The same thiobacilli can also greatly accelerate the corrosion of concrete and limestone buildings. Where possible, the source of sulphur should be eliminated.

7.9.4.3 Biodeteriation of plastics

Plastics suffer attack from a great variety of microorganisms. Polymers derived from natural products incorporate structures to which enzymes can key or which may be broken down into products upon which microorganisms can feed and are therefore prone to attack. Resistance to attack is promoted by increased halide content, increased chain length, increased cross linking, toxicity of breakdown products to bacteria and the presence of sulphur. Thus fluoroplastics, vinyls, epoxies and polystyrenes are (as far as is known) immune, whereas animal and vegetable glues, melamine formaldehyde, cellulose derivatives, polyvinyl acetates, polyester-type polyurethanes and natural rubbers are attacked.

Most plastics are, however, formulations of a polymer with a filler reinforcer and/or a plasticizer or stabilizer. Natural fillers or reinforcers such as sawdust, starch paper or cellulose may be attacked. The major cause of breakdown in properties of plastic materials is, however, attack of the plasticizer (usually a long-chain organic acid or ester) which can embrittle and cause changes in shape and texture of individual vinyls.

Complete exclusion of moisture inhibits microbiological attack. Where this is not practicable an internally plasticized thermoplastic resin should be used.

7.9.4.4 Biodeterioration of natural products

Natural products such as wool, cotton and wood are all subject to attack by bacteria or moulds. The golden rule in every case is to keep the material clean and dry, in the case of wood by good design and regular painting, in the case of textiles by correct conditions of storage. Alternatively (or in addition) the material should be impregnated with a biocide, such as a chlorinated phenol or an organic wood preservative. (Further information on biodeterioration is available from the Department of Biodeterioration, University of Aston.)

7.9.4.5 Corrosion of ceramics and glasses

Ceramics are, in general, highly corrosion resistant. They will resist strongly acid aqueous solutions much better and more economically than most metals and, when used for this purpose, have glazed surfaces. Glasses are also available that will resist strong alkalis. Borosilicate glasses can contain phosphoric acid. All glasses, however, dissolve slowly in hydrofluoric acid.

Corrosion of ceramics at elevated temperatures Oxide ceramics resist oxygen at elevated temperatures but may be attacked by gases containing sulphur. In air, carbide ceramics oxidize at high temperatures, boron carbides and graphite oxidize rapidly above 500°C while silicon carbide is limited to 1400°C. Silicon nitride can withstand temperatures up to 1400°C whereas boron nitride oxidizes rapidly above 900°C.

Corrosion of ceramics by liquid metals Many ceramics resist attack by liquid metals and silica and aluminium-based refractories are widely used to contain them. Sometimes corrosive attack is advantageous. In basic steel furnaces attack by sulphur and phosphorus on a dolomite lining play an essential role in removal of these metals from steel.

Corrosion of ceramics by fused salts and slags Fused salts and slags are perhaps the most aggressive corroding media. Ceramic materials probably form the most suitable containers for these materials but the correct choice of refractory is important, particularly with silicate slags.

Stress corrosion of oxide ceramics Stress corrosion caused by the moisture in air exerts a most important influence on the performance of oxide ceramics stressed in tension. Cracks propagate through the material from the surface and when the stress intensity reaches a critical value the material fractures. (Since this is a statistical phenomenon it follows that a large component is weaker than a small one and great caution must be exercised in subjecting ceramics to tensile loading.) This cracking process (which has been incorrectly termed 'Static Fatigue') may not necessarily occur with carbide or nitride ceramics.

7.9.4.6 Corrosion of plastics

An attempt to provide a brief summary dealing with the corrosion of plastics is made difficult by the very large number of polymers whose behaviour needs to be considered and complicated by the presence of fillers and reinforcing agents. Plastics are called on to withstand the action of four main classes of environment: air often in conjunction with heat, water, organic solvents and ionizing radiation.

The most important requirement for many plastics is their resistance to combined heat and air. There are two criteria by which this may be assessed: the Oxygen Index ASTM 02863-70 test and the Underwriter's Laboratory UL 94 Burning Rating Code, which also assesses the performance under electrical stress.

The most resistant materials are the fluoroplastics followed by high-temperature thermoplastics and thermosets, most of which char gradually when heated. Many commodity thermoplastics burn freely and some (typically, celluloid) almost explosively. This danger can, however, be reduced by the addition of suitable anti-flash additives. All suppliers will provide suitable guidance.

Second in performance to flame resistance is the volume and toxicity of the smoke which may be generated when a plastic catches fire. ABS, polyester, PVC and polystyrene are particularly poor in this respect. PEEK and polyetherimide are outstandingly good.

Water, whose effect may be aggravated by acids, alkalis, ultraviolet light and general weathering, can hydrolyse certain plastics, causing general deterioration in many thermoplastics, cellulose esters and some polyesters. Fluoroplastics and epoxide resins are highly resistant. The effect may be critical with glass reinforcement which may retain negligible strength in a polyester matrix under marine conditions whereas carbon fibre in epoxide is resistant. Nylons will absorb water and this reduces tensile strength but greatly increases elongation and notch toughness.

Resistance to water and air at and above 100°C is essential for polymers used in medicine which have to withstand sterilizing. Polypropylene is good, polysulphone, polyether sulphone and PEEK are excellent.

Resistance to acids, alkalis and organic solvents varies with the type of acids and polymer. Generally, thermosetting polymers such as epoxide resins, polyimides and fluoroplastics have good resistance to most agents. Some thermoplastics such as acrylics, cellulosics and nylons have very variable resistance. Manufacturers should be consulted.

The resistance of polymers to sun (ultraviolet) light is variable. Fluoroplastics, polyimides, polyacetals and silicones are excellent, the rest rank from 'good' to 'poor'. Where a plastic with inferior resistance to sunlight has to be specified, an outer layer of resistant polymer should be provided. Alternatively, a filler which absorbs radiation may be incorporated.

Ionizing radiation has a beneficial effect on some plastics, converting, in some cases, a thermoplastic into a resistant thermoset by promoting cross branching.

7.9.5 The prevention of corrosion

7.9.5.1 Factors influencing corrosion

The chance that a component may fail by corrosion should, whenever possible, be eliminated by attention to:

Material choice
Control of environment
Design
Operation

The material may be a metal, ceramic, mineral, plastic or natural product. If a metal, it should be sufficiently high in the electropositive series or should form an adequately resistant oxide film. Plastics are usually resistant to the environment in which they normally operate but certain plastics (for example, epoxide resins and fluorocarbons) are exceptionally resistant. Ceramics are normally highly resistant but some (e.g. alumina silica and zirconia) may have superior resistance. Some natural products are better than others (e.g. oak and reed thatch outlast soft wood and wheat straw).

Control of environment may involve the exclusion of water and industrial pollution from air or the exclusion of halides, sodium hydroxides, sulphur compounds or other industrial waste from water. At high temperatures alkali chlorides, sulphates and vanadates should, whenever possible, be eliminated from gaseous environments.

Design to prevent corrosion may include temperature limitation (e.g. by eliminating hot spots and flame impingement in furnaces). It must eliminate crevices and stagnant areas and prevent electrical contact between metals wide apart in the galvanic series in aqueous systems. Where appropriate, operating lives must be limited. Operating procedures should avoid temperature excursions, prevent stagnation in aqueous systems, eliminate stray currents, provide regular maintenance (cleaning and greasing) and should arrange to replace components which suffer corrosion at regular intervals. Requirements of cost and mechanical strength may, however, prevent the use of an adequately resistant single material and it may be necessary to provide additional protection.

7.9.5.2 Corrosion protection of metals

Metals may be protected against corrosion in three ways (which may be combined).

Provision of a surface barrier layer A surface layer may be provided that excludes contact with the corrosive environment. This barrier layer may be paint, polymer, vitreous enamel, conversion coating (anodizing, phosphating or chromating), diffusion coating (aluminizing, chromizing or siliconizing) or a metallic coating. A metallic coating may be rhodium, platinum, gold, silver, chromium, nickel, cadmium, aluminium, zinc or a zinc/aluminium alloy.

Provision of a protective surface layer A surface layer that affords cathodic protection may be provided. This consists of a metal, cadmium, aluminium, zinc or zinc/aluminium alloy lower in the electro positive series than the substrate. Such a layer will continue to protect even if incomplete and may, with advantage, underlie a barrier layer.

Provision of cathodic protection When the environment is a corrosive liquid protection may be afforded by immersing electrodes in the liquid connected electrically with the substrate. The electrodes may be sacrificial (e.g. zinc which dissolves preferentially and requires periodic renewal) or resistant, such as platinized titanium which requires a source of potential to be connected in series and electrical energy provided.

Coating processes Paints are easy to apply and normally cheap and readily renewable.

Polymer coatings are more expensive but more resistant than paint.

Vitreous enamelling is expensive, gives complete protection, is heat and acid resistant, electrically insulating, easy to clean and has an excellent appearance. It requires a hard and heat-resistant substrate.

Conversion coatings are cheap and form an excellent basis for paint. Anodizing, which can be applied only to certain aluminium magnesium and zinc alloys, is very adherent, wear resistant and durable. Chromating and phosphating, which can be carried out in a bath or continuously, can be applied to steel, zinc or cadmium.

Electroplating may be used for zinc, cadmium, chromium, nickel, copper, tin, silver, gold, platinum and rhodium. This process can be used for exterior and marine environments but its bonding is not as strong as hot-dip and diffusion coatings and its use in corrosive media is limited.

Electroless deposition may be used for nickel (and nickel phosphide), copper, gold and cobalt. It has good throwing power and is used for aggressive environments subject to wear.

Hot-dip coating may be used for zinc, tin, aluminium and zinc–aluminium alloy. It forms a good bond with the substrate and applies thicker coats than electroplating. Its cost is low, it is suitable for exterior use and it forms an excellent basis for paint.

Metal spraying is applicable to most metals. It is, as a method of depositing zinc, competitive with galvanizing for one-off applications and for applying to specific areas which require lengthy protection.

Diffusion coatings include aluminizing, chromizing, siliconizing and sheradizing (zinc). The process is slow and relatively expensive but will produce very resistant coatings for high duties.

Vacuum evaporation and sputtering can be used to deposit thin but continuous films of aluminium or gold. For some purposes the economy in deposited material outweighs the high cost of the plant.

Plasma coating is used for depositing wear- and corrosion-resistant coatings of materials such as stellite or tungsten carbide-based material.

Choice of coating material and process is governed by engineering, economic and environmental considerations. A steel structure protected by galvanizing or zinc spraying normally lasts between 10 and 15 years (which usually covers its design life) without further treatment other than for decoration purposes in most atmospheric environments. Paint is much cheaper and easier to apply but requires maintenance at periods between 3 and 12 years. The aggregate costs over 25 years of painting could well be much greater than galvanizing.

An additional consideration is that a barrier layer is only effective if it is complete. If a coating is defective at one point the effect of a corroding liquid may be much greater at that point (because of the concentration of the electric potential) than it would have been if it had access to the whole surface, and the structure will be damaged more quickly than if it had not been coated. If there is any risk of this, a protecting coat (e.g. zinc) should be applied beneath the barrier layer (e.g. paint).

7.9.5.3 Protection of plastics

Plastics are painted for a great many reasons, among them protection from corrosion, light and weathering. Great care must be taken with the process and choice of material to obtain good adherence and avoid damaging the material.[130]

7.9.5.4 Protection of concrete and masonry

The only protection that can reasonably be afforded to concrete and masonry is to prevent, wherever possible, atmospheric pollution and to take extreme precautions to avoid the possibility of 'jacking corrosion'.

7.9.5.5 Protection of wood

There are two golden rules to follow to ensure the long life of wooden architectural and other components:

1. Keep the wood dry by design and operation and apply and maintain a good coat of paint.
2. Impregnate the wood with one or more of a number of agents toxic to insects, moulds and bacteria.

7.9.6 Procedure for identifying origin and mechanism of a corrosion failure

Corrosion failures occur in plant and the procedure for identifying the cause must start at the plant and will probably continue in a laboratory. The procedures are complex and their detailed description would occupy many pages. Figure 7.148 lays down a logical basis of procedure which, if followed, will ensure that the investigation acquires all relevant information.

7.10 Non-destructive testing

7.10.1 Definition

Non-destructive testing (NDT) forms an integral part of quality control, a term used to describe the procedures which contribute to total quality assurance. A formal definition of the subject, agreed by the International Committee for Non-destructive Testing (ICNDT) and accepted later by the International Standards Organization (ISO) states:

> Non-destructive testing is a procedure which covers the inspection and/or testing of any material, component or assembly by means that do not affect its ultimate serviceability.

In practice, the scope and importance of NDT can tend to be confused by the diffuseness of its boundaries as set by this definition, and by differing interpretations of how it should best be used with economy and effect to achieve its objectives.

It is difficult to quantify the savings that can be achieved by the effective application of modern techniques of NDT to control the quality and reliability of manufactured products; or by adopting a change of philosophy from using NDT merely for post-production inspection to one of incorporating suitable techniques in management planning to ensure an adequate level of quality assurance and general fitness-for-purpose of a product. However, from evidence that is available from many industries, it is apparent that savings of both a direct and consequential nature can be very substantial and worthwhile.

On the other hand, there is no lack of awareness of the expense and loss of commercial credibility which can so easily accrue from improperly planned and managed NDT, or from unfortunate errors of judgement in defect interpretation, leading to a poor-quality product, or plant failure, with consequent loss of life or environmental pollution.

7.10.2 Overall scope

There are four main ways in which non-destructive testing can be incorporated into manufacturing practice:

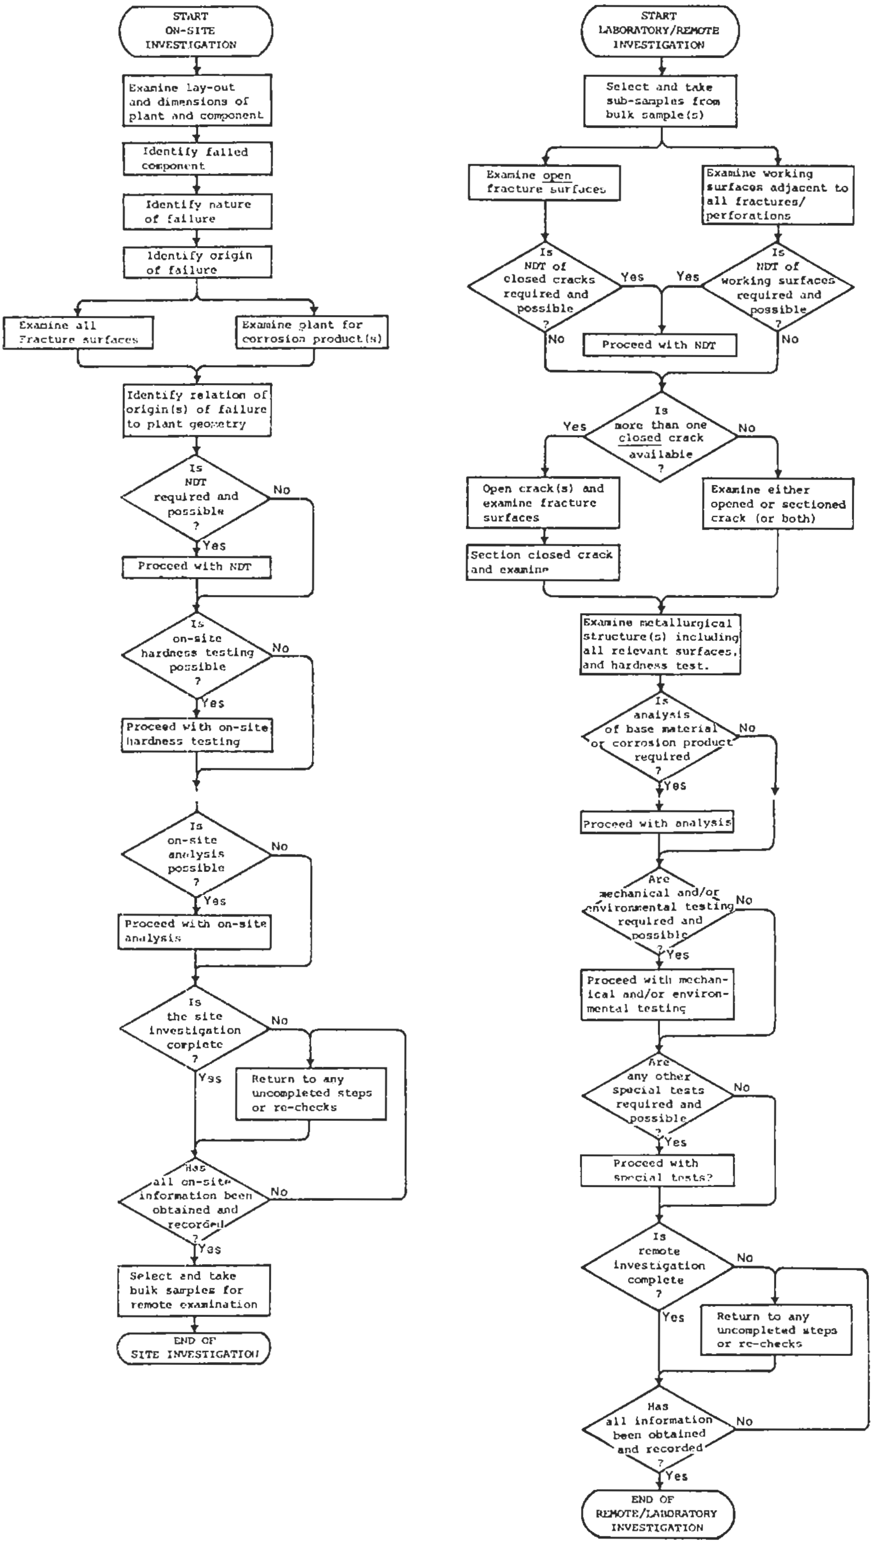
1. To provide control of quality at product manufacture or during plant fabrication;
2. To ensure that an item conforms to specification;
3. To examine plant, equipment or components during service, in order to meet statutory requirements or as an insurance against premature breakdown or failure;
4. As a diagnostic tool in research and development.

There is a tendency in some quarters to associate non-destructive testing merely with 'flaw detection'. This narrow interpretation has unfortunately tended to identify the subject with 'testing for scrap', so that it has come to be regarded rather disparagingly by some industrial managements as an unavoidable but costly overhead charge on production. However, non-destructive testing, if judiciously used, has a far more positive role to play; not least, in significantly lowering total manufacturing costs. This is particularly true if one can reject potentially defective material at an early stage of processing, especially in industries where significant scrap can occur in the manufacture of products with a high added value.

With engineering and constructional materials, properties of prime concern, such as strength, fracture toughness, fatigue or corrosion resistance cannot generally be measured non-destructively and, as a consequence, it is necessary to approach the problem indirectly and look for secondary features likely to be significant. For example, shrinkage and porosity in cast metals, defective welding, lamination in sheet and cracks in forgings are obvious suspect features, for which efficient non-destructive testing techniques have been developed. As materials and conditions of service get more complex, less obvious features such as microstructure, composition, internal stress and homogeneity become important. This means that they too may need to be carefully controlled and, as a consequence, monitored non-destructively.

Non-destructive testing is not confined to the factory and foundry. On-site testing of pressure vessels, pipelines and bridges, and in-service maintenance of airframes, aero-engines and refinery installations all present special problems to both instrument designer and operator. Then again, automated inspection, computer-aided manufacture and in-line process control raise quite different problems.

Although the non-destructive testing techniques required may be similar, different situations may call for very different levels of sensitivity, and working in this way to a specification requires experience and considerable interpretative skill, whichever NDT technique is used. Indeed, many of the techniques of non-destructive testing are now so well developed and advanced as regards sensitivity that what they are capable of revealing in the limit is often an embarrassment, and of little practical relevance to performance. Figure 7.149 shows a range of surface and internal variables that may need



START ON-SITE INVESTIGATION
Examine lay-out and dimensions of plant and component

to be controlled and hence monitored non-destructively, again emphasizing that flaw location and sizing represents only one of the many facets that may need to be considered when assessing overall quality.

Non-destructive testing during production and fabrication is closely allied with 'condition' monitoring of plant during service and regular 'health' monitoring of installed machinery. Many of the techniques can also be adapted for manufacturing control, enabling flaws to be eliminated as early as possible during the manufacturing process. NDT is also now an important element in the 'fitness-for-purpose' philosophy of manufacture in which design, materials selection, manufacture and quality control are integrated and properly coordinated.

7.10.3 Application areas

7.10.3.1 Materials control

Control of materials 'quality', which can be so easily influenced and modified by casting, forging or machining aberrations, represents the traditional use of NDT, and the variability to be monitored can broadly be classified into that associated with surfaces and that hidden within the volume of the material (Figure 7.150). Cracks and visible discontinuities have always tended to capture the imagination as potential and often catastrophic sources of failure and, as a consequence, have developed an almost emotive association with the 'folklore' surrounding non-destructive testing. However, the overall 'quality' of a material and its ability to match up to a performance specification can be affected by many other, perhaps more insidious, pockets of structural variability which are often difficult to define and categorize, let alone locate and identify. These might be locked-in stresses, grain variability, distributed porosity, depth of surface treatments, inclusion distribution or constituent diffusion. Many of these still present a challenge when it comes to specifying reliable non-destructive tests that can be used and simply interpreted outside of a laboratory.

7.10.3.2 Assembly

At assembly, the problems of the test multiply (Figure 7.151) Welding, bonding and bolting all introduce their own brand of specialized defects and many of these, because of orientation, geometry or lack of accessibility, still tax the ingenuity and skill of those to whom the problems of their detection and sizing are presented – often in unfriendly environments and inconvenient situations. It is here that close links between designer, tester and operator are so important.

Every effort must be made by the designer to build in inspectability, to understand the problems and frustrations of

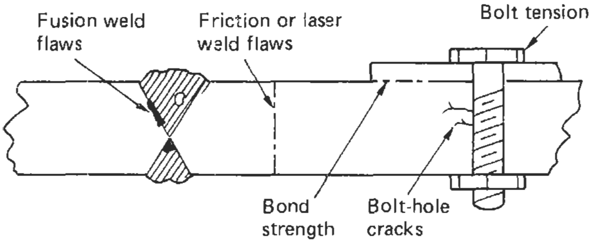

Figure 7.151 Joint quality

the tester and to realize the limitations of NDT technology on which the tester's judgement – and hence reputation – are based. Every effort must also be made to set up a dialogue between design and inspection teams as early as possible so that when design demands special inspection problems, sufficient time is available to develop, evaluate and calibrate suitable inspection procedures and train and validate the operators.

7.10.3.3 Automated metrology

The physical principles on which the more conventional flaw-detection NDT techniques are based can also be adapted for automated metrology and so, in a sense, this is a subject which is appropriately included under the NDT 'banner'. Ultrasonic techniques have been developed for accurate and high-speed monitoring of tube-wall, or plate, thickness; capacitance gauges have been designed for tube-bore measurement; and laser beam techniques have been used to obtain quantitative data on surface profiles and surface smoothness, where such factors need to be precisely controlled for reasons of heat transfer, assembly precision or to optimize performance. Most techniques can be adapted to give digital signals and in measurement-type tests on production components, where very large numbers of individual readings are inevitably made, data reduction and analysis can then be readily performed to simplify interpretation and provide archival data.

7.10.3.4 Materials sorting

Another area of application of non-destructive testing methods is in product or materials sorting to ensure uniformity of size, heat treatment or composition (Figure 7.152). Composition control, in particular, is a problem of growing importance as nuances in alloy composition become subtler, as specifications reflect the importance of trace-element constituents, or as property tolerances need to be controlled in alloys of the same nominal composition. The glib answer is that the problem of manufacturing variability can be solved by good 'housekeeping', but accidents and oversights occur in the most carefully organized factory. There is no 'panacea' instrument and each problem has to be carefully analysed around existing NDT technique possibilities. Portable spectroscopes, electrical or magnetic property analysis, thermoelectric (hot-probe voltages) or triboelectric (friction-generated voltages) techniques all have (or have had) a part to play, but this is still a fertile field for further technological exploration.

7.10.3.5 Plant surveillance

A major call on NDT expertise is to satisfy surveillance requirements for installed plant to ensure that an appropriate level of structural integrity is being maintained during service. Much of the requirement is covered by legislation and is closely specified by regulatory Codes of Practice. The requirement, of course, particularly applies to installed pressure vessels and pipework, ships operating to Classification Society rules, operating aircraft and aerospace structures, nuclear power plant installations and offshore platforms and their associated pumping plant and pipelines.

It is here that traditional NDT technology is pushed to its limits. Problems of access and geometry, site hazards, difficulties of positive interpretation and quantitative evaluation of defect dimensions, pressures to get plant back 'onstream' and interference with other maintenance work if radiation sources are required, all add up to a challenge of considerable magnitude and one where the inspector needs all the support and cooperation possible. The concept of 'fingerprinting' a structure before it is put into operation, so that changes in defect content or growth of cracks during service can be more positively monitored, is becoming a favoured approach to this particular problem. This raises attendant problems of long-term control of test sensitivity, data recording, archival storage and the need for automated test procedures which are reliable and repeatable over what might be 20–40 years of periodic application.

7.10.4 Methods of employing NDT in practice

Bearing in mind that non-destructive testing is an integral part of the wider management function of quality assurance, there are different ways in which NDT tests can be incorporated (as illustrated in Figure 7.153).

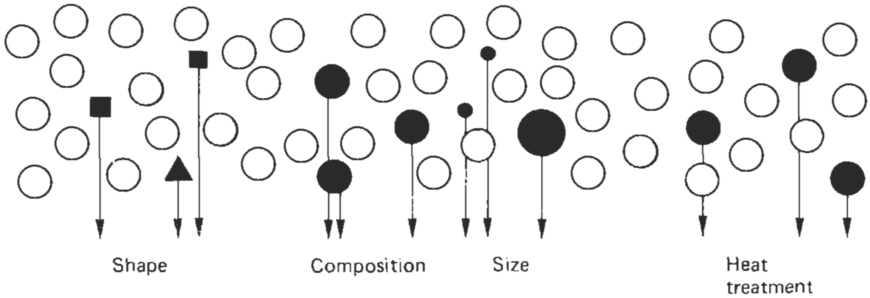

Figure 7.152 Materials sorting

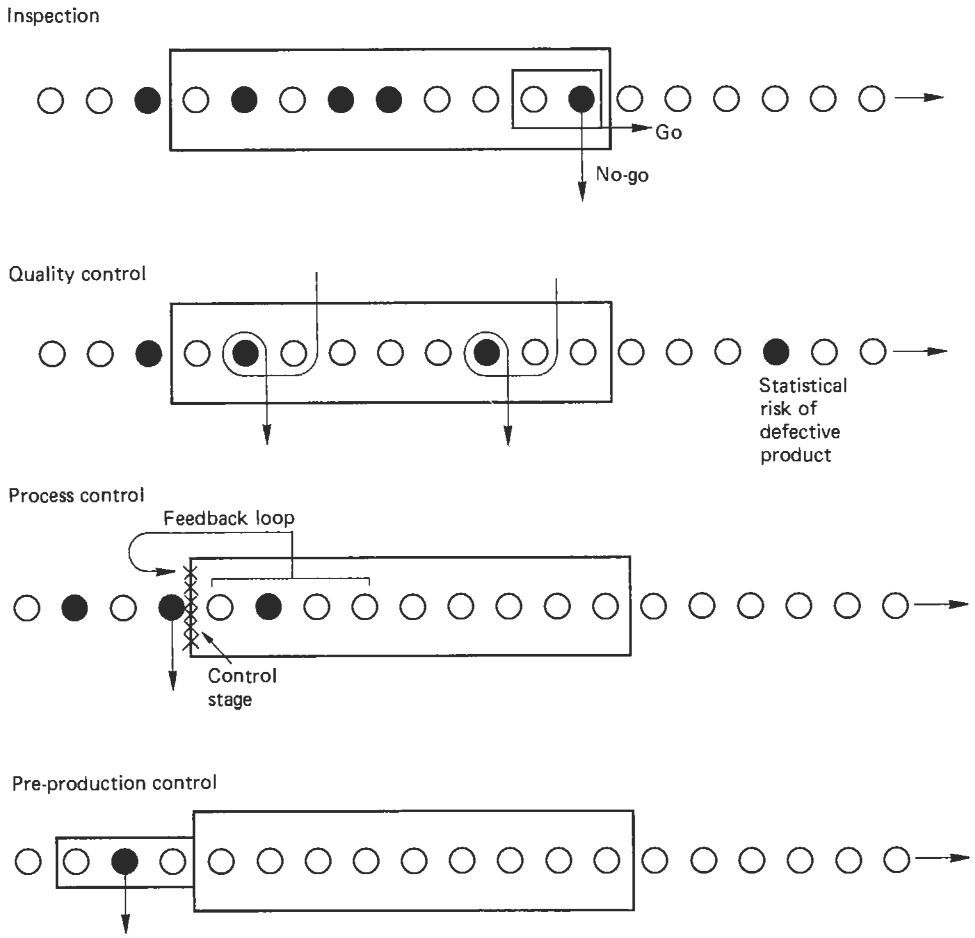

Figure 7.153 Methods of incorporating NDT into a production line

7.10.4.1 Inspection

At various points appropriate to the production (often only at the end of the line), some or all of the product is inspected and the 'sheep' separated from the 'goats'. This can be costly, time consuming and wasteful, although, in many situations, necessary. Such, unfortunately, is the limited measure of confidence that some managements place on the technology and in the way it is sometimes applied that this process is often used when a product leaves a supplier firm and the same inspection repeated by the customer when the product comes into the input stores!

7.10.4.2 Quality control

By invoking the concept of statistical checking at all stages along a production line to identify out-of-specification products as they arise, a smoother and less disruptive method of control results, and a measured risk is taken of the uniformity and correctness of the final product. Non-destructive testing techniques naturally have a role in this product-monitoring function and complement the more usual metrological measurements from which statistical quality-control procedures have traditionally evolved.

7.10.4.3 Process control

The third principle of operation is to have continuous monitoring of a product line with a feedback signal to the mechanics controlling the process. Thickness control by feedback adjustment of roll pressure, property control by feedback adjustment of furnace temperature, coating control and spot welding control are all manifestations of this positive approach to product quality uniformity.

7.10.4.4 Pre-production control

Yet a fourth philosophy which has not yet been fully developed is to introduce control at such an early stage in a process that quality is assured before added manufacturing costs are significant. Inspection for potential defects and quality rectification *during* a casting process, while a spot weld is being fabricated, or as an arc weld is cooling, are examples of how non-destructive testing techniques can be usefully pushed right back in the manufacturing cycle to improve to the utmost the effectiveness and economics of quality assurance. Similar reasoning can be applied to the incentive for developing NDT methods of monitoring NC machining by positive metrological control before the component is removed from the machine.

7.10.5 Range of techniques available

7.10.5.1 Surface flaws

The surface of a component has always attracted considerable attention from the standpoint of non-destructive testing. This is partly, of course, because the accessibility of surfaces makes inspection easier and interpretation more direct. It is, however, primarily because so many of the variables associated with surfaces have a significant effect on either the serviceability or saleability of a product. From economic considerations, inspection for saleability can often be as important as inspection for serviceability, and to satisfy both requirements, surfaces may be protectively or decoratively treated. These surface-treatment processes themselves often require special non-destructive tests to ensure adequacy of protectiveness and uniformity of coverage.

Surface discontinuities can act as stress raisers: they can reduce mechanical strength, especially bend strength and fatigue strength; and they can act as initiating points for brittle failure. Not only do surface discontinuities need to be located, but the depth, shape, nature, orientation and position are usually significant. Non-destructive methods for detecting surface discontinuities are well established and widely practised and are summarized in Figure 7.154.

7.10.5.2 Internal flaws

An internal flaw is one that cannot be detected by visual inspection, or one whose depth or extent cannot be accurately gauged by a surface-inspection technique. It may be an original casting defect or a defect introduced subsequently by a deformation process such as forging, extrusion, heat treatment or a joining process such as welding or brazing. The detection of internal defects is an area of non-destructive testing which has received considerable attention over the years and one which has resulted in major technological advances, particularly in the fields of radiology and ultrasonics. The range of currently available techniques is illustrated in Figure 7.155.

7.10.5.3 Structural variability

Discrete flaws are not the only cause of product failure. General microstructural variability (both at the surface and internal), preferred orientation, residual stress levels, heat-treatment variations, anisotropy, compositional non-uniformity, variations in electrical or magnetic properties, moisture content, and dislocation density are just some that may need to be controlled. 7.10.6 Individual techniques

7.10.6.1 Direct surface inspection

Visual inspection is the oldest, simplest and most widely used of all non-destructive testing techniques. All visual inspections are subjective and so may be influenced by outside factors. They should therefore be carried out under the best possible conditions. There must be adequate lighting with no dazzle or glare, and the inspector should be comfortable and protected from disturbing factors such as noise, draughts, extremes of temperature and inclement weather.

A systematic approach is essential; if it is not possible to cover a large area in a natural viewing sequence then a grid system should be used and one square examined at a time. Beware of eye fatigue and plan the work so that there are opportunities for the eyes to be rested. Technical aids to the humen eye to extend visual inspection include:

- Lenses, microscopes, telescopes
- Fibre-optic devices, boroscopes, endoscopes, etc. for viewing surfaces with limited or difficult access
- Mono and stereo TV systems for remote viewing
- High-speed cine or TV for studying fast events
- Computer image processing and pattern recognition for automated inspection
- Schlieren photography for surface texture studies

Another group of direct non-destructive tests for surfaces is based on tactile interaction and requires some contact. Thus stylus movement over a surface is the recognized method of measuring and defining surface roughness; indentation of the surface is the classic method of monitoring hardness (i.e. resistance to indentation). This group could also contain the classic metrological tools of the inspector – the micrometers and the callipers – for dimensional measurement, although conventional metrology is normally considered outside the accepted boundaries of non-destructive testing.

7.10.6.2 Optical metrology

Lasers and other optical devices are now available to extend direct visual and tactile techniques and provide accurate, non-contacting means of measuring size, position, component spacing, profile, etc.:

- Laser interferometers measure displacements to the highest accuracy, e.g. in linear measuring machines. They can also measure vibration amplitudes in machinery, bearings, loudspeakers, ultrasonic transducers, etc. and display these in three-dimensional form.
- Optical diode arrays can provide passive means of monitoring displacement, automated size measurement, etc.
- Reflectometers and laser-scatter devices can provide ways of monitoring and mapping surface smoothness of metals and other reflective materials.

Optical holography is a method of storing three-dimensional images on film for detecting strain regions and defects, particularly in composite structures.

Microwaves with wavelengths of 1–10^3 mm (radar range) can also be used for non-contact detection of surface cracks in metal as well as to pinpoint moisture or chemical composition variations in non-metals.

7.10.6.3 Thermographic techniques

Infrared cameras are commercially available which produce thermal images on a CRT or TV monitor screen. Typical working range is 0–800°C. They provide a rapid, remote (non-contact) way of inspecting large areas of plant for

- Hot spots due to failed insulation, fouling, coolant blockages, etc.
- Location of leaks, corroded regions, hidden objects, embedded building construction features, etc. which affect the rate of inward diffusion of heat.

Thermochromic paints can provide a low-cost alternative way of mapping out surface temperatures.

SPATE (Stress Pattern Analysis by Thermal Emission) is a non-contact thermographic way of measuring local stresses by observing the minute surface temperature rises that occur in cyclically loaded structures. Pulsed Video Thermography (PVT) is a developing technique using transient heat sources to show up sub-surface defects on a video monitor (e.g. voids, delaminations in composites, poor adhesion of coated materials, etc.).

7.10.6.4 Liquid penetrant inspection

This is a simple, widely used, low-cost way of detecting surface-opening cracks, porosity, etc. in non-porous, clean objects (e.g. metal castings, forgings, weldments and ceramics). A liquid (containing a coloured dye or UV-sensitive substance) is sprayed onto the object. The liquid is drawn into any surface-opening crack by capillary action, thereby highlighting its presence after subsequently cleaning the surface and applying a developing agent. The technique can detect minute defects and be automated for continuous production application, but is generally unsuitable for rough, or dirty surfaces. Penetrants are formulated in three groups:

- Solvent-removal penetrants;
- Post-emulsion penetrants where an emulsifier is subsequently applied for a predetermined time and the whole removed by water;
- Water-washable penetrants.

Developers are also of three basic types:

- A hard-drying developer paint which cannot be accidentally removed;
- A soft-drying developer paint which is easily removable;
- A dry-powder developer which is applied by blowing or dusting.

Stages in liquid penetrant testing

- Precleaning and degreasing; a vapour-phase degreasing bath is ideal;
- Preliminary inspection;
- Application of penetrant;
- Soaking to allow the penetrant to enter the cracks;
- Spraying of post-emulsifier (where applicable);
- Removal of penetrant: (a) excess by tissues or rags: (b) remainder by solvent or water;
- Dry, hot air is very suitable (except where dry powder developer is used);
- Application of developer;
- Soaking of developer: this may take anything from 10 minutes to 24 hours, depending on size of crack and sensitivity required;
- Final visual inspection.

Safety in using penetrant materials Solvents used in penetrant materials and cleaning agents may be both flammable and toxic. When carrying out liquid penetrant testing great care should be taken to ensure good ventilation and that precautions are made when using flammable liquids. Aerosols should not be used in confined spaces and indeed are now regarded as environmentally 'unfriendly' and to be avoided.

7.10.6.5 Magnetic inspection

Magnetic Particle Inspection (MPI) is a technique for locating surface and near-surface defects (in ferromagnetic materials only). The principle is that locally magnetized and magnetic discontinuities around defects are shown up by patterns formed by magnetic powder particles applied to the object's surface, usually in fluid form. It is a rapid, low-cost and sensitive way of detecting surface and near-surface cracks, inclusions, porosity and seams in castings, forgings, bars, etc. The methods is used both during manufacture and for in-service inspection of plant. It is excellent for detecting very small, tight service-induced cracks and can be used in either portable or on-line automated systems.

There are five principal ways of applying the magnetic field:

- Permanent magnet
- Electromagnet, solenoid coil or magnetic yoke
- Current flow, using prods or contacts
- By means of a threading bar
- Induction, or induced current flow

The selection of the most suitable magnetizing method depends on the size and shape of the object and also the orientation of the defect. It may be necessary to apply the magnetizing field in more than one direction, or indeed to apply more than one technique, in order to achieve a complete examination.

Sensitivity levels vary, but a field strength of between 3 and 6 kA/m (38 and 75 oersteds) is generally acceptable. The field strength (and direction) may be measured with a tangential field strength meter. The magnetic particles are coloured black, red or yellow and may also be fluorescent in order to achieve maximum contrast against the background colour of the item being inspected. Specially formulated white paints may also be applied before the test in order to obtain better contrast.

Magnetic particle testing requires skill and training in interpreting indications. In addition to discontinuities, particles may be attracted to sharp changes of section, surface scratches and boundaries of dissimilar metals. Sub-surface defects are recognized by their slightly blurred outline. A suspected crack may be confirmed or otherwise by removing a film of metal with emery paper or a smooth file and retesting.

Many engineering components need to be demagnetized after testing. This is achieved by passing the components two or three times through a coil carrying alternating current.

An extension of MPI is the magnetic flux leakage technique. If ferromagnetic components are magnetized (by a permanent or electro magnet) to near-saturation, local flaws or metal thinning can divert some of the magnetic flux outside the component and this can be detected by Hall-type search probes. This provides a relatively fast, 'first-look' method for detecting corrosion thinning and pits in large-area steel plates up to 1 cm thick such as the 'bottom' plates of oil storage tanks, reinforcing bars in concrete, broken strands in cables, etc.

7.10.6.6 Electrical techniques

Eddy currents are produced in any electrically conducting material when influenced by a coil placed close to it in which an a.c. is flowing. For the purpose of non-destructive testing, two coils are generally used, a small a.c. being generated in the primary coil and this induces an alternating magnetic field in the specimen; this in turn generates an a.c. of similar frequency in the secondary receiver coil which induces an opposing alternating magnetic field in the component.

Eddy currents provide a sensitive, versatile method of inspection using either portable instruments or in-line automated systems, and are used for inspecting electrically conducting materials. These are generally below 1 cm in thickness since the a.c. probe coil (1 kHz–5 MHz) only excites eddy currents within the object's surface layers. The flow of these currents is affected by many surface or near-surface defects or regions of varying conductivity or permeability. The currents picked up in the search coil are then amplified, analysed and displayed in terms both of amplitude and phase on either a meter or oscilloscope or as a digital signal. Calibration with reference blocks is usually required. Applications include:

- Detection of surface-opening or near-surface cracks, seams, pits, etc.
- Sorting metals of dissimilar composition, heat treatment or microstructure
- Measuring thickness of coatings on metals

Heat exchanger tubes in non-ferrous or austenitic materials can be inspected by using internal coils pulled through the tubes.

Eddy currents are not as penetrating as either ultrasonics or radiography, but have three outstanding advantages:

- Physical contact is not required.
- It is a very rapid form of inspection.
- It is easily automated.

Multifrequency and pulsed eddy current techniques are now available which increase the sensitivity and selectivity of the testing.

An alternative electrical technique is based on potential difference measurements. An electric current (a.c. or d.c.) is induced to flow between two contact prods pressed onto the surface of the object. Surface cracks in the current path between these contact points increase the apparent electrical resistance between the prods. These resistance changes, measured by the potential difference across a second pair of contact probes, can be related to crack depth. The technique forms the basis of low-cost portable instruments for measuring depths of surface-opening cracks in conducting materials, but results can be variable if cracks are 'tight' or provide an electrical 'bridge' for the current.

7.10.6.7 Radiography

X-rays and gamma-rays at the short wavelength end of the electromagnetic spectrum have the important characteristic of being able to penetrate considerable thicknesses of materials that are opaque to light. They have, therefore, been widely used to provide non-destructive techniques to locate internal flaws. Fortunately, they produce, like light, an image in a photographic emulsion (X-ray film) and so radiographs can be obtained directly to provide a pictorial and permanent inspection record.

Although a powerful non-destructive testing tool, radiography does require considerable skill and training to achieve the correct sensitivity and image definition, and considerable experience and judgement in interpreting the images correctly in relation to the flaws contributing to the 'image' pattern. It is essentially a 'shadow' technique and, as image contrast is caused by differential absorption, the technique is more suited to finding 'volumetric' defects (i.e. pores and cavities) than cracks and laminations. Indeed, these latter can be virtually invisible if the radiation is directed across the tight interfaces of such defects. Penetration depends on the energy of the radiation and a range of X-ray sources from 50 kV to 400 kV potential (in hot-cathode Coolidge tubes) are widely used in engineering practice and cover section thicknesses up to around 10 cm of steel or 25 cm of aluminium alloy.

Linear accelerator ('Linac') X-ray sources, up to 8–9 MeV, allow radiography of very thick sections (e.g. 1.5 m concrete or 0.5 m steel). They are used for inspecting reinforced concrete bridge sections, heavy castings or large assemblies such as gas turbines. Linacs are expensive, heavy sources posing a significant potential radiation hazard.

Microfocal X-ray sources are now available which produce sharp, enlarged images (up to 15 ×) projected onto film placed a metre or so from the object. Main applications are in the detection of tiny cracks or microporosity (down to 20 μm in size) in high-performance materials (e.g. ceramics and Nimonics) or resolving fine detail in small mechanisms, fibre composites, etc.

Gamma-rays provide an alternative to X-radiography for thick sections or in-field applications where access is difficult or power for an X-ray set is not available. Gamma-rays from a portable isotope source pass through an object and, like X-rays, form a direct image on film. Gamma radiography is also used for detecting cracks, corrosion defects, inclusions and for resolving internal structures. Isotope sources are selected for the penetration required (e.g. cobalt-60 can inspect up to 250 mm of steel). Image resolution is generally inferior to X-radiography and some isotopes have relatively short useful lifetimes. Panoramic (360°) imaging is possible, using small isotopes inside hollow objects, tubes, etc.

Historically, gamma-rays from radium, mesothorium and radon sources were used for materials inspection around 1925 and the pioneer work on the systematic investigation and evaluation of gamma radiography was carried out around 1930 when artificial radioisotopes were first produced by cyclotron bombardment. Satisfactory source activities for gamma radiography were not practically possible until preparation by reactor irradiation became feasible. There is now a wide choice of sources and their characteristics relevant to radiography have been widely evaluated and documented. The three most commonly used are given in Table 7.76.

Because of their different characteristics, X-ray and gamma-ray sources complement each other in their application:

- For light-alloy and low density specimens there is no suitable high-intensity radioisotope source. The preferred radiation source for such applications will, therefore, practically always be X-rays. Generally, for steel or copper alloys in thicknesses less than about 20 mm, X-rays will be preferred.
- For steel thicknesses less than about 50 mm the highest sensitivities can always be obtained with X-rays, but the differences between X- and gamma-radiography are not so large at the upper thickness end of this range.
- If large amounts of radiography are contemplated there will be a preference for using X-rays because of the shorter exposure times which are possible.
- If the radiation source has to be taken to the specimen, gamma-ray sources in their shielded containers are more portable than large X-ray sets, and the relative importance of convenience and sensitivity must be assessed for the particular application. X-rays will usually give the better sensitivity, but it may not be possible to handle an X-ray set under 'site' conditions. X-ray sources can be 'switched off', gamma-ray sources cannot.
- If only a small amount of radiography is required and the highest attainable sensitivities are not essential, a gamma-

Table 7.76 Properties of the three most common isotopes used in industrial radiography

Isotope	*Half-life*	*Optimum thickness range for steel (mm)*
Iridium-192	74.4 days	12-60
Caesium-137	30 years	50-100
Cobalt-60	5.26 years	50-200

ray source would initially be cheaper to buy. Again, choice of source must finally depend on the specimen thicknesses involved: gamma-rays, for example, should not be used for the radiography of very thin specimens unless there are very strong reasons for not employing an X-ray set.

Other radiation-based techniques include the following.

Radiometry This is used for detecting voids and density variations, and measuring wall thickness or fill-levels in concrete or metal components. The attenuation of gamma- or X-rays passing through the object is measured by a radiation detector, and can be related to density, thickness, etc. Lightweight isotope sources are used for in-field applications and backscatter methods for single-sided access. It is fast, accurate and easily automated and is sometimes referred to as the 'Source-and-counter' method.

'Real-time' radiography Replacing radiographic film by a fluorescent imaging screen linked to a TV system allows test objects to be inspected immediately (i.e. in real time), with the object either static or in motion. Resulting images can be stored on video tape and replayed, and, if required, enhanced or analysed automatically by computer-image processing. Real-time techniques can be used with neutrons and gamma-rays as well as X-rays. Main uses include on-line NDT of components, foreign-body detection and studies of internal workings of engines and other machinery.

Neutron radiography This is a technique which uses a beam of neutrons as the sensing radiation. Neutrons of various energies can be used (usually referred to, in order of decreasing energy as fast, epithermal, thermal and cold) and the source can be a nuclear reactor, an accelerator or certain isotopes. Neutrons do not produce a photographic image directly on film and some intermediate foil is necessary to give fluorescence, or an intermediate radioactive image which can subsequently be transferred to a film by autoradiography. Neutron radiography is particularly useful for inspecting brazed and adhesively bonded structures, monitoring the filling of ordnance devices and for locating hydrogen-rich areas and certain structural components with a hydrogen content (e.g. paper and rubber) which cannot be revealed by X- or gamma-rays. It is also widely employed for detecting residual refractory core material in the cooling channels of precision-cast turbine components. Neutron diffraction and scattering can be used for accurate measurement of residual stresses in thick components or evaluation of microstructures.

Electron radiography – beta-radiography This is a radiographic technique using beta particles (electrons). Since electrons are so readily absorbed this form of radiography can only be used effectively with foils, papers and paper products for studying fibre structures and watermarks, etc. The electrons can be excited in a front foil of metal or in a metal backing plate. Alternatively, the source can be a beta-emitting radioactive foil placed on one face of the specimen with the film on the other.

Positron annihilation This is a technique which uses a beam of positrons from a small, low-intensity isotope source for detecting early (pre-crack) fatigue or creep damage in metals and for monitoring moisture levels in composites.

Low-voltage radiography This is a radiographic technique for inspecting thin samples (e.g. papers) or low-density samples (e.g. fibre-reinforced plastics or beryllium). Low-voltage (5–10 kV) X-ray sources are used to give as high an attenuation as possible within the sample. It is often necessary to have a vacuum or helium path between the X-ray source and sample to cut down air absorption of the low-energy X-rays. It is usually necessary to expose on bare film in a darkened room to cut out the image of the paper of the film envelope.

Panoramic radiography This is a 360° degree radiographic arrangement using a central isotope source or a rod-anode X-ray tube. It can also be applied to a radiograph built up by moving sample and film on opposite sides of a narrow slit in an opaque screen during the radiographic exposure.

Dynamic radiography – in-motion radiography This refers to radiographic techniques which 'freeze' a situation in a sample in which changes are occurring with time. It is usually applied to the study of moving machinery or assemblies during operational functioning (e.g. aero engines or pumps), or to structural changes occurring more slowly due to metallurgical failure processes (e.g. creep cavitation), or to heat treatments and corrosion.

Flash radiography – high-speed radiography This is a technique of dynamic radiography in which motion is 'frozen' by using an extremely short pulse (tens of nanoseconds duration) of high-intensity radiation. Field-emission X-ray tubes have been constructed which can give sufficient output in 50 ns to produce a radiograph during very high speed motion, such as in studies of high-speed liquid flow and molten metal pouring during casting.

Xeroradiography Here a radiographic image is formed on a semiconductor (usually a selenium coating supported on a metal plate) instead of on film. The semiconductor is charged initially and the loss of charge when the plate is irradiated is proportional to the radiation dose received at every point. The residual charge pattern is revealed by dusting the plate with powder, which is preferentially attracted to the charge. On the radiograph there is a characteristic pattern of image enhancement at density steps such as edges, which can often help to improve image visibility. The technique is cheaper to operate than film radiography but is not widely used at present.

Tomography By suitably rotating, rocking or translating the specimen in relation to the source of radiation and the film, or vice versa, it is possible to produce a sharp radiograph of a particular plane within a solid sample. The rest of the image detail is blurred because of the geometric unsharpness caused by the relative motion purposely introduced between the rest of the sample and the film.

Computerized tomography (or CAT scanning), originally developed for medical use, is now finding wider application in industry for observing detail in a particular plane at right angles to the X-ray beam.

Legislation The use of ionizing radiations for the purpose of industrial radiography is subject to special legislation in most countries. In the UK there is:

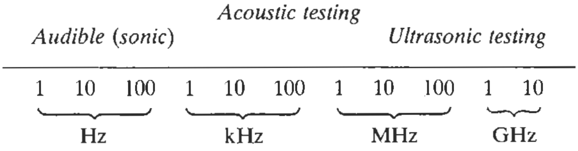
- *The Radioactive Substances Act 1960*. This requires all users of radioactive material to register with (or apply for exemption from) the appropriate government department. It is also concerned with registration of mobile radioactive apparatus and the right of entry and inspection by the government department Inspectors.

- *The Ionizing Radiations (Sealed Sources) Regulations 1969*. These deal principally with industrial radiographic processes and the protection of both users of ionizing radiations and the general public. The Factory Inspector for the district must be notified in writing before any work with ionizing radiations takes place for the first time in any factory. Workers are 'classified', which means they are under medical supervision and detailed records are kept of their individual radiation dosages. The regulations also deal with administration, notification and records, basic principles of protection, radiological supervision, organization of work, monitoring and the schedule of maximum permissible radiation doses.
- *The Radioactive Substances (Carriage by Road) GB Regulations 1940*. These impose requirements on packaging, labelling and procedures involved in the transportation of radioactive substances on roads to which the public has access.
- *The Radioactive Substances (Road Transport Workers) GB Regulations 1970*. These are concerned with the protection of workers engaged in the transportation of radioactive substances. The Code of Practice for the Carriage of Radioactive Materials by Road is intended to assist all concerned to discharge their obligations under the law. Notification containing prescribed information on vehicles employed in regulated transport operations must be given to the local licensing authority.

Radiation protection The basic principles of radiation protection are distance, shielding and time and, in practice, combinations of all three factors are used. The most efficient form of protection is, wherever possible, to use the radiation in a directional beam pointing vertically into the ground. Shielding is either by the use of dense materials like steel or lead or greater thicknesses of cheaper, less dense materials such as concrete and brick. Shielding is usually used in conjunction with distance as the most effective and economical form of protection.

7.10.6.8 Ultrasonic and acoustic testing

Moving out of the electromagnetic spectrum we can look into the frequency spectrum of elastic waves. This is another very fruitful source of NDT techniques since, again, elastic waves can move fairly freely through solid materials and can carry with them information about any imperfections or reflecting interfaces that lie in their path:



The techniques either use fairly well-defined beams which can readily be generated in the megahertz ultrasonic range (generally 0.2–25 MHz) or rely on an analysis of vibrations in a lower frequency range generated by setting up forced resonances in a sample, or by analysing the 'white acoustic noise' introduced by striking a sample.

Ultrasonic techniques are now widely used and are proving an extremely versatile complement to radiography since they are particularly sensitive for detecting lamellar and planar flaws (such as forging and lack-of-fusion welding defects) which can be quite invisible to X-rays. However, beam orientation is important and significant lack-of-fusion flaws can also be missed by ultrasonics if they are not orientated suitably for reflection or if the transducers are not positioned in such a way that the reflected energy can be received.

Ultrasonic energy is 'transduced' to and from electrical voltage signals by ceramic piezoelectric plates built into 'probes' and the resonant frequency of the plate governs the frequency of the ultrasound that is emitted from the probe. The response characteristics, size, damping, pulse length and attachment of these piezoelectric plates in the ultrasonic probe are important and often insufficient attention is paid to this vital aspect of the whole test. Within the metal, the ultrasound pulses can be transmitted in a number of modes and an understanding of their velocity, beam direction and attenuation is essential if the test is to be carried out in an optimum way. 'Compression' and 'shear' waves are used as probing beams for detecting internal flaws, the latter being particularly useful for weld inspection. Rayleigh or 'surface' waves can be generated for locating near-surface flaws and Lamb or 'plate' waves for inspecting sheet, plate and tubing.

The ultrasound pulses travel through materials by transferring energy from atom to atom and thus their velocity depends on the elastic properties and density of the medium. The wavelength of the ultrasound (typically in the range 0.3–3 mm) roughly defines the minimum size of defect that can be detected; this varies quite significantly in different materials.

Flaw *location* is now well established by ultrasonic techniques, by accurately timing the round trip of the pulses. However, flaw *sizing* is less well established but is currently receiving considerable attention in order to back up the quantitative predictions being made by fracture mechanics analyses of critical crack dimensions for brittle fracture. Ultrasonic techniques are also widely used to monitor thickness of sections in order to check for corrosion or erosion. Pulse transit timing is used for thicknesses over 0.5 mm, although for the 0.1–2.5 mm range detecting the frequency at thickness resonance usually gives a more precise measurement.

Much sophistication and improvement has gone into ultrasonic instrumentation over the years and at one end of the range reliable, rugged, portable equipment is now widely available both for flaw location and thickness monitoring. At the other end of the scale automated, modular, instrumentation with computerized digital data processing is available for on-line product quality monitoring and flaw analysis.

Determination of position and size of flaws Before use, a flaw detector is calibrated over a suitable range using an approved calibration block. The position of a flaw is then ascertained by a direct reading in the case of a compression-wave probe, and by simple trigonometry or a specially designed slide rule when using a shear-wave probe. The size of flaws may be estimated by using one or more of the following methods:

- The maximum amplitude technique in which the defect is scanned from as many angles and orientations as possible. At the point of maximum amplitude the beam path and surface distance readings are noted and plotted. The plots give a facsimile outline of the flaw.
- In the 20 dB technique, the beam profile of each probe is plotted out 20 dB each side of the centre of the beam. This beam is then logged on a slider of transparent plastic. A cross-section of the weld or detail of the item under examination is drawn full size onto another piece of plastic. The slider is superimposed onto the latter, duplicating the position of the probe on the item being examined. The origins of any indications are simply identified and the flaws may be sized by noting the position of probe and reflection when the defect reflection falls 20 dB either side of the maximum.

- Ultrasonic velocity measurements are in use for in-field measurement of residual (retained) stresses in structures, and for monitoring process control parameters (e.g. flow rate and fluid concentration).
- In the 'acoustic' range of frequencies there is growing interest in developing techniques for fairly coarse quality assessment based on small changes in resonant frequency when the structure contains a flaw; or by changes in spectral content in a pulse of energy induced by a short sharp hammer blow (acoustic impact testing). At these frequencies there are no directional beam characteristics as such so that large structures can be examined 'globally' as a prelude to a more detailed examination should an anomaly be indicated.

In all the above techniques acoustic or ultrasonic energy is introduced into the sample as a necessary precursor to the inspection. However, the initiation or growth of cracks and relative movement of crack faces can themselves produce elastic waves at sonic or ultrasonic frequencies. A network of piezoelectric detector probes clamped to a structure can locate the position of cracks and continuously monitor their growth over long periods by monitoring this in-built acoustic emission. The main applications of this technique are in pressure vessels and other plant. Problems can arise from background noise and in the interpretation of complex signals.

Another parallel technique for 'health' monitoring of plant is based on analysing the noises and vibrations (over a broad frequency spectrum) emanating from moving machinery and engines and interpreting the information in terms of bearing wear and component alignment. Indeed, plant surveillance and machinery condition monitoring are important potential areas for further development, and new forms of 'health' monitor are continually being sought to meet improved safety and integrity requirements.

7.10.7 NDT method selection

Because of the range and complexity of NDT techniques now available or the subject of current research, it is becoming increasingly important to ensure that an optimum approach is made to any particular inspection requirement. The NDT Method Selector (Table 7.77) relates the techniques referred

Table 7.77 NDT method selector

29 Ultrasonic velocity measurement
30 Ultrasonic time-of-flight diffraction

From 'Quality Technology' wallchart published by the National NDT Centre in collaboration with the British Institute of NDT.

to in this section to some of the more common inspection problems likely to be encountered in practice. However, professional guidance on the current state-of-art of the techniques and available instrumentation should be sought in the first instance. Two ready sources of such guidance are the Trade Group of the British Institute of NDT in Northampton and the National NDT Centre, operated by AEA Technology at Harwell Laboratory. Advice on the status of appropriate National, European and International Standards which set down the methods of applying many of the techniques are available from the British Standards Institution in London.

Information on the nationally approved and internationally accepted NDT operator approval scheme PCN (Personnel Certification in Non-destructive Testing) is available from the PCN secretariat at the British Institute of NDT in Northampton.

Further up-to-date information on all aspects of NDT is listed in the annual *NDT Yearbook* published by the British Institute of NDT.

7.10.8 Conclusions

NDT has a vital role to play in monitoring and improving the quality of manufactured products and ensuring integrity of fabricated plant. The techniques available are many and varied and there is a range of new methods and equipment likely to emerge from the active research and development now being directed to this subject, anticipating the requirements of new materials, new manufacturing processes and new legislation. NDT is part of a wider management function in mechanical engineering and should be considered and developed with full appreciation of its proper context and wide potential.

Acknowledgements

The author has incorporated and updated some material from the Non-destructive Testing section of the previous 11th edition of this book prepared by Mr J. G. Rees. Some of the information on NDT techniques and the NDT Method Selector have been drawn from the wallchart 'Quality Technology: A Guide to Non-destructive Testing Methods, Services and Information Sources' in the preparation of which the author was associated. Due acknowledgement is given to the National NDT Centre and the British Institute of NDT who jointly distributed the wallchart. The author has also drawn freely from specialist papers on NDT subjects that he personally authored or presented at conferences when employed by AEA Technology.

Section 7.3

The following organizations publish information on all aspects of their subjects: The Welding Institute, Abington, Cambs; The Steel Castings Research and Trade Association, 5 East Bank Road, Sheffield; The Drop Forging Research Association; The British Cast Iron Research Association. Some (but not all) of this information is restricted to their members

Section 7.4

More than 20 brochures, giving technical data, properties, manufacturing procedures, applications and suppliers of copper alloys are available without charge from The Copper Development Association, Orchard House, Mutton Lane, Potters Bar, Herts EN6 7AP

Magnesium Elektron Ltd, Royal House, London Road, Twickenham TW1 3QA, publishes brochures detailing the properties of the principal magnesium alloys

IMI, PO Box 704, Witton, Birmingham B6 7UR, publishes a series of brochures listing the properties, fabrication procedures and applications of their standard range of titanium alloys

Inco Alloys International, Holmer Road, Hereford, publish free of charge a series of brochures on the properties and applications of nickel alloys

The Wear Technology Division of the Cabot Corporation (Deloro Stellite), Stratton St Margaret, Swindon, Wilts, issue publications on their 'Deloro' series of wear-resistant cobalt-base alloys and 'Triballoy' intermetallic compounds for wear-resistant coatings

Wall Colmonoy Ltd, Pontardawe, West Glamorgan, publish brochures listing their nickel alloys for wear-resistant coatings

The Lead Development Association, 3 Berkeley Square, London W1X 6AS, publishes a number of brochures on lead and its alloys

The International Tin Research Institute, Fraser Road, Perivale UB6 7AQ, will provide information on the properties of tin and its alloys

Section 7.5

Metals and Materials, Volume 2, Nos 4, 6, 7, 9, 10 and 12, contain a series of articles, contributed by members of the Materials Development Division of the AERE, dealing with all aspects of filamentary and short-fibre composites (with the exception of cement-based composites). Volume 4, No. 5 contains additional information on filament winding techniques.

Volume 3, No. 11 deals with some aspects of automotive applications of composites and Volume 4, No. 7 with aircraft applications.

Volume 4, No. 9 contains two articles on carbon–carbon composites. Volume 2, No. 3 has an article on metal matrix composites

8.1 Stress and strain

8.1.1 Fundamental definitions

8.1.1.1 Direct stress σ

The level of direct stress at a point within a loaded body may be considered analogous to the pressure acting in a fluid. It is the measure of the level to which the bonds that hold a structure are being pushed closer (compression – defined negative) or pulled apart (tension – defined positive) (see Figure 8.1). It is defined as the normal force per unit area, acting at a point within a material and not associated with any specific area.

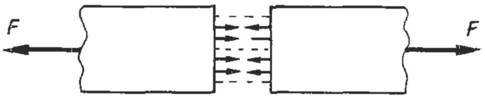

Figure 8.1 Direct stress acting on a section in a bar

8.1.1.2 Shear stress τ

This is again a point quantity and is measured in units of force per unit area. It measures the level by which the bonds are translated with respect to each other. In reality, there is no sign convention for shear stress since there is no physical difference between shearing from right to left or left to right (see Figure 8.2).

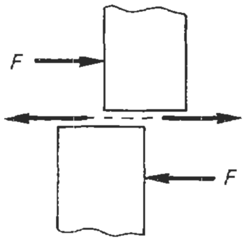

Figure 8.2 Shearing action at a section

8.1.1.3 Strain ϵ

Strain is a measure of how far apart the bonds are pulled, pushed or translated with respect to each other. Strains are usually quoted as dimensionless quantities with respect to some length dimension.

Engineering strain is that strain which is dimensionalized with respect to the original shape before any strain is induced into the material (see Figure 8.3), i.e.

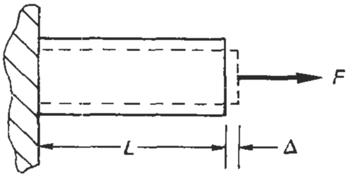

Figure 8.3 Deformation of a loaded bar

$$\epsilon = \frac{\Delta}{L} \tag{8.1}$$

Strain values for materials such as steel and aluminium are very low in the working environment (usually $\pm 1 \times 10^{-3}$).

8.1.1.4 Poisson's Ratio ν

This ratio is that of lateral strain to longitudinal strain under conditions of uniaxial longitudinal stress.

8.1.1.5 Elasticity

A material may be considered to behave elastically if, when the force/stress is applied to it, the resulting deformation/strain appears instantaneously; and if, when the forces are removed, the material returns to its initial shape.

8.1.1.6 Modulus of elasticity – Young's Modulus E

If under elastic conditions there is a linear relationship between stress and strain, the ratio of the induced stress to its corresponding strain is defined as Young's Modulus. Materials with a linear relationship between stress and strain are termed Hookean.

8.1.1.7 Plasticity

This is the property of sustaining appreciable permanent deformation without rupture. Materials such as steel and cast iron when stressed beyond the elastic limit become partially plastic, the degree of plasticity growing with increased stress.

8.1.1.8 Yield point

This is the lowest stress at which strain increases without an increase in stress. Only a few materials exhibit a true yield point; for other materials the point is used as a transition point.[1]

8.1.1.9 True stress

When dealing with stresses in the plastic condition the stresses must be calculated using the current deformed state of the material and not on the original geometry as for elastic behaviour.

8.1.1.10 True strain – natural strain or logarithmic strain e

As with true stresses, plastic strains are based on the current deformed geometry and not on the original geometry. It is equal to $\log_e(1 + \epsilon)$, where ϵ is the engineering strain.

8.1.1.11 Dynamic stresses

These are associated with any system where loads applied to a component are time dependent. They include creep, fatigue, impact and relaxation stresses.

8.1.1.12 Creep stresses

When the strain varies progressively with time under constant or decreasing stress the material is under a state of creep. This phenomenon usually occurs at elevated temperatures.

8.1.1.13 Fatigue stresses

Stresses that vary periodically with time (cyclic) are classed as being under a fatiguing environment. Fracture under fatigue can occur at stresses much lower than the levels achieved under steadily increasing load conditions.

8.1.1.14 Impact stresses

Components which are subjected to transient loading have shock or stress waves induced into them, provided the duration of the load is of the same order of magnitude as the natural period of vibration of the component.

8.1.2 Linear elasticity

The most common form of stress analysis used in engineering deals with material behaviour that is said to be linear elastic, hence conforming to Hooke's law, which states that strain is linearly proportional to stress.

The constant of proportionality is termed Young's Modulus or the Modulus of Elasticity. When the strength and elastic properties are the same in any direction the material is said to be isotropic. If the strength and elasticity are different for different directions the material is said to be anisotropic.

Hookean behaviour can be assumed for most common engineering materials up to a specific strain level, and mathematical theories can be applied with an acceptable level of accuracy for engineering approximations. A level of caution must be used when detailing certain materials such as wood and cement where the material's response is dependent upon the rate of loading. The apparent Young's Modulus must also be carefully chosen for such applications.

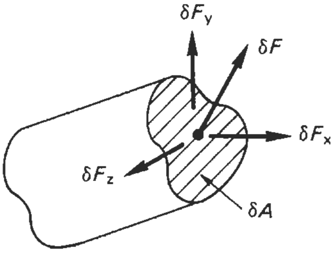

Figure 8.4 Resolution of force δF along cartesian axes

8.1.3 Stress systems for isotropic materials

Consider a point in a material subjected to a force δF acting on a plane (area) δA. If the force is resolved into three mutually perpendicular planes giving three forces δF_x, δF_y and δF_z and using the definition of stress in Section 8.1.1, three stresses can be identified:

$$\mathop{\mathrm{limit}}\limits_{\delta A \to 0} \frac{\delta F_x}{\delta A} = \sigma_{xx}, \quad \mathop{\mathrm{limit}}\limits_{\delta A \to 0} \frac{\delta F_y}{\delta A} = \sigma_{xy} \tag{8.2}$$

$$\mathop{\mathrm{limit}}\limits_{\delta A \to 0} \frac{\delta F_z}{\delta A} = \sigma_{xz}$$

The first suffix gives the direction of the normal to the area on which the stress acts and the second the direction of the stress with respect to the plane (Figure 8.4)

8.1.4 Plane stress system

Many engineering systems can be regarded as or approximated to a plane stress system (e.g. plates and shell). A plane stress system is where one of the three mutually perpendicular stresses σ_{xx}, σ_{yy} and σ_{zz} is taken to be constant or zero. This state of stress occurs when a component is 'thin' in the thickness direction. In other words, the thickness dimension is an order of magnitude smaller than any other dimension.

The state of stress acting in a body at a point can be described by the system acting in the xy plane shown in Figure 8.5(a). By taking moments about a corner of the element, it can be shown, ignoring secondary terms, that $\tau_{xy} = \tau_{yx}$. A state of plane stress can then be expressed by a combination of three stresses σ_{xx}, σ_{yy} and τ_{xy}. The above system describes the general state of stress at a point. By taking a plane at an angle θ relative to the xy system (Figure 8.5(b)) another system acting on the θ plane can be expressed in terms of the three stresses acting in the xy plane. From equilibrium,

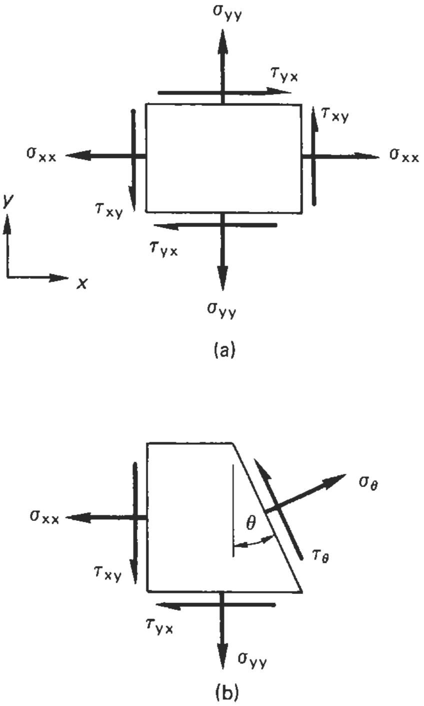

Figure 8.5 (a) Plane stress representation; (b) stresses acting on a plane inclined at $\theta°$ to the xy plane

$$\sigma_\theta = \frac{\sigma_{xx} + \sigma_{yy}}{2} + \frac{\sigma_x - \sigma_y}{2} \sin 2\theta + \tau_{xy} \sin 2\theta \tag{8.3}$$

$$\tau_\theta = \tau_{xy} \cos 2\theta - \frac{\sigma_x - \sigma_y}{2} \sin 2\theta \tag{8.4}$$

Equations (8.3) and (8.4) describe the stresses as a function of θ. The maximum and minimum stresses can be obtained by differentiating equation (8.3) and equating this to zero, i.e.

$$\frac{d\sigma_\theta}{d\theta} = -\sigma_x - \sigma_y \sin 2\theta + 2\tau_{xy} \cos 2\theta = 0$$

Hence

$$\tan 2\theta = \frac{2\tau_{xy}}{\sigma_x - \sigma_y} \tag{8.5}$$

Substituting this angle into equation (8.3) gives the maximum and minimum stress as:

$$\sigma_1 = \frac{\sigma_{xx} + \sigma_{yy}}{2} + \sqrt{\left[\left(\frac{\sigma_{xx} - \sigma_{yy}}{2}\right)^2 + \tau_{xy}^2\right]}$$
$$\sigma_2 = \frac{\sigma_{xx} + \sigma_{yy}}{2} - \sqrt{\left[\left(\frac{\sigma_{xx} - \sigma_{yy}}{2}\right)^2 + \tau_{xy}^2\right]} \qquad (8.6)$$

Occurring at an angle

$$\theta = \frac{1}{2}\tan^{-1}\left(\frac{2\tau_{xy}}{\sigma_{xx} - \sigma_{yy}}\right) \qquad (8.7)$$

Equations (8.3) and (8.4) can be used in a very useful form graphically known as the Mohr's stress circle. If a graph is plotted whose ordinate is the shear stress and the abscissa the normal stress the locus of a stresses can be plotted with the circle centre located on the horizontal axis at $(\sigma_{xx} + \sigma_{yy})/2$ and whose radius is

$$\sqrt{\left[\left(\frac{\sigma_{xx} - \sigma_{yy}}{2}\right)^2 + \tau_{xy}^2\right]}$$

All angles associated with the circle are double those acting on the actual elements.

A positive shear pair produces a shear couple acting on an element (Figure 8.6). If the couple tends to rotate the element clockwise this is defined as a positive shear pair and is plotted vertically on the circle.

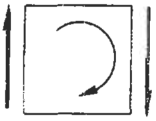

Figure 8.6 Shear couple notation

As an example, consider the state of stress shown in Figure 8.7. By inspection: $\sigma_{xx} = 45$ N/mm^2, $\sigma_{yy} = -15$ N/mm^2 and $\tau_{xy} = 40$ N/mm^2. Using these values the circle can be constructed in stages as outlined below.

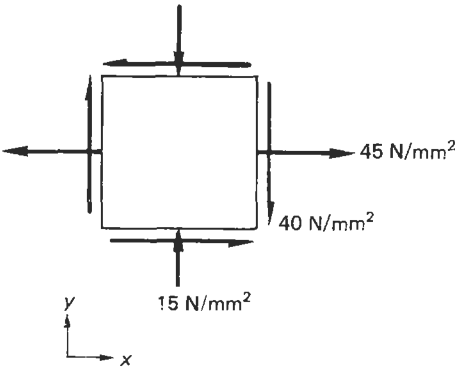

Figure 8.7 Stressed element example

Two points are plotted in $\sigma = \tau$ space using the shear notation (Figure 8.8). Then the centre of the circle is obtained and, using Pythagoras, the circle radius calculated (Figure 8.9). The circle can now be constructed, and where the circle intercepts the σ axis the maximum and minimum stresses are given. These stresses are termed principal stresses. The direction of these stresses can be obtained from the circle by following the direction given on the circle. For the above case σ_1 is acting at angle θ clockwise relative to the x direction as in Figures 8.10 and 8.11. The maximum shear stress is given by the radius of the circle, and this occurs on a plane at ±45° from the principal planes, i.e. ±90° on the circle. In this particular example, $\sigma_1 = 65$ N/mm^2, $\sigma_2 = -35$ N/mm^2 and $\tau_{max} = 50$ N/mm^2; $\theta = 35°$ cw from the x axis.

In a two-dimensional stress field several sets of lines describing the state of stress are used in producing information about the stress distribution within a component. The most common terms are:

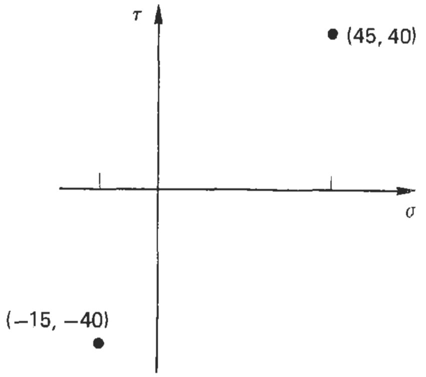

Figure 8.8 Mohr's circle coordinates

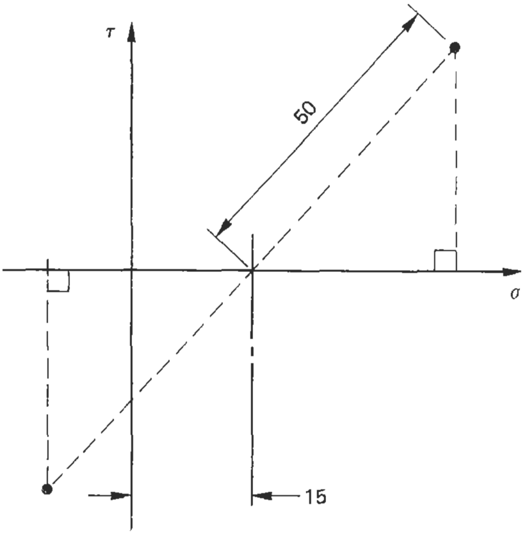

Figure 8.9 Mohr's circle centre and radius

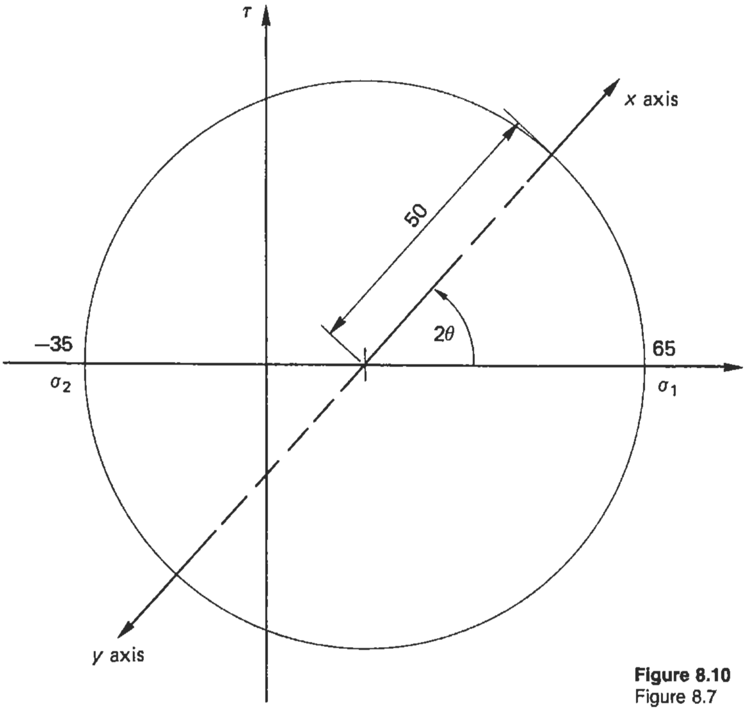

Figure 8.10 Completed Mohr's circle for the stressed element in Figure 8.7

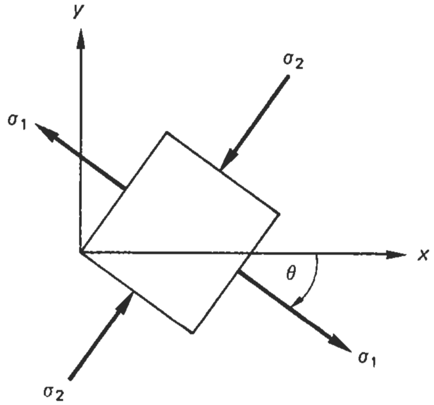

Figure 8.11 Principal stress directions

Isoclinic: A line of constant, θ, used extensively in photoelastic analysis (see Section 8.2.2);
Isostatic: An orthogonal network of curves, one set representing maximum principal stress, the other representing the minimum principal stress. These are sometimes termed stress trajectories and are used in finite element stress plots or observed in crack patterns occurring in brittle coatings (see Section 8.2.8);
Isochromatic: A line along which the maximum shear stress ($\alpha[\sigma_1 - \sigma_2]$) is constant, so called because this represents a constant colour band in photoelasticity. This is also useful in estimating ductile failure;
Isopachic: A line along which the sum of the principal stresses, $\sigma_1 + \sigma_2$, is constant. These are usually associated with field problems.

While stress is an engineering concept and not measurable, engineering strains which are associated with body deformations can be measured. In most applications elastic strains are small in magnitude (between $\pm 1 \times 10^{-3}$) and are measured by techniques discussed in Section 8.2.1.

Using the notation in Section 8.1.2, the representation of strain in any plane can be expressed similarly to those obtained for stresses. Consider Figure 8.12, which shows a small element within a component subjected to a direct stress, shearing stress and the induced strains. The normal and shear strain acting on any plane θ are given by

$$\epsilon_\theta = \frac{\epsilon_x + \epsilon_y}{2} + \frac{\epsilon_x - \epsilon_y}{2}\cos 2\theta + \frac{\gamma_{xy}}{2}\sin 2\theta \qquad (8.8)$$

$$\gamma_\theta = \gamma_{xy}\cos 2\theta - (\epsilon_x - \epsilon_y)\sin 2\theta$$

Comparing these equations with equations (8.3) and (8.4) there is a direct substitution of ϵ for σ and $\gamma/2$ for τ. This leads to the principal strain axes at

$$\theta = \frac{1}{2}\tan^{-1}\left(\frac{\gamma_{xy}}{\epsilon_x - \epsilon_y}\right) \qquad (8.9)$$

Relative to these planes the shearing strain will be zero. Further, a Mohr's circle of strain can also be constructed using ϵ (the normal strain) as the abscissa and $\gamma/2$ (half of the shearing strain) as the ordinate. Thus the circle will have its centre on the horizontal axis at

$$\frac{\epsilon_{xx} + \epsilon_{yy}}{2}$$

and a radius of

$$\sqrt{\left[\left(\frac{\epsilon_x - \epsilon_y}{2}\right)^2 + \left(\frac{\gamma_{xy}}{2}\right)^2\right]}$$

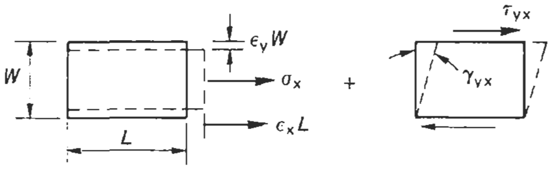

Figure 8.12 Strain notation

In determining principal strains at a point in a component, equation (8.8) is often used with three strain-measuring elements (see Section 8.2.1) attached at angles θ_1, θ_2, θ_3 such that

$$\epsilon_{\theta i} = \frac{\epsilon_x + \epsilon_y}{2} + \frac{\epsilon_x + \epsilon_y}{2}\cos 2\theta i + \frac{\gamma_{xy}}{2}\sin 2\theta i \qquad (8.10)$$

where $i = 1, \ldots, 3$

Choices of angles are usually 0, 45, 90 or 0, 60, 120 for most commercial applications. Using the three measured strains in a known direction the Mohr's circle can be constructed and hence the principal strains evaluated. If knowledge of the principal directions is available a two-element system may be used. A 0, 60, 120 unit can be represented by the Mohr's circle shown in Figure 8.13.

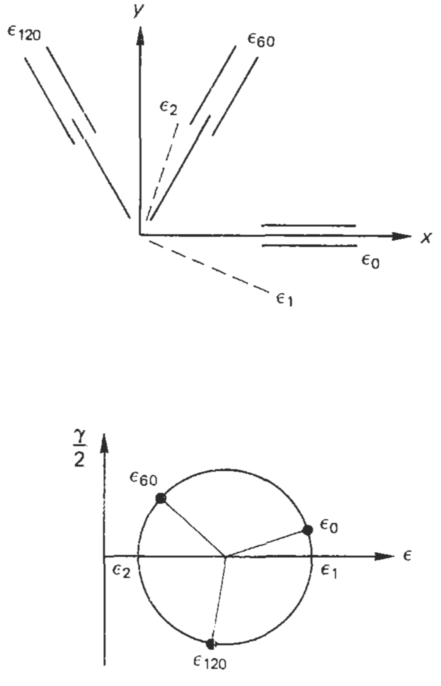

Figure 8.13 Mohr's circle of strain for a 0, 60, 120 rosette

8.1.5 Compliance relationship

Two important phenomena are associated with homogeneous, isotropic materials in the relationship between stress and strain at a point:

1. Hooke's law in one dimension, which states the proportionality between uniaxial stress and strain in the same direction, i.e. $\sigma_x = E\,\epsilon_x$, the constant of proportionality E termed Young's Modulus or elastic modulus.
2. The Poisson effect, i.e. the observation that a stress in one direction induces not only strain in that direction but also strains in the other two orthogonal directions, $\epsilon_y = \epsilon_z = -\nu\,\epsilon_x$, where the constant of proportionality, ν, is known as Poisson's ratio.

Using the two effects, a generalized expression of Hooke's law in three dimensions can be obtained by simple superposition, e.g.:

$$\begin{aligned} E\,\epsilon_x &= \sigma_x - \nu\,\sigma_y - \nu\,\sigma_z \\ E\,\epsilon_y &= \sigma_y - \nu\,\sigma_z - \nu\,\sigma_x \qquad (8.11) \\ E\,\epsilon_z &= \sigma_z - \nu\,\sigma_x - \nu\,\sigma_y \end{aligned}$$

Expression (8.11) can be rearranged in terms of stress in the following format:

$$\sigma_z = \frac{1-\nu}{1+\nu}\,\frac{E}{1-2\nu}\left\{\epsilon_z + \frac{\nu}{1-\nu}(\epsilon_y + \epsilon_x)\right\} \qquad (8.12)$$

These expressions may be reduced for plane stress problems to

$$\sigma_x = \frac{E}{1-\nu^2}(\epsilon_x + \nu\epsilon_y)$$

$$\sigma_y = \frac{E}{1-\nu^2}(\epsilon_y + \nu\epsilon_x)$$

$$\tau_{xy} = G\,\gamma_{xy} = \frac{E}{2(1+\nu)}\,\gamma_{xy}$$

or in matrix form

$$\begin{Bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{Bmatrix} = \frac{E}{1-\nu^2}\begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & \frac{1-\nu}{2} \end{bmatrix}\begin{Bmatrix} \epsilon_x \\ \epsilon_y \\ \tau_{xy} \end{Bmatrix} \qquad (8.13)$$

or

$$\{\sigma\} = [D]\,\{\epsilon\}$$

Conditions of stress or strain within a material can be difficult to calculate mathematically for most shapes, with the exception of a few geometries such as bars, cylinders and plates. To obtain the stresses in other shapes it is necessary to use experimental techniques or computational procedures such as finite or boundary element analyses.

8.1.6 Stress concentrations

When designing load-bearing components the engineer uses the basic strength of materials equations in order to obtain stresses in, for example, beams and plates. In carrying out these calculations the engineer must proceed with the utmost caution, since these equations assume no discontinuities within the material. The presence of cracks and holes is very common. These discontinuities introduce stress concentrations which, in some instances, are the critical stress levels and lead to localized yielding or failure, depending upon the material property behaviour. As a result, it is necessary to consider a stress-concentration factor K_t, which is defined by the following relationship:

$$K_t = \frac{\text{Maximum stress}}{\text{Background stress}} = \frac{\sigma_{\max}}{\sigma_n} \qquad (8.14)$$

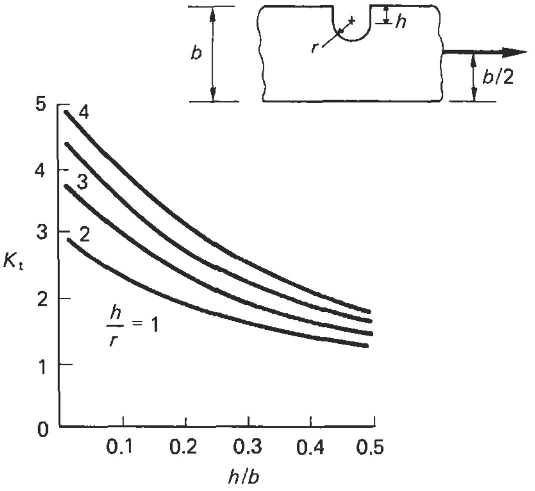

Figure 8.14 Stress concentration factor K_t for a notched sample

In general, σ_{max} will be determined by computational or experimental methods, and σ_n by simple theory such as $\sigma_n = P/A$, $\sigma_n = (My)/I$, $\tau = (Tr)/J$. For ductile materials stress concentrations may not be critical when under static loading but critical under dynamic loading. For brittle materials such as carbon-fibre composites, stress concentrations can be the governing conditions because the material cannot relieve the stresses by yielding. A full list of stress concentration factors for components under such loads as bending and torsion are given in references 2–4.

8.1.7 Impact stresses in bars and beams

8.1.7.1 Stress waves or pulses

A stress wave passes through a material when the different sections are not in equilibrium, as in the case of colliding bodies. Due to the material properties of a body, a finite time is required for this disequilibrium to be felt by other parts of the body. The lack of load equilibrium is observed by the presence of stress waves moving through a particular section.

The two most common wave forms are longitudinal and torsional. Longitudinal waves are of the form of tensile waves or compression waves. In the case of tensile pulses, sections of a body move in the opposite direction to the travelling wave, whereas compression pulses travel in the same direction. Torsional waves travel or oscillate in a plane which is transverse to the direction of the wave motion.

The conditions of one-dimensional impact stress waves can be devised from basic energy principles. Consider the prismatic section in Figure 8.15. Defining:

C_L = the longitudinal wavefront speed
V_o = the velocity of the prismatic section
A_o = the plane area of the prismatic section
σ_o = the stress acting on area A_o
ρ = the density of the section

and equating the change in momentum to the impuse load gives

$$(A_oC_Lt\rho)V_o = (\sigma_oA_o)t$$

Thus

$$\sigma_o = \rho C_L V_o \tag{8.15}$$

where

$$C_L = \sqrt{\frac{E}{\rho}} \tag{8.16}$$

A similar expression can be derived for torsional loading on a 'thin-walled' tube, outside diameter d_o:

$$\tau = \rho C_T d_o \frac{\omega}{2} \tag{8.17}$$

where

$$C_T = \sqrt{\frac{G}{\rho}} \tag{8.18}$$

and ω = angular velocity.

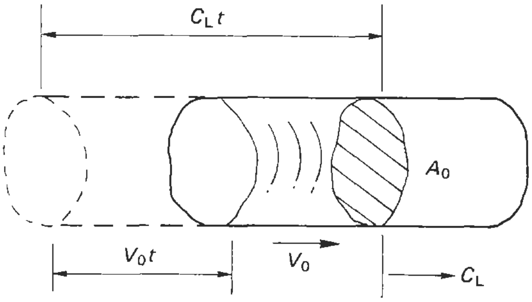

Figure 8.15 Uniform bar under the action of a stress wave

8.1.7.2 Typical elastic longitudinal and torsional wave speeds

In Table 8.1 C_L and C_T vary with temperature because E is especially sensitive to temperature. Also, C_L varies with direction for non-isotropic materials such as fibre-reinforced composites. With material such as concrete, Young's Modulus is different between tension and compression, producing unusual behaviour.

The mathematical and experimental behaviour of materials under impact loading can be very complex and is described in more detail in references 5 and 6. The analysis outlined in these references is the foundation upon which explosive forming or welding is based.

Table 8.1

	C_L (m/s)	C_T (m/s)
Mild steel	5150	3230
Aluminium	5090	3110
Glass	5300	3260
Epoxy resin	1540	950
Cast iron	3960	2470

8.1.8 Orthotropic material

An important classification of material used more frequently in recent years is the fibre-reinforced composite. This material has different properties in different directions, the high-stiffness properties being in the direction of the reinforcing

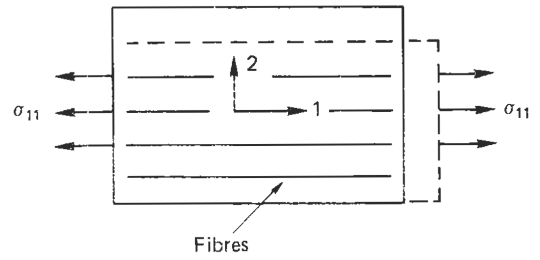

Figure 8.16 Principal directions for a laminate

fibres. A set of equations similar to those used for isotropic materials can be derived and used with care for certain design considerations.

These types of materials are constructed from thin sheets, known as laminates. They are fabricated by stacking together sets of unidirectional or bidirectional layers (also termed plies or lamina) in predetermined directions and thickness to give the desired performance characteristics.

Consider a single lamina with the axis set shown in Figure 8.16 and assuming plane stress conditions, the relationship between stress and strain is as follows:

$$\epsilon_{11} = \frac{\sigma_{11}}{E_{11}} - \nu_{21}\frac{\sigma_{22}}{E_{22}}$$

$$\epsilon_{22} = \frac{\sigma_{22}}{E_{22}} - \nu_{12}\frac{\sigma_{11}}{E_{11}} \qquad (8.15)$$

$$\epsilon_{12} = \frac{\tau_{12}}{G_{12}}$$

From symmetry,

$$\frac{\nu_{12}}{E_{11}} = \frac{\nu_{21}}{E_{22}}$$

By manipulating equations (8.15) a stress–strain stiffness matrix can be formed:

$$\begin{Bmatrix}\sigma_{11}\\ \sigma_{22}\\ \sigma_{12}\end{Bmatrix} = \begin{bmatrix} Q_{11} & Q_{12} & 0\\ Q_{21} & Q_{22} & 0\\ 0 & 0 & Q_{66}\end{bmatrix} = \begin{Bmatrix}\epsilon_{11}\\ \epsilon_{22}\\ \epsilon_{12}\end{Bmatrix} \qquad (8.16)$$

where

$$Q_{11} = \frac{E_{11}}{(1 - \nu_{12}\nu_{21})}$$

$$Q_{12} = Q_{21} = \frac{\nu_{12}E_{22}}{(1 - \nu_{12}\nu_{21})} = \frac{\nu_{21}E_{11}}{(1 - \nu_{21}\nu_{12})}$$

$$Q_{22} = \frac{E_{22}}{(1 - \nu_{12}\nu_{21})}$$

$$Q_{66} = G_{12}$$

Equation (8.15) reduces to equation (8.11) if $E_{11} = E_{22}$ and $\nu_{12} = \nu_{21}$. If the stiffness matrix $[Q]$ is inverted by matrix manipulation the compliance matrix $[S] = [Q]^{-1}$ is obtained. The corresponding strain–stress relationship can then be written

$$\begin{Bmatrix}\epsilon_{11}\\ \epsilon_{22}\\ \epsilon_{12}\end{Bmatrix} = \begin{bmatrix} S_{11} & S_{12} & 0\\ S_{21} & S_{22} & 0\\ 0 & 0 & S_{66}\end{bmatrix} \begin{Bmatrix}\sigma_{11}\\ 12\\ \sigma_{12}\end{Bmatrix} \quad \sigma_{22} \qquad (8.17)$$

where

$$S_{11} = 1/E_{11} \quad S_{22} = 1/E_{22} \quad S_{21}$$

$$S_{12} = -\nu_{12}/E_{11} \quad S_{66} = 1/G_{12}$$

When a unidirectional reinforced orthotropic lamina is loaded only in the principal material directions the deformation is independent of any shearing effects and there is no coupling between in-plane and shear strain. This is not the case when the loading is applied at some arbitrary angle θ to the principal axis (Figure 8.17).

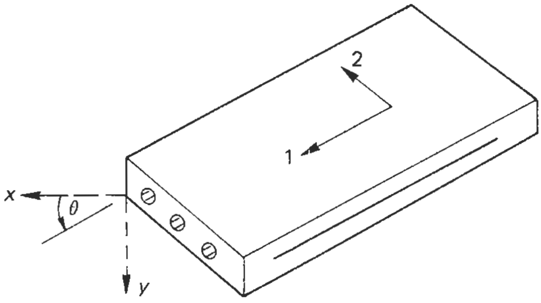

Figure 8.17 Orientated

It is possible to derive a transformation relating strains and stresses in two axes by a process similar to that used to derive Mohr's circle. As with Mohr's circle, half the 'engineering' shear strain must be used in the transformation.

Expressing stress in the x,y coordinate system in terms of stresses in the 1,2 coordinate system in the following way:

$$\begin{Bmatrix}\sigma_x\\ \sigma_y\\ \sigma_{xy}\end{Bmatrix} = \begin{bmatrix} m^2 & n^2 & -2mn\\ n^2 & m^2 & 2mn\\ mn & -mn & m^2 - n^2\end{bmatrix} \begin{Bmatrix}\sigma_1\\ \sigma_2\\ \tau_{12}\end{Bmatrix} \qquad (8.18)$$

where $m = \cos\theta$ and $n = \sin\theta$,

$$\{\sigma_{xy}\} = [T]\,\{\sigma_{12}\}$$

$$\{\sigma_{xy} = [T]Q\{\epsilon_{12}\} = [T]\,[Q]\,[T]^{-1}\{\epsilon_{xy}\} = [\overline{Q}]\,\{\epsilon_{xy}\}$$

where

$$\overline{Q}_{11} = Q_{11}m^4 + 2m^2n^2(Q_{12} + 2Q_{66}) + Q_{22}n^4$$

$$\overline{Q}_{22} = Q_{11}n^4 + 2m^2n^2(Q_{12} + 2Q_{66}) + Q_{22}m^4$$

$$\overline{Q}_{12} = m^2n^2(Q_{11} + Q_{22} - 4Q_{66}) + Q_{12}(m^4 + n^4)$$

$$\overline{Q}_{66} = m^2n^2(Q_{11} + Q_{22} - 2Q_{12} - 2Q_{66}) + Q_{66}(m^4 + n^4)$$

$$\overline{Q}_{16} = m^3n(Q_{11} - Q_{12} - 2Q_{66}) + (Q_{12} - Q_{22} + 2Q_{66})n^3m$$

$$\overline{Q}_{26} = n^3m(Q_{11} - Q_{12} - 2Q_{66}) + (Q_{12} - Q_{22} + 2Q_{66})m^3n$$

and $[T]$ is called the transformation matrix.

Using the same matrix manipulation, the reduced compliance matrix can be generated as follows:

$$\begin{Bmatrix}\epsilon_x\\ \epsilon_y\\ \epsilon_{xy}\end{Bmatrix} = \begin{bmatrix} \overline{S}_{11} & \overline{S}_{12} & \overline{S}_{16}\\ \overline{S}_{12} & \overline{S}_{22} & \overline{S}_{26}\\ \overline{S}_{16} & \overline{S}_{26} & \overline{S}_{66}\end{bmatrix} \begin{Bmatrix}\sigma_x\\ \sigma_y\\ \sigma_{xy}\end{Bmatrix} \qquad (8.19)$$

where

$$\overline{S}_{11} = S_{11}m^4 + m^2n^2(2S_{12} + S_{66}) + S_{22}n^4$$

$$\bar{S}_{22} = S_{11}n^4 + m^2n^2(2S_{12} + S_{66}) + S_{22}m^4$$
$$\bar{S}_{12} = m^2n^2(S_{11} + S_{22} - S_{66}) + S_{12}(m^4 + n^4)$$
$$\bar{S}_{66} = 2m^2n^2(2S_{11} + 2S_{22} - 4S_{12} - S_{66}) + S_{66}(m^4 + n^4)$$
$$\bar{S}_{16} = m^3n(2S_{11} - 2S_{12} - S_{66}) - (2S_{22} - 2S_{12} - S_{66})n^3m$$
$$\bar{S}_{26} = n^2m(2S_{11} - 2S_{12} - S_{66}) - (2S_{22} - 2S_{12} - S_{66})m^3n$$

Using equations (8.19) it can be shown that the elastic properties can also be defined in the *x*,*y* direction relative to the principal planes, so that

$$\frac{1}{E_x} = \frac{m^2}{E_1} + \left(\frac{1}{G_{12}} - \frac{2\nu_{12}}{E_1}\right)m^2n^2 + \frac{n^2}{E_2}$$
$$\frac{1}{E_y} = \frac{n^2}{E_1} + \left(\frac{1}{G_{12}} - \frac{2\nu_{12}}{E_1}\right)m^2n^2 + \frac{m^2}{E_2} \qquad (8.20)$$
$$\frac{1}{G_{xy}} = 2\left(\frac{2}{E_1} + \frac{2}{E_2} + \frac{4\nu_{12}}{E_1} - \frac{1}{G_{12}}\right) m^2n^2 + \left(\frac{m^4n^4}{G_{12}}\right)$$
$$\nu_{xy} = E_x\left\{-\frac{\nu_{12}}{E_{11}}(m^4 + n^4) - m^2n^2\left(\frac{1}{E_1} + \frac{1}{E_2} - \frac{1}{G_{12}}\right)\right\}$$

8.1.8.1 Laminates

In the cases of laminates fabricated from individual lamina equations (8.15) to (8.19) are used to evaluate the properties of each layer. The layers are then summed to obtain the in-plane and bending stiffnesses of the laminate. This stiffness is then used in conjunction with the known applied loads in order to obtain the laminates in-plane strains and curvature based on plate or beam theory.

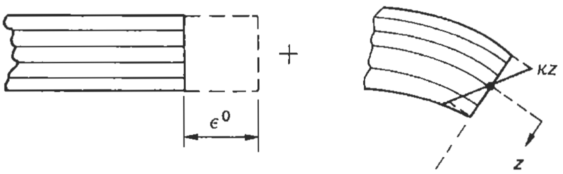

Figure 8.18 Laminate strains

Using the notation in Figures 8.18 and 8.19, the relationship between strain and load is given by

$$\begin{Bmatrix} N \\ M \end{Bmatrix} = \begin{bmatrix} A & B \\ B & D \end{bmatrix} \begin{Bmatrix} \epsilon \\ \kappa \end{Bmatrix} \qquad (8.21)$$

where

$$A_{ij} = \sum_{k=1}^{n} [\overline{Q}_{ij}]_k\{Z_k - Z_{k-1}\}$$
$$B_{ij} = \frac{1}{2}\sum_{k=1}^{n} [\overline{Q}_{ij}]_k\{Z^2{}_k - Z^2{}_{k-1}\}$$
$$D_{ij} = \frac{1}{3}\sum_{k=1}^{n} [\overline{Q}_{ij}]_k\{Z^3{}_k - Z^3{}_{k-1}\}$$

ϵ = strain to normal extension
κ = curvature

Thus the stress at any layer is given by

$$\sigma_x = \overline{Q}_j\epsilon_x + z\overline{Q}_j\kappa_x$$
$$\sigma_y = \overline{Q}_j\epsilon_y + z\overline{Q}_j\kappa_y \qquad (8.22)$$
$$\sigma_{xy} = \overline{Q}_j\epsilon_{xy} + z\overline{Q}_j\kappa_{xy}$$

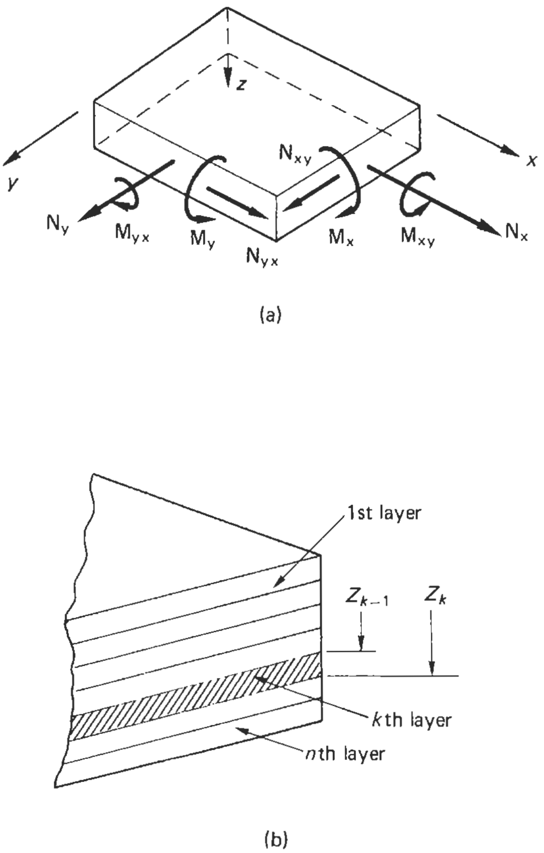

Figure 8.19 (a) Notation for a full laminate; (b) notation for a single laminate

These calculations can be carried out on almost any commercial microcomputer that has matrix inversion routines. This type of analysis can also be adapted for finite-element methods in order to obtain the relative stiffness of a particular section in a component. The above analysis must be used with caution if the laminate becomes quite thick and plane stress conditions no longer occur, i.e. through-thickness stresses may become significant (see references 5–10 for more information).

8.1.9 Plasticity

The behaviour of materials beyond the level of strain whereby there is no longer a linear relationship between stress and strain is called plasticity. In this type of behaviour the material will no longer return to its original shape once the load is removed; in fact a permanent deformation will occur in the material (Figure 8.20).

In dealing with stress systems beyond the elastic limit, similar to those associated with metal forming, the 'engineer's' definition of stress and strain becomes obsolete and stress and strain are defined with respect to the current deformed states. These stresses and strains are usually termed 'true stress and true strain'.

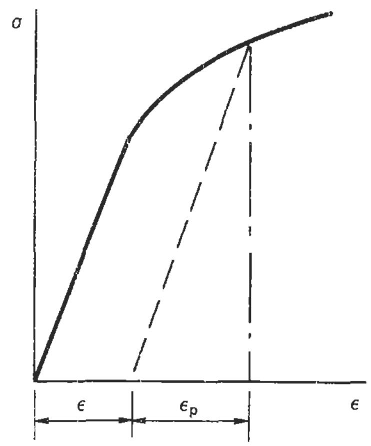

Figure 8.20 Typical stress–strain curve

$$\text{True stress, } \sigma, \text{ is defined as } \frac{\text{Load}}{\text{Current cross-sectional area}} \tag{8.23}$$

$$\text{True strain, } \epsilon_p, \text{ is defined as } \frac{\text{Change in length}}{\text{Current length}}$$

$$\epsilon_p = \int_{L_0}^{L} \frac{dL}{L} = \ln\left(\frac{L}{L_0}\right) = \ln(1 + \epsilon) \tag{8.24}$$

where L is current length and L_0 is the original length.

True strain is often quoted as natural or logarithmic strain. The advantage of natural strains over engineering strains is that the strains are additive and for most large strain (plastic) processes the change in volume during the processes is approximately zero. Hence, the sum of the three principal strains can be approximated to zero, i.e. $\epsilon_{p1} + \epsilon_{p2} + \epsilon_{p3} = 0$, a condition exploited in the analysis of metal forming.

Problems associated with plasticity can sometimes be those in which a section has partly yielded but other connecting sections remaining elastic, the plastic strains being of similar magnitude to the elastic strains. The compatibility equations and the stress–strain relationships become difficult to handle and complete solutions are very rare.

In cases where the plastic strains are large compared to the elastic strains it is sometimes permissible to neglect the elastic strains, hence greatly simplifying the solution process. The idealization of the material behaviour within this range of applicability is used by engineers for design work in the fields of structural design, dynamic behaviour and metal forming.

Material idealization usually falls into five categories:

1. Perfectly elastic (Figure 8.21(a));
2. Rigid, perfectly plastic (Figure 8.21(b));
3. Rigid, linear work hardening (Figure 8.21(c));
4. Elastic, perfectly plastic (Figure 8.21(d)); and
5. Elastic, linear work hardening (Figure 8.21(e)).

Models can be more complicated to take structural damping or load rating into account but analyses become extremely complex.

In the field of structural engineering the use of rigid-perfectly plastic idealization can be a useful design tool for selecting a specific structural member. The philosophy is based on that a frame or beam cannot deflect indefinitely or collapse until the full plastic moment, M_p, has been developed at critical sections to form a collapsed structure.

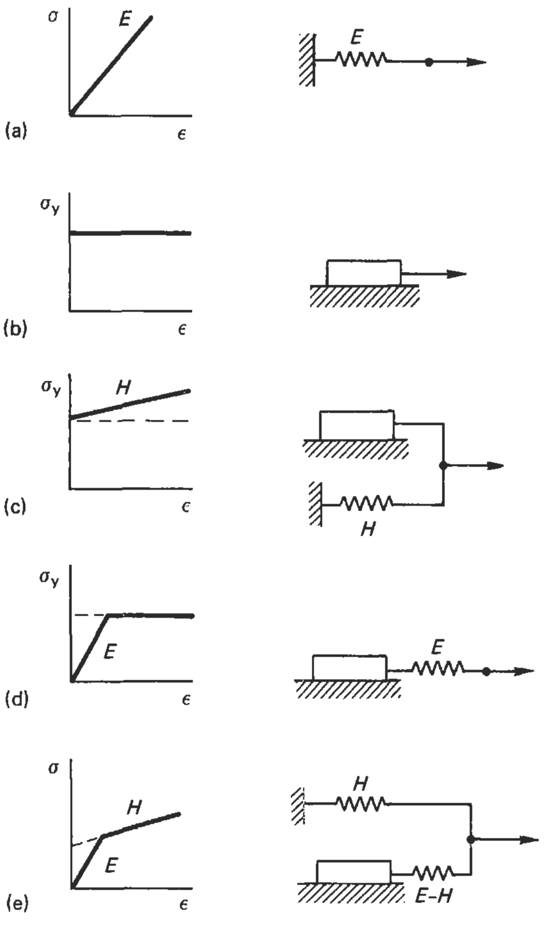

Figure 8.21 Schematics of material behaviour

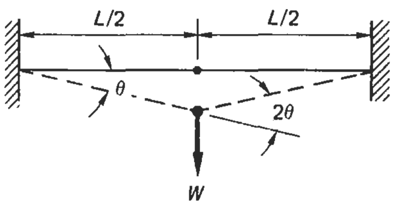

Figure 8.22 Plastic collapse mechanism for a built-in beam

A simple illustration of the procedure is shown in the following example of a uniform beam built in at both ends carrying a central concentrated load as in Figure 8.22. Under the action of increasing load, W, plastic hinges form once the section becomes fully plastic at three points. No collapse will occur unless three hinges are formed. Between the region of the plastic hinge the beam is considered to be rigid. At the instant of collapse the work done by the load W is $W(L/2)\phi$. The rate of energy loss by the plastic hinges is $M_p\phi + M_p \cdot 2\phi + M_p\phi$. Thus equating the two gives

$$W = \frac{8 \cdot M_p}{L}$$

This method produces an upper-bound solution or an overestimate to the collapse load. The stress–moment relationship is the same as that for simple bending providing that the plastic modulus (z_p) is used, i.e.

$$\sigma = \frac{M_p}{z_p}$$

Values of plastic modulus are given in most beam-design tables.

In determining loads for more complex problems (e.g. portal frames) it is the practice to 'guess' the position of the plastic hinges so that the structure will become a mechanism. The procedure becomes a trial process, the optimum solution being the mechanism that gives the lowest collapse load.

Consider the design of a rectangular portal frame (Figure 8.23) made from column and beam sections. Since the columns have different collapse moments from the beams, hinges can occur in a variety of combinations producing six possible modes of collapse. Denoting beam collapse by M_b and column by M_c we have:

(a) $4M_b = Wl$

(b) $2M_c = Wl$

(c) $2M_c + 4M_b = 3Wl$

(d) $2M_b + 2M_c = Wl$

(e) $2M_b + 2M_c = 2Wl$

(f) $4M_c + 2M_b = 3Wl$

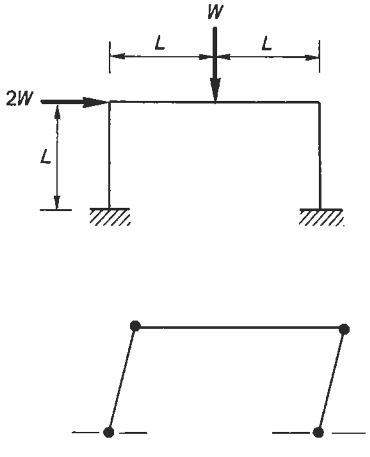

Figure 8.23 Rectangular portal frame

These sets of equations can be represented by coordinate axes in Figure 8.25. It follows that all possible combinations of M_b and M_c required by the frame under the given loads are represented by the line segments a–f which are convex towards the origin. The shaded region in the figure is called the permissible region, since plastic collapse does not occur for any design represented by a point lying in this region. Points to the origin side of the boundary a,b,c,d,e,f represent designs which cannot support the given loads.

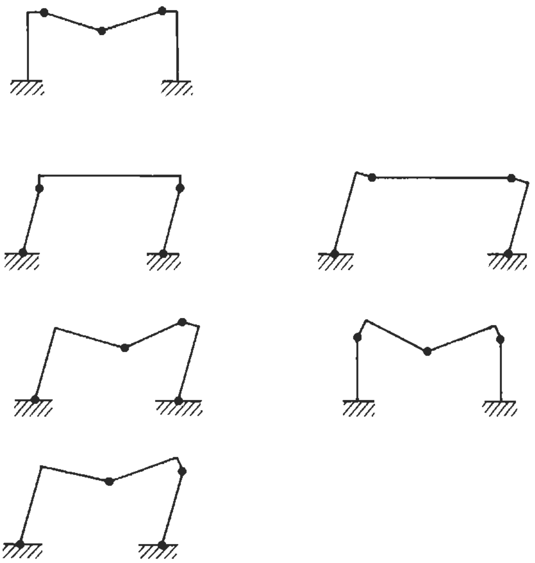

Figure 8.24 Collapse mechanism for the portal frame in Figure 8.23

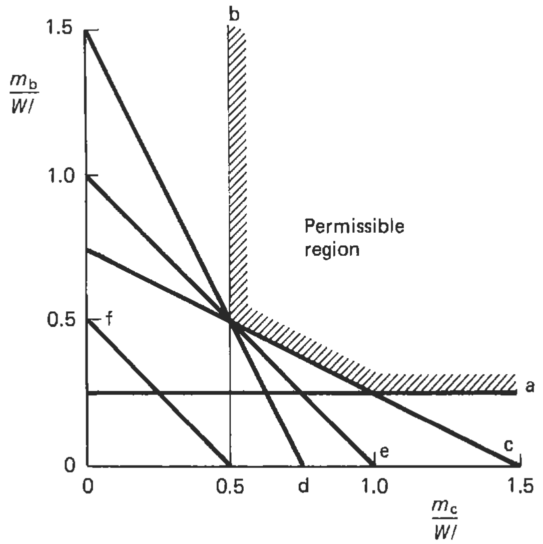

Figure 8.25 Geometrical analog for the plastic design of a portal frame

8.2 Experimental techniques

8.2.1 Strain gauges

Electrical resistance strain gauges are the most frequently used devices in experimental stress analysis today. This type of gauge is frequently employed as a sensor in transducers to measure load, torque, pressure and acceleration.

The basic principles go back to 1856, when Lord Kelvin used copper and iron rods to observe the characteristic of the modern strain gauge. This has led to the following developments and observations:

1. The resistance of wire changes as a function of strain.
2. Different materials have different sensitivities.
3. The Wheatstone bridge can be used to measure the relevant quantities more accurately than single gauges.

Today bonded foil gauges monitored with a Wheatstone bridge has become a high perfected (accurate) measuring system. Precise results can be obtained quickly using relatively simple methods with inexpensive gauges and instrumentation systems.

8.2.2 Basic principles

The resistance, R, of a uniform conductor length, L, cross-sectional area, A, specific resistance, ρ, is related by

$$R = \frac{\rho L}{A} \tag{8.25}$$

Differentiation with respect to R gives

$$\frac{\mathrm{d}R}{R} = \frac{\mathrm{d}\rho}{\rho} + \frac{\mathrm{d}L}{L} + \frac{\mathrm{d}A}{A}$$

$$= \frac{\mathrm{d}\rho}{\rho} + (1 + 2\nu)\frac{\mathrm{d}L}{L} \tag{8.26}$$

Defining sensitivity by

$$\frac{(\Delta R/R)}{\epsilon} = 1 + 2\nu + \frac{(\mathrm{d}\rho/\rho)}{\epsilon} = F \tag{8.27}$$

The sensitivity is not constant but is dependent upon the amount of coldwork, impurities and strain rate. Most commercial gauges are based upon a copper–nickel alloy because of the linearity over a wide range and excellent thermal stability.

Modern gauges are of the foil type, that is, a thinly etched pattern on a metal foil (Figure 8.26). Common foil gauges have a lower limit on resistance of about 90 Ω, ranging in length from 2 mm to 100 mm. Standard resistances are 120 Ω and 350 Ω, although some gauges are available in 1000 Ω resistance.

The gauges are commercially supplied on a thin plastic (epoxy or polyamide resins) base because of the fragile nature of the metal foil. The carrier base also acts as an electrical insulation. Gauges are also commonly supplied in the form of rosettes (two or three gauges) as in Figure 8.29 or stack configurations or specific arrangements for diaphragm transducers used in pressure measurement (see Figure 8.28). Occasionally, special-purpose gauges are available for which bonded wire, weldable strain gauges or semiconductor gauges are the most suitable solution to the problem, but they are usually expensive.

A major concern with the application of the strain gauges is the surface adhesion between the gauge unit and the surface of the component. The adhesive serves as a vital function: it must transmit the strain from the component's surface to the gauge. Adhesives can influence the gauge factor, hysteresis and temperature performance. Modern adhesives are relatively cheap but incorrect application can prove to be very costly. Surfaces for strain gauge application must be clean, degreased and surface treated if metals are involved. Environment effects attack most adhesives, so if hazardous conditions prevail, the gauge unit and adhesive are usually covered with a polymeric coating.

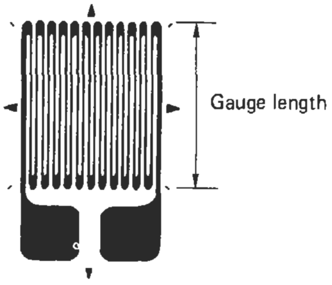

Figure 8.26 Typical strain gauge unit

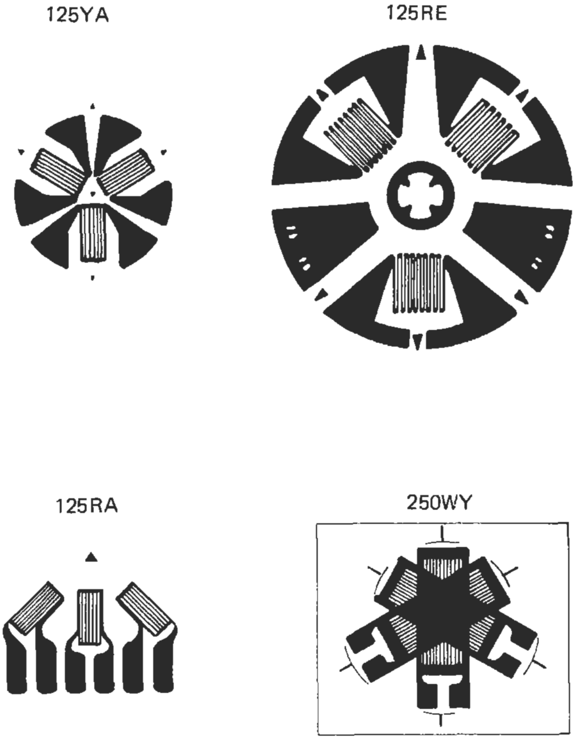

Figure 8.27 A selection of strain gauge rosettes (by permission of Welywn Strain Ltd, UK)

8.2.3 Gauge factor

The end loops of a foil gauge (see Figure 8.26) are enlarged to desensitize the effects of cross (transverse) sensitivity. The axial segments of the grid pattern have a large width-to-thickness ratio, hence some amount of transverse strain will be transmitted through the adhesive and the carrier will produce some response in addition to the axial-strain response. The magnitude of transverse strain is a function of all three materials, namely, the gauge, the adhesive coating and the component.

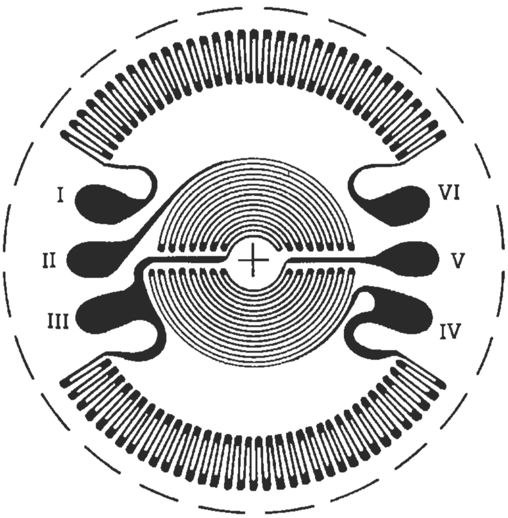

Figure 8.28 Micro-Measurements 'JB' pattern strain gauge for diaphragm pressure transducers (by permission of Welwyn Strain Ltd, UK)

The response of a bonded strain gauge to a biaxial strain field can be expressed as

$$\frac{\mathrm{d}R}{\mathrm{R}} = F_a\epsilon_a + F_t\epsilon_t + F_s\gamma_{at} \tag{8.28}$$

where ϵ_a is the normal strain in the axial direction of the gauge, ϵ_t is the normal strain in the transverse direction of the gauge, γ_{at} is the shear strain, F_a is the sensitivity of the gauge to the axial strain, F_t is the sensitivity of the gauge to the transverse strain and F_s the sensitivity of the gauge to the shearing strain.

For most gauges the shear sensitivity is small and can be neglected. Hence equation (8.28) can be reduced to

$$\frac{\mathrm{d}R}{R} = F_a(\epsilon_a + K_b\epsilon_t) \tag{8.29}$$

where $K_t = F_t/F_a$ is defined as the cross- (transverse) sensitivity factor for the gauge.

Strain gauge manufacturers provide a calibration constant known as the gauge factor F for each gauge supplied, defined as $\mathrm{d}R/R = F\epsilon$. The calibration test is usually carried out by a uniaxial tensile test on a piece of material with a Poisson's ratio, ν_c; thus $\epsilon_t = -\nu_c\epsilon_a$. Equation (8.29) now can be written as

$$\frac{\mathrm{d}R}{R} = F_a(1 - \nu_c K_c)\epsilon_a \tag{8.30}$$

Comparing equations (8.28) and (8.30) gives

$$F = F_a(1 - \nu_c K_t) \tag{8.31}$$

It is important to realize that for any strain field except that corresponding to a uniaxial stress field on a material with the same Poisson ratio as the calibration material there will always be an error in the indicated strain if the cross sensitivity is not zero. In many instances, the error is small enough to be neglected, but in some cases it is not. The error due to cross sensitivity for a strain gauge oriented at any angle, in any strain field, on any material, can be expressed as

$$n\epsilon = \left\{\frac{K_t(\epsilon_t/\epsilon_a) + \nu_c}{1 - \nu_c K_t}\right\} \cdot 100 \tag{8.32}$$

where $n\epsilon$ is the error as a percentage of the actual strain along the gauge axis. By inspecting equation (8.32) it can be observed that the cross sensitivity increases with the absolute values of K_t and ϵ_t/ϵ_a. Equation (8.28) can be approximated to

$$n\epsilon \sim K_t\frac{\epsilon_t}{\epsilon_a} \cdot 100 \tag{8.33}$$

provided the strain ratio ϵ_t/ϵ_a is not close to ν_c. A plot of equation (8.32) is shown in Figure 8.29 for convenience in estimating errors indicating strain readings. The approximated equation can also be checked against these curves.

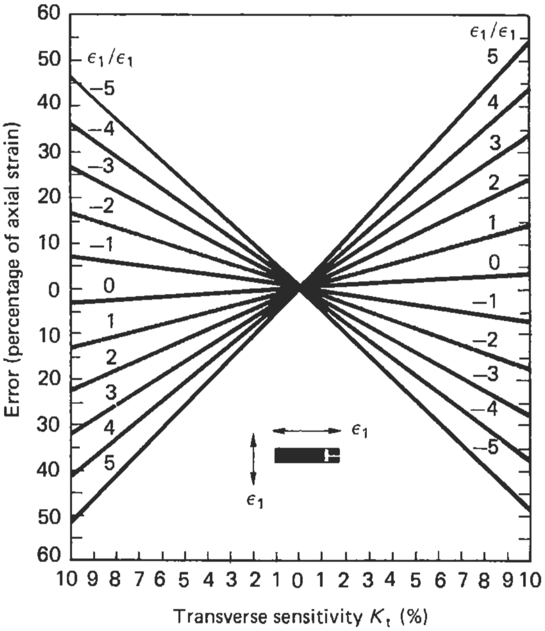

Figure 8.29 Errors due to transverse sensitivity of a strain gauge

8.2.4 Strain gauge arrangements

8.2.4.1 The Wheatstone bridge

Wheatstone bridges are common circuits frequently used in strain gauge systems in order to improve the sensitivity and cancel out temperature effects.

In the circuit shown in Figure 8.30 the change in output voltage (ΔV_o) is proportional to the strain reading, and can be shown to be

$$\Delta V_o = \frac{V_i R_2}{R_1[1 + (R_2/R_1)]^2}\left(\frac{\Delta R_1}{R_1} - \frac{\Delta R_2}{R_2} + \frac{\Delta R_3}{R_3} - \frac{\Delta R_4}{R_4}\right) \tag{8.34}$$

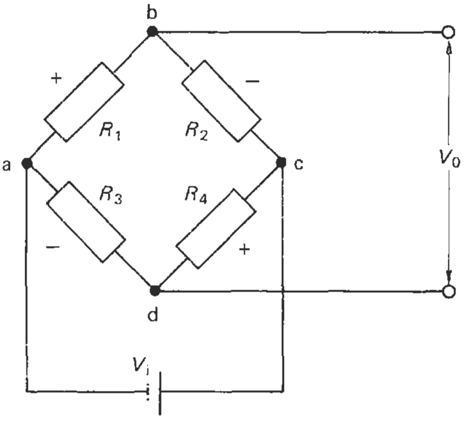

Figure 8.30 Constant-voltage Wheatstone bridge

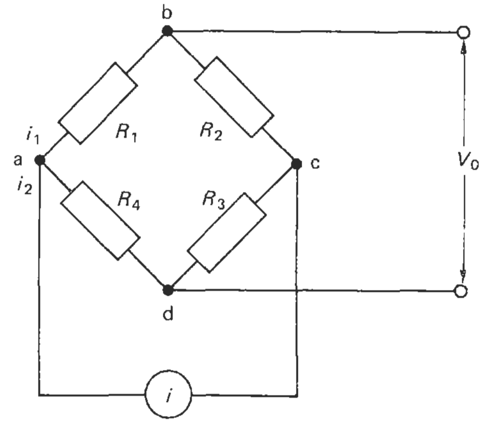

Figure 8.31 Constant-current Wheatstone bridge

Defining sensitivity of the circuit by

$$S_o = \frac{\Delta V_o}{\epsilon} = \frac{V_i R_2}{R_1[1 + (R_2/R_1)]^2}\left(\frac{\Delta R_1}{R_1} - \frac{\Delta R_2}{R_2} + \frac{\Delta R_3}{R_3} - \frac{\Delta R_4}{R_4}\right) \tag{8.35}$$

it can be seen that the circuit sensitivity is a function of the number of active arms, the gauge factor, the input voltage and the ratio of resistances R_1/R_2. The maximum sensitivity of the circuit is when $R_1 = R_2$. With four active arms in the bridge a circuit sensitivity of $F_g V_i$ can be achieved, whereas with one active arm a circuit sensitivity of only $F_g V_i/4$ can be obtained. When the bridge supply voltage V_i is selected to drive the gauges in the bridge so that they dissipate the maximum allowable power, a different sensitivity equation must be used. This is fully described in reference 13. Most experimental tests use single-active-arm circuits with the signal from a bridge amplified by factors of 10–1000 before records are taken. Multi-active-arm circuits are normally employed for transducer application where care must be taken as to which arm is used for either temperature or the Poisson gauge to give maximum sensitivity (see reference 13).

Constant-current systems are also used, though these systems exhibit non-linear output whenever the changes in resistance are large; this therefore limits their usage. Recent advances in the area of electronics have led to constant-current devices being common in modern industry. These are based on a high-impedance system which changes the output voltage with respect to the resistive load in order to maintain a constant-current set-up.

Consider the arrangement in Figure 8.31 for a Wheatstone bridge with a constant current. It can be shown that the change in output voltage ΔV_0 is given by

$$\Delta V_o = \frac{I_i R_1 R_3}{\Sigma(R + \Delta R)}\left(\frac{\Delta R_1}{R_1} - \frac{\Delta R_2}{R_2} + \frac{\Delta R_3}{R_3} - \frac{\Delta R_4}{R_4} + \frac{\Delta R_1 \Delta R_3}{R_1 R_3} - \frac{\Delta R_2 \Delta R_4}{R_2 R_4}\right) \tag{8.36}$$

where

$$\Sigma(R + \Delta R) = R_1 + \Delta R_1 + R_2 + \Delta R_2 + R_3 + \Delta R_3 + R_4 + \Delta R_4$$

Equation (8.36) shows that there are non-linear terms in the equation. However, the non-linear effects in this circuit are less than those associated with constant-voltage systems. Good circuit design can lead to the non-linear terms being negligible, even for large changes in resistance.

The resistance change for a metallic foil strain gauge is quite small. Consequently, any item which produces resistance changes within the Wheatstone bridge is extremely important. Since all foil gauges have lead wires, soldered joints and binding posts connected to them, their effects on the resistance to a particular gauge can be significant. Lead wires which, in general, are long compared to the strain gauges can cause significant errors due to the temperature effects associated with these leads. These effects are usually minimized by employing the three- or five-wire system similar to that shown schematically in Figure 8.32. In this circuit, both the active and dummy gauges are placed at a remote location. One of the three wires is used to connect terminal a of the bridge to a remote location. This wire is not a lead wire since it is not connected to R_1 or R_4. The active and dummy gauges have one long wire each with a resistance R_i and one short wire with negligible resistance. The bridge is still initially balanced since both arms R_1 and R_4 are increased by R_l. The change in output voltage is now given by

$$\Delta V_o = \frac{V_o R_1}{R_4[1 + (R_1/R_4)]^2}\left\{\left(\frac{\Delta R_1}{R_1 + R_l}\right)_\epsilon + \left(\frac{\Delta R_1}{R_1 + R_l}\right)_{\Delta t} + \left(\frac{\Delta R_l}{R_1 + R_l}\right)_{\Delta t} - \left(\frac{\Delta R_1}{R_1 + R_l}\right)_{\Delta t} - \left(\frac{\Delta R_l}{R_1 + R_l}\right)_{\Delta t}\right\} \tag{8.37}$$

where ϵ represents induced strain and ΔT temperature changes. Temperature compensation is thus achieved since all the temperature-related terms (ΔT) cancel each other out.

Other effects such as switches, electrical noise and slip rings are beyond the scope of this chapter but are described in detail in reference 13.

8.2.4.2 Load cells

Strain gauge circuits are used frequently in load cell design because of their relative ease and cheapness. To produce a simple load-measuring transducer, a simple tension bar is used

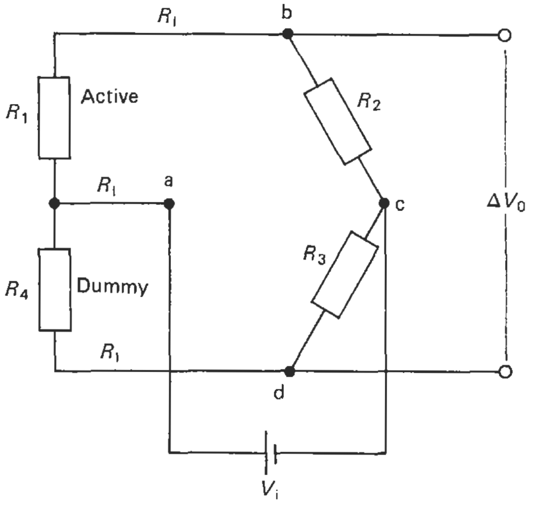

Figure 8.32 Three-wire compensation arrangement

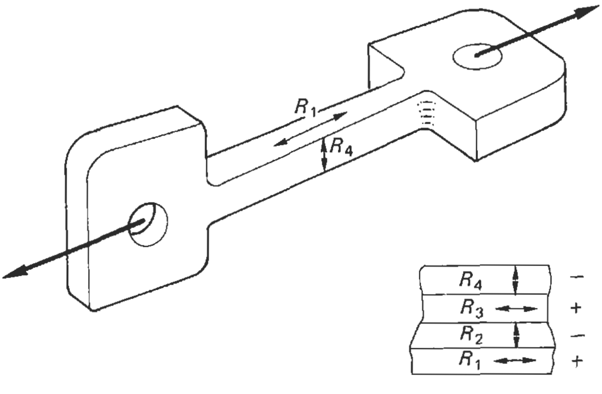

Figure 8.33 Strain gauge set-up for a load cell

with four or eight gauges attached to the surface at the central region of a simple bar. Two gauges are mounted in the axial direction and two opposite gauges in the transverse direction as shown in Figure 8.33. If the tension bar is subjected to a load P the following strains are produced:

$$\epsilon_a = \frac{P}{AE}, \ \epsilon_t = \frac{\nu P}{AE} \tag{8.38}$$

where A is the cross-sectional area,
E is the Young's modulus, and
ν is the Poisson ratio,

If the four gauges are positioned in the Wheatstone bridge as shown in Figure 8.30, the ratio of output voltage to supply voltage $\Delta V_o/V_i$ is given by

$$\frac{\Delta V_o}{V_i} = \frac{1}{4}\left(\frac{\Delta R_1}{R_1} - \frac{\Delta R_2}{R_2} + \frac{\Delta R_3}{R_3} - \frac{\Delta R_4}{R_4}\right) \tag{8.39}$$

since

$$\frac{\Delta R_1}{R_1} = \frac{\Delta R_3}{R_3} = F\epsilon_a = \frac{FP}{AE}$$

and

$$\frac{\Delta R_2}{R_2} = \frac{\Delta R_4}{R_4} = F\epsilon_t = -\frac{\nu FP}{AE}$$

$$\frac{\Delta V_o}{V_i} = \frac{FP}{2AE}(1 + \nu) \approx \frac{P}{AE}(1 + \nu) \text{ for } F \approx 2.0 \tag{8.40}$$

Equation (8.36) shows that the output is proportional to the applied load P.

The advantage of placing the four gauges allows for the nullifying of an eccentricity of load, producing bending or torsion loads since tensile and compressive strains will cancel out each other. Temperature compensation is also achieved with four active gauges in the bridge.

A special type of strain gauge is used as part of a pressure transducer. The strain gauge pattern is called the 'JB' pattern and fits centrally on one side of a thin diaphragm (see Figure 8.28). The diaphragm pressure transducer is small, easy to fabricate and inexpensive. Maximum strains occur at the centre and edges of the diaphragm, hence the requirement for the design pattern shown in Figure 8.28. Note that the solder tabs are positioned at regions of low strain. Averaging the strains over the region covered by each sensing element and averaging the output, the total gauge output ϵ_o can be expressed as

$$\epsilon_o = 820\frac{PR_0^2}{t^2E}(1 - \nu^2)\text{mV/V} \tag{8.41}$$

where P is the pressure, R_0 the diaphragm radius, t the diaphragm thickness and the gauge factor is assumed to be 2.0.

Strains induced by the pressure are non-linear if the central deflection of the diaphragm is greater than a quarter of the thickness. Therefore this type of transducer is usually calibrated for a specific pressure range in order to keep non-linear effects small.

Diaphragm pressure transducers are also used to measure pressure response, therefore it is important that, when designing the transducer, the diaphragm should have a natural frequency greater than five times the highest applied frequency. The natural frequency, F_n, can be expressed as

$$\frac{0.471t}{R_0^2}\sqrt{\left[\frac{E}{\rho(1 - \nu^2)}\right]} \tag{8.42}$$

where ρ is the density of the diaphragm material (kg/mm^3). The natural frequency of an existing unit can easily be determined experimentally by tapping the transducer at the centre of the diaphragm and noting the response on an oscilloscope.

8.2.5 Photoelasticity

Photoelasticity is a useful tool for estimating stress distributions in components with complicated geometries with or without complex load cases for which mathematical techniques are difficult or almost impossible. It provides quantitive evidence of highly stressed regions and peak stresses. Equally important, it highlights areas of low stress, leading to designs whereby materials can be utilized efficiently. It is widely used for problems in which stress or strain information extends into regions of the structure.

The photoelastic phenomenon occurs in particular plastics when they are subjected to a strain, and under this strain the light becomes polarized. When a particular plastic model (early work was carried out on glass) is stressed a ray of light enters along one of the principal stress directions (see Figure 8.34) and is divided into two component waves each with its plane of vibration (plane of polarization) parallel to one of the remaining principal planes. Furthermore, the relative retardation of the light along these paths is dependent upon the magnitude of the two remaining stresses. This phenomenon is termed birefringence or double refraction. The two pheonomena are brought together in the photoelastic polariscope (see Figure 8.35).

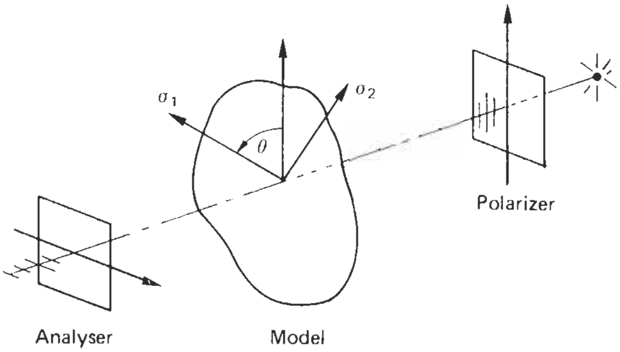

Figure 8.34 A stressed photoelastic model in a plane polariscope

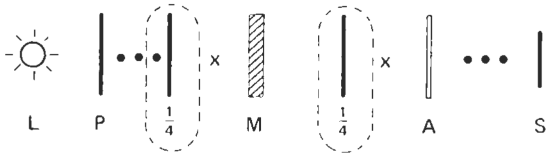

L = Light source
P = Polarizer
M = Model
A = Analyser
S = Screen
$\frac{1}{4}$ = Quarterwave plate

Figure 8.35 Polariscope arrangement with circular polarized light

If the relative retardation N is 0,1,2,3, etc. cycles, the waves of the light intensity diminish to zero (extinction) in a dark-field polariscope. Extinction may also occur in 1/2, 3/2, 5/2, 5/2, etc. cycles in a light field polariscope. That is, in a darkfield polariscope a locus of dark bands corresponding to the level of maximum shear stress are observed in the model, like the pressure potentials on a weather map. A succession of light and dark bands in a monochromatic light source or filter (usually sodium) occurs. These bands are called fringes and their value is defined as the fringe order (see Figure 8.36).

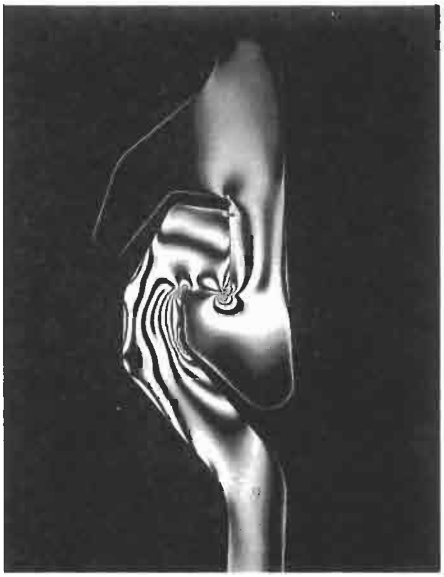

Figure 8.36 Fringe pattern for a tension coupling in a sodium light source (by permission of Sharples Stress Consultants)

8.2.5.1 *Two-dimensional analysis – plane stress*

Models used for plane stress analysis are those in which the thickness of the material through which the light travels is small relative to the other dimensions. If the principal stresses and their associated angles are required for the model they can be quickly obtained at the model's boundary and relatively easily internally by the equations of elasticity.

In order to determine these values a model is first placed in a plane polariscope and then loaded. Dark lines are seen on the model. These lines correspond to the principal planes or planes of symmetry and are termed isoclinics. Under load they define the planes but not stress magnitude. When the model is loaded a series of fringes occurs in monochromatic light which are proportional to the stress levels. Unfortunately, the fringe patterns are undistinguishable from the isoclinics, therefore the plane polariscope is only used to determine the principal planes. In order to determine the stress levels in a model it is inserted in what is termed circular polarized light. This is achieved by inserting quarter-wave plates which, due to their nature, extinguish the isoclinics, leaving only the isochromatics (fringe patterns).

In a monochromatic light source a pattern of dark and light bands is formed under load which are proportional to the model loading. Care must be taken not to exceed the elastic limit of the material.

The fringe pattern is related to the stress system by the stress optical law:

$$2\tau_{\max} = (\sigma_1 - \sigma_2) = \frac{FN}{t} \qquad (8.43)$$

where t is material thickness (mm), F is the fringe value (N/mm/fringe) and N is the measured fringe value. In terms of the fringe pattern this is defined as the number of fringes (N) that pass through these points during the application of external loading and is given as the fringe order at that point.

By removing the quarter-wave plates either manually or optically the direction as well as the magnitude at this point can instantly be obtained. Measurements of fractional fringe values as well as integer values can also be obtained by a variety of compensation techniques described in detail in references 13–16.

The F value for the model is material-dependent and is usually calibrated from the same batch of material as the model. This is obtained from testing on a piece of material with a known stress distribution, i.e. a simple tension bar, a beam under four-point bending (pure flexure) or a disk in diametrical compression.

In general, the photoelastic model is much smaller than the actual one. Thus, the prototype stress, σ_p, can be calculated from the model stress, σ_m, from

$$\sigma_p = \sigma_m \frac{t_m}{t_p} \frac{P_p}{P_M} \frac{L_M}{L_p} \tag{8.44}$$

where the subscript m represents the model and p the prototype, P is the loading, t the thickness and L the relative length. Displacements, δ, can also be calculated by

$$\delta_p = \delta_m \frac{P_p}{P_M} \frac{E_M}{E_p} \frac{t_M}{t_p} \tag{8.45}$$

where E is the relative Young's modulus.

It is clear from the above equations that component stresses can be obtained for most two-dimensional problems. The modulus of elasticity is never a problem in determining the stress distributions unless the loading is such that contact stresses occur. Also, Poisson's ratio need not be considered when the model is simply connected and the body force (gravity) is negligible.

8.2.5.2 Two-dimensional model

Materials used to produce the models must fulfil the following criteria if successful results are to be obtained:

- Linear properties
- Mechanical and optical isotropy and homegeneity
- Low creep
- Low moisture absorption
- Inexpensive
- Easily machined

Epoxy resins are the most common material for static stress conditions because of their high photoelastic sensitivity and increased freedom from mechanical and optical creep. Urethane rubber is also used, especially for dynamic problems since the material has a low modulus and the stress waves (see Section 8.1.7) induced are less than 90 ms^{-1}. Machining problems do occur with this material since the material has to be below its transition temperature before it can be machined.

An extremely useful extension of two-dimensional photoelasticity is the surface-coating method, whereby the photoelastic material is applied as a thin layer on the surface of an actual component. The cement bonding the coating to the component is usually a small-volume fraction of powdered aluminium in order to produce a reflective surface so that light travels through the coating and reflects back for a second traversal of the coating. This method is extremely useful for obtaining stresses on free surfaces of three-dimensional coatings. Measurements are usually carried out by hand-held instruments and are not limited to the linear ranges of the component, although the accuracy and resolution is much reduced.

8.2.5.3 Three-dimensional analysis

Photoelastic techniques can be applied to three-dimensional problems but with a great deal extra of work and analysis compared to two-dimensional ones. Accuracy is also reduced and sensitivity can be a problem due to large amounts of careful machining that must be carried out before any readings can be obtained.

Three-dimensional analysis is performed by using 'frozen stress' or scattered-light methods. With stress freezing techniques the stresses are locked into the model due to heat and are retrieved by slicing the model in order to produce a quasi-two-dimensional model. Scattered-light techniques do not use sliced models.

Stress freezing is the most common method adopted for stress analysis. The stresses are locked into the model by loading the model and applying a uniform heat up to a temperature above the critical temperature which unlocks the secondary bonds. The load is then kept constant for the remainder of the procedure. The temperature is set constant for a period of time and then allowed to drop with the secondary bonds permanently set into the model. The primary bonds are permanently locked into the model by the reforming of the secondary bond, producing a permanent stress pattern locked into the model. At the same time as the model is subjected to the heat cycle a calibration piece must be under the same heat cycle, since the material's fringe value will be different from that obtained by room-temperature tests.

After stress freezing the model it is carefully cut into thin slices ready for inspection in a polariscope. The stresses are then obtained by similar methods to two-dimensional analysis. Unfortunately, unless the model can be cut on a principal axis, the secondary principal stress method will have to be employed (see references 18 and 19). However, sometimes stresses are assumed not to change through the thickness of the slice and two-dimensional technique can be used. In order to check this, models are sometimes shaved by taking small cuts off the thickness and the stress pattern checked to see if it is independent of the thickness. Since all epoxy materials are abrasive, carbon-tipped tools should be used.

The use of photoelasticity and strain gauges still tend to be the most common forms of experimental stress analysis. In recent years there has been an influx of new methods available to the stress analyst, although, due to the complexity of the equipment, they are relatively expensive and require specialist knowledge. A selection of the new developments is given below.

8.2.6 Holography

By recording a holographic image of an object's visible surface, any changes in shape can be monitored by comparing the new shape with the recorded image. This is commonly known as holographic interferometry. The technique uses a fine laser to produce full-field quantitative strain maps. When used with computer-image processing, general-purpose plots can be produced for a wide range of engineering products with complex geometries, such as turbine blades and piston rings. Holography can be used for both dynamic and static loading.

Since holography is an optical technique it is a non-contacting method and problems associated with strain gauge technology do not exist. Future development in the equipment may yield cheaper and more compact apparatus, thus giving the prospect of portable systems. A detailed discussion on the usage of holography is given in references 20–23.

8.2.7 Thermo-elastic analysis

When a material is compressed adiabatically it has work done on it, and this work is evidenced by a rise in temperature. This temperature change, however, is very small – about 0.2°C at the elastic limit. By inducing a cyclic strain on the component surface, and measuring the temperature changes by infrared thermography, in conjunction with computer enhancement a sensitivity of 1×10^{-3}°C can be obtained in the measurement of temperature. This means that a typical scan of a component section can take several hours of cyclic loading, but the only specimen preparation needed is to apply a coat of matt-black paint to the surface.

Infrared radiation is emitted from a surface in all directions and therefore measurement can be made on surfaces which are not normal to the reading lens. This enables cyclindrical components to be scanned and, in some instances, irregular curved shapes. Sensitivity of stress is around 0.5–1 N mm^{-2} for common metals, although coarser readings can be used for general stress analysis. It is also possible to monitor cracks and their development under cyclic loading.

One of the present drawbacks of this technique is that it cannot tolerate large movements acting normal to the line of sight of the scanning unit.

Present thermo-elastic analysis in the UK often comes under the heading of stress-pattern analysis by thermal emission (SPATE) and is detailed in references 24 and 25.

8.2.8 Brittle-coating[13,26,27]

This technique provides a simple and direct solution to the stress distribution in a component when extreme accuracy is not required. It assumes perfect adhesion of a coating to the component. The coating is designed to have brittle characteristics.

Coatings are selected such that they fracture (crack) at relatively low levels of stress. Thus the technique is classed as non-destructive.

Modern coatings tend to be room-temperature cure resins which are pigmented.

8.2.9 X-ray analysis[28,29]

This method is particularly useful in determining residual stresses occurring in a component. It is perhaps the only non-destructive technique available to the stress analyst at present which can carry out this task.

A disadvantage of this technique is the limitation on the test sample size imposed at the X-ray diffractometer stage in the process, although this may be remedied by equipment developments in the future.

8.3 Fracture mechanics

8.3.1 Introduction

If the stresses in a cracked structure close to the tip of an infinitely fine crack were computed by elastic stress concentration factors the stress would approach infinity and a material with a crack of any size would fail under any tensile stress. The linear elastic fracture mechanics (LEFM) approach avoids this difficulty by analysing the stress field that surrounds the crack tip rather than the infinite stress at the crack tip and then identifying certain features of the field which are common to all elastic bodies.

Only a summary of the results of the analysis can be given here. For a full analysis the reader is referred to texts in the Further Reading at the end of the chapter. (Note: To facilitate comparison with the references throughout this section σ, the resolved or calculated stress, has been used for stress. In Section 8.4 S, the applied load, has been used. σ and S are sometimes (but not always) interchangeable. Some references use P for S.)

8.3.2 Linear elastic fracture mechanics

For a brittle material, A. H. Griffiths showed in 1920 that the fracture stress for an elliptical crack is

$$\sigma = (4\gamma_s E\pi^{-1}a^{-1})^{1/2} \qquad (8.46)$$

where γ_s is the surface energy of work of fracture per unit area de/da, E is the modulus of elasticity and a is the critical crack length for equilibrium.

Equation (8.46) satisfactorily predicts the behaviour of a brittle material but, for a material in which plastic flow will occur at the crack tip, a plastic work term must be added to the γ_s term. $4\gamma_s$ then becomes G_c, the strain energy release rate and a stress intensity factor K is defined as $K = \sigma\sqrt{\pi a}$ for an infinite plate. K_c, the fracture toughness, is the critical value of K for crack propagation (K_{Ic} is K_c in tension). Then

$$K_c = \sqrt{EG_c} \qquad (8.47)$$

$$= A\sigma_{crit}\sqrt{\pi a} \qquad (8.48)$$

If, for a given material, the value of K_c is determined for one value each of σ_{crit} and a, the result can be used to determine the value of σ_{crit} for any other value of a (or size of flaw) *provided the stress–strain system is identical to that in an infinite plate (plane strain conditions).*

8.3.3 Fracture toughness testing

Test procedures for carrying out such a test are laid down in ASTM 399-83 Standard Test Method for Plane Strain Fracture Toughness of Metallic Materials and the nomenclature used is defined in ASTM E616-82. BS 5447: 1977 stipulates similar methods.

There are a number of specimen designs but the most straightforward compact tension (CT) specimen 1 is shown in Figure 8.37 (Figure A4.1 from ASTM 399). Plane strain conditions are maintained by ensuring that both specimen thickness B and the crack length, a, exceed 2.5 $(K_{Ic}/\sigma_y)^2$. K_{Ic} should be overestimated. Testing under these conditions measures plane strain fracture toughness K_{Ic} in tension σ_x. Fracture toughness K_{2c} and K_{3c} can also be measured in xy shear and yz shear respectively. The customary coordinate system is illustrated in Figure 8.38 (Figure 2 from ASTM E 616). If the specimen is too small, shear will initiate at the ends of the crack and the test is then stated to be invalid.

8.3.4 Influence of shape of defect

Fracture toughness specimens contain (so far as can be ensured) cracks which are straight and orthogonal in the specimens. Crack-like defects which occur in practice are often irregular and are usually considered to have the form of an enveloping ellipse transverse to the applied stress.

For an elliptical surface flaw (see reference 35)

$$K = \sigma\sqrt{\left(2\frac{\pi}{Q}a\right)} \qquad (8.49)$$

and for an elliptical embedded flaw

$$K = \sigma\sqrt{\left(\frac{\pi}{Q}a\right)} \qquad (8.50)$$

where

$$Q \text{ (the shape parameter)} = (\phi^2 - 0.212\sigma^2 \cdot \sigma_y^{-2}) \qquad (8.51)$$

and

$$\phi = \int_0^{\pi/2} \left[\sin^2\theta + \left(\frac{a}{e}\right)^2 \cos^2\theta\right] d\theta \qquad (8.52)$$

ϕ is the complete elliptical integral of the second kind, σ the working stress and σ_y the 0.2% proof stress.

Q is plotted in Figure 8.39 for elliptical flows having crack depth and semi-minor axis a, crack length and major axis $2c$

8.3.5 Typical ranges of fracture toughness values

The properties of high-tensile steels, aluminium and titanium alloys are such that plane strain conditions can be obtained from specimens that can readily be produced. Typical values are listed in Table 8.2. Linear elastic fracture calculations can be readily carried out on structures made from these materials provided that the size and shape of defect can be determined or estimated.

Many structural steels have lower yield strengths and superior fracture toughness, and rigorous fracture toughness tests at room temperature for such materials would require specimen thicknesses of at least 300 mm. Material of this section and apparatus for carrying out such a test are by no means universally available, nor, if they were, would the results necessarily reproduce the behaviour of a component of smaller section size.

Table 8.2 Typical values of fracture toughness and yield strength for steels, titanium and aluminium alloys and pressure vessel steels

	Yield strength σ_y (MPa)	*Fracture toughness* K_{Ic} (Mn$^{-3/2}$)
Hardened steels	1500–1100	30–160
Titanium alloys	1300– 700	30–150
Aluminium alloys	600– 400	18– 35
A533 Grade B 12-inch pressure vessel steel plate	350	>160

When tests are carried out over a range of temperatures on ferritic steels the results correspond to those shown in Figure 8.40 (see reference 36). The high-temperature shelf (the upper shelf) of the fracture toughness value is characteristic of high toughness ductile fracture behaviour.

8.3.6 Post-yield fracture mechanics

When materials fail under ductile fracture conditions, LEFM is not applicable. The extra plasticity associated with the ductile fracture mechanism requires a rigorous elastic plastic fracture analysis.

There are many methods for performing elastic plastic fracture analysis. Each of them is tailored to a different type of problem, but they all reduce to one of two basic failure concepts, the J integral and the crack opening tip displacement δ. The different methods centre around the methodology of calculating and using these two parameters. Moreover, there is an identity between the two parameters, i.e.

$$J = m\sigma_y\delta \qquad (8.53)$$

where m is a constant factor, hence there is a common link between all modern methods of fracture mechanics analysis.

8.3.6.1 The J integral method

The J integral was first proposed by Rice:[30,31]

$$J = \int_P (ud_y - T_i\left(\frac{\delta u_i}{\delta x}\right)ds \qquad (8.54)$$

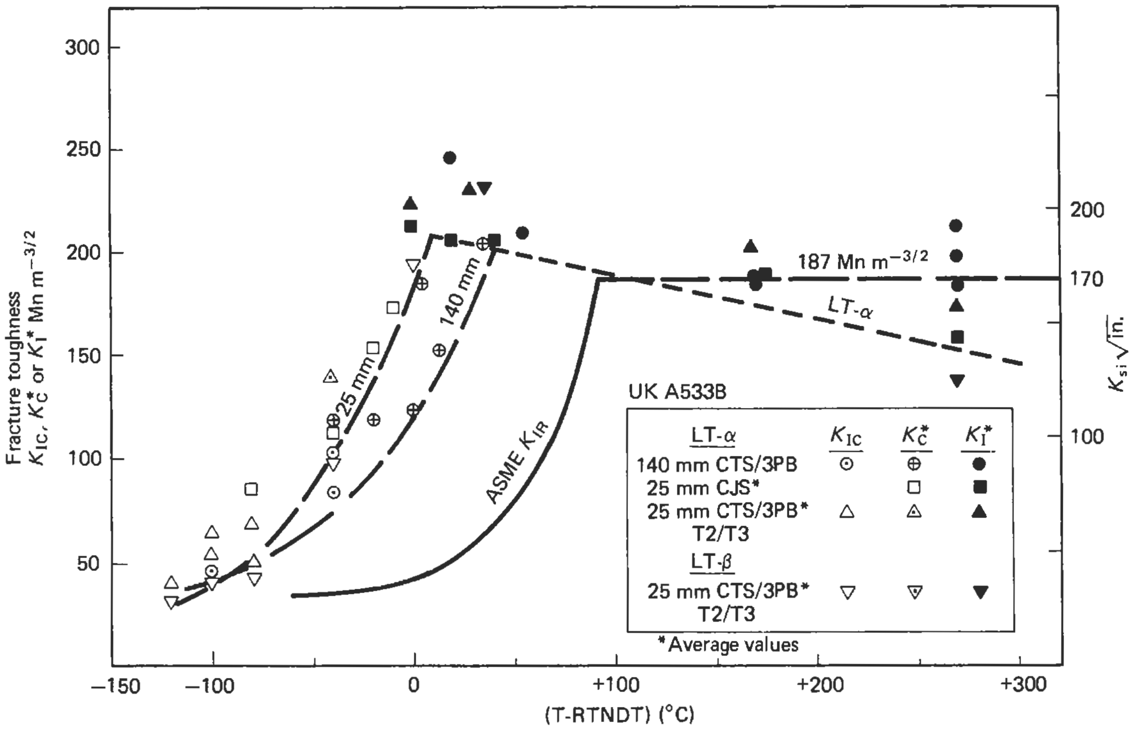

Figure 8.40 Comparison of fracture toughness data for A533 Grade B Class 1 steel of UK origin with the ASME K_{IR} curve and a constant upper shelf plateau of 170 ksi √in (reproduced by permission of Applied Science Publishers)

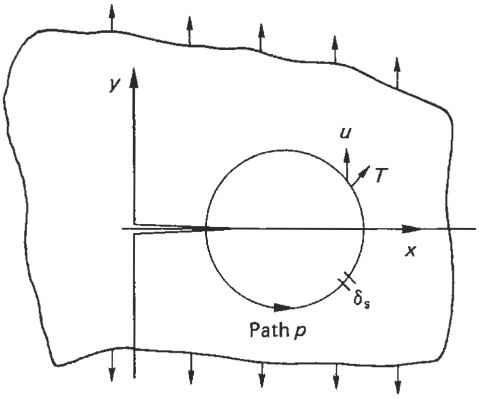

Figure 8.41 Integration path (anti-clockwise direction) about the crack tip for Rice integral (reproduced by permission of Applied Science Publishers)

where J is the path-independent integral (where $J = G$ in an LEFM case), $\mathrm{d}s$ is an element of the path P (see Figure 8.41), U is the strain energy density, T_{i} is the tension vector and $T_{\mathrm{id}u}$ is the work done when components of T move through a distance $\mathrm{d}u$.

To perform an analysis, it is necessary to calculate the J applied to a structure under the loading conditions pertinent and to compare this with J_{c}, the calculated material fracture toughness. Calculation of J applied is often a complicated business, frequently requiring finite element analysis. This is time consuming and expensive and makes the J method difficult to apply. Compendia have been developed[37–39] which use standardized routines to calculate J for a given set of geometries, and these may be used when the geometry of interest is closely simulated to the geometry contained within the compendium. However, for most practical cases, this situation does not apply.

8.3.6.2 The crack-tip opening displacement (COD) method

This method was the first practical method of performing an elastic plastic analysis.[33,40,41] The method depends upon the critical crack opening displacement on a specimen of the material and comparing this with the applied crack-tip opening displacement. The applied COD value is calculated from a curve developed to describe pessimistically the failure condition of a number of tests on cracked wide plates loaded to failure. The method is therefore empirical, but has a large body of supporting data to validate it. Consequently, this method was the main one contained in the British Standard Institute's published document PD6493, 1980.

8.3.6.3 The CEGB's R6 method

The R6 method uses a concept of a failure assessment diagram (FAD) to link LEFM with fully plastic fracture mechanics. It was written as a standardized method which is revised periodically and is now in its third revision, where it is capable of performing a full J analysis for any type of structure. The concept of the failure-assessment diagram simplifies an otherwise very complex analysis by requiring only two basic calculations to be performed. The first is in the LEFM regime and requires the calculation of K_r:

$$K_r = K_I/K_{Ic} \tag{8.55}$$

and the second is in the fully plastic regime and requires a calculation of L_r:

$$L_r = \sigma/\sigma_u^{\text{(load applied/plastic yield load)}} \tag{8.56}$$

The R6 (and J analysis) failure-assessment diagrams for a carbon manganese steel are shown in Figure 8.42 together with data obtained from centre cracked panel test specimens.

R6 is at the time of writing the most universally applied method of analysis. It is being incorporated into BSI document PD6493, along with a revised version of COD analysis based upon the R6 FAD, and it is being adapted for use in many other countries, most notably in the USA, where a new ASME X1 Appendix will be based upon R6.[33,42,43]

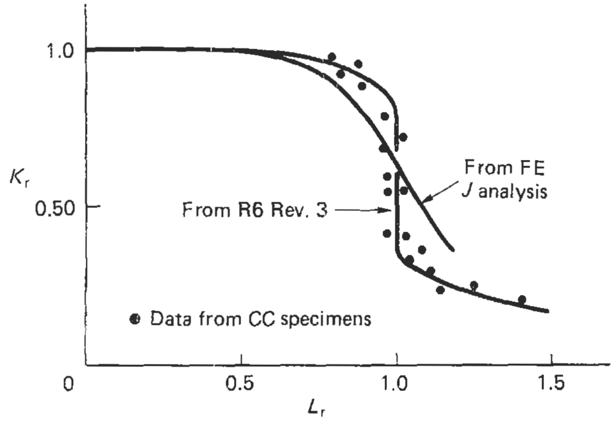

Figure 8.42 FADs for C–Mn steel and tensile test results

8.4 Creep of materials

8.4.1 Introduction

This section describes the behaviour of materials under the combined effects of (constant) elevated temperature and stress.

Creep is the strain developed in a material over a period of time by the application of a (constant) uniaxial or biaxial stress. Creep is sensibly permanent in a metal but may, to some extent, be reversible in a plastic.

Stress relaxation is the progressive reduction in stress in a material which is held for a period of time with one or two of its orthogonal dimensions greater than its rest dimensions.

The creep stress, σ_ϵ, is the stress at which a test piece made from a material strains by a specified proportion (often 1%) when held for a specific time at a specific temperature.

The creep rupture stress, σ_R, is the stress at which a test piece made from a material fractures when held for a specified time t_R at a specified temperature.

The creep rupture elongation is the proportion, expressed in percentage of the original length, by which a test piece made from a material extends before fracture.

The creep range is a range of temperature within which the criterion for design in a material is σ_ϵ or σ_R, *not* σ_y or S_n. The lower limit of the creep range approximates to $0.5T_m$. (T_m is the melting point of a material in °K.)

Static fatigue is a term frequently used to describe the failure of non-metallic materials after a sustained period of loading. In some cases static fatigue is an alternative and misleading designation for creep rupture. In others it refers to a separate phenomenon (see Section 7.6).

8.4.2 Creep and stress rupture testing

Most creep and stress rupture testing is carried out in tension at a fixed elevated temperature on cylindrical specimens 5 mm or more in diameter. Where rupture data only are required the specimens are identical in shape to the corresponding tensile test specimens.

As many as ten specimens may be loaded as a longitudinally connected string in one testing machine. Strain measurements are normally carried out cold on the specimens at infrequent intervals after the furnace holding them has cooled and also following the failure of one of the specimens.

Where precise creep data are also required circumferential vee-shaped ridges are machined on the specimen at the ends of the gauge length. Extensometer systems are clamped on the ridges, and connected to precise measuring equipment. At low temperatures strain gauges may be used. Usually, only one specimen is tested in a machine.

Tests may be carried out in special or protective environments, but normally for components operating in steam or flue gas, air is used. Conditions of testing, including accuracy and reliability of temperature control, stress and strain measurement are laid down in BS 3500 Methods for creep and stress rupture testing of metals and ASTM E139 Standard practice for conducting creep, creep rupture and stress rupture testing.

Creep, in common with most metal properties, is a statistical phenomenon and many tests must be undertaken before data that may be used with confidence in design are obtained. Figure 8.43 gives some idea of the variability in tests carried out by a number of laboratories on one grade of steel of a similar section thickness from a number of sources.

A number of other test procedures have been employed. Rectangular section specimens are sometimes used for sheet or strip materials. Testing with stress systems other than uniaxial tension have included the internal pressure testing of hollow cylinders. In this case, longitudinal tension is sometimes also applied to equalize stress in two orthogonal directions.

In one series of tests torsional shear and longitudinal tension have been applied simultaneously. Uniaxial compression may be used for brittle materials. Bend testing has been employed.

The creep testing of plastics is discussed in BS 4618: Part 1 and ASTM D2990.

8.4.3 Deformation mechanisms and laws

Creep may occur by a number of atomic mechanisms which include: thermally activated glide, viscous glide, dislocation climb and diffusional mass transport through grain interiors and along grain boundaries. The relative contribution of a particular mechanism depends on the value of stress and temperature and the relationships between strain, stress and temperature vary according to which mechanism is operative. Deformation mechanism maps[44] have been produced for a number of materials.

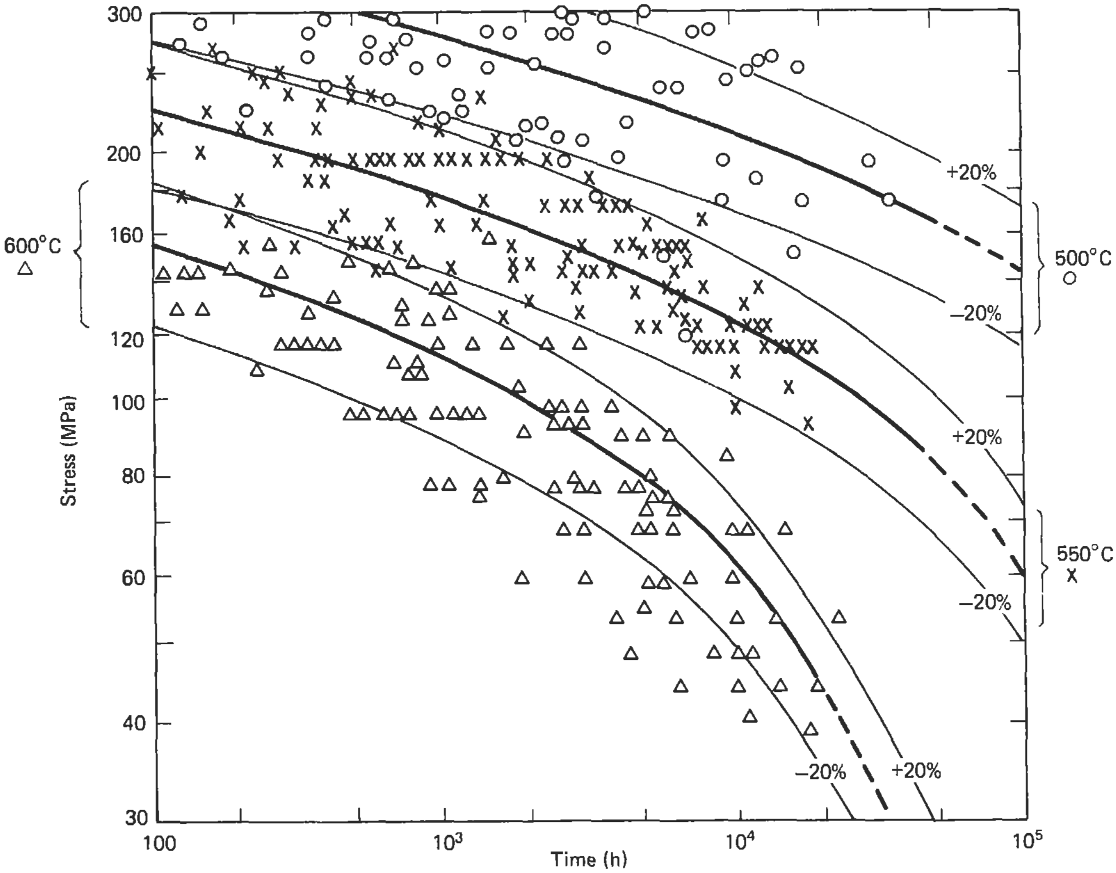

Figure 8.43 Comparison of derived curves with data points, ½Cr ½Mo ½V steel, 1.0% creep strain (reproduced by permission of the I. Mech. E.)

A simplistic mechanism, which forms the basis for most dislocation creep theories put forward by Bailey and Orowan considers that creep results from the competing processes of work hardening and thermal recovery.

'Creep' in metals is the summation of five processes. These include first, an initial, recoverable, elastic extension. This is followed by 'primary creep' during which, in the case of most alloys, the rate of deformation, $\dot{\epsilon}$, decreases and deformation follows approximately the relation

$$\dot{\epsilon} = A't^{1/3} \tag{8.57}$$

where A' is a constant and t is time.

At low temperatures (below 0.3–$0.5T_m$) the creep rate approaches zero at shorter or longer times and the three later stages do not exist. At temperatures above $0.3T_m$ some alloys which have been designated class 1 (for example, Al-3% Mg) exhibit a continuously increasing creep rate in the early stages of creep. At temperatures above $0.5T_m$ primary creep is succeeded by 'secondary creep' during which the rate is sensibly constant with time and at intermediate stress levels, follows the relationship for stress:

$$\dot{\epsilon}_s = A''\sigma^n \tag{8.58}$$

and for temperature and stress

$$\dot{\epsilon}_s = A'''\sigma^n \exp - (Q_c/RT) \tag{8.59}$$

where Q_c is the activation energy for creep.

The exponent n is an important parameter for design under creep conditions because it controls the distribution of stress in complex structures. For pure metals at intermediate stresses it generally varies between 4 and 5, for solid solution alloys it is approximately 3 and it can range as high as 30 for dispersion-strengthened alloys. At very high stresses creep rate varies exponentially with applied stress.

The constant A'' is related to the activation energy of the mechanism that controls the creep process. The activation energy is relatively low at low temperatures but increases to a value equal to that for self-diffusion at $0.6T_m$ where dislocation climb is the dominant deformation mechanism. In this temperature regime and where stress dependence follows a power law, steady-state creep follows the Dorn equation[45]

$$\dot{\epsilon}_s = AD_L \frac{Gb}{kT}\left(\frac{\sigma}{G}\right)^n \tag{8.60}$$

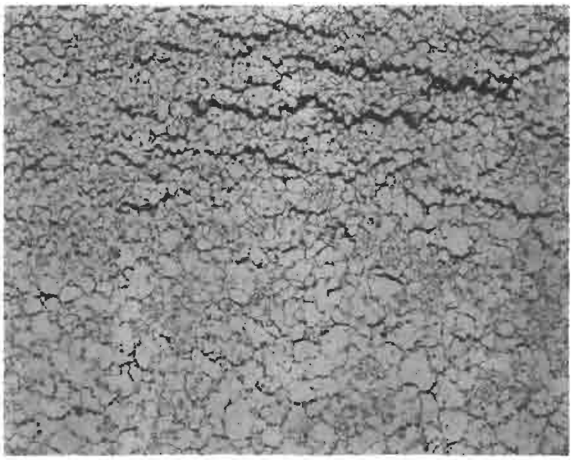

Figure 8.44 Cavitation in a material at a late stage of tertiary creep (produced by replica technique) (reproduced by permission of ERA Technology)

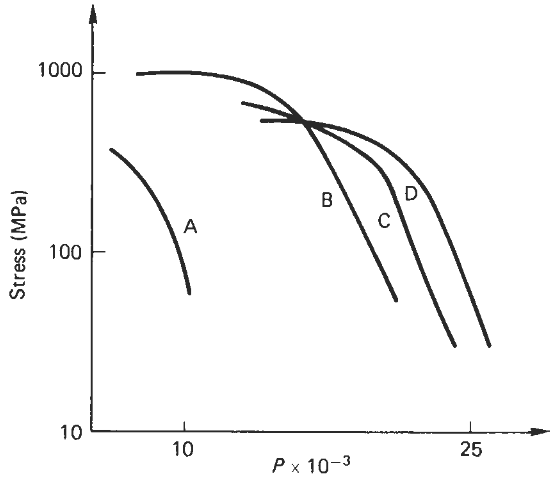

Figure 8.45 Larson–Miller master creep curves (reproduced by permission of Prentice-Hall). A: heat-treated aluminium alloy; B: titanium alloy; C: cobalt-molybdenum steel; D: 18–8 austenitic stainless steel

where A and n are constants that must be measured empirically, b is the burgers vector representative of the discontinuity caused by the strain, D_L is the self-diffusion coefficient, k is Boltzman's constant, T the absolute temperature, σ the applied stress and G the shear modulus.

Secondary creep eventually gives place to 'tertiary creep' which follows a power law, usually approximately cubic $\epsilon = ct^3$

$$\epsilon_t = ct^3 \tag{8.61}$$

The early stages of tertiary creep may be marked initially by metallographic changes through which the microscopic and sub-microscopic constituents that restrain dislocation movement lose their effectiveness. Precipitates coarsen and carbides spheroidize. Later, cavities develop along grain boundaries (and elsewhere) and cracks originate at triple points where grain boundaries meet. These defects decrease cross-sectional area locally, increase the strain rate, and therefore the size and number of defects. Figure 8.44 shows the microstructural appearance of a material at a late stage of tertiary creep.

Finally, the defects and cavities unite and the material ruptures.

8.4.4 The interpretation of creep and stress rupture data

Creep tests suffer from scatter of data arising from material and testing variables. The replication required to allow for the scatter and the extended life of components, particularly in power plant, make the complete experimental characterization of the creep and stress rupture properties of a material prohibitively expensive. Moreover, the power plant would be built and operating long before such a test programme could be completed.

There is therefore a great incentive to develop a formula which relates stress, temperature and strain and allows long-term behaviour to be predicted from relatively short-term data. Such methods or parameters have been put forward by Larson-Miller, Manson-Haferd, Goldhoff-Sherby, Manson-Succop, Or-Sherby-Dorm and Monkman Grant.

Most of these parameters derive from:

$$P = \frac{\log t/\sigma \cdot Q - \log t_A}{(T - T_A)^R} \tag{8.62}$$

where t is the rupture time (in hours), σ is stress, T is test temperature and T_A, t_A, Q and R are constants derived from the experimental test data. They facilitate interpolation and may be used with reasonable success to extrapolate the creep behaviour of relatively simple materials. None of them, however, can deal with a curve with an inflection such as is shown in Figure 8.46 because they all have an increasing downward-slope characteristic. Most creep-resisting steels exhibit an inflection.

It is clear that extrapolation from data up to time A to time B will give an optimistic value, while extrapolation from time B to time C will give a pessimistic value of rupture strength. The design strengths of many creep-resisting steels have been determined from the second type of extrapolation. The results of this are considered in Section 8.4.8.

It is not possible to place the techniques in order to merit. Some fit some data best while others are more suitable for other data. That technique which best fits the data under consideration should be chosen. The Larson–Miller method, which has been most extensively used, assumes that the steady-state creep rate is equivalent to the reciprocal of the time for complete failure to occur. The rate equation is

$$P = T(\log t_R + C) \tag{8.63}$$

where P is the Larson–Miller parameter, C is an empirically determined constant (approx. 20), t_R is the time to rupture (in hours) and T is the absolute temperature. Values of P are determined over a range of stresses, usually from short-term results at high temperatures.

Figure 8.45 shows a series of master Larson–Miller Curves for different materials from which creep rupture performance may be derived. Too much confidence should not be placed on the results of extrapolation to conditions diverging widely from those of the tests actually carried out.

8.4.5 Parameters favouring high creep and rupture strengths

A high melting point relative to service temperature favours resistance to creep. This trend may, however, be modified if there is an allotropic modification in the solid state, because atomic mobility increases at temperatures approaching the phase change temperature. Therefore, austenitic steels have creep properties superior to those of ferritic steels, and cobalt and nickel alloys are better still.

The presence of certain elements in solid solution (for example, molybdenum in austenitic steels) restrains dislocation movement and increases creep resistance. Precipitates precipitated from solid solution increase resistance to creep provided that they are stable and do not coarsen. The most effective is the γ' precipitate in nickel alloys. Carbides in ferritic and austenitic steels have similar effects.

Very high creep resistance is imparted by the presence of hard dispersed particles such as alumina in metals. The problem with dispersion-strengthened alloys is that it has not yet proved possible to confer strengthening at lower temperatures comparable with the improvement in creep resistance at the higher temperatures.

Other things being equal, a material with a coarse grain structure has a higher creep resistance than one with a fine grain structure. In particular, castings which usually have a coarser grain structure (and often also a cast intermetallic network) have substantially higher resistance to creep than forgings. This more than compensates for their lower ductility. Single crystals are best of all.

8.4.6 Design in the creep range

For any material the lower temperature limit of the creep range depends on the design lifetime, which may vary from seconds for a missile to 10^5 hours for power plant and on the code to which a component is designed. For a short-lived component control by σ_Y extends to a higher temperature than for a long-lived one. If a design code lays down a relatively high safety factor on σ_R compared with that on σ_Y, σ_R takes over at a relatively lower temperature than when this situation is reversed.

The lower limit of the creep range varies therefore from industry to industry and from one country to another, and a higher proof stress material may have advantages economically in some locations and for some applications and a higher rupture stress in other cases.

In the creep range at least two out of three parameters are required for design. For rotating and other machinery where minimum clearances must be maintained it is essential to know the maximum total strain for given values of stress, time and temperature.

For components where strain is not critical the value of the creep rupture stress, σ_R, must be known. σ_R varies statistically and design codes specify a factor, usually 0.6 × mean or/and 0.8 × minimum for the design stress.

Whether the design is strain or rupture controlled, it is essential to know the stress distribution, and for this a knowledge of the stress/strain exponent n is required. When the value of this parameter differs significantly from unity, stress analysis becomes very much more complex than under linear elastic conditions.

The stress distribution can be calculated reasonably accurately for straightforward geometries such as a hollow cylinder, but component geometries such as a cylinder/cylinder intersection require finite-element analysis and have, in the past, been designed using empirical thickness compensation rules which depend on experience for safety in design.

Provided that data such as are described in Section 8.4.7 are available, computer programs can analyse designs as complex as the cylinder/sphere intersection. 'Bearsafe', produced by the CEGB Berkeley Nuclear Laboratory, is a typical program. In principle, these programs are capable of analysing non-axisymmetric designs such as the cylinder/cylinder intersection, but the cost of computer time would be prohibitive. The cylinder/cylinder intersection has to be stressed by a procedure involving analogy with the cylinder/sphere.

A further parameter derived from creep rupture testing is rupture ductility, but this relates more to performance under high strain fatigue loading (see Section 8.3) rather than to creep.

8.4.7 Creep of ferritic pressure vessel steels

The creep properties of the ferritic pressure vessel steels have received very intensive study. The results have been analysed and reported in reference 49. Examples relating to one material are taken from this publication to illustrate characteristics and methods of presentation of creep and stress rupture data. The material selected is $\frac{1}{2}$Cr $\frac{1}{2}$Mo $\frac{1}{4}$V steel of light section.

Elevated temperature proof stress values which are design criteria below the creep range are listed in Table 8.3 and hot tensile curves in Figure 8.47.

Table 8.3 Elevated temperature proof stress values of a ½Cr ½Mo ¼V steel (MPa)

Proof strain (%)	*Temperature (°C)*						
	20	*100*	*200*	*300*	*400*	*500*	*600*
0.1	265	254	240	170	150	130	115
0.2	270	259	235	192	177	155	135
0.5	272	261	235	240	220	185	158
1.0	286	269	271	275	260	205	167

The 0.2% proof stress is that given by ISO 2604/IV steel – Figure 8.47 gives the averaged experimental stress–strain curves to 5% strain, the post-yield stresses having been scaled down to comply with this minimum 0.2% proof stress. Other proof stresses in the table have then been taken from Figure 8.47. (Reproduced by permission of the IMechE.)

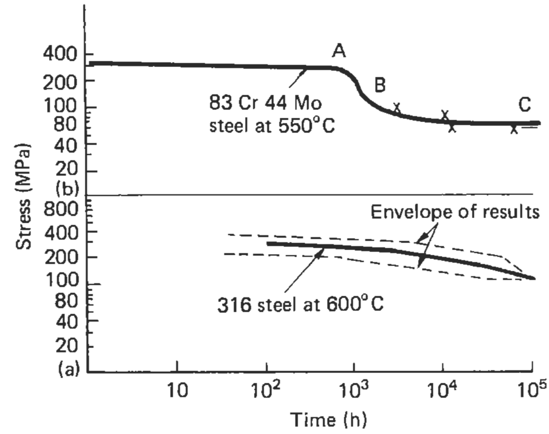

Figure 8.46 Comparison of rupture behaviour of 316 and a Cr 0.5 Mo steel showing an inflected curve

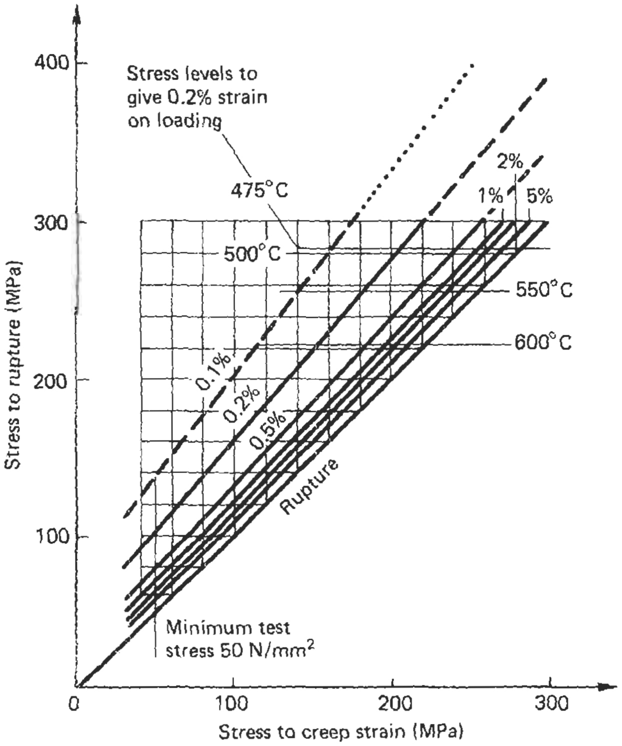

Figure 8.48 Parametric lines relating stress to rupture and stress to a certain creep strain in the same time and temperature, ½Cr ½Mo ¼V steel, light sections (0.1% line obtained by extrapolation) (reproduced by permission of the I. Mech. E.)

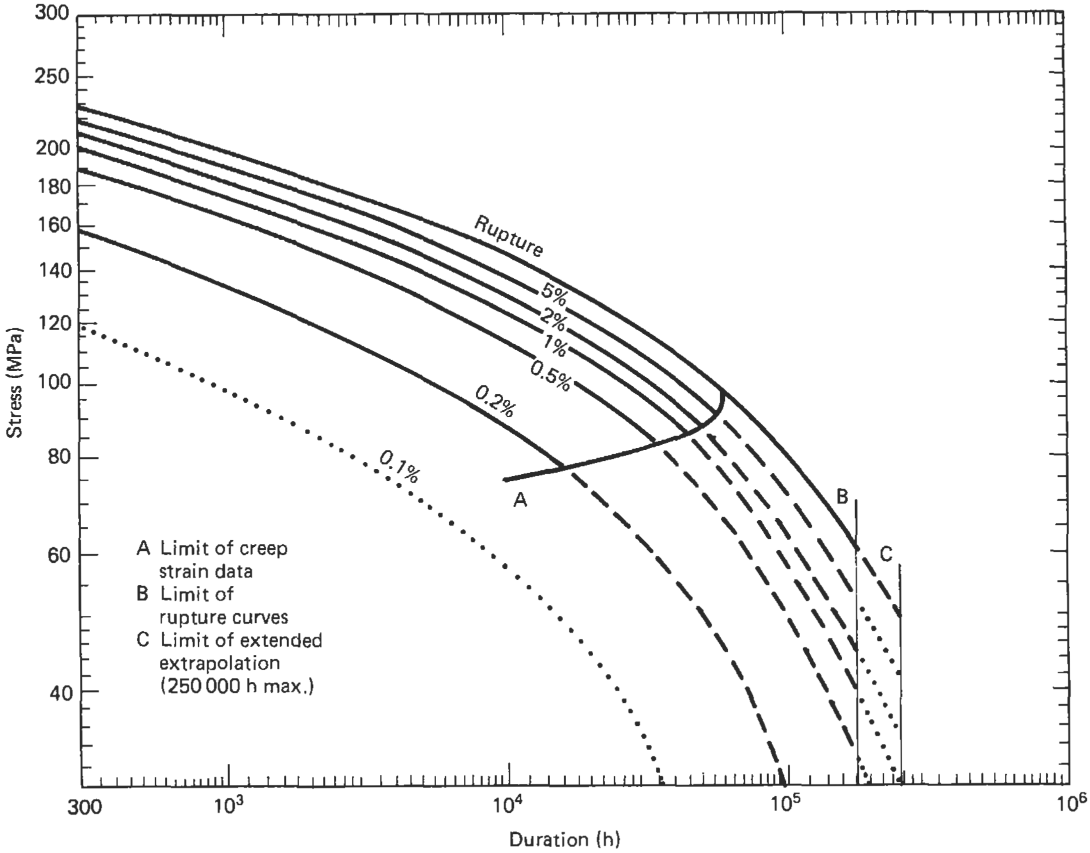

Figure 8.49 Creep strain and rupture contours, ½Cr ½Mo ¼V steel, light sections (reproduced by permission of the I. Mech. E.)

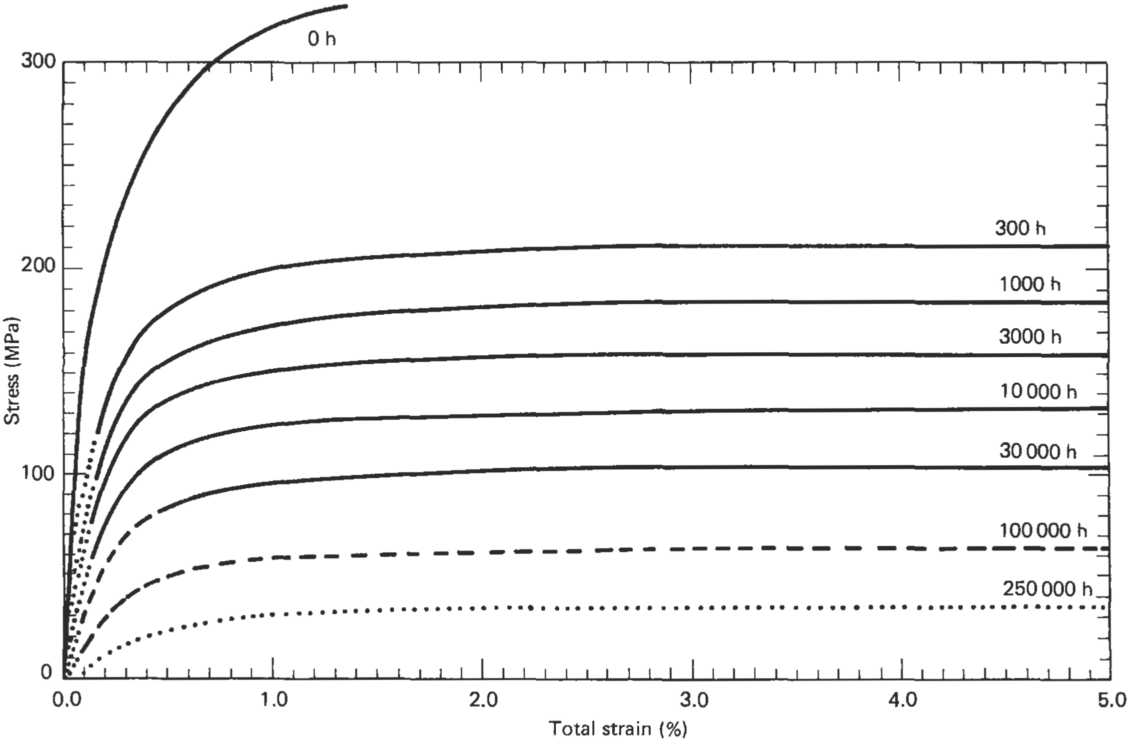

Figure 8.50 Isochronous curves of stress against total strain, ½Cr ½Mo ¼V steel, 550°C, light sections (reproduced by permission of the I. Mech. E.)

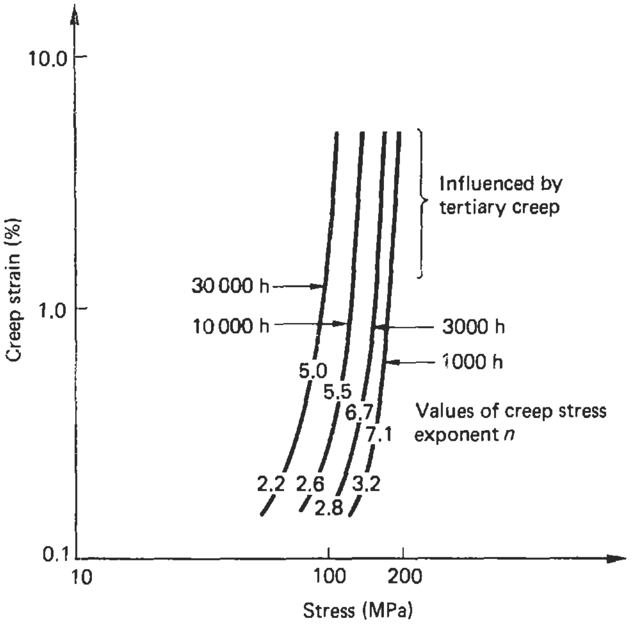

Figure 8.51 Isochronous curves of creep strain against stress, ½Cr ½Mo ¼V steel, light sections, 550°C (reproduced by permission of the I. Mech. E.)

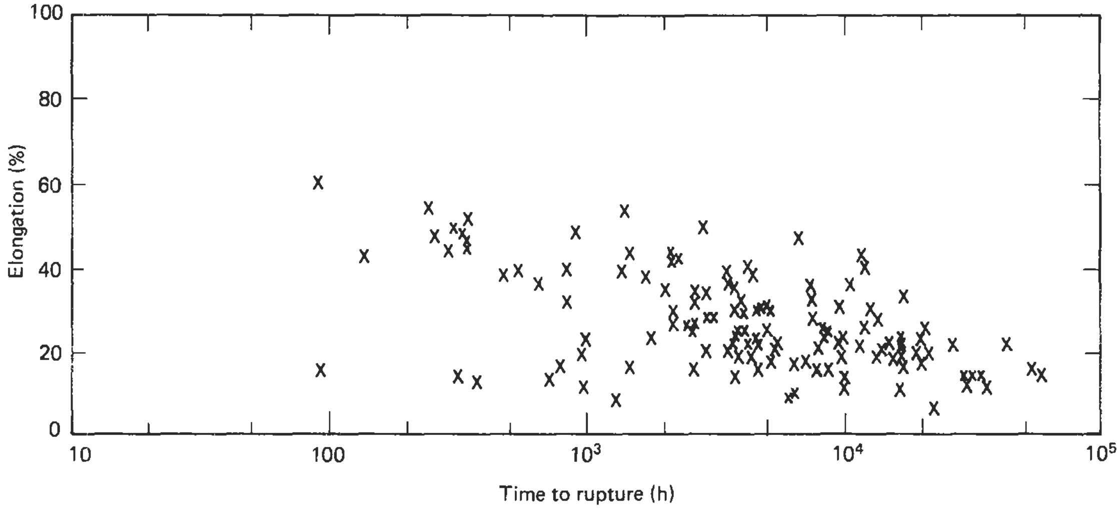

Figure 8.52 Creep rupture elongation for ½Cr ½Mo ¼V steel, 526–575°C, light sections (reproduced by permission of the I. Mech. E.)

A typical parametric equation relating the stress to rupture, σ_R (MPa), to the stress, σ_ϵ, to produce a given strain ϵ% in the same time and at the same temperature is

$$\sigma_R = \left(1 + \frac{0.0287}{\epsilon}\right) \sigma_\epsilon + 11.58 + \frac{7.714}{\epsilon} - \frac{0.1621}{\epsilon^2} - 0.2\epsilon^2 \qquad (8.64)$$

between 30 and 300 MPa stress, 0.1–5% creep strain and at temperatures between 475° and 600°C.

Parametric lines relating stress to rupture and stress to a certain creep strain are shown in Figure 8.48 and typical creep strain and rupture contours in Figures 8.49 and 8.50. Typical isochronous curves of creep against total strain are illustrated in Figure 8.49 and isochronous curves of creep strain against stress showing a range of values of the creep stress exponent n are given in Figure 8.51. Figure 8.52 shows creep rupture elongations.

8.4.8 Remanent life

It is often necessary, when an item of plant approaches its design life or has been operated for a period under more severe conditions than were allowed for in design, to assess whether and for how long operation can safely continue. Life-fraction rules have been devised which allow for the effects of out-of-design operation provided that the times, stresses and temperatures are known. The simplest empirical rule defines the life fraction as

$$[(t/t_R)(\epsilon/\epsilon_R)]^{1/2} \tag{8.65}$$

Often, the design conditions for plant impose very little creep damage from service exposures up to 200 000 hours. This applies to carbon, carbon molybdenum and chromium molybdenum steels operated at ASME boiler and pressure vessel code allowable stress. Some of the reasons for this have been discussed in Section 8.4.4.

A further reason is that the effect of oxidation on small-sized rupture specimens tested for long times in air is more severe than it is on relatively large section plant items and σ_R values are therefore pessimistic. An accurate determination of the remanent life of plant which, for these reasons, has been overdesigned will, by deferring replacement, provide substantial cost savings.

There are two experimental procedures for examining a plant item whereby its remanent creep rupture life may be determined; metallographic examination and measurement of rupture properties after service. Metallographic examination can be used to detect structural changes or creep cracking and cavitation damage.

Structural changes in creep-resisting steels consist mainly of spheroidization of carbides. This usually marks the onset of tertiary creep but can be detected only if there is good documentation of the original metal structure. This type of creep damage may be removed completely by giving the component a heat treatment similar to the original heat treatment. The rupture properties are fully restored.

Creep cavitation damage can be assessed quantitatively by determining the number fraction of cavitated or cracked grain boundaries which is related to the remanent life fraction, t/t_r, by the relationship:

$$A = 1 - \left(1 - \frac{t}{t_r}\right)^{(\lambda-1)/n\lambda} \tag{8.66}$$

where

A = the number fraction of cavitated or cracked grain boundaries,
n = the creep rate exponent,
λ = ϵ_r/ϵ_s (ratio of rupture strain to secondary creep strain),
e_s = $\dot{e}_{min}t_r$ (e_{min} is minimum creep rate), and
t_r = rupture life.

The relationship between A and t/t_r is shown graphically in Figure 8.53 and the time that is expected to be taken for an observed defect to grow is illustrated in Figure 8.54.

The most effective non-destructive technique for monitoring microstructural degradation and crack initiation is surface replication. The area to be examined is prepared as for conventional metallography and a cellulose acetate film softened by immersion in acetone is applied to the surface. The film is peeled off when dry and examined by optical and scanning electron microscopy. A typical replicated microstructure is shown in Figure 8.55. If the results of examination indicate that cavities or cracks are present, but that a substantial time interval is likely to elapse before failure, this is not necessarily a reason for complacency.

Stresses and material properties can change very sharply in critical geometries such as the angle of a welded cylinder/cylinder intersection. Unless the surface examined is known to include the position of peak stress or minimum strength the worst situation will not be revealed and the component may be on the point of failure.

Unless staff experts in remanent life assessment are available it is better to remove cracked or cavitated material as soon as conveniently possible by machining and depositing weld metal or by replacing the component than to defer action on the basis of judgement that may be faulty. Subject to the above warning, guidance on action to be taken is given in Table 8.4.

Post-exposure accelerated creep rupture testing on specimens taken from a component is more costly and requires a longer time to yield information than replica examination. Also, weld repairs have to be made to the component. However, this technique provides information on material in the secondary as well as in the tertiary stages of creep.

The usual procedure is to subject the specimens to creep rupture tests at the design stress and at a series of temperatures above the design temperature. If the log times to failure are plotted against temperature the resulting line will approximate the linearity and will extrapolate to the value of remanent life at the design temperature. Rupture testing at constant temperature but varying stress and measurements of creep rate on material taken from service have also been used to determine remanent life.

8.5 Fatigue

8.5.1 Introduction

Fatigue is the failure of a metal under repeated (or cyclic) loading under stress(es) lower than would lead to failure if applied singly. Failure occurs by the propagation, under repeated loading, of a crack which may have initiated at a surface or started at a defect at the surface or internally. This section is confined to fatigue of metals but analogous phenomena occur in polymers (see Section 7.5) and composites (see Section 7.7).

There are two basic types of fatigue; *high-strain fatigue* in which the maximum tensile stress in the cycle is larger in magnitude than the yield stress of the material and leads to failure in from 2 to 10^5 cycles; and *high-cycle fatigue* in which the stress may be smaller in magnitude than the yield stress and failure occurs at more than 10^5 cycles. Stresses are usually applied mechanically. *Thermal fatigue* failure is caused by stresses arising from cyclic temperature gradients. Historically, the term has also been applied to the distortion and weakening of tin (and, presumably, other anisotropic materials such as uranium) which derives from the thermal cycling of adjacent crystals of differing orientations (and therefore differing thermal expansion coefficients).

The term 'fatigue' is sometimes applied to the failure of ceramics (see Section 7.7) or polymers (see Section 7.5) under constant loads of long duration. *Corrosion fatigue* refers to the situation which arises when the influence of the environment is such as to accelerate failure significantly relative to fatigue in air. *Creep fatigue* is a term loosely applied to describe the influence of interactions between creep and fatigue.

The study of fatigue has recognized a number of parameters which, insofar as they have not been defined in Sections 7.1 and 8.3, are listed and defined in Section 8.5.9 (see Table 8.5).

Failure by fatigue takes place in three stages: initiation, propagation and sudden failure of the remaining cross-section by rupture or buckling. (See note to Section 8.3.1.)

8.5.2 Fatigue crack initiation

A fatigue crack may initiate at the surface of a metal when it is subjected to cyclical shear in the plane of the surface. The presence of a tensile stress is generally considered essential. The commonest (and most easily understood) mechanism results from slip bands ratcheting on two planes at separate parts of the cycle, generating tongues of metal and intrusions (see Figure 8.56 and reference 51) which may be observed microscopically. Other observed phenomena are tubular holes which are associated with nucleation on persistent slip bands

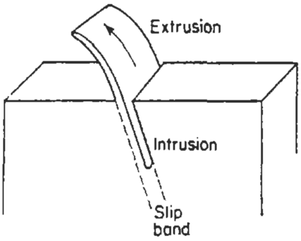

Figure 8.56 Fatigue initiation caused by extrusion and intrusion on a slip band (reproduced by permission of John Wiley)

and twin boundaries. Grain boundaries are also nucleation sites – the nucleation process in this instance being the creation of voids and their coalescence to form a crack. This nucleation process is particularly prevalent when creep, and consequential grain boundary cavitation, play a part in accelerating failure by fatigue. Increasing hardness reduces shear strain and therefore increases the stress required to initiate fatigue. Reducing grain size, particularly of a softer phase, also increases resistance to nucleation.

Fatigue cracks grow very slowly during the nucleation stage and under the lower stresses at which high-cycle fatigue occurs this stage may last 75% of the fatigue life of a component. Cracks may stop growing altogether because of (1) some stress relief effect (if they have started from a very sharp defect), (2) some form of strain ageing, (3) some inherent saturation mechanism or (4) environmental action.

If the fatigue crack growth curve (see Figure 8.57) is asymptotic to a value of stress intensity ΔK_{th} there will be a value of load range ΔS below which failure will not result, however much of the number of cycles, N, is increased. Half this value of ΔS is called the endurance limit S_f. This is the case with steels and titanium alloys.

On the other hand, an initiated intrusion may extend along the slip plane until the stress intensity factor range ΔK reaches a value at which a crack will propagate.

When the fatigue crack growth curve shows no sign of becoming asymptotic to any value of stress intensity there is no endurance limit S_f and an increase in the value of N will lead to failure at a lower value of ΔP. This has generally been considered to be the case with aluminium alloys but the fatigue crack growth curve may become asymptotic to very low values of ΔK even with these (see Section 8.5.5).

8.5.3 Fatigue crack propagation[55,56]

When the fissure produced by crack initiation reaches the size at which the stress intensity range in the cycle is sufficient the crack propagates in a direction normal to the tensile stress. The characteristics of fatigue crack propagation are summarized in Figure 8.57. This shows three regions of fatigue crack growth. The first region, slow crack growth, may exhibit a fatigue crack growth threshold stress intensity range, ΔK_{th} below which cracks do not propagate. The magnitude of the threshold value is sensitive to both stress ratio R and environment, and in some materials is believed not to exist.

During the second stage the log-log plot of ΔK versus da_p/dN usually follows a straight line corresponding to the relationship

$$\frac{da_p}{dN} = C(\Delta K)^n \qquad (8.67)$$

where C and n are constant for a given material, stress ratio R and environment.

8.5.4 Unstable crack growth

During the third stage crack growth rate increases rapidly and becomes unstable as failure of the specimen is approached. This instability is due (in the case of high-strength low-toughness metals) to the peak stress intensity equalling the fracture toughness K_{Ic}. In the case of ductile metals, the instability is due to the peak loading equalling that required to cause (in the size of specimen generally used to measure fatigue crack growth) plastic flow of the reduced metal section behind the crack.

8.5.5 Final specimen failure

Unless vibration, leakage or the results of non-destructive testing have already caused the component to be taken off-load, a stage is reached, as the length of the crack increases and the thickness of residual material behind the crack decreases, when the component fails either by brittle fracture or by elastic collapse.

The appearance of fatigue fracture is shown in Figure 8.58. Illustrated in Figure 8.58(a) is a low-magnification view showing origin, leading lines and bench marks where fatigue has been interrupted.

8.5.6 Parameters that influence fatigue performance

For simplicity, this account has so far assumed that the component or specimen is smooth and uniform, the load constant is sinusoidal in form with constant amplitude, and the environment is dry air at room temperature. The following parameters must be considered in design and testing.

1. The form of the cycle may be sinusoidal, triangular, square or trapezoidal; the frequency of the cycle may be constant or variable; and the load amplitude may be constant or vary in a random or regular manner. Variations in frequency, cycle shape or hold time under load have significant influence (a) when the environment is aggressive, (b) in high-strain fatigue and (c) at elevated temperature (when creep plays a part in the process). They have little influence on region two high-cycle fatigue crack growth rates or on endurance value in benign environments. Increase in R value has usually little effect on the component n of creep crack growth (although it sometimes causes n to reduce). It does cause an increase in the constant C in equation (8.67) and a decrease in K_{th} and, therefore, a decrease in endurance limit. Typical experimental values obtained from fatigue crack growth tests in steel and aluminium are shown in Figure 8.59. The influence of R value and the tendency of growth rates in steel to approach a threshold limit at much higher values of ΔK and da_p/dN than aluminium are apparent.
2. Notches and other stress raisers affect fatigue life. In particular, inclusions or defects may increase stress intensity to a value at which the initiation stage is bypassed and life calculations need only consider propagation and final failure.
3. Environment has a very significant effect on fatigue initiation and propagation – usually adverse, but a more aggressive environment does not always impair fatigue performance.
4. Different materials behave in different ways. Higher-strength and finer-grained materials usually have higher endurance limits, but the effect of increasing hardness on fatigue properties usually reaches a limiting value at a certain hardness. The value of n in equation (8.67) varies

(c)

Figure 8.59 (*continued*)

little from 2.25 for most engineering materials but the value of the constant C is lowest for steels, intermediate for titanium and highest for aluminium alloys. Fatigue properties can be improved by suitable heat treatment, but a heat treatment that increases ΔK_{th} may also increase C and vice versa. This is exemplified in the heat treatment of titanium alloy IMI 834, which can, according to the requirements of the design, be heat treated either from the $\alpha\beta$ phase to optimize fatigue endurance limit or from the β phase to optimize fatigue crack growth (see Section 7.4.3).

8.5.7 Fatigue testing

Design data in fatigue may be collected by three distinct procedures:

1. Rotating beam-fatigue testing machines are cheap and inexpensive to build, simple to operate and represent the least expensive method of determining endurance limits or fatigue strengths. They are, however, limited to high cycle fatigue, a sinusoidal wave form and one value of R ($= -1$).
2. Uniaxial fatigue testing machines are free from these limitations. Stress-controlled tension/tension testing with sinusoidal loading and an R value of 0.1 is standard procedure. Negative R values require very rigid machines and very accurate alignment and expense is augmented if capacity to provide non-sinusoidal wave forms, strain measurement and control and/or special environments are required.
3. Fatigue crack growth testing uses similar test pieces and equipment to that used for measurement of fracture toughness (see Section 8.3). As in (2) above, an R value of 0.1 is standard practice and negative R values, non-sinusoidal waveforms and special environments increase complexity and expense.

Standards issued by the ASTM (listed in Table 8.5) cover uniaxial fatigue testing procedures. The materials engineer is recommended to study the relevant standard before embarking on a programme of fatigue testing.

8.5.8 Design for fatigue

8.5.8.1 High-strain fatigue

The Coffin–Mansion relationship (see Figure 8.60) for failure in high-strain fatigue

$$\Delta\epsilon_p \propto N^{-1/2} \tag{8.68}$$

(where $\Delta\epsilon_p$ is the plastic strain range and N the number of cycles to failure) has been derived theoretically and shows little variation experimentally for metals and alloys (and indeed for all materials having measurable ductility). The relationship may be used with confidence in design provided:

1. The material does not undergo a structural change during service;
2. The environment does not significantly influence crack initiation or propagation;
3. There is no significant creep at any stage of the cycle.

The influence of environmental attack, which can seriously reduce fatigue resistance, may be gauged from a study of references 70–72. The influence of creep which can, at cycles intermediate between 2 and 10^5, reduce fatigue resistance by as much as 50% is illustrated in Figure 8.61.

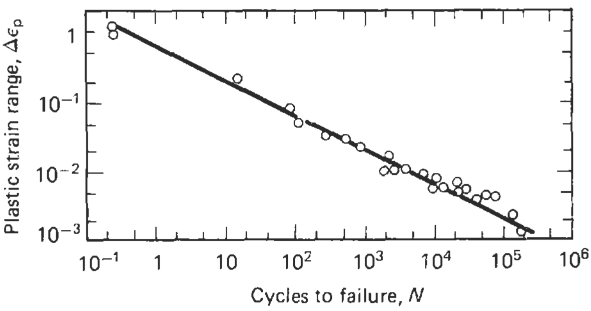

Figure 8.60 Low-cycle fatigue curve ($\Delta\epsilon_p$ versus N) for type 347 stainless steel (reproduced by permission of the ASM *Metals Handbook*)

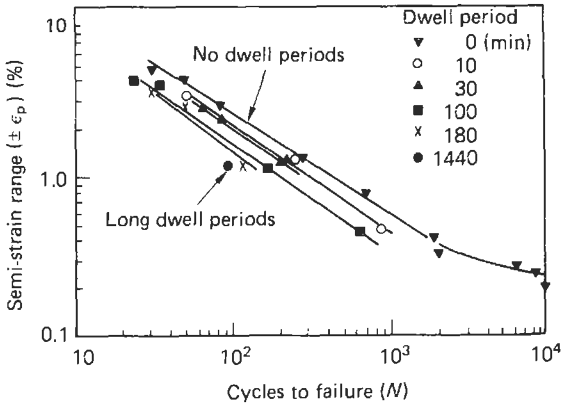

Figure 8.61 High strain fatigue resistance of IP rotor materials

8.5.8.2 High-cycle fatigue[52,59,62,63]

The behaviour of a material in high-cycle fatigue (which is stress related) up to 10^5 cycles may be derived by combining the Coffin–Manson relationship (which is strain related) and the stress–strain relationship in the standard tensile test. Above 10^5 cycles the log-log SN curve continues with a decreasing downward slope. With some materials, the curve levels off at the endurance limit which, for titanium alloys and medium-strength steels, is roughly half the UTS. Conventionally manufactured steels with UTS above 500 MPa show a considerable scatter, the best values of endurance limit continuing along the 50% of UTS line, while the worst are roughly 50% of 500 MPa, which is therefore a limiting value for design. (High-tensile steels refined by vacuum arc or ESR have superior fatigue properties.)

With other materials the log-log SN curve continues its decreasing downward slope. Design with such materials should be based on the fatigue strength at a specified number of cycles (10^8, for example) set by the designer.

8.5.8.3 Influence of mean stress

The effect of mean stress on the fatigue limit for a given number of cycles may be calculated from the empirical relationship[76]

$$S_a = S_f\left[1 - \left(\frac{S_m}{S_u}\right)^m\right] \tag{8.69}$$

where S_a is the limiting alternating stress associated with a mean stress S_m. (When $m = 1$ this becomes the modified Goodman Law and when $m = 2$, Gerber's Parabolic Law.) If, as in Figure 8.61, a set of curves is plotted relating S_a/S_f to S_m/S_u, and results appropriate to some value of mean stress are available in addition to the value of S_f, the value of m can be determined and the value of S_a thereby also obtained for a required value of S_m/S_u. If S_f only is known it should, for purposes of provisional estimation, be assumed that $m = 1$.

This procedure has the effect that the yield point of the material is exceeded at the peak of the cycle for certain values of S_m and S_a. If a straight line (shown interrupted in Figure 8.62) is drawn between the values of the yield point S_p on the two axes (points A and B) yielding can be avoided by designing to ensure that stress conditions always lie to the left of this line.

8.5.8.4 *Influence of stress concentration*

The presence of a notch in a component or a test piece might be expected to reduce the fatigue or endurance limit by a factor equivalent to the elastic stress concentration factor K_t. In fact, yielding is likely to occur at the tip of the notch and the actual stress cycle at that point has a lower value than elastic calculations using the formula

$$S_n = \frac{S}{K_t}\left[1 - \left({K^1}_t\left(\frac{S_m}{S_u}\right)^m\right)\right] \tag{8.70}$$

would imply.[75]

A sharp notch therefore reduces the fatigue strength of a strong but less ductile material more than that of a softer more ductile material. Figure 8.62[53] shows the influence of variation in notch radius of a steel heat treated to a range of UTS values.[75]

Because initiation occurs at the surface, fatigue properties are generally very sensitive to surface conditions, including variations in finish, composition and residual stress. Rough finishes introduce notches and stress raisers and the fatigue properties of surfaces improve roughly in the order: sandcast, forged, hot rolled, die cast, cold rolled, machined, ground and polished. A hard surface improves fatigue resistance whereas cracks may develop in a soft surface layer and propagate into the core. Case-hardening steel or work hardening its surface therefore improves fatigue resistance, whereas decarburizing a steel or bonding a surface layer of soft aluminium onto Duralumin worsens resistance. The greatest improvement in fatigue resistance is gained by nitriding the surface of a stress-raising notch.

Introducing a compressive stress by case hardening[67] or shot peening increases resistance to fatigue as does quenching a uniform-shaped component. If, however, a component core in which tensile stresses have been introduced by quenching is bared locally by machining its fatigue resistance is impaired.

8.5.8.5 *Influence of variable-amplitude loading*

Miner[68] proposed the hypothesis that each load cycle of any amplitude damages the material and that the damage is the same per cycle as would lead to failure under constant amplitude. This hypothesis leads to the equation

$$p_f = D_f\left\{\sum_{b=1}^{b=B}\left(\frac{n_b}{N_b}\right) = \frac{D_f}{D_1}\right. \tag{8.71}$$

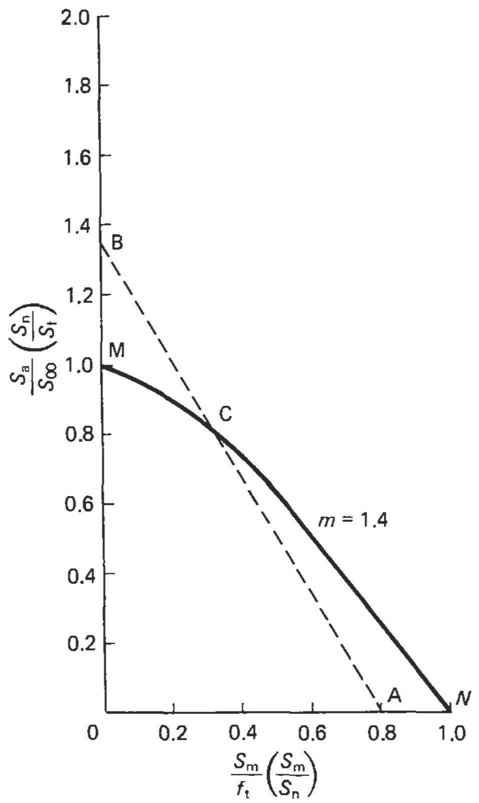

Figure 8.62 Curves obtained by assigning values to m in equation (8.70)

where p_f is the number of programmes to failure,
D is the summation of damage increments,
D_f is the value of D at failure,
B is the number of cycles in cycle by cycle programme or a number of blocks in block programme,
b is the cycle number in any one cycle by cycle programme or block number of blocks in any one block programme,
N_b is the endurance, in cycles under constant amplitude loading at same stress cycle as block or cycle b, and
n_b is the number of stress cycles in programme block b (equals unity for cycle by cycle programme).

This approach has some application when the peaks of all the stress cycles remain below the yield point. However, the stress–strain conditions at the root of a notch where yielding occurs differ significantly between constant- and variable-amplitude loading. In cases where this applies the designer is advised to consult reference 74.

8.5.8.6 *Differing stress configurations*

It has been stated that the presence of a tensile stress at some part of the cycle is a necessary condition for fatigue failure. However, drive shafts and torsion bars, which, in principle, are loaded in shear, are known to fail by fatigue. Fatigue cannot be caused by compressive loading alone.

Where, as is the case with cylinders containing gas under pressure, a material is subject to fatigue under multiaxial tensile loading it has been stated that the effective fatigue behaviour can be calculated by using von Mises yield criterion.[51]

8.5.8.7 Influence of environment

Figure 8.63 shows how atmospheres with varying capacity to introduce hydrogen have very significant influence on ΔK_{th} and on rate of creep crack growth but little (if any) influence on the exponent *n*.

Etching and electroplating components which will later be subject to fatigue must be very carefully controlled and any hydrogen introduced should be removed by annealing. An environment which favours stress corrosion may also have a catastrophic effect on fatigue failure. These considerations apart, accurate prediction of the effect of a specific environment on fatigue is extremely difficult, although it may well be very significant.

It cannot always be assumed that fatigue performance will be worse in a more aggressive environment. The fatigue resistance, for example, of magnesium in helium is worse than that in carbon dioxide. Oxidizing seawater, by a blunting mechanism, may stop the growth of fatigue cracks which would propagate under the same stress conditions in air.

The designer who wishes to subject a material to fatigue in an environment other than air at room temperature is advised to consult references 52 and 70–72.

8.5.8.8 Fatigue crack growth calculation

Fatigue crack-growth calculation techniques[53,55–58,71] are employed to determine the number of cycles required for a crack to grow from the size of an existing defect to one at which the component will fail. The size of the existing defect is the crack size a_{pf} (calculated by procedures described in Section 8.3 from the size and shape of the largest defect) that will *not* be detected by the system of inspection employed, oriented in the most damaging direction possible. The component will fail when the crack attains a size a_{pf}, at which the component will leak, buckle or crack in plane strain K_{Ic} or plane stress K_c under the action of the peak stress of the cycle. Failure in plane strain is usually the most sensitive and, because of its relative simplicity, is the criterion that will be considered here, but the possibility of a soft material buckling should not be forgotten.

Fatigue cracks propagate according to a law of the form

$$\frac{da_p}{dN} = f(R\Delta K) \tag{8.72}$$

and can be represented graphically by curves similar to those shown in Figure 8.57. In region 1 the curves approach a threshold value K_{th} which is very sensitive to R and is of interest in the design of lightly stressed components that are subject to a large number of service loadings.

Designs that lead to fatigue crack growth in region 3 must be avoided. Most cases of fatigue crack growth that are of interest in design occur in region 2, where it can be represented by:

$$\frac{da_p}{dN} = C(\Delta K)^n \tag{8.73}$$

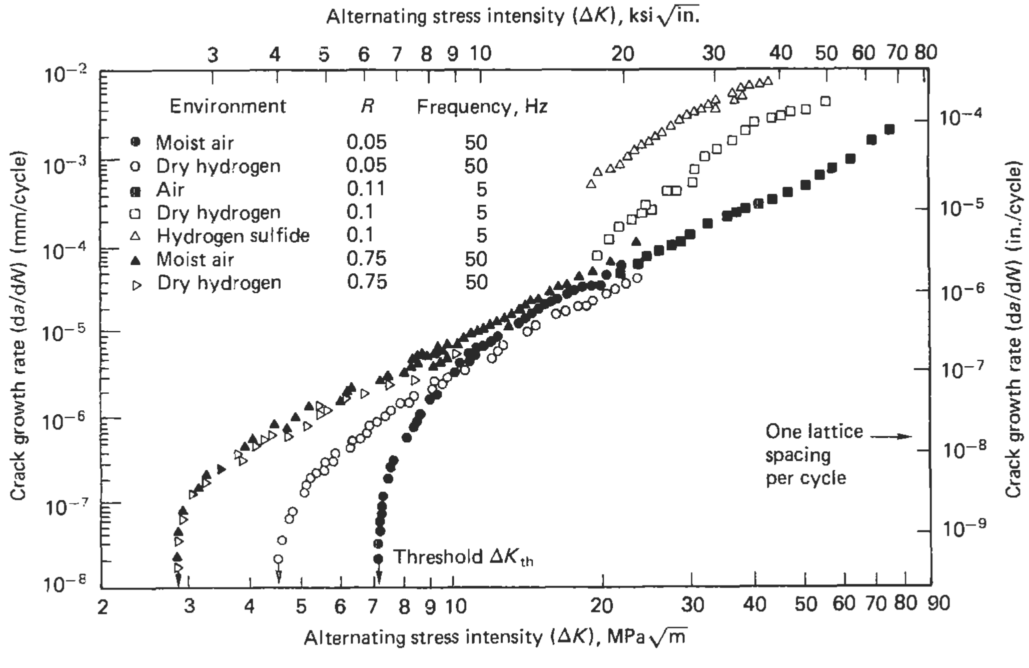

Figure 8.63 Fatigue crack propagation data in a martensitic 2¼Cr IMo steel (SA542-C12) in atmospheres with differing hydrogen potential and at varying values of *R* (reproduced by permission of the ASM *Metals Handbook*)

Many attempts have been made to derive laws that describe the complete crack-propagation curves.[55,56] One example which takes account of high crack growths in region *C* but not the low crack growth regimes is

$$\frac{da_p}{dN} = \frac{C(\Delta K)^n}{(1-R)K_c - \Delta K} \tag{8.74}$$

It is essential, if the simpler equation (8.67) is used, to ensure that the value of R in the component is the same as the value from which the test data are derived. The designer can estimate the life of a structure or of a component by analytical or graphical methods.

For plane strain the integration of equation (8.67) yields the solution

$$N\,_{N_i}^{N_f} = \frac{1}{C[S_{\max} - S_{\min})\pi^{1/2}]^n}\left[\frac{a_p{}^{(1-n/2)}}{1-n/2}\right]_{a_{pi}}^{a_{pf}} \tag{8.75}$$

If N_f, the number of cycles at which a component will fail, is calculated from equation (8.75) to be smaller than will be imposed during the design life of a component the following options may be available:

1. A higher standard of inspection possibly coupled with an improved manufacturing procedure may reduce the value of a_{pi}.
2. A design modification may have the effect of reducing $S_{\max} - S_{\min}$ or of reducing C by means of reducing the value of R.
3. A material or heat-treatment change may have the effect of reducing the value of C.
4. A change in operating procedure may have the effect of reducing the number of cycles imposed, or of reducing $S_{\max} - S_{\min}$ or of reducing the value of C.
5. Reducing the service life of the component before repair or replacement will decrease the number of cycles imposed.

The option, or combination of options which are least damaging economically, should be adopted.

8.5.9 Parameters and symbols employed (that have not already been defined in Sections 7.1 or 8.3)

Cycle (fatigue cycle, stress cycle, load cycle or strain cycle): the smallest segment of the stress-time or strain-time cycle which is repeated periodically.

N (dimensionless number): the number of cycles.

$S_{\max}$ $[F]$ maximum load: the load having the highest algebraic value in the cycle, tensile load being considered positive and compressive load negative.

$S_{\min}$ $[F]$ minimum load: the load having the lowest algebraic value in the cycle, tensile load being considered positive and compressive load negative.

ΔS $[F]$ range of load: the algebraic difference between the maximum and minimum loads in one cycle:

$$\Delta = S_{\max} - S_{\min}$$

R (dimensionless ratio) load ratio (stress ratio): the algebraic ratio of the minimum to the maximum load in a cycle:

$$R = P_{\min}/P_{\max}$$

$\Delta\epsilon_p[L]$ range of plastic strain: the algebraic difference between the maximum and minimum plastic strains in one cycle.

$K_{\max}$ $[FL^{-3/2}]$: maximum stress intensity factor. The highest algebraic value of the stress intensity factor in a cycle.

$K_{\min}[FL^{-3/2}]$: maximum stress intensity factor. The lowest algebraic value of the stress intensity factor in a cycle. (This is set equal to zero when R is less than or equal to zero.)

ΔK $[FL^{-3/2}]$: range of stress intensity factor. The algebraic differences between the maximum and the minimum stress intensity factor in a cycle.

ΔK_{th} (orΔK_{TH}) $[FL^{-3/2}]$: threshold value of ΔK. The highest value of ΔK that does not cause crack extension.

da/dN (L) (in fatigue, a always implies a_p, see Section 8.3): the rate of crack extension caused by constant-amplitude loading expressed in terms of crack extension per cycle.

S_a $[F]$: half the stress range in a fatigue cycle:

$$S_a = S_r/2 = (S_{\max} - S_{\min})/2$$

S_m $[F]$: the static or mean stress in a fatigue cycle.

SN curve: the results of fatigue tests plotted as S_m or S_a to number of cycles to failure using a logarithmic scale for the number of cycles and a linear or logarithmic scale for stress.

S_f $[F]$ fatigue (endurance) limit: the value of S_a corresponding to the horizontal portion of the SN curve with a 50% probability of failure. For many non-ferrous metals the 'fatigue strength' at 10^8 cycles is quoted. This is *not* the endurance limit.

K_t (dimensionless ratio): stress concentration factor. The ratio of the area test stress in the vicinity of a notch (or other stress concentration) to the corresponding nominal stress.

K_f (dimensionless ratio): fatigue notch factor. The ratio of the fatigue strength of a plain unnotched specimen to that of a notched specimen at the same number of cycles.

Note: throughout, S has been used for stress based on cross-sectional area of a component (not to be confused with σ, the calculated local stress). Calculations based on ASTM or ASME procedures will use P instead of S.

9.1 Basic principles

9.1.1 Introduction

Machines transmit power between their moving components which gives rise to friction and wear of the components. Tribology is, essentially, concerned with minimizing this friction and wear, and is formally described as *'the science of interacting surfaces in relative motion'*. The tribologist has to understand about the roughnesses of surfaces, the properties of liquid and solid lubricants, the principles of hydrodynamic and hydrostatic lubrication, the design of rolling element bearings, the behaviour of surfaces under stress, the nature of wear processes, and many other items which demand an interdisciplinary approach to design and problem solving.

9.1.2 Lubrication regimes

The most usual way to reduce friction and wear is by lubrication, employing gases, liquids or solids. Four basic lubrication regimes can be considered, characterized by the ratio, M, of the combined roughness, R, of both surfaces (in R_a) to the mean film thickness, h, i.e. $M = R/h$. Three of these regimes are illustrated in Figure 9.1, where the roughness of the surfaces is greatly exaggerated for presentation reasons. In reality, most surfaces more resemble gentle rollings hills on the earth's surface than the craggy, mountainous features illustrated. Figure 9.2 shows the more realistic dimensions and structure of a real surface, and a more detailed discussion of surface topography is presented in Section 9.10.

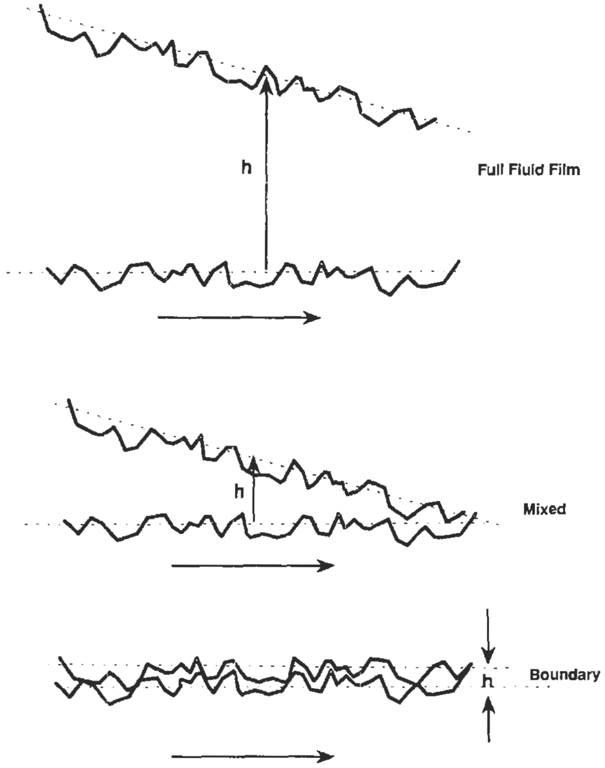

Figure 9.1 Lubrication regimes

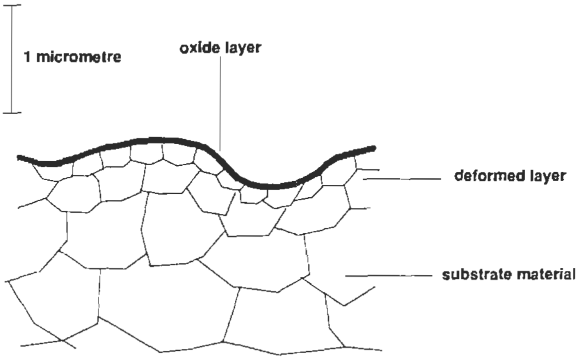

Figure 9.2 A typical engineering surface

9.1.2.1 *Rigid, full fluid-film (5 < M < 10)*

In this situation the surfaces are kept apart by a pressurized fluid such as oil or air. The clearance space is much larger than the average surface roughness, and therefore the surfaces can be considered smooth. The pressurization of the fluid is achieved by external means in hydrostatic bearings, but is accomplished in hydrodynamic contacts by the relative motion and geometry of the surfaces. Examples are crankshaft main bearings in internal combustion engines (oil-lubricated hydrodynamic journal bearings), shaft support bearings in power-generating turbines (often a combination of oil-lubricated hydrostatic and hydrodynamic journal bearings), piston rings (oil-lubricated hydrodynamic slider bearings), dentists' drills (air-lubricated hydrostatic bearings for shaft support) and magnetic disk heads (air-lubricated hydroynamic slider bearings). The friction coefficient in liquid-lubricated contacts falls typically within a range of 0.004 to 0.01. An outline of the principles of rigid, hydrodynamic lubrication is presented in Section 9.4.

9.1.2.2 *Elastic full fluid-film (1 < M < 10)*

There are situations in liquid lubricated arrangements where the loads are so high that the pressure in the lubricant causes local elastic distortions of the surfaces. This form of hydrodynamic lubrication is called elastohydrodynamic lubrication. The nominal clearance can still be such that surface roughness effects can be ignored, although mixed elastohydrodynamic lubrication can occur.

Elastohydrodynamic lubrication is most commonly found in gears and rolling element bearings, which are discussed in Sections 9.5 and 9.6, respectively.

9.1.2.3 *Mixed (1 < M < 5)*

Loads or speeds can be such that the opposing surfaces occasionally come into contact. In these contacts, part of the load is carried by the liquid or gaseous lubricant, and part by the interacting asperities. The rubbing together of asperities will increase friction, and this can be minimized by attention to the compounds which can be made to adhere to the surfaces. Hypoid gears in automobile rear axles at times exhibit this regime. Increased wear occurs, and friction coefficients in liquid-lubricated contacts of between 0.01 and 0.06 are found.

9.1.2.4 Boundary ($M < 1$)

In this regime, all the applied load is carried by the surface asperities, and the friction and wear which arises depends upon the lubrication properties of the molecules on the surfaces. Coefficients of friction between 0.06 and 0.1 are typical when a low shear strength surface film is present. If no such film is present, then coefficients ranging between 0.2 and 0.4 can be exhibited, even rising as high as 1.0 in some cases. The friction and wear of materials in dry sliding is discussed in Section 9.7.

9.1.3 Friction, wear and lubrication

9.1.3.1 Friction

There are three general laws of friction:

1. Friction is independent of apparent contact area
2. Limiting friction is proportional to the normal load
3. Limiting friction is independent of sliding speed

Limiting, or breakout, friction is the friction force obtaining at the point of slippage. The first two laws, proposed by Amonton in 1699, are generally applicable. The third law, proposed by Coulomb in 1785, has a reduced area of applicability.

The second law is more commonly written as:

$$\mu = F/W$$

where

μ = static, or breakout, coefficient of friction,
F = limiting friction force,
W = load applied normal to the surfaces.

In the light of law 3, a dynamic coefficient of friction can also be defined as the ratio of the sliding friction force to the normal load. It can be significantly lower than its static counterpart.

The friction occurring at asperity contacts is usually attributable to one of two causes: abrasion, where the harder surface (or a harder particle) ploughs through the softer counterface; or adhesion, where the intimate contact between asperities generates local adhesive bonds which break when motion is initiated. Friction can also arise due to hysteresis, as in the case of rolling friction.

The simple adhesive theory of friction deduces that:

$$\mu = \text{shear strength of surface/hardness of surface}$$

This is a gross oversimplification[1] but serves to indicate that adhesive friction can be reduced by reducing the shear strength of the bonds (by using dissimilar materials in opposition), introducing low shear strength surface layers (often as boundary lubricants such as stearates, sulphides, etc.), and/or increasing the hardness of the surface. There is evidence that a soft, thin layer of low shear strength material on a harder substrate can produce a component whose surface exhibits both low shear strength and high hardness – the latter being acquired from the parent material if the surface film is sufficiently thin.

The friction effects of abrasion can be minimized by suitable choice of counterface materials so that ploughing is reduced or prevented, and/or the addition of boundary lubricants which can ease the ploughing process. Sometimes boundary lubricants occur naturally as, for example, oxide layers; sometimes a boundary lubricant can be added to a liquid lubricant, e.g. stearates which have polar properties permitting them to attach to a surface like bristles on a brush (see Section 9.5.2). Arnell *et al.*[1] and Rabinowicz[2] provide more detailed discussions.

9.1.3.2 Wear

Wear occurs through adhesion, abrasion, fretting, corrosion or fatigue. The first two modes are sometimes called sliding wear and are discussed below. Further detailed discussion of wear is presented in Sections 9.7–9.9. Suh[3] has suggested that sliding wear can also be caused by delamination of surfaces. In addition to the discussion in this chapter, the reader is referred to the *Wear Control Handbook*[4] for further details.

Adhesive wear arises from the breaking of the adhesive bonds formed when asperities contact and deform. The resulting wear particles may be smeared on one of the surfaces, form work-hardened abrasive particles, or be ejected from the contact. Abrasive wear occurs when harder asperities plough through a softer counterface (two-body abrasion) or when a harder third particle gouges the surface of a softer material (three-body abrasion).

Wear equations Wear by sliding (adhesive, abrasive or delamination) is usually measured in terms of the specific wear rate, k, defined as the volume of material worn away for a unit load and unit sliding distance. Thus:

$$k = v/(W.L) \tag{9.1}$$

where

v = volume of worn material (m^3),
W = normal applied load (N),
L = total sliding distance (m).

The standard units are $m^2\ N^{-1}$. Values of 10^{-16} or lower are indicative of mild wear, and values greater then 10^{-14} represent severe wear. Most material wear rates lie within the range 10^{-17} and 10^{-12}.

PV factors in wear Rearrangement of equation (9.1) can be effected to produce:

$$v = k.W.L \tag{9.2}$$

Dividing both sides of this equation by the apparent area of contact, a, yields:

$$h = (k.W.L)/a \tag{9.3}$$

where h is the wear depth.

Since W/A is the bearing pressure, P, equation (9.3) can be written as:

$$h = k.P.l \tag{9.4}$$

Dividing both sides of the equation by time, t, and rearranging gives

$$k = h/(P.V.t) \tag{9.5}$$

where the sliding speed, V, is equal to L/T.

Sometimes the constant, k, which is numerically identical to that in equation (9.1), is called the Wear Factor.

Equation (9.5) can be rearranged to yield:

$$k.t/h = 1/(P.V) \tag{9.6}$$

If the parameter k is a constant for a particular configuration, then an acceptable value for the term $(k.t/h)$ can be determined since the required life, t, and the acceptable maximum wear depth, h, can both be specified. Equation (9.6) then shows that the parameter $(k.t/h)$ is inversely proportional to the product of P and V. This is often quoted by manufacturers of dry or partially lubricated bearings as the bearing's 'PV factor'.

This same product, PV, also influences the temperature rise at the sliding contact. This can be deduced from the fact that:

- Power loss is proportional to the product of friction force and speed.
- Heat loss by conduction is proportional to temperature difference, T, between the sliding surface and its surroundings, the apparent area of the contact, A, and the conductivity of the bearing and its surroundings.

Thus the temperature rise, T, at the sliding interface is given by:

$$T = c.\mu P.V$$

where c is a constant which characterizes the resistance of the bearing configuration to heat dissipation. This is discussed further in Section 9.7.

9.1.3.3 Fluid film lubrication

This form of lubrication can be achieved using liquids or gases. The aim is to keep the surfaces separated during normal operation. The most common liquid lubricants are mineral oils, which are discussed in Section 9.2. Air is probably the most common gaseous lubricant.

Liquid film bearings usually exhibit laminar flow, and can be designed using the Reynolds equation as discussed in Section 9.3. A modified form of the familiar Reynolds number, Re, is used in fluid film lubrication studies, defined as:

$$Re = (\rho.u.l./\eta).(h/l)$$

where

ρ = density of the lubricant,
u = a representative velocity of the lubricant,
l = characteristic dimension of the bearing (e.g. length or width),
η = dynamic viscosity of the lubricant,
h = characteristic film thickness.

This ratio assesses the relative importance of viscous and so-called inertia forces. If $Re \ll 1$, the former dominate the latter and laminar flow pertains. When $Re \gg 1$, the latter dominate the former and turbulent flow is present. Some higher speed bearings operate in the turbulent regime. Further reading on turbulent flow can be found in reference 5.

9.2 Lubricants (oils and greases)

9.2.1 Physical characteristics

Reference will be made to the physical characteristics of lubricants as they affect their selection for various applications. These terms are well known to the lubricant supplier but are not always fully understood by the user. Brief descriptions of these characteristics are therefore given so that their significance may be appreciated.

9.2.1.1 Viscosity

This is the most important physical property of a lubricating oil; it is a measure of its internal friction or resistance to flow. In simple terms, it provides a measure of the thickness (not density) of a lubricating oil at a given temperature; the higher the viscosity, the thicker the oil. Accurate determination of viscosity involves measuring the rate of flow in capillary tubes, the unit of measurement being the centistoke (cSt). As oils become thinner on heating and thicker on cooling a viscosity figure must always be accompanied by the temperature at which it was determined.

The number of commercial viscosity systems can be confusing, and as kinematic viscometers are much more sensitive and consistent, there is a growing tendency to quote kinematic viscosities. The International Standards Organization (ISO) uses kinematic viscosity in its viscosity grade classification (Table 9.1). These ISO grade numbers are used by most oil companies in their industrial lubricant nomenclature. This provides the user with a simple verification of conformity regarding viscosity between plant manufacturer and oil supplier recommendations and also in the monitoring of correct oil usage on his plant.

9.2.1.2 Viscosity Index (VI)

This is a way of expressing the rate of change of viscosity with temperature. All oils become less viscous as the temperature increases. The rate of change of viscosity varies with different oils and is mainly dependent on the type of crude from which the oil is derived and the refining method. The higher the VI figure, the lower is the variation in viscosity relative to temperature. The VI of an oil is an important property in applications where the operating temperature is subject to considerable change.

9.2.1.3 Pour point

This is a rough measure of a limiting viscosity. It is the temperature 2.5°C above that at which the oil ceases to flow when the vessel in which it has been cooled is held horizontally for 5 s. The pour point is a guide to behaviour and care should always be taken that operating temperatures are above the figure specified by the oil manufacturer as the pour point of a given oil.

9.2.1.4 Flash point

The flash point of an oil is the temperature at which it gives off, under specified conditions, sufficient vapour to form a flammable mixture with air. This is very different from the

Table 9.1 ISO viscosity grade chart

ISO viscosity grade	*Mid-point kinematic viscosity*	*Kinematic viscosity limits cSt at 40°C (104°F)*	
		min.	*max.*
2	2.2	1.98	2.42
3	3.2	2.88	3.52

68	68	61.2	74.8
100	100	90.0	110
150	150	135	165
220	220	198	242
320	320	288	352
460	460	414	506
680	680	612	748
1000	1000	900	1100
1500	1500	1350	1650

temperature of spontaneous combustion. The test is an empirical one and the result depends upon the instrument used and the prescribed conditions. For example, the flash point may be 'closed' or 'open', depending on whether the test apparatus has a lid or not. As far as lubricating oils are concerned, the test is of limited significance, although it can be indicative of contamination (for example, the dilution of crankcase oil by fuel).

9.2.1.5 Penetration of grease

The most important physical property of a lubricating grease is its consistency, which is analogous to the viscosity of a liquid. This is determined by an indentation test in which a weighted metal cone is allowed to sink into the grease for a specified time. The depth to which the cone penetrates, in tenths of a millimetre, is a measure of the consistency. There is a widely accepted scale, that of the American National Lubricating Grease Institute (NLGI), that relates penetration to a consistency number.

The penetration test is used mainly to control manufacture and to classify greases and is, within limits, a guide to selection. Penetrations are often qualified by the terms 'worked' and 'unworked'. As greases are thixotropic, that is, they soften as a result of shear but harden again after shearing has stopped, the worked penetration for a particular grease may be appreciably greater than the unworked penetration. The difference between these two figures may be a useful guide to the selection of greases for operating conditions that involve much churning – as small a difference as possible being desirable (see Table 9.2).

9.2.1.6 Drop point of grease

The drop point of a grease is an indication of change from a soft solid to a viscous fluid; its value depends completely on the conditions of test, particularly the rate of heating. The grease sample, which is held in a small metal cup with an orifice, is heated at a predetermined rate. The drop point is the temperature at which a drop of the sample falls from the cup.

The drop point is of limited significance as far as the user is concerned, for it gives no indication of the condition of the grease at lower temperatures, or of change in consistency or structure with heat. It is a very rough indication of a grease's resistance to heat and a guide to manufacture. The difference between the highest temperature at which a grease can be used and the drop point varies very much between types. It is at its maximum with some soda greases and much smaller with multi-purpose lithium products and modern complex greases.

Table 9.2 NLGI consistency classification for greases

NLGI number	*ASTM worked penetration at 77°F*
000	455–475
00	400–435
0	355–385
1	310–340
2	265–295
3	220–250
4	175–205
5	130–160
6	85–115

9.2.2 Additives

Much highly stressed modern machinery runs under conditions in which a straight mineral oil is not adequate. Even the highest quality mineral oil can be unsatisfactory in response of its resistance to oxidation and its behaviour under pure boundary conditions, but it is possible to improve these characteristics by the addition of relatively small amounts of complex chemicals. This use of additives resembles in many ways the modification of the properties of steel by the addition of small amounts of other chemicals. It will be of value to have some knowledge of the effect of each type of additive.

9.2.2.1 Anti-oxidants

When mixed with oxygen, lubricating oil undergoes chemical degradation resulting in the formulation of acidic products and sludge. This reaction, which is affected by temperature, the presence of catalysts such as copper and the composition of the oil, can be delayed by the inclusion of suitable additives.

Anti-oxidants are the most extensively used additives and will be found in oils and greases which are expected to operate for considerable periods or under conditions which would promote oxidation. Typical examples are crankcase oils and bearing greases.

9.2.2.2 Anti-foam

The entrainment of air in lubricating oil can be brought about by operating conditions (for example, churning) and by bad design such as a return pipe which is not submerged. The air bubbles naturally rise to the surface, and if they do not burst quickly, a blanket of foam will form on the oil surface. Further air escape is thus prevented and the oil becomes aerated. Oil in this condition can have an adverse effect on the system which, in extreme cases, could lead to machine failure. The function of an anti-foam additive is to assist in the burst of air bubbles when they reach the surface of the oil.

9.2.2.3 Anti-corrosion

The products of oil oxidation will attack metals, and this can be prevented by keeping the system free from pro-oxidative impurities and by the use of anti-oxidants. These additives will not, however, prevent rusting of ferrous surfaces when air and water are present in the mineral oil. The presence of absorbed air and moisture is inevitable in lubricating systems and therefore the oil must be inhibited against rusting. These additives, which are homogeneously mixed with the oil, have an affinity for metal, and a strongly absorbed oil film is formed on the metal surface which prevents the access of air and moisture.

9.2.2.4 Anti-wear

The increasing demands being made on equipment by the requirement for increased output from smaller units create problems of lubrication, even in systems where full-fluid film conditions generally exist. For instance, at start-up, after a period of rest, boundary lubrication conditions can exist and the mechanical wear that takes place could lead to equipment failure. Anti-wear additives, by their polar nature, help the oil to form a strongly absorbed layer on the metal surface which resists displacement under pressure, thereby reducing friction under boundary conditions.

9.2.2.5 Extreme pressure

Where high loading and severe sliding speeds exist between two metal surfaces, any oil film present is likely to be squeezed out. Under these conditions very high instantaneous pressures and temperatures are generated. Without the presence of extreme pressure additives the asperities would be welded together and then torn apart. Extreme pressure additives react at these high temperatures with the metal or another oil component to form compounds which are more easily deformed and sheared than the metal itself, and so prevent welding. Oils containing extreme pressure additives are generally used in heavily loaded gearboxes which may also be subjected to shock loading.

9.2.2.6 Detergent/dispersant

The products of combustion formed in internal combustion engines, combined with water and unburnt fuel, will form undesirable sludge which can be deposited in the engine and so reduce its operation life and efficiency. Detergent/dispersant additives prevent the agglomeration of these products and their deposition in oilways by keeping the finely divided particles in suspension in the oil. They are used in engine-lubricating oils where, when combined with anti-oxidants, they prevent piston-ring sticking. They are essential for high-speed diesels, and also desirable for petrol engines.

9.2.2.7 Viscosity Index improvers

When mineral oils are used over an extended temperature range it is frequently found that the natural viscosity/temperature relationship results in excessive thinning out in the higher-temperature region if the desired fluidity is to be maintained at the lower region. The addition of certain polymers will, within limits, correct this situation. They are of particular value in the preparation of lubricating oils for systems sensitive to changes in viscosity such as hydraulic controls. They are also used in multigrade engine oils.

9.2.3 Lubricating-oil applications

There is a constant effort by both the supplier and consumer of lubricants to reduce the number of grades in use. The various lubricant requirements of plant not only limit the extent of this rationalization but also create the continuing need for a large number of grades with different characteristics.

It is not possible to make lubricants directly from crude oil that will meet all these demands. Instead, the refinery produces a few basic oils and these are then blended in varying proportions, together with additives when necessary, to produce an oil with the particular characteristics required. In some instances the continued increase in plant performance is creating demands on the lubricant which are at the limit of the inherent physical characterisics of mineral oil. Where the operational benefit justifies the cost, the use of synthetic base stocks is being developed.

Where these are considered for existing plant, seal and paint compatibility needs to be reviewed before such products are introduced. The problems which face the lubricant supplier can best be illustrated by looking at the requirements of certain important applications.

9.2.4 General machinery oils

These are lubricants for the bearings of most plant, where circulating systems are not involved. These are hand, ring, bottle or bath lubricated bearings of a very wide range of equipment; line shafting, electric motors, many gear sets and general oil-can duties. The viscosity of these oils will vary to suit the variations in speed, load and temperature.

While extreme or arduous usage conditions are not met within this category, the straight mineral oils which are prescribed must possess certain properties. The viscosity level should be chosen to provide an adequate lubricant film without undue fluid friction, though this may also be influenced by the method of application. For instance, a slightly higher viscosity might be advisable if intermittent hand oiling has to be relied upon. Although anti-oxidants are not generally required, such oils must have a reasonable degree of chemical stability (Figure 9.3).

9.2.5 Engine lubricants

The type of power or fuel supply available will influence the decision on prime mover to be used. This is often electric power, but many items of plant such as compressors, generators or works locomotives, will be powered by diesel engines, as will most of the heavy goods vehicles used in and outside the works.

The oils for these engines have several functions to perform while in use. They must provide a lubricant film between moving parts to reduce friction and wear, hold products of combustion in suspension, prevent the formation of sludges and assist in cooling the engine. Unless the lubricant chosen fulfils these conditions successfully, deposits and sludge will form with a consequent undesirable increase in wear rate and decrease in engine life.

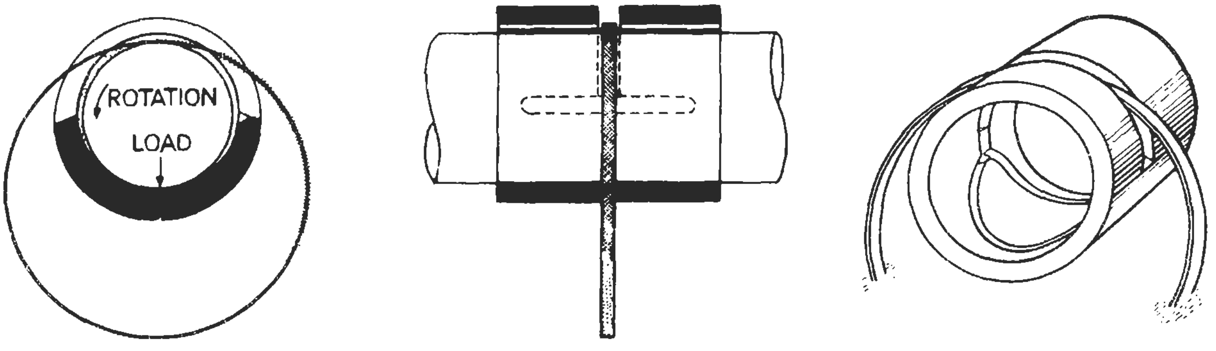

Figure 9.3 Ring oiled bearings

9.2.5.1 *Frictional wear*

If the effects of friction are to be minimized, a lubricant film must be maintained continuously betwen the moving surfaces. Two types of motion are encountered in engines, rotary and linear. A full fluid-film between moving parts is the ideal form of lubrication, but in practice, even with rotary motion, this is not always achievable. At low engine speeds, for instance, bearing lubrication can be under boundary conditions.

The linear sliding motion between pistons, piston rings and cylinder walls creates lubrication problems which are some of the most difficult to overcome in an engine. The ring is exerting a force against the cylinder wall while at the same time the ring and piston are moving in the cylinder with a sliding action. Also, the direction of piston movement is reversed on each stroke. To maintain a full fluid oil film on the cylinder walls under these conditions is difficult and boundary lubrication can exist. Frictional wear will occur if a lubricant film is either absent or unable to withstand the pressures being exerted. The lubricant will then be contaminated with metal wear particles which will cause wear in other engine parts as they are carried round by the lubricant.

9.2.5.2 *Chemical wear*

Another major cause of wear is the chemical action associated with the inevitable acidic products of fuel combustion. This chemical wear of cylinder bores can be prevented by having an oil film which is strongly adherent to the metal surfaces involved, and which will rapidly heal when a tiny rupture occurs. This is achieved by the use of a chemical additive known as a corrosion inhibitor.

9.2.5.3 *Products of combustion and fuel dilution*

As it is not possible to maintain perfect combustion conditions at all times, contamination of the oil by the products of combustion is inevitable. These contaminants can be either solid or liquid.

When an engine idles or runs with an over-rich mixture the combustion process is imperfect and soot will be formed. A quantity of this soot will pass harmlessly out with the exhaust but some will contaminate the oil film on the pistons and cylinders and drain down into the crankcase. If there is any water present these solids will emulsify to form sludges which could then block the oilways. Filters are incorporated into the oil-circulation system to remove the solid contaminants together with any atmospheric dust which bypasses the air filters.

One of the liquid contaminants is water, the presence of which is brought about by the fact that when fuel is burnt it produces approximately its own weight in water. When the engine is warm this water is converted into steam, which passes harmlessly out of the exhaust. However, with cold running or start-up conditions this water is not converted and drains into the sump. Having dissolved some of the combustion gases, it will be acidic in nature and will form sludges.

Another liquid contaminant is unburnt fuel. A poor-quality fuel, for example, may contain high boiling point constituents which will not all burn off in the combustion process and will drain into the sump. The practice of adding kerosene to fuel to facilitate easy starting in very cold weather will eventually cause severe dilution of the lubricating oil. Excessive use of over-rich mixture in cold weather will mean that all the fuel is not burnt because of the lack of oxygen and again, some remains to drain into the sump.

Poor vaporization of the fuel will also produce oil dilution. Generally, this fuel will be driven off when the engine becomes warm and is running at optimum conditions. However, severe dilution of the oil by fuel could have serious results as the viscosity of the oil will be reduced to an unacceptable level.

9.2.5.4 *Oxidation*

The conditions of operation in an engine are conducive to oil oxidation, and this is another problem to be overcome by the lubricant. In the crankcase, the oil is sprayed from various components in the form of an oil mist which is in contact with a large quantity of air and at a fairly high temperature. Oxidation produces complex carbonaceous products and acidic material and these, combined with fuel contaminants, will form stable sludges. In the combustion chamber, where the temperatures are very much higher, the oil is scraped up the cylinder walls by the piston ascending at very high speeds and is again present in the form of an oil mist. A form of carbon deposit is produced by a combination of heat decomposition and oxidation. Some of this deposit will remain, but some will pass into the sump. The effect of oxidation adds to the problem of oil contamination by the products of combustion, resulting in the formation of a resin-like material on the pistons and hot metal parts known as 'lacquer' and acidic material which will attack bearing metals such as copper-lead.

These problems of engine lubrication can be overcome by using a highly refined oil. The resistance to oxidation is further enhanced by the use of anti-oxidants. The addition of corrosion-inhibitors counters acidic materials produced by combustion at low engine temperatures.

Detergent–dispersant additives are incorporated so that the carbonaceous matter produced by imperfect combustion is retained in suspension in the oil, preventing it from being deposited on the engine surfaces. Such an oil is known as a fully detergent-type lubricant. All these additives are gradually consumed during operation and the rate of decline in their usefulness will determine the oil-change period. This rate is, in turn, influenced by the conditions of operation.

9.2.5.5 *The SAE viscosity system*

This classification was devised by the Society of Automotive Engineers (SAE) in America by dividing the viscosity span into four and giving each of the divisions a number – SAE 20, 30, 40 and 50. The thinnest (SAE 20), for example, covered the range 5.7–9.6 cSt specified at 210°F, which was considered to be a temperature typical of a hot engine. (The SAE originally specified temperatures in °F, because that was the convention. Today, temperatures are quoted in °C.)

Later, the SAE series was extended to include much lower-viscosity oils because of the growing demand for easier winter starting. The viscosities of the three new grades were specified at 0°F (typical of cold morning temperatures) and each was given the suffix W for Winter – SAE 5W, 10W and 20W. Later still, grades of 0W, 15W and 25W were added to satisfy the more precise requirements of modern engines (Table 9.3).

9.2.5.6 *Multigrades*

All oils become less viscous when heated and more viscous when cooled, but some are less sensitive than others to these viscosity/temperature effects. The degree of sensitivity is known as Viscosity Index (VI). An oil is said to have high VI if it displays a relatively small change of viscosity for a given change of temperature.

In the 1950s, developments in additive technology led to the production of engine oils with unusually high VIs, known as

Table 9.3 Viscosity chart

	Maximum viscosity cP at °C[a]	*Maximum borderline pumping temperature (°C)*[b]	*Viscosity (cSt) at 100°C min.*	*Viscosity (cSt) at 100°C max.*
0W	3250 at −30	−35	3.8	—
5W	3500 at −25	−30	3.8	—
10W	3500 at −20	−25	4.1	—
15W	3500 at −15	−20	5.6	—
20W	4500 at −10	−15	5.6	—
25W	6000 at −5	−10	9.3	—
20	—	—	5.6	9.3
30	—	—	9.3	12.5
40	—	—	12.5	16.3
50	—	—	16.3	21.9

[a] As measured in the Cold Cranking Simulator (CCS).
[b] As measured in the Mini Rotary Viscometer (MRV).

multigrade oils. A multigrade oil's high resistance to temperature change is sufficient to give it the combined virtues of a low-viscosity grade at low (starting) temperatures and a high-viscosity one at running temperatures. An SAE 20W-40 multigrade, for example, is as thin at −20°C as a 20W oil, but as thick at 100°C as an SAE 40 oil. Thus the multigrade combines full lubrication protection at working temperatures with satisfactorily easy starting on frosty mornings. Figure 9.4 is a viscosity–temperature graph for six monograde oils and a 10W-40 multigrade, showing how the multigrade has the high-temperature properties of an SAE 40 oil and the low-temperature properties of an SAE 10W. Thus the multigrade is suitable for all-year-round use.

9.2.5.7 Performance ratings

The SAE numbering system refers purely to the viscosity of the oil, and is not intended to reflect lubricating performance (there is no such thing as an 'SAE quality' oil, for example).

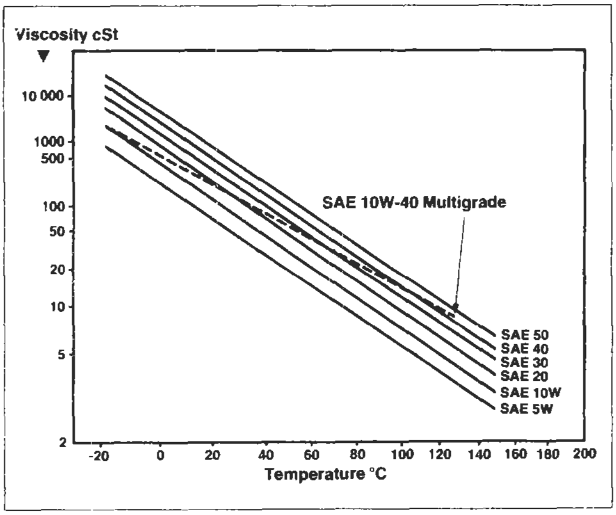

Figure 9.4 Multigrade chart

Engine oils are marketed in a range of performance levels, and need to be classified according to the severity of service conditions in which they are designed to operate. Accordingly, the American Petroleum Institute (API) has drawn up a coding system in which oils are subjected to a series of classifying bench-tests known as the 'Sequence' tests.

9.2.5.8 The API service classifications

In the API system the least demanding classification for a petrol engine was originally designated SA. The most demanding is, at present, SG. (The S stands for Service Station.) Constant development of both engines and oils means that from time to time the highest ratings are superseded by even higher ratings. The API system also classifies diesel engine oils by their severity of service. Here the categories have the prefix C, which stands for Commercial.

Petrol engines

SA	Service typical of engines operated under mild conditions. This classification has no performance requirements.
SB	Service typical of engines operating in conditions such that only minimum protection of the type afforded by additives is desired. Oils designed for this service have been used since the 1930s; they provide only anti-scuff capability and resistance to oil oxidation and bearing corrosion.
SC	Service typical of petrol engines in 1964–1967 cars and trucks. Oils designed for this service provide control of high- and low-temperature deposits, wear, rust and corrosion.
SD	Service typical of 1967–1970 petrol engines in cars and some trucks; but it may apply to later models. Oils designed for this service provide more protection than SC against high- and low-temperature deposits, wear, rust and corrosion; and may be used where SC is recommended.
SE	Service typical of petrol engines in cars and some trucks in 1972–1979. Oils designed for this service provide more protection against oxidation, high-temperature deposits, rust and corrosion than SD or SC, and may be used where those classifications are recommended.
SF	Service typical of petrol engines in cars and some trucks from 1980. Oils developed for this service provide better oxidation stability and anti-wear performance than SE oils. They also provide protection against engine deposits, rust and corrosion. Oils meeting SF may be used wherever SE, SD or SC is recommended.
SG	Service typical of petrol engines in present cars, vans and light trucks. Oils developed for this service provide improved control of engine deposits, oil oxidation and engine wear relative to oils developed for previous categories. Oils meeting SG may be used wherever SF, SE, SF/CC or SE/CC are recommended.

Diesel engines

CA	Service typical of diesel engines operated in mild to moderate duty with high-quality fuels. Occasionally this category has included petrol engines in mild service. Oils designed for this service were widely used in the late 1940s and 1950s; they provided protection from bearing corrosion and light-temperature deposits.
CB	This category is basically the same as CA, but improved to cope with low-quality fuels. Oils designed

for this service were introduced in 1949.

CC Service typical of lightly supercharged diesel engines operated in moderate to severe duty. Has included certain heavy-duty petrol engines. Oils designed for this service are used in many trucks and in industrial and construction equipment and farm tractors. These oils provide protection from high-temperature deposits in lightly supercharged diesels and also from rust, corrosion and low-temperature deposits in petrol engines.

CD Service typical of supercharged diesel engines in high-speed high-output duty requiring highly effective control of wear and deposits. Oils designed for this service provide protection from bearing corrosion and high-temperature deposits in supercharged diesel engines running on fuels of a wide quality range.

CDII Service typical of two-stroke cycle diesel engines requiring highly effective control over wear and deposits. Oils designed for this service also meet all the requirements of CD.

CE Service typical of certain turbocharged or supercharged heavy-duty diesel engines operating under both low speed–high load and high speed–low load conditions. Oils designed for this service must also meet the requirements specified for CC and CD classifications.

Before an oil can be allocated any given API performance level it must satisfy requirements laid down for various engine tests. In the SG category, for example, the engine tests are as follows:

Service IID measures the tendency of the oil to rust or corrode the valve train and to influence the value lifter operation.
Sequence IIIE measures high-temperature oil oxidation, sludge and varnish deposits, cam-and-tappet wear, cam and lifter scuffing and valve lifter sticking.
Sequence VE evaluates sludge deposits, varnish deposits, oil-ring clogging and sticking, oil-screen plugging and cam wear.
Caterpillar IH2 determines the lubricant effect on ring sticking, ring and cylinder wear, and accumulation of piston deposits.
CRC L-38: the characteristics assessed are resistance to oxidation, bearing corrosion, tendency to formation of sludge and varnish, and change of viscosity.

In the CE category the tests are:

Caterpillar IG2: the lubricant characteristics determined are ring sticking, ring and cylinder wear, and accumulation deposits under more severe test conditions than those for Caterpillar IH2.
Cummins NTC-400 measures crownland and piston deposits, camshaft roller follower pin wear and oil consumption.
Mack T6 assesses oil oxidation, piston deposits, oil consumption and ring wear.
Mack T7 evaluates oil thickening.
CRC L-38 (as above).

Other specifications Various authorities and military bodies issue specifications relating to the service performance of engine oils. In some instances the ratings are almost identical with those of the API, but most of them are not precisely parallel because they cover performance factors encountered in particular engines and particular categories of service.

The most common of the other specifications are those with the prefix MIL, issued by the US military authorities. MIL-L-2104E approximates to the API CE rating for diesel lubricants, although it also relates to petrol engines that require API SE performance. MIL-L-46152D covers oils for both diesel and petrol engines, and approximates to API SG/CC (Figure 9.5).

CCMC ratings Another important set of performance specifications is produced by the European Vehicle Manufacturers' Association, known by its initials CCMC*. The CCMC rating G-1 corresponds roughly to API SE, and G-2 to API SF. G-3 (comparable to MIL-L-46152B, for petrol engines only) covers fuel-efficient and light-viscosity lubricants blended from special high-quality base oils. CCMC also issues specifications for diesel lubricants: D-1 approximates to API CC, D-2 to API CD and MIL-L-2104D, and D-3 to API CE and MIL-L-2104E.

To qualify for the CCMC categories G and D, an oil must meet the requirements of the following tests in addition to the relevant API classification tests.

For the G category
Ford Kent, which evaluates cold ring sticking, piston skirt varnish, oil thickening and consumption.
Fiat 132, to evaluate the tendency of the oil to cause pre-ignition.
Daimler Benz OM 616 to evaluate wear of cylinders and cams.
Bosch Injector Rig, measuring the mechanical stability of the oil to assess its shear stability.
Noack Test, to measure the weight loss due to evaporation of the oil.

High shear/high temperature viscosity test, to assess the oil's capability for resisting shear, and so retaining its viscosity, at high temperatures.
Tests for oil/seal compatibility and oil consumption are still to be established.

For the D category
Bosch Injector Rig, *Noack*, and *D-B OM* 616 tests as above together with:

For D1 and D2 only, *MWM-B* evaluating varnish, carbon deposits, and ring-sticking;
For D3 only, *D-B OM 352A* bore polishing and piston cleanliness;
For PD1 only, *VW 1.6L* to evaluate ring sticking and piston cleanliness.

9.2.6 Hydraulic fluids

The wide application of hydraulic systems has undoubtedly been stimulated by the increasing use of fully automatic controls for sequences of operations where the response to signals must be rapid and the controls themselves light and easily operated. These needs are met by hydraulic circuits which, in addition, provide infinitely variable speed control, reversal of high-speed parts without shock, full protection against damage from overhead and automatic lubrication.

Over the years the performance standards of hydraulic equipment have risen. Whereas a pressure of about 7000 kPa used to be adequate for industrial hydraulic systems, nowadays systems operating with pressures of 15 000–25 000 kPa are common. Pressures above 35 000 kPa are to be found in applications such as large presses for which suitable high-

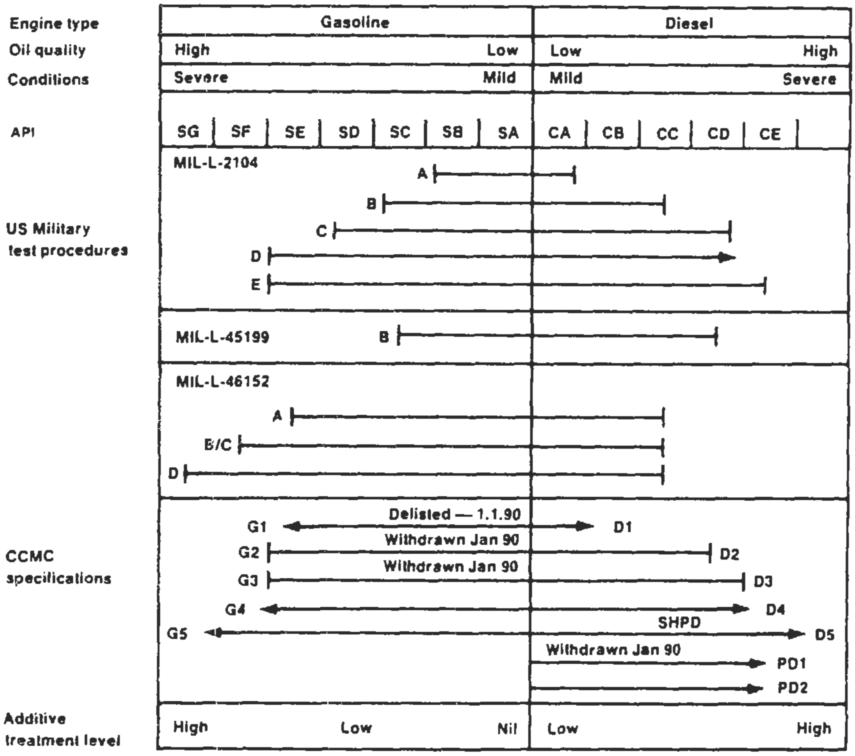
*Comité des Constructeurs d'Automobiles du Marché Commun represents joint industry opinion on factors such as lubricant specifications, emissions, vehicle design and safety standards. With regard to crankcase lubricants, CCMC defines sequences of engine tests, and the tests themselves are defined by CEC (Coordinating European Committee for the Development of Performance Tests for Lubricants and Engine Fuels: a joint body of the oil and motor industries).



SHPD = Super High Performance Diesel
PD = Passenger (Car) Diesel

Figure 9.5 Approximate relationship between classifications and test procedures

pressure pumps have been developed. Additionally, systems have to provide increased power densities, more accurate response, better reliability and increased safety. Their use in numerically controlled machine tools and other advanced control systems creates the need for enhanced filtration. Full flow filters as fine as 1–10 μm retention capability are now to be found in many hydraulic systems.

With the trend toward higher pressures in hydraulic systems the loads on unbalanced pump and motor components become greater and this, coupled with the need for closer fits to contain the higher pressures, can introduce acute lubrication problems. Pumps, one of the main centres of wear, can be made smaller if they can run at higher speeds or higher pressures, but this is only possible with adequate lubrication. For this reason, a fluid with good lubrication properties is used so that 'hydraulics' is now almost synonymous with 'oil hydraulics' in general industrial applications. Mineral oils are inexpensive and readily obtainable while their viscosity can be matched to a particular job.

The hydraulic oil must provide adequate lubrication in the diverse operating conditions associated with the components of the various systems. It must function over an extended temperature range and sometimes under boundary conditions. It will be expected to provide a long, trouble-free service life; its chemical stability must therefore be high. Its wear-resisting properties must be capable of handling the high loads in hydraulic pumps. Additionally, the oil must protect metal surfaces from corrosion and it must both resist emulsification and rapidly release entrained air that, on circulation, would produce foam.

Mineral oil alone, no matter how high its quality, cannot adequately carry out all the duties outlined above and hence the majority of hydraulic oils have their natural properties enhanced by the incorporation of four different types of additives. These are: an anti-oxidant, an anti-wear agent, a foam-inhibitor and an anti-corrosion additive. For machines in which accurate control is paramount, or where the range of operating temperatures is wide – or both – oils will be formulated to include a VI improving additive as well.

9.2.6.1 Viscosity

Probably the most important single property of a hydraulic oil is its viscosity. The most suitable viscosity for a hydraulic system is determined by the needs of the pump and the circuit; too low a viscosity induces back-leakage and lowers the pumping efficiency, while too high a viscosity can cause overheating, pump starvation and possibly cavitation.

9.2.6.2 Viscosity Index

It is desirable that a fluid's viscosity stays within the pump manufacturer's stipulated viscosity limits, in order to accommodate the normal variations of operating temperature. An oil's viscosity falls as temperature rises; certain oils, however, are less sensitive than others to changes of temperatures, and these are said to have a higher VI. Hydraulic oils are formulated from base oils of inherently high VI, to minimize changes of viscosity in the period from start-up to steady running and while circulating between the cold and hot parts of a system.

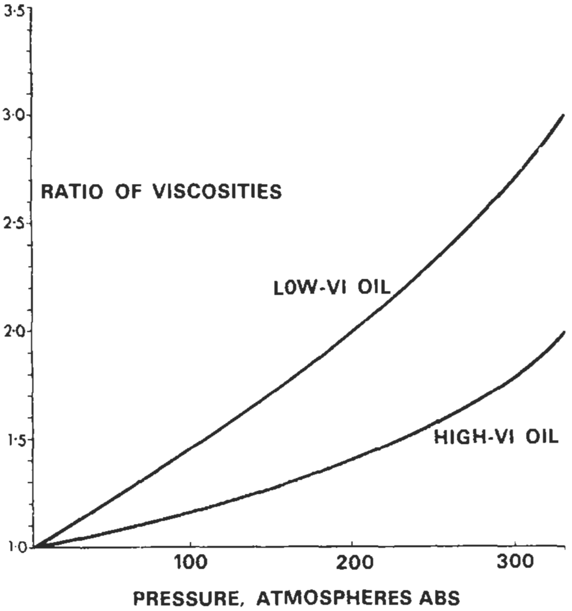


Figure 9.6

9.2.6.3 *Effects of pressure*

Pressure has the effect of increasing an oil's viscosity. While in many industrial systems the working pressures are not high enough to cause problems in this respect, the trend towards higher pressures in equipment is requiring the effect to be accommodated at the design stage. Reactions to pressure are much the same as reactions to temperature, in that an oil of high VI is less affected than one of low VI. A typical hydraulic oil's viscosity is doubled when its pressure is raised from atmospheric to 35 000 kPa (Figure 9.6).

9.2.6.4 *Air in the oil*

In a system that is poorly designed or badly operated, air may become entrained in the oil and thus cause spongy and noisy operation. The reservoir provides an opportunity for air to be released from the oil instead of accumulating within the hydraulic system. Air comes to the surface as bubbles, and if the resultant foam were to become excessive it could escape through vents and cause loss of oil. In hydraulic oils, foaming is minimized by the incorporation of foam-breaking additives. The type and dosage of such agents must be carefully selected, because although they promote the collapse of surface foam they may tend to retard the rate of air release from the body of the oil.

9.2.6.5 *Oxidation stability*

Hydraulic oils need to be of the highest oxidation stability, particularly for high-temperature operations, because oxidation causes sludges and lacquer formation. In hydraylic oils, a high level of oxidation stability is ensured by the use of base oils of excellent quality, augmented by a very effective combination of oxidation inhibitors.

A very approximate guide to an oil's compatibility with rubbers commonly used for seals and hoses is given by the Aniline Point, which indicates the degree of swelling likely to arise; a high figure indicates a high level of compatibility. This system has been superseded by the more accurate Seal Compatibility Index (SCI), in which the percentage volume swell of a 'standard' nitrile rubber is determined after an immersion test in hot oil.

9.2.6.6 *Fire-resistant fluids*

Where fire is a hazard, or could be extremely damaging, fire-resistant hydraulic fluids are needed. They are referred to as 'fire resistant' (FR) so that users should be under no illusions about their properties. FR fluids do not extinguish fires: they resist combustion or prevent the spread of flame. They are not necessarily fireproof, since any fluid will eventually decompose if its temperature rises high enough. Nor are they high-temperature fluids, since in some instances their operating temperatures are lower than those of mineral oils. FR fluids are clearly essential in such applications as electric welding plants, furnace-door actuators, mining machinery, diecasters, forging plant, plastics machinery and theatrical equipment. When leakage occurs in the pressurized parts of a hydraulic system the fluid usually escapes in the form of a high-pressure spray. In the case of mineral oils this spray would catch fire if it were to reach a source of ignition, or would set up a rapid spread of existing flame. FR fluids are therefore formulated to resist the creation of flame from a source of ignition, and to prevent the spread of an existing fire.

Four main factors enter into the selection of a fire-resistant fluid:

1. The required degree of fire-resistance
2. Operational behaviour in hydraulic systems (lubrication performance, temperature range and seal compatibility, for example)
3. Consideration of hygiene (toxicological, dermatological and respiratory effects)
4. Cost

9.2.6.7 *Types of fluid*

The fluids available cover a range of chemical constituents, physical characteristics and costs, so the user is able to choose the medium that offers the best compromise for operational satisfaction, fire-resistance and cost effectiveness. Four basic types of fluid are available and are shown in Table 9.4.

In a fully synthetic FR fluid the fire resistance is due to the chemical nature of the fluid; in the others it is afforded by the

Table 9.4 CETOP classifications of fire-resistant hydraulic fluids

Class	*Description*
HF-A	Oil-in-water emulsions containing a maximum of 20% combustible material. These usually contain 95% water
HF-B	Water-in-oil emulsions containing a maximum of 60% combustible material. These usually contain 40–45% water
HF-C	Water–glycol solutions. These usually contain at least 35% water
HF-D	Water-free fluids. These usually refer to fluids containing phosphate esters, other organic esters or synthesized hydrocarbon fluids

CETOP: Comité European des Transmissions Oleohydrauliques et Pneumatiques.

presence of water. The other main distinction between the two groups is that the fully synthetic fluids are generally better lubricants and are available for use at operating temperatures up to 150°C, but are less likely to be compatible with the conventional sealing materials and paints than are water-based products.

When a water-based fluid makes contact with a flame or aaa hot surface its water component evaporates and forms a steam blanket which displaces oxygen from around the hot area, and this obviates the risk of fire. Water-based products all contain at least 35% water. Because water can be lost by evaporation, they should not be subjected to operating temperatures above about 60°C. Table 9.5 shows a comparison of oil and FR fluids.

9.2.6.8 High water-based hydraulic fluids

For a number of years HF-A oil-in-water emulsions have been used as a fire-resistant hydraulic medium for pit props. Concern over maintenance costs and operational life has created interest in a better anti-wear type fluid. Microemulsions are known to give better wear protection than the normal oil-in-water emulsions. At the same time the car industry, in attempts to reduce costs especially from leakages on production machinery, has evaluated the potential for using HWBHF in hydraulic systems. As a result, in many parts of industry, not only those where fire-resistant hydraulic fluids are needed, there is a increasing interest in the use of HWBHF.

Such fluids, often referred to as 5/95 fluid (that being the ratio of oil to water), have essentially the same properties as water with the exception of the corrosion characteristics and the boundary lubrication properties which are improved by the oil and other additives. The advantages of this type of fluid are fire resistance, lower fluid cost, no warm-up time, lower power consumption and operating temperatures, reduced spoilage of coolant, less dependence on oil together with reduced transport, storage, handling and disposal costs, and environmental benefits.

In considering these benefits the the user should not overlook the constraints in using such fluids. They can be summarized as limited wear and corrosion protection (especially with certain metals). increased leakage due to its low viscosity, limited operating temperature range and the need for additional mixing and in-service monitoring facilities.

Because systems are normally *not* designed for use with this type of fluid, certain aspects should be reviewed with the equipment and fluid suppliers before a decision to use such fluids can be taken. These are compatibility with filters, seals, gaskets, hoses, paints and any non-ferrous metals used in the equipment. Condensation corrosion effect on ferrous metals, fluid-mixing equipment needed, control of microbial infection together with overall maintaining and control of fluid dilution and the disposal of waste fluid must also be considered. Provided such attention is paid to these design and operating features, the cost reductions have proved very beneficial to the overall plant cost effectiveness.

Table 9.5 Comparison of oil and FR fluids

	Mineral oil	*Water-in-oil emulsion*	*Water-glycol*	*Phosphate ester*
Fire resistance	Poor	Fair	Excellent	Good
Relative density	0.87	0.94	1.08	1.14
Viscosity Index	High	High	High	Low
Vapour pressure	Low	High	High	Low
Special seals	No	Partly	Partly	Yes
Special paints	No	No	Yes	Yes
Rust protection	Very good	Good	Fair	Fair

9.2.6.9 Care of hydraulic oils and systems

Modern additive-treated oils are so stable that deposits and sludge formation in normal conditions have been almost eliminated. Consequently, the service life of the oils which is affected by oxidation, thermal degradation and moisture is extended.

Solid impurities must be continuously removed because hydraulic systems are self-contaminating due to wear of hoses, seals and metal parts. Efforts should be made to exclude all solid contaminants from the system altogether. Dirt is introduced with air, the amount of airborne impurities varying with the environment. The air breather must filter to at least the same degree as the oil filters.

It is impossible to generalize about types of filter to be used. Selection depends on the system, the rate of contamination build-up and the space available. However, a common arrangement is to have a full-flow filter unit before the pump with a bypass filter at some other convenient part of the system. Many industrial systems working below 13 500 kPa can tolerate particles in the order of 25–50 μm with no serious effects on either valves or pumps.

Provided that the system is initially clean and fitted with efficient air filters, metal edge-strainers of 0.127 mm spacing appear to be adequate, although clearances of vane pumps may be below 0.025 mm. It should be remembered that an excessive pressure drop, due to a clogged full-flow fine filter, can do more harm to pumps by cavitation than dirty oil.

If flushing is used to clean a new system or after overhaul it should be done with the hydraulic oil itself or one of lighter viscosity and the same quality. As the flushing charge circulates it should pass through an edge-type paper filter of large capacity. It is generally preferable to use a special pump rather than the hydraulic pump system, and the temperature of the oil should be maintained at about 40°C without local overheating.

9.2.7 Machine tools

Lubricants are the lifeblood of a machine tool. Without adequate lubrication, spindles would seize, slides could not slide and gears would rapidly distintegrate. However, the reduction of bearing friction, vital though it is, is by no means the only purpose of machine-tool lubrication. Many machines are operated by hydraulic power, and one oil may be required to serve as both lubricant and hydraulic fluid. The lubricant must be of correct viscosity for its application, must protect bearings, gears and other moving parts against corrosion, and, where appropriate, must remove heat to preserve working accuracies and aligments. It may additionally serve to seal the bearings against moisture and contaminating particles. In some machine tools the lubricant also serves the function of a cutting oil, or perhaps needs to be compatible with the cutting oil. In other tools an important property of the lubricant is its ability to separate rapidly and completely from the cutting fluid. Compatibility with the metals, plastics, sealing elements and tube connections used in the machine construction is an important consideration.

In machine-tool operations, as in all others, the wisest course for the user is to employ reputable lubricants in the manner recommended by the machine-tool manufacturer and the oil company suppying the product. This policy simplifies the selection and application of machine-tool lubricants. The user can rest assured that all the considerations outlined above have been taken into account by both authorities.

The important factors from the point of view of lubrication are the type of component and the conditions under which it operates, rather than the type of machine into which it is incorporated. This explains the essential similarity of lubricating systems in widely differing machines.

9.2.7.1 Bearings

As in almost every type of machine, bearings play an important role in the efficient functioning of machine tools.

9.2.7.2 Roller bearings

There is friction even in the most highly finished ball or roller bearing. This is due to the slight deformation under load of both the raceway and the rolling components, the presence of the restraining cage, and the 'slip' caused by trying to make parts of different diameter rotate at the same speed. In machine tools the majority of rolling bearings are grease-packed for life, or for very long periods, but other means of lubrication are also used (the bearings may be connected to a centralized pressure-oil-feed system for instance). In other cases, oil-mist lubrication may be employed both for spindle bearings and for quill movement. In headstocks and gearboxes, ball and roller bearings may be lubricated by splash or oil jets.

9.2.7.3 Plain journal bearings

Plain bearings are often preferred for relatively low-speed spindles operating under fairly constant loads, and for the spindles of high-speed grinding wheels. These bearings ride on a dynamic 'wedge' of lubricating oil. Precision plain bearings are generally operated with very low clearances and therefore require low-viscosity oil to control the rise of temperature. Efficient lubrication is vital if the oil temperature is to be kept within reasonable limits, and some form of automatic circulation system is almost always employed.

9.2.7.4 Multi-wedge bearings

The main drawback of the traditional plain bearing is its reliance on a single hydrodynamic wedge of oil, which under certain conditions tends to be unstable. Multi-wedge bearings make use of a number of fixed or rocking pads, spaced at intervals around the journal to create a series of opposed oil wedges. These produce strong radial, stabilizing forces that hold the spindle centrally within the bearing. With the best of these, developed especially for machine tools, deviation of the spindle under maximum load can be held within a few millionths of a centimetre.

9.2.7.5 Hydrostatic bearings

To avoid the instabilities of wedge-shaped oils films, a lubricating film can be maintained by the application of pressurized oil (or, occasionally, air) to the bearing. The hydrostatic bearing maintains a continuous film of oil even at zero speed, and induces a strong stabilizing force towards the centre which counteracts any displacement of the shaft or spindle. Disadvantages include the power required to pressurize the oil and the necessary increase in the size of the filter and circulatory system.

9.2.7.6 Slideways

Spindles may be the most difficult machine-tool components to design, but slideways are frequently the most troublesome to lubricate. In a slideway the wedge-type of film lubrication cannot form since, to achieve this, the slideway would need to be tilted.

9.2.7.7 Plain slideways

Plain slideways are preferred in the majority of applications. Only a thin film of lubricant is present, so its properties – especially its viscosity, adhesion and extreme-pressure characteristics – are of vital importance. If lubrication breaks down intermittently, a condition is created known a 'stick-slip' which affects surface finish, causes vibration and chatter and makes close limits difficult to hold. Special adhesive additives are incorporated into the lubricant to provide good bonding of the oil film to the sliding surfaces which helps to overcome the problems of table and slideway lubrication. On long traverses, oil may be fed through grooves in the underside of the slideway.

9.2.7.8 Hydrostatic slideways

The use of hydrostatic slideways – in which pressurized oil or air is employed – completely eliminates stick-slip and reduces friction to very low values; but there are disadvantages in the form of higher costs and greater complication.

9.2.7.9 Ball and roller slideways

These are expensive but, in precision applications, they offer the low friction and lack of play that are characteristic of the more usual rolling journal bearings. Lubrication is usually effected by grease or an adhesive oil.

9.2.7.10 Leadscrews and nuts

The lubrication of leadscrews is similar in essence to that of slideways, but in some instances may be more critical. This is especially so when pre-load is applied to eliminate play and improve machining accuracy, since it also tends to squeeze out the lubricant. Leadscrews and slideways often utilize the same lubricants. If the screw is to operate under high unit stresses – due to pre-load or actual working loads – an extreme-pressure oil should be used.

9.2.7.11 Recirculating-ball leadscrews

This type was developed to avoid stick-up in heavily loaded leadscrews. It employs a screw and nut of special form, with bearing balls running between them. When the balls run off one end of the nut they return through an external channel to the other end. Such bearings are usually grease-packed for life.

9.2.7.12 Gears

The meshing teeth of spur, bevel, helical and similar involute gears are separated by a relatively thick hydrodynamic wedge of lubricating oil, provided that the rotational speed is high enough and the load light enough so as not to squeeze out the lubricant. With high loads or at low speeds, wear takes place if the oil is not able to maintain a lubricating film under extreme conditions.

Machine-tool gears can be lubricated by oil-spray, mist, splash or cascade. Sealed oil baths are commonly used, or the gears may be lubricated by part of a larger circulatory system.

9.2.7.13 *Hydraulics*

The use of hydraulic systems for the setting, operation and control of machine tools has increased significantly. Hydraulic mechanisms being interlinked with electronic controls and/or feedbacks control systems. In machine tools, hydraulic systems have the advantage of providing stepless and vibrationless transfer of power. They are particularly suitable for the linear movement of tables and slideways, to which a hydraulic piston may be directly coupled.

One of the most important features for hydraulic oil is a viscosity/temperature relationship that gives the best compromise of low viscosity (for easy cold starting) and minimum loss of viscosity at high temperatures (to avoid back-leakage and pumping losses). A high degree of oxidation stability is required to withstand high temperatures and aeration in hydraulic systems. An oil needs excellent anti-wear characteristics to combat the effects of high rubbing speeds and loads that occur in hydraulic pumps, especially in those of the vane type. In the reservoir, the oil must release entrained air readily without causing excessive foaming, which can lead to oil starvation.

9.2.7.14 *Tramp oil*

'Tramp oil' is caused when neat slideway, gear, hydraulic and spindle lubricants leak into water-based cutting fluids and can cause problems such as:

- Machine deposits
- Reduced bacterial resistance of cutting fluids and subsequent reduction in the fluid life
- Reduced surface finish quality of work pieces
- Corrosion of machine surfaces

All these problems directly affect production efficiency. Recent developments have led to the introduction of synthetic lubricants that are fully compatible with all types of water-based cutting fluids, so helping the user to achieve maximum machine output.

9.2.7.15 *Lubrication and lubricants*

The components of a hydraulic system are continuously lubricated by the hydraulic fluid, which must, of course, be suitable for this purpose. Many ball and roller bearings are grease-packed for life, or need attention at lengthy intervals. Most lubrication points, however, need regular replenishment if the machine is to function satisfactorily. This is particularly true of parts subjected to high temperatures.

With the large machines, the number of lubricating points or the quantities of lubricants involved make any manual lubrication system impracticable or completely uneconomic. Consequently, automatic lubrication systems are often employed.

Automatic lubrication systems may be divided broadly into two types: circulatory and 'one-shot' total-loss. These cover, respectively, those components using relatively large amounts of oil, which can be cooled, purified and recirculated, and those in which oil or grease is used once only and then lost. Both arrangements may be used for different parts of the same machine or installation.

9.2.7.16 *Circulatory lubrication systems*

The circulatory systems used in association with machine tools are generally conventional in nature, although occasionally their exceptional size creates special problems. The normal installation comprises a storage tank or reservoir, a pump and filter, suitable sprays, jets or other distribution devices, and return piping. The most recent designs tend to eliminate wick feeds and siphon lubrication.

Although filtration is sometimes omitted with non-critical ball and roller bearings, it is essential for most gears and for precision bearings of every kind. Magnetic and gauze filters are often used together. To prevent wear of highly finished bearings surfaces the lubricant must contain no particle as large as the bearing clearance.

Circulatory systems are generally interlocked electrically or mechanically with the machine drive, so that the machine cannot be started until oil is flowing to the gears and main bearings. Interlocks also ensure that lubrication is maintained as long as the machine is running. Oil sight-glasses at key points in the system permit visual observations of oil flow.

9.2.7.17 *Loss-lubrication systems*

There are many kinds of loss-lubrication systems. Most types of linear bearings are necessarily lubricated by this means. An increasingly popular method of lubrication is by automatic or manually operated one-shot lubricators. With these devices a metered quantity of oil or grease is delivered to any number of points from a single reservoir. The operation may be carried out manually, using a hand-pump, or automatically, by means of an electric or hydraulic pump. Mechanical pumps are usually controlled by an electric timer, feeding lubricant at preset intervals, or are linked to a constantly moving part of the machine.

On some machines both hand-operated and electrically timed one-shot systems may be in use, the manual system being reserved for those components needing infrequent attention (once a day, for example) while the automatic systems feeds those parts that require lubrication at relatively brief intervals.

9.2.7.18 *Manual lubrication*

Many thousands of smaller or older machines are lubricated by hand, and even the largest need regular refills or topping up to lubricant reservoirs. In some shops the operator may be fully responsible for the lubrication of his own machine, but it is nearly always safer and more economical to make one individual responsible for all lubrication.

9.2.7.19 *Rationalizing lubricants*

To meet the requirements of each of the various components of a machine the manufacturer may need to recommend a number of lubricating oils and greases. It follows that, where there are many machines of varying origins, a large number of lubricants may seem to be needed. However, the needs of different machines are rarely so different that slight modification cannot be made to the specified lubricant schedule. It is this approach which forms the basis for BS 5063, from which the data in Table 9.6 have been extracted. This classification implies no quality evaluation of lubricants, but merely gives information as to the categories of lubricants likely to be suitable for particular applications.

A survey of the lubrication requirements, usually carried out by the lubricant supplier, can often be the means of significantly reducing the number of oils and greases in a workshop or factory. The efficiency of lubrication may well be increased, and the economies effected are likely to be substantial.

Table 9.6 Classification of lubricants

Class	*Type of lubricant*	*Viscosity grade no. (BS 4231)*	*Typical application*	*Detailed application*	*Remarks*
AN	Refined mineral oils	68	General lubrication	Total-loss lubrication	May be replaced by CB 68
CB	Highly refined mineral oils (straight or inhibited) with good anti-oxidation performance	32 68	Enclosed gears – general lubrication	Pressure and bath lubrication of enclosed gears and allied bearings of headstocks, feed boxes, carriages, etc. when loads are moderate; gears can be of any type, other than worm and hypoid	CB 32 and CB 68 may be used for flood-lubricated mechanically controlled clutches; CB 32 and CB 68 may be replaced by HM 32 and HM 68
CC	Highly refined mineral oils with improved loading-carrying ability	150 320	Heavily loaded gears and worm gears	Pressure and bath lubrication of enclosed gears of any type, other than hypoid gears, and allied bearings when loads are high, provided that operating temperature is not above 70°C	May also be used for manual or centralized lubrication of lead and feed screws
FX	Heavily refined mineral oils with superior anti-corrosion anti-oxidation performance	10 22	Spindles	Pressure and bath lubrication of plain or rolling bearings rotating at high speed	May also be used for applications requiring particularly low-viscosity oils, such as fine mechanisms, hydraulic or hydro-pneumatic mechanisms electro-magnetic clutches, air line lubricators and hydrostatic bearings
G	Mineral oils with improved lubricity and tackiness performance, and which prevent stick-slip	68 220	Slideways	Lubrication of all types of machine tool plain-bearing slideways; particularly required at low traverse speeds to prevent a discontinuous or intermittent sliding of the table (stick-slip)	May also be used for the lubrication of all sliding parts – lead and feed screws, cams, ratchets and lightly loaded worm gears with intermittent service; if a lower viscosity is required HG 32 may be used.

HM	Highly refined mineral oils with superior anti-corrosion, anti-oxidation, and anti-wear performance	32 68	Hydraulic systems	Operation of general hydraulic systems	May also be used for the lubrication of plain or rolling bearings and all types of gears, normally loaded worm and hypoid gears excepted, HM 3X and HM 68 may replace CB 32 and CB 68, respectively
HG	Refined mineral oils of HM type with anti-stick-slip properties	32	Combined hydraulic and slideways systems	Specific application for machines with combined hydraulic and plain bearings, and lubrication systems where discontinuous or intermittent sliding (stick-slip) at low speed is to be prevented	May also be used for the lubrication of slideways, when an oil of this viscosity is required

Class	*Type of lubricant*	*Consistency number*	*Typical application*	*Detailed application*
XM	Premium quality multi-purpose greases with superior anti-oxidation and anti-corrosion properties	1 2 3	Plain and rolling bearings and general greasing of miscellaneous parts	XM 1: Centralized systems XM 2: Dispensed by cup or hand gun or in centralized systems XM 3: Normally used in prepacked applications such as electric motor bearings

Note: It is essential that lubricants are compatible with the materials used in the construction of machine tools, and particularly with sealing devices.

The grease X is sub-divided into consistency numbers, in accordance with the system proposed by the National Lubricating Grease Institute (NLGI) of the USA. These consistency numbers are related to the worked penetration ranges of the greases as follows:

Consistency number	*Worked penetration range*
1	310–340
2	265–295
3	220–250

Worked penetration is determined by the cone-penetration method described in BS 5296.

9.2.8 Compressors

Compressors fall into two basic categories: positive-displacement types, in which air is compressed by the 'squashing' effect of moving components; and dynamic (turbo)-compressors, in which the high velocity of the moving air is converted into pressure. In some compressors the oil lubricates only the bearings, and does not come into contact with the air; in some it serves an important cooling function; in some it is in intimate contact with the oxidizing influence of hot air and with moisture condensed from the air. Clearly, there is no such thing as a typical all-purpose compressor oil: each type subjects the lubricant to a particular set of conditions. In some cases a good engine oil or a turbine-quality oil is suitable, but in others the lubricant must be special compressor oil (Figure 9.7).

9.2.8.1 Quality and safety

Over the years the progressive improvements in compressor lubricants have kept pace with developments in compressor technology, and modern oils make an impressive contribution to the performance and longevity of industrial compressors. More recently a high proportion of research has been directed towards greater safety, most notably in respect of fires and explosions within compressors. For a long time the causes of such accidents were a matter of surmise, but it was noticed that the trouble was almost invariably associated with high delivery temperatures and heavy carbon deposits in delivery pipes. Ignition is now thought to be caused by an exothermic (heat-releasing) oxidation reaction with the carbon deposit, which creates temperatures higher than the spontaneous ignition temperature of the absorbed oil.

Experience indicates that such deposits are considerably reduced by careful selection of base oils and antioxidation additives. Nevertheless, the use of a top-class oil is no guarantee against trouble if maintenance is neglected. For complete safety, both the oil and the compressor system must enjoy high standards of care.

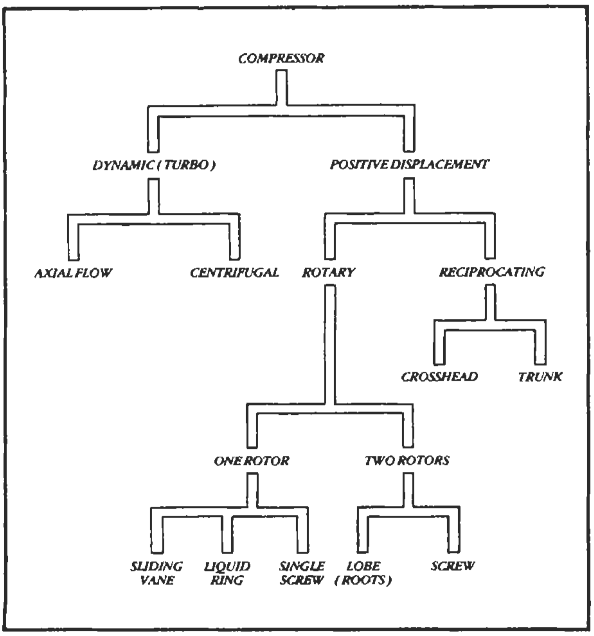

Figure 9.7 Compressor types

9.2.8.2 Specifications

The recommendations of the International Standards Organization (ISO) covering mineral-oil lubricants for reciprocating compressors are set out in ISO DP 6521, under the ISO-L-DAA and ISO-L-DAB classifications. These cover applications wherever air-discharge temperatures are, respectively, below and above 160°C For mineral-oil lubricants used in oil-flooded rotary-screw compressors the classifications ISO-L-DAG and DAH cover applications where temperatures are, respectively, below 100°C and in the 100–110°C range. For more severe applications, where synthetic lubricants might be used, the ISO-L-DAC and DAJ specifications cover both reciprocating and oil-flooded rotary-screw requirements.

For the general performance of compressor oils there is DIN 51506. This specification defines several levels of performance, of which the most severe – carrying the code letters VD-L – relates to oils for use at air-discharge temperatures of up to 220°C.

The stringent requirements covering oxidation stability are defined by the test method DIN 51352, Part 2, known as the Pneurop Oxidation Test (POT). This test simulates the oxidizing effects of high temperature, intimate exposure to air, and the presence of iron oxide which acts as catalyst – all factors highly conducive to the chemical breakdown of oil, and the consequent formation of deposits that can lead to fire and explosion.

Rotary-screw compressor mineral oils oxidation resistance is assessed in a modified Pneurop oxidation test using iron naphthenate catalyst at 120°C for 1000 h. This is known as the rotary-compressor oxidation test (ROCOT).

9.2.8.3 Oil characteristics

Reciprocating compressors In piston-type compressors the oil serves three functions in addition to the main one of lubricating the bearings and cylinders. It helps to seal the fine clearances around piston rings, piston rods and valves, and thus minimizes blow-by of air (which reduces efficiency and can cause overheating). It contributes to cooling by dissipating heat to the walls of the crankcase and it prevents corrosion that would otherwise be caused by moisture condensing from the compressed air.

In small single-acting compressors the oil to bearings and cylinders is splash-fed by flingers, dippers or rings, but the larger and more complex machines have force-feed lubrication systems, some of them augmented by splash-feed. The cylinders of a double-acting compressor cannot be splash-lubricated, of course, because they are not open to the crankcase. Two lubricating systems are therefore necessary – one for the bearings and cross-head slides and one feeding oil directly into the cylinders. In some cases the same oil is used for both purposes, but the feed to the cylinders has to be carefully controlled, because under-lubrication leads to rapid wear and over-lubrication leads to a build-up of carbon deposits in cylinders and on valves. The number and position of cylinder-lubrication points varies according to the size and type of the compressor. Small cylinders may have a single point in the cylinder head, near the inlet valve; larger ones may have two or more. In each case the oil is spread by the sliding of the piston and the turbulence of the air.

In the piston-type compressor the very thin oil film has to lubricate the cylinder while it is exposed to the heat of the compressed air. Such conditions are highly conducive to oxidation in poor-quality oils, and may result in the formation of gummy deposits that settle in and around the piston-ring grooves and cause the rings to stick, thereby allowing blow-by to develop.

Rotary compressors – vane type The lubrication system of vane-type compressors varies according to the size and output of the unit. Compressors in the small and 'portable' group have neither external cooling nor intercooling, because to effect all the necessary cooling the oil is injected copiously into the incoming air stream or directly into the compressor chamber. This method is known as flood lubrication, and the oil is usually cooled before being recirculated. The oil is carried out of the compression chamber by the air, so it has to be separated from the air; the receiver contains baffles that 'knock out' the droplets of oil, and they fall to the bottom of the receiver. Condensed water is subsequently separated from the oil in a strainer before the oil goes back into circulation.

Vane-type pumps of higher-output are water-jacketed and intercooled: the lubricant has virtually no cooling function so it is employed in far smaller quantities. In some units the oil is fed only to the bearings, and the normal leakage lubricates the vanes and the casing. In others, it is fed through drillings in the rotor and perhaps directly into the casing. This, of course, is a total-loss lubrication technique, because the oil passes out with the discharged air.

As in reciprocating units, the oil has to lubricate while being subjected to the adverse influence of high temperature. The vanes impose severe demands on the oil's lubricating powers. At their tips, for example, high rubbing speeds are combined with heavy end-pressure against the casing.

Each time a vane is in the extended position (once per revolution) a severe bending load is being applied between it and the side of its slot. The oil must continue to lubricate between them, to allow the vane to slide freely. It must also resist formation of sticky deposits and varnish, which lead to restricted movement of the vanes and hence to blow-by and, in severe cases, to broken vanes.

Rotary compressors – screw type The lubrication requirements for single-screw type compressors are not severe, but in oil-flooded rotary units the oxidizing conditions are extremely severe because fine droplets of oil are mixed intimately with hot compressed air. In some screw-type air compressors the rotors are gear driven and do not make contact. In others, one rotor drives the other. The heaviest contact loads occur where power is transmitted from the female to the male rotor: here the lubricant encounters physical conditions similar to those between mating gear teeth. This arduous combination of circumstances places a great demand on the chemical stability, and lubricating power, of the oil.

Other types Of the remaining designs, only the liquid-piston type delivers pressures of the same order as those just mentioned. The lobe, centrifugal and axial-flow types, are more accurately termed 'blowers', since they deliver air in large volumes at lower pressures. In all four cases only the 'external' parts – bearings, gears or both – require lubrication. Therefore the oil is not called upon to withstand the severe service experienced in reciprocating and vane-type compressors. Where the compressor is coupled to a steam or gas turbine a common circulating oil system is employed. High standards of system cleanliness are necessary to avoid deposit formation in the compressor bearings.

Refrigeration compressors The functions of a refrigerator compressor lubricant are the same as those of compressor lubricants in general. However, the close association between refrigerant and lubricant does impose certain additional demands on the oil. Oil is unavoidably carried into the circuit with refrigerant discharging from the compressor. In many installations provision is made for removal of this oil. However, several refrigerants, including most of the halogen refrigerants, are miscible with oil and it is difficult to separate the oil which enters the system which therefore circulates with the refrigerant. In either case the behaviour of the oil in cold parts of the systems is important, and suitable lubricants have to have low pour point and low wax-forming characteristics.

Effects of contamination The conditions imposed on oils by compressors – particularly by the piston type – are remarkably similar to those imposed by internal combustion engines. One major difference is, of course, that in a compressor no fuel or products of combustion are present to find their way into the oil. Other contaminants are broadly similar. Among these are moisture, airborne dirt, carbon and the products of the oil's oxidation. Unless steps are taken to combat them, all these pollutants have the effect of shortening the life of both the oil and the compressor, and may even lead to fires and explosions.

Oxidation High temperature and exposure to hot air are two influences that favour the oxidation and carbonization of mineral oil. In a compressor, the oil presents a large surface area to hot air because it is churned and sprayed in a fine mist, so the oxidizing influences are very strong – especially in the high temperatures of the compressor chamber. The degree of oxidation is dependent mainly on temperature and the ability of the oil to resist, so the problem can be minimized by the correct selection of lubricant and by controlling operating factors.

In oxidizing, an oil becomes thicker and it deposits carbon and gummy, resinous substances. These accumulate in the piston-ring grooves of reciprocating compressors and in the slots of vane-type units, and as a result they restrict free movement of components and allow air leakages to develop. The deposits also settle in and around the valves of piston-type compressors, and prevent proper sealing.

When leakage develops, the output of compressed air is reduced, and overheating occurs due to the recompression of hot air and the inefficient operation of the compressor. This leads to abnormally high discharge temperatures. Higher temperature leads to increased oxidation and hence increased formation of deposits, so adequate cooling of compressors is very important.

Airborne dirt In the context of industrial compressors, dust is a major consideration. Such compressors have a very high throughput of air, and even in apparently 'clean' atmospheres, the quantity of airborne dirt is sufficient to cause trouble if the compressor is not fitted with an air-intake filter. Many of the airborne particles in an industrial atmosphere are abrasive, and they cause accelerated rates of wear in any compressor with sliding components in the compressor chamber. The dirt passes into the oil, where it may accumulate and contribute very seriously to the carbon deposits in valves and outlet pipes. Another consideration is that dirt in an oil is likely to act as a catalyst, thus encouraging oxidation.

Moisture Condensation occurs in all compressors, and the effects are most prominent where cooling takes place – in intercoolers and air-receivers, which therefore have to be drained at frequent intervals. Normally the amount of moisture present in a compression chamber is not sufficient to affect lubrication, but relatively large quantities can have a serious effect on the lubrication of a compressor. Very wet conditions are likely to occur when the atmosphere is excessively humid, or compression pressures are high, or the compressor is being overcooled.

During periods when the compressor is standing idle the moisture condenses on cylinders walls and casings, and if the oil does not provide adequate protection this leads to rusting. Rust may not be serious at first sight, and it is quickly removed by wiping action when the compressor is started, but the rust particles act as abrasives, and if they enter the crankcase oil they may have a catalytic effect and promote oxidation. In single-acting piston-type compressors, the crankcase oil is contaminated by the moisture.

9.2.9 Turbines

9.2.9.1 Steam

Although the properties required of a steam-turbine lubricant are not extreme it is the very long periods of continuous operation that creates the need for high-grade oils to be used. The lubricating oil has to provide adequate and reliable lubrication, act as a coolant, protect against corrosion, as a hydraulic medium when used in governor and control systems, and if used in a geared turbine provide satisfactory lubrication of the gearing. The lubricant will therefore need the following characteristics.

Viscosity For a directly coupled turbine for power generation a typical viscosity would be in the range of 32–46 cSt at 40°C. Geared units require a higher viscosity to withstand tooth loadings typically within the range of 68–100 cSt at 40°C.

Oxidation resistance The careful blending of turbine oils, using components which, by selective refining, have a reduced tendency to oxidize, produces the required long-term stability. The high temperatures and pressures of modern designs add to these demands, which are combatted by the incorporation of suitable anti-oxidant additives.

Demulsibility The ability of the lubricant to separate readily and completely from water, in either a centrifuge or a settling tank, is important in a turbine lubricant. Otherwise the retained water will react with products of oxidation and particle contaminants to form stable emulsions. These will increase the viscosity of the oil and form sludges which can result in a failure. Careful and selective refining ensures a good demulsibility characteristic. Inadequate storage and handling can seriously reduce this property.

Corrosion resistance Although the equipment is designed to keep the water content at a minimum level, it is virtually impossible to eliminate it entirely. The problem of rusting is therefore overcome by using corrosion inhibitors in the lubricant formulation.

Foaming resistance Turbine oils must be resistant to foaming, since oil-foam reduces the rate of heat transfer from the bearings, promotes oxidation by greatly extending the area of contact between air and oil. It is also an unsatisfactory medium for the hydraulic governor controls. Careful refining is the primary means of achieving good resistance to foaming. Use of an anti-foam additive may seem desirable but this should be approached with caution. If it is used in quantities higher than the optimum it can in fact assist air entrainment in the oil by retarding the release of air bubbles.

9.2.9.2 Gas

The lubricants generally specified for conventional gas turbines invariably fall within the same classification as those used for steam turbines and are often categorized as 'turbine oils'. In those cases where an aircraft type gas turbine has been adapted for industrial use the lubricant is vitally important to their correct operation. Specifications have been rigidly laid down after the most exhaustive tests, and it would be unwise, even foolhardy, to depart from the manufacturers' recommendations. No economic gain would result from the use of cheaper, but less efficient, lubricants.

9.2.9.3 Performance standards

In the UK there is BS 489:1983. In Europe there is DIN 51515 together with manufacturers' standards such as those set by Brown Boverie and Alsthom Atlantique. In the USA there are the ASTM standards and the well-known General Electric requirements.

The total useful life of a turbine oil is its most important characteristic. ASTM method D943 (IP 157) measures the life indirectly by assessing the useful life of the oxidation inhibitor contained in the formulation and is often referred to as the TOST 'life' of the oil. Rust prevention is generally assessed by the ASTM D665 (IP 135) method.

There are many other specifications designed by equipment builders, military and professional societies, as well as users. Care always needs to be taken when purchasing turbine oil to specification. The cheapest oil, albeit conforming to the specification, may not necessarily be the best within that specification for the particular purpose. For instance, the additive package is rarely (if ever) defined, so that unexpected reactions can occur between oils which could affect overall performance.

9.2.10 Transformers and switchgear

The main requirement for a power-transmission equipment oil is that it should have good dielectric properties. Oil used in transformers acts as a coolant for the windings; as an insulant to prevent arcing between parts of the transformer circuits; and prevents the ionization of minute bubbles of air and gas in the wire insulation by absorbing them and filling the voids between cable and wrapping. In switchgear and circuit breakers it has the added function of quenching sparks from any arc formed during equipment operation. Oils for use in power transmission equipment should have the following properties; high electric strength, low viscosity, high chemical stability and low carbon-forming characteristics under the conditions of electric arc.

9.2.10.1 Performance standards

The efficiency of transformer oils as dielectrics is measured by 'electric strength' tests. These give an indication of the voltage at which, under the test conditions, the oil will break down. Various national standards exist that all measure the same basic property of the oil. In the UK it is BS 148: 1984. There is an international specification, IEC 296/1982, which may be quoted by equipment manufacturers in their oil recommendations.

9.2.10.2 Testing

How frequently the oil condition should be tested depends on operating and atmospheric conditions; after the commissioning sample, further samples should be taken at three months and one year after the unit is first energized. After this, under normal conditions, testing should be carried out annually. In unfavourable operating conditions (damp or dust-laden atmospheres, or where space limitations reduce air circulation and heat transfer) testing should be carried out every six months.

Testing should include a dielectric strength test to confirm the oil's insulation capability and an acidity test, which indicates oil oxidation. While acid formation does not usually develop until the oil has been in service for some time, when it does occur the process can be rapid. If acidity is below 0.5 mg KOH/g no action would seem necessary. Between 0.5 and 1 mg KOH/g, increased care and testing is essential. Above 1 the oil should be removed and either reconditioned or discarded. Before the unit is filled with a fresh charge of oil it should be flushed. These suggestions are contained in a British Standards Code of Practice.

Sludge observations will show if arcing is causing carbon deposits which, if allowed to build up will affect heat transfer and could influence the oil insulation. There is also a flash point test, in which any lowering of flash point is an indication that the oil has been subjected to excessive local heating or submerged arcing (due to overload or an internal electrical fault). A fall in flash point exceeding 16°C implies a fault, and the unit should be shut down for investigation of the cause. Lesser drops may be observed in the later stages of oil life, due to oxidation effects, but are not usually serious. A 'crackle' test is a simple way of detecting moisture in the oil. Where water is present the oil should be centrifuged.

9.2.11 Greases

Grease is a very important and useful lubricant when used correctly, its main advantage being that it tends to remain where it is applied. It is more likely to stay in contact with rubbing surfaces than oil, and is less affected by the forces of gravity, pressure and centrifugal action. Economical and effective lubrication is the natural result of this property and a reduction in the overall cost of lubrication, particularly in all-loss systems, is made possible.

Apart from this, grease has other advantages. It acts both as a lubricant and as a seal and is thus able, at the same time as it lubricates, to prevent the entry of contaminants such as water and abrasive dirt. Grease lubrication by eliminating the need for elaborate oil seals can simplify plant design.

Because a film of grease remains where it is applied for much longer than a film of oil, it provides better protection to bearing and other surfaces that are exposed to shock loads or sudden changes of direction. A film of grease also helps to prevent the corrosion of machine parts that are idle for lengthy periods.

Bearings pre-packed with grease will function for extended periods without attention. Another advantage is the almost complete elimination of drip or splash, which can be a problem in certain applications. Grease is also able to operate effectively over a wider range of temperatures than any single oil.

There are certain disadvantages as well as advantages in using grease as a lubricant. Greases do not dissipate heat as well as fluid lubricants, and for low-torque operation tend to offer more resistance than oil.

9.2.11.1 Types of grease

The general method of classifying greases is by reference to the type of soap that is mixed with mineral oil to produce the grease, although this has rather less practical significance nowadays than it had in the past. One example of this is the multi-purpose grease that may replace two or three different types previously thought necessary to cover a particular field of application. Nevertheless, there are unique differences in behaviour between greases made with different metal soaps, and these differences are still important in many industrial uses, for technical and economic reasons.

Calcium-soap greases The line-soap (calcium) greases have been known for many years but are still probably the most widely used. They have a characteristic smooth texture, thermal stability, good water resistance and are relatively inexpensive. The softer grades are easily applied, pump well and give low starting torque. Their application is limited by their relatively low drop points, which are around 100°C. This means that, in practice, the highest operating temperature is about 50°C.

Nevertheless, they are used widely for the lubrication of medium-duty rolling and plain bearings, centralized greasing systems, wheel bearings and general duties. The stiffer varieties are used in the form of blocks on the older-type brasses. Modifications of lime-base grease include the graphited varieties and those containing an extreme pressure additive. The latter are suitable for heavily loaded roller bearings such as in steel-mill applications.

Sodium-soap greases The soda-soap (sodium) greases were, for some considerable time, the only high-melting point greases available to industry. They have drop points in the region of 150°C and their operating maximum is about 80°C. These greases can be 'buttery', fibrous or spongy, are not particularly resistant to moisture and are not suitable for use in wet conditions. Plain bearings are very frequently lubricated with soda-based greases.

For rolling-contact bearings, a much smoother texture is required, and this is obtained by suitable manufacturing techniques. Modified grades may be used over the same temperature range as that of the unmodified grade and, when they are correctly formulated, have a good shear resistance and a slightly better resistance to water than the unmodified grades.

Lithium-soap greases These products, unknown before the Second World War, were developed first as aircraft lubricants. Since then the field in which they have been used has been greatly extended and they are now used in industry as multipurpose greases. They combine the smooth texture of the calcium-based greases with higher melting points than soda-soap greases, and are almost wholly manufactured in the medium and soft ranges. Combined with suitable additives, they are the first choice for all rolling-contact bearings, as they operate satisfactorily up to a temperature of 120°C and at even higher for intermittent use. Their water resistance is satisfactory and they may be applied by all conventional means, including centralized pressure systems.

Other metal-soap greases Greases are also made from soaps of strontium, barium and aluminium. Of these, aluminium-based grease is the most widely used. It is insoluble in water and very adhesive to metal. Its widest application is in the lubrication of vehicle chassis. In industry it is used for rolling-mill applications and for the lubrication of cams and other equipment subject to violent oscillation and vibration, where its adhesiveness is an asset.

Non-soap thickened greases These are generally reserved for specialist applications, and are in the main more costly than conventional soap-based greases. The most common substances used as non-soap thickeners are silicas and clays prepared in such a way that they form gels with mineral and synthetic oils. Other materials that have been used are carbon black, metal oxides and various organic compounds.

The characteristic of these non-soap greases which distinguishes them from conventional greases is that many of them have very high melting points; they will remain as greases up to temperatures in the region of 260°C. For this reason, the limiting upper usage temperature is determined by the thermal stability of the mineral oil or synthetic fluid of which they are composed. Applications such as those found in cement manufacturing, where high-temperature conditions have to be met, require a grease suitable for continuous use at, say, 204°C. Although it is difficult to generalize, the non-soap products have, on the whole, been found to be somewhat less effective than the soap-thickened greases as regards lubricating properties and protection against corrosion, particularly rusting. Additive treatment can improve non-soap grades in both these respects, but their unique structures renders them more susceptible to secondary and unwanted effects than is the case with the more conventional greases.

Filled greases The crude types of axle and mill grease made in the early days frequently contained large amounts of chemically inert, inorganic powders. These additions gave 'body' to the grease and, possibly, helped to improve the adherence of the lubricating film. Greases are still 'filled' but in a selective manner with much-improved materials and under controlled conditions. Two materials often used for this purpose are graphite and molybdenum disulphide.

Small amounts (approximately 5%) of filler have little or no effect on grease structure, but large amounts increase the consistency. However, the materials mentioned are lubricants in themselves and are sometimes used as such. Consequently it is often claimed that when they are incorporated into the structure of the grease the lubricating properties of the grease are automatically improved. A difference of opinion exists as to the validity of this assumption, but it is true that both molybdenum disulphide and graphite are effective where shock loading or boundary conditions exist, or when the presence of chemicals would tend to remove conventional greases.

Mixing greases The above comments on the properties of the various types of grease have shown that very real differences exist. Each one has its own particular type of structure, calls for individual manufacturing processes and has its own advantages and disadvantages. It is because of these distinct differences that the mixing of greases should never be encouraged. If greases of different types are mixed indiscriminately there is a risk that one or other of them will suffer, the resulting blend being less stable than either of the original components and the blend may even liquefy.

9.2.11.2 Selecting a grease

A few brief notes on the fundamental factors that influence a choice of grease may be helpful. The first essential is to be absolutely clear about the limitations of the different types, and to compare them with the conditions they are to meet. Table 9.7 gives the characteristics of high-quality greases.

Greases with a mixed base are not shown in the table because, in general, they are characterized by the predominant base; for example, a soda-lime grease behaves like a soda grease. Temperature limits may be modified by the required length of service. Thus, if a soda grease requires to have only a short life, it could be used at temperatures up to 120°C.

When the type most suitable for a particular application has been chosen, the question of consistency must be considered.

Table 9.7 Characteristics of high-quality greases

Grease (type of soap)	*Recommended maximum operating temperature (°C)*	*Water resistance*	*Mechanical stability*
Lime	50	Good	Good
Soda	80	Poor	Good
Lithium	120	Good	Good
Aluminium	50	Fair	Moderate

The general tendency over the last two decades has been towards a softer grease than formerly used. Two factors have probably contributed to this trend; the growth of automatic grease dispensing and the use of more viscous oils in grease making.

In practice, the range of grease consistency is quite limited. For most general industrial applications, a No. 2 consistency is satisfactory. Where suitability for pumping is concerned, a No. 1; for low temperatures, a No. 0; and for water pumps and similar equipment, a No. 3.

9.2.11.3 Grease application

In applying lubricating grease the most important aspect is how much to use. Naturally, the amount varies with the component being serviced, but some general rules can be laid down. All manufacturers agree that anti-friction bearings should never be over-greased. This is particularly true of high-speed bearings, in which the churning of excess lubricant leads to overheating. The rise in temperature of a bearing as the amount of grease increases has been recorded. With the bearing housing one-third full, the temperature was 39°C; at two-thirds full the temperature rose to 42°C; and with a full charge of grease it went up to 58°C.

The general recommendations for grease packing are:

1. Fully charge the bearing itself with grease ensuring that it is worked around and between the rolling elements.
2. Charge the bearing housing one-half to two-thirds full of grease.

Churning, and its attendant high temperature, may change the structure of the grease permanently, in which event softening may result in leakage and stiffening in lubricant starvation. There is no fixed rule for the period between re-greasings, since this depends on the operating conditions. Most recommendations suggest inspection and possible replenishment every six or twelve months, though the general tendency as grease quality improves has been to extend this period. The higher the temperature of a machine, the more frequently it must be greased because of possible losses of softened lubricant or changes in its structure.

It is not always incorret to over-grease. With a sleeve bearing, for instance, gun pressure may be maintained until old grease exudes from the ends of the bearing, and the same is true of spring shackles. For the sake of economy and cleanliness, however, this should never be overdone.

9.2.12 Corrosion prevention

Most plant has to work under adverse conditions, in all sorts of weather, and subject to contamination by various agents. However, as long as it is in use it can be reasonably sure of receiving at least a minimum amount of regular maintenance and attention, and this will reduce the likelihood of working parts being attacked by corrosion when plant is in service. However, when plant has to be laid up until required, no matter how carefully matters have been planned, corrosion is always a serious possibility. Modern machinery, with highly finished surfaces, is especially susceptible to atmospheric attack. The surfaces of components also require protection during transport and storage.

Even today, rusting of industrial plant and material is accepted by some as an inevitable operating expense. There is no necessity for this attitude, however, as the petroleum industry has evolved effective, easily applied temporary protectives against corrosion, which are well suited to the conditions met in practice.

9.2.12.1 Categories of temporary corrosion preventives

Temporary corrosion preventives are products designed for the short-term protection of metal surfaces. They are easily removable, if necessary, by petroleum solvents or by other means such as wiping or alkaline stripping. Some products for use in internal machine parts are miscible and compatible with the eventual service lubricant, and do not, therefore, need to be removed.

The major categories of temporary corrosion preventives are:

Soft-film protectives
Dewatering fluids giving soft/medium films
Non-dewatering fluids giving soft films
Hot-dip compounds
Greases

Hard-film protectives
Oil-type protectives
General-purpose
Engine protectives

The development of products in these categories has been guided by known market demands and many manufacturers have made use of established specifications for temporary protectives. In the UK, for example, British Standard 1133, Section 6 (covering all categories) and British Government Specifications CS 2060C (PX10 dewatering fluid) are frequently followed.

9.2.12.2 Selection of a corrosion preventive

Temporary corrosion preventives are in some cases required to give protection against rusting for periods of only a few days for inter-process waiting in factories. Where the protected components are not exposed to the weather, protection can be given for up to a year or more for stored components in internal storage conditions. On the other hand, components may require protection for a few days or even weeks under the most adverse weather conditions. Some components may have to be handled frequently during transit or storage. In general, therefore, the more adverse the conditions of storage, the longer the protective periods, and the more frequent the handling, the thicker or more durable the protective film must be.

Because of the wide variation in conditions of exposure it is not possible to define the length of protection period except in general terms. Solvent-deposited soft films will give protection from a few days to months indoors and some weeks outdoors; a solvent-deposited medium film will give long-term protection indoors and medium-term protection outdoors. Hot-dip compounds and cold-applied greases give films that can withstand considerable handling and will give medium to long protection. Solvent-deposited hard-film protectives will give long-term protection but are fairly difficult to remove. Oil protectives give short- to medium-term protection of parts not subjected to handling and are also much used for the preservation of internal working parts; they need not be removed and can in some instances serve as lubricating oils.

'Short term', 'medium term' and 'long term' are expressions that are not rigorously defined but are generally accepted as meaning of the order of up to 6 months, 12 months and 18 months, respectively, in temperate climates. Where local conditions are more severe (in hot, humid climates, for example) the protection periods are less. These protection periods are related to the preventive film alone, but where transit or storage conditions call for wrapping or packaging then longer protection periods can be obtained.

The distinction between a simple part and a complex assembly is an important factor in selecting a temporary protective. The solvent-containing protectives may not be suited to treating assemblies, because:

1. Assemblies may contain non-metallic parts (rubber, for example) that could be attacked by the solvent;
2. The solvent cannot evaporate from enclosed or shielded spaces and the intended film thickness will not be obtained;
3. Evaporated solvent could be trapped and could then leach away the protective film.

Hence the hot-dip compounds, or greases smeared cold, are better for assemblies with non-metallic parts masked if necessary. Solvent-containing protectives therefore find greater application in the protection of simple parts or components. The available means of application, the nature of any additional packaging and the economics and scale of the protective treatment are further factors that influence the choice of type of temporary corrosion preventive.

9.2.13 Spray lubricants

There are several applications where the lubrication requirement is specialized and very small, needing precise applications where access is limited because of equipment design or location. In these instances lubricant application by aerosol is the most suitable method. Extreme-pressure cutting fluid for reaming and tapping, etc., conveyor and chain lubricant, anti-seize and weld anti-spatter agents, release agents, electrical component cleaner and degreasants are examples of the ever-widening range of products available in aerosol packs.

9.2.14 Degreasants

Often, before any maintenance work starts it is necessary (and desirable) to remove any oil, grease and dirt from the equipment concerned. It may also be necessary to clean replacement components before their installation. Solvents, emulsions and chemical solutions are three broad types of degreasants. The method of degreasing (direct onto the surface, by submersion, through degreasing equipment or by steam cleaners), component complexity and the degree of contamination will all have to be taken into account when selecting the type of product to be used.

9.2.15 Filtration

Some 70–85% of failures and wear problems in lubricated machines are caused by oil contamination. Clean oil extends machine and oil life and gives greater reliability, higher productivity and lower maintenance cost. Hence some type of filter is an essential part of virtually all lubrication systems.

Cleaning of oil in service may be accomplished quite simply or with relatively complex units, depending on the application and the design of the system. Thus for some operations it is enough to remove particles of ferrous metal from the oil with a magnetic system. In a closed circulatory system, such as that of a steam turbine, the nature of the solids and other contaminants is far more complex, and the treatment has therefore to be more elaborate. In an internal-combustion engine both air and fuel are filtered as well as crankcase oil.

The efficiency of filtration must be matched to the needs of the particular application, and this is true both quantitatively (in relation the anticipated build-up of solids in the filters) and qualitatively (in relation to the composition of the contaminants and their size). Dirt build-up varies considerably, but it is probably at its maximum with civil engineering equipment. In this field, diesel engines in trucks will steadily accumulate something like 0.3 kg of solids in the crankcase oil within a month.

Particle size is naturally important. It is generally assumed that particles of less than 3 μm in diameter are relatively harmless. However, this is on the assumption that the oil film is itself of this, or greater, thickness; in other words, that full fluid-film hydrodynamic lubrication persists during the whole working cycle of the machine. This is seldom the case, for there are either critical areas or critical phases at or during which mixed or even wholly boundary conditions prevail – when, in fact, the oil film is less than 3 μm thick. The tendency of modern industrial equipment to operate at higher speeds and under greater pressures leads to higher wear rates. Increased pump capacity, as in hydraulic circuits, coupled with a decreased oil volume means a relatively greater amount of contamination. All in all, much more is demanded of the filter today, whatever the application, than at any time in the past.

9.2.15.1 Types of filter

The terms 'filter' and 'strainer' are in common use and many lubricant systems contain both. The word 'strainer' is often associated with the removal of large particles, and though it is true that in the majority of cases a strainer is in fact employed to remove coarse particles, the fundamental difference between it and a filter is not one of porosity but purely one of geometry. In a strainer the liquid passes through in a straight line, but in a filter a far more devious route is followed.

Strainers are usually made from woven wire gauze, like a sieve, and though today the pre-size can be made very small indeed (BSI 300 mesh gauze separates particles of roughly 50 μm) they are mainly included for the exclusion of large particles. Filters deal with the removal of very much smaller particles.

Naturally from the above definition there is some unavoidable overlapping, and a really fine strainer of, say, stainless steel 'cloth' is regarded as a filter. There are five main types of filtering units as follows.

Surface films These are usually constructed of woven metal gauze, paper or cloth. The paper filter may have the working surface enlarged by pleating and the paper impregnated and strengthened. As an example, one proprietary pleated model gives, from an element 11.5 cm long and 8.5 cm in external diameter, a filtering surface of some 3250 cm^2. This type, sometimes described as a radial-fin unit, has a good throughput and is easy to clean or replace. Filters in this class generally have porosities from 100 μm down to 10 or, in extreme cases, even down to 2μm.

Edge filters A typical unit comprises a pack of metal or paper discs with a washer between each, the gauge of the latter governing the degree of filtration. The oil flows from the outside and is discharged through a central channel. Some designs can be cleaned without dismantling or interrupting the flow.

An alternative method of manufacturing is to employ a coil of flat metal ribbon as the element, each turn spaced from the next by small lateral protuberances. The principle of filtration is the same. Porosities of both types are identical and cover a wide range, usually from 100 μm down to 0.5 μm.

Depth filters (absorption-type filters)

1. *Chemically inactive*: There are made from a variety of materials that include wound yarn, felt, flannel, cotton waste, wood pump, mineral wool, asbestos and diatomaceous earths. The solid particles are trapped and retained within the medium. Certain types will remove water, as well as large and small particles of solids in a range down to 10 μm. Ceramics are sometimes employed for depth filtration, as also are special sintered metals.
2. *Chemically active*: These filters are similar in design to the non-active depth units but the filtering media used are so chosen that contaminants adhere by chemical attraction. Thus there is a dual action, mechanical and chemical. The materials used include various activated clays, Fuller's earth, charcoal and chemically treated paper. Their cleansing action is much more thorough than that of the purely mechanical devices, for they are capable of removing matter actually in solution in the oil.

Magnetic and combined magnetic filters In its simplest form the magnetic filter comprises a non-magnetic outer casing with an inner permanent magnetic core round which the liquid flows. Because of the magnetic anisotropy of the field the ferrous particles are continuously diverted to the area of strongest attraction coinciding with the direction of flow. A more elaborate design of magnetic clarifier has its elements mounted in a rotating disc. The dirty fluid flows through the chamber in which the disc dips, and ferrous particles adhering to the magnetized areas are removed by the action of scrapers and collected in containers. The capacity of one such disc has been given as 2250 l/h with a range of sludge removal as high as 30 kg/h. Combined units may have the magnet located within a coil of wire that forms the permeable, mechanical filter.

For its specialized application (cleaning the coolants used for metal-machining operations such as grinding and honing) the magnetic filter is easily maintained and cleaned. It has a high throughput and will remove ferrous particles as small as 1 μm. Some of the non-magnetic material is associated with the ferrous particles suspended in the fluids and this is also removed with them.

The centrifugal filter This is a specialized design and is, in effect, a true centrifuge of small size that operates on the reaction turbine principle, an oil-circulating pump providing the necessary power. One advantage claimed for this type is that it operates at a steady flow rate, whereas the flow rate through a felt or paper element diminishes as the bed of dirt is built up. The centrifugal filter has been successfully applied to diesel engines where the greater part of the dirt particles are under 2 μm in diameter.

9.2.16 Centrifuging

The centrifugal separation of solid impurities is adopted either as an alternative to filtration or combined with it. For example, a lubricant circulating system can be cleaned by having fixed-element filters that arrest larger particles, and a centrifuge system that removes the finer solids in suspension together with any water contained in the oil.

The centrifuge is a powerful tool. The magnitude of the available centrifugal force – the product of the mass of the particle and its acceleration – is easily appreciated when the speeds and dimensions of a commercial unit are considered. A vessel with a diameter of 25.4 cm spinning at 1700 rev/min gives an acceleration at the centrifuge wall of some 400 g. In terms of settling this means that centrifuging a crude oil for 30 s is at least equivalent to simple gravitational settling over a 24 h period.

The advantage of the modern continuous centrifuge is the rapidity with which it will separate both solids and immiscible liquids. Another stems from the larger volume of oil it can handle in a given time.

9.2.17 Centralized lubrication

Manual application of lubricants has the inherent risk of failure due to omission. With the increasing complexity of plant, the costs of lost production and of manpower to try to prevent such omissions are becoming unacceptable.

Mechanized methods of pumping oil and grease to bearings and other components are becoming increasingly utilized. Some of these systems are fundamentally suited to either oil or grease, but others, including all those where continuous circulation is involved, are suitable only for oil.

Built-in mechanized grease lubrication is nearly always of the centralized 'one-shot' variety, in which a single pump stroke supplies grease simultaneously to a number of bearings. The amount supplied to each station is regulated by suitable valves or adjustable metering orifices. The pump may be manually operated or connected to a suitable machine component, whereby grease is fed only when the machine is actually running and at controlled temperatures. Pneumatic or electric pumps are also used, set in operation at regular intervals by an automatic timing device.

One-shot metered lubrication is eminently suited to oiling systems and can be employed either in an 'all-loss' arrangement or as part of a circulatory system. Sight-glasses or other indicators should be incorporated, since such lubricating mechanisms are nowadays so reliable that a blockage or other failure might not be suspected until too late.

Circulatory systems often use an intermediate header tank, from which the bearings are supplied by gravity. The complete system may comprise, in addition and according to the size of the installation, heat exchangers or coolers, filters, strainers, settling tanks, centrifuges and other purifying equipment.

Oil mist feeds are used less for plain bearings than for lubricating some other types of machine parts, but applications are increasing in number. A stream of dry compressed air is used both to generate the mist and to carry it to the bearing. The atomized oil droplets are released from air suspension at points of turbulence around bearings, gears and other moving components or in a special re-classifying fitting at the end of the supply line. Reclassifiers are generally employed when plain bearings are to be lubricated by oil mist, but the method is fundamentally unsuited for bearings requiring hydrodynamic thick-film lubrication.

Special precautions must be taken with oil-mist feeds to ensure that the compressed air, which greatly enhances the rate of heat dissipation, can escape from the housing. If vents or other outlets become blocked, the back pressure may stop the flow of lubricant.

9.2.18 Storage of lubricants

It cannot be emphasized too strongly that dirt and correct lubrication are incompatible. The lubricant manufacturer has a comprehensive system of classification, filtration and inspection of packages which ensures that all oils and greases leaving his plant are free from liquid and solid contaminants. It is in his own interests that the user should take the same care to ensure that the lubricant enters his machinery in as clean a condition as that in the bulk tank or barrel. The entry of abrasive dust, water and other undesirable matter into bearings and oilways may result if lubricants are handled carelessly.

The conditions in a plant are often far from ideal and usually storage facilities are limited. This, however, should serve as a constant reminder of the need for continual care, the adoption of suitable dispensing equipment, organized storekeeping and efficient distribution methods. Furthermore, the arrangements on any particular site will be governed by local organization and facilities. Technical personnel from lubricant suppliers are available to assist and advise plant management on the best methods for a particular site. The general recommendations given about the care of lubricants consist of elementary precautions which are mainly self-evident and yet, unfortunately, are often ignored.

The modern steel barrel is reasonably weatherproof in its original condition, but if stored out of doors and water is allowed to collect in the head, there may, in time, be seepage past the bung due to the breathing of the package. Exposure may also completely obliterate the grade name and identification numbers, as is evidenced by the frequent requests made to sample and test lubricants from full packages that have been neglected on-site because no other method of identification is possible. Unless it is absolutely unavoidable, packages should never be stored in the open and exposed to all weather. Even an elementary cover such as a sheet of corrugated iron or a tarpaulin may provide valuable protection.

However rudimentary the oil stores, the first essential is cleanliness; the second is orderliness. These two essentials will be easily achieved if maximum possible use is made of bulk storage tanks. In the case of bulk storage of soluble oils the need for moderate temperatures is vital, and the tanks should be housed indoors to protect their contents against frost. There are several other benefits to be derived from the use of tanks, i.e. reduction in storage area, handling of packages and, possibly, bulk-buying economics. All barrels should be mounted on a stillage frame of suitable height, fitted with taps and the grade name clearly visible. The exterior surfaces of both tanks and barrels should be kept scrupulously clean and each container provided with its own drip tray or can.

The storage and handling of grease presents more problems than are encountered with fluid lubricants, as the nature of the material and design of the conventional packages make contamination easier. Lids of grease kegs must be kept completely free from dust and dirt, and should be replaced immediately after use. The most common way in which solids enter a grease package is by the user carelessly placing a lid either on the ground or on some other unsuitable surface. Fortunately, there are available today a number of simple dispensing units which can entirely obviate this danger and which can be adapted to all types of packages.

Wherever manual distribution has to be adopted, containers should be reserved for the exclusive use of specific units and their operators and, as far as possible, for a particular grade. When not in use they must be stored away from all possible sources of contamination. To promote economy and reduce waste due to spillage, their shape and proportions must be suited to the application.

While it is impossible to describe a system of storekeeping and distribution suitable for every site there are certain essential principles which should be adhered to if cleanliness, order and economy are to be maintained. How these principles should be applied is for individual managements to decide. The keynote, however, should be simplicity. Distribution should be controlled by a storekeeper familiar with both grades and needs. While the lubrication schedule for any particular unit is generally the concern of the operator, the storekeeper must equally be aware of it and have a comprehensive list of the different grades, their applications, quantities, daily and other periodic needs. On such a basis he will be able to requisition and store the necessary lubricants in the most convenient and economic quantities and packages, and ensure that supplies are used on a 'first in, first out' basis.

Care and good housekeeping at every stage from handling, stacking and storage, right through to dispensing and application will:

- Ensure that the correct product reaches the point of application and is free from contamination;
- Help towards maximum efficiency in the use of lubricants and the equipment in which they are employed;
- Avert accidents and fire hazards arising from mishandling;
- Prevent any adverse effects on people, equipment and the environment.

9.2.19 Reconditioning of oil

Reconditioning is the removal of contaminants and oxidation products (at least in part) but not previously incorporated additives. It may also involve the addition of new oil and/or additives to adjust the viscosity and/or performance level. This process is sometimes referred to as 'laundering' or 'reclamation'. The method treats used lubricating oil to render it suitable for further service, either in the original or a downgraded application. Two types of treatment are generally employed.

1. Filtration to remove contaminants, followed by the addition of new oil and/or additives to correct performance level;
2. A simple filtration process to remove contaminants.

In practice, treatment (1) usually involves a contractor collecting a segregated batch of oil, reconditioning and returning it for re-use. The simple filtration process can be carried out by a contractor, but is more usually done on-site. Re-refining is the removal of contaminants and oxidation products and previously incorporated additives to recover the lube base stock for new lubricant or other applications.

9.2.20 Planned lubrication and maintenance management

Having the correct lubricant in each application will only give the maximum benefit if and when it is applied at the correct frequency and quantity. With the increasing complexity of plant this is becoming more vital and, at the same time, more difficult to achieve. The solution to this problem is planned lubrication maintenance, which, in essence, is having the right lubricant in the right place at the right time in the right amount.

Most oil companies offer a planned lubrication maintenance (PLM) service that will meet these requirements with the minimum of effort on the part of the customer. These schemes provide logical routing for the lubrication operative, balanced work loads and clear instructions to those responsible for specific tasks associated with lubrication and fault-reporting facilities. Many schemes are now designed for computer operation which also accommodate plant and grade changes, operation costings and manpower planning. It is essential that any such scheme should be adaptable to individual requirements.

There are a few computerized PLM schemes which are dynamic systems and can be integrated into an overall maintenance management information system. These contain maintenance, inventory and purchase order modules and go far beyond 'just another work order system'. They provide the necessary information to control complex maintenance environments, thereby improving productivity and reducing operational costs.

9.2.21 Condition monitoring

Condition monitoring is an established technique which has been used by capital-intensive or high-risk industries to protect their investment. The concept has developed radically in recent years largely due to advances in computerizations which offer greater scope for sophisticated techniques. These fall into three types of monitoring: vibration, performance and wear debris. The last monitors particulate debris in a fluid such as lubricating oil, caused by the deterioration of a component.

Oil-related analysis encompasses a variety of physical and chemical tests such as viscosity, total acid number and particulate contamination. This is often extended to include the identification of wear debris, as an early warning of component failure, by either spectrographic analysis or ferrography or both. The former is commonly used in automotive and industrial application for debris up to 10 μm and the latter mainly for industry users covering wear particles over 10 μm. Ferrography is relatively expensive compared with many other techniques, but is justified in capital-intensive areas where the cost is readily offset by quantifiable benefits such as longer machinery life, reduced loss of production, less downtime, etc.

9.2.22 Health, safety and the environment

There are a wide variety of petroleum products for a large number of applications. The potential hazards and the recommended methods of handling differ from product to product. Consequently, advice on such hazards and on the appropriate precautions, use of protective clothing, first aid and other relevant information must be provided by the supplier.

Where there is risk of repeated contact with petroleum products (as with cutting fluids and some process oils) special working precautions are obviously necessary. The aim is to minimize skin contact, not only because most petroleum products are natural skin-degreasing agents but also because with some of them prolonged and repeated contact in poor conditions of personal hygiene may result in various skin disorders.

9.2.22.1 Health

It is important that health factors are kept in proper perspective. What hazards there may be in the case of oil products are avoided or minimized by simple precautions. For work involving lubricants (including cutting fluids and process oils) the following general precautions are recommended:

- Employ working methods and equipment that minimize skin contact with oil;
- Fit effective and properly positioned splash guards;
- Avoid unnecessary handling of oily components;
- Use only *disposable* 'wipes';
- Use soluble oils or synthetic fluids at their recommended dilutions only, and avoid skin contact with their 'concentrates'.

In addition to overalls, adequate protective clothing should be provided. For example, a PVC apron may be appropriate for some machining operations. A cleaning service for overalls should be provided and overalls should be cleaned regularly and frequently. Normal laundering may not always be sufficient to remove all traces of oil residues from contaminated clothing. In some instances dry cleaning may be necessary. Where this applies to cotton overalls they should first be dry cleaned and then laundered and preferably starched, in order to restore the fabric's oil repellancy and comfort. As a general rule, dry cleaning followed by laundering is always preferable to minimize the risk of residual contamination wherever heavy and frequent contamination occurs and when the type of fabric permits such cleaning.

Overalls or personal clothing that become contaminated with lubricants should be removed as soon as possible – immediately if oil soaked or at the end of the shift if contaminated to a lesser degree. They should then be washed thoroughly or dry cleaned before re-use.

Good washing facilities should be provided, together with hot and cold running water, soap, medically approved skin-cleansers, clean towels and, ideally, showers. In addition, reconditioning creams should be available. The provision of changing rooms, with lockers for working clothes, is recommended.

Workers in contact with lubricants should be kept fully informed by their management of the health aspects and the preventive measures outlined above. Any available government leaflets and/or posters should be prominently displayed and distributed to appropriate workers.

It should be made clear to people exposed to lubricants that good standards of personal hygiene are a most effective protection against potential health hazards. However, those individuals with a history of (or thought to be particularly predisposed to) eczema or industrial dermatitis should be excluded from work where, as in machine-tool operation, contact with lubricants is virtually unavoidable.

Some industrial machining operations generate a fine spray or mist of oil, which forms an aerosol – a suspension of colloidal (ultra-microscopic) particles of oil in air. Oil mist may accumulate in the workshop atmosphere, and discomfort may result if ventilation is inadequate. Inhalation of high concentrations of oil mist over prolonged periods may give rise to irritation of the respiratory tract, and in extreme cases to a condition resembling pneumonia. It is recommended that the concentration of oil mist in the working environment (as averaged over an 8-h shift) be kept below the generally accepted hygiene standard of 5 mg/m^3. This standard does, however, vary in some countries.

9.2.22.2 Safety

In the event of accident or gross misuse of products, various health hazards could arise. The data provided by the supplier should outline these potential hazards and the simple precautions that can be taken to minimize them. Guidance should be included on the remedial action that should be taken to deal with medical conditions that might arise. Advice should be obtained from the supplier before petroleum products are used in any way other than as directed.

9.2.22.3 Environment

Neat oils and water-based coolants eventually reach the end of their working lives, and then the user is faced with the problem of their correct disposal. Under *no* circumstances should neat oils and emulsions be discharged into streams or sewers. Some solutions can, however, be fed into the sewage system after further dilution – but only where permitted.

There are many companies offering a collection service for the disposal of waste lubricating oil. The three main methods employed are:

1. Collection in segregated batches of suitable quality for use by non-refiners
2. Blending into fuel oil
3. Dumping or incineration

If method (3) is used due regard must be paid to the statutory requirements that must be met when disposing of waste material. These are covered in two main items of legislation; namely, the Deposit of Poisonous Waste Act 1972 and the Control of Pollution Act 1974. It is the responsibility of the producer of waste oil to ensure that the waste is disposed of in the correct manner, to ensure that no offence is committed and that the contractor is properly qualified to execute the service.

9.3 Bearing selection

Neale[6] suggests that bearings can be classified according to the type of relative movement which they permit between the opposing surfaces. Four categories are proposed, namely, movement about a point, about a line, along a line, and in a plane. Each of these categories can be subdivided into oscillatory or continuous motion. Probably the most common bearings are those which exhibit continuous motion either about a line (such as journal bearings) or in a plane (such as thrust bearings). In turn, these bearings can be classified according to their load-carrying capacity/speed characteristics. The selection of an appropriate bearing for an application will entail matching the required characteristics to those provided by a particular bearing type. This matching of characteristics is only one step, and the designer must also consider geometric and environmental constraints, cost and predicted bearing life. Reference 6 provides useful further reading, along with appropriate ESDU Design Guides.[7]

9.3.1 Characteristics of bearings with continuous motion

In all the figures in this subsection the acceptable operating range for the bearing is below the solid line and within the maximum speed limit.

9.3.1.1 Liquid-lubricated, hydrodynamic journal bearings (Figure 9.8)

At lower speeds, the operating limit is determined by the minimum operating film thickness allowed. This in turn will be determined by the roughness of the opposing surfaces (asperity contact must be avoided) and the filtration level of the lubricant (particles of the same order as the minimum film thickness may cause surface damage). As speed increases, the lubricating liquid gets hotter and its viscosity reduces. This in turn reduces the maximum load which can be carried for an acceptable minimum film thickness. The upper speed limit is determined by the bursting speed of the shaft. A similar

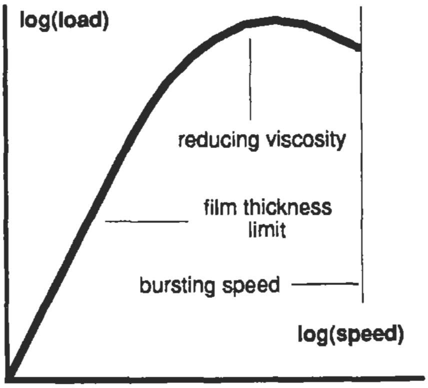

Figure 9.8

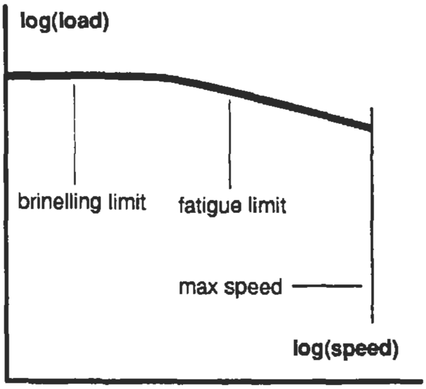

Figure 9.10

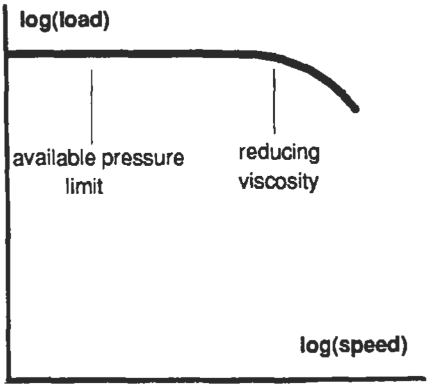

Figure 9.9

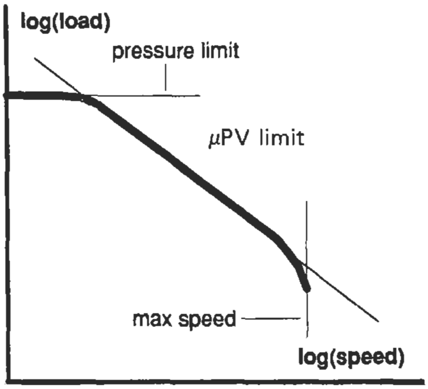

Figure 9.11

similar diagram can be drawn for liquid-lubricated hydrodynamic thrust bearings.

9.3.1.2 Liquid-lubricated, hydrostatic bearings (Figure 9.9)

These bearings have a sizeable load-carrying capacity at zero surface speed because this parameter is determined by the pressure of the supply liquid. The magnitude of this pressure is limited by the capabilities of the pressurizing apparatus and the associated equipment. At higher speeds, viscosity effects due to sliding become more pronounced, as in the case of hydrodynamic contacts.

9.3.1.3 Rolling element bearings (Figure 9.10)

The load limit at zero or low speeds arises from the tendency of the rolling elements to deform the races because of the high contact pressures. Since this is similar to the effect produced by the Brinell hardness test, the term 'brinelling limit' is employed. At higher speeds the races tend to fail through fatigue caused by the cyclical stress patterns induced as the elements pass repeatedly over the same points. For cylindrical rollers, the slope of this line is ($-10/3$), and for ball bearings it is (-3). At the highest speeds, failure may be due to excessive forces on the cage, or unwanted skidding of the rolling elements giving rise to severe wear.

9.3.1.4 Partially lubricated bearings (Figure 9.11)

These bearings have a lubricant embedded in the solid material. The former slowly escapes into the contact thus providing a partial level of lubrication. At low speeds, the maximum load is dictated by the structural strength of the bearing material. As speed increases, the load is limited by the temperature rise at the sliding interface, and the bearing life which are controlled by the product PV (see Section 9.1). An upper limit on speed is determined from temperature limitations.

9.3.1.5 Dry bearings (Figure 9.12)

Similar characteristics apply to these bearings as to partially lubricated contacts, but poorer load/speed characteristics are exhibited because of the absence of a lubricant.

9.3.2 Bearing selection charts

Figures 9.13 and 9.14 are taken from reference 6 and indicate the operating characteristics of the bearing types in Section 9.3.1. Figure 9.13 gives guidance on the type of bearing which has the maximum load capacity at a given speed and shaft size. It is based on a life of 10 000 h for rubbing, rolling and porous metal bearings. Longer lives may be obtained at reduced loads

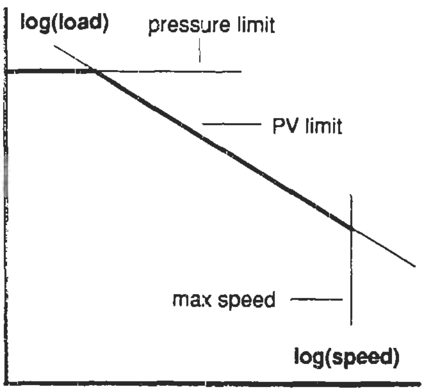

Figure 9.12

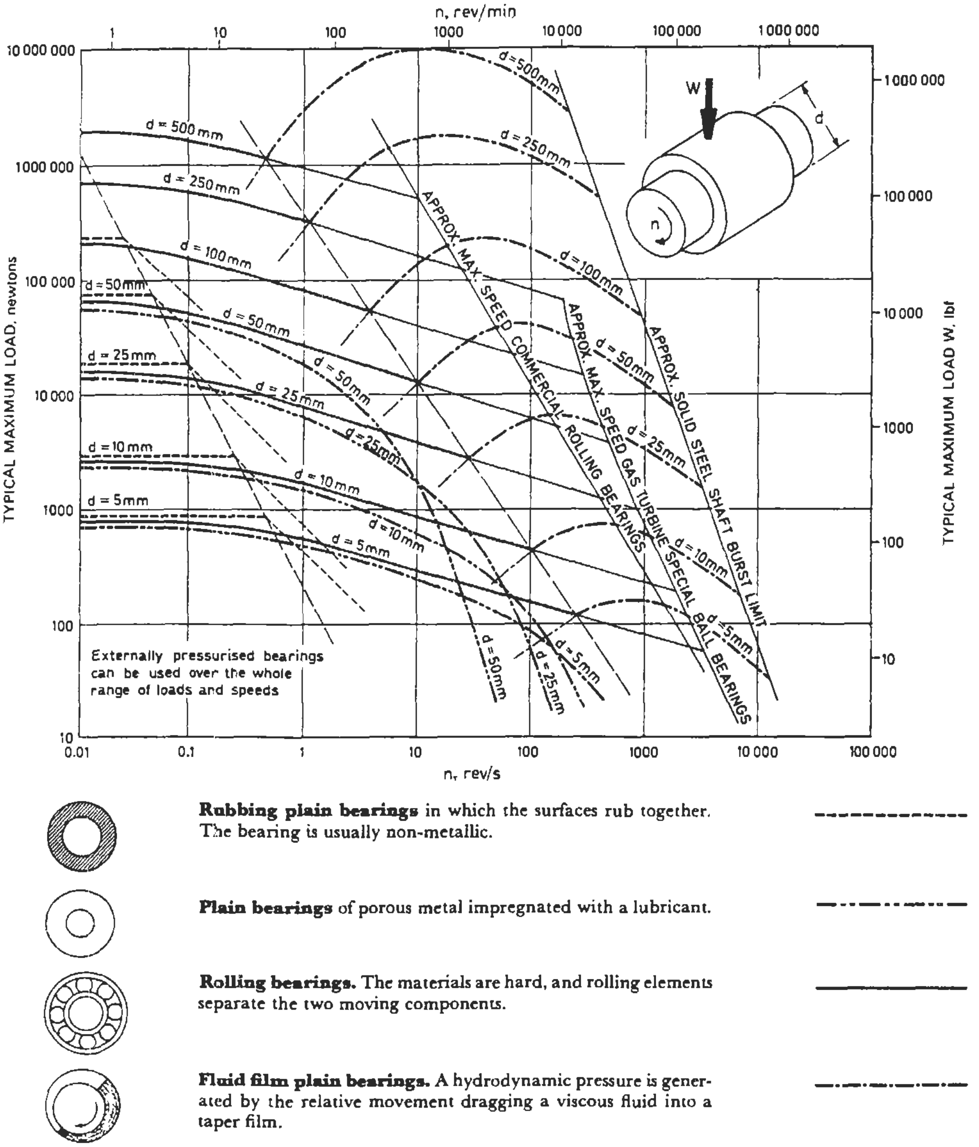
and speeds. For the various plain bearings, the width is assumed to be equal to the diameter, and the lubricant is assumed to be a medium-viscosity mineral oil. In many cases the operating environment or various special performance requirements, other than load capacity, may be of overriding importance in the selection of an appropriate type of bearing. See the tables in Section A2 of reference 6 in these cases.

Figure 9.14 gives guidance on the maximum load capacity for different types of bearing for given speed and shaft size. In many cases the operating environment or various special performance requirements, other than load capacity, may be of overriding importance in the selection of an appropriate type of bearing. See the table in Section A3 of reference 6 in these cases. Further details on design with these bearings can be found in reference 7, where advice is given on the selection and design of an appropriate bearing for a particular duty.



Rubbing plain bearings in which the surfaces rub together. The bearing is usually non-metallic.

Plain bearings of porous metal impregnated with a lubricant.

Rolling bearings. The materials are hard, and rolling elements separate the two moving components.

Fluid film plain bearings. A hydrodynamic pressure is generated by the relative movement dragging a viscous fluid into a taper film.

9.4 Principles and design of hydrodynamic bearings

9.4.1 Introduction

The subject of hydrodynamic (liquid film) bearings is essentially the subject of lubrication, therefore the design of such bearings is concerned principally with the behaviour of the liquid film separating the relatively moving components. Engines, turbines, motors, gearboxes, pumps, rolling mills and many of the machines used in industry (for example, in packaging, printing and production manufacture) are basically made of stationary and moving parts, the two being separated – at least in the ideal case – by a film of liquid, usually oil but not always. The moving part is usually a rotating shaft carrying a gear, impeller, armature, etc., and the bearings are the stationary components with which the liquid film is in immediate contact.

Typically, film bearings are fitted to accurately locate the rotating system within the machine. Two bearings are normally required for radial location of the shaft, plus a thrust bearing (usually two) mounted one either side of a collar or disk fixed to one end of the shaft, to locate the rotating system axially.

The major reasons for adopting film bearings, however, are to optimize load-carrying capacity, film thickness, power loss and heat generation for a given speed and diameter. Although the bearing diameter is usually set by the shaft or rotor of the machine, the length can be adjusted at the design stage for optimum performance. Note that the frictional resistance of a typical liquid film is extremely low, being about two orders of magnitude lower than that for metal-to-metal contact. Moreover, when the film thickness is of sufficient magnitude to completely separate the relatively moving surfaces – the ideal case – then the rate of wear of the bearing/shaft surfaces is effectively zero and a long service life is ensured.

Almost all fluids, even gases, can be used in film bearings. Indeed, process fluids are often used for convenience (e.g. in some types of water pump). Nevertheless, the fluid usually preferred for bearings of any type is mineral oil. This is because it is cheap, possesses inherently good boundary-lubricating properties (useful when inevitable contact occurs when starting and stopping) and can be dosed with chemical additives to enhance its properties (e.g. improved oxidation resistance, rust inhibition, anti-wear etc.). Also, and very importantly, mineral-based lubricating oils are available in about 18 viscosity grades ranging from 2 to 1500 cSt at 40° C. It is possible therefore to select the most suitable oil for any particular bearing application.

9.4.2 Principles of hydrodynamic lubrication

The basic requirements of a hydrodynamic bearing are that the bearing has a finite area; that the bearing surface be presented to the fluid at a slight attack (or wedge) angle; and that there is a relative 'sliding' motion between the components. If these conditions are met then a hydrodynamic pressure is generated along the bearing surface by compression of the fluid along the converging wedge, and this integrated film pressure can be sufficient to support the applied bearing load on the fluid film.

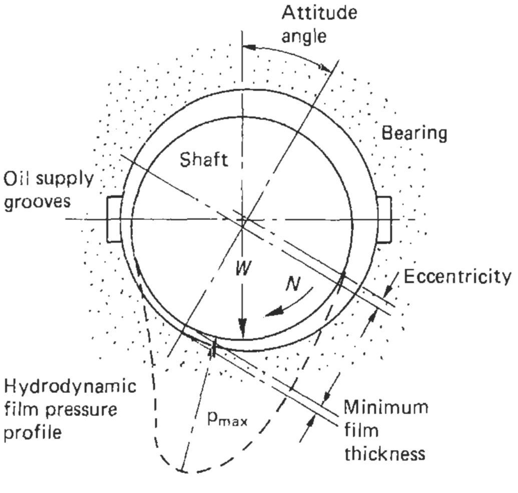

Figure 9.15 Hydrodynamic journal bearing

A converging wedge fluid film is generated automatically in a lubricated journal bearing by virtue of the necessary running clearance between the journal and the bearing bore, combined with the effect of load and rotation which produces a displaced, eccentric disposition of the journal (Figure 9.15).

The principle of hydrodynamic film pressure lubrication in a journal bearing was first observed experimentally by Towers[8] in 1883. Sponsored by the Institution of Mechanical Engineers, his 'First report on friction experiments (friction of lubricated bearings)' describes how a cork, then a wooden plug, fitted in the loaded zone of the bearing crown to stop up the oil hole, was 'forced out by the oil in a way which showed that it was acted on by a considerable pressure'.

Reynolds's paper[9] to the Royal Society in 1886 explained the phenomenon by analysis showing that a converging wedge-shaped film was necessary to generate pressure within the film. This classic paper is the basis of all hydrodynamic bearing theory.

A simplified version of Reynolds's equation is

$$\frac{\partial}{\partial x}(h^3.\partial p/\partial x) + \frac{\partial}{\partial y}(h^3.\partial p/\partial y) = 6.U.\eta.\mathrm{d}h/\mathrm{d}x$$

where

p = pressure in lubricant (Pa),
h = film thickness (m),
x, y = coordinates within the plane of the film,
U = velocity in the x-direction (m s^{-1}),
η = the lubricant dynamic viscosity (Pa.s).

However, in 1854 Hirn[10] in France had established some important factors from friction tests on oils and other fluids. He found that bearing lubrication was a function of: lubricant viscosity; rotating speed; and applied load. Hirn's results were analysed in 1883 by a Russian scientist, Nikolai Pavlovich Petrov, who used Newton's hypothesis of 1668 regarding fluid shear friction or viscosity, and showed that bearing friction could be explained by the behaviour of the fluid film. Petrov's Law is:

$$\mu = F/W = \eta.U.A/(W.c) = 4.\pi^2.r^2.b.(\eta.N)/(W.c)$$

where

μ = friction coefficient,
F = friction force (N),
W = applied load (N),
A = bearing wetted area (2.π.r.b),
r = bearing radius (m),
b = bearing length (m),
c = radial clearance (m),
N = rotational speed (s^{-1}).

As the average pressure (p^{av}) exerted by the load on the relevant area of a journal bearing is W/A (load divided by projected area $2.r.b.$), then the basic equation for hydrodynamic film friction for a constant value of clearance ratio c/r (commonly 1/1000) becomes:

$$\mu = \mathrm{f}(\eta.N/p^{\mathrm{av}})$$

The basic equation for the dimensionless minimum film thickness ratio in the loaded zone of a bearing is similar:

$$h_{\mathrm{min}}/c = \mathrm{f}(\eta.N/p^{\mathrm{av}})$$

where h_{min} = minimum film thickness (m).

Therefore in all studies of hydrodynamic bearings the essential factors are those which determine the behaviour of the separating film, which, for our purposes, we will refer to as the oil film. These factors are:

Oil viscosity
Oil flow
Bearing dimensions
Bearing geometry
Applied load
Rotating speed.

For practical use in bearing design, however, Reynolds's equation was too difficult to solve and Petrov's Law could only be applied to a non-representative case – that of a concentric or nearly concentric bearing. It was not until some 20 years later in 1904 that Sommerfeld[11] in Germany derived from Reynolds's differential equation a simple and usable set of equations for load capacity, friction moment and friction.

Sommerfeld's work showed that, neglecting cavitation in the unloaded portion, and assuming no end leakage of fluid (i.e. an infinitely long bearing), the load-carrying capacity of a journal bearing per unit length could be described using all the physical parameters normally available to the designer.

Michell[12] in 1905 proposed a method of integrating Reynolds's equation for application to plane surfaces whereby the $\delta/\delta x$ term was dropped. Twenty-five years later the method was applied to journal bearings by other workers, and by 1952 Ocvirk[13] produced the following usable equation for short bearings which has been shown to correlate well with experimental results:

$$p = \pi^2.\eta.N.(b/d)^2.(d/C_{\mathrm{d}})^2.(\epsilon/(1-\epsilon^2)^2).(1+0.62.\epsilon^2)^{0.5}$$

where

b = bearing length (m),
d = bearing diameter (m),
C_{d} = total diametral clearance (= 2.c),
ϵ = eccentricity ratio (= ratio journal centre displacement to the radial clearance).

Note minimum film thickness $h_{\mathrm{min}} = c.(1-\epsilon)$ or $C_{\mathrm{d}}/2.(1-\epsilon)$.

There are several other milestones in the development of our understanding of film bearings, but one in particular should be mentioned for background.

9.4.3 Viscosity

Sir Isaac Newton's hypothesis of 1668 is still recognized as the basis for understanding viscous or laminar flow in a fluid.

Newton explained the internal friction property of fluids as resembling the friction between two solid sliding surfaces. He demonstrated from experiments with two concentric cylinders, submerged in water, that a force was required to rotate one cylinder with respect to the other. Newton showed that the required force was a measure of the internal frictional shear resistance (or viscosity) of the fluid, and that it was associated with the shear area, the rotational speed and the film thickness in the following manner:

$F = \eta.A.U/h \qquad \text{therefore: } \eta = F.h/(A.U)$

This equation defines Absolute (or Dynamic) Viscosity which, in appropriate units, is required for bearing analysis and design.

It has become standard practice to specify lubricating oils by their kinematic viscosity, which is a convenient method of measuring viscosity using gravity flow. Multiplying by the fluid density is necessary to convert to absolute viscosity for use in bearing calculations.

A lubricating oil may have many chemical and physical properties which affect its behaviour, but for hydrodynamic bearings it is clear that the characteristic of viscosity is the most important. For a given bearing, such as is used in typical engineering applications, and for given operating conditions of load, speed, oil flow and supply temperature, it is the viscosity of the lubricating oil in the bearing separating film that finally determines the power loss, the heat generation, the system temperature and the load-carrying capacity.

If we regard the basic parameter $\eta N/p^{av}$, or, as it is frequently referred to, ZN/P, as an index of bearing performance then clearly the correct oil viscosity can be chosen to match the speed, the applied loading and the size of bearing. Viscosity is a measure of the physical ability of the oil to maintain a separating film under the specified bearing conditions.

However, viscosity is also a measure of the internal frictional shear resistance of the fluid, and so the process of shearing the oil film in a bearing has the effect of generating frictional heat within the film. Inevitably, the work done in shearing the film raises the film temperature, and in many applications a flow of oil in and out of the bearing is necessary to remove the generated heat and to maintain a reasonable system temperature.

The business of designing hydrodynamic bearings is therefore also associated with the selection of the lubricant and the bearing material, and specifying the oil feed system details such that:

1. The applied load will be carried on an adequate separating oil film at the operating speed.
2. The heat generation will be reasonably low commensurate with maintaining acceptable oil and bearing temperatures.
3. The bearing material fatigue strength will be adequate to tolerate the imposed pressure and the generated temperature, and will operate safely without serious surface damage when inevitable contact occurs at starting and stopping.

A major difficulty in analysing the performance of oil film bearings is the marked variation of viscosity with temperature. A typical bearing oil may show at least an order and possibly two orders of magnitude viscosity variation between the full range of operating conditions from cold start to maximum film temperature.

The viscosity within the film will vary between inlet and maximum temperature conditions. Estimating the effective temperature to obtain the effective film viscosity therefore requires iteration, and this is where modern computer methods are useful.

Some of the heat generated will be lost via the structure, but this proportion is usually small in pressure-fed applications and can be neglected. For non-critical applications, lubrication is by static oil bath, in which case all the generated heat is lost to the surroundings via the structure and shaft, and a reasonable estimate of the effective film temperature is therefore required.

9.4.4 Journal bearing design

Methods have been established from theory, experiment and practice to produce bearing design solutions. The basic non-dimensional parameter required to be specified and which incorporates all the relevant factors is a term which has become known as the Sommerfeld Number or Sommerfeld Reciprocal. This is a variation of ZN/P which includes the 'clearance ratio' (the ratio of the diametral clearance to the diameter) and is conveniently used in reciprocal form as 'dimensionless load'.

Much work has been done over the years in analysing bearings of various length-to-diameter ratio to establish the variation of several parameters against dimensionless load. These are heat generation, oil flow, eccentricity ratio (i.e. the eccentricity of the shaft within the bearing ($\epsilon = 0$ for concentric operation and $\epsilon = 1$ for fully eccentric, i.e. touching)) and the attitude angle, i.e. the angle of disposition of the shaft/bearing centres to the load line which is always beyond the load line in the direction of rotation (Figure 9.15). Typical values are shown in Figure 9.16.

Another variable which may have to be considered is the angle of bearing arc (Pinkus and Sternlicht[14]). Few bearings have a full 360° bore, because of the need for oil supply which is usually pressure fed to longitudinal grooves cut within the bore and along the bearing length, and normally terminating short of the ends. Typically, bearings are made in two halves to allow assembly into the machine (e.g. engine main bearings), and this allows the oil grooves to be conveniently cut at the joint faces, thus reducing the bearing to two plain halves of, say, 150° each.

It is evident that with longitudinal oil supply grooves the direction of load application must be fairly constant and towards the centre plane portion as in turbines or engine main bearings. A bearing has a much-reduced load-carrying capacity if the load is applied towards the oil groove, because the hydrodynamic wedge length is significantly shortened. In cases where the load direction is indeterminate or variable (e.g. engine big-ends) then the answer can be to use a circumferential oil groove at the centre of the bearing length.

Charts of dimensionless parameters are useful for setting out the basic design of bearings operating under constant speed and load. A well-developed chart method by the Engineering Sciences Data Unit[15] for typical split bearings enables the relevant parameters to be determined, and computer programs are also available for standard designs. Programs also exist which allow evaluation of designs incorporating complicated multi-arc geometry, and which will solve for thermal variations, distortion and oscillating load.

Assuming a typical bearing, the first step for a preliminary design evaluation is to collect the physical data for the bearing system and to calculate the dimensionless load:

$$\text{Dimensionless load} = \frac{W.(C_d/d)^2}{\eta.N.d.b}$$

The value of the viscosity term must be assumed initially because of its dependence on temperature, heat generation, etc. The other parameters are usually known (e.g. load, speed, diameter).

The bearing eccentricity ratio (ϵ) is then obtained from charts of eccentricity ratio against dimensionless load such as

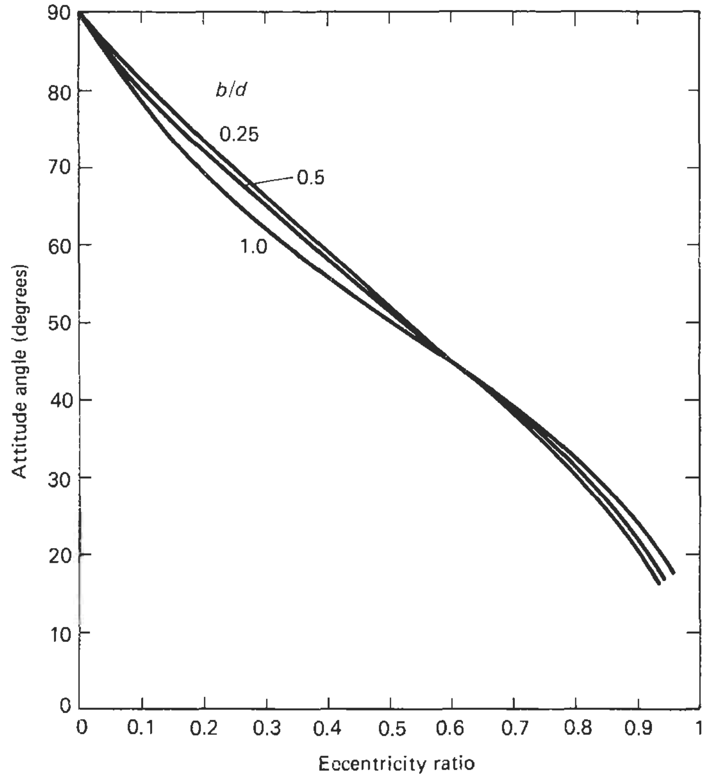

Figure 9.16 Journal bearing: attitude angle

Figure 9.17 and the associated minimum film thickness (h) determined where:

$h_{\min} = (C_d/2).(1 - \epsilon)$

The oil flow, heat generation, etc. are also determined from charts. The process is repeated until reasonable coincidence is obtained depending on whether the requirement is to design a bearing for a particular duty or to evaluate an existing design.

For an initial assessment of a typical bearing the assumptions to make for a safe and reliable design are generally length-to-diameter ratio (b/d ratio) of, say, 0.7, and a minimum clearance ratio (C_d/d) of about 0.001 (remember to take tolerance limits into account). Long bearings (of b/d ratio greater than unity) are prone to misalignment problems. Small values of clearance ratio less than 0.001 can lead to reduced oil flow and high temperatures, particularly in high-speed bearings where a larger clearance is required (see below).

The dimensionless load should be in the range 10–60. Values approaching 100 indicate very high eccentricity and small film thickness and are only acceptable in large bearings. However, values exceeding 100 are usual in very large, heavily loaded, slow-speed bearings where the shaft surface finish dimension is very small in relation to the diameter. Low values (say, below 10 (high-speed light-loads)) increase the risk of instability. Eccentricity ratio should generally be in the range 0.7–0.95.

There are other limiting factors which define the safe operating zone and which must be properly considered in producing a design to operate reliably in service. These are discussed below.

9.4.4.1 *Diametral clearance*

The bearing clearance can be adjusted at the design stage to optimize the film thickness, the heat generation, the oil flow and the temperature. Note that as the clearance dimension is very small and may vary on manufacturing tolerances by a factor of two, the calculations should therefore cover the extreme limits of tolerance. As a general rule, the minimum clearance should be adequate to allow sufficient oil flow so as to limit the temperature rise within the bearing to an acceptable value.

High-speed bearings are generally lightly loaded but need large clearances to reduce heat generation and to promote stability against film whirl. Heavily loaded slow-speed bearings have marginal film separation and need small clearances to improve the hydrodynamic performance and to allow greater film thicknesses to be generated. Empirical selection is adequate for the initial design, and guidance for typical bearings is given:

Minimum clearance ratio = 0.0005. (shaft speed in rev/sec)$^{0.24}$
i.e. C_d/d = 0.0005.(rps)$^{0.24}$ (for diameters of 0.1 m or greater)
Clearance ratio should be increased for bearings of diameter less than 0.1 m.

9.4.4.2 *Surface roughness*

The roughness of engineering surfaces is usually measured by traversing a stylus and recording the undulations as a root mean square (RMS) or centre line average (Ra) value.
Typical Ra values for shafts and bearings are:

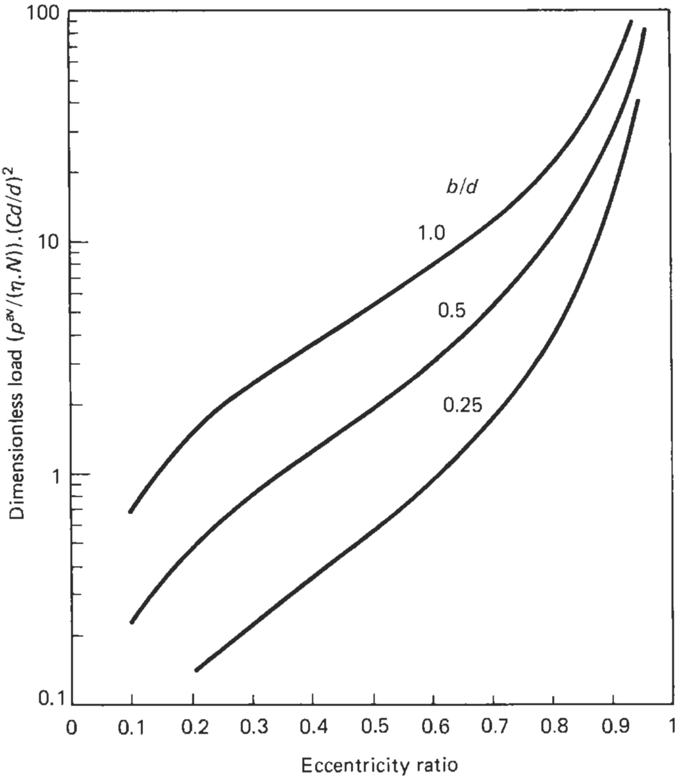

Figure 9.17 Journal bearing: dimensionless load

Turned surfaces:	3.2 to 12 μm
Fine turned:	1.6 to 0.8 μm
Ground surfaces:	1.6 to 0.4 μm
Fine ground:	0.4 to 0.1 μm
Lapped:	0.2 to 0.05 μm

The peak-to-valley dimension is, however, much greater than indicated by these averaging methods, and can be from about four to ten times greater, dependent on the method of machining and the magnitude of the average dimension. It is the peak-to-peak contact that represents the ultimate 'touch-down' condition of bearing operation and the design must take it into account.

9.4.4.3 Minimum allowable film thickness

The basic calculation of minimum film thickness inherently assumes the bearing and journal surfaces to be smooth and parallel to one another. This happy condition is, of course, seldom true, and while parallelism may be achieved on assembly, thermal distortion inevitably introduces a degree of misalignment when in operation, and this should be considered in the design.

In a precisely aligned system the ultimate minimum allowable film thickness is set by the combined roughness of the surfaces at the point which will just allow the surface asperities to come into contact, thus increasing friction and heat generation. (see Figure 9.18) At best, the result will be light burnishing or polishing of the surfaces, at worst, failure due to wear, local melting or seizure dependent on the sliding speed and the materials. 'Safe' minimum film thickness values are therefore specified in design which take account of bearing size, rotating speed, materials, application and method of surface finishing.

Note from Figure 9.18 that the 'knee' of the curve represents the point of surface asperity contact, and its position in relation to *ZN/P* for a precisely aligned system is only dependent on the combined surface finish. 'Running-in' of new bearings has the effect of reducing the point at which the 'knee' occurs.

For normal use, empirical data for typical bearing and shaft surfaces are adequate to produce recommended safe values of minimum film thickness. The values given by the following equation allow a factor of >1.5 on the peak-to-valley dimension of typical journal surfaces. This minimum margin is generally safe for correctly aligned and clean systems:

Minimum allowable film thickness = dia(mm)$^{0.43}$ (μm)

i.e. $h_{\min} = d^{0.43}$ (μm) (d in millimetres)

In many heavily loaded slow-speed applications of large bronze bearings with grease lubrication the operating minimum film thickness falls well below the safe recommended value as given by the above equation, and wear inevitably takes place. This is usually unavoidable, but nevertheless acceptable, as the wear rate can be minimized by adopting self-aligning features; very fine surface finishes, particularly of the shaft; by maximizing the lubrication using a high-viscosity oil component in the grease; by careful detail design of the bearing and grease grooves; and by using effective grease-feeding arrangements.

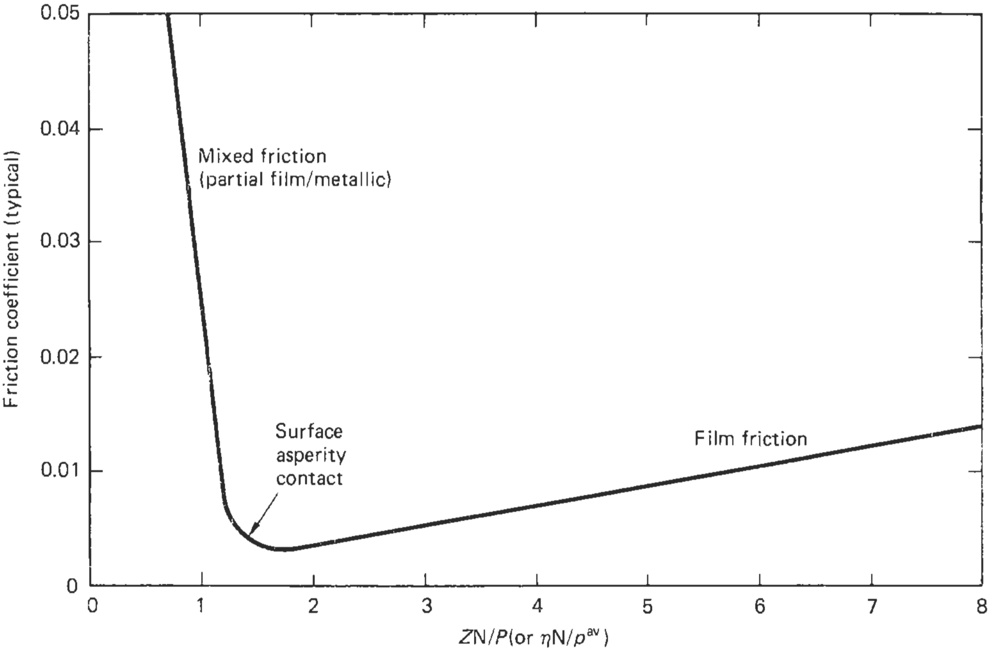

Figure 9.18 Journal bearing: friction coefficient

9.4.4.4 *Lubrication*

The preferred lubricant for most bearings is oil. Lubricating oils are designed to operate satisfactorily in terms of the oil itself to give a long life in properly maintained and clean systems, but, as previously stated, the important property for hydrodynamic bearings is the oil viscosity. Oils are formulated to be suitable for given applications (e.g. turbines, compressors, gears, internal combustion engines), therefore turbine oils are solvent refined and usually incorporate only anti-oxidant and anti-rust additives. They are particularly efficient at separating out from water, which is an inevitable contaminant in a steam turbine system. Gear oils, on the other hand, may contain additives to protect against gear tooth scuffing and other surface damage. Such additives are not generally required for film bearings.

The life of the oil is usually limited by oxidation, which produces acidic residues. Oxidation life is very sensitive to temperature and by rule of thumb can be assumed to halve for every 10°C. A maximum safe upper limit temperature for most mineral oils is 120°C, which coincides with the safe upper operating limit for white metals, but the oil would have a short life at this temperature. Typical bulk temperatures in a large system would be 40–60°C with a maximum bearing metal temperature of, say, 80–90°C. In automobile engines oil temperatures frequently reach 150°C but then these systems are comparatively small and are required to be changed frequently due not only to oxidation but also to contamination by sludge, carbon, fuel, water, etc. For very high temperatures up to about 250°C, synthetic oils are available.

While the correct viscosity grade of oil can be identified from rigorous bearing calculations to optimize the film thickness, heat generation and temperature rise, it is quite adequate and certainly more convenient to use empirical selection for a preliminary assessment.

The general guidance in Table 9.8 applies, where VG represents the viscosity grade of the oil according to the ISO definition: 'kinematic viscosity in centistokes at 40°C.' Data are given in oil company literature which usually specifies the viscosities at 40°C and 100°C to enable the variation over the working temperature range to be estimated.

9.4.4.5 *Pressure-fed lubrication systems*

Bearings in large machines (e.g. turbines, industrial and marine gears, compressors, automotive engines) are usually supplied with oil from a pressurized positive-feed system to ensure safety, reliability, uniform operating conditions and effective cooling. The system requires a storage tank, pump and return line, and can be usefully enhanced by the inclusion of filtration equipment, and instrumentation to measure and control pressure and temperature.

Table 9.8

Diameter × speed (mm × rps)	*'Viscosity grade' of oil required at the operating temperature of:*			
	40°C	*60°C*	*80°C*	*100°C*
3400–6000	15 VG	32 VG	68 VG	150 VG
1700–3400	22	46	100	220
850–1700	32	68	150	320
500–850	46	100	220	460
250–500	68	150	320	680
140–250	100	220	460	1000
80–140	150	320	680	1000
30–80	220	460	1000	1500

The total bearing design procedure must consider all the factors which control the effective operating bearing film temperature and the effective viscosity, which in turn controls all other relevant parameters: minimum film thickness; bearing attitude angle; heat generation or power loss; rate of oil flow; maximum oil/bearing temperature; and the outlet oil temperature. All these factors are interrelated and therefore the equilibrium operating condition for the total bearing system is determined by simultaneous solution of all the variables.

Oil flow through a journal bearing is principally from two components: the pressurized local flow through the bearing clearance via the feed grooves, and the hydrodynamic flow, which depends on the disposition or eccentricity of the rotating shaft. Pressurized film flow occurs whether the system is rotating or stationary, and is the flow from the feed grooves out through the clearance space. Assessment is based on a modification of the general expression for fluid flow through thin slots:

Pressurized flow rate = $dp.R_s.t^3/(12.\eta)$ ($\mathrm{m^3\ s^{-1}}$)

where

dp = pressure drop (Pa),
R_s = width-to-length ratio of the rectangular slot,
t = thickness of the thin film (m), and
η = fluid film viscosity (Pa.s).

Modification of the equation is necessary for a journal bearing, because the slot width is not constant but widens out from the groove ends as the flow progresses out through the clearance spaces to the ends of the bearing. A factor is therefore used based on eccentricity and length/diameter ratio.

Hydrodynamic flow is controlled by the bearing dimensions, geometry, clearance, the journal's eccentricity and running speed. It is zero at zero eccentricity (concentric, no-load operation). For normal operation of a loaded bearing the hydrodynamic oil flow is calculated from the following basic equation, and factors are used to take account of eccentricity, length/diameter ratio and oil groove length.

Hydrodynamic flow rate = $f(C_d.N.d.b)$

9.4.4.6 *Heat generation*

The heat generation or power consumption in a bearing film is produced by the work done in shearing the film. This is related to Petrov's Law which gives a good approximation for lightly loaded (therefore near-concentric) bearings. For typical bearings carrying load, the basic Petrov relation is modified by a dimensionless number[15] appropriate to the design and the operating eccentricity:

Power loss: $H = H^1.(\eta.N^2.d^3.b/C_d)$

where H = film power loss (Watts) and H^1 = dimensionless power loss (see Figure 9.19).

9.4.4.7 *Bearing materials*

The bearing material must be of adequate hardness and strength to support the load, particularly if there is a fatigue element in the load cycle as would be the case, for example, in

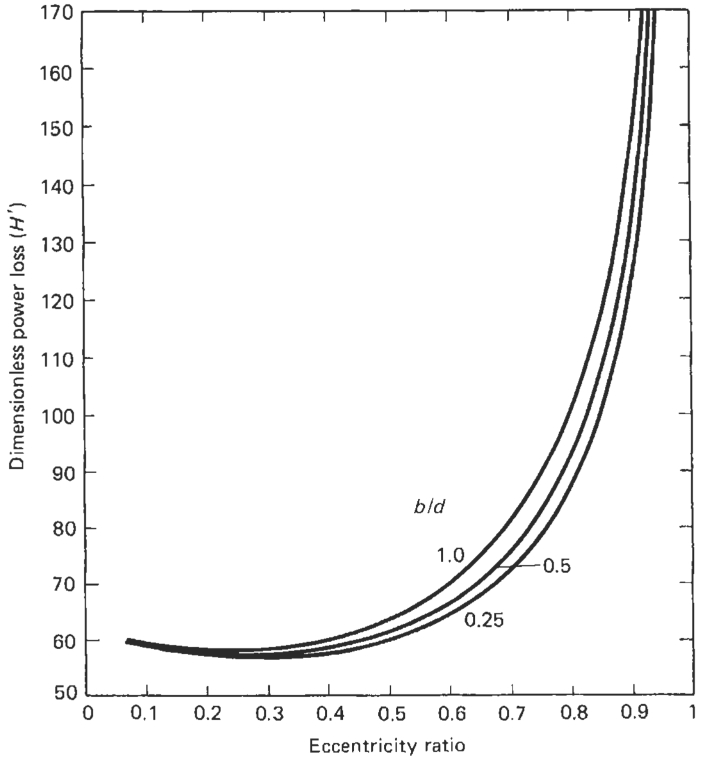

Figure 9.19 Journal bearing: dimensionless power loss

an internal combustion engine. Conversely, the material should be soft enough to embed particulate debris so as not to score the shaft. Good compatibility is important, that is, the ability to 'self-heal' or to withstand an occasional 'touch' by the shaft, particularly if lubrication becomes marginal. Corrosion resistance is necessary to prevent the acidic products of oxidation in the lubricating oil from corroding the bearing surfaces. The bearing material must satisfy in measure all these requirements.

Some of the more common bearing materials used with oil or grease lubrication and their general properties are given in Table 9.9. The fatigue limit values given in the table relate to the average bearing pressure (p^{av}), i.e. the load divided by the 'projected' area ($b.d$). The localized peak film pressures (p_{max}) are several times the average (Figure 9.20).

Within each group of bearing material there are available many variations of the proportions of constituent elements to give selected properties. Also, the high strength capacity of the harder materials can be used to support thin surface layers of softer material to allow improved contact compatibility and to enhance the fatigue life of the softer material. Production-manufactured engine bearings are normally tin plated to protect against corrosion from acidic residues in the oil.

In general, the softer bearing materials (e.g. the white-metals) are best for high-speed lightly loaded applications such as turbine bearings and will withstand an occasional 'touch' without serious damage. Comparatively, the harder bronzes generate higher local temperature on contact and are best for low-speed heavy-load applications such as gearboxes and general engineering equipment. Hard phosphor–bronze is used for highly loaded small-end bearings in some internal combustion engines because of its excellent fatigue capacity.

Table 9.9

Material	*Hardness at room temp. (HV)*	*Fatigue limit (MPa)*	*Operating temperature limit (°C)*	*Min. shaft hardness (HV)*
White-metal (Pb base)	16–20	7	120	160
White-metal (Sn base)	27–32	7–14	120	160
Aluminium–tin	30–60	16	160	200
Copper–lead	45–50	10	190	300
Lead–bronze	60–80	25	200	400

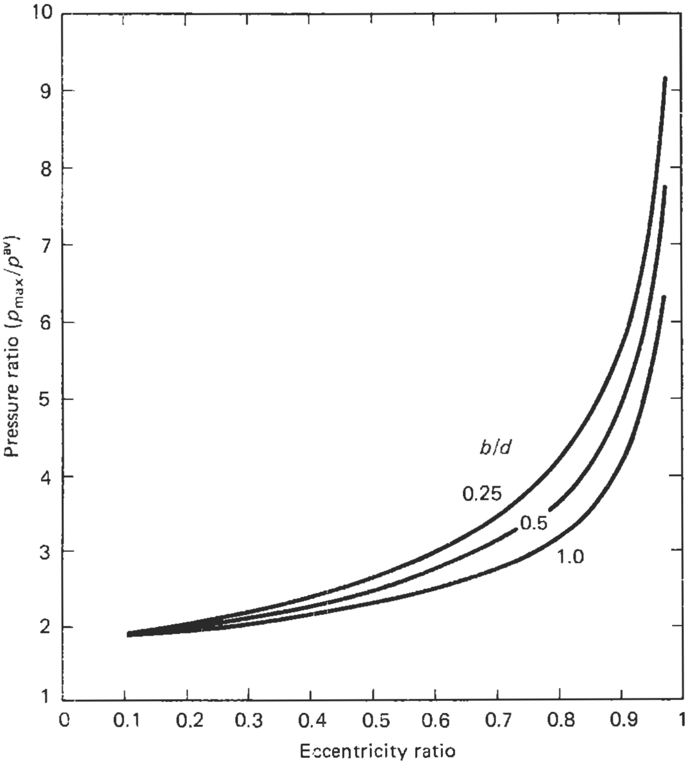

Figure 9.20 Journal bearing: film pressure ratio

9.4.4.8 *Oscillating load*

In some applications the bearing load is not steadily applied, but oscillates with rotation. These include bearings in engine crankshafts (mains and big-ends) and piston-pins, as well as forging and coining presses. In this situation the bearing load capacity is enhanced over and above the limit for a steadily applied load. The reason is that, although the film thickness begins to reduce as the peak cyclic load is applied, it takes a finite time for the oil to be squeezed out from the small clearance. During this period of time and before an equilibrium minimum film condition is reached, the peak load is relieved which then allows the high eccentricity to reduce and the film to recover. This is known as the 'squeeze-film' effect.

Several theories and empirical methods have been suggested to consider this effect. Unfortunately, the results appear to vary markedly. The general principle adopted is to relate the change in shaft eccentricity with the time interval required to squeeze the oil in the small reducing clearance space from one shaft position to another. The direction of flow has to be assumed.

A simple approximation for hand calculation was proposed in 1954 by Archibald[16] based on the general equation for flow through thin slots (previously discussed). Archibald's equation for a full (360°) bearing is:

$$dt = (6.\pi.\eta.b.d^3/[C_d^2.W]).(\epsilon_2/[1-\epsilon_2^2]^{0.5} - \epsilon_1/[1-\epsilon_1^2]^{0.5})$$

where

dt = time interval from ϵ_1 to ϵ_2 (s),
η = viscosity (Pa.s),
b = bearing length (m),
d = bearing diameter (m),
C_d = diametral clearance (m),
W = applied peak load (N),
ϵ_1 = initial eccentricity ratio, and
ϵ_2 = final eccentricity ratio.

Generally, the usefulness of the above equation is as a check on the likely change in eccentricity for a given time interval based on rotating speed to ensure that the reduced film thickness is adequate. The equation is only applicable to bearings which are long in relation to their diameter, because the flow is assumed to be circumferential, therefore the end flow negligible. The method can only give an approximation of the bearing behaviour, but, nevertheless, will usually indicate whether or not the design is adequate. Computer programs have also been devised based on finite-element and finite-difference analyses.

9.4.4.9 *Film instability*

While it is obviously desirable to operate with an adequate separating film to give a high degree of reliability, care must be taken in design to ensure that the bearing will behave in a stable manner and will not induce self-sustaining oil film whirl, a common problem with lightly loaded, high-speed journal bearings. The problem is associated with the operation of circular bearings at low eccentricity where the journal tends to operate in an almost concentric disposition relative to the bearing and with a large attitude angle (Figures 9.15 and 9.16). In this condition the oil film which rotates at about 0.48 times shaft speed tends to push the journal around bodily, also at about half shaft speed.

Oil film whirl is particularly worrying when the rotating shaft speed is about twice its first critical frequency. The resultant vibration which can occur at operating speeds between, say, 1.8 and 2.4 times the first critical can be very difficult to remedy.

Changes in bearing clearance generally have only a small effect on the running eccentricity of an oil-fed journal bearing because oil flow, heat generation and film temperature also change. Adjusting the clearance, however, can have a useful effect on whirl frequency and can be used to change the frequency if film whirl is present, as the following approximation[17] shows:

$$f_{oil} = ([3-\epsilon]/4\pi).(g/c)^{0.5} \quad \text{for } b/d = 1$$

where

f_{oil} = whirl frequency (Hz),
ϵ = eccentricity ratio,
c = radial clearance (m), and
g = gravitational acceleration (m s^{-2})

Other techniques for shifting the operating mode to a more stable condition involve either adjusting the operating conditions in the case of a running bearing (e.g. by allowing a higher oil film temperature) or, for a new machine, by using a shorter bearing or a different geometrical concept. The objective in all cases is to de-rate the load-carrying capacity of the bearing such that the minimum oil film thickness is reduced and the shaft disposition moved to a condition of greater eccentricity and smaller attitude angle, thus producing a more stable operating mode, as is the case with a heavily loaded bearing.

Several designs have been produced (Figure 9.21), including:

Elliptical bore ('Lemon' bearing)
Three-lobe and
Four-lobe bore
} in which the bearing lobe radii are greater than the bearing contact radius
Four longitudinal grooves
Offset-halves
Tilted offset-halves
Tilting pads/pivoting pads

Of all these alternative bearing designs, only the tilting pad or pivoting pad concept is really successful in suppressing film whirl. This type should be specified for lightly loaded vertical shaft units for critical applications (e.g. boiler circulators).

9.4.4.10 *Shaft critical frequency*

In high-speed machines the vibrational frequency of the rotating shaft system is determined in design to ensure that the operating speeds do not coincide or even come near to a critical frequency at which a self-sustaining destructive vibration can develop. However, it must be appreciated that the critical frequency value calculated for the rigid shaft can, in practice, be reduced to a lower value by the spring stiffness of the bearing oil film. For this reason, bearing spring and damping coefficients have to be taken into account in the overall design, particularly where lightly loaded, high-speed oil film bearings are used.

The natural frequency of the undamped system is defined[17] by:

$$f = (1/2\pi).(\text{film stiffness/journal mass})^{0.5} \text{ (Hz)}$$

When the shaft centre becomes positionally displaced, squeeze-film forces are generated which are quite large and have a significant effect on the frequency. Moreover, shaft movement is never linear but always at an angle to the applied force, thus producing a changing attitude angle (Figures 9.15 and 9.16). It is necessary therefore to evaluate four stiffness and four damping terms *YY*, *YX*, *XX* and *XY* which define the force in the *Y* direction corresponding to movement in the *Y* direction and so on, the units of stiffness being N/m, and damping N.s/m.

Offset halves

Figure 9.21 Alternative journal bearing designs

For a simple assessment the effect of bearing whirl on the shaft critical speed may be approximated by adding the reciprocals squared of the frequencies of the rigid rotor and the oil whirl value (previous section) to produce the reciprocal squared of the effective rotor critical frequency:

$$(1/f_{\mathrm{eff}})^2 = (1/f_{\mathrm{oil}})^2 + (1/f_{\mathrm{rotor}})^2$$

9.4.4.11 Process fluid lubrication

It is sometimes convenient to operate film bearings in the process fluid. Typical examples are boiler circulators, long-shaft river-water pumps and acid pumps. Unlike oil, water has no boundary lubricating properties and has a low viscosity (0.001 Pa.s = 1 cP at 20°C) therefore the unit loading has to be kept low and the materials have to be suitable.

Fluted rubber bearings are generally very effective for lightly loaded long-shaft river-water pumps and small-boat propeller shafts, as they can accommodate grit and sand without damage. The bearing works hydrodynamically by a wedge-shaped surface contour which develops by elastic deformation of the rubber, thus allowing separating films to be generated on the several lands. Rapid failure occurs if the rubber is allowed to run dry.

Glandless boiler circulators frequently employ bearings made from fabric-reinforced thermosetting resins of which there are many types available. Some designs incorporate helical debris wash-out grooves which inevitably reduce the load-carrying capacity. Nevertheless, using hardened and finely ground shaft sleeves a long operational life is obtained even with calculated film thicknesses as low as 0.005 mm in small bearings.

Water-lubricated bearings tend to be long in relation to diameter to give greater bearing area in view of the low viscosity of water (which reduces with increasing temperature). A high standard of surface finish is therefore required on the mating shaft (say, 0.1–0.4 μm R_a). Good alignment is also essential. Carbon bearings are used for very high temperature water.

For bearings operating in corrosive fluids an important property is their resistance to corrosive attack. Hard materials such as austenitic high-nickel cast iron are used but have poor bearing properties relating to the accommodation of debris, which then tends to score and damage the shaft. Thermoplastic polymers have solved these problems and many filled and unfilled types are quite suitable in acids and alkalis, the filled thermoplastics being generally preferred because of their low wear rate.

9.4.5 Self-contained bearings

Assemblies of self-contained bearing systems are available for incorporation into machines such as turbines, centrifugal compressors, pumps and motors. The action of the rotating film is utilized to pump oil from the bearing to an associated cooler then back to the bearing. One end bearing would be journal only, the other combined with a thrust bearing for axial location.

9.4.6 Thrust bearings

Multi-pad thrust bearings operate on hydrodynamic principles. However, unlike journal bearings which automatically adjust to allow the converging or tapered film wedge, the taper

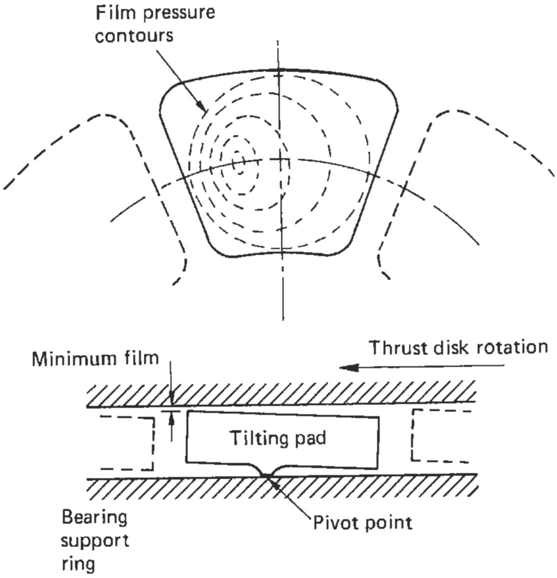

Figure 9.22 Hydrodynamic thrust bearing

has to be either machined into the bearing surface (fixed pad bearing) or the bearing arranged in such a way as to allow it to tilt when in operation (tilting pad bearing) (Figure 9.22). The shaft incorporates a collar or thrust disk which is normally located by two thrust bearings, one either side. Each bearing comprises several pads (Figure 9.23). The preferred pad geometry is nearly 'square', that is the radial breadth equal to the circumferential length, or: $b/L = 1$.

Fixed pads have to be machined to a very accurate surface taper, the pad rise dimension being about three times the generated minimum oil film thickness for best performance, and to allow for wear and unequal pad loading due to misalignment and varying pad thickness. Difficulties can be experienced in manufacturing to such small dimensions, but the advantages are simple one-piece construction and cheapness, particularly for small bearings. Fixed pads with flat surfaces have been shown to operate quite well in some applications due principally to differential thermal expansion effects which allow a contour to develop along the metal pad surface as the oil film temperature rises as a result of the frictional work done in its passage along the pad.

Theoretically, tilting pad thrust bearings can be optimized for maximum film thickness, minimum heat generation or minimum temperature. For a given geometry of inside/outside diameter and pad circumferential length, optimization is controlled by setting the position of the pivot line which, in most applications, is at a point about 60% along the pad length from the inlet edge.

In the case of oil-lubricated pad bearings it is not uncommon to site the pivot at the half-way point. This has obvious advantages in both manufacture and assembly interchangeability, and allows rotation in either direction. From the performance aspect there is shown to be only a small practical difference using a centre pivot compared to the optimum pivot position, probably because of pad surface convexity caused by differential thermal expansion. This effect may not apply to the same degree with water lubrication due to the high specific heat and low viscosity of water, which reduces the temperature rise along the pad to very small values.

The tilting pad automatically adjusts when in operation to the optimum tilt angle, which will vary with changes in operating conditions: load, speed and temperature/viscosity. The leading-edge film thickness for a 0.6 pivot position is

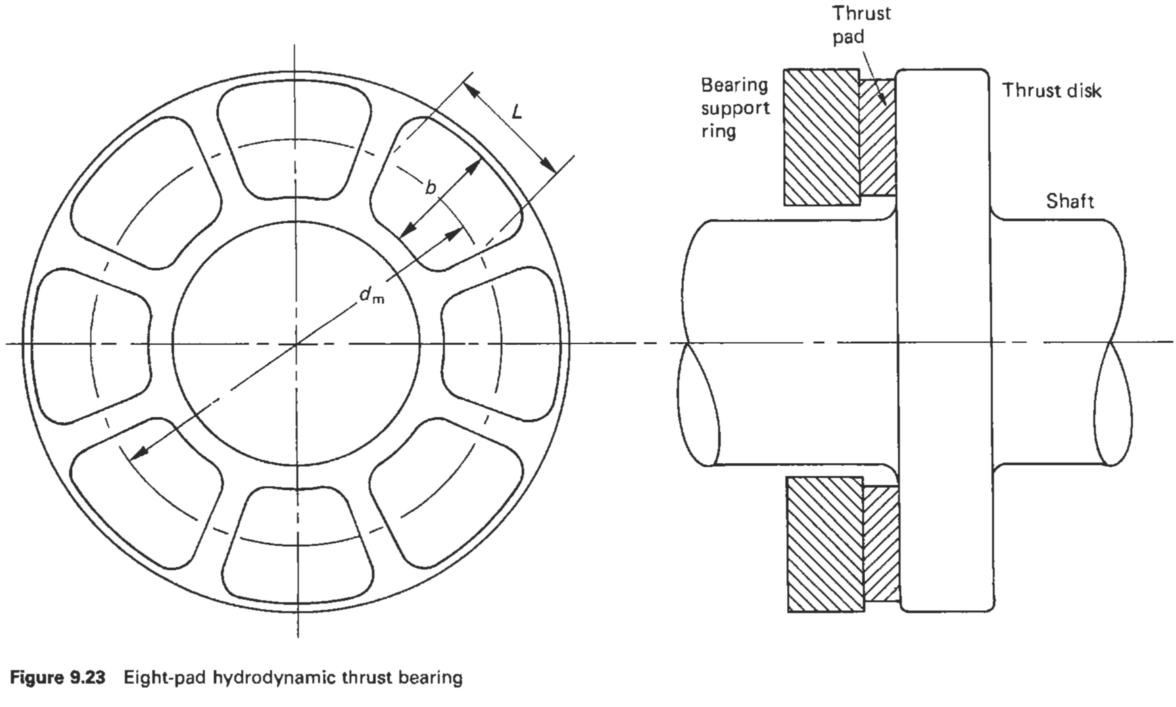

Figure 9.23 Eight-pad hydrodynamic thrust bearing

approximately equal to 2.4 times the trailing-edge film thickness under all conditions of film operation.

For a preliminary bearing design assessment the effective film viscosity is required, therefore the film temperature is assumed, and should be at least of the same order as the expected drain temperature. The minimum or trailing-edge film thickness can then be calculated from the following equation, which is suitable for 'square' or nearly square pads (i.e. $b/L = 1$):

$$h_0 = 0.46(\eta.N.d_m.b/p^{av})^{0.5}$$

where

h_0 = minimum film thickness at the trailing edge (m),
η = effective film dynamic viscosity (Pa.s or cP/1000),
N = speed (Hz),
d_m = mean diameter of disk (m),
b = radial width of pad (m),
L = circumferential length of pad (m)
p^{av} = mean pad pressure = total load/($b.L.z$) (Pa), and
z = number of pads.

The safe minimum allowable film thickness for design purposes is generally based on the pad dimension rather than the diameter. The following equation is for a precisely aligned high-quality bearing:

Minimum allowable film thickness = 1.7.pad width(mm)$^{0.44}$ (μm)

i.e. $h_0 = 1.7.b^{0.44}$ (μm) (b in millimetres)

However, some degree of misalignment is unavoidable in most machines, as are variations in pad thickness within the manufacturing tolerance band. These factors must therefore be taken into account at the design stage and the design film thickness adjusted accordingly.

An important difference between pad-type thrust bearings and journal bearings is the behaviour of the oil flow through and out of the bearing. In pressure-fed journal bearings, fresh cool oil is pumped into the grooves incorporated into the bearing surface, and most of it – apart from the groove end leakage – is carried by the rotating journal into the loaded area. In bath-lubricated pad thrust bearings, however, the hot oil film emerging from the trailing edge of one pad tends to be dragged by the rotating disk into the entry gap of the next pad, thus giving a hot oil carryover effect.[18] In some cases this can raise the effective film temperature to a value significantly higher than the oil drain temperature, considering that most of the oil flowing between the pads to drain plays little or no part in film cooling. Correct assessment of the oil film temperature is therefore very important in the calculations.

In a typical multi-pad bearing, however, most of the generated film heat is transferred by convection and conduction to the rotating disk, which usually acts as a very good heat sink.[19] Nevertheless, film temperatures can be quite high in some cases. For such applications the pad film temperature can be reduced significantly by adopting directed lubrication from spray nozzles positioned between each pad, which direct discrete jets of oil onto the rotating disk surface. The jets tend to displace the adhering hot film and allow cool oil to enter the pad surface.

The heat generated at each pad by oil film friction only is:

$$H_{pad} = 13.8.L.(N.d_m)^{1.5}.(\eta.b.p)^{0.5} \text{ (Watts)}$$

and the total bearing heat from oil film friction only is:

$$H_{film} = z.H_{pad}$$

Heat is also generated in conventional oil bath bearings due to churning of the oil by the rotating disk, and this effect is also eliminated by using directed lubrication. The heat generated by oil churning can be the significant component, particularly in large, high-speed units.

Modern methods for the design of multi-pad thrust bearings are available.[20,21] These take account of all the relevant factors needed to determine operating performance.

9.5 Lubrication of industrial gears

In order to ensure the effective lubrication of industrial gears it is first necessary to have a basic knowledge of the tribological implications in their design, i.e. to study the conditions which can arise when interacting surfaces are in relative motion. All types of gear teeth transfer power and motion through relatively small areas of contact in the form of very narrow bands or ellipses which are known as the 'lines of contact'. Since these contact areas are so small they are subjected to very high stresses and the gear teeth therefore have to be made from strong, hard materials such as steel and the harder bronzes.

Figure 9.24 shows a pair of contacting involute gears with their respective 'pitch circles' and the 'line-of-action' which is determined by the pressure angle selected during design. Contact of the gear teeth begins as the trailing edge or the top of the driven gear tooth crosses the line-of-action and engages with the root of the leading face of the pinion gear tooth. Contact continues until the leading edge of the tip of the pinion tooth crosses the line-of-action. Lines drawn on the gear tooth edge for equal angular displacement as the contacting faces cross the line-of-action show that sliding takes place during tooth contact. It can also be seen that the sliding velocity is at a maximum at the start of contact but decreases continuously as the line of contact approaches the pitch circle. At this point sliding becomes zero and with continued movement the direction of sliding reverses and accelerates until the teeth disengage.

During contact it will be noted that on the pinion, sliding is always away from the pitch line, whereas on the driven gear, sliding is always toward the pitch line. Also, tooth contact only occurs on the line-of-action.

Pure rolling motion, which only occurs momentarily at the pitch point, does not promote rapid wear of the surfaces, but sliding, which occurs over the remainder of the contacting surfaces, does. Also, the faster the rate of sliding, the more severe the rate of wear and consequently the more difficult the conditions of lubrication become. Since sliding speed increases with increased pitch-line speed of the gears and the distance of the point of contact from the pitch point, high-speed gears are made with a large number of small teeth to reduce their sliding speed.

When studying tooth action, consideration must also be given to the important differences in gear tooth contact between spur and helical gears and between straight-bevel and spiral-bevel gears. In spur and straight-bevel gears there are alternately one pair and then two pairs of teeth in contact. Any wear that occurs during single-pair contact will not result in relief by transferring the load to another pair of teeth, so that, once started, wear will continue. In contrast, in helical and spiral-bevel gears there are always at least two pairs of teeth in contact so that should wear occur between one pair of teeth, more load is transferred to the other teeth in contact, thus reducing the load on the teeth subjected to wear. For this reason helical and spiral bevel gears are easier to lubricate than spur or straight-bevel gears. Figures 9.25 and 9.26 show the lines of tooth contact for spur and helical gears.

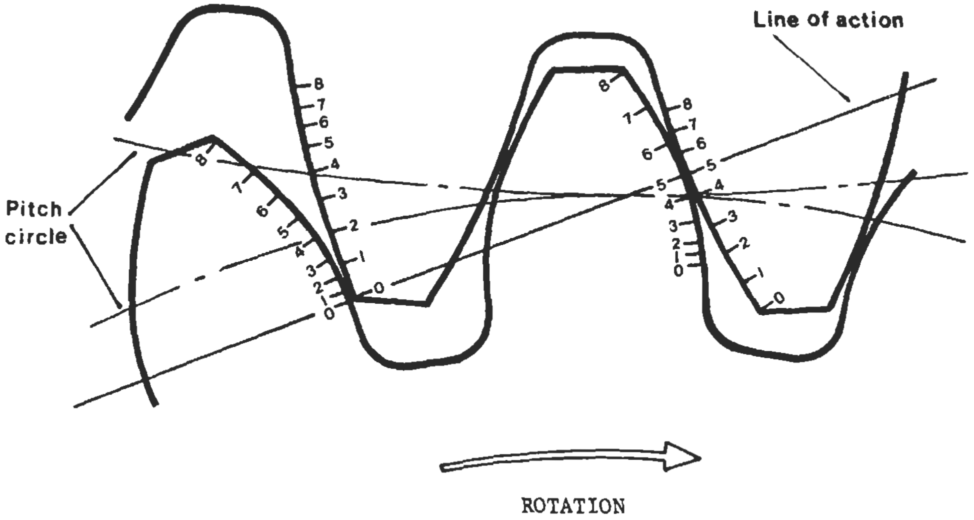

Figure 9.24 Relative sliding in tooth contact area

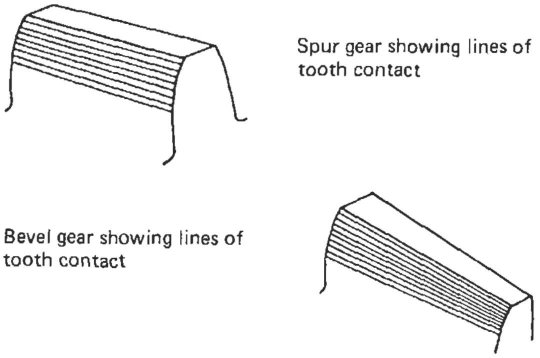

Spur gear showing lines of tooth contact

Bevel gear showing lines of tooth contact

Figure 9.25 Lines of contact – spur and bevel gear

As shown in Table 9.10, the various types of gears may be divided into groups whose conditions of tooth operation, i.e. sliding and rolling, are similar.

9.5.1 Methods of lubrication

There are three principal methods of applying gear lubricants: by spraying, by bath and by hand. With enclosed spur, helical and bevel gear units, at pitch line speeds above about 12.5 m/s, the oil is forced by a pump through special nozzles to spray onto the gear teeth at a pressure of about 0.7–6 bar, depending on the viscosity of the oil and the speed of the gear. Usually special nozzles with deflector surfaces are adopted so that the oil is projected in a fan-shaped spray over the gear teeth. These nozzles are generally pitched at intervals of 75–125 mm across the width of the gear. They are sensitive to

blocking by dirt, paint flakes, etc., and must be regularly inspected and cleaned. To minimize blocking, the spray holes are generally not less than approximately 2.5 mm diameter, or if the orifice is a slit, a width of not less than 0.75 mm. To obtain a suitable spray from such a hole, a minimum flow rate of about 0.05 litres per second is necessary. Large and high-speed gears may need a greater rate of oil flow than this minimum and approximately 3×10^{-4} litres per second per kW transmitted may be required for each gear train, or otherwise 1.5×10^{-4} litres per second per kW for both gears and bearings.

The oil is usually directed onto the teeth as they go into mesh, but sometimes for high-speed gears the oil is sprayed onto the teeth as they come out of mesh in order to reduce power loss due to excessive churning in the gear mesh while supplying sufficient oil to the gears to keep them cool. The round jet of oil delivered from the hole in the nozzle is often directed straight onto the gear teeth, where it spreads over the surface. It is possible with high-speed gears that the peripheral speed is greater than the speed of the oil leaving the nozzle, with the result that the tips of the teeth overtake the jet of oil. At very high speeds this has been known to cause tip erosion of the teeth. This can be avoided by directing the oil onto a deflecting surface attached to the nozzle so that the oil jet is spread out into a fan-shaped and less concentrated spray. Worm gears having a surface speed of the worm greater than about 10 m/s are best lubricated by two solid high-pressure jets as distinct from sprays, at right angles, and parallel, to the worm axis.

For slow and medium-speed enclosed gear units below about 12.5 m/s pitch line speed for spur, helical and bevel units and below about 10 m/s worm surface speed for worm gears, bath lubrication is commonly adopted. At such speeds, provided the extent of dip is not excessive, the churning loss in the bath amounts to only about 0.75% of power transmitted per train compared with a total loss of about 1.5%. The dipping wheel need not be immersed in the oil bath to more than three times the height of the tooth and this should not be exceeded by very much in high-speed units if high temperature rise and power loss is to be avoided. Slow-speed units may have a greater depth of immersion without these disadvantages and therefore can tolerate greater variations in oil level.

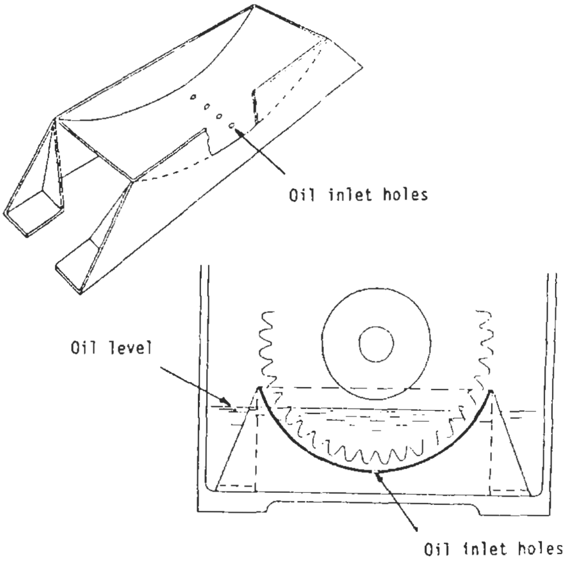

Figure 9.27 Typical trough or shroud to provide restricted dip lubrication

For some applications of helical gears it is feasible to use bath lubrication at speeds in excess of 12.5 m/s by partially enclosing the lower part of the gear in a trough or shroud, as shown in Figure 9.27. Oil is fed from the bath to the gear through a row of holes in the bottom of the casing for lubrication and cooling while minimizing churning.

Where sealing is difficult, low-power gear units are sometimes lubricated with grease. Grease, however, has a number of disadvantages when compared with oil. If the grease is too stiff, it will 'channel', i.e. the gears will cut a channel through it which will not be refilled quickly enough to prevent lubricant starvation and gear failure. Tests have shown that the optimum consistency of the grease to avoid this happening is

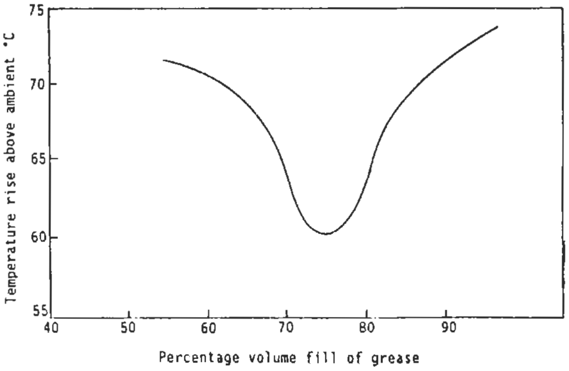

Figure 9.28 Variation of temperature rise with the amount of lubricant used

approximately an NLGI grade 00 or 0. Even greases of this soft consistency will still have a tendency to channel and therefore the grease fill quantity is important. The optimum quantity should be sufficient to ensure adequate lubrication but not too much to increase churning losses and temperature rise. This amount will depend on the design of the gearbox and the orientation in which it is run and can only be determined by carrying out heat-rise tests. A typical graph showing variation of temperature rise with the amount of grease used is given in Figure 9.28.

An important function of a gear lubricant is to carry away the heat generated in the contact region. Greases have poor heat-transmitting properties and are therefore not very efficient in this respect. They also have the disadvantage of retaining abrasive wear debris in the vicinity of the gear teeth. The development of greases based on polyglycol fluids has overcome many of these problems and are now used in small worm and helical gearboxes where a 'lubricated for life' system is required.

Below pitch line speeds of about 2.5 m/s gears are normally not enclosed and are referred to as 'open'. Very slow-speed gear units may be lubricated from small open baths or 'slush pans' by heavy oils or by the more liquid of the bitumen compounds. Otherwise, up to 2.5 m/s, the stiffer bitumen compounds either heated or cut back with solvent may be applied intermittently by hand at intervals of up to about two weeks. It is generally an advantage to apply the lubricant by hand at the end of a working shift when the gears are hot and the lubricant has time in which to set to a tough, durable film.

Intermittent mechanical spray systems are now frequently used, particularly for the higher-speed or less accessible open gears, and are capable of spraying both heavy oils and residual compounds.

9.5.2 Types of gear oils

The principal function of a gear lubricant is to provide a constant film which will effectively reduce the metallic contact between the opposing surfaces, thereby reducing the amount of wear. Normalized and through-hardened gears are satisfactorily lubricated by straight mineral oils. These oils are petroleum products which do not contain additives to enhance their properties, and their ability to keep surfaces separated and so reduce friction and wear depends largely on their viscosity.

In certain applications although straight mineral oils will give adequate wear protection, operating conditions can be such that additional protection is necessary against corrosion of the metal and oxidation of the oil. In these applications turbine-type oils should be used which are inhibited against rust and oxidation. These oils are often referred to as R&O type oils.

Probably the most commonly used lubricants in industrial gear units are those containing anti-wear or extreme-pressure additives. These oils are necessary where operating conditions are severe or where adequate protection cannot be given by straight mineral oils. With these oils protection is achieved by incorporating so-called boundary lubricants into the oil to produce, by physical absorption or chemical reaction, a film which will be soft and easily sheared but difficult to penetrate or remove from the surfaces.

One such boundary lubricant is long-chain fatty acids, a typical example of which is stearic acid. This forms a closely packed film either by absorption of its acid end groups onto the surface oxide or by reaction with the oxide to form a soap of the gear metal. This type of film is illustrated schematically in Figure 9.29. Unfortunately, the life of all metal soaps is limited by their melting point or desorption temperature, above which the films become ineffective and provide little more protection than a straight mineral oil. For long-chain fatty acids the desorption temperature would be about 100°C and within this limit there will be a very low level of friction. In gear lubrication, this type of boundary additive is used mainly in worm gear lubricants, where the bronze wheel forms a chemically reactive partner and where low friction is especially desirable.

These long-chain fatty acids are not suitable, however, for the more severe conditions which are encountered in some steel–steel gears where loads and sliding speeds are high. For these applications additives are required which form films with higher melting points and have greater adherence to the metal surface. These additives are generally known as 'Extreme Pressure' or EP additives, although a more appropriate description would be 'Extreme Temperature'. These types of

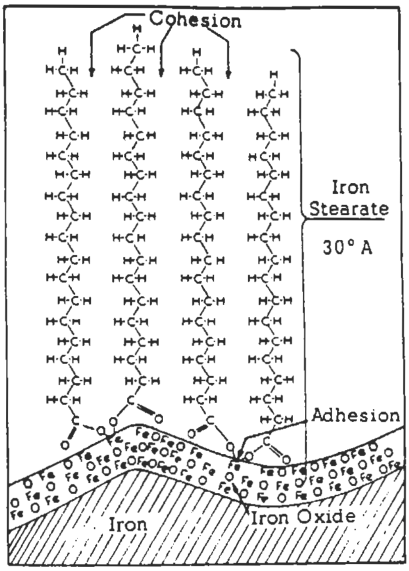

Figure 9.29 Schematic diagram representing chemisorption of stearic acid on an iron surface to form a monolayer of iron stearate with an essentially organic outer surface

additives are usually the more chemically reactive oil-soluble materials containing one or more of the elements chlorine, phosphorus, sulphur, lead and zinc.

The detailed mechanism involved with these additives in practice is seldom fully understood, but it would appear that under mild operating conditions they produce a mainly hydrocarbon film which is firmly attached to the metal surface by their reactive groups. Under more severe conditions, however, these additives decompose and react with the metal surfaces to produce a film which is softer, less brittle, more adherent and therefore more effective than the oxide layer. The films found are largely inorganic (for example, iron phosphates, chlorides and sulphides). This type of film is illustrated schematically in Figure 9.30. Phosphorus-containing additives are generally effective under relatively mild conditions, whereas additives containing chlorine and especially those containing sulphur are required for the more severe operating conditions. Since these additives are not effective until the temperature of reaction is reached, a combination of additives such as sulphur and phosphorus is used to give good anti-wear protection for mild conditions and protection against scuffing when operating under more severe conditions.

To be effective the additive should absorb onto the metal surface and highly polar substances are therefore advantageous. To achieve this economically, the oil should not contain components or other additives which are more polar than the EP additive, since this may give insufficient EP activity or require the EP additive to be used at a higher concentration than would otherwise be necessary.

These additives are soluble in the base oil but additives which are a dispersion in the base oil are also used. In the past, the large particle sizes of these types of additives have given problems of storage instability. However, newly developed additives such as the finely dispersed borate materials have shown very good EP and anti-wear performance combined with very good thermal and oxidation stability. Molybdenum disulfide dispersed in colloidal form in mineral oil has also been shown to give improved efficiency in worm gear speed reducers, but non-colloidal molybdenum disulfide did not give the same improvement. Results obtained with the FZG Gear Tester have shown that in the presence of certain EP additives, the effectiveness of molybdenum disulfide can be inhibited.

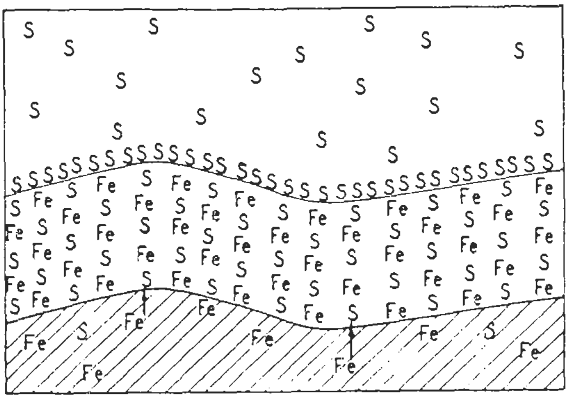

Figure 9.30 Schematic diagram representing inorganic film of iron sulphide on iron formed by sulphur in the oil

9.5.2.1 *Synthetic lubricants*

Increasing interest is developing in the use of synthetic and semi-synthetic lubricants for gears, particularly where operating conditions are severe or where temperatures are extreme. Where operating temperatures are constantly above 100°C the life of mineral oil-based lubricants is limited due to the increased rate of oxidation and the formation of deposits, which may cause operating problems. At very low operating temperatures the increase in the viscosity of mineral oil-based lubricants may impair its flow properties, resulting in lubricant starvation or channelling. Under these extreme temperatures the viscometric properties of some synthetic lubricants have a distinct advantage. Figure 9.31 gives an indication of the comparative temperature limits for mineral oils and some synthetic fluids. The actual temperature limits will depend on a number of factors, such as viscosity, composition, operating conditions and system design.

Not all the synthetic fluids give improved lubrication performance in gears when compared with mineral oil-based lubricants. An indication of their comparative performance in respect of anti-wear and friction is given in Table 9.11. The use of polyglycols, particularly in worm gears, has many advantages. Its very low frictional properties with the material combination of steel and phosphor-bronze results in lower operating temperatures.

Figure 9.32 shows that considerably higher critical torques at the tooth/flanks can be achieved with the use of polyglycols. The figure also illustrates their potential for energy saving. When considering the use of synthetic fluids to replace mineral oil-based lubricants, compatibility with paints and sealants and miscibility with mineral oil should not be overlooked. Polyalphaolefins have an advantage in this respect since they are miscible in any proportion with mineral oils.

9.5.3 Heat dissipation

The importance of the surface temperature of gear teeth, as discussed above, underlines the significance of the cooling function of the oil. The quantity of oil necessary to dissipate the heat generated by a pair of gears is usually greater than the quantity required for adequate lubrication.

For splash-lubricated gears the level of oil necessary is determined in the gear design stage and is specified by the gear manufacturer. It is important, however, that this oil level should not be exceeded, since this could increase the churning losses in the oil and thereby the temperature of the gears.

Note:
M 220 = mineral oil gear lubricant without additives; MEP 220 = EP additive containing gear oil ISO-viscosity grade 220; PG 150 = polyglycol ISO-viscosity grade 150; PG 220 = polyglycol ISO-viscosity grade 220.

Figure 9.32

For spray-lubricated spur, helical and bevel gears the amount of oil required to dissipate the heat generated by the contacting teeth can be calculated using the following formula:

$$Q = \frac{0.588\,(1 - E)k}{t_2 - t_1}$$

where

Q = quantity of oil (litres/second),
E = gear tooth efficiency,
t_1 = temperature of inlet oil (°C),
t_2 = temperature of outlet oil (°C), and
k = kilowatts transmitted.

In addition to the heat generated by the gears themselves, account must also be taken of that generated by the bearings.

High-speed gears mounted on rolling element bearings are less exacting in their lubrication demands than those mounted on plain bearings, and consequently higher viscosity oils can be used. Also, since very little frictional heat is generated in rolling element bearings they required no additional quantity of oil. However, in plain bearings which are normally used in large gear sets considerable heat can be generated and additional oil to dissipate this heat is required. A guide to the quantity of oil required may be derived from the Petroff equation:

$$Qb = \frac{3.3\, ln^2 d^3 \eta}{(t_2 - t_1)\, c \times 10^5} \text{litres/second/bearing}$$

where

l = length of bearing (m),
d = diameter of journal (m),
c = clearance (m),
n = journal speed (Hz),
η = oil viscosity (cS at inlet temperature),
t_1 = temperature of inlet oil (°C), and
t_2 = temperature of outlet oil (°C).

To allow for adequate heat disposal and to give an acceptable life for the oil, the quantity in the system should be equal to a minimum of 3 minutes' supply.

The quantity of oil required to dissipate the heat generated in forced lubricated worm gears can be calculated from the following:

$Q = 5C$ litres/second

where C = centre distance of gears (m). Again, the quantity of the oil in the system should not be less than 3 minutes' supply.

9.5.4 Selection of gear lubricants

An oil selected for the lubrication of a gear set should fulfil certain basic requirements which, although simple, are often overlooked. These basic requirements can be summarized as follows:

- To minimize friction and reduce wear between sliding surfaces by the provision of a thin film of lubricant which will prevent metal-to-metal contact between the elements of bearings and the faces of gear teeth at the point of contact;
- To protect the gear set against rust and corrosion;
- To transfer the heat generated in enclosed gears to the gear case walls or to other cooling surfaces.

The ability of the lubricant to satisfy these together with any other special requirements depends on its fundamental characteristics, some of which may be inherent properties of the straight lubricants while others stem from the use of suitable additives. The most important of these properties are reviewed below.

9.5.4.1 Viscosity

Undoubtedly, the most important single property of any gear lubricant is its viscosity or, to be more accurate, its viscosity/temperature/pressure relationship. Irrespective of the types of additive that may be used, the efficient lubrication of a gear train under hydrodynamic conditions is dependent on viscosity.

One of the major considerations in the lubrication of gears is to prevent scuffing of the gear teeth, and it is possible, given sufficient data, to calculate approximately the minimum oil viscosity required to prevent this type of damage. One method is the use of the following equation:

$\nu = 352\,[F(R+1)/(bd\,RV)]^{0.415}$

where

ν = viscosity at 38°C (cSt),
F = tooth force (Newtons),
b = gear face width (mm),
d = pinion pitch diameter (mm)
R = gear ratio, and
V = pitch velocity (m/s)

Elasto-hydrodynamic and flash temperature theory can be applied in certain cases but the calculations are somewhat involved and are often outweighed by practical considerations. Use is therefore often made of the various empirical methods and viscosity recommendations supplied by gear manufacturers. For situations where a viscosity recommendation is not available, use can be made of alternative methods such as the Deutsche Industrie Normen (DIN) system, DIN 51 509 or the American Gear Manufacturers Association, AGMA standard 251.02 for open gears and AGMA standard 250.04 for enclosed gears.

It is common knowledge that, as the viscosity increases, the thicker will be the film of oil that it provides between the mating surfaces, and consequently the greater the protection against scuffing. There are also indications that an increase in viscosity of the oil is accompanied by greater protection against other forms of tooth surface failures such as deformation, peening and, possibly, pitting (see Figure 9.33).

It has been recognized for many years that pitting fatigue life increases with the viscosity of the lubricating oil, but it was assumed that viscosity was important only in determining whether the oil could penetrate and propagate cracks in the manner described above. Recent developments in elasto-hydrodynamic lubrication have shown, however, that viscosity is important in other respects. In contrast with earlier beliefs, it is now accepted that full oil films can exist in heavily loaded contacts and that viscosity is the most important property of the oil in determining the thickness of the films. In any given contact, film thickness is approximately proportionate to (oil viscosity × rolling speed of the surfaces)$^{0.7}$. The significance of this in relation to pitting is that an increase in film thickness might be expected to reduce asperity contact and so raise the fatigue limit and extend fatigue life in the same way as a reduction in surface roughness. Experiments conducted with disk machines at a constant stress greater than the fatigue limit of the materials used show that a very close correlation between tendency to pitting, and the ratio, D, can be derived as follows:

$$D = \frac{\text{Sum of initial peak to valley roughness}}{\text{Theoretical elasto-hydrodynamic film thickness}}$$

The practical implication of these observations is that if a machine is operated at contact stresses greater than the fatigue limit of the softer surface, the onset of pitting may be delayed by using a higher viscosity oil. However, since the loaded

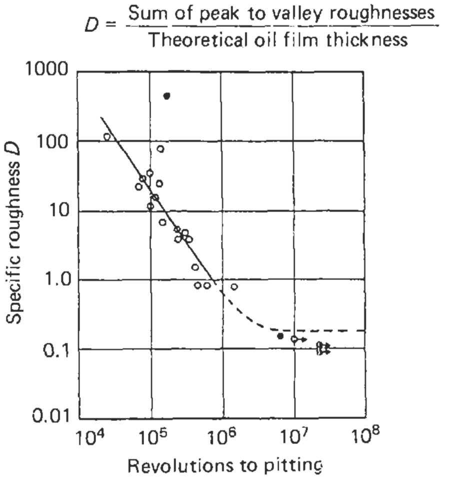

Figure 9.33 Influence of specific surface roughness D on fatigue pitting

surfaces will then tend to run hotter than with a less viscous oil, the potential benefit of using an oil of higher viscosity will not be fully realized.

From these considerations it would appear that the higher the viscosity of the oil, the more effective it should be as a gear lubricant. Unfortunately, this is not so, and to understand why, the disadvantages of using such an oil must be considered. The main disadvantage is that an increase in oil viscosity gives rise to increased power losses and a higher temperature rise of the gear unit and of the oil. At very high temperatures, bearings may fail and the oil may rapidly oxidize and thicken, thereby reducing the life of the oil. In addition, lubrication starvation may occur through channelling or by blockage of oil holes, oil galleries, etc. by insoluble oxidation products.

An extremely important factor in the lubrication of gears is that the viscosity of all gear lubricants is markedly affected by changes in temperature, the viscosity decreasing sharply with increasing temperature and vice versa. As a result, a lubricant may become too thin to give satisfactory service at high temperatures or so thick in cold weather that it may be difficult to start a gear set. In practice, some lubricants are more resistant than others to changes in viscosity with temperature, as shown in Figure 9.34, which compares the effect of temperature on the viscosity of a typically highly refined mineral oil and on a synthetic oil. This resistance to change to viscosity with temperature can be conveniently indicated by the viscosity index, the higher viscosity index number signifying the greater resistance to change. All oils have a natural viscosity index which can be improved by incorporating an additive suitable for this purpose.

From these considerations it is obvious that in cases where gears are required to operate over a wide temperature range it is essential to use lubricants with a high viscosity index to ensure satisfactory performance and the avoidance of difficulties arising from channelling, excessive pressure drops in circulating systems and excessive starting torque.

Another point in connection with viscosity is that it is now becoming increasingly important for the life of an oil charge to be as long as possible, because of not only the cost of the lubricant but also the down-time involved in carrying out oil changes. To a large extent, the selection of the correct viscosity of the oil for a gear unit can be a strong contributory factor in determining the life of the oil. This is because low-viscosity oils are able to shed contaminants more quickly or easily than high-viscosity oils. The usual contaminants encountered in enclosed gear units are dust, scale, abrasive metal particles and water. With solid contaminants, settling is quicker in thinner oils, which assists in reducing the chances of abrasive wear of teeth and bearings. Furthermore, filtration is easier with thin oils as a fine-mesh can be used.

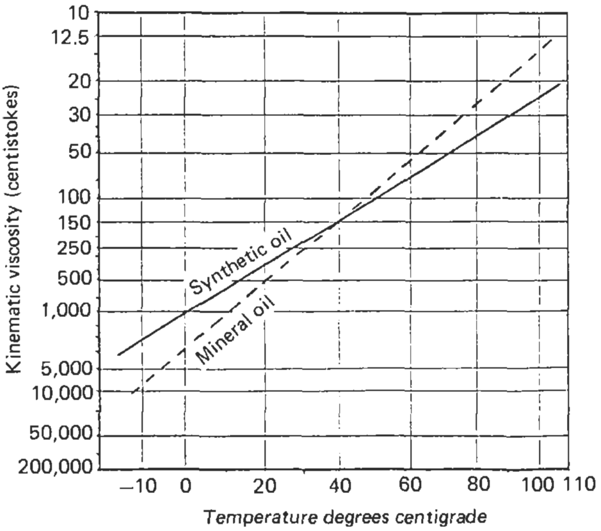

Figure 9.34 Viscosity as a function of temperature for a typical highly refined straight mineral oil and a typical synthetic gear oil

It should also be noted that, as a general rule, low-viscosity oils have less tendency to foam than high-viscosity oils, the rate of release of air entrained by the oil being inversely proportional to the viscosity. At the same time, the demulsibility of an oil, i.e. its ability to separate from water, is better with low-viscosity oils than with high-viscosity oils.

It can be seen, therefore, that the use of an oil of correct viscosity is very important and that it can, in certain gear units, be critical. For this reason, much time and effort is still being spent on investigating means of calculating the correct viscosity for any gear unit.

9.5.4.2 Anti-foaming properties

With medium- and high-speed gears some foaming of the oil is inevitable, and this condition is particularly aggravated in circulating oil systems. Although, as already mentioned, low-viscosity oils can normally release entrained air rapidly, occasions can arise when the rate of release is insufficient. In such cases, oils containing anti-foaming additives may be used.

9.5.4.3 Anti-corrosion properties

The prevention of rust and corrosion in the gear unit must always be considered and it may, in fact, be the determining factor in the choice of an oil. Gears operating in a moist or wet atmosphere are easily recognizable and can be catered for by the selection of a suitable lubricant, but moisture can also be present in a gearbox when operating in apparently dry conditions. This moisture is due to condensation in the box as a result of cooling of the unit when not in use, and it can be particularly troublesome when the gears are inoperative for long periods.

If the oil is to prevent corrosion it must be able to deny the access of moisture to the metal surfaces. In other words, it must have good metal-wetting properties. New straight mineral oils are limited in this respect but their metal-wetting properties generally improve soon after use. This is due to the small amounts of products caused by early deterioration, including the polar compounds which promote metal-wetting. Where a high degree of resistance to rust and corrosion is required, it is common practice to add to the oil special rust inhibitors, the molecules of which are strongly polar and have the property of attaching themselves firmly to the metal, thereby promoting the displacement of moisture at the surface.

9.5.4.4 Oxidation resistance

Oils exposed to high temperatures and contact with air will inevitably oxidize the rate and extent of oxidation, depending on the chemical composition of the oil and the conditions of exposure, i.e. the higher the temperature and the greater the exposure to air, the more rapid will be the reaction. Contact with certain metals and metallic compounds, particularly copper and oxides of iron, will also speed up the reaction.

Oxidation results in a formation of oil-soluble organic acids and insoluble compounds which appear as lacquer, sludge and carbonaceous deposits, with a consequent reduction in the life of the lubricant. In some gear systems, the operating conditions may increase the rate of oxidation appreciably, in which case it is necessary to use oils containing oxidation inhibitors.

In gears lubricated by oil spray, the mixture of air and oil passing through the mesh of high-speed gears can be considerably heated by compression. Temperatures as high as 160°C have been measured in gears running at 150 m/s, although tooth temperatures were only around 110°C.

9.5.4.5 *Anti-wear properties*

Since the highest viscosity oil that can be used is limited by the considerations previously reviewed, the margin of safety against wear with straight mineral oils is less in some gears than in others. Straight mineral oils may therefore prove inadequate under certain operating conditions (for example, during the running-in of some gears or in subsequent service with heavily loaded gears). To meet these requirements, oils containing anti-wear additives are used. The action of these additives has been discussed above.

9.5.4.6 *Extreme-pressure properties*

Under severe conditions of loading, anti-wear additives are ineffective and it is therefore necessary to utilize the more active substances designated extreme pressure (EP) additives. Depending on the degree of reactivity conferred, lubricants embodying these additives are known as mild extreme-pressure oils and full extreme-pressure oils, the latter being intended for very severe conditions. Extreme-pressure additives are stable at normal ambient temperatures but decompose at the high local temperatures which are likely to occur at the point of contact between heavily loaded gear teeth. The additives then react with the metal to produce compounds which form a film on the gear teeth which is more readily sheared, thereby preventing damage to the metal.

9.5.5 Service life of gear lubricants

In terms of the physical and chemical properties of gear lubricants, it can be seen that, apart from giving the desired performance characteristics, the careful selection of viscosity and appropriate additives can materially increase their service life. There are, however, other factors which can have a marked effect on service life and which are mainly related to the conditions to which the lubricant is subjected in use. Of these factors, the most important are oxidation and contamination. It has been pointed out that the rate of oxidation is governed by the operating temperature and the extent of aeration of the oil. Systems should therefore be designed to reduce the influence of these factors to a minimum.

For example, insofar as an operating temperature is concerned, it should be noted that some systems, particularly large gear sets in steel works, utilize heavy gear oils which must be heated to facilitate pumping. In some systems it is important that the heaters used for this purpose are carefully selected to avoid the possibility of local overheating and cracking of the oil. The greatest danger arises when the heaters are functioning but the oil is not circulating, in which case the rate of flow of the oil over the heated surfaces will be low, as it will depend on natural convection. To combat the risk of overheating, the ratings of heaters should therefore be in accordance with the type of oil concerned. Thus, with straight mineral oils a heater rating of approximately 520 kW m^{-2} of heater surface is usually recommended. Much lower ratings are necessary with additive-type oils, particularly the extreme-pressure leaded oils, and these ratings can be as low as 160 kW m^{-2} with the heaviest grades.

A major requirement in regard to excessive aeration of the oil is to maintain the ingress of air into the system at a minimum. Probably the most common cause of turbulence in an oil tank is unsuitable design of oil-return pipes. These should be carried to a point well below the surface of the oil to eliminate the possibility of the returning oil splashing into the tank and creating excessive turbulence and entrainment of air. In addition, the tank should be designed to permit air bubbles to rise freely to the surface, and this can be accomplished by means of baffles which divide the tank into inlet and outlet sections and rise vertically from the bottom of the tank to a point approximately one-third of the depth of the oil below the surface.

Entrainment of air will also be reduced by locating the suction connection of the tank well below the surface of the oil and as far as possible from the return pipe. However, to minimize contamination, care must be taken not to locate the suction connection so low in the tank that water and other impurities can be collected from the tank bottom. It is also advisable to fit a drain cock at the lowest point in the tank to enable impurities to be drained off at regular intervals.

The service life of an oil can also be affected by the presence of certain materials in the system. For instance, although copper is widely used owing to its strong catalytic oxidation effect on the oil it is preferable that some alternative material be used. Also, components with galvanized and other zinc-coated surfaces should not be allowed to come into contact with the oil, as the zinc may react with the additives it contains, particularly those present in many of the extreme-pressure oils.

9.6 Rolling element bearings

9.6.1 Introduction

The use of rolling elements, balls or some form of cylinder to separate the two moving components within a mechanical system has been universally accepted by design engineers since the turn of the twentieth century. The development of superior bearing steels over the past 40 years, constant improvement in manufacturing techniques and the detailed development of many different bearing types and variants has resulted in the universal availability of standard bearing ranges of outstanding performance at relatively low cost.

In terms of their speed capability, rolling element bearings are ideally applied in the mid-ground of bearing usage between rubbing plain bearings and fluid film plain bearings, providing good load capacity for their projected area. They have excellent friction characteristics and very low system power consumption. The rolling contact is inherently low friction and the majority of assemblies are self-contained requiring no external oil circulation system.

Rolling element bearings, correctly applied, are zero-wear systems, hence high location accuracy of a shaft can be achieved and maintained over a long period of time. The great majority of rolling bearings throughout the world are metric sized; typically, bore sizes in 5 mm steps, i.e. 25 mm, 30 mm, 35 mm, etc. Inch-sized bearings are still available for replacement purposes, particularly deep-groove ball bearings and taper roller bearings, but their use for new equipment is not recommended. Figure 9.35 shows the terminology generally used. The cage is not universally fitted as some low-speed, high-load capability bearings are completely filled with rolling elements. This is known as a crowded assembly.

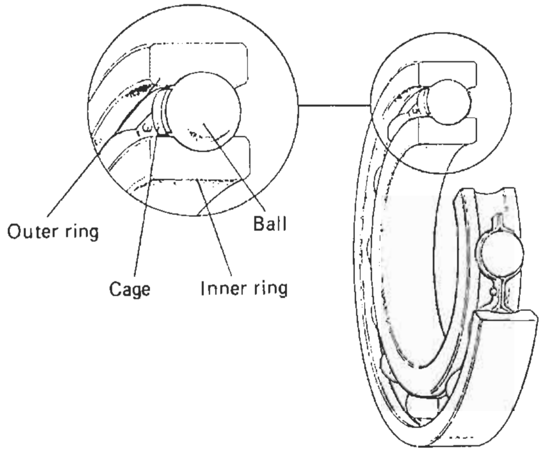

Figure 9.35 Bearing terminology

9.6.2 Types

All rolling element bearings can be divided into two main categories, i.e. those using balls as the rolling element and those using a roller of some form as the rolling element. Ball bearings basically have point contact between rolling elements and rings, implying a lower load capacity for the same sized bearing than roller bearings, which all have a line contact between rolling elements and rings.

9.6.2.1 Deep-groove ball bearings

Deep-groove ball bearings are the most common type and are particularly used in low to moderate load applications such as domestic appliance electric motors. Ball bearings are non-separable, usually with two-piece pressed steel cages riveted or welded together. They are designed for high radial load capability, and the high conformity between balls and raceway grooves enables them to carry considerable axial loads in either direction.

Ball bearings have been particularly developed in recent years for their inherent low noise characteristics, high accuracy and the availability of sealed and greased-for-life variants. Contacting seals and non-contacting shields are usually available (Figure 9.36), the choice depending upon the friction characteristics required and the severity of the external environment.

Ball bearings have a high maximum speed capability (e.g. a 608 bearing, 8 mm bore, has a nominal speed limit of 32 000 rpm using grease lubrication). Larger bearings have lower speed limits (e.g. a 6207 bearing, 35 mm bore, has a nominal speed limit of 9000 rpm for grease lubrication). In general, the bearing manufacturer's stated limiting speed values can be exceeded with careful attention to lubrication and heat extraction.

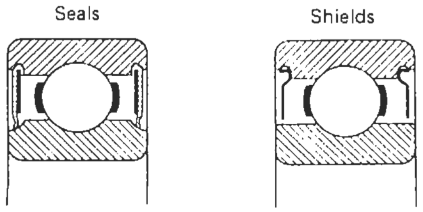

Figure 9.36 Contacting seals, non-contacting shields

9.6.2.2 Angular-contact ball bearings

Angular-contact ball bearings are similar to deep-groove ball bearings except that the line of action of the load acting through the contacts between balls and raceways forms an angle with the bearing axis. The bearings are therefore particularly suitable for carrying combined (axial and radial) loads. Several different contact angles are available but the 40° version is a generally available variant, giving excellent axial and moment load capability while retaining sufficient radial load capacity. Angular-contact bearings are often used in pairs mounted side by side; back-to-back or face-to-face to carry axial loads in both directions, or tandem to carry very high axial loads (see Figure 9.37). It is essential that the bearings are specified as suitable for pairing by the manufacturer to ensure correct sharing of the loads. A typical application of angular-contact bearings is in centrifugal pumps, where a back-to-back arrangement is often used to give moment stiffness to an overhung shaft load.

Cages are available in pressed steel, reinforced polyamide, solid brass, and, less commonly, pressed brass and solid steel. There is a general trend towards reinforced polyamide giving excellent dynamic features. A steady-state temperature limit of 110–120°C can be problematic in high-temperature environments. The pressed steel or solid brass cages may then be preferred.

Angular-contact ball bearings have excellent high-speed capability, low-contact angle variants for the aerospace industry being the fastest bearings currently in use.

9.6.2.3 Self-aligning ball bearings

These bearings have two rows of balls and a common sphered raceway in the outer ring (Figure 9.38). The latter feature gives the bearing its self-aligning property, permitting minor angular misalignment of the shaft relative to the housing – both static and dynamic. The bearings are particularly suitable for applications where misalignment can arise from errors in mounting, due to structural inaccuracy or from shaft deflection. The self-aligning ball bearing has the high-speed capability of all ball bearings but only a moderate load capability, which limits the possible uses of these bearings. They are, however, widely used in applications such as

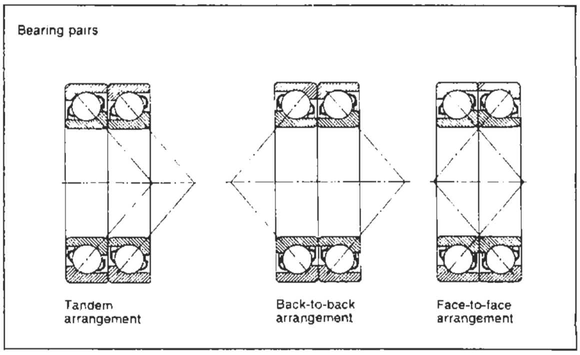

Figure 9.37 Angular-contact ball bearing paired arrangements

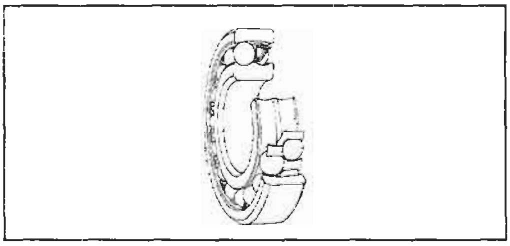

Figure 9.38 Self-aligning ball bearing

high-speed fan assemblies which are required to run with long relubrication intervals.

The self-aligning ball bearing is commonly available with cylindrical or tapered bores. The tapered bore variant can be fitted, using an adaptor sleeve, onto a parallel shaft with no machining or further fastening required. This feature is available on some other bearing types.

9.6.2.4 *Cylindrical roller bearings*

A line contact bearing is one in which the cylindrical rollers are axially guided between integral flanges on one bearing ring (Figure 9.39). The flanged ring with the roller and cage assembly forms a unit which can be removed from the other ring. This separable feature of the bearing design facilitates mounting, particularly where interference fits for both rings are necessary.

Cylindrical roller bearings have exceptionally low friction characteristics, allowing high-speed operation and a high radial load capability. The variant with thrust flanges only on one ring, type N or NU, is free to float axially and can be used in a shaft system to allow for axial displacement, perhaps due to temperature effects. These are known as non-locating bearings. Type NJ with one thrust flange on the inner ring as well as two flanges on the outer ring is used as a locating bearing and can be used to carry axial load. Type NUP, having a full set of flanges, may be used to locate the shaft in both directions or carry axial loading in both directions. Recent developments in cylindrical roller bearings have significantly increased the axial load capability but actual capacity values vary from one manufacturer to another. Reinforced polyamide cages are widely used. These suffer from the temperature limitation of 110–120°C indicated above but have otherwise been found to be excellent in service. Pressed steel cages would be the normal substitute for the polyamide in high-temperature environments. Full-complement cylindrical roller bearings have exceptionally high radial load capability and are particularly suitable for high-load, low-speed applications. The high friction inherent in the crowded assembly considerably reduces the maximum speed capability.

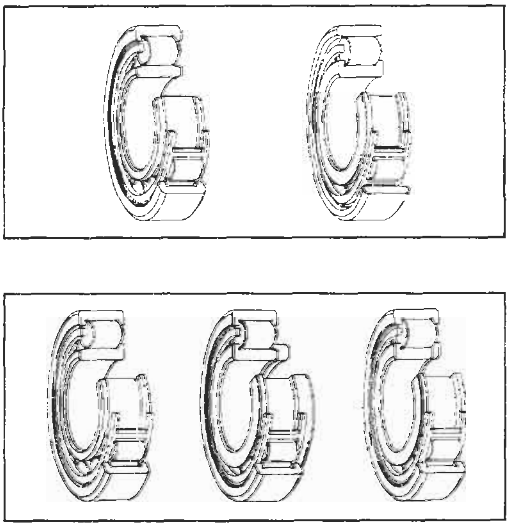

Figure 9.39 Cylindrical roller bearing flange variants

9.6.2.5 *Taper roller bearings*

The single-row taper roller bearing (Figure 9.40) has the ability to carry combinations of large radial and thrust loads or to carry thrust loads only. In the taper roller bearing the line of action of the resultant load forms an angle with the bearing axis. There is a difference in the inner and outer raceway contact angles, resulting in a force component which drives the tapered rollers against the guide flange. Because of the relatively large sliding friction generated at this flange, the bearing is not generally suitable for high-speed operations. The bearings are of separable design. The outer ring (cup) and the inner ring with roller and cage assembly (cone) may be mounted separately.

Single-row taper roller bearings can carry axial loads in one direction only. A radial load imposed on the bearing gives rise to an induced axial load which must be counteracted. The bearing is therefore generally adjusted against a second taper roller bearing. The setting of axial end float or preload of the bearing pair is critical to the success of the application. A taper bearing arrangement has high moment stiffness and is therefore frequently applied in areas, such as gearboxes, where correct alignment is important.

Double and four-row taper bearings are also available for specific, very high load applications. These usually have a built-in clearance requiring no adjustment.

9.6.2.6 *Spherical roller bearings*

Spherical roller bearings have two rows of rollers which run on a common sphered raceway in the outer ring (Figure 9.41). The two inner ring raceways are inclined at an angle to the bearing axis. The bearings are self-aligning and insensitive to minor misalignments of the shaft. In addition to radial loads, the bearing can also accommodate axial loads in both directions but cannot support moment loading. Spherical roller bearings are most commonly applied in heavy engineering applications where the misalignment capability, high load

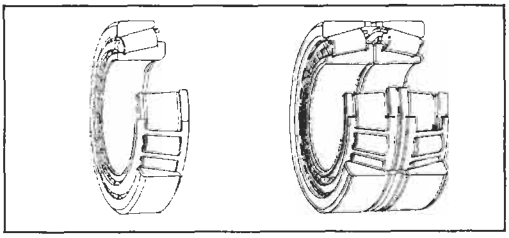

Figure 9.40 Taper roller bearing. Single row and paired

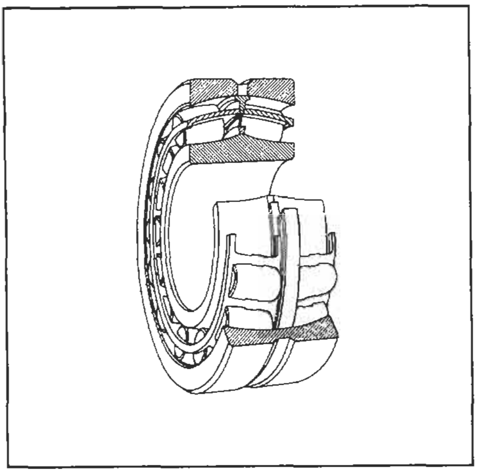

Figure 9.41 Spherical roller bearing

capacity and general robustness are most appreciated. They are manufactured in a very wide size range (e.g. 20 mm bore to 1180 mm as standard, or larger to special order from one major manufacturer).

9.6.2.7 Needle roller bearings

A needle roller bearing is a cylindrical roller bearing having rollers of considerably greater length than diameter. They are designed to fit into applications where radial space is at a premium. In some applications the needles run directly on a hardened shaft, saving the space of the inner ring.

Generally, needle roller bearings are less accurate than cylindrical roller bearings and have considerably higher friction. They are most suited to applications where the loading is light or intermittent.

9.6.2.8 Thrust bearings

The bearing types described in Sections 9.6.2.1 to 9.6.2.7 are basically designed to sustain radial loads, albeit with a considerable thrust capacity in many cases. In a situation where the thrust (axial) load is greater than the radial, then one of the thrust bearings is often preferable. Both ball and roller versions are available. Generally, the speed capability of the bearings is much reduced compared to their radial equivalents and the friction increased.

9.6.3 Selection

The selection of the correct bearing for a particular application requires consideration of several main parameters for the bearing type:

- Misalignment/stiffness requirements
- Speed requirement
- Available space and existing geometric constraints
- Mounting and dismounting considerations
- Friction consideration.

Table 9.12 gives an overall assessment of the main bearing types. Additionally, to decide on the precise bearing size and designation we must consider:

- The possible shaft and housing sizes
- The service life requirement
- The lubrication and, if applicable, relubrication intervals
- The sealing arrangements
- The axial location arrangements
- Static and shock/impact loading.

The general procedure would be to select the type of bearing most appropriate to the load directions in the application, bearing in mind that the simplest bearing type will usually be the easiest to adjust and be most economical. The bore size of the bearing is usually given by the shaft diameter. Consideration of the service life requirement will indicate the minimum basic dynamic load rating of a suitable bearing, and a nomogram (Figure 9.42) will be of use. Knowing the speed of the bearing and the required service life in hours (or millions of revolutions), the ratio C/P can be found from the chart, where C = basic dynamic load rating of the bearing (N) as defined in ISO 281 and P = equivalent dynamic load acting on the bearing (N).

Typical service life requirements for types of machines are given in Table 9.13. Knowing the working load, P, the minimum dynamic capacity, C, necessary to do the job can be easily determined. Inspection of the bearing tables from the manufacturers will indicate which bearing section will be appropriate.

Further consideration must then be given to manufactured clearance for a one-piece bearing, grease type and seal execution for self-contained bearings and other optional features to obtain the exact bearing designation. More information is given in subsequent sections.

9.6.4 Bearing life

Bearing life calculations carried out for design and selection purposes have been based upon a prediction of a rolling contact, subsurface initiated, spall or pit in the raceway. The method was first described by Lundberg and Palmgren (1952) and is specified in ISO 281.

The basic rating life of a rolling bearing is the life in millions of revolutions associated with 90% reliability of a bearing population, i.e. an L_{10} life is the life to failure of 10% of the population. The median life (L_{50}) is normally about five times the L_{10} life. The actual life of an individual bearing is therefore meaningless when used to describe bearing performance. For radial ball bearings $L_{10} = (C/P)^3$ and for radial roller bearings $L_{10} = (C/P)^{10/3}$. P is the radial load which will have the same effect upon the bearing as the actual radial and axial load conditions. It can be calculated from the radial and axial loads using X and Y factors:

$$P = XF_r + YF_a$$

where

P = equivalent dynamic bearing load (N),
F_r = actual radial bearing load (N),
F_a = actual axial bearing load (N),
X = radial load factor for the bearing, and
Y = axial load factor for the bearing.

Actual X and Y factors are given in bearing manufacturers' literature and vary from type to type.

Often the loads on the bearings must be calculated from gear loads, out of balance, etc. external to the bearing. Computer programs are available to assist in this process and can be applied to most situations.

The basic rating life is a conservative estimate of the service life of good-quality bearings used with good-quality, clean

Table 9.12 Selection guide for rolling bearings

Bearing type	*No. of rows*	*Load capability* *Radial*	*Axial*	*Allowable misalignment (degrees)*	*Comments*
Deep-groove ball bearing	1	Medium	Medium	0.01–0.05	General-purpose. Widely used, particularly smaller sizes.
Self-aligning ball bearing	2	Medium	Light	2.0–3.0	High speed with misalignment capability.
Angular-contact ball bearing	1	Medium	Medium-heavy	0	Frequently used in matched pairs for combined loads.
Cylindrical roller bearing					
Cage	1	Heavy	Light[a]	0.03	Heavy radial loads, high speed. Locating and non-locating variants.
Full-complement	1	Very heavy	Light	0.03	Very heavy radial loads at low speed.
Taper rolling bearing	1	Heavy	Medium-heavy	—	Mounted as opposing pair. Very stiff assembly.
Spherical roller bearing	2	Very heavy	Light-medium	1.5–3.0	High radial loads with misalignment, reasonable speed capability.
Needle roller bearing	1	Light-medium	Zero	0	Excellent radial load capability for section height.
Thrust ball bearing	1	Zero	Light-medium	0	Single direction thrust, no radial capability.
Spherical roller thrust bearing	1	Medium[b]	Heavy	1.5–3.0	Single direction thrust with some radial, takes misalignment.

[a] Suitable flanged designs variant required.

[b] Radial load must not exceed 55% of simultaneous axial load.

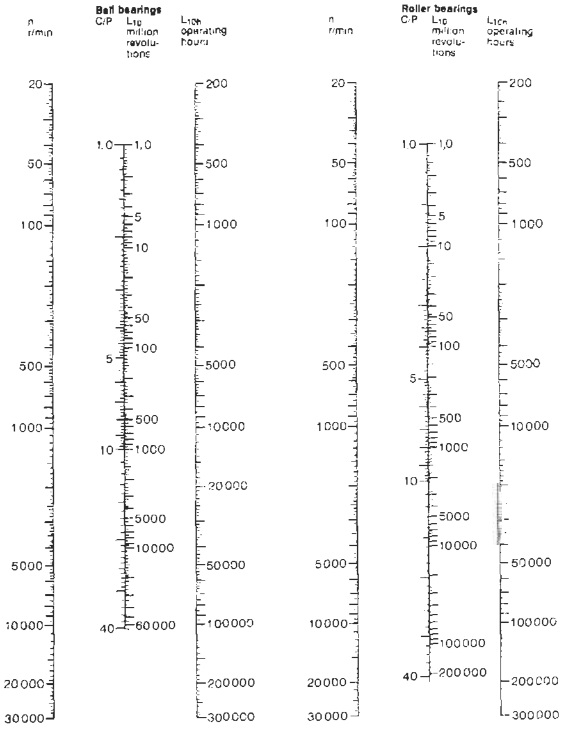

Figure 9.42 Life calculation chart

lubricant. Where the real bearing operating conditions can be more exactly described an accurate modified life equation may be used:

$$L_{na} = a_1 a_2 a_3 \left(\frac{C}{P}\right)^p$$

where

L_{na} = adjusted rating life (M revs),
a_1 = life adjustment factor for reliability (Table 9.14),
a_2 = life adjustment factor for material, and
a_3 = life adjustment factor for operating conditions.

The a_2 material factor is accepted as 1 for modern bearings accurately manufactured from clean chromium steel. Values higher than 1 may be appropriate for special steels or heat treatments. The a_3 factor is essentially determined by bearing lubrication quality provided that temperatures are not greater than 150°C. The lubricant provides an oil film which ideally keeps the rolling contact surfaces of the bearing apart. The fatigue life of the bearing lengthens as the separation of the surfaces increases. Under the conditions prevailing in an adequately sealed rolling bearing the a_3 factor is based on the viscosity ratio, κ. This is defined as the ratio of the actual viscosity of the lubricant in the bearing, V, to the viscosity V_1 required for adequate lubrication. Both viscosity values are at the operating temperature of the bearing, which is usually the highest temperature within the bearing system. The determination of V_1 is described in Section 9.6.7. Both factors a_2 and a_3 depend, to some extent, on the bearing manufacturer's processes – quality, steel cleanliness, heat treatment, raceway surface roughness specifications. Some manufacturers prefer to combine a_2 and a_3 and give an a_{23} factor, others use only the a_3 factor. A sample plot of the effect of the viscosity ratio κ on the life adjustment factor a_{23} is shown in Figure 9.43.

In practice, the calculated life is often exceeded by bearings running lightly loaded in clean conditions with good lubrication (e.g. a sealed and greased-for-life bearing in an electric motor). However, bearings running in contaminated conditions, such that solid or liquid contamination works its way into them, will frequently achieve a much inferior life which may be reduced to only 10% of the calculated value. Heavily loaded bearings running in clean conditions probably achieve their calculated life. A calculation method taking the effect of contamination into account and introducing a fatigue limit stress is now available and, provided sufficient detailed information of the application is available, will give a more exact service life prediction.

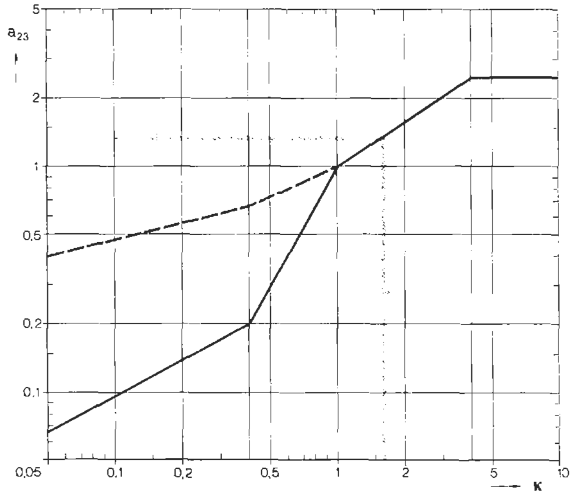

Figure 9.43 Life adjustment factor a_{23} derived from viscosity ratio κ

9.6.5 Bearing friction and speed limits

9.6.5.1 *Friction*

The friction within rolling element bearings is dependent upon several factors, of which the bearing type and specific design features, the load, the lubricant properties and the rotational speed are the most important. The coefficient of friction varies for different bearing types (see Table 9.15). As a guide, the frictional moment, M, can be calculated as

$$M = uP\ \frac{d}{2}\ \ (\mathrm{Nm})$$

where u = coefficient of friction for the bearing type, P = bearing load (N) and d = bearing bore diameter (m).

For more accurate calculations the total frictional moment must be considered as having two components: M_0 (which is load independent) and M_1 (which is load dependent):

$$M = M_0 + M_1$$

M_0 predominates in lightly loaded bearings at high speed as it results from the energy losses within the lubricant. M_1 predominates in slowly rotating bearings under load as it results from the elastic deformation and local slip in the

Table 9.15 Coefficient of friction

Bearing type	u
Deep-groove ball bearings	0.0015
Self-aligning ball bearings	0.0010
Angular-contact ball bearings	0.0020
Cylindrical roller bearings	
With cage	0.0011
Full-complement	0.0020
Spherical roller bearings	0.0018
Thrust ball bearings	0.0013
Spherical roller thrust bearings	0.0018

raceway contacts. While accurate calculation of M_0 and M_1 is possible, knowing the precise application conditions and the internal design of the bearing, it is best left to the bearing manufacturers.

It should be noted that rubbing seals can often produce more friction than the bearings they are protecting. This is particularly true of small deep-groove ball bearings where non-contacting shields may be the best low-friction seal solution, even though lubricant loss or contaminant ingress may then be problematical.

9.6.5.2 Speed limits

The limiting factor for the maximum speed of operation of ball and roller bearings is primarily the permissible operating temperature of the lubricant. The lubricant is heated by the bearing friction, hence higher speeds can generally be attained from a lower friction bearing or, indeed, if the heat can be removed by cooling, so that the lubricant does not reach its permissible temperature limit.

The limiting speeds for oil and grease lubrication are given in manufacturers' tables. These usually apply to a so-called 'normal' application situation and can be exceeded provided attention is given to cooling or use of a lubricant with a higher temperature limit. Only very rarely is the maximum speed for a bearing the result of a structural strength limitation.

9.6.6 Application

9.6.6.1 Axial location

The bearing arrangement of a rotating shaft usually requires at least two bearings to support and locate the shaft relative to the stationary part of the machine. One bearing should be locating, providing radial support and axial guidance in both directions, and the other non-locating, giving only radial support. Only bearings capable of taking both radial and axial loads are suitable for the location position. The non-locating bearing must permit axial displacement either by movement of the whole bearing in the housing or by movement within the bearing as for NU- or N-type cylindrical roller bearings. Examples of locating and non-locating arrangements are shown in Figure 9.44. The arrangement where each of the two bearings supports the shaft axially in one direction is known as cross-location and is used on short shafts with, principally, taper roller bearings to provide a very stiff arrangement with very precise location for a gear mesh.

The ring with the tightest fit (usually the inner one) must always be axially secured. The other ring on locating bearings must also be axially secured. On non-locating bearings the loose ring must be axially free to attain its own equilibrium position. Inner ring axial location is usually by means of a shoulder on the shaft on one side and a locknut and washer on the other. Lightly loaded bearings can be located using circlips and larger bearings using an end plate on the shaft end. Location onto a parallel shaft is carried out using an adaptor sleeve pulling into a taper bore bearing. This system does have an axial load limitation, dependent on the friction between shaft and sleeve.

Outer ring axial location is usually by means of the housing end cover but a threaded ring screwed into the housing bore or an external circlip can also be used.

9.6.6.2 Radial location

The inner and outer rings of rolling bearings must be correctly secured on the shaft or in the housing to prevent the 'progression' of the ring and the onset of fretting damage and

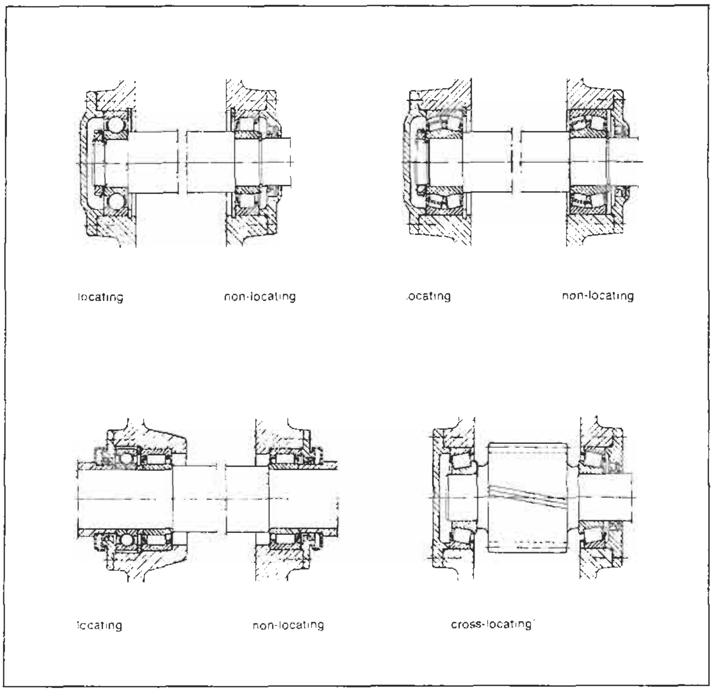

Figure 9.44 Examples of locating and non-locating bearing arrangements

possible overheating. Generally, a machine arrangement with a rotating shaft and steady radial (and axial) loads on the bearings will require an interference fit on the inner ring/shaft position and a clearance fit on the outer ring. If the direction of load is indeterminate or if heavy loads are involved, it is desirable that both rings have an interference fit. This requires the use of either separable bearings or non-separable bearings with tapered bores and adaptor sleeves to be used. Recommended fits for solid shafts and housings are given in Tables 9.16 and 9.17. Rolling bearings of the same size from different manufacturers made to ISO 281 standards will have common external dimensions and tolerances, and should therefore be interchangeable without the need to modify shaft or housing tolerances.

An interference fit on one or both of the bearing rings means that the manufactured internal clearance is reduced. Clearance must therefore be selected with the reduction in mind so that an internal clearance will remain after assembly. This clearance will in turn generally be further reduced during operation by thermal expansion of the bearing inner ring. The extent of expansions can be accurately predicted using computer programs.

A bearing fitted onto a hollow shaft will, in principle, require a heavier interference fit than that used if the shaft were solid to achieve the same contact pressure between inner ring and shaft. There is generally no correction necessary to the fit until the shaft wall thickness is less than 0.25 of the shaft outside diameter.

9.6.7 Lubrication

Effective lubrication is essential for rolling bearings to achieve their performance potential. Lubrication prevents the metal-to-metal contact between rolling elements, raceways and cage which would otherwise result in wear, friction and poor service life. The lubricating properties of an oil or grease deteriorate with time as a result of mechanical working and ageing, and will therefore require replenishment at some time.

Grease lubrication is generally used when rolling bearings operate under moderate conditions of load, speed and environmental temperature. Grease is particularly convenient to handle in service and is less likely to leak – all reasons for its use for the majority of bearings. Housings should not be fully packed with grease, and a 30–50% fill of the free volume is recommended. When selecting a grease, the consistency, temperature range and the rust-inhibiting factors must be considered. Consistency is quoted in terms of the National Lubricating Grease Institute (NLGI) scale. Metallic soap

thickened greases of consistency 1, 2 or 3 are those normally used for rolling bearings. The consistency should not change greatly with mechanical working or the elevated temperatures encountered in service. Vibrating applications will require mechanically stable greases. Calcium-, sodium- and lithium-based greases are commonly used with differing operating temperature ranges. The lithium-based greases are now becoming more common due to generally hotter environments. Synthetic greases are also becoming more used in special applications where their extreme temperature ranges are required.

In heavily loaded applications, and particularly at low speeds, greases containing EP additives will give superior bearing performance, but such greases will not give any benefit on small bearings. Mixing of different grades and brands of grease is not recommended. Greases having the same thickener and a similar base oil should be compatible but, although lubricating properties may not be impaired, the resultant mixture may have a softer consistency than either of the component greases and leakage may occur.

Oil lubrication is used when high speeds or temperatures rule out greases or when adjacent machine parts are oil lubricated. Bearing limiting speeds are higher for oil lubrication than for grease lubrication.

Oil lubrication can most simply be carried out by an oil bath in which the oil is picked up by the rolling elements and returns to the sump by gravity. The oil level, at standstill, should be no higher than the mid-point of the lowest ball or roller in the bearing to avoid excessive oil churning. An oil-circulation system is recommended for arduous conditions. The oil within the bearing is then at a minimum but is constantly replaced by cool oil from a large reservoir. Such a system, while more expensive to install, results in extended oil life and optimum bearing performance.

For extremely high speeds the extraction of heat from the bearing by the oil is of paramount importance and oil jet systems may be necessary. Solvent refined mineral oils should be used for the lubrication of rolling bearings. The minimum kinematic viscosity of the mineral oil required to ensure adequate lubrication at the operating temperature is calculated using Figure 9.45. The mean diameter of the bearing, d_m ($= 0.5\ (d + D)$) is required and the operating speed. The required viscosity, V_1 (mm^2 s^{-1}), can then be read off. Knowing, or predicting, the operating steady state temperature of the oil in the vicinity of the bearing the viscosity V at 40°C can be obtained from Figure 9.46 (40°C is the internationally accepted standardized reference temperature). This will define the minimum grade of oil required. Bearing life can, however, be extended by selecting an oil with viscosity greater than V_1 (see Section 9.6.4).

Example A bearing having a bore diameter, d, of 340 mm and outside diameter, D, 420 mm, is required to operate at a speed, n, of 500 rpm. From Figure 9.45 the minimum viscosity, V_1, to give adequate lubrication for a speed of 500 rpm is 13 mm^2 s^{-1}. Assume the operating oil temperature to be 70°C (a reasonable first estimate for normal conditions).

From Figure 9.46 an oil having a viscosity of 30 mm^2 s^{-1} at 40°C will have the required 13 mm^2 s^{-1} viscosity at 70°C. The correct oil will be one having a viscosity greater than

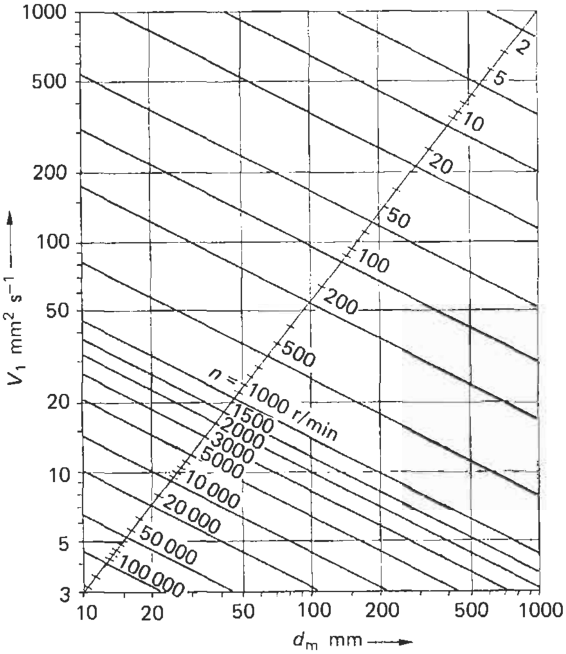

Figure 9.45 Calculation of minimum required viscosity, V_1

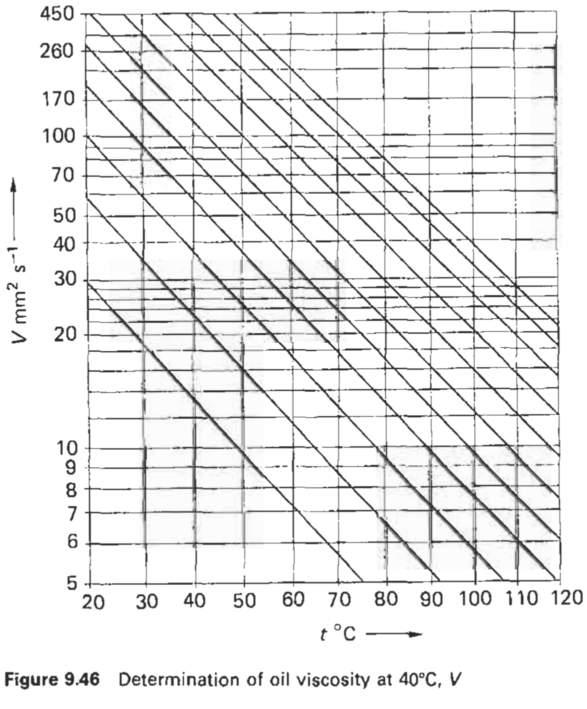

Figure 9.46 Determination of oil viscosity at 40°C, V

39 mm^2 s^{-1}. The nearest thickness grade from a quality supplier would be preferred.

Oil change intervals are mainly dependent on the operating conditions and on the quantity of oil used. Oil bath systems should be changed once a year, provided the oil temperature does not exceed 50°C and there is no contamination. Circulating-oil systems contain a higher volume of oil and may therefore run longer. Oil changes should be determined by regular oil examination or reference to the equipment manufacturer's handbook, particularly when gears or other equipment are lubricated by the same oil supply.

9.6.8 Bearing mounting and maintenance

Rolling bearings are high-precision engineering components and must be treated as such during their entire working life. Large-scale original equipment manufacturers who build in large numbers of rolling bearings take great care in the design and execution of their assembly equipment. It is rare that bearing damage will occur in such circumstances. The major areas of concern are where the assembly of bearings is infrequent. It must be done in a field environment, or where the correct tools are not available.

The study of a suitable mounting procedures guide will repay itself handsomely and attendance at a course on bearing maintenance is advised. In service, repairs are difficult because of the possibility of airborne contamination getting into the bearing assembly. Bearings should be taken out of their protective wrapping at the last possible moment and covered (for example, with a plastic bag) if left exposed on a shaft. Grease tins should not be left open and the grease should be applied with clean implements.

Inexpensive tooling such as drifts and pullers will ease assembly and disassembly on small to medium-sized bearings. Larger bearings will require heavier-duty equipment such as induction heaters (which have largely replaced oil baths or hot plates on safety grounds), hydraulic nuts and oil injection equipment. These items can often be hired if their use does not justify purchase.

It is very important that the bearing rings, cages or rolling elements do not receive direct blows during mounting as this will cause damage. Under no circumstances should pressure be applied to one ring in order to mount the other ring. Before mounting, the seating surfaces should be lightly smeared with oil.

One-piece bearings with cylindrical bores are usually mounted on the ring having the tighter fit first. Small bearings normally having a light interference fit on the inner ring may be positioned using light hammer blows to a soft metal drift or a length of tubing applied to the inner ring face.

If a non-separable bearing is to be pressed into position on the shaft and in the housing at the same time a mounting ring should be placed between the bearing and the mounting dolly so that the mounting force can be applied evenly to both inner and outer rings.

Separable bearings can be mounted independently on the inner and outer rings. When the shaft, with the bearing inner ring already mounted, is fitted into the housing containing the outer ring, great care must be taken to avoid scoring the raceways and rolling elements. Even light scores will rapidly develop into failure sites during rotation.

Larger bearings cannot always be pressed into position due to the large forces required. The larger of the two mating surfaces are therefore heated before mounting. The expansion of a bearing inner ring or housing when heated to 100°C is sufficient to allow troublefree fitting. The inner rings of bearings with a tapered bore are always mounted with an interference fit. The degree of interference is determined by the amount the bearing is driven up the taper of the shaft or adaptor sleeve. During mounting the radial internal clearance of the bearing is reduced. The clearance reduction is a measure of the degree of the interference fit. Self-aligning ball bearings are driven up until the outer ring can still be easily rotated, but a slight resistance is felt when the outer ring is swivelled. Spherical roller bearings are driven up until a specified internal radial clearance is attained. The resultant clearance is specified in bearing manufacturers' tables. Alternatively, the axial displacement of the bearing from an initial position of contact can be used. This method is, however, more liable to error.

Maintenance requirements vary for the type of bearing, its duty cycle and its working environment. The smaller ball and roller bearing used in domestic appliances and private cars generally do not require any attention during the working life of the machine. Larger industrial plant, generally using roller bearings, running with grease or oil lubrication will require regreasing or an oil change at regular intervals to ensure that the quality of the lubricant remains adequate.

Regreasing intervals for rolling element bearings are shown in Figure 9.47. The figure is based upon the use of an age-resistant average quality grease and is valid for bearing temperatures of +70°C measured on the outer ring. The relubrication interval should be halved for every 15°C increase above 70°C. The maximum operating temperature of the grease should obviously not be exceeded. Conversely, if operating temperatures are lower than +70°C the intervals can be lengthened to about twice for operating temperatures of 50°C and below.

Where there is a risk of the grease becoming contaminated the relubrication intervals should be reduced. The amount of grease needed for relubrication can be obtained from

$$G = 0.005\, D.B$$

where G = grease quantity (g), D = bearing outside diameter (mm) and B = bearing total width (mm). Where infrequent lubrication is indicated it is sufficient to expose the bearing in its housing, remove the used grease and pack the fresh grease between the rolling elements.

Where more frequent relubrication is required proper provision should be made for regreasing. Preferably a grease nipple should be fitted to the housing, positioned so that the fresh grease actually reaches the bearing and replaces the old. Provision should be made for the escape of excess used grease so that the bearing assembly does not become fully packed with grease. This will result in hot running.

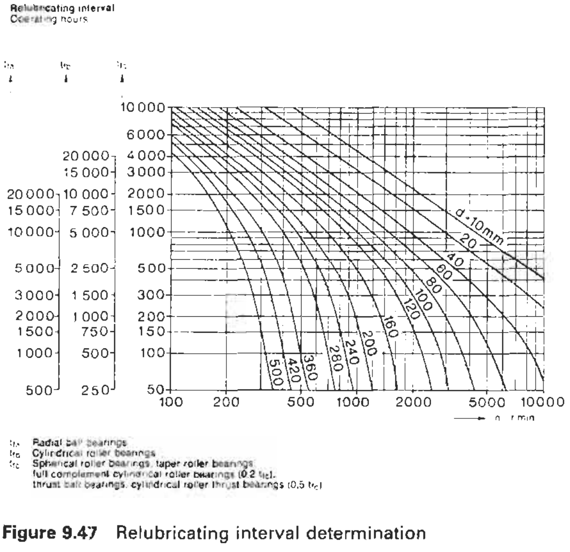

Figure 9.47 Relubricating interval determination

9.6.9 Bearing failures

Repeated bearing failures on a particular machine can be indicative of a number of problems (e.g. a misapplied bearing, poor maintenance or incorrect mounting practice). It is therefore important to examine the failed bearing and attempt to interpret the cause of the failure so that effective remedial action can be applied. A systematic approach must be adopted. Samples of the grease or oil lubricant should be examined for their quality and possible contamination by solids or liquids. The distribution of lubricant should be noted. Bearings should be cleaned and disassembled for a thorough analysis. Careful observations should include the following points.

9.6.9.1 Load paths

The burnished areas on inner and outer ring raceway which show where the balls or rollers have actually been working repay close observation. Very often the actual load path differs from what it was designed to be. The difference then accounts for the failure. Failures under this heading could be caused by:

- Radial preload in a bearing, leading to a load path all around the inner and outer rings. This could be caused by too tight a fit on the inner ring, an expansion of the inner ring due to temperature rise on a bearing that was selected with too small a manufactured clearance.
- Axial loading on a bearing that was intended only to be a radial bearing. Often this is a result of axially locating both bearings on a shaft not giving a facility for axial expansion.
- Misalignment of a shaft causing excessive internal loading of a bearing.
- A bent shaft or misfitment of the bearing in the housing or on the shaft. This will result in a load pattern running circumferentially from one side of the raceway to the other in ball bearings.
- Out-of-balance loads on rotating equipment. This is particularly devastating on heavy machinery running at high speeds where the design specification assumes good balance. The telltale markings on the bearing rings will be a path completely around the outer ring and a localized load area on the inner ring (coincident with the radial direction of the out-of-balance).

9.6.9.2 The raceway surfaces

The classical rolling element bearing failure is a localized, subsurface-initiated spall or pitting, rolling contact fatigue. Due to improvements in bearing steel quality and manufacturing accuracy over recent years, this failure mode is now comparatively rare. It represents the best life that can be attained from the bearing. Further endurance from a new bearing will only be attained by improving the lubrication quality or reducing the applied loads.

The more common failure mode is a surface-initiated distress over the entire surface of the failed ring caused by metal-to-metal contact of the rings and rolling elements – two-body abrasive/wear. This failure is indicative of inadequate lubrication quality, i.e. the lubricant viscosity at the operating temperature is inadequate to create a sufficiently thick lubricant film between rings and rolling elements to escape the dangerous metal-to-metal contacts. In the early stage raceways will become glazed in appearance, followed by a dull frosty surface, eventually leading to flaking.

A general surface distress failure can also be caused by contaminants within the bearing assembly resulting in three-body abrasive wear. Solid and liquid contaminants have the same effect. Both can usually be identified by examination of the grease (oil) or of the bearing cavities.

Poor lubrication can often be distinguished from other surface-initiated failures by examination of the cage pockets. The rolling element/cage contact is a sliding mode and, as such, is susceptible to wear if the lubricant is suspect.

9.6.9.3 Raceway indentations

Regular raceway indentations at ball or roller pitch indicate overload damage under non-rotating conditions. Poor bearing mounting techniques, pushing the interference fit ring into place through the rolling elements and loose ring, can very easily indent one or both rings. Failure will occur very quickly once the bearing is in service.

Indentations can also be caused by false brinelling, i.e. the internal oscillation of the bearing due to vibration of the whole machine. This is common on standby equipment situated in a vibrating environment. The remedy is either to regularly rotate the machine to spread the load and relubricate the bearings or to preload the bearing in some manner. Brinelling can only occur where there is movement within the bearing.

9.6.9.4 Electrical discharge damage

Electrical current leakage across a rolling element bearing will frequently result in severe arcing pits or valleys on the raceways. These will typically have a regular washboard appearance and will cause severe vibration. The use of inadequately earthed electric arc welding, perhaps during repairs on a structure containing bearings, is a common originator of such damage. The remedy is either better earthing using an earth strap or, in extreme cases, insulation of the bearing by coating the bearing outer diameter with a suitable non-conducting layer. Such bearings, obtainable from the major manufacturers, are becoming common in traction motors and other bearings in electrical environments.

9.7 Materials for unlubricated sliding

9.7.1 Introduction

There are literally hundreds of materials which are suitable for unlubricated sliding. The main selection criterion is the maximum acceptable level of friction and wear which can be tolerated in the bearing contact. In general, this level will be higher than in lubricated contacts and therefore dry rubbing bearings find application where the use of a fluid lubricant is not possible. In practice, this is where:

- Fluids are adversely affected by the environment (e.g. high or low temperature, vacuum, radiation or solvents);
- Product contamination is undesirable (e.g. food or optics);
- Maintenance and relubrication is not possible (e.g. in remote locations);
- A combination of low speed and high load breaks down the fluid film (e.g. oscillatory, offshore buoy moorings).

In addition to satisfying tribological requirements, the material must support the applied load without significant distortion, under the operating conditions, to prevent severe surface damage during sliding. Provided these criteria can be met, the use of dry bearings can offer advantages in terms of cost, simplicity of design and weight.

Five groups of materials can be identified which exhibit relatively low friction and wear characteristics under unlubricated sliding conditions:

Polymers and polymer composites
Solid lubricants
Self-lubricating bronzes
Carbons and graphites
Hard-facing alloys, ceramics and cermets.

The different mechanical, thermal and tribological properties of these groups of materials satisfy a wide range of operating specifications. They include materials capable of continuous operation in extremes of temperature, from −250°C to in excess of 500°C, at bearing pressures in excess of 100 MPa and at sliding speeds over 10 m/s. When sliding is intermittent, even higher pressures and speeds can be tolerated.

The tribological performance and operating limits of materials within these groups is presented in the following sections. The best known and most frequently used dry bearings are polymers and polymer composites. While there is an abundance of information available on these materials, data on some of the other groups are extremely limited. Wherever possible, a list of material suppliers is therefore included from whom further technical advice can be obtained.

In addition to these five groups of dry bearing materials, there are certain porous metals which can be impregnated with fluid lubricants and operate without external lubrication for limited periods. Since a requirement for regular, wet lubrication can prevent the use of many metallic materials in sliding applications, consideration will be given to these prelubricated materials which can exhibit extremely low friction and wear under relatively high load and sliding speed conditions.

Before presenting specific data on materials, the parameters used to rate performance, their limitations and the factors which can influence them must be considered. The interpretation of manufacturers' data, when predicting bearing performance, without an appreciation of these factors can be extremely misleading.

9.7.2 Performance rating

9.7.2.1 Wear

As discussed in Section 9.1, wear data are normally expressed in terms of a specific wear rate, k. This is defined as the volume of material worn, per unit load, per unit sliding distance. Hence

$$k = \frac{v}{WL} \qquad (9.7)$$

where

v = worn volume of material,
W = load between the bearing surfaces (m^3), and
L = total sliding distance (m).

Standard units are m^2 N^{-1}. Values of 10^{-16}m^2 N^{-1} or lower are indicative of mild wear and values higher than 10^{-14}m^2 N^{-1} represent severe wear. Most material wear rates are within the range 10^{-17} to 10^{-12}m^2 N^{-1}.

Two common features of dry bearing wear should be noted:

1. The wear rate is often time dependent. A typical plot of wear volume versus time for polymer-based materials sliding against a smooth, hard counterface is shown in Figure 9.48. From this graph it can be seen that linear or steady-state wear is only observed after a more rapid running-in period. During this period, transfer from the bearing material to the counterface takes place and the polymer surface conforms to the harder surface geometry. Subsequent contact is between the bearing material and the transferred film which gives the low friction and wear

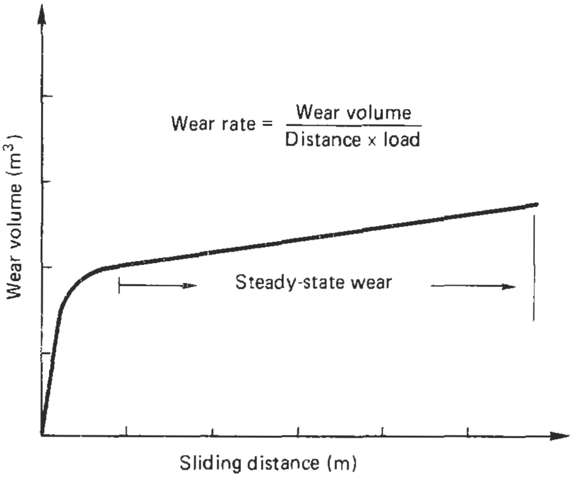

Figure 9.48 Typical plot of wear versus sliding distance for PTFE-based materials under dry conditions

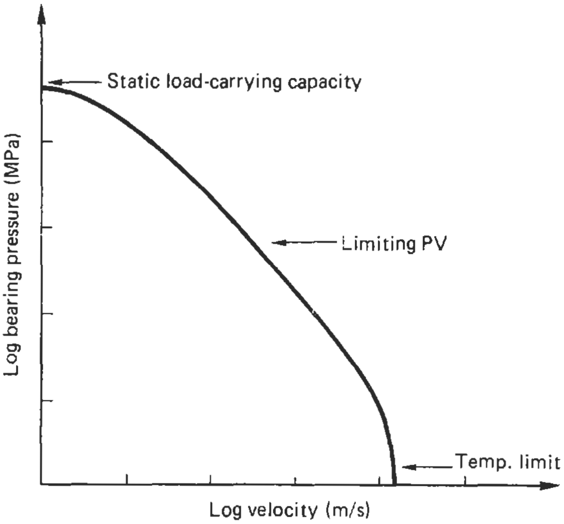

Figure 9.49 Typical 'PV' plot for dry bearings

characteristics generally quoted in manufacturers' literature. Wear rates during running-in can be an order of magnitude higher than the steady-state value. Allowance for this wear in terms of fits and tolerance may be necessary during the design stage.

2. The concept of a material-specific wear rate is based on the assumption that changes in the applied load do not cause changes in the wear characteristics of the material. This is generally the case under low loads but the wear performance of many materials, especially polymers, is influenced by the bearing pressure and operating temperature once they exceed a critical limit. Since the temperature rise at the surface due to frictional heating is proportional to the sliding speed, it is appropriate to incorporate a pressure velocity term into this wear equation, as discussed in Section 9.1, equation (9.5).

9.7.2.2 PV factors

Limiting pressure velocity (PV) values are normally quoted in manufacturers' data. Alternatively, a PV factor may be quoted in terms of a maximum wear rate. Above these limits, either excessive frictional heat will be generated at the bearing surface, which will cause the wear rate and friction to increase, or the stresses in the material will exceed the elastic limit.

There are, however, several limitations on the use of PV limits:

1. Quoted PV values normally refer to operation at ambient temperatures of about 20°C. For higher-temperature applications a reduced PV limit will apply since the ambient temperature will be superimposed on the frictional heat generated at the surface. Guidance on PV temperature correction factors is given in an ESDU polymer materials selection guide.[22]
2. If the in-service PV value is within the limit only because one of the two parameters is very low, the wear rate may again be adversely affected, due either to frictional heat in the case of excessive speed or overloading. It is therefore useful if a complete PV curve is presented, as shown in Figure 9.49.
3. If the heat generated at the rubbing surface can be readily dissipated from the contact area, either by forced air cooling or through the bearing housing, a higher PV limit can be applied.

Since frictional heat is often the limiting factor, especially with polymer sliding, the concept of a pressure temperature limit is, at first sight, attractive. However, whereas the calculation of bearing pressure and sliding speed is normally straightforward, the bearing surface temperature is the sum of three components:

- The ambient temperature;
- The mean surface temperature rise during sliding;
- The flash temperature rise at the localized asperity contacts on the surface.

The temperature rise over the apparent surface area due to frictional heating is proportional to the friction coefficient between the mating surfaces, the applied load and the sliding speed. However, an estimate of the heat dissipated from the bearing or through the housing is also required for an accurate prediction of this temperature rise. Hence:

$$T = R.\mu.W.V \tag{9.8}$$

where

T = mean surface temperature rise,
μ = friction coefficient,
W = normal applied load, and
V = sliding velocity.

This equation can, alternatively be expressed as in Section 9.1:

$$T = c\mu.PV$$

R and c are constants which characterize the resistance to heat dissipation from the rubbing surfaces. Details of this calculation are given in several design guides on polymers.[22,23]

The calculation of flash temperature is fairly complex.[24,25] However, if the sliding speed is well below its limiting value, as given by the pressure velocity curves, this component can normally be ignored in the estimation of the bearing surface temperature.

This pressure temperature approach is adopted in several dry bearing selection guides.[23,26] For simplicity, the pressure velocity limit approach will be adopted in this section.

9.7.2.3 *Friction*

Two different friction coefficients can be quoted:

1. The dynamic friction coefficient, which is the ratio of the friction force to the normal force during sliding;
2. The static or breakout friction coefficient. This is the ratio of the friction force required to initiate relative sliding, to the normal force. This breakout friction coefficient can be considerably higher than the dynamic value.

It is also important to recognize that the friction characteristics, like the wear rate of most materials used for unlubricated sliding applications, vary not only with operating and environmental conditions but also with time. Information on the friction coefficients of specific groups of materials and the effects of these factors on them will be discussed in the relevant material sections.

9.7.3 Counterface materials

In any dry contact there are two mating surfaces. The counterface material and its surface finish greatly influence the friction and wear characteristics of most dry bearing materials. In general, lower wear rates will be obtained with hard, smooth counterfaces but the costs of preparation often dictate the choice of material and finish within acceptable tribological performance limits. Surface treatments and coatings are available which can produce a hard bearing surface on a relatively cheap substrate (Section 9.8). Considerable development has been made in these fields during the past ten years and their application as a technique for controlling wear is becoming more widespread.[27]

From this brief discussion of material performance data presentation and its limitation, it should be apparent that a universally applicable material wear rate and friction coefficient does not exist for a given material. It is important, therefore, to ascertain whether quoted values can be justly applied to a specific application when predicting bearing performance. Whenever possible, short-term, accelerated laboratory tests should be carried out under representative in-service conditions to obtain relevant tribological data.

9.7.4 Polymers and polymer composites

9.7.4.1 *Material classification*

The main advantage of polymers over metals is their inherently low friction and wear characteristics in the absence of external lubrication. In comparison to mild steel, their tensile strength is a factor of ten lower, their elastic modulus a factor of one hundred lower and their coefficient of thermal expansion a factor of ten times higher. These properties, which would impose severe limitations on their use, are greatly improved by the use of fillers and there are over 70 commercially available polymers and polymer composites in the UK today.

Polymers fall into two distinct classes: thermoplastics and thermosets. Thermoplastics are characterized by softening on heating and retaining their plastic properties on cooling. Thermosets undergo extensive cross linking of their molecular chains on heating which causes irreversible hardening of the material. Most thermoplastics therefore have the advantage over thermosets that they can be injection moulded. This facilitates cheap mass production. Thermosets are generally produced as bars, tube or sheets and are machined to their required shape.

For convenience, the polymer-based materials will be further categorized here into six groups according to their appearance, performance or load-carrying capacity. The groups and examples of materials within each group are listed in Table 9.18.

As explained earlier, the friction and wear characteristics of polymer-based materials depend on many factors, including bearing pressure, temperature, sliding speed, the mating surface material and its finish, and the environment. Each of these factors will be considered individually but their effects are often combined.

9.7.4.2 *Environmental suitability*

Polymers are extremely inert and can operate as dry bearings in a wide range of environments. Many are highly resistant to chemical attack and are therefore suitable for application in

Table 9.18 Polymers and polymer composite classification

	Suppliers
1. *Unfilled thermoplastics*	
Polyamide (nylon)	Du Pont, ICI
High-density polyethylene	BP
Polytetrafluorethylene (PTFE)	Du Pont, ICI, Hoechst
Ultra-high molecular weight polyethylene (UHMWP)	Hoechst
Polyacetal

acids, alkalis and solvents. The effect of chemicals on any fillers present in the material must, however, be considered. Polymers have a lower resistance to ionizing radiation than metals, but doses as high as 1000 MRads can be tolerated by polyimides with only a slight reduction in mechanical properties and tribological performance. Table 9.19 summarizes the suitability of the polymers and fillers for use in different environments and can be used to eliminate materials on an environmental suitability basis. This is often the simplest and first stage of the materials selection process.

Several general observations can be made from Table 9.19:

1. Composites containing graphite are unsuitable for use in a vacuum or dry, inert gas. This is because graphite requires the presence of a condensible vapour, such as water, to maintain its natural lubricity. Further information on the properties of carbon graphites is given in Section 9.7.5.
2. Immersion in water has an adverse effect on the performance of many of these dry bearing materials since it removes or prevents the establishment of a transfer film, on which their low friction and wear characteristics depend. Since many of the polymers are, to some extent, porous, swelling can occur in water. This is particularly notable with polyamide materials, which can increase in volume by up to 3% in water. This can result in a reduction in clearance between bushes and shafts and an increase in bearing pressure. Where this may present a problem, only those materials ticked as suitable in Table 9.19 should be considered.
3. Unfilled polyimide and PEEK are extremely inert and can operate in most environments. They are slightly porous but swelling in water is limited to about 0.1% by volume. The main limitation on the use of these two materials is their high cost, which is about £30/kg for PEEK.
4. Although a radiation dose of 0.1 MRads causes a severe reduction in the mechanical properties of bulk PTFE-based materials, tests have shown that thin-layer materials containing PTFE can withstand doses as high as 100 MRads without any major increase in wear rate. This is because the reinforcement carries the load and the reduction in properties of the PTFE has little effect on load-bearing capacity.

9.7.4.3 Pressure velocity limits

The pressure velocity limiting curves presented here (Figures 9.50 to 9.52) are based on a depth wear rate of 25 μm per hundred hours sliding in air at an ambient temperature of 20°C. Where the ambient temperature is hotter, a lower pressure velocity limit will apply. These indicate a range of bearing pressures of up to 100 MPa at low speeds and a maximum sliding speed of about 10 m/s at low loads within this group of materials.

The filled polyimide and PEEK high-temperature materials are well suited to high-load, high-speed applications (Figure 9.50). This is to be expected, since heat generated at the rubbing surface due to friction is often the limiting factor in material performance. At lower speeds, the thin-layer materials offer extremely good load-carrying capacity (Figure 9.51), the limitation on speed being imposed by softening of the resin due to frictional heating. In contrast, the pressure velocity limits of unfilled PTFE are low but increase by a factor of two with the addition of most fillers (Figure 9.51).

The performance of reinforced thermosets is directional with optimum conditions when sliding is normal to the laminate. In this orientation, they are suitable for high-load, low-speed sliding applications.

The pressure velocity limits of unfilled thermoplastics are lower than those of the reinforced grades (Figure 9.52). The use of fillers can increase their maximum sliding speed from 1 m/s to 3 m/s and their load-carrying capacity from 4 MPa to in excess of 10 MPa.

9.7.4.4 Temperature limits

With the exception of PTFE which does not mechanically degrade at temperatures below 200°C, the unfilled and filled

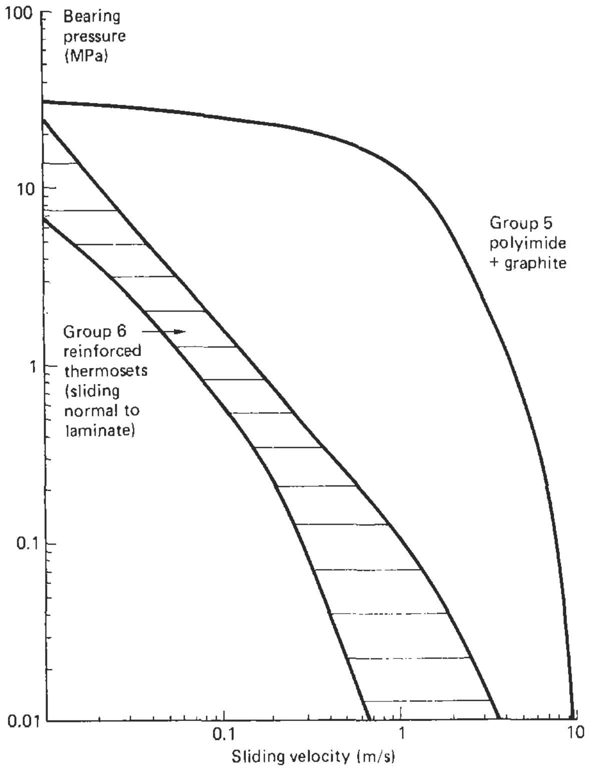

Figure 9.50 PV limiting curves for reinforced thermosets and polyimides

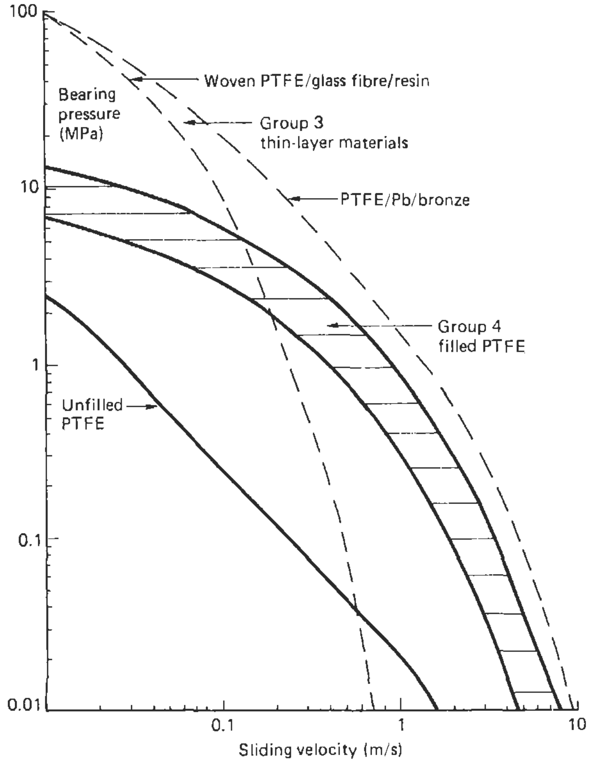

Figure 9.51 PV limiting curves for PTFE-based materials

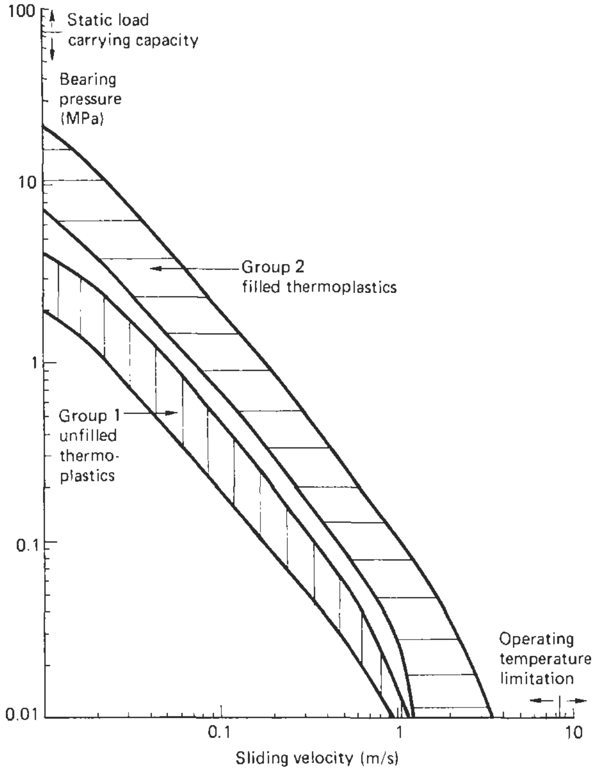

Figure 9.52 PV limiting curves for unfilled and filled thermoplastics

grades of thermoplastic materials start to degrade when their surface temperature exceeds 100°C. For higher-temperature applications, most of the thin-layer materials (Table 9.18) are largely unaffected by temperatures of up to 150°C and the filled PTFE materials can be used at temperatures of up to 250°C. When the bearing surface temperature is expected to reach up to 300°C, polyimide or PEEK may be suitable.

9.7.4.5 Friction and wear data

The effect of pressure and temperature on the wear rate of polymer-based materials is illustrated in Figure 9.53. From this graph it is apparent that there is a low-pressure, low-temperature region where the wear rate is essentially independent of these factors. This wear rate is referred to as the K_0 wear rate. The K_0 values presented in Figure 9.54 were measured using an annular thrust washer test geometry. The polymer washer was loaded against a static mild steel counterface, ground to a surface finish of 0.2 μm R_a, under a bearing pressure of 1 MPa and continuously rotated at a sliding speed of 0.03 m/s. Under these conditions, all the materials tested were within their K_0 limits.

Although renowned for its low friction, the wear rate of unfilled PTFE is very high. The addition of fillers reduces the wear rate but increases friction. Its use in the unfilled form is not therefore recommended where high rates of wear are unacceptable (e.g. rotary seals).

The thin-layer materials all exhibit low wear rates but their wear depth is limited to between 0.05 mm and 0.3 mm depending on the material. Beyond this limiting depth, their tribological properties deteriorate rapidly. Figure 9.55 shows a typical wear volume versus sliding distance plot for these materials. It is recommended that, where possible, the pro-

Figure 9.53 Bearing pressure and temperature limits for polymer-based dry bearing materials

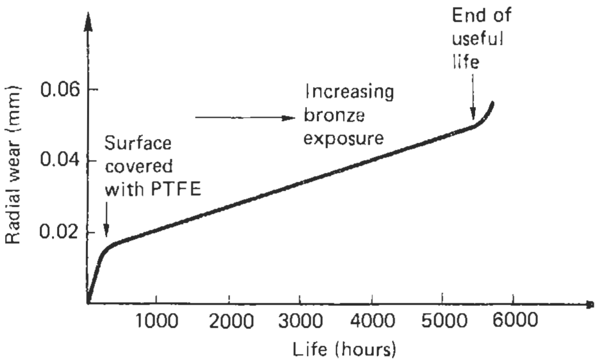

Figure 9.55 Typical plot of wear versus time for thin-layer bronze/PTFE material

gressive wear of these materials should be monitored to predict useful operating lives.

Pressure effects on wear rate are often closely linked to temperature rise.[28] This is not surprising, since frictional heating is a function of the applied load. Anderson has derived pressure temperature wear correction factors for a wide range of polymers which permit a prediction of the wear rate under different operating conditions.[23,29] This wear correction factor is multiplied by the K_0 value to predict the in-service wear rate. For most polymer-based materials, this factor increases from one to twenty as the temperature increases (Figure 9.56) to the softening point of the material. This increase in wear

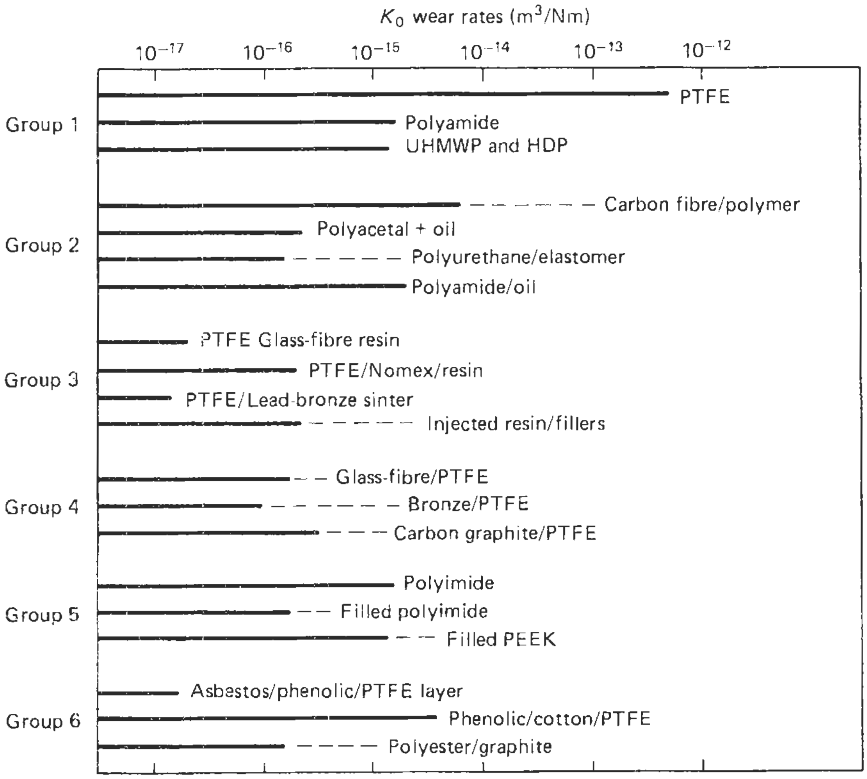

Figure 9.54 K_0 wear rates

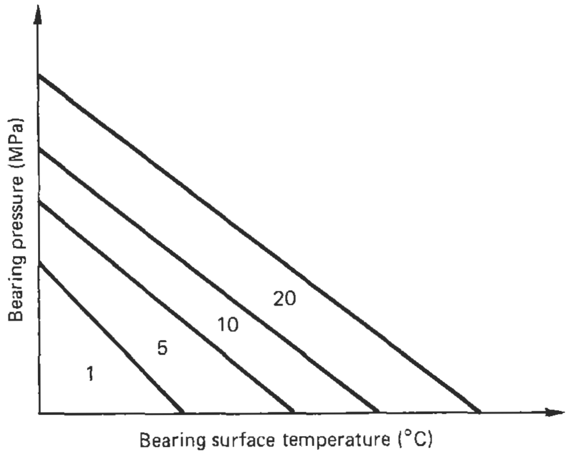

Figure 9.56 Typical wear correction factor plot from reference 23

correction factor is offset against a reduction in value with decreasing pressure. In general, to maximize wear life, the bearing surface temperature should be maintained in the range 0–40°C and the bearing pressure kept as low as possible.

These K_0 wear rate values were measured during sliding against a smooth, polished counterface. If the counterface material corrodes or the surface becomes contaminated with relatively hard particles such as sand, the wear rate of the materials will increase significantly. Figure 9.57 shows the effect of counterface roughness on the wear rate of a range of polymers. It should be remembered that the presence of lubricants, even in trace quantities, will reduce the wear rate of most polymers.

The range of dynamic friction coefficients exhibited by polymer materials within their pressure velocity limits are presented in Figure 9.58. The dynamic friction coefficient of both unfilled and filled grades of PTFE increases from about 0.1 to 0.3 with decreasing pressure and increasing temperature. At high bearing pressures of about 100 MPa the friction coefficient of the thin-layer PTFE materials can be as low as 0.03 provided the surface temperature remains below about 150°C. This value increases to 0.2 mainly with decreasing pressure. The trend of friction increasing with decreasing pressure and increasing temperature is also true for most thermoplastic materials, in both unfilled and filled forms. With reinforced thermosets the friction actually reduces slightly with increasing temperature but still increases with decreasing pressure.

The static friction coefficient of most thermoplastics is similar to their dynamic value. Certain thermosets, however, exhibit static friction coefficients almost 50% higher than their dynamic value. Where this is the case, stick slip or jerky motion often ocurs. An indication of materials prone to stick slip is given in Figure 9.58.

Material suppliers from whom additional technical information can be obtained are listed in Table 9.20.

9.7.4.6 Design considerations

Aspect ratio The aspect ratio of journal bearings is the ratio of the bearing length to its internal diameter. Normal practice is to design with a ratio of between 0.5 and 1.5. If this range is greatly exceeded, problems are encountered with bearing alignment. If the ratio is much smaller, the establishment of a coherent low-friction polymer transfer film on the counterface, as observed with PTFE and UHMWP, is less likely. Reinforced thermoset materials have a higher flexural modulus than most filled thermoplastics and the aspect ratio with these materials can, if necessary, slightly exceed these guideline values.

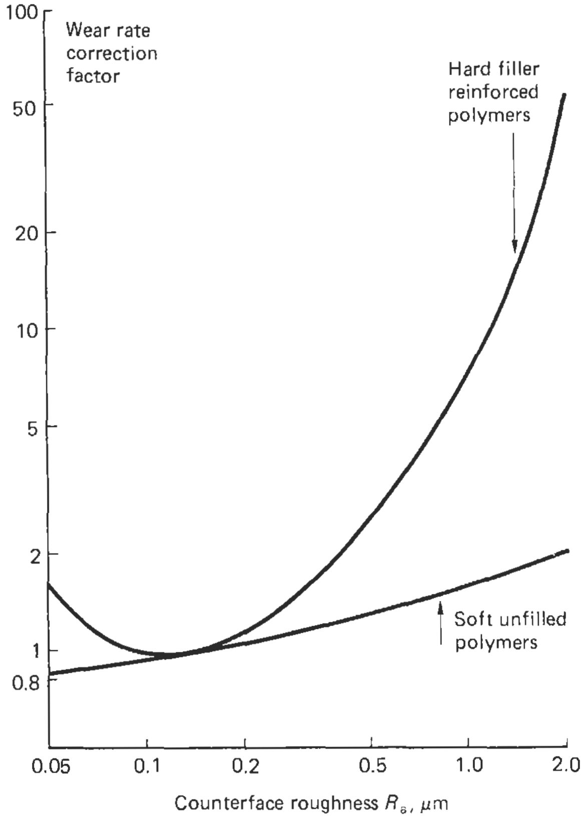

Figure 9.57 Wear rate correction factors for polymer and composites sliding on steel (hardness < 300 HV)

With thrust bearings, the ratio of the outer to inner diameter is important. A ratio of less than two is advisable since the outside edge can become overheated if high sliding speeds are attained at this position.

Clearances Because of their high thermal expansion, polymeric materials require a larger running clearance than lubricated metal bearings. A typical running clearance is 5 μm per mm diameter with a minimum clearance of 125 μm. For thin-layer materials, the manufacturer should be consulted since the required clearance is influenced by the backing material (Table 9.20).

Wall thickness and installation Wall thickness of polymer bearings should be made as thin as possible, within wear limitations. This will aid in the dissipation of heat to the housing and reduce distortion under high loads. They are generally located in their housings by an interference fit. The recommended degree of interference varies between 5 μm/mm and 10 μm/mm for the relatively rigid thermoplastics (e.g. polyamides, polyacetals, UHMWP) to between 10 μm/mm

and 20 μm/mm for the less rigid material (e.g. PTFE). Thin-layer metal-backed bearings should be designed using the properties of the backing material. Further advice can be obtained from the suppliers listed in Table 9.20.

Counterface materials The choice of counterface material is influenced by both the fillers present in the polymer and the environmental conditions. Where potential abrasives are present, such as grit or sand, hard fillers can improve the abrasion resistance of polymers. In general, hard particles can become embedded in the softer polymers and scoring of the counterface is often more severe than polymer wear under these conditions. When hard fillers are present in the polymer (for example, glass) the use of a counterface material with a hardness value exceeding 600 HV is recommended to prevent counterface damage.

In water, the possibility of electrolytic corrosion must be considered when selecting counterface materials for use with graphite-reinforced polymers. Laboratory tests are recommended to ascertain the potential for corrosion which will lead to significant increases in friction and wear.

9.7.5 Carbon graphites

9.7.5.1 Material properties

Carbon graphite materials possess several attractive properties which make them suitable for applications where polymers and lubricants cannot be used. They can operate at temperatures of up to 500°C in air, this temperature being limited by the oxidation resistance of the rubbing surface. They are therefore able to operate at relatively high sliding speeds compared to other unlubricated materials. Their high thermal conductivity also promotes dissipation of the frictional heat, generated at the bearing surface, to the housing. Although their porosity can be as high as 15%, they exhibit good dimensional stability and this can be further improved by impregnation of the pores with fillers, as discussed below. Their high electrical conductivity makes them ideal dry bearing materials for applications such as electric motor contact brushes and slip rings. Since these are brittle materials, care must be taken to minimize impact loads in service.

Carbon graphites are only suitable for unlubricated sliding in the presence of a condensible vapour, such as water. If the water vapour content of the atmosphere surrounding the sliding surface falls below 600 ppm, high wear or dusting will occur.[30] This dusting is so called on account of the dust generated from the carbon graphite surface which can wear at a rate measured in centimetres per hour under these drier conditions. Consequently, these materials are unsuitable for use as bearings or sliding contacts in a vacuum or dry, inert gas. However, in these environments, there is little change in their mechanical properties at temperatures of up to 1000°C.

Three graphitic grades are commonly used for unlubricated sliding: carbon graphite, metal-impregnated carbon graphite and electrographite.

Furnace-fired carbon graphites are porous and can operate at temperatures up to 350°C. Their compressive strength varies between 80 MPa and 160 MPa,[31] increasing with graphite content. Their tensile strength is considerably lower. Impregnation with thermoset resins, such as epoxide resin, limits operating temperatures to about 200°C but reduces permeability and increases their strength and wear resistance.

Metals impregnated into carbon-graphites include copper and copper–lead mixes.[32] These increase load-carrying capacity without reducing temperature limits.

Electrographite is produced by heat treatment of hard carbons at temperatures of up to 2800°C.[31] These resist oxidation in air better than the ungraphitized materials. The more graphitized materials readily transfer to the counterface and their friction and wear characteristics are generally lower than other grades. Since water can disrupt this transfer layer its presence is detrimental to performance.

The wear rate of most grades of graphite is within the range $10^{-15}m^3/Nm$ to $10^{-14}m^3/Nm$. Dynamic friction coefficients of these materials vary between 0.1 to 0.3; the higher value is exhibited by metal-filled grades in high-load, low-speed situations and the lower value by electrographite (bearing grade) under low-load, high-speed conditions.

The wear rate of most grades of graphite is within the range $10^{-15}m^3/Nm$ to $10^{-14}m^3/Nm$. Dynamic friction coefficients of these materials vary between 0.1 to 0.3; the higher value is exhibited by metal-filled grades in high-load, low-speed situations and the lower value by electrographite (bearing grade) under low-load, high-speed conditions.

9.7.5.2 Limiting pressure velocity

Limiting PV curves for these materials are presented in Figure 9.59 for a wear rate of 25 μm per 100 h.[31] These indicate a maximum possible sliding speed of 10 m/s. However, other sources claim that the sliding speed of all carbon graphite materials should be limited to 1.25 m/s.[32,33] It is therefore recommended that manufacturers be consulted for information on specific grades of these materials.

9.7.5.3 Design considerations

A ground, hard counterface (400–600 HV) is recommended for use with carbon graphites to promote material transfer and minimize abrasion. In the presence of an electrolyte, such as water, the shaft material must be selected to avoid electrolytic corrosion.

Typical wall thickness for carbon graphite bushes is about 4 mm for a 25 mm bore and 12 mm for a 100 mm bore.[33] This relatively thick wall is necessary on account of the low impact and tensile strengths of these materials. Bushes of up to 25 mm bore can be press fitted in their housings with an interference of up to 2 μm/mm. Larger bushes are normally shrink fitted (for example, by freezing in liquid nitrogen) with an interference of about 4 μm/mm. This interference should be increased if the housing material is expected to expand considerably more than the bush during operation.

9.7.6 Solid lubricants

9.7.6.1 Applications

The inclusion of solid lubricants in a section on materials for unlubricated sliding may appear inappropriate. However, in many applications where the presence of a lubricant (or, more specifically, a wet lubricant) is considered undesirable or impossible, the use of a dry, solid lubricant can reduce friction and wear without adversely affecting the materials or the environment.

At extremes of temperature where oils and greases cease to lubricate due to changes in viscosity, dry lubricants can maintain a low-friction film between mating surfaces in relative motion. Many solid lubricants are also extremely inert and can withstand radiation levels and chemicals which cause wet lubricants to degrade. They are also usually very clean and adhesive to the bearing surface. This reduces the likelihood of product contamination which is essential in many industries.

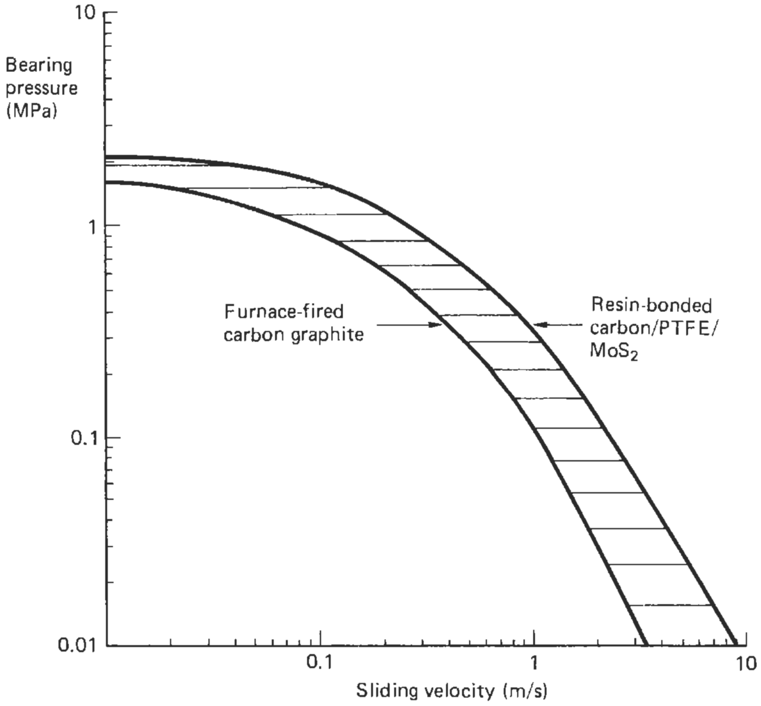

Figure 9.59 PV limiting curves for carbon graphites

The three most popular solid lubricating materials are PTFE (which has already been discussed in the section on polymers), graphite and molybdenum disulfide. As lubricants, they are normally contained in a resin binder, such as phenolic, epoxide or cellulose resins. In general, a high ratio of lubricant to resin will lower friction whereas lowering the ratio minimizes wear. They are available as spray or paste, both of which are easily applied to bearing surfaces.

The low shear strength of all these materials ensures rapid transfer to the counterface and subsequent low friction. Adhesion to the surfaces becomes important after the initial transfer and the presence of fluids such as water is often detrimental to performance.

9.7.6.2 *Molybdenum disulfide*

Molybdenum disulfide is a lamellar solid, particularly suited to vacuum applications. The simplest method of applying lamellar solids is burnishing of the dry powder into the surface with a cloth, taking care not to scratch the surface. Sprays are also available containing bonding agents which cure at room temperature. For applications where thin films of very high quality are required this lubricant can be applied by a sputtering process.[34] Tests in vacuum indicate that sputtered coatings of this material, only 0.5 μm in thickness, have better tribological properties than bonded films over ten times thicker. The maximum operating temperature of molybdenum disulfide is 350°C.

The wear rate of MoS_2 coatings is influenced by environmental factors and the type of binder.[35,36] The substrate has little effect on wear rate provided the coating is not penetrated. Specific wear rates in the range of 1×10^{-15}m^3/Nm to 1×10^{-14}m^3/Nm are typical for all but the hardest and softest coatings. Dynamic friction coefficients as low as 0.03 are not uncommon with sputtered coatings of MoS_2 at high loads in air. This rises to within the range 0.15–0.2 as film thickness increases and the load decreases.

9.7.6.3 *PTFE and graphite*

The properties of these two materials in bulk form are discussed in Sections 9.7.4 and 9.7.5. Both are available in spray form with binders which cure at room temperature.

The most common dry lubricant sprays are based on PTFE or molybdenum disulfide. Typically, the coating thickness is between 1 μm and 15 μm, although thicker coatings are possible. It is difficult to predict the life of the coating and when no other lubricant is present their main use is in assembly of components and where only a small amount of sliding will occur. Friction coefficients can be as low as 0.03. They are also used as a surface coating with the pocket lubricated materials described in Section 9.7.7.2. The coating protects the pockets during installation and promotes rapid formation of a transfer film on the mating surface. When sprayed on metal, the maximum bearing pressure limit is considerably higher than those quoted for their bulk properties.

Lead, gold and silver are also used as dry lubricants for space applications but the deposition process is expensive.[34]

9.7.7 Metallic alloys and composites

9.7.7.1 *Copper-based alloys*

The main group of metallic alloys used for bearing applications are bronzes. These copper-based alloys offer advantages over most polymeric materials in terms of higher load-carrying capacity, lower thermal expansion and greater resistance to high temperatures. In contrast, their friction and wear characteristics are higher than most polymers and polymer composites. The use of dry lubricants is therefore becoming increasingly popular with these materials to reduce friction and wear.

Bronzes range in hardness from the relatively soft leaded bronze, through the harder phosphor bronze to the aluminium bronzes.[37] The compressive strength of the harder materials can be as high as 300 MPa. Specific data on their tribological properties are limited but wear rates of about 1×10^{-13}m^3/Nm and dynamic friction coefficients of between 0.5 and 0.6 are typical under low-load, low-speed conditions. The addition of graphite powder (Devametal by Glacier Ltd) or lead during sintering of the bronze can reduce the material wear rate by an order of magnitude and also reduce friction. Bearing pressures of up to 400 MPa are possible. Graphite in nickel–copper alloys has a similar effect on wear rate and this material can operate in temperatures up to 500°C. Both these materials exhibit friction coefficients in the range 0.25–0.4.

9.7.7.2 *Dry lubricated bronzes*

Bronzes with discrete pockets of dry lubricant in the bearing surface are commercially available. The pockets normally contain a combination of thermoset resin, PTFE, molybdenum disulfide, graphite and wax in various quantities. If graphite is present, the possibility of electrolytic corrosion in service must be considered. Pressure velocity limits with the pocket-lubricated materials are in the range 0.5–4 MPa × m/s and the maximum bearing pressure (at low speeds) is about 100 MPa. These materials are marketed by several firms including FW Birketts Ltd, Merriman Inc. and Johnson Metals Ltd. Their operating temperature is limited, by the softening point of the resin, to between 150°C and 250°C. Wear rates of as low as 1×10^{-15}m^3/Nm have been measured at The National Centre of Tribology (NCT) when sliding against hard, smooth counterfaces and friction values are reduced to between 0.1 and 0.2.

In general, the leaded bronzes should be used in conjunction with an unhardened steel shaft whereas the harder phosphor and aluminium bronzes perform better with a hardened steel counterface. The strength of all these alloys can be increased by applying them as a thin lining to a steel backing.

9.7.7.3 *Self-lubricating porous metals*

Although dry bearings are normally selected for applications where the use of an oil is undesirable or impossible, this can be due to the problems associated with maintenance or the supply of lubricant to the rubbing surface. Oil-impregnated porous metal bearings do not require an external lubricant supply and offer low friction and wear characteristics over a range of relatively high loads and speeds compared with polymers.

Porous metals are produced by the sintering of loosely compacted metal powders. The degree of porosity can be increased or decreased by varying the compacting loads during the sintering process but is normally in the region of 20–30%[37] of the total volume. Oil is then impregnated into the pores. To ensure maximum penetration of the oil into the material, this is normally carried out under a vacuum.

The two main self-lubricating porous metals are porous bronze and iron. These can be impregnated with a range of oils. In general, higher-viscosity oils, in the range 75–100 centipoise at 600°C should be used for high-load, low-speed applications.[37] Lower-viscosity oils should be selected for the low-load but high sliding velocity conditions. Most porous metal bearings are supplied with a medium viscosity oil such as SAE30.

The life of these bearings is difficult to predict. As the oil in the pores becomes depleted, the absorption ability of the metal increases. Oil loss from the bearing is therefore more rapid during the early stages of operation, reducing to a lower rate with decreasing oil content. The rate of loss is also governed by the operating temperature of the bearing. Since oil viscosity reduces with increasing temperature, the rate of oil usage increases under high speeds as the frictional heat generated at the surface is high. A pressure velocity limit of about 3 MPa × m/s is recommended to minimize the wear rate of these materials when used in bulk form.

A composite material of porous bronze, filled and overlaid with an acetal resin co-polymer is available in strip form which can be formed into bushes and thrust washers (Glacier DX). The friction and wear characteristics of this material are inferior to those of the thin-layer polymer based materials described in Section 9.7.4. However, the material can operate under conditions which would not normally sustain a film of lubricant between the sliding surfaces.

The bearing surface is indented and can be packed with grease. The indentations retain the lubricant and sustain a film on the surface. This enables the material to operate under oscillating conditions where conventional lubricated materials would not sustain a film of lubricant between the surfaces.

Friction coefficients during sliding against steel or cast iron mating surfaces are claimed to be in the range 0.01–0.1. Since the lubricant remains on the surface, the static friction coefficient is also low in the range 0.02–0.15. The maximum operating temperature is limited by the softening point of the acetal resin to 130°C. A new, similar material with PEEK in place of acetal is now available which can operate at 250°C (Glacier Hi-Ex). Above temperatures of 80°C, the use of silicone grease is recommended. With grease lubrication, a pressure velocity limit of 0.7 MPa × m/s is specified but this can be increased to almost 3 MPa × m/s if oil lubrication is possible.

As with polymers, a counterface surface finish of 0.4 μm R_a or less is recommended. The dimensional stability of both these materials is extremely good. The recommended operating clearance for journal bearings manufactured in this material are influenced by the operating pressure and velocity. For a journal diameter of 10 mm the clearance varies between 0.02 mm and 0.06 mm as the pressure velocity term increases from 0.1 MPa × m/s to 2.8 MPa × m/s. For larger journals of about 100 mm diameter, a clearance of between 0.06 mm and 0.2 mm is recommended over a similar range of pressure velocity limits.

9.7.8 Surface treatments and coatings

Surface coatings and treatments offer an ideal solution to many tribological problems. The substrate material can be chosen for strength or corrosion resistance and then treated or coated to give a hard wear-resistant bearing surface.

9.7.9 Conclusions

The prediction of the friction and wear characteristics of materials in sliding contact is not straightforward. Many factors influence performance, including pressure, sliding speed and surface temperature and their effects are often combined. Selection of materials from generalized catalogue data can therefore lead to problems in service. Where an accurate prediction of these characteristics is required, laboratory tests under conditions representative of those found in service should be conducted. With the wide range of dry bearing materials available, the designer should be able to identify one that suits her or his particular requirements.

9.8 Wear and surface treatment

9.8.1 Introduction

Surface engineering is an old concept. A classic example is that of the wooden stagecoach wheels fitted wth a cast-iron hoop to give improved strength and wear resistance. This example embodies all the principles of surface engineering; the wooden wheel is light, tough, flexible, cheap and easy to manufacture. The iron hoop, shrunk fitted, gives increased surface wear resistance and strengthens the whole structure by placing the body of the wheel in compression. Moreover, a worn hoop can be removed and replaced by a new one.

The principles arising in the example above are no less relevant to modern engineering. In all engineering applications it is the surface material of any component which has to co-exist with the external environment, such as contacting surfaces and process fluids. It is, therefore, not surprising that the majority of engineering failures arise from deficiencies in the surface material in dealing with fatigue, friction, wear, corrosion and so on. It follows that the designer, like the wheelwright, should choose the bulk material from the standpoint of structural and economic criteria, and the surface material to deal with the external conditions. The required surface properties can be achieved either by the application of specialized coatings or by modification of the bulk material.

In many applications the concept described above is not correctly applied. All too often it is the engineer, when making and using a component, who discovers the unexpected problem of wear, fatigue or corrosion and then returns to the designer to seek a solution. This usually turns out to be a compromise, in the form of a surface treatment or coating which does not affect the existing design or structural requirements of the component but gives only a partial solution to the tribological problem. It is better if the tribological demands are considered at the design stage and that surface engineering is employed alongside the requirements of the bulk material.

It is the designer, therefore, who has the job of engineering a component while it is still on the drawing board. He or she needs to assess the operational and environmental demands before deciding on the bulk material. Also, an understanding of the tribology of the application is required before an appropriate surface can be selected.

It would be a rare service situation that exhibited a single environmental feature that needed consideration, and most engineering components are subject to a complex range of factors, each affecting material selection. It is widely known, for instance, that complex demands are placed on turbine blade and ring materials for jet engines, where resistance to creep, fatigue, high-temperature oxidation, erosion, fretting, thermal shock, thermal cycling and thermal stability are all required in a single component. Similarly, complex demands are placed on many components in highly sophisticated modern engineering plant, typically in the petrochemical, nuclear process and manufacturing industries. However, even when the environmental demands are not as exacting as those mentioned, there is still a need to consider the effects of service and environmental factors on performance.

To be in a position to make a choice of a particular wear-resistant surface for an engineering application, the designer must first be able to predict the mechanism of wear that is likely to take place in service. He or she then should have some knowledge of what surface treatments and coatings are available. It is not necessary to know the precise details of how the processes are applied, but an awareness of the basic properties such as coating or case-depth, hardness and the likely effect of distortion or tempering on the substrate should suffice. It has to be remembered that surface treatments cover a very wide scale, from several centimetres thick to only fractions of a micrometre, and from comparatively soft materials to extremely hard ceramics. The task would also be made easier if data on friction and wear, preferably obtained under wear conditions appropriate to the particular application, were available.

Accordingly, this section is aimed at the designer; providing some insight into different wear mechanisms and how to identify them, listing and describing the main types of surface treatments and coatings available and then discussing tribological data and their use and interpretation. Finally, it presents a selection philosophy and discusses the vital area of quality control; an important aspect when applying any new process to critical or expensive components.

9.8.2 Wear types

Before prescribing a solution, it is important that the designer or engineer should understand which wear process will be in operation in a particular application. The main wear processes occurring in industry are listed below. For a further description of the fundamental aspects of friction and wear the reader is referred to Section 9.1.

9.8.2.1 Abrasive wear

This form of wear, which is said to account for more than 50% of wear problems in industry, occurs when hard particles such as rocks or metal fragments slide or roll under pressure across a surface. This action tends to cut grooves in much the same way as a cutting tool, displacing elongated chips or slivers of metal.

'Two-body' abrasive wear occurs when particles such as coal or metal ores are transported across a surface. A similar wear process, on a much finer scale, is found in areas such as printing or textiles. This time, the abrasion is by the small particles of pigment carried in the product.

'Three-body' abrasion results from high-stress situations where the particles are trapped between the loaded surfaces in relative motion. The particles are often reduced in size as they would be in ore-crushing machines or when foreign particles ingress into bearings. Generally, only a small proportion of the particles cause wear, those rolling or sliding produce little wear but, as the attack angle is raised, high wear rates are experienced. With abrasive wear, the load on the particles, their shape and hardness are all important; as, together with component hardness, they will determine whether surface penetration or particle crushing occurs.

9.8.2.2 Adhesive wear

When metal surfaces slide over one another, and the contact pressure is sufficiently high to cause local plastic deformation and welding, adhesive wear occurs. Clean surfaces, non-oxidizing conditions and chemical similarities promote this type of wear, which accounts for about 15% of industrial wear problems. Initially, it occurs between a few particles, which increase in size as motion continues and eventually the junctions rupture to give material transfer. The adhesion and transfer process can lead to debris trapping which may add a three-body abrasive wear mechanism to the process.

Wear under adhesive conditions is often subject to sharp transitions in behaviour and two regimes, 'severe wear' and 'mild wear', can be encountered. These are caused when changes in load or sliding speed produce thermal changes at the rubbing surface. In 'mild wear', the surface oxide protects the rubbing parts and damage is slight. In 'severe wear', the oxide is disrupted, metal-to-metal adhesion results and wear rates can rise by two orders of magnitude. This form of severe wear is common with metals having only thin, brittle oxide films and results in 'galling' of materials such as stainless steel and aluminium and titanium alloys.

Another form of adhesive wear is termed 'scuffing'. It occurs under partially lubricated conditions when the oil film thickness is insufficient to give complete protection to the rubbing surfaces. Metal-to-metal contact leads to considerable surface deformation and heating, and with additional carbon being supplied by degradation of the lubricant, metallurgical changes are produced at the surface. It is quite common to find hard and brittle layers of carbide produced at the surface and for subsequent cracking and spalling to occur.

9.8.2.3 Erosive wear

Erosion is a form of abrasive wear resulting from impact and cutting by hard particles carried in a gas or liquid. It occurs in components such as turbines, pipework, pumps and valves. Erosion requires a different treatment because the contact stresses arise from the kinetic energy of the particles as they encounter the surface. Particle velocity, abrasive size and impacting angle are all important in determining the amount of erosion. Generally, the wear volume is proportional to the cube of the velocity. When the impacting angle is small, a cutting action takes place and an increase in the material hardness reduces the wear. At large impacting angles, the solution can be quite complex; the wear is due to surface deformation and soft materials may perform better than hard ones.

A particular form of erosion can occur without any abrasive content in the fluids. High-velocity impact of fluid droplets can cause plastic deformation of local areas of a surface and the repeated action results in a fatigue-type pitting failure. Additionally, 'cavitation' erosion damage can be caused by the impact produced from the collapse of vapour or gas bubbles formed in contact with a rapidly moving or vibrating surface. Again, the resultant damage is typical of a fatigue-type process.

9.8.2.4 Fretting wear

Fretting is produced by small oscillatory displacements at interfaces; it occurs in heat exchangers, gas turbines, bearings and where there is a source of continual vibration. There are a number of stages, starting with adhesion and metal transfer between the rubbing parts. This produces wear debris which then oxidizes to form an abrasive. Because the motion is small, the abrasive is retained in the contact area and itself becomes a source of further wear. Eventually, a steady-state wear rate is established.

When dealing with ferrous materials, operating in air, it is normal to get reddish-brown oxide particles or a 'red mud'-like substance surrounding the damaged area; this is the result of 'fretting corrosion'. The high-cycle oscillatory displacements can also lead to surface fatigue and thus 'fretting fatigue' can apply.

Fretting, therefore, involves a complex interaction of adhesion, corrosion, abrasion and fatigue. Further details are given in Section 9.9.

9.8.2.5 Corrosive wear

Oxidative or corrosive wear occurs when the sliding surfaces are attacked by a highly oxidizing or corrosive environment. This results in a build-up of loosely adherent corrosion products which are quickly removed by the wear process. Thus, a fresh metal surface is exposed to further rapid corrosion. Since no passivating layer is maintained, the rate of material loss can be very rapid and can far exceed the sum of the two processes (dry wear or simple corrosion) acting separately.

9.8.2.6 Fatigue wear

Fatigue wear is characteristic of surfaces contacting under high Hertzian contact stresses; typically, the rolling/sliding conditions in ball bearings and gears. The surfaces are usually lubricated and, for long periods, no significant wear takes place. However, the cyclic compressive and tensile stresses produce metallurgical changes in the surface and cracks are initiated. The cracks propagate steadily into the material at an acute angle to the rolling direction and then parallel to the surface to detach material and form a pit. Once such a situation is reached, the rate of material loss becomes rapid and catastrophic failure results.

9.8.2.7 Identifying the wear process

There are two approaches to wear identification. The first is to anticipate it at the design stage; the second usually takes the form of failure analysis; examining worn parts or wear debris with a view to prescribing a solution.

With careful thought at the design stage, it is usually possible to anticipate likely wear problems. If there is metal-to-metal contact in a clean, marginally lubricated machine, wear problems are likely to be of an adhesive type. With unhardened surfaces and no lubrication, the wear may be in the severe regime. If materials such as stainless steel, aluminium or titanium are involved in high load, dry contact, then severe adhesive wear and galling are almost inevitable. When abrasives are present, one needs to obtain data on the size and hardness of the particles, together with information on likely contact loads. This will enable one to characterize the probable stress. If a corrodent is present, then one can anticipate aggressive chemical wear. When vibrations are present, then fretting is likely and with cyclic loading, particularly under Hertzian contact conditions, fatigue wear could occur. Stress calculations, particularly those occurring sub-surface, are a vital part of any selection procedure.

Examination of worn parts, even with a simple low-powered magnifying glass, can yield a useful insight into the wear process. Grooving and cutting (Figure 9.60(a)) indicates abrasive wear, while a torn and rough bright surface (Figure 9.60(b)) suggests severe adhesive wear. Mild adhesive wear is characterized by a smooth oxidized rubbing surface (Figure 9.60(c)). Significant quantities of oxidized debris (Figure 9.60(d)) indicates fretting, and fatigue wear is, of course, characterized by pitting (Figure 9.60(e)).

Although it is possible for the engineer to make some characterization of the wear process, the analysis is best left to the expert in tribology. An alternative approach is to monitor the wear debris since wear particles are unique, having individual characteristics which bear evidence of the conditions under which they were formed. Careful examination of the morphology and determination of the composition of wear particles can thus yield specific information concerning the surface from which they were produced, the mechanism of their formation and the operative wear mode in the system from which they were extracted. Ferrography[38] is a technique developed to separate wear debris and contaminant particles conveniently from a lubricant for examination and analysis. It consists of decanting a sample of diluted machine lubricant down a glass slide held over a magnetic field. Particles are then separated according to size and composition. Particles generated by different wear mechanisms have characteristics which may be identified with a specific wear mechanism. For

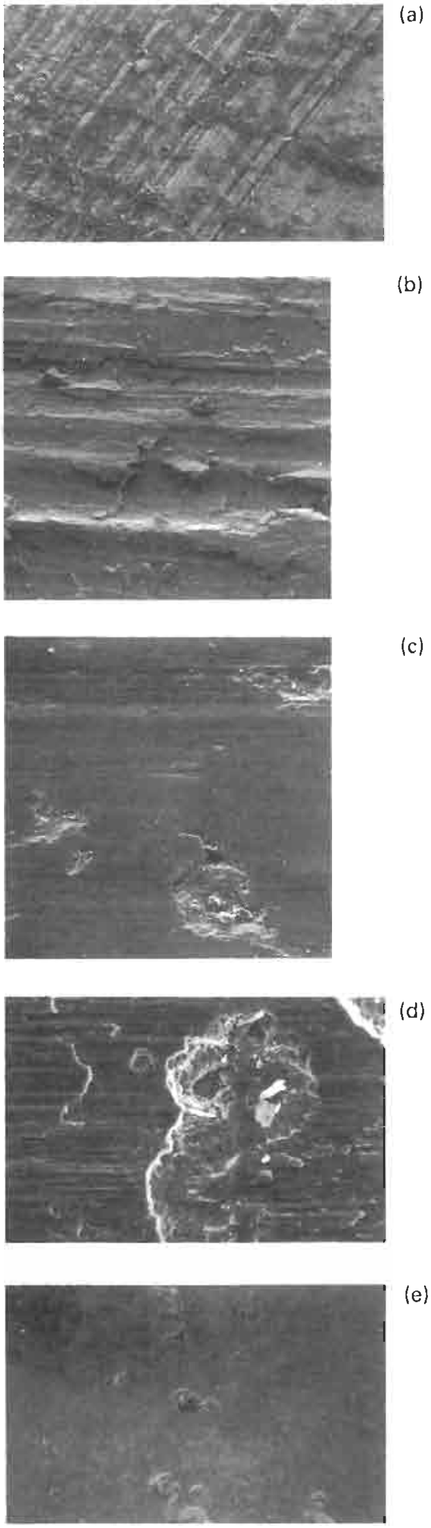

Figure 9.60 Appearance of worn surfaces. (a) Abrasive wear; (b) severe adhesive wear; (c) mild oxidative wear; (d) fretting wear; (e) fatigue pitting

example, wear particles found in most machines have the form of platelets and indicate normal permissible mild adhesive wear. Abrasive wear gives a debris in the form of miniature spirals, loops and bent wires similar to cutting swarf from a machining operation. A concentration of such particles is indicative of severe abrasive wear. Severe adhesive wear produces large metallic particles and fatigue gives laminar, spherical and then chunky particles as the failure progresses. A wear particle atlas[39] has been produced to assist with particle characterization.

It is possible, therefore, to identify wear processes, but by this time costly failures have occurred and there is no substitute for addressing the problems at the design stage and employing the correct form of surface engineering.

9.8.3 Surface treatments and coatings

There are many ways of treating metal surfaces to improve their wear resistance or to reduce friction. They can be grouped into three broad categories:

1. Modifying the surface without altering the chemistry;
2. Changing the chemistry of the surface;
3. Adding a layer of new material to the surface.

Techniques from any of these categories may be used in combination with others; for example, electroplating may be followed by a diffusion treatment, a sprayed coating may be sealed with a polymer or lubricant or two different coating processes may be used to lay down duplex layers. The various processes are described in detail below and the main properties are summarized in Table 9.21.

9.8.3.1 Modifying the surface without altering the chemistry

The most common method of modifying the surface is to transformation-harden the outermost region of the component by localized heating. The method of heating is usually by induction or by flame, but more specialized treatments using a laser or electron beam as the heat source are also available. First, the desired core properties are developed by standard heat treatment practices. The surface is then hardened by rapid heating to transform the surface regions to austenite, and quenched to produce martensite. In most cases, it is usual to follow the hardening by a low-temperature tempering treatment to relieve the internal stresses. The process has the advantage that it can be applied to selected areas of a component without affecting the bulk properties of the material.

Transformation-hardening is used to combat wear under high loads, where there is sufficient case depth generated to support the contact stresses. Hardening the steel surface results in increased support to the oxide layer and, in adhesive wear situations, gives mild wear. It is also effective against high-stress abrasive wear (unless the abrasive is exceptionally hard, such as alumina or silicon carbide). However, transformation-hardening produces little change in the corrosion properties and components can suffer both corrosive wear or fretting damage.

Induction hardening[40] When an electric current is passed through a conducting coil a magnetic field is produced inside it. If the magnetic flux is created by a high-frequency alternating current it gives rise to eddy currents in the surface of any metal object placed within the coil and surface heating results. In this way, the surface of steel parts can be heated above the austenitic transformation temperature. Quenching of the surface is usually achieved by using a water- or oil-emulsion spray attached to (or below) the heating coil, with the component being passed through at a predetermined rate.

Steel grades suitable for induction hardening are those having a carbon content in the range 0.30–0.50%. If steels with a higher carbon content than 0.5% are to be treated, there is a risk of cracking and the heat treatment must be carefully controlled. The steel, prior to induction hardening, should be in the hardened and tempered or normalized state. Fully annealed steel is unsuitable, because the time needed to dissolve the carbides is longer than the heating-up time.

The depth of hardening and actual hardness depend on a number of factors. The carbon content of the steel has a decisive influence on the hardness, and the depth of hardening is determined by the temperature, the holding time, the frequency of the inductive current and the quench rate. For

Table 9.21 Important properties of wear-resistant surface treatments and coatings

Treatment type	*Substrates*	*Treatment temperature (°C)*	*Typical case or coating depth*	*Hardness (HV)*
Induction hardening	0.3–0.5%C steels	Over 800 (surface)	Several millimetres	600–800
Flame hardening	0.3–0.5%C steels	Over 800 (surface)	Several millimetres	600–800
Laser hardening	0.3–0.5%C steels	Over 800 (surface)	Up to 0.75 mm	600–800
Cold working	Steels	Ambient	Up to 0.25 mm	Slight increase
Carburizing	Steels	Over 800 (bulk)	Several millimetres	600–800
Carbonitriding	Steels	Over 800	Several millimetres	600–800
Boriding	Steels	800–1000	0.1 mm	Up to 1500
Carbide diffusion	High-carbon steels	1000	10 μm	Up to 3500
Nitriding	Alloy steels	500–600	0.2 mm	700–1200
Nitrocarburizing	(i) Alloy steels	500–600	0.2 mm	700–1200
	(ii) Carbon steels	500–600	20 μm	500–700
Oxidation	Steels	300–600	5 μm	approx 350
Plating/diffusion	Steels	500–600	20 μm	200–950
Anodizing	Aluminium alloys (low Cu+Si)	60	20 μm	500–600
Electrolytic/diffusion	(i) Aluminium alloys	150	20 μm	400–450
	(ii) Copper alloys	400	20 μm	400–450
Ion implantation	All metals	100	0.1 μm	Unknown
Physical vapour deposition	Steels	200–500	3 μm	Up to 4000
Chemical vapour deposition	Tungsten carbide steels	Over 800	5 μm	Up to 2000
Chromium plating	Most metals	60	20–100 μm	900
Electroless nickel	Most metals	60	10–50 μm	550–1000
Flame spraying	Most metals	100–200	Up to 0.5 mm	Depends on material
Spray/fuse	Steels	700–800	Up to 0.5 mm	Up to 900
Plasma spraying	Most metals	100	Up to 0.2 mm	800–1600
High-velocity spraying	Most metals	100	Up to 0.2 mm	800–1600
Welding/cladding	Steels	Over 800	Several centimetres	Depends on materials

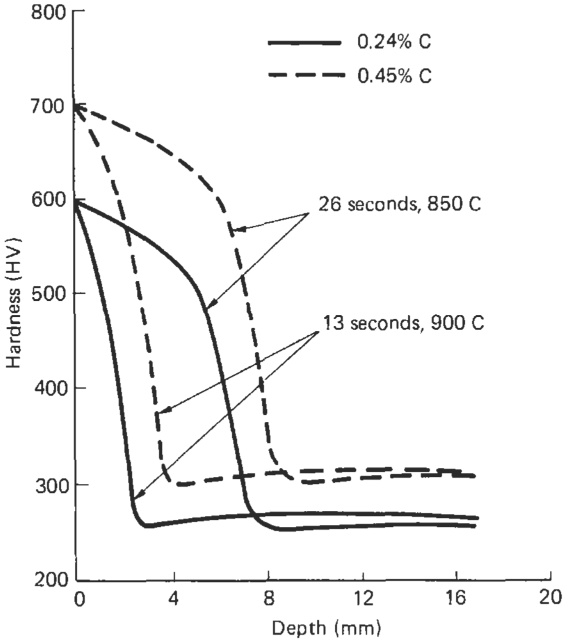

Figure 9.61 Hardness profiles for 0.24%C and 0.45%C steels after induction hardening (after Thelning[40])

instance, Figure 9.61 shows the typical behaviour of two steels with 0.24% and 0.45% carbon with different holding times. In fact, the temperature, heating time and holding time during induction hardening can all be closely controlled, so it is possible to select in advance the required hardness and depth.

Induction hardening is ideal for large objects and has the advantages of low cost, short heating periods with minimum surface decarburization and oxidation. Dimensional changes are minimal and case depths are of the order of several millimetres.

Flame hardening[40] Flame hardening and induction hardening give broadly equivalent results. Flame hardening is achieved by heating the steel to the hardening temperature using a welding torch and then quenching in oil or water. It is less easy to control and surfaces can sometimes be overheated, oxidized and decarburized. Best results are obtained on bodies having rotational symmetry by spinning them on a rotating table under the flame.

The grades of steel recommended for induction hardening are also suitable for flame hardening and the resulting hardness and case depth is again determined by carbon content, hardening temperature and quench rate. Flame hardening has the advantage that it can be directed to selected surface areas.

Laser and electron beam hardening Lasers are traditionally used for welding and cutting but they can now be employed as a versatile heat treatment tool.[41] The laser is focused onto the surface and scanned over the specific area where increased hardness is required. Because of the massive amount of steel around the narrow heated area, the process is self-quenching. As with induction and flame hardening, the ideal steels are those with a medium carbon content but the achievable case depth is limited by the onset of surface melting and is usually 0.5–0.75 mm.

There are many advantages in using laser processes; they provide fast production, low distortion and avoid the necessity for post-treatment operations, including machining or grinding. However, lasers are expensive and there is some indication that electron beam processes may be more economical than laser techniques since both capital and operating costs are lower. In electron beam hardening the beam operates in a vacuum but the workpiece needs only to be at 0.06 m bar pressure. Area hardening is obtained by scanning the area in a raster; the dwell time, beam energy and focus all being controlled by computer.

Cold working An alternative to transformation hardening the surface is to increase the hardness by cold working. The most common method is to use shot peening[42] where compressive stresses are induced in the exposed surface layers of metallic parts by the impingement of a stream of shot. The shot, made of iron, steel or glass, is directed at the metal surface at high velocity with careful control of angle, scanning rate and shot recycling.

The increase in hardness produced by this treatment is modest. The most important effect is the production of a surface compressive stress, extending to a depth of up to 0.25 mm. If a bar is treated on one side only, the effect is dramatically illustrated by significant bending of the component. The process is, therefore, used more to improve fatigue properties and to increase resistance to stress corrosion cracking rather than to give better abrasive or adhesive wear resistance.

9.8.3.2 Changing the chemistry of the surface

The surface chemistry can be altered in many ways. Most commonly, it involves the introduction of interstitial elements[43] such as carbon, nitrogen or boron or a combination of carbon and nitrogen into the metal (usually ferrous) surface at elevated temperature. Other processes, such as aluminizing, chromizing and siliconizing, use metallic or metalloid elements to alter the chemistry of the surface. Equally, the interstitial element can be implanted into the surface (at ambient temperature) in the form of a high-energy ion beam (ion implantation). There are also processes which combine electroplating and diffusion treatments. These involve the deposition of materials such as tin, sulphur or bronze onto a ferrous component followed by a diffusion treatment to form compounds at the surface. Similar types of treatment are also available for non-ferrous materials such as bronze–titanium alloys and aluminium alloys. Oxide layers can produce significant tribological advantages and these can be produced on both ferrous materials (by thermal treatment) and on some non-ferrous materials (by anodizing).

By far the most important of these techniques are the thermochemical diffusion treatments for ferrous metals. These come under two headings: those carried out at relatively low temperatures in the ferritic range, and those performed at high temperature in the austenitic range. The high-temperature processes are discussed first.

Carburizing Carburizing[40] (also called case hardening) is the most commonly used of the surface-modification processes. Ferrous alloys are heated to a temperature above the ferrite/austenite phase transformation temperature (825–925°C) while in contact with a solid, liquid or carbonaceous medium. This results in the diffusion of carbon into the steel to a depth controlled by the diffusion time and temperature, so that the surface can then contain up to 0.7–1.0% carbon. The steel is then quenched to produce a martensitic structure with a hardness of up to 1150 HV. Tempering, to reduce residual stresses, is usually performed at between 150°C and 180°C.

There are four different techniques for carburizing. In pack carburizing, the parts are placed in contact with charcoal in a sealed box and carburizing takes place via a reaction at the surface to carbon dioxide and carbon monoxide. In salt bath carburizing, the active agent is sodium cyanide and the reaction again proceeds by the gaseous phase. Nowadays, the most popular method is by gas curburizing, when hydrocarbons, as well as carbon monoxide and carbon dioxide, are employed. Finally, there is also the possibility of plasma carburizing,[44] a technique using a low-pressure glow discharge. It is still in its infancy but promises to be more energy-efficient and can produce deeper cases than conventional carburizing.

Carburizing, like induction hardening, produces hardened layers to a depth of several millimetres. The depth of case hardening is defined as the distance from the surface to a plane at which the hardness is 550 HV. Figure 9.62 shows, schematically, the hardness profile across a section of a typical case-hardened steel. The actual hardness and depth of hardening are dependent on several factors; for instance, the carbon potential of the carburizing medium, the quenching temperature, the quenching medium (water quenching produces a greater hardened depth than oil quenching) and the steel composition.

The dimensional changes that occur during case hardening are critical, since they determine the extent of any post-grinding operations. Changes are usually of the order of 0.1% but they can be both expansion or contraction, depending on the type of steel, the depth and method of hardening and material dimensions. The user is referred to reference 40 for detailed examples on how different-shaped components are distorted during treatment.

Carburizing is used for a wide range of components, specifically to improve abrasive or adhesive wear resistance and to reduce fatigue. A high hardness and good case depth are essential to combat high-stress abrasive wear (for instance, on pump parts). Fatigue properties are improved by the increased hardness and also by the production of a compressive stress. Many gears are carburized. However, carburizing will have little benefit to corrosion resistance so that corrosive wear or fretting situations may not be suitable applications.

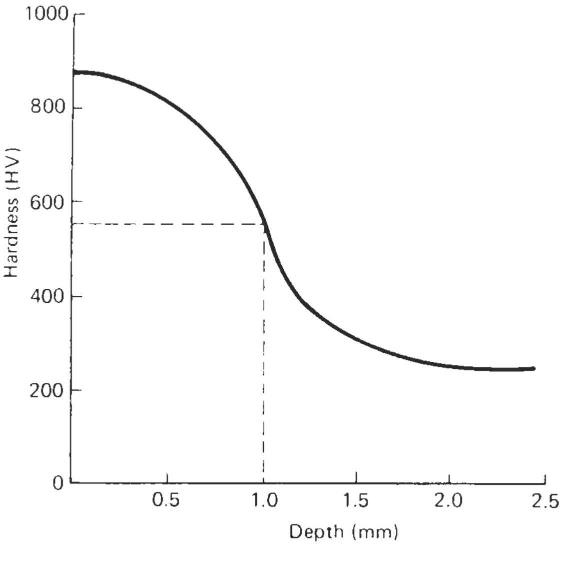

Figure 9.62 Schematic representation showing depth of case-hardening

Carbonitriding[40] In the case of carbonitriding, the name is misleading. It is not a form of nitriding, which is performed at a relatively low temperature with the steel in the ferritic condition, but it is a form of carburizing. The treatment involves the introduction into the steel of nitrogen as well as carbon at temperatures between 700°C and 900°C, either from a molten salt bath or in a gas-carburizing atmosphere into which ammonia gas has been introduced. It might have been more logically named nitrocarburizing but this term has been used to describe processes at lower temperature (discussed later) and confusion is bound to continue.

The addition of nitrogen to the case of a steel considerably increases its hardenability and it leads to improved wear resistance compared to ordinary carburizing. Consequently, engineering components made from plain carbon steel, which on carburizing would have to be quenched in water, can be quenched in oil with less danger of distortions.

There are several proprietary variations on this type of process designed to give surface layers with specialized properties. The Noskuff[45] treatment consists of an initial carburizing treatment at 800–900°C before the hot parts are transferred to a Noskuff bath. This contains cyanide and 10–20% sodium cyanate at a temperature of 700–760°C and parts are treated for 5–15 min. The parts are then quenched into oil or water, in order to harden the carbon-rich case which would have remained in the austenitic conditions during the time of the Noskuff treatment. As the name implies, this treatment gives good resistance to scuffing by producing a hard martensitic layer near the surface (Figure 9.63).

Boriding[40,46,47] This heat treatment is based on the diffusion of boron into plain carbon and low-alloy steels, converting the metallic surface of components into iron boride. It is a pack process in which engineering components are placed into a muffle furnace and entirely surrounded by a boron-rich granulate. Heat treatment is carried out at 800–1000°C for 1–8 h, depending on the depth of the required layer. The surface hardness of treated steels is high, typically 1500 HV, and the case depth to a hardness value of 500 HV is typically 0.05 mm.

All steels can be borided but the thickness of the borided layer decreases as the alloying element content increases.

Chromizing, aluminizing, siliconizing[48] There are a number of high-temperature pack processes aimed at surface diffusion

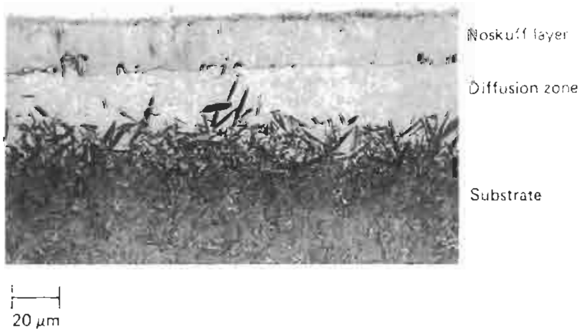

Figure 9.63 Polished microsection through a Noskuff layer

of metals such as chromium, aluminium and silicon into ferrous surfaces. These are very specialized techniques for improving wear and corrosion at elevated temperatures in hostile environments. For instance, they are used in plant in nuclear reactors and for containing agressive chemicals in electrical batteries.

Carbide diffusion treatment Carbide diffusion coating is a relatively new addition to the range of high-temperature processes. By using very specialized salt baths at closely controlled temperatures (typically, 1020–1050°C), compound layers of alloy carbides, such as vanadium carbide, niobium carbide and chromium carbide, can be produced on the steel surface. The mechanism of carbide layer formation relies on carbon from the substrate migrating to the surface to combine with the metallic elements in the salt. The process produces a dense layer with a clear substrate boundary (for example, the Toyota Diffusion Process[49] – Figure 9.64). The hardness varies with the type of carbide, but can be as high as 3500 HV.

The process is used extensively to treat tools used for steel forming, cutting, forging or press tools and greatly reduces adhesive wear and metal pick-up. The high surface hardness also gives good resistance to abrasive wear. However, the layers are relatively thin (5–15 μm) and loads should not be excessive.

Component growth is equivalent to the thickness of the layer.

Nitriding[40] All the processes described above are performed at a high temperature, with the steel in the austenitic condition. They involve the diffusion of interstitial alloying elements followed by a quench and temper and, therefore, significant distortion. Nitriding is carried out with the steel at a lower temperature, in a ferritic condition and there is no phase transformation on cooling and, consequently, less distortion. Because the temperature is lower, diffusion is slower and the case depths are more shallow than those produced by austenitic thermochemical diffusion treatments.

Nitriding is a case-hardening process in which nitrogen is diffused into the steel surface. The process is carried out at 500–525°C, which is below the eutectoid temperature, and involves the formation of hard, wear-resistant iron-alloy nitrogen compounds. No phase transformation can occur on cooling of the steel and no quenching is required to develop surface hardness. Only steels which contain stable nitride-forming elements such as aluminium, chromium, molybdenum and vanadium are suitable for nitriding. Prior to nitriding, the steel must be hardened and tempered at a temperature of about 650°C to produce a fully stabilized tempered martensitic structure.

There are three methods of nitriding – gas nitriding, plasma (or ion) nitriding and powder nitriding. These can each involve the absorption of nitrogen only, but a fourth technique, the salt bath process, always employs the diffusion of both nitrogen and carbon. This is often referred to as salt bath nitriding but it is more properly called 'nitrocarburizing'. This process is discussed below and is not to be confused with the austenitic treatment; 'carbonitriding' (Section 9.8.3.2). Certainly, any engineer or designer can be excused if they become confused. The gas or plasma nitriding processes produce only nitrides but if hydrocarbons are added to the gas mixtures, both nitrogen and carbon are diffused into the surface. Hence, both 'gas nitrocarburizing' and 'plasma carburizing' can be added to the bewildering list of processes.

Gas nitriding[40] takes place at about 520°C for periods between 10 and 100 h, giving case depths between 0.2 and 0.7 mm. (The case depth for nitrided layers is usually defined as the depth at which the hardness falls to 400 HV.) The process uses ammonia flowing over the components in an electrically heated furnace. A typical nitrided case is shown in Figure 9.65 for a 3%CR 0.5%Mo alloyed steel. There is a surface compound layer of iron nitrides (called 'which' layer because it is non-etching) which can be up to 50 μm thick. Below that there is a hard diffusion zone with alloy nitride precipitates.

Plasma nitriding[40,50] uses an ionized low-pressure gas, usually a mixture of nitrogen and hydrogen, which serves as both a source of heat and a supply of nitrogen. Ionization is created by applying a potential (up to 1000 V) between the workpieces and the chamber. The characteristics of the nitrided cases are similar to those produced by gas nitriding but the plasma process is flexible and can be more closely regulated. The temperature can be varied between 420°C and 700°C and the composition of the surface iron nitride compound layer can be closely controlled. The process can effectively treat the internal surface of holes as small as 2 mm diameter and chambers are available that can accommodate components up to 5 m long. Powder nitriding[40] is probably the least used of the nitriding processes. It is similar to pack carburizing, the parts being packed in contact with a nitrogen-

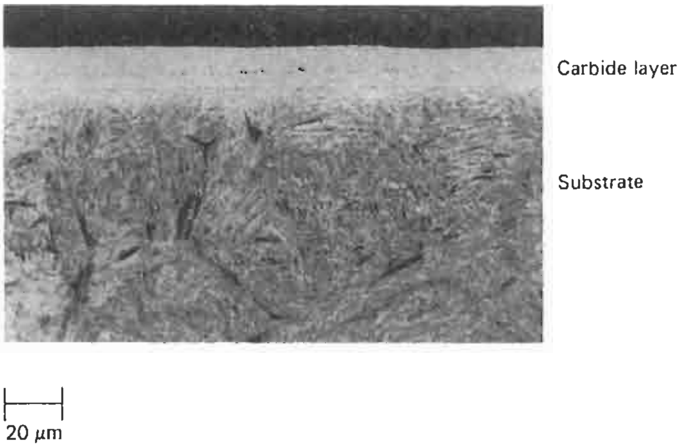

Figure 9.64 Toyota diffusion treatment

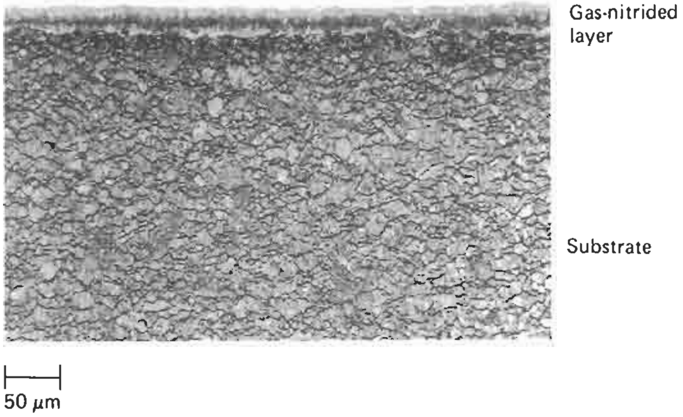

Figure 9.65 Gas-nitrided Cr/Mo steel

rich powder. It gives equivalent results to gas nitriding but is limited in processing time (and, therefore, case depth) to about 10 h because of the possibility of pitting.

As stated above, any steel with a nitride-forming alloying element can be treated. However, the response to nitriding differs greatly according to the composition of the steel. Figure 9.66 shows typical hardness profiles for four plasma nitrided steels; a 3%Cr 0.5%Mo steel, a high-speed steel, a hot-work steel and an austenitic stainless steel. Broadly, the case hardness increases as the content of alloying element increases (e.g. chromium) but the case becomes more shallow and abrupt. Steels that are very rich in chromium can only be effectively treated by the plasma process, ion bombardment being the only method of breaking down the chromium oxide surface layer to allow diffusion of the nitrogen. There is also a difference in the corrosion properties. A nitrided low-alloy steel can form a surface compound layer (iron nitrides), which improves corrosion resistance over that of the substrate. In contrast, plasma nitrided stainless steel forms no compound layer and corrosion resistance is seriously impaired. In fact, nitriding a stainless steel which has been selected for its corrosion properties is generally a pointless exercise.

Compared to the austenitic processes, the dimensional changes associated with nitriding are small. Typically, a component will swell by 0.02 mm per side.

Although nitriding produces high values of surface hardness, the treatment is not necessarily suitable for abrasive wear situations. Under high point loadings, the case is liable to chip or flake and parts with sharp corners or cutting edges can be particularly vulnerable. In fact, nitriding finds most of its uses in reducing adhesive wear; particularly eliminating severe wear and scuffing. The compound layer tends to give reduced friction and, because of its improved corrosion resistance, can reduce chemically assisted wear. It must be remembered, however, that if the compound layer is removed (for instance, by grinding to a required dimension) or if the substrate is a stainless steel, no such improvement will be gained.

Nitriding also improves the fatigue properties and, because of its good hot hardness and resistance to tempering, it can be applied to parts that might operate at temperatures up to 600°C.

Nitrocarburizing[40,51] The longest-established method of nitrocarburizing is, as stated above, the salt bath process. It uses a mixture of salts based on sodium and potassium cyanide which react to form cyanates and supply nitrogen and carbon to the surface being treated. Treatment times are usually 2–4 h. There are a number of proprietary variations on the process, each bringing a new development. The Tufftride process uses a titanium rather than an iron crucible to minimize decomposition of the salt and air is injected into the bath to promote the formation of the cyanate. In the Sulfinuz process, sulphides are added to the salt and these help to catalyse the conversion of the cyanides to cyanates and also lead to diffusion of sulphur into the surface. This gives excellent anti-scuffing properties and parts which have been Sulfinuz treated should not be finish ground. A second variation of the sulphur-rich treatments is the Sursulf process, where lithium

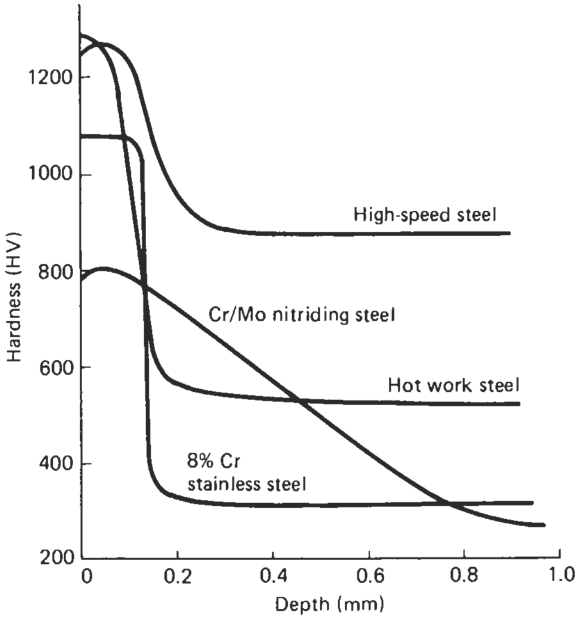

Figure 9.66 Typical hardness profiles for four different plasma-nitrided steels

compounds are used instead of cyanides to reduce environmental problems.

It is these environmental problems with salt baths that have led to the development of the gas nitrocarburizing and plasma nitrocarburizing processes. The gas process involves treatment at about 570°C in an atmosphere of ammonia and endothermic gas for 2–3 h, followed by a quench in oil (to give maximum improvement in fatigue properties) or cooled under recirculating gas. As with the salt bath processes, there are several proprietary variations and some of these (for instance, the Nitrotec[52] process) are finished with an oxidation stage, to give a slightly porous surface, and then waxed or oiled. This reduces friction and improves corrosion resistance.

The plasma process is similar to that for nitriding but methane gas is added to the gas mixture to contribute carbon as well as nitrogen.

Broadly, nitrocarburizing acts in a similar way to nitriding and, for alloy steels, gives equivalent case properties and dimensional changes. However, the nitrocarburizing processes are now used increasingly to treat (and uprate) plain carbon steels. The improved control over the chemistry now allows the processes to produce hard, dense surface layers of iron nitrocarbides; the same 'white' or 'compound' layers which used to be regarded as a nuisance during plain nitriding. They are usually 25–50 μm thick. In the absence of any alloying elements in the steel, there is no hardened diffusion zone under the surface and there is a sharp transition from the hard layer (over 600 HV) to the soft substrate (Figure 9.67). This means that applications should be limited to those employing light loads but there can be no doubt that these processes provide an excellent way of improving the wear and corrosion properties of cheap carbon steels.

Oxide treatments[53] Oxides which are deliberately grown on the surface of steel components can produce significant tribological advantages particularly in preventing adhesive wear and, when oil is present, preventing scuffing wear and metal-to-metal transfer.

There is a range of possibilities for treating steels. Oxide coatings can be produced by immersion in caustic nitrate solutions and this treatment is commonly applied to components such as needle or roller bearings, gears and piston rings. Other methods can involve a simple thermal exposure at a temperature between 300°C and 600°C to produce the oxide, or the parts can be steam tempered or autoclaved. The most striking example of the use of steam tempering is on high-speed steel cutting tools where the oxide reduces pick-up and extends the life by about a factor of 2 over that given by bright components. The oxide film is mainly Fe_2O_3 and is about 3 μm thick.

Iron oxides are not particularly hard or tough and cannot be expected to be effective in reducing abrasive wear.

Plating/diffusion treatments Although these processes involve the addition of a new material to the surface in the form of a coating, the post-diffusion treatment brings them under the category of 'altering the surface chemistry'. There are a number of proprietary treatments under this heading, each aimed at giving a ferrous surface the desirable tribological properties associated with some non-ferrous materials.

The Stanal[54,55] process is a two-stage treatment involving electrodeposition on ferrous metals of a tin–antimony alloy, followed by heat treatment at 500°C in a nitrogen atmosphere. The alloy coating becomes integrated with the metal base and tin, being the principal element added by diffusion, forms intermetallic Fe–Sn–C such as Fe_3SnC.

The hardness of the diffused layer can vary between 600 and 950 HV, depending on the carbon content of the steel. In addition, the presence of carbon assists the mutual diffusion of iron and tin, and increases the depth of the diffused layer. Carbon steel treated by this process has exceptional corrosion resistance and, when tested in a salt spray, is claimed to be only marginally inferior to stainless steel. Treatment thickness is about 20 μm.

The Forez[54,55] process was designed to apply to ferrous components (principally, mild steels and cast iron) a bronze coating which was capable of deforming plastically during running-in wear. The process is based on the electrolytic deposition of copper and tin followed by heat treatment at between 550°C and 600°C. This provides complete mutual diffusion of the elements within the coating and some diffusion of these metals into the steel. The hardness of the bronze coating can vary between 170 and 550 HV but is usually of the order of 300 HV. Thickness is typically 20 μm.

In the case of the Sulf-BT[55] process, a coating of iron sulphide (FeS) is applied to the surface of steel components. This electrolytic process uses a molten salt bath as the electrolyte at a temperature of only 190°C; the components to be treated are made the anode and the bath is made the cathode. The treatment time is nominally 10 min for which an FeS conver-

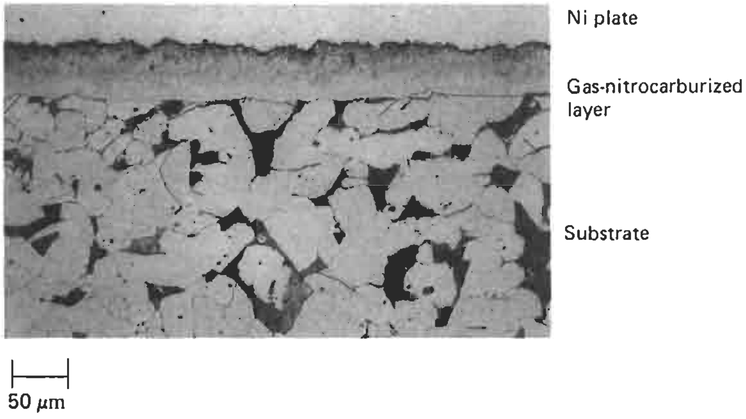

Figure 9.67 Gas-nitrided 0.4%C steel

sion coating of 7.5 μm may be expected. The treatment may be applied to all iron and steel components including those containing up to 13% chromium, whether or not they have been previously heat treated. The low operating temperature allows hardened or case-hardened parts to be treated without tempering-back as would occur after treatment by the nitrocarburizing processes.

Treatments for non-ferrous materials Although the majority of tribological applications involve steel components, there will be some occasions when the designer will wish to use non-ferrous materials. This may, for instance, be for reasons of weight saving, for increased specific strength or to satisfy a need for good thermal conductivity. These requirements might be met by titanium, aluminium or copper alloys but their use will inevitably bring tribological problems. In particular, aluminium and titanium alloys are very prone to severe wear, seizure and galling, and some sort of surface treatment will be required.

Anodizing[56,57] can be applied to a range of metals, including aluminium and titanium. It is an electrolytic process with the metal as the anode so that an oxide coating is developed on the surface (Figure 9.68). For wear resistance, a thickness of at least 20 μm is required, giving a growth in the surface of half that value. Oxide layers produced by anodizing have a hardness around 500–600 HV and, provided the loads are low, do give protection from adhesive wear. For aluminium in particular, the situation is very much one of 'ice-on-mud' with a hard, brittle layer on a very soft substrate. Also for aluminium, some anodizing processes are available with the addition of a solid lubricant such as PTFE. This further reduces friction and gives good 'non-stick' properties.

Other treatments are available for aluminium and titanium alloys. The Zinal[56] treatment for aluminium alloys involves a two-stage process; electrolytic deposition of 1 μm of zinc, 2 or 3 μm of copper and 12–15 μm of indium, then a diffusion treatment at 150°C for 3 h. The polymetallic coating becomes integrated within the aluminium alloy and intermetallic compounds of indium and copper are formed which gives rise to a surface layer hardness of 400–450 HV. The process improves the resistance to adhesive wear and galling (cold welding) and has no significant detriment to electrical or thermal conductivity or to corrosion resistance. Titanium alloys can be plasma nitrided, giving a thin layer of titanium nitride, but the process requires a temperature near 900°C and may give unacceptable distortion. Alternatively, they can be salt bath treated (the Tiduram[56] process) giving a compound layer of nitrides and carbides with good resistance to adhesive wear.

The Delsun[55] process has been developed specifically for copper-based alloys, brasses and bronzes. The process is similar in principle to the Zinal process for aluminium alloys, and involves the electrolytic deposition of an alloy of tin, antimony and cadmium followed by heat treatment at a temperature of 400°C. Diffusion occurs and intermetallic compounds are formed giving a surface layer with a hardness of 400–450 HV. It increases resistance to adhesive wear and seizure and improves corrosion resistance of both brass and bronze. Treatment thickness is of the order of 2 μm.

Ion implantation[58,59] Ion implantation involves the bombardment of the metal component surface with a high-energy beam of ions. Any species can be implanted but the usual material is nitrogen. The process takes place in a vacuum chamber and the accelerating voltage is of the order of 100 kV, giving a depth of penetration of about 0.1 or 0.2 μm. Thus, the affected zone is extremely shallow but the local effect on the surface properties is significant. A high-volume fraction of ions is forced into the metal (irrespective of the mutual solubility), creating a high compressive stress and increasing the hardness. The actual effects, because they act over such a shallow depth, are difficult to quantify but the process does bring benefits to both wear resistance and corrosion protection. The process appears to be most effective in situations where component wear is already low but further improvement is required. For instance, ion implantation can reduce adhesive wear on tungsten carbide forming tools and it is also effective against low-stress abrasive wear in plastic moulding tools.

Ion implantation is a low-temperature process (about 100°C) giving insignificant dimensional changes to the component. It is a 'line-of-sight' process so the parts to be treated have to be manipulated under the beam, inside the vacuum chamber. It is not, therefore, a cheap process but, for high-value components, the benefits can be well worth while.

9.8.3.3 *Adding a layer of material to the surface*

There is an enormous list of processes which involve coating a component with an extra layer of material. They range in thickness from just 1 or 2 μm to several centimetres and can

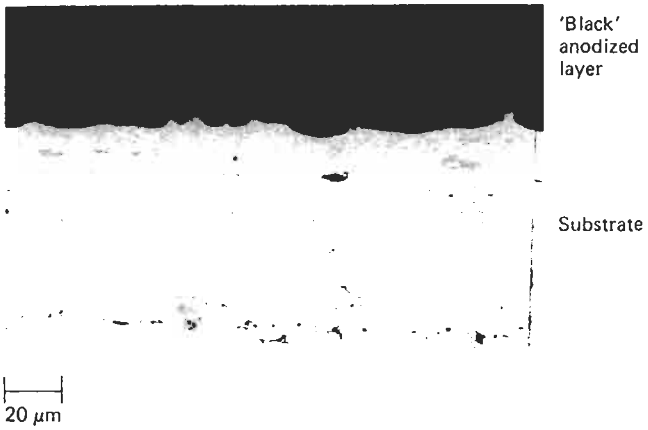

Figure 9.68 Anodized aluminium alloy

be ceramics, metals, alloys, plastics, solid lubricants or composites of more than one of these materials. They are applied for a variety of reasons; to reduce wear or friction, to give corrosion protection or to reclaim a component which has already suffered material loss by corrosion or wear. The main processes are described below in approximate order of thickness, starting with the thinnest coatings.

Ion plating, physical vapour deposition Ion plating[60] involves the deposition of thin coatings on components placed within a vacuum chamber. The system is evacuated and then refilled to a low pressure of argon gas. A high voltage is applied and a glow discharge is struck between the components (the cathode) and the chamber wall (the anode). When the material to be deposited is introduced into the discharge (say, by evaporation using a crucible with resistive heating) some of the atoms become ionized and are attracted towards the components. The ions transfer energy to the remaining neutral atoms by collisions and these, too, deposit on the components. Thus, a coating is steadily built up.

The wider terminology for this type of process is physical vapour deposition (PVD). Many materials can be deposited and there are many variations on the main principle, the differences occurring in the way material is introduced into the discharge. Metals such as aluminium or lead can be evaporated by resistive heating; aluminium coating being used for corrosion protection while lead is employed as a solid lubricant for applications in vacuum. To evaporate the high melting point refractory metals such as titanium or zirconium it is necessary to use either an electron beam (E-beam evaporative PVD) or an electric arc discharge (arc-evaporative PVD). Such systems are used to deposit coatings such as titanium or zirconium nitride, the nitrogen being added to the argon to create a reaction with the evaporating metal within the glow discharge. The process is also termed reactive ion plating. An alternative way of introducing the metal is to use the argon ion-bombardment from the glow discharge itself to 'knock off' atoms from the target by momentum transfer. This is called sputtering[61] and is a slower process than evaporative PVD. The sputtering process can be enhanced by the use of magnetic fields; this is termed 'magnetron sputtering'.[62]

PVD has two basic advantages. The first is that the thermal energy that would normally be required is replaced by ionization energy so that the temperature of deposition is relatively low (450°C or below). This minimizes distortion or tempering of components. The second advantage is that, prior to deposition, the components can be negatively biased so that they are atomically cleaned by ion-bombardment. This gives good adhesion to the coating.

The main coating applied by these PVD techniques is titanium nitride[63] (TiN). It has a gold colour, is extremely hard (more than 3000 HV) and significantly reduces adhesive wear. The coating thickness is usually 2–5 μm (Figure 9.69). TiN is applied widely to high-speed steel cutting tools and can increase the life of twist drills by up to a factor of 6 or, more usefully, can allow tools to be operated at greatly increased production rates (higher feeds and speeds – Figure 9.70). This is also used on tool-steels, improving the life of tools in cold forming, warm forming, blanking, rolling and shearing; typically by a factor of 3.

Because of its resistance to oxidation and adhesive wear, TiN can be used to resist fretting wear. It can be applied to shafts or housings for contact with plain or ball-bearings. However, like any thin coating, TiN is best suited to hard substrates which give it proper support.

Because of its very high hardness, TiN is excellent at resisting low-stress abrasive wear. It is particularly useful for protecting components that handle materials such as paper,

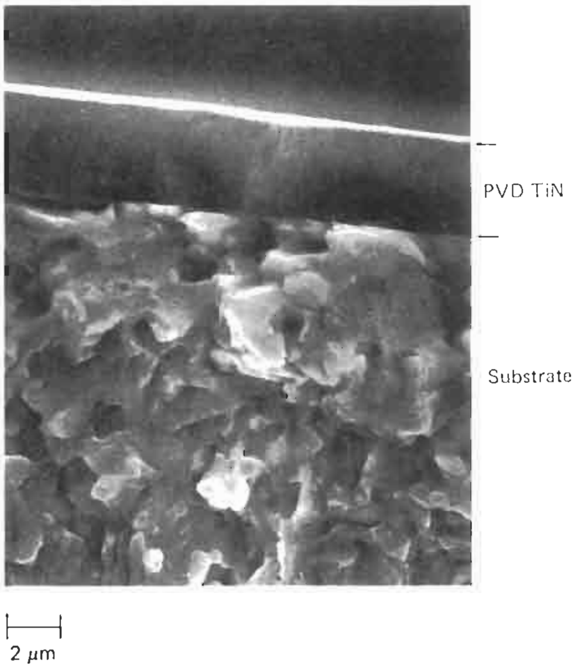

Figure 9.69 Fracture section through PVD TiN coated high-speed steel

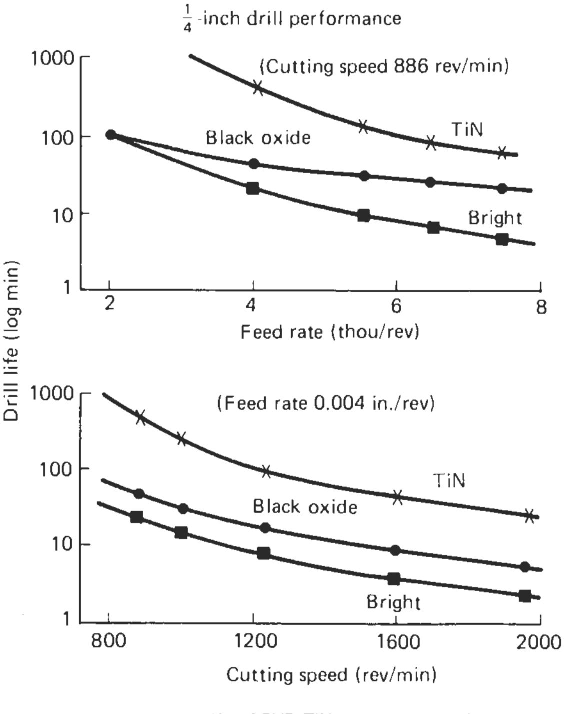

Figure 9.70 Improved life of PVD TiN coated twist drills

textiles and filled plastics. It can also be applied to shafts, gears or plain bearings in equipment handling abrasive slurries. If there is an element of corrosion then the substrate itself needs to be resistant. Alternatively, TiN can be applied over the top of another coating (for instance, electroless nickel). It can be applied to carburized surfaces with only minimal tempering, but if it is to be applied to a nitrided or nitrocarburized material, the compound layer must be removed first.

There are now PVD chambers that can coat components up to 3 m long and processing time and costs are being continuously reduced. PVD is a semi-'line-of-sight' process and so holes and re-entrant areas will receive less coating. Typically, at the equivalent of one diameter deep down a hole, the coating thickness will be 30% of that outside the hole. The coatings replicate the underlying surface texture without build-up on edges or corners.

Finally, PVD is a high-technology process. It is best suited for high-quality components; bright, clean, free from oxide, burrs and contaminants.

Chemical vapour deposition[64,65] Chemical vapour deposition (CVD) is, in many ways, a competitor of physical vapour deposition. The process is used to deposit metals and ceramics by the decomposition of a reactive gas at the surface of components placed within the chamber. For instance, titanium carbide is produced by a reaction between titanium tetrachloride and methane, or titanium nitride can be produced by replacing the methane with nitrogen or by using hydrogen and ammonia.

Deposition temperatures are very high, usually above 800°C. Thus there are potential problems with softening and distortion of substrates. In fact, the CVD process is most commonly used to coat tungsten carbide tooling, particularly the indexable inserts used for high-speed turning. The cobalt-cemented carbide is an ideal substrate because it has a similar coefficient of thermal expansion to the TiC or TiN coatings. Also, it does not suffer any volume change during cooling and gives good support.

There can be problems of decarburization of substrates during deposition and it is common to apply duplex or multiple coatings (for instance, TiN on TiC or Al_2O_3 on TiC) to produce graded properties. The coating thickness is typically 1–5 μm. It is possible to apply the process to high-speed or tool steel components but these must be reheat-treated to retrieve the substrate hardness. This will produce distortion and, in many cases, will bring an unacceptable loss in precision. However, for tools with non-critical dimensions, CVD coatings can bring the same benefits to life as those applied by PVD. Equally, because the coatings have high hardness, they can be used to resist low-stress abrasive wear. The system is well suited to handling large numbers of small items, the parts being simply jigged on trays in the furnace.

CVD coatings are also used to protect against corrosion and corrosive wear. For instance, chromizing (referred to in Section 9.8.3.2), even though it is a pack process, can be considered as CVD because it occurs by the decomposition of a gas.

Finally, it is now possible to combine the PVD and CVD principles in the form of plasma-assisted chemical vapour deposition (PACVD) bringing the flexibility of the chemical process at a much lower temperature (less than 300°C). However, as yet, deposition rates are low and applications are mainly in thin (sub-micron) coatings for electronics applications.

Electrolytic and electroless coatings Over 30 metals can readily be deposited from aqueous solution[66] but they do not include alkali or alkali-earth metals and refractory metals such as tungsten, molybdenum and vanadium. While there is a tendency to think that electrolytic deposits are mainly for corrosion resistance, decorative purposes or electrical/electronics uses, there are many engineering/tribological applications for electroplates. Hard and soft plates are used, depending on the particular function required. To resist abrasive wear, adhesive pick-up and corrosion, hard chromium plates[67] are ideal. Porous or intentionally cracked chromium plates are used for oil retention, as in automotive cylinder liners. The hardness is 850–900 HV and coatings thickness is typically 20–100 μm. There are several proprietary variations on the plating techniques; some baths giving ultra-hard (1110 HV) deposits and others giving a dense, crack-free, but rather softer (700 HV) coating. Electrolytic coatings tend to build up on outside corners and sharp edges (because of a concentration in the current density) and to give reduced thickness in holes and on inside corners.

Soft plates of tin are used to facilitate 'running in', prevent fretting and confer corrosion resistance. Plates of silver, lead, cadmium, tin and antimony are used in heavy-duty sleeve bearings, particularly in aircraft power units. Nickel plate can be deposited from a wide range of solutions and is used to minimize abrasive wear in cases such as sliding contacts on hydraulic rams. Some care should be taken in the selection of electrolytic nickel, particularly with respect to the counterface, because of its tendencies to gall. Nickel is a good undercoat plate for hard chromium. However, because the shock resistance of chromium is poor, it is prudent to make the bulk of the layer nickel, and give a relatively thin top-coat plate of chromium.

Electroless nickel plates,[68] autocatalytically depositing nickel-phosphorus (Ni–P) or nickel–boron (Ni–B), have many useful tribological applications. In the case of the Ni–P deposits, a hardness of about 500 HV is obtained but can be thermally aged to a hardness in excess of 1000 HV. This is achieved after one hour at 400°C by the precipitation of nickel phosphides. Such hardness is not retained at high temperatures but the Ni–B deposits are superior in this respect. The range of applications of nickel plates can be increased by incorporating fine dispersions of wear-resistant particles in the plating solution (NiC, SiC or Al_2O_3). Such coatings are particularly effective in high-temperature wear situations. Electroless nickel is also available with the addition of PTFE. This duplex coating is less hard but has excellent non-stick properties.

In general, electroless nickel is not as abrasion resistant as hard chromium plate but, because it is not an electrolytic process, it does perfectly replicate the component surface without build-up on edges or corners. It is normally applied in thickness between 10 and 50 μm and it has excellent corrosion resistance, particularly in the 'as-plated' condition, i.e. straight from the plating bath.

Both electroless nickel and hard chromium plate are commonly applied to ferrous materials but they are now also used increasingly for components made in aluminium. Plating baths can usually accommodate components up to a metre or more in size.

Phosphating[69] These coatings are mainly used as a base for paint but they are effective in the presence of a lubricant to ease the deep drawing of steel, and to decrease the wear and fretting of sliding parts, particularly during 'running-in' processes. The identity of the phosphating process is often concealed under a proprietary treatment. In general, they are based on dilute phosphoric acid solutions of iron, manganese and zinc phosphates either separately or in a combination. Accelerators are added to shorten the process time to just a few minutes (in the temperature range 43–71°C). The simplest phosphate coating consists of grey to black crystals of $Fe_3(PO_4)_2$ and FeH PO_4. Zinc and manganese phosphates produce more complex layers which absorb lubricant more readily, and are effective in reducing adhesive processes such as galling, pick-up and scuffing. In addition to phosphating, there are many chemical conversion coatings which involve dipping components in solutions to develop specific compounds. Treatments such as chromating, used on non-ferrous alloys to prevent corrosion, will hold lubricants, and provide a base for bonded lubricant coatings.

Sprayed coatings[70] In spraying techniques, powders are heated to a semi-molten state and deposited at high velocities onto the component surface. Coating thicknesses vary from about 0.05 to 1.00 mm. The techniques can be divided broadly into flame gun, arc, plasma-arc and detonation gun processes. The merits of any one technique over another need to be assessed with reference to the particular job in hand. Obviously the selection must be on a cost-effective basis taking due account of the integrity required for a particular duty. One of the difficulties with these processes is to assess the substrate bond integrity, porosity and general coating qualities on a production basis. Suppliers are well aware of this, and the usual approach is to design their coating methods with care, so that tight control of the process variables is maintained by following the set procedure at every stage.

Electric arc spraying is used for metal deposition for wear resistance, corrosion resistance or reclamation. The coating material is fed as two wires and an electric arc is struck between them to cause melting. The molten metal is then propelled onto the substrate by compressed air.

In flame spraying, the source of heat is a burning gas, such as acetylene, and the coating material is fed into the gun either as a wire or a powder. It is a relatively cheap process and gives a high deposition rate but, in general, the bond strength is lower and the porosity is higher than that achieved by the electric arc process. The spray-fuse process takes the technique a step further by first spraying and then fusing with a second heat source, such as flame, torch or by induction. This is the basic technique used for the nickel- or cobalt-based Stellite-type alloys and gives excellent resistance to corrosion, erosion, abrasion and fretting. Alloys can have hardnesses up to 900 HV with near-zero porosity. There will, of course, be substrate distortion and the parts will require finish grinding. Coating thicknesses are typically up to 0.5 mm.

The plasma spray process makes use of an ionized gas (usually argon or nitrogen) to produce much higher temperatures than those created during flame spraying. This allows deposition of higher melting point materials such as metal oxides or metal/ceramic mixtures. Such coatings have relatively good substrate adhesion and porosity levels are usually in the range 2–4% (Figure 9.71). A typical coating thickness would be 0.1 mm and the process finds a wide range of applications in resisting abrasive wear. Substrate heating is minimal.

There are several variations on the plasma arc technique. The process can be conducted in a partially evacuated chamber (Low Pressure Plasma Spraying – LPPS), giving reduced porosity, reduced oxidation of the coating material and, because the substrate reaches a higher temperature, better adhesion. The same advantages can be gained by shrouding the arc in a non-oxidizing gas (Inert Atmosphere Plasma Spraying) and both these processes are now used increasingly to deposit the nickel–cobalt–chromium–aluminium–yttrium (MCrAlY)-type alloys which are used extensively in the aircraft industry to resist high-temperature oxidation erosion and fretting. A third variation is the Transferred Plasma-Arc process in which a secondary electric current is established between the arc and the workpiece. This promotes substrate heating and surface melting and gives more dense and more adherent coatings. Deposition rates can be very high and the technique is typically used to deposit thick (up to 10 mm) abrasion- and erosion-resistant coatings for use in applications such as mining and agriculture. The substrate must be electrically conducting and be able to withstand some thermal distortion.

The ultimate spray techniques are those producing the highest particle temperatures and velocities. These are achieved in the proprietary techniques such as Detonation Gun, Jet Coat and Mach Stream. As their names suggest, they are high-velocity techniques based on combustion of high-octane fuels. Porosity is very low (less than half of 1%) and substrate adhesion is excellent. They are used to deposit tough, abrasion- and erosion-resistant coatings such as chromium carbide or tungsten carbide/cobalt cermets. Thickness is typically 0.1 mm and substrate heating is minimal.

For all spray techniques, a correct substrate preparation is essential. The surface should be clean, free from scale, flash and burrs and should be pre-roughened by a grit-blasting procedure. Attention should be paid to the required coating

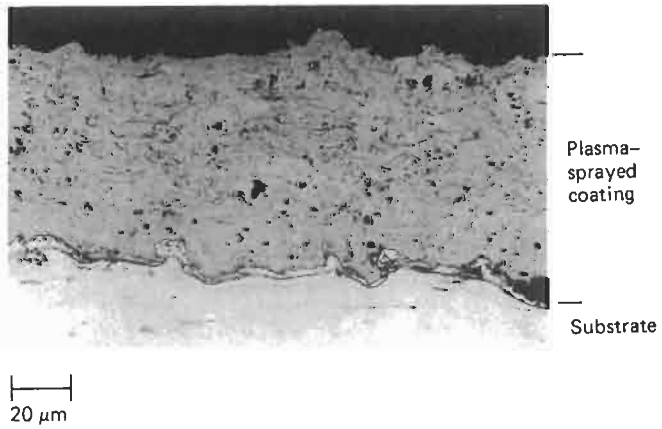

Figure 9.71 Plasma-sprayed chromium oxide layer

distribution so that the spraying procedure can be optimized and, for mass production, automated and computer controlled.

Laser alloying and cladding[41,71] These are relatively new processes. For cladding, the powdered material is blown directly into the laser-generated melt pool. Laser alloying is a similar process, except that the energy is increased to produce more substrate melting and complete surface alloying with the powdered material. The reaction area is shielded with an inert gas. A particular advantage of such techniques is that a specific area can be treated, thus minimizing component distortion.

Corrosion-resistant surfaces and metallic glasses are being produced but more development is required before the processes have wide industrial application. One of the problems is that of controlling the depth of heating, particularly when thin-layer fusion zones are required.

Welding and roll-cladding[72] These processes involve relatively thick layers, typically up to 2 or 3 cm. Welding can be used to good effect in tribological situations where high-stress abrasive wear is the problem, such as coating digger teeth, tank tracks and on ore-handling equipment. For instance, some of the Stellite-type coatings are applied by weld deposition.

Cladding is usually associated with corrosion or mild wear problems that are encountered in the chemical, food processing or printing industries. The two processes, roll-cladding and weld cladding, are complementary; hard abrasion-resistant materials are difficult to fabricate and are best deposited by welding, while the more corrosion-resistant materials are based on ductile austenites and are amenable to roll-cladding and forming.

9.8.4 Tribological data

Friction and wear data are available for surface treatments and coatings. Designers can sometimes find them in the open literature or in the advertising information which accompanies the various products. However, before they can make use of such data, they need to consider how the wear tests were performed, i.e. the type of laboratory wear machine that was used, and relate the conditions to those present in their own applications. The object of this sub-section is to acquaint the designer with the wear data that are available and to assist in interpretation and application.

As described in Section 9.1, wear is expressed in terms of the rate of material volume removal, usually as a function of applied loading and rubbing distance. For metal-on-metal rubbing under dry conditions, the rate of wear is often proportional to load and distance, and it is just possible that data could be related to a designer's specific application. However, it is more likely that there will be some further influence on the rubbing situation (for instance, a process fluid or lubricant) and that absolute wear data cannot be obtained.

The situation in abrasive wear is even more complex. Wear rate is a function of so many factors (for example, hardness, impact velocity and particle shape and size) that there is no prospect of users finding data which have any absolute meaning to their applications. Relative wear data that rank a range of treatments in order of wear resistance can usually be found but, even then, the range of wear will depend greatly on the aggressiveness of the abrasive. For instance, two sets of wear tests, one using SiC (2500 HV) as the abrasive, the other using SiO_2 (800 HV), may both produce the same ranking for a number of coatings or treatments but the relative wear rates will be very different. The harder abrasive will tend to compress the apparent differences between coatings and it will be difficult for users to predict the effects in their own applications, where completely different abrasives are likely to be present. In addition, a designer or user has to be sure that wear data were obtained under relevant conditions. If high loads are present, it is no use relying on data produced under low-load conditions. Thin coatings or treatments, even though they might be very hard, can be crushed into the substrate and torn away without any benefit.

For other wear situations the idea of wear rates is equally doubtful. The designer will rely on data or experience which shows, for instance, that certain coatings are better in fretting situations than others, or that some treatments are effective in corrosive applications. Equally, in situations involving severe wear problems such as seizure, galling and scuffing, wear rate has no meaning. Material is transferred, torn and deformed; surfaces weld and seize. The objective is to eliminate the problem, not merely to reduce it. Wear data, therefore, are most commonly published for relatively simple situations of adhesive or abrasive wear. The range of wear machines is extensive and some, together with examples of wear data, are described below.

Adhesive wear data are produced in many test geometries. In most cases, the geometry is chosen because it allows a quick and easy measure of wear, rather than in any attempt to simulate a particular application. The most common wear machine is probably a 'pin-on-disk' arrangement, with the wear on the pin being measured from its weight loss or reduction in length and that of the disk from profilometry of the worn groove. Figure 9.72 illustrates the typical mild/severe wear transition that takes place with a normalized medium-carbon steel rubbing dry against itself. If the disk is through-hardened, the severe wear regime is suppressed and a mild

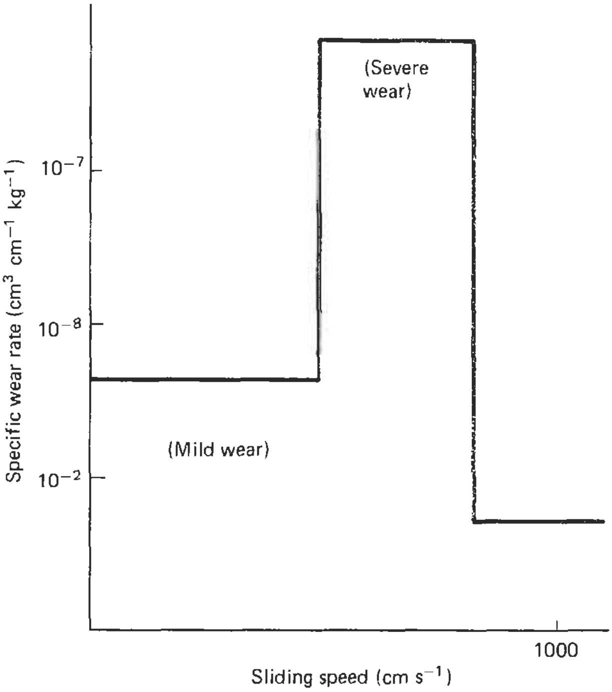

Figure 9.72 Pin-on-disk tests for normalized 0.4%C steel, showing transition in wear

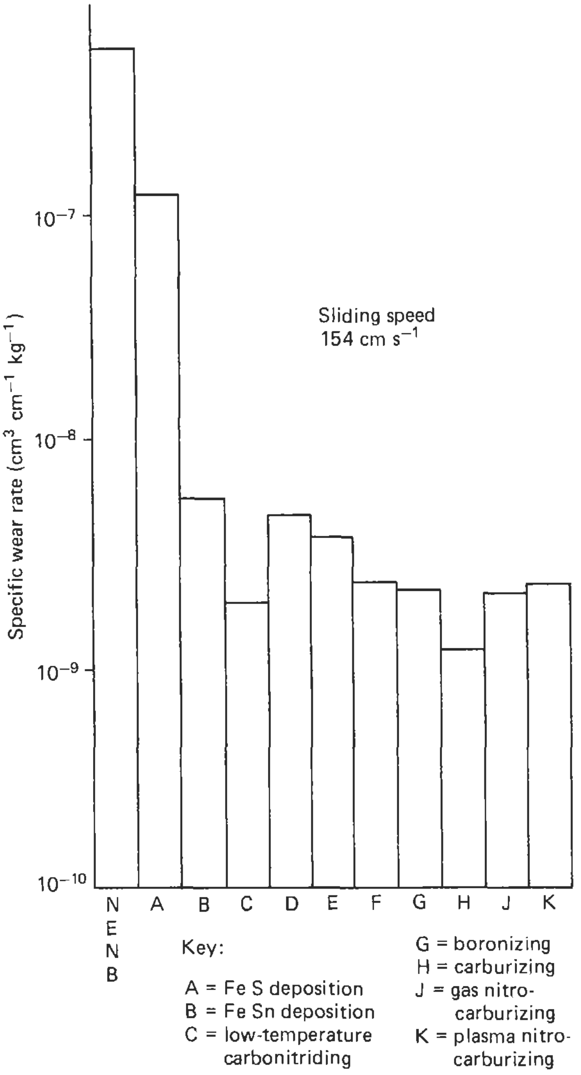

Figure 9.73 Pin-on-disk tests on various surface treatments on 0.4%C steel

wear rate of about 1 × 10^{-9} cm^3 cm^{-1} kg^{-1} (volume per distance travelled per unit load) is maintained. Figure 9.73 shows that most of the thermochemical diffusion treatments have the same effect, with only the sulphur-based process failing to give mild wear. This provides an excellent example of the difficulties inherent in wear testing. The sulphur-based treatment is aimed specifically at eliminating scuffing, i.e. under lubricated conditions, and a different test is required to highlight its advantages.

Figure 9.74 shows similar wear data for an aluminium alloy, demonstrating the reduction in wear achieved by anodizing (particularly when PTFE is incorporated into the layer) and by the Zinal electrolytic deposition process. In this case, the wear rates are about a factor of 10 higher than those found with medium-carbon steel. Another test geometry used for producing adhesive wear data is 'crossed-cylinders'. Here, the contact stress is high and certainly unsuitable for evaluating thin

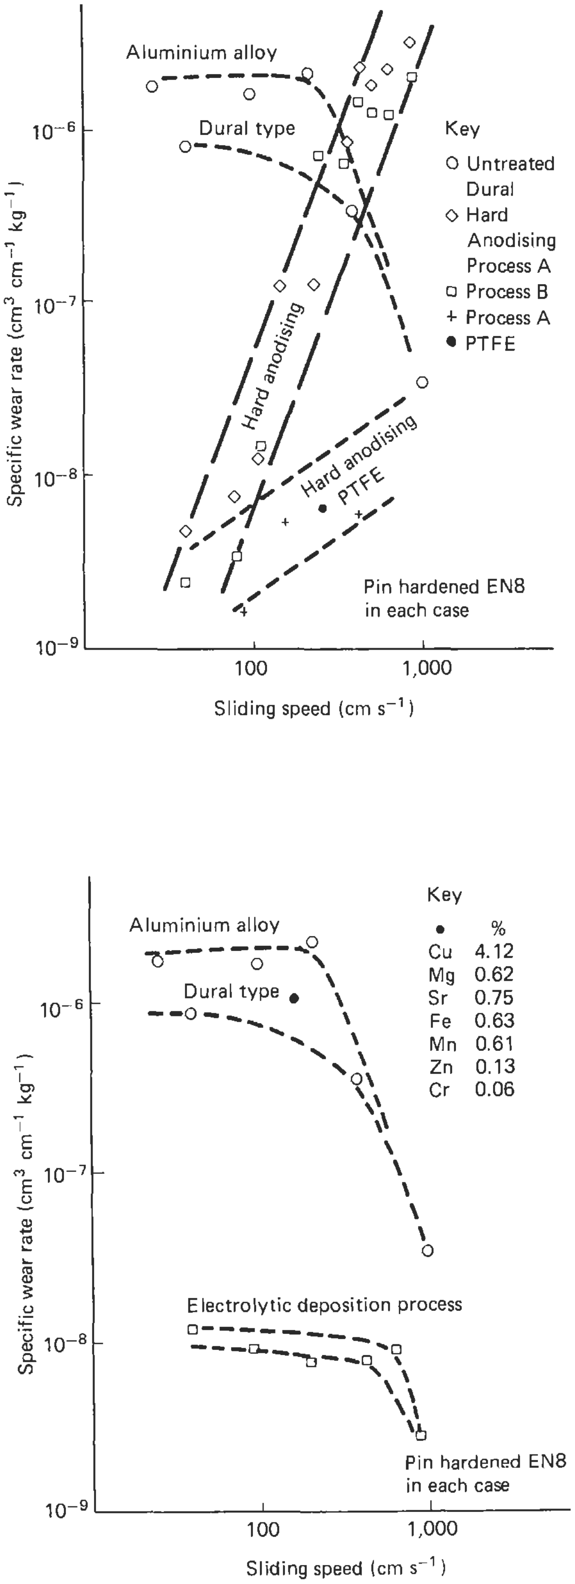

Figure 9.74 Pin-on-disk tests on treated aluminium alloy

coatings. Tests may also be quoted from Falex 'pin-and-jaw', or 'four-ball' machines. These evaluate scuffing or seizure resistance and a 'failure-load' rather than a wear rate is the usual quoted result. A 'disk-on-disk' geometry (sometimes tested with a combination of rolling and sliding) gives a line contact and tests can lead to fatigue pitting as well as adhesive wear.

The range of machines used for performing abrasive wear tests is more limited. Data are produced by rubbing samples against abrasive paper disks (sometimes in a spiral to ensure that fresh abrasive is acting throughout the test). It may also be produced from a grit-blasting machine (erosion) or from a rubber wheel tester. In each case the result is likely to be expressed as a weight loss or penetration depth per unit time; i.e. simple relative data. An example of rubber wheel test data for abrasion by SiO_2 is shown in Table 9.22. It demonstrates the excellent abrasion resistance of PVD titanium nitride under the light load that was used. However, if high loads or large abrasive particles are employed the results would be completely changed, with only the thicker surface treatments surviving.

Table 9.22 Abrasive wear rates for several coatings and substrates: rubber wheel test

Coating/material	*Hardness (HV 100 g)*	*Worn volume after 100 revs at 130 N load (mm^3) ($\times 10^{-3}$)*
PVD TiN	3500	0.5
CVD TiN	1800	1.0
CVD TiC	3200	5.1
Sprayed WC	1500	9.8
Sprayed Al_2O_3	1200	19.3
Sprayed Cr_2O_3	1300	23.2
High-speed steel	850	5.7
Mild steel	180	142.0

The lesson on wear data is, therefore, very clear. The designer should treat it with caution, making sure that it involves the appropriate wear mechanism and that the test conditions have some relevance to the particular application.

9.8.5 Selection philosophy

As stated earlier, the process of selecting the wear-resistant surface should be started at the design stage. If due consideration is given to the environmental factors, and if the user processes are considered at the onset, then preliminary selection will be relatively easy (Figure 9.75).

The first stage will be to satisfy the mechanical engineering demands for the component. Ideally, the lowest cost component which will meet their demands is required. This usually means that, when manufacturing a component, it must be made with the cheapest material compatible with its design requirements, and be fabricated with the minimum number of low-cost operations. During this stage, the designer will be considering all the mechanical and environmental requirements; for example, there may be a need for corrosion resistance, good fatigue properties or resistance against creep or impact damage.

The next stage is to consider the wear. If the environment or engineering demands dictate that a material, or the condition in which it must be used, are not compatible with the wear processes likely to be encountered in the system, then wear-resistant surface treatments must be employed. It is important that the type of wear is carefully identified; abrasive (two-body, three-body, high or low stress), adhesive, erosive,

fretting, chemical or fatigue. Also, it is necessary to obtain data on likely rubbing conditions, such as sliding speed, contact pressures, load cycles, hardness and type of any abrasives and the presence of any corrosive medium.

If wear data are available and those data are relevant to the load, sliding speed, environment and counterface material, then this will assist in the selection process. However, the designer should look carefully at any wear data found in the trade literature supplied by the surface treatment specialist, or in published papers and journals, and ensure that they were obtained under a relevant wear regime. It is totally inappropriate to assume that wear data obtained under, say, abrasive conditions, would have any meaning to an application involving another wear process such as adhesion, fatigue or corrosion. Obviously, each design and component cannot be subjected to tribological testing, but there are wear and performance characteristics of classes of materials and surface treatments which allow a primary selection.

By this stage of the selection process, the engineer should have a reasonably short list of materials and surface treatments that could be used, and should have considered possible manufacturing routes and worked out some detailed requirements; for instance, depth of surface treatment (determined by the loading conditions), hardness, core properties, whether the total surface area of the component needs treating, the required wear life, number of components to be produced, etc. However, a number of options for surface treatment will remain and should be reconsidered when assessing the 'local' factors. The final selection must be based on what is practicable, available and economic (Figure 9.76).

First, there will be the question of availability. Usually, the user will like to sub-contract any surface treatment fairly locally. The designer will have to ensure that the selected process is available and that the processor has the necessary equipment, working skill and quality control to provide the treatment reliably and reproducibly at the volume of production anticipated.

Second, the designer must consider the geometry of the component. Complex geometries, incorporating a number of section thicknesses, are likely to distort when treated at high temperature. This may limit the choice to low-temperature treatments. The heat-treatment history of the component is important. Specific core properties may have been produced by hardening and tempering so that any subsequent surface treatment must be applied at a temperature below that of the final temper. If this is not so, the core may be softened and the coating/substrate combination may then have insufficient load-carrying capacity to withstand the service contact stresses. Depending on the areas to be treated, the geometry may also exclude all 'line-of-sight' plating or coating processes. Obvious examples of this are the ceramic and cermet spray processes such as plasma arc and detonation gun. Ion implantation is also a line-of-sight process and physical vapour deposition techniques have only limited ability to penetrate re-entrant surfaces or holes.

In some applications, the replication of the surface shape may be important. The electrolytic plating processes tend to deposit thicker coatings on sharp corners and peaks while leaving valleys with little or no coverage. In contrast, electroless coatings tend to replicate the shape perfectly and may be preferred. On a finer scale the designer may need to preserve a particular surface finish, perhaps applied to the component for reasons of controlling friction or to provide specific optical properties, and so may be limited to ion implantation, physical vapour deposition or electroless coatings.

In all cases, the designer will be considering the dimensional requirements and making allowances for any final machining or grinding after treatment. Low-temperature processes that require no post-treatment finishing operations and retain dimensions after treatment are particularly attractive.

PRACTICAL COATING THICKNESS
LABOUR SUITABILITY TOXICITY ETC
ECONOMICS OF THE PROCESS

Figure 9.76 Selection of wear-resistant surfaces – local factors

Third, the question of component mass, size and numbers must be considered. These are obvious points to look for but it is surprising how easy it is to overlook such facts as: the length of the component you want to nitride is a few inches longer than any salt bath available in the country, a component requiring a coating applied by physical vapour deposition turns out to be too heavy to be handled inside a vacuum chamber, or a particular heat treatment service does an excellent job on 10 components but is totally impracticable to deal with 100 000, because the logistics and cost of jigging would be prohibitive. The designer should always seek advice from the contractor before finalizing on the surface treatment.

A fourth point to consider is the practical coating or treatment thickness. Although the wear performance of a particular treatment may be excellent it is advisable to check whether the particular process is capable of giving the desired depth of treatment to withstand the design pressure throughout its anticipated service life. Some of the processes, particularly ion plate deposits, have excellent hardness, low friction, good corrosion and anti-galling characteristics but it is impractical to deposit more than a few microns onto a substrate. Similarly, some thermochemical diffusion treatments, electrolytic/electroless plates and sprayed surfaces cannot be developed to adequate depths for highly stressed surfaces. For this reason, the design engineer must consider not only the surface but also sub-surface stressing on a particular component.

If the coating or surface treatment technique is to be brought 'in-house', i.e. out of the hands of sub-contractors, it is important to consider all the implications. When introducing new skills, new processes, high technology, processes requiring the use of chemicals, salt baths, toxic materials or radiation, all the technical and practical aspects must be appreciated. It is equally important to consider how they will be received at shopfloor level.

Finally, it is important to consider the economics. Surface treatments can provide tribological and environment-compatible surfaces on relatively cheap substrates, and unless the designer has a knowledge of the range of treatments available, it will be difficult to select the most cost-effective solution.

9.8.6 Quality control

A designer or engineer who is proposing the use of a surface coating or treatment on a critical component requires confidence, not only that he or she has chosen the correct solution to the problem, but confidence in the integrity and reliability of the treatment process. Certification of a product should, of course, be the duty of the supplier, but it is up to both the user and the surface treater to agree what surface properties are important and how to specify them. This should lead to a formal quality-control procedure with full documentation.

The surface properties to be specified depend on the specific application. However, it is likely that, for modification techniques such as case hardening, nitriding, induction hardening, etc., the two key properties will be hardness and case depth. For coatings, the thickness and hardness will again be important but the bond strength to the substrate will be critical. No matter how hard or thick it is, if the coating falls off, it cannot do its job. For sprayed coatings, porosity may be an issue (for instance, allowing a corrosive medium access to the substrate) and, in some applications, surface finish may need to be specified.

A further question to be answered is whether the quality-control tests should be carried out on the actual component (in which case they may need to be non-destructive) or whether they should be performed on a test coupon (a small, flat plate sample) that is treated at the same time. The danger in using a coupon is that it may not experience the same treatment conditions as the component. For instance, it is nearly always easier to effectively treat a flat plate than to deal with a sample with complex geometry. The ideal solution is to include with the batch some components (or representative sections) that are expendable and can be used for destructive quality-control tests. The number of samples and the frequency of checks would, again, be a matter of agreement between user and supplier. It should be decided on the basis of batch sizes and on the likely consequences to the end product of faulty surface treatment being undetected.

The detection of mistakes is, of course, the very purpose behind quality-control tests and some ideas for test procedures are given below. However, the real key to control is in quality *assurance*, i.e. the close definition and monitoring of the treatment procedure itself. The key treatment parameters should be identified and the user should demand full documentation of each treatment cycle. This way, the product is reliable and there is less need for costly and time-consuming monitoring of the final items. There should always be some quality-control testing, the unknown can sometimes occur and, with good documentation, faults can be traced back through the process and quickly rectified.

9.8.6.1 Hardness and case-depth of treated surfaces

The only reliable way of determining the hardness and depth of hardening is to prepare a polished cross-section through the treated sample and perform a series of hardness tests from the surface into the bulk. Obviously, this is destructive and must be performed either on a tab sample or on sacrificed components.

For case-hardened components the depth of hardening is defined as the distance from the surface to a plane at which the hardness is 550 HV. The measurements must be made using a load of 1 kg. The same method is applied to induction and flame-hardened surfaces but this time the convention is to define the limiting hardness at 400 HV. This definition also applies to nitrided surfaces, but only for conventional nitriding steels. For other nitrided steels (for instance, a high-alloy stainless steel) the specification would have to be agreed between the parties concerned. All these conventions apply to steels with a case depth of more than 0.3 mm and are covered by ISO Standards 2639, 3754 (1976) and 4970 (1979). For cases less than that value it will be necessary for parties to draw up their specification. In particular, for very shallow treatments (for instance, the surface 'compound' layers produced by nitrocarburizing processes) it may be necessary to use very light hardness loads, perhaps as low as 0.1 kg. This demands expert metallographic preparation and careful measurements, taking account of the wide statistical spread in low-load hardness values. For ultra-thin diffusion layers, such as those produced by ion-implantation, detection of the hardened surface is possible only by an ultra micro-hardness technique.[73] However, this is really an academic tool and not suitable for quality control.

9.8.6.2 Hardness of coatings

In the case of coatings, the whole layer usually has a constant hardness, so the idea of a 'case-depth' is inappropriate. For dense coatings such as electrolytic chromium plate or electroless nickel the measurement of hardness on a polished section is straightforward, usually being performed at a load of 1 kg. For sprayed coatings the results may be affected by porosity, the material collapsing into sub-surface voids and giving low hardness values. In this case, hardness would be quoted alongside porosity (discussed below).

With very thick coatings, the hardness can be measured directly on the surface, provided that the surface finish is good and the load is not so high that the coating collapses into the substrate. For very thin coatings, only 1 or 2 μm thick (typical of coatings applied by physical vapour deposition), no direct method is practicable. The hardness can be predicted by performing a series of tests into the surface at different loads and using the analysis described by Thomas.[74]

9.8.6.3 Coating thickness

Obviously, a micrograph prepared at a known magnification from a polished section provides a positive record of coating thickness. However, this is a measure at one single point and it is often important to map the coating thickness over the contours of the components.

For coatings in the thickness range up to 30 μm, X-ray fluorescence[75] gives excellent results (provided there is atomic number contrast between the coating and substrate). It now supersedes the traditional method using electrons – Beta-backscattering. It is particularly effective for measuring the thickness of coatings such as titanium nitride or zirconium nitride applied by either physical or chemical vapour deposition.

For thicker coatings, other techniques are available. These can be based on the use of eddy currents, ultrasonics, thermal waves, etc.

9.8.6.4 Coating porosity

Porosity is important in most sprayed coatings and the best method of measurement is to prepare micrographs of polished sections. Porosity can then be assessed by a visual comparison with 'standard' photographs. The major coating companies have established such standards, usually covering a range from 0.25% to 10% porosity. An absolute measure of porosity can be made from a micrograph by making an area of line tracing and determining either the area or length of the voids as a ratio of the total (for a homogeneous structure, volume, area and line porosity are equal). It is important that the polished section is prepared with care, so that the polishing procedure itself does not pluck out material and create 'false' porosity. This is a particular problem with the harder plasma-sprayed ceramics and causes frequent disputes between users and coating contractors. The polishing procedure should have been worked out previously and it should then be included in the overall quality-control specification.

A second possibility is to measure porosity by vacuum impregnating the coatings with a low-viscosity fluid and measuring the weight taken up. This relies on accurate knowledge of the volume of coating (i.e. the area and the average thickness), on the pores being interconnected and on all the pores being filled. (For very fine pores, capillary forces may prohibit complete filling.) These are significant points but, if the process can be perfected, it does have the merit of determining a volume porosity. In contrast, a polished section gives only a single point value.

9.8.6.5 Coating adhesion

The adhesion is the key property and the most difficult to quantify. In fact, measurements are usually qualitative rather than quantitative.

To produce an absolute measure of bond strength (in units of force/unit area required to detach the coating) it is possible to use a tensile-type test. This relies on gluing a peg to the coating with a high-strength epoxy and measuring the tensile force required to pull off the coating. In practice, the glue usually has a lower bond strength than the coating/interface or the coating fails cohesively. Additionally, the difficulties in setting up and pulling the pins accurately at right angles to the surface mean that a statistical approach, with multiple tests, is required.

For thin coatings, such as those applied by physical or chemical vapour deposition, a scratch test technique[77] is available. This uses a spherical diamond which is dragged across the surface at a steadily increasing load. The point of coating detachment is detected by measuring the friction or by monitoring the acoustic emission, and a 'critical' load is assigned as a measure of adhesion. Such a test usually requires a flat plate tab sample.

For thicker coatings there are a number of alternatives. Samples can be bent in a closely defined way and the bent area inspected for flaking. Alternatively, they can be thermally shocked, thermally cycled, impacted or subjected to high-load indentations (for instance, using a Vickers hardness tester with a pyramidal diamond indentor). In such tests, it is usual for coatings to crack, but without flaking from the substrate. The procedure should be worked out between the user and contractor and designed so that an unsatisfactory coating is highlighted. It may actually be necessary for the coater to deliberately produce coatings with a poor bond so that a relevant procedure can be developed. It is also preferable for the test to bear some relation to the actual application so that, for instance, components subjected to bending in service would be given a bend-type adhesion test.

9.8.6.6 Surface finish

If there is a need to preserve a particular surface finish, the quality control is a matter of a 'before' and 'after' texture measurement using a stylus profilometer. In most cases, it will be sufficient to determine the most common texture parameter, R_a, the 'centre-line-average'. However, some coatings, even though they may generally replicate the underlying surface, have a subtle texture of their own. This is true of some of the evaporated physical vapour deposition coatings and also some electrolytic coatings. In that case, it may also be necessary to monitor other surface finish parameters, particularly those relating to the 'shape' of the surface (skewness) and the sharpness of peaks and valleys (rms slope or average wavelength).

9.8.7 Closure

Surface engineering is the obvious solution to many of today's engineering and wear problems. It allows optimization of the surface and the substrate in a cost-effective way. To be most effective, the principle of surface engineering must be adressed at the design stage of a component, with the designer making full use of available data on the coating or treatment properties, including friction and wear. Then, having made a selection, the designer should be entitled to a good quality and reliable treatment service and it is the duty of the coating contractor to provide a certified product.

The science of surface engineering is expanding quickly. There are increasing possibilities of combining treatments and coatings to produce even more specialized properties. Coatings might be ion-implanted, either after or during their deposition. They might be laser-glazed to further increase hardness or diffusion. One coating might be applied to another to produce a combination of properties (e.g. abrasion resistance and corrosion protection). The time may come when expensive alloying elements can be added exclusively to the surface of a cheap component (perhaps by ion-plating) so that it can then be effectively nitrided. Designers and engineers should be kept abreast of developments and be continuously aware of possibilities for improving component life, reliability and economics.

9.9 Fretting

9.9.1 Introduction

Tomlinson[78] first investigated the phenomenon of fretting in 1927 after observations of red rusting of the grips of fatigue-testing machines. He coined the term 'fretting corrosion', by which name it is commonly known, and carried out the first quantitative study.[79] He considered that damage of the surfaces by fretting was initiated by mechanical wear produced by sliding of one surface on another and that the corrosion observed with base metals in air was a consequence of the wear. He stated that 'although the presence of oxidation products shows that chemical action accompanies fretting, the process is nevertheless certainly not one of corrosion as ordinarily understood'.

The distinction between fretting wear and ordinary wear is that fretting generally occurs at contact surfaces that are intended to be fixed in relation to one another but which actually undergo minute alternating relative movement. A classical example is the damage to the races of wheel bearings of automobiles during shipment by rail or ship, initially ascribed to brinelling caused by impact as a result of vibration but now known to be caused by slip between ball and race (and called 'false brinelling').

When fretting occurs on base metal in air, the wear debris always consists of oxides of the metal so that the most common symptom of fretting is the red-brown mud (comprising essentially red iron oxide mixed with oil or grease) shown as a patchwork over contacting steel surfaces.

Fretting damage occurs when two loaded surfaces in contact undergo relative oscillatory tangential movement (known as 'slip') as a result of vibration or stressing. Amplitudes of relative moment are small and often difficult to measure or even to predict by analysis. It is a deterioration process often ignored or not understood by designers. As a consequence, many fretting problems often come to light only late in the product development or, even worse, when the product is out in service. In such cases it is often too late to allow anything but minor redesign, and the only option then available is to employ some type of palliative (which is rarely a long-lasting solution), when fundamental changes in design concept can be the only successful solution. Possible situations in which relative movement and hence fretting can occur, either intentionally or otherwise, are legion. More common ones are flexible couplings, press fits of bearing raceways and hubs on axles, riveted aircraft structures, screws in surgical implants, steel ropes, heat exchangers, business machines and electrical contacts.

Reports of the occurrence of fretting have increased over the years, in part due to the increased demands placed on materials by virtue of higher power densities and stresses in modern machinery. Fretting and fretting fatigue have become increasing problems in the aerospace industry, particularly with the use of exotic alloys based on titanium and aluminium. A number of excellent review papers are available in the literature which provide summaries of the state of knowledge at various times.[80–84]

Although fretting damage by itself is seldom sufficient to cause failure directly, the irregularities produced in the surface cause loss of dimensional accuracy and wear products can cause excessive friction and seizure of closely fitting parts.

A number of different terms have been used in the literature, including fretting, fretting wear, fretting corrosion, fretting fatigue, false brinelling, rubbing fretting, impact fretting and impact-slide fretting. It is worth providing some definitions to distinguish between these various terms. Although fretting was initially described as fretting corrosion, it is better to use the term 'fretting' as a general title to cover a number of aspects of the phenomenon. In the first instance, fretting was observed with materials such as low-carbon steels, which at room temperature and in the presence of oxygen and water vapour, produce copious amounts of finely divided red oxide identified as haematite (Fe_2O_3) and fretting was understood to be closely associated with corrosion on the material surface. The oxidized particles are extremely hard and become embedded in the contact surfaces producing a red staining which even mild abrasive cleaning will not remove. This staining can often be used to diagnose the occurrence of fretting. It has often been stated that the oxidized debris was responsible for abrasive wear of the surfaces or even that it alleviated the damage by acting as a miniature ball bearing. However, fretting is known to occur in non-oxidizing environments such as high-purity inert gases where there is no oxidized debris and corrosion effects are minimal.

It is generally accepted that fretting processes are caused by high-frequency relative movement of contacting surfaces even with slip amplitudes of less than 1 μm. The upper transition between fretting and oscillatory wear is not well defined, but somewhere between 100 and 200 μm is the upper limit at which the wear process assumes the characteristics of unidirectional or reciprocating sliding wear.

Fretting wear is best used to describe processes in which ultimate failure of the component occurs by loss of the material surface leading to fracture, loss of function or pressure boundary rupture (applies to heat exchanger tubes, pressure vessels). In such instances, the component geometry is such as to allow escape of the wear debris with continuing penetration of the component thickness. This is to be contrasted with the more common fretting processes in which the geometry traps the debris, restricts access of the environment and produces little loss of section. Seizure of closely fitting parts such as bearing raceways, press fits, machine tool slideways and gear couplings is a characteristic mode of failure for fretting wear.

Fretting fatigue is a consequence of fretting damage to components subjected to cyclic stressing in which the fretting scar acts as a fatigue crack initiator. It usually occurs where fretting wear is minimal since either the production of copious amounts of wear debris interfere with the fretting process or the wear front progresses at such a rate so as to obliterate the propagating crack. The elimination of excessive wear of a component can often lead to fretting fatigue problems, much to the consternation of the machine designer, developer or operator. A number of papers and publications provide reviews of this extensive topic.[85,86]

False brinelling is a specific term used to describe the damage to rolling element bearings particularly where the bearing has been subjected to vibration from neighbouring machinery during a period of inoperation. The damage does resemble a brinelling indentation and can lead to rough running and premature fatigue failure during subsequent operation of the bearing.[87]

Although the classical forms of fretting involve loaded contacting surfaces, it is now recognized that fretting can occur between surfaces that undergo separation and repeated contact. Thus, the term *rubbing fretting* should be used to differentiate between loaded non-separating surfaces and those which experience periodic impact and slide, for which the terms *impact fretting* or *impact-slide fretting* are used. It should be noted that oblique collision of elastic bodies yields small-scale sliding under the Hertzian contact forces and milliseconds contact duration which can cause significant fretting wear damage. It is largely due to such occurrences of impact fretting problems in nuclear power plant that this topic has received much attention in recent years.[88–93]

9.9.2 Source of relative movement

9.9.2.1 Force/stress excited

Since it can be stated that wear cannot arise from surfaces which are not subject to relative slip and that the most successful method of overcoming fretting is to eliminate the fretting movement, it is worth examining how the relative movement between surfaces is generated. An important distinction can be made between systems in which the relative movement comes from an alternating force or stress applied to elements of a machine, and ones in which the movement is caused by defined displacements. This distinction must be made, as the nature of any palliative is critically dependent upon the source of relative movement.

In force- or stress-excited systems the degree of slip at a surface is a non-linear function of the applied force or stress. It is influenced mainly by damping, which is a function of normal load, static and dynamic friction coefficients and a number of other parameters. The success of a palliative such as a soft interfacial layer, which changes not only the fretting wear resistance but also the friction coefficient, cannot be guaranteed if perhaps the vibration amplitudes increase as a result of the use of such a layer.

Forces or stresses can arise from a large number of sources, including acoustic noise, eddy or vortex shedding (flow-induced vibration), pressure pulsations, mechanically transmitted vibrations, aerodynamic loading and electrical noise. As part of any solution to a fretting problem, consideration must be given to the vibration source and, if possible, some attempt made to reduce it.

In many mechanical systems subject to force or stress excitation, the fretting wear rate has a maximum at some level of load between the contacting surfaces (Figure 9.77). For low-contact forces, the wear rate is low because the surfaces are lightly loaded. Suppose one decided that an increase in load was necessary to attempt to reduce the fretting damage. It is possible for the wear rate to increase as the increased load has little effect upon the amplitude of slip. However, as one passes the maximum, a further increase in load results in a reduction in wear rate as the increased load damps out vibrations and significantly reduces the relative slip. The effectiveness of changing load in this type of system critically depends therefore on where the machine is currently operating on this curve and in part explains the contradictory results obtained with some palliatives. Force- or stress-excited systems probably comprise 90% of the systems in which fretting is observed and, in general, the movements are not intentional.

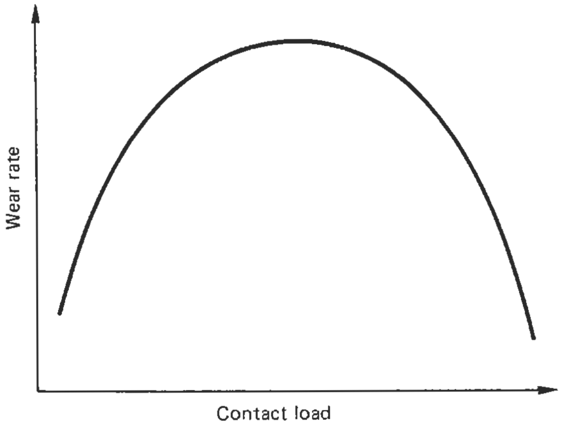

Figure 9.77 Variation of wear rate with load for force-induced vibration systems

9.9.2.2 *Amplitude driven*

There are some mechanical components which are subjected to a fixed amplitude of movement irrespective of loading (for example, misaligned gear couplings where the amplitude of movement is related to the degree of angular misalignment and not to the transmitted torque). Other examples are in business machines such as impact printers where the print head is designed to move through a defined travel. A characteristic of these systems is that movements are generally intentional and little can be done to reduce or limit the relative slip at the surface without affecting the function of the machine.

9.9.3 Characteristics

9.9.3.1 *Nature of damage*

The debris produced by fretting in oxidizing environments is largely the oxide of the metals involved and therefore occupies a greater volume than the metal destroyed. Conventional static oxidation kinetics are not necessarily obeyed with oxidation of all constituents of an alloy, including those generally conferring corrosion resistance. In a confined contact zone with little possibility of debris escape, considerable pressure can build up, leading to seizure (for example, in closely fitting parts, shrink or press fits) or the formation of corresponding debris-filled pits in both surfaces as a result of wear from the mechanical action of the sheared debris. In some instances, surfaces can be jacked apart by these oxide-filled pits. Some examples of components in which debris entrapment can occur are machine governors, vehicle leaf springs and locked coil steel ropes.

Where debris can escape, loss of fit can result, with continuing and perhaps accelerating fretting wear (particularly if slip amplitudes increase as loads reduce and wear progresses). The presence of oxide can affect the performance of electrical contacts or create safety hazards such as the pyrophoric oxide produced by the fretting of stacked aluminium ammunition boxes subject to vibration in ships' holds.

Under some circumstances the production of debris can lead to a significant reduction in fretting wear rate if, for example, the oxide can be compacted into a wear-resistant layer, such as occurs in steels used in high-temperature carbon dioxide for nuclear reactor heat exchangers; while in other situations, corrosion is accelerated by the continual removal of oxide (e.g. the passivating chromium oxide on austenitic stainless steels), particularly in aqueous environments.

9.9.3.2 *Nature of debris*

On steel surfaces fretted in air at temperatures less than 150°C, the debris is largely hexagonal alpha-Fe_2O_3, a reddish-coloured oxide which is non-magnetic and often contains metallic iron. On aluminium, the debris is black alumina containing about 25% metallic aluminium. There is increasing evidence to suggest that the fretting debris is platelike in nature and these observations have led to proposed theories of a delamination process along the lines suggested by Suh.[94] In some instances spherical particles have been observed in the fretting of silver[95] and mild steel in argon at room temperature to 500°C.[96]

9.9.3.3 *Mechanism of fretting wear*

It was originally thought that three processes were involved in fretting:

1. The production of loose metallic particles by local welding and adhesion which were subsequently oxidized;
2. Abrasion of the surfaces by hard oxide debris;
3. Continual scraping off and regrowth of oxide films.

On this basis, an accelerating wear process would be expected as more debris is produced, which is contrary to most observations. Indeed, debris may have a beneficial effect. As theories of fretting have developed, a review by Hurricks[82] considered three stages to be involved:

1. Adhesion and metal transfer;
2. Production of wear debris by mechanicochemical action;
3. Steady-state production of debris by fatigue action rather than abrasion,

and this is now largely accepted to be the most plausible explanation of fretting processes. Adhesion and welding in the early stages, with steel and noble metals causing material to be raised above the level of the original surface, followed by smearing and, finally, metal removal by a delamination process. Suh's[94] delamination theory of wear envisages the coalescence of subsurface voids produced by dislocation pile-ups at obstacles such as inclusions under the action of the alternating shear stress. It is possible that slip amplitude effects (discussed later) may be explained by a critical amplitude above which dislocations do not return to their original position, thus accelerating fatigue crack initiation and growth. Delamination theory explains the platelike appearance of the debris and sub-surface cracks have been observed in sections through fretted surfaces. Observations made by Sproles and Duquette,[97] Jahanmir[98] and Waterhouse[99] also suggest that a form of delamination wear also takes place in fretting. The delamination model proposes that fatigue cracks nucleate beneath the surface. The cracks then propagate parallel to the surface, until instability or a material flaw forces the crack to the surface to produce a flake wear particle. Sproles and Duquette describe how delamination occurs in multiple layers over the fretting contact, resulting in a flaky metallic scale-like covering over the surface. The observations were made under fretting fatigue conditions, i.e. in the presence of a bulk alternating stress; the surface stress level was high.

The current theory therefore suggests that initial damage arises from adhesion and welding at points of real contact, resulting in material being raised above the original surface. The extent and severity of this stage depends upon the reactivity of the metal and the corrosivity of the environment. Raised material is then smeared out and the surface is removed by a delamination process to produce plate-like debris which are essentially metallic but covered with oxide. Comminution of debris by grinding between the surfaces may take place with further oxidation as the particles are reduced in size. Complete oxidation of very fine debris may ultimately occur. The compaction of debris in the contact zone allows continued transmission of the alternating shear stresses. Work hardening and work softening can have adverse effects upon the fatigue properties and accelerate the process.

For cyclically stressed surfaces, propagating fatigue cracks may be initiated in the early stages from boundaries between slip and no-slip regions. Although wear rates in the initial stage are comparable with adhesive wear, in most cases the wear rate falls significantly as steady-state conditions are established. For further discussions on fretting theories, see references 100–103.

9.9.3.4 Concept of specific wear rate

Archard[104] has expressed the wear behaviour of materials under unidirectional or reciprocating sliding with the term 'specific wear rate', which relates the volume of material worn to the load and total sliding distance. The specific wear rate, k, can be calculated as follows:

$$k = \frac{\text{Volume of material removed}}{\text{Load} \times \text{sliding distance}} \tag{9.7}$$

The normal units for specific wear rate are $\mathrm{m^3N^{-1}m^{-1}}$. It is useful to use a similar concept for fretting in order to express the specific wear rate as a function of the normal load, frequency and slip amplitude. The relationship becomes:

$$k = \frac{\text{Volume of material removed}}{2 \times \text{load} \times \text{frequency} \times \text{cycles} \times \text{p-t-p slip}} \tag{9.8}$$

where the slip amplitude is the peak-to-peak value. The specific wear rate can therefore be used to express results of tests to evaluate fretting wear, from which calculations of wear behaviour under different conditions of time, load and slip amplitude may be made.

9.9.4 Parameters influencing fretting

There are a significant number of parameters which can affect the fretting damage sustained by a sliding interface. Among these are:

- Time or number of cycles
- Slip amplitude
- Normal load
- Slip frequency and surface velocity
- Contact geometry
- Materials properties (hardness, work hardening)
- Environment (humidity, temperature, medium, oxygen potential)
- Lubrication

9.9.4.1 Time or number of cycles

Figure 9.78 presents a schematic representation of the progression of wear with time or number of cycles. An initial

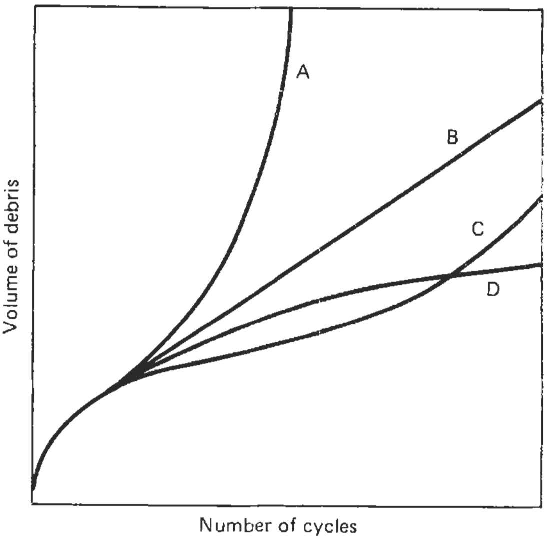

Figure 9.78 Schematic representation of debris production as a function of time

high wear is followed by a decrease in the volumetric removal rate. As oxidized debris is formed, the pattern for mild steel falls to that of curves B or D, with the latter typical of low slip amplitude. Curves A or C typify soft materials with a hard abrasive oxide which can dominate the material wear behaviour in the second stages of wear.

When expressed in terms of change in specific wear rate with time, the wear rate shows a decrease with time (Figure 9.79) for mild steel fretted in air at 20°C using the results of Ming-Feng and Uhlig,[102] Ohmae and Tsukizoe[105] and Ming-Feng and Rightmire.[106] The specific wear rate reduces by more than two orders of magnitude when tests are taken from a few hours to a few hundred hours. This demonstrates the necessity to extend any laboratory to realistic timescales in order to reach an equilibrium value of specific wear rate.

9.9.4.2 Slip amplitude

There is general agreement that above an amplitude of 100 μm the volume of material removed is directly proportional to the slip amplitude. In other words, the wear volume is directly proportional to the load and the sliding distance and specific wear rates correspond typically to those of sliding wear. At low slip amplitudes, the evidence suggests that damage is much lower. Some investigators claim that there is no measurable damage below 100 μm and elastic movement takes up all the displacement betwen the surfaces. Stowers and Rabinowicz[107] claim difficulty in measuring the actual movement and comment upon the possibilities of lost motion in the test apparatus. However, Tomlinson[78] found damage down to 2 nm, and data on mild steel at 20°C, compared by Lewis and Didsbury[108] to other workers[102,105,109] have shown an increase in specific wear rate of over two orders of magnitude over the slip amplitude range 50–100 μm (Figure 9.80). This observation has an important effect in any attempt to cure a fretting problem since a twofold reduction of slip amplitude from 100 to 50 μm can lead to over a hundredfold reduction in wear volume.

The occurrence of fretting damage even at very low levels of slip means therefore that any machine element at which relative movement can occur will see some level of damage. A lower limit of damage of 0.75 μm has been suggested by Kennedy *et al.*[110] so that it very difficult to reduce slip to a level at which no damage will occur. The exact threshold is, to some extent, dependent upon the properties of the materials in use. Microslip can occur in many supposedly fixed or rigid connections (e.g. press or shrink fits of hubs or bearing raceways). At very low levels of slip, fretting fatigue becomes a potential problem at the boundary between slip and no-slip regions.

It should be noted that slip amplitude effects are not necessarily a feature of all materials and are dependent upon the environmental conditions. Slip amplitude effects for mild steel disappear with increasing temperature, which is probably more a reflection of the increasing influence of protective oxides (to be discussed later).

9.9.4.3 Normal load and surface pressure

Most workers[102,103] report a constant specific wear rate as a function of load, providing the movement is forced and takes place over the entire contact area (Figure 9.81). If, however,

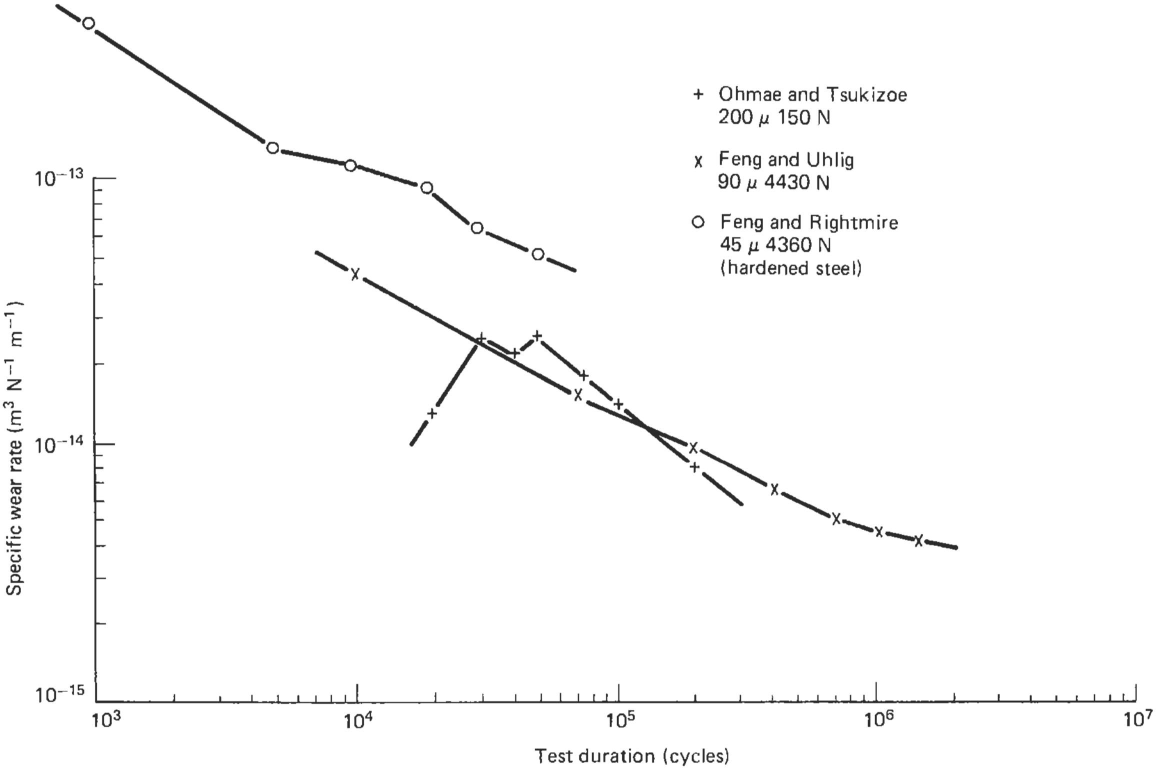

Figure 9.79 Effect of test duration on specific wear rate for mild steel under rubbing fretting conditions

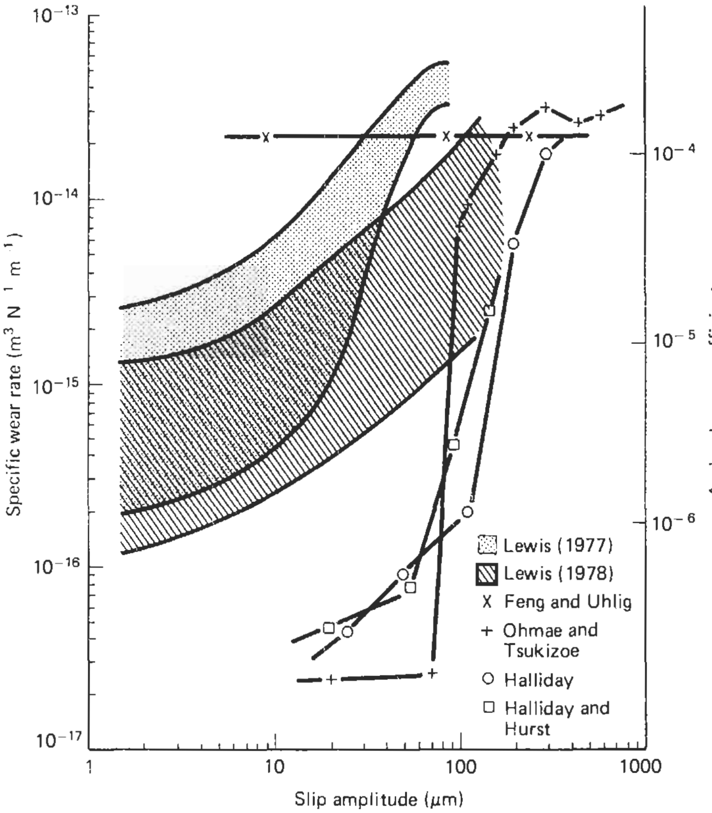

Figure 9.80 Effect of slip amplitude on specific wear rate for mild steel under rubbing fretting conditions: comparison with other workers

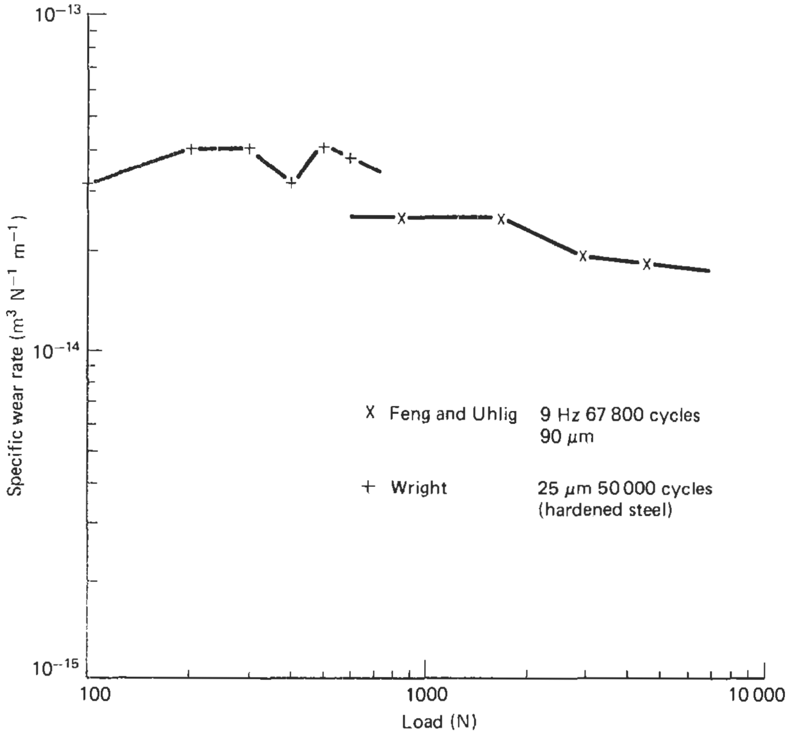

Figure 9.81 Effect of load on specific wear rate for mild steel under rubbing fretting conditions: results of Feng and Uhlig and Wright

the increased load results in a decrease in the slip amplitude then the rate at which fretting occurs can be reduced. A reduction in contact area to increase the pressure has often been used to overcome fretting problems, but one should be careful that the increased pressure does not exacerbate fretting fatigue problems since the increased pressure increases the stress concentration at the slip boundary.

9.9.4.4 Slip frequency and surface velocity

Slip frequency may affect the rate of fretting if the process is removal and regrowth of oxide. If the oxide grows according to a logarithmic law, then frequency effects are probably negligible above 17 Hz, because only that portion of the oxidation curve at short exposure times is in effect.

Figure 9.82 shows results from Ming-Feng and Uhlig[102] for mild steel fretted in air over the frequency range 1–60 Hz. There is little influence of frequency indicated, while Soderberg *et al.*[111] suggest little effect at high slip amplitudes for a frequency range of 10–1000 Hz and recommend frequency as a useful parameter for accelerating fretting wear tests.

It is interesting to note that greater surface damage has been reported for very low frequencies (in which surface velocity is typically 1 mm/day) and oxide growth and removal effects dominate. This has been particularly important in electrical contacts which can be subject to low slip at very low frequency.

9.9.4.5 Hardness and surface finish

Observations would generally suggest that increased hardness gives lower fretting damage. It is believed that combinations of similar metals of differing hardness give good fretting resistance, though wear in general is thought to be alleviated by combinations of materials which have low mutual alloying tendencies. This view is partially supported by Sakman and Rightmire,[101] who produced a ranking of fretting wear resistance (given in Table 9.23).

Opinions on the effect of surface finish are quite contradictory in the literature. Some investigators believe that a smooth

surface is more susceptible to fretting damage while others consider that super-finishing can prevent excessive damage. The weight of evidence points to the superiority of a rough surface for lubricated contacts, the surface irregularities providing a reservoir for lubricant.

9.9.4.6 Contact geometry

The geometry of contact is an important variable in fretting. In general, large-area nominally flat or conforming contacts tend to trap the debris produced and give an over-deepened pitted surface during fretting. Conforming contacts are poor from the point of view of lubricant access since the sliding movement is not sufficient to entrain lubricant. Some surface treatments which are used to alleviate fretting problems are most effective with conforming contacts because of their low thickness. Conforming contacts are most prone to seizure. In contrast, non-conforming contacts allow debris to escape.

9.9.4.7 Environment

In an inert atmosphere, such as nitrogen or vacuum, the fretting wear of steel reduces but the incidence of material transfer between the surfaces increases. The initial phase of adhesion and welding is preserved rather than the transition to oxidative wear appearing. Little loose wear debris tends to be produced. Humidity also reduces the amount of fretting damage as the hydrated oxides of iron are less hard than their dehydrated counterparts.[102]

Since fretting involves both the mechanical properties of a material and its reactivity with the environment, it is to be expected that changes in temperature would have considerable effect on fretting wear. The fretting behaviour of mild steel has been investigated by Hurricks[112,113] and his results are given in Figure 9.83. A significant reduction in specific wear rate is observed at 150–200°C due to the greater thickness and adherence of the oxide magnetite (Fe_3O_4) formed. This behaviour has also been found by Lewis[114] with mild steel in air up to 500°C, in which the specific wear rate for high-amplitude (100 μm) fretting shows a considerable reduction with increasing temperature with a lesser reduction for low slip (10 μm).

It would appear that the formation of a compacted oxide layer on mild steel increasingly reduces the fretting wear rate by providing a protective wear-resistant film. These so-called 'glazes' are observed at high temperatures on corrosion-resistant materials such as austenitic stainless steels and nickel-based alloys similar to those formed in reciprocating sliding.[115,116]

In aqueous environments a passivating film is relied upon to limit corrosion of the metal surface. Disruption of the film by fretting can produce large changes in electrode potential for the baser metals. Fretting can therefore show its effects more by continuous disruption of the passivating film. Experiments in which the potential of the fretting surfaces is kept constant show a linear relationship between corrosion current and slip amplitude. Calculations show that the bulk of the material removed is the result of mechanical action rather than chemical dissolution.[84]

Corrosion reactions can be controlled by imposing a cathodic potential on the system (or on metals which display passivation, an anodic potential). It has been observed that cathodic protection can give a significant improvement in fretting fatigue behaviour.[81]

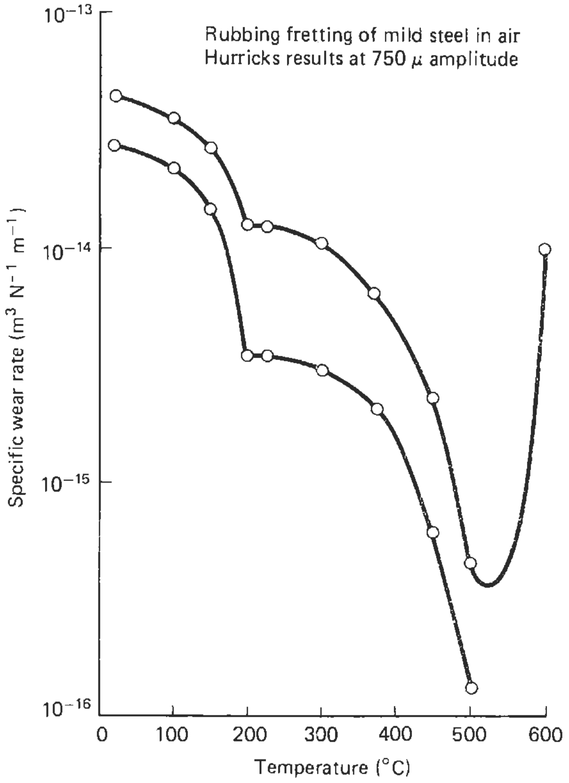

Figure 9.83 Rubbing fretting of mild steel in air (after Hurricks)

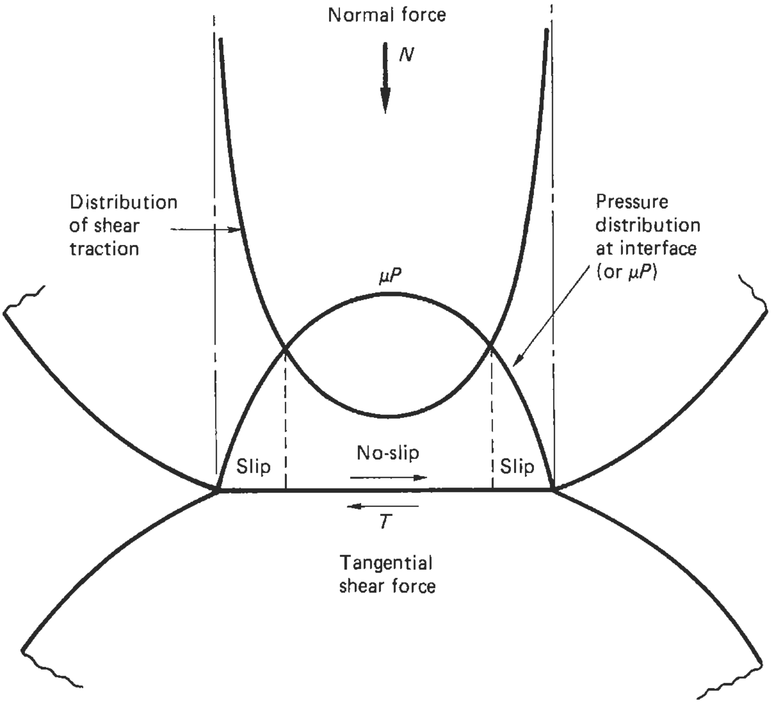
9.9.4.8 Lubrication

The low relative velocity and high contact pressures of fretting surfaces are not conducive to effective lubrication. In addition, the escaping debris provides a barrier to lubricant access, as well as thickening the oil or grease by mixing with it (e.g. the thick red 'cocoa' observed in many lubricated fretted contacts). Shear-susceptible greases (i.e. those whose viscosity falls with shearing) appear to be the most effective and the literature generally recommends greases of low base viscosity to improve the flow into the fretting zone. The selection of greases for lock coil steel ropes is quite different, however, with high viscosity being most suitable.

Lubricants containing molybdenum disulfide have frequently have recommended for the alleviation of fretting. However, in line with other work for unidirectional sliding, the effectiveness of MoS_2 is much reduced in the presence of a liquid because it cannot effectively attach to the metal surface when there are other surface-active agents competing (e.g. anti-wear additives). Considerable promise, however, has been shown in dry-bonded MoS_2 films for the control of fretting.[117]

9.9.5 Theoretical considerations

A classic example of microslip in fretting contacts is given in the elastic contact of two spheres or a sphere on flat where the surfaces are subject to an alternating tangential force. Mindlin[118] showed that for a sphere pressed against a plane by a normal force, N, and subjected to a tangential force, T, the shear traction is unbounded towards the edge of the contact (see Figure 9.84). In reality, this distribution is not possible



Normal force
N
Distribution of shear traction
μP
Pressure distribution at interface (or μP)
Slip
No-slip
Slip
T
Tangential shear force

Figure 9.84 Pressure and shear stress distributions at elastic contact of two spheres

and a relief mechanism must operate. This mechanism is provided by micro-slip, which occurs over an annular area at the edge of the contact. As the tangential force is increased, the annular area of micro-slip grows until:

$T = \mu N$

where μ is the coefficient of friction. At this point the whole of the two surfaces are in relative motion, i.e. gross sliding takes place.

Mindlin's analysis illustrates how the localized concentration of shear traction gives rise to fretting. Elimination of the shear concentration is therefore a fundamental means of avoiding fretting. Furthermore, the designer has the potential to predict fretting early in the design process. By carrying out a stress analysis of the contact interface, areas of potential fretting can be identified where the following inequality holds:

$\tau > \mu \sigma_n$

where τ is the shear stress at the surface and σ_n is the in-plane stress normal to the surface.

The shear traction also has an important effect on the generated contact stress field which is now considered important in the mechanism of fretting fatigue. Without a shear traction (zero friction coefficient) only a small tensile stress is generated at the edge of a hemispherical contact. In such cases, failure is likely beneath the surface where the material is subjected to the maximum yield stress. As the friction coefficient increases the point of maximum yield stress moves towards the surface, reaching it at a friction coefficient of 0.33.

In the fretting of steels, friction coefficients approaching unity are not uncommon. Figure 9.85 illustrates the rapid increase in the tensile stress at the trailing edge of contact as the friction coefficient is increased. Figure 9.86 shows the damage developed between a steel sphere and a flat as a result

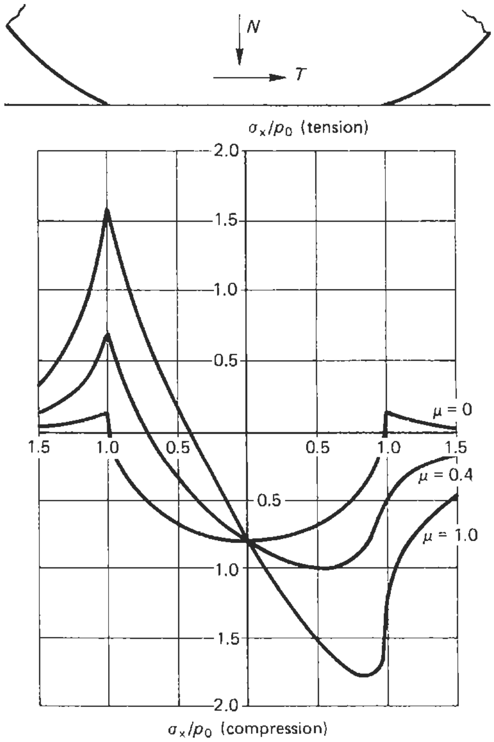


Figure 9.85 Ratio of in-plane stress σ_x to maximum contact pressure p_0

(2) $\frac{\phi}{\mu_s} = 0{\cdot}40.$

(3) $\frac{\phi}{\mu_s} = 0{\cdot}64.$

(4) $\frac{\phi}{\mu_s} = 1.$

Figure 9.86 Fretting damage for sphere-on-flat for various applied shear forces

of fretting under increasing values of tangential force.[119] Figure 9.86(1) shows a very slight outer ring for a value of $\phi/\mu_s = 0.16$ where $\phi = T/N$ (the shear coefficient) and μ_s = static friction coefficient. The damage extends inwards as the area of microslip grows until the entire surface is subjected to gross slip when the value of ϕ/μ_s reaches 1 (Figure 9.86(2)).

It is at the boundary between the regions of slip and no-slip that fretting fatigue cracks can initiate and grow, though fretting wear in the outer area of slip causes a redistribution of the contact pressure and often fatigue effects are halted as the wear zone progresses inwards.

9.9.6 Fretting wear evaluation

There are a plethora of testing facilities described in the literature, each developed to study a particular aspect of fretting or fretting fatigue. Confusion over the effects of slip amplitude has arisen in the past, largely because some investigators have ignored or underestimated the lost motion that inevitably occurs. Modern fretting apparatus are generally designed with very stiff drive mechanisms in order to ensure that relative slip is occurring at the contact interface and often take great care to measure the actual slip close to the interface.

There are no standard fretting test machines, each industry developing a design to suit its needs. There is no standard test geometry, with test specimen designs varying from hemisphere-on-flat to crossed-cylinders, cylinder-on-flat and flat-on-flat. In many instances, actual component geometries have been used. The particular difficulties in fretting machine design to ensure area contact with flat-on-flat specimens lead to the use of hydrostatic bearings to allow a self-aligning feature. A number of organizations have attempted to create a standard for fretting evaluation, including the American Society for the Testing of Materials.[120]

9.9.7 Preventative measures – some palliatives

9.9.7.1 Some lines of attack

There are a number of methods which may be used to reduce or eliminate fretting damage:

- Prevent the relative movement by a change in design or modifying the source of vibration.
- Provide a treatment to the surfaces to reduce or eliminate welding and adhesion processes, remembering that all materials are subject to fretting to a greater or lesser extent.
- Encourage movement to allow access of lubricants, usually a difficult line of attack in view of the high contact pressures, the generation of wear debris and low relative velocity of sliding.

A number of observations can also be made which can assist in solving a fretting problem:

- No wear takes place between surfaces subject to vibration unless its amplitude is sufficient to produce slip.
- Damage is produced on any solid surface, whether metallic or non-metallic, if slip takes place.
- Fretting wear of base metals in the absence of oxygen gives less rapid accumulation of debris and less intense damage than in air or oxidizing atmospheres.
- No liquid lubricant entirely prevents fretting but some can produce a considerable improvement.

Additionally, one must make the distinction between the fretting of components (such as shrink fits, press fits, bolted flanges, etc.) which are not intended to undergo relative motion and those (such as flexible couplings, bearings, universal joints) which undergo intentional oscillatory movement.

9.9.7.2 Prevention of gross slip

In order to overcome fretting damage in components not intended to slip, gross slip can be reduced or eliminated by:

- Increasing the load or closeness of fit;
- Increasing the coefficient of friction (e.g. with grit blasting followed by lead plating[121]);
- Interposing a layer having high elastic strain limit (e.g. rubber or polymers).

9.9.7.3 Design analysis to prevent or reduce fretting damage

Fundamentally, the best solution to a fretting problem is to 'design it out' if at all possible by using all-welded or unit construction. Design modifications may be necessary to reduce or eliminate the source of vibration (e.g. isolation from local excitation sources). Bearing in mind that slip occurs at an interface because the shear force is greater than the opposing friction force, one can reduce the shear stress or increase the friction force. This reduces to the problem of eliminating the concentration of shear stress over the surface. The friction force may be increased by reducing the apparent area of contact while keeping the load constant, thus increasing the pressure. Similarly, some platings such as cadmium can increase the friction coefficient by promoting seizure.

In situations where the concentration of shear traction occurs at the edge of the contact, a simple design modification may be all that is required. For example, on a clamped joint, undercutting at the edge is an effective means of reducing the shear concentration (Figure 9.87). Another simple example is a press-fitted hub on a shaft in which stepping down the shaft diameter significantly reduces the shear concentration (Figure 9.88). Unfortunately, simple geometries such as these are the exception. In the majority of real engineering assemblies, while geometric modifications are usually possible, it is not often clear how effective the modifications will be in eliminating the shear concentration. In these cases the answer is to carry out investigations of the joint by a numerical stress analysis technique such as finite-element analysis.

Several commercially available finite element codes have special elements for modelling Coulomb friction which will provide detailed information about the behaviour of a potential fretting interface. However, since sliding is a non-linear element in the problem, these programs are usually expensive in computing time. Fortunately, in the majority of cases the main interest is in predicting whether fretting will occur or not. This simplifies the analysis and allows the interface to be

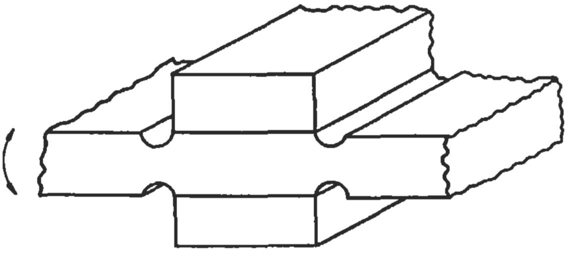

Figure 9.87 Undercutting at clamped joints to avoid stress concentration

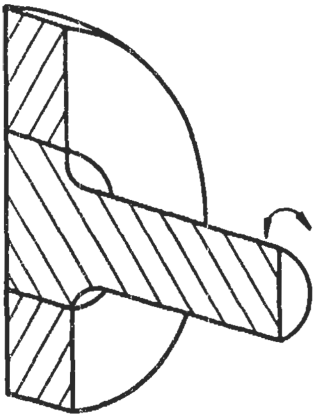

Figure 9.88 Stepped shaft to avoid stress concentration

modelled by simpler linear elastic elements. Provided a sufficient refinement of elements is used in modelling the joint, the design can be established as satisfactory, if the surface shear stress is less than the product of contact pressure and friction coefficient (i.e. $\tau < \mu\sigma_n$) everywhere across the joint. If the condition fails at any element node, then the extent of fretting cannot be predicted, and the design should be considered as prone to fretting.

In certain cases, optimizing the design of an assembly on the basis of other essential design criteria may mean that fretting becomes inevitable. For this situation, a palliative may be the only option available to minimize the fretting damage. In such instances a detailed analysis of the fretting interface can be useful to categorize the type of fretting problem. This, in turn, can assist with the selection of a suitable palliative.

9.9.7.4 Selection of fretting palliatives

To aid with the selection of a palliative, fretting problems can be classified into one of two categories determined by whether the movement is force controlled or amplitude controlled. To explain these categories, it is useful to consider again the Mindlin problem. In the partial slip regime according to Johnson,[122] the ratio $T/\mu N$ determines the level of micro-slip. The slip amplitude is therefore a function of the forces involved, and it is proposed that the problem can defined in the category 'force controlled'. Under gross sliding, i.e. $T = \mu N$, clearly the forces involved play no part in determining the slip amplitude. Fretting in this case is put in the category 'displacement controlled' since the slip amplitude is essentially fixed.

In reality, defining in which category the problem falls is not, in the majority of cases, straightforward. Fretting involving wear between components which are intended to move (e.g. oscillating bearings, ball joints, slideways, etc.) is, in general, a displacement controlled problem and there is little ambiguity. However, in clamped assemblies where movement occurs unintentionally, fretting allows strains of different magnitudes in the component mating surfaces. If this 'differential strain' is largely unaffected by the applied loads, then the problem effectively is one of displacement controlled fretting. If, however, the differential strain is substantially modified by the applied loads, then the problem should be classed as one of force controlled fretting. A finite-element analysis can be used to determine in which category the problem falls.

For a displacement controlled problem the approach to alleviate fretting wear or fretting fatigue is to try to reduce the normal load and the friction coefficient. With fretting fatigue this palliative is clearly aimed at reducing the contact stress levels. In a fretting wear problem the palliative should also be effective since it has been found that the wear volume is proportional to the applied load.[104]

In a force controlled fretting wear problem the requirements of a palliative are completely the reverse. Increasing normal load and friction coefficient can act as effective palliatives by lowering slip. Slip has been shown to be one of the most important fretting parameters. Work by Ohmae and Tsukizoe,[105] Halliday,[123] Halliday and Hirst[109] and Lewis and Didsbury[108] all suggest that the specific wear rate decreases with decreasing slip amplitude. Figure 9.80 summarizes the results of these investigations into the effects of slip amplitude. The data from the individual experiments suggest that the specific wear rate (volume lost per unit load per unit sliding distance) varies as a function of the slip amplitude raised to a power ranging between 2 and 4. Clearly, if fretting cannot be entirely prevented. even a modest reduction in slip may be sufficient to reduce the level of wear down to acceptable proportions.

In the alleviation of force controlled fretting fatigue, reducing the shear traction is the primary objective. Thus, reducing the friction coefficient and normal load are desirable palliatives providing the increase in wear can be tolerated.

9.9.7.5 Lubricants

The detailed choice of a palliative treatment is still largely empirical. However, with a basic understanding of fretting and a detailed analysis of the problem, a rational decision about the selection of the most appropriate category of palliative can be made. For instance, in the general category of lubricants, while it may not be possible to identify immediately the most suitable individual lubricant, one can say in what circumstances a lubricant should be tried.

Lubricants can obviously produce a large decrease in the coefficient of friction. In force controlled situations this effect is likely to result in unsatisfactorily high slip levels. Also, with clamped assemblies the load transmission across the joint may be modified and fasteners may become overloaded. However, lubricants can prove very useful in displacement controlled fretting fatigue. Application of a lubricant will lower the level of shear traction which will considerably reduce the contact stress level. Also, in displacement controlled fretting wear, boundary lubrication can significantly improve performance. However, unless continuously replenished, the self-cleaning action of fretting very quickly removes the boundary-lubricating film. Gaining access to the inner regions of the fretting contact without separating the surfaces is difficult for oils of high viscosity and virtually impossible with greases. A thin, penetrating oil is therefore the best choice. Vapour blasting or phosphating may also assist in providing a reservoir for the lubricant.

9.9.7.6 Solid lubricants

Often the difficulty of containment precludes the use of an oil and an alternative in this situation is a solid lubricant such as molybdenum disulfide or zinc oxide. Solid lubricants are very effective at reducing fretting damage over a limited life.[117] If the problem involves high numbers of fretting cycles ($>5 \times 10^5$), then solid lubricants such as described are unlikely to be satisfactory without re-application.

Phosphate treatment prior to application of the MoS_2 coating can produce a significant improvement in fretting wear resistance.

9.9.7.7 Thermochemical treatments

These treatments involve the diffusion of carbon, nitrogen and, less usually, chromium or boron. The most common thermochemical treatments are carburizing, carbonitriding, nitrocarburizing and gas nitriding. The factors involved in the selection of a thermochemical treatment are too numerous to go into in detail here, but it is possible to make generalizations about this form of palliative.

This category of treatments is designed to increase surface hardness. In general, the adhesive and abrasive resistance improve with increased surface hardness. The most effective treatment against fretting wear is therefore likely to be the one producing the largest increase in hardness. However, the effect of the treatment on the friction coefficient must not be ignored. For instance, on En32 steel, liquid nitrocarburizing using the Cassel Sulfinuz process reduced the friction coefficient in slow linear sliding from 0.8 down to 0.2.[124] Clearly, for displacement controlled fretting, reduced frictional traction will enhance the effectiveness of the palliative. However, in a force controlled situation the reduction in friction may negate the benefits.

By virtue of the compressive stresses developed in the outer surface layers the fatigue strength of steel is normally enhanced by thermochemical treatments. As a general principle, any process which increases the normal fatigue strength of the steel, providing it is not accompanied by a significant increase in friction coefficient, will improve the fretting fatigue performance. The process giving rise to the greatest increase in normal fatigue strength is likely to provide the largest improvement in fretting performance.

9.9.7.8 Surface coatings

In previous investigations of palliatives, both hard and soft coatings have been employed to mitigate both fretting wear and fretting fatigue. However, it is probably true to say that there are more conflicting opinions in the literature on the performance of individual coatings than for any other class of palliative. The reasons for the conflicting opinions on coating performance are not always clear. However, sometimes a successful coating performance can be dependent on the characteristics of the test rig.

For example, in a rig producing low-amplitude force controlled fretting, such as that described by Budinski,[125] coatings having high coefficients of adhesion may bring about seizure of the contacts. A palliative which is given a favourable assessment by such a rig may in fact only be effective in force controlled situations where seizure can be brought about.

Sikorskii[126] has correlated high coefficients of adhesion with soft coatings such as silver, indium and lead. It is perhaps therefore no surprise to find that these are precisely the coatings which are said to be beneficial in fretting.[127] It has also been suggested that soft metal coatings work by absorbing the fretting movement.[84] However, the amount of movement which can be absorbed is likely to be so low that it does not seem to the author a credible explanation.

With thin soft coatings applied on a hard substrate, a good palliative performance may be the result of a low coefficient of friction which can occur. Halling[128] has proposed an explanation for this low-friction phenomenon. In general, however, the poor durability of soft coatings leads the author to believe that, with one or two special exceptions, soft coatings are likely to be of little benefit as a fretting palliative.

With electroplated chromium, Alyab'ev *et al.*[129] found that the conditions of deposition and the coating thickness can influence the wear resistance. In this work it was also found that the chromium deposition with the highest hardness had the best fretting wear resistance. However, under fretting fatigue the high levels of residual stress present in the coating reduce the normal fatigue performance considerably; and the coating has little effect on the friction coefficient. Therefore, although improvements in the fretting fatigue performance have been claimed for chromium plating,[130] there is no reason why under dry conditions this treatment should be of any significant benefit in fretting fatigue.

In general, because of the adverse effect on the normal fatigue limit, it is not considered that hard coatings are effective palliatives for fretting fatigue unless the coating significantly reduces the friction coefficient. Electroless nickel impregnated with PTFE can reduce friction and therefore has the potential to give improved fretting fatigue performance. While improved wear performance using electroless nickel has been reported by Gould *et al.*[131] there is no reported work to test the effectiveness on fretting fatigue of a nickel coating impregnated with PTFE.

Hard coatings deposited by spraying or welding can give high wear-resistant surfaces. There are numerous coatings commercially available, and deposition can be by several methods. Little is known about the effectiveness of the majority of these coatings as palliatives in fretting wear situations. However, in work carried out at the National Centre of Tribology (NCT), various coatings applied by the Union Carbide detonation-gun process based upon bonded carbides have been tested. At temperatures below 200°C in a carbon dioxide environment, the application of these coatings to mild steel or stainless steel reduced the wear rate by up to an order of magnitude.

9.9.7.9 Polymeric materials

Replacing one of the fretting surfaces with a polymer material can be effective in reducing fretting damage to a steel surface. However, the choice of polymer is all-important. This is because hard abrasive oxide debris produced from a steel surface can become embedded in the polymer. The polymer then becomes an effective carrier of the abrasive debris and the wear process becomes two-body abrasion. One of the best polymer materials to use in a fretting wear problem is PTFE. This is probably because PTFE works by forming a transfer film on the steel counterface. Any abrasive debris is then encapsulated by the PTFE transfer film.

Unfortunately, PTFE is a rather soft polymer that will move under load, and it is therefore not generally suitable for the high-load situations of fretting fatigue. However, in commercial bearings additional support has been achieved by incorporating PTFE into a sintered phosphor-bronze matrix.

Tests at NCT have also shown the benefits to be gained by the use of PTFE-based materials (see Table 9.24). The fretting wear of mild steel was considerably reduced by the use of a fabric-based PTFE weave counterface, the steel exhibiting an almost imperceptible level of damage and wear, while wear of the polymer was also low. Clearly, consideration should be given to these types of material for fretting problems in flat-on-flat geometries.

PTFE can also be constrained and supported by incorporating it into a hard electroless nickel coating. The fretting resistance of the hard nickel is enhanced and certainly for low-cycle fretting wear this coating is a very effective palliative.[131] In fretting fatigue the benefits are likely to come from the low friction, therefore the palliative may not be effective in force controlled situations. Also, the reduction in fatigue

Table 9.24 Rubbing fretting wear of various materials versus mild steel at 125 μm slip amplitude

strength associated with the hard nickel plating may be detrimental to the fretting fatigue performance.

9.9.7.10 Interfacial layer

It has been shown that micro-slip can be prevented when a thin layer of flexible material (for example, rubber or Terylene) is interposed between the fretting surfaces.[133] With a layer of the right compliance and thickness, the shear stress concentration at the edge of the contact giving rise to the slip can be eliminated from flat contacting surfaces. With Hertzian contacts because the contact pressure goes to zero at the edge, to achieve the same results it is necessary to bond the layer to both the surfaces.

Although this palliative can be effective at preventing relative sliding there are design limitations to its applicability. Clearly, the palliative can, in practice, only be used with relatively small slip amplitudes, therefore it is not likely to be suitable in large-amplitude displacement controlled situations. The increase in compliance produced by the palliative may also be unacceptable to the overall performance of the design. The durability of the interfacial layer under the alternating loading may also be a limiting factor.

Notwithstanding these limitations, the ability of interfacial layers to eliminate the shear concentration can prove very effective in many fretting fatigue problems involving bolted or riveted joints. Sandifer[134] has carried out practical testing of interfacial layers for use in the aircraft industry and found the palliative to be a success.

9.9.7.11 De-stressing notches

This has been suggested as a palliative only to fretting fatigue problems. This palliative was investigated by Kreitner,[135] who tested a flat fatigue specimen machined with closely spaced de-stressing notches (0.4 mm deep) running laterally and longitudinally over the contact area. The tests showed that with the de-stressing notches fretting was prevented from influencing the fatigue strength of the specimen. Moreover, although there was a reduction in the fatigue limit caused by the notches, the improvement in fretting fatigue strength was still in excess of 100%. The effectiveness of this palliative has been confirmed by Bramhall,[136] who also obtained a significant increase in fretting fatigue strength using de-stressing grooves cut in a lateral direction only.

The advantage of this palliative is that the fatigue strength is governed purely by the notch effect of the de-stressing notches; it is therefore more predictable. Also, the palliative is applicable to both displacement and force controlled problems.

9.9.7.12 Surface cold working by shot peening

Shot peening is one of a number of treatments which can be used to produce surface cold working. This type of treatment increases the hardness and induces a compressive stress in the surface layers. Both of these features, as previously explained, can be advantageous in reducing fretting damage.

In addition, shot peening produces surface roughening which may well have benefit in both fretting fatigue and fretting wear problems. It has been suggested that rough surfaces are more resistant to fretting fatigue.[137] This may be because a rough surface has, to a limited extent, the same de-stressing effect as the notches described previously.

A shot-peened surface will also retain lubricant better, each indentation acting like a small oil reservoir. Therefore, in both displacement controlled fretting fatigue and wear, shot peening may be expected to enhance the effectiveness of an oil lubricant.

9.9.8 Summary of palliatives

9.9.8.1 Palliatives for fretting fatigue

Palliatives for fretting fatigue problems have been reviewed by Chivers and Gordelier[86,138,139] in an attempt to provide a rational approach to their selection. They observed that a useful starting point is provided by the work of Nishioka and Hirakawa[140] in which an equation is developed for the initiation of fretting fatigue cracks in flat fatigue specimens which are fretted by cyclindrical fretting pads. The fretting pads were orientated such that the direction of slip was orthogonal to the cylinder axes. They derived the expression:

$$\sigma_{\mathrm{fwl}} = \sigma_{\mathrm{wl}} - 2\mu P_0 \left\{ 1 - \exp\left(-\frac{s}{k} \right) \right\} \tag{9.9}$$

where σ_{fwl} is the alternating stress necessary to initiate fretting fatigue cracks, σ_{wl} the alternating stress necessary to initiate cracks in the absence of fretting, μ the coefficient of friction, P_0 the peak Hertzian stress, s the relative slip and k a constant depending on the material and surface condition. This equation relates to the condition of partial slip in which relative movement takes place over only part of the contact area. When the full slip condition is reached and s becomes large, equation (9.9) reduces to:

$$\sigma_{\mathrm{fwl}} = \sigma_{\mathrm{wl}} - 2\mu P_0 \tag{9.10}$$

An improvement in fretting fatigue behaviour can therefore be achieved by raising the fatigue strength, σ_{wl}, of the base material, reducing the relative slip, s, either to achieve partial slip or to reduce the degree of partial slip present, lowering the contact pressure such that P_0 is reduced or lowering the coefficient of friction μ.

Excluding a change in base material, the problem is that the remaining options are interactive since a reduction either in contact pressure or in friction coefficient may result in an increase in the slip amplitude. An important consideration is what form the driving force to produce the movement takes, that is, whether conditions are controlled by displacement or force.

With displacement control, the amplitude of movement will be constant regardless of the force required. Considering equations (9.9) and (9.10), it is apparent that for either partial or full slip conditions, and with constant slip amplitude, reductions in either friction coefficient or contact force should result in an improvement in fretting fatigue performance.

With force control, the peak oscillating force to produce the movement is fixed in magnitude. In some circumstances therefore a modest increase in either contact force or friction coefficient could have a large effect in inhibiting the slip that occurs. If, however, these increases should fail to achieve a partial slip condition, equation (9.10) shows that a deterioration in fretting fatigue performance would be expected and hence the result of a modification to the conditions of contact is dependent on the slip regime. These results are summarized in Table 9.25. Additionally, Chivers and Gordelier reviewed possible mechanisms of alleviation and these are summarized in Table 9.26.

9.9.8.2 Palliatives for fretting wear under force excitation

A similar distinction based upon the source of excitation may be made for fretting wear. There are a wide range of possible palliatives for control of fretting wear caused by force or stress excitation and these are summarized in Table 9.27.

9.9.8.3 Palliatives for fretting wear under amplitude excitation

Palliatives for control of fretting wear under amplitude-driven movements are summarized in Table 9.28.

9.10 Surface topography

9.10.1 Effects of surface topography

All machining processes leave characteristic topographic features on the surfaces of components. These features vary in amplitude, spacing and shape and can exert a significant effect on the component's function or aesthetic appearance.

The British Standard, BS 1134: 1988,[141] identifies two components of surface topography which are generated by most common machining processes and classified according to their cause:

1. Roughness: 'The irregularities in the surface texture that are inherent in the production process but excluding waviness and errors of form.'
2. Waviness: 'That component of surface texture upon which roughness is superimposed. This may result from machine or work deflection, vibrations or release in machinery.

Three surface characteristics are illustrated by Figure 9.89. In addition to the above definitions a third surface shape component, that of 'form', is generally recognized as being the

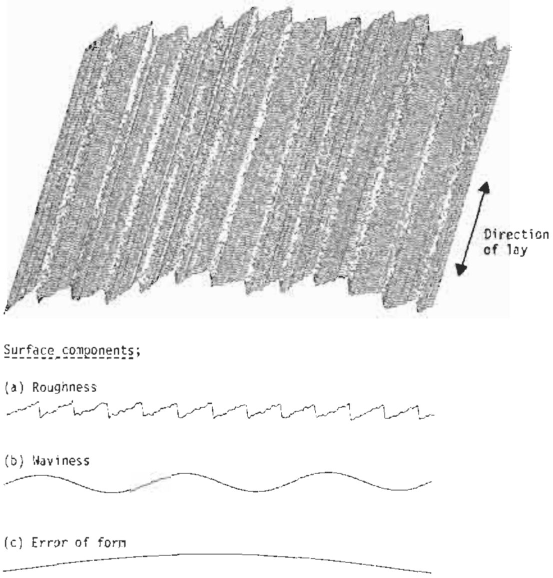

Figure 9.89 Diagrammatic representation of a machined surface illustrating the classification of topography by the separation of profile components

nominal shape of the component. i.e. the surface shape when roughness and waviness are neglected. Normally, deviations from ideal form are referred to as 'errors of form'. Figure 9.89 also shows that machining marks in surfaces may predominantly fall along one direction. This is frequently called the 'lay' of the surface.

These definitions of surface features are arbitrary and, therefore, also ambiguous. It is possible for surface features of entirely different scales, produced by different machining processes, to have the same classification. The term 'surface roughness' is also frequently regarded to be synonomous with 'surface texture' and 'surface topography' and, as a result, could potentially be confused with the 'roughness component' of a surface structure. Despite such difficulties, these terms are well established.

The sizes of machining marks are usually discussed in units of millionths of a metre, i.e. micrometres (abbreviation μm). In mechanical engineering metrology, the size of features of interest generally ranges from a few hundred micrometres down to hundredths of a micrometre and the scale of these features is not easy to visualize. Figure 9.90 attempts to place objects of this scale into perspective by relating their dimensions to physically important parameters of interest in the study of surface topography and the size of some items familiar from daily life.

It appears that no surface can be regarded as being perfectly flat. (Even though its imperfections may arise only as a result of misalignment in the positions of atoms in its surface.) As a consequence, considerations relating to surface finish stretch across a broad band of subjects which relate to the functional performance and manufacture of engineering components. The influence of surface topography on physical phenomena varies widely in scope and includes lubrication, electrical contact resistance, heat transfer, fluid flow, noise generation, the performance of optical components and the fidelity of thin-film coating processes. The influence of surface topogra-

9.10.1.1 Liquid-film lubrication

Theoretical investigations into the influence of surface roughness in lubrication has been a topic of considerable interest over recent years. Surface roughness is of importance because fluid flow rate, the fundamental principle on which the Reynolds equation is formulated, depends on the cube of film thickness. Flow rates will suffer perturbation as a result of local changes in film thickness due to surface roughness.

Several analyses of lubrication which involve surface roughness have been described and the simplest of these studies investigate the influence of longitudinal striated roughness on hydrodynamic lubrication. Michell[142] examined the effect of sinusoidal roughness in slider bearings while Dowson and Whomes[143] investigated the lubrication of cylindrical rollers containing vee-shaped, square, and sinusoidal roughness running along a circumferential direction. A study which examined the effects of non-dimensional roughness was conducted by Christensen.[144]

The investigation of transverse roughness is a more difficult problem because an additional term arises in the Reynolds equation when the direction of motion of a surface does not coincide with the direction of its tangent. Dyson[145] points out that some analyses of transverse roughness (e.g. Christensen and Tonder[146]) did not appreciate this and consequently their results are only applicable in situations where a plane surface moves over a stationary rough one. An accurate analysis of the effects of transverse roughness was given in a study of the lubrication of rough disks by Berthe and Godet.[147]

The inclusion of surface roughness effects in the solution of the Reynolds equation in EHL problems is uncommon, as the situation is very complicated even in the treatment of ideally smooth surfaces. However, a perturbation analysis, applicable in situations where the rms surface roughness is less than one third of the film thickness has been developed[148] and applied in a study of finite bearing lubrication.[149]

The effects of surface roughness in hydrodynamic lubrication and EHL can be summarized. In general, for an infinitely long bearing the effect of transverse roughness is to increase load capacity while longitudinal roughness decreases load capacity. This occurs because transverse roughness ridges inhibit lubricant flow, generating an increase in pressure in the load-bearing zone. In contrast, longitudinal ridges provide flow channels for the lubricant to escape from the load-bearing zone, reducing its load capacity. In a finite bearing the situation is more complex. Narrow bearings have the greatest side leakage flow and, therefore, support the lowest loads. Longitudinal roughness tends to inhibit side leakage and, as a consequence, will tend to improve the load-carrying capacity of 'short' bearings. However, it should be noted that the net effect of roughness depends on the length-to-width ratio of the bearing as well as the nature of its roughness. Load-carrying capacity is reduced when the bearing is wide and increased for very narrow configurations. The friction force also depends on the bearing length-to-width ratio, with friction for longitudinal roughness being greater than that for transverse roughness.

The influence of surface roughness in mixed lubrication has also been considered. Patir and Cheng[151,152] have derived a model which allows any three-dimensional roughness structure to be analysed. Mixed lubrication is a complex situation but, in general, this model shows that as 'roughness' is increased, friction and load-carrying capacity of a surface is also increased. Additionally, it has been of value in studying the power loss at the piston-ring/cylinder interface in internal combustion engines.[153]

The majority of lubrication analyses employ the Reynolds equation, which assumes that the cross-film lubricant flow is negligible compared with the flow in other directions. It should be noted that as surface roughness is increased this assumption becomes less valid. Under such conditions the more complex Navier–Stokes equations should be used in principle. The lubrication of a rigid slider bearing has been considered using the Navier–Stokes equations and it has been demonstrated that the Reynolds equation progressively underestimates the load capacity of such an arrangement as roughness is increased.[154]

Since surface roughness has an influence on friction it is not surprising that it also affects wear. Dawson[155] found that the ratio, D, given by

$$D = 1/M$$

was inversely proportional to the tendency for a bearing to begin pitting; a standard mode of fatigue failure experienced by roller bearings and gear teeth. The stresses generated by the repeated elastic deformation caused by the passage of a ball or roller result in this failure which manifests itself as a small 'pit' in a component where a fragment of metal has fallen out. (The mechanism of pitting in relation to surface roughness is described in detail in reference 156.)

Scuffing is a second form of failure which is influenced by surface roughness. When brief inter-asperity contact or asperity-particle contact occurs it causes friction which generates heat. Scuffing is thought to arise when the speed and pressure at the contact are increased so much that, at a critical point, the heat generated cannot be dissipated in the surrounding bulk material without melting at the contact. An expression to describe friction in gears which includes a surface roughness term has been developed[157] and it appears that over a limited range of roughness friction can be reduced by selecting an appropriate surface roughness for gears. As a consequence, resistance to scuffing is increased.

The phase of wear which occurs in the early stages of sliding is usually referred to as running-in. The influence of surface topography in running-in has been reported under both lubricated conditions[158] and dry sliding conditions.[159] During the running-in phase rough surfaces tend to become smoother, the rate of wear depending on both the initial surface topography and the applied load. Other studies have found that once running-in is complete the wear rate becomes independent of the initial surface roughness[160] and can be described by a mechanism known as delamination.[161] According to delamination theory, a material fatigued under sliding develops subsurface dislocations and voids which run parallel to the surface. When these faults coalesce, sheet-like wear particles are released. Under low loads the initial wear rate of a smooth surface is higher than that of a rough one because delamination commences relatively quickly compared to rough surfaces, where delamination is delayed until the asperities are worn smooth. The opposite is true under high loads as rough surface asperities are easily and quickly removed by adhesive and abrasive processes under such conditions (see Halling[162] for descriptions of adhesive and abrasive wear mechanisms).

Bayer and Sirico[163] have conducted tests into the influence of anisotropy of surface roughness on wear. Spherical specimens with isotropic surface topography were positioned against flat planes with a well-defined lay and caused to slide under a fixed load in the boundary lubrication regime. Using sliding parallel and perpendicular to the lay of the anisotropic plane Bayer and Sirico showed that as the coarseness of surface increased, the sensitivity of wear to orientation became greater. However, below a limiting roughness the influence exerted on wear by changes in roughness was a more significant effect than the directional dependence.

9.10.1.2 Contact mechanics

Surface topography exerts an influence on the processes which occur at static junctions as well as ones where surfaces are in relative motion. Theoretical and experimental studies of static contact are diverse and range from such subjects as the analysis of the stiffness of machine tool joints[164] to the investigation of heat transfer and electrical resistance.[165]

The main aim of theoretical studies of static contact is to predict the real area of contact between the components which form the interface so that related physical characteristics can be derived. During the last three decades several models of various levels of geometric and statistical complexity have been proposed to describe contact at interfaces.

One of the earliest contact models was of a geometric nature and was proposed by Archard.[166] Archard considered the deformation of spherical asperities as they were loaded against a non-deformable plane. He showed that by progressively covering each asperity with similar ones of smaller radius the relationship between the true area of contact and the load which it supported elastically approached direct proportionality. This would seem to support the validity of Archard's model, as it is usually assumed that the force of friction is proportional to the true area of contact between two bodies. (Since friction is proportional to load, according to Amonton's law, it is reasonable to expect that the true area of contact is proportional to load.)

Subsequent models of surface contact, based mainly on statistical approaches, have introduced descriptions of surface topography which have varying levels of realism. Many models assume surface asperities to have a Gaussian height distribution. Experimental investigations imply that at least some surfaces produced by engineering processes do have near Gaussian height distributions, so such an assumption can be justified.[167]

There are several versions. Greenwood and Williamson[168] constructed a model which used Gaussian and exponential functions to describe the height distribution of parabolic asperities prior to contact with a non-deformable plane. Greenwood and Tripp[169] constructed a similar model which employed spherical asperities on both surfaces. Whitehouse and Archard[170] conducted an analysis which avoided stringent assumptions regarding the geometry of individual asperities by assuming instead that the surfaces had an exponentially decaying autocorrelation function. Nayak[171] applied the technique of random process theory to describe engineering surfaces in a modification of the more complex analysis of random, moving, ocean surfaces conducted by Longuet-Higgins.[172,173] This work enabled useful relationships between the statistics of surfaces and profiles to be derived and applied later in an analysis of plastic contact.[174]

An academic debate exists regarding the nature of the deformation at asperity contacts. Some of the authors of the surface models outlined above derive a dimensionless parameter, the plasticity index, in an attempt to establish the proportion of plastic/elastic deformation which ocurs at asperity contacts. These plasticity indices relate the elastic modulus, the material hardness and a measure of surface roughness in order to achieve this.

The Greenwood and Williamson[168] model considers the deformation of a rough surface of hardness, H, which has a Gaussian distribution of asperity peak heights with standard deviation, σ, and constant tip radius β, in contact with a plane. If the joint, elastic modulus of the contact is E the plasticity index, ψ, of the rough surface given by this model is

$$\psi = \frac{E^1}{H}\left(\frac{\sigma}{\beta}\right)^{1/2}$$

where $\frac{1}{E^1} = \frac{1-\nu_1^2}{E_1} + \frac{1-\nu_2^2}{E_2}$. Note that if $E_1 > E_2$ then

$E^1 = \frac{E}{(1-\nu^2)}$ with E_1, E_2 and ν_1, ν_2 being Young's Modulus and Poisson's Ratio respectively for the interface materials 1 and 2.

The index indicates if a surface is likely to suffer a significant proportion of plastic deformation of asperities at a nominal pressure, P. Surfaces which have a plasticity index greater than unity will undergo plastic deformation at very low loads and can be expected to deform plastically in most practical applications. If ψ is less than 0.6, significant plastic deformation will only arise under very high loads, which would not be encountered in routine applications. Greenwood and Williamson[168] give an example in which a 'significant' proportion of plastic deformation is defined as plastic deformation over an area $\geqslant 2\%$ of the real area of contact. They state that a nominal pressure of 2.0×10^{-2} is required to cause significant plastic deformation if $\psi = 1$ and that a nominal pressure of 4.3×10^5 kg m^{-2} is required to generate the same proportion of deformation for a surface where $\psi = 0.6$. They also point out that, in practice, the index ψ can vary between 0.1 and more than 100.

Whitehouse and Archard[170] derived a more general version of the plasticity index from their surface model which does not rely on the assumption that surface asperities have a constant radius. It has the form

$$\psi^* = K\left(\frac{E'}{H}\right)\left(\frac{\sigma}{\beta^*}\right)$$

where K is a numerical constant, H is the hardness of the material, β^* is a parameter (defined in Section 9.10.3.8, called the 'correlation distance', and derived from the autocorrelation function of the surface shape).

Onions and Archard[175] found that if the constant, K, took the value unity then the plasticity index, ψ^*, could coincidently, be interpreted in the same way as the index proposed by Greenwood and Williamson. This suggestion appears to be generally accepted.

The plasticity index is potentially a very valuable parameter because it provides an assessment of the physical and geometrical properties of a surface. It has been suggested that it could provide a useful guide to the condition of a surface during the running-in process since the variation of the index with time will show how quickly the surfaces involved approach an elastic contact condition.[176]

Differences between the predictions of these surface models are discussed by Thomas.[177] These differences arise principally from variations in the form of the asperity models adopted, illustrating that the character of a surface, as well as its scale of roughness, has an effect on the nature of the contact between the surfaces.

9.10.1.3 Fluid flow

The topography of a surface influences the flow of fluids in other situations in addition to lubrication. This influence is economically significant in a number of engineering applications, including sealing and the propulsion of ships and aircraft.

Many different types of seal are used in engineering applications. Establishing the desirable surface characteristics of an efficient seal is not a trivial problem. One approach has been outlined in an investigation of the performance of lip seals.[178,179] This approach involved dividing the members of a collection of lip seals into two categories: those which sealed effectively and those which leaked. The topography of all the seals was characterized by measuring a number of commonly used surface parameters, and some of these parameters showed a loose correlation with the tendency of a seal to leak. By constructing a suitable algebraic function it was possible to use all the measured parameters together to differentiate between sealing and leaking topography much more effectively, making it possible to identify the characteristics of an ideally good and an ideally bad lip seal surface.[180]

Fundamental work on fluid flow conducted by Nikuradse in the 1930s has been recently reviewed.[181] Nikuradse investigated the flow of fluids through pipes roughened by sand grain coatings and demonstrated that the skin friction factor was a function of the ratio of the grain size to the pipe diameter. He showed that in the turbulent flow regime of a rough pipe, the logarithm of the friction factor is not inversely proportional to the logarithm of the Reynolds number as it is in the case of an ideal smooth pipe. Instead, the linear dependence ends at some point and the friction factor tends to a constant value which is related to the surface roughness/pipe diameter ratio as the Reynolds number increases.

The work of Nikaradse has been criticized on the basis that it does not simulate the topography generated by machining processes very effectively and is, therefore, of limited value. As a consequence, alternative methods of analysing fluid flow over rough surfaces in the form of model cracks have been investigated.[182]

Fluid flow over rough surfaces is of considerable importance in ship hull design, and it is reported that between 80% and 90% of the total resistance of a ship to motion is due to skin friction.[183] In addition, relatively small changes in roughness exert a significant effect. Conn *et al.*[184] describe an early investigation into ship hull roughness effects. For one particular ship they observed that different paint finishes could vary its frictional resistance by up to 5% while allowing the ship hull to foul could increase it up to nearly 50%.

A discussion of ship trial results collected over many years indicates that, typically, a 1% increase in power is required to maintain ship speed for every 10 μm increase of a roughness parameter called the mean apparent amplitude (MAA).[185] It is also stated that typical hull deterioration rates are between 10 μm and 40 μm MAA per annum, with new ships having a hull roughness of approximately 130 μm MAA while that of old ships may exceed 1000 μm MAA.

The efficiency of aircraft is also strongly influenced by skin friction. However, methods being considered to reduce skin friction seem to be directed along lines which are not associated with studies into the effect of the surface topography of the wings/fuselage.[186]

9.10.1.4 Vibration

Machines with moving parts inevitably produce noise when in operation. Noise can be generated as a result of the misalignment of components and the occurrence of mechanical resonances at particular speeds. However, a contribution to the noise spectrum can also arise as a result of surface roughness. Thomas[187] discusses three separate sources of noise arising as a consequence of surface roughness:

1. Noise generated by the elastic deformation and release of form and waviness features during rolling. This type of noise can be generated in EHL. At low speeds it contributes to the low-frequency end of the noise spectrum and it is unlikely to cause problems. However, at higher speeds both the frequency of the noise and its energy are increased and its effect may be significant.
2. Shock noise caused by the elastic deformation and release of asperities within the Hertzian contact zone. This form of noise arises in both rolling and sliding contacts. It is apparently the most dominant form of surface-generated noise and it may affect a broad range of frequencies, although its most severe influence is exerted between 300 Hz and 10 000 Hz.
3. Shock noise arising from asperity collisions and debris collisions. This form of noise arises in EHL where very thin films separate moving surfaces. Under such conditions inconsistencies in surface roughness can cause inter-asperity contact or collision with entrained debris to generate transient noise.

Two principal conclusions may be drawn with regard to noise generated by surface roughness:

1. By identifying the operating conditions of a component it should be possible to determine a surface finish which maintains low levels of acoustic noise.
2. Surface-generated noise may be valuable as a form of 'non-invasive' surface monitoring. It has already been

shown that surface-generated noise can be used to detect wear.[188] It is therefore potentially useful for the diagnosis of potential failure in rolling and sliding contacts.

9.10.1.5 Coating technology

The appearance and service performance of coated surfaces depends strongly on the surface topography of the overlaid substrate. As a result, materials which are to be coated are generally required to have a surface finish which is uniform and of a high quality, i.e. free from pits and scratches.

Cold-rolled steel is a typical example of a material for which a good-quality surface finish is essential to maintain the aesthetic appearance of objects constructed from it. It is widely used for the body panels of cars where small blemishes are visible even when sprayed. Avoiding visible defects is exceedingly difficult. The human eye can detect pits only 0.05 μm deep in a 'smooth' surface, and such features are only just within the range of routine surface-measurement procedures. Eliminating them by improvements in the manufacturing method can be difficult and expensive. Other applications in which control of surface roughness plays an important part in maintaining an acceptable aesthetic appearance include the manufacture of card, paper and photographic film.

As well as influencing aesthetic appearance, substrate roughness can also affect the service performance of painted materials. Substrate roughness causes variability in the film thickness of painted materials, which has an observable effect on corrosion resistance and ease of cleaning.[189] In general, it seems that the effect of painting a 'rough' surface is to make it 'smoother' whilst the consequence of painting a 'smooth' surface is to make it 'rougher'.[190]

9.10.1.6 Optics

Optical components such as lenses, prisms and mirrors are used in many different types of equipment. This equipment is used in a wide range of applications for both conventional purposes (e.g. microscopy, photography, astronomy) and more 'exotic' ones (e.g. laser beam collimation, the control of synchrotron radiation and infrared surveillance). Common applications also include the rapidly increasing use of optical components in communication devices,[191] transducers[192] and data-storage equipment.[193]

In general, in order to achieve satisfactory performance, exceedingly stringent tolerances on the roughness of optical components must be attained. Typically the standard deviation of their roughness is in the range 0.001–0.01 μm.[194] It is important to be able to characterize the surface topography of optical components so that limitations in performance can be estimated. Beckmann and Spizzichino[195] explain how a statistical description of a component such as a lens or mirror can be used to predict its scattering properties. In addition, Mie theory which requires a knowledge of the size, shape and optical constants of the feature can be used to predict scattering from small isolated features on a surface[196]. The effects of scratches, digs and other surface defects which have dimensions much greater than the wavelength of light can be determined only by relating their dimensions to those of standard scratches whose scattering characteristics are known.

9.10.1.7 Electronics and computer hardware

In recent years the size of integrated circuits has been reduced considerably while the number of electronic elements in a given area has approximately doubled each year. Ultimately, fundamental physical criteria will limit this progress.[197] However, for the moment, such factors are not constraining ones and the difficulties which limit the miniaturization of electronic circuits are engineering problems.

The surface roughness of component substrates appears to be one consideration in this respect. Photolithographic processes are used in the manufacture of integrated circuits. Deviation from flatness in the substrate surface causes gaps between the substrate and the emulsion of the photoplate which allows stray light to enter, causing defective circuit geometry.[198] Similar problems are encountered when circuit films are deposited through an evaporation mask. Deviation in flatness between the deposition mask and the substrate permit evaporated material to enter and thus destroy line geometry.[199] In addition to these effects, substrate roughness has been found to influence the resistance of thin-film resistors[200] and the charge-storage capabilities of thin-film capacitors.[201] Roughness effects appear to become significant when the thickness of the film layer – typically, 0.1–0.01 μm – is of the same order as the average roughness of the substrate.[199]

The design of magnetic recording media is another branch of modern technology in which surface topography is of importance. The quality of a magnetically recorded signal depends on head-to-media spacing and, therefore, on surface roughness. Computer disk systems are one important application of magnetic recording technology. The read/write heads which transfer data to and from hard disks must maintain close proximity to the disk without actually coming into contact and causing wear. They operate as small air slider bearings located between 0.25 μm and 0.4 μm from the disk surface, whose roughness amplitude is generally an order of magnitude less than the air/film thickness. White[202] has analysed the performance of thin-film air slider bearings with two-sided roughness. He suggests that, in practice, the character of the topography of the read/write head and the disk will not have an important influence on its operation, and shows that only the amplitude of the surface roughness therefore needs to be considered in the design of such components.

9.10.1.8 Bio-engineering, pharmacy and hygiene

There are several naturally occurring circumstances in biology where surface topography is important (e.g. the lubrication of synovial joints as described by Tandon and Rakesh[203]). However, such examples cannot strictly be regarded as engineering applications! More valid examples are to be found in the discipline of bio-engineering.

The performance of temporary artificial blood vessels is one aspect of this subject. The range of roughness in tubes used to bypass blood during heart operations varies from about 2 μm up to 15 μm.[204] One problem associated with these tubes is that they can damage the red blood cells flowing through them. Stewart[204] found that twenty times more red blood cells were destroyed by some tubes in comparison with others. His investigation established a correlation between the scale of roughness of the bypass vessel and the damage to red blood cells passing through them. In addition, surface character appeared to exert an effect: 'smooth' tubes were found to cause less damage than 'rough' ones.

Another aspect of the influence of surface topography on performance is evident in the pharmaceuticals industry. The manufacture of tablets is conducted in shaped dies and the efficiency and reliability of the tableting process is influenced by the surface roughness of these dies. Dies which have an unsuitable topography result in the incorrect formation of tablets or their fracture on removal.

Surface topography also has an important bearing on hygiene. Many surgical, catering and household implements are manufactured with high-quality surfaces because smooth, polished surfaces possess relatively few sites which harbour bacteria during cleaning.

9.10.1.9 Considerations in production

As long ago as 1933 a pioneering paper published by Abbott and Firestone[205] recognized some of the inadequacies of simplistic schemes of surface characterization. The fact that it is not possible to fully specify the character and scale of a surface with a small set of arithmetic indicators still remains a serious problem for production/design engineers. Often a description of a surface is made by specifying a particular machining process to identify the principal surface character and accompanying this by statistical parameters which give further detail.

The topography of an engineering component is largely determined by two factors. The type of machining method used controls its character, while the 'coarseness' of the operation, and to a point the time spent on manufacture, determines the roughness scale.

BS 1134[206] indicates that in a number of finishing processes there is a range of finish over which the cost of production changes only minimally with reductions in surface roughness. It also points out that there is normally a transitional finish beyond which the cost of producing a surface with further reductions in roughness increases rapidly. It is, therefore sensible to manufacture components with the scale roughness which still maintains acceptable performance. In addition the least costly process which produces a surface character with acceptable functional performance should also be selected.

Selection of an appropriate manufacturing process is not a straightforward decision because it involves a detailed consideration of how the entire component is to be made. Many components are made by multi-pass operations in which a coarse maching process is used to obtain the nominal component shape while a fine is used to establish the desired surface finish. This might involve applying the same type of operation more than once using different tool or machine settings or it may mean that a combination of entirely different processes are used to obtain the final surface. The combination of operations which gives rise to target specification most economically may not be obvious.

Establishing the machining conditions for a finishing process to obtain a specified topography is also not straightforward, as many interacting factors are involved. Under ideal circumstances the factors to be considered would involve only the operational setting of the machine (e.g. the geometric characteristics of the cutting tool, the work speed, the tool feed rate and the type of cutting fluid used). Even under ideal conditions it is only possible to calculate the theoretical roughness developed in a machining operation for the simplest types of process, i.e. single-point tool cutting. Relationships of this type for turned surfaces generated by tools with a range of tip profiles have been reported by Dickinson.[207] Relationships for less traditional metal-shaping processes such as electro-discharge machining (EDM), electro-chemical machining (ECM) and ultra-sonic machining (USM) have also been deduced.[208] However, they cannot be applied directly as they involve a parameter called a 'surface finish factor', which depends on the material of the workpiece/tool and the ultimate surface finish of the component. In order to apply the equations it is necessary to conduct trial tests to determine the surface finish factor for specific situations. (Some values of the surface finish factor for specific situations are given by Ghabriel *et al.*[208].)

Expressions which describe the relationships between operating conditions and surface roughness for complex cutting operations such as grinding and milling are apparently not available. Companies employ their own heuristic guidelines to estimate surface finish in these cases.

In practice, it is not usually feasible to obtain the surface finish predicted by theoretical conditions. Several factors combine to prevent this. Probably the most significant factor is the accretion of cutting debris on the tip of the tool. This accretion is in a dynamic state, continually breaking down and being replaced with new debris, causing the tool to have variable cutting characteristics. In general, the roughness of the surface produced by the built-up edge of the tool increases as the built-up edge grows larger. Changes in machining conditions which tend to reduce chip-tool friction/adhesion result in improved surface finish. These include increased workpiece speed, use of different tool materials (e.g. carbide tool tips) and the application of a good cutting lubricant. A detailed study of the effect of built-up edge on the surface roughness of a turned component is presented by Selvam and Radhakrishnan.[209]

Many other factors contribute to non-ideal surface finish arising under practical machining conditions. The most common of these are: chatter vibration of the machine tool, inaccurate tool movement, defects in the composition of the workpiece and discontinuous chip formation in the machining of brittle materials. In addition to these problems it appears that where several types of machining are applied in the manufacture of a component the 'shadows' of earlier operations sometimes remain evident in the topography of the finishing process.[210]

From these studies it is apparent that many problems are associated with the production aspects of surface roughness. Some are concerned with achieving good functional performance but just as many are of an economic nature. BS 1134[206] points out that 'seeking too good a finish' is a common error leading to waste in production time. It also outlines two simple philosophies to guide designers in controlling surface texture, but it concedes that the practice to be adopted depends very strongly on the area of engineering concerned.

The optimization of manufacturing operations is a highly complex subject, even when only the problems outlined above are considered. However, in the real manufacturing environment many other important variables also become involved (e.g. the power consumed by the various machining processes, the effect of the type of material being worked, and the quantities of raw material wasted in manufacture). Surface finish is just one consideration that must be reconciled with many others.

9.10.2 Measurement

Surface structure exists in two directions: the vertical direction, where it is characterized by height (or amplitude) parameters, and the horizontal direction where it is characterized by spatial (or wavelength) parameters. Any measurement method should be able to record roughness variations in both directions.

In the vertical direction roughness amplitudes vary widely. Coarse machining operations can produce features several hundred micrometres high. However, in contrast, some surfaces manufactured for special applications may contain perturbations of only molecular dimensions. In the horizontal plane, roughness variations arise on a scale which varies from the dimensions of the specimen down to atomic diameters. It is clear, therefore, that wide extremes of range need to be encompassed by any technique used to measure surface topography.

The relevance of surface topography to the functional performance and production cost of a component over a very wide range of applications has precipitated the development of a plethora of instruments to record and parameterize the structure of surfaces, and each of these devices has different limitations and advantages. In recent years development has centred largely on instruments which measure surface topography without contact with the specimen, i.e. mainly optical methods. However, these devices are, as yet, not particularly well established in terms of the number of applications in which they are used routinely. This situation may change in the future but, for the moment, more traditional techniques (i.e. stylus instruments and 'mechanical' comparators) share the bulk of the workload.

9.10.2.1 Stylus instruments

For many years the most popular device used to measure surface topography has been the stylus instrument. Despite some disadvantages, it has proved versatile and reliable in both the manufacturing and research environments. It is also the instrument in terms of which all national standards are defined.[211]

Construction and operation A typical commercial stylus instrument comprises five basic components: a stylus transducer, an amplifier, a chart recorder, a traverse unit and a meter system, as illustrated by the block diagram in Figure 9.91(a).

A common form of stylus transducer, which employs a linear variable differential transformer (LVDT), is manufactured by Rank Taylor Hobson. It consists of a beam which is pivoted on two knife edges and carries the stylus at one end with a ferrite block at the other (Figure 9.91(b)). The ferrite block is located between two coils. As the stylus is drawn over the irregularities of a surface by the traverse unit the stylus is displaced, causing the ferrite block to move between the coils. The coils form part of an inductance bridge circuit which is balanced when the stylus is in a neutral position. When the stylus changes position it causes a change in the mutual inductance in the coils modulating a high-frequency carrier signal in proportion to the displacement of the stylus. The relative change in the phase of the carrier signal indicates the direction of displacement of the stylus. The carrier signal is amplified and demodulated to yield a signal representing a surface profile which may be output to a chart recorder or used to evaluate some parametric assessment of surface roughness given on a meter or visual display unit.

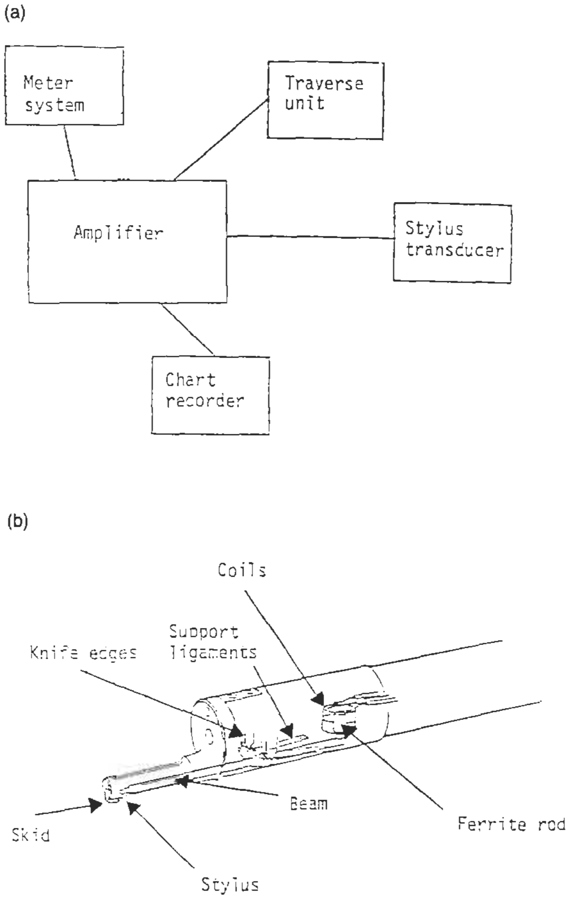

Figure 9.91 (a) Principal components of a commercial stylus instrument; (b) construction of a linear variable differential transformer stylus transducer (based on Figure 66 of *Exploring Surface Texture* by H. Dagnall and reproduced with the permission of Rank Taylor Hobson)

In addition to LVDTs, several other forms of displacement transducer are in use (e.g. optical interferometers, variable capacitors[213]).

Range and resolution LVDT transducers usually have a maximum vertical range of between 0.5 mm and 1.0 mm. The vertical resolution of stylus instruments depends mainly on the level of ambient vibration in the vicinity of the instrument but it is also influenced by electrical noise inherent in the amplifier. Divisions of 0.01 μm are common on the output of chart recorders, suggesting that this level of accuracy can be approached under controlled conditions.

The horizontal range of a stylus instrument is determined by the distance which the stylus is able to traverse. The horizontal resolution depends on the shape and dimensions of the stylus tip, and it is a limit which cannot be defined exactly.[214]

Datum arrangements The output of a stylus transducer depends on the difference in height between the stylus and a reference datum. To exclude the form of a component from measurements of topography it is necessary to generate this datum by causing the transducer to follow a path parallel to the nominal shape of the component. This can be achieved in two ways:

1. Using an independent datum as illustrated in Figure 9.92(a). Here an accurately flat or curved shape which corresponds to the nominal shape of the specimen is used to constrain the vertical position of the transducer as it traverses the specimen.
2. Using a skid datum which is attached to the transducer. The skid rests on the specimen and follows its form as the transducer is drawn along by the traverse unit in the manner illustrated by Figure 9.92(b).

When the independent datum is used, all departures from the nominal shape are recorded. However, it is a time-consuming method of measurement as an extensive setting-up procedure is often required to align the specimen and datum. Use of the skid datum circumvents this difficulty but surface profiles recorded using this datum may not be accurate. A specimen surface containing features with wavelengths greater than the length of the skid surface profile will be subjected to a high-pass filtering operating as the skid changes its vertical position when crossing these features. Isolated peaks in a surface can also generate spurious artefact valleys.[212]

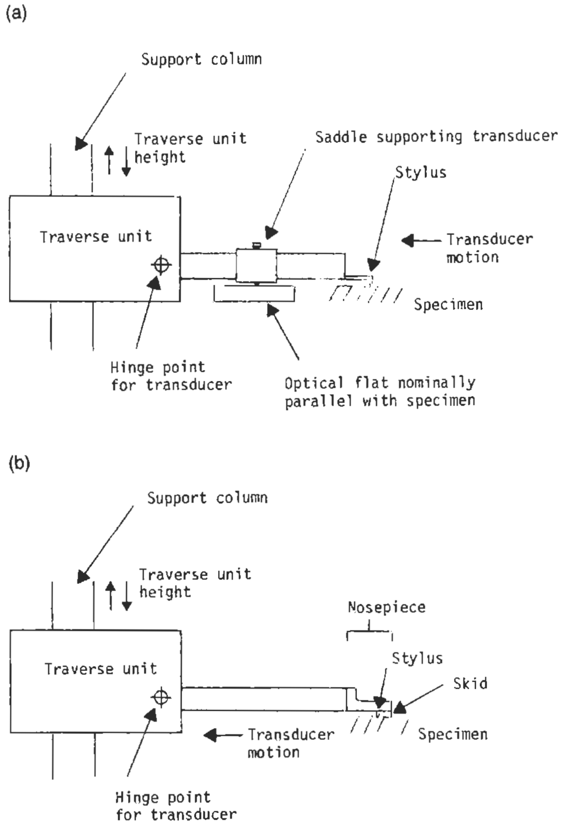

Figure 9.92 Datum arrangements for nominally flat specimens. (a) Use of the independent datum; (b) use of the skid datum

A number of experimental and theoretical investigations have been conducted to examine the extent of profile distortion by the skid datum. The main conclusions are:

1. Use of the skid datum, in appropriate circumstances, only has a small influence on the parametric characteristics of a profile.[215]
2. When parametric influences are observed the peak parameters of a profile are those most significantly affected.[216]
3. Inaccuracies caused by use of a skid are greater for surfaces with prominent directional characteristics.[217]

Stylus effects Early publications report that gramophone styli were used as the transducer probe.[218] These have since been replaced by specially designed styli which are smaller and tipped with diamond to improve resistance to wear. Two types of stylus shape are commonly used: a conical stylus with a spherical tip and a pyramidal stylus with a truncated, nominally flat tip. The spherical tip of a conical stylus usually has a radius of less than 10 μm. The flat area of a pyramidal stylus is typically a rectangle of dimension 8 μm × 4 μm, the longer side being normal to the direction of traverse.

The profile recorded by the stylus tip is never a perfect assessment of the shape of the specimen. This arises as a consequence of two factors; the finite size/geometry of the stylus and the load it applies to the specimen surface:

- *Geometric/size considerations*
  The shape recorded by a stylus as it traverses a surface is the locus of a fixed point on the stylus and is known as the 'effective profile'.[141] As a consequence of its shape and finite size the profile recorded by the stylus can differ from the true surface shape; i.e. its shape can be distorted and, in some circumstances, its amplitude may be attenuated. In general, the shape and finite dimensions of the stylus cause the radius of curvature of peaks to be slightly enhanced and the width of valleys to be slightly reduced (Figure 9.93). Attenuation of high-frequency contributions to the profile shape also occurs. This arises because the stylus is unable to enter valleys which are narrower than its own length. This is a progressive effect which begins when the radius of curvature of a profile valley is smaller than the effective radius of curvature of the stylus.
- *Physical interactions*
  In most stylus instruments a spring is used to apply a small force, approximately 0.001 N, to the stylus to ensure that it always remains in contact with the specimen. As this load is supported by a very small area at the stylus tip, high pressures are generated at the contact with the specimen and temporary or permanent deformation can ensue. A number of investigators have estimated the magnitude and form of deformation caused by styli. However, theoretical estimates of deformation due to stylus pressure tend to vary widely depending on the assumptions made in the calculation. Many physical and chemical factors such as variation in hardness, oxidation level and fatigue influence the result as well as parameters which relate to the stylus geometry. Additional problems can also arise as the bulk properties of a material do not necessarily give an acceptable model of its microscopic behaviour (e.g. microscopic hardness has been found to be a function of load[219]).

It appears to be accepted that the errors caused by the effects described above are negligible under most circumstances. However, care should be taken when features of interest have the same order of magnitude of width as the stylus tip and, additionally, when the specimen has a low bulk hardness value. Methods for estimating errors due to the shape and load of styli are given in reference 214.

Digital data-acquisition systems The development of flexible digital systems has permitted the value of stylus instruments in experimental studies in surface topography to be extended considerably. Digitized data are commonly acquired by sampling the amplifier output from stylus instruments. In the earliest systems, analogue data were converted into digital form and stored on punched paper or magnetic tape and then taken to a remote computer for subsequent analysis. Such an approach was adopted by Williamson.[220]

More recently, there has been an increase in the use of on-line systems. Equipment typically used in on-line data acquisition is illustrated in Figure 9.94. The principal components are a commercial stylus instrument which is linked to a computer through an analogue-to-digital converter (ADC) and an interface which usually includes a filter to set a high-frequency cut-off point in the data. To generate the output signal the transducer gearbox may be operated manually or automatically by the computer via a series of electric relays. Collected data are normally stored on-disk or in memory for subsequent processing rather than being analysed in real time. A number of on-line data systems have been described.[221–224]

One common criticism of stylus instruments is that they are normally restricted to supplying only profile data. However, stylus instruments can be adapted to allow an areal record of a surface to be obtained, rather than a simple profile. This is achieved by recording several parallel profiles, each displaced laterally from the previous one by a short distance. If all the profiles are referenced to a common origin they form a raster-scan record of the surface. A raster scan recorded using

9.10.2.2 *Comparative techniques*

A wide range of instruments which use comparative techniques have been developed. Generally, their principle of operation is based upon a physical phenomenon which shows some dependence on surface roughness. Sometimes these devices are designed to give a parametric assessment of surface roughness, although the reliable operation of this type of instrument is often limited to a given class of surface topography.

Comparative devices have several advantages; they are relatively inexpensive, they are quick to apply, and they do not require extensive special training to operate.

Friction tests Probably the most well-known comparative measurement technique is the tactile test. In this test the finger is drawn across a specimen and its 'feel' (i.e. the frictional resistance) is then compared to that produced by a set of calibrated samples manufactured by the same process. The sample whose 'feel' most closely resembles that of the specimen is noted.

It has been found that the tactile test is significantly more reliable than visual inspection as a method for assessing surface roughness. However, the range of accurate comparison appears to depend on the character of the surface under inspection.[228]

Electrostatic techniques The distance separating two plane metal surfaces can be estimated by using them to form a capacitor. If they are separated by an insulating layer of air of thickness t_a, the capacitance, C, of the combination is given by

$$C = \frac{K\epsilon_a A}{t_a}$$

where A is the area of the smaller plane, ϵ_a is the permittivity of air and K is a constant. Measuring the capacitance of the combination using a bridge circuit permits t_a to be calculated. In principle, by forming a capacitor using a free electrode and a rough surface it is possible to obtain some assessment of surface roughness by measuring the capacitance of the arrangement and calculating t_a, which will then be some average measure of separation. (Note that it is not the distance of the mean plane of the surface from the probe.)

A number of transducers of this form have been described in publications[229,230] and the most reliable one has a flexible electrode coated with a dielectric material.[230] The flexible electrode allows the transducer to conform to the surface shape to remove the effect of waviness and form errors. The dielectric layer serves to make the transducer less sensitive to contact pressure. Capacitance measured roughness, t_a, shows

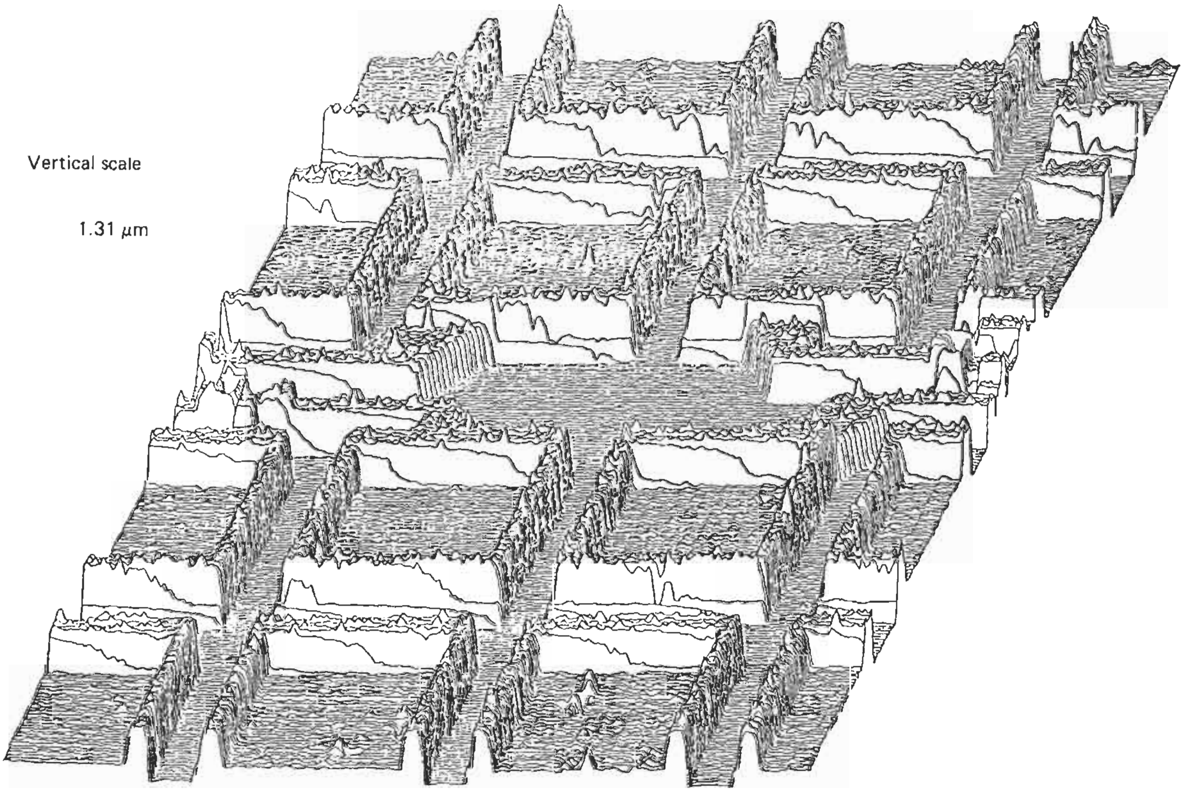

Figure 9.95 A raster-scan of the surface of an integrated circuit

some correlation with a parameter called 'depth of surface smoothness', defined by reference 231.

Pneumatic methods Surface roughness can be measured by a method called air gauging, which assesses the flow of air through a gap between a specimen surface and an open-ended nozzle placed facing downwards onto it. The nozzle is normally connected to a source of air at a constant pressure, P, via an intermediate chamber. The flow of air into this chamber is regulated by a valve whose open area is a; its flow out is controlled by the area, A, of the gap between the nozzle and the surface asperities which support it. Escape of air from the nozzle causes the pressure in the intermediate chamber to fall to p. It can be shown that, over a certain range, the relationship between p/P and a/A is linear, allowing the method to be used to assess surface roughness.[232]

Experimental measurements made by air gauging have been found to exhibit a linear relationship with an average roughness of $R_a = 0.1\ \mu m$ to $R_a = 5\ \mu m$.[233] The extent of correlation of back pressure with other roughness parameters has also been investigated by experiment.[234]

A novel approach to air-gauging techniques has been described by Tanner.[235] Rather than measuring pressure differences, a null method based on a pneumatic analogue of a Wheatstone bridge was used to measure pressure in the nozzle. Several stages of development resulted in a compact device able to give an electrical signal/readout proportional to the average surface roughness.[236–238]

Air-gauging methods provide a simple, inexpensive, portable, quick and robust way of assessing surface roughness well suited to use in the quality control of surfaces on the shopfloor and the technique appears to find particular favour in the paper industry. British Standards have been compiled in an attempt to develop a common approach in its use in this application (e.g. reference 239). Table 9.29 summarizes the performance of three comparative techniques used to assess surface roughness.

Table 9.29 A summary of the performance of parametric techniques of surface roughness measurement

Technique	*Usable R_a range*	*Notes*
Friction tests	0.025–3.2 μm Ref. 228	Accuracy depends on surface type
Electrostatic measurements	1.5–10 μm Ref. 230	Data not available on wider range measurements
Pneumatic methods	0.16–5.69 μm Ref. 233	Range apparently extendable if required Ref. 235

Note: R_a range is given as a measure of performance. This is not intended to imply that the raw instrument output correlates best with this parameter.

9.10.2.3 *Optical methods*

Although the stylus instrument is currently very widely used in the measurement of surface roughness, it suffers several significant disadvantages:

1. It normally provides information only for a profile section of a surface.
2. The finite size of the stylus and the load it applies to the specimen can give rise to measurement errors and specimen damage.
3. Its operation is relatively slow. It cannot be used as an 'in-process' measurement technique (e.g. to monitor the performance of numerically controlled tools).

The advent of sophisticated digital electronic systems has, in recent years, allowed optical data to be processed more easily, and this has encouraged the development of instrument systems which measure surface roughness through optical phenomena. These methods have several attributes which no other single technique can claim:

1. Normally, areal data can be obtained easily.
2. There is no contact between the specimen and the instrument, so no surface damage is caused during measurement.
3. Measurements can be performed quickly.
4. Measurements can be made on any type of material (i.e. they are not restricted to observations of electrically conductive materials as required by electron microscopy).
5. The specimen does not need to be in a vacuum.
6. Complex specimen preparation is not required.

Techniques which measure surface roughness using optical phenomena can be divided into two broad categories: non-parametric techniques, which are able to record the actual topographic structure of a specimen, and parametric techniques, which are only able to assess the general characteristics of an area of surface (e.g. its rms roughness).

Non-parametric instruments A number of non-parametric techniques are available and can be divided into three categories by their principle of operation:

1. Light sectioning
2. Interference microscopy
3. Focus feedback methods.

Light sectioning is a non-destructive analogue of the process of taper sectioning whereby an optical microscope is used to examine a section cut through a specimen surface at a shallow angle to magnify height variations.[240] Light (or optical) sectioning is sometimes referred to as the Schmaltz technique, after its inventor. Figure 9.96 illustrates the principle of light sectioning. The surface is illuminated by a light beam collimated by a narrow slit. This is then viewed from the side, usually by means of a microscope. Topographic features in the surface, illuminated by the beam, appear as profile sections. Illumination and viewing angles of 45° are normally adopted, leading to a magnification of the height of features in the profile by a factor of $(\sqrt{2})$.

The practice of illuminating the specimen from an angle introduces distortion into the observed image. The features visible in it do not represent a true cross section of the surface because the valleys are displaced laterally from the peaks by a small distance. This can be overcome by illuminating the specimen from a normal angle, although this reduces the vertical magnification.

Optical sectioning is suitable for examining surfaces whose roughness range is between 2 μm and 200 μm. The vertical resolution of the technique is about 0.5 μm.[241]

Until recently, because of the difficulty of extracting quantitative information, optical sectioning has only been used to assess the profile range, R_t, and for quantitative examination of surface features. This difficulty has been overcome by digitally recording an image delineated by a narrow laser beam using a television camera. This image is then transferred to a computer for storage, processing and display.[242,243]

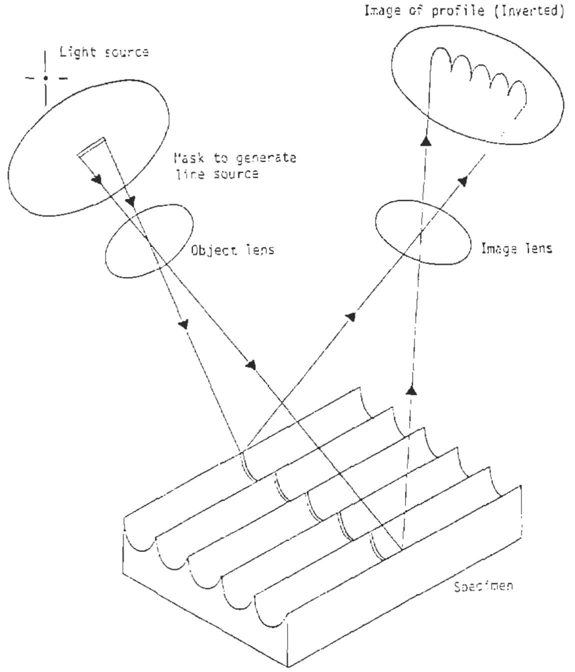

Figure 9.96 Principle of the light-sectioning method. (Based on Figure 128, Dagnall, H. *Exploring Surface Texture* and reproduced by permission of Rank Taylor Hobson)

In *interference microscopy*, if two slightly inclined glass plates are illuminated by a coherent monochromatic light source, a series of parallel light and dark bands will be visible when the arrangement is viewed from above (see Figure 9.97). The dark bands arise as a result of the destructive interference of light wave fronts. The distance between neighbouring fringes is $\lambda/2$, where λ is the wavelength of the illumination. In principle, interference techniques can be used to examine surface topography by replacing the lower glass plate with a reflective specimen and the upper one with some form of reference plane nominally aligned with the specimen. Interference between light beams from these surfaces will generate a contour pattern of the surface irregularities of the specimen. Interference microscopy is suitable for measuring surface irregularities with low slopes and roughness ranges less than 1 μm. (In areas of high slope, surface contours blend together and cannot be interpreted.) Several types of interference microscopes exist and their design and capabilities are reviewed by references 244–246. The two main categories of interferometer are the double- and the multiple-beam types.

Typically, the double-beam interferometer has a horizontal resolution of 1.0 μm and a vertical resolution of 0.01 μm. The corresponding figures for the multiple-beam device are 2.5 μm and 0.001 μm.[247] (In multiple-beam interferometry the beam is displayed sideways at each of the 50–100 reflections, causing a reduction in horizontal resolution.)

Until recent years interferometric measurements have been restricted in their use to the examination of specific features, such as the height of steps and the depth of grooves, because interferograms could not be readily transformed into an electronic signal which could be submitted for further analysis.

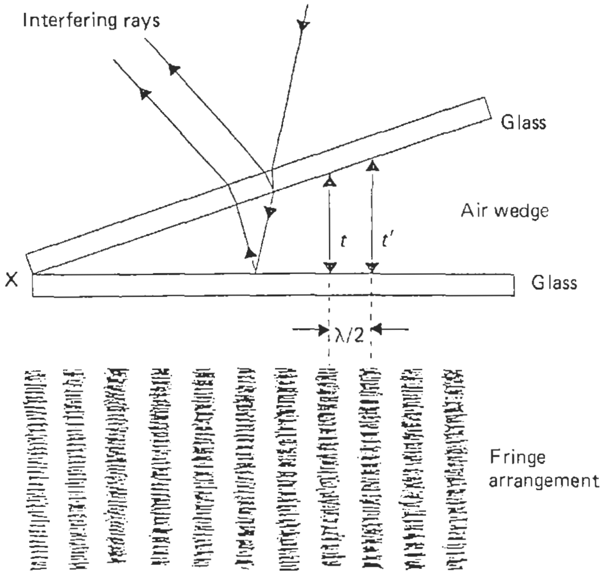

Figure 9.97 Interference fringes caused by an air wedge (wedge angle exaggerated). At X, the path difference, PD, is zero but a dark fringe is observed. This is caused by the 180-degree phase change which occurs when light is reflected at a dense medium. The phase change is equivalent to a PD of $\lambda/2$. At the mth dark fringe where the wedge thickness is t, the effective PD, $m\lambda$, is therefore

$m\lambda = 2t + \lambda/2 \quad m$ – integer

At the next fringe where the thickness is t' the PD is

$(m + 1) = 2t' + \lambda/2$

Hence the fringe separation is

$t - t' = \lambda/2$

Developments in the field of electronics in the last fifteen years have made the automatic collection of qualitative details in interferograms more straightforward, permitting them to be used to obtain parametric assessments of surface topography.

The use of television cameras, charged coupled devices (CCDs) and phototransistors now allows fringe patterns to be recorded relatively easily for storage and processing by computers. With this modification, 'standard' interferometers have been used to examine the surfaces of semiconductor wafers,[248] magnetic recording media,[249] gauge blocks[250] and optical components.[251] Digitized images are also of value because they can be signal averaged to allow the fidelity of fringe patterns to be enhanced. This technique has been used to obtain accurate surface statistics for use in verifying light-scattering theory.[246]

Interferometric measurements of even higher accuracy can be obtained using phase detecting systems in which two polarized beams of slightly different frequency are focused onto a point on the specimen surface and a stationary reference. The beat frequency of interfering return beams is directly proportional to any change in height of the specimen surface. The 'interrogating' beam can then be swept around the surface to obtain height measurements at specific points. Circular[252] and linear[253,254] scan patterns have been used in surface examination. These systems are able to examine small areas about 0.5 mm × 0.5 mm and have vertical and horizontal resolutions of 0.5 nm and 1.25 nm, respectively.

An ingenious variation on the use of interferograms involves holography. The approach involves the use of standard holographic techniques to form two holographic images of an object on the same plate. Each image is generated using illumination of slightly differing wavelengths. When the plate is developed and re-illuminated with monochromatic light, interference between wavefronts produced by the two slightly different images generates a fringe contour map. The difference in the height represented by these contours can be varied between 1 μm and several millimetres, allowing surface form as well as roughness to be examined. Holographic techniques have been applied to study wear[255] as well as surface shape.[256,257]

A number of research instruments have been developed and tested which can be classified as *focus feedback methods*. They all operate on similar principles although the detailed design of these instruments may differ significantly.

The operation of all these devices relies on a narrow beam of light 0.5–4 μm in diameter which is accurately focused on the specimen surface. If the spot is caused to traverse the specimen surface, undulations will cause the vertical location of the spot to be modified, thus destroying its exact focus. A number of methods of assessing the extent of this defocus are available. They are used to evaluate an error signal which refocuses the spot by adjusting the position of the specimen,[258] or a lens,[259–261] or to calculate the vertical displacement of the spot directly by monitoring parameters related to its size.[262] Several optical configurations can be used to monitor defect of focus.[263] Sometimes the best aspects of two designs can be combined to give better performance.[264,265]

In general, the performance of focus feedback-based instruments can be as good as that of stylus instruments. Their horizontal resolution falls in the range of 5–0.01 μm and their vertical resolution typically is 0.1 μm, although vertical resolution of 0.001 μm has been claimed.[261] The output of these devices is rather similar to the output of stylus instruments, i.e. a voltage proportional to the height of the surface relative to a fixed point. However, their vertical range is usually larger than that of a stylus instrument of comparable resolution and, in addition, no contact is involved in the measurement of height, and sometimes surfaces which have variable reflectance create problems. Despite this, instruments based on focus feedback appear to have the potential to be a serious commercial rival to the stylus instrument in the future.

Parametric methods A wide range of measurement methods use the reflection of light to quantify surface roughness in parametric terms. Many of these techniques have considerable potential for 'in-process' use as they offer a 'real-time' assessment. In addition, they examine an area of a surface rather than a profile. This is often considered to be a desirable attribute for any method which quantifies surface topography.

Three basic optical phenomena are employed in attempts to measure surface topography:

1. Scattering
2. Speckle
3. Polarization.

Scattering measurements Theories which reliably predict the distribution of light scattered from a rough surface are only available for cases where the surface structure takes specific forms. The domain of validity for those theories available has been evaluated for the case when the target surface is a sine wave.[266]

However, it was found that these theories only provided a good approximation for the distribution of light reflected from 'general' engineering surfaces when the rms roughness of the surface, R_q, was much less than the wavelength of illumination, λ. Nevertheless, a number of studies have addressed measuring surface roughness in this range using scattered light. These measurements are classified according to the component of the reflected beam which is recorded. These are:

1. The specular beam
2. The diffuse beam
3. Total scatter
4. The angular distribution.

When a collimated beam of light is reflected from a plane, conducting surface, all the light remains in a collimated beam known as the *specular beam*. If the reflecting surface is rough, light is scattered into a distribution of angles. In general, as 'roughness' increases, less light is scattered along the specular direction.

Measurement of the intensity of the specular beam produced by a narrow incident beam reflected from a rough surface is the most straightforward type of reflectance assessment to conduct. Measurements of this type have been used for many years, strictly for comparative purposes, using an instrument called a glossometer.[267]

Measurements of the intensity of this beam can also be used to predict the R_q roughness of surfaces with a Gaussian height distribution provided $R_q < \lambda/10$.[268] Beyond this limit the specular beam disappears. However, it appears that some form of correlation between specular intensity and roughness can still be identified, even when the surface height distribution is not Gaussian.[269]

As surface roughness increases, the pattern of the scattered radiation tends to become more diffuse. Investigators who use the *diffuse beam* to assess surface roughness attempt to identify a parameter which characterizes the 'diffusiveness' of the scattered radiation and then try to relate this parameter to surface roughness by empirical studies.

Attempts to measure diffusiveness have involved comparing the intensity of the specular beam with the intensity of rays at a fixed angle away from it[270] and measuring the 'width' of the specular beam itself.[271] The techniques only appear to show limited correlation with surface roughness parameters but may provide the basis of useful 'in-process' comparators.

Total scatter measurements involve assessing the total intensity of light diffusely scattered from a surface, i.e. it is the total integrated scatter (TIS). The arrangements required to make TIS measurements are more elaborate than those necessary to assess specular reflectance. The main component required to record TIS is a reflective sphere, called a Coblentz sphere, which surrounds the specimen and collects all the light reflected from it. (Except for that projected along the specular direction. Light collected by the sphere is thrown onto a detector.) The proportion of diffuse light reflected by the specimen is deduced by directing the incident beam alternately onto the specimen and directly onto a second detector, and comparing the output of the two detectors.[272]

TIS measurements give the same information as specular reflectance measurements about surface roughness. However, it appears that TIS measurements are particularly valuable in the optics industry as they provide a fundamental method of appraising the performance of optical components which can be automated relatively easily.[272]

Under the usual condition that $R_q \ll \lambda$ it can be shown, using scalar scattering theory, that the angular distribution of light scattered from a rough surface directly is a map of the power spectral density of the surface topography.[273] For light normally incident on a specimen surface it has been reported that the scattering angle, θ_s, is related to the roughness component of frequency, r, by

$$\sin \theta_s = (\lambda/2\pi)^r$$

and the *angular distribution* of the scattered radiation can be related to the power spectrum.[266]

The bandwidth of the roughness spectrum which can be measured using the angular distribution can also be predicted. The long wavelength limit is set by $\theta_s = 90°$ with the short wavelength limit being determined by the minimum scattering angle which can be measured with respect to the specular beam, typically 0.5°. HeNe and CO_2 lasers are commonly used to provide illumination. The long and short wavelength limits spanned by these sources are approximately 0.8–80 μm and 10–1000 μm, respectively.[273]

The great advantage of angular distribution measurements over other forms of scatter measurement is that they supply spatial data as well as height information about surface roughness. Several investigators have constructed apparatus to measure the roughness of optical components and other 'high-finish' surfaces using angular distribution measurements.[274–279]

Speckle pattern measurements When a rough surface is illuminated with partially coherent light, random patterns of bright and dark regions can be observed in the reflected beam. This phenomenon is known as speckle. The spatial distribution and contrast of speckle patterns has been found to depend on surface roughness. As a result, the use of such patterns for the measurement of surface roughness has been investigated. Three main forms of speckle measurement are under development:

1. Monochromatic speckle contrast
2. Polychromatic speckle contrast
3. Speckle pattern correlation

1. *Monochromatic speckle contrast*: In speckle contrast investigations changes in intensity of the speckle pattern are commonly assessed by a parameter called average contrast, V. The contrast in speckle patterns produced by monochromatic light has been found to correlate with the average roughness, R_a, of surfaces up to a limit of about 0.13 μm.[280] Beyond this point a saturation effect is evident. Further increases in roughness produce no change in the speckle contrast, V. The use of radiation of longer wavelength will, theoretically, permit surfaces of roughness up to about $R_a = 1$ μm to be assessed. Further increases in the measurement range of speckle techniques can be achieved by using polychromatic illumination.
2. *Polychromatic speckle contrast*: Speckle patterns can also be produced by reflecting light which covers a band of frequencies, $\Delta\nu$, from rough surface specimens.[281] Speckle patterns produced using polychromatic illumination display contrast variations which increase initially and then decrease near to the point where monochromatic speckle begins to saturate. This measurement technique has been used to obtain an assessment of rms roughness, R_q, on a range of manufactured surfaces.[282] The range of validity for measurement of R_q is

$$\frac{\lambda}{2} < R_q < \frac{2c}{\Delta\nu}$$

   where c is the velocity of light. With the laser sources currently available this allows roughness measurements up to $R_q = 5$ μm to be made.[273]
3. *Speckle pattern correlation*: In this technique two speckle patterns are produced from a specimen using illumination either from two different angles or from two sources of different wavelength. Discrimination of these patterns can be achieved either by double exposure of a photographic plate or by the use of frequency-sensitive photodetectors. This permits their degree of correlation to be established by means of the intensity cross-correlation function. Good agreement between roughness assessments by speckle contrast measurements and stylus instrument measurements has been observed over wide ranges ($R_q = 0.13$–6 μm,[283] $R_q = 8$–32 μm[284]).

Polarization measurements The science of measuring the change in the state of polarization of a beam of light when it is reflected from a surface is known as ellipsometry, which is conventionally used to measure the thickness of surface films. However, the polarization of a reflected beam is also influenced by surface roughness, so the possibility that it may be used to measure roughness arises.

The value of ellipsometry in surface studies has not been firmly established. There is some evidence that suggests an almost linear relationship between the R_a roughness of specimen surfaces and parameters which describe the state of polarization of light reflected from them.[285,286] However, other studies have encountered difficulty because it has not been possible to isolate changes in polarization due to oxide film effects from those due to surface roughness.[287,288] This problem appears to be a significant drawback to this method of roughness measurement.

9.10.2.4 Microscopy

The use of conventional optical microscopes is limited by a compromise which exists between the resolution and depth of field obtained in the image of a specimen. An inspection of resolution/depth of field data for optical microscopes reveals that they are not suitable for general use in the study of engineering surface topography because they cannot offer a depth of field which maintains all parts of the specimen in focus simultaneously while providing enough resolution to expose the relevant details of machined surfaces.[289] (This excludes interference microscopes, which operate on a different principle and are discussed in Section 9.10.2.3.)

Electron microscopes offer significantly better resolution and depth of field than optical counterparts.[290] The improvement is chiefly due to the very short wavelength of electron microscope beams in comparison with visible light.[291] As a consequence, electron microscopes tend to be more useful in the study of surface topography than conventional optical light microscopes.

Electron microscopy There are two basic types of electron microscopy:

1. Transmission electron microscopy (TEM)
2. Reflection electron microscopy (REM)

In TEM an image is produced when electrons are incident on a thin specimen (<1 μm thick) which deflects and scatters the electrons as they pass through it. A lens system magnifies and focuses scattered electrons to form an image on a screen which can be viewed directly or photographed.

In order to examine the surface of a metal component using TEM it is usually necessary to fabricate a replica of the specimen surface. This arises because it is difficult to remove a thin layer from a component for inspection without distorting it and/or the investigator may wish to examine the specimen without destroying it. The process of manufacturing surface replicas is not without problems.[289] TEM is typically able to resolve features up to a separation of around 0.3 nm[291] and has been employed to study the changes in surface structure during wear.[292]

In REM, electrons scattered from the surface of the specimen are focused to form an image. (This removes the requirement for specimens to be thin.) Commonly, this image is produced by a beam of finely focused electrons which scans the specimen in a raster pattern, a process called scanning electron microscopy (SEM). Scanning electron microscopes have a typical optical resolution of about 10 nm, a little less than that available in TEM.[291] However, this disadvantage is compensated by the fact that specimen preparation is considerably easier. Conductive specimens can be inspected directly and replicas can have a deep construction, which makes them more robust. SEM is also a popular technique used in the study of wear mechanisms.[293]

Several special problems arise when examining specimens with any form of electron microscopy. First, specimens must be small enough to fit into the specimen cell of the microscope (typically, no more than 20 mm by 20 mm). As a result, the examination of the surfaces of large components can only be achieved by destructive means (i.e. cutting the specimen) or by fabricating replicas which may be unreliable. Specimens must preferably be electrically conductive, but non-conductors can be examined successfully by coating them in a thin layer of metal by a vacuum evaporation process. Special techniques to observe non-conductors for long periods without this preparation are also available.[294] The examination of surfaces using electron microscopy is never a quick operation. The preparation of the specimen takes some time, as does the formation of the vacuum in the microscope – required so that electrons can travel through the microscope without being scattered by air molecules.

Electron microscopy is a popular technique used in the investigation of surface structures and wear particles. However, the interpretation of the images it forms is not necessarily straightforward. Additionally, these images do not readily yield quantitative data about the height of surface features. Recently some attempts have been made to derive height data from this process.[295] This was achieved by digitizing micrograph images using a microdensitometer to produce an array of grey scale points. As it has been shown that the slopes of surface elements are proportional to the micrograph density, integrating the density data allows a surface profile to be generated.[296] Assembling an ensemble of parallel profiles calculated in this way allows three-dimensional views of the surface to be drawn and parameters to characterize the surface shape to be calculated.

Photogrammetric methods have been used to obtain height data from both TEM and SEM images.[297,298] In this technique two micrographs of the surface are formed by viewing the specimen at different inclinations to the main beam. Surface contours are then calculated by viewing the images as a stereoscopic pair and evaluating changes in relative height from parallax differences using a photogrammetric plotter.

An alternative method of deriving topographic information from SEM images using feedback control has also been described.[299] This approach relies on feedback adjustment of the objective lens of the microscope through computations based on the intensity gradient of the image. The signal required to keep the image in an exact in-focus condition reflects height changes at the specimen surface. The method has a vertical resolution of about 1 μm.

Vacuum tunnelling microscopy The development of an instrument called a 'topografiner' was reported by a member of the US Bureau of Standards in 1966.[300] This device uses piezoelectric translators to position the specimen and probe. (The length of piezoelectrical crystals can be controlled very accurately by applying a potential difference across them.) Two piezoelectric translators are used to position a pointed emitter probe in the x-y plane and a third to adjust the position of the specimen in the z (vertical) plane. The emitter probe, located 50 nm above the specimen surface, is connected to a constant-current supply, establishing a potential difference between the emitter probe and the specimen. This potential difference is dependent on the spacing between the specimen and the probe, which is controlled by a servo system which applies a signal to the z-axis piezo crystal. As the emitter probe is translated in a raster pattern by the x and y axis piezo crystals the specimen is raised and lowered to compensate for changes in the specimen-emitter potential due to the specimen roughness. The signal to the z-axis piezo crystal corresponds to the specimen surface shape and is used to fabricate areal representations of its topography.

Following further developments, the topografiner ultimately had a vertical resolution of 3 nm and a horizontal resolution of 0.4 μm.[301,302] This performance is in about the same range as that of an electron microscope and suffers similar limitations of application (e.g. specimens must be small, conductive and contained in a vacuum).

The topografiner was a forerunner of a device called the scanning tunnelling microscope, which was similar in construction, but operated on a different physical principle. Development of this instrument by Binnig and Rohrer has led to substantial improvements in resolution.[*] It is reported[303] that one of their early effective microscopes had a horizontal resolution of 0.1 nm and a vertical resolution of 0.001 nm. This high resolution made the device suitable for the study of surfaces on the atomic level, including investigations of the shape of catalytic molecules, viruses and semiconductors.[304] Further development of the device was undertaken by Binnig to produce a variant instrument called the 'force microscope', which is able to examine the surface shape of insulating materials. It has a vertical resolution of less than 0.1 nm and a horizontal resolution of 3 nm.[305]

For convenient comparison, Table 9.30 summarizes the typical performance of several types of microscope along with the specification of a commercially available stylus instrument.

9.10.3 Characterization of surface measurements

Parameters which are used to characterize measurements of surface topography are defined almost entirely in terms of the profile signal generated by stylus-type measuring instruments. This arises for historical reasons. For several decades, stylus instruments have provided the only reliable means of obtaining a qualitative record of the shape of a specimen surface. The design and form of this instrument has consequently influenced the development of parameters used to assess surface topography. Until recently, any method adopted as a means of parameterizing the transducer signal needed to be relatively simple and based on mathematical expressions which could easily be evaluated by means of analogue circuits. Several surface parameters evolved within this constraint and

---

[*] In recognition of their outstanding contribution to the development of the tunnelling microscope Binnig and Rohrer were jointly awarded the 1986 Nobel Physics Prize, sharing the award with Ernst Ruska, acclaimed as the inventor of the electron microscope.

Table 9.30 A summary of the typical specifications of instruments used in the laboratory measurement of surface topography

Device	*Resolution*				*Vertical measurement range or depth of field*		*Measurable area*
	Lateral		*Vertical*		*At lowest resolution*	*At highest resolution*	
	Lowest	*Highest*	*Lowest*	*Highest*			
Stylus instrument (Talysurf VI; Rank Taylor Hobson, Leicester)	Not easily defined Ref. 214		0.5 μm	0.00025 μm	500 μm	0.25 μm	Depends on traverse length. Typically, a few millimetres
Optical light microscope (OLM)	2.5 μm Ref. 290	0.1 μm	Not applicable		42 μm Ref. 290	0.04 μm	Depends on magnification
Transmission electron microscope (TEM)	2.5 nm Ref. 290	0.5 nm	Approximately the same as the lateral resolution Ref. 297		400 nm Ref. 290	80 nm	Depends on magnification
Scanning electron microscope (SEM)	5 μm Ref. 290	10 nm	Not available		1 mm Ref. 290	2 μm	Depends on magnification
Tunnelling microscope	0.4 μm Ref. 298	0.1 μm Ref. 302	3 nm Ref. 298	0.001 nm Ref. 302	Depends on range of piezoelectric elements. Typically, 1 μm or less Ref. 298		Depends on range of piezoelectric elements. Typically less than 10 μm² Refs 298, 301

they were mainly related to the statistical properties of the amplitude distribution of an arbitrarily filtered version of the transducer output. Their suitability for assessing surface topography was limited although some remain in common use in the manufacturing environment (e.g. R_a). The advent of digital electronics has removed most computational restrictions so that parameters of virtually unlimited complexity can now be defined and evaluated for surface data. The availability and flexibility of this new computational power beckons investigations which develop more useful and relevant ways of characterizing surface topography.

This section presents several parameters and methods used to characterize surface topography in both industry and research. The inherent advantages and weaknesses of these techniques are discussed.

9.10.3.1 The influence of measurement bandwidth

The length of a profile determines a long wavelength limit for the features which may be observed within it. If the profiles measured from the surface of a specimen with a periodic structure are not sufficiently long to admit all the periodic content, parameters assessed using profiles recorded from different sites on the specimen will be inconsistent. Parameters assessed from profiles of differing lengths will also yield variable results. Even more intractable difficulties arise if the specimen surface contains an appreciable random component in its structure. A non-stationarity has been identified in manufactured surfaces which have a random structure.[306] Consequently, the statistical properties of a profile depend on its length. Its power spectral density function, $G(\omega)$, is described by the relationship

$$G(\omega) = \frac{2\pi K}{\omega^2} \tag{9.11}$$

where $\omega = (2\pi/\text{wavelength})$ and K is a constant known as the 'topothesy' of the surface. As power spectral density is a function which describes the variance of a signal as a function of wavelength and the variance of a sine wave is half the square of its amplitude, it can be seen that equation (9.11) effectively states that the amplitude of the sine wave components in the spectrum of a profile are proportional to wavelength. As a consequence, it was proposed that the total variance of a profile, σ_T, could be written as the sum of the periodic component, σ_P, and the random component, σ_R, thus:

$$\sigma_T = \sigma_P + \sigma_R = \sigma_P + (KL)^{1/2}$$

where L is the length of the profile.

Manufacturers of surface-measurement instruments attempt to overcome the non-stationarity of surface profile measurements by filtering away frequency components of the transducer signal which lie below a given limit called the 'cut-off'. Standardized limits are defined by National Standards documents such as BS 1134.[307] Surface roughness parameters are usually evaluated from a profile called the 'assessment length', which is normally taken to be five times longer than the cut-off limit of the amplifier filter. (The cut-off limit is referred to as the 'sampling length'.) Such filtering is effective because it removes the variance contribution of surface features with wavelengths longer than the 'cut-off' distance. However, resulting roughness measurements are arbitrary, as the selection of the cut-off point does not seem to be based on any physically significant criterion.

The short-wavelength limit of surface structures presents similar difficulties. Irregularities smaller than atomic dimensions are believed to exist, indeed it would be surprising if this were not so. Effectively, this means that a clear, natural cut-off point is absent. The problems that this situation causes are eloquently outlined by Thomas and Sayles.[308] They define the moments, m_n, of power spectra, $G(\omega)$, of profiles to be of the form

$$m_n = \int_0^{\infty} \omega^n G(\omega)\, d\omega \qquad (9.12)$$

The density and curvature of asperities and the mean slope of a surface are functions of the first three even spectral moments: m_0, m_2 and m_4.[309] As equation (9.12) is not integrable, due to the infinite upper limit, the existence of a fixed value for these important and widely used parameters is excluded.[308,309]

The solution to this problem is again a pragmatic one. National Standards documents define standard styli in an attempt to make the high-frequency cut-off points of all measurement devices similar. Although the choice of a standard dimension for the stylus tip is an arbitrary one, depending largely on a compromise between useful lifetime and ease of manufacture, at least this arrangement means that measurements made by different instruments are likely to agree to within an acceptable tolerance of each other. (Note that the 'frequency response' of a stylus depends strongly on its shape and size. This dependence is a complex one which is discussed in detail elsewhere.[214])

Thus it can be seen that in the absence of natural physical constraints on the bandwidth of measurements from surfaces, an artificial limit is imposed by National Standards which define standard high- and low-frequency 'cut-off' points. The choice of these limits is arbitrary, defining a measurement bandwidth which is more suitable for quality control rather than fundamental study of phenomena associated with surface topography.

9.10.3.2 The effect of sampling conditions

Surface parameters are frequently calculated from a set of discrete samples $f(y_k)$ drawn from a continuous profile $f(y)$. These discrete samples are separated by a short horizontal interval Δy. It has been shown that the choice of sampling interval, Δy, influences the assessment of some parameters, such as the mean slope and mean curvature of a profile.[310] Subsequently, such parameters cannot be considered to be intrinsic properties of a surface profile. For surfaces with a Gaussian height distribution it has been shown that mean slope is proportional to $(\Delta y^{-1/2})$.[310]

The effect of sample interval size on the evaluation of other parameters has also been examined.[311] It has been found that sample interval size 'has no appreciable effect' on pure height parameters such as average roughness. However, shortening the sample interval is found to increase the value of extreme range parameters and to reduce the 'width' of those parameters which had some dependence on the spatial characteristics of the profile, such as average wavelength. Further discussion of the influence of sample interval size on profile parameters can be found in reference 312.

9.10.3.3 Reference lines

Many statistical parameters assess surface roughness by measuring the departure of the profile from a reference (mean) line. Two systems which define mean lines exist: the M-system and the E-system. Of these, the M-system is by far the most widely used.

The M-system This system is specified by several National Standards.[313,314] In this system the mean line is defined by the electrical filter through which the profile is passed to remove its long-wavelength components.

The E-system The E (or envelope) system mean line is the locus described by the centre of a circle with a radius of a few millimetres as it rolls across a profile and is then displaced downwards by a distance such that the areas enclosed by the effective profile above and below it are equal.[315]

Neither of these systems has any particular physical importance but they do provide an effective practical reference for statistical parameterization of profiles. A number of these parameters are discussed below.

9.10.3.4 Amplitude parameters

A wide range of parameters are used to assess the height deviations of the profile from the mean line.

Average roughness (R_a) Average roughness, R_a, is also known as 'centre line average', or 'arithmetic average' being denoted by 'cla' or 'AA'. However, average roughness, R_a, is the preferred designation. It is defined by

$$R_a = \frac{1}{L}\int_0^L |f(y)|\, dy$$

where $f(y)$ is the departure of the profile from the mean line and L is the length of the profile. In digital implementations R_a is given by

$$R_a = \frac{1}{M}\sum_{k=1}^{M} |f(y_k)|$$

where M discrete samples $f(y_k)$ are drawn from $f(y)$.

One of the main criticisms of R_a is that it cannot distinguish between profiles of different shape. Profiles having the same R_a value may be entirely different in character. Despite this drawback, R_a is in almost universal use for quality control, being defined by standards authorities in many countries, including Britain, Germany, France and the USA.[316] To obtain a reasonably reliable assessment of R_a an average over several sampling lengths, L, is normally evaluated.

Root mean square roughness (R_q) The root mean square roughness is identical to the standard deviation, σ, of the profile height distribution. It is defined by

$$R_q = \left(\frac{1}{L}\int_0^L f^2(y)\, dy\right)^{1/2}$$

and its digital implementation is

$$R_q = \left(\frac{1}{M}\sum_{k=1}^{M} f^2\,(y_k)\right)^{1/2}$$

For surfaces with a Gaussian height distribution the R_q parameter can be used to calculate R_a via the relationship

$$R_a = \left(\frac{2}{\pi}\right)^{1/2} R_q \approx 0.8R_q$$

This relationship is a good approximation for most surface types provided their height distribution is almost symmetric, even if it is not Gaussian.[317]

One advantage which the R_q parameter offers over R_a is that it appears to be more sensitive to changes in shape of the profile when material is conserved than R_a.[318] This arises as a result of the form of the definition of R_a. R_a is assessed by reference to a mean line positioned so that the areas enclosed by the profile above it and below it are equal. Redistribution of material from one side of the mean line to the other will cause a shift in the position of the mean line and may leave the R_a value unchanged. The R_q value, however, is more likely to be modified by the operation. This lower sensitivity to changes in profile shape when material is conserved means that R_a is less suitable than R_q for monitoring certain surface processes e.g. running-in under pure rolling.[319] (It should be noted, however, that R_q itself is not certain to identify changes in material redistribution. Neither R_a or R_q have values which are unique to specific profile shapes.)

Although the R_q parameter suffers fewer drawbacks than R_a, it is less widely used than R_a. This is particularly surprising when many theoretical treatments of surface topography yield results which are expressed in terms of R_q rather than R_a.

Depth of smoothness (R_p) Depth of smoothness is a roughness parameter which can be measured by friction tests.[320] It has also been found to correlate well with capacitance measurements of surface roughness.[321] Depth of smoothness is defined by

$$R_p = \frac{1}{L}\int_0^L (f(y)_{\max} - f(y))\,dy$$

where $f(y)_{\max}$ is the highest peak in a profile. This parameter is not commonly evaluated by stylus methods.

Extreme-value parameters It is sometimes useful to have a measure of the extremes of departure of a profile and many different forms of these parameters have been defined. The most commonly used of these are: maximum peak-to-valley height, R_t, a parameter known as ten-point height, R_z, and the maximum departures of the profile above and below the mean line referred to as R_p and R_v, respectively. Sometimes these parameters are assessed for individual sampling lengths. The maximum peak-to-valley height within a sampling length is then denoted by R_{ti}, and the maximum R_{ti} in a whole profile is designated R_y (formerly $R_{\max}$). Note that R_y is distinct from the maximum peak-to-valley height of the profile, which is given by ($R_y + R_p$).

Ten-point height, R_z, is the mean separation of the five highest peaks and the five lowest valleys in the profile and is defined by

$$R_z = \frac{1}{5}\left(\sum_{i=1}^{5} P_i - \sum_{i=1}^{5} V_i\right)$$

where P_i and V_i denote maxima and minima of $f(y)$.

Extreme-value parameters are sensitive indicators of high peaks or deep scratches in a surface. As a consequence, their principal use is in quality-control applications. They are also of use in lubrication studies.

Moments of amplitude distribution None of the parameters described above provide information regarding the shape of the profile. However, such details can be derived from moments of the amplitude distribution $P(f(y))$ of the points in the profile.

The third moment of the amplitude distribution is known as skewness and denoted by R_{sk}, where

$$R_{sk} = \frac{1}{R_q^3}\int_{-\infty}^{\infty} f^3(y)\,P(f(y))df(y)$$

or, for discrete data,

$$R_{sk} = \frac{1}{MR_q^3}\sum_{k=1}^{M} f^3(y_k)$$

The fourth moment is known as kurtosis, R_k, and given by

$$R_k = \frac{1}{R_q^4}\int_{-\infty}^{\infty} f^4(y)P(f(y))\,df(y)$$

and in digital implementation by

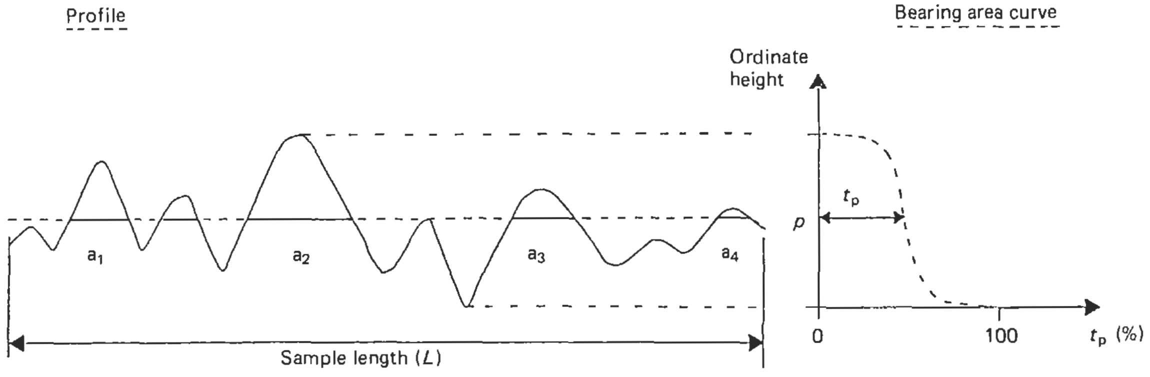
$$R_k = \frac{1}{MR_q^4}\sum_{k=1}^{M} f^4(y_k)$$

Symmetric profiles with equal numbers of peaks and valleys of the same height/density have zero skewness. Profiles in which peaks dominate have positive skewness and profiles dominated by valleys have negative skewness.

Kurtosis can be used as an assessment of the 'spikiness' of a profile. If $R_k < 3$ the profile has relatively few tall, narrow spikes. As R_k increases above 3 the shape of its peaks and valleys become less rounded. When $R_k = 3$ the profile heights have Gaussian distribution.[321a]

Skewness and kurtosis have been shown to be of value in studies of running-in wear[322] and analyses of surfaces which attempt to relate profile character and the functional requirements of surfaces.[323]

Bearing ratio (t_p) In applications where two surfaces are in loaded contact, a parameter known as the bearing ratio has been found useful for defining the characteristics of surfaces



Bearing length ratio $t_p = \frac{\sum^{i} a_i}{L} \times 100$ (%)

Figure 9.98 Definition of the bearing ratio parameters

which will perform a given function reliably. It is frequently used to assess surfaces in finishing processes such as honing and lapping. Figure 9.98 illustrates its method of evaluation. The bearing ratio is given by

$$t_p = \frac{\Sigma a_i}{L} \times 100\ (\%)$$

In practical situations a surface profile is recorded prior to finishing. If experience shows that a bearing ratio of 69% is required for effective and reliable operation, the height, p, to which the surface crests must be reduced, can be determined.

An alternative method of measuring the bearing ratio has been suggested.[324] The cumulative height distribution of the profile, also known as the Abbott bearing area curve, is illustrated in Figure 9.98. The curve describes the percentage of solid material lying above a certain height. Abbott and Firestone[324] have suggested that 'bearing area fraction' was identical to the bearing (length) ratio, and this has since been verified for random surfaces.[325]

9.10.3.5 *Spatial parameters*

Several parameters have been devised to describe spatial characteristics of surfaces. They have not been included as standard instrument readings until recent years and this may account for their use being less widespread than parameters such as R_a and R_q.

Average wavelength (λ_a) The average wavelength, λ_a, of the spatial features in a surface profile, $f(y)$, is given by

$$\lambda_a = 2\pi \frac{R_a}{\Delta_a}$$

where Δ_a is the average slope of the profile as defined in reference 326 (see Section 9.10.3.6). This parameter is apparently useful for assessing the surface quality of sheet steel. It is able to measure the 'openness' of a surface and is found to correlate well with its visual appearance. It is sometimes used to measure the quality of sheet steel for car bodies.[326a]

Another valuable use of the average wavelength parameter has been found to be in machine condition monitoring.[327] Average wavelength is a sensitive detector of the feed marks of a machine tool. If machine settings are incorrect, λ_a will change significantly even though changes in R_a or other height parameters may be relatively small.

Root mean square wavelength (λ_q) Root mean square wavelength is defined by

$$\lambda_q = 2\pi \frac{R_q}{\Delta_q}$$

where Δ_q is the root mean square slope of a profile and has similar attributes to λ_a discussed above.

High spot count (HSC) Peaks in a surface profile are frequently important from a functional viewpoint. It has been reported that the spacing of roughness peaks exerts an important influence on the manufacture of sheet steel.[327] Careful control of the roughness of the steel is necessary when pressing the sheet to obtain consistent lubrication and thus avoid scoring.

Normally, high spot count is assessed by determining the number of peaks within a sampling length. However, several different definitions of a 'peak' are encountered.[328] Most commonly, high spot count is determined by counting the number of excursions per unit length above a profile mean line.[316]

A further spatial parameter which is sometimes used instead of HSC is the mean high spot spacing, S_m. This parameter is the reciprocal of HSC.

9.10.3.6 *Hybrid parameters*

A small number of parameters are in use which do not measure solely amplitude or spatial characteristics of profiles but serve to assess other familiar geometric characteristics.

Mean slope (Δ_a) The average slope, Δ_a, of a profile $f(y)$ is given by

$$\Delta_a = \frac{1}{L} \int_0^L \left| \frac{\mathrm{d}f(y)}{\mathrm{d}y} \right| \mathrm{d}y$$

In digital implementations Δ_a is calculated using

$$\Delta_a = \frac{1}{M-1} \sum_{k=1}^{M-1} \left| \frac{f(y_{k+1}) - f(y_k)}{y_{k+1} - y_k} \right|$$

The average slope of a profile can be used to estimate the actual length of a profile L', so that it may be compared with its nominal length, L, using the relationship

$$\frac{L'}{L} \approx 1 + \frac{\Delta_a^2}{2}$$

as illustrated by Figure 9.99.

It has been indicated that the ratio (L/L') is useful in painting applications, where it can be used as a guide to the surface available for 'keying'.[328a] In addition, average slope itself is a valuable parameter in several applications such as the

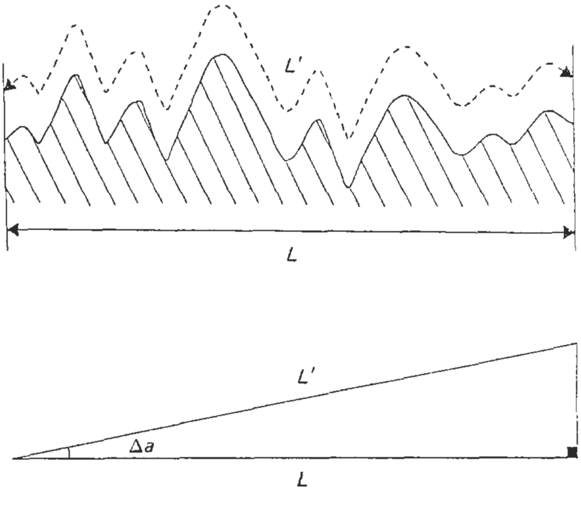


Figure 9.99 Estimation of the true length (L') of a profile:

$$\frac{L}{L'} = \cos \Delta a$$

$$\frac{L'}{L} = \frac{1}{\cos \Delta a} = \frac{1}{1 - \frac{1}{2}(\Delta a)^2}$$

$$[(1 - (\tfrac{1}{2}\Delta a^2)]^{-1} = 1 + (-1)(-\tfrac{1}{2}\Delta a^2) + \ldots$$

$$= 1 + \tfrac{1}{2}\Delta a^2 + \ldots$$

Hence $\frac{L'}{L} \approx 1 + \frac{1}{2}\Delta a^2$ provided $-1 < (-\frac{1}{2}\Delta a^2) < 1$

estimation of sliding friction[329] and the study of the reflectance of light from surfaces.[330]

Mean peak radius (ρ_m) The numerical value of ρ_m depends on the definition of a peak. Thomas[316] defines a peak for a digitized profile $f(y_k)$ as an ordinate which is greater than the two adjacent to it, so that its curvature, C_p, is given by

$$C_k = \frac{(d^2 f(y_k))/dy^2}{\{1 + (df(y_k)/dy)^2\}^{3/2}} = \frac{d^2 f(y_k)}{dy^2}$$

As $df(y_k) = 0$ at a turning point,

$$C_k = \frac{2f(y_k) - f(y_{k-1}) - f(y_{k+1})}{(y_{k+1} - y_k)^2}$$

Peak radius, ρ, is the inverse of curvature so that mean peak radius, ρ_m, is given by

$$\rho_m = \frac{1}{M-2} \sum_{k=1}^{M-2} (1/C_k)$$

The parameter ρ_m has been found useful in theoretical and experimental studies of the friction and adhesion of elastomers.[331]

9.10.3.7 *Relationships between topographic parameters*

When the distribution of ordinate heights in a profile is Gaussian a relationship between R_a and R_q can be obtained and an estimate of one parameter calculated from a knowledge of the other. Such relationships can be derived for many theoretical height distributions. For example, the ratio between R_a and R_q for a sinusoidal profile which has a 'U-shaped' height distribution is $R_a/R_q = 2^{2/3}/\pi = 0.90$.[332]

The relationships between a wide range of profile parameters have been investigated. It has been shown that a knowledge of R_a, R_q, R_{sk} and R_k defines the shape of a certain class of height distribution curves of the ordinates (i.e. Pearson distributions and Johnson distributions) sufficiently well to allow a number of well-known parameters to be estimated reliably from them.[332] For example, a knowledge of the skew and kurtosis of a profile permits the ratio R_a/R_q to be determined. The skew and kurtosis parameters have also been used to estimate parameters of the bearing area curve.[332]

Extreme parameters such as R_y, R_t, R_p, etc. cannot be estimated from a knowledge of the height distribution alone as they depend on spatial considerations for a given length of profile. However, a method of estimating a variable called the 'equivalent uncorrelated sample size', M_{eq}, using time-series models of surface profiles has been suggested.[332] This parameter can then be used with reduced (i.e. uncorrelated) profile data in equations which estimate the expected values of R_t and R_y for examples of uncorrelated points of size M (where $M = M_{eq}$). Thus the parameters R_t and R_y are obtained from

$$E(\text{Range}) = \int_{-\infty}^{\infty} 1 - (1 - P(f(y)))^M - (P(f(y)))^M \, dy$$

where $P(f(y))$ is the probability density function of the ordinate heights. For $M \gg 1000$ the relationship

$$E(\text{Range}) = 2\left(\frac{0.577}{(2 \log_e M)^{1/2}} + (2 \log_e M)^{1/2}\right)$$

is proposed to be sufficiently accurate.

It is possible to use a statistical approach of the above type to estimate unknown parameters of a profile given a suitable set of variables which describe the height distribution of its ordinates. However, estimating parameters which describe the surface as a whole from details of profiles is more difficult. This arises for two principal reasons: first, the statistical parameters that characterize a profile from a surface do not characterize the surface as a whole; second, large variations can arise in the same parameter when it is measured on different parts of a specimen.

Attempts have been made to study the link between surface and profile parameters and some limited success has been achieved using an idealized surface model and carefully manufactured surface specimens.[333]

An experimental study of the parametric variation in profiles recorded from different parts of the same surface has also been undertaken.[311] Calibration specimens as well as surfaces produced by standard machining processes were examined. On calibration specimens it was found that the least variable parameters were R_a, R_q and Δ_a. However, even on standards for R_a, variations of R_a of nearly 9% were observed. On machined surfaces variations of 50% in some parameters such as R_z and HSC were not uncommon. (A cursory statistical discussion indicated that such variations were within the bounds expected under statistical fluctuation.)

9.10.3.8 *Autocorrelation analysis*

Autocorrelation analysis reveals details of the spatial structure of a profile. Bendat and Piersol[334] define the autocorrelation function (ACF), $R(\tau)$, as

$$R(\tau) = \lim_{L\to\infty} \frac{1}{L} \int_0^L f(y) f(y + \tau) \, dy \qquad (9.13)$$

The equivalent digital form of this equation is

$$R(\tau) = \frac{1}{M-i} \sum_{k=1}^{M-i} f(y_k)\, f(y_{k+i})$$

$$i = 0, 1, 2 \ldots M - 1$$

From equation (9.13) it can be seen that $R(\tau)$ is the average product over the profile length, L, of the profile $f(y)$, and a version of this profile displaced in space by a distance τ, i.e. $f(y + \tau)$. The ACF is often normalized by dividing $R(\tau)$ by the variance of the profile R_q^2. To distinguish between the normalized and non-normalized ACF, some authors refer to equation (9.13) as the autocovariance function (ACVF), with its normalized form being the ACF.[335]

Certain characteristics of profiles are clearly reflected in the form of their autocorrelation functions. Profiles with a periodic structure possess periodic ACFs while those with a random structure possess ACFs which slowly decay from unit to zero. Penklenik[336] recognized this and suggested a scheme for grouping surface types according to the form of the ACF. The approach provided a qualitative method for profile description but not a qualitative method of characterization.

Whitehouse and Archard[310] recognized that many types of surfaces were random and had Gaussian height probability density functions. Consequently, their ACFs took on an exponential form, which could be approximated by

$$R(\tau) = \exp(-\tau/\beta^*)$$

where β^* was called the correlation distance. At $\tau = 2.3\,\beta^*$, $R(\tau)$ has decayed to 10% of its initial ($\tau = 0$) value. β^* was regarded as the spacing at which two points on a profile could be regarded as independent events. By applying a statistical analysis known as a Markov process to profiles it was found that many statistical properties of the surface could be derived as functions of only R_q and β^*. This work was later applied to obtain tribological parameters such as the elastic contact area and the plastic force per unit nominal area in terms of R_q and β^* for surfaces with parabolic asperities in contact with a non-deformable plane.[337]

One serious problem associated with the Whitehouse and Archard model is that the parameter is strongly influenced by the frequency bandwidth of the profile measurement from which the ACF is calculated.[308] In order to obtain consistent data it is necessary to standardize the measurement bandwidth of the profile, particularly in the light of the non-stationarity of random surfaces discussed in Section 9.10.3.1. Nayak[309] discusses some consequences of this position in formal mathematical terms.

Although the ACF is valuable for obtaining statistical and tribological details of surfaces in some circumstances, it is less suitable for studying changes in topography during wear, deformation or similar processes. King and Stout[338] calculated the ACFs of profiles recorded from a phosphor-bronze pin at various stages of wear, and although the shape of the profile was modified considerably at each stage the ACF exhibited only small changes. (Smith and Walmsley[339] discuss why this arises.) In order to enhance the value of ACF data in such studies the use of an alternative relation the 'structure function', $S(\tau)$, given by

$$S(\tau) = 2R_q(1 - R(\tau))$$

has been proposed.[340]

9.10.3.9 *Spectral analysis*

As an alternative to autocorrelation, profile spatial information can also be presented as a spectrum; i.e. a function which decomposes a profile into a number of frequency components of varying amplitudes. The power spectral density function (PSDF), $G(p)$, a tool borrowed from communication theory, is often used for this purpose. The PSDF is given by

$$G(p) = \frac{1}{L}\left|\int_0^l F(y)\exp(-2\pi py)\,\mathrm{d}y\right|^2$$

where p is the frequency of a given component. (Special techniques exist for evaluating this function digitally.[341]) The PSDF is related to the ACF by

$$G(p) = 4\int_0^{L-\tau} R(\tau)\cos 2\pi p\tau\,\mathrm{d}\tau$$

where $R(\tau)$ is defined by equation (9.13).

The nth moment, M_n, of the power spectral density function is defined by

$$M_n \int_0^\infty G(p)\,\omega^n\,\mathrm{d}\omega$$

where $\omega = 2\pi p$.

In the 1950s the moments of power spectra were used to develop theoretical models to predict the statistics of sea surfaces with random, Gaussian height distributions.[342] More recently, this work has been successfully adapted to describe engineering surfaces with both isotropic (i.e. non-directional[309]) and anisotropic (i.e. directional[343]) characteristics. Attempts have also been made to estimate plasticity indices from these models to predict the predominant mode of contact between a surface of this type and an inelastic flat plane.[344]

Further forms of modelling in spectral analysis involve the use of the Fourier coefficients rather than those of the power spectrum. Fourier series retain details of the phase relationships between frequency components of the original signal and can, therefore, be used to reconstruct the original signal. These series have been used to describe the frequency content of surface profiles in this way. It has been shown that many terms in the Fourier series of profiles from some surfaces are negligibly small, permitting the original profile to be reconstructed by using only a fraction of the Fourier coefficients.[345] The error in the reconstructed profile depends on the number of Fourier coefficients used to synthesize it. It has been demonstrated that 99.5% of the power in profiles recorded from shaped, turned and ground specimens is contained by 12, 20, and 50 of the most significant terms of the Fourier series, respectively. This effect has also been observed in the power spectra of areal data.[346]

In addition to surface modelling, the spectral analysis of surface profiles recorded from manufactured parts has been proposed as a method of machine-tool surveillance.[347] Normally such surveillance is conducted by the analysis of machine noise and vibration which does not readily yield information regarding the total performance of the machine. However, such problems as bearing faults and spindle assembly errors are likely to be manifest in the workpiece as characteristic profile shapes, permitting the fault to be identifiable by spectral analysis of the surface profile. Although work in this area as yet does not extend to such classifications, it has been shown that specific indicators of the condition of certain parts of numerically controlled machines can be identified.

Spectral analysis can be performed by decomposing a signal using elementary functions other than the traditional trigonometric ones of sine and cosine. It has been suggested that the two-state Walsh functions may be appropriate for analysing surface profiles as the discontinuous state of a digitized surface may be more satisfactorily represented by discontinuous basis functions than continuous ones.[339] Additional conveniences of computational efficiency are also available. Spectral analyses of surface profiles using Walsh functions have subsequently been compared with conventional spectral analysis in the investigation of wear processes.[348]

9.10.3.10 *Time-series modelling*

Analytical models of surface profiles are normally highly idealized, and this tends to limit their range of practical applicability. The use of computers extends the possibility of using simulation techniques which describe actual profile shapes in a more representative way. Time-series methods provide an appropriate tool for this approach and have been proposed by some investigators as a means of modelling surface profiles.

Three basic types of time-series models – autoregressive (AR), moving average (MA) and mixed autoregressive/moving average (ARMA) – are available. An AR model of order p of a digitized profile $f(y_k)$ is given by

$$f(y_k) = \phi_1 f(y_{k-1}) + \phi_2 f(y_{k-2}) \ldots + \phi_p f(y_{k-p}) + a_{y_k}$$

where a_{y_k} is residual white noise of zero mean and, usually, a Gaussian distribution. An MA model of order q is given by

$$f(y_k) = \theta_0 a_{y_k} + \theta_1 a_{y_{k-1}} \ldots + \theta_q a_{y_{k-q}} (\theta_0 = 1)$$

An ARMA model is given by

$$f(y_k) = \phi_1 f(y_{k-1}) + \theta_2 f(y_{k-2}) \ldots + \theta_p f(y_{k-p})$$
$$+ \theta_0 a_{y_k} + \theta_1 a_{y_{k-1}} + \ldots + \theta_q a_{y_{k-q}}$$

The parameters ϕ_0 and θ_q can be determined from the ACF of the process being modelled using methods described by Box and Jenkins.[349]

AR models have been employed by several investigators to model surface profiles.[350–352] The theory of AR models is formally applicable only to random data and it has been confirmed that only random profiles and not periodic ones can be analysed successfully by this approach.[351] AR models have been used successfully for profiles with random, Gaussian and non-Gaussian height distributions.[352] However, the presence of long-wavelength components, such as those found in real random surfaces, was not taken into account by low- (second-) order models.

ARMA models have also been used for modelling profiles with both Gaussian and non-Gaussian height distributions.[353,354] One of these models includes an account of a method for modelling profiles which contain periodic as well as random components in their structure.[354] Modelling is achieved by separating the random and periodic parts of the signal using a time-domain technique described by Hannan.[355] (Another method for separating the random and periodic parts of the profile by manipulating its PSD and ACF has also been suggested.[350])

It is clearly possible to employ time-series models as methods for accurately characterizing the shape of measured profiles. Such models would be of much greater value if they could then be used to predict tribological parameters or to describe the details of wear processes. However, no work appears to have been conducted in this area up to the present.

9.10.4 Summary, conclusions and future developments

Surface topography has importance in engineering from both a functional and a production standpoint. There are many applications in which an appropriate choice of finish for a component will optimize some aspect of its performance (e.g. efficiency or lifetime). It is also desirable to minimize the production cost of a component. This can be achieved at the design stage by recognizing the correlation between the functional suitability of the finish of a component.

It is particularly important to avoid overstringent specification of topography. A greater freedom of choice in the character of a component surface permits more flexibility in the selection of the machining method used to produce it and, in addition, a larger scale of permitted roughness normally reduces the machining time required to produce it. Consideration of both these factors can lead to more economic production.

Appreciation of the importance of surface topography in many areas of technological endeavour has led to the development of a wide range of instruments which are able to measure and record surface roughness. Of these, the stylus instrument is the most widely used. Although several forms of inaccuracy are inherent in the data produced by these instruments, the sources of these errors are well known as they are widely discussed in research publications.

Other methods of assessing surface topography are also in use. Electron microscopy is commonly employed to study qualitative changes in topography during wear experiments. Interference microscopes are proving to be a valuable tool for inspecting the high-quality surfaces of the substrates of electronic components and magnetic recording media. The potential of both these forms of microscopy has been extended considerably in the last decade as the capability to interface them with computers has allowed the generation of quantitative output in a much more rapid, varied and convenient form.

The influence of digital electronics is also evident as a factor which has encouraged the development of other optical methods of measuring surface topography. Focus feedback techniques can provide measurement accuracy as good as that of stylus instruments. As they offer several operational advantages over the latter device (e.g. they are non-contact devices). It is likely that commercial development will be considered and it is possible that these instruments will become a serious rival to stylus instruments in the market at some future date.

Many instruments are designed to directly record the topography of a surface in terms of the variation in its height as a function of position. However, it is possible to design instruments which use changes in a physical phenomenon which depends on surface structure to provide a parametric assessment of its height/spatial variations over a defined area. These include measurements based on gas flow, electrical capacitance and friction. These measurement methods provide a useful means of checking the quality of surface finish on the production line. However, they require contact with the specimen and cannot really be used to provide an 'in-process' assessment of large areas of a surface being produced. Again recent developments in the field of electronics mean that optical methods which provide a parametric assessment of surface roughness can be implemented with more convenience and cost effectiveness.

One limitation of most optical techniques which supply a parametric assessment of surface roughness is they can only be applied reliably in the measurement of 'high-quality' surfaces such as those found on some optical components. However, it appears that one of these methods (i.e. assessment of speckle pattern contrast) has great potential as a technique which can be applied to inspect components with a wide range of roughness. It is one alternative which may allow 100% real-time inspection for quality control of the surface of components produced by numerically controlled systems. This is an industrial requirement which is likely to become more pressing in the next few years.

The assessment of surface topography is a two-part process involving both measurement and characterization of the data it produces. Methods which characterize surface roughness ideally need to parameterize both height and spatial characteristics.

The most common method of characterizing surface topography is by statistical assessment of profiles of the type recorded by stylus instruments. A wide range of parameters which assess the amplitude and spatial characteristics of profiles, either independently or simultaneously, have been discussed. The main drawback in the interpretation of these parameters is that their numerical value depends on the bandwidth of the profile measurement and, for digital data, on the sampling interval employed during acquisition of the profile. This effect arises because specimen surfaces have no natural bandwidth limit, so an arbitrary limit is unavoidably imposed by the measurement operation.

The value of profile parameters is also restricted because the statistical properties of profiles do not necessarily reflect the overall statistical properties of the surface from which they were recorded. Under some idealized circumstances it is possible to derive relationships between surface parameters and profile parameters. However, in many practical circumstances material quality, tool wear/damage, machine characteristics and the presence of cutting debris can cause inhomogeneity in the surface structure of the specimen and render such estimates invalid.

In spite of these drawbacks, profile parameters remain widely used and commonly form the basis of theoretical models of surface topography. Indeed, it seems likely that the future will see an extension of such models to include both profile and areal parameters along with material data in attempts to predict phenomenological parameters of many types. Clearly, the development of these models, even if they are of limited applicability, is of great potential benefit in many areas of technology.

10.1 Power units

10.1.1 Heat engines

10.1.1.1 Heat engine cycles

Carnot cycle

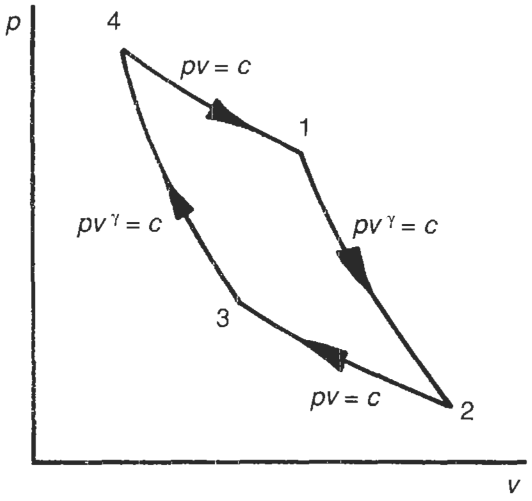

Figure 10.1 The Carnot cycle

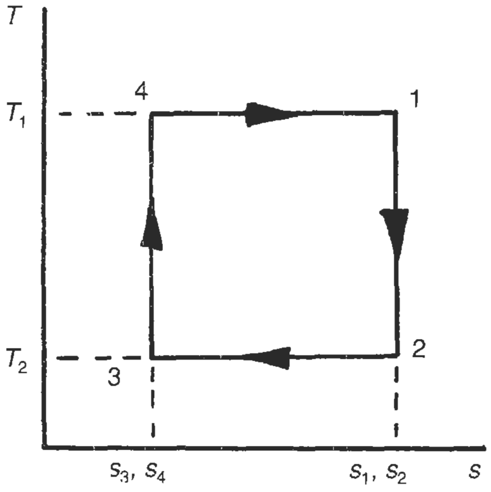

Figure 10.2

Efficiency $\eta = 1 - \dfrac{T_2}{T_1}$

$(s_1 - s_4) = R \ln \dfrac{p_4}{p_2} - c_p \ln \dfrac{T_1}{T_2}$

Work done per kg $W = (T_1 - T_2)(s_1 - s_4)$

Work ratio $= \dfrac{W}{W_{\text{gross}}} = \dfrac{(s_1 - s_4)(T_1 - T_2)}{T_1(s_1 - s_4) + c_v(T_1 - T_2)}$

Heat supplied per kg $Q = T_1(s_1 - s_4)$

The idea gas cycle is the Carnot cycle, and, in practice, only about half of the Carnot cycle efficiency is realized between the same temperature limits (see Figures 10.1 and 10.2).

Constant-pressure cycle

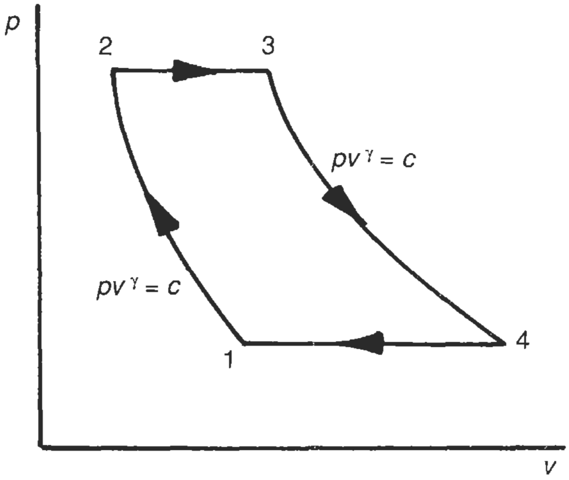

Figure 10.3 Constant-pressure cycle

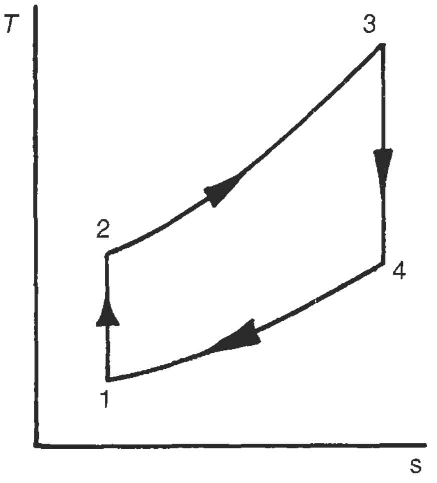

Figure 10.4

Efficiency $\eta = 1 - \dfrac{1}{r^{\frac{\gamma-1}{\gamma}}}$, where $r = \dfrac{p_2}{p_1}$

$W = c_p(T_3 - T_4) - c_p(T_2 - T_1)$,

Work ratio $= 1 - \dfrac{T_1}{T_3}\, r^{\frac{\gamma-1}{\gamma}}$

$Q = c_p(T_3 - T_2)$

In this cycle heat is supplied and rejected at constant pressure; expansion and compression are assumed to take place at constant entropy. The cycle was once known as the Joule or Brayton cycle and was used for hot-air engines. It is now the ideal cycle for the closed gas-turbine unit (see Figures 10.3 and 10.4).

Otto (constant-volume) cycle

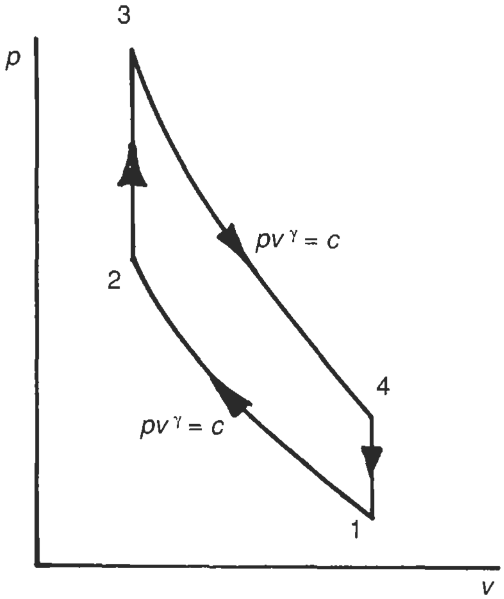

Figure 10.5 Otto cycle

$$\text{Efficiency } \eta = 1 - \frac{1}{r^{\gamma-1}}$$

$$\text{where } r = \frac{v_1}{v_2} \text{ and } \frac{T_2}{T_1} = \frac{T_3}{T_4} = r^{\gamma-1}$$

$W = c_v(T_3 - T_2 - T_4 + T_1)$

$Q = c_v(T_3 - T_2)$

This is the basic cycle for the petrol engine, the gas engine and the high-speed oil engine. Heat is supplied and rejected at constant volume, and expansion and compression take place isentropically. The thermal efficiency depends only upon the compression ratio (see Figure 10.5).

Diesel (constant-pressure) cycle

$$\text{Efficiency } \eta = 1 - \frac{(\beta^\gamma - 1)}{(\beta - 1)\gamma r^{\gamma-1}}$$

$$\text{where } r = \frac{v_1}{v_2} \text{ and } \beta = \frac{v_3}{v_2}$$

$W = c_p(T_3 - T_2) - c_v(T_4 - T_1)$

$Q = c_p(T_3 - T_2)$

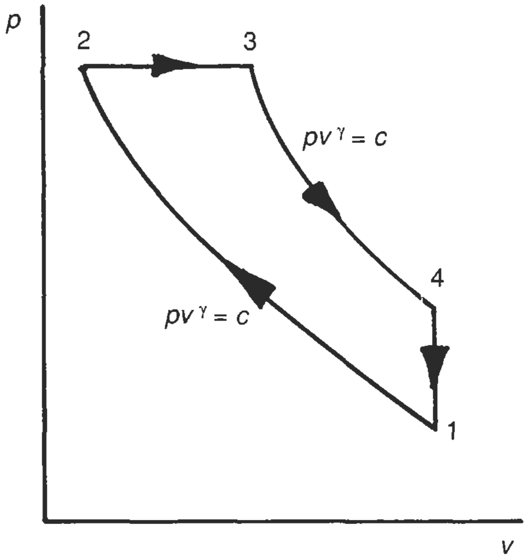

Figure 10.6 Diesel cycle

Although this is called the Diesel cycle, practical diesel engines do not follow it very closely. In this case heat is added at constant pressure, otherwise the cycle is the same as the Otto cycle (see Figure 10.6).

Dual-combustion cycle

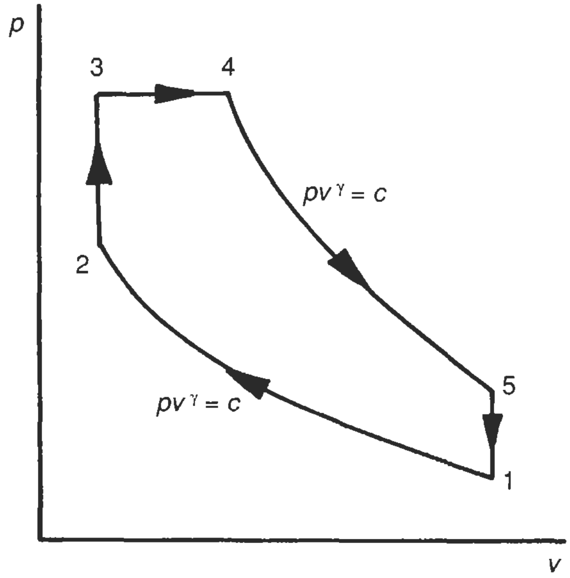

Figure 10.7 Dual-combustion cycle

$$\text{Efficiency } \eta = 1 - \frac{(k\,\beta^\gamma - 1)}{[(k - 1) + (\beta - 1)\gamma k]r^{\gamma-1}}$$

where $r = \frac{v_1}{v_2}$, $k = \frac{p_3}{p_2}$, $\beta = \frac{v_4}{v_3}$

$$W = c_v(T_3 - T_2) + c_p(T_4 - T_3) - c_v(T_5 - T_1)$$

$$Q = c_v(T_3 - T_2) + c_p(T_4 - T_3)$$

Modern diesel engines follow a cycle similar to this ideal one. In this case combustion takes place partly at constant volume and partly at constant pressure (see Figure 10.7).

Practical engine cycles In actual engines the working substance is air only in the induction and compression strokes. During expansion and exhaust the working substance consists of the products of combustion with different properties to air. In addition, the wide variation in temperature and pressure results in variations in the thermal properties. Another factor is 'dissociation', which results in a lower maximum temperature than is assumed by elementary treatment of the combustion process.

10.1.1.2 Reciprocating spark-ignition internal-combustion engines

Four-stroke engine The charge of air and fuel is induced into the engine cylinder as the piston moves from top-dead-centre (TDC) to bottom-dead-centre (BDC). The charge is then compressed and ignited by the sparking plug before TDC, producing a high pressure and temperature at about TDC. The gas expands and work is produced as the piston moves to BDC. A little before BDC the exhaust valve opens and the gases exhaust. The process is completed during the next stroke. A typical pv diagram is shown in Figure 10.8 and formulae are given for power, mean effective pressure, efficiency and specific fuel consumption (see also Figures 10.9–10.11).

Pressure–volume (pv) diagram

A = area of power loop (mm^2)

L_d = length of diagram (mm)

B = area of pumping loop (mm^2)

K = indicator constant (N m^{-2} mm^{-1})

Indicated mean effective pressure

$$p_i = (A - B)\frac{K}{L_d} \quad \text{N m}^{-2}$$

Indicated power

N = rev. s^{-1}

n = number of cylinders

A_p = piston area (m^2)

L = stroke (m)

Indicated power $P_i = p_i A_p L N \frac{n}{2}$ watts

Torque

$T = F R$ (Nm) where F = force on brake arm (N)

R = brake radius (m)

Brake power

$P_b = 2\pi N T$, watts

Friction power

$P_f = P_i - P_b$

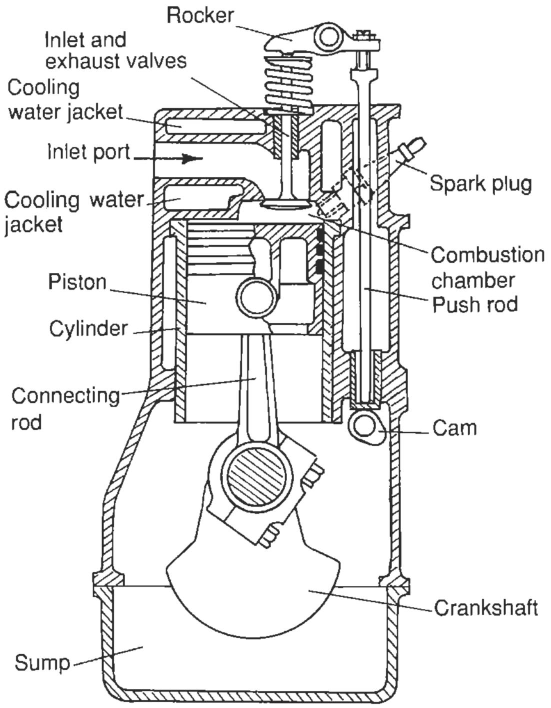

Figure 10.11 Four-stroke petrol engine

Mechanical efficiency

$$\eta_m = \frac{P_b}{P_i}$$

Brake mean effective pressure (bmep)

$$p_b = \frac{4\pi T}{A_p\, L\, n} = \text{constant} \times T \text{ N m}^{-2}$$

Brake thermal efficiency

$\dot{m}$ = mass flow rate of fuel kg.s^{-1}
LCV = lower calorific value of fuel, J.kg^{-1}
Brake thermal efficiency $\eta_b = \dfrac{P_b}{\dot{m}\, LCV}$

Specific fuel consumption

$$\text{SFC} = \frac{m}{P_b}, \text{ kg.s}^{-1}.\text{W}^{-1}$$

Volumetric efficiency

$$\eta_v = \frac{\text{Volume of induced air at NTP}}{\text{Swept volume of cylinder}}$$

Two-stroke engine In an engine with crankcase compression, the piston draws a new charge into the crankcase through a spring-loaded valve during the compression stroke. Ignition occurs just before TDC after which the working stroke commences. Near the end of the stroke the exhaust port is uncovered and the next charge enters the cylinder. The exhaust port closes shortly after the transfer port and compression begins. The piston is shaped to minimize mixing of the new charge with the exhaust.

Compression-ignition engines Both four- and two-stroke engines may have compression ignition instead of spark ignition. The air is compressed to a high pressure and temperature and the fuel injected. The high air temperature causes combustion (see *Figures 10.12–10.14*).

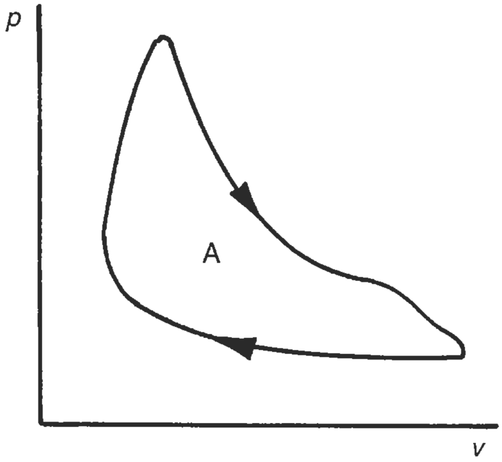

Figure 10.12 Cylinder diagram

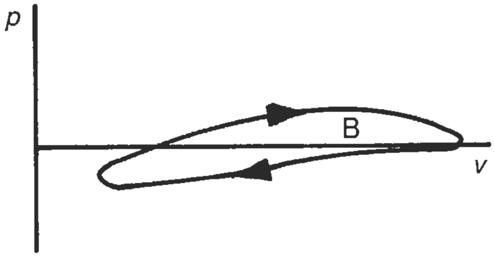

Figure 10.13 Crankcase diagram

PV diagram for two-stroke engine

A = area of power loop
B = area of pumping loop

Indicated mean effective pressure (imep)

$$p_i = (A - B)\frac{K}{L_d}, \quad K = \text{indicator constant}$$

Indicated power

$$P_i = p_i\, A_p\, L\, N\, n$$

Brake mean effective pressure (bmep)

$$p_b = \frac{2\pi T}{A_p\, L\, n}$$

Other quantities are as for four-stroke engines.

10.1.2 Steam turbines and steam plant

10.1.2.1 Steam plant

The simplest steam cycle of practical value is the Rankine cycle with dry saturated steam supplied by a boiler to a power unit (e.g. a turbine) which exhausts to a condenser where the condensed steam is pumped back into the boiler. A higher efficiency is obtained if the steam is initially superheated and also a fall in specific steam consumption which means smaller plant. If the steam is 'reheated' and passed through a second turbine the final dryness fraction is increased with beneficial effects (e.g. reduced erosion of turbine blades due to water droplets). In addition, there is a further reduction in specific steam consumption.

In the 'regenerative cycle' the efficiency is improved by bleeding off a proportion of the steam at an intermediate pressure and mixing it with feedwater pumped to the same pressure in a 'feed heater'. Several feed heaters may be used but these are of the 'closed' variety to avoid the necessity for expensive pumps.

Rankine cycle – dry saturated steam at turbine inlet (*Figures 10.26–10.27*). From the Ts diagram:

$s_2 = s_1$, $x_2 = \dfrac{(s_2 - s_{f2})}{s_{fg2}}$

$h_2 = h_{f2} + x_2 h_{fg2}$

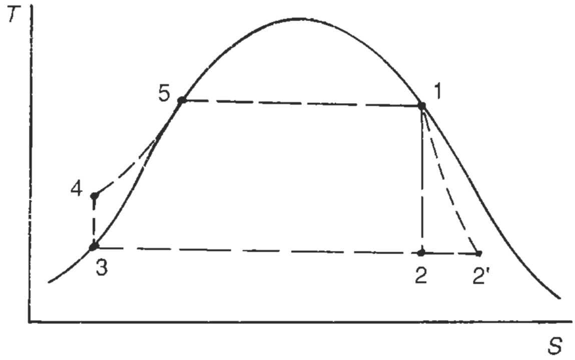

Figure 10.24 Rankine cycle

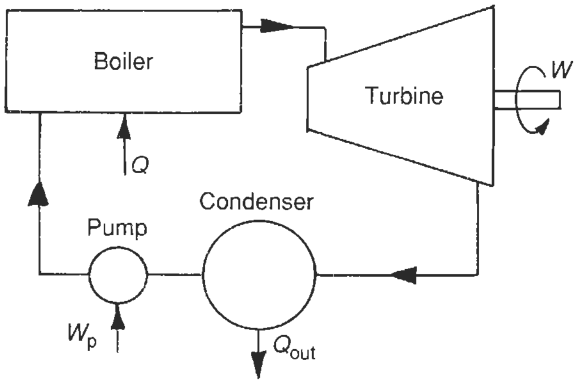

Figure 10.25 Rankine cycle – steam boiler plant

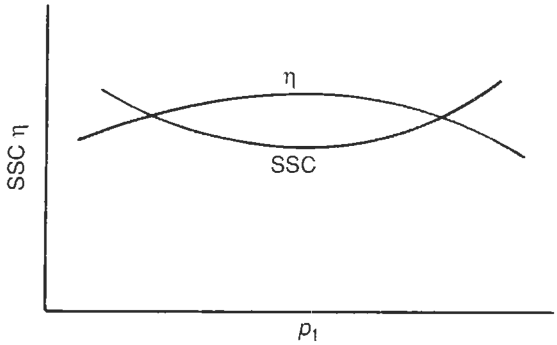

Figure 10.26 Rankine cycle – effect of inlet pressure

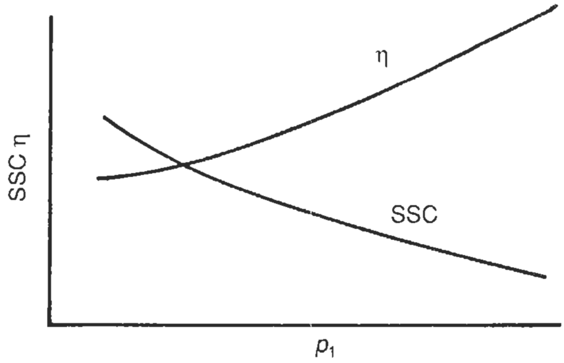

Figure 10.27 Rankine cycle – effect of superheat temperature

Work output $W = (h_1 - h_2)$

Heat supplied $Q = (h_1 - h_{f3})$

Cycle efficiency $\eta = W/Q$ (neglecting pump work)

Specific steam consumption (SSC) = 3600/W kg/kWh

Note: If the turbine isentropic efficiency η_i is allowed for:

$W = (h_1 - h_2)\eta_i$ and expansion is to 2′.

Rankine cycle – with superheat (*Figure 10.28*) h_1 is the enthalpy for superheated steam. The method is the same as for dry saturated steam. The graph shows the effect of superheat temperature on efficiency and specific steam consumption.

Rankine cycle with reheat (Figure 10.29) At 2 the steam is reheated to 6 and passed through a second turbine:

$W = (h_1 - h_2) + (h_6 - h_7)$
$Q = (h_1 - h_3) + (h_6 - h_2)$

p_6 is found from $T_6 = T_1$ (usually) and $s_{g2} = s_1$, from which h_6 is found. h_7 is found from $s_7 = s_6$.

Regenerative cycle (*Figures 10.30 and 10.31*)
Turbine inlet conditions p_1, t_1, h_1

Turbine outlet conditions p_2, t_2, h_2

Bleed steam conditions p_b, t_b, h_b

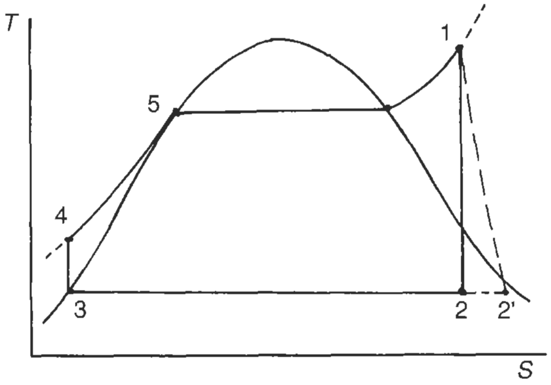

Figure 10.28 Rankine cycle with superheat

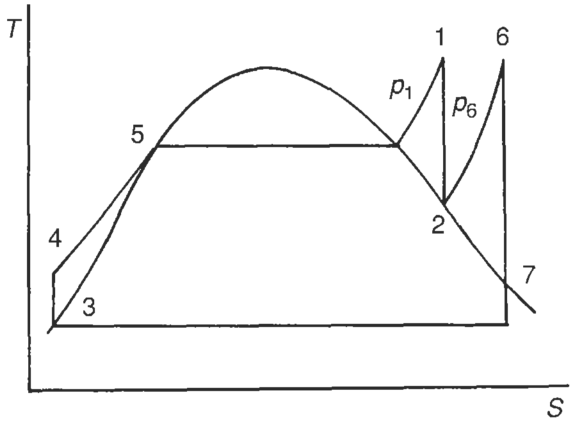

Figure 10.29 Rankine cycle with reheat

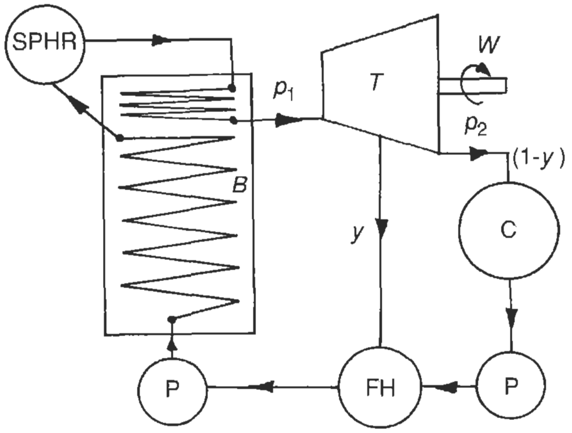

Figure 10.30 Steam plant for regenerative cycle. T = turbine, C = condenser, P = pump, FH = feed heater, B = boiler, SP = superheater

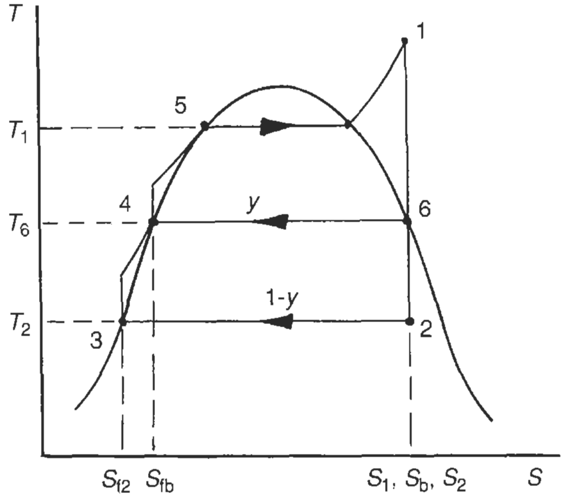

Figure 10.31 Regenerative cycle on Ts diagram

For maximum efficiency – $t_b = \frac{(t_1 + t_2)}{2}$

A bleed pressure p_b is selected to correspond to the saturation temperature t_b.

Dryness fractions: $x_b = \frac{s_1 - s_{fb}}{s_{fgb}}$, $x_2 = \frac{s_1 - s_{f2}}{s_{fg2}}$

Enthalpy $h_b = h_{fb} + x_b h_{fgb}$, and $h_2 = h_{f2} + x_2 h_{fg2}$

Quantity of bled steam $y = \frac{h_{fb} - h_{f2}}{h_b - h_2}$ kg/kg total steam

Work done/kg steam $W = (h_1 - h_b) + (1 - y)(h_b - h_2)$

Heat supplied/kg steam $Q = (h_1 - h_{fb})$

Cycle efficiency $\eta = \frac{W}{Q}$

Specific steam consumption (SSC) $= \frac{3600}{W}$ kg/kW h

10.1.2.2 Steam turbines

There are two main types of steam turbine: the 'impulse turbine' and the 'impulse-reaction turbine'. The theory is given for a single-stage impulse turbine and velocity compounded impulse turbine.

In the impulse-reaction turbine the fixed and moving blades are of similar form consisting of converging passages to give a pressure drop in each case. In the case of 50% reaction (Parson's turbine) the enthalpy drop is the same for both fixed and moving blades.

Impulse turbine

1. Single-stage impulse turbine (Figures 10.32–10.34)

Symbols used:
C = nozzle velocity
C_b = blade velocity
C_a = axial velocity
ρ = ratio of blade to nozzle velocity
β_1 = blade inlet angle
β_2 = blade outlet angle (in this case $\beta_1 = \beta_2$)

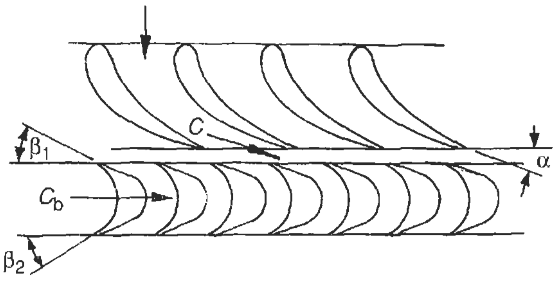

Figure 10.32 Impulse turbine

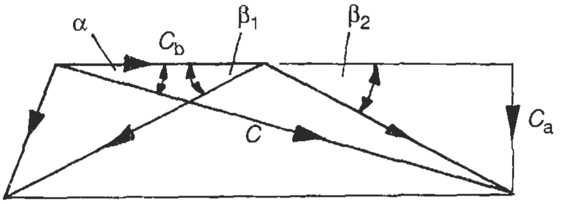

Figure 10.33 Single-stage impulse turbine velocity triangles

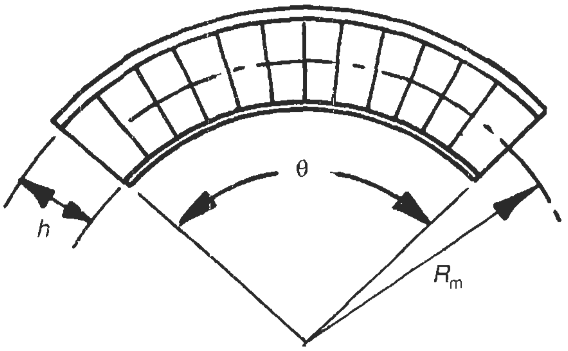

Figure 10.34 Nozzles

α = nozzle angle
$\dot{m}$ = mass flow rate of steam
k = blade friction coefficient = $\dfrac{\text{outlet relative velocity}}{\text{inlet relative velocity}}$
P = stage power
η = stage diagram efficiency
T_a = axial thrust on blades
R_m = mean radius of nozzle arc
v = specific volume of steam at nozzle outlet
θ = nozzle arc angle (degrees)
N = speed of rotation
h = nozzle height
A = nozzle area

Power $P = \dot{m}C^2\rho(\cos\alpha - \rho)(1 + k)$

where $\rho = \dfrac{C_b}{C}$ and $C_b = 2\pi R_m N$

Stage efficiency $\eta = 2\rho(\cos\alpha - \rho)(1 + k)$

Maximum efficiency $\eta_{max} = (1 + k)\cos^2\dfrac{\alpha}{2}$, at

$\rho = \cos\alpha\,\dfrac{(1 + k)}{2}$

Axial thrust $T_a = \dot{m}\,C(1 - k)\sin\alpha$

Mass flow rate $\dot{m} = \dfrac{C_a A}{v}$

Nozzle area $A = \dfrac{\pi R_m \theta h}{180}$

2. Pressure-compounded impulse turbine (Figure 10.35)
The steam pressure is broken down in two or more stages. Each stage may be analysed in the same manner as before.
3. Velocity-compounded impulse turbine (Figures 10.36–10.38)
One row of nozzles is followed by two or more rows of moving blades with intervening rows of fixed blades of the same type which alter the direction of flow.
Two-row wheel: Assume $\beta_1 = \beta_2$ and $k = 1$ and that all blades are symmetrical.

Maximum efficiency $\eta_{max} = \cos^2\alpha$ at $\rho = \dfrac{\cos\alpha}{4}$

In which case the steam leaves the last row axially.

Impulse-reaction turbine (*Figures 10.39* and *10.40*) In this case there is 'full admission', i.e. $\theta = 360°$. Both nozzles and moving blades are similar in shape and have approximately the

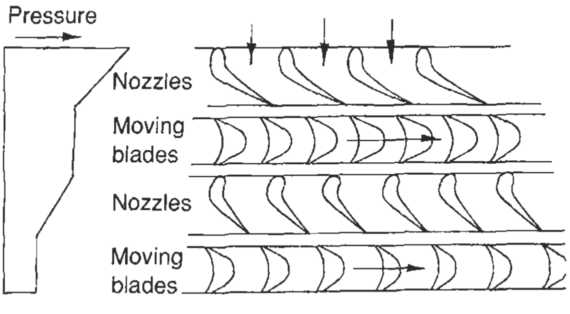

Figure 10.35 Pressure-compounded impulse turbine

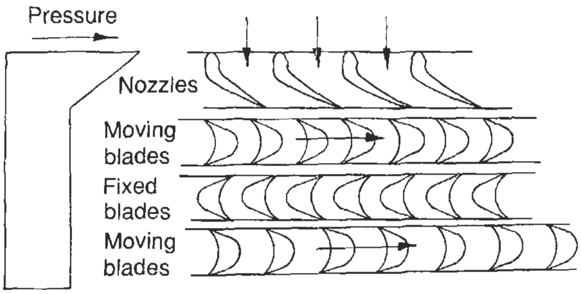

Figure 10.36 Velocity-compounded impulse turbine

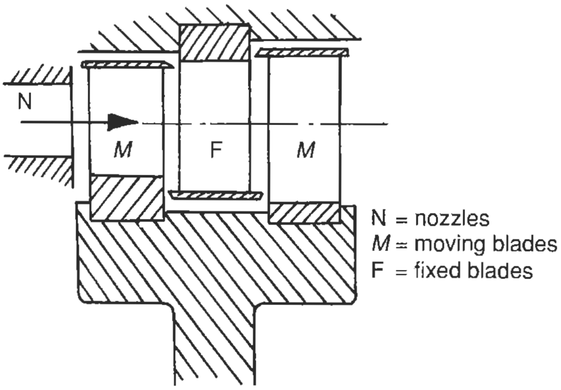

Figure 10.37 Two-row wheel, M = moving blade row, F = fixed blade row

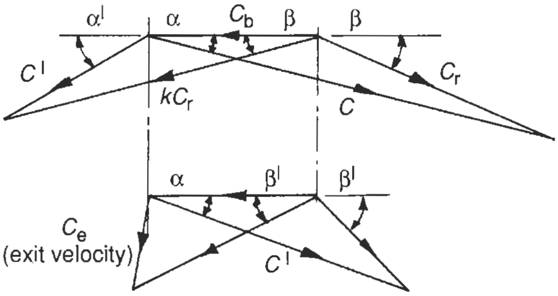

Figure 10.38 Two-row wheel velocity triangles

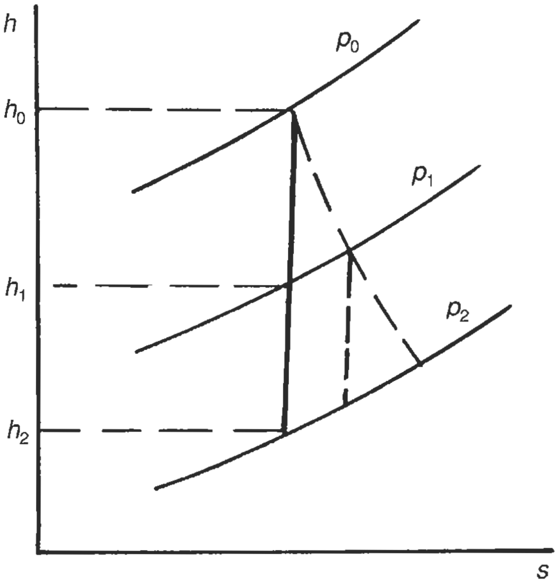

Figure 10.39 Stage heat drops

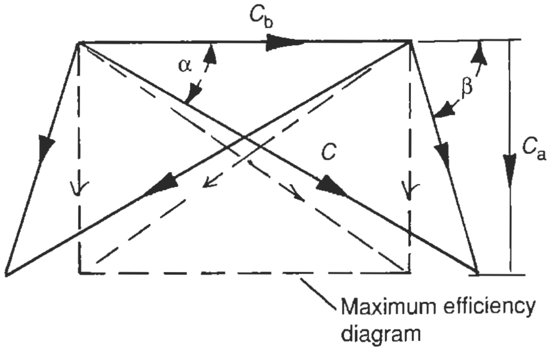

Figure 10.40 Impulse reaction turbine: velocity triangles

same enthalpy drop. Referring to Figure 10.39, enthalpy drop is $(h_0 - h_1)$ for the fixed blades and $(h_1 - h_2)$ for the moving blades.

Mass flow rate $\dot{m} = \dfrac{C_a A}{v}$

Area of flow $A = 2\pi R_m h$

Degree of reaction $R = \dfrac{(h_1 - h_2)}{(h_0 - h_1) + (h_1 - h_2)} = \dfrac{h_1 - h_2}{h_0 - h_2}$

50% reaction (Parson's) turbine In this case the velocity diagram is symmetrical:

Mass flow rate $\dot{m} = \dfrac{2\pi R_m h C \sin\alpha}{v}$

where α = blade outlet angle

Enthalpy drop per stage $\Delta h_s = C^2\rho\,(2\cos\alpha - \rho)$

where $\rho = \dfrac{C_b}{C}$ and $C_b = 2\pi R_m N$

Stage power $P_s = \dot{m}\,\Delta h_s$

Stage efficiency $\eta_s = \dfrac{2\,\rho(2\cos\alpha - \rho)}{1 + \rho\,(2\cos\alpha - \rho)}$

Maximum efficiency $\eta_{max} = \dfrac{2\cos^2\alpha}{(1 + \cos^2\alpha)}$ when $\rho = \cos\alpha$

Reheat factor and overall efficiency (Figures 10.41 and 10.42) Referring to the 'condition curve' in Figure 10.42:

Δh_A = available stage enthalpy drop
Δh_I = isentropic stage enthalpy drop
Δh_{OA} = available overall enthalpy drop
Δh_{OI} = isentropic overall enthalpy drop

Stage efficiency $\eta_s = \dfrac{\Delta h_A}{\Delta h_I}$

Overall efficiency $\eta_o = \dfrac{\Delta h_{OA}}{\Delta h_{OI}}$

Reheat factor (RF) $= \dfrac{\eta_o}{\eta_s}$

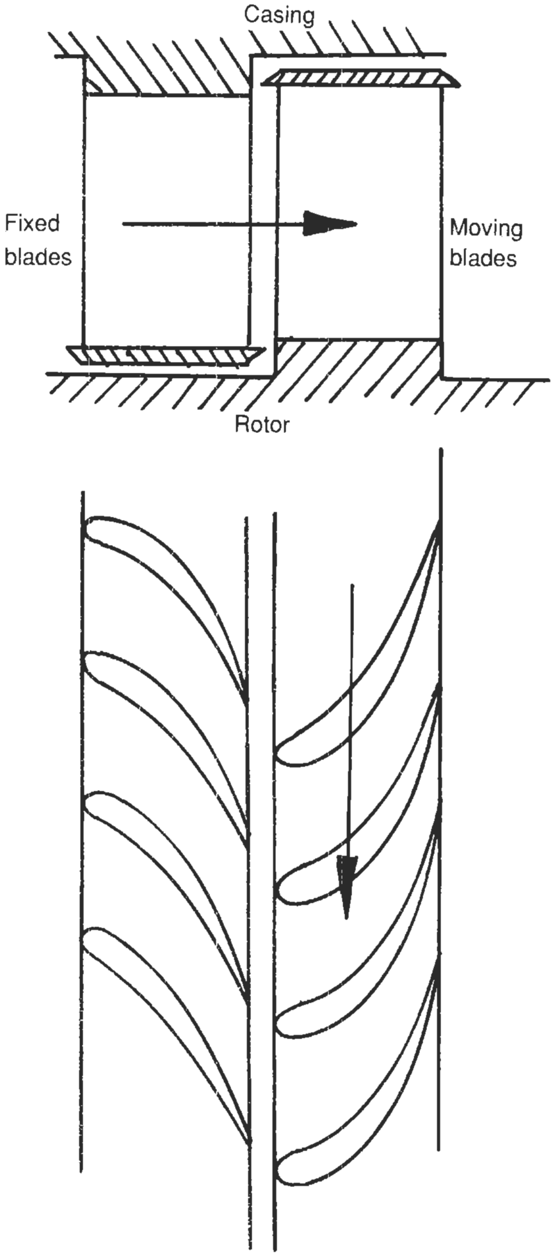

Figure 10.41 Reaction blading. F = fixed blades, M = moving blades

10.1.3 Gas turbines

The gas turbine unit operates basically on the constant-pressure cycle, particularly in the case of the 'closed cycle'. In the 'open cycle' air is drawn in from the atmosphere, compressed and supplied to a combustion chamber where fuel is burnt with a large amount of 'excess air'. The hot gases drive a turbine which drives the compressor and also provides useful work. The efficiency increases with compression ratio and the output power increases with both compression ratio and turbine inlet temperature.

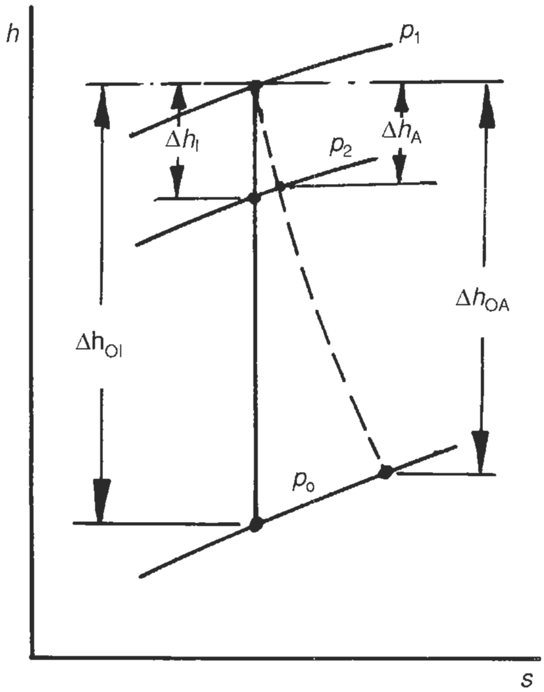

Figure 10.42 Reheat factor and overall efficiency

The effect of losses and variation in fluid properties is shown on the basic cycle. The efficiency of the basic cycle can be greatly increased by incorporating a heat exchanger between the compressor outlet and the combustion chamber inlet. It uses the exhaust gases from the turbine to preheat the incoming air.

10.1.3.1 Simple cycle (Figures 10.42–10.45)

Compression ratio $r = \frac{p_2}{p_1} = \frac{p_3}{p_4}$,

Let $c = r^{(\gamma-1)/\gamma} = \frac{T_2}{T_1} = \frac{T_3}{T_4}$, and $t = \frac{T_3}{T_1}$

Heat supplied $Q = c_p T_1(t - c)$ per kg of air

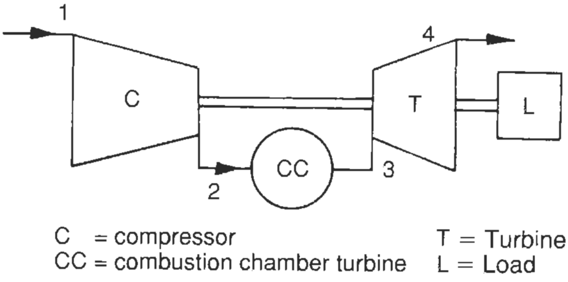

Figure 10.43 gas turbine – simple cycle

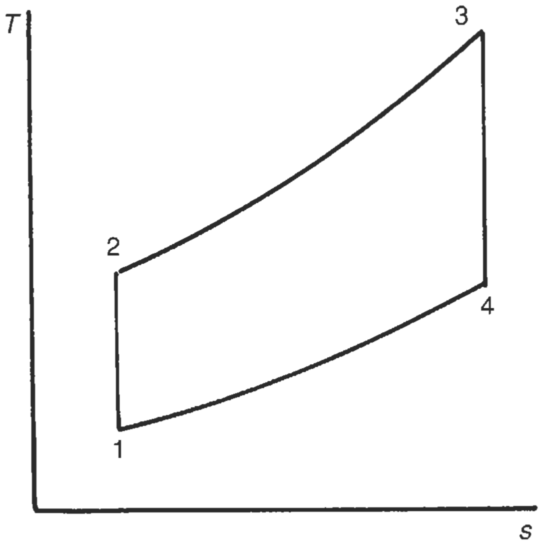

Figure 10.44 Constant-pressure cycle

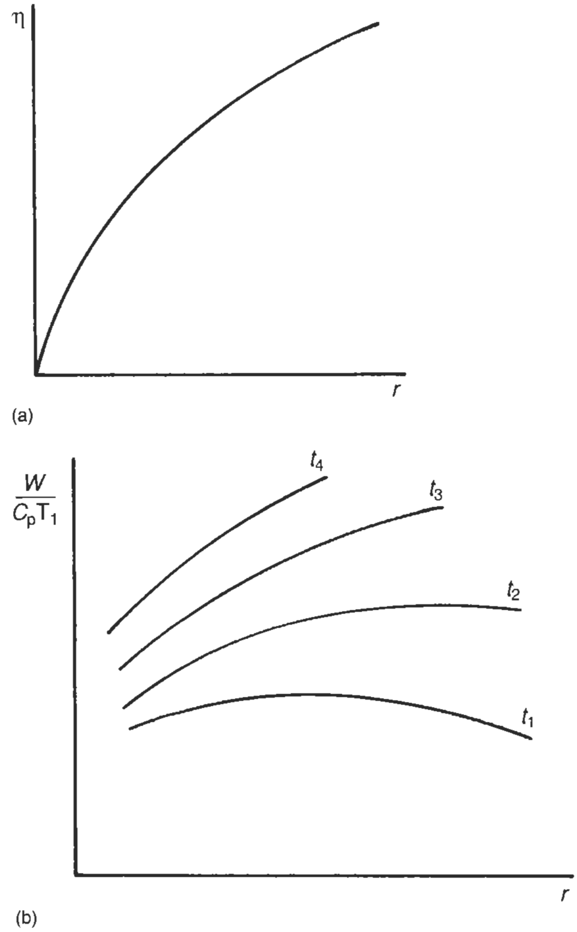

Figure 10.45 (a) Efficiency of simple gas turbine; (b) work function versus compression ratio characteristics

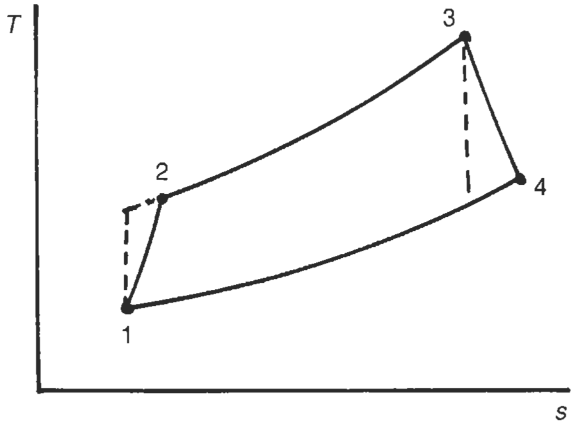

Figure 10.46 Ts diagram for a simple gas turbine

Work done = turbine work out – compressor work in

$$= W = c_{\mathrm{p}}\, T_1\left[t\left(1 - \frac{1}{c}\right) - (c - 1)\right]$$

$$\text{Efficiency } \eta = 1 - \frac{1}{c}$$

Simple cycle with isentropic efficiencies and variable specific heats (*Figure 10.46*) Let

${}_{\mathrm{c}}c_{\mathrm{p}}$ = specific heat for compressor

${}_{\mathrm{t}}c_{\mathrm{p}}$ = specific heat for turbine

${}_{\mathrm{cc}}c_{\mathrm{p}}$ = specific heat for combustion chamber

γ_{c} = ratio of specific heats for compressor

γ_{t} = ratio of specific heats for turbine

η_{c} = isentropic compressor efficiency

η_{t} = isentropic turbine efficiency

Work done = turbine work out − compressor work in

or

$$W = {}_{\mathrm{t}}c_{\mathrm{p}}(T_3 - T_4)\eta_{\mathrm{t}} - {}_{\mathrm{c}}c_{\mathrm{p}}\frac{(T_2 - T_1)}{\eta_{\mathrm{c}}} \text{ per kg of air}$$

$$\text{Heat supplied } Q = {}_{\mathrm{cc}}c_{\mathrm{p}}\left(T_3 - T_1 - \frac{(T_2 - T_1)}{\eta_{\mathrm{c}}}\right) \text{ per kg of air}$$

$$\text{Work ratio} = \frac{\text{Net work out}}{\text{Gross work}} = \frac{W}{{}_{\mathrm{t}}c_{\mathrm{p}}(T_3 - T_4)\eta_{\mathrm{t}}}$$

$$\text{Efficiency } \eta = \frac{W}{Q}$$

$$\text{Note that } r = \frac{p_2}{p_1}, \frac{T_2}{T_1} = r^{(\gamma_{\mathrm{c}}-1)/\gamma_{\mathrm{c}}}, \frac{T_3}{T_4} = r^{(\gamma_{\mathrm{t}}-1)/\gamma_{\mathrm{t}}}$$

10.1.3.2 Simple cycle with heat exchanger (Figures 10.47–10.49)

$$\text{Heat supplied } Q = c_{\mathrm{p}}T_1\, t\left(1 - \frac{1}{c}\right)$$

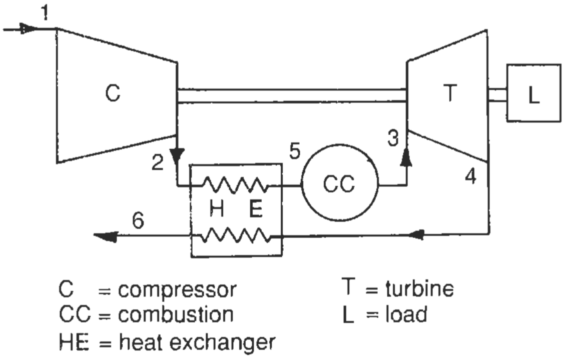

Figure 10.47 Gas turbine cycle with heat exchanger

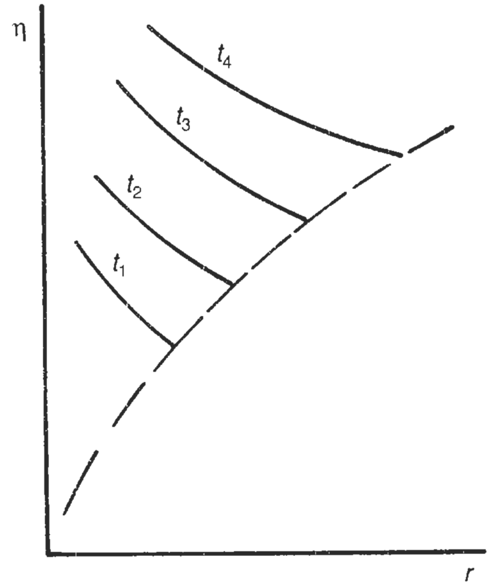

Figure 10.49 Efficiency curves for gas turbine with heat exchanger

$$\text{Work done } W = c_p T_1 \left[t\left(1 - \frac{1}{c}\right) - (c - 1) \right]$$

$$\text{Efficiency } \eta = 1 - \frac{c}{t}$$

10.2 Power transmissions

Good design demands that the power source is placed as close as possible to the driven unit and is one reason why the unit gearbox integral with electric motor is so popular. Unfortunately, in many instances, circumstances such as geometry, environmental considerations or lack of electricity supply dictate placing the prime mover at a distance from the driven unit and probably not in the same plane. Thus the designer must adopt a system of power transmission which may be shafts, belts, chains, gears, fluid power or all five. Inevitably, these will introduce complications and the successful system is one that is fundamentally simple, with the least number of parts that are able to transmit the required power. Modern machinery and equipment frequently also demand the installation of clutches, brakes and couplings, etc. and the selection of the right components for a specific task is usually a compromise. Nevertheless, engineers accept these limitations and successfully bring together many component parts to operate at a high degree of efficiency backed with established reliability.

10.2.1 Belt drives

The simplest form of power transmission is probably the belt drive. Progress in power belts has been considerable within the last decade and much of this effort has been concerned with finding improved materials more suited to specific types of transmissions. Belts can be round, flat, V-form or toothed and some designs incorporate features of more than one type. The original form of round belting for power transmission was the rope drive using cotton ropes and, while this form of drive is still used, the modern round belt is usually elastomeric or woven from synthetic fibres.

For light loads extensible round belts ranging from 3 mm (or smaller) to 12 mm diameter are available with elastomeric cores. These are useful as, within limits, they can be stretched to different lengths. They can also damp out vibration and, after fitting, tension can be maintained without the need for adjustment or idler pulleys. A further advantage is that they can be fitted to pulleys without the need to first reduce the centre distance. Round belts are usually intended to run in U-grooved pulleys which are essential for cotton-based ropes, but other materials will usually operate efficiently in V-grooves of 40–45°. With cotton ropes, the pulley grooves should be highly polished to minimize the wear of the cotton.

A modern hard-wearing material with a high coefficient of friction is polyurethane, while various other polymer formulations (sometimes with a mix of suitable elastomers) can provide a flexible, strong and long-lasting belt.

10.2.1.1 Flat belts

For light loads, and where small-diameter pulleys are in use, a flat belt made from woven fibres provides a highly flexible drive. However, historically, the flat belt was usually made of leather and enabled overhead shafts to be driven over considerable distances with power take-off at convenient points along their length. These drives were very tolerant of misalignments and were also highly flexible since they could be crossed

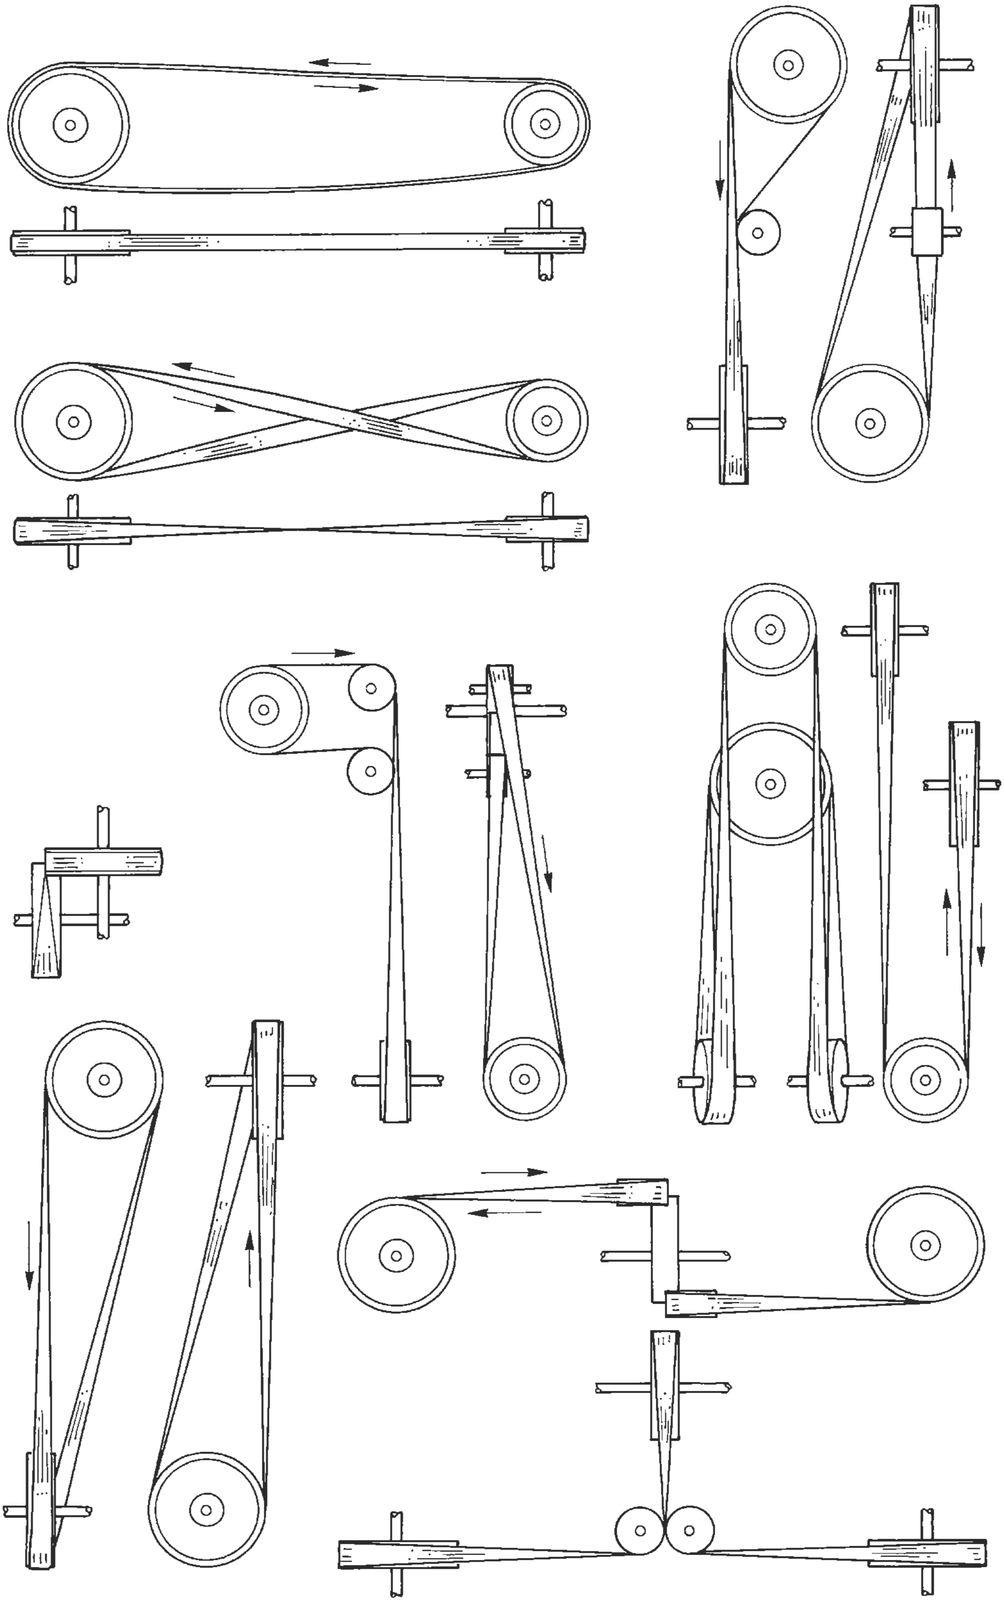

Figure 10.50 Various ways in which a belt drive may be used

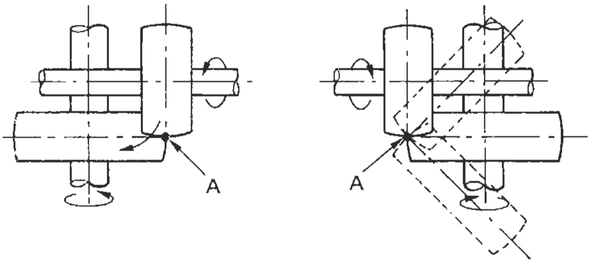

Figure 10.51 A general rule for aligning belt pulleys connecting non-parallel shafts

to give opposite direction of rotation and could be used to drive shafts which were not necessarily in the same plane (see Figure 10.50). In this connection, a general rule for aligning belt pulleys connecting shafts which are not parallel is for the centre of the face of the driven pulley to be aligned with the centre of that face of the driving pulley from which the belt leaves, as at A in Figure 10.51. The manner in which the belt passes over the pulleys is indicated by the arrows showing the direction of rotation. The driven pulley can be set at any angle in relation to the driving pulley provided it is turned about point A, as indicated by the dotted lines. The direction of rotation should not be reversed unless the relative positions of the pulleys are changed in accordance with the above rule.

The modern flat belt is usually of composite construction, power being transmitted by a high-tensile core often made from nylon or other high-tensile fibres (metal is also used) with the friction grip provided by leather or suitable polymer bonded to the core. Nevertheless, belts have several disadvantages, some of which arise from exposure to atmospheric and environmental changes that affect their stability, particularly those employing leather. Such belts often need dressing to avoid high slippage, while over-tensioning places heavy loads on the shaft bearings. Improvements in materials with the introduction of rubber and rubber/cotton composite belts followed by plastics belts ameliorates some of these disadvantages. However, the death knell of large-scale flat belt drives was sounded with the introduction of unit construction for machines and equipment. Electric motors became smaller and more efficient and their price was low enough for them to be economically used on the basis of one motor to each machine, or indeed several motors to provide the power for different tasks in a single machine. There was still the need for drives, but these were considerably shorter while the power requirements were still rising. The V-Belt, in its different forms, became the generally accepted method of efficiently transmitting power.

Nevertheless, there are still some applications for flat belt drives and the following information will help the engineer to arrive at a belt size for specific applications. As in gears, the ratio of speed of driven to drive shaft is a matter of pulley diameter and is derived from the following formulae (see also Figure 10.52):

$$\text{Rev/min of driven pulley} = \frac{\text{Dia. of driver} \times \text{rev/min of driver}}{\text{Dia. of driven}}$$

The length of a belt is derived from the formula:

Open belt: $L = \pi(R + r) + 2\sqrt{[c^2 + (R - r)^2]}$ (approx.)

Equal pulleys: $L = \pi(R + r) + 2c$

Crossed belt: $L = \pi(R + r) + 2\sqrt{[c^2 + (R + r)^2]}$ (approx.)

where

R = radius of larger pulley,
r = radius of smaller pulley,
c = centre distance,
L = total length of belt.

Allowable power that can be transmitted by a particular belt is best derived in conjunction with manufacturers' literature, as it will be dependent on the choice of belt material.

Tension relationship between the slack side of the belt (which should be above the pulleys) is given by:

$T_1/T_2 = 2.7^{\mu\theta}$

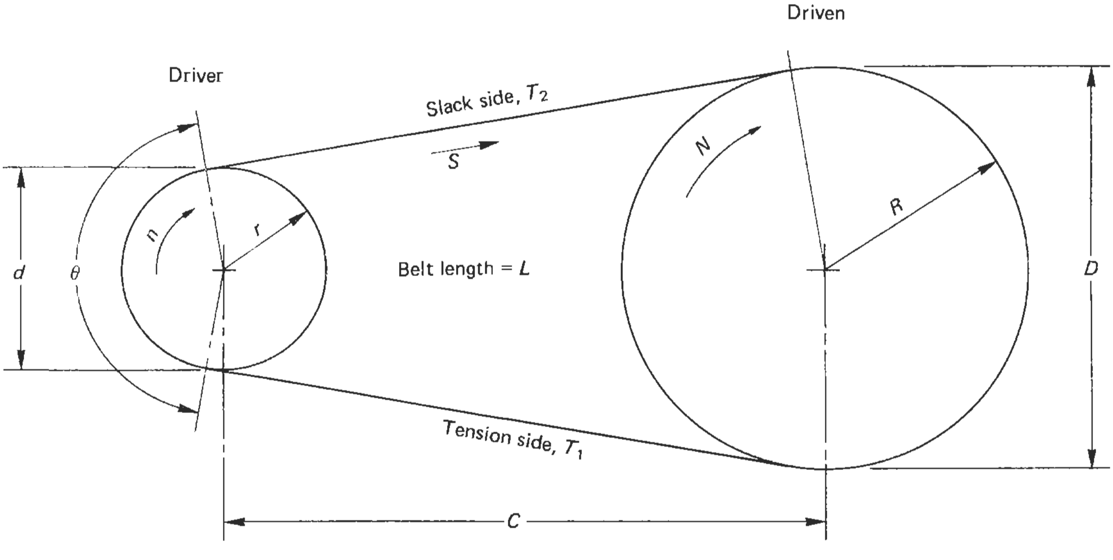

Figure 10.52 Drive geometry

and

$$T_1 - T_2 = \frac{\text{kW} \times 1000}{S} \text{ Newtons}$$

where

T_1 = tension in tight side of belt,
T_2 = tension in slack side of belt,
θ = angle of wrap of belt around the smaller pulley (in radians)
$= 2\text{Cos}^{-1}\dfrac{(D - d)}{2c}$
μ = coefficient of friction,
S = belt speed (m/s)
$= \dfrac{d \times n}{19\,100}$ m/s

Pulleys should slightly exceed the belt width and should be slightly crowned. Ideal belt speed is around 18 m/s. At belt speeds above 18 m/s there may be a loss of power due to centrifugal force, and it is common for belts, apparently tight when stationary, to fail to exert a grip when centrifugal effects predominate.

10.2.1.2 V-Belts

The endless V-Belt drive, used either singly or in multiples, has a very wide range of uses and has applications in almost all types of machinery. There are two families of belts: classical, sometimes called industrial, and wedge, sometimes called narrow. The wedge belt differs from the classical belt, from which it was developed, in having a greater height-to-top width ratio. The benefit to the user of the wedge belt system is that generally a more compact (and possibly cheaper) drive can be designed on account of the greater individual belt load-carrying capacity. Both belt types are the subject of a Standard Specification, BS 3790: 1981, and this document embodies, where appropriate, the work of the International Standards Organization (ISO). This conformity with ISO permits a high level of international interchangeability.

Applicationally, V-Belt drives provide a high degree of flexibility, with a wide choice of speed ratios and shaft centre distances. The drives are quiet in operation and the use of multiple belts removes the likelihood of a sudden breakdown. Special drives for shafts at right angles and V-flat drives, where the driven pulley is flat and can be part of the machine (such as a tanning drum), can be designed, although particular criteria must be observed.

Automotive belt drives are selected and operated under quite different conditions to industrial belts and are the subject of BS AU150: 1984. Their design and performance are usually agreed between manufacturers.

The V-Belt is manufactured with a core of high-tensile cord embedded in rubber or synthetic rubber and encased in a fabric and rubber reinforcement. The core supplies the tensile strength and the casing forms the friction surface in contact with the pulleys. Different belt constructions are available which provide anti-static capacity, oil tolerance and flame-resistance properties. All the belts have a standard angle of 40°, and the angle of the pulley groove varies to accommodate the slight bulging of the sides of the belt as it flexes around the pulley.

BS 3790: 1981 specifies six sizes of classical belt, designated Y, Z, A, B, C and D, and four sizes of wedge belt, SPZ, SPA, SPB and SPC. The cross-sectional dimensions of the sections are shown in Table 10.1. It should be noted that while the overall dimensions are given for recognition purposes, the pitch dimensions are used for the calculation of power, centre distance, etc. Pitch dimensions must be regarded as absolute and used for the derivation of other dimensions, which can be nominal or toleranced.

V-Belt pulleys: Figure 10.52 and Table 10.2 show the standard profiles, which in four cases are equally suitable for either classical or wedge belts. These profiles, which are defined in BS 3790, also conform to ISO 4183. (See also Figure 10.54.) In Table 10.2, dimensions *b* and *h* are minima, although in the case of the four dual profiles (e.g. Z-SPZ) dimension *h* can be reduced by 20% if it is intended to use only classical belts. The tolerances for dimensions *e*, *f* and *a* can be found in BS 3790: 1981.

Pulleys must be produced from materials with adequate strength for the power and speed requirements of the drives. Light alloys are not usually employed for continuous industrial duty because groove wear would cause damage to the belts. Cast iron pulleys are the most common: BS 1452, Grade 12 for belt speeds up to 25 m/s, and Grade 14 up to 40 m/s. For belt speeds above 40 m/s special pulleys may be necessary.

Table 10.1

Belt section	*Pitch width* (mm)	*Nominal top width* (mm)	*Nominal height* (mm)	*Minimum recommended diameter* (mm)
SPZ	8.5	9.5	8.0	67
SPA	11.0	13.0	10.0	100
SPB	14.0	16.0	14.0	160
SPC	19.0	22.0	18.0	224
Y	5.3	6.5	4.0	20
Z	8.5	10.0	6.0	50
A	11.0	13.0	8.0	75
B	14.0	17.0	11.0	125
C	19.0	22.0	14.0	200
D	27.0	32.0	19.0	355

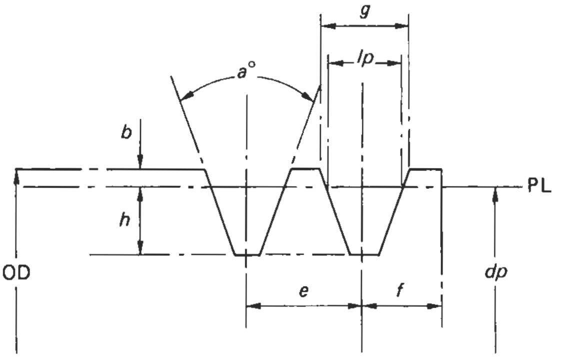

Figure 10.53 Multi-groove pulley cross section. PL = pitch line, OD = outside diameter, h = groove depth from PL, b = distance between OD and PL, $a°$ = groove angle, e = centre-to-centre of grooves, f = edge of pulley to centre of first groove, g = top width of groove, dp = pulley pitch diameter, lp = pitch width of V-Belt

The pulley surfaces and especially the groove sidewalls should be machined such that the surface finish is a maximum of 3-2 μm when determined by the method described in BS 1134. Pulleys must be balanced either statically or dynamically, depending on the rim speed and ratio of face width to diameter. BS 3790 contains comprehensive balancing information. In general, for all pulleys operating below 10 m/s rim speed, and for pulleys with face widths half or less of the diameter operating below 20 m/s rim speed, static balancing is adequate.

Pulleys employing split-taper bushings are most convenient for installation and removal in that they avoid the need for interference fits, keys, etc. A Taper-Lock pulley manufactured by J. H. Fenner & Co. Ltd is shown in Figure 10.55.

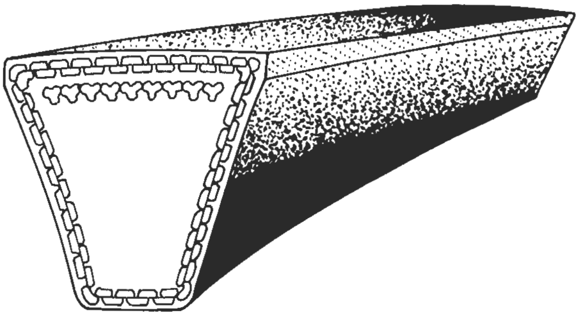

Figure 10.54 Narrow V-Belts (better known as wedge belts) have a narrower profile than classical V-Belts, with a relative height of approximately 0.9. There is a more even distribution of the tension forces between the reinforcing cords and thereby a higher power rating compared to classical V-Belts of the same top width

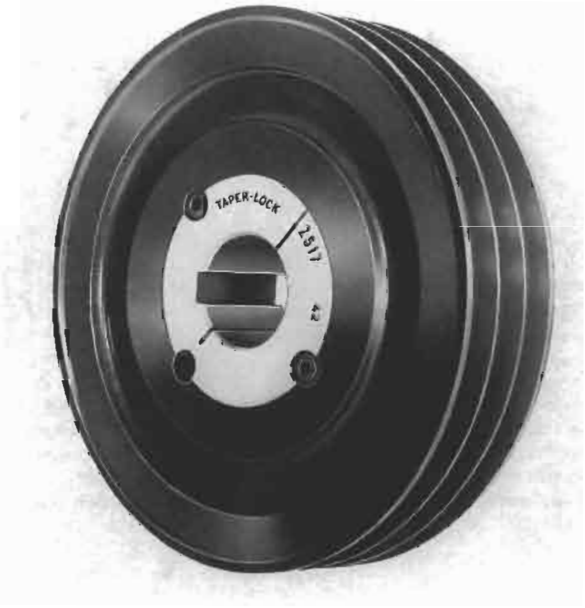

Figure 10.55 A Fenner Taper-Lock bushing for securing a large pulley to a shaft

						38	>500	32.6

Selection of belt drives BS 3790: 1981 contains all the information necessary to design a drive; power ratings, standard pulley diameters, service factors, correction factors for belt length, arc of contact and speed ratio. Similar details are usually given in the catalogues of manufacturers, some of whom operate a technical advisory service.

The number of belts required for a particular drive can be obtained using the power table for the selected type and size of belt. The power rating given in the table for the particular pulley diameter and shaft speed is multiplied by the correction factors for belt length, arc of contact, etc., and then divided into the design power (actual power × service factor) of the drive. If the result of the division contains a fraction, the next whole number of belts is used.

Power-correction factors for industrial service These are based on prime movers classified into two separate groups, with reference to Driven Machinery classified into four separate groups as detailed below. Table 10.3 gives the factors for periods of up to 10 hours, 10 to 16 hours and over 16 operational hours per day. The four separate groups of driving machines are defined as follows:

Light duty – Agitators for liquids, blowers and exhausters. Centrifugal pumps and compressors. Fans up to 7.5 kW. Light-duty conveyors.
Medium duty – Belt conveyors for sand, grain, etc. Dough mixers. Fans over 7.5 kW. Generators. Line shafts. Laundry machinery. Machine tools. Punches, presses and shears. Printing machinery. Positive-displacement rotary pumps. Revolving and vibrating screens.
Heavy duty – Brick machinery. Bucket elevators. Exciters. Piston compressors. Conveyors (drag-panscrew). Hammer mills. Papermill beaters. Piston pumps. Positive-displacement blowers. Pulverizers. Sawmill and wood-working machinery. Textile machinery.
Extra heavy duty – Crushers (gyratory-jaw-roll). Mills (ball-rod-tube). Rubber calenders, extruders, mills.

For the above four groups (1) for speed-up and reversing drives multiply the factor given in Table 10.3 by 1.25, except where high torque is not present on starting. (2) If idler pulleys are used, add the following to the service factors: (a) idler pulley on slack side, internal, 0; (b) idler pulley on slack side, external, 0.1.

Power ratings Table 10.4 shows typical power ratings for each of the belt sections. The ratings are based on the range of motor pulley diameters normally associated with each section and the speeds are for the faster shaft. The values are only a guide and can vary considerably and it is prudent to consult the Standards or manufacturers' catalogues for a precise selection. Normally, pulleys should be chosen which will give a belt speed in the 15–20 m/s speed range and are of adequate diameter in relation to the motor bearings (see Table 10.4).

Minimum motor pulley diameter Table 10.5 shows the minimum pulley diameter suitable for British metric electric motors, to BS 5000: Part 10: 1978. The diameters were calculated to give a minimum bearing life (B_{10}) of 12 000 hours, and a tight to slack side tension ratio of 5 was assumed (180° arc of contact). All dimensions are in millimetres. Smaller diameters can be used but the drive end load should be calculated and referred to the motor manufacturer.

Arc of contact correction factor The arc of contact x on the small pulley can be calculated from the following formula (see Table 10.6):

$$x = 180 - \frac{(D - d) \times 60}{C}$$

where
x = angle of contact,
D = pitch diameter of larger pulley (mm),
d = pitch diameter of smaller pulley (mm),
C = centre distance (mm),
F = arc of contact factor.

177	0.99	157	0.94	136	0.88
174	0.99	154	0.93	133	0.87
171	0.98	151	0.93	130	0.86
169	0.97	148	0.92	127	0.85
166	0.97	145	0.91	123	0.83
163	0.96	142	0.90	120	0.82

Note: Arcs of contact below 120° should not be used without confirmation of the drive details by the belt manufacturers.

V-Belt formulae Let

R = speed ratio
C = centre distance (mm)
L = pitch length of belt (mm)
d = pitch diameter of small pulley (mm)
D = pitch diameter of large pulley (mm)
V = velocity or speed of belt (m/s)
F = arc of contact correction factor
K = service factor
E = belt length factor
N = number of belts required
R = prime mover speed ÷ driven machine speed
$V = d \times \text{rev/min of small pulley} \div 19.100$
$L = 2C + (D - d)^2/4C + 1.57\,(D + d)$
$C = A + \sqrt{(A^2 - B)}$ where $A = L/4 - 0.3925\,(D + d)$ and $B = (D - d)^2/8$

$$N = \frac{\text{Actual power} \times K}{\text{Basic power per belt} \times F \times E}$$

Note: Although contemporary practice uses pitch dimensions for all calculations, in the past it was common to define classical belts by inside length. In the event of only the inside length of a belt being known, a conversion to pitch length can be made by adding the following constants (dimensions in millimetre units):

A	*B*	*C*	*D*
35	43	56	79

Example Determine the basic drive equipment for a piston pump running at 1150 rev/min and driven by a 1440 rev/min, 22 kW electric motor, star delta starting 12-hour day duty, approximate centre distance 730 mm.

1. Service factor = 1.3
2. Minimum motor pulley = 140 mm
3. Speed ratio = 1440 ÷ 1150 = 1.25:1
4. Choose standard pulleys 160 and 200 mm
5. By observation it can be seen that a 160 SPB pulley running at 1440 rev/min transmits 9.00 kW
6. Belt length required = $2 \times 730 + (200 - 160)^2 \div 4 \times 730 + 1.57\,(200 + 160) = 2026$ mm (SPB 2020 will suffice)
7. Arc of contact $= 180 - \dfrac{(200 - 160) \times 60}{730} = 177°$

   $\therefore$ Factor = 0.99
8. From BS 3790, belt length factor for SPB 2020 = 0.93
9. $N = \dfrac{22 \times 1.3}{9.00 \times 0.99 \times 0.93} = 3.45$ (say, 4 belts)

Installation of V-Belts When fitting it is necessary to move the motor towards the driven pulley so that the belts may be placed in their grooves by hand. The use of a lever of any kind to force the belts onto the pulley can damage the load-bearing cords leading to premature failure.

The accepted method of belt tensioning is by the application of a force normal to the belt spans, at the span centre, to achieve a stated deflection. This method is fully described in both BS 1440 and BS 3790, and also in manufacturers' catalogues and installation instructions. The high performance of modern belts, especially wedge, can only be realized by proper tensioning and this is particularly important in the early life of the drive when bedding-in and initial stretch are taking place; nothing damages belts more rapidly than the heat generated by slip.

Where an adjustable centre distance cannot be arranged it is necessary to use a jockey pulley tensioning device. With classical belts this may be either a flat-faced pulley running on the outside of the belts or a grooved pulley running on the inside. For wedge belts only the latter should be used. In either case, it should be positioned so as to preserve the arc of contact on the powered small pulley and any adjustment to the service and arc of contact factors, occasioned by its use, made to the design calculations.

When multi-belt drives are installed, matched sets of belts, coded for length, must be used to ensure correct load sharing. When replacing belts always order a matched set and do not mix old and new belts. Finally, pulleys should be properly aligned by normal workshop methods and the drive fitted with a ventilated guard for safety and to allow heat dissipation and air calculation.

Raw-edge V-Belts Recent years have seen the development of the raw-edge V-Belt. These are available with a smooth flat underside or a cogged underside and are manufactured by accurately cutting cured sleeves to the required section dimensions. Raw-edge V-Belts have no textile case, and this, together with a cogged underside, reduces resistance to bending and allows them to operate on smaller pulley diameters than the conventional V-Belt. However, when cogged belts are used in larger pulleys the contact area and therefore the power-transmission capability are somewhat reduced.

Raw-edge V-Belts are normally manufactured in the wedge belt sections but they are also available from some manufacturers in the classical sections. They are commonly used as fan belts for cars but have become of growing importance in the industrial market.

10.2.1.3 Synchronous belt drives

Both flat belts and V-Belts lose a very small amount of speed (less than 1%) due to belt 'creep' (a condition not to be confused with slip) which is due to the change in belt section and tension as it moves around the pulley. If absolute synchronization is required then some type of geared drive is called for.

The idea of cogged, rubber driving belt for synchronous power transmission originated with the Singer Sewing Machine Company in America. The aim was to maintain register of the different moving parts of the machines without the possibility of oil contamination. The idea became a reality in 1940 and the use of synchronous belts spread to other small machines and instruments. This concept was developed and applied to other machinery and became more generally accepted during the 1950s.

As with chain, the tooth pitching became standardized and the early types were based on the inch system of units. There are five pitches generally available: XL, L, H, XH and XXH. XL is generally restricted to small business machines such as electric typewriters and photocopiers and XXH tends to be uneconomical for the power capacity, leaving L, H and XH in general industrial use. The teeth have an involute shape the same as gears to ensure smooth, rolling contact as the belt enters and leaves the pulley. Tooth form and size are covered by BS 4548. Figures 10.56 and 10.57 show the tooth profile and dimensions for L and H pitch.

Because stable length is essential for synchronous belts they were originally reinforced with steel. Today glass-fibre reinforcement is common and aramid is used if maximum capacity is required. The load-carrying tension numbers are moulded into a very thin layer of neoprene (synthetic rubber). To this are moulded the uniformly spaced and pitched neoprene teeth. The facing material is a layer of nylon fabric, providing

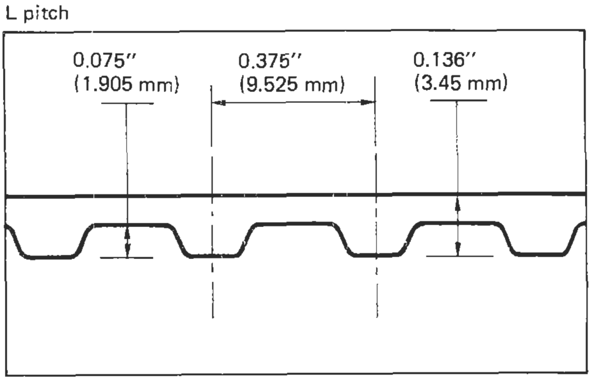

Figure 10.56

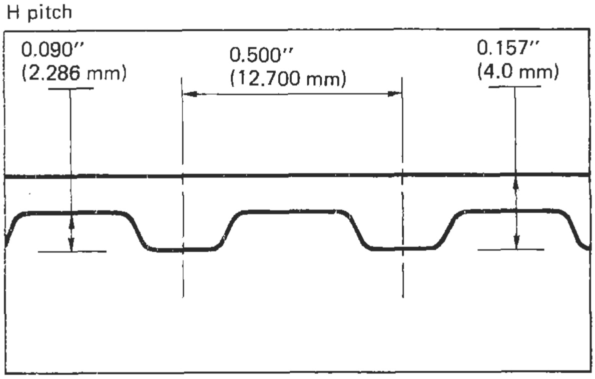

Figure 10.57

a wear-resisting surface for the entire running surface of the belt and its teeth. Figure 10.58 illustrates the typical components of a timing belt.

Depending on the application, timing belts have considerable advantages over chains, gears, V-Belts and flat belts due to one or more of the following features:

1 Owing to the use of a fibre-glass cord the timing belt has no stretch whatsoever in service, and this in itself eliminates the necessity of expense on automatic take-up devices and/or periodic maintenance. It also permits installation in otherwise inaccessible locations. Fixed-centre drives become possible. Except gears, all other forms of indirect transmission require periodic take-up.
2 The timing belt drive requires no lubrication and this allows for very substantial economies in initial drive design since oiltight housing and gear cases, seals, lubrication lines and accessories are all completely eliminated, while, at the same time, maintenance costs are also drastically reduced. In many industries such as food handling, strict process restrictions do not permit the use of lubricants in close proximity to the products being processed.
3. The timing belt drive allows for positive synchronization and this feature is daily becoming of more importance with the greatly increased use of automation, computerization and the necessity for very accurate, synchronized industrial drives.
4. Because of the very thin cross section, timing belts are extremely flexible and will operate efficiently over smaller pulleys than those used with comparable V-Belt or flat belt drives. Since arc of contact is not as critical a feature in timing belt drive design, larger ratios and shorter centre distances can be easily accommodated, ensuring considerable saving in space and weight. While arc of contact is not a critical design feature, it is most important, in order to gain the full advantage of belt width, to note that the belt teeth in mesh with the pulley grooves must not be less than 6. When the belt teeth in mesh are 5 or less the shear strength of the tooth becomes the critical factor in design, and this invariably results in an increase in belt width.

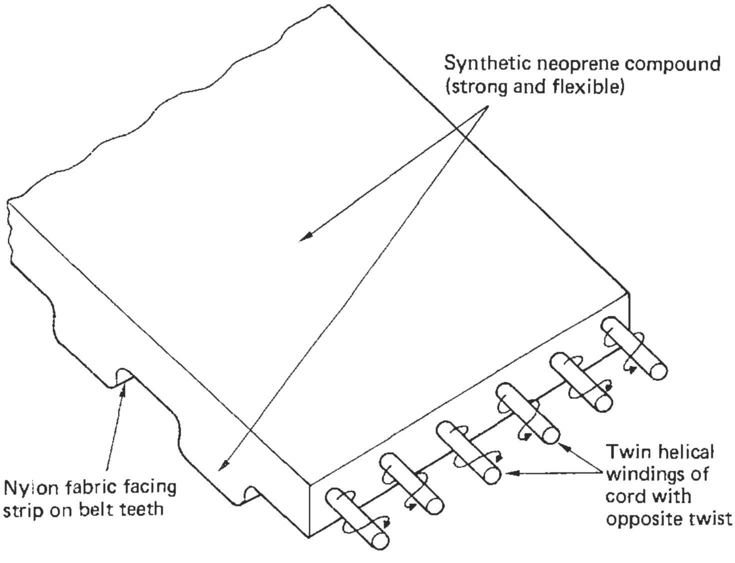

Figure 10.58

5. The very thin section ensures that the heat generation when the belt is flexing around the pulley is kept to an absolute minimum; furthermore, there is no creep or slip to generate heat. The belt profile also allows for very high belt speeds of up to 60 m/s, although drives of above 30 m/s must be carefully considered because of pulley material.

Timing pulleys Standard timing pulleys are normally produced from steel and cast iron, and most manufacturers follow a similar coding system consisting of numbers and letters. The first numbers indicate the number of grooves in the pulley, the letter represents the pitch of the grooves and the final number the belt width that the pulley accepts.

Therefore, the code symbol 24H200 represents a timing pulley with 24 grooves, $\frac{1}{2}$-inch pitch and accepts a 2-inch wide belt. Pulleys are also recognizable by 'type', which refers to the particular design of pulley. All timing pulleys up to and including 48 grooves in L and H pitch are supplied with flanges. Even on perfectly aligned pulleys, a standard construction timing belt will 'track', and it is for this reason that one pulley (generally, the smaller of the two) is flanged to prevent the timing belt 'walking off' the drive. Figure 10.59 shows a typical flanged pulley.

Unlike any other type of drive, the pitch diameter of the timing pulleys is so arranged that it is actually in the centre of the flexing part of the timing belt where the load-carrying cords are situated. As mentioned previously, because of this, the pitch diameter of the timing pulley is always greater than its o.d. Figure 10.60 shows the basic dimensional details.

HTD drives Recent modifications of traditional trapezoidal tooth profiles to more circular forms offer a more uniform load distribution, increased capacity and smoother, quieter action. These newer synchronous belts with rounded curvilinear tooth design are known as HTD, which stands for High Torque Drive. Figure 10.61 shows a comparison between the standard involute belt and the newer HTD curvilinear design and illustrates the different stress patterns.

The HTD belt was developed to handle the higher torque capabilities normally associated with chain. The new design allowed, for the first time, metric pitched drives, and the standard pitch dimensions are 3 mm, 5 mm, 8 mm and 14 mm. Figure 10.62 shows dimensional details of 5, 8 and 14 mm pitch belts.

Both the belts and pulleys are manufactured in similar materials to the standard timing belt range. As the belt is fully metric the designation is straightforward. For example, in 1610-14M-85 mm, the first figure indicates the pitch length in

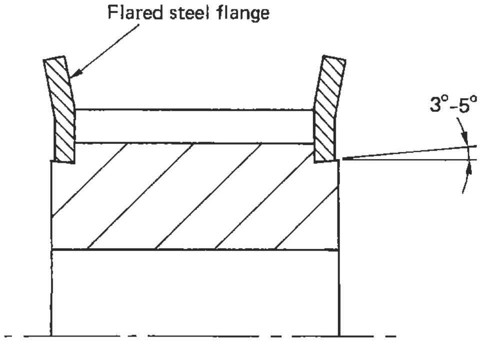

Figure 10.59

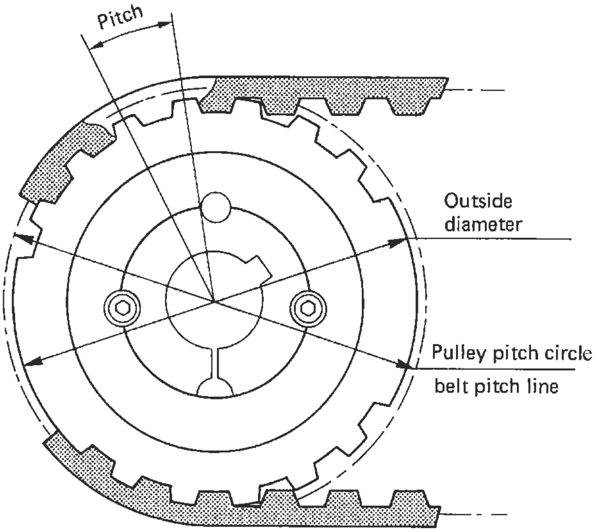

Figure 10.60

5 mm HTD

8 mm pitch

14 mm pitch

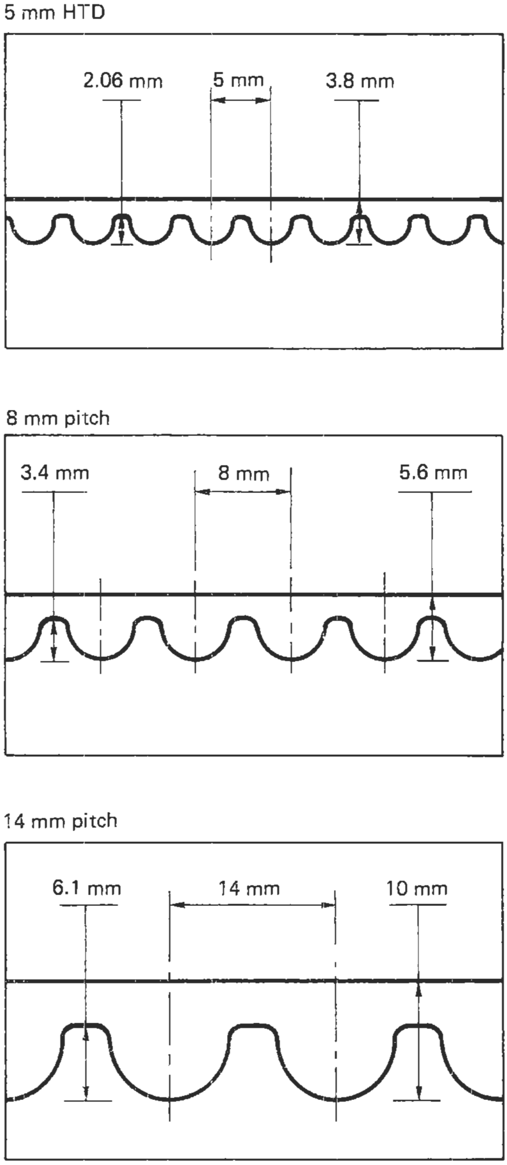

Figure 10.62

millimetres, followed by the metric pitch and lastly the belt width. The belt pitch length is the total length (circumference in millimetres as measured along the pitch line). The theoretical pitch line of a HTD belt lies within the tensile member (see Figure 10.63). The belts are available in a range of standard lengths up to 4500 mm pitch length and a range of widths from 9 mm to 125 mm.

10.2.1.4 Miscellaneous belt drives

In addition to the flat belts and V-Belts described above, there are also V-link belts made up from a number of separate links fastened together to form an endless belt. With these, access to pulley areas necessitated by the use of endless belts does not apply. Second, since belt length can be adjusted by increasing or decreasing the number of links, fixed pulley centres can be used.

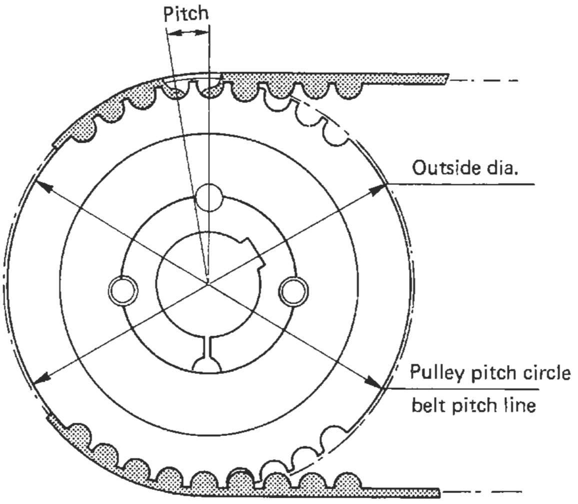

Figure 10.63

In general, V-link belts are more expensive than the endless belt but some economic advantages may be gained by holding a stock of links rather than a variety of endless belts. When flexing round a pulley, V-link belting does not suffer distortion as does the solid V-Belt; adjacent links slide over one another and there is little or no internal stress generated and in consequence, lower heat. Thus smaller-diameter pulleys can be used.

While most of these belts are made from various polymers in combination with fibre reinforcements, there are also all-metal belts. These are made from thin metal strips ranging from carbon steel through beryllium copper to stainless steel, titanium and, in the case of high temperatures, Inconel. The belt is perforated with holes and the pulleys can have teeth of various shapes, ranging from round or rectangular pegs to formed teeth. These belts are not in common use but offer potential in new projects.

10.2.2 Gears and gearing

Gearing is an essential part of most power transmission systems and, wherever possible, the use of ready-prepared units is recommended. Gear design and manufacture is a highly specialized venture, and success can only be bought at the price of experience. Noise, vibration and short life are some of the penalties to be paid for gears imperfectly designed and manufactured.

An ambitious research programme involving a further investment of £8 million has been approved by the government without which it is believed that much of the UK gear industry would decline significantly. The programme is the result of several years of planning by the BGA (British Gear Association) Gear Research Council which has determined and prioritized the industry's research needs and established where the research might be carried out. The programme relates to four main technological themes: gear materials, gear design, gear lubrication and gear manufacturing and metrology. It is expected that it will develop to include projects in other areas of mechanical power transmission technology such as clutches and flexible couplings. The programme will be flexible to cater for the changing needs of the industry and as such, indicates the prudency of buying-in ready-made gears.

This programme is timely, as a deal of confusion exists in the mind of many engineers regarding gear design and selection. It appears to be centred first, on the change from imperial to metric working and second, the introduction of new geometry considerations. It must also be recognized that the majority of manufacturers' literature and technical data is still given in imperial dimensions. This is primarily to cater for spares and replacements, although most companies cover metric gears which are not direct replacements for imperial-dimensioned gears.

As part of the engineering commitments of the BGA, new teaching modules are being developed in conjunction with the University of Sheffield. In the following, formulae have been given using descriptive terms together with the new symbols from the teaching modules (where these are known) in parentheses.

It is, of course, recognized that the use of standard gear units may not always be possible but the guiding principle is that, wherever possible, use standard bought-out manufactured gears of gear units. The cost of cutting, grinding and finishing is likely to be expensive with any new in-house operation.

However, it is important that basic aspects of gear design are understood so that the limitations are recognized. Other matters of significance include methods of securing gears to their shafts, their lubrication, their size in relation to their duties and the selection of appropriate materials.

10.2.2.1 Tooth profile

The profile of a gear tooth must be chosen bearing in mind the following:

1. All the gears must mate and mesh with a smooth uniform action.
2. The tooth must have a section sufficiently strong for the applied loads.
3. The tooth must be free from weakening undercuts.
4. The tooth will mesh at the correct shaft centre distance.
5. The profile of the teeth offers no manufacturing difficulties.
6. The geometry provides an adequate tooth overlap.

The involute curve provides the most widely used profile for gear teeth although there are other profiles such as the cycloid and a variety of profiles found in horological designs. There has also been a revival of the basic Russian Novokov gear, which never found favour in the West until Westland Helicopters Ltd recently redeveloped the profile under the name of conformal gears. In industry, the involute profile has been the subject of intensive design and manufacturing studies and had enabled manufacturers to provide silent, accurate and long-lasting gears while the use of vacuum-melted steels has removed the dangers of inclusions, and peening and honing have improved surfaces.

Westland adopted the conformal tooth form in a parallel shaft gear configuration because:*

1. They are more tolerant than involutes to the large out-of-plane shaft misalignments experienced in high power-to-weight ratio aircraft transmissions. This is explained by the differences in contact geometry (see Figure 10.64) misalignment resulting in localized concentration of the narrow line contact of the involute form compared with an inconsequential axial movement of the elliptical conformal contact. Contact stresses would thus be increased in involute teeth but unaffected in conformals.
2. Power losses in conformal teeth are lower than in equivalent involute gears (particularly a planetary set) due to the lower sliding velocities and increased surface separation.
3. Lubricant film generation benefits from the greater entraining speeds – an order of magnitude higher than involutes because conformal contact traverses a large proportion of tooth length during rotation of one tooth pitch.
4. Conformal gears have proved to be more tolerant to tooth imperfections than involutes, whether these be surface damage or variations in long-wave surface finish characteristics within manufacturing tolerances.

10.2.2.2 Involute profile

An involute curve can be constructed by tracing the end of a cord unwound from the periphery of a circular disk (see Figure 10.65). The contour of the involute curve is governed only by the diameter of the disk from which it is developed. As there is no limit to the length of an involute curve, in practice, the best portion to meet working conditions has to be chosen. Under working conditions, the contact between two teeth at the pitch point is pure rolling contact. Either side of that point, the contact is sliding and the rate of sliding constantly varies. Standard gear tooth forms are obtained using cutters of standard geometry and corresponding to a basic rack as defined in BS 436: Parts 1 and 2.

Gear teeth are sometimes crowned (see Figure 10.67(b)), which is a progressive reduction of the tooth thickness from the middle part towards each end face, in order to ensure the transmittance of the stresses of a flank to its mating flank under the best conditions.

The choice of a suitable pressure angle for the basic rack (see BS 436: Part 2) is important, for it governs the thickness of the tooth at the root, the length of contact made by teeth on the flanks of the mating gear and the number of teeth in a small-diameter pinion before tip interference commences. Although pressure angles used in the past varied from $14\frac{1}{2}°$ to 20°, experience has shown that the generally accepted pressure angle is the British Standard value of 20°. As the number of teeth in a gear diminishes, a point is reached where good

contact between the mating gears cannot be maintained. For a full-depth involute tooth form, the minimum number of teeth is given by the expression:

$\frac{2}{\text{Sin}^2\,\alpha}$ where α is the pressure angle (20°)

$\therefore$ Minimum number of teeth $= 2/\text{Sin}^2\,20 = 2/0.342^2 = 17.09$

In practice this would mean, say, 17 teeth, but with adequate radius at the tip of the tooth the minimum could be reduced to 14 without undercutting the roots of the teeth (see Figure 10.66).

Table 10.7, used in conjunction with Figures 10.67 and 10.68, indicates some of the general terms and formulae used in connection with the design of gears and gearing. For efficient running it is important that correct meshing of teeth is ensured, and with bought-out gears this comes down primarily to establishing the correct centre distances for the shafts. Tolerances will depend on size and duty, and values are given in BS 436: Parts 1 and 2. The addendum modification consists of shifting the profile of the gear teeth to compensate for deflection under load and for manufacturing errors, and this involves certain limiting values which are summarized in British Standards PD 6457.

Table 10.7 General formulae for spur gears (without addendum modification) (dimensions in mm)

Pitch circle diameter (reference circle diameter) (d)	=	$z \times m_n$
Overall diameter (d_a)	=	$(z + 2) \times m_n$
Diametral pitch (not used with metric gears) (p_n)	=	$1/m_n$ or z/d (reciprocal of m_n)
Module (denotes tooth size) (m_n)	=	p_n/π or d/z (reciprocal of p_n)
(number of teeth) (z)	=	d/m_n or $(d_a \times p_n) - 2$ or $d \times p_n$
Circular pitch on reference circle (p_n)	=	$\pi \times m_n$
Addendum (h_a)	=	$1 \times m_n$
Tooth thickness	=	$p_n/2$ or $\pi/2p_n$ or $1.57/p_n$

Figure 10.68 Nomenclature for meshing gears

For fine-pitch gears ($m_n < 1.0$ mm) some manufacturers tend to increase the tip/root clearance by reducing the diameter of the dedendum circle. For machine-cut gears these can be stated as follows.

Standard dedendum = $1.4 \times m_n$ for fine-pitch gears with modules below 1.00
Dedundum = $1.25 \times m_n$ for fine-pitch gears with modules 1.00 and above

For general considerations the dedendum can be $1.25 \times m_n$, which is taken from the British Standard rack. Variations in these values for the tooth profile in the past gave rise to some confusion. The reason is that experience and method of manufacture dictated to individual manufacturers the best values for them to accept and, not unnaturally, different manufacturers took different values.

Obviously, when choosing gears of different overall diameters it is important that the tooth sizes are identical, and this can be expressed by the module which is the reference circle diameter (d) divided by the number of teeth (z), i.e.

$m_n = d/z$

This can be seen from the illustration in Figure 10.66 of two meshing gears of differing diameters. As an example we can give each gear a physical size:

Gear A		*Gear B*
$(z) = 35$	Ratio 2:1	$(z) = 70$
$(d) = 31.5$ mm		$(d) = 63$ mm
$(m_n) = 31.5/35 = 0.9$		$(m_n) = 63/70 = 0.9$
(p_n) 0.9 = 2.83		$(p_n) = 0.9 = 2.83$

Theoretical tooth thickness (s) = 2.83/2 = 1.42
Addendum (h_a) = 1×0.9 = 0.9
Dedendum (h_f) = 1.4×0.9 = 1.26
Working depth = $h_a + h_f$ = 2.16
Whole depth = $h_a + h_f + 0.4$ = 2.302

It will be seen that, by cross checks with the individual formulae given in Table 10.7, irrespective of gear diameter, providing the module and basic generating rack are identical, the gears will mesh satisfactorily (see Figure 10.69).

Gears used in clocks have already been briefly mentioned and there is currently a growing interest in small mechanisms

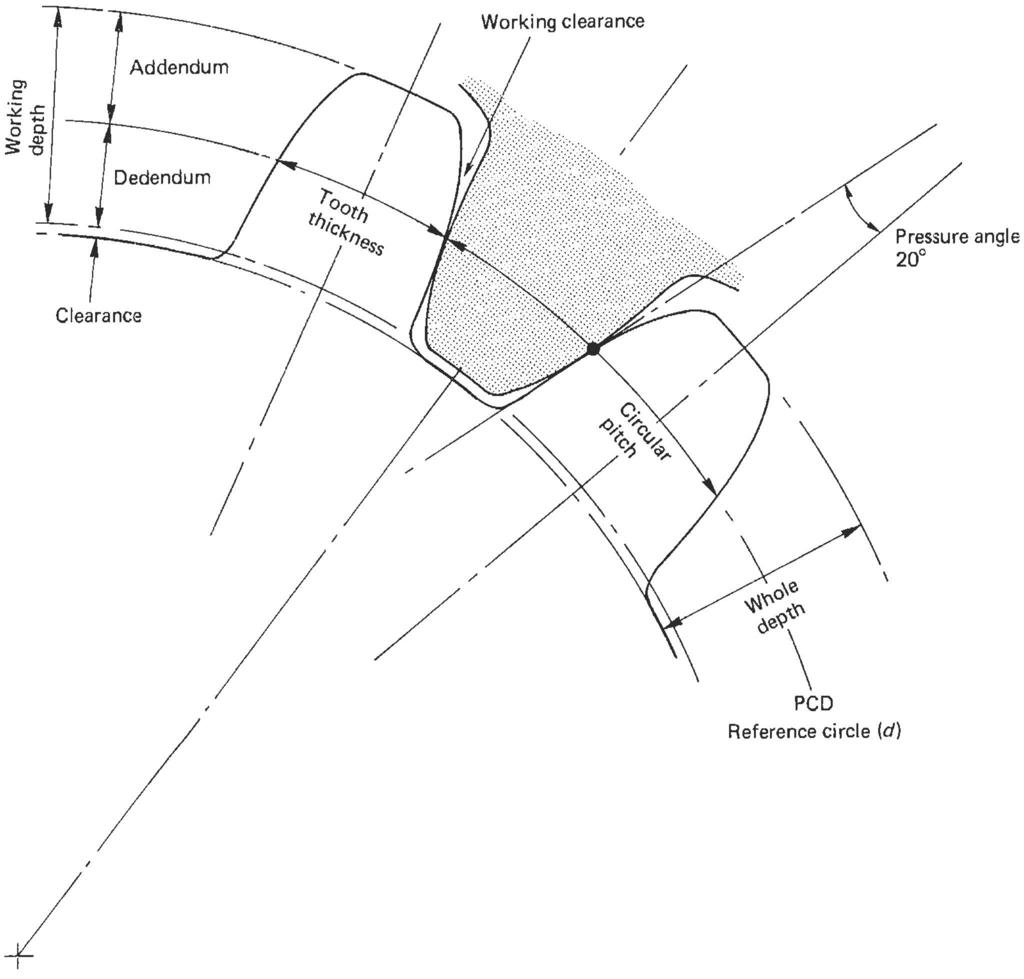

Figure 10.69 Tooth engagement

such as may be used in instrumentation, etc. These interests have focused attention on the need for a standard tooth configuration for small gears. While these mechanisms cannot be regarded as power transmissions, they may be of interest to readers, since the British Standards Institution have put forward recommendations in BS 978 (imperial) and BS 4582 (metric module) which discuss the use of involute tooth profiles together with a double-arc profile for very small pinions with between six and 12 teeth. The scope of these British Standards relates to four accuracy grades for involute spur, helical and crossed helical gears having modules of 1 or finer (diametrical pitches finer than 20 in imperial units). Examples are:

Class A	Scientific instruments and control systems
Class B	Navigational instruments and high-speed components of control systems where quietness and smooth running are essential and machine tool speed control
Class C	General-purpose instruments, counters, clockwork mechanisms

10.2.2.3 Helical gears

Helical gears have several advantages over straight-cut spur gears. One is that shafts can be inclined at any angle from 0° (parallel) to 90° (crossed axis helicals with small load capacity), the helix being adjusted to suit. One advantage of parallel axis helicals is that, unlike the spur gear in which the load is taken over the width of the next tooth instantaneously (unless the tooth has tip relief), with the helical gear, the teeth mesh gradually so that at no time is the full width of the tooth fully engaged. This eliminates some of the shock loading associated with straight teeth and makes for much quieter running. The cost of producing helical gears is not the disadvantage that it used to be. Modern designs of gear-cutting machines can handle helical gears with the same ease as spur gears.

One drawback to the helical gear is the side thrust arising from the helix angle. This can be overcome by either using thrust bearings or a double helical gear, often referred to as a herringbone gear. This may be cut from the solid or two separate gears used, one with a left-hand helix and the other with a right-hand helix. Some authorities suggest that these gears should be avoided, as spur gears are as good for low-quality drives with the single helical being superior for precision drives.

For shafts lying parallel to each other one gear will have a right-hand helix and the matching wheel a left-hand helix. On both gears the helix angle of generation will be the same. With shafts at 90° to each other both gears will have the same hand (either left- or right-hand helix). Thrust reactions are shown in Figures 10.70 and 10.71. With shafts arranged at less than 90° to each other, if the sum of the helix angle of both gears equals the shaft angle, the hand will be the same on both gears. If, however, the helix angle of one gear is greater than the angle between the shafts, then each gear will be handed (see Figure 10.70).

10.2.2.4 Bevel gears

Bevel gears are used to connect shafts whose axes lie at an angle to each other, although in most applications the shafts are at right angles. The tooth profile is basically the same as used for spur gears except that the tooth gets progressively smaller as it approaches the apex of the projected cone. Normally the teeth are straight cut and radiate from the apex of the pitch cone, but it is possible to give them curved, skew or spiroid form. Generally, the shafts of conventional bevel

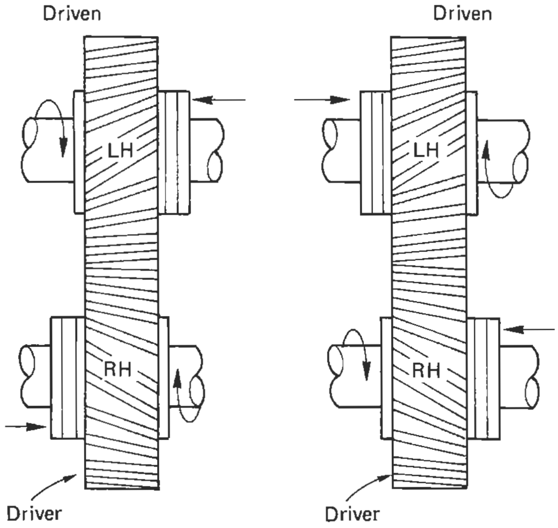

Figure 10.70 Thrust reactions using helical gears on parallel shafts

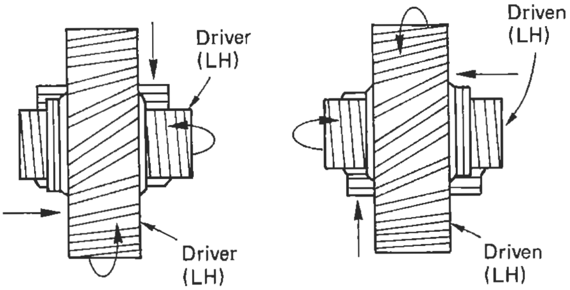

Figure 10.71 Thrust reactions using helical gears on shafts at right angles

gears intersect, although bevels can be designed to have the pinion offset. When such a pinion has radial teeth, the crown wheel will also have straight teeth but offset in relation to the axis. A variation is the hypoid, where the teeth on both gears are cut on the skew (Figure 10.73), in which situation they will act similarly to helical gears with consequent smoother running. The spiroid gear has curved teeth and, in many cases, can be likened to an offset worm drive. These systems do, however, cause higher tooth pressures and, as a result, it is important that really efficient lubrication is provided.

10.2.2.5 Worm drives

Worm drives have a number of advantages, one being that, given the helix angle is around 20° or less, the drive is considered to be unsatisfactory in reverse although not positively irreversible. Where the coefficient of friction, which can vary from 0.01 to 0.1 (with indifferent lubrication), equals the tangent of the helix angle, the gear is self-locking and cannot be turned by the gearwheel. However, the coefficient is not accurately predictable, as it can be affected by vibration, the

finish of the tooth surface and, above all, the degree and efficiency of the lubrication. For this reason, if a truly irreversible drive is required it is prudent to fit a brake in the system. Experiments have shown that the efficiency of a worm can be quite high; the best figures being when the helix angle is about 45° although the rate of increase in efficiency is markedly slower between 25° and 45° helix angle.

Shafts normally lie at right angles with a worm drive but other angles can be accommodated by adjusting the helix angle on the worm. While the worm can work in conjunction with a spur gear, the contact area between the teeth is limited and full power cannot be transmitted. It is usual for the worm wheel to fit closely to the diameter of the worm itself, thus providing the maximum surface on which to transfer the load (see Figure 10.74).

Worms can be single-start or multi-start. With a single-start worm the velocity ratio between worm and wheel is equal to the number of teeth on the wheel. With multi-start worms the velocity ratio can be expressed thus:

$$\text{Velocity ratio} = \frac{\text{Number of teeth on wheel}}{\text{Number of teeth on worm}}$$

The worm should be kept as small as possible consistent with stiffness needed to avoid deflection, as this will keep down surface speeds and friction. BSI recommendations for the design of worms and worm wheels are given in BS 721.

10.2.2.6 Gear trains

Internal gears are used in a variety of designs such as reduction gears and epicyclic units. In general, such units use standard pinions or bevels and have the involute tooth form. Figure 10.75 shows a typical epicyclic gear train and Figure 10.76 a differential unit as used in an automobile for drive to the wheels.

10.2.2.7 Gear materials

Materials are normally selected according to the duties intended for the gears. For power transmissions, the physical properties are critical and selection becomes more a question of choosing the right steel rather than any other particular material. The exception would be if environmental conditions dominated the specification. For example, in a corrosive atmosphere, stainless steel or reinforced plastics may be considered. Slow-moving gears at low stress levels will find cast iron a suitable material while worm wheels are generally made from phosphor-bronze. Plastics gears are widely used for various mechanisms, but for reliable power transmissions they could be more expensive than a suitable steel. They do, however, have the advantage that they are quieter running and have the ability to take up small deformation in tooth profile without causing damage.

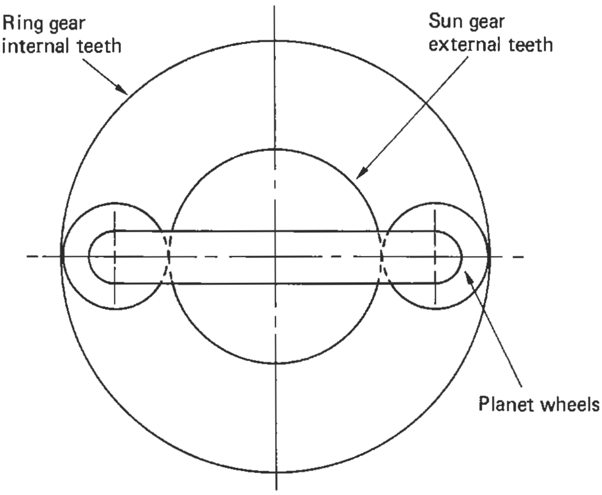

Figure 10.75 Epicyclic gear train

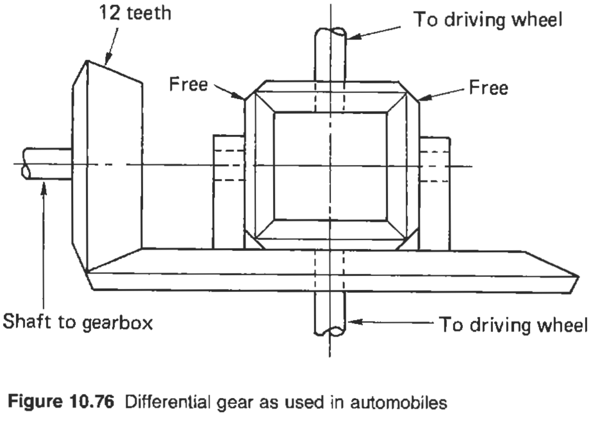

Figure 10.76 Differential gear as used in automobiles

When choosing a suitable material for gears the questions of first cost, ease of machining, its response to heat treatment and its behaviour in service must be considered. A point to bear in mind is that case-hardened gears should not be used with softer metals such as mild steel.

For heat-treatable steels, the addition of *nickel* tends to increase the hardness and strength with little sacrifice in ductility. Its use as an alloying element produces less distortion due to lower quenching temperature. In the case-hardening group, carburization takes place more slowly but grain growth is restricted. *Chromium* increases the hardness and strength over that obtained by the addition of nickel but loss of ductility is greater. It refines the grain and imparts a greater depth of hardness. *Manganese* gives greater strength than nickel and a higher degree of toughness than chromium. *Vanadium* has a similar effect to manganese but the loss of ductility is greater: hardness penetration is also greater but machining is difficult. *Molybdenum* has the property of increasing the strength without affecting ductility. For the same hardness, steels containing molybdenum are more ductile than any other alloy steel and, having nearly the same strength, are tougher without increasing the difficulty of machining.

For spur gears it is common practice for the pinion to be made from a harder material than the mating gear. Carbon steel to BS 970 is in wide use in gear units and is of low cost and offers reasonable wear resistance. A Ni/Cr/Mo alloy steel to BS 970 gives good hardenability and, when through-hardened and tempered, is widely used for pinions and wheels. A slightly less expensive alloy containing Cr/Mo offers good wear resistance. A nitriding steel gives a very hard case but this is not deep enough to sustain continual shock loads. A carburizing case-hardening steel offers a deep hard case but subsequent tooth grinding will be needed, as distortion often occurs during quenching. A direct air-hardening steel is often used for worms and for volume-production speed reducers.

When considering case-hardened steel the aim should be to have a core hardness of between 30 and 40 Rc. A general run of hardness for the surface layer after suitable tempering should be in the 55–65 Rc region with general-purpose gears at the lower end and maximum capacity highly loaded precision gears at the high end.

10.2.2.8 Securing gear wheels to shafts

Securing the gear wheel to the shaft can be done in a variety of ways. The criterion should be that the gear remains square with the shaft, that the means of securing can meet the imposed loading without loosening and that it does not unduly weaken the shaft or gear. Figure 10.77 shows a number of different ways of securing the gear in small or lightly loaded drives, but in many cases the arrangement for securing may be part of an assembly and therefore a special integral arrangement may be devised. Friction holds such as a set screw (A in Figure 10.77) must be carefully considered. It would be inexcusable to use this method in, say, an automobile gearbox and for positive engineering applications, keyways and splined shafts are to be preferred.

A standard square key (B in Figure 10.77) is ideal for a positive drive in one direction only. For very large gears undergoing shock loads, two square keys – a tangential key (Figure 10.78) or a Kennedy key (Figure 10.77) – can be used.

E
F

Figure 10.77 Methods of securing gear wheel to shaft (B and F are the preferred engineering solutions)

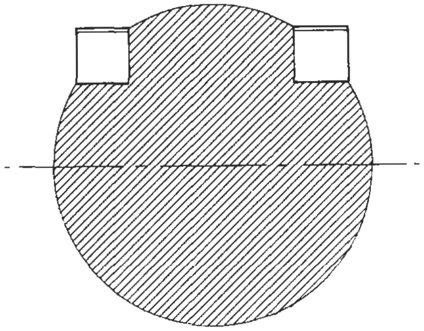

Figure 10.79 Kennedy keys

For smaller high-speed gears, splined or serrated shafts, though more expensive to produce, provide a positive drive and can allow, where necessary, some axial movement (see Figures 10.80 and 10.81). There are also a number of proprietary devices on the market in the form of a bushing which can be expanded to grip both gear wheel and shaft.

10.2.2.9 Gear units

During the last decade there has been a marked increase in the ranges of standard gearboxes employing spur, helical, bevel and worm gears suitable for a wide range of powers and with an extensive selection of fixed ratios in single- and multiple-reduction types, with a choice of parallel shafts, right-angled output shafts, co-axial shafts and offset parallel axis shafts. A high degree of standardization has been achieved and interchangeable components have been developed by many manufacturers. There are now British Standards for many external dimensions, particularly in respect to methods of mounting the units.

It is usual to consider the use of motorized units so that a complete package of motor/reduction unit is available requiring only the choice of coupling to the driven machine. This gives a single form of transmission and provides an economical and efficient package.

10.2.2.10 Lubrication

An essential factor in the lubrication of gearing is the maintenance of a fluid film between the surfaces of the gear teeth. By separating the surfaces in this way, there is a reduction in the degree of contact between the asperities on the mating parts. Inadequate separation leads to scuffing and possibly the localized welding together of the mating surfaces. In practice, gearing will most often be operating under combined conditions of boundary and hydrodynamic lubrication, which means that some of the loading will be taken directly by the opposing asperities and some by the fluid film. Choosing a lubricant for a given duty thus becomes a matter of ensuring that an adequate film thickness is always present at the mating surfaces. This film thickness should be in excess of the combined heights of the asperities, and will depend on the relative velocity of those surfaces, their dimensions and the viscosity of the oil. The major oil companies have considerable documentation which they will generally make available to engineers concerned with the selection of the correct lubricant.

Surface finish is dependent, within limits, on the method of manufacture and the material used. Lightly loaded gears hobbed from steel banks will probably have a surface finish of 1.0–2.5 μm (cla) and require no further finish. Those intended for heavier duties will possibly be hardened and tempered, and the teeth may then need grinding or shaving, which will produce a surface finish of around 0.13–1.0 μm (cla).

While it may be seen that the higher the viscosity of the lubricant, the better for providing an adequate film thickness, a high viscosity also means oil drag or frictional loss in the transmission system. This in itself will raise the operating temperature and thus reduce the viscosity until an equilibrium is attained. Thus the higher the loading between the teeth, the higher the viscosity of the oil that is needed while the higher the speed, the lower the viscosity needed.

In practical terms, most gearing is of the straight-tooth spur or helical types and can be lubricated with straight oils. Helical gears with lower tooth stresses for the same power transmitted would be happy with a lighter, less viscous grade. Additives would only become necessary if the gears were loaded beyond their designed capacity or other circumstances dictated a lighter oil. Bevel gears, with either straight- or spiral-cut teeth, will have requirements similar to the spur and helical gear, although two additional factors may be relevant. One is that the angle between the shafts needs to be accurately maintained and second, the thrust, particularly with the spiral bevel, may adversely affect the bearings so that bearing lubrication may be the governing factor in a bevel unit.

Generically, the hypoid gear falls between the spiral bevel and a worm gear. The offset pinion produces a high slide-to-roll ratio so that tooth stresses are high. This combination of high loading and high rubbing velocity should be met with the use of a full EP (Extreme Pressure) oil. Worm gears have the distinction that the relative motion between the worm and worm wheel is virtually all sliding, which generates considerable heat. The lubricant helps to dissipate this heat and, in most cases, the power transmitted by the worm is limited by this temperature rise. Worm gear lubricants are mostly straight mineral oils designed to resist thermal breakdown and oxidation.

The essence of gear lubrication is to keep apart the conforming surfaces of mating gear teeth. Since this objective is never achieved, gear teeth will always wear in service, and the best to be hoped for is a nominal rate of wear. Accelerated wear may be due to abrasive wear conditions in which the surface of the teeth is removed and circulates in the oil, producing additional abrasion and scratching. Thus some method of filtering the oil to remove any hard particles should be considered, although the most obvious way is to ensure that the teeth have as smooth a surface as economically possible. Further details are presented in Chapter 9.

10.2.2.11 Transmission shafts

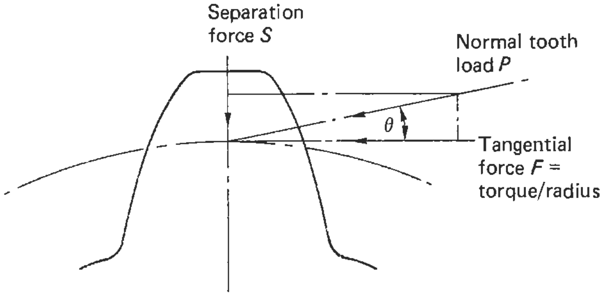
Shafts used in power transmissions will invariably be either solid or thick-walled tubes. In gearboxes and similar assemblies, the shafts will be comparatively short and the design objective will be for these to be made as stiff as possible. Torsional stresses are unlikely to be of major concern.

In many applications a transmission shaft will be machined, will incorporate many different diameters along its length and may contain splines or serrations as well as through-diametric holes. All these features add up to stress discontinuities, and therefore adequate attention must be given to avoiding a sudden change of section and to ensure adequate blending radii. If the shaft is particularly complicated it is likely that the chief mode of failure will be one of fatigue.

For relatively short straightforward shafts where torque is transferred from one end to the other, the stresses are limited to torsion and bending. Standard textbook formulae for solving the working stresses under these conditions exist. For more complex shaft geometries, recourse to the computer and finite-element methods will give the best analysis.

10.2.2.12 Bearing reactions

When a single-spur gear is mounted on a shaft and the bearings are assumed to provide simple support, the bearing loads can be assessed by taking moments in terms of the nominal tooth load. This load in all but the most detailed of calculations can be taken as the resultant of the tangential load at the PCD and what can be termed the separation load tending to force the teeth out of mesh. In the simple arrangements in Figures 10.82 and 10.83 it can be seen that the major bearing reaction will be to the tooth load; reaction to the separation force, S, will be at right angles to the tooth load. With a helical gear, part of the tooth load will be translated into axial thrust.



Separation force S
Normal tooth load P
θ
Tangential force F = torque/radius

Figure 10.82 Resolution of tooth loads

With straight-cut bevels there will be an end thrust in both shafts tending to force the gears out of mesh. The magnitude of these thrusts will alter proportionally when curved teeth are used in the bevels.

In a worm drive the major load is end thrust in the worm shaft, its magnitude depending on its helix angle. There is also a side thrust on both worm and worm wheel arising from the frictional force between worm and worm wheel teeth.

10.2.3 Chains

Through the industrial ages, chains have provided a positive means of transferring power from one shaft to another, parallel, shaft. Today, bushed roller chains provide a simple, robust drive with the minimum of friction, their manufacture being laid down in BS 228: 1984 (ISO 60–1982). Until the introduction of flexible toothed belts, chain drives were almost universally used in automobile engines to drive the camshaft. A disadvantage of the chain drive is that centre distance for sprockets has to be either adjustable or worked on the basis of standard chain pitches. Alternatively, a jockey wheel or similar device can be used on the slack side of the chain, although this will generally preclude the drive being reversed.

Chains need to be adequately lubricated and must work in a clean environment. Dust and dirt will quickly wear chains and

they will become noisy. A section through a typical roller chain is shown in Figure 10.84.

In addition to the standard roller chains, attempts have been made to design chains to operate even more quietly. These are based on a shaped link plate that rolls on a sprocket tooth rather than impacting.

For 15 000-hour chain life, the selection chart in Figure 10.85 is based on a steady load application with a 19-tooth sprocket. For different numbers of teeth, the relevant selection factor should be included. Where impulsive loads are encountered the selection factor should also be applied, irrespective of the sprocket size. Tables 10.8 and 10.9 indicate the types of loading likely to be encountered.

In general, the smallest pitch should be used, even if it means going to duplex or triplex chains. The centre distance should normally be kept to within 30–80 times the chain pitch. For large ratio drives the angle of lap on the sprocket should be not less than 120°. Manufacturers' literature usually contains the necessary data to establish which chain should be used for a specific task.

10.2.4 Shaft couplings

An important element in power transmission systems is the coupling whereby two relating shafts can be joined together. For large-diameter shafts revolving at low speeds, the simplest device is a solid flanged coupling but this does not allow for any misalignments in the shafts. For smaller installations it would be prudent to introduce a coupling that could cater for small shaft offsets and deviations in parallelism. A coupling becomes even more important if one of the shafts is the output from a prime mover where there are inherent vibrations. Selecting the right coupling will avoid transmitting these vibrations into the second shaft and its assembly.

There are numerous designs of couplings to cater for almost every conceivable condition, and the task of the engineer is to choose the right sort of coupling at the lowest cost commensurate with performance. Torsion stiffness is another factor which should receive consideration. The majority of couplings tend to fall into two groups – those that have some flexible

medium interposed between two halves each of which is carried by the shafts to be connected, and those that are mechanically flexible, examples being the internal gear coupling and Hooke joint. Some of the many variations are given below. Most manufacturers carry a wide range of variations in each half of the coupling to allow the use of different methods by which these can be secured to the shafts (e.g. using standard keys or proprietary shaft locking bushes).

The optimum choice of a flexible coupling for any application is the result of a compromise between many factors, and while performance at minimum cost is important, subsequent maintenance should also be considered. Specifically, the following points should be investigated:

1. Decide if the coupling should be torsionally soft or rigid. Soft types are generally less expensive.
2. Consider whether a small amount of backlash is acceptable. Backlash-free couplings are usually more expensive.
3. Calculate the required torque and add in any appropriate service factors. For example:

   Torque = $9550 \times (P/N) \times k \times S$
   where P = power transmitted (kw); N = rev/min, k = starting frequency based on maximum number of starts:

   k = 1 for 0–30 starts/h
   1.2 for 30–60
   1.5 for 60–120
   2.0 for 120–180

   and S = service factor which, for continuous rating, ranges from

   1.0 to 1.75 for light even loads
   1.25 to 2.25 for irregular shock loading
   1.5 to 2.5 for arduous drive conditions

10.2.4.1 Types of couplings

In addition to the standard types given below there are special couplings made to meet specific requirements and may incorporate the features of one or more of the standard types: for example, telescopic couplings to allow considerable axial movements; quick-disconnect couplings; spacer-type couplings to take up any space between the ends of the two shafts; couplings with shear pins which free one half of the coupling when a severe overload is transmitted, etc.

Pin couplings These couplings can cater for a wide range of power ratings by the optimum use of pins ranging in numbers usually from three to 16. The pins are rigidly fixed to one half of the coupling with the free end terminating in a flexible bush of rubber or plastics material. An example would be the Renold Pinflex (see Figure 10.86).

Flexible disk couplings This type uses steel pins fixed in the metal half bodies of the coupling to transmit the torque through a flexible disk interposed between the two halves. The disk can be of staggered layers of rubberized fabric or a suitable solid polymer such as polyurethane (see Figure 10.87).

Flexible spider coupling The flexible spider coupling transmits the torque through an oil-resistant rubber spider assembled between two metal half bodies. In some designs the spider is replaced by separate rubber blocks, manufacturers having their own particular designs to give a positive drive and to take up angular and linear displacements as well as to absorb any shock loads (see Figure 10.88).

Tyre-type coupling This coupling consists of two half bodies connected by an external polymer tyre and is available in a range of shaft sizes to cater for torques from 65 to 1690 Nm,

each size being able to handle 4° angular misalignment as well as end-float and axial displacement. A typical example is the Renold Uratyre (see Figure 10.89).

Chain coupling A chain coupling comprises two chain sprockets encircled by a duplex chain and contained within a housing. Disconnecting the chain provides a quick and easy means of disconnecting the shafts. This type of coupling is not designed to cater for anything other than minimal misalignment (see Figure 10.90)

Internal gear coupling Two basic types of internal gear couplings are available, the operating principle using a pair of externally cut gear hubs engaging the teeth of an internally cut gear in the housing. The teeth on the hubs are radiused so that the coupling can accommodate limited angular deflections (see Figure 10.91(a)). An alternative is to use one gear hub and to fit the engaging ring on the other shaft (see Figure 10.91(b)).

Duplex chain

Figure 10.90 Section through a chain type coupling (with acknowledgements to Renold Gears)

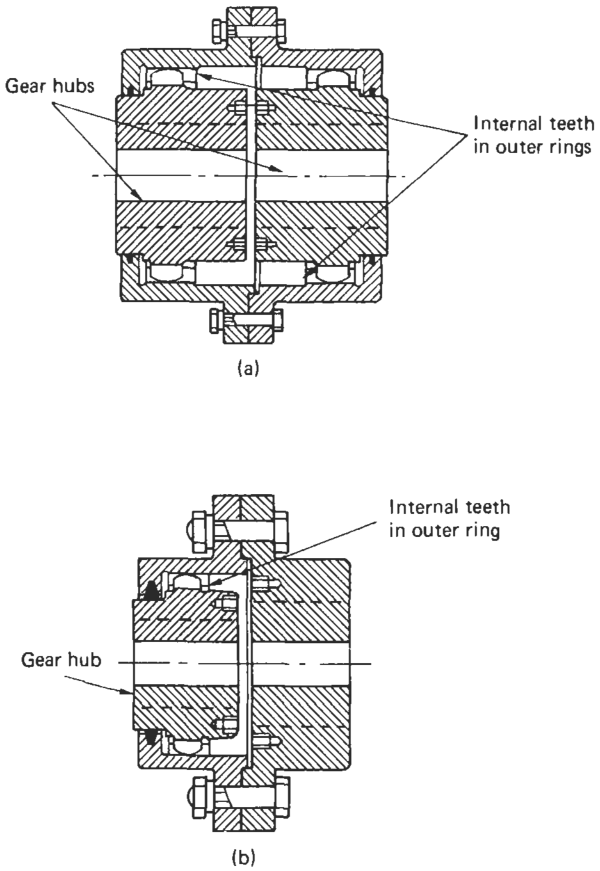

Figure 10.91 Sections through internal gear coupling. (a) Renold standard double-engagement type); (b) Renold single-engagement type

Oldham coupling This coupling consists of two halves each containing a diametric tenon placed at 90° to each other and mating with a centre-floating disk with two mating grooves. This is historically one of the earliest designs of couplings and will accommodate both angular and axial displacements. A typical example of the small size of the Huco Oldham coupling is shown in Figure 10.92.

Face tooth coupling Face tooth coupling rings may be used wherever precise indexing or positioning of one shaft to another is required. A pair of rings constitute a coupling for accurate location capable of transmitting high torque. The mating faces of each ring are machined to produce straight-sided radial V-teeth which, when meshed together, form a rigid angular and radial location. The rings can be bolted direct to a flanged member fitted to the ends of each shaft (see Figure 10.93).

Hooke coupling or universal joint This form of coupling has long been used in automobiles to accommodate the angular movement of the carden shaft connecting the gearbox to the rear axle; it is similarly used in front-wheel drive cars. Basically, the joint consists of two fork members attached to the ends of each shaft, the fork ends being secured to a centre cruciform member. Because there are speed fluctuations proportional to the angle of the two shafts, as given in the following example, it is usual to employ a universal joint at each end of a power transmission shaft, the combination cancelling out any speed variations (see Figure 10.94).

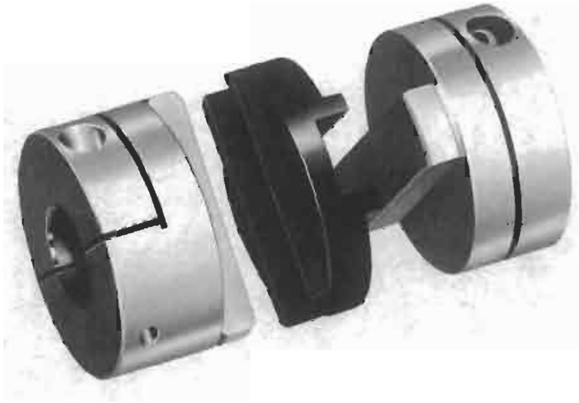

Figure 10.92 Exploded view of a Huco Oldham coupling for light power transmission

Thus, if the driver rotates at a constant speed of 100 rev/min and the shaft angle is 25°, the maximum speed of the driven shaft is at a rate equal to the secant of the angle times 100, which equals 1.1034 × 100 = 110.34 rev/min. The minimum rate speed equals the cosine of the shaft angle multiplied by the revolutions per minute which, in the example, is 0.9063 × 100 = 90.63.

Spring coupling These consist of two hubs connected by single or multiple torsion spring elements. They can be wound different hands to cater for reversible drives. Standard couplings can be used for torques up to 900 Nm and different hub fittings are widely available (see Figure 10.95).

Bellow coupling These are usually regarded as more suitable for low-power transmission with standard couplings from, for example, Simplatroll, available to take torque up to 1 Nm. They are torsionally rigid, free from backlash and extremely light (see Figure 10.96).

All-metal dry flexible coupling The all-metal construction of this type of coupling avoids the need for any form of lubrication or extensive maintenance. High-torsion rigidity and good inherent balance makes the coupling ideal for high-speed applications. In essence, it is similar to the disk coupling shown in Figure 10.87, except that the centre disk is usually made of layers of thin flexible metal disks.

The future for dry membrane couplings is excellent as industry looks more and more for increased machinery life between shutdowns and reduced maintenance services. Another trend is towards gas turbine drives for non-generating equipment such as pumps and compressors. Gas turbine makers have developed aero-derivatives for industrial applications. Here the needs of the couplings will be lighter weight, reduced overhung moments and higher speed and power capabilities. Performance monitoring is another area that is developing as rotating equipment operators seek improved plant efficiencies, preventative maintenance programmes and

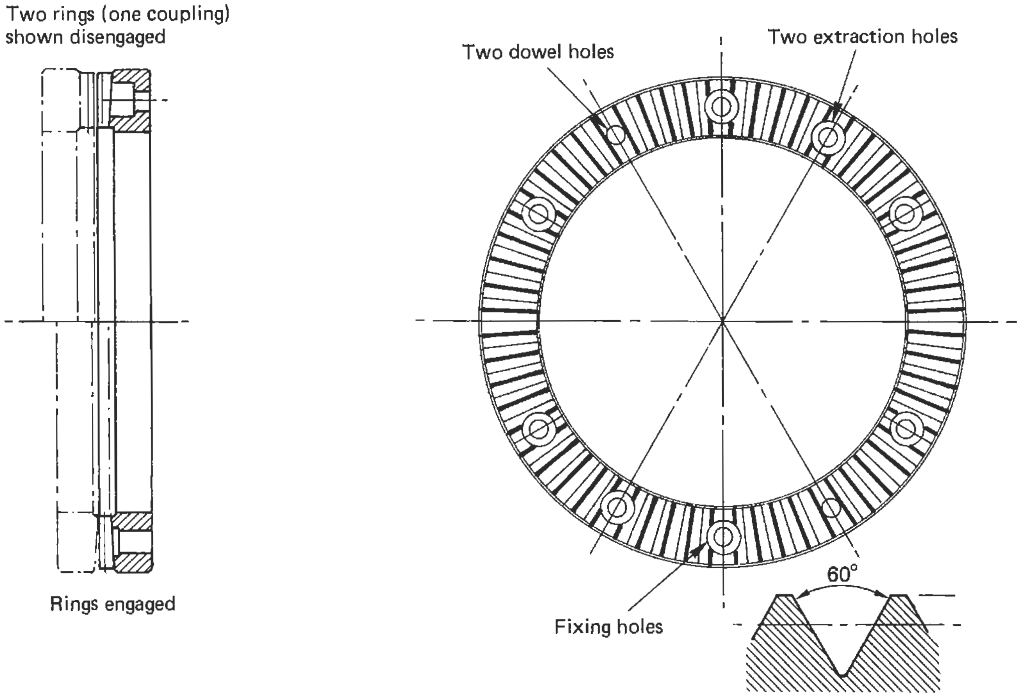

Figure 10.93 A TI Matrix Engineering face tooth coupling ring

longer operating life. To this end, Flexibox have developed a torque measuring system as an integral part of their Metastream flexible couplings.

The following (contributed by Flexibox Ltd) will give users and designers an appreciation of the capability and design of all-metal multiple membrane type power transmission couplings and, by the application of simple disciplines, obtain the practically infinite life for which the couplings are designed. While reference is made extensively to Flexibox Metastream ranges of power transmission couplings, many of the principles and most of the practices can be applied to power transmission couplings in general. Flexibox Metastream power transmission couplings have proved their effectiveness in transmitting torque under shaft misalignment in a wide variety of driver/driven machinery combinations.

10.2.4.2 All-metal mebrane couplings

The M, LS and T series couplings are all-metal non-lubricated membrane couplings which require no additional services, have no wearing parts and are easily installed without special tools. These couplings accommodate shaft misalignment in deflection of thin metal membranes. These are normally stainless steel, although non-ferrous membranes in Monel and Inconel are used for special applications where safety or corrosion merit particular attention. A number of these membranes are assembled into a pack (membrane bank) according to torque rating of the coupling. The membrane bank is (usually permanently) built into a membrane unit. In the spacer type coupling a membrane unit is fitted to either end of a spacer piece to produce a spacer unit (transmission unit). The M series range includes a double-bank membrane

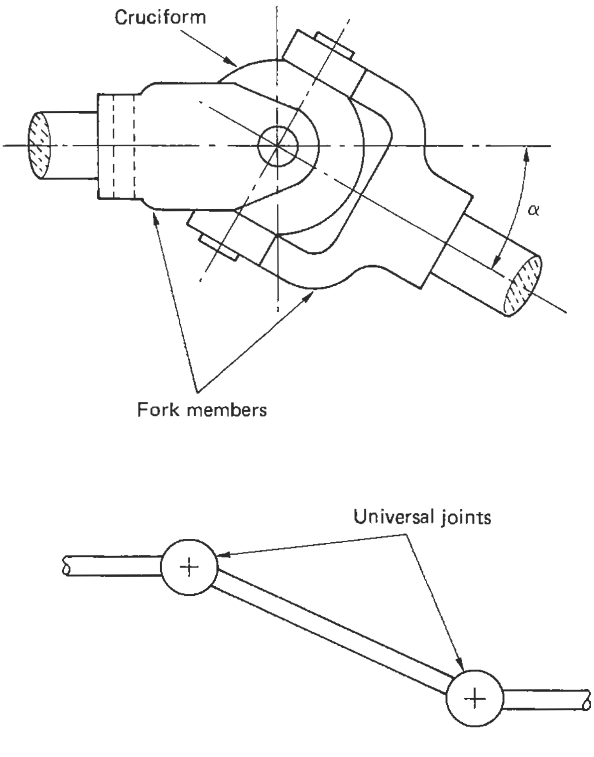

Figure 10.94 Hooke coupling or universal joint

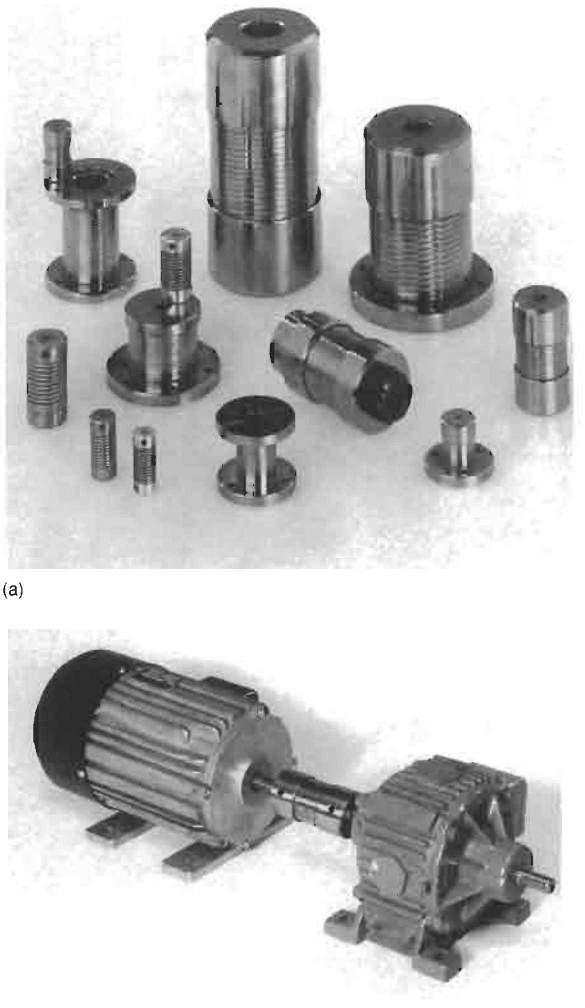

(a)

(b)

Figure 10.95 (a) Examples of torsion spring type couplings; (b) typical application of torsion spring coupling (with acknowledgements to Simplatroll Ltd)

unit (MODO) where two membranes banks are permanently fixed to a central ring, which is effectively a short spacer. The transmission unit is fitted between the driving and driven flanges of hubs or adaptors on the respective machines. The membrane units and transmission units include spacer-retention features that prevent parts of the couplings being thrown if the membranes shear.

In the ring form LS and T series ranges a spacer-retention feature is provided by bushes on the drive bolts. These bushes are shrouded by clearance holes in the coupling flanges and retain the spacer assembly if the membranes are damaged. This shrouded bush arrangement also provides an emergency/overload drive facility.

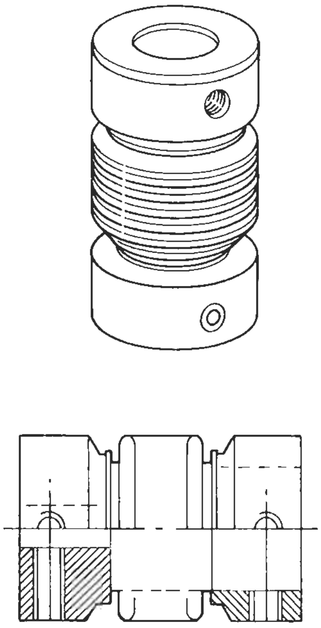

Figure 10.96 Examples of bellow type shaft couplings (with acknowledgements to Simplatroll Ltd)

Speed and dynamic balance All-metal membrane couplings are the ideal choice for high-speed rotating machinery because they can be dynamically balanced to high qualities and, as there are no wearing parts, this quality will not deteriorate during the life of the coupling, provided a few basic disciplines are observed.

Couplings are dynamically balanced to reduce the dynamic loads generated by mass eccentricity and rotation of non-symmetric masses.

Concentricity between coupling components and machinery shafts is achieved by close control of spigot/recess locations and is maintained by rigid assembly at the interfaces.

The influences of non-symmetrical masses are minimized by either removing material or adding counterbalance masses. Dynamic balancing equipment is used to indicate the magnitude and position of such corrections.

Match-marking of corresponding flanges and match-weighing of replaceable fasteners enable duplication of the quality achieved on balancing machines to be ensured.

The high-quality manufacturing procedures used by Flexibox produce couplings that are symmetrical and will rotate concentric with machine shafts. The couplings have no wearing parts and are torsionally rigid so the balance quality will not change over the coupling life. Standard membrane couplings are used on most low- and medium-speed applications without dynamic balancing.

Coupling ranges such as MHS, TSK and the high-performance ranges for high-speed operation are dynamically balanced according to the needs of the equipment. The ultimate speed limit of balanced couplings is dictated by the material strength under centrifugal forces. A change of material (for example, to a high-grade steel such as EN24T or high-strength alloy) can increase the coupling speed capability.

Dynamic balancing ISO 1940, 'Balancing quality of rotating rigid bodies', specifies permissible residual unbalance of rotating components as a function of machinery type and speed of operation. The type of machinery is denoted by a Quality Grade 'G'.

Thus, a component for a relatively heavy diesel engine would be balanced to quality grade G16, whereas a component for a comparatively lightly constructed gas turbine would require a balance quality grade G2.5.

Although the majority of applications where dynamic balancing is necessary would be satisfied by quality grade G6.3, Flexibox has standardized on the higher-quality grade G2.5 for normal commercial balancing. The acceptable residual unbalance and couple per unit of rotor mass in 8 mm/kg on centre of gravity displacement in micrometres is shown in Figure 10.97.

Normal commercial practice produces a coupling with only the transmission unit dynamically balanced. The hubs or adaptors are balanced after fitting to their appropriate shafts as part of the machine rotor assembly by the machine builder.

For very high-speed applications and lightweight equipment, Flexibox have supplied couplings balanced to a higher quality as well as individually balanced hubs and adaptors. The high-performance range is balanced to higher specifications in line with the needs of high-speed lightweight turbine drives.

Torque and misalignment Power transmission coupling elements are subjected to various stresses which may initially be considered separately as steady and cyclic stresses:

Steady
Torque
Centrifugal
Axial misalignment
Design and manufacturing technique stresses
Cyclic
Axial shuttle
Torsional fluctuations
Angular and lateral misalignment

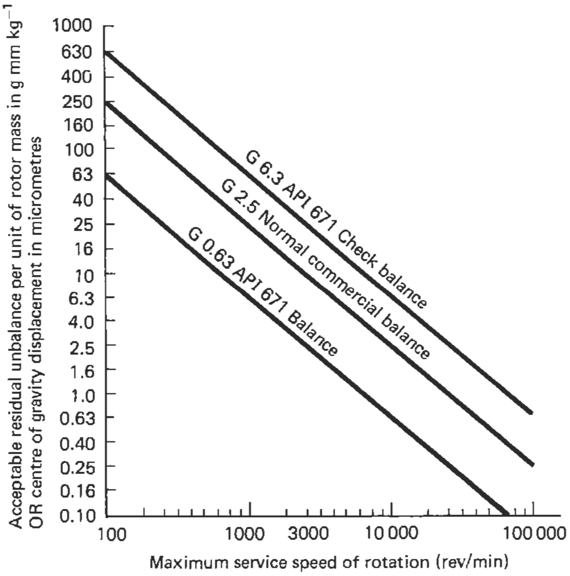

Figure 10.97 Unbalance versus speed (with acknowledgements to Flexibox Ltd)

Steady stress factors are accommodated in the basic coupling design, giving an adequate design margin over ultimate stress capabilities of the membrane material used. Maximum torque capacity is usually expressed as a power-to-speed ratio, i.e. the coupling rating:

$$\text{Selection: Coupling rating} = \frac{\text{Power}}{\text{Speed}}$$

This is usually expressed in kW per 1000 rev/min or HP per 100 rev/min.

Maximum axial misalignment capacities of couplings are very generous and alignment within 10% of the coupling's limit is easily achieved. Allowance for the thermal growth of shafts can normally be made without exceeding the coupling's capacity in the cold and hot dynamic states.

Because cyclic stresses have a great effect on coupling life, these must be given more attention.

Axial shuttle is not normally a problem on machines where the shaft positions are axially located within the bearing arrangements. Moreover, stress levels caused by axial shuttle are low, and Flexibox membrane couplings have a non-linear axial stiffness characteristic which tends to damp out axial exciting vibrations.

Occasionally, however (for example, on sleeve bearing motor applications), it may be necessary to move the operating position up the stiffness curve by deliberately adding an axial displacement, thereby inducing a resisting force against the axial excitation. Cyclic stresses due to torsional fluctuations are usually accommodated by the use of a service factor in the coupling selection procedure. These service factors have been derived from a wealth of experience and knowledge of the torque characteristics of driving and driven machinery:

$$\text{Max. torque} = \frac{\text{Power}}{\text{Speed}} = \frac{\text{Coupling rating}}{\text{Service factor}}$$

Therefore:

$$\text{Required rating} = \frac{\text{Power} \times \text{service factor}}{\text{Speed}}$$

While the service factor effectively reduces the coupling rating by increasing the design margin, the axial and lateral misalignment capacities are unaffected. However, because higher speeds mean higher cyclic frequencies, it becomes necessary at very high speeds to reduce the angular (and, consequently, lateral) misalignment limit of flexible couplings according to design and speed.

Lateral (or angular) misalignment leads to many more coupling failures than all other causes combined. Lateral misalignment is accommodated in an angular deflection of each of the membrane banks in a spacer coupling configuration. The effects of angular and lateral shaft misalignment are therefore additive in producing cyclic stresses in the coupling.

To reduce these stresses within the membrane material capacity, therefore, accurate shaft alignment is crucial. A relatively small improvement in angular/lateral alignment greatly reduces cyclic stress levels and consequently extends coupling life expectancy. Coupling misalignment capacities and ratings given in suppliers' technical literature should allow for the anticipated stresses due to misalignment and torque simultaneously.

10.2.4.3 Flexible coupling ranges

Metastream Flexible couplings are designed to accommodate the inevitable displacement which occurs between the centre lines of two rotating shafts. Flexible elements are in the form of membrane banks, usually made of stainless steel or other corrosion-resistant materials. As all flexing occurs within the membranes, there are no wearing parts and therefore no necessity for lubrication, adjustment or any other form of maintenance. All Flexibox M, LS and T series membrane couplings incorporate spacer-retention anti-fly devices.

M series 'spoke form' membrane couplings The flexible element of the M series is a bank of spoked membranes secured rigidly at their inner and outer diameters. Designed for low-, medium- and high-speed operation, the M series design meets the API 610 specification and is particularly suitable for process pump applications. The axial stiffness of the M series membrane unit is strongly non-linear, making it inherently self-damping and therefore ideal for unlocated rotor motor applications without recourse to end stops.

In the event of a seizure or mal-operation of the driven or driving machinery, the coupling will spin freely after membrane failure and can therefore be used to protect major equipment. The MHSO Single bank non-spacer coupling accommodates axial and angular misalignment only. Its use is limited to such applications as three-bearing systems and cardan shaft configurations, using one coupling at each end of long spacer shaft or tube. The MHSS single-bank spacer coupling accommodates axial, angular and lateral misalignments. Lateral misalignment capacity is increased by longer DBSEs (distance between shaft ends). The coupling is used in most process and industrial machinery, particularly where there is a need for a shaft gap when changing machine bearings, seals, etc., without disturbing either machine.

The MODO non-spacer double-bank coupling accepts axial, angular and limited lateral misalignment and is used on close coupled machinery, where some lateral shaft misalignment has to be anticipated.

Ring-form tangential transmission link designs Metastream 'T' series flexible couplings employ ring-form banks of stainless steel membranes to combine a high power transmission/weight ratio with maximum flexibility and high torsional stiffness. The membranes are arranged to transmit the driving torque as a pure tensile load. The 'waisted' form ensures that the bending and fatigue stresses arising from misalignment are at a minimum in the critical areas around the driving bolts. This form permits high torque ratings with relatively small diameters so that the coupling can be used at high speeds without exceeding acceptable levels of stress.

The T series is sub-divided into the several ranges of couplings which, between them, offer a wide variety of capabilities and features required by rotating equipment designers. The LS spacer coupling design is an inexpensive simple arrangement for general industrial applications at low and medium speeds, with ratings from 2 up to 24 000 kW per 1000 rev/min.

High-performance couplings The high-performance range of Metastream couplings has been specifically designed to meet the requirements of manufacturers and users of high-performance rotating equipment and comply with API standard 671. High-performance coupling speeds can be as high as 30 000 rev/min. Coupling sub-assemblies are dynamically balanced to a limit of G1.25 ISO 1940, and assemblies check balanced to G6.3. The designs are specified for unspaced turbine and compressor applications at ratings up to 38 MW per 1000 rev/min. The inverted hub design allows the coupling effective centre of gravity to be moved close to the bearing for reduced overhung moment and minimized bearing loads (see Table 10.10).

Condition-monitoring couplings Torsionally stiff membrane couplings have no wearing parts; they need no lubrication or adjustment; they have a predictable high torsional stiffness that does not alter over a period of time and they have accessible low-stressed spacer tubes. These features make such couplings ideal for both the train-gauge and phase-displacement torque-measuring systems. The coupling is supplied with a factory-assembled transmission unit ensuring dynamic balance integrity and measuring system accuracy throughout the virtually unlimited life of the coupling.

Axially split couplings The TSEW coupling is a precision built, six-link, non-spacer T series coupling with two membrane units connected by an axially split spacer. The coupling is designed to allow maintenance of the membrane assemblies without moving either of the rotating machines. Shaft separations of only 3 mm can be achieved while allowing a practical misalignment capacity.

Optional features Membrane couplings can be supplied in spark-resistant designs for hazardous areas. Normal atmospheric corrosion protection is provided by stainless steel membranes and a phosphated finish on other steel parts. For more severe environments, other materials such as titanium, aluminium alloys and other types of finishes can be specified. For applications that need continuity of drive under overload or after membrane failure, modifications are available to meet these requirements. There are also torque-limiting devices and overload shear devices as well as an *in-situ* line-balancing correction.

10.2.5 Clutches, freewheels and brakes

Clutches, freewheels and brake units are important components in transmission systems and can be included as separate items or integrated with other transmission units. In the following the various types of clutches and brakes will be described as separate items.

In most machinery, the clutch or brake is remote from the operator and consequently they are provided with the means of remote control. These may be electric, pneumatic or hydraulic, and most manufacturers have a range of components catering for all these alternative means of control. For example, a typical air-operated clutch from Wichita is shown in Figure 10.98.

10.2.5.1 Dog clutches

These are positive-drive components and are normally operated only when they are stationary. Various tooth forms are used (see Figure 10.99); (1) straight-cut square teeth, (2) sawtooth formation and (3) gear type radial teeth. Because these components are more often regarded as couplings, mention has been made of ring-face tooth couplings in Section 10.2.4. An example of an electromagnetically operated tooth clutch is shown in Figure 10.100.

10.2.5.2 Freewheel clutches

These are more often referred to as freewheel, or overrunning, clutches or even jamming roller clutches. There are two types. The first uses either balls or rollers spaced in inclined wedge-shaped spaces around the periphery of the hub (see Figure 10.101). If the speed of the driven shaft overtakes that of the driver, the balls or rollers tend to roll back out of contact with the driven member and a positive drive is disconnected. If the speed of the driver increases beyond the driven member, the balls or rollers are dragged into contact

Table 10.10 Gear coupling versus dry membrane coupling

	Gear	*Membrane*
Initial cost	Low on low-duty applications	Competitive
Operating and maintenance costs	High-lubrication and cooling circulation and filtration. Oil and oil seals frequently renewed	Negligible
Spares costs	Up to full replacement and regular oil seals	Membrane assemblies
Refurbishing costs	New coupling. Frequent new oil seals	Low, even if re-aligning and balancing
Inspectability	Dismantle coupling	Membranes are visible
Lubrication considerations	Lube oils can be tailored to suit specific application for best service, but 'compromised' by economic expedient. Must be clean and cool. Oil must be chemically compatible. The oil seal can limit misalignment capacities	None
Speeds	High	Very high
Temperature range	Limited by oil and oil seals (100°C typical)	Not usually a problem up to 200°C
Angular misalignment	Comparable	Comparable
Axial misalignment	High	Adequate even with thermal growth
Power:weight ratio	Very efficient use of materials	Very efficient use of materials
Close-coupled	Ideal	Standard modification
Dirty environment	Lube oil contamination	Generally no problem
Wear	Progressive. Rate is sensitive to the efficiency of the lube system. 'Wear band' can reduce misalignment capability unless designed with 'full tooth engagement'	None
Corrosion	Plating and oil seals must resist environmental and internal (oil) attack. Teeth are exposed to oil	Stainless St membrane and phosphated steel parts. Painting/special materials available for hostile areas
Mechanical properties	Change with wear.	Accurately predictable and consistent
Balance	Changes with wear, lube oil path, centrifuging	High qualities achievable Consistent over coupling life.
Torque overload effects	Excessive overload will do permanent damage	Taken by collars to protect against permanent damage
Anti-fly	By nature	By guard ring designs
Failure analysis	Chemical and metallurgical analyses can give clear indication of causes	Membrane fracture pattern point to possible causes
Backlash	Some, initially increasing with wear	Virtually zero
Sleeve-bearing rotors	Needs end stop	Non-linear axial stiffness gives inherent damping. No end stop needed
Vertical	Needs modification	Usually no modification
Misalignment loads	Negligible in ideal conditions. But 'torque lock' is common and imposes high loads on bearings, gears, seals, etc.	Very low generally, but excessive axial displacement produces high thrust reaction forces
Quality design and manufacture	Manufacturing accuracy is crucial to evenly stressed teeth and shared torque load sharing. Staggeringly complex design calculations lead to arbitrary and empirical formulae	Relatively easy to get right
Failure mode	Disintegration and loss of drive function	M series – drive disconnected LS & T series – drive maintained

with the outer member and the positive drive is established. Balls are only used in very light power applications as they have only a point contact; rollers, on the other hand, have a line contact and can be used for substantial torque loadings.

Generally, the larger the angle of the wedge, the greater the roller diameter and hence torque capacity while a small angle provides a more positive engagement. Response is virtually instantaneous since the rollers are always in contact with the inner and outer races. Thus, taking up the drive is a matter of breaking the intervening oil film and the natural deformation of the material under load. Rollers are normally energized by spring and plunger assemblies acting on them in the direction of the trapping angle. In a phased roller clutch, the rollers are precisely located and guided by a cage which is spring energized so that all rollers engage in unison. Compared with the individual roller clutch, it can offer more uniform loading of the rollers and a greater torque capacity for a given size.

A variation of this type of clutch or freewheel is the sprag clutch in which the space between an inner and outer revolving race is filled with a series of cams or sprags whose major diameter is slightly greater than the radial space between the races (see Figure 10.102). Rotation of one race in the driving direction causes the sprags to tilt, thus transmitting the torque in full from one race to the other. Conversely, rotation of the

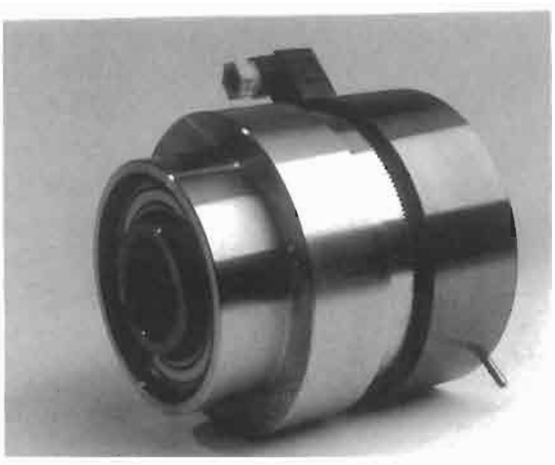

Figure 10.100 Suredrive electromagnetic tooth clutch (with acknowledgements to TI Matrix Engineering)

race in the other direction frees the sprags and permits over-running between the races. A tilting force keeps the sprags in light contact with both inner and outer races and this can be done using various spring arrangements. There is thus no loss of motion, the driving torque being instantaneously transmitted between race. In general, sprag clutches are able to transmit greater torques for a given overall size than other types of freewheel devices.

10.2.5.3 Cone friction clutch

The cone clutch (see Figure 10.103) embodies the mechanical advantage of the wedge which reduces the axial force required to transmit a given torque. In general engineering its use is restricted to the more rugged applications such as contractors' plant. In a smaller form it is often used in machine tools.

10.2.5.4 Plate friction clutch

This can be of single-plate type (see Figure 10.104) or multi-plate construction (Figure 10.105). Basically, the clutch consists of friction lining(s) sandwiched between driving and driven plate(s). Springs usually provide the clamping pressures. With

multi-plate clutches the diameter can generally be reduced for a given torque as against a single-plate clutch. Many multi-plate clutches run in oil which helps to conduct away the generated heat.

10.2.5.5 Expanding ring friction clutch

This will transmit high torque at low speed and centrifugal force increases the gripping power but adequate clutch withdrawal force must be provided for disengagement (see Figure 10.106).

10.2.5.6 Centrifugal friction clutch

Automatic in operation, the torque, without spring control, increases as the square of the speed. Motors with low starting torque can commence engagement without shock. A spring control can be added (see Figure 10.107) so that engagement does not take place until the motor has reached a predefined speed (often 75% of full speed).

10.2.5.7 *Magnetic friction clutches*

These are compact units and operated by a direct magnet pull with no end thrust on the shafts (see Figures 10.108 and 10.109). It is ideal for remote control.

10.2.5.8 *Particle clutches*

These consist of inner and outer races with the annular space between being filled with magnetic particles. When a suitable current is applied the particles lock together with the races and form a drive. They can be used when constant slip is required and are suited to repetitive starts and stops or controlled accelerations. The same principle can be applied to braking.

Figure 10.109 Typical multi-plate electromagnetic clutch

For example, the Magne range of magnetic particle clutches and brakes from R. A. Rodriguez consist of only two parts, the inner race called the rotor and the outer race or drive cylinder. The space between the members is filled with a fine magnetic powder, and when a magnetic field is created through a stationary d.c. coil the powder forms a link between the two members and torque is thus transmitted. With the Magneclutch, both members are rotating to provide transmitted torque; with the Magnebrake, the outer member is held stationary, resulting in braking torque. Transmitted torque is proportional to the strength of the magnetic field. A typical application is shown in Figure 10.110.

10.2.5.9 *Wrap spring clutch*

These are generally used for low-torque applications and low speeds. They consist of a helical spring arranged to wrap against a drum surface. As the grip of the spring increases in proportion to the transmitted torque, the helical spring locks the driving and driven drum together. When the sleeve is released, the clutch is engaged; holding the sleeve unwinds the spring and this engages the clutch.

10.2.5.10 Fluid coupling

A very important type of coupling or clutch is that employing a fluid drive. These couplings give the engineer an efficient, simple and reliably mechanical means of controlling the speed of the driven machinery at the same time, allowing the use of comparatively low-cost constant-speed squirrel-cage motors. In addition, they offer the advantage of a no-load start, smooth and progressive acceleration and protection from shock loadings.

The fluid drive is situated in the drive line between the motor and driven machine. As in all fluid couplings operating on the hydrodynamic principle, there are only two basic elements – the impeller and the runner (see Figure 10.111). The power is transmitted from input to output by the flow of oil between the two elements. There is no mechanical connection between them. The speed of the output shaft can be varied steplessly between maximum and minimum speeds by adjusting the quantity of oil in the working circuit between impeller and runner. To stop the machine, the oil is emptied from the working circuit and the drive is thus disconnected. A fluid coupling can be used in conjunction with other transmission elements as shown diagrammatically in Figure 10.112.

10.2.5.11 Brakes

Many of the principles used in friction clutches can be applied to brakes. Large brake units of the type used in contractors' equipment can be band, caliper disk or drum types (Figures 10.113–10.115). Smaller versions than those used in contractors' machinery are available and an example of a caliper brake is shown in Figure 10.116. It can be used for dynamic braking to bring equipment to rest or as a holding brake to prevent motion.

11.1 Introduction

The conventional chemical (i.e. non-nuclear) fuels are essentially materials containing stored energy that can be released as heat by the oxidation reaction of combustion. The released heat may be utilized as such for space heating, cooking, the generation of steam or treatment of industrial products. Alternatively, the heat may be converted partially into mechanical work through some type of heat engine, the extent of conversion being limited fundamentally by the second law of thermodynamics, and practically by the nature of the engine and its conditions of operation. Combustion performance is thus a prime parameter of any fuel, but the handling characteristics involved in storage, distribution and fire safety are also all of practical importance. Fuels are therefore required to burn readily and completely when required within the combustor but not at all outside it, and to resist the disturbing effects of extreme conditions of storage, with no damage to the materials of the fuel and combustion systems, and all at realistic costs. As a result, several property requirements may conflict, and specifications are customarily drawn up by authoritative bodies to establish the compromises necessary, and set the standards for fuel quality.

In this chapter, properties, specifications, handling, applications and, finally, combustion performance are considered for typical members of the conventional gaseous, liquid and solid fuels in use today, with brief reference to the likely candidates for the future.

11.2 General fuel types

Most conventional fuels are derived from sources of fossil origin, mainly by direct processing into the required commercial products but, in some cases, manufactured as by-products from other industrial processes. There is also a small but growing input from industrial and municipal wastes, used either directly or as derivatives.

The demise of living organisms results in deposits of hydrogen–carbon–oxygen compounds (carbohydrates) and water which, through the long passage of time, tend to lose their oxygen and water components. The main constituents of naturally occurring gases and petroleum liquids therefore comprise hydrogen–carbon compounds (hydrocarbons) only, whereas the solids still retain some oxygen and water, depending on the extent of coalification that has taken place. Industrially manufactured gases may also contain free hydrogen, carbon monoxide, carbon dioxide, nitrogen and hydrogen sulphide. Traces of sulphur, lead, vanadium, etc. exist in most liquid and solid fuel sources, and may need to be either reduced or removed to meet specification limits.

Atoms of carbon and hydrogen combine in very precise patterns dependent upon their bond-forming capacity (valency). With a valency of four for carbon and unity for hydrogen, and with single and multiple bonds possible between carbon atoms in both straight- and ring-chain structures, several million different molecular structures are possible, ranging from the simplest (CH_4, methane) upwards, each with its individual name, and physical and chemical properties.[1] With a few exceptions such as the naturally occurring gases, individual hydrocarbons are not used as such in large-scale practice since their extraction and preparation would be inordinately expensive. A conventional liquid fuel, for example, consists of several hundred different types of hydrocarbon that have been separated as a group from the parent crude oil, the overall properties of the group being determined by the combined properties of the individual components.

The physical nature of a fuel is determined largely by its component molecular size. The chemical bonding referred to above is mainly electrostatic in nature, some influence of which is also felt beyond the outer boundaries of the molecule. These external forces around small molecules, e.g. from C_1 (methane) to C_4 (butanes and butenes), are so weak that the molecules are able to move freely relative to each other, the bulk materials thus existing as gases. Since the external fields of larger molecules are correspondingly stronger, these materials take the form of liquids, any imposed relative movement giving rise to viscous resistance forces. Very large molecules, on the other hand, are so strongly bound together that they comprise solids (Table 11.1).

The chemical nature of a fuel is determined largely by molecular shape and by the nature of the carbon–carbon bond. As discussed later, compact shapes of molecules imply greater resistance to thermal agitation and spontaneous ignition. Single bonding between carbon atoms results from hydrogen saturation of the molecule and indicates storage stability, whereas multiple bonding arising from unsaturation leads to instability due to the tendency of these bonds to open out and form new bonds with like molecules (polymerization), so increasing the overall size of individual molecules, resulting in self-contamination with solid particles.

11.3 Major property overview

Whereas certain properties are specific to a given fuel type and its application, the following major properties apply throughout the chemical fuel range, and are therefore presented here on an overview basis.

11.3.1 Fuel density

Density is defined as mass per unit volume. For fluid fuels, this is qualified with some standard conditions of test in order to allow for volume change with temperature and, in the case of gases, with pressure. For solid fuels, allowances may be made for the air voids between individual lumps. This gives rise to the following definitions, shown with units recommended by the Institute of Petroleum:

Density of gaseous fuel at t_1 and p_1 =

$$\frac{\text{Mass of sample}}{\text{Volume of sample at } t_1 \text{ and } p_1}\text{, kg/m}^3 \text{ at 15°C and 1 atm}$$

Density of liquid fuel at t_1 =

$$\frac{\text{Mass of sample}}{\text{Volume of sample at } t_1}\text{, kg/l at 15°C}$$

Lump density of solid fuel =

$$\frac{\text{Mass of single lump of sample}}{\text{Volume of single lump of sample}}\text{, kg/l}$$

Bulk density of solid fuel =

$$\frac{\text{Mass of sample lumps}}{\text{Volume of sample lumps and voids}}\text{, kg/l}$$

These density terms are largely replacing the original 'specific gravity' (SG) and 'relative density' (rel. d), the numerical values themselves being equal in all three cases when applied

Table 11.1 Typical fossil-derived fuels (in increasing level of density)

G = Gas L or S = Liquid or solid ( ) = Average [a] At boiling point and 1 atm.

to liquids and solids. Relative density is still used in connection with API gravity (see below) and Wobbe number (Section 11.4.1.1), and is given by expressions of the following type:

$$\text{rel. d at } t_1/t_2 = \frac{\text{Mass of given volume of sample at } t_1}{\text{Mass of equal volume of reference fluid at } t_2}$$

For gases, the reference fluid is atmospheric air, and for liquids and solids is pure water.

The test method used for the density of gaseous fuels can be the direct measurement of the mass of the sample in a Chancel flask of known volume. Alternatively, the relative density can be determined using a single orifice by comparing the flow rates of equal volumes of sample and air at common upstream conditions, since flow rate is inversely proportional to $(\text{density})^{1/2}$. Hence

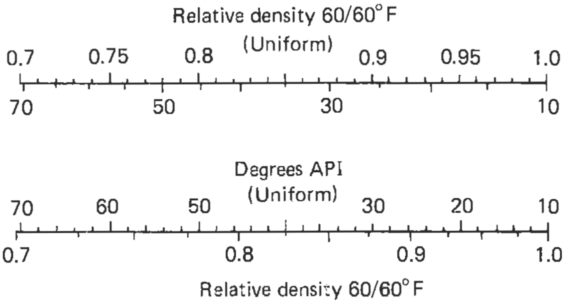
$$\text{rel. d of sample} = \left(\frac{\text{Sample flow time}}{\text{Air flow time}}\right)^2$$

For a liquid fuel, as before, the most direct method of determining density involves measuring the mass of the sample contained in a density bottle of known volume, but the commonly used indirect method for the less viscous liquids is based on the buoyancy of a hydrometer floating in the sample, with a correction for every degree of displacement from the standard temperature level. For liquid petroleum fuels in the United States, relative density is used in terms of the gravity system of the American Petroleum Institute, as follows:

$$\text{Degrees API} = \frac{141.5}{\text{rel. d at } 60/60°\text{C}} - 131.5 \quad \text{(see Figure 11.1)}$$

For solid fuels, the more precise lump density is determined by the displacement method in which the sample lump is weighed both in air and in water, the difference indicating the weight of the volume of water displaced by the lump, and therefore the volume of the lump itself. Bulk density can be determined by using measured quantities of water, mercury or other immiscible liquid to fill the voids between a representative number of lumps of sample in the normal packing density.

For the conventional fuels, typical densities range from 0.679 to 2.53 kg/m^3 at 15°C and 1 atm for gases, 0.72 to 1.25 kg/l at 15°C for liquids and 0.5 to 2.21 kg/l for solids and, as shown in Figure 11.2, the progressive rise in density from gaseous methane to solid graphite is associated with a reduction in hydrogen content, and corresponding increase in carbon content. The density of conventional fuel therefore gives an instant approximate indication of the general type of



$$\text{Degrees API} = \frac{141.5}{\text{rel. d } 60/60°\text{F}} - 131.5$$

Note: rel. d 15/4°C = 0.99904 (rel. d 60/60° F)

Figure 11.1 Relationship between relative density and degrees API[2]

the fuel (e.g. natural gas, kerosene or coal) in terms of a simply determined single value. In the case of liquid fuels, it also relates the more fundamental unit of mass to the customary handling quantity of volume, and therefore permits the determination of the storage tank size for a given mission or energy requirement.

With the blending of a number of fluids of different densities, and on the assumption of no chemical or physical interactions between them, blend density bears a linear relationship with concentration on a component volume basis, but not on a component mass basis, as shown in the following expressions:

$$\text{Blend density} = 0.01\,(v_A\,d_A + v_B\,d_B + \ldots)$$

$$\text{Blend density} = \frac{100}{(m_A/d_A + m_B/d_B + \ldots)}$$

where v_A, v_B, etc. are percentage volume concentrations of components A, B, etc., m_A, m_B, etc. are percentage mass concentrations of components A, B, etc. and d_A, d_B, etc. are densities of components A, B, etc.

11.3.2 Calorific value

Since a fuel is, in essence, an energy store, the quantity of energy stored within a given fuel is a property of fundamental importance. For gaseous fuels, the volumetric basis is invariably used, and calorific value is then defined as Energy Density, with recommended unit MJ/m^3. For liquid and solid fuels, on the other hand, the gravimetric basis is generally employed, together with the term Specific Energy, and recommended unit MJ/kg; when Energy Density is required in these cases, the recommended unit is MJ/l.

Laboratory determination of these quantities is based on complete combustion at conditions of constant-pressure steady-flow for the gaseous fuels, and constant-volume non-flow for the liquids and solids, the released heat being absorbed in cooling water. This is not only convenient experimentally, but in each case meets the thermodynamic requirements for the energy to be released entirely as heat transfer rather than partly as work transfer, the latter being far more difficult to measure. In the flow test, corrections are made for the energy remaining in the flue gases, and for the expansion of the cooling water, whereas in the non-flow test allowance is made for the energy contributions of the ignition wire (and of the gelatine capsule used for containing the more volatile samples), together with the heat of formation of the acids produced. Gaseous fuels burn completely at atmospheric pressure, but liquids and solids require higher pressures and an oxygen atmosphere. All the experimental results are 'gross' values since the final temperature is so slightly above ambient that the combustion-generated water condenses and so adds its latent heat of vaporization to the combustion energy. In practice, however, combustion products invariably leave the combustor at high temperature, either to provide draught in the case of boilers/furnaces, or as constrained by the heat–work conversion limit imposed by the second law of thermodynamics in the case of heat engines. Hence, 'net' values are more meaningful, and are obtained by suitable corrections for latent heat, as indicated in the latest issue of reference 4.

As shown in Figure 11.2 for the hydrocarbon fuels, the level of hydrogen content falls with increase in fuel density, and since the specific energy for hydrogen is far greater than that for carbon, the level of specific energy also tends to fall, as shown in Figure 11.3(a). Using the recommended units, values of energy density in MJ/l for the liquids and solids are determined directly by multiplying specific energy with density (MK/kg × kg/l). As seen from Figure 11.3(b), the small fall in specific energy is more than compensated by the relatively large rise in fuel density, consequently energy density rises with fuel density. Thus the highly attractive specific energy of hydrogen, for example, is offset to some extent by its very low energy density necessitating large storage volumes.

The above considerations on calorific value are important in terms of storage capacity and combustor fuel consumption for a given power output. One additional point of interest follows from the fact that combustors necessarily operate with mixtures of fuel and air rather than fuel alone, hence the key parameters here are the calorific values of these mixtures. Using stoichiometric mixtures (see Section 11.5.1) as a basis for comparison, the air/fuel mass ratios are found generally to fall with increasing fuel density. Hence, although the level of specific energy is lower with the heavier fuels, less air is required for their combustion and thus less mass in which to distribute the resulting heat. Broadly, therefore, little change is expected in the specific energies of the stoichiometric-air mixtures for all the fuels within the hydrocarbon range. This conclusion can be seen to hold also with fuels that already contain some components of air (e.g. carbon monoxide, CO; methanol, CH_3OH; and ammonia, NH_3). As shown in Figure 11.4, a mean value of about 2.9 MJ/kg of stoichiometric fuel–air mixture applies to a wide range of hydrocarbons and related fuels, and similar remarks apply to energy densities of these mixtures. Thus a changeover from a high- to a low-energy fuel with a constant *mixture* mass flow rate and comparable mixture strength would not be expected to entail a marked change in power output, but would, nevertheless, give rise to a higher rate of fuel consumption.

11.4 Major fuel groupings

Having reviewed those properties applying throughout the range of conventional chemical fuels, attention now turns to the main fuel groups in which certain production procedures and properties are specific.

11.4.1 Gaseous fuels

This group subdivides into those that occur naturally throughout the world, with broadly comparable characteristics, and

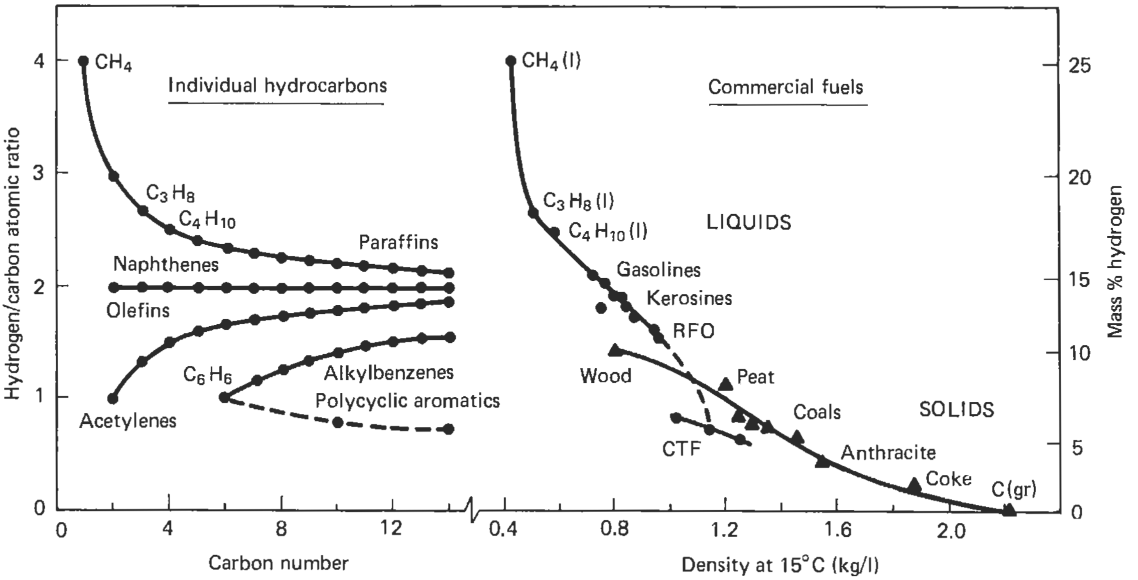


Figure 11.2 Hydrogen content of hydrocarbons and commercial fuels[2]

those that are manufactured within industry, frequently as by-products, and utilized wherever possible on-site.

11.4.1.1 Naturally occurring gases

These comprise the 'natural gases' based largely on methane, and the 'petroleum gases' based on propane and butanes. Worldwide deposits of natural gas exist either freely or in association with petroleum. In addition to methane, sources of natural gas may contain some condensable higher hydrocarbons (from ethane to octanes), and are hence referred to as 'wet' gases, together with traces of such inerts as nitrogen, carbon dioxide, water vapour and hydrogen sulphide. Expanding the gas at the well head reduces the temperature and freezes the water and heavier hydrocarbons which are separated from the gas stream and subsequently melted. At the gathering station, further stripping of the gas takes place by means of compression and cooling, together with sweetening by absorption or adsorption. In some instances, methane-containing gases are collected from coalmines, landfill garbage sites and sewage farms, and then used to power diesel-electric generating sets.

Natural gas has now become the standard commercially supplied gas for industrial and domestic space heating, hot water supplies and cooking, and also for some applications to boilers, furnaces, kilns and industrial gas turbine engines.

The condensate gases extracted from wet natural gas consist mainly of propane and butane together with traces of lighter and heavier hydrocarbons, as do the gases released from petroleum itself. The commercial grades of propane and butane each contain a minimum of 95% by volume of the named gas, with concentrations of other materials limited by such specifications as BS 4250.[5] Commercial mixtures of propane and butane are available under the name of petroleum gases and, when liquefied by compression and cooling for convenient storage, of LPG. The principal treatment of petroleum gases comprises either the removal or sweetening of mercaptan sulphur compounds in order to combat odour and corrosion. Petroleum gases are used for industrial, commercial, agricultural and domestic heating, drying and cooking, and one particular use of propane is in hot-air balloons. The major properties of the naturally occurring gases are shown in Table 11.2.

In some heating applications where different fuel gases become available, interchangeability requires that the thermal throughput remains constant. Using the same upstream gas pressure and fixed orifice size, the volumetric flow rate is inversely proportional to (fluid density)$^{1/2}$, as discussed in Section 11.3.1. Hence the fuel interchangeability for constant heating rate requires near-constancy of the following parameter:

$$\text{Wobbe number} = W_0 = \frac{\text{Energy density}}{(\text{rel. d})^{1/2}}\ \text{MJ/m}^3$$

If a different gas pressure is used with the different fuel, interchangeability is based on

$$\text{Extended Wobbe number} = W_0(\Delta p)^{1/2}\quad \text{MJN}^{1/2}/\text{m}^4$$

This leads to the concept of a 'simulated' fuel, as, for example, with a volumetric blend of 61 propane/39 air to simulate natural gas by matching the net Wobbe number of 45.61 MJ/m^3. A difference in W_0 of 5% is usually acceptable.

11.4.1.2 Industrially manufactured gases

Members of this group range in increasing density from hydrogen to blast-furnace gas, and are mostly by-products of other manufacturing processes. The source material is either coal or coke, and production is by carbonization (heating in the absence of air), by gasification through partial oxidation (heating with limited air), or by catalytic hydrogenation of coal directly to gas. More recent processes involve nitrogen-free gases for blast purposes, higher pressures, fluidized solid beds and/or removal of ash in the form of slag.[6]

ΔH_{vap} = enthalpy of vaporization.

The data for the gaseous fuels in Table 11.3 show that, broadly, the total volume content of combustibles falls with increasing density, and this is reflected in the levels of specific energy and energy density shown in Table 11.1. The exception is CWG, which has relatively high values due to the 'carburation', that is, the addition of energetic hydrocarbon gases from cracked petroleum oils. The high nitrogen content of BFG constrains the levels of calorific value, whereas the high concentration of CO in BWG is responsible for the characteristic blue coloration of the flame. The general term 'water gas' follows from the water–gas reaction

$$C(gr) + H_2O(g) \rightleftharpoons CO(g) + H_2(g)$$

and the water–gas shift reaction

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$$

where (g) = gas, and (gr) = graphite

Due to the wide variations in composition and corresponding properties, it is common practice to classify the fuel gases within families, sometimes containing sub-groups, based on the level of gross Wobbe number, as shown typically in Table 11.4.

11.4.2 Liquid fuels

This group sub-divides into the liquefied fuel gases, and the wide range of products derived from refining the various types of crude oil found worldwide, and the tars derived from coals.

3	72.6–87.8	PG, C_2H_2

11.4.2.1 Liquefied fuel gases

After sweetening at the gathering station, natural gases destined for liquefaction have the remaining water vapour removed by refrigeration, absorption in concentrated glycol solution, or adsorption in such solid desiccants as silica gel, alumina or molecular sieves. Liquefaction itself follows by compression and cooling below the dew point. Since its critical temperature of −82.6°C is below ambient, methane-based natural gas is a true gas rather than a vapour, and needs to be stored at its boiling point (−161.5°C) if required in the liquid phase at atmospheric pressure. Loss of refrigeration by inward heat leakage during storage is restricted by the use of double-skinned cryogenic tankage of metal, or sometimes of pre-stressed concrete or underground caverns. Such vaporization as does occur (e.g. 0.1% per day) is handled by reliquefaction on site. Rapid revaporization for immediate usage is achieved by means of heat exchangers fed with combustion gases, steam, or water.

The petroleum gases propane and butane are readily liquefied, either individually or as LPG mixture, by compression and cooling. Since their critical temperatures are above ambient, and their boiling points not far below ambient, their storage as liquids at ambient temperature requires only moderate pressures, and hence reasonably lightweight containers.

11.4.2.2 Natural gasoline

The vapours of the heavier hydrocarbons ranging from C_5 (pentanes) to C_8 (octanes) obtained by stripping natural gases comprise 'natural gasoline' which is usually stabilized by removal of traces of petroleum gas components through more precise distillation at pressures above atmospheric. Such stabilized natural gasoline is commonly blended with conventional petroleum-derived gasoline.

11.4.2.3 Petroleum fractions

Most crude petroleums are yellowish-brown to black, relatively free-flowing liquids of densities ranging from about 0.78 to 1.0 kg/l, consisting essentially of hydrogen-saturated hydrocarbon compounds. The precise composition, and hence properties, depend upon the location, age and nature of the organic source materials, and crudes are classified on a semi-empirical basis, with increase in density showing a change from paraffinic to naphthenic.

The primary step in refining is the thermal separation by distillation into a number of fractions ranging from gasolines to residual fuel oils (Tables 11.1 and 11.5), each of which contains several hundred different hydrocarbons boiling within certain predetermined ranges of temperature. The relative quantities of these 'straight-run' products are then adjusted to meet the demand pattern by chemical methods of molecular-

bond breaking and joining, followed by various forms of finishing treatment ready for the energy market. For convenience, the following UK Joint Services Designations are used to identify the lower-density fuels:[7]

AVGAS – Aviation gasoline
MOGAS – Motor gasoline
AVTAG – Aviation wide-cut turbine fuel (a blend of gasoline and kerosene components used widely until recently for military aircraft)
AVTUR – Aviation turbine fuel (aviation kerosine)
AVCAT – Aviation high-flash turbine fuel (lower-volatility aviation turbine fuel for naval aircraft)

A number of properties relevant to petroleum fuel blends are grouped in the following two sections.

Volatility This concerns the readiness of a liquid to convert to vapour at the prevailing conditions of temperature and pressure. Vaporization takes place relatively slowly at ambient conditions, as with the humidity of the atmosphere, but becomes vigorous with the rapid evolution of bubbles when the level of vapour pressure reaches that of the atmosphere itself, i.e. at the boiling point. Broad comparisons of fuel volatility are therefore made using a standard test method by measuring the boiling point or, in the more usual case of fuel blends, the boiling range. A sample of the fuel is vaporized at a controlled rate by heating in a flask, condensed in an ice-cooled side tube, and collected in a graduated cylinder. Corresponding readings of vapour temperature and condensate recovery are plotted as a distillation curve showing the boiling levels of the various components (Figure 11.5 and Table 6). With petroleum fuels, a maximum test temperature limit of 370°C is set in order to avoid cracking of the heavier hydrocarbon molecules. More precise results for research purposes are obtained by measuring the vapour/liquid volume ratios on either side of the initial boiling point.

For the lower-density fuels at the more volatile end of the range, volatility is also assessed by measuring the absolute vapour pressure. In the standard Reid test, the liquid fuel sample is heated in a container to a moderate temperature (37.8°C), the vapour rising through an air chamber fitted with a pressure gauge. A modified method is used for liquefied gases, and a micro method is also available.

For the range of petroleum fuels from gasolines to fuel oils, the weak *mixture* limit of flammability is common at about 1% by volume of fuel vapour in the mixture with air, as outlined in Section 11.5.2. However, due to a progressive reduction in volatility over this range, the weak *temperature* limit of flammability at which this 1% fuel concentration is reached rises with fuel density. This temperature limit is known as the 'flash point', and is determined by warming the liquid sample in a standard design of container with successive introductions of a standard-sized flame into the vapour space until the temperature is reached when the flame flashes across the space and then extinguishes. Since flash points lie below ambient for the light fuels, the method is generally used for

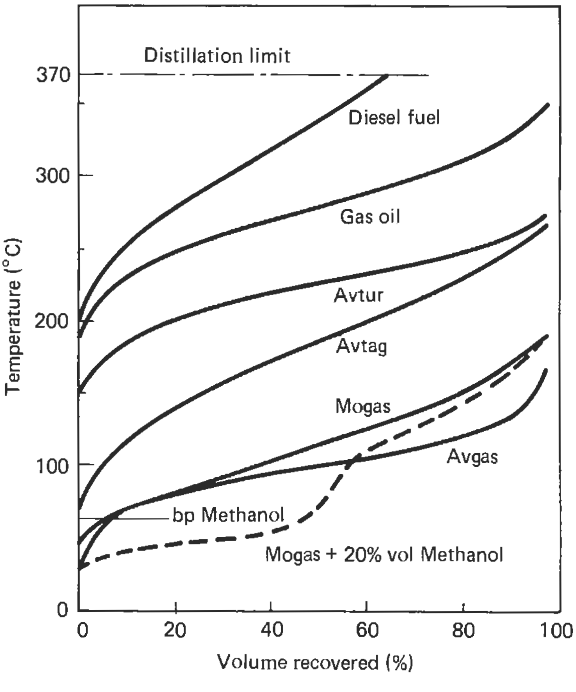

Figure 11.5 Distillation curves for representative petroleum fuels, showing effect of blending methanol with motor gasoline[2]

Table 11.5 Influence of volatility changes on gasoline performance

kerosines and heavier fuels. Flash point is mainly of concern with regard to fire safety in handling, and materials with flash points lying within the ranges 0°C and below, 0–20°C, and 21–55°C are classified respectively as extremely flammable, highly flammable, and flammable.[8]

Viscosity and freezing At the lower end of the temperature scale, fuel pumping, filtering and spraying are influenced by the ability of the fuel to flow. As discussed in Section 11.2, the attractive force fields between individual molecules give rise to resistance to internal displacement and flow. This resistance constitutes 'viscosity'.

The dynamic viscosity (symbol η) of a sample may be defined as the tangential force on unit area of either of two parallel planes at unit distance apart when the space between them is filled with the sample, and one of the planes moves with unit velocity in its own plane relative to the other. Hence, it is the force per unit area to produce a unit velocity gradient, as shown in Figure 11.6. The units are g cm^{-1} s^{-1}, or poise, P. Since this is inconveniently large in practice, the centipoise, cP, is adopted, where 1 cP = 0.01 P = 1 mN s/m^2. The viscosity of heavy fuel is determined on a dynamic basis from the resistance incurred by motor-driven rotation of one cylinder inside another when located in the sample.

The kinematic viscosity (symbol ν) may be defined as the quotient of the dynamic viscosity and the density (ρ) of the sample. Hence, $\nu = \eta/\rho$, and the units are cm^2/s, or stokes, St. Again, the smaller unit is more convenient, where 1 cSt = 0.01 St = 1 mm^2/s. Kinematic viscosity is of general interest with the light and medium-heavy fuels in connection with pumping and spraying, bearing a direct relationship with the mean droplet size of the spray. Kinematic viscosity may be determined from the efflux time of a given volume of sample flowing under its own pressure head through a capillary forming one leg of a glass U-tube viscometer suspended in a thermostatically controlled water bath. This follows because the force *resisting* the laminar (low-speed) flow of fluid through a restriction is directly proportional to the dynamic viscosity, whereas the force *promoting* the flow is that due to gravity, and thus directly proportional to density. The resultant flow time is thus a function of the quotient of these two properties, and an equation converts the measured time to kinematic viscosity in cSt units.

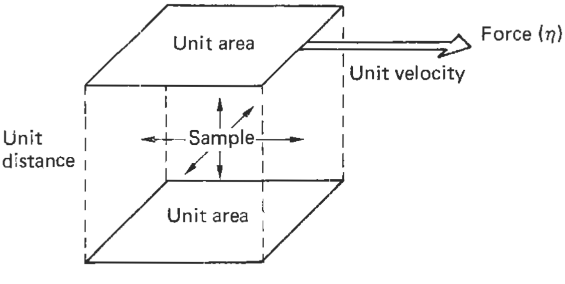

Figure 11.6 Schematic for definition of dynamic viscosity[2]

Since the electrostatic forces between the fuel molecules vary with molecular spacing on an inverse square basis, fuel expansion on heating results in a similar relationship between kinematic viscosity and temperature. However, the greater convenience of straight-line plotting is achieved by modifying both scales on a logarithmic basis, as in the ASTM and 'Refutas' methods, examples of which are shown plotted in Figure 11.7.

On cooling, individual materials freeze at fixed temperatures, commonly described as 'melting points'. With fuel

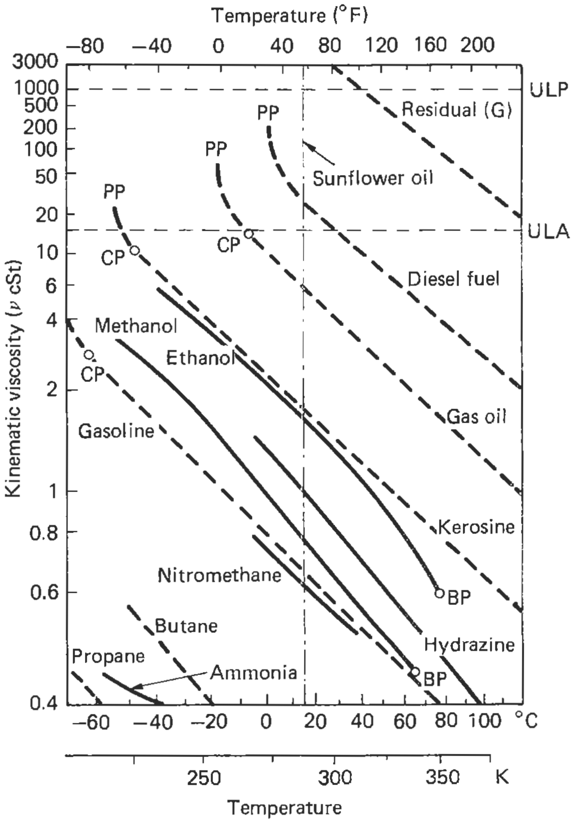

Figure 11.7 Variation of fuel kinematic viscosity with temperature[2]
ULP = upper limits on pumping; ULA = upper limits on atomization; CP = cloud point; PP = pour point

blends, however, the process of solidification is progressive, comparable to the variation in boiling temperatures throughout the distillation process. With continuous reduction in temperature, the heavy fractions of the blend will start to solidify and promote a cloud of wax crystals within the body of the liquid, the temperature at which these first appear being defined as the cloud point. In the case of aviation fuels, a comparable condition is noted as the freezing point when the wax crystals just disappear while the chilled sample is warmed and stirred.

With further cooling of a sample, the crystals increase in size and number, and eventually coalesce to form a rigid structure which shows no movement on tilting the test jar to the horizontal for a period of 5 s. A temperature 3°C above this test temperature is defined as the pour point. Clearly, wax crystals within a liquid will create interference in the capillary tube of a viscometer, and give an apparent increase in viscosity over and above that due to the falling temperature. For this reason, the modified plot of viscosity versus temperature loses its linearity, and curves upwards as the temperature falls from the cloud to the pour point, as shown in Figure 11.7.

11.4.2.4 Coal tar fuels

The tars produced by high-temperature carbonization of coal may be distilled to yield light oils, carbolic oil, creosote oil and anthracene oil, leaving residual pitch.[9] Re-blending of these liquid distillates gives rise to a range of aromatic-rich coal tar fuels (CTF). The original classification ranges from CTF 50 through CTF 100, 200, 250, 300 and 400 to pulverizable CTF, the figures in the middle members of the range representing the temperature (°F) at which the viscosity falls to the acceptable spraying level of 100 Redwood 1 seconds (24.1 cSt). However, the use of these fuels outside the tar industry itself has now dropped to a very low level, and no changes in the original classification are envisaged at this time. The first two fuels are blends of light oil fractions, whereas the following three are blends of the liquids with the medium soft pitch residue CTF 400. The densities range from about 0.95 to 1.31 kg/l.

Coal tar fuels are not compatible with petroleum fuels since admixture leads to unmanageable deposits of pitch from solution but, for use in oil burners, the following pairs are regarded as roughly equivalent:

CTF 100 – light fuel oil, class E
CTF 200 – medium fuel oil, class F
CTF 250 – heavy fuel oil, class G

Although the specific energies are lower, and the difficulties of spraying greater, coal tar fuels can be used on occasions in preference to petroleum fuels owing to their relative freedom from sulphur and vanadium, and their higher luminosity.

Table 11.7 Wheat straw data in UK, 1986

	Straw		
	Untreated	*Compressed and heated*	*Coal*

[a] Allowing for energy input at 1000 bar and 80°C in Cranfield rig.
EJ = J × 10^{18}.

11.4.3 Solid fuels

The majority of solid fuels stem from vegetable matter, either as sources that are continuously renewed within the span of human life or as fossil material derived during periods of formation up to several million years. The following examples are presented in increasing order of age.

11.4.3.1 Fuel wood and straw

In view of its wide availability, rapid reproduction, free-burning quality and relative lack of ash (0.6% only), fuel wood still represents a major source for domestic heating and cooking in areas where other fuels are not available. The water content of woods ranges from about 50% by mass in the freshly cut 'green' condition, to about 10% when air dried, and the oxygen content is also high. The modern approach to fuel wood preparation is to reduce both bulk timber and forestry wastes into small chips which are then compressed into dry briquettes for furnace combustion with almost complete absence of smoke and ash.

Interest in straw as a fuel has been heightened by the adverse public opinion of on-field burning of stubble, and the major handling problem of bulk due to low density is being tackled by high-intensity compression, either cold or with added heat to melt the waxes (see Table 11.7). Projects are in hand whereby large rural buildings can be heated by using straw grown on part of their own estates (for example, Woburn Abbey).

11.4.3.2 The peat-to-anthracite series

The solid fuels derived from vegetable matter deposited in water constitute the 'peat-to-anthracite' series, and arise through a process of coalification initiated by anaerobic bacteria, and continued under the action of temperatures and pressures within the earth's crust over periods of several million years. This process is associated with a progressive loss in the volatile matter (VM) containing the water vapour, and an increase in the relative proportion of carbon. Since variable amounts of water and ash will be present, solid fuel samples are usually air-dried under specified conditions before testing, with the results expressed on a dry mineral-matter-free (dmmf) basis (Table 11.8).

The first stage in the overall process is peat, a partly decomposed material with a growth rate of about 1 mm per year. Raw peat is associated with over 90% of water, and so requires draining before harvesting and subsequent drying to about 25% of water.

The second member of this series is lignite, or brown coal, which is dark brown in colour with a pronounced earthy or woody texture, the moisture content ranging from about 60% as mined to about 20% when air-dried. The third member is black lignite, or high-volatility sub-bituminous coal, which is pitch-like, being sufficiently mature to show signs of fibrous structure. Medium-volatility bituminous coal is black, hard and usually banded parallel to the bedding plane. Two signifi-

Table 11.8 Solid fuels (composition and property)

Fuel	*Composition % mass dmmf*						$(a/f)_s$

Coke	96.5	0.5	2	1	0	7	9.6
Carbon (graphite)	100	0	0	0	0	0	11.48

cant properties of coal fuels are their ability for individual particles to adhere to one another on heating (caking), and to soften, swell and resolidify with shrinkage to form coke (coking) rather than remaining as a soft, easily crushed charred residue. All coking coals are therefore caking, but only some caking coals are able to form hard coke of sufficient strength to maintain a cellular structure on the furnace bed, permitting gaseous through-flow. The ability to cake is determined by the Gray–King assay test involving slow all-directional heating for $1\frac{1}{2}$ h, and increases with level of rank up to a maximum at about 90% carbon. The swelling necessary for coking is determined by the crucible test involving violent unidirectional heating for $2\frac{1}{2}$ min, followed by visual assessment of the shape of the residual coke button.[10]

Low-volatility semi-bituminous coal, or semi-anthracite, represents a hard intermediate stage between bituminous coal and true anthracite which itself is the ultimate form of metamorphosis of the original vegetable matter, and is produced by the intense pressures exerted during geological movement. Anthracite has a sub-metallic lustre, with zero caking power.

More precise methods for classifying the various types of coal include Seyler's coal chart in which percentage carbon is plotted against percentage hydrogen, the location of the point within a broad band representing the types of coal in the given coalfield, and being related to many other properties superimposed on the chart. More recent systems include the Coal Rank Number of British Coal, based jointly on the percentage content of volatile matter and the caking quality. Some coals exist outside the above peat-to-anthracite series owing to their derivation from spores, algae and other small types of plant life. Cannel coal, for example, contains a relatively high proportion of hydrogen and volatile matter generally, and is so named from the candle-like nature of its flame. It is hard and tough, with a dull black lustre, whereas boghead coal or torbanite appears dull brownish.

11.4.3.3 Cokes

The production of coke is achieved by thermal decomposition of suitable types of coal. On heating in the absence of air, an initial release of hydrocarbon gases occurs at the decomposition temperature of about 350°C. At the same time, a plastic layer forms on the outer surface of the coal lump, and begins to advance towards the centre with the penetration of the heat. Since the plastic layer is impervious to gas, the internally released gases cause the lump to swell. The plastic layer subsequently resolidifies into a soft, dull black semi-coke which, in turn, releases hydrogen and carbon monoxide, shrinking and cracking into the much harder coke at about 1000°C, with a conversion mass ratio of about 0.7 of the original coal.

11.4.3.4 Graphite

Although graphite is not used as a fuel, being far more valuable for other applications, it is of interest chemically as one form of elemental carbon and since it represents the heavier end of the hydrogen–carbon range within which lie all the hydrocarbon fuels. Because of its plate-like structure of benzene-type hexagon rings, the space between the plates is sufficient to accommodate gaseous molecules which then act as bearing balls, permitting the plates to slide over each other.[1] Graphite is therefore a valuable solid lubricant, and being unaffected by radiation is suitable for use in nuclear plants. It is of interest to note that, in another allotropic form, this time based on the methane structure, carbon exists as diamond. In one of its third, amorphous, forms it constitutes soot.

11.4.3.5 Solid wastes

In industry, combustible materials arising as waste frequently lend themselves to useful consumption on-site, particularly with the more tolerant furnaces as distinct from engines, since fuel transfer, and probably preparation, costs are minimal, and the overall efficiency of the industry is improved accordingly.

In addition, everyday human life generates appreciable quantities of waste on a steady basis, the traditional method of disposal being by dumping in landfill sites. Eventually, the shortages of suitable sites led to the introduction of incineration – without heat recovery – in order to reduce the bulk by about 90%, and render the residue sterile and odourless. About 40% by mass of solid municipal waste (SMW) is combustible and, with the development of incineration towards the useful application of the heat, SMW becomes classified as a fuel, with a net specific energy of about 8 MJ/kg, i.e. about one fifth that of coal. The waste can be pulverized and compressed into briquettes, then burnt under a boiler either alone or as a 50/50 mixture with coal. Alternatively, the waste may be processed physically, or by fermentation, and then upgraded by removal of some impurities and/or by the addition of refinery wastes or sewage sludge to give solid refuse-derived fuels (RDF) of about 15 MJ/kg net specific energy.

11.5 Combustion

The term 'combustion' is generally accepted to mean oxidation with the evolution of light and heat, the most common oxidant being atmospheric air except in the case of certain metallurgical furnaces and rocket engine applications. In broad terms, the ultimate requirements for fuels on reaching the combustor are ease of ignition, rapidity and completeness of combustion, with minimal production of unburnt products and associated pollutants. For boilers and furnaces, the additional requirement is for radiant heat transfer to be a maximum, whereas for engines this should be a minimum, since work transfer is the desired objective.

11.5.1 Fundamentals

Certain basic aspects of the combustion process that are relevant to all practical applications concern the proportions of the initial fuel–oxidant reactants and their resulting products, the maximum temperature reached in the flame, the behaviour of flame after its initiation, and the initiation itself, as discussed below.

11.5.1.1 Stoichiometry

Stoichiometry is the study of the proportions in which materials react chemically, and a 'stoichiometric' combustible mixture is one in which no excess or deficiency exists in either fuel or oxidant, being thus described as 'chemically correct'. The standard oxidant considered is atmospheric air, with a nitrogen/oxygen molar (i.e. volumetric) ratio of 3.76 and a molar mass of 28.96. (Note: 1 mole of a material is the quantity having a mass, in grams, equal to the molecular weight – now described as the 'molar mass' – of the material concerned. Hence the masses of one mole of oxygen *gas* and nitrogen *gas* are 32 g and 28 g, respectively, and a mole of any gas occupies a volume of 22.414 l approximately at 1 atm and 0°C.)

For a hydrocarbon fuel of general formula C_xH_y, the various molar quantities in the stoichiometric combustion equation are readily determined by balances of carbon, hydrogen, oxygen and accompanying atmospheric nitrogen, as follows:

$$C_xH_y + m_s(O_2 + 3.76\ N_2) = x\ CO_2 + \frac{y}{2}H_2O + 3.76\ m_sN_2 \tag{11.1}$$

where m_s = stoichiometric moles of O_2 per mole of fuel. The molar balance for oxygen gives the following values:

$$m_s = x + y/4$$

$$\text{Stoic. air/fuel molar ratio} = (A/F)_s = \frac{4.76}{1}m_s = 4.76(x + y/4) \tag{11.2}$$

$$\text{Stoic. air/fuel mass ratio} = (a/f)_s = (A/F)_s \frac{28.96}{\text{Molar mass of fuel}} = \frac{4.76(x + y/4)\ 28.96}{12x + y} = \frac{137.85(x + y/4)}{12x + y} \tag{11.3}$$

Based on the approximate mean formulae for conventional hydrocarbon fuels, values of stoichiometric air/fuel ratios are as listed in Tables 11.2, 11.3, 11.5 and 11.6.

The hydrogen component of hydrocarbon fuel burns fairly directly to H_2O, whereas the released carbon goes through an intermediate stage of CO before completion to CO_2. In practice, heat evolved from the combustion is of sufficient magnitude for the oxidation products to become so agitated thermally as to start dissociating, that is, breaking down and reverting back to their H_2, CO and O_2 reactant forms. For this reason, the individual elemental combustion reactions are written with reversible arrows, as shown:

$$H_2 + (1/2)O_2 \rightleftharpoons H_2O \quad \text{and} \quad CO + (1/2)O_2 \rightleftharpoons CO_2$$

The extent of this dissociation is determined by the level of temperature obtaining, and recourse must be made to the literature for the values of tbe equilibrium constant, which can be expressed in terms of the ratio of the moles of products and reactants concerned, indicating the dissociated quantities at any given temperature.[11]

At the moderately high levels of combustion temperature for hydrocarbons (> 2000 K), therefore, the stoichiometric equation would appear in the following form:

$$C_xH_y + m_s(O_2 + 3.76\ N_2) = n_1CO_2 + n_2H_2O + n_3CO + n_4H_2 + n_5O_2 + 3.76m_sN_2 \tag{11.4}$$

with all n values calculable using the values of equilibrium constants appropriate to the level of combustion temperature. These effects also occur, on a smaller scale and particularly at the higher temperatures, in reactions between atoms of H, O and N, giving a more comprehensive and complex stoichiometric equation of the following form:

$$C_xH_y + m_s(O_2 + 3.76\ N_2) = n_1CO_2 + n_2H_2O + n_3CO + n_4H_2 + n_5O_2 + n_6H + n_7O + n_8OH + n_9NO + n_{10}NO_2 + n_{11}N_2 \tag{11.5}$$

Subsequent cooling of the combustion products should, theoretically, bring an end to this dissociation and a return to the completely burnt quantities shown in equation (11.1). In practice, however, due to local chilling of the reactions by turbulence and/or contact with the cooler walls of the container, parts of the mixture endure in the dissociated form, hence equations (11.4) or (11.5) still apply. The resulting product concentrations may then be determined experimentally using such techniques as chemical absorption or adsorption, infrared radiation, or paramagnetism.

As discussed in the following section, fuels can burn effectively at mixtures other than stoichiometric, in which case the non-dissociated combustion equations may be expressed as follows:

Fuel-weak mixtures:

$$C_xH_y + m(O_2 + 3.76_2) = xCO_2 + (y/2)H_2O + n_5O_2 + 3.76mN_2 \tag{11.6}$$

where the moles of excess oxygen = $n_5 = m - (x + y/4)$

Fuel-rich mixtures:

$$C_xH_y + m(O_2 + 3.76N_2) = n_1CO_2 + n_2H_2O + n_3CO + n_4H_2 + 3.76mN_2 \tag{11.7}$$

where the insufficiency of oxygen results in a sharing between the CO and H_2, and the moles of incompletely burnt products, n_3 and n_4, may be determined using the equilibrium constant from the water–gas reaction (Section 11.4.1.2).

When additional dissociation into molecular and/or atomic species is considered, as in the stoichiometric case above, the more comprehensive equations (11.4) or (11.5) also apply to these non-stoichiometric cases, and the complexity of solution generally warrants computation.

11.5.1.2 Combustion temperature

The maximum temperature reached in the flame occurs when combustion is just complete, and no energy is permitted to escape from the products (i.e. adiabatic conditions with no work transfer). For a fuel of known composition, this combustion temperature may be calculated from a knowledge of the mixture proportions and the calorific value of the fuel (usually expressed as enthalpy of reaction), since a thermal balance is envisaged between the energy released by the reactants and that absorbed by the products. Even in the non-dissociated case, the calculation must be iterative, since a temperature must first be assumed in order to select the appropriate values for energy absorbed by each product. The energy released is then compared with the total energy absorbed, and the final non-dissociated temperature found by trial and error to give equality to these two energy quantities.

A similar procedure is followed in the dissociated case, except that the assumed temperature must first be used by trial and error to determine the quantities of products in the combustion equation before proceeding to the energy comparison, which is unlikely to balance at the first attempt. Derivation of the correct temperature is usually possible by linear interpolation with the result of a second attempt.[12]

In the event, little difference is found between combustion temperatures over a wide range of fuels. This follows because although those fuels with higher concentrations of hydrogen exhibit high levels of calorific value, these same fuels generate more H_2O as a product, and this has a specific heat capacity nearly three times that of CO_2. Consequently, this additional heat capacity absorbs the additional heat released, and most theoretical adiabatic combustion temperatures for stoichiometric mixtures of hydrocarbon fuels in air at 1 atm lie within the range 2300 – 2500 K, although acetylene reaches about 2600 K. In practice, of course, variable heat losses are inevitable, and temperatures do not exceed about 2200 K.

Combustion temperatures are reduced on the weak side of stoichiometric due to the additional heat capacity of the excess air, and on the rich side due to the unavoidable incompleteness of combustion. Values for both dissociated and non-dissociated mixtures are shown in Figure 11.8 for methane and iso-octane, indicating the extent of the effects of both mixture strength and dissociation on combustion temperature.

11.5.1.3 Flammability

Although the stoichiometric mixture represents the ideal case with maximum release of heat energy and no excess reactants to limit the temperature by absorbing part of the heat, fuels are able to burn at mixtures both weaker and richer than stoichiometric, as outlined above. However, mixture limits are reached when the flame is unable to propagate owing to the local insufficiency of molecules of either fuel or oxygen. These weak and rich mixture limits of flammability in air lie at 5 and 15 volumetric per cent of fuel vapour (34.3 to 10.2 air/fuel mass ratio) for methane, and reduce progressively through the hydrocarbon gases to almost constant values of 1 and 5 (22 to 4 air/fuel ratio) for the petroleum liquids ranging widely from aviation gasoline to residual fuel oil.[2]

As indicated in Section 11.4.2.3, the flash point, that is, the liquid temperature required to derive the weak mixture limit above the free surface, is not common throughout this range of fuels owing to the differing volatilities. An upper flash point can be envisaged, corresponding to the reasonably constant rich mixture limit of flammability, but this is not normally measured, being accepted as lying approximately 30°C above the conventional flash point. Plotting curves for both flash points in Figure 11.9 indicate the temperature range of flammability, and it is worth noting that, under ambient storage, the vapour–air mixtures in a kerosene tank lie within the flammable range, whereas those in a gasoline tank do not. Nevertheless, fire danger from the gasoline tank is still considered greater since high volatility demands tank venting, and the vented over-rich mixture rapidly weakens in the presence of atmospheric air, generating flammable mixtures *outside* the tank where vulnerability to ignition may be greater.

In addition to fire safety in handling, flammable mixture limits together with speed of flame propagation determine the behaviour of flames within practical combustors, and a certain extent of control lies in the design of the combustor and the fuel–air feed systems. The flame speeds of fuel–air mixtures can be measured, usually on a laminar basis, by igniting the mixtures in glass tubes or soap bubbles and recording the movement of the resulting flame. Laminar flame speeds of gaseous and vaporized liquid hydrocarbon fuels in air at atmospheric pressure are generally fairly common at the relatively low level of 0.5 m/s. Hydrogen exhibits a comparatively high level of 3.5 m/s. In practice, these values are increased considerably by the effects of turbulence, temperature and pressure.

Flame control can be exercised either by propagation across a confined space, as in spark-ignition piston engines, or by stabilization, as in an intermittent spray-generated flame in a compression-ignition engine, or a continuous spray or vapour-generated flame within a furnace, gas turbine, ramjet or rocket engine. In the former case, propagation rates and patterns are determined by chamber geometry, levels of turbulence, wall temperatures, stratified mixture strengths, and so on. In the latter case, matching of the low flame speed with the high speed of entry air is achieved by decelerating the air in a diffuser, and diverting (even reversing) the direction of the airstream so that the flame is able to maintain a constant location. At all points in the stabilized flame, a balance is achieved between the opposing speeds of the approaching mixture and the flame. High flame speeds permit shorter lengths of combustor and/or higher engine speeds and, together with wide ranges of flammability, give greater flexibility for changing combustion conditions without the hazard of flame-out.

11.5.1.4 Ignitability

The ignition of a fuel–air mixture may be either forced or spontaneous. In the former case, a localized addition of concentrated energy creates a small nucleus of flame which then grows outwards under the control of the flammability of the mixture. In the latter, a bulk addition of energy results in spontaneous ignitions at widely diffuse points, with an overall effect of the whole bulk igniting at the same instant. Forced ignition is involved in the flash point apparatus (Section 11.4.2.3) and in the spark-ignition engine (Section 11.5.2.1), whereas spontaneous ignition can be examined by means of a heated flask into which is injected a small predetermined quantity of fuel sample. The test starts at high temperature so that ignition is assured, and the delay between injection and ignition is noted. The test continues at progressively lower levels of temperature until the minimum level is found to promote ignition, this being associated with the maximum delay of several seconds. This minimum temperature is commonly referred to as the spontaneous ignition temperature, or SIT.

The variation with fuel density of SIT can be appreciated, in simple terms, by noting the size and shape of the fuel molecules, and their behaviour under the action of the thermal agitation within the flask. Small, compact molecules can be imagined as resisting this agitation quite effectively, consequently exhibiting high levels of SIT. The larger and more complex molecules, on the other hand, can be visualized as vulnerable to the energetic disturbances within the heated air, and tending to be cracked, i.e. broken into smaller sub-groups of atoms. The free bonds exposed by cracking of the molecules of fuel and oxygen lead to the possibilities of partial oxidation to certain C–H–O compounds which may be unstable and proceed to further reactions, many of which are exothermic (heat producing). These localized energy releases, repeated in many other points within the mixture, can be sufficient to cause ignition, consequently levels of SIT could be expected to be lower than those for the lower-density fuels. The curve in Figure 11.10 shows this to be the case, consequently the heavier fuels are more ignitable than their lighter counterparts, whereas the latter were seen to be more flammable (Section 11.5.1.3).

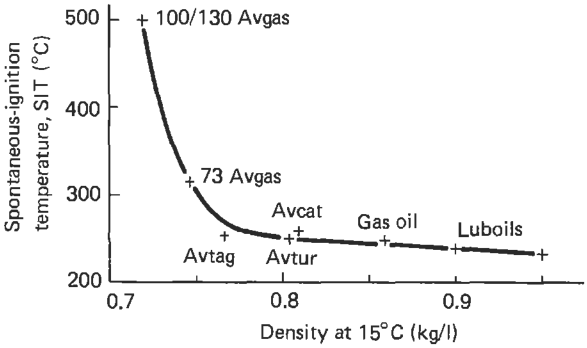

Figure 11.10 Variation of spontaneous-ignition temperature with density for representative commercial hydrocarbon fuels¹

Research at Cranfield has shown these clear-cut differences in ignitability to be lost at atmospheric pressure when higher temperatures are used to reduce the delay periods to milliseconds, but to be regained when these short-delay tests are conducted at the higher pressures used in practical combustors.[13]

11.5.2 Applications

All practical applications of combustion involve mixtures of fuel and oxidant which lie within the limits of flammability and are subjected to some form of ignition. However, each application is associated with a particular form of mixture preparation and of flame generation, and has its own specific requirements for optimal performance, as discussed below.

11.5.2.1 Discontinuous combustion engines

The long-established internal-combustion engines operating on repeated mechanical cycles comprise the reciprocating-piston type engines, recently joined by the rotary Wankel type, in each case sub-divided by the mode of ignition into spark (forced) and compression (spontaneous).

The spark energy required for ignition of a stagnant fuel–air mixture has been found to vary from about 0.2 to 0.3 mJ, but considerably more energy is supplied in practice to cater for mixture turbulence and a wide range of operating conditions. Under normal circumstances in the spark-ignition engine, the flame, once ignited, propagates across the chamber until all the mixture is consumed, the resulting rise in pressure serving to drive the piston towards bottom dead-centre and so provide the required power.

Under adverse circumstances where the operating pressure and temperature become excessive, as in low-speed hill climbing in high gear, or due to inadequate quality of fuel, the rising pressure and temperature in the chamber are sufficient for the remaining end gases to ignite instantly and spontaneously, giving rise to an uncontrolled explosion rather than a progressive burn under the control of the advancing flame. This phenomenon is termed 'spark knock', and is manifested by a high-frequency noise as the gaseous vibrations excite the engine structure. Although light knock may be tolerated for short periods, sustained heavy knock at high speed can result in damage to the cylinder-heat gasket on the side opposite the plug, plus erosion of the piston crown and top land, with eventual break-up of the top piston ring.

The thermal efficiency of any piston-type engine improves with rise in compression ratio (volume at bottom dead-centre/volume at top dead-centre), but spark knock sets a limit of about 10/1 on the compression ratio of automobile engines and, should a change have to be made to lower-quality fuels, the ignition timing may have to be retarded by several degrees of crank angle to avoid knock. To be suitable for spark-ignition applications, therefore, a fuel must be low in radiation and also *poorly ignitable*, hence, as shown in Figure 11.10, gasoline (which happens to be *highly flammable*) is optimal. Anti-knock quality of a gasoline is determined by means of a specially designed engine that permits variation in compression ratio while the engine is running. Using the test sample, the compression ratio is increased until the onset of a standard intensity of knock. At the same compression ratio, a blend of two reference fuels is found that matches the knock intensity of the test sample. The reference fuels used are iso-octane, $i\text{-}C_8H_{18}$ (with a compact molecule giving high resistance to spontaneous ignition) and normal heptane, $n\text{-}C_7H_{16}$ (with a non-compact straight-chain molecule). The anti-knock quality of the sample is then specified in terms of the Octane Number, which is the volume percentage of iso-octane in the matching reference blend. The 'Research' octane number is appropriate to moderate-speed cruising, and the 'Motor' octane number, determined under more severe conditions of test, to high-power high-speed driving (Table 11.9). Standard aviation gasoline (designated 100LL, i.e. Low Lead), of which comparatively little is now in use, has an octane number of 100 at weak-mixture cruising conditions, together with a performance number of 130 (30% more power than iso-octane) under rich-mixture take-off conditions.

Spark-ignition engines can also suffer from pre-ignition when combustion deposits within the chamber are caused to glow. This is equivalent to multiple ignition, which is advantageous in principle but, in this case, is dangerous since it is uncontrolled and can eventually lead to melting of the piston crown. Some fuel molecules, such as alcohols and aromatics, although highly resistant to spark knock, are prone to pre-ignition at the lower pressures and temperatures of operation. Pre-ignition, which is now virtually eliminated through improved design and materials, sometimes gave rise to continuing operation of the engine (run-on) on a regular basis after the electrical ignition was switched off. With modern engines, low-speed run-on may occur erratically owing to the spontaneous ignition arising from the high temperature level of the charge and the time available for reaction.

Under normal conditions in the compression-ignition engine, air alone is compressed in the cylinder and the fuel then introduced by means of an injector, the initial droplets in the spray igniting spontaneously after a short delay within the compression-heated air. The flame then propagates upstream towards the injector, burning the remaining fuel charge as it enters. The compression ratio must be high, typically from 13.5/1 to over 20/1, in order to achieve the high temperatures and pressures required for ignition, consequently the engine needs to be rugged and tends to be heavier than its spark-ignition counterparts. Furthermore, the fuel-injection system must operate at very high pressures in order to provide adequate pressure drop across the injector for good-quality spray into the chamber.

Table 11.9 Specified minimum octane ratings for motor gasoline

Leaded (BS 4040) Max. lead 0.15 $g\ l^{-1}$			*Unleaded* (BS 7070) Max. lead 0.013 $g\ l^{-1}$		
Grade	RON	MON	Grade	RON	MON
4 star	97	86	–	–	–
–	–	–	Premium	95	85
3 star	94	82	–	–	–
2 star	90	80	Regular	90	80

Under adverse conditions where the temperatures and pressures are insufficient, as in cold starting, or due to inadequate quality of fuel, the ignition delay of the initial droplets is so extensive that most of the fuel charge has entered the chamber by the time ignition does occur. The resulting combustion is so rapid and uncontrolled as to be explosive, giving rise to rough running and the characteristic heavy noise of 'diesel knock'.

To be suitable for compression-ignition applications, therefore, a fuel must give low radiation and be *readily ignitable*, hence, as shown in Figure 11.10, gas oil and diesel fuel (which happen to be *poorly flammable*) are optimal. Anti-knock quality of a compression-ignition engine fuel is also determined in a variable-compression engine, and a blend of two reference fuels is found which matches the ignition delay of the test sample. These reference fuels are normal cetane, $n\text{-}C_{16}H_{34}$ (a non-compact straight-chain molecule), and, currently, a compact isomer of cetane, the anti-knock quality of the sample being specified in terms of Cetane Number, which is the volume percentage of normal cetane in the matching reference blend. The minimum anti-knock limits for UK diesel fuels are specified as 50 CN for automotive use and 45 CN for general purposes.[14]

Since the ignition requirements are diametrically opposed in these two types of piston engine, it follows that an inverse relationship holds with octane and cetane number (Figure 11.11), and that fuels suited to one type of engine are unsuited to the other.

11.5.2.2 Continuous-combustion engines

Clearly, the power-density of an engine, in either watts/m^3 or watts/kg, would be increased if the combustion could be maintained on a continuous basis. This is achieved by continuous spraying of the fuel into an open chamber where the supply of air, and rejection of products, can also be continuous. In the gas-turbine engine, some of the energy in the

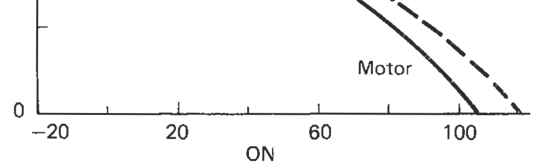

Figure 11.11 Representative relationships between octane and cetane numbers[2]

product gases is extracted by means of a rotary turbine, which, in turn, drives the shafting to an upstream compressor, the remaining energy being extracted either by an additional turbine stage or by a rearward propelling nozzle. For hypersonic flight (greater than Mach 5), the compression effect within the entry air duct is sufficient for combustion purposes, so that the rotating elements of compressor, shaft and turbine may be discarded, and the engine is then described as a ramjet. For still higher velocities, and for flight outside the earth's atmosphere, the vehicle must carry its oxidant as well as its fuel, consequently the entry air duct is not necessary, and the engine is described as a rocket. In all these cases, the flame is established in a location constant within the chamber, and mixtures of fuel and oxidant are fed to it. Combustion requirements therefore include ready vaporization of the fuel and mixing of the vapour with oxidant, together with adequate flame speed and flammable mixture range, and clean complete combustion with minimal emissions.

In continuous-flow combustors, the air pattern is designed to assist flame stabilization by means of swirlers and secondary air side entries, the primary requirement being high relative velocity between fuel and air. In gas-turbine engines, the turbine blades not only experience mechanical stress through high-speed rotation but are exposed constantly to the temperature of the working gas stream in contrast to piston engines, where such metal heating occurs during only part of the cycle.

Consequently, a large proportion of the incoming air is used for cooling the combustion gases immediately downstream of the flame zone. For gas-turbine engine fuels, the best compromises are found in kerosine (aviation) and gas oil (industrial), although in the latter case adaptations can be made to suit gaseous fuels and the heavier fuel oils. Hypersonic ramjets call for specially designed fuels of high energy density in order to minimize storage volume and thus aircraft drag, and high heat capacity to be able to withstand the kinetic heating effects of high-speed flight. The candidate fuels include kerosines of high thermal stability, specially selected heavy hydrocarbons, and, eventually, endothermic fuels that react to absorb heat during flight. Supersonic combustors call for particularly high flame speeds, as with hydrogen. Space rockets, on the other hand, require fuel-oxidant pairs of maximum specific energy, and these include hydrogen–oxygen, kerosine–oxygen, hydrazine–hydrogen peroxide, and a range of solid materials that contain both fuel and oxygen components. In view of the absence of diluent nitrogen, combustion temperatures are particularly high in rocket chambers (e.g. 3000 K), consequently the chemical dissociation and re-association reactions within the propelling nozzle are complex, but they can be handled by computation. The performance of such high-speed engines is usually assessed on a basis of the thrust produced per unit mass flow rate of propellants (i.e. fuel + oxidant), and this parameter is termed the 'specific impulse', with unit N s/kg.

11.5.2.3 Continuous-combustion heaters

Applications of heat to manufactured stock for processing, or to water for raising steam, usually take place in a continuous-flow combustion chamber with the flame stabilized in the stream of air and fuel, as in Section 11.5.2.2.

Fuel may be introduced by the following methods;

- As gas into a mixing zone with air
- As low-pressure liquid for vaporization within a flame-heated tube
- As a centrifugal spray from a rotary-cup burner fed at low pressure
- As a low-pressure spray subjected to locally high velocities of air or steam
- As a high-pressure-jet spray into relatively low-speed air.
- As a bed-supported layer of solids, with streams of air supplied below and above
- As solids fluidized with air in a vertical reactor
- As pulverized solids suspended in a large-scale chamber

Since the output of a pressure-jet burner is proportional to the square root of the pressure drops across the orifice, a turn-down ratio (maximum/minimum flow rate) of, say, 10/1 requires a pressure ratio of 100/1. Furthermore, since low pressures tend to degrade spray quality, and high pressures incur excessive mass and expense of fuel systems, high turn-down ratios are achieved by such means as concentric, multiple nozzles designed for different entry pressures, by over-supplying the nozzle and spilling the excess back to the tank, or by variable opening of the entry ports to the nozzle.

The transfer of combustion heat from the flame takes place by a combination of forced convection and radiation. The former process is used in the low-temperature furnaces, augmented by an air fan, whereas at temperatures above about 750°C, radiation, which varies with the fourth power of absolute temperature, becomes dominant, and the heat transfer may take place either directly from the flame or indirectly from heated refractory surfaces.

The gases are the most convenient fuels for furnace use because of their control flexibility and clean burning, and pre-heating of air and fuel is used with the low-energy gases in order to achieve the required combustion temperatures. Liquid fuels used in furnaces range from gas oil through to the heaviest residual fuel oil and coal tar fuels, the presence of particles of solid carbon in the flame increasing radiation. Solid fuels tend to be used more for the larger power-station boiler furnaces, where large-scale provision can be made for mechanical stoking, ash removal and flue-gas treatment. Ash can be removed in part by prior fuel washing, or handled subsequently by controlling the temperature below the level at which the ash becomes sticky. Improved overall control of solid fuel appears to result from the use of a pulverized fuel in a fluidized bed giving better heat conduction and greater tolerance to coarse particle size with high ash content.

11.5.2.4 Emissions control

In Section 11.5.1.1, the major products of combustion were seen to comprise carbon dioxide and water plus, of course, unreacted atmospheric nitrogen, together with variable quantities of carbon monoxide, oxygen and, possibly, unreacted hydrogen, depending upon the strength of the mixture. Since these volumetric concentrations within the total products lie above about 1%, they are described as macro. In addition, there may well be micro concentrations of nitrogen oxide and dioxide (together represented as NO_x), the hydroxyl radical, and atomic oxygen and hydrogen. A method of calculating all these concentrations was outlined in Section 11.5.1.1, and practical methods of measurement include chemical absorption in liquid or solid reagents, or physical methods based on thermal conductivity, infrared absorption, chromatography, paramagnetism or sonic velocity.

Although the water vapour produced by combustion eventually condenses and returns to the global water cycle, such carbon dioxide that is not absorbed by the world's vegetation and oceans has been identified as a major cause of extending the greenhouse effect. Carbon monoxide is a recognized poison, and the nitrogen oxides, together with unburnt hydrocarbons, give rise to smog. The polynuclear aromatic hydrocarbons are also suspected of carcinogenic effects, whereas any sulphur in the fuel will emerge as corrosive sulphur dioxide. Carbonaceous soot particles are probably also formed in fairly copious proportions in most flames as a result of imperfect mixing, cracking and/or slow reaction rates, but they tend to be oxidized in later stages of combustion. Luminous non-sooting flames are required for heat transfer in furnaces, and non-luminous non-sooting flames for work transfer in engines. Unburnt soot gives rise to smoke as a further pollutant of the atmosphere, and also to the possibilities of carbon deposits within the engine and exhaust systems. Such additives as lead have also become unacceptable to the public, and unleaded fuels are now becoming increasingly available.

Typical volumetric concentrations of the combustion products from a spark-ignition engine are shown in Figure 11.12. These indicate, as discussed in Section 11.5.1.1, that the normally expected weak and rich products do, in fact, extend into each other's domains. Operation on the weak side not only improves fuel economy but reduces most of these products, the exception being NO_x, which is generated by direct reaction of atmospheric nitrogen and oxygen at high temperatures. Methods of controlling these emissions include exhaust air injection, afterburners and catalytic reactors in the exhaust system to handle CO and hydrocarbons, and exhaust recirculation into the cylinder, and/or catalytic reactors, for the NO_x. Exhaust recirculation has the two effects of lowering the availability of oxygen, and the level of the peak flame temperature, but also reduces the power. Similar effects result from retarded ignition timing, but fuel economy is then impaired. Overall weak-mixture operation is feasible using a stratified charge in the chamber, and is achieved using fuel injection and suitable chamber design.

Similar problems of emissions arise with compression-ignition engines, where high utilization of air is the target, and where soot reaches objectionable levels if the fuel–air mixing and/or the maintenance of the pumps and injectors is poor. Control can be effected by the use of pre-combustion chamber, and of fuel additives based on barium.

The continuous-flow combustors tend to protect the flame region so that the mixture strength is near-stoichiometric, and then dilute the combustion products with sufficient air to reduce the mixed temperature to a level that downstream surfaces can withstand. Emission concentrations are therefore diluted, but their overall quantities are still significant, and careful combustor design for good mixing and flame control is always important.

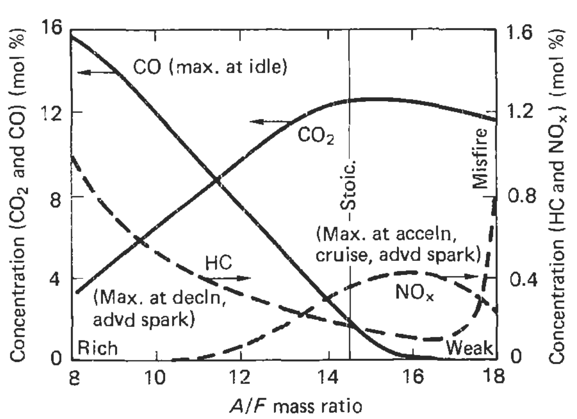

Figure 11.12 Volumetric concentrations of products of hydrocarbon combustion[1]

11.6 Conclusions

Over many decades of use, the optimal fuel-combustor pair has emerged for each application, but developments continue into improving efficiency, startability, smooth running, clean burning and general overall performance. However, these targets never remain stationary for very long, and two of the current concerns are the continuing availability of conventional fuels well into the next century, and the sinister extension of the essential greenhouse effect owing to increased concentrations of combustion-generated carbon dioxide, and some hydrocarbons themselves.

The subject of alternative fuels has comprised a special study at Cranfield since the first warnings in 1973, and brief conclusions appear as follows. The remaining lifetimes of conventional fossil sources are, of course, dependent on many – as yet unknown – factors of an economic and political nature, but a broad assessment is gained from the simple (reserves/production) ratios. In effect, this assumes no changes either in the global reserves of a particular resource or in the annual production rate over the period concerned (whereas in fact both may rise slightly initially), but the results are useful on a comparative basis and, for 1991, appear as follows;

Natural gas:	58.7 years
Petroleum:	43.4 years
Coal:	239 years

Several alternative fuels could be made available, and are classified under the two headings of Supplemental and Substitute in Table 11.10. From the above lifetime figures, coal is seen as not only likely to endure as a fuel in its own right well into the future, but also to serve as a potential source for supplementing the conventional oil- and gas-derived fuels.

Applications for all the substitute fuels can be found, and some actually offer improved performance in certain instances, their higher prices being offset to some extent eventually by bulk production. However, only hydrogen offers relief from CO_2 pollution and even with this fuel oxides of nitrogen would still be produced. Methane is also a greenhouse gas and, although it, in turn, produces CO_2, it could be used to advantage as a substitute fuel rather than allowed to escape to the atmosphere.

Table 11.10 Alternative fuels (suggested nomenclature)

1. Conventional	C_xH_y
2. Supplemental Similar to conventional fuels but alternative sources	Petroleum-type products from: NG Coal Shale oil Tar Peat Biomatter
3. Substitute Unrelated to conventional fuels or sources	Alcohols, C_xH_yOH Nitroparaffins, $C_xH_yNO_2$ Nitrohydrides, N_xH_y Liquid methane, LCH_4 Liquid hydrogen, LH_2 Biofuels, $C_xH_yO_z$

Certain engine developments may bring success to the hybrid-type piston engine, which is so closely allied to both the spark- and compression-ignition engines that octane and cetane rating will have no significance, and a wide range of fuels be acceptable. Many furnaces are already omnivorous, tolerating a wide range of gaseous, liquid and solid fuels, including wastes. Electric propulsion is already in small-scale use for delivery vehicles, etc., the parent chemical fuel being burnt under more controlled conditions within power stations, and further development of the fuel cell will permit higher efficiencies by direct conversion from chemical to electrical energy without the thermodynamic constraints imposed by the intermediate form of heat energy.

Should the greenhouse effect threaten to expand to disastrous proportions, consideration would have to be given not only to further reduction of energy demands but also to sources other than those generated by oxidation. Nuclear power is one such, and environmental objections may be allayed by success in the development of cleaner-reacting fusion. The ultimate sources may be geothermal, or more direct forms of solar power received either as such or through the media of winds, waves or tides, in each case converted to conveniently handled electricity.

Conventional fuels and combustion engines therefore occupy a unique position in the technical world by offering a very valuable and versatile service, but with disadvantages that may eventually be resolved only by abandonment and replacement before irreparable damage is done to the environment. As ever in such situations, research is the key, and adequate support for its continuation is nothing less than vital.

12.1 Introduction

Renewable energy sources have been recognized as major alternatives for many years, but it is only since 1973 that substantial research, development and demonstration projects have been undertaken. Two of the main applications are to supply heat and electricity. Many examples can be found throughout the world and the opportunities to develop export markets in the supply of materials, equipment and services are considerable.

The analysis commences with an overview of the Earth's energy flows. It can be seen that solar energy is by far the greatest resource and effectively 'drives' most of the other renewable sources. The one major alternative which cannot strictly be regarded as renewable is geothermal energy, but it will be shown that new research work could release very significant amounts of energy from this resource.

The availability of solar radiation is then discussed and it can be seen that the main drawback in high-latitude countries such as the UK is that there are long periods in the winter months when the total radiation received is probably too small to make a useful contribution.

Solar energy can be easily converted into heat and could provide a significant proportion of the domestic hot water and space heating demand in many countries. The main applications are discussed in the following sections. Active solar systems absorb solar radiation on a collecting surface. This converts the radiation into heat, which can be transferred by a circulating fluid (often water or air) to the point of use or to a heat-storage system. Solar heat can also be used for cooling.

Thermal systems for power generation have a potential in the lower latitudes and details of some of the main systems are given in this chapter.

Passive systems use solar energy naturally by involving conventional building elements for its collection, storage and distribution. Although passive solar and associated building design features involve extra design effort, they do not necessarily lead to extra construction costs in new buildings. It has been found that passive features in the refurbishment of older buildings can also be cost-effective.

Photovoltaic systems are well established in the growing consumer product market. Other applications in the UK are limited to a few small-scale systems (e.g. marine light beacons). Applications in warmer countries range from small-scale power supplies for rural villages to power generation in the megawatt range.

The one renewable resource which has a long-established record for electric power generation is hydropower. It is still the fourth-ranking major energy resource (after oil, coal and natural gas) and the potential for further development is still considerable.

Biomass is often completely overlooked as a potential energy source, but estimates of its present position suggest that it supplies up to 15% of world energy demand, mainly in the form of fuelwood use in the developing countries.

Windpower has had a long history of development in many countries, with mechanical power mentioned for many years in the literature. Modern developments are discussed, together with an assessment of wind energy potential and some national programmes. The UK has, perhaps surprisingly, one of the best wind-energy regimes in the world.

Geothermal energy is often considered to be of minor importance and limited to the major fault lines in the Earth's surface in countries such as Iceland or New Zealand. However, the UK are leaders in research into the development of 'hot rock' technology and this is examined.

Tidal power on a world scale is insignificant, but a few countries, including the UK, have suitable tidal sites and their potential is assessed.

Wave power is, in theory, a massive alternative energy resource, but the development problems have been very considerable. Here the UK, as an island community, probably leads in the development of land-based wave energy conversion systems.

12.1.1 The Earth's energy flows

There is a continuous flow of energy through the Earth's atmosphere and surface. By far the greatest energy source is the sun. The other two sources, heat from the Earth's interior and tidal energy caused by the gravitational forces of the earth–moon–sun system, are almost negligible in comparison. A world energy flow diagram is shown in Figure 12.1.[1] The main flow paths were originally suggested by Hubbert[2] in 1962, who subsequently quantified all of them in 1971.[3] Some of these values have been revised to include later work, but it must be appreciated that all the values are approximate.

12.1.2 Energy from solar radiation

The rate at which the incoming solar radiation is intercepted at the edge of the Earth's atmosphere is 1373Wm^{-2} with a probable error of 1–2%.[4] This is known as the 'solar constant', defined as the energy received by a unit surface perpendicular to the solar beam at the Earth's mean distance from the sun. During the year the solar constant can vary by ±3.4%, partly due to variations in the Earth–sun distance. The total solar power intercepted by the Earth is given by $1373\pi r^2$, where r is the mean radius of the earth (6.371×10^6 m). This gives a figure of 1.75×10^{17} W or an annual total of 5.52×10^{24} J. For comparison, the world's total commercial energy consumption in 1988 was 3.61×10^{20} J[5] or some 15 000 times smaller than the solar energy intercepted by the Earth.

12.1.3 Energy from the Earth's interior

Heat flow by conduction through the Earth's solid crust has been estimated to be approximately 0.063 Wm^{-2}.[3] Although there are a few areas surrounding active volcanoes and hot springs where the heat flow can be very much greater than this value, these sources are estimated to contribute at a rate of perhaps 1% of the conduction rate. The conduction rate is given by $0.063\ 4\pi r^2$, where $4\pi r^2$ is the Earth's surface area. This gives a figure of 3.21×10^{13} W for conduction and a total of approximately 3.24×10^{13} W for the terrestrial energy flow.

12.1.4 Energy from the tides

Tidal energy has been estimated from studies of the rates of change of the periods of rotation of the Earth and moon to be 3×10^{12} W.[3]

12.1.5 The energy flow system

Some 30% (5.25×10^{16} W) of the incoming solar radiation is directly reflected and scattered back into space as short-wave radiation. The Earth's atmosphere, the oceans and the land masses absorb about 47% (8.17×10^{16} W). This is converted directly into heat at the ambient surface temperature and is reradiated as long-wave radiation. The hydrological cycle uses about 23% (4.04×10^{16} W). As water evaporates and changes into water vapour, heat is absorbed. This heat is released when the water is precipitated. The water vapour is often convected high up in the atmosphere. When precipitation occurs, water from these high levels provides all the potential energy available in lakes and the kinetic energy of rivers. Most of this energy is dissipated as low-temperature heat as it descends to sea level. A very small proportion of the incoming

solar radiation, about 0.21% (3.68×10^{14} W), creates the movements in the Earth's atmosphere which cause the winds and ocean waves and currents. These are also dissipated as low-temperature heat.

The amount of organic matter synthesized annually on land and in the oceans by photosynthesis is equivalent to 3.1×10^{21} J of stored energy.[6] This represents less than 0.06% (9.83×10^{13} W) of the incoming solar radiation, but is nevertheless about ten times the world's total commercial energy consumption in 1982. Photosynthesis is the conversion of solar energy into the fixed energy of carbohydrates through the reaction:

$$\text{Solar energy} + CO_2 + H_2O \rightarrow \text{carbohydrates} + O_2$$

About 0.5% of this photosynthetically fixed carbon is consumed annually as food[7] and up to 1.5% is directly consumed throughout the world as fuelwood. During the past 600 million years the fossil fuels, coal, oil and natural gas, were formed from a very small fraction of the synthesized organic matter. This matter is laid down each year in places such as swamps and peat bogs where its rate of decay is greatly retarded. The annual rate of formation can be calculated by dividing the estimated total fossil fuel resources, approximately 2×10^{24} J, by the total formation period. This gives a figure of up to 4×10^{14} J. In these calculations the various potential energy resources from nuclear fuels have been omitted.

12.2 Solar radiation

The two major problems associated with all applications of solar energy are its relatively low intensity at the Earth's surface and its intermittent nature, both from day to night and through the seasons. The maximum intensity of solar radiation received at the Earth's surface occurs within an hour or two of mid-day on clear days and is limited to about 1 kW m^{-2}.

A detailed description of solar radiation and its availability throughout the world is beyond the scope of this chapter, but can be found in many of the standard texts (for example, references 8–10). For the European Community countries a *Solar Radiation Atlas* was published in 1984[11] giving full details of global radiation on horizontal surfaces and both global and diffuse radiation on vertical and inclined surfaces on a monthly averaged basis. For most practical purposes the simple classification of solar radiation into direct, diffuse or global is adequate.

Direct solar radiation, I, is the solar radiation flux associated with the direct solar beam from the direction of the sun's disk, which may be assumed to be a point source, and is measured normal to the beam (that is, on a plane which is perpendicular to the direction of the sun). Diffuse radiation, D, reaches the ground from the rest of the whole sky hemisphere from which it has been scattered in passing through the atmosphere. Global solar radiation, G, includes all the radiation, direct and diffuse, incident on a horizontal plane. The distribution of diffuse radiation is not uniform over the whole sky hemisphere and is more intense from a zone of about 5° radius surrounding the sun. This is known as circumsolar radiation. Radiation may also be reflected from the ground onto any inclined surface, though this is very difficult to assess. The relationship between direct radiation, I, the diffuse radiation, D, and the global radiation, G, is given by

$$G = D + I \sin \gamma \tag{12.1}$$

where γ is the solar altitude above the horizon.

Solar radiation, or irradiance, received on the Earth's surface averaged over 24 hours on each day throughout the year, is shown in Figure 12.2. The average in the UK is close to 100 $\mathrm{W m^{-2}}$ while in the Arab countries, such as Egypt and the Sudan, it is close to 300 $\mathrm{W m^{-2}}$. A detailed look at the mean daily totals of solar radiation, averaged for each month, in London and Khartoum is shown in Figure 12.3.

In the UK and other Northern European countries there is about a fourfold variation between the worst three-month winter period and the best three-month summer one. About half the radiation in Northern Europe is diffuse and this puts a limit on applications which require focusing. In many of the Arab countries there is only a small variation from one month to the next and there is a greater proportion of direct radiation. The worst month in the Sudan has a considerably greater total than the best month in the UK.

In the UK it can be seen from data derived from Meteorological Office records[12] that there are two main trends – higher levels of global radiation in the west of the country, where the skies are, in general, clearer, and lower levels towards the north, due to the higher latitudes. These data are for the period 1965–1970, with the exception of Aldergrove, which is for 1969 and 1970 only. The comparatively low radiation levels in the winter period are combined with an increased proportion of diffuse radiation, which greatly reduces the effectiveness of potential solar applications (Table 12.1).

Many solar applications require a knowledge of the total radiation on an inclined surface facing in any direction while the only available datum is the total global radiation on a horizontal surface in the same location or within a reasonable distance. Sometimes the only records consist of daily sunshine hours. There are numerous examples in the literature giving various approaches to modelling solar radiation data. For example, reference 13 cites over 50 other references. Another approach can be adopted where a country has an established radiation network. This is to select an 'example year' which most closely represents the statistical average (e.g. reference 14).

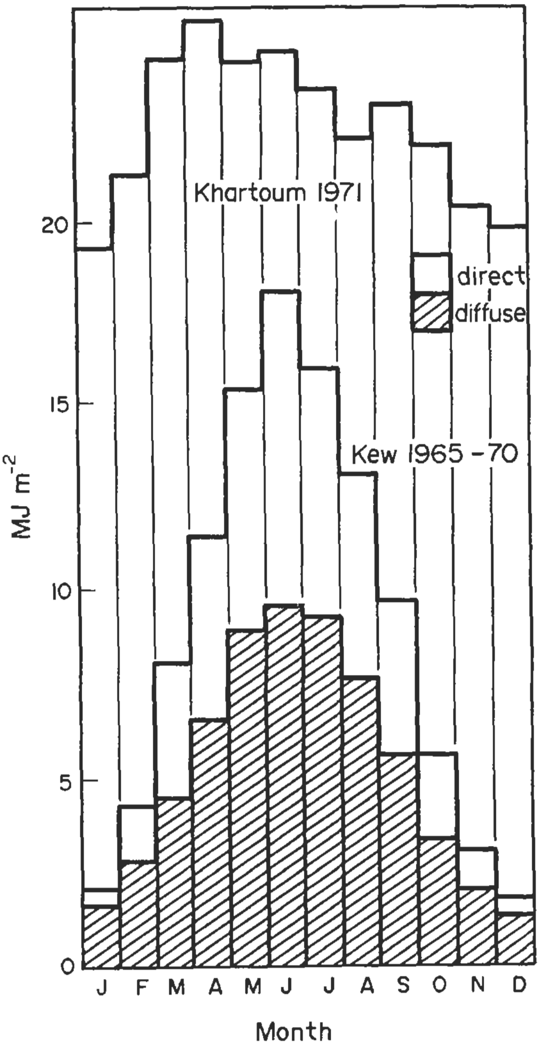

Figure 12.3 Mean daily totals of solar radiation in London and Khartoum (after McVeigh[1])

12.2.1 Flat-plate collectors

Solar energy can be easily converted into useful heat which could provide a significant proportion of the domestic hot water and space heating demand in many countries. One of the drawbacks in high-latitude countries, such as the UK, is that there are many days in the winter months when the total radiation received will be too small to make any useful contribution. The most widely known and understood method for converting solar energy into heat is by the use of a flat-plate collector for heating water, air or some other fluid. The term 'flat plate' is slightly misleading and is used to describe a variety of different collectors which have combinations of flat, grooved and corrugated shapes as the absorbing surface, as well as various methods for transferring the absorbed solar radiation from the surface of the collector to the heated fluid. Many different types of collector have been built and tested by independent investigators over the past 90 years, the early work being carried out mainly in the USA, Australia, Israel, the UK and South Africa.[10] Tests were made in specific locations with wide variations in test procedures and availability of solar radiation. The main objective of these tests has been to convert as much solar radiation as possible into heat, at the highest attainable temperature, for the lowest possible investment in materials and labour.[15]

The majority of flat-plate collectors have five main components, as shown in Figure 12.4:

1. A transparent cover which may be one or more sheets of glass or a radiation-transmitting plastic film or sheet;
2. Tubes, fins, passages or channels integral with the collector absorber plate or connected to it, which carry the water, air or other fluid;

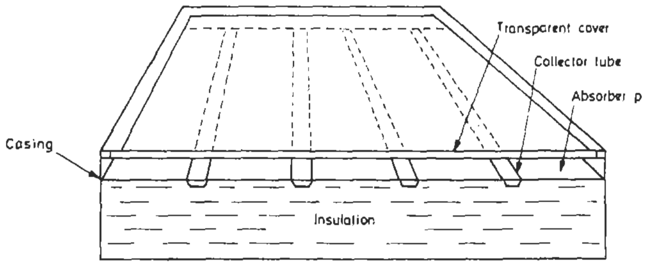

Figure 12.4 The components of a flat-plate collector (after McVeigh[10])

3. The absorber plate, normally metallic and with a black surface, although a wide variety of other materials can be used, particularly with air heaters;
4. Insulation, which should be provided at the back and sides to minimize the heat losses;
5. The casing or container which encloses the other components and protects them from the weather.

Components (1) and (4) may be omitted for low-temperature-rise applications, such as the heating of swimming pools.

Flat-plate collectors can also be classified into three groups according to their main applications:

1. Applications with a very small rise in temperature, such as in swimming pools where the collector needs no cover or insulation at the back or sides. A high rate of flow is maintained to limit the temperature rise to less than 2°C;
2. Domestic heating and other applications where the maximum temperature required is not more than 60°C. Insulation at the back and at least one transparent cover are necessary;
3. Applications such as process heating or the provision of small-scale power, where temperatures considerably above 60°C are necessary. A more sophisticated design approach is needed to reduce heat losses from the collector to the surroundings.

One basic equation, the Hottel–Whillier–Bliss equation,[16] expresses the useful heat collected, Q, per unit area, in terms of two operating variables, the incident solar radiation normal to the collector plate, G_c, and the temperature difference between the mean temperature of the heat-removal fluid in the collector, T_m, and the surrounding air temperature, T_a, as follows:

$$Q = F\,[(\tau\alpha)G_c - U(T_m - T_a)] \tag{12.2}$$

where F is a factor related to the design of the collector plate and the effectiveness of heat transfer from the collector plate to the heat-removal fluid.

The transmittance–absorptance product $(\tau\alpha)$ takes account of the complex interaction of optical properties in the solar radiation wavelengths.[16] It is actually some 5% greater than the direct product of the transmittance through the covers, τ, and the collector plate absorptance, α, because some of the radiation originally reflected from the collector plate is reflected back again from the cover. The heat loss coefficient, U, rises very rapidly with increasing wind velocity if there are no covers, but is less dependent when the collector has at least one cover. The number and spacing of the covers and the conditions within the spaces can be significant; for example, an evacuated space greatly reduces heat losses.

The three design factors, F, $(\tau\alpha)$ and U, define the thermal performance of the collector. The overall efficiency of the collector, $\eta = Q/G_c$, can then be expressed in terms of the temperature difference, $(T_m - T_a)$, and the incident solar radiation, G_c:

$$\eta = \frac{Q}{G_c} = F\left((\tau\alpha - \frac{U}{G_c}(T_m - T_a)\right) \tag{12.3}$$

The longwave radiation emitted from the collector plate surface can be considerably reduced by treating the collector surface. The treatment reduces its emissivity in the longwave spectrum without greatly reducing the absorptivity for shortwave radiation. Any collector surface with this treatment is known as a selective surface. Many methods have been used to achieve these surfaces, including chemically applied coatings.

Equation (12.3) can be used to compare the performance characteristics of different types of collector and to explore the effects of altering the various design parameters. This is illustrated in Figure 12.5, which describes the performance of six different types of collector.

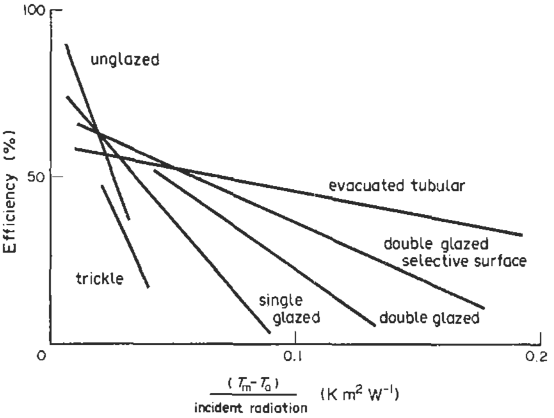

Figure 12.5 Performance of six different types of collector (after McVeigh[1])

The unglazed collector performs well for small values of $(T_m - T_a)$ and with good radiation conditions. A similar performance is obtained from the trickle collector, based on the use of black corrugated sheets with water flowing down the channels from a perforated pipe. For higher temperatures one or two transparent covers are needed and the use of a good selective surface also enhances the performance with lower incident radiation values. The best all-round performance to provide temperatures above 60°C is given by the evacuated tubular collector described later in Section 12.4.

By the end of the 1980s a solar water heating industry had been established in many of the Western industrial countries. Its size depended on many factors, the main influences being the annual solar radiation level and the extent of government subsidies and support. Countries such as the United States, France, Germany, Italy and Japan had a substantial number of the larger multinational companies involved in solar water heating, while solar industries were also being established in many of the Arab countries. In the UK a possible potential market of some 20 million houses was identified, apart from commercial, industrial and government buildings. By 1985, after a research and development programme on active solar heating, the Department of Energy[17] pointed out that although the technical potential was as much as 45 Mtce (million tonnes of coal equivalent) annually, the high cost of the installations could reduce this to as little as one million tonnes per annum. Even this would require an installation rate substantially above that attained in recent years. Despite the publishing of Codes or Guides to good practice[18–22] a number of adverse factors had combined to inhibit the development of a satisfactory market in the UK for active solar water and space heating systems.[23] The main factor was the collapse in oil prices and the correspondingly small rises in the price of coal and natural gas. Nevertheless, one application in the UK has been successful – the heating of swimming pools in the summer season, where the demand for water at about 25°C can be met.

An example of one of the many urban solar water heating projects to be found in countries with lower latitudes than the UK is illustrated in Figure 12.6, where several systems with several thousands of square metres of flat-plate collector are shown on the roofs of blocks of flats in Bucharest.

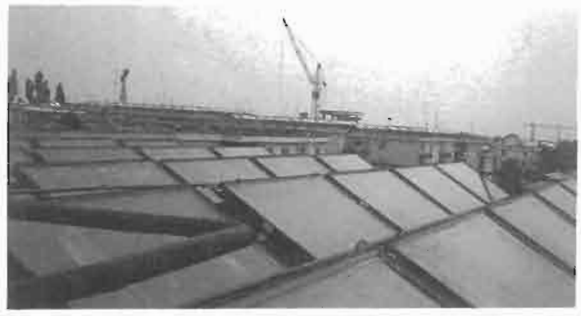

Figure 12.6 Flat-plate collectors on the roofs of blocks of flats in Bucharest

12.2.2 Space heating

The possibility of at least partially heating a building by solar energy has been demonstrated on many occasions over the past 40 years. The criteria originally suggested by Telkes[24] in 1949 for solving the problems of collection, storage and distribution of solar energy have been somewhat modified since then as experience has been gained with an increasing number of installations. In the early work, emphasis was placed on the collection of winter sunshine. This has been broadened to include the very substantial contribution that can be obtained from diffuse radiation. The three terms 'efficient', 'economic' and 'simple' used by Telkes in relation to the collector have always been the goal of sound engineering practice and an analysis of some of the earlier solar installations indicated that very few can satisfy all three.

The associated problem of storing the solar energy collected in the summer for use the following winter has attracted a considerable research effort. The principle of using a very large, heavily insulated water storage tank buried underneath the building was tried some 50 years ago at the first Massachusetts Institute of Technology solar house.[25] The comment that this approach was highly uneconomical had a considerable influence on the direction of storage system research over the next two decades. The effect of latitude and local radiation characteristics are now widely appreciated. It was originally thought that only a few days' storage could be economically viable so that the solar energy received during clear winter days would be made available for successive overcast periods and that this could only occur to any extent in parts of the world where there are appreciable amounts of winter sunshine. However, longer storage periods of up to several months were achieved in several solar houses during the mid-1970s and by the end of the decade interseasonal storage has been shown to be not only possible but also cost-effective. For shorter-term storage considerable reductions in the total volume of the store are possible by the use of chemical storage methods pioneered by Telkes.

The term 'solar house' first became familiar in the USA during the 1930s, when architects began to use large, south-facing windows to let the lower-slanting rays of the winter sun penetrate into the back of the room.[26] At that time there was no real distinction made between the active systems, which use pumps or fans to circulate heat, and passive systems, which use solar energy naturally, involving the conventional building elements for solar energy collection, storage and distribution. The large windows saved fuel during the day, but it was not possible to store the solar energy. At night and during cloudy days the heat loss was so great that there was a relatively small saving on fuel during the entire heating season. This approach was later known as the 'direct gain' system.

Prior to 1973 there were probably less than 50 well-known solar houses or buildings in the world. Among these, Europe's largest, and for many years the world's largest passive building was the annexe to St George's School, Wallasey,[10] completed in 1962. There are now many thousands of solar houses and buildings throughout the world. In parts of the USA and Northern Europe the earlier designs in the 1970s were mostly active systems and the need for long-term interseasonal heat storage began to attract considerable attention. By the late 1980s over 30 operating solar heating systems using interseasonal heat storage in some 12 countries had been identified and characterized.[27] Proposals to use large plants with over 100 000 m^2 of collector arrays were planned. Most of these systems involved some type of *in-situ* construction using aquifers, earth coils, drilled rock, water pits or rock caverns.[27] One common feature noted was the economy of scale as storage volume increased.

The great majority of all these systems used some form of active solar collector system, with pumped circulation of the heat transfer fluid (usually water). Results from the early monitored tests also indicated that large interseasonal stores are not suitable for smaller individual houses and the emphasis for this category, including commercial buildings, changed to passive applications. Passive systems use solar energy naturally by involving conventional building elements for the collection, storage and distribution of solar energy.

In addition to the direct gain system, mentioned above, four other passive systems have been categorized[28] as follows:

1. *The Trombe wall* or thermal storage wall in which the heat is stored in a wall which also absorbs the solar energy when it comes through the glazing;
2. *The solar greenhouse*, in which the features of the solar thermal storage wall and the direct gain approach can be combined by building a greenhouse on the south side of a building (in the northern hemisphere). This approach attracted very considerable attention in the 1980s;
3. *The roof pond*. In this system a shallow pond or tank of water sits on a flat roof with its surface generally contained by a transparent plastic sheet. Movable insulation is essential because solar input during the summer months can be very large and it is needed to protect the building from heat losses in the winter. In the winter, the movable insulation covers the top of the pond at night and the heat from the pond can radiate down to the house. During the summer, the insulation covers the top of the pond in the day and is removed at night when the heated water can radiate out to the colder night sky;
4. *The natural convective loop*. In this system air is usually used as the heat-transport medium and works in the same way as the classic thermosyphon water heating system.[10]

Many countries now have their own national passive solar programmes. Within the Commission of the European Communities a major research, development and demonstration programme has already resulted in the publication of a *European Passive Solar Handbook*[29] which covers basic principles and concepts. Also included are case histories, references and suggestions for further reading.

12.3 Passive solar design in the UK

Passive solar design is now regarded by the government as one of the most promising renewable energy technologies in the UK.[30] The combination of current energy efficiency measures with passive solar design techniques could reduce energy costs in buildings by as much as 40% from today's levels with existing standards. The initial passive solar programme funded by the Department of Energy concentrated on establishing the worth of the resource in energy terms and it found that a contribution of up to 14 Mtce (million tonnes of coal equivalent) annually could be expected.[31].

Their first two groups of studies were carried out on housing and non-domestic buildings. Design studies were selected rather than field tests so that comparative tests could be made with one particular thermal simulation model. In the second phase of the programme several design practices have been invited to prepare building designs incorporating passive solar features. An additional feature of the second phase has been the appointment of a 'solar expert' to each project. His or her role will be to comment on all the proposals in the design. The client or customer will also be represented at this stage by a person who is already a builder or property developer. These two additions to the design process (the 'expert' and the 'client') will provide extra technical knowledge and an appreciation of real market forces.

The main objective of the Department of Energy's programme is the establishment of a Design Advice Scheme.[32] One of the anticipated outcomes from the preliminary programme is the preparation of a solar design guide for UK conditions. The Department of Energy's Passive Solar Programme is closely coordinated with other government building research and development programmes, e.g. the Department of the Environment and the Energy Efficiency Office. The Building Research Establishment also takes an active part in providing advice and participating in the programme.

12.3.1 The main technical issues in passive design

A number of issues have been identified in the literature and the UK government programme will broadly follow the guidelines already laid down elsewhere, i.e.:

1. The influence of the local climate on the optimum design;
2. How the patterns of occupancy affect the various criteria which are being evaluated;
3. The perceived advantages and disadvantages of the various passive design elements in the selected project, measured against energy use and cost, the feeling of comfort and general well-being, the amenity value and whether or not people are likely to pay for the passive features – the marketability of the design;
4. The integration of energy use into the overall design process.

12.3.2 The energy-performance assessments

As well as these design studies, a number of both domestic and non-domestic buildings have been monitored for a year each to determine the energy flows and to evaluate the quality of the environment as perceived by the users. Each study is carried out according to a clear and well-defined methodology. Standard profiles are produced at the end of each assessment and the performance is assessed alongside a similar building design without such passive features.

12.3.3 Technology transfer

This has been identified as perhaps the most important and significant part of the whole project. However, until the pattern of designs and assessments begins to emerge, it will not be possible to do more than hold some pilot or trial dissemination studies, based on the present results. Commercial clients, the householder or house purchaser, local and public authorities and institutions, and the decision makers will all need to be informed, as well as the energy professionals, especially those in the design practices not yet involved in this work. Details of the Department of Energy's pilot Design Advice Scheme were announced in 1989.[32]

12.3.4 Some UK applications

12.3.4.1 Parklands Estate, Bourneville[33]

The Parklands Estate forms part of the Bourneville Solar Village. The Solar Village covers seven sites, each containing a variety of low-energy or passive houses and believed to be the largest single solar housing project in Europe. The entire project has been supported by the Bourneville Village Trust, the Housing Corporation and the Commission of the European Communities.

The project was started in 1984 following detailed consultations with local residents and various national and government organizations. There are a number of different house types, including direct-gain passive houses for single families and two blocks of flats for elderly people. The aim of Parklands was to provide 90 single-family houses for first-time buyers and the houses had to be built within strict cost limits. Particular attention was paid to the orientation of the houses, with the majority facing south to maximize solar gain. Monotony of appearance was avoided by variety in design and by placing some houses off due south. It has been found that, on average, there is a direct-gain solar contribution of some 33% to the gross space heating load. A number of improvements have been suggested for future designs.[33] North-facing windows were thought to be too small to allow enough daylight to penetrate. The remedy would be to have larger, perhaps triple-glazed windows. There were component problems with double glazing, cavity-wall insulation and the thermal blinds (about half the houses reported blind failures). The value of the energy savings were compared with the additional cost of the energy saving measures and gave an average payback period of just under 15 years – a figure which the Bourneville Village Trust considered acceptable.

One of the 90 houses was specially adapted to have other solar and passive features, and is separately monitored. In addition to heavy insulation and large south-facing direct-gain windows, it has a large attached greenhouse (or sun space), a variable flowrate active solar water heating system linked to variable volume storage, another active solar space-heating system with phase-change energy storage, a heat-recovery system and some photovoltaic power generation.[34] This house is illustrated in Figure 12.7.

12.3.4.2 The JEL Building, Stockport[33]

This is a low energy production and office building for a company heavily involved in the manufacture of energy control and monitoring systems. It has a fully glazed south facade, in the centre of which is a two-storey atrium. The top of this atrium serves as a collection point for the solar-heated air which can be transferred directly to the production area or used as preheated air as the input to conventional heaters. Blinds on the south wall are set automatically to admit or reflect solar radiation, and other measures include a zoned building energy management system. The energy savings are approximately 50% annually for an additional 3% spent on building costs, giving an estimated simple payback period of 6 years.

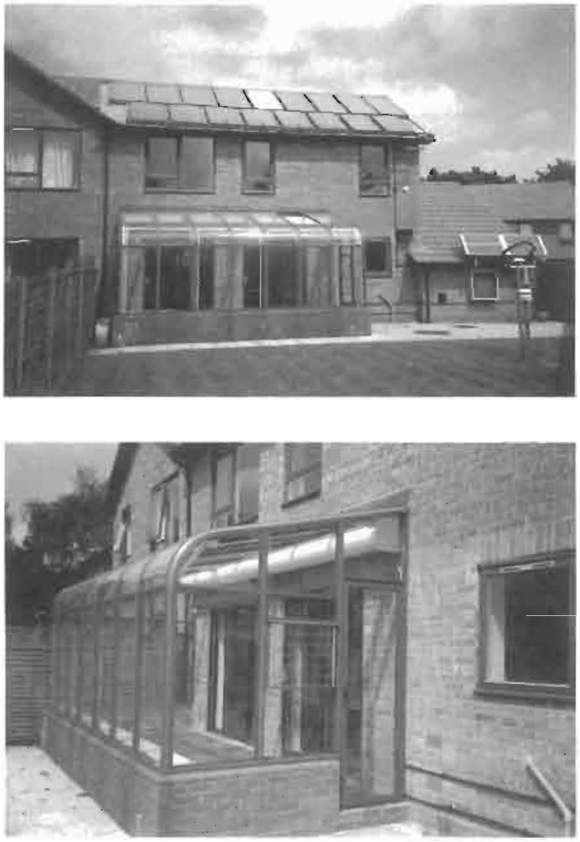

Figure 12.7 One of the houses from the Parklands Estate, Bournville

12.3.5 Atria

Modern interest in the glazed courtyard or atrium has been said to date from 1967, when two innovative buildings were completed in the USA. Since then there have been many developments in North America and Scandinavia. In the UK the majority of the 500 retail and leisure developments at present under construction are reported to feature atria.[35] Atria provide buffer spaces which protect the occupied parts of the building from the full impact of the external environment. Care is needed during the design stage in the UK to ensure that the provision of passive solar gains for heating during the heating season do not result in overheating in the summer. Another advantage of atria is that the glazed space has relatively high daylight levels. Thus window sizes can be increased as the energy penalties are reduced and daylight can be used more consciously as an alternative to artificial lighting.[36] One of the best-known examples of this design approach is the Wiggins Teape's headquarters at Basingstoke, designed by Arup Associates. This consists of a hollow rectangle built around a full-height atrium 20 m wide by 40 m long. Half the offices look outward and the rest face into the atrium, which makes daylighting and natural ventilation possible without the associated energy penalties. The economics appear to be very encouraging as the building cost 30% less than its deep-plan, artificially lit, air-conditioned predecessor (also designed by Arup Associates) and is planned to use 25% less energy.[37]

12.4 Thermal power and other thermal applications

The earliest recorded example of a solar-powered engine was reported in France in 1860 and a solar thermal water distillation plant was built in Chile with a total area of some 4700 m^2 of glass in 1872.[10] There has always been a major need for water pumping in arid regions where clear sky conditions often give long periods of direct solar radiation. The early experiments led to the most spectacular solar engine development of the time – the Shuman–Boys Sun-Heat Absorber at Meadi in Egypt in 1913. The absorber consisted of five large parabolic mirror sections each 62.5 m long and 4.1 m wide between the edges of the mirrors, giving a total collecting area of 1277 m^2. Although the maximum recorded pumping horsepower was only 19.1, this was attributed to the poor performance of the steam engine and pumping plant.[38] Using the same steam conditions a modern low-pressure steam turbine could produce about 100 hp. After these technically promising early results, very little more work was carried out on solar thermal applications for the next 40 years. Power generation from coal and oil became widespread and relatively inexpensive.

System efficiency is proportional to the product of the collector efficiency, the ideal Carnot efficiency and a factor relating actual engine efficiency to the Carnot efficiency. There is clearly a conflict between the desired collector temperature for maximum collector efficiency and the desired temperature for high Carnot efficiencies for any given ambient temperature. High collector efficiencies require the maximum temperature to be as low as possible, while high Carnot efficiencies need as high a maximum cycle temperature as possible.

It can be shown that unless a large area of relatively inexpensive collectors can be used, collectors capable of working at temperatures up to at least 250°C are essential for thermal power applications. These can be classified into two main classes – tracking and non-tracking focusing collectors – with a number of sub-groups in each class.

The two most important non-tracking focusing collectors are the compound parabolic concentrator (CPC) and the evacuated tubular collector. The CPC was developed in 1974 by Winston.[39] In cross section it appears to take the form of a truncated parabola with a vertical axis. Winston's innovation was to place the focus of the parabola forming the right-hand section at the base of the left-hand section and vice versa. With careful choice of dimensions all the incoming direct radiation was concentrated on the absorber near the base. Concentration factors up to ten can be achieved without diurnal tracking. Evacuated tubular collectors use vacuum technology to surround the absorbing collector surface, often a selectively coated pipe, with a double-walled evacuated glass tube. The focusing element plays a relatively minor role with this type. These collectors are commercially available, with typical values of between 0.84 and 0.86 for $(\tau\alpha)$ and 1.5 W m^{-2} K^{-1} for U.[40]

Tracking focusing systems can be classified into three groups. Point focusing collectors usually have a tracking parabolic reflecting dish, in which the direct solar beam is reflected to a central collecting point fixed to the dish. Line focusing collectors have an absorbing pipe placed at the focus. They are either parabolic in cross section or focused through a linear Fresnel lens, which consists of a series of wedge-shaped sections in a single flat unit, with each segment designed to concentrate the incident radiation onto the absorbing pipe. This type is often known as a trough collector. Concentration ratios of up to 40:1 can be achieved.

For high temperatures and large-scale power generation, the central 'Power Tower' system was considered. A large field of steered mirrors, or heliostats, reflect solar radiation to a single central receiver mounted on a tall tower. Concentration ratios approaching 3000:1 have been achieved with this type. The best example in the 1970s was the 1 MW solar furnace at Odeillo, built by the French Centre National de la Recherche Scientifique.[41] The parabolic mirror, which is 39.6 m high and 53.3 m wide, contains 9500 individual mirrors with a total reflecting area of 1920 m^2. It faces a field of 63 heliostats, with a total mirror area of 2839 m^2. During the 1970s studies in the United States[42] considered the design of individual units of 100 MWe capacity. The next major step towards this concept was the commissioning of a 10 MWe plant, solar one, at Barstow, California, in January 1982.

In Europe there were a number of smaller-scale complementary programmes supported by the EEC and the IEA. Their largest, known as Eurelios, was completed in Sicily for the EEC in 1981 and had two types of heliostat with a total area of 7800 m^2 and a designed output steam temperature of 450°C. Europe's largest solar power tower system was the French Themis, rated at 2.5 MW and situated a few kilometres from Odeillo at Targasone at an altitude of 1700 m. The main system consisted of a group of 201 heliostats with a total area of 10 740 m^2, facing a receiver on the top of a 101.5-m tower. There was also an auxiliary system of eleven parabolic mirror concentrators, each with a surface area of 75 m^2, to maintain the salt solution used as the heat transfer fluid above its solidification point of about 150°C. Problems were experienced with the corrosive salt solution at high temperatures and with gusty wind conditions shattering some mirrors. By July 1984 it was producing between 7000 and 8000 kWh daily, but further work on the system was terminated.

Writing about this phase of the developments in 1987, Kesselring[43] commented that there had been a number of important achievements. The amount of material (and hence overall costs) needed to build plants had been reduced, systems for higher temperatures and heat fluxes had been developed and significant progress had been made in both heliostat and receiver design.

Progress in the development of commercial line focusing solar thermal collector systems had been far more successful.[44] By 1990 over 200 MW of thermal-electric capacity had been installed in the USA, with the latest system, the Luz SEGS VIII, rated at 80 MW and having a total collector area of nearly 500 000 m^2. Estimated costs in the region of 8 cents kWh^{-1} were forecast.[45]

12.4.1 Solar ponds

A solar pond is a body of saline water in which the concentration increases with depth. In a natural pond when solar radiation heats the water below the surface the action of convection currents causes the heated water to rise to the surface and the pond temperature normally follows the mean temperature of the surroundings. A solar pond contains concentrations of dissolved salts which gradually increase with depth, causing the density of the water to increase towards the base of the pond, which is often black. Solar radiation penetrates to the base, heating the water at this lower level, but any convection currents are suppressed by the density gradient. Heat losses from the surface are reduced, compared with a natural pond, and the temperature at the bottom of the pond rises.

While there are daily fluctuations in both ambient air temperature and in the upper water layers, the temperature at the bottom of the pond, where heat would be extracted, remains fairly uniform.[46] A solar pond is both a massive heat collector and heat storage system and, compared with a conventional collector and heat store, is relatively inexpensive. Other advantages are:

1. Problems which could occur with dirt settling on the surface and reducing collection efficiency are eliminated;
2. Extracting energy from the pond is very straightforward as the lowest hot layer can be pumped to the power station and returned to the pond for reheating;
3. Solar ponds can operate continuously throughout the year provided the storage capacity is chosen to match the demand;
4. A solar pond power system can – like a hydroelectric plant – provide peaks of power on demand.

The system is illustrated in Figure 12.8.

The development of the solar pond concept has been in a series of order-of-magnitude steps, with the few kilowatts of the early 1960s being followed by the 150 kWe solar pond at Ein Bokek in the Dead Sea area, developed by Dr Harry Tabor of the Scientific Research Foundation in Israel. This was switched on at midnight on 16 December 1979 and has subsequently given outputs approaching 300 kWe. The third stage was the 5 MWe solar pond at Beth Ha'arava, also in the Dead Sea area. During the commissioning stage in 1983 temperatures above 86°C were achieved in March.[47]

Following these successful trials, in 1984 plans were announced in Israel to develop up to 2000 MW from solar ponds over a 10- to 20-year period. A disadvantage of the system is that overall conversion efficiencies from solar radiation to electricity are relatively low – in the order about 1%. However, this is offset by the equally low relative costs of the 'collector'.

Solar ponds could be particularly interesting for developing countries as they are likely to have good solar radiation conditions and about half the total costs could be found locally (in the simple materials used for the construction of the pond). The range of possible applications continues to increase, with space heating for buildings and greenhouses, process heating, space cooling, desalination and salt production already either in operation or under consideration.[10]

12.4.2 Heliohydroelectric power generation

The concept of heliohydroelectric power generation is to convert solar energy into electricity by first transforming it into hydraulic energy. If a closed reservoir is completely sealed off from the sea, the level of the reservoir will tend to decrease as a result of evaporation. Hydroelectric generators

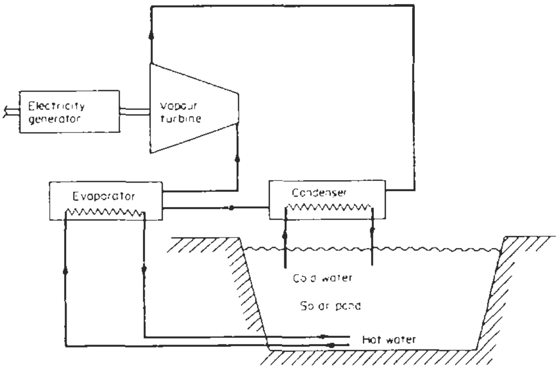

Figure 12.8 A solar pond system (after McVeigh[10])

could be placed at the reservoir end of pipes connecting the reservoir to the sea. The fall in the level of the reservoir induces a flow of water from the sea, and the potential energy caused by the difference in water levels could be transformed into electrical power. By choosing suitable water levels and power systems, it would be possible to have a continuous process. This topic has been extensively studied in Saudi Arabia by Kettani and Gonsalves,[48] who have measured evaporation rates and compared these with meteorological data. Kettani has also explored the possibility of building a dam across the Gulf of Bahrain, using the whole sealed-off Bay to create a hydraulic head from the open sea in the Gulf.

Connecting the Mediterranean Sea with the Qattara Depression for a hydroelectric scheme was first considered in 1916. This project was revived during the 1970s by a joint Egyption–Federal Republic of Germany feasibility study. The results of this study, which was completed in December 1980, were reported in 1982 but a firm decision on whether or not to proceed with the scheme was not taken.

12.4.3 Distillation

One of the major problems in many parts of the world is the scarcity of fresh water, and the development of inexpensive large solar distillation units capable of easy transportation and handling is increasingly important.[10] Solar distillation is another application which dates back to the nineteenth century and the simplest form still now in use is basically unchanged from the early designs, which consisted of a shallow tray, filled with salt or brackish water, and covered by a sloping glass cover plate. The solar radiation heats the water in the tray and evaporates it. When the vapour comes in contact with the colder surface of the glass it condenses, forming fresh water which runs down the inner surface in the form of droplets and can be collected in a trough at the lower edge. Under good radiation conditions an output of about 4 litres of fresh water can be obtained daily per square metre of cover.

Australia has gained considerable practical experience over many years, and a guide to the design, construction and installation of a solar still developed by the Commonwealth Scientific and Industrial Research Organization was published in 1965.[49] One of the best-known large installations in recent years, with an evaporating surface area of 8667 m^2, was completed on the island of Patmos in the Aegean in 1967.[50] The average distillation rate was 3.0 kg m^{-2} per day, with a maximum of 6.2 kg m^{-2} at midsummer. The first large installation designed and manufactured in the UK was a 185 m^2 unit for Aldabra in the Indian Ocean[51] in 1970. The development of various methods of improving simple still designs, such as the use of stepped salt water shelves or wicks, up to the early 1980s has been reviewed.[10] Later developments include the use of an 8 kW (peak) photovoltaic array to provide power for a reverse osmosis water desalination unit for a community of 250 people near Jeddah, Saudi Arabia.[52]

12.4.4 Ocean thermal energy

The use of the temperature difference between the surface of the ocean and the colder deep water to operate a heat engine was proposed towards the end of the nineteenth century. The oceans are natural solar energy collectors and require no special storage systems or manufactured collectors and, because of their enormous size, have considerable potential to compete economically against other methods of power generation. The earliest system was a 22 kW power plant off the coast of Cuba developed by Claude[53] in the late 1920s. It had an overall efficiency of less than 1% and operated with an open Rankine cycle in which the higher-temperature sea water was passed directly to a low-pressure evaporator to provide steam to power the turbine. It was uneconomic at that time, as was a subsequent larger project by the French some 20 years later, and further work was discontinued.

Renewed interest in the concept came in the 1960s when the possibility of using a closed Rankine cycle was suggested[54] in the USA. This work formed the basis for several major large-scale theoretical investigations which showed very similar overall net cycle efficiencies, ranging from 2.1% to 2.4%. Following these systems feasibility studies, a joint project called Mini-OTEC was developed by the State of Hawaii, Lockheed Missiles and Space Company and the Dillingham Corporation. Mini-OTEC was a 50 kW (18 kW net) plant which operated off the coast of Hawaii during 1979 to establish that the problems raised in the feasibility studies were surmountable. It was also intended to draw public and political attention to the OTEC system in contrast to the better-known solar technologies. The project was described by Henry J. White,[55] who concluded that all the goals had been achieved and that a combination of private industry with enlightened state support could design, construct, test and operate a sophisticated energy system at a cost, and in a time scale, which a more formalized procedure might be unable to attain.

Among the advantages listed for OTEC by Avery and Dugger of the Ocean Energy Program at the Johns Hopkins University[56] were

1. It can deliver energy to regions bordered by warm ocean waters via direct electric-power transmission;
2. It can also deliver energy to all other regions via an energy-intensive material such as ammonia, produced on OTEC plant ships in the tropics.

Ammonia was considered to be an outstanding choice as it could save the natural gas already used in conventional ammonia plants, it could serve as a synthetic fuel or it could provide an easily transported and storable source of hydrogen for fuel cells to generate electric power. The costs of OTEC electricity delivered directly or via fuel cells were projected to be competitive with costs from coal or nuclear plants if rapid OTEC development were to be pursued.

In the 1980s, several other countries apart from the USA had active OTEC programmes. These included France, Japan and Eurocean, a European consortium.[57] However, it was found that the main obstacles to the rapid development of OTEC systems were those facing a number of other interesting large-scale renewable energy systems. There is clearly a concern that some of the environmental problems may not have been fully appreciated. The enormous cost of the development of full-size systems in the order of 400 MW could only be provided by government funding, and there were no signs that this was likely in the early 1990s.

12.4.5 Refrigeration and cooling

The great advantage of using solar energy in refrigeration and cooling applications is that the maximum amount of solar energy is available at the point of maximum demand. There are two quite different major applications, the first in the cooling of buildings and the second in refrigeration for food preservation or for storing vaccines for medical purposes.[1]

In building applications, solar collectors can be used to provide a high-temperature input to cooling systems using solar-powered engines or absorption systems. This part of the system could be used to provide heating outside the hot midsummer period and the cost of the system could be shared between the two functions. The cooling demand is also at a maximum during the early afternoon, depending on the orientation of the building and its thermal mass, so that the storage capacity for cooling is only a few hours, in contrast to the very much greater periods required for heating systems.

Solar-powered refrigeration was first demonstrated over a hundred years ago[10] and several different systems based on the familiar absorption refrigerator were commercially available by the early 1980s. The four main methods used for refrigeration and cooling systems are as follows:

1. The vapour compression refrigeration cycle
2. Absorption systems
3. Evaporative cooling
4. Radiative cooling

In its simplest theoretical form the well-known domestic refrigerator can be thought of as a reversed heat engine. In practice, nearly all vapour-compression refrigerators are driven by electric motors. Although small solar-powered engines have been used to replace the electric motor in laboratory trials, it has proved to be too expensive to proceed to commercial applications. For future small-scale applications it is likely that conventional electrically powered refrigerators will be driven by photovoltaic cells through a d.c. to a.c. inverter, a method which is already proving to be economic in some applications.

There are two main types of absorption cooling systems. For continuous operation, the cycle is illustrated in Figure 12.9. The working fluid is a solution of refrigerant and absorbent, the most common being ammonia–water or water–lithium-bromide. When solar heating is supplied to the generator some refrigerant is vaporized and a weak mixture is left behind. The vapour is then condensed and expands to the lower-pressure evaporator, where it is vaporized and refrigerates the external working fluid, which would be air for an air-conditioning application. The cycle is completed in the absorber when the refrigerant recombines with the original solution and is pumped back to the generator.

The technology was well established by the end of 1983 when one of the largest systems in the world, the solar air-conditioning system at the Chaim Sheba Medical Centre in Israel, had been operating successfully for three years.[58] The system is powered by approximately 3000 m^2 of flat-plate solar collectors and annual savings of electricity are about 120 kWh per square metre of collector.

Intermittent ammonia–water absorption units are relatively simple to operate and have been successfully developed at the Asian Institute of Technology (AIT), Bangkok, by Professor R.H.B. Exell.[59] During the day, heat from solar collectors vaporizes the ammonia and it condenses in the condenser. At night the ammonia is passed through an expansion valve into an evaporator, where the refrigeration effect produces ice.

During the early 1980s the principal unit at the AIT could produce up to 30 kg of ice from water at 28°C, with a collector area of 5 m^2 linked to the ammonia–water system. The solar radiation was enhanced by the use of plane reflecting mirrors. Subsequently a much larger unit was developed for use in rural village communities.

Evaporative systems achieve a cooling effect through the evaporation of water. Evaporative cooling can be achieved without making the air within a building more humid by combining a vertical water heating panel with a horizontal shaded roof pond.[60] Heat is absorbed from the room, as shown in Figure 12.10. The heated water rises to the roof pond where it is cooled by evaporative cooling. An earlier simple

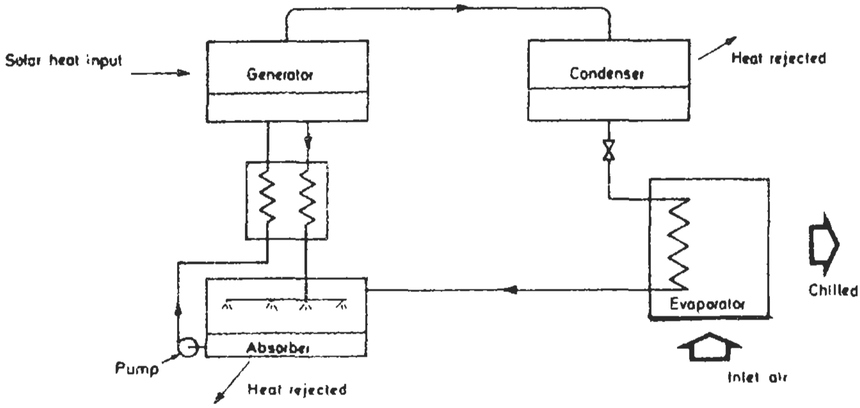

Figure 12.9 An absorption cooling system for continuous operation (after McVeigh[10])

method described by Thomason[61] takes water from a house storage tank and trickles it down an unglazed north-facing (in the northern hemisphere) roof.

Radiative cooling to the sky is possible at night with clear atmospheric conditions. Several examples of the use of the technique of pumping water into various roof-mounted collectors have been described.[10] Further examples of various applications, together with a detailed examination of the theoretical aspects of solar cooling and refrigeration, are given in a report to UNESCO by McVeigh.[62]

12.5 Photovoltaic energy conversion

12.5.1 Introduction

The direct conversion of solar energy into electrical energy has been studied since the end of the nineteenth century.[10] The early work was concerned with thermocouples of various different alloys and efficiencies were very low, usually less than 1%. Modern developments date from 1954, when the Bell Telephone Laboratories discovered that thin slices of silicon, when doped with certain traces of impurities, achieved efficiencies some ten times greater than the traditional light-sensitive materials used in earlier devices. Since then, photovoltaic cells, modules and systems have developed rapidly.[63] Improvements in their cost-effectiveness, reliability and life have resulted in photovoltaics becoming the first choice in a wide range of applications on both engineering and economic grounds, with the more recent emphasis on 'clean' electricity likely to become an increasingly important factor.

The cost of the photovoltaic module, described as 'the basic building block of the system', has fallen in real terms to about one tenth of its value in 1980 and is expected to continue to fall, unlike almost all other competitive electricity-generation systems.[64] Among the advantages listed for the modern solar cell during the 1970s were that it had no moving parts and an indefinitely long life, required little or no maintenance and was non-polluting.[65] The lifetime should now be modified to 'probably more than 20 years' and there are the normal environmental hazards associated with the manufacture of semiconductors. Unlike other types of electric generator, it is suitable for a very wide range of power applications from a few milliwatts to several thousand megawatts. Photovoltaics is now widely recognized as a mature technology, ready to move into a new phase in an expanded product market which already includes telecommunications, cathodic protection, remote power and utility demonstration projects.[64]

12.5.2 Basic principles

The basic principle of the solar cell is that the doping of a very pure semiconductor with small traces of impurities can modify its electrical properties, producing the p-type, having fixed negative and free positive charges, and the n-type (fixed positive, free negative). A typical p-type (positive) is boron-doped silicon and a typical n-type (negative) is phosphorus-doped silicon. If these two types are placed together and the surface is exposed to sunlight, electrons will diffuse through the p–n junction in opposite directions, giving rise to an electric current. The positive contact is usually a metal layer, or contact plate at the back of the cell, while the negative contact at the top (or front) of the cell collects the current and also allows as much light as possible to enter the cell. Manufacturers often quote the output of their cells in 'peak watts' or Wp. This is measured at a standard temperature of 25°C with a sunlight intensity of 1 kW m^{-2}, which is sometimes reached at noon in many Middle East countries. The power output of the solar cell varies almost directly with the intensity of the light falling on it. Halving the light intensity would also halve the current output, but the voltage would drop by only a few per cent. However, the voltage output is very temperature dependent, and decreases by about 0.5% for every degree Celsius rise above 25°C.

12.5.3 Developments

Three main types of photovoltaic module design have shown particular promise in both performance and cost. These are the crystalline flat plate, the thin-film flat plate and concentrator modules. Currently available commercial flat-plate modules are based on either crystalline silicon or thin-film amorphous silicon cells. Concentrator module installations all use single-crystal silicon cells. Crystalline silicon flat-plate modules dominated the power market, defined as arrays larger than 50 Wp, by the early 1990s, but informed opinion agreed that amorphous silicon thin-film flat-plate modules were getting an increasing share and could be dominating the market by the end of the decade.

Amorphous silicon cells have had considerable development for the consumer market. This includes all products in which the power supply is built in, such as calculators or watches. The expanding consumer market accounted for over 25% of total world production by 1990, mostly in Japan.[64]

For power applications the commonest module type is the flat-plate crystalline silicon module, using cells made from single crystal or polycrystalline material. Individual cells are series strung and then encapsulated behind low-iron-content tempered glass. By 1990, module efficiencies of 11% for single crystal cells and 10% for polycrystalline cells had been reported,[64] with the possibility that module efficiencies greater than 15% could be achieved using cells with 18% efficiency.

A European Standard exists for the testing of photovoltaic modules. UK suppliers can have equipment tested for electrical characteristics at the Royal Aircraft Establishment, Farnborough, and for mechanical integrity and environmental tests at the Solar Energy Unit at Cardiff University.[64]

It is expected that the design features leading to this improved efficiency will soon be introduced into commercial modules and that module efficiencies of 17–18% could be anticipated with single-crystal cells. One of the advantages of the crystalline silicon flat-plate module is its excellent reliability. A lifetime of between 5 and 10 years is normally guaranteed at present and operation for periods greater than 20 years is expected.

The cost of crystalline silicon modules in the early 1990s was in the order of $4–$5 per Wp. At this level they were becoming increasingly competitive with other electricity supplies.

Thin-film modules have much lower fabrication costs, because a smaller amount of the expensive semiconductor material is used and large-scale automated fabrication processes are possible. Hence the costs of amorphous silicon modules are lower than those of crystalline silicon modules. However, they have a lower efficiency, typically 6–7%, and production costs less than $1 per watt were anticipated during the early 1990s.[64]

Efficiencies of 10–11% have been reported in laboratory tests of amorphous silicon cells and these should soon be available in commercial modules. Other types of thin-film modules based on both copper indium diselenide and cadmium telluride will also be commercially available in the near future.[64]

Considerably more expensive cells can be used through optical concentration and high-efficiency cells based on both gallium arsenide and silicon as well as multi-junction cells are under development. This work aims to achieve cells with over 30% efficiency, and already an efficiency of 37% has been reported in laboratory tests[63] with a tandem of GaAs/GaSb cells. Should cells of this efficiency potential be incorporated into commercial modules, then efficiencies greater than 20% are technically feasible.

12.5.4 Systems

In addition to the basic photovoltaic module, both a supporting structure and some form of electrical conditioning are required. In space applications the supporting structure and associated electrical conditioning are highly specialized to provide both protection from the space environment and to withstand severe launching and operational conditions.

A typical terrestial module produces about 14 V d.c. and about 3 A under the peak watt intensity of 1 kW m^{-2}. Series and/or parallel connection can be used to obtain higher power levels. The load must be matched to the array and the module must be mechanically supported to withstand wind loads. Correct orientation is essential and higher outputs can be obtained if the array tracks the sun. The power output must be delivered in an acceptable form, such as a constant d.c. voltage or 240 V 50 Hz a.c. Normally this requires power-conditioning equipment.

Electrical power must be used as efficiently as possible in any stand-alone system to minimize array size and cost for any specific application. Items of equipment other than the photovoltaic modules are known as the Balance of Systems (BOS). Their cost is the BOS cost. Some BOS costs are directly related to array area and can be reduced through increased module efficiency. Area-related BOS costs include the cost of the land, preparation of the site, the array structure and associated wiring and maintenance. Small arrays can often be fitted into otherwise unused land or onto an existing supporting structure, but for arrays above 1 kWp this may not be possible. However, the area-related BOS costs can show considerable benefits of scale if large numbers of identical sub-arrays can be installed at the same time on the same site.

Power-related BOS costs include the relatively inexpensive (for all except the smallest systems) electronic control equipment. The major costs are for batteries in d.c. systems and inverters for a.c. systems. Battery characteristics (e.g. storage density and charging efficiency for low currents) are being continually improved. Battery costs represent about 50% of the module costs for most typical applications.

Inverters have also been developed specifically to match photovoltaic arrays, but the scope for significant cost reduction is limited unless a completely new inverter technology can be discovered. Total BOS costs for large arrays on low-cost easy-access land could be in the order of $5 per Wp, but can often be well above $10 per Wp. However, this might reduce to about $3 per Wp by the end of the decade, with the introduction of the improvements discussed above.

12.5.5 Applications

In addition to battery charging for many different applications in the leisure and military markets, photovoltaic modules are used in applications where a grid supply cannot reach. Photovoltaic power systems are already the first choice for some telecommunications applications and for cathodic protection because of their reliability and low maintenance requirements. Photovoltaics is also economically competitive in certain situations in developing countries (e.g. for water pumping, lighting and providing small-scale power). When problems of limited distribution and a maintenance network for modules and systems are removed, these markets could grow rapidly.

It is not yet economically feasible to connect photovoltaics into a utility grid, although there have been exceptions. For example, in the south-west of the USA, where the utility peak load coincides with the period around noon, photovoltaics are competitive with the utility peak load costs, mainly for air-conditioning loads. Several countries in Southern Europe are examining the possibility of using photovoltaics to supply mountain or island communities, especially those with large summer tourist populations.

An alternative approach to the identification of the markets for terrestrial photovoltaics has been given by Hill,[66] who identified the following four categories:

1 *Professional*. This includes cathodic protection, telecommunications, utility demonstration projects and remote power, including hybrid systems, for a variety of loads (e.g. desalination plants or navigation lights).
2 *Developing countries*. These are usually quite small-scale applications such as lighting, refrigeration, radio and TV, water pumping and normal village electrification.
3 *Consumer power*. Applications where an individual is both the purchaser and the user (e.g. in caravans, boats, in the leisure industry, or in a remote location).
4 *Consumer products*. This market is mainly for the solar-powered calculator, but includes other small items.

A major role for electricity generation within the next 25 years, using photovoltaic cells as cladding on commercial buildings, has also been envisaged by Hill.[67] This could well be the first major role for photovoltaics in the UK, as these buildings are normally only occupied during the daylight hours. To make maximum use of winter sunshine, the photovoltaic cells would be placed on south-facing vertical panels. On completion of the first stage of feasibility studies[68] the next stage should be government-supported installations of appropriate hardware to gain 20 years of real-time experience. This would give architects and clients the confidence to specify and install photovoltaic cells when they become cost-effective.

The next stage could be 500 kW (0.5 MW) plants in selected areas to provide grid-support for local utilities (e.g. for the more isolated communities). Photovoltaics could then be seen to be cost-effective on buildings other than commercial office blocks.

The UN Conference on the Environment and Development in Rio, June 1992, was asked to endorse a major role for photovoltaics, particularly for basic electrical services to the 2000 million rural poor people. Approximately 1 million basic photovoltaic systems, ranging in power from some 30 to 100 W, could be in place by 1995, rising to some 10 million by the end of the century. This would give a total installed capacity of some 300 MW. The present annual world output is estimated to be some of 60 MW (1991 estimate) and growing at about 20% per annum.

12.6 Solar chemistry

12.6.1 Introduction

The direct conversion of solar energy into stored chemical free energy has attracted research workers for many years. For example, Tsubomura[68] cites Ciamician,[69] who, in 1912, described his dream of new industry based on solar photochemical conversion which is self-sustaining and pollution-free. Ciamician also pointed out that even if in a distant future the supply of coal became completely exhausted, life and civilization would continue as long as the sun shines. An excellent review of the work in the field up to the early 1960s by Farrington Daniels[70] included a description of basic processes and suggested that detailed studies of the reaction of photosynthesis (the conversion of carbon dioxide and water into carbohydrate and oxygen) could help to point the way towards research in the quest for new photochemical reactions.

By the early 1990s, reaction temperatures between 300 K and 2500 K could be achieved by several solar collector/receiver systems. This meant that, in principle, a very large number of different thermal and/or catalysed chemical processes could be carried out.[71] The objectives of solar chemistry could be defined as the use of solar radiation to produce fuels and chemicals, or to drive chemical processes such as detoxification.[72] The three main paths which can be followed in the conversion of solar radiation are:

1. Pure thermally driven processes;
2. Totally photodriven processes; and
3. Electrochemical process;

with the end uses to thermochemistry, photochemistry and electrochemistry and the pairwise hybrids.

12.6.2 Photochemical processes

Photochemical processes have been defined by Bolton and Archer[73] as those in which the absorption of solar photons in a molecule produces excited states, or alternatively in a semiconductor raises electrons from the valence band to the conduction band. As a result of the chemical reactions which may then occur, some of the excitation energy may be stored as chemical energy or a useful chemical reaction may be catalysed. Tsubomura[69] defines photochemical conversion as a technology to synthetize valuable chemical materials or fuels by the use of solar energy. Approximately half of the total solar radiation which reaches the Earth arrives in the ultraviolet and visible range (300–700 nm) and can be used in various photochemical reactions. This often leads to systems containing highly coloured substances. The other half, which occurs in the infrared region, cannot make a useful contribution as its energy concentration is too low. The maximum overall efficiency of any photochemical energy conversion is limited to about 30% because some of the higher-energy photons of shorter wavelengths have some energy degraded as heat during the reaction. The majority of photochemical reactions are exothermic and are not suitable for converting solar radiation into stored chemical energy. The known endothermic (energy-storing) reactions which occur with visible light are, in theory, capable of producing valuable chemical fuels. A major problem has been that most of these endothermic reactions reverse too quickly to store the energy of the absorbed light.

It can be seen that two types of chemical reaction driven by sunlight are outlined above: those in which there is a net storage of solar energy and the product of the reaction could be either a fuel, such as methane or hydrogen, or electricity; and those where the reaction may be photocatalytic and the sunlight would be used to catalyse the synthesis of useful chemicals. Bolton and Archer[73] further divided the subject into the following two major areas:

1. Direct processes, in which the direct absorption of solar photons by dye molecules or a semiconductor leads to useful photochemistry or photoelectrochemistry. Work in this area is normally on a laboratory scale.
2. Thermal processes, in which concentrated sunlight generates the high temperatures used to drive useful chemical reactions. There are only a few large-scale facilities where high-temperature concentrated sunlight is available.

The general criteria for the selection of useful photochemical conversion and storage systems have been evolving since a 1957 Symposium on photochemistry in the liquid and solid states[74] (e.g. Porter and Archer,[75] Bolton,[76] Bolton and Hall[77]) and have been summarized by Bolton and Archer[73] as follows:

1. The overall photochemical process must be endergonic, i.e. result in a net storage of solar energy.
2. Side reactions leading to the irreversible degradation of the photochemical reactants and/or sensitizers must be almost totally absent.
3. The photochemical reaction should be capable of operating over a wide bandwidth of the solar spectrum, with a threshold wavelength in the red or near infrared region.
4. The quantum yield for the photochemical reaction should be very near unity.
5. The back reaction must be extremely slow under ambient conditions, but should proceed rapidly under controlled catalytic conditions, or at elevated temperatures to release the stored energy when needed.
6. The product(s) of the photochemical reaction should be readily separated from the reaction mixture and easily stored or transported.
7. The reagents and any container materials should be cheap and non-toxic, and the reaction should not be inhibited by the presence of oxygen.

Most of these requirements were not essential in photocatalytic processes where energy storage was not a consideration.[73] However, all the various systems which had been investigated up to 1990 were considered by Tsubomura[78] to be unsatisfactory because they failed to meet some of these criteria. He strongly believed that chemical conversion by means of semiconductor photoelectrochemical methods seemed to be more promising. He also pointed out that the technique of electrochemical synthesis combined with solar photoelectric conversion (by the use of solar cells) was more feasible and readily applicable, if not yet economic.

12.6.3 Chemical conversion with photoelectrochemical cells

The distinctive feature of the photoelectrochemical cell is that it can transform solar energy directly into stable chemical energy.[78] Research in this field expanded very rapidly since the work of Fujishima and Honda on water splitting with TiO reported in 1972.[79] The principle of the photoelectrochemical cell (PEC) is that either an *n*-type or a *p*-type semiconductor electrode is immersed in an electrolyte solution together with a counter-electrode. With an *n*-type semiconductor electrode an electric field is formed inside the semiconductor electrode which drives the light-induced conductive electrons into the outer circuit and drives the light-induced positive holes out into the electrolyte solutions. Where the solution contains redox agents R/Ox, the reduced species R will transform to the oxidized form Ox. If this is stable it drifts towards the counter-electrode, where the reverse reaction Ox + e → R occurs and no ultimate chemical change has taken place in the solution. As both a photovoltage and a photocurrent are generated in the outer circuit, the PEC is behaving like a photovoltaic cell. Memming[80] lists 14 PECs with different semiconductors and redox couples, four of which had relatively high (greater than 10%) conversion efficiencies. The advantage of using PECs for producing electrical energy is that they can be fabricated very easily without needing any diffusion or evaporation techniques for making the junction. Their disadvantage is that many of the known semiconductor electrodes with suitable band gaps are corrosive in aqueous solutions, while those which are stable in water have too wide a band gap.

12.6.4 Fuels

Environmental considerations are increasingly becoming more important in the utilization of solar energy to obtain new fuels at a competitive cost. One of the ideal cycles is water splitting to produce hydrogen. Hydrogen can be made by following any of the paths outlined above. e.g. thermochemical, photochemical, electrochemical or in a pairwise hybrid process.

The main features of the use of hydrogen as an energy carrier, the 'Hydrogen Energy' concept, were first outlined by Bockris and Triner[81] in 1970 and are shown in Figure 12.11.

Hydrogen forms the intermediate link between the primary energy sources and the energy-consuming sectors.[1] It is also independent of the primary energy sources used for its production. Even if these change, the intermediary energy systems of transmission, storage and conversion can remain unaltered. The hydrogen economy system is completely cyclic. Water from lakes, rivers or oceans is converted into hydrogen and oxygen. Its combustion product is water vapour, which is returned to the biosphere, and it is the least polluting of all the synthetic fuels. The well-known solar furnace at Odeillo[82] was first used to produce hydrogen and oxygen in the early 1980s, but the challenge is to make the process cost-effective, something which could come with the increasing emphasis on the true costs of fossil-fuel-induced environmental pollution. Hydrogen can also be applied in the traditional reactions of the chemical industry, or can be reacted with carbonaceous material, such as carbon dioxide, carbonates, or biomass to produce organic fuels and chemicals.[72]

Another route for the thermochemical transport of solar energy is through the CO_2 reforming of methane. The endothermic reaction of CO_2 with CH_4 to yield CO and H_2 was suggested over ten years ago.[83] Methane and carbon dioxide are reacted in a solar receiver (reformer) at high temperature to produce energy-rich products. These can be stored at ambient temperatures and can be transported over distances of some hundreds of kilometres to the consumer site. Here the reverse reaction takes place in a thermal reactor (methanator), releasing the chemical energy.[84] The process could take place on one site, with the reformer–storage–methanator linked by pipework.

12.6.5 Chromogenic materials

Chromogenic materials offer the possibility of developing advanced glazings which combine variable control of solar gain with efficient thermal insulation.[85] In a major review of the technical properties and merits of known electrochromic phenomena in 1984, Lampert[86] pointed out that most of the wealth of technical literature and patents dealing with electrochromic materials and devices was primarily for electronic information display or other small-scale applications. Consequently, only minor attention had been paid to electrochromic devices as transmissive devices. Since then, transparent apertures employing photochromic, thermochromic or electrochromic materials have been the focus of intensive worldwide research by many groups[87,88] concerned with the efficient use of energy in buildings.

The electrochromic window is the most advanced example of these efforts. It is basically a multilayer thin-film device which performs as an electric cell, and consists of an electrochromic layer and a counter-electrode, or ion-storage layer, separated by an ion conductor. For window applications these layers are commonly sandwiched between two transparent electronic conductors which are deposited onto transparent substrates (e.g. glass or polymeric materials). In operation a d.c. electric field is applied across the transparent conductors and ions are driven either into or out of the electrochromic layer, causing reflectance and/or absorptance modulation of visible and near-infrared electromagnetic radiation and hence changes in the optical properties of the device. The electrochromic layer may be caused to colour or bleach in a reversible way under the influence of the external electric field. The principal aim of current research is the development of a stable, durable, all solid-state electrochromic device – the 'smart window'.[87]

Liquid-crystal-based chromogenic materials have also been successfully used as electrically activated devices.[89] Two transparent electrodes provide an electric field to change the orientation of liquid-crystal molecules interspersed between the electrodes. The orientation of the liquid crystals alters the optical properties of the device. Two main types of liquid crystal systems, the guest–host and polymer-dispersed or encapsulated devices, have been identified for large areas. Their disadvantages are that their unpowered state is diffuse, haze remains in the activated (transparent) state and ultraviolet stability is poor. A third approach uses suspended particle devices, but various technical problems such as long-term stability and cyclic durability have slowed their development.

Two non-electrically activated devices use photochromic or thermochromic materials. Their research histories date back at least 100 years.[87] When photochromic materials are exposed to light they change their optical properties, only reverting to their original properties in the dark. Photochromic plastic has been developed for ophthalmic use and could become useful for regulating solar glazings.[87] Thermochromic materials display a large optical property change when a particular temperature is exceeded. Above this critical temperature, transmittance is reduced and if this temperature is close to a comfort temperature thermochromism could be used for automatic temperature control in buildings.[89]

12.6.6 Transparent insulation materials

A new technology is emerging from European initiatives which will bring about revolutionary changes in the building industry.[90] Transparent (or translucent) insulation materials are a relatively new class of materials which combine the uses of glazing and insulation in the traditional design of any solar thermal system. While the primary use of glazing in buildings has also been to allow light to enter, its ability to transmit radiation gives it the subsidiary function of providing solar heat.

Insulation suppresses conduction and convection losses from buildings, but the traditional opaque materials such as polystyrene granules or foam which have been developed for this purpose are equally effective in suppressing solar gain from the outside of the building. For large energy gains both high irradiation levels and high values for the product of the solar transmittance and absorptance of the absorber are essential. The influence of insulation (*U*-value) depends on the temperature level of the system and the desired heat storage period. For low *U*-values very good absorption is needed in the thermal wavelengths, although infrared selective coatings can also be used on the front cover or the absorber plate to reduce infrared radiation losses.[91] Convection losses can be greatly reduced by the use of structured materials such as capillaries and honeycombs or low-pressure systems. Until recently no natural or man-made product could offer both high-transmission, low-conduction and strong convection suppressant characteristics, but by the mid-1960s it was possible to conceive the potential benefits of such a material.[92] Following rapid advances made in Germany during the 1980s the term 'transparent insulation' was accepted as best describing the goal of the technology.[93]

The first experimental results were presented in 1985 by Wittwer *et al.*[94] and the following four generic types which display different physical properties were first proposed in 1986:[95]

Type	*Examples*
Absorber-parallel	Multiple glazing, plastic films
Absorber-perpendicular	Honeycombs, capillaries
Cavity structure	Duct plates, foam
(Quasi)-homogeneous	Glass fibres, aerogels

By 1990 several systems had become commercially available and considerable potential for more scientific research work had been identified.

12.6.7 Solar detoxification

The ability of sunlight to detoxify waterborne chemicals is well known through the cleansing of polluted streams as they flow through areas open to direct solar radiation. Solar detoxification uses this natural process of degradation to produce non-hazardous substances from hazardous organic chemicals. As conventional detoxification methods do not always deal adequately with chemical wastes, the solar route is attracting attention.[96] Among the advantages are that, by using the sun as the energy source, there is no added airborne pollution or use of conventional fossil fuels. Solar detoxification breaks down the hazardous chemicals into an environmentally benign or easily treated end-product in one step. However, conventional processes often remove the wastes from the water and take them elsewhere for treatment, thus increasing the possibility of further contamination.

The detoxification of water is a photochemical process which destroys contaminants by the chemical action of light and a semiconductor catalyst.[97] When exposed to sunlight, the catalyst absorbs the high-energy photons and reactive chemicals, the hydroxyl radicals, are formed. These radicals are powerful oxidizers and break down the contaminant molecules, typically forming carbon dioxide, water and dilute mineral acids (e.g. hydrochloric acid), which can be neutralized in a post-treatment process before the treated water is discharged.

Among the common toxic chemicals which could be solar treated are trichloroethylene and other chlorinated solvents,[96] pesticides, wood preservatives, dyes typically found in textile mill effluent and leakages or spills of various liquid fuels.[96] Dioxins in PCBs can now be destroyed by solar energy and these laboratory techniques should reach the market by 1995.[98]

12.6.8 Chemical heat storage

Thermal energy storage is essential for many solar thermal applications. The properties of suitable salt hydrates were first discussed by Telkes[99] in 1974. Sodium sulphate decahydrate, mixed with 3–4% borax as a nucleating agent if complete crystallization is to be obtained, was the most-tried material, with a transition temperature close to 30°C. The problem of a barrier being formed between the liquid and solid phases proved very difficult to solve and numerous polymeric stabilizers were tried. Many different salt-phase change materials have been tried in the past two decades, including calcium chloride hexahydrate and sodium acetate trihydrate, and modified varieties covering a range of transition temperatures from about 8°C to 58°C, several of which were commercially available in 1990.[97] For high temperatures, molten nitrate salt receivers have been designed for the 10 MWe Solar One electricity generating pilot plant discussed in Section 12.4.

12.6.9 Other applications

12.6.9.1 Surface transformation of materials

Highly concentrated solar energy, typically greater than 1 MW m^{-2}, provides a controlled method for delivering large flux densities of broadband radiation to solid surfaces, thus creating the solar-induced surface transformation of materials. Candidate technologies identified by Pitts *et al.*[101] are shown in Table 12.2.

12.6.9.2 Thermochemical heat pump

A thermochemical heat-pump system, consisting of a fixed-focus parabolic solar collector, a stationary thermochemical metal hydride storage unit and various sub-systems has been investigated at the laboratory stage.[102] It could provide a small, independent solar-powered home-energy centre for countries with good solar radiation conditions. The basic principles are that sunlight is concentrated in the fixed-focus solar concentrator and heats the Stirling engine generator, producing electricity, and dehydrogenates the high-temperature magnesium hydride storage unit. The freed hydrogen is transferred to a second low-temperature hydride storage unit, and may be recycled to the high-temperature unit (hydrogenation) through a valve. The chemical systems are as follows:

Storage: $MgH \rightarrow Mg + H - 75\ \mathrm{kJ\ mol^{-1}}$
Release of stored heat: $Mg + H \rightarrow MgH + 75\ \mathrm{kJ\ mol^{-1}}$

Table 12.2

Technology	*Present uses*
(1) Chemical vapour deposition	Electronics, hard-facing corrosion
(2) Diffusion coatings	Pack cementation
(3) Layered thin films	Electronics, photovoltaics
(4) Melted powdered coatings	Corrosion, hard-facing, ceramics
(5) Rapid thermal annealing	Electronics, photovoltaics
(6) Self-propagating high temperature	Ceramics, refractory powders synthesis
(7) Transformation hardening	Steel industry
(8) Zone-melting recrystallization	Electronics

As yet, a Stirling engine for remote, maintenance-free applications has not been developed, but this remains one of the main development goals of the project team.[102] Main parameters for an aperture area of 3 m^2 are 4 kWh of high-temperature energy (heat) for cooking + 3.4 kWh of electricity + 3 kWh of heat for domestic hot water + 3 kWh cooling energy for a refrigerator.

12.7 Hydropower

12.7.1 Introduction

Hydroelectric power is the world's largest commercially available renewable energy source, accounting for about 6.7% of the total primary energy consumption.[103] Water has been used as an energy source for thousands of years, but the various traditional designs of watermill used until the nineteenth century could only lead to a technical dead end.[104] None of them were capable of using a head of water much greater than their own diameter. Further progress followed with the development of the water turbine which was subsequently linked to an electric generator. Although credit for the world's first hydroelectric plant is often attributed to the US plant which started in the autumn of 1882 at Appleton, Wisconsin, two plants were already operating in the UK at that time.[105] The earliest was Sir William Armstrong's small hydroelectric plant, rated at just under 5 kW, which was constructed in 1880 to light his picture gallery at Cragside, Northumberland, some 1.5 km away. The first public supply of electricity was reported from Surrey in 1881, when electric current generated from the waters of the River Wey was used to light the streets of Godalming. The cables had to be laid in the gutters as there was no legal authority to dig up the streets.

The world's first large hydroelectric plant was built in 1895 at the Niagara Falls in the United States, with two turbines each rated at 4100 kW.[106] The subsequent development of alternating current by George Westinghouse in 1901 allowed electric power to be transmitted over long distances.[107] By 1903 Canada had a 9.3 MW plant, also at Niagara Falls, and the era of modern hydropower had commenced. The first reliable survey of water turbines manufactured and installed throughout the world in the late 1920s[108] suggested that about 40% of the world's electricity was generated by hydropower, with the United States and Canada having a combined operating potential capacity of over 13 000 MW and five other countries (France, Japan, Norway, Sweden and Switzerland) with operating potential capacities greater than 1000 MW. A few of the earlier hydropower plants, known as run-of-the-river plants, could not generate any power when the river was low during the dry season, but by the 1930s the use of large dams had been established in the United States. The creation of the Tennessee Valley Authority in 1933 with their comprehensive approach to the planning and development of river basins set a pattern which has been widely followed in other countries.[107] Since then there has been a steady growth in hydropower throughout the world although the percentage share of hydropower in meeting world electricity demand had fallen to about 25% by the early 1990s.

During the 1980s, the total output from North America and Europe remained unchanged, but their share of the total world output dropped from just under 60% to 45%. Among the developing countries, Brazil, Ghana, Mozambique, Zaire and Zambia obtained over 85% of their electricity from hydropower.[103,109]

The potential for development of hydropower over the next 40 years is so great that it could provide an output equivalent to the total electricity generated in the world from all sources in the early 1980s. Most of this potential is in the developing countries, some of whom could, in theory, increase their present use of hydropower by a factor of ten or more.

12.7.2 The basic hydropower plant

The basic principles of hydroelectric power generation are shown in Figure 12.12. Water at a high level, often stored behind a dam, falls through a head z. Its gravitational potential energy is converted to kinetic energy and the flowing water drives a water turbine. The rotating turbine shaft drives the electric generator to produce electricity.

The theoretical maximum velocity is obtained by equating the gravitational and potential energies as follows:

$$gz = 1/2\ v^z$$

If the volumetric flowrate is Q ($m^3\ s^{-1}$), density ρ ($kg\ m^{-3}$), then the power output in watts is given by

$$\rho\ Q\ g\ z$$

12.7.3 Types of turbine

Turbines can be classified according to the direction of the water flow through the blades, e.g. radial, axial or combined-flow turbines, or as reaction, impulse or mixed-flow turbines. In reaction turbines there is a change of pressure across the turbine rotor, while impulse turbines use a high velocity jet impinging on hemispherical buckets to cause rotation. There are three basic types of turbine broadly related to low, medium or high heads.[1]

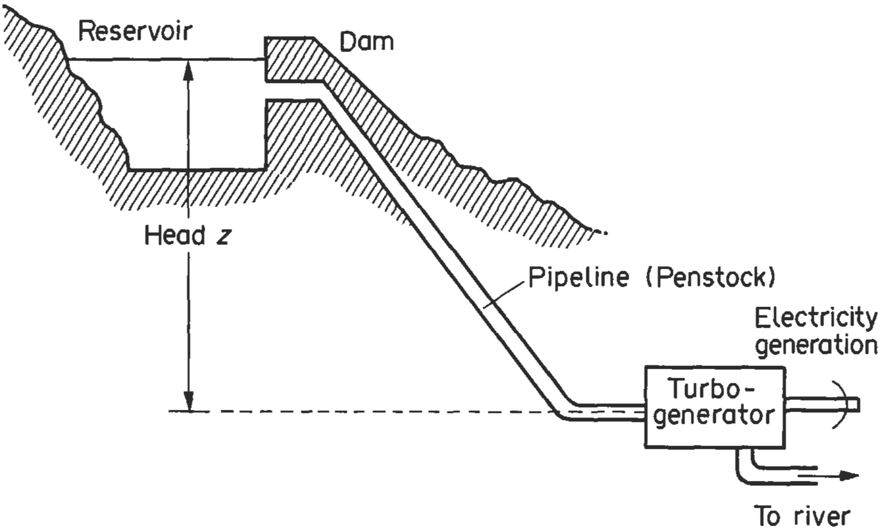

Figure 12.12 The basic principles of hydroelectric power generation (after McVeigh[1])

Propeller or axial flow turbines are used for low heads in the range from 3 to 30 metres. They can have relatively inexpensive fixed blades, which have a high conversion efficiency at the rated design conditions but a poorer part-load efficiency, typically 50%, at one third of full rated output. Alternatively, the more expensive Kaplan turbine has variable-pitch blades which can be altered to give much better part-load efficiency, perhaps 90% at one third of full rated output.

The Francis turbine is a mixed-flow radial turbine and is used for medium heads in the range from 5 to 400 m. It has broadly similar performance characteristics to the fixed-blade propeller type and its speed is controlled by adjusting the guide vane angle.

The best-known impulse turbine is the Pelton wheel. Each bucket on the wheel has a centrally placed divider to deflect half the flow to each side of the wheel. It is normally used for heads greater than 50 m and has good performance characteristics over the whole range, very similar to the Kaplan turbine, reaching 60% efficiency at one-tenth of full rated output.[1] The speed is controlled by a variable inlet nozzle, so that with a constant head, the delivered torque to the generator is proportional to the flowrate and the turbine speed can be held at that required for synchronous generation at the particular grid frequency. This type of installation is known as a constant-speed/constant-frequency system and optimization of the power output is relatively easy.[110] In smaller installations, optimum power cannot be obtained at constant speed where the hydraulic head is both relatively low and variable over a wide range.

A detailed description of methods which can be used for optimizing electric power from small-scale plant has been given by Levy.[110] He points out that small hydroelectric systems will become more financially attractive through developments of low-cost power converters (from 100 W upwards), special variable-speed/constant-frequency generators and cheap computing units for on-line power measurement and optimizing control. This means that many run-of-the-river sites that were considered in the past to be unsuitable for electricity generation can now be used.

12.7.4 Hydropower potential

The Earth's energy flow diagram (Figure 12.1) shows that just over 4×10^{16} W flows in the hydrological cycle of evaporation, rain, other precipitation and storage in water and ice. A very small proportion of this hydrological energy flow, probably between 0.01 and 0.015%, is considered to be theoretically available for conversion into hydropower.[109,111] This theoretical world hydropower potential is calculated as the total energy potential of river discharges relative to a datum of sea level or the base level of erosion for closed basins and is widely quoted as 44.28×10^{12} kWh per annum.[109,111] However, this figure does not seem to include the 3.94×10^{12} kWh for the former USSR, which was separately listed by the 1980 World Energy Conference,[109] and there is also some doubt as to whether the 6×10^{12} kWh estimated for the People's Republic of China has been included.[111] A better assessment is the 'technically usable hydropower potential', which allows for the unavailability of certain river reaches, mainly those near estuaries. This is less than half the theoretical value. The 'economic potential' includes all hydropower resources which are regarded as economic compared with alternative sources of electric power at the time of the assessment. These can be classified into three categories: operating, under construction and planned, as shown in Table 12.3. The economic operating hydropower potential of 372.1 GW represented just under 16% of the technically usable potential.

The world operating potential of some 372.1 GW could, in theory, have provided $372.1 \times 10^9 \times 365 \times 24$ watt-hours or 3.26×10^{12} kWh. The actual energy generated was 1.65×10^{12} kWh.[7] This represents 50.6% of the potential, a typical figure for most hydroelectric plant. Not only are there seasonal fluctuations in water availability, but the demand for electricity fluctuates and plants need to close for maintenance. In the United States and Canada the figure of (actual energy generated) divided by (theoretically available potential) was 47.7% in 1979. This ratio is known as the load factor. As the electrical power from a hydroelectric plant can be used directly without the conversion losses and wasted heat associated with conventional fossil fuel power plant, the primary energy equivalent of

[a] Figures from Asia probably do not include data from the People's Republic of China.[111]
[b] Figures may not include all small hydropower plant.
[c] Estimated.

hydroelectricity is usually taken as about three times its actual output.

A common conversion is that 4000 kWh of 'electricity generated' is considered to have the primary energy equivalent of one tonne of oil.[103]

By 1980 there had been a steady growth in hydropower for many years at about 3.5% per annum, representing a doubling period every 20 years. This figure was used by the 1980 World Energy Conference to estimate that hydropower could be quadrupled by 2020, reaching a total of over 1600 Mtoe. A more realistic figure was suggested by McVeigh[1] with a logistic equation approach giving a growth rate of just under 3%. By the early 1990s, however, it could be seen that growth in the decade of the 1980s had only averaged 2.0%, and that the doubling period had stretched to about 35 years. Reasons for this could include the gradual reduction in performance of some of the older hydro schemes due to silting, and the changing patterns of rainfall, which, in turn, could be due to global warming.

12.7.5 Pumped storage

Pumped storage systems are used at times of peak demand for electricity. The water can be pumped to an upper storage reservoir usually at night when the demand is low, and then allowed to flow down through the turbines, generating electricity when it is required.

Although small pumped storage schemes were first built in the 1890s, the first large system in the UK was built at Ffestiniog, Wales, in 1963, with four 90 MW generators each coupled to separate pumps and turbines on the same vertical shaft.[112] This was soon followed by a 4 × 100 MW system at Cruachan in Scotland.

The largest pumped storage system in Europe was completed in 1984 at Dinorwig, near Llanberis in North Wales. During its construction 3 million tonnes of rock were excavated from the heart of the mountain between two reservoirs and 16 km of shafts and tunnels were created.[112] The upper reservoir is 568 m above the underground power station and the horizontal distance between the upper and lower reservoirs is 3200 m. There are six turbogenerator units, each rated at a nominal 300 MW. It can generate at full output for about 5 hours. The overall efficiency of any pumped storage system is less than the 'once-through' conventional plant, as the pumping efficiency during the return flow to the upper reservoir must be included. This pumping efficiency, typically about 90%, reduces the overall efficiency to about 70–75%. However, the economics are quite different. Pumping to the upper reservoir only occurs when the electricity tariffs are low. Electricity is supplied to meet peak demands when tariffs are usually at their highest. Further, the use of a pumped storage system reduces the need for additional conventional plant which would only be needed for very short periods each year. The pumped storage plant at Dinorwig can be generating electricity within 10 seconds of requirement.

Other benefits, apart from the reduction in utilization of both high-cost oil-fired and low-efficiency coal-fired plant during the peak demand periods, include a reduction of both the extent and the duration of frequency excursions arising from large losses of generation output or the sudden increase in consumer demand experienced at the end of many popular television programmes.[112] This is often up to 2000 MW in a few minutes. Dinorwig has given the system the ability to pump prior to the impact of the television 'pick-up', thus creating an artificial demand. As the real demand increases, the pumps can be reversed to generate within 90 seconds.[112]

12.7.6 Small-scale hydropower

One of the needs in many parts of the world is for electrical power in remote regions far from a conventional transmission system. Small-scale hydropower is again becoming considered for an increasing number of these applications.

Recently, the energy policies adopted by the different Member States of the European Economic Community to reduce their dependence on third countries as suppliers of energy, together with the technical improvements outlined above, have made it possible for small hydropower plants to become competitive in many parts of Europe.[113]

The early history of hydropower up to the 1930s was largely dominated by small plants, less than 1 MW in capacity, but then the economies of scale began to favour large-scale development. Until fairly recently it was necessary to match the turbine design very carefully to the particular site. This resulted in an expensive special 'one-off' hydropower generator. The smaller the application, the greater the installed cost per kilowatt of capacity. The need for these specially designed systems has been largely overcome by the use of standardized turbines and associated equipment, with the acceptance of some loss in overall plant efficiency and performance.

As outlined above, one of the major factors which could favourably influence the economics of small-scale hydropower is the development of microprocessor-based electronic load governors. These can overcome problems of instability in matching waterflow to a variable demand and can also reduce costs as expensive mechanical controls are no longer necessary.

Definitions of the size of any hydro scheme into Large, Small, Mini and Micro appear in the literature, but there seems to be no agreement on what these sizes represent, as Table 12.4 shows.

Bazaga[113] points out that the definition of small hydropower plant is 'not exactly the same in the different Member States of the EEC' and bases his analyses on a power capacity less than or equal to 10 MW. Among the distinctive features of small hydropower plants which he identifies are:

1. They are usually run-of-the-river and the energy produced depends on the available flow.
2. They rarely contaminate the environment and do not give off heat.
3. They can be built in a short period of time, with standard equipment and well-known construction processes.
4. Projects can be developed which combine electricity generation with other uses.
5. The power source is reliable, within its hydrological limitations. The equipment and facilities involved have a long life, require little maintenance and seldom break down.
6. The technology involved is well developed and overall efficiency is over 80%.
7. Operating systems are often automatic, leading to low operation and maintenance costs.

By the 1980s the country with the greatest experience in small-scale hydropower development was the People's Republic of China, where nearly 100 000 plants have been constructed in the past 20 years.[111] Most of their recent plants have a rated output of some 300 kW and much of their projected increase in hydropower over the next 20 years will also be small-scale.

12.7.7 Economic, social and environmental issues

The costs and benefits of hydropower plant are usually evaluated by an economic comparison with conventional thermal or nuclear power stations. The main factors which must be considered, in addition to increases in construction costs, are changes in the cost of fossil fuels and in environmental protection regulations. Although there has been a steady growth in power station construction costs in all countries over the past two decades, thermal and nuclear power station costs have risen at a greater rate than those of hydropower plants. There are two reasons for this. The technology and management of the construction of hydropower plants has improved relative to conventional power station construction and new environmental protection and safety regulations have adversely affected the cost of nuclear and coal-fired power stations.[111] These new regulations have resulted in greatly increased expenditure for the control of air and water pollution with coal-fired stations, and for radiation monitoring and control together with improved safety standards in nuclear installations. Some of the adverse effects of hydropower schemes, such as the essential reinforcement of river banks or compensation for moving and resettling whole communities from flooded land, have always been included in the overall construction costs.

An economic advantage when considering the later stages in any hydropower scheme is that dams with existing hydropower schemes can be raised to provide both additional storage capacity and a potentially increased output. Turbine generators can be added to some existing storage reservoirs to create new generating capacity.

The economics of any hydropower system are absolutely site-specific, depending critically on the topology, geology and hydrology of the site.[64] These factors influence the power capacity and developments costs, which, in turn, depend on what is required from the system (e.g. a high or low load factor) or whether storage is required or not. Hydropower, like tidal power, is highly capital-intensive and can have a very long life, often over a hundred years for the basic civil engineering work. With the low operation and maintenance costs, together with the other advantages outlined by Bazaga above, the main economic problems arise from the financial requirements of high interest rates and the demand for short 'payback' periods.[64] Again, as with tidal power, there is a zero fuel cost, and the UK Watt Committee also commented[64] that it is paradoxical that investment in hydro schemes looks extremely favourable in retrospect.

Rivers and streams are regarded in the great majority of countries throughout the world as a public resource. Their use in potential hydropower schemes is subject to government control. Hydropower development may be socially acceptable to some sectors of the community and have quite disastrous effects on others. For example, the construction of the Aswan High Dam in Egypt resulted in the destruction of the sardine fishing industry in the Eastern Mediterranean, but this was balanced by the development of a new fishing industry on the newly created Lake Nasser.[107] There have been many studies on the adverse impacts on health which can result from the large dams associated with hydropower projects[107] and it would appear that there is still a need for major health-education programmes to be associated with these projects, so that diseases such as bilharzia and malaria could be eliminated. Other associated environmental problems include the need for extensive drainage systems on newly irrigated land and the threats to new dams caused by widespread deforesta-

Table 12.4 Power output ranges

Micro	Less than 500 kW	Less than 100 kW	

tion and soil erosion many kilometres upstream. Some existing aquatic and terrestial ecosystems have been disrupted and there may have been a loss of visual amenities in scenic areas.

On the other hand, the United Nations Hydropower Panel[111] has also drawn attention to the positive effects of hydropower reservoirs on the environment. The creation of regulating reservoirs has been shown to make a substantial improvement in the water supply for domestic, industrial and agricultural purposes in many cases. The danger of catastrophic floods has often been eliminated. The overall effects of hydropower schemes throughout the world have been beneficial, although there have been some largely unanticipated adverse reactions with the environment. These could either be reduced or eliminated through careful resource planning.

12.7.8 Summary

Hydropower is the only renewable energy resource with a fully developed technological base and a relatively predictable growth rate over the next few decades. Its industrial infrastructure is well established in many countries, and it provides very substantial proportions of the electricity demand in a number of countries. Although it accounted for only 6.7% of the world's primary energy consumption in 1990, this figure could easily rise to over 10% by the middle of the next century. It is particularly suitable for the needs of remote communities in the developing countries.

12.8 Wind power

12.8.1 Introduction

Energy from the wind is derived from solar energy, as a small proportion of the total solar radiation reaching the Earth causes movement in the atmosphere which appears as wind on the Earth's surface.[1] The wind has been used as a source of power for thousands of years and the traditional horizontal axis tower mill for grinding corn, with sails supported by a large tower, rather than a single post, had been developed by the beginning of the fourteenth century in several parts of Europe. Its use continued to expand until the middle of the nineteenth century, when the spread of the steam engine as an alternative, cheaper, source of power started its decline. Nevertheless, before the end of the nineteenth century several countries used the windmill as one of their main sources of power. In the Netherlands[115] there were about 10 000 windmills giving power outputs of up to 50 kW. In Denmark housemills were often mounted on the roofs of barns and, together with industrial mills, were estimated to be producing about 200 MW from over 30 000 units.[116] In the United States[115] an estimated 6 million small multi-bladed windmills for water pumping were manufactured between 1850 and 1940.

Work on the development of wind-generated electricity started in Denmark in 1890 when Professor P. La Cour obtained substantial support from the Danish government, which not only enabled him to erect a windmill at Ashov but provided a fully instrumented wind tunnel and laboratory. Between 1890 and his death in 1908, Professor La Cour developed a more efficient, faster-running windwheel, incorporating a simplified means of speed control, and pioneered the generation of electricity. The Ashov windmill had four blades 22.85 m in diameter, mounted on a steel tower 24.38 m high. Power was transmitted, through a bevel gearing, to a vertical shaft which extended to a further set of bevels at ground level, and the drive was connected to two 9 kW generators – the first recorded instance of wind-generated electricity. By 1910 several hundred windmills of up to 25 kW capacity were supplying villages with electricity. The use of wind-generated electricity continued to increase in Denmark and a peak of 481 785 kWh was obtained from 88 windmills in January 1944.[117]

Large-scale modern windpower dates from the designs of an American engineer, Palmer C. Putnam[118] in the 1930s. He was responsible for the Smith–Putnam windmill which was erected at Grandpa's Knob in central Vermont in 1941. It had two blades with a diameter of 53.34 m, and at that time it was the world's largest ever windmill, a record it was to hold for the next 35 years. The synchronous electric generator and rotor blades were mounted on a 33.54 m tower and electricity was fed directly into the Central Vermont Public Service Corporation network. The windmill was rated at 1.25 MW and worked well for about 18 months until a main bearing failed in the generator, a failure unconnected with the basic windmill design. It proved impossible to replace the bearing for over two years because of the war and during this period the blades were fixed in position and exposed to the full force of the wind. Also, in 1942, cracks had been noticed around some rivet holes, but these were considered to be so small that they could be ignored. On 26 March 1945, less than a month after the bearing had been replaced, the cracks widened suddenly and a spar failed, causing one of the blades to fly off. The S. Morgan Smith Company, who had undertaken the project, decided that they could not justify any further expenditure on it, apart from a feasibility study on the installation of other units in Vermont. This indicated that the capital cost per installed kilowatt would be some 60% greater than conventional systems.

Although sceptics have tended to regard this experiment as an expensive failure, it was the most significant advance in the history of windpower. For the first time, synchronous generation of electricity had taken place and been delivered to a transmission grid. Both mechanical failures were due to a lack of knowledge of the mechanical properties of the materials at that time. Bearing design and the problems of fatigue in metals have been studied extensively since then and similar failures are less likely to occur in modern windmills.[119] Their research programme included an extensive series of on-site measurements, which proved that the actual site at Grandpa's Knob had a mean wind velocity of only 70% of the original estimated velocity and that many other sites should have been selected. The technical problems of converting wind energy into electricity had been largely overcome and the possibility of developing wind power as a national energy resource in any country with an appropriate wind climate has been established. However, very few wind turbines were to be built over the next 30 years.[1]

12.8.2 Wind-energy potential

Wind has a dependable annual statistical energy distribution but a complete analysis of how much energy is available from the wind in any particular location is rather complicated. It depends, for example, on the shape of the local landscape, the height of the windmill above ground level and the climatic cycle. Somewhat surprisingly, the British Isles have been studied more extensively than practically any other country in the world[120,121] and the west coast of Ireland, together with some of the western islands of Scotland, have the best wind conditions with mean average wind speeds approaching 9 ms^{-1}. The kinetic energy of a moving air stream per unit mass is $\frac{1}{2}V^2$ and the mass flow rate through a given cross-sectional area A is $\rho A V$, where ρ is the density. The theoretical power available in the air stream is the product of these two terms:

$$\tfrac{1}{2}\rho A V^3$$

If the area A is circular, typically traced by rotor blades of diameter D, then $\pi/4D^2 = A$, and the power available becomes

$$\frac{\pi}{8}\,\rho D^2 V^3$$

The actual power available can be conveniently expressed as

$$C\,\tfrac{1}{2}\rho A V^3$$

where C is the coefficient of performance or power coefficient.

The maximum amount of energy which could be extracted from a moving airstream was first shown by the German engineer Betz, in 1927, to be 16/27 or 0.59259 of the theoretical available power. This efficiency can only be approached by careful blade design, with blade-tip speeds a factor of six times the wind velocity, and is known as the Betz limit. Modern designs of windmills for electricity generation operate with power coefficient values (C) of about 0.4, with the major losses caused by drag on the blades and the swirl imported to the air flow by the rotor.[122] Any aerogenerator will only operate between a certain minimum wind velocity, the starting velocity V_S, and its rated velocity V_R. Typically, V_R/V_S lies between 2 and 3. If the pitch of the blades can be altered at velocities greater than V_R, the system should continue to operate at its rated output, the upper limit depending only on the design. In some systems the whole rotor is turned out of the wind to avoid damage at high wind speeds. An annual velocity duration curve for a continuously generating windmill is shown in Figure 12.13.

The effect of the height of the windmill tower on the performance can be significant and empirical power law indices have been established[123] relating the mean wind velocity V to the height H, in the equation $V = H^a$. A value of $a = 0.17$ is the accepted value in the UK for open, level ground, but this rises to 0.25 for an urban site and 0.33 for a city site. An ideal site is a long, gently sloping hill.

The mean annual wind velocity is normally used to describe the wind regime at any particular location, but the output from a windmill is proportional to V^3. Since a transient arithmetic increase in wind velocity will contribute much more energy to the rotor than an equal arithmetic decrease will deduct, the mean of V^3, which is always much greater than the cube of the mean annual wind velocity, should be used. For example, if the mean wind velocity is 8 ms^{-1} the most common variation in wind velocity occurs at frequent short intervals between 6 ms^{-1} and 10 ms^{-1}[116] and $8^3 = 512$, whereas $\tfrac{1}{2}(6^3 + 10^3) = 608$. A useful concept is the velocity exceeded for 50% of the year (4380 hours), shown in Figure 12.13 as V_{50}. This is quite close to the mean annual wind speed and has been used to give the annual extractable energy E_a if the rotor shaft is attached to an electrical generator as[124]

$$E_a = 3.2289\, D^2\, V_{50}{}^3 \text{ kWh}$$

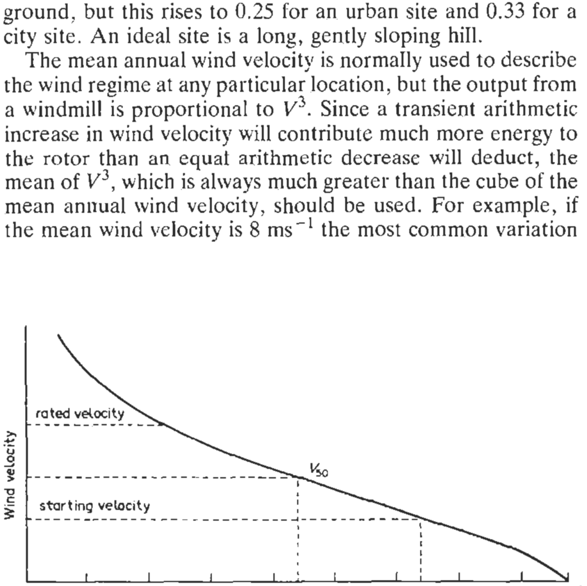

Figure 12.13 Annual velocity duration curve for a continuously generating windmill (after McVeigh[1])

The Betz limit, outlined above, is purely theoretical, and in practice the power extraction efficiency will be reduced if either:[125]

1. The blades are so close together or rotating so rapidly that a following blade moves into the turbulent air created by a preceding blade; or
2. The blades are so far apart or rotating so slowly that much of the air passes through the cross section of the device without interfering with a blade.

The rotational frequency of the wind turbine must be matched to particular wind speeds to obtain the optimum efficiency. The power extraction is therefore a function of the time taken by a following blade to reach the position occupied by the preceding blade, and the time taken for the normal airflow to become re-established once the disturbed air has left that position. This has resulted in a very important parameter – the tip speed ratio – defined as the speed of the turbine blade tip divided by the speed of the normal airstream, or oncoming wind. A more detailed analysis can be found in the standard literature.[125]

For the great majority of wind-power applications, however, it is more important to know the probability that a minimum site wind velocity will be exceeded. Long periods of no wind or only light winds are obviously unacceptable. Matching the wind turbine to the characteristics of any particular site has needed the use of probability functions, the best known being the Weibull function.

12.8.3 Small to medium-range windmills

Multi-bladed windmills for water pumping are still being manufactured in several countries and an estimated one million were in use in the early 1980s.[115] These windmills have a high solidity, or area of blade relative to total swept area. This gives a high starting torque but a relative low power coefficient, typically about 0.2. Wind energy was considered to have a significant role in pumping water in the developing countries by the United Nations Technical Panel,[115] but they also identified three problems with existing designs: they were too complicated for local manufacture, too expensive and too difficult to maintain and repair. Several new designs appeared in the late 1970s and early 1980s. These could be made locally and were relatively inexpensive, but a wider educational programme was still needed before the technology could be disseminated.[115]

Small low-solidity wind turbines for generating electricity in the range up to 10 kW are widely available in many countries. Windmills in Sri Lanka, for example, locally developed in the early 1980s, could give an output of up to 400 W and would cost no more than $200 to build.[126] Prototypes are used to charge locally manufactured lead-acid batteries which power low-energy consumption fluorescent tubes. This provides an electric lighting system at about half the cost of conventional kerosene lamps.

Isolated communities in good wind areas, especially in mountain regions, on islands or in coastal areas, can meet their power needs in the 10–1000 kW range by a combination of wind power and a suitable back-up system.

By the mid-1980s the combination of wind and diesel generators was attracting very considerable international research and development activity. The results of much of this work were summarized by Lipman in 1990,[127] who pointed out that a wind power system may be fully meeting an autonomous load at one moment and be in considerable power deficit a few seconds later. Strategies which were being tried included various types of load control, both long- and short-term energy storage, hybrid systems using flywheels and multiple diesels[127] or a pumped hydroelectric system.[115]

Among the smaller UK companies the Northumbrian Energy Workshop (NEW) have helped the government of the Seychelles with wind-resource assessment using data loggers they have installed under a United Nations Development Programme (UNDP).[128] NEW is also continuing to support a UNDP project in the very different climatic conditions of Mongolia for which they supplied 27 Marlec WG910 50 W windchargers and four Dyna Technology 200 W windchargers. NEW, together with the National Centre for Alternative Technology in Wales, and Marlec, have also supplied some small solar-photovoltaic-wind hybrid systems for projects in Tanzania and Kenya.

Most of the Marlec WG910 windchargers are exported to remote parts of both developing and developed countries. A particularly interesting user is the 'Footsteps of Scott Expedition', which reported using their Marlec aerogenerator at temperatures down to −40°C and windspeeds exceeding force 12 and averaging 40 mph over 12 h. They reported 'faultless' operation under these extreme conditions.[128,129]

12.8.4 The vertical-axis windmill

The modern vertical-axis windmill is a synthesis of two earlier inventions. These are the Darrieus[130] windmill with blades of symmetrical aerofoil cross section bowed outward at their mid-point to form a catenary curve and attached at each end to a vertical rotational axis perpendicular to the wind direction and the Savonius[131] windmill or S-rotor, in which the two arcs of the 'S' are separated and overlap, allowing air to flow through the passage. The Darrieus windmill is the primary power-producing device, but, like other fixed-pitch high-performance systems, is not self-starting. The blades rotate as a result of the high lift from the aerofoil sections, the S-rotor being used primarily to start the action of the Darrieus blades. The wind-energy conversion efficiency of the Darrieus rotor is approximately the same as any good horizontal system[132] but its potential advantages are claimed to be lower fabrication costs and functional simplicity.[133] In 1981 the largest American Darrieus machine, with three blades, had developed 500 kW. A 4 MW machine jointly funded by the Canadian National Research Council and the Institut de Recherche d'Energie du Quebec was completed on a site in the St Lawrence river valley, Quebec, in 1985. An earlier feasibility study concluded that Darrieus machines up to 8 MW in size could be built.

In the UK, an analysis of the Darrieus rotor suggested to Musgrove[134] that straight-bladed H-shaped rotors, with the central horizontal shaft supporting two hinged vertical blades, could be a more effective system. A variety of designs based on Musgrove's work in the UK during the 1970s and early 1980s have been studied and a small, 6 m diameter, three-bladed version was commercially available by 1980.

This work was followed by a 25 m diameter 130 kW machine at Carmarthen Bay, which started a test and monitoring programme in November 1986. Full details of the development of this design are available.[135] Following the highly successful trials, a larger version, known as VAWT 850, was inaugurated in August 1990. The '850' refers to the swept area of the blades. Its rated capacity is 500 kW, with a cut-in windspeed of 6 m s^{-1} and a shutdown windspeed of 23 m s^{-1}.[136]

Musgrove also considered the possibility of siting groups or clusters of windmills in shallow offshore locations in the UK such as the Wash. Two advantages of this proposal are the higher mean windspeeds and the greatly reduced environmental objections.

12.8.5 The development of large horizontal-axis wind turbines and some national programmes

Details of the largest horizontal-axis wind turbines built or planned in Europe during the period from the late 1970s to the mid-1980s showed that four countries, Denmark, Germany, Sweden and the UK, had major programmes.[1] In 1979, the Danish machine at Twind, rated at 2 MW with a blade diameter (three blades) of 54 m, became the largest in the world since the Smith–Putnam machine.[137] This was a private venture and it never achieved the full rated power.

The official Danish programme for large electricity producing wind energy systems started in 1977 with a joint programme directed by the Energy Ministry and the Electricity Utilities. Their major project was the design, construction and operation of two machines, Nibe A and B, which were erected in 1979. These turbines are sited close to each other and are identical, apart from their rotor blades. Those for the A machine are supported by stays while the blades of the B machine are self-supporting.

Construction of a 2 MW wind turbine near Esbjerg, in Western Jutland, was completed in 1988, with grants from the EC.[138] The main parameters were a blade diameter (three blades) of 61 m, a hub height of 60 m and a rated windspeed of 15 m s^{-1}. The estimated annual output was 3.5 GWh y^{-1} and the estimated capacity of Danish windfarms was approaching 100 MW at the same time.[139]

The German wind programme, known as the Growian programme, had some 25 projects in operation during the early 1980s, ranging from some small, low-cost units rated at 15 kW for production in developing countries and a medium-sized 25 m diameter twin-bladed 265 kW machine, the Voith-Hutter commissioned in 1981, to the large Growian I machine, rated at 3 MW, with the world's largest blade diameter of 100 m. The rated capacity of the German Research, Development and Demonstration programme was 8 MW towards the end of the 1980s.

The main feature of the Swedish programme was related to the design, construction and operation of two large-scale prototypes, located at Maglarp in the province of Skane in southern Sweden, and Nasudden on the island of Gotland. These projects, with rated capacities of 3 MW and 2 MW, respectively, formed the main basis of Swedish work during the decade.

In the United States the first major project in the official wind energy programme was the ERDA Model Zero (MOD-0) 100 kW windmill which consisted of a two-bladed, 38.10 m diameter, variable-pitch propeller system driving a synchronous alternator through a gearbox, mounted on a 30.48 m high steel tower.[140] The blades were located downstream from the tower and a powered gear-control system replaced the traditional tail fin of earlier designs. This initial test programme was designed to establish a database concerning the fabrication, performance, operating and economic characteristics of propeller-type wind turbine systems for providing electrical power into an existing power grid.

The next in the series, the MOD-1 windmill, became the world's largest machine in May 1979, when it was commissioned. This was also a twin-bladed downwind horizontal axis machine with a blade diameter of 60.96 m and rated at 2 MW. Problems of interference with television signals were overcome but a low-level, low-frequency noise could only be reduced by lowering the speed of rotation and output. This resulted in design changes in the later machines in the series. The MOD-1 machine was dismantled in 1983.[141]

Subsequent machines in the programme were planned to reach the MOD-5, rated at 7.3 MW with a blade diameter of 122 m, but the overall economics of windpower meant that efforts concentrated on designs in the 300–500 kW range. As early as 1983 a spokesman for the General Electric Company said that the future market for large wind turbines was very doubtful as forecasts of electricity load growths were lower than expected and subsidies for the use of renewable energy systems in the United States were planned to end.[142]

The UK programme could be regarded as dating from the early 1950s when two 100 kW machines were built, the John Brown machine which was erected in the Orkneys, and the Enfield-Andreau machine, which was eventually built in Algeria in 1957.[10] A wind database was also established in the 1950s by the Electrical Research Association. Preliminary work with a design feasibility and cost study of large wind turbine generators suitable for network connection was carried out in 1976 and 1977 by a group comprising British Aerospace Dynamics Group, Cleveland Bridge and Engineering Co. Ltd. Electrical Research Association Ltd, North of Scotland Hydro-Electric Board, South of Scotland Electricity Board and Taylor Woodrow Construction Ltd.[143] A reference design was evolved for a 60 m diameter turbine in 1977. This became the WEG (Wind Energy Group) 3 MW design for the machine which was eventually inaugurated at Burgar Hill, Orkney, in November 1987. The main design features of the twin-bladed horizontal axis machine included a rated output of 3 MW at 17 m s^{-1}, a blade diameter of 60 m and a hub height of 46 m. A smaller prototype, a 20-m diameter 250 kW machine, was commissioned in the summer of 1983.

A 1 MW wind turbine at Richborough, Kent, began generating at the end of 1989. It is also a project in the European Commission's large wind-energy machines programme. The site was selected as typical of an average mainland UK location, and has a mean annual windspeed of 6.8 m s^{-1} at a hub height of 45 m, compared with the 10.5 m s^{-1} at Burgar Hill. It has three blades, each 26.5 m long and is an 'extended' version of the James Howden 300–750 kW horizontal-axis range.[144]

In parallel with the development of the range of prototype machines outlined above, plans for the first commercial windfarm in the UK were being finalized at Delabole, Cornwall, in 1991.[145]

During 1985 the National Engineering Laboratory (NEL) at East Kilbride, Glasgow, established a National Wind Turbine Centre (NWTC) at Myres Hill, some 8 km to the south-west of the NEL, near the village of Eaglesham. The 7-ha site is on a moorland ridge 350 m above sea level with an open outlook and clear view of the Irish coast.[129] It has three 'universal' concrete foundation pads, each complete with a monitoring hut and capable of taking a wide range of machines of both the conventional (horizontal-axis) type and vertical-axis machines. A further test pad of the same design is located at the NEL. A high mast fitted with a wide range of anemometry and other metereological instrumentation will provide information of the wind profile and climate over the 50 m height.

The NWTC has been created to assist companies by:

1. Providing independent accreditation of machine performance and quality;
2. Supplying engineering and technical expertise to improve the design and cost-effectiveness of machines;
3. Seeking to promote reliability through assuring high standards of materials and quality of manufacture.

The main data system collects signals at a central building at Myres Hill, and transmits these data by microwave link to the NEL Power Systems Engineering Division for analysis in a real-time facility. The microwave link allows two-way communication and some control activities may be undertaken remotely in the future.[129] Facilities for loading the different types of machine are as follows:

1. Machines with induction generators will supply electricity to the National Grid;
2. Machines with synchronous generators will be connected to individual resistive load units with programmable controllers;
3. Water pumping and direct heat production machines will utilize a 70 000-litre water reservoir on the test site.

A major review of renewable energy in the UK carried out in 1988[31] concluded that the onshore technical potential of windpower was 45 TWh yr^{-1}, and that, in principle, some 30 TWh yr^{-1} could be provided by the year 2025. Making the assumption that a broadly similar ratio of installed capacity to annual output experienced in California[119] could be applied to these projected UK figures, the equivalent UK installed capacity in 2025 would be about 20 GW. This methodology, based on California data, but remembering that several UK systems have been installed in California, was probably used as the basis for the 1991 ETSU report to the CEC,[146] which gives a potential of 17 GW for land-based windpower in the UK. This is quoted as being 'technically available' in 1990, with a further 12 GW for offshore wind by the year 2000.

There now appears to be no technical barrier to this potential. For example, the Watt Committee[64] considered that the main strategic reason for introducing wind power or any other renewable energy source into the UK system would be to increase the security of the system by adding to the diversity of the plant. At least 20% of the system peak load could be accepted from variable supply sources, such as windpower, without significant cost penalties on the operation of existing plant.

12.8.6 Some environmental issues

The most important effect of wind energy is that it is relatively non-polluting during its working lifetime when it has a zero fossil fuel input. A life-cycle analysis would show that very minor pollutants were emitted during the construction and site works period.

Several negative effects are often quoted in the literature.[1,64] The first is the visual impact, but visual impact is difficult to quantify and depends on subjective judgements. The blades could also cause a rotating shadow pattern which might present visual problems. A major area of concern has been the danger of birds colliding with the blades, but this was considered to be a negligible hazard.[141]

Electromagnetic interference can be caused by a windmill and the considerable amount of research suggests that where significant TV interference appears possible, remedial action should be taken before the problem arises. The area around the Burgar Hill site for the WEG 3 MW machine on mainland Orkney had poor reception prior to 1983. A new repeater station was installed so that better signal reception was established before the wind turbines were operating. Noise is also a problem, particularly at low frequencies, and the amount of data is sparse.[141] A large amount of low-frequency noise appears to be common to all machines and the only solution is to site them sufficiently far away from objectors.

This could severely limit potential wind sites. Safety is an obvious problem and blades have been known to become detached and fly off. Some towers have suffered structural failure in high winds.

12.8.7 Summary

By the end of the 1980s approximately 100 manufacturers had been identified who had supplied well over 100 000 wind turbines and pumps of various sizes throughout the world.[139] Of these, some 20 000 were connected to the grid with a total installed capacity of over 2000 MW. The largest single group of installations is in California, where they are situated mainly in the Altamont Pass region, some 60 miles east of San Francisco near Livermore, the Tehachapi region, about 100 miles from Los Angeles near Mojave, and the San Gorgonio Pass region, again about 100 miles from Los Angeles and near Palm Springs.[119] In Europe the installed capacity in 1991 was as shown in Table 12.5.

Of the 100 manufacturers identified above, only about 30 were regarded as 'well established' by the European Wind Energy Association. 'All but a handful' were based within the European Community and a series of goals for the exploitation of Europe's wind energy was also established in 1991[147] as follows:

4 000 MW by the year 2000
11 500 MW by the year 2005
25 000 MW by the year 2010
100 000 MW by the year 2030

The final figure is equivalent to 10% of the Community's total electricity demand in 1990.

The three leading countries (Table 12.5) had plans to enhance their installed capacities during the 1990s. Both Denmark and the Netherlands were aiming at 1000 MW each, with 250 MW in the Netherlands by 1995. Germany was planning to install at least 100 MW over a five-year period.[147] Italy's projections were to provide an additional 300 MW to 600 MW over the decade.

12.9 Geothermal energy

Geothermal energy is thermal energy stored in the Earth. Although the Earth's heat can be regarded as an infinite source of energy, prolonged exploitation can exhaust a geothermal field. Geothermal energy is, therefore, not strictly a renewable source of energy compared with, for example, solar energy or hydro power.

In the nineteenth century it was believed that the residual heat in the centre of the Earth was the source of the natural geothermal phenomena such as hot springs with jets of steam that could be seen on the Earth's surface.[148] It is now widely accepted that there are two heat sources. The first arises from radioactive decay and the geological evidence points strongly to potassium, uranium and thorium contained in the rocks that form the Earth's crust.[149] The second comes from the mantle which lies below the crust and which may also contain small concentrations of radioactive elements. The crust is some 30–35 km thick below the continental land masses and the boundary between the crust and the mantle is known as the Mohorovicic seismic discontinuity, or Moho.[148,149] According to plate tectonic theory the crust is not a solid shell but consists of rigid segments or plates which can move relative to each other over the mantle. Pressure builds up at plate boundaries and the resulting sudden movement results in earthquakes and promotes the movement of large masses of molten rock or magma upwards into the Earth's crust, causing volcanic activity.[149] The thermal effects of the interaction between plates can extend several hundred kilometres from the boundaries. Major plate boundaries are well known and indicate the areas where exploitation of Earth's heat would be most likely to be successful.

Measurements of temperatures taken in mines and boreholes penetrating into the crust show that, with the exception of a very shallow zone near the Earth's surface, the temperature rises as the depth increases. The rate of increase, or thermal gradient, is between 20 and 30 K per kilometre for non-volcanic regions, with a smaller increase for older rock[149] and a much higher increase near magma penetration. Most of the heat which reaches the Earth's surface does so by conduction, but some is transferred by convection to the free water in the outer few kilometres of the crust. This can occur by the simple process of groundwater sinking through permeable rock such as the sandstones or limestones, or where the rock has been fractured, into the hotter regions and then circulating back towards the surface, or by the heating of the groundwater by igneous activity.[149] Temperatures of these hydrothermal fluids in the range from 100° to 200°C are common and in places have reached 400°C, conditions which can result in some of the water flashing (changing state from liquid to vapour with rapid reduction in pressure) into steam and appearing as hot springs or geysers. The average value for terrestrial heat flow on the continental land masses is about 0.06 $\mathrm{Wm^{-2}}$.[150,151] A slightly higher value, 0.063 $\mathrm{Wm^{-2}}$, is also widely quoted in the literature,[152,153] but in the exploited geothermal fields the heat flow carried to the surface by the fluids can be from 200 to 1700 times this value.[153]

12.9.1 Geothermal resources

Compared with the proved reserves and ultimate resources for the fossil fuels, which are published at regular intervals, estimates for both national and world geothermal heat resources must be regarded with very considerable caution. Armstead[154] points out that it is of more immediate interest to have an approximate idea of the amount of geothermal energy that could be obtained under existing economic and operating conditions, but that any attempt to estimate this must be highly speculative. Many regions in the world have had no geothermal exploration and it is very difficult to place any confidence in much of the published work. However, as a starting point the World Energy Conference[155] produced an assessment which is given in Table 12.6.

In the early 1990s total world primary energy consumption was approximately 3.6×10^{20} J and the primary energy equivalent of electricity generated was about a quarter of this

Table 12.6 Estimates of geothermal resources for electricity generation (10^{20} J)

Resource base, taking into consideration the continental land masses to a depth of 3 km and a datum of 15°C	410 000
Of this resource base only 2% is assumed to be of adequate temperature for electricity generation	8 200
Assume that the overall recovery and conversion efficiency is about 2.2%	180
One fifth is convertible by existing technology	36

Data derived from references 154 and 155.

figure. Table 12.6 suggests that the convertible geothermal resource is some forty times greater than the world annual production of electricity. This figure may be of the right order, but cannot be regarded with confidence.

The World Energy Conference also gave a figure of 2.9×10^{24} J for the estimated recoverable thermal energy which was theoretically available for direct applications at lower temperatures. Again, this figure must be fairly speculative as it amounts to over 7% of the total estimated resource base for electricity generation. When estimates of geothermal resources are made for individual countries the same reservations must be applied. The wide range of estimates which can be given emphasize the need for caution. For example, a series of estimates for Japan ranged from 40 000 MWe for the next thousand years, representing some 35% of the total world potential, to 8650 MWe.[154]

12.9.2 Geothermal areas, fields and aquifers

The surface of the Earth can be classified into three main areas as follows:[154]

1. Non-thermal areas with temperature gradients between 10 and 40 K per kilometre of depth;
2. Semi-thermal areas with temperature gradients approaching 80 K per kilometre of depth;
3. Hyperthermal areas with considerably larger temperature gradients.

An important distinction must be made between a geothermal area and a geothermal field. Many thermal areas are associated with rock of low or zero permeability and cannot be exploited under existing economic and operating conditions. Geothermal fields contain the hot water or steam in permeable rock formations and a number of these are operating commercially. They can also be classified into three main types:[154]

1. *Semi-thermal fields* which can produce hot water at temperatures up to 100°C from depths up to 2 km;
2. *Wet fields* which produce water under pressure at temperatures greater than 100°C. When this water reaches the surface, its pressure falls and some flashes into steam, the remainder being boiling water at atmospheric pressure;
3. *Dry fields* which produce dry saturated or superheated steam at pressures above atmospheric pressure.

Another source of useful hot water is the low-grade aquifer, which can produce water up to a temperature of about 75°C by drilling to depths of between 1.5 and 2 km, corresponding to a temperature gradient of 30 K per kilometre. Low-grade aquifers can be found in non-thermal areas but are only worth exploiting if they are located fairly close to an appropriate application, such as space heating in a town or city.

12.9.3 Thermal applications

The earliest application of geothermal energy was the use of natural hot springs for bathing or medical purposes. One hot spring near Xian, the capital city of ancient China, has been used for over a thousand years and still attracts many bathers. The history of the use of geothermal energy for industrial applications probably started in the Larderello area of Tuscany, in central Italy, in 1827. Thermal energy from the hot wells was used in the crystallization of boric acid, which was also obtained from the natural pools formed from condensed steam and rainwater[153] and a flourishing chemical industry developed there over the next hundred years.

In Europe, one of the richest geothermal sources is in Hungary, where geothermal baths have been used for hundreds of years. Geothermal heating was first introduced in the 1960s and is used in greenhouses covering a total area of 2 million m^2. Uses in other agricultural applications include corn drying and poultry farms.[156]

An increasing number of applications for space heating have also been reported since the 1960s. Examples of two different types are the semi-thermal fields in Iceland and the low-grade aquifer found in the Paris basin. In Iceland the Reykjavik Municipal District Heating Services were able to sell hot water at less than one fifth of the cost of heating with oil.[157]

The capital cost of the geothermal plant installed in the Paris basin per housing unit was US$ 2000 (at 1980 prices) which was said to be comparable with any conventional system.[157] District heating using geothermal energy was first introduced in Hungary in 1985, and by 1990 over 6000 dwellings in six cities were being supplied during a heating period which lasts about six months.[156] The main development in the UK is in the Wessex basin. The first borehole at Marchwood in 1979/1980 produced a flow of 30 l s^{-1} at 72°C from a depth of 1700 m. This was originally intended to pre-heat feedwater for the power station, but this was closed before the project could be taken further.[158] The second was the Southampton borehole. The pumping rate was too low for an extensive heating scheme, but a later, smaller, scheme proposed by the Southampton City Council in 1987 now provides about one MW of geothermal heat as part of a larger 12 MW system. The maximum pumping rate is limited to 12 l s^{-1} to ensure an operating life of 20 years.[158] A very small warm water scheme (*ca* 22°C) is operating from a 250 m experimental borehole in Cornwall for a horticultural application.[64]

The main features of a typical geothermal district heating system are shown in Figure 12.14, based on information from reference 159. The first borehole establishes the chararacteristics of the aquifer and then becomes the production well, out of which the hot water is pumped. The second borehole is the reinjection well, which is used to dispose of the saline water after the heat has been extracted in the heat exchanger. This well is approximately one kilometre from the production well to delay the return of cold water for 25–30 years. The auxiliary boiler can provide additional heat at periods of high demand and the whole system is connected to the housing units and buildings by a pipeline system. This must be no further than one kilometre from the geothermal wells, both for reasons of cost and prevention of heat loss. Among other thermal applications widely quoted in the literature are greenhouse heating including soil warming, drying of organic products, salt extraction and industrial process heating.

12.9.4 Electricity generation

The history of electricity generation also started in the Larderello area, when a simple steam engine coupled to a d.c. generator was driven by steam from the geothermal field. This provided some electric lighting for the town of Larderello.[152,153] The steam engine was replaced by a 250 kW turbo-alternator in 1913. Until 1958 Italy was the only country where natural steam was used for power generation on an industrial scale. Production commenced in New Zealand in that year, followed by the Geysers field in the United States in 1960, when the total installed capacity in the world was 369 MW.[150] Development over the next decade to 697 MW by 1970 represented an annual growth rate of 6.5%, but the 1970s saw a considerable increase in growth. Table 12.7 shows the installed and projected geothermal electrical generating capacity for 1980, 1987, 1989, 1990 and 2000, taken from data presented at the United Nations Conference on New and Renewable Sources of Energy in 1981[157] and from references 64 and 160 in 1990.

Data published by Shaw and Robinson[150], also in 1981, put installed capacity in 1980 as 2082 MW. This gives a growth rate of 11.6% per annum during the 1970s. By examining the known orders for new plant they concluded that a realistic assessment of installed capacity in 1990 would be between 3786 MW and 5645 MW, less than half the figure suggested by the United Nations Conference.[157] Their projected figures of 3786 MW and 5645 MW for 1990 would represent average annual growth rates over the decade of 6.1% and 10.5%, respectively. McVeigh's comment[1] in 1984 that the Shaw and Robinson projection seemed reasonable compared with the nearly 20% per annum growth rate to achieve the figures suggested by the UN Conference was fully justified with the publication of the 1989 data.

Table 12.7 Installed and projected geothermal electrical generating capacity (MW)

1980[a]	*1987*[b]	*1989*[c]	*1990*[d]	*2000*[d]

[a] UN installed figure.[157]
[b] UN Watt Committee, derived installed figure.[64]
[c] Dickson and Fanelli installed figure.[160]
[d] UN projected figures. (These UN projections were qualified by the comment that they were 'minimum' figures.)

The risks and problems associated with geothermal projects are not unlike those in searching for oil. The success rate of geothermal drilling, when measured by the proportion of wells which strike exploitable hot water or steam, is probably greater than that of oil drilling. However, the rewards are much smaller and there are risks, as the first UK experience outlined above indicates.

12.9.5 Hot dry rocks

Geophysicists have suggested that rock at temperatures of 200°C can be found at drillable depths, less than 10 km, over large regions of the Earth's surface.[150] This has resulted in a number of major research projects in which deep holes are drilled into these hot rocks and a system of cracks is propagated between them.[150,154,157,159] Most of the research is aimed at establishing an optimum method for generating these fracture patterns. The basic technique uses hydraulic fracturing, and the first successful tests were carried out at Los Alamos in the United States during the early 1970s.[159] A fracture system some 600 m in diameter was created between wells 3 km deep and up to 4.5 MW was removed as heat during the initial test period of 2000 hours. This showed that the concept was valid. In the UK the Camborne School of Mines have extended the work in the United States by a more sophisticated approach to fracturing. They initiate the fracture system by explosives and then follow up with hydraulic fracturing.

Formal reviews of progress were undertaken in 1984, 1987 and 1990.[161] By 1984, two 2-km deep wells had been drilled, but the reservoir, or heat exchanger, between the two wells had relatively poor hydraulic properties. A third well was drilled and the second review concluded that while considerable progress had been made, there were several specific problems. The main one was still with the reservoir. This was a hundred times smaller than the size calculated to be necessary for a commercial reservoir and a reliable reservoir design process had not been validated. Three more years of experiments and studies still revealed that a satisfactory procedure for creating a commercial-scale reservoir had not been demonstrated. There was no reliable information about the properties of the rock likely to be encountered at the 6–7 km depths necessary for commercial exploitation. In a technical analysis of the work up to 1990, Parker[162] stated that until holes have been drilled to these depths the uncertainty will never be removed. Hot dry rock projects were unlikely to attract any private sector income in the short term.[161] Nevertheless, the potentially exploitable granites in south-west England alone contain the equivalent of 8000 million tonnes of coal.[163]

12.9.6 Some factors influencing developments

The economics of the applications of geothermal energy depend on the costs of competitive fuels. Where there are active geothermal fields and scarce indigenous resources, such as in Iceland or Hungary, geothermal power is already the economic choice. Financial constraints and the lack of a suitable technical infrastructure can inhibit development in some of the poorer developing countries who would appear to have considerable hyperthermal field potential.

Several other possibilities for using geothermal energy have been discussed, including the direct exploitation of the heat from active volcanoes.[149,154,157] This would have very considerable practical difficulties as it would involve tapping the magma at a depth of several thousand metres below the volcano, a technology which has not yet been developed. Among the ideas put forward for exploiting this source, Armstead[154] has suggested injecting water into the hot basaltic magma to produce hydrogen by dissociation.

The possible environmental problems which can arise from geothermal exploitation have been identified[154,159] and can include:

1. The use of land for initial drilling operations and possible noise and damage;
2. The long-term visual impact and use of land for the power or heat-extraction plant;
3. The development of a suitable heat-distribution and pipeline system;
4. The release of gases, fluids and various chemicals during operation;
5. The physical effects on the geological structure of the area.

The earliest geothermal operations were carried out at a time when environmental issues were not taken into consideration. These early steam plants were reported to have unsightly tangles of steam-transmission pipes, clouds of waste steam accompanied by a strong smell of hydrogen sulphide and, eventually, significant surface subsidence. However, in recent years these adverse effects have been minimized. For example, air pollution standards at the world's largest field, the Geysers in the United States, have resulted in 'cleaner' air than before the field was exploited. For the low-temperature aquifer systems the environmental impact should be negligible.[159] The main problem is the safe disposal of the warm chemically laden water after it has passed through the heat exchangers. It has become normal practice to reinject the brine back into the other end of the aquifer as shown in Figure 12.14.

12.9.7 Summary

Unlike the other alternative energy sources, geothermal energy is capable of providing continuous heat and power. With electricity generation, the plant is particularly suitable for base-load operation. The use of low-grade aquifers can provide space heating at costs comparable with or below conventional systems. However, the long term future is still quite unpredictable. Several authorities believe that heat mining, the exploitation of hot dry rocks, could become a commercial reality within the next two decades.[153,154] Should this happen, a major new energy resource, comparable in size to the ultimate oil and gas resources, would be available, but the UK experience at the Camborne School of Mines serves as a warning against over-optimism.

12.10 Tidal power

12.10.1 Introduction

Tides are caused by the interaction of the gravitational and kinematic forces of the Earth, the moon and the sun. The gravitational force at any point on the surface of the ocean depends on the position of the moon and the sun and on their distance from the point. The period of the tides depends upon the 29.53-day period of rotation of the moon about the Earth, the Earth's daily rotation and upon the orientation of the Earth during its path round the sun.[164] The difference in length between the 24-hour solar day and the 24.813-hour tidal day causes the spring and neap tides. When the sun and moon are almost in line with the Earth the tides have their maximum amplitude and are known as the spring tides. When the moon–Earth–sun angle is a right angle the tides have their minimum amplitude and are known as the neap tides. The ratio between the greatest spring tide and the smallest neap tide can be up to 3:1.[122] The overall effect of tidal forces is surprisingly small. In the open ocean the tidal range, defined as the difference in amplitude between low and high tides, is typically about 1 metre.[122] Over the continental shelves the tidal range increases to about 2 metres and in some estuaries or deep narrow bays it can be up to 16 metres.

These increased tidal ranges in estuaries or bays are caused by the interaction of two types of wave. The first is the tidal wave advancing from the open sea and the second is the reflected waves from the sides of the estuary.[165] These two waves can reinforce each other at certain times, depending on the shape of the estuary and the period of tide, causing an amplification. Peak amplification occurs at resonance. Theoretically, a channel of uniform cross section would be resonant if its length were equal to one-quarter of the wavelength of the tidal movement. In practice, this length is modified by actual variations in depth and width. The rise and fall of the tide is also limited by the frictional losses caused by the action of the water over the sea bed.

Scientific publications on tidal schemes date from the early eighteenth century and various designs for dams and associated turbines appeared from the end of nineteenth century.[166] Modern proposals for exploiting tidal power are based on the use of the stored potential energy in a dam.[164] The use of the kinetic energy of the tidal current has been limited to a few very small-scale developments.[167]

12.10.2 Tidal power principles

Tidal power can be obtained from the flow of water caused by the rise and fall of the tides in partially enclosed coastal basins. This energy can be converted into potential energy by enclosing the basins with dams. This creates a difference in water level between the ocean and the basin. The resulting flow of water as the basin is filling or emptying can be used to drive turbo-generators. Electricity conversion removes the geographical restrictions placed on the earlier uses of tidal energy.[165]

The potential energy of a body of mass, m, at a height, z, above the datum line is mgz. If the surface area of a tidal basin is A m^2 and the mean tidal range is r m, then the maximum potential energy available during the emptying or filling of the basin is given by

$$\tfrac{1}{2}\rho g A r^2$$

The tide rises and falls twice during the tidal day of 24.814 hours, so the theoretical average power is four times the maximum potential energy divided by the total time in the tidal day or

$$\frac{4 \times \tfrac{1}{2}\rho g A r^2}{24.813 \times 3600}$$

Taking ρ as 1000 kg m^{-3} and $g = 9.81$ m s^{-2} the theoretical average power becomes

$$0.220\ A r^2$$

If generation is only on the ebb tide the figure is halved. The actual power output is up to 25% of the theoretical average.

Some locations are particularly favourable for large tidal schemes because of the focusing and concentrating effect

Table 12.8 Mean tidal range in selected locations (m)[165]

Location	*Range*
Bay of Fundy, Canada	10.8
Severn Estuary, UK	8.8
Rance Estuary, France	8.45
Passamaquoddy Bay, USA	5.46
Solway Firth, UK	5.1

which can be obtained from the shape of their bays or estuaries. Typical ranges are shown in Table 12.8, which includes the world's largest tidal range in the Bay of Fundy and Europe's largest, the Severn Estuary.

In an ebb generation system the use of pumps to increase the level of water contained in the basin at high tide appears to be attractive. The principle is illustrated by a simple example. The additional energy required to raise the water level z m at high tide is

$$\tfrac{1}{2}\rho g A z^2$$

The maximum potential energy now available during the emptying of the basin becomes

$$\tfrac{1}{2}\rho g A(r + z)^2$$

giving a net gain of

$$\tfrac{1}{2}\rho g A(r^2 + 2rz + z^2 - z^2 - r^2)$$

$$= \rho g A r z$$

In practice there are two problems. Pumping involves some loss of overall efficiency and turbines capable of pumping as well as generating are more expensive. The power needed for pumping may be required when demand on the whole electricity system is high and could involve the use of an expensive form of generation in another section of the network.[122] The net gains in revenue from flood pumping in the proposed Mersey barrage (UK) have been examined[168] for various ratios of imported energy cost against exported energy value.

12.10.3 Tidal power schemes

There are a number of different schemes which can be grouped into two main combinations, depending on whether one or two basins are used:

1. Single basin, generation only on the ebb tide;
2. Single basin, generation only on the flood tide;
3. Single basin, generation with both the ebb and the flood tides;
4. Single basin, generation with both tides and pumped storage;
5. Double basin;
6. Double basin with a pumped storage system.

Any particular scheme could be optimized against any one of a number of different and distinct parameters. These include maximum net energy output; constant power output; constant-head operation; maximum pumped storage capacity or lowest initial capital requirements.[165]

Single-basin ebb generation allows the incoming tide to flow through sluice gates and the turbine passageways. These are closed at high tide and the water is retained until the sea has ebbed sufficiently for the turbines to operate. This is normally at about half the tidal range. Initially, the flow is restricted to maintain a high head and to operate the turbines at maximum efficiency. Later in the cycle the turbines are usually operated at maximum power.[122]

Single-basin flood generation is the reverse of ebb generation. It has a number of potential disadvantages, the main one being the prolonged periods of low tide experienced above the dam. A second disadvantage is that the amount of energy would be less than with an ebb generation scheme, as the surface area of the estuary decreases with depth.

Two-way generation with a single-basin system generates electricity from both the flood and ebb tides. This does not result in a greatly increased power output. Neither phase of the cycle can be taken to completion because of the need to reduce or increase levels in the basin for the next phase. There are also economic disadvantages. The turbines are more complex and less efficient if they are required to operate in both directions and the turbine water passages must be longer. An advantage is that power is available four times in the tidal day, rather than for two longer periods.

Double-basin schemes often include provision for pumped storage, but in their simplest form they could operate as two independent two-way generation schemes. In another form water would always flow from the higher-level basin to the second lower-level basin. The second basin could only be emptied at low tide.

A detailed discussion of the relative merits of the different schemes has been given by Taylor,[122] who points out that it is difficult to generalize, as a large number of variables, which vary from one site to another, need to be considered.

12.10.4 Tidal power sites

Many of the various design studies carried out until the early 1970s suggested that while tidal power systems were technically possible they would be unable to generate electricity at a competitive price. A notable exception was the first major report on the Severn Barrage, published in 1933,[169] but the recommendations were ignored and over half a century later further feasibility studies were still being carried out.[168]

Only three modern tidal power schemes were operating in the 1980s. The largest and oldest is the Rance Barrage near St Malo on the Brittany coast of France. Two much smaller schemes are in the former USSR and China. All three schemes have been built primarily to gain operating experience for the possible development of much larger systems.[122]

Work on the Rance site commenced in June 1960, the final closure of the estuary against the sea took place in July 1963 and the last of the 24 10 MW turbo-generators was commissioned in November 1967.[164] The overall width of the barrage is 750 m. The tides follow a fairly constant two-week cycle throughout the year. During the first week of the cycle the tidal range is between 9 m and 12 m and in the following week between 5 m and 9 m.[164] The mean tidal range is 8.45 m. For the lower tidal ranges the barrage operates only on the ebb tide with the basin level increased by pumping. For mean and spring tides two way generation is used, sometimes augmented by pumping. Electricité de France have shown[164] that the output/input ratio for pumping can be as high as 2.8:1. The operation of La Rance is computer controlled and optimized to match the period when it would be most expensive to generate electricity for the French national grid from conventional power stations. The nominal average output of between 50 and 65 MW is therefore not the maximum which could be obtained.

Nevertheless, it has been pointed out[168] that while La Rance tidal power is the cheapest electricity on the French system, Electricité de France comment that it would be too expensive to build any further tidal power systems.

In the former USSR a small 400 kW pilot scheme was completed in 1968 at Kislogubsk on the Barents Sea. The main objective was to try out a new construction method, the use of floated-in prefabricated caissons to form both the main powerhouse and spillway structures.[170] The overall dimensions of this structure were 36 m × 18.3 m by 15.35 m high and the single reversible turbine was purchased from the French company that supplied turbines for the Rance Barrage.[164] The People's Republic of China have a broadly similar pilot scheme rated at 500 kW at Jangxia Creek in the East China Sea.[122]

In the UK one site has been considered to be outstanding for nearly 70 years, the River Severn. Government interest in the Severn commenced in 1925 when the House of Commons established a Sub-Committee, which later became the Severn Barrage Committee of the Economic Advisory Council. The main conclusion of its report in 1933 was that the cost of power generated by a Severn Barrage with secondary storage some 20 km away would be only two thirds of the cost of that generated at equivalent coal-fired stations.[169] The scheme included road and rail crossings and the rated output was 804 MW. A further report in 1944 suggested doubling the output of the turbines to 25 MW while maintaining the rated output at some 800 MW. A later report in the early 1950s drew attention to the potentially high capital cost of any scheme.

Several further reports which appeared up to 1975 have been summarized by McVeigh,[1] who noted that in a comment on the various proposals that had been made over the past 50 years, the authors of an Institution of Chemical Engineers report[171] stated in 1976: 'A curious feature has been the regular conclusion that the scheme would have been economic if embarked upon on earlier occasions, but never on the current one . . .'

In 1977 the Department of Energy summarized the various proposals,[165] including the results of their own specially commissioned studies.[172,173] This was followed in 1978 by the establishment of a further pre-feasibility Severn Barrage Committee which reported in 1981[174] that it is 'technically feasible to enclose the estuary by a barrage located in any position east of a line drawn from Porlock due north to the Welsh coast'.

The most cost-effective of three schemes considered in detail was a single-basin, ebb-generation scheme with a 13 km barrage from Brean Down, a few kilometres south of Weston-super-Mare, to Lavernock Point, with an estimated annual output of 13 TWh at a cost of some 2.4 pence per kWh, at that time close to the official cost of nuclear electricity. This particular scheme was the subject of a two-year study jointly funded by government and industry which commenced in June 1983.

By 1990 all the recent studies concluded that the Severn Barrage was technically feasible and the main design parameters had been agreed for the Brean Down–Lavernock Point line outlined above.[168] These parameters included a nominal design life of 120 years, which was selected on the basis of it being a multiple of 30 and 60 years, time spans regarded as periods for major refurbishments. In practice, it was felt that the barrage could have an indefinite life. Other main parameters included an estimated total installed capacity of 8640 MW, obtained from 216 turbine generators, each 9 m in diameter and rated at 40 MW, and an annual output now estimated to be 17.0 TWh. This represented some 7% of the electricity consumption of England and Wales in 1989. But the possibilities for promoting and financing the scheme had to be delayed until after the UK electricity supply industry had been privatized.

The second largest potential tidal project in the UK is the Mersey Barrage.[168] Although the potential installed capacity is only in the order of 600 MW, it could have a major impact on the local economy. Overall in the UK, the theoretical tidal barrage capacity is approximately 25 GW.[168] Other possible smaller sites in the UK include Morecambe Bay, the Humber, the Wash and the Solway Firth.

In Canada tidal ranges of up to 16 m have been recorded in the upper regions of the Bay of Fundy in north-east Canada. This has been the subject of several investigations, including the working of the Atlantic Tidal Power Board[175] in 1969 (development not economically justified) and the Bay of Fundy Tidal Power Review Board[176] in 1977, who assessed the potential of 30 possible sites. The three with the best prospects, Cobequid Bay, Shepody Bay and Cumberland Basin, had an estimated potential output of 6.4 GWe.

Estimates of some 500 possible sites in the People's Republic of China have suggested a potential of over 110 GW.[122] Those for the former Soviet Union have concentrated on the White Sea between Murmansk and Archangel, where the potential could range from 16 to over 50 GW.

Other parts of the world with potential large-scale sites include the Kimberley Region of Western Australia, and South America, India and South Korea.

A series of estimates reviewed by Hubbert[177] suggested that the total tidal energy dissipated in the world's shallow seas was no more than 10^{12} W although these data appeared to omit any estimates from the People's Republic of China. The average maximum potential power which could be recoverable from these sites was estimated to be 64 GWe in 1969. When it is appreciated that some of the sites are very long distances away from any potential main user, this figure does not seem to be unduly pessimistic.

12.10.5 Possible impacts of tidal schemes

It is difficult to quantify the social, industrial and environmental impacts which any proposed scheme in the UK or elsewhere could have. These have been widely reviewed in the literature[122,178] and some of the main points are discussed briefly below:

1. *Water levels* both in the basin upstream of the barrage and to seaward could be changed.
2. *Tidal flows* reduce the strength of the currents upstream of the barrage. Downstream and to sea the effects could extend over 50 km.
3. *Sedimentation* may occur in the basin and could lead to a slow and possibly small reduction in basin volume. To seaward the sediments previously swept out by tidal flows may stay deposited.
4. *Mixing* will occur less in the water above the basin because of reduced currents and tidal excursions.
5. *Navigation*. Ships could be slowed by passing through locks; on the other hand, predictable periods of deeper water could be an advantage.
6. *Industry* could benefit during construction but may have to adopt higher standards in dealing with possible polluting liquid effluents.
7. *Land drainage* could be affected inside the barrage because of higher low-water levels.
8. *Sea defences* will be less liable to storm damage after the construction of a barrage.
9. *Ecosystem*. The aquatic ecosystem will always be affected by any changes in turbidity and salinity.
10. *Migratory fish* will face the obstacle of the barrage, but the

inward journey will probably be straightforward through the sluices in ebb-generation schemes.

11. *Recreational* opportunities could be enhanced in suitable locations, with less turbid water above the barrage.

There was unanimous agreement among members of the discussion panel at the third UK Tidal Power Conference[168] that several more years of environmental assessment would be needed before specific plans could be brought forward for the Severn Barrage. There were still many poorly understood or completely unknown oceanographic, sedimentary, engineering or environmental issues which had not yet been pursued, mainly because they were not 'make-or-break' issues in respect of the viability of the Severn project. The effect of global warming on mean sea levels, however, was not thought to impose any problems over the next few decades.

Some ideas of the scope and range of the environmental work on the Severn Barrage Project can be found by examining the full list of the 59 Environmental Impact Studies (and their associated contractors) during the two-year period from 1987 to 1989. It is difficult to see how all this work could be replicated for the many smaller UK sites.

12.10.6 The economics of UK tidal power (and of many of the renewables)

The discussion panel at the third UK Tidal Power Conference[168] were asked if they could assure the assembled delegates that there was common ground between, on the one hand, the opportunity to generate power without damaging emissions or radiation risks and, on the other, the need to provide power to the consumer on a commercially attractive basis. Dr John Chesshire[179] responded that he had stressed in his own publications and research work that there were inconsistencies in approach to capital expenditure and investment appraisal in the UK energy sector. A fourfold disaggregation was the best way to make this point briefly, i.e. between public and private sectors, and between energy efficiency and new energy supply projects.

Thus the financial return and depreciation period required from tidal barrage schemes would be similar to those expected by the UK financial sector for nuclear power and would lead to barrage generating costs in excess of 10 p $\mathrm{kWh^{-1}}$ (in 1989), as compared with combined cycle gas turbine generating costs of 2.2–2.5 p $\mathrm{kWh^{-1}}$. It was therefore unlikely that, without regulatory or fiscal adjustment, there can be any common ground between the opportunity to generate power from nuclear and most renewable sources of energy and the need to provide electricity to consumers on a commercially attractive basis.

12.11 Wave power

12.11.1 Introduction

The history of wave energy conversion probably dates from the last few months of the eighteenth century, when the first patent for a wave energy device was filed in Paris.[180] Since then there have been hundreds of patents filed throughout the world with well over 300 in the UK alone between 1856 and 1973.[181]

Only a few proposals appear to have had model tests and these showed poor efficiency. Modern developments started in 1945 when Yoshio Masuda commenced privately funded research in Japan on a wide range of devices.[182] In 1960 his work received government support and he concentrated on wave-activated air turbines, one of which was installed in a lighthouse in Tokyo Bay. This had a maximum output of 130 W. By the early 1970s over 200 small units were operating in Japan, mostly on buoys.

The UK Department of Energy wave energy programme commenced in 1974. This early work showed that the waves arriving at Britain's Atlantic coastline delivered a surprisingly large amount of energy[183,184] and the national programme quickly established that it was physically possible to generate useful power from ocean waves with reasonable efficiency.[185] However, after a decade of development, always exciting and sometimes frustrating, none of the devices investigated seemed to be capable of generating power at a cost which would be comparable to more conventional sources.[185] Some of the more promising concepts are discussed after the introduction to simple wave theory and characteristics, and the prospects for wave power in the 1990s are assessed.

12.11.2 Wave theory and characteristics

The basic characteristics of wave power can be studied from standard linear wave theory.[186] This considers a simple progressive sinusoidal wave of amplitude, a, wave length, λ, and period, T, progressing in deep water. Sinusoidal waves of a single wavelength are known as monochromatic waves and 'deep water' is defined as having a depth greater than half a wavelength. The velocity with which the wave propagates, the phase velocity, can be written as

$$\frac{\lambda}{T} \text{ or } \frac{gT}{2\pi}$$

By considering the rate of change of potential energy as the water in a wave above sea level falls into the troughs in front of the wave, the power in a wave front of width, W, is given by[187]

$$\frac{W\rho g^2 a^2 T}{8\pi}$$

Real ocean waves are quite different from the theoretical ideal wave described above. Ocean waves are generated by the wind, so that wave energy is an indirect form of solar energy. The ocean acts effectively as an extremely large integrator for wind energy[122,188] and, in addition, the inertia of the water can provide a limited amount of short-term energy storage which can compensate for variations in wind velocity with time and place.[183] The waves arriving at a point can have originated from storms hundreds of kilometres away, the 'swell' sea, or from local winds, the 'wind' sea.[188]

The distance from the origin of swell waves is known as the fetch. Swell waves can appear to be substantially plane and monochromatic so that the longer the period between waves, the faster they travel. However, the local wind sea which is superimposed on it can be more complicated and random in wavelength, phase and direction. Any record of sea waves is therefore very complex and is best described as 'the linear sum of many monochromatic waves of random relative phase distributed both in direction and across the frequency spectrum'.[188] A detailed discussion of the spectral density function has been given by Pierson and Moskowitz.[189] However, for most practical purposes a very simplified relationship has been derived which is probably accurate to within ± 30%. This gives the power of a wind-generated wave system for any location in terms of the significant wave height, H_s, defined as the average height of the highest third of the waves, and the zero crossing period, T_z, defined as the time interval between successive upward movements of the water level past the mean position. For the Ocean Weather Ship *India* (50°N, 19°W) the power per metre of wave front has been shown[190] to be approximately

$0.55\ H_s{}^2T_z$ kW

The estimates of power availability for wave energy systems in the mid-1970s were based on *India* data which suggested that an average power of 91 kW per metre of wave front was available.[184] This ranged from periods with very little power to severe storm conditions when the power level could exceed several megawatts.[191] More recent measurements near South Uist reported by the CEGB in 1983 showed that at inshore sites more suitable for the deployment of wave energy systems, power levels between 40 and 50 kW m^{-1} could be expected in water about 50 m deep. Levels of 25 kW m^{-1} could be expected off the north-east coasts of England or south-west Wales.

By the early 1980s a number of overall estimates had been made for the UK, giving a total resource capacity estimated to be 120 GW, based on a mean potential of 80 kW m^{-1} along a 1500-km coastline. When simple geographical limits were imposed, the potential dropped to 48 GW, and with further limitations such as device configuration, station design, capture and power train limitations, the achievable resource would reduce to about 6 GW, according to an ETSU assessment.[192] The 1988 UK review of renewable energy in the UK gave a technical potential of 30 GW, capable of providing some 50 TWh yr^{-1}, mainly off the Western Isles of Scotland and the coast of Cornwall,[31] but in 1991, a later report to the CEC[193] showed only 0.23 GW theoretically available by the year 2000.

12.11.3 Types of wave energy convertor

There have been a number of different classifications in the past decade, starting with Salter's flaps, floats, ramps, converging channels and liquid pistons or air bells.[187] The concept of 'active' and 'passive' systems has also been suggested,[194] active systems having parts which respond to the waves with power generated from the relative motion of these components while passive systems absorb wave energy by virtue of a fixed structure. One of the simplest methods for using wave energy would be to construct an immovable structure to capture large volumes of water which can subsequently be used to drive a water turbine. This system could also be classified as a ramp or passive system. The best-known proposal was initiated in Mauritius in the 1950s and has been the subject of a series of official reports, summarized by Bott[195] in 1979. All the reports agreed that the project would be technically feasible, but the economic viability has proved to be the stumbling block. By the early 1980s the more generally accepted scientific classification was that of terminators, attenuators and point absorbers.[191]

A terminator is defined as a wide structure which is aligned perpendicular to the incident wave direction. Much of the experimental work on this type has been carried out in narrow wave tanks and thus has resulted in good agreement with extensive theoretical studies, so that the performance of terminators is generally more fully understood than other types of device.

The best known is probably the 'Salter Duck', a system originally proposed by Salter in 1974.[187] The floating 'duck' section is an asymmetric cam-shaped device designed to extract energy through semi-rotary motion induced by the incident waves.[191] The system would consist of a long central core, or spine, upon which the duck sections are mounted. Large gyroscopes would be placed inside the nose of each duck, which rotates along its principal axis. The precessing motion of the gyroscopes could be used to drive hydraulic pumps. The concept is revolutionary, as it would be designed to be maintenance-free over a 25-year lifetime.

The Cockerell raft was based on a simpler concept, that of a series of pontoons or rafts connected by hinges, with power generated from the relative movement of the rafts. Both the Duck and the Raft were taken to 1/10 scale model tests.[196,197] Several systems known as oscillating water column devices and which could also be considered as variations of Masuda's original air bell concept have been studied. One which was considered very promising and capable of proceeding to full-scale testing was the National Engineering Laboratory's breakwater system, which consists of a concrete structure mounted on the seabed. The motion of the waves causes a column of water inside the structure to rise and fall, inducing air flow through turbines. Proposals were suggested in 1982 by a private consortium and the National Engineering Laboratory for a 4 MW prototype to be built off the island of Lewis in the Outer Hebrides,[1] but this was not followed up. Almost a decade later a 30 MW array of oscillating water columns was being considered in Plymouth Sound. The estimated capital cost in 1991 was £35 million and the cost of the electricity generated would be 6p kWh^{-1}.[193] Other terminators have been studied in the UK, including the Russel Rectifier and the Sea Clam, and detailed descriptions are widely available.[122]

An attenuator is a long, thin structure which is aligned parallel to the incident wave direction. It was originally thought that energy could be progressively extracted along its entire length, but this has proved impractical because the rear element would need to extract as much energy as the front one for optimal operation.[191] Two devices considered in the UK were the Vickers Attenuator and the Lancaster flexible bag. Neither device was able to show a satisfactory performance in model testing.

The point absorber is an axially symmetric device, constrained to move vertically, which can absorb wave energy from any direction. Theoretically, it can absorb wave energy from an effective wave frontage of $\lambda/2\pi$.[191] This means that a number of interconnected but widely distributed point absorbers could produce as much power as a continuous line absorber having the same total length.

Research into the development of composite materials at Queen's University, Belfast, resulted in the development of a glass-fibre reinforced polyester resin and its utilization in the prototype of a new type of wave energy convertor, the Belfast Buoy. This can be considered as an oscillating water column device with an important difference; the vertical axis air turbine rotates in the same direction, irrespective of the direction of air flow. The turbine system has been named after its inventor, Professor Alan Wells.[198] Several different configurations have been suggested, but a good hydrodynamic performance can only be obtained from a very limited bandwidth.[191]

In 1982 a major review of renewable energy in the UK resulted in a recommendation that no new development work should be supported on large-scale offshore wave energy devices[192] mainly on economic grounds, as other renewables (e.g. wind and tidal power) were considered to be more economically attractive. Since then, wave energy work has concentrated on three systems:[199]

1. Point absorber devices, mainly at Lancaster University (the Flounder, Frog and PS Frog);
2. The Circular SEA Clam;
3. The shoreline wave energy resource, through the generation of electricity from oscillating columns located in shoreline rock gullies. This has included studies of the potential shoreline resource and the building by Queen's University, Belfast, of a device on Islay, which is described below.

12.11.4 Shore-based systems

Small shore-based wave power systems have been used by the Japanese to power lighthouses for nearly two decades.[200] During 1984–1985 the Wells turbine was used by the Kraener Brug company in a Norwegian 500 kW wave power station built on a cliff edge at Tostestallen, north of Bergen. This system was partially destroyed later in a severe storm. Another Norwegian device is the Norwave Tapchan, or tapering channel, invented by a mathematician, Even Mehlum.[200] This uses a funnel-shaped channel blasted out of rock to a predetermined profile which causes resonance with the local wave spectra. At the inner end of the channel is a wall, about 3 m above sea level. Waves enter the channel and propagate. As the walls narrow, the wave height increases until the water reaches the top of the wall and flows over it into a storage lagoon with a surface area of 8000 m^2. Water can then flow out of the lagoon and back to the sea through a 350 kW Kaplan turbine.[200]

In the mid-1980s, the Queen's University, Belfast, team followed their earlier work with a proposal to harness wave energy in relatively shallow natural rock gullies. The island of Islay in the Inner Hebrides was selected for the first prototype shore-based wave power system in the UK. The principle is illustrated in Figure 12.15. The device spans a natural rock gully in relatively shallow water and is being used as a test bed for a new two-stage Wells turbine.[201] The wave entering the gully oscillates a column of water inside the box, causing air to pass through the turbine in either direction. The official inauguration ceremony was held in 1991.

12.11.5 Summary

The future of wave power is particularly uncertain. None of the systems tested in the past decade have been able to demonstrate that they could generate electricity at a cost which would be comparable with other, more conventional, sources, except for a few specific locations in remote islands. The economics would alter in favour of wave power if conventional methods become more expensive, which many authorities believe is inevitable.[1]

However, a major reassessment of wave power was being carried out in the UK in the early 1990s, and the publication of the interim report in October 1991[199] showed a new approach, with all the active members of what is described as 'the wave energy community' participating, to produce a 'forward-looking review . . . based on best current knowledge'.

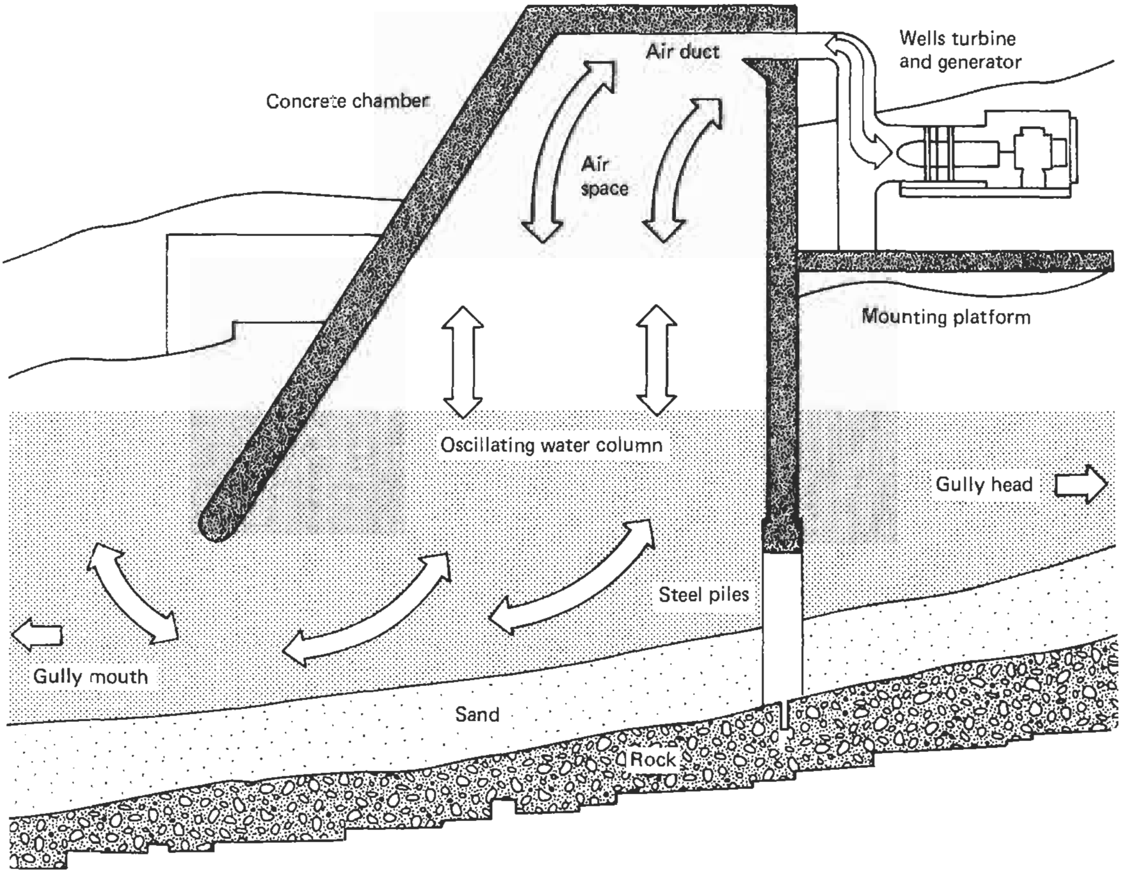

Figure 12.15 Schematic diagram of an oscillating water column device (after Review 7[201])

12.12 Biomass and energy from wastes

12.12.1 Introduction

The development of human life can be directly traced through biological conversion systems, initially through the provision of food, then food for animals, the materials for housing and energy for cooking and heating. The commencement of industrial activities was followed by the development of agriculture and forestry to their present levels. The renewed emphasis on biological conversion systems arises from the fact that solar energy can be converted directly into a storable fuel and other methods of utilizing solar energy require a separate energy-storage system. The carbohydrates can be reduced to very desirable fuels such as alcohol, hydrogen or methane, a process which can also be applied directly to organic waste materials which result from food or wood production.

Biomass can be defined as all types of animal and plant material which can be converted into energy. It includes trees and shrubs, grasses, algae, aquatic plants, agricultural and forest residues, energy crops and all forms of wastes. Estimates of how much of the world's energy demand is met by biomass range from 6% to 13%.[202,203] Among developing countries, biomass is the single most important source of energy, especially within the domestic sector, although some local industries such as bakeries, brick firing or steam production are also dependent on fuelwood. Nine tenths of the population in the poverty belts rely on wood as their chief source of fuel, and although in cooler regions some is used for heating, by far the most important energy need is for cooking.[204] Cooking fuel represents approximately 50% of fuel use in many rural areas and up to 90% of energy needs in warmer regions.[205]

The quantities of biomass produced throughout the world are very large. The annual net production of organic matter has an energy content of about 3×10^{21} J, some eight times the world's annual energy use in the early 1990s. In forests alone the biomass productivity was estimated to be about three times the world's annual energy use at the end of the 1970s.[203] At that time the potential biomass resource already standing in the world's forests was 1.8×10^{22} J, a figure comparable with the proven world oil and gas reserves. Even with the depletion of the world's forests and the increase in both oil and gas reserves in the past decade, biomass remains the largest and most familiar of all the renewable energy resources.

12.12.2 Photosynthesis

Solar energy can be used by all types of plants to synthesize organic compounds from inorganic raw materials. This is the process of photosynthesis. In the process, carbon dioxide from the air combines with water in the presence of a chloroplast to form carbohydrates and oxygen. This can be expressed by the following equation:

$$CO_2 + H_2O \xrightarrow[\text{Chloroplast}]{\text{Sunlight}} > C_x(H_2O)_y + O_2$$

A chloroplast contains chlorophyll, the green colouring matter of plants. The carbohydrates may be sugars such as cane or beet, $C_{12}H_{22}O_{11}$, or the more complex starches or cellulose, represented by $(C_6H_{10}O_5)_x$. All plants, animals and bacteria produce usable energy from stored carbon compounds by reversing this reaction. Compared with other methods, biological or photosynthetic conversion efficiencies are much lower, but are potentially far less expensive. Photosynthetic efficiency is based on the amount of fixed carbon energy produced by the plant compared with the total incident solar radiation. Plants can only use radiation in the visible part of the solar spectrum between wavelengths of 400–700 nm, known as the photosynthetically active radiation (PAR) region. This represents about 43% of the potentially available total radiation. At the plant some of the PAR is reflected and with other losses due to internal chemical processes the maximum attainable efficiency lies between 5% and 6%.

Under very favourable conditions, conversion efficiencies of between 2% and 5% have been recorded in the field for growth periods of a few weeks, but considerably lower efficiencies are achieved over longer periods of growth. Irish grasslands or forests with Sitka spruce are capable of dry matter yields greater than 16 tonnes ha^{-1} which represents an efficiency of about 0.7%. The main reasons for these relatively low efficiencies are environmental constraints, nutritional limitations and the incidence of pests and diseases.[206] Typical environmental constraints would include a drought or daily variations in ambient temperature. Nutritional limitations depend on the soil quality which, in turn, relies on the output of fertilizers.

12.12.3 Energy resources

There are five routes which can be followed to obtain the organic material or biomass which is the starting point for the energy conversion process. The first, and by far the simplest, is to harvest the natural vegetation. There are fertile regions in many parts of the world where the topography or some other reason makes the land unsuitable for agriculture or other valuable activities. With the harvesting of natural vegetation, no costs are involved in planting or clearing and the land would be given a new use. A major disadvantage of this method is that the yields are, at best, about half those which could be obtained from an energy plantation. The second is through the cultivation of a specific energy crop, grown only for its energy content, or the use of agricultural surpluses, so that the stored chemical energy can be converted into useful energy by combustion or converted into a storable fuel.

A land crop should have as high a conversion efficiency as possible, but it does not have to be digestible by animals or edible by humans. The entire material or biomass of the crop can be used, including the leaves, stalks and roots. By careful genetic selection and intensive cultivation the conversion efficiency should reach 3% under normal conditions. In the third route, trees and other types of lignocellulose material are grown specifically as fuel in energy plantations. Short-rotation forestry (described later) is a good example. The fourth uses the wastes from agro-industrial processes or residues from agriculture, animal wastes, straw, and all forms of urban wastes. The fifth route is through algae in the sea or grown in inland ponds.

12.12.4 Conversion of biomass to fuels and other products

A selection from some of the main conversion processes is illustrated in Figure 12.16, which shows that there are often several different routes to the same end product. Combustion is by far the simplest and best-known technique, particularly with forestry residues and industrial and urban wastes. A number of the processes are well known and are ideally suitable for producing fuels. With aerobic fermentation, materials containing starches and simple sugars can be used to produce ethyl alcohol or ethanol. Anaerobic fermentation has the added advantage of producing a valuable by-product, the nutrient-rich fertilizer from the digested slurry, when used to treat domestic sewage or animal wastes and produce biogas. In

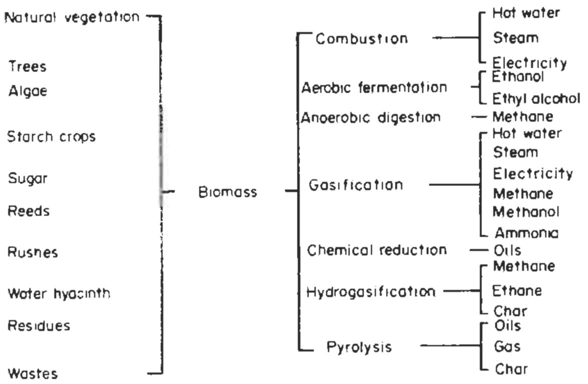

Figure 12.16 Some of the main conversion processes (after McVeigh[19])

Table 12.9

Product	*Energy content*[64]
Wood chips	18.6–20.9 MJ per kg dry weight
Biogas (two thirds CH_4, one third CO_2)	22–28 MJ m^{-3}
Ethanol	19 MJ l^{-1}
Methane	38 MJ m^{-3}
Methanol	16.9 MJ l^{-1}
Oils	30–40 MJ kg^{-1}
Pyrolytic oils	23–30 MJ kg^{-1}
Pyrolytic gas	8–15 MJ m^{-3}
Char	19–31.5 MJ kg^{-1}

the pyrolysis process the organic material is heated to temperatures between 500° and 900°C at ordinary pressures in the absence of oxygen, producing methanol, which was a by-product of charcoal in the last century. Methanol was first used as a fuel for high-performance racing cars and was subsequently studied as an additive in many laboratories. It is now considered to be an essential part of the future automobile fuel mixture.[207] The typical energy content of some of the products in Figure 12.16 is shown in Table 12.9.

12.12.5 Cooking – the major application of biomass

The United Nations have warned for many years that over 90% of wood cut in Africa is burnt as fuel.[208] Deforestation and desertification are widespread and increasing, with the southern edge of the Sahara extending by over 5 km yr^{-1}.

The scarcity of wood in some areas has meant that local inhabitants have had to move on or turn to substitutes. The World Bank[203] reported that between a half to one billion people use agricultural or animal wastes to fuel their fires. In India, cattle dung represents three quarters of the Indian domestic fuel consumption, robbing the land of valuable nutrients.[209] In parts of Africa crop residues and stubble are uprooted and used for fuel.

Cooking is a very cultural-specific activity. However, the most common means of cooking throughout the developing world is on an open fire. The most basic stove is simply three stones arranged on the ground in a triangle. The pan rests on the stones, between which three or more pieces of wood are placed. Efficiencies are low, between 2% and 10%, although much depends on the rate of burning, the air convection and other factors such as the height of the pan above the fire. Compared with the three-stones method, traditional woodfuel stoves are more efficient and the technology for improving their use of fuel exists. With a potential 30% fuel saving through the adoption of improved designs, fuel demand would be considerably reduced. Another possibility is the adoption of solar cookers, but these are too expensive and often local cooking habits or other sociological factors inhibit their acceptance, and they are unlikely to provide an adequate substitute for fuelwood, although they could provide a complementary energy source.

Adoption of alternative cooking methods also depends on such factors as aesthetic appeal and even attributes of social status. Each community is unique with regard to cooking modes and each will pertain to different values with consequent perceptions of suitability. It is therefore difficult to generalize from one community to another as to the most appropriate and acceptable fuelwood stove or solar cooker.[1]

12.12.6 Energy from waste materials

In the UK over 70 Mt of waste materials are generated annually[210] in homes, agriculture, commerce and industry. Because of changes in living patterns, especially in central heating and in the consumption of packaged goods, up to two thirds of collected domestic waste can be combustible. A breakdown of waste production and the distribution of combustible content are given in Table 12.10 (after Jackson and Tron[210]).

The calorific value of combustible waste can vary from 5.0 to 40 MJ kg^{-1} so that even at the lowest level (which predominates) a potential primary fuel content of 364×10^6 GJ per year or an installed generating capacity of 12 GW is available, of which some 60% is in domestic waste. A recent (1991) assessment of the overall gross calorific value of UK municipal waste was about 11 MJ kg^{-1}, a figure which was said to underline the advantage for energy-recovery purposes of burning the total combustible waste, rather than transporting the bulky waste and landfilling.[211]

The recent history of the use of waste as a fuel is not particularly encouraging. The variability of content of waste materials, the cost of acquisition and clean air legislation generally precludes all but the largest schemes, which inevitably mean district heating schemes run by local authorities. There are such installations in the UK at Edmonton and Nottingham, both of which are combined heat and power schemes.[23]

The late 1970s and early 1980s saw the development of pelleted Waste Derived Fuel (or Refuse Derived Fuel – RDF). Some types of refuse were dried, shredded and refined to concentrate the combustible and compressible fraction and produce a hard pellet-type fuel which could be used as a direct replacement for small coal. Only a few plants were built and operated in the UK. The completion of the plants coincided with the fall of conventional energy prices in the mid-1980s and new electricity tariffs made direct combustion of wastes a more economic proposition.[211]

Estimates for the annual average production of straw as a by-product of cereal crops in the UK range between 12 and 13.7 Mt.[23,64] Probably over half (50–60%) has been burnt in the fields to recycle minerals, but this was being phased out in the early 1990s. A total of some 166 000 t is used directly for farmhouse and animal house heating annually in over 7000

Table 12.10 Estimated UK waste and its energy content

	Gross weight (t × 10^{-6})	*Weight of combustible content* (t × 10^{-6})	*Energy content* (GJ × 10^{-6})	(%)
Domestic refuse (including vegetable and putrescibles)	18.0	12.0	166	46
Commercial refuse	3.8	1.6		
Industrial refuse	19.0	4.1	50	14
Industrial process wastes	23.0[a]	2.3	30	1
Total: Domestic, Commercial and Industrial solid waste	63.8[a]	20.0	246	68
Agricultural (surplus) straw, plastics only	8.0	8.0	105	29
Forestry	1.0	1.0	13	3
Total: all sectors	72.8	29.0	364	100

[a] Excludes mining, quarrying, construction site wastes and power-station ash.

boilers.[64] Proposals have been made for a number of applications from heat production to producer-gas fuelled vehicles, particularly tractors.[212] The maximum UK potential for on-farm straw combustion is 1.9 Mt yr^{-1}, but 0.9 Mt yr^{-1} by the end of the century is thought to be more realistic.[213] Industrial heating in small industries such as food and drink, cement and brickmaking, and in light engineering could use a further 5 Mt, but this was not considered to be likely in the short term.[64]

Domestic and commercial refuse contains large quantities of organic matter. In the UK, over half this refuse is carbohydrate in origin, and each of the estimated 3300 active landfill sites can be considered as large 'bio-reactors' for the decomposition of this organic matter. In the first stage, microbial activity is high and the rapid depletion of the available oxygen results in anaerobic conditions. Anaerobic digestion is a complex process, involving the degradation of large organic compounds, such as vegetable matter or paper, to simpler substances such as sugars.[214] This is followed by the production of hydrogen, carbon dioxide and fatty acids prior to the generation of biogas in the final stage. This is, by definition, 'landfill gas', with a chemical composition and calorific value indicated for biogas in Table 12.9.

It has a fairly recent history, being first noticed in the United States and Germany in the 1960s,[214] and its first use as a gaseous fuel in the UK followed in the 1970s with the firing of brick kilns.[214] By the end of 1987, some 14 sites in the UK were using landfill gas directly[214] and the first five small electricity-generation stations had commenced operation. The total capacity of those sites fitted with generating equipment had reached 30 MW towards the end of 1991.[215]

In a survey of world trends at the end of the 1980s, the UK came second only to the United States in the commercial exploitation of landfill gas, with the main UK use being in gas kilns, furnaces and boilers. World use was projected to reach some 3.5 Mtce by 1992, with electricity generation at 440 MW. The UK potential for landfill gas is considered to be about 3 Mtce.

Anaerobic digestion occurs naturally in organic swamps, producing marsh gas. Man-made digesters can provide the best conditions for the controlled continuous production of biogas. Air is excluded and the digester container is held at about 35°C. The People's Republic of China has been recognized as the world's major user of biogas systems for many years and biogas production has become a comprehensive controlled method of waste disposal, supplying fertilizer and improving rural health in addition to providing a renewable energy source. By 1983 there were between 5 and 6 million operating biogas units and about 60 special biogas institutes in the provinces.[216] Their sole function is to carry out research and development work on biogas units and also to develop a trained group of technical teachers who would go out into the countryside to instruct others in the construction techniques, operation and maintenance.[1]

A basic Chinese family biogas unit is shown in Figure 12.17. This would use the wastes from the smallholding activities of a number of families. Most units of this type could produce about 6–7 m^3 gas daily during the summer months.[1]

It is formed from a horizontal concrete cylinder, buried about 1 m underground. Square-sectioned vertical entrance and exit chambers have tight-fitting concrete lids. The gas is generated in the upper section of the cylinder and the delivery pipe to the family kitchen branches to a large vertical water manometer, mounted on the kitchen wall, so that a careful check can be kept on the gas pressure, normally about 250 mm of water above atmospheric pressure. Both human and animal wastes are used as raw material for the units, as well as various types of vegetable waste matter. Basic loading and clearing the processed waste for use as fertilizer takes between one and two hours per week in the summer months and slightly longer in the spring and autumn, as more care has to be taken with the quality of the wastes in colder conditions.[216]

India has also had considerable experience with the development of biogas systems and some countries are now basing their designs on the established Chinese and Indian systems. For example, over 1000 *gobar* (cow-dung) plants have been built in Nepal, biogas has been used to replace diesel fuel in Botswana and plans to develop some 300 000 biogas systems in rural Thailand have been studied.[217] Among the industrial countries Romania, with extensive pig farms, was using biogas in an experimental bus during the 1980s.[1]

Figure 12.17 A Chinese family biogas unit (after McVeigh[1])

In the UK, the temperate climate is less encouraging for biogas, but careful overall system design can overcome this problem. A prototype unit for a dairy herd of 320 cows was completed in Kent in 1979. Electrical power was generated from a Ford diesel generator modified for gas combustion with spark ignition, with a continuous maximum power calculated to be about 25 kW.[218] A number of smaller units were also operating in other parts of the country.[219]

A leading commercial organization in the UK, Farm Gas, developed a range of small digesters mainly for farm use, from the mid-1970s. In 1991 they were examining the use of small digesters for municipal solid waste for the UK Department of Energy.[220]

12.13 Energy crops

12.13.1 Short-rotation forestry

The use of trees as energy crops has been proposed in several countries since the early 1970s. Detailed feasibility studies in the USA have shown that biofuels can be produced at competitive costs, by choosing the appropriate plant species, planting density and harvest schedule for each plantation site, thus minimizing the overall cost of the plant material.[221] In Ireland about 6% of the land area consists of bogland and less than a fifth of this area is being harvested for peat, which is either used directly as fuel in the home or for generating electricity.

Until recently it had been thought that bogland was unproductive, but grass, shrubs and trees have all been successfully grown. Even with a conversion efficiency of 0.5% for Sitka spruce, the same bogland area at present used for turf could produce exactly half the quantity of electricity through the combustion of the trees. The Irish government has demonstrated that woodchips obtained from short-rotation forestry can provide an economic alternative to oil.[222]

Briefly, the short-rotation forestry concept follows the sequence of selecting, planting, harvesting and utilizing as fuel the woodchips obtained from coppicing hardwood trees. The chips will be left to dry naturally in the fields, then collected, transported and burnt directly in specially modified power stations. Alternatively, they can be bagged and sold directly for burning in central heating plants or for gasification. Harvesting would occur every three or four years. The trees are expected to regrow up to eight times from the existing root structure before replanting is necessary. A major advantage of the system is that the fuel can be stored indefinitely.[222]

An interesting statistic from the UK in 1991 pointed out that there were well over 200 woodfuelled combined heat and power plants.[223] While most of these were using by-products from sawmills or joinery works, the possibility of an alternative use of farmland for fuelwood production was being seriously considered, with support from the European Social Fund.

12.13.2 A fuel-alcohol plant

An important factor in considering energy crop conversion is the energy needed for harvesting and for fertilizers to increase the crop yields. Net energy analysis is used to assess the energy cost/benefit ratio of any proposed fuel conversion process. The energy inputs and outputs of the system can be measured and the net energy ratio (NER) can be defined as the ratio of the energy outputs to the energy inputs. Any application of this concept requires a careful definition of the system boundaries. The NER concept has been used in the world's first cassava (mandioca) fuel-alcohol commercial plant in Brazil.[224]

The system boundaries and energy flows are shown in Figure 12.18. The system consists of the cassava plantation, the fuel-alcohol distillery and the forest from which the fuelwood is obtained to provide process steam for the distillery. Energy optimization of cassava distilleries could lead to the development of varieties of cassava with larger stalk-to-root ratios, so that the cassava stalks could replace the fuelwood requirement.

Another self-sufficient process is the sugarcane fuel-alcohol system. The bagasse or by-product can generate all the necessary process steam. The NER of both systems is shown in Table 12.11 and based on 1 m^3 of anhydrous ethanol and total on-site generation of electric power.[224]

12.13.3 Marine and aqueous applications

In oceans the production of organic matter by photosynthesis is generally limited by the availability of nutrients and they have been compared to deserts because of their low productiv-

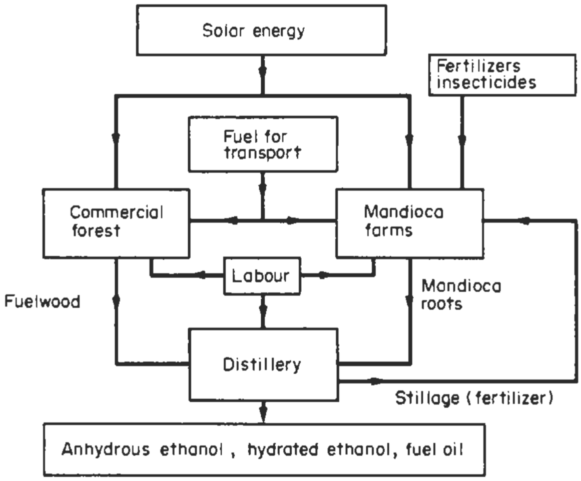

Figure 12.18 System boundaries and energy flows (after McVeigh[1])

ity. However, there are a few areas where natural flows bring the nutrients from the bottom of the ocean to the surface so that photosynthesis can take place. Particular interest has been shown in the cultivation of giant kelp (*Macrocystis pyrifera*), a large brown seaweed found off the west coast of the USA.

An early estimate examined the yield from an area of 600 000 km^2 and concluded that the equivalent of some 2% of the US energy supply could be provided.[225] One of the disadvantages of harvesting natural kelp beds would be the relatively low output caused by the lack of nutrients. Artificial kelp 'farms' have been suggested[226] and a 1000 m^2 system, with nutrient-rich deep water being pumped from deep water to the surface kelp, has been developed, as the first stage of a project which could lead to a 40 000 ha system.

Aquatic weeds can easily be converted to biogas. The water hyacinth (*Eichhornia crassipes*) has been extensively studied as a biogas source, particularly at the US National Aeronautics and Space Administration (NASA).[227] On a dry weight basis, one kilogram of water hyacinth can produce 0.4 m^3 of biogas with a calorific value of 22 MJ m^{-3}. Aquatic weeds grow prolifically in many tropical regions and are costly to harvest. However, as weed clearance is essential to keep waterways clear, biogas production could be regarded as a valuable by-product in these applications.

12.13.4 Choice of system

The factors affecting the choice of a particular biological conversion system identified by Hall and Coombs[228] include considerations of agricultural capacity, environmental factors, population density, labour intensity in the agricultural sector and the energy demand per capita. Four regimes were distinguished in their simple classification:

1. Temperate industrial areas such as North America, Western Europe and Japan, where biomass will only produce a small fraction of the energy demand. Emphasis will be placed on the production of scarce chemicals from biomass. The by-products from certain industries may be used to provide heat and power, while the use of wood as a direct fuel source is also possible.
2. Tropical and sub-tropical regions with good soil and high rainfall such as parts of India and Africa, Brazil, Indo-China and north Australia. Energy from biomass has the greatest potential in these regions, with many examples already competing economically, e.g. biogas and the more efficient use of fast-growing wood species.
3. Northern polar and arid regions where biological systems are only possible in an artificial environment, e.g. use of the nutrient film technique.
4. Marine and aqueous regions through the use of fast-growing water weeds, seaweeds or micro-algae.

The development of photobiological energy-conversion systems can take place more readily in the temperate Western countries with their high technological background. However, these systems can function more effectively in the developing tropical and sub-tropical countries and could make a very significant contribution towards reducing their dependence on increasingly scarce and expensive oil.

12.13.5 Summary

Biomass is already the most important energy resource for between a quarter and half of the world's population. Its use on a commercial scale is increasing through technical development. Further rises in the costs of competitive energy will bring many more applications into widespread use. The resource base is very large and capable of at least a fourfold expansion from today's level, which is estimated to lie between 6% and 13% of total world energy use. There would appear to be no major technical obstacle to a fourfold expansion.[1]

13.1 Introduction

Advances in physics that occurred towards the end of the nineteenth century in understanding the make-up of atoms and their nuclei led in the twentieth century to engineering applications of nuclear energy. The two major applications have been to nuclear weapons and to the production of electricity. There are a number of peripheral uses of the energy released in nuclear reactions.

It is the task of the nuclear engineer to exploit the energy of the nucleus to the benefit of humankind. Nuclear engineering shares with other branches of engineering, metallurgy, chemistry, etc. the history of having been bred in war and only subsequently applied in peace. It is perhaps the most stark in its contrasts of the benefit it might bring to humankind and the dangers of misusing the power our command over the nucleus of matter can give.

The energy coming from nuclear reactions may be specific in terms of the major radiations (alpha-particles, beta-particles and gamma-rays and neutrons in particular) or may be exploited for the general energy associated with them as an intense source of heat. Table 13.1 lists some of the major facts about the energy of nuclear radiations. It is the intensity of the nuclear energy source that is the underlying phenomenon for both nuclear weapons and power stations.

Nuclear engineering calls for many skills and, arguably, is not a basic engineering discipline. It certainly has a major element of mechanical engineering involved in the economic and safe development of nuclear power. But it is a discipline that must synthesize abilities in physics and chemistry, mechanical and electrical engineering, metallurgy, process control, economics, biology and health physics and a broad view of the social responsibilities of engineers. The present survey seeks to cover two points only: an illustration of the role of the mechanical engineer in major aspects of the use of nuclear power for the production of electricity in land-based plants; and to summarize some of the restrictions and regulations involved in using ionizing radiations in the workplace.

It is necessary first to survey briefly the nature of the energy arising from nuclear reactions and the radiations produced. We also list some of the other applications involving mechanical engineers in nuclear engineering.

13.2 Nuclear radiations and energy

A number of naturally occurring elements are radio-active, particularly the higher mass elements immediately starting with uranium and thorium. The transformation of the nucleus is accompanied by the emission of energy (Table 13.2).

Table 13.2 Nuclear radiation examples

Natural chain, alpha-emission

$^{238}\text{U} \rightarrow {}^{234}\text{Th} + \text{He}\ (\alpha) + \gamma$

Beta decay – cobalt source

$^{60}\text{Co} \rightarrow {}^{60}\text{Ni} + \beta + \gamma + \text{neutrino}$

Fusion

$\text{D} + \text{T} = {}^{2}\text{H} + {}^{3}\text{H} \rightarrow {}^{4}\text{He} + {}^{1}\text{n} + \text{Q: } 17.6\ \text{MeV}$

Fission

$^{235}\text{U} + {}^{1}\text{n} \rightarrow {}^{236}\text{U}^{*}$ (typically)

$\rightarrow {}^{147}\text{La} + {}^{87}\text{Br} + 2\ {}^{1}\text{n} + \text{Q: approx. } 200\ \text{MeV}$

Fission fragments

$^{135}\text{I} \xrightarrow[6.7]{\beta} {}^{135}\text{Xe} \xrightarrow[9.2]{\beta} {}^{135}\text{Cs}$ long-lived: half-lives (h)

Common forms for this energy to take are:

- Alpha-particles (the nucleus of helium) – recoil energy;
- Beta-particles (an electron; more rarely its complement, the positron) – recoil energy;
- Gamma-radiation; in nature identical to X-rays and characterized by a wave-frequency value proportional to the energy of the gamma photon.

Three chains exist in nature for the decay of the heavy elements to lead; the fourth has already decayed. One or two other naturally occurring radioactive elements include the potassium-40 isotope (present in fertilizers) and carbon-14 produced in the atmosphere by interaction with cosmic or solar radiation. Each radioactive species is characterized by its half-life (i.e. the mean time for half the nuclei to decay). For these chains, the shorter half-lives go with increasing kinetic energy of the radiation.

Neutrons, which with protons (the nucleus of hydrogen) form the building blocks or nucleons of the nuclei, can be obtained by stripping the proton out of deuterium, the naturally occurring heavy isotope of hydrogen, in a charged particle accelerator. However, neutrons are formed in more copious quantities in fusion and fission reactions.

In fusion, light elements have their nuclei brought together to fuse into a heavier nucleus that is more stable, thus releasing energy. In particular, the deuterium–deuterium fusion can proceed either to a nucleus of helium-3 and a neutron or to a nucleus of hydrogen-3 (tritium) and a proton.

Table 13.1

Radiation	*Symbol*	*Rest mass (u)*	*Charge(e)*	*Ionizing*	*LET(a)*
Alpha	He	4.003	+2	Direct	High
Beta	β	1/1873	−1	Direct	Low
(Positron)	β^+	1/1873	+1	Direct	Low
Gamma (X-ray)	γ	Zero	0	Direct	Low
Neutron	n	1.000	0	Indirect	High

u: one unified atomic mass unit, 1.66057×10^{-27} kg

e: one atomic charge, 1.60219×10^{-19} C

a: linear energy transfer

Such a process occurs in the stars and is being investigated (so-called cold fusion) in the laboratory. The competing fusion reaction being studied in magnetic and inertial confinement systems is the more favourable deuterium–tritium (d–t) reaction. Such a reaction yields 17 MeV (megaelectron-volts) of energy. The energy taken off by the neutron is 14 MeV, which therefore forms the principal source of energy to be exploited in making electricity, a formidable engineering task that has not yet been demonstrated. The favoured d–t route to fusion requires tritium. This can be bred locally from lithium and the excess neutrons leaving the fusion plasma. Tritium, a further isotope of hydrogen, is notoriously difficult to contain and is radioactive with a half-life of some 12 years. It therefore forms a hazard in such fusion reactors.

Fission, discovered in late 1938 and exploited in reactors and weapons in World War II, is the process of disrupting a heavy element, typically uranium-235 or plutonium-239, with a neutron to give neutron-rich fission products. In the process two or three neutrons are released making a chain reaction feasible. The energy release in fission is about 200 MeV of which 160 MeV are found in the kinetic energy of the fission products. These can be expected to be slowed down in the solid fuel which thus becomes hot. Coolants are essential and the hot coolant in turn can be made to raise steam to produce electricity. The fragments are unstable and decay largely by intense beta emission, thus heating the fuel even after the neutron reaction is shut down. This decay or 'after-heat' is a major safety implication of fission reactors calling for highly reliable design to ensure safety during an accident.

The excess neutrons that are not absorbed in a further fission will be captured by other elements in the fuel or structure or leak into the surrounding shield. This material, in turn, has radioactivity induced in it which may last, depending on the half-lives of the isotopes produced, for hundreds of years, a major factor in decommissioning fusion or fission reactors.

Capture in uranium-238 (the common isotope) leads to the production of plutonium-239. The former is called a 'fertile' material and is converted to the latter, a 'fissile' material, i.e. one that is readily fissioned by a slow or thermal neutron. (Essentially, any heavy element would fission if struck by a sufficiently energetic or fast neutron but there might then be no energy gain.) Breeder reactors (FBR) exploit this conversion of fertile to fissile material particularly using neutrons around 1 MeV to cause fission at an energy that produces about three neutrons per fission.

13.3 Mechanical engineering aspects of nuclear power stations and associated plant

In this section the broad outline of the nuclear electricity industry is described with reference to mechanical engineering aspects that embrace: pressure vessel design, heat transfer and fluid flow, remote manipulators and robotics, automatic control, etc.

13.3.1 Fuel provision

The only significant fuel currently used is natural uranium. Uranium is widely distributed throughout the world (and in sea water) and economic supplies are found particularly in Canada, the USA, Southern Africa, the former USSR and Australia. That these areas are in part distinct from oil-producing regions is a strategic attraction. Commercial ores are exploited to around 1% uranium so that mining, often open-cast, is accompanied by an on-site concentration process.

Thorium, more widely distributed than uranium, is a potential fertile fuel since it can, in a reactor, breed the fissile uranium-233 isotope. It is not yet exploited commercially.

Natural uranium undergoes considerable further processes from the imported yellow cake (oxide) before final fabrication into fuel elements. Natural uranium has little risk of leading to a spontaneous critical reaction (except in some liquid processes) but has a natural radioactivity that may be an industrial hazard, particularly in the mining stage, where it is associated with radon gas as well as other decay daughters. In general, however, the metal needs more protection from the sweat of its handlers than vice versa. Impurities in the fuel and in structural or moderating materials used in reactors must be kept to exceptionally low levels to avoid competition for neutrons in the chain reactions.

Most commercial reactors now use slightly enriched uranium where the natural concentration of uranium-235 (around 0.7%) is raised to between 2.5% and 3%. Such enrichment is needed to offset the neutron capture in fuel clad with stainless steel or zirconium and to provide for long fuel life before the fissile material is burnt up.

The technology of uranium enrichment is well advanced. The major route in World War II and immediately after was through gaseous diffusion (more properly, gaseous fusion) with preferential separation through membranes of the low-pressure gas uranium hexafluoride or 'hex'. Major mechanical problems with these plants are the large runs of pipes at low pressures, the corrosive nature of fluorine compounds and the design of pumps. The high pumping costs of this process fostered the development of the rival ultra-centrifuge process for enrichment in which hex is separated by a thermally enhanced centrifuge. Major mechanical problems here are the reliability of the centrifuges, operating at a rim speed of some 300 m/s in vast cascade halls where the mechanical failure of one unit risks knock-on damage to the remainder. Gas and magnetic bearings have been developed to meet this challenge (Figures 13.1 and 13.2).

The UK's enrichment takes place at Capenhurst, where the centrifuge process has superceded the diffusion process since 1982. These plants are operated in conjunction with plants in Germany and Holland by URENCO in which British Nuclear Fuels plc have a third interest.

The enrichment plants, of necessity, produce depleted uranium. There is some prospect of this being used in fast breeder reactors and thus, like thorium, offering a greatly increased availability of fission fuel. Large stocks of depleted uranium are available from store in the UK. Its exploitation rests on rising fuel prices until the extra capital expense of the fast breeder reactors is offset by their cheap fuel. At least the availability of depleted uranium and the demonstrated ability of fast breeders to produce electricity puts a ceiling on competing fuels.

Enrichment also plays a part in preparing supplies of other items for the nuclear industry, particularly heavy water, and the isotopes of boron and lithium.

Plutonium bred in a nuclear reactor by the capture of neutrons in uranium-238 is an artificial source of nuclear fuel available from thermal and fast reactors. The immediate product of such breeding is the fissile isotope plutonium-239. It should be known that, like highly enriched uranium-235, this isotope of plutonium is a potential weapons material. Fuel removed from a reactor after a short exposure contains principally this weapons-grade plutonium. However, fuel left longer – with economic advantage in peaceful use – allows further neutron capture to the successive 240, 241 and perhaps 242 isotopes of plutonium. Plutonium-241 is fissile but the

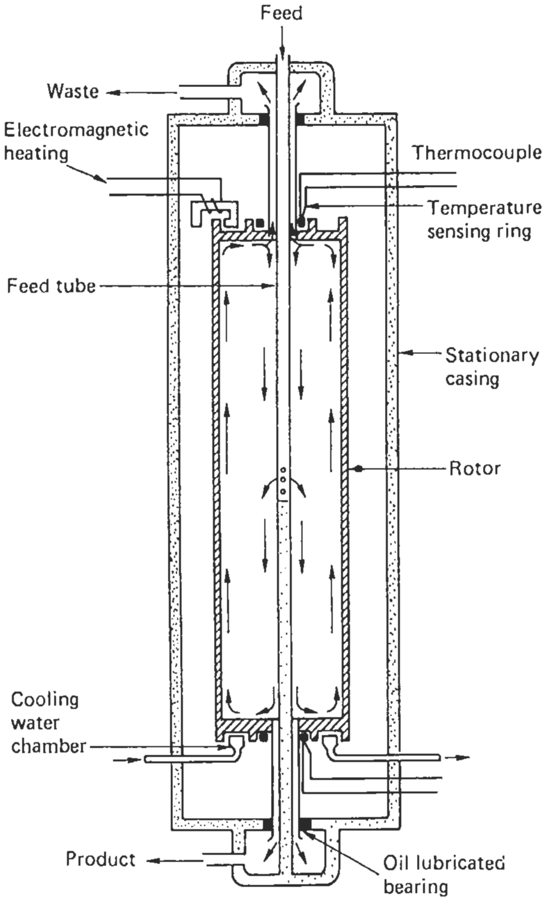

Figure 13.1 Centrifuge diagram

Figure 13.2 Centrifuge hall (courtesy BNFL and URENCO)

intermediate plutonium-240 is not. Thus such fuel is far less suitable for weapons and is known as commercial fuel.

Plutonium is separated in the reprocessing stages. If it is to be incorporated into fuel elements, either for the core of fast reactors or as a substitute for uranium-235 in thermal reactors, account must be taken of the greater radio-toxicity (some ten times more than uranium) and the risks of criticality accidents in the concentrated fissile plutonium. It is essential therefore for production to be undertaken in a controlled atmosphere, usually at lower than ambient pressures inside glove boxes to direct the leakage of air safely. The major risk is of inhalation with deposit in the lungs or of entry to the bloodstream via cuts. Ingestion is appreciably less risky as plutonium is not easily absorbed by the gut.

The fissile material is used in the dioxide form in most reactors since such ceramics can operate at considerably higher temperatures than the metal. Final preparation of fuel, usually after enrichment in uranium-235 or as a mixed oxide with plutonium (MOX), involves fabrication and cladding. Cladding is generally in a zirconium alloy (or in stainless steel for higher operating temperatures) with the major purpose of retaining fission products whose radioactivity would otherwise contaminate the plant. Extremely high standards of manufacturing integrity are required of fuel elements so that quality control and assurance, including non-destructive testing and the documentation of individual fuel elements, is essential.

Major mechanical implications of the special nature of producing nuclear fuel include therefore: the radiation and criticality hazard, the reliability of high-speed centrifuges, the leaktightness of many miles of vacuum pressure piping in enrichment plant, corrosion of hexafluoride material, the use of glove boxes and the control of quality in the final fuel element assembly.

13.3.2 Reactor types

Reactors may be classified in several ways, first by the predominant energy of the neutrons causing fission. Fast reactors produce neutrons that directly induce fission. They generally require highly enriched uranium or plutonium cores. Alternatively, in thermal reactors, the fast neutrons produced in fission are slowed down or moderated to thermal energies. The better yield of neutrons in fission allows natural or only slight enrichment of fuel.

Hydrogen is an effective moderating material and finds a particular role in light (ordinary) water-cooled reactors (LWR) which may be pressurized (PWR) or boiling (BWR). Alternatively, heavy water (deuterium oxide) is used. The other major category of thermal reactor has gas cooling and graphite moderation, as in the UK Magnox and Advanced Gas-Cooled Reactors (AGR).

Thus a second categorization of reactors is in their coolant and/or moderator: Light Water Reactors (LWR), Heavy Water Reactors, Gas-Cooled Reactors and Metal-Cooled Reactors where sodium or sodium potassium alloy (NaK) are used for good heat transfer in fast reactors in which moderation is not wanted.

13.3.3 The coolant challenge

Reactors are operated at high energy density to make them economic despite high capital costs. The energy density in a PWR is comparable to the boiler of an oil-fired station; in a FBR it is comparable to a chemical rocket. It is essential that coolant capacity is maintained throughout operation. In this respect, there is competition between a gaseous coolant with poorer heat transfer capability and a liquid coolant with greater heat transfer but the risk of two-phase loss of heat

transfer on depressurization. Nuclear power has made considerable demands on the prediction of heat transfer in one- and two-phase flow.

Coolant capacity must be provided not only during normal operation but also on shutdown, particularly in accident conditions. Whereas the neutron chain reaction can be terminated rapidly with neutron-absorbing control rods, etc., the after-heat from the decay of previously formed fission products cannot be turned off. Roughly, this after-heat is at 10% of previous steady operating power for a few minutes from shutdown, decaying slowly until, say, 1% after a week, 0.1% after a month. Thus a reactor that had been designed for operation at 3000 MW (thermal) must be provided with a reliable shutdown and emergency cooling circuit(s) to cope with 300 MW after-heat.

PWRs operate with water as coolant-moderator at some 170 bar and with a core of some 3 m diameter. There is therefore a considerable challenge in providing a reliable pressure vessel. The challenge is eased in systems having multiple pressure tubes, one for each fuel bundle and therefore of smaller diameter (Figures 13.3 and 13.4).

A major failure of the vessel of a PWR would be catastrophic. It would imply no availability of coolant water and the overheating and probably meltdown of the fuel with the release of its residual radioactivity. Suffice it to say that 29 of the initial 31 casualties at Chernobyl (1986) died from radia-

tion burns from the exposed fuel and fission fragments, following failures in a pressure-tube reactor.

The sodium coolant of a fast reactor has some disadvantages. The sodium is a fire hazard on contact with water in the steam-raising plant and sodium passed through the reactor core is activated by neutron capture. It is therefore seen to be essential to have an intermediate sodium loop between the primary core sodium and the boilers to prevent the reaction of active sodium and water. However, the metal coolant offers the advantages of good heat transfer at ambient pressures; no elaborate pressure envelope is called for and a pool design is possible.

Gas-cooled reactors have a pressure envelope between the high pressure of PWRs and the low pressure of FBRs. Carbon dioxide pressures were increased in successive designs, from around 10 bar in the early Magnox stations through 28 bar at Wylfa, the last Magnox, to around 35 bar for the AGRs.

The most challenging pressures are therefore found in PWRs, and here the loss of coolant capacity if the primary water were allowed a change of phase to steam might be catastrophic. It follows that pressure vessel design, fabrication and testing are a major goal in the PWR plant. It is inevitable that there will be some cracks in the forging and welding of a vessel using steel of more than 250 mm thickness. It is desired than any crack should allow leakage and hence detection before catastrophic (Griffiths) failure. Early comparisons under the Plate Inspection Steering Committee (PISC) cast doubt upon the guarantees of pressure vessel safety but non-destructive testing, chiefly ultrasonic, has been greatly developed under this challenge, including formal systems of validating testing methods and testers. Major developments in the UK in this area have included the establishment of the Inspection Validation Centre (IVC) at the UKAEA/AEA Technology site, Risley. This centre operates in the context of two competing systems of certification for non-destructive testing in the UK: the PCN or Personal Certification in Non-Destructive Testing and the ASNT or American Society for Non-Destructive Testing scheme.

Control of reactors is exercised using control rods loaded with neutron-absorbing materials such as hafnium, backed up with boron-loaded particles for use in emergencies and, in some cases, neutron-absorbing gases such as nitrogen or helium-3. There is a considerable mechanical challenge in designing the control rods and their motors for reliable operation in the fierce radiation and temperature environment of the reactor core. High-speed flow, particularly in gas-cooled reactors, has led to major problems of induced vibration resulting in fretting and cracking. Boiler tube failure can, in part, be met by overprovision of boiler tubes so that a small proportion can be lost from use by plugging to prevent transfer between the radioactive primary and the secondary sides; this also allows some margin for fouling.

However, where parts of the reactor core deteriorate or fail in operation, a major problem of repair in a radiation environment is faced. This has called for the development of remote sensing and manipulation tools able to penetrate into the reactor, often through tortuous paths.

Overall control is now the function of direct digital controllers which provide for the processing of great volumes of data needed for a historical verification of quality as well as an assessment of past accidents and near-accidents (incidents).

Special problems of fast reactors arise from the high energy density (for economy) and the liquid metal coolants. There is both a high temperature and a high-temperature gradient in Liquid-metal Fast Breeder Reactors (LMFBR). Fluctuations in the coolant flow lead to thermal striping or temperature cycles of around 1 Hz which imply problems of temperature creep. The fast neutron flux also leads to lattice displacement with problems of swelling and loss of structural integrity. Furthermore, there has been generally poor experience in the provision of sound heat exchangers between sodium and water. Since the primary sodium is activated in the reactor core and must not be allowed to come into contact with water in the steam generators, it is customary to provide an intermediate sodium–sodium loop. A further complication of the mechanical design has been, at least in practice so far, the provision of additional core supports since, unlike the well-moderated thermal reactor, it is conceivable that a collapse of the core of a fast reactor might lead to a supercritical and unacceptably dangerous condition. It follows that the capital costs of the FBR tend to be higher than for, say, PWR, and hence FBRs are unlikely to be economic until such times as a rise in the cost of natural uranium outweighs their greater capital cost.

13.3.4 Post-reactor fuel processes

Once exposed in a reactor, the fuel, which may have yielded 30–80 MWdays/kg, is highly radioactive and must be both cooled and shielded. Pressurized water reactors are shut down, flooded externally and the bolted vessel heads removed before fuel can be moved. (The design of the stud tensioners used in replacing a PWR vessel head is a major mechanical challenge; see Figure 13.5.) Fuel may be shuffled from one region of the reactor core to another as well as having a quarter or a third removed and replaced with fresh fuel. The exposed fuel is kept on-site for a period to allow immediate decay of fission products, either under water or in a dry, gas-cooled store. The older UK Magnox and Advanced Gas Cooled Reactors, however, are designed on the philosophy of on-line fuel changing, with its economic advantages; they require a major commitment to fuel loading/unloading machines (Figure 13.6).

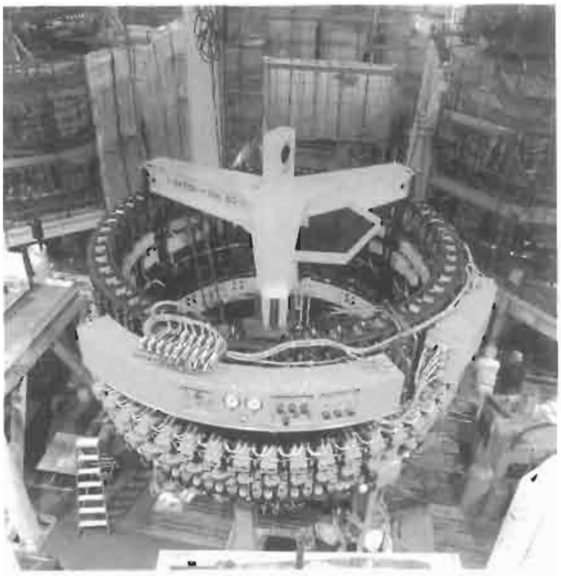

Figure 13.5 Pressure vessel stud tensioner

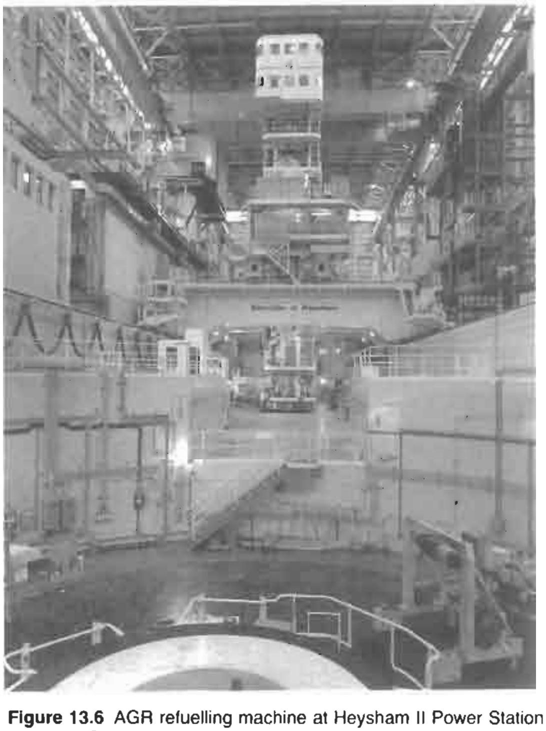

Figure 13.6 AGR refuelling machine at Heysham II Power Station (courtesy Strachan & Henshaw)

Whether the used fuel is reprocessed – to recover the unused uranium (for re-use after possible further enrichment), to obtain the plutonium bred in the reactor but not yet consumed *in situ* and to concentrate the fission products (about 1% of the used fuel mass) – is a decision that has been made on political as well as technical grounds. It is the practice in the UK and France to reprocess fuel. This has been done routinely for Magnox (metal-fuelled) reactors. It is proposed (but not yet practised in the UK) to reprocess the oxide fuel from AGRs and PWRs. In the USA, however, commercial-grade fuel is not reprocessed, in accordance with national policy associated with the non-proliferation of weapons.

Where reprocessing is undertaken, highly concentrated and radioactive fission products are obtained. Currently these are stored in double-lined stainless steel cans, perhaps for 50 years to allow the activity to decay. If the contents are then to be disposed of, i.e. without expectation of recovery, this must be done in a way that will prevent the escape of the residual active products to the biosphere over many thousands of years. A favoured route is for the fixing of the fission products in a glass followed by encapsulation in bitumen and metal containers for disposal in a deep vault on land or under the sea. There will be major mechanical engineering challenges when this stage is undertaken.

The reprocessing plant is largely a chemical engineering industry. It has major mechanical engineering aspects in: provision of reaction vessels, criticality control and shielding; the provision of heat transfer/coolants for used fuel elements and concentrated fission products; remote manipulation (Figure 13.7); and design of waste storage and disposal vaults.

13.3.5 Quality assurance and control

From the above it will be seen that quality is an essential element in nuclear engineering (as in much else). Its importance lies in two mutually supporting aspects: a necessity in the provision of safety and in the protection of commercial investment. The accident at Chernobyl in 1986 has led to massive direct costs associated with the contamination by radioactivity of the surrounding area. Yet the accident in 1978 at Three Mile Island in the USA, while leading to negligible activity release off-site, has in similar fashion enormous direct and indirect economic consequences. In both cases the cost of clean-up is measured in billions (gigapounds); the indirect costs have similar magnitudes, providing for substitute electricity or in the halting and perhaps denial of public acceptance of a nuclear power programme.

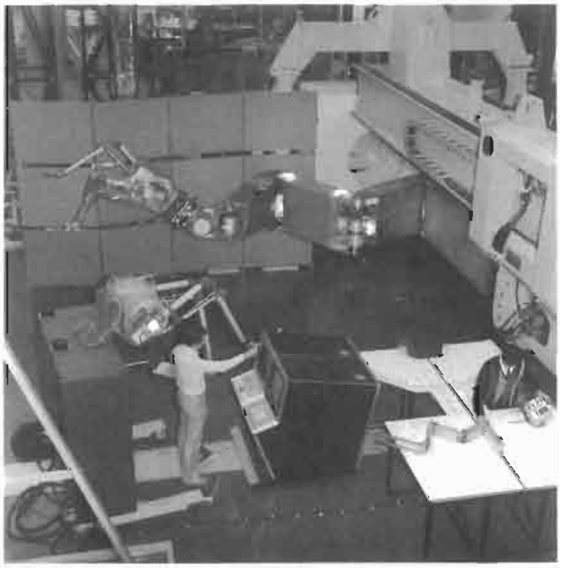

Figure 13.7 Remote manipulator for JET fusion experiment (courtesy JET Joint Undertaking)

The emphasis on quality assurance and control is therefore understandable. The principles of quality assurance were indeed laid down in the US nuclear submarine programme by H. G. Rickover in 1942 and were re-expressed in 1970 as the eighteen criteria of quality assurance (US Code of Federal Regulation 10CFR50 Appendix B), much as the nuclear weapons programme was the driving force in the development of digital computers in the 1950s.

13.4 Other applications of nuclear radiation

13.4.1 Gauging and detection

Use is made of the specific nature of radiation in such instruments as beta gauges for determining the thickness of paper on rolling mills; to trace leakages and blockages in underground pipes from a gamma-radiation 'pig'; and in the testing of welds by gamma-radiation. In this respect, gamma-radiation and X-rays are indistinguishable in application and thus gamma-rays show up contrast in heavy elements. Neutrons can be used, however, to contrast good and poor scattering elements and neutron radiographs and even holographs of hydrogenous material are feasible. Ionizing radiation is used in fire (smoke) detectors and is cleared for domestic use in the UK.

13.4.2 Compact power sources

Medium-sized pressurized water reactors (PWR) are widely used in major navies for submarines (where their underwater endurance is unsurpassed) and capital ships, aircraft carriers and ice breakers. Only demonstrations have been made of commercial marine applications. In space, small fission reactors have been employed but simpler and more reliable long-life power plants can be made using the decay heat and charge release from isotopes of plutonium, etc. Some of these devices have been adapted to remote sea-navigation beacons and to heart pacemakers.

13.4.3 Materials and sterilization effects

Gamma-radiation promotes polymerization of plastics and is routinely used. Gamma-radiation, from, say, activated cobalt-60 is used to sterilize pre-packed medical instruments and is proposed for the treatment of food such as vegetables to delay decay. Such treatment does some damage (e.g. to vitamins) but does not induce radioactivity in the food which has been cleared for human consumption in a number of countries.

13.4.4 Medical applications

Ionizing radiations (X-ray and gamma) are also used for diagnostic visualization including tomography and for treatment, notably for cancer. Some experimental use has been made of neutron beams to treat cancer of the brain after ingestion of a suitable neutron-capture agent such as boron. The behaviour of the lung can be visualized by inhaling artificially produced technetium.

13.4.5 Dating and tracing

Activated isotopes may be incorporated into materials and are particularly helpful in tracing metabolic reactions in biological substances. Dating of artefacts by measuring carbon-14 activity (or the modern method of isotopic analysis) has enabled wood and similar materials to be dated back some 8000 years.

13.5 Elements of health physics and shielding

Any engineer wishing to make use of nuclear energy in any form needs to understand the effect of the associated radiations on matter, inert and biological materials. Alpha- and beta-particles, and gamma-rays are directly ionizing; that is, their passage through matter is accompanied by the disruption of the neutral molecule to form charged radicals or ions. Neutrons are not directly ionizing but the results of their reactions are ionizing radiations. The damage done may also include displacement of the nucleus, particularly by neutrons, alpha-particles and other heavy ions. Thus the steel cladding of a nuclear fuel element may need to be designed for the swelling and atomic displacement in which an average atom is struck over one hundred times in its lifetime. The Windscale fire of 1957 is associated with the sudden release of the Wigner displacement energy imparted by neutrons to the graphite moderator.

In the modern approach to the measurement of the effects of ionizing radiation the physical nature is described in terms of the energy deposited per unit mass. The SI unit of one joule per kilogram is given the special name of the gray (symbol Gy). It replaces the older, obsolete and obsolescent units of the roentgen and the rad (Table 13.3).

The biological effects of ionizing radiations spring from their energy but vary with the nature of the radiation. To account for this, quality factors are employed to multiply the physical dose in gray to express an effective dose equivalent in sievert (symbol Sv), also in J/kg. These quality factors are thus non-dimensional numbers. Values of quality factors for some radiations are listed in Table 13.4. The primary reason for the variation in biological effectiveness is associated with the energy density along the track of the particle, described as LET (linear energy transfer). Thus alpha-particles, the nuclei of helium, being relatively massive and doubly charged have a high LET and correspondingly cause such severe damage to individual cells that they are less liable to recover. Gamma-rays, however, have a low LET (if they can be said to have a track at all), and even though the energy deposited per kg may be the same, the energy is spread over more cells which may therefore recover from the insult, leading to noticeably smaller biological damage.

On the other hand, the high LET radiations will be stopped more readily than low LET radiations. A sheet of paper might serve to stop most alpha-particles; beta-particles can penetrate a few centimetres of flesh; but gamma-rays have a mean-free path in air of several metres, depending on their energy. Thus alpha-particles may be seriously damaging if ingested but shielding suitable for beta and gamma radiation will be more than adequate against external alphas. Protection against radiation involves therefore shielding against external sources and the prevention of ingestion leading to internal doses.

Table 13.3 Radiation units: current and obsolescent

Activity		
Bequerel	Bq	1 disintegration/s
Curie	Ci or ci	37×10^9 Bq
Absorbed dose		
Gray	Gy	1 joule/kilogram
Rad	rad	100 Gy
Roentgen	R	see below
Dose equivalent		
Sievert	Sv	1 joule/kilogram
Rem	rem	100 Sv

Notes

Sv = Gy time-weighting factors. The most important weighting factor is the *quality factor*, Q (see Table 13.4).

The roentgen, R, has been defined in different ways at different times. One definition is 'that quantity of X- or gamma-radiation which produces in air at s.t.p. ions carrying a total charge of one electrostatic unit of either sign'. It is approximately 88 Gy.

The SI units of Bq, Gy and Sv are preferred.

Table 13.4 Quality factors for ionizing radiation

Radiation	*Q*
Photons (gamma- or X-rays)	1
Beta-particles	1
Protons	10
Alpha-particles and heavy multiply charged particles	20
Neutrons	
thermal	2.3
fast	10

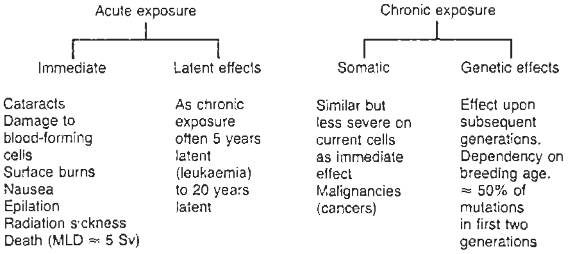
13.5.1 Biological effects

The effects of radiation on living matter depend on the energy deposition (in gray), the quality factor for the radiation and thus the equivalent dose in sievert but also upon the rate at which the dose is applied. The slower dose rate provides for some opportunity for the body's defence mechanisms to counter its gross effects (Figure 13.8).

Another important distinction is between stochastic and non-stochastic (deterministic) consequences. Some consequences of disease can be correlated with the effective dose (e.g. clouding of the retina under neutron irradiation). The response is not necessarily linear but such effects can have an associated lower dose limit below which the effect is essentially not seen.

In other cases, however, only the incidence of the disease, not the consequence, is a function of the effective dose. In particular, cancers and genetic defects are initiated by radiation with a certain probability; the result, however, is not itself a function of the radiation received.

It follows that whereas safety limits could be stipulated such that injury of a deterministic nature is prevented, no such limit can be set for conditions of a stochastic type. Thus a lower limit can only be set comparatively; is the probability of injury acceptable in comparison with other, non-radiation, occupations?



Acute exposure
Chronic exposure

Malignancies (cancers)
Effect upon subsequent generations.
Dependency on breeding age.
≈ 50% of mutations in first two generations

Figure 13.8 Biological effects of ionizing radiation

It does not follow that the incidence of stochastic symptoms is linearly proportional to the dose received, although this assumption of linearity is common in all administrative regulation of dose limits. On the one hand, there might be a threshold under which no incidence occurs; indeed, there are even arguments for homesis, where a little radiation (as perhaps the natural background we evolved in) does you good. On the other hand, there are arguments to support the quadratic relationship of stochastic incidence to effective dose. The linear hypothesis is simple and allows a ready assessment of radiation from combined sources.

A consequence of the assumption of linearity is the role of the population exposure, measured in (say) person sieverts. If the population dose is (say) one person-Sv, then the incidence of cancer can be expected to be the same, whether this is spread over a population of ten or of 100. It follows that the idea of enlarging the workforce to lower the average exposure per worker is not good practice.

13.5.2 Radiation limits

Formal statutory limits are imposed by national legislation and, in the UK, their observance is a matter for the Health and Safety Commission and its Executive (HSE). A distinction is made between normal practice and emergencies and between industrial limits and limits for the public.

To appreciate these limits, it should be said that the average exposure of the population in Britain is some 2 mSv a year, the major part coming from radon gas (and thus varying markedly over the country) and less than 1 μSv from the nuclear power industry. Acute exposure, on the other hand, of 5 Sv (some 2000 times natural background) may be fatal.

The limits are based on recommendations of the ICRP (International Commission for Radiation Protection). In arriving at these limits, the ICRP have made clear that they expect good practice to keep the average exposure below the limits (approximately one tenth of the limit itself). Industrial limits are arrived at by comparing current estimates of genetic damage and incidence of cancer with risks currently accepted in other, non-ionizing, industries. They are therefore subject to review over the years, generally downwards.

The following are based on the recommendation of the ICRP No. 60 (1990).

13.5.2.1 Industrial limits

Deterministic limit 500 mSv/annum (a) (eye 150 mSv/a)
Stochastic limits 20 mSv/a

In practice therefore, limits based on stochastic effects apply. The overall limit is arrived at by a suitable weighting of different organs.

In UK practice, an intermediate level of 30% of the limit is introduced as a reference level, i.e. at 6 mSv/a. If the working practice is such that it can be demonstrated that exposure to this intermediate level is unlikely, then the workers and the workplace need not be specially designated. If this demonstration cannot be made, then special precautions and administration is required of the plant, including long-term records of actual exposure, etc. It is obviously attractive to design the work involving small quantities of radiation to avoid 'designation' and a useful figure of merit is to convert the 6 mSv on the basis of a 2000-hour working year to give 3 μSv/h. If the dose equivalent rate is below this figure, designation is not required.

Obviously, this escape is not available in major installations. Such industries must have, by law, a Radiation Protection Adviser and a formal system of monitoring exposure. Special national records are maintained for workers with uranium and plutonium.

13.5.2.2 Public exposure

On the philosophy that the public have less choice of working conditions, the exposure limits for the public are set at one tenth of the industrial limit.

13.5.2.3 Emergencies

Somewhat higher than annual average limits can be accepted for special operations, such as planned maintenance, if the workers' dose over a number of years averages out satisfactorily. In an emergency where lives are at risk, larger doses again can be countenanced. There is obviously no easy way to provide for a legislative limit in these circumstances.

13.5.3 Elementary shielding

Protection of personnel, perhaps animals, and equipment can be provided by suitable application of the following guidelines:

1. Reduce the exposure to the source to a minimum time.
2. Use distance for protection; the radiation from a point source goes down about as rapidly as the square of the distance.
3. Employ a material shield suitable to interrupt the passage of the radiation.

A too-simple approach to shielding can be dangerous. Thus thermal neutrons can be captured by cadmium. But a cadmium suit would be fatal to the wearer in view of the gamma-rays emitted upon neutron capture. The high-energy gamma-rays go through several competing reactions before eventual absorption in material (where they ionize and ultimately heat matter). Material that is opaque to gammas at one energy may be transparent at another – there is a dangerous window in iron. Also, the travel of the gammas in these processes can lead to radiation appearing from unexpected directions – sky shine over a shielding wall.

There are other aphorisms arising in elementary shielding such as 'water has no cracks'; solid shields invariably have weaknesses at joints which may lead to unacceptable radiation streaming for which 'dogleg' design is appropriate.

Small sources can be shielded against in elementary ways by over-designing the shield. The cost, in size and weight, may be acceptable. But major nuclear sources require elaborate and expensive shielding. Correspondingly, major resources involving much computing time and perhaps experimental verification are devoted to the design of the shield.

These elements of shielding and the restrictions of radiological control lend themselves to an approach generally known as ALARA:

> As Low As Reasonably Achievable, economic and social factors taken into account.

It is implied in ALARA that no radiation shall be employed for its own sake, but only if there is a benefit. Where there is a benefit, comparisons are due with non-radiation methods to the same end. Finally, statutory limits shall not be exceeded.

ALARA is internationally recognized, although in the UK the regulating authorities have made modifications such as ALARP (reasonably practical), etc.

In principle, the optimization of the design process and the operating process are conducted until the user is able to satisfy the regulators that ALARA has been achieved. There is, of course, no scientific optimum to be obtained because the regulating process is as much economic and political as it is scientific.

14.1 Historical review

The oceans of planet Earth exercise a dominant influence on its weather systems and ecology. They are believed to have been the medium in which life first appeared on the planet and gradually evolved into land-based plant and animal species. The continued existence of land-based life is still dependent on the oceans through their effect on the planet's weather and the crucial role that the oceans play in global ecology. Since prehistoric times and up to the early part of this century, however, our use of the oceans has been largely restricted to near-shore transportation and fisheries, although there is evidence to suggest migrations of people across very large oceanic distances. Since the fifteenth century, the pace of ocean transportation and deep-water fishing has gradually increased, but our utilization of the oceans has still been restricted to these two activities.

Over the last five decades, however, traditional uses of the oceans have expanded to include the exploitation of hydrocarbons below the sea bed and the potential of large-scale mineral gathering and energy extraction. The development of offshore oil and gas has, however, led the way, with land-based exploration and production for crude oil being extended to the sea bed as early as 1887, when the first exploration drilling was carried out, from over a few feet of water, in California.

Since then, the pace of oil exploration and production in shallow water has gradually increased, with the next major development occurring in 1910, when wells were sunk in Ferry Lake, Louisiana. This was followed in 1929 by the exploration and production of a large oil reservoir on Lake Maracaibo in Venezuela. The development of the Gulf of Mexico as an offshore area started in the 1930s, with oil first being produced in 1938 from a timber platform in 4.3 m (14 ft) of water, on the Creole Field, which was located 1.6 km (1 mile) off the coast of Louisiana. Following the Second World War, offshore activity in the Gulf of Mexico rapidly evolved with oil exploration and production in deeper water until by 1959, an oil production platform had been installed in 30.5 m (100 ft) of water by Shell on a block in Grand Isle. At the same time, British Petroleum were developing shallow-water oil finds in the Persian Gulf.

Such oil and gas exploration and development spread to most of the continental shelf areas of the world from the mid-1950s, starting first in the Gulf of Mexico, then spreading to the waters off Mexico, Brazil and Brunei in the Far East. The map of Figure 14.1(a) presents an overview of this worldwide offshore exploration and production activity, whereas Figure 14.1(b) uses sea-bed contours to show the extent of the continental shelves around all the major land masses. The continental shelves cover only a small fraction of the total ocean areas, but they are potential sites for exploration or are already known to have large reserves.

The offshore industry began a technically more challenging phase when the North Sea was first explored as a potential offshore area in the early 1960s. Figure 14.2 presents an overview of the fields developed in the North Sea since the mid-1960s. These fields range from large gas accumulations in the relatively calm waters off East Anglia in the south to harsh northerly environments in the vicinity of 60° North, where fields such as Magnus, Thistle, Murchison and Cormorant are exposed to some of the most hostile wind and wave conditions of any maritime area in the world. The North Sea is typical of many offshore areas where the development of technology and structures to exploit oil and gas fields has had a significant positive impact on the economies of surrounding countries.

The development of land-based and offshore oil and gas deposits has played an essential role in laying the foundations of the modern world with its high living standards. Figure 14.3 displays the relative volumes of onshore and total oil production over the last two decades and shows that offshore oil production is now approaching 30% of total worldwide production.

14.2 Types of fixed and floating structures

The design of offshore structures used for oil and gas production offers some indication of the following problems. A typical steel-framed jacket structure used for offshore oil drilling and production will encounter largely steady environmental forces from wind and current flows, and from the structure's self-weight. The jacket will also be subjected to high levels of cyclic load due to gravity waves (see Section 14.4), its sea-bed equipment will be working in the presence of very high sea-water pressure, the steel making up its structure will have to survive sea-water corrosion for long periods since large parts of the jacket structure are difficult to access and maintain. At the same time, the physical processes that govern interactions between the atmosphere and the ocean surface, the effect of the structure on the fluid around it and on the behaviour of the sea-bed foundation are not completely understood in scientific terms.

These problems are compounded by the uncertainties of predicting the most extreme environment likely to be encountered by the structure over its lifetime, which is measured in decades, and the uncertainty of categorizing the geology and recoverable resources of the hydrocarbon reservoir that the steel structure is designed to develop. All of these interacting problems offer unique challenges for advanced scientific analysis and engineering design.

The technical evolution of the modern offshore industry can be measured by the depth at which it has been able to carry out exploration drilling and by the structures or vessels that have made such drilling possible. Initially, exploration drilling was carried out from shallow water fixed platforms which were made of timber and piled to the sea bed. This was later followed by drilling from barges or drilling tenders mounted in sheltered locations. The water-depth capability of drilling equipment has gradually increased, first by the use of jack-up rigs – a typical modern jack-up rig is shown in Figure 14.4. These rigs are generally of triangular construction, containing steel-framed legs at each corner which can be jacked up or down by electric or hydraulic machinery. The jack-up hull is transported to the drilling site either by loading onto a barge or by towing the self-floating hull. The legs are jacked down at the drill site, and the platform hull is raised a sufficient distance above mean water level to prevent waves hitting the underside of the platform. Drilling then commences, usually for a work programme of between 2 to 4 months. When the drilling programme has been completed, the hull is lowered down to the sea surface, or onto a transportation barge, and the rig is moved to the next drilling location. Some jack-ups have also been used for oil production in shallow water, with modern jack-ups able to operate in severe weather at water depths of up to 107 m (350 ft).

Exploration drilling in waters of up to 18 m (60 ft) depth was also carried out from floating vessels with one or more pontoons or caissons supporting a deck with vertical columns. Such platforms were floated onto the drilling site and then ballasted down to the sea bed to carry out a drilling programme. During the flotation phase of deployment it was noticed that such column-stabilized platforms had exceptionally low motion response to waves. This feature was utilized to develop so-called semi-submersible floating platforms which did not have to be ballasted down to the sea bed

in order to carry out drilling. Figure 14.5 shows a perspective view of one such modern vessel with two parallel submerged pontoons at keel level supporting a large deck area using eight vertical surface-piercing columns. The columns, pontoons and deck are braced to form a space frame structure which can be moored on location by a spread of catenary mooring ropes or chains. The deck contains a central opening called the moonpool through which drilling activities take place. Most semisubmersible vessels are equipped with accommodation, helicopter pads for crew transport, propulsion engines, pipe-handling equipment, cranes and a variety of marine services to support crew and drilling operations.

Drilling into the sea bed is carried out through a vertical pipe called the marine riser which connects the area under the moonpool to a subsea wellhead. A drill bit on the end of the drill pipe is passed through the riser to penetrate the sea bed and carry out the actual drilling. A lubricating fluid called drilling mud is pumped to the drill face at high pressure through the hollow drill pipe and returned through the annulus between the drill pipe and riser. The drilling mud pressure is used to drive rotating cones on the drill bit with the drill bit and pipe itself rotating at up to 250 rev/min. The drilling mud serves several purposes. It lubricates the drill bit, drives the drill bit cones, sweeps out drill cuttings to the surface and provides a hydrostatic pressure head to contain high-pressure oil or gas that may be encountered. The small, but significant, heave motions of the floating drilling rig due to ocean waves are compensated for by a slip joint at the base of

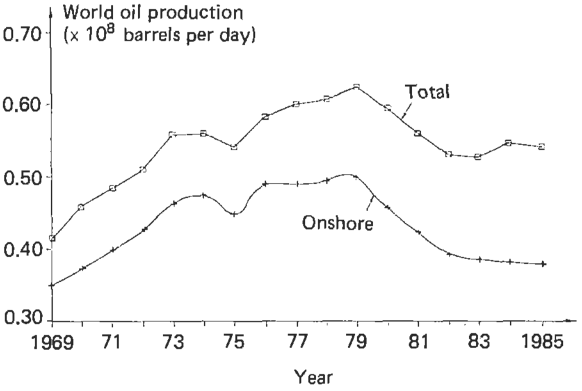

Figure 14.3 Growth of onshore and total oil production (from American Petroleum Institute[2])

the drilling derrick. A tensioner also provides an upward force on the riser to keep it in tension and prevent buckling of its slender structure. The moorings of a drilling semi-submersible have to maintain station to less than 7% of the water depth, in order to continue drilling. The maximum water depth and weather conditions in which a semi-submersible vessel drills are governed by its mooring system, by the amount of drill pipe and riser pipe that it can carry, and by heave compensator limits imposed by the vessel's motion response and prevailing weather.

A caternary line mooring system is impractical above water depths of about 457 m (1500 ft), and in such cases a dynamically positioned vessel is required. Dynamic positioning requires a vessel, whether a ship or a semi-submersible, to be installed with rotating thruster pods and propulsion machinery which is able to work against and balance environmental disturbing forces due to wind, current and wave drift. Dynamic positioning has been most commonly employed on drill ships which utilize position signals from sensors, such as a taut

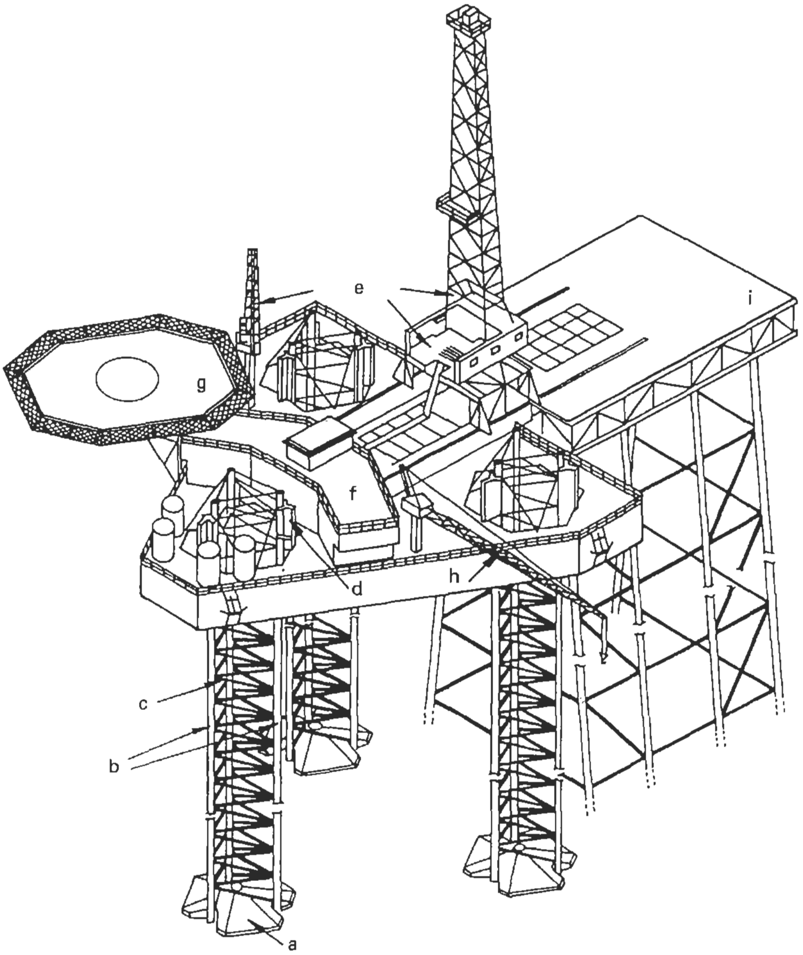

Figure 14.4 Typical jack-up rig: a – spud cans, b – elevating racks, c – legs, d – gear units, e – drilling derrick and equipment, f – accommodation, g – helicopter pad, h – cranes, i – nearby jacket platform

vertical wire to the sea bed or from acoustic beacons on the sea bed around the wellhead, to obtain an error signal representing horizontal offset from above a subsea wellhead. The vessel is fitted with thrusters controlled from an automated computer-based algorithm which is programmed to reduce this offset and maintain the vessel as close to directly above the wellhead as is possible.

Figure 14.6 shows a schematic view of this arrangement with the drill ship connected by a riser to the blow-out preventer (BOP) stack, prior to that being connected to the wellhead. Acoustic beacons provide a position reference to the drill ship – the position data are then used by a computer to control the main propulsion system and lateral thrusters to resist wind, current and wave drift forces on the vessel. It is necessary to maintain position within a 'watch' circle that has a radius of about 7% of the water depth to continue drilling.

Several modern semi-submersibles have also been equipped with dynamic positioning systems. The maximum water depth to which a dynamically positioned drilling vessel can work is theoretically unlimited, although, in practice, limitations are imposed by the length of marine riser that can be carried on the vessel and by tensioner and heave compensator performance. Dynamically positioned vessels, nevertheless, have to disconnect the riser in extreme weather conditions, to ride out storms and then to reconnect in calmer weather.

There are approximately 500 offshore drilling rigs worldwide made up of about 250 jack-up rigs, 130 semi-submersible vessels, 90 drill ships and 30 bottom-standing submersible rigs – the last being of the type which can be floated out onto a shallow-water location and then ballasted down to rest on the sea bed prior to commencement of drilling. The worldwide active jack-up rig fleet began in 1954 and developed to 27 rigs by 1960 and 103 by 1970; whereas the first semi-submersible drilling vessel started operation in 1962, with 25 active vessels

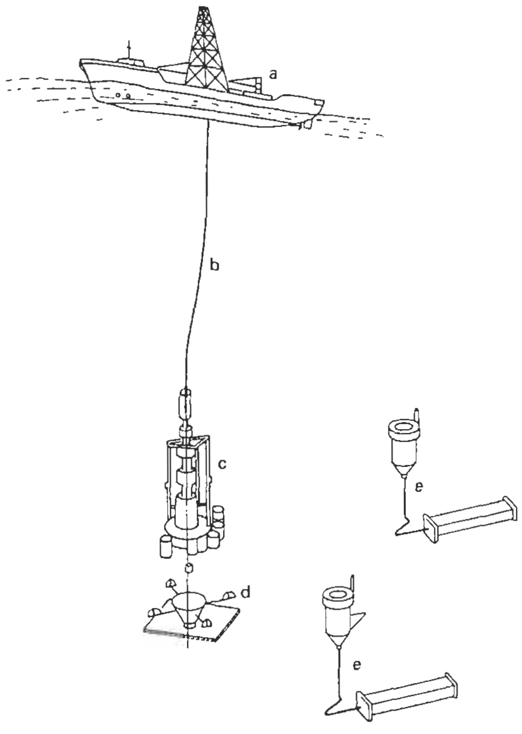

Figure 14.6 Dynamically positioned drill ship: a – drill ship, b – riser, c – blow-out preventer, d – wellhead on sea bed, e – acoustic positioning beacons

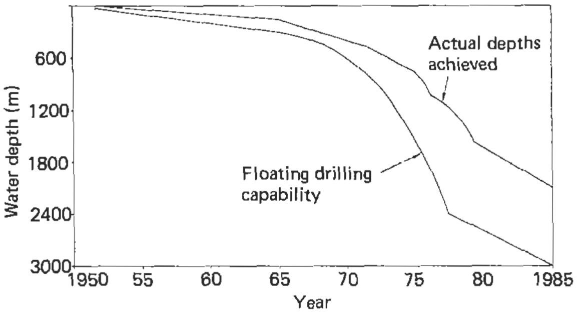

Figure 14.7 Deep-water drilling capability and achievements

by 1970. The first drill ship started operation in 1953, with 16 being developed by 1960, and 39 by 1970. The expansion of the worldwide drilling fleet has been matched by considerable increase in the water depths at which drilling can be carried out. This is illustrated most vividly by Figure 14.7, which presents water depth against year with two lines showing the maximum drilling depth capability, as well as the actual water depth records that were achieved in the years between 1952 and 1985. It can be seen that in the period from 1970 to 1985 the water depth at which drilling was carried out increased from around 1366 m (1200 ft) up to 2128 m (6981 ft). Some drilling in very high water depths has been carried out for geological research into the structure of the land mass below the oceans.

The water depths at which exploration drilling is carried out is an indicator of future requirements for oil production. In drilling programmes where significant discoveries of hydrocarbons are made, a decision on oil production is dependent on the prevailing price of oil and the economics of platform construction and operation. Unlike exploration drilling, production platforms have to be capable of carrying large amounts of development drilling and oil process equipment. The process equipment has to separate water, gas and sand from crude oil emerging from the reservoir, to prepare the crude oil for transportation, and to provide a transportation pumping station. At the same time, the hydrocarbon reservoir depletion procedure may require gas lift, which involves the use of gas to assist in raising the oil if the reservoir pressure is insufficient to do so. Water injection may be required to increase reservoir pressure and therefore permit more oil to be extracted. It is common for one platform to be used to deplete a large plan area of the reservoir by using directional drilling or employing step-out satellite wells.

All of these, and many other requirements, mean that the complexity of equipment on board a production platform can resemble a chemical plant or refinery. At any one point in time, therefore, the depth capability of production platforms tends to be considerably lower than the drilling depth capability. Furthermore, the engineering equipment demands of development drilling, oil production, enhanced recovery and oil export are such that the water-depth capability with time for production platforms has not increased as steeply as it has for drilling vessels.

This is illustrated by Figure 14.8, which shows the evolution of jacket size and water-depth capability starting with 1947 through to a large deep-water jacket in 1978. In general terms, the 1930s were marked by the use of timber platforms, both in the swamps of Louisiana as well as the Gulf of Mexico, with 1947 being the first year in which a steel platform was installed in 6 m (20 ft) water depth off the Louisiana coast and out of sight of land. By the mid-1950s, jacket platforms were being installed in water depths of about 30 m (98 ft) with the framed structures becoming more open. The 1950s to the early 1970s saw platform water depths extend to approximately 120 m (394 ft). Between 1970 and 1987, fixed-platform water-depth

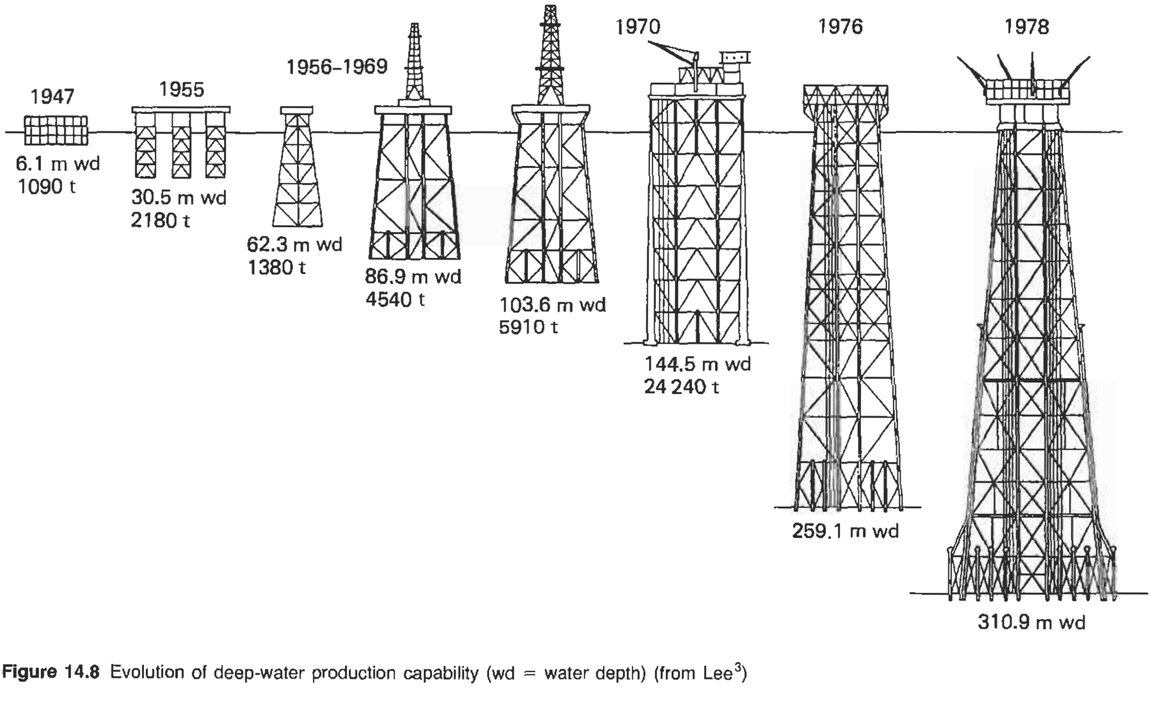

Figure 14.8 Evolution of deep-water production capability (wd = water depth) (from Lee[3])

capability increased substantially from around 120 m (394 ft) through to the largest depth to date for a fixed jacket structure – the Cognac platform in the Gulf of Mexico which stands in 311 m (1020 ft) of water.

It is instructive to examine the structure of a typical jacket for deployment at moderate water depth in the North Sea as illustrated by Figure 14.9. The jacket consists of a steel-framed tubular structure, connected to the sea bed by piles which are driven through pile guides on the outer members of the jacket. The jacket topsides consist of a series of modules which house drilling eqipment, production equipment, living quarters, gas flare stack and revolving cranes. The topside also has facilities for living quarters, survival craft, hotel and catering facilities, and a helicopter pad for transfer of crews from and to a shore base. The topside modules are supported on a module support frame, which is mounted on the water surface-piercing jacket structure. The drilling and production tubulars are brought up from the sea bed to the topsides through conductor guides located within the jacket framing. Crude oil and gas are brought up to the surface from the reservoir for processing and then pumped back down through an export pipeline, either to a tanker loading buoy or by subsea pipeline to a shore terminal.

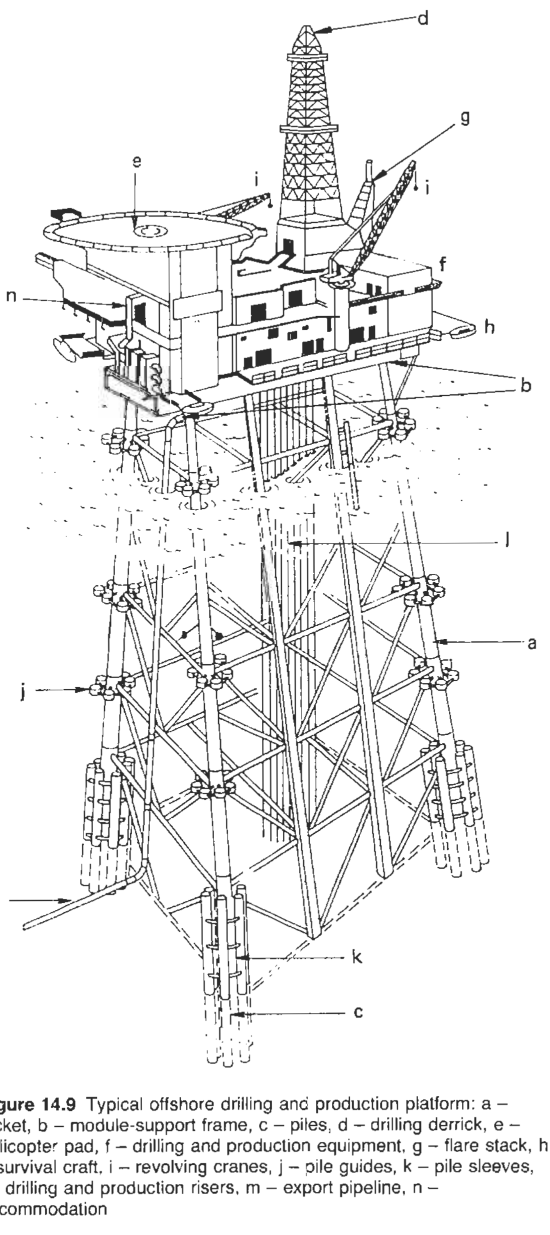

Figure 14.9 Typical offshore drilling and production platform: a – jacket, b – module-support frame, c – piles, d – drilling derrick, e – helicopter pad, f – drilling and production equipment, g – flare stack, h – survival craft, i – revolving cranes, j – pile guides, k – pile sleeves, l – drilling and production risers, m – export pipeline, n – accommodation

The detailed design of the framing for a jacket structure can vary considerably, depending on requirements of strength, fatigue and launch procedure. The main structural members and bracing can be connected by 'X' or 'K' shaped joints with sizes that can range from an extensive space frame of small-diameter 'X' braced or 'K' braced members to an alternative sparser framing with larger diameter members.

A jacket designer has to cope with an extensive list of constraints imposed on a jacket structure through its life. The life cycle consists of design, construction, load-out, launch, installation, piling and hook-up phases of the platform before it comes into oil production service. This is followed by a 10–25-year operational life through which the platform has to be maintained followed by the ecologically desirable requirement to remove and dispose of the platform after the reservoir has been depleted.

Jacket topside weights in the Central and Northern North Sea vary between 17 400 tonnes for the North Cormorant jacket up to 35 000 tonnes for the Statfjord and Brae platforms. This topside weight has to be broken down into a number of modules which can be installed offshore onto the module support frame on top of the jacket by crane barges. The design of the jacket and module arrangement is greatly influenced by the availability of crane barges and by their maximum lift capacities. Recent construction of several semi-submersible crane vessels with large lift load capacities is beginning to have a significant influence on offshore installation practice. The semi-submersible configuration offers a low downtime to weather, and the very large size of the vessel means that lift loads of up to 12 000 tonnes can currently be lifted. It is, therefore, feasible to construct and lift fewer modules each of larger tonnage and, therefore, reduce the complexity and cost of module installation and hook-up operations. The availability of larger module sizes also reduces hook-up times and enables earlier oil or gas production to be achieved.

Offshore oil developments in the North Sea have also pioneered a completely different design of fixed platform based on the use of concrete to create a large, heavy structure which can rest on the sea bed and remain stable under its own weight. The first such platform was installed in the North Sea on the Ekofisk field in 1973, and since then over 17 platforms have been installed. Although concrete gravity structures are considered relatively expensive compared to steel frame jackets, the structures do offer an attractive alternative to jackets in hostile waters like the North Sea and in situations where the uncertainty of a tanker export system demands a certain amount of oil storage on the platform. Other advantages of concrete gravity platforms over jackets are that the structures can be constructed onshore or in sheltered waters, with all the topsides installed, hooked up and tested prior to floating out and towing the structure to its offshore location. Installation then only requires ballasting the platform down onto the sea bed and consolidating the foundation below the platform by pumping grout into the spaces between the platform base and foundation.

The elimination of steel piling and of having a concrete structure tolerant to overloading and to degradation due to exposure to sea water offers other advantages over the use of steel. It has been demonstrated that concrete used in coastal installations in the 1930s and 1940s has survived, essentially unaffected by exposure to sea water up to the present day, whereas conventional steel structures would have been susceptible to sea-water corrosion and require substantial levels of maintenance and protection. These advantages have to be set against the fact that concrete gravity structures are relatively expensive. They often actually employ a greater mass of steel in their reinforcing members than would be required by an equivalent steel-frame jacket structure. Concrete gravity structures are likely to suffer from foundation settlement during their working lives which can reduce the air gap between the mean water level and the underside of the structure. Another disadvantage with concrete gravity structures is that no feasible means of removing the structure has been defined at present. Figure 14.10 shows a typical design for a Condeep concrete gravity structure.

The total cost for developing an offshore oil or gas field clearly plays a major part in the selection of the production platform. In the early growth years of the offshore industry, when very large oil deposits were being found, the economics of each development permitted large, expensive structures to be built. However, as more of the larger reservoirs were discovered and developed, the remaining reservoirs have a higher probability of containing smaller oil deposits and being in deeper waters and harsher environments. At the same time, the cost of fixed steel-frame jackets or gravity structures tends to increase in an approximately exponential fashion with water depth, primarily due to the larger platform structure and the greater volume of material required for structural integrity in deeper water.

Figure 14.11 illustrates a typical variation of jacket weight with water depth for two locations – the Gulf of Mexico and offshore California – as well as for the North Sea. The jacket

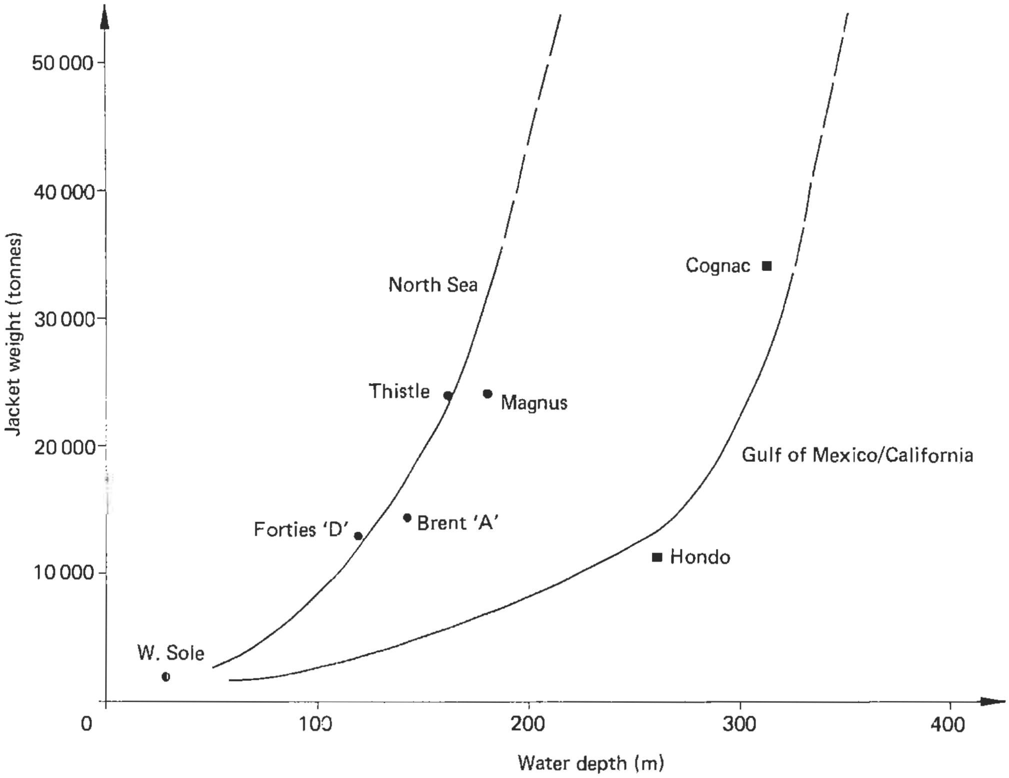

Figure 14.11 Variation of platform jacket weight with water depth (from Thornton[5])

weight on the vertical axis can be considered to be representative of the platform cost whereas the lines denoting North Sea and Gulf of Mexico and California are illustrative of the influence of environmental conditions on jacket weight. The full lines denote current developments and the dashed lines are an estimate of future projections using the same kind of technology. Figure 14.11 shows that the effect of more extreme environmental conditions for the North Sea in the 100–200 m (328–656 ft) water-depth range increases jacket weight and, therefore, cost by a factor of between 3–6. The figure also illustrates that a jacket weighing 30 000 tonnes in the Gulf of Mexico or offshore California could be used in up to 320 m (1050 ft) water depth whereas that jacket weight would only suffice for approximately 175 m (574 ft) water depth in the North Sea.

14.3 Future development

It is clear that the approximately exponential increase of jacket weight and therefore cost with increasing water depth is unsustainable for the North Sea sector since new discoveries are tending to have smaller recoverable reserves and are, therefore, of economically marginal value. This has set the scene for the development of new technology in oil production to try to reduce the rate of increase of cost with water depth. This need for reducing costs has prompted feasibility studies on a wide variety of new types of production platforms based on compliant structures which are fixed to the sea bed but respond with some degree of flexibility to the ocean environment. The consequent reduction in the volume of steel or concrete material that connects the surface facility to the sea bed can lead to a potential reduction in costs. This is illustrated by Figure 14.12, which presents the cost of design, fabrication and installation for different platform types plotted against water depth.

It can be seen that new platform concepts such as the tensioned buoyant platform and semi-submersible or tanker-based floating production systems – all of which are described later – offer significant reductions in the rate of increase of

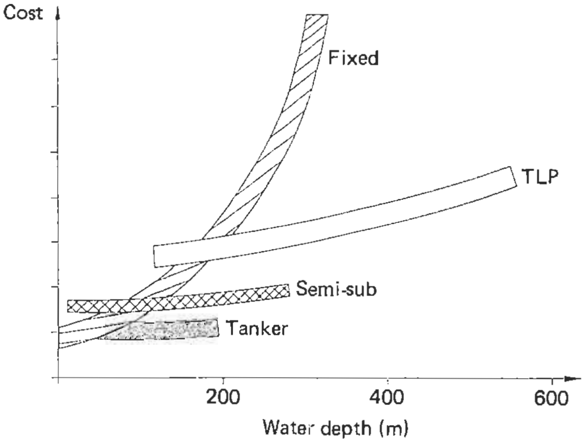

Figure 14.12 Cost comparisons for deep-water structures (from Hamilton and Perrett[6])

cost with water depth. It is now becoming increasingly obvious in the industry that oil production in deep water up to the end of this century is likely to be carried out by compliant or floating production platforms in all cases, except for the very largest of fields or for fields in shallow water. In deep waters above 457 m (1500 ft), a compliant or floating production system may in fact be the only means of producing a field. There are a number of existing and proposed alternatives for cheaper compliant or floating production systems.

One of the most popular floating production platforms is shown in Figure 14.13, and is based round a converted or new-build semi-submersible vessel which is catenary moored to the sea bed and is connected to a subsea manifold or wellhead either by rigid tensioned vertical multi-tube risers or by flexible risers. Such systems are technically suitable for depth ranges of between 70 and 250 m (230 and 820 ft) approximately. They are, however, limited by a number of factors and technical risks. Semi-submersibles only have a relatively small deck payload capacity and, therefore, the range of available oil process options is restricted compared to what is possible on fixed platforms. The compliancy of the platform and the catenary mooring system poses a risk of the vessel losing station and damaging its risers during severe environmental conditions or damage to a mooring line. The platform cannot directly offer oil-storage facilities and the heave, roll and pitch motions of the platform to waves can limit or degrade processing operations. Nevertheless, catenary moored semi-submersibles offer an economic means of exploiting small reservoirs which have sufficiently good hydrocarbon field characteristics so as to require only a small amount of processing on the surface facility.

A technically more advanced form of compliant structure is offered by the tension or tethered buoyant platform, shown in Figure 14.14. The surface platform configuration resembles that of a semi-submersible but is tethered to the sea bed by vertical legs, which are kept in tension by excess buoyancy in the platform. The excess buoyancy is of the order of 15–25% of the platform displacement and tensions the tethers to such an extent that heave, roll and pitch motions of the platform to ocean waves are virtually eliminated. The platform does, however, experience surge, sway and yaw due to wave action but the vertical tethers are a reliable means of keeping the platform permanently on station above the subsea wells. These wells are connected to the surface facility by an array of risers. Oil processing is carried out on the platform and the hydrocarbon products are pumped back down to the sea bed to an export pipeline. Conoco Ltd in 1984 installed the world's first tethered buoyant platform in 148 m (485 ft) of water on

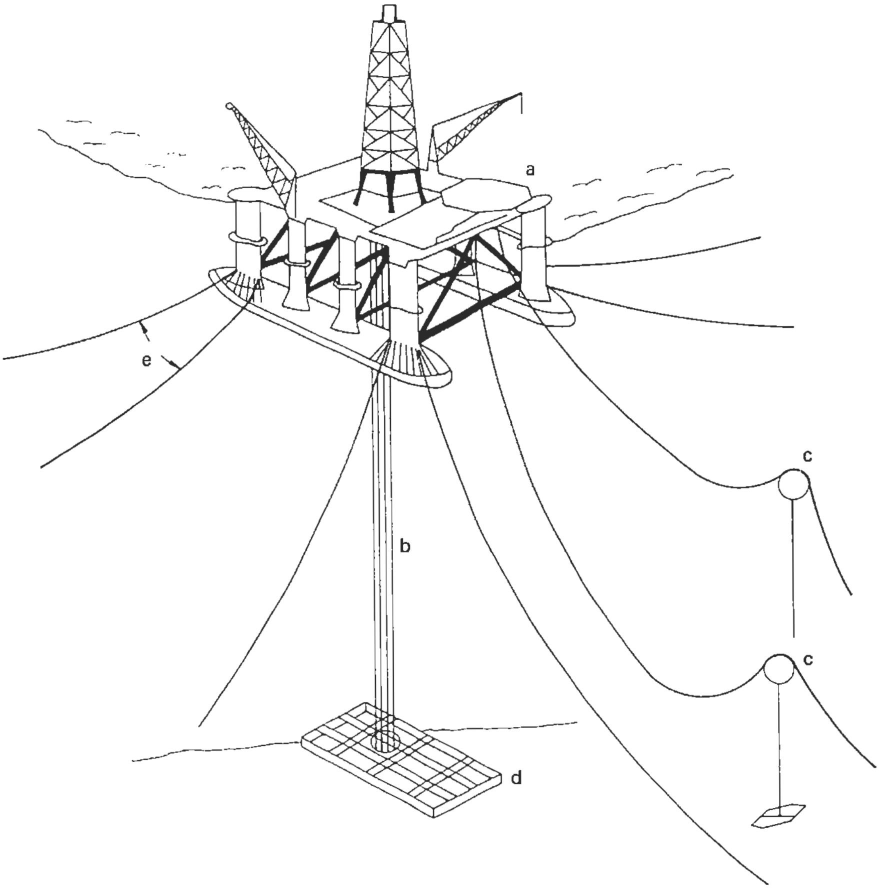

Figure 14.13 Typical semi-submersible-based floating production system: a – surface platform, b – multi-tube vertical drilling and production riser, c – flexible production risers, d – sea-bed template, e – catenary moorings

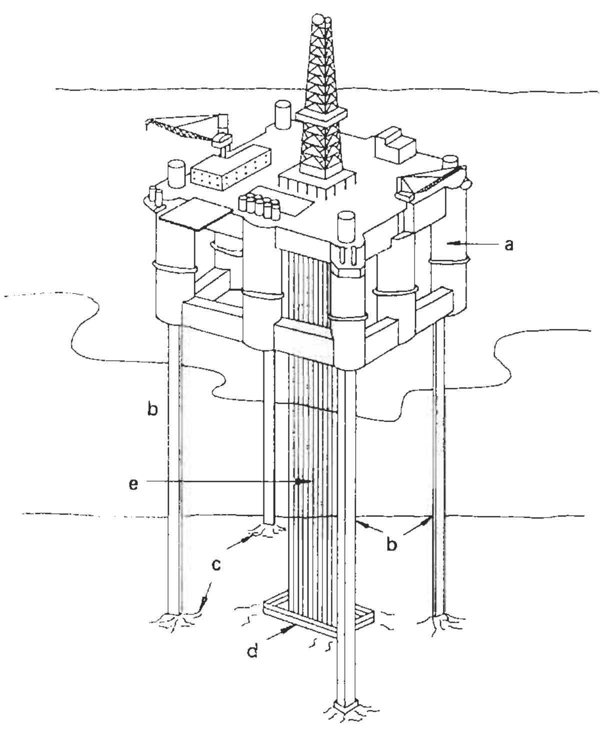

Figure 14.14 Typical tensioned buoyant platform: a – surface platform, b – tensioned tethers, c – tether foundations, d – template on sea bed, e – marine risers

the Hutton field in the North Sea. Due to the success of this development, it is likely that tethered buoyant platforms will be considered for a number of future field developments. The probable depth range of tensioned buoyant platforms is from approximately 120 m (394 ft) up to as high as 1500 m (4921 ft).

It is also possible to develop small isolated fields in water depths of up to 170 m (558 ft) in calm-weather areas by the use of articulated column or single-anchor leg storage and tanker systems. Another form of economically viable compliant structure is offered by the guyed tower. These advanced compliant production platforms are described further by Thornton.[5]

14.4 Hydrodynamic loading

The design and operation of offshore structures requires a thorough understanding of the physical character and behaviour of the ocean environment and also of the atmosphere above it. Planet Earth is a globe with equatorial and polar diameters of 12 756 km (7926 mile) and 12 714 km (7900 mile), respectively, and a total surface area of 509.859×10^6 km^2 (19.686×10^7 mile^2). Over 70% of this surface area is covered by three large ocean areas which, in their order of size, are the Pacific, Atlantic and Indian Oceans. These oceanic areas also extend into the waters of the Antarctic, although this region can be regarded as a distinct southernmost ocean. The Arctic ocean is another body of water of significant size but is not comparable to the three major oceans of the globe.

Figure 14.1(b) gives a map of the surface of planet Earth and illustrates the extent of all the major and minor sea areas and continents. The average depths of all the oceans, including adjacent seas, is 3795 m (12 451 ft) and, therefore, on a global length scale, the oceans are very widely spread but thin sheets of water with an average vertical dimension of about 4 km (2.49 mile) compared to the Earth's equatorial circumference of 40 074 km (24 901 mile). Table 14.1 gives a summary of the physical properties of sea water, pure water and air.

Offshore structures in the oceans are subjected to environmental forces due to wind, current, tides and gravity waves. Atmospheric winds are induced by the latitude imbalance in the solar radiation absorbed by Earth. The general worldwide circulation pattern of atmospheric winds is caused by the consequent redistribution of energy that must take place. Atmospheric mean wind speeds can vary from still calm up to 52 m/s (101 knots) or more, with wind gust components having greater transient velocities. There also exists a corresponding current circulation in the oceans induced by a combination of

wind effects and the rotation of the planet. Typical current speeds vary between 0.25 m/s (0.49 knots) and 0.75 m/s (1.46 knots) at the ocean surface, although in some areas current speeds can be as high as 2.5 m/s (4.9 knots). A Meteorological Office publication[7] gives further details of global wind and current phenomena. Ocean waters are also subjected to the oscillatory astronomical phenomenon of tidal action caused by the gravitational acceleration of the Earth to the Moon and Sun – see Strahler and Strahler[8] for details.

However, by far the largest environmental loads on offshore structures are due to gravity waves. These can exist at the interface between any two fluids of different densities – air and water, for example – and are driven by an interaction between inertia of the fluid at the interface and its potential energy under gravitational action. The physical mechanisms underlying gravity wave formation by wind action and decay by internal losses are complex. Winds blowing over a water surface generate waves, with the length over which this occurs being called a 'fetch' and the resultant 'forced' waves classified as 'wind waves' or 'a sea'. Gravity waves are progressive (or travelling) in nature and can, therefore, move out of their area of formation and, when running free of the winds that generated them, are called 'a swell'. Such swell waves lose energy very gradually due to air resistance, internal friction and by friction with the sea bed in shallow water.

Thus swell waves can travel substantial distances across the Earth's surface with little reduction in intensity. Gravity waves are, however, dispersive in nature– their celerity (wave or phase speed) is a function of wave period or wave length so that they spread out (disperse) along their direction of wave propagation. Non-progressive (that is, standing) gravity waves also occur in confined waters such as harbours, inland waterways and in wave-testing tanks. These waves are not of interest for the design of offshore structures and so are not considered here.

In nature, many components of periodic waves with different wave heights, periods and directions of travel occur at the same time in a given area. The superposition of all of these wave components coupled with their dispersive behaviour leads to a randomly varying sea-surface elevation which can be treated by statistical methods. The simplest mathematical representation of gravity waves is known as linear wave theory. This theory permits the determination of irregular ocean waves by superposition of regular wave motions at different periods and from different directions. Gravity waves have periods ranging from as low as 0.8 s up to 25 s, with corresponding wave lengths of from 1 m (3.3 ft) up to 1 km (3290 ft), and with wave heights as high as 33 m (108 ft) from trough to crest.

Initially, some basic parameters describing the characteristics of a progressive wave are defined with reference to Figure 14.15. The wave number, k, is defined as

$$k = \frac{2\pi}{\lambda} \tag{14.1}$$

Wave frequency can be defined as f in Hz, ω in radians per second or period T in seconds. These parameters are related by

$$\omega = 2\pi f,\ T = \frac{2\pi}{\omega},\ T = \frac{1}{f} \tag{14.2}$$

This theory, originally developed by Airy,[9] offers a powerful analytical solution for gravity waves. The following assumptions have to be invoked:

1. The water is assumed to be of uniform density with constant water depth.

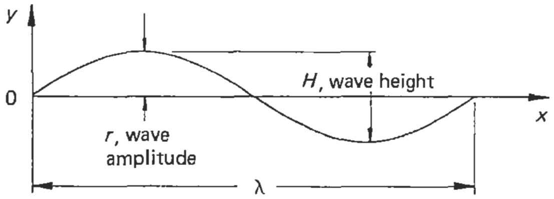

Figure 14.15 Wave elevation for a unit amplitude wave

2. Viscosity and surface-tension effects are neglected.
3. The square of particle velocities are considered to be negligible but vertical accelerations are not neglected. The wave heights are accordingly assumed to be very low, hence the theory is often called small-amplitude wave theory.
4. The wave motion is assumed to be irrotational.

Table 14.2 summarizes the velocity potential, stream function and derived properties for linear deep-water gravity waves. Equivalent expressions for shallow water are also listed. The expressions for shallow-water theory differ from the deep-water equations in having hyperbolic variations of vertical and horizontal particle displacements, velocities and accelerations with depth. The resultant difference in wave fluid behaviour is illustrated in Figure 14.16, which shows wave particle orbits with depth for deep and shallow water. In shallow water, particle motions describe ellipses instead of circles. The ellipses become shallower with decreasing depth and at the bottom the motion is purely horizontal. In terms of numerical values, the shallow-water equations tend to their deep-water simplifications for water depth d\>\λ/2.

Offshore structures are subjected to both steady and time-dependent forces due to the action of winds, currents and waves. Winds exert predominantly steady forces on the exposed parts of offshore structures, although there are significant gust or turbulence components in winds which induce high unsteady local forces on structural components as well as a low-frequency total force on the whole structure. Ocean currents also exert predominantly steady forces on submerged structures together with the localized effects of vortex shedding which can induce substantial unsteady forces on structural members. However, gravity waves induce by far the largest force on most offshore structures. The applied force is periodic in nature, although non-linear wave properties give rise to mean and low-frequency drift force. Non-linearities in the wave-loading mechanism also give rise to superharmonic force components. Both of these secondary forces can be significant if they excite resonance in a compliant structure. Only gravity wave loading is, therefore, considered here for brevity – see Patel[10] for further details on wind and current loading.

The procedure for calculating wave forces on offshore structures can be divided into fundamentally different approaches depending on the size of the structural member and the height and wavelength of incident waves. These parameters can be written in the form of two ratios: structural member diameter to wavelength (D/λ) and wave height to structural member diameter (H/D). Table 14.3 uses approximate values for the ratio K (which is a measure of (H/D)) to separate the wave regimes into its constituent parts.

For small structural members where $D/\lambda < 0.2$, Morison's equation is used to estimate forces due to wave action, with the implicit assumption that the diameter of the member is small enough in relation to the wave length so as not to alter incident wave characteristics to any significant extent. Mori-

Table 14.2 Summary of water wave properties

Quantity	*Deep water*	*Shallow water (d/λ < 1/2)*
Surface profile	$\eta = a\sin(kx-\omega t)$	$\eta = a\sin(kx-\omega t)$
Velocity potential	$\phi = -ace^{ky}\cos(kx-\omega t)$	$\phi = -ac\dfrac{\cosh k(y+d)}{\sinh kd}\cos(kx-\omega t)$
Stream function	$\psi = +ace^{ky}\sin(kx-\omega t)$	$\psi = +ac\dfrac{\sinh k(y+d)}{\sinh kd}\sin(kx-\omega t)$
Horizontal water velocity	$u = \partial\phi/\partial x$ $= +kcae^{ky}\cos(kx-\omega t)$	$u = +ack\dfrac{\cosh k(y+d)}{\sinh kd}\sin(kx-\omega t)$
Vertical water velocity	$v = \partial\phi/\partial y$ $= -kcae^{ky}\cos(kx-\omega t)$	$v = -ack\dfrac{\sinh k(y+d)}{\sinh kd}\cos(kx-\omega t)$
Horizontal acceleration	$= -k^2c^2ae^{ky}\cos(kx-\omega t)$	$= -k^2c^2a\dfrac{\cosh k(y+d)}{\sinh kd}\cos(kx-\omega t)$
Vertical acceleration	$= -k^2c^2ae^{ky}\sin(kx-\omega t)$	$= -k^2c^2a\dfrac{\sinh k(y+d)}{\sinh kd}\sin(kx-\omega t)$
Wave celerity	$c = \dfrac{\lambda}{T} = \dfrac{g}{\omega} = \left(\dfrac{g\lambda}{2\pi}\right)^{1/2} = \dfrac{gT}{2\pi}$	$c^2 = \dfrac{g\lambda}{2\pi}\tanh kd^{a}$
Wave length	$\lambda = \dfrac{2\pi c^2}{g} = \dfrac{2\pi g}{\omega^2} = \dfrac{gT^2}{2\pi}$	
Wave number	$k = \dfrac{2\pi}{\lambda} = \dfrac{\omega^2}{g} = \dfrac{g}{c^2} = \dfrac{4\pi^2}{gT^2}$	
Pressure[b] $P' - P_a$	$p = +\rho gae^{ky}\sin(kx-\omega t)$	$p = +\rho ga\dfrac{\cosh k(y+d)}{\cosh kd}\sin(kx-\omega t)$
Horizontal pressure gradient[b] $\partial p/\partial x$	$+\rho gake^{ky}\cos(kx-\omega t)$	$+\rho gak\dfrac{\cosh k(y+d)}{\cosh kd}\cos(kx-\omega t)$
Vertical pressure gradient[b] $\partial p/\partial y$	$+\rho gake^{ky}\sin(kx-\omega t)$	$\rho gak\dfrac{\sinh k(y+d)}{\cosh kd}\sin(kx-\omega t)$
Maximum wave slope	$\theta = ka = \dfrac{2\pi a}{\lambda}$	

[a] For very shallow water ($d \leq \lambda/20$), this expression becomes

$$c^2 = gd$$

with $c^2 = 0.968\,gd$ at $d = \lambda/20$.

For deeper water ($d > \lambda/2$), the expression becomes

$$c^2 = \frac{g\lambda}{2\pi}$$

with $c^2 = 0.996\,g\lambda/(2\pi)$ for $d = \lambda/2$.

[b] These terms exclude hydrostatic pressure.

son's equation, which was first put forward by Morison *et al.*,[11] is based on the assumption that wave forces can be expressed as the sum of a drag force due to wave fluid velocity and an inertia force due to wave acceleration. On the other hand, for larger structural members (with $D/\lambda > 0.2$), diffraction theories are necessary to account for the reflection and radiation of waves from the structural member. These potential flow methods, however, cannot account for viscous drag forces.

The second parameter of interest is the ratio H/D. Its importance is based on the fact that drag forces on structures (say, a pipe of circular cross section) in an oscillatory wave flow are dominated by the separation of flow behind the

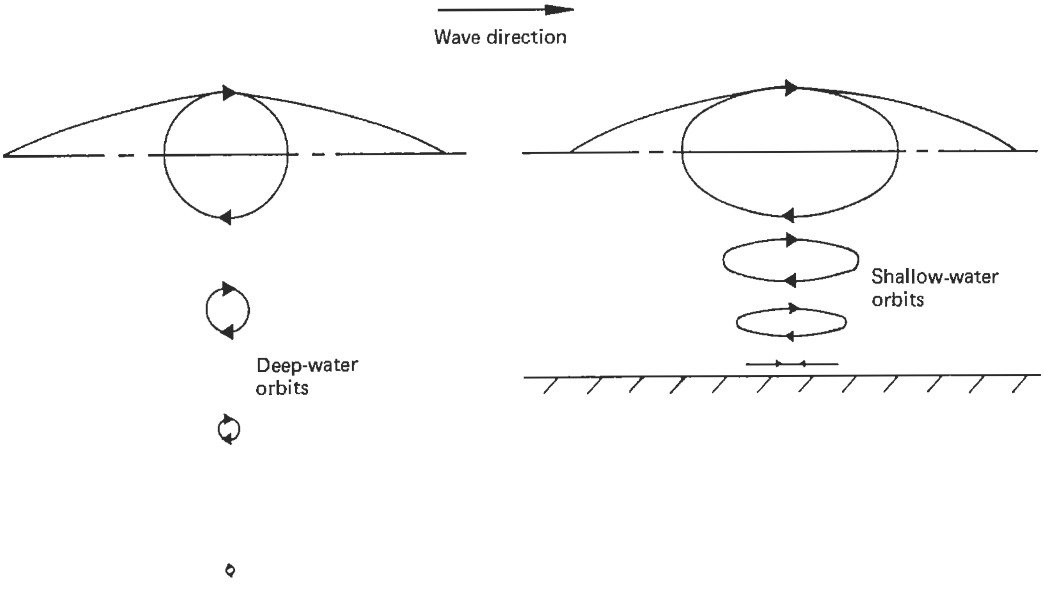

Figure 14.16

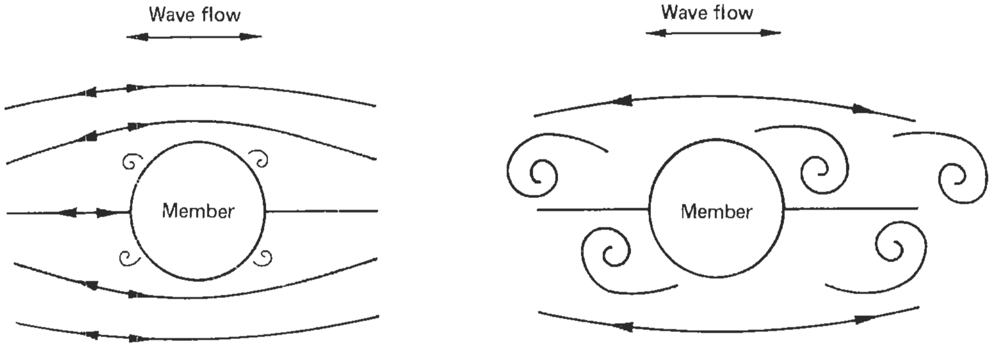
cylinder and the formation of large vortices. For a small H/D ratio (<1.5), the wave height (and thus orbital diameter) are not unidirectional long enough for the flow to initiate separation and develop or shed vortices. In this case, drag forces are very small, acceleration-dependent inertia forces dominate and potential flow diffraction theory can be used to predict wave forces with confidence. At the other extreme for $H/D >$ 8, approximately, the wave flow will have been unidirectional long enough for a substantial vortex flow to develop. Drag forces will then be large and a Morison formulation, which accounts for these, must be used. An intermediate region, where $1.5 < H/D < 8$, also exists where the flow regime can be



No vortex shedding, inertia dominated $H/D < 1.5$

Substantial vortex shedding, drag dominated $H/D > 8$

Figure 14.17 Inertia- and drag-dominated flows

highly complicated and wave forces are difficult to compute. The two flow regimes corresponding to H/D of < 1.5 and > 8 are illustrated in Figure 14.17. A non-dimensional parameter called the Keulegan–Carpenter number is a more rational measure of the ratio of water particle motion double amplitude to cylinder diameter than H/D, which is only valid close to the water surface. The Keulegan–Carpenter number is defined as

$$K = \frac{U_m T}{D} \tag{14.3}$$

where U_m ms^{-1} is the maximum normal velocity in the oscillatory flow of period T seconds about the cylinder of diameter D metres.

The approximate range of numerical values encountered is from 0 up to 30 m for H and from 60 m to 620 m for λ. Thus a subsea pipe or the space frame of a tower jacket structure (with typical D from 0.4 to 3 m) would give large H/D and small D/λ – indicating a drag-dominated wave loading with use of Morison's equation being appropriate for computing the loading. Alternatively, a large monolithic gravity structure (with typical $D = 80$ m) would yield small H/D and large D/λ; thus pointing to an inertia-dominated loading regime and requiring potential flow diffraction theory for computing wave loads. The combination of both H/D and D/λ being small can occur but the other extreme of both H/D and D/λ being large cannot, because of the height limitation for stable waves which constrains the ratio H/λ to a maximum value of approximately 1/7.

Table 14.3 illustrates the wave-loading regimes described above. The Keulegan–Carpenter number (K) is used as a measure of ratio H/D.

14.4.1 Wave loads on slender structures

The mechanics for wave loading on slender tubular subsea pipelines or members of offshore jacket structures is described here. Such structures (with $D/\lambda < 0.2$) will be subjected to so-called Morison wave loading, which is based on the assumption that wave properties are not affected by the presence of the structure and that the total wave force can be expressed as a sum of inertia forces (due to wave fluid acceleration) and drag forces (due to wave fluid velocity).

An equation to represent this loading can be written as

$$\mathrm{d}F = \underbrace{C_M \rho \, \mathrm{d}V \, \dot{U}_n}_{\text{inertia force}} + \underbrace{C_D \frac{1}{2} \rho \, \mathrm{d}S |U_n| U_n}_{\text{drag force}} \tag{14.4}$$

where $\mathrm{d}F$ is the total wave force on a pipeline element of volume $\mathrm{d}V$ and frontal area, $\mathrm{d}S$, U_n, $\dot{U}_n$, are instantaneous wave fluid velocities and accelerations normal to the pipe axis, ρ is the fluid density and C_M and C_D are inertia and drag coefficients. The inertia coefficient is conventionally taken as the added mass coefficient plus one to account for the Froude–Krylov or undisturbed pressure force due to wave fluid acceleration – see Patel[8] for further details. The drag force term has a modulus sign to ensure that the drag force remains in the same direction as the wave velocity.

Although the Morison equation was originally developed for vertical piles in shallow water, for engineering purposes, it is assumed to be valid for cylinders of arbitrary orientation in deep and shallow water with the proviso that the coefficients C_M and C_D are chosen experimentally for the appropriate condition. Application of the Morison equation can be illustrated by developing expressions for the wave force on vertical and horizontal pipe segments.

Consider an element, $\mathrm{d}y$, of a vertical circular cylinder of radius, r, as shown in Figure 14.18. The total force, $\mathrm{d}F$, acting on this element in the direction of wave propagation is the sum of inertia and drag force components. This force can be integrated to yield the total force, F, and moment about the sea bed as

$$F = C_M \rho \pi r^2 \int_{-d}^{0} \dot{u} \, \mathrm{d}y + C_D \rho r \int_{-d}^{0} |u| u \, \mathrm{d}y$$

and

$$M = C_M \rho \pi r^2 \int_{-d}^{0} (d + y) \dot{u} \, \mathrm{d}y + C_D \rho r \int_{-d}^{0} (d + y) |u| u \, \mathrm{d}y \tag{14.5}$$

where u and $\dot{u}$ are horizontal components of wave velocity and accelerations. Using expressions for u and $\dot{u}$ for linear wave

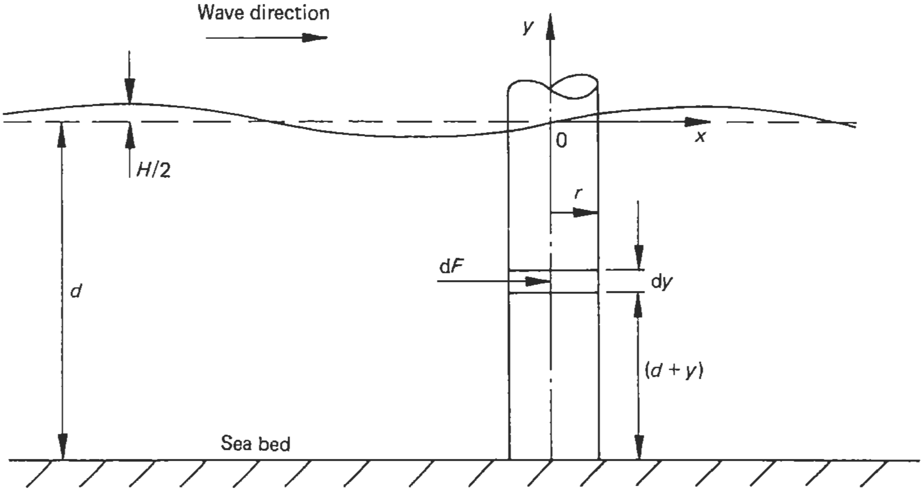


Figure 14.18 Wave force on vertical cylinder

theory from Table 14.2 with $x = 0$ and $\theta = \omega t$, equations (14.5) can be readily integrated to yield

$$F = -\frac{2\pi\rho r H^2\lambda}{T^2}\{K_2\, C_M \cos\theta + K_1\, C_D|\sin\theta|\sin\theta\}$$

and

$$M = -\frac{2\rho r H^2\lambda^2}{T^2}\{K_4\, C_M \cos\theta + K_3\, C_D|\sin\theta|\sin\theta\}$$

where

$$K_1 = \frac{1}{16\sinh^2 kd}[2kd + \sinh 2kd] \qquad (14.6)$$

$$K_2 = \frac{\pi r}{2H}$$

$$K_3 = -\frac{1}{64\sinh^2 kd}\{2k^2d^2 + 2kd\sinh 2kd + 1 - \cosh 2kd\}$$

$$K_4 = \frac{\pi r}{4H\sinh kd}\{1 + kd\sinh kd - \cosh kd\}$$

14.4.1.1 Drag and inertia coefficients

The value of drag coefficients, C_D, to be inserted in Morison's equation can only be obtained experimentally. In theory, the value of the inertia coefficient, C_M, can be calculated (it is, for example, 2.0 for a smooth cylinder in an ideal fluid). However, measured values are used in practice, particularly when drag is the dominant force. For irregular shapes, the inertia coefficient can be calculated from diffraction theory.

Many experiments have been designed to measure values of drag and inertia coefficients in steady or planar oscillatory flows but their results can only be used for wave force prediction with caution. The most useful experimental measurements have been made in circumstances which model full-scale conditions within the ocean environment. Measurements made offshore on large test structures in real seaways are especially valuable.

One problem facing the user of Morison's equation is the large scatter in values of the inertia and drag coefficients. However, there is a useful degree of correlation between the coefficients and two flow parameters – Keulegan–Carpenter number, K, and Reynolds number, R. Nevertheless, the scatter and hence some uncertainty remain. Table 14.3 gives a summary of generally accepted added inertia and drag coefficients for flow around circular cylinders in unconfined flow remote from solid boundaries such as the sea bed for pipelines. The effects of such sea-bed proximity on coefficient values are examined in more detail by Patel.[10]

Sarpkaya[12,13] has carried out many systematic studies of the variations of inertia and drag coefficients for circular cylinders in planar oscillatory flow.

14.4.2 Wave loads on large bodies – diffraction theory

The calculation of wave forces on bodies with dimensions that span a significant proportion of the wave length ($> 0.2\lambda$) must account for the fact that the wave flow will be influenced by the presence of the body. The solution of the Laplace governing equation with the usual sea-bed and free surface boundary condition together with the additional condition of no flow through the body surface will give rise to additional component waves in the solution which are called scattered or diffracted waves. The wave force on the body is then due to the incident wave as well as the scattered wave field arising from the presence of the body. Furthermore, the Froude–Krylov force in such a flow field with a large body can no longer be written as $\rho V\dot{U}$ (see Patel[10]) because the wave-induced pressure gradient around the body is no longer constant. At the same time, the conditions that require diffraction theory to be used ($D/\lambda > 0.2$) also imply that the ratio of wave height to body dimension, H/D, is less than unity since $H/\lambda < 1/7$. For such small values of H/D, drag forces will be small since flow amplitudes will be less than the body dimension and flow separation will not occur. These fortuitous circumstances mean that a potential flow solution of the wave diffraction problem will represent a physically realistic situation.

A statement of the full-wave diffraction problem in three dimensions can be written as follows using an axes system with

Oxy in the still water surface and Oz pointing vertically upwards. The governing equation is

$$\frac{\partial^2\phi}{\partial x^2}+\frac{\partial^2\phi}{\partial y^2}+\frac{\partial^2\phi}{\partial z^2}=0 \tag{14.7}$$

with the linearized free surface boundary condition at $z = 0$ of

$$\frac{\partial^2\phi}{\partial t^2}+g\frac{\partial\phi}{\partial z}=0 \tag{14.8}$$

and the sea-bed boundary condition at $z = -d$ of

$$\frac{\partial\phi}{\partial z}=0 \tag{14.9}$$

together with the no-flow through the immersed body boundary condition of

$$\frac{\partial\phi}{\partial n}=0 \tag{14.10}$$

at the body surface, where n denotes a direction normal to this surface. All the assumptions inherent in the governing equations and the linearized free surface boundary condition, therefore, apply to this linear diffraction problem, that is, irrotational and inviscid flow of small wave amplitude.

The solution to this wave-diffraction problem is obtained by writing the velocity potential as the sum of the incident and scattered potential, ϕ_i and ϕ_s, respectively. Thus

$$\phi=\phi_i+\phi_s \tag{14.11}$$

Furthermore, the scattered waves generated by the presence of the body boundary have to be restricted in the mathematical formulation to outgoing waves only. This requires that the scattered wave potential satisfies the condition

$$\frac{\partial\phi_s}{\partial r}+\frac{1}{c}\frac{\partial\phi_s}{\partial t}=0 \tag{14.12}$$

where r is radial distance from a point on the body surface and c is wave celerity. This can be written[14,15] as

$$\operatorname{Lim}_{r\to\infty} r^{1/2}\left[\frac{\partial\phi_s}{\partial r}-ik\,\phi_s\right]=0 \tag{14.13}$$

where the factor $r^{1/2}$ takes account of the directional spreading of waves.

Since the incident wave potential, ϕ_i, is known, the boundary condition at the body surface can also be written as

$$\frac{\partial\phi_s}{\partial n}=-\frac{\partial\phi_i}{\partial n} \tag{14.14}$$

Once ϕ_s is obtained as a solution to this problem, wave-induced pressures can be obtained from the linearized Bernoulli equation and integrated to obtain forces and moments. Note that equations (14.11) and (14.14) only apply to a stationary body. A moving body will induce additional potentials due to its motions and the above equations will need to be extended to account for this as is described subsequently in Section 14.6.

Patel[8] gives a review of solution schemes for a diffraction analysis. Typical methods in the research literature are presented by MacCamy and Fuchs,[16] Garrison and Chow,[17] Eatock-Taylor and Waite[18] and Zienkiewicz *et al.*[19]

14.5 Structural strength and fatigue

This section describes the final stages of the design process for an offshore structure where static and dynamic environmental forces calculated from the methods outlined earlier are converted to structural stresses and stress load cycles. These are then used to deduce design safety factors and estimate fatigue lives. Static and dynamic structural analyses of offshore structures are complicated by non-linear effects, due predominantly to soil structure interaction in the former case and non-linearities arising from gravity wave mechanics and drag force loading in the latter. These methods of analysis and the effects of non-linear behaviour are considered in detail in this section.

14.5.1 Structural analysis method

Steel-framed jackets in shallow water can be analysed for structural stresses with acceptable accuracy by using a quasi-static environmental loading coupled with an elastic structural analysis modified for the non-linear behaviour in the soil foundation. In this approach, winds and currents are assumed to apply static loads with wave action applying a dynamic loading which is translated into dynamic structural stresses through a quasi-static stress analysis. The technique assumes that resonant frequencies of structural vibrations are sufficiently separated from wave frequencies so that dynamic magnification has a negligible effect on calculated stresses.

In the early days (before the 1960s), structural analysis of jackets was carried out using hand calculations with simple frame theory. However, the advent of computers and the development of finite-element structural analysis methods has revolutionized structural calculations in the offshore industry. Finite-element analysis program packages such as NASTRAN and STRUDL are used in conjunction with wave-loading and foundation-analysis programs to carry out complex computer-aided design calculations for three-dimensional steel-framed structures as well as for monolithic concrete ones.

The basic theory underlying one such finite-element analysis called the direct stiffness method is described here. The basis of the method is that the structure to be analysed is discretized into a number of small elements – with a framed jacket structure represented by an assembly of beam elements where as a concrete gravity structure could also be described by beam elements or, alternatively, by cylindrical shell elements. The displacements of nodal points on the elements are taken as unknowns and the finite-element method is implemented using the following steps:

1. Initially, physical data for the structure configuration, member properties and support constraints are identified. The structure is then discretized into finite elements and the unknown nodal displacements are identified and numbered using a systematic indexing procedure.
2. This is followed by evaluation of member-stiffness matrices using local member axes. These matrices are then transformed into global structure axes and assembled into a global stiffness matrix.
3. The loads acting on the members and nodes are also assembled into a global load vector. This requires that forces acting on each member other than at the nodes are transformed into equivalent joint loads before being added onto the known loads at the nodes such that the structure is considered as being loaded at the nodes only.
4. It is then necessary to rearrange the equation relating the nodal displacement vector and stiffness matrix to the load vector in order to substructure out degrees of freedom which are constrained (that is, their nodal displacements

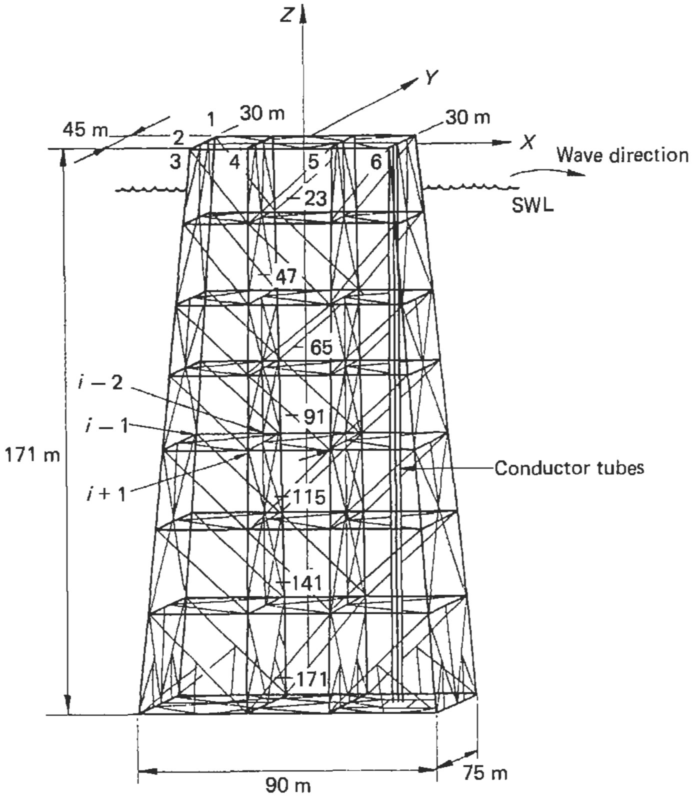

Figure 14.19 Typical idealization of a jacket structure

are known or are zero) in order that a matrix equation for the unknown displacements only can be formed.

5. The penultimate step in the procedure is to use the stiffness matrix and load vector to arrive at a solution for the displacements at each of the nodes.
6. In the final step, the displacements are used in combination with the equivalent joint loads to compute member forces and resultant internal stresses.

The mathematical formulation of the above procedures is described in detail for item (1) above as an example.

A three-dimensional (space frame) beam element idealization of a typical jacket structure is shown in Figure 14.19. The jacket structure consists of up to 600 beam elements to represent each of the tubular members making up the frame. A global axes system *Oxyz* is first defined with respect to the whole structure and all of the structural nodes are numbered in a systematic manner around the structure. A typical numbering system could, as shown in Figure 14.19, start from a horizontal level at the origin with increasing node numbering in a prescribed direction around the nodes at that level, followed by a similar procedure at the next level down, and so on. Once this node definition is complete, structure data on node coordinates relative to global axes, member lengths, areas of cross section and second moments of area can be systematically identified in terms of the node numbering. This is followed by definition of six degrees of freedom for each node – three in translation and three in rotation parallel to and about the global axes directions O*x*, O*y* and O*z*. Thus the number of degrees of freedom will be six times the number of nodes, although a small proportion of these freedoms (at the base of the jacket of Figure 14.19, for example) will be constrained to be zero or prescribed in other ways to account for the effect of foundations.

The next step in the analysis is to define the stiffness of each member in the framework as described in item (2) above. This and the subsequent procedures are described in more detail by Patel.[10]

Application of the above technique to gravity structures differs in a number of ways. The structural analysis can be carried out through a simple beam element model or, alternatively, more representative cylindrical shell elements can be used to model the caisson structure and vertical walls. In both cases, it is necessary to include some idealization of the foundation elasticity either by equivalent springs or by continuing the finite-element idealization into the foundation using solid elements as described by Penzien and Tseng.[20]

Furthermore, wave forces are calculated using diffraction theory only or a combined Morison/diffraction approach. It is usual to calculate the forces separately and to define them as a distribution of equivalent nodal loads for input to the analysis. Since the structural deflections of these relatively rigid structures are very small compared to water-particle displacements, the non-linear drag force in the Morison equation can be explicitly computed and does not present analysis problems. More flexible structures in deep-water locations and other compliant structures need to be analysed using the methods of structural dynamics. Patel[10] gives an overview of these with details presented by Bathe and Wilson[21] and Malhotra and Penzien,[22] among others.

14.5.1.1 Foundation effects

For piled jackets, the structural calculations described above have to be supplemented by a lateral pile-loading analysis which quantifies the coupled response of an embedded pile and non-linear material behaviour of the surrounding soil. When a single pile is loaded by a horizontal force due to environmental loading of the jacket structure of which it is a part, the pile will deflect against the surrounding soil and take up a typical deflection and bending moment profile shown in Figure 14.20. The magnitude of deflection, rotation and bending moment at the end of the pipe will depend on a balance of forces between the pile and surrounding soil. Determination of this behaviour requires data on the lateral soil reaction on the pile as a function of depth together with a means of structural analysis of the pile itself due to a varying soil loading. Taking the former first, the soil reaction is a function of soil type, pile properties, its loading, deflection and the soil depth, and may be expressed as

$$p = - E(x,y)\, y \qquad (14.15)$$

where p is the distributed soil reaction force, y is the lateral pile deflection and E is the modulus of elasticity of the soil which will vary with soil deflection, y, and depth, x. From basic beam-bending theory, the structural behaviour of the pile can be written as

$$E_pI_p \frac{d^4y}{dx^4} = w \qquad (14.16)$$

where E_pI_p is the elastic modulus of the pile and w is the distributed lateral load on the pile. Combining equations (14.15) and (14.16) yields the basic differential equation for a laterally loaded pile as

$$E_pI_p \frac{d^4y}{dx^4} + E(x,y)\, y = 0 \qquad (14.17)$$

One of the greatest difficulties in solving this equation arises from the fact that the soil modulus, E, varies both with pile deflection, y, and with depth, x. For many soil types, E increases with depth and can be modelled by the equation

$$E = k\, x \qquad (14.18)$$

where k is a constant. A simple but very approximate method for calculating pile behaviour is obtained by assuming that the pile is completely fixed against rotation at some point below the mud line (such as A in Figure 14.20). The position of this point is selected from experience and the forces exerted on the pile by the soil are neglected above the point. Despite the desirable simplicity of this method, it does not reflect the physical behaviour of the pile and soil and is not recommended for use.

An alternative method for computing pile/soil interaction is to solve equation (14.18) by a finite-difference numerical scheme, although analytical solution can be obtained for the special case of constant E (see Poulos and Davis[23] and Reese[24]).

However, this numerical analysis can only be carried out if the soil modulus of elasticity function $E(x,y)$ is known. One form of E that is commonly used is

$$E = E_L \left[\frac{x}{L}\right]^N$$

where E_L is the value of the modulus at the pile bottom and N is an empirical index equal to or greater than zero. $N = 0$ corresponds to a constant modulus whereas $N = 1$ gives a linear variation as in equation (14.18). In general, N is taken between 0 and 0.15 for clay soils and N equals 1 for granular soils. Analytic solutions for equation (14.17) are available for $N = 0$.

For real soils, however, the relationship between soil reaction and deflection is non-linear with the reaction reaching a limiting value when the deflection is sufficiently large. Figure 14.21 presents typical soil reaction against deflection curves for a consolidated clay soil and demonstrates the flattening out of the reaction/deflection curves at large deflections. These curves are conventionally referred to as p-y curves.

The non-linear soil reaction curves are accommodated in analysis by rewriting equation (14.17) as

$$\frac{d^2M}{dx^2} + S(x)\frac{d^2y}{dx^2} + E(x,y)\, y = 0 \qquad (14.20)$$

where M is the pile moment at depth x and the additional effect of a variation of axial force S with depth x is accounted

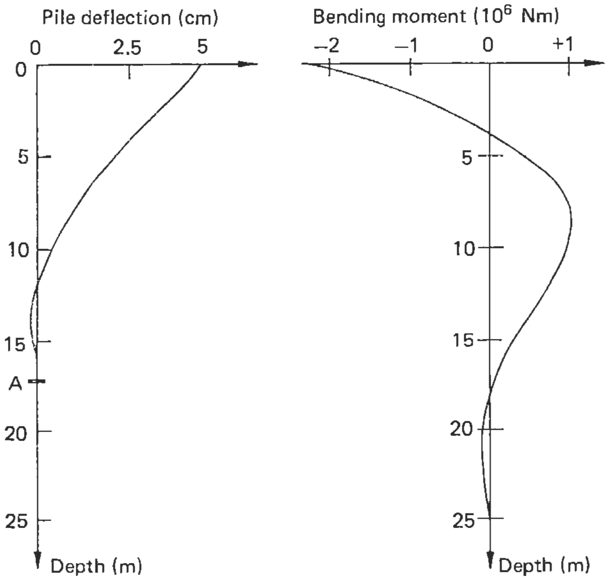

Figure 14.20 Deflection and moment of an embedded pile

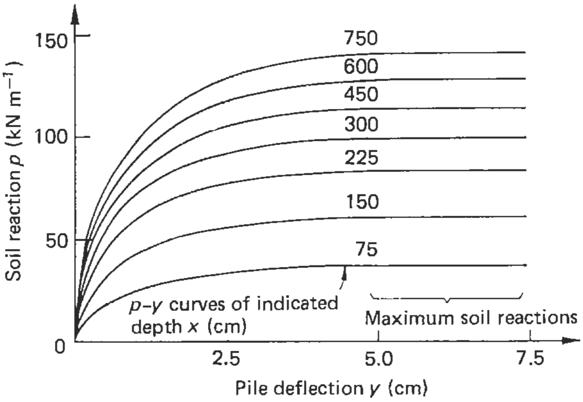

Figure 14.21 Typical p-y curves for a consolidated clay

for (see Reese[24] for further details). This equation can be solved by a finite-difference technique similar to that described above. The solution requires inputs of *p-y* curves at various depths (see Figure 14.21), although the method implicitly assumes that the soil behaviour at a particular depth is independent of that in adjacent layers. Equation (14.20) and the *p-y* curves are solved using an iterative finite-difference technique. The resultant shear forces and bending moments at the pile surface are derived as functions of pile top displacement and rotation, respectively, and combined with a jacket finite element analysis as in Figure 14.22 to complete definition of the pile and structure interaction.

The *p-y* data necessary for the analysis can be obtained in three different ways – full-size or model-scale lateral loading tests on instrumented piles are one of the most reliable methods, although practical considerations often restrict *p-y* data sources to laboratory tests or empirical correlations based on soil survey data.

Other pile and foundation analyses also use an elastic continuous mathematical model of the surrounding soil together with a finite-beam element model of the pile to quantify pile deflections, and soil behaviour. Poulos and Davis[23] give further details. Analysis of piles for jacket platforms often needs to account for pile groups and their interaction with the soil. Focht and Kock[25] and O'Neill *et al.*[26] describe extensions of the techniques described above for pile groups.

14.5.2 Structure failure and fatigue life calculations

The safe structural design of a jacket structure ultimately depends on the detailed design of individual tubular joints. The analyses described above are readily able to ensure that members between joints do not fail from buckling or overstressing in tension or bending. There are, however, several failure mechanisms that have to be designed against in the definition of a tubular joint. A tubular joint brace loading the main member in compression can initiate failure by local buckling or by punching shear of the main member wall. Tensioned braces can cause failure due to crack growth or lamellar tearing of the main member wall.

However, a large amount of structural design studies, finite-element analyses and model tests have ensured that these failure mechanisms can be almost completely avoided. The majority of useful recommendations made by such work have been incorporated into codes of practice, of which those issued by the American, Petroleum Institute[27] and the British Standards Institution[28] are good examples.

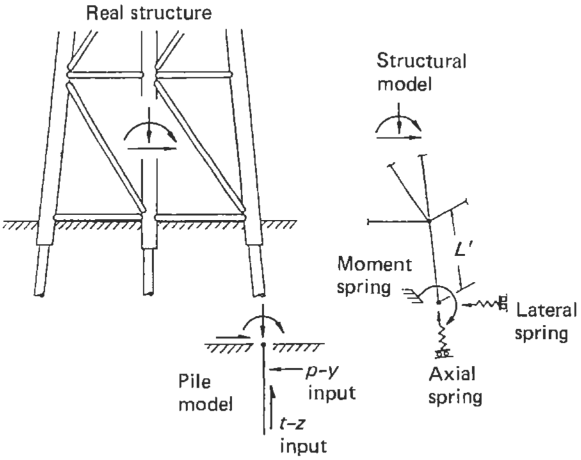

Figure 14.22 Spring model to represent pile

At present, the largest source of structural failures in operation are due to fatigue damage compounded by the effects of corrosion. A metal will fail under repeated cycles of relatively low stress levels due to the growth of internal cracks that can be initiated from local construction defects or at stress-concentration sites. Such metal fatigue failures are quantified from experimental data by the use of *S-N* curves which are plots of stress range, *S*, against number of cycles to failure, *N*, with both axes plotted in logarithmic form. The fatigue behaviour of a variety of steels can, therefore, be characterized by *S-N* curves of the type shown in Figure 14.23 obtained from BS 6235: 1982. These curves show that steel specimens in air do exhibit a low stress range level (called the fatigue limit) below which the metal would have a theoretically infinite life, although this property disappears if the effects of combined stress range cycles and corrosion are considered.

The Palmgren–Miner cumulative fatigue damage rule is used to quantify fatigue damage caused by a large number of cycles at low stress ranges. The rules give the resultant cumulative damage ratio, *D*, as

$$D = \sum_{i=I}^{N} \frac{n_i}{N_i} \leqslant 1 \tag{14.21}$$

where N denotes the total number of stress range intervals being considered, n_i is the number of cycles experienced by the structure within the ith stress range and N_i is the number of cycles to failure given by the *S-N* curve for this ith stress range. Failure will occur when parameter D reaches unity. If the number of stress range cycles used in the calculation correspond to one year's operation then the fatigue life of the structure in years can be given by the reciprocal of the cumulative damage.

In design practice, the fatigue life is calculated using a deterministic approach illustrated by the left-hand column of the flow diagram of Figure 14.24. The starting point for such an analysis is the significant wave height against average zero crossing period scatter diagram, typically averaged for one year's weather conditions. The number of occurrences (expressed in parts per thousand) in each row of the scatter diagram are converted to number of waves in one year by using the appropriate average zero-crossing period and added to build up a variation of maximum wave height (converted from the significant height in the scatter diagram) against number of waves that exceeded this height, as in box 2 of Figure 14.24. Each wave height range in this figure has an associated period range that is also presented with the figure.

The wave heights and period ranges are used through the wave theory, loading and response analyses described earlier to yield an equivalent curve of stress range against number of loading cycles that will be applied at this range in box 3. It is usual practice in the calculation to select a wave period for any wave height that will produce the largest stress, although the choice of an average between the range of wave periods will yield a less conservative result. A curve such as in box 3 of Figure 14.24 is obtained for each of the fatigue-prone zones on the structure. A stress–concentration factor is then applied to the data of box 3 and combined with the Palmgren–Miner damage rule and a material *S-N* curve to yield the annual cumulative damage, *D*, and fatigue life of 1/*D* years.

A probabilistic approach can also be applied to estimating the stress range exceedence of box 8 by using a parameterized spectral density to represent each significant wave height/zero-crossing period range in the scatter diagram of box 1. A linear structural response analysis is then carried out to yield the

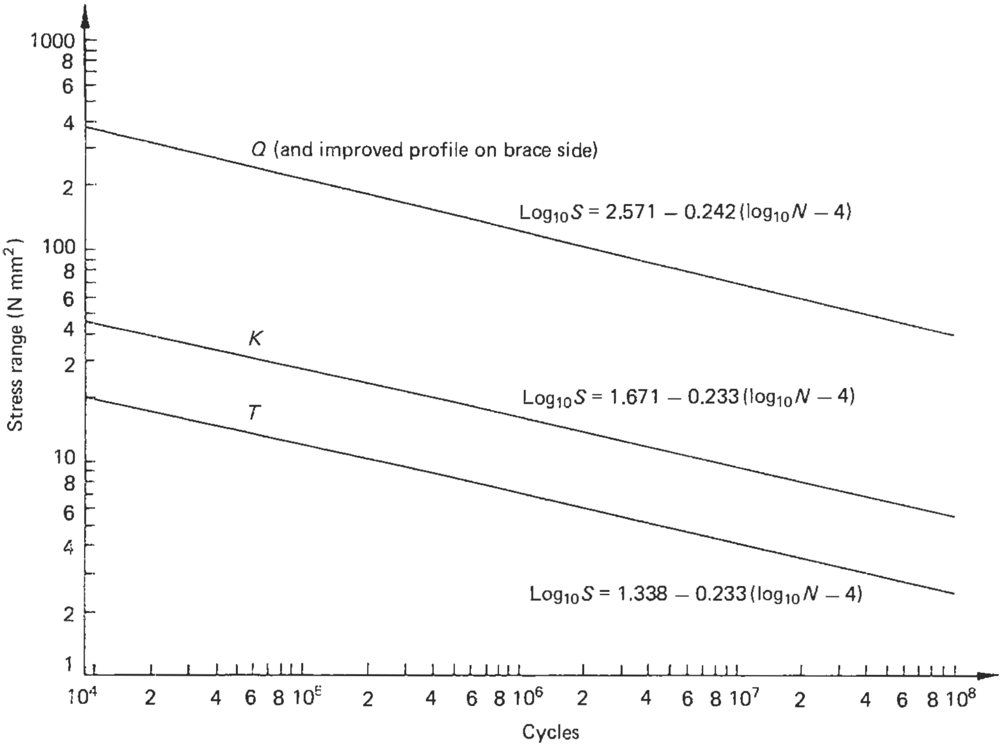

Figure 14.23 Typical *S*-*N* lines for welded tubular joints. *Q* line is used for general fatigue-life calculations and the *K* and *T* lines for an appropriate 'punching shear' method (from British Standards Institution[28])

stress spectrum (as in box 6) at all points of interest. A Rayleigh probability distribution of stress peaks (box 7) is then assumed to estimate the probability of occurrence of each stress range from which the figure of box 8 can be derived and the fatigue analysis completed. It should be noted that the average zero-crossing period of the stress spectrum in box 6 will be different from that of the wave spectrum of box 5, and will need to be calculated in order to determine the numbers of stress cycles applied in a year.

The effect of sea-water corrosion and the value of stress concentration factors to be used are two of the most important sources of uncertainty in fatigue analysis of an offshore structure. The American Petroleum Institute[27] and the British Standards Institution[28] give some guidance on these matters.

Much recent progress has been made on quantifying fatigue crack growth in tubular joints by the application of the theory of fracture mechanics coupled with more accurate in-service crack-detection techniques – see, for example, the work of Dover and Connolly[29] and Dover and Wilson.[30] Their combined use is leading to more reliable monitoring and rectification of fatigue crack growth during the life of an offshore structure.

14.6 Dynamics of floating systems

14.6.1 Heave motion of cylindrical buoys

The transformation of a problem concerned with fluid structure interaction of a floating body into the governing equation of a second-order dynamic system is illustrated by considering heave motion of the small buoy shown in Figure 14.25. Coordinate y denotes vertical motion of the water surface and z the resultant buoy vertical motion. Now the total force acting on the buoy will be due to added mass, damping and hydrostatic stiffness induced forces due to differential motion between the buoy and surrounding fluid. The net force due to these effects will serve to accelerate the buoy. Thus the equation of motion can be written as

$$m\,\ddot{z} = A\,(\ddot{y} - \ddot{z}) + B(\dot{y} - \dot{z}) + C\,(y - z) \qquad (14.22)$$

where m is the buoy mass and A, B, C are coefficients expressing the added mass, damping and hydrostatic stiffness induced forces on the buoy. Here the damping force is taken to be linear and the Froude–Krylov force – applying through dynamic wave pressure on the buoy base – is given by the stiffness term Cy for a buoy.

Rearranging equation (14.22) to bring unknown buoy motion terms to the left-hand side gives

$$(m + A)\,\ddot{z} + B\,\dot{z} + C\,z = F(t) \qquad (14.23)$$

where

$$F(t) = A\ddot{y} + B\,\dot{y} + C\,y \qquad (14.24)$$

Thus, there are two equations governing the behaviour of the buoy in waves. Equation (14.24) is concerned with the mechanism of wave elevation motion, y, exerting an exciting force $F(t)$ on the buoy whereas equation (14.23) is of similar form to the governing equation for a second-order dynamic system. The form of the above equations is typical of that obtained for all floating bodies in that two transfer functions

Figure 14.24 Fatigue-life calculation procedures

(from wave elevation to force and from wave force to motion) are involved in deriving a body-motion response from wave elevation.

A typical but very simplified solution procedure for the above equations is presented here to illustrate these ideas further. Taking buoy height, h, as very small compared to wave length, a wave of amplitude a with elevation

$$y = a \cos \omega t \tag{14.25}$$

can be used with equation (14.24) to give

$$F(t) = a\,[(C - A\,\omega^2) \cos \omega t - B\,\omega \sin \omega t] \tag{14.26}$$

Thus the wave force is a function of A, B, C, frequency, ω, and wave amplitude, a, and can be expressed as an amplitude and phase transfer function of the form

$$F(t) = F_a \cos (\omega t + \epsilon)$$

where

$$\frac{F_a}{a} = [(C - A\omega^2)^2 + (B\omega)^2]^{1/2} \tag{14.27}$$

and

$$\epsilon = \tan^{-1}\left[\frac{-B\omega}{C - A\omega^2}\right]$$

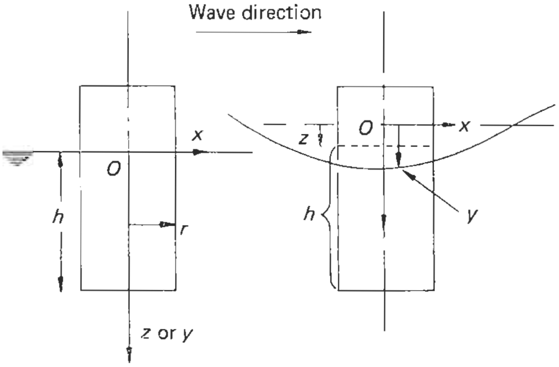

Figure 14.25 Heave motion of a buoy

Equation (14.27) possesses all the features of a second-order dynamic system transfer function (see Warburton[31]) with its amplitude and phase varying with frequency of excitation. Equation (14.23) then becomes

$$(m + a)\,\ddot{z} + B\dot{z} + Cz = F_a \cos(\omega t + \epsilon) \tag{14.28}$$

and has a solution of the form

$$\left.\begin{aligned} &z = z_a \cos(\omega t + \epsilon + \varnothing)\\ &\text{where}\\ &\frac{z_a}{F_a} = \frac{1}{\{[C - (m + A)\omega^2]^2 + (B\omega)^2\}^{1/2}}\\ &\text{and}\\ &\phi = \tan^{-1}\left[\frac{B\omega}{C - (m + A)\omega^2}\right] \end{aligned}\right\} \tag{14.29}$$

Note that the wave force leads the wave elevation by ϵ and the buoy motion lags the wave force by ϕ. When $m \rightarrow 0$, $\epsilon + \phi = 0$ and suggests that a mass-less buoy will follow the wave profile exactly without phase lag. The amplitude and phase transfer functions from wave force to buoy motion will be like that of a second-order dynamic system, but the overall wave elevation to buoy motion amplitude and phase transfer functions will be distorted by the presence of the wave elevations to wave force transfer functions. It is recommended that both of these transfer functions be evaluated independently during the motions analysis of a floating body to obtain a clearer physical understanding of its behaviour. (Figures 14.27, 14.29 and 14.30 present phase transfer for typical floating offshore structures.)

For a cylindrical buoy of radius, r, and height, h, floating in water of density, ρ, the terms m, c and A can be given by

$$\left.\begin{aligned} m &= \rho\pi r^2 h\\ C &= \rho\pi g r^2\\ A &= \frac{1}{3}\pi\rho r^3 \end{aligned}\right\} \tag{14.30}$$

where the added mass, A, in vertical motions of the cylinder end is approximated by that of a hemisphere of radius, r, and added mass coefficient 0.5 on the cylinder end. Other approximations for A involve treating the cylinder end as a flat disk moving along its axis of symmetry.

14.6.2 Heave motion of a semi-submersible

The heave motion to waves of a semi-submersible of simple geometry can be evaluated by treating the vessel as a collection of slender members on which the loading can be calculated using the Morison equation with deep-water linear wave theory. In this particular derivation, the damping and wave-induced drag forces are neglected for simplicity. Thus the equation of vertical motion for a four-column, twin-pontooned semi-submersible of the configuration shown in Figure 14.26 can be written as

$$(m + A)\,\ddot{z} + C\,z = F(t) \tag{14.31}$$

For a simple four-column, twin-pontooned semi-submersible of the type shown in Figure 14.26 the coefficients of this equation are

$m = 4\rho[A_v d + A_h L]$
$A = 4\rho C_m A_h L$
$C = 4\rho g A_v$

where A_v and A_h are the areas of cross section of the vertical columns and rectangular pontoons, respectively, and C_m the added mass coefficient for the pontoons in vertical motions.

The vertical wave-exciting force on the vessel can be taken as the sum of wave forces on the pontoons and columns to yield

$$\left.\begin{aligned} F(t) = &\int_{-L}^{L} 2\rho A_h\,(1 + C_m)\,\dot{w}\,.\,dx\\ &+ 2A_v\,(p_f + p_r) \end{aligned}\right\} \tag{14.32}$$

where $\dot{w}$ is the vertical wave particle acceleration at $z = -d$ and p_f, p_r are wave pressures at $z = -d$ and $x = +L$ and $-L$, respectively. Note that the pontoon/column intersections have been approximated by lengths d and L to simplify the above algebra.

The Froude–Krylov force normal to the pontoon axis is calculated using an inertia coefficient $(1 + C_m)$ whereas the axial Froude–Krylov force on the vertical columns is calculated as a product of dynamic wave pressure and column area of cross section. The former approach is valid for calculating normal forces on a slender member about which wave properties can be considered constant, whereas the wave-pressure formulation is necessary for axial forces on members whose length is comparable to incident wave length.

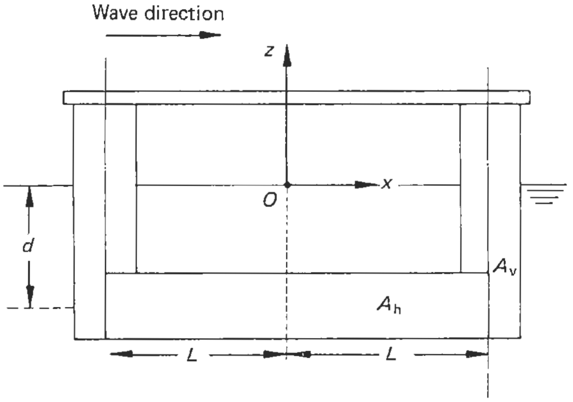

Figure 14.26 Side view of a four-column semi-submersible

Using the Oxz axes of Figure 14.26, the wave particle vertical acceleration and pressure can be written as

$$\left.\begin{aligned} \dot{w} &= -a\omega^2 e^{-kd}\sin(kx-\omega t) \\ &\text{and} \\ p &= +a\frac{\rho\omega^2}{k}e^{-kd}\sin(kx-\omega t) \end{aligned}\right\} \qquad (14.33)$$

and substituted into equation (14.32) to yield the wave force relationship

$$\begin{aligned} F(t) &= 4a\rho g e^{-kd}[-A_v\cos kL \\ &+ A_h(1+C_m)\sin kL]\sin\omega t \end{aligned} \qquad (14.34)$$

Evaluation of equation (14.34) followed by the solution of equation (14.32) yields the wave-induced force and motion response, which can be written as

$$\left.\begin{aligned} F(t) &= F_a\sin(\omega t+\epsilon) \\ &\text{and} \\ z(t) &= z_a\sin(\omega t+\epsilon+\phi) \end{aligned}\right\} \qquad (14.35)$$

Figure 14.27 presents the variations of $|F_a|/|a|, |z_a|/|a|$, ϵ and $(\epsilon+\phi)$ as functions of frequency for a semi-submersible with $d = 13.5$ m, $L = 36$ m, $A_h = 70\ \text{m}^2$ and $A_v = 90\ \text{m}^2$. A value of 1.2 is used for the added mass coefficient. These curves exhibit several interesting features. The wave force amplitude cancels out to zero at certain wave frequencies when instantaneous wave forces on the pontoons balance wave forces on the columns. At these cancellation frequencies, phase, ϵ, shifts by 180° such that over some wave frequencies, the vertical force on the vessel is out of phase with wave elevation. The motion response transfer function shows the combined effects of the wave force cancellation and resonance with the total phase difference between vessel motion and wave elevation around the resonant frequency exhibiting some complex behaviour.

14.6.3 Heave and surge motions of tensioned buoyant platforms

A tensioned buoyant platform (TBP) is a floating structure connected to a sea-bed foundation by vertical mooring tethers which are kept in tension by excess buoyancy over weight in the platform structure. The use of TBPs as alternatives to oil

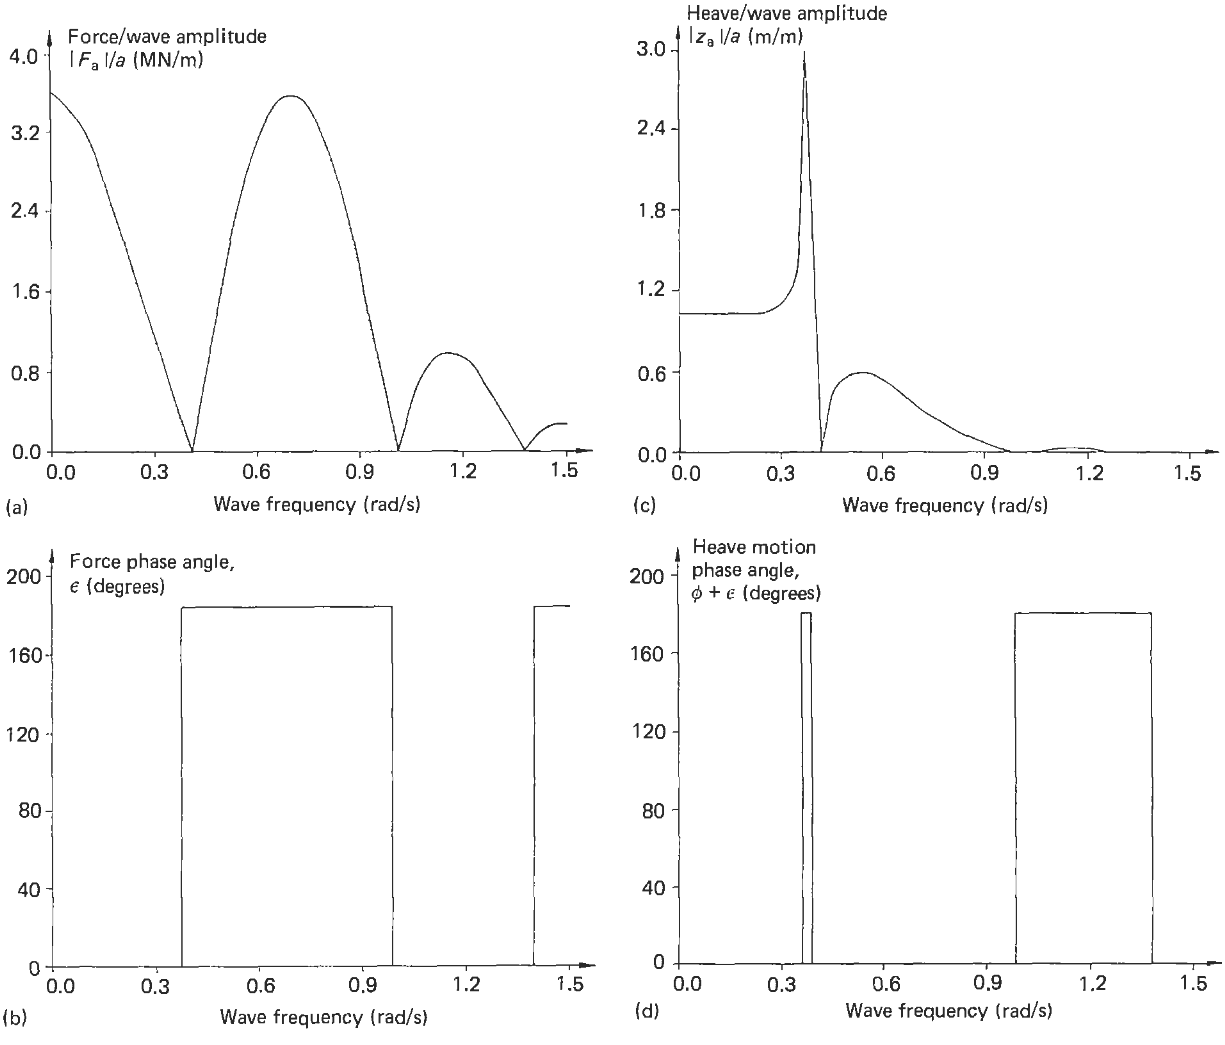

Figure 14.27 Heave force and motion response of a four-column semi-submersible

production from fixed or catenary moored semi-submersibles or other floating structures is now well established. A TBP possesses a combination of desirable characteristics as an offshore work platform. The absence of a fixed rigid structure from sea surface to sea bed coupled with the excellent station-keeping characteristics of tensioned vertical tethers satisfy the two important demands of economy and safe operation. Additionally, a TBP exhibits very much smaller wave-induced heave, roll and pitch motions due to the presence of the vertical mooring tethers. Large surge and sway offsets due to wind and current steady force components will, however, cause the platform to be drawn down lower in the water and exhibit a so-called 'set-down'. Nevertheless, the wave frequency surge and sway motions of a TBP are desirable, since horizontal wave loads are not fully reacted by the surface platform structure.

Conventional TBPs have structural features which are similar to those of semi-submersibles. These include the presence of deeply submerged main buoyancy chambers which give rise to a significant reduction in wave-induced forces due to the exponential decay of wave particle velocities and accelerations with depth below the surface. The combination of horizontal pontoons and vertical columns supporting the working deck produces wave force cancellation at certain frequencies. This occurs because the upward wave force on vertical columns due to buoyancy changes can be almost exactly cancelled out by the downward wave force on horizontal pontoons. Additionally, the stiffness of the tethers and their axial tensions will radically influence the dynamic response of the platform to waves.

Methods of analysis for a TBP are very similar to those outlined earlier for a semi-submersible structure, except for the insertion of a stiffness matrix induced by the presence of the relatively stiff platform tethers. Thus the equation of motion, the evaluation of the coefficient matrices and the solution of the equation are the same as above with the tether stiffness matrix C_t included.

The governing equation for heave motion of a tensioned buoyant platform of the configuration shown in Figure 14.28 is derived below. The platform is square in plan view with transverse pontoons (marked A in Figure 14.28) of length $2L$ and cross-sectional area, A_h. The equation for heave motions is

$$\left.\begin{aligned} &(m + A)\,\ddot{z} + (C + C_t)\,z = F_z(t) \\ &\text{where} \\ &m = 4\rho\,[A_v d + 2A_h L] - \frac{4T}{g} \end{aligned}\right\} \qquad (14.36)$$

with T being the tension in each of the tethers on the four corners of the platform,

$$\left.\begin{aligned} &A = 8\rho\, C_{mz} A_h\, L \\ &C = 4\rho\, g\, A_v \\ &\text{and} \\ &C_t = 4\lambda' \end{aligned}\right\} \qquad (14.37)$$

where C_{mz} is the added mass coefficient for the pontoon cross section in vertical motion and λ' is the axial stiffness of each of the tethers. In this analysis, the drag damping coefficient and wave-induced drag forces are neglected for simplicity. The wave force in heave is

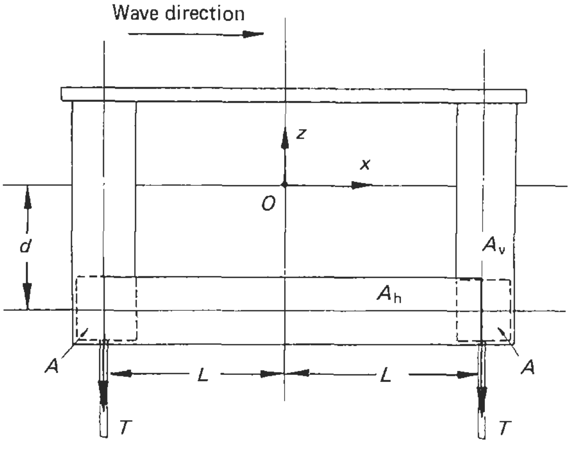

Figure 14.28 Side view of a four-column tensioned buoyant platform. A are transverse pontoons of length 2 L and area of cross section A_h

$$\left.\begin{aligned} F_z(t) = &\int_{-L}^{L} 2\rho\, A_h\,(1 + C_m)\,\dot{w}\,dx + 2A_v\,(p_f + p_r) \\ &+ 2\,\rho\,A_h\,L\,(1 + C_m)\,[\dot{w}_f + \dot{w}_r] \end{aligned}\right\} \qquad (14.38)$$

where $\dot{w}_f$ and $\dot{w}_r$ are the vertical wave particle accelerations at $z = -d$ and $x = +L$ and $-L$, respectively, with the remaining notation from earlier in this section. Then, using equation (14.33), we get

$$\begin{aligned} F_z(t) = {} & 4a\,\rho\,g\,e^{-kd}\,[-A_v \cos kL + A_h\,(1 + C_m) \sin kL \\ & + A_h.kL.(1 + C_m) \cos kL] \sin \omega t \end{aligned} \qquad (14.39)$$

These equations have most of the characteristics of the governing equation for semi-submersibles except for the presence of stiffness term, C_t, which is large and tends to substantially reduce the heave natural periods of such platforms to the range of 3 to 5 s from the usual semi-submersible heave reasonance period of from 18 to 25 s. Using the definition of equation (14.35), Figure 14.29 presents variations of the wave force and motion transfer functions with frequency for a TBP with $d = 35$ m, $L = 50$ m, $A_h = 100\ \text{m}^2$ and $A_v = 150\ \text{m}^2$. The total tether pre-tension and stiffness are taken to be 3.75 MN and 56.53 MN/m, respectively. The added mass coefficient for vertical motion of the rectangular pontoons is taken to be 1.2. The wave force is slightly modified due to the additional transverse pontoons, but the motion response exhibits a substantial reduction in magnitude due to the shift in resonant frequency.

A similar analysis to that above can be carried out for surge motion of a TBP with a governing equation of the form

$$(m + A')\,\ddot{x} + (C' + C'_t)\,x = F_x(t) \qquad (14.40)$$

The additional terms in the above equation are

$$\left.\begin{aligned} &A' = 4\rho\, C_{mx}\, A_h\, L + 4\rho\, A_v d \\ &C' = 0 \qquad C'_t = \frac{4T}{s} \end{aligned}\right\} \qquad (14.41)$$

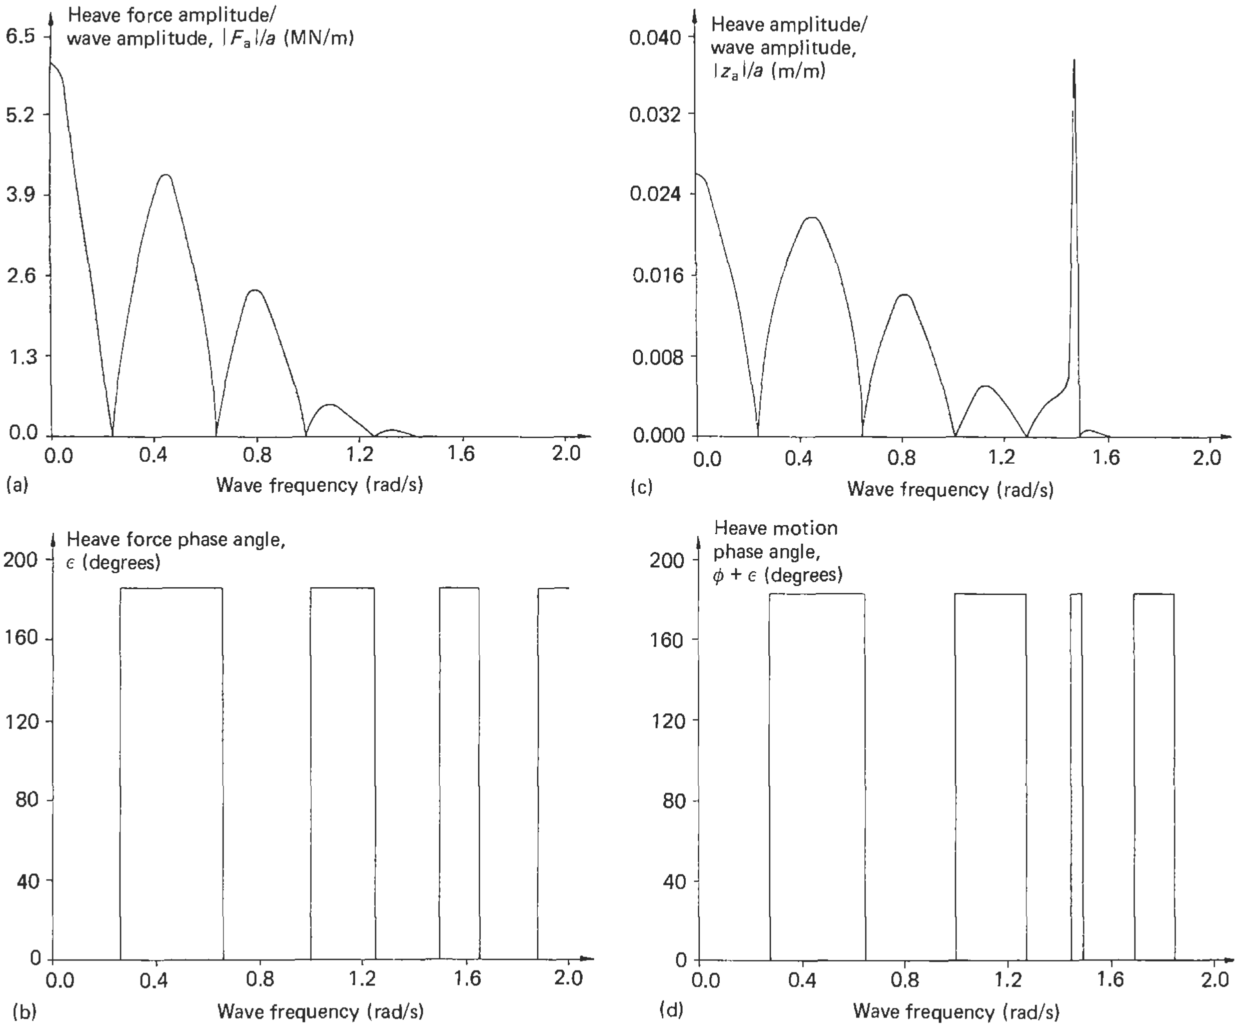

Figure 14.29 Heave force and motion response of a four-column tensioned buoyant platform

where C_{mx} and 1.0 are the added mass coefficients for horizontal flow normal to the pontoons and vertical columns, respectively. The hydrostatic stiffness term, C', is zero and the tether stiffness is expressed in terms of tension and tether lengths. An expression for $F_x(t)$ can be derived in the same way as for heave motion to be

$$F_x(t) = \int_{-d}^{0} 4\rho A_v [\dot{u}_f + \dot{u}_r]\, dz + \rho A_h L (1 + C_{mx}) [\dot{u}_f + \dot{u}_r]_{z=-d} - 2A_h [p_f - p_r]_{z=-d} \qquad (14.42)$$

where $\dot{u}_f$, p_f and $\dot{u}_r$ p_r denote horizontal wave particle accelerations and wave pressures at $x = +L$ and $x = -L$, respectively, and are given by

$$\dot{u} = -a\,\omega^2 e^{+kz} \cos(kx - \omega t) \qquad (14.43)$$

and equation (14.33) with C_{mx} and 1.0 taken as the added mass coefficients for horizontal flow normal to the pontoons and vertical columns, respectively. Then, the wave force $F_x(t)$ can be written as

$$F_x(t) = -\left\{\frac{8\rho a\omega^2 A_v}{k}[1 - e^{-kd}] + 2\rho a\omega^2 A_h L (1 + C_{mx})e^{-kd}\right\} \cos kL \cos \omega t - 4\rho g a A_h e^{-kd} \sin kL \cos \omega t \qquad (14.44)$$

Note that the only force cancellations occurring in equation (14.44) are due to zeroes of the combined cos kL and sin kL terms.

Figures 14.30 present the surge force and motion response transfer function calculated from these equations. The tether length, s, is taken to be 450 m and $C_{mx} = 1.2$ with all other parameters being as in the calculation of heave response

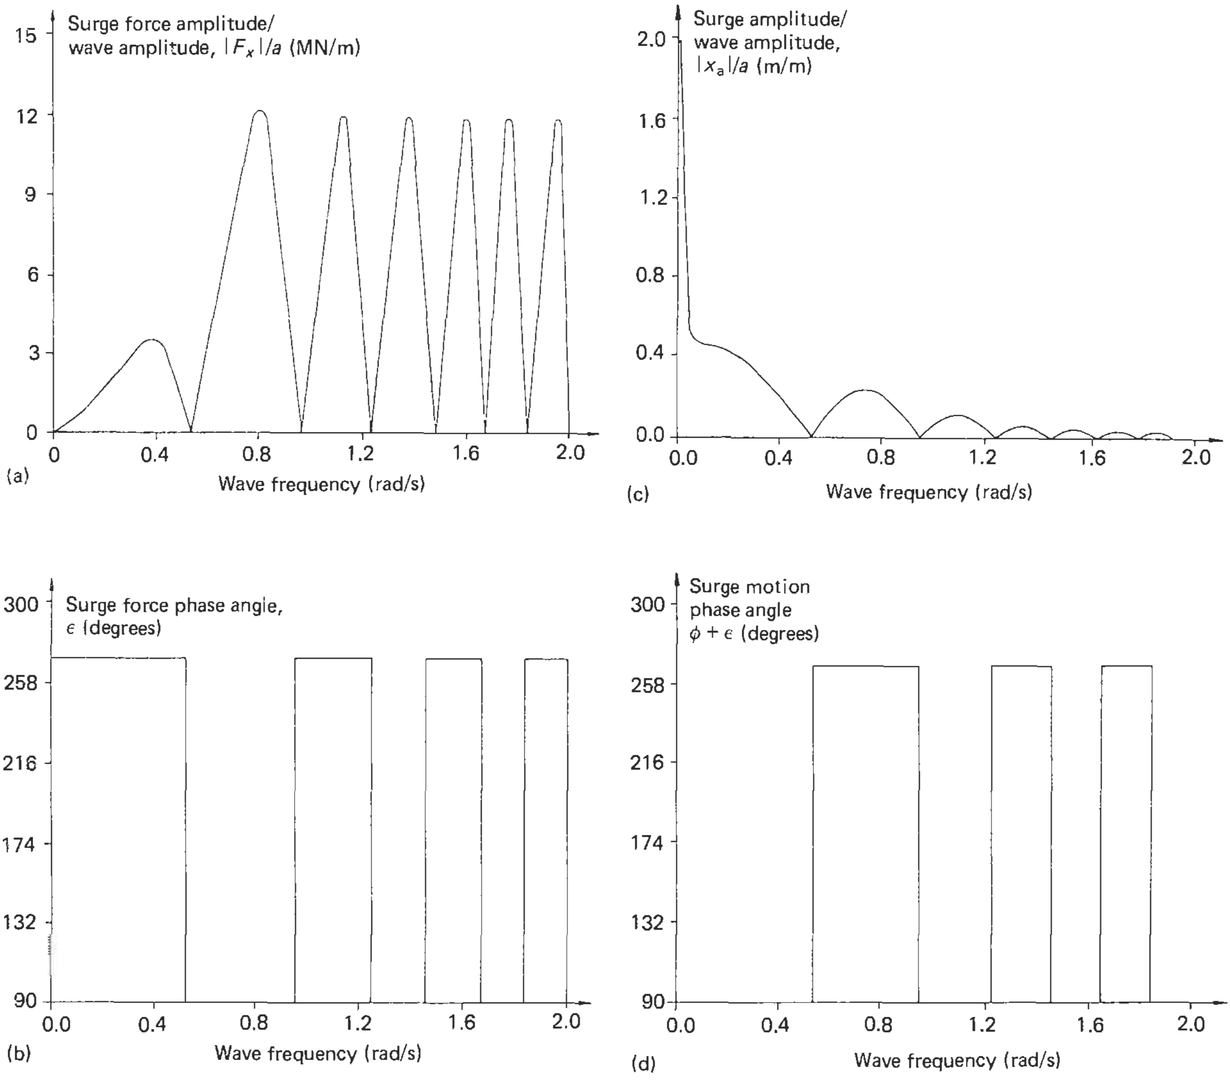

Figure 14.30 Surge force and motion response of a four-column tensioned buoyant platform

described above. Again, the effect of tether stiffness dominates the motion transfer function with a low natural period and relatively large surge motions at predominant wave periods.

14.6.4 Analysis with multiple degrees of freedom

The general multiple-degree-of-freedom equations of motions for a stationary floating body in gravity waves can be formulated using an approach similar to that used for single degrees of freedom earlier. It is usual to formulate these matrix equations in the six rigid-body degrees of surge, sway, heave, roll, pitch and yaw described by a column vector, **X**, although additional degrees of freedom (such as structural deformations) can be incorporated, if required. The matrix equation of motion is

$$(\mathbf{M} + \mathbf{M}_A)\,\ddot{\mathbf{X}} + \mathbf{B}_V\,|\dot{\mathbf{X}}|\dot{\mathbf{X}} + (\mathbf{K} + \mathbf{K}_m)\,\mathbf{X} = F(t) \qquad (14.45)$$

where **M** and $\mathbf{M}_A$ are the (6 × 6) coefficient matrices quantifying structure physical mass and added mass, respectively, $\mathbf{B}_V$ is a (6 × 6) matrix representing a non-linear drag force while **K** and $\mathbf{K}_m$ are (6 × 6) stiffness matrices describing the hydrostatic and mooring restoring forces acting on the vessel.

The formulation of the equation of motion for a monolithic ship-shape hull form differs from that used for a semi-submersible since for ship shapes the diffraction of incident waves due to the large size of the hull form has to be accounted for. For these hull forms, the basic equation of motion can be written simply as

$$[\mathbf{M} + \mathbf{M}_A]\ddot{\mathbf{X}} + \mathbf{B}_p\dot{\mathbf{X}} + [\mathbf{K} + \mathbf{K}_m]\,\mathbf{X} = \mathbf{F}\,e^{i\omega t} \qquad (14.46)$$

where **M**, $\mathbf{M}_A$, **K** and $\mathbf{K}_m$ are defined above, $\mathbf{B}_p$ is the matrix of potential damping coefficients and $\mathbf{F}\,e^{i\omega t}$ is a complex vector of wave forces obtained by summing hull surface pressures from a diffraction analysis.

The above basic equations of motion are solved using different approaches for slender space-framed structures and for large hull forms.

14.6.5 Morison-equation approach for slender structures

This is applicable to slender space-framed structures with characteristic cross-sectional dimensions that are less than 20% of incident wave lengths. The following additional assumptions are implied in the formulation of the equation of motion (14.44) above:

1. The vessel structure is assumed to be an assembly of cylindrical elements and horizontal rectangular pontoons. The cylindrical members and rectangular pontoons are assumed to have large ratios of length to cross-sectional dimension.
2. The motion amplitudes of the platform and the wave motions are assumed to be small. As a consequence, linear wave theory is used.
3. Wave forces on individual elements of the structure are computed as though other members were not present, that is, hydrodynamic interference between members is ignored.
4. The forces associated with sinusoidal wave motions are computed independently of the forces associated with absolute motions of the structure.
5. The non-linear drag damping term is linearized by assuming an equivalent linear damping which would dissipate the same energy at resonance as the non-linear damping. The contribution of wave radiation effects to the damping terms is assumed to be negligibly small.

The floating vessel is described by orthogonal coordinate axes with origin at the centre of gravity, x pointing forwards, y to port and z vertically upwards. The physical mass matrix is computed using the mass distribution of the vessel and is diagonal if the reference axes are principal axes of the vessel. The added mass matrix for the structure is obtained using a summation of the added mass matrix for each individual cylinder. Details of this approach are given by Patel.[10] These equations can readily be modified to account for rectangular cylinders.

The fluid damping matrix, **B**, for the structure is evaluated in a similar manner to the added mass matrix – as a sum of the contributions from each individual member. The derivation of the generalized damping matrix for an arbitrarily orientated circular cylinder can be derived using the method described by Patel[10] with the assumption that only drag forces normal to the cylinder axis are significant. Unlike the added mass matrix, the non-linear velocity square proportionality generates an asymmetric damping matrix. The corresponding matrices for the rectangular cylinder and non-elongated body are evaluated as special cases of the circular cylinder.

Contributions to the hydrostatic stiffness matrix, **K**, will only arise in the heave, roll and pitch degrees of freedom due to buoyancy forces in the water plane cutting members of the hull. If, for a member number, n, A_{wn} denotes the water plane area and (x_{wn}, y_{wn}) are the coordinates of the centroid of this water plane area, then the hydrostatic stiffness matrix elements k_{ij} can be written as the summations

$$\left.\begin{aligned} k_{33} &= \rho g \Sigma A_{wn} \\ k_{43} &= \rho g \Sigma y_{wn} A_{wn} \\ k_{53} &= -\rho g \Sigma x_{wn} A_{wn} \\ k_{54} &= -\rho g \Sigma A_{wn} x_{wn} y_{wn} \\ k_{44} &= \rho g V (GM)_{\mathrm{P}} \\ k_{55} &= \rho g V (GM)_{\mathrm{R}} \end{aligned}\right\} \qquad (14.47)$$

where V is the vessel displacement by volume and $(GM)_r$, $(GM)_p$ are metacentric heights in roll and pitch, respectively, while all other stiffness terms are zero. A linearized mooring systems stiffness matrix, $\mathbf{K}_m$, can be obtained from the calculations described by Patel[10] and inserted in the equation of motion to obtain motion responses of the moored rather than the free vessel.

The wave force calculation is based on obtaining an oscillating force column vector by summing the effects of wave pressures, particle velocities and accelerations on all structural members of the semi-submersible.

The vessel response to this applied oscillating wave force vector is then computed by using an iterative technique to account for the non-linear drag damping force. A first approximation diagonal linear damping coefficient matrix is obtained by ignoring all non-diagonal terms in the total mass and stiffness matrices and assuming linear damping to be 10% of critical. The equations of motion are solved with this first approximation to the damping value. The column vector of these velocities is then substituted into the modulus sign in the damping term such that the equation

$$(\mathbf{M} + \mathbf{M}_A)\ddot{\mathbf{X}} + \mathbf{B}_v \frac{8}{3\pi} |\dot{\mathbf{X}}_{\substack{\text{last}\\\text{approx}}}| \dot{\mathbf{X}} + (\mathbf{K} + \mathbf{K}_m)\mathbf{X} = \mathbf{F}(t) \qquad (14.48)$$

is solved to obtain a better approximation for the column vector **X**. The equivalent damping matrix $\mathbf{B}_{eq}$

$$\mathbf{B}_{eq} = \mathbf{B}_v \frac{8}{3\pi} |\dot{\mathbf{X}}| \qquad (14.49)$$

is a standard result obtained by assuming equal work done at resonance by the non-linear and the equivalent linear damping terms – see Patel.[10] The iteration is continued until a specific tolerance (such as 1%) between successive approximations is achieved.

A typical heave motion response is presented in Figure 14.31 and shows a strong influence of the drag force non-

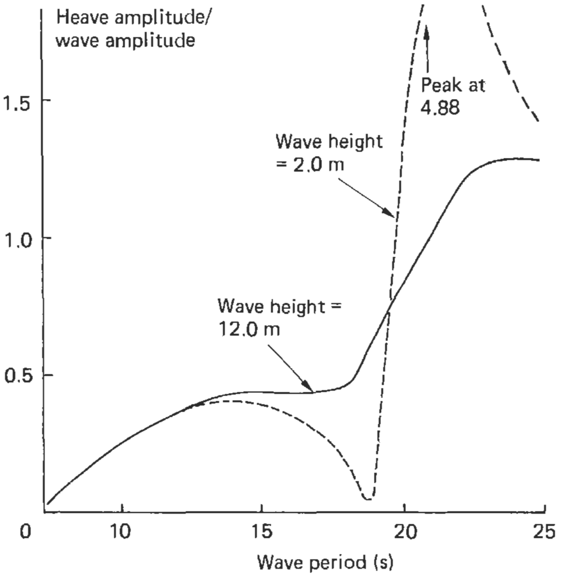

Figure 14.31 Heave motion response of a semi-submersible vessel in head seas

linearity around resonance with the heave response amplitude per unit wave amplitude reducing from 4.88 m/m at 1 m wave amplitude to 1.26 m/m at 6 m wave amplitude. The vessel motion response away from resonance is not significantly affected, although there is some increase in response around 16–19 s due to the corresponding increase in wave force amplitude at these periods. The large change in the unit heave response at and around resonance is to be expected, since the damping force in a vibratory system is dominant at resonance.

14.6.6 Diffraction theory

Calculations of wave-induced motions of a large non-space frame structure in gravity waves requires a solution of the wave problem with no flow boundary conditions at the moving body surface in addition to the free surface and sea-bed boundary conditions. The solution can be split into two related problems – the scattering wave problem defines wave forces on a floating body when fixed in space and with waves incident on it in an identical manner to the technique for computing wave forces on a fixed body described in Section 14.4. The radiation wave problem is concerned with defining forces on the body (added mass and damping) due to its oscillation in otherwise still water. These oscillations will induce wave potentials such that the total wave potential in the fluid is the sum of the incident, ϕ_w, scattered, ϕ_s, and forced wave potentials, ϕ_f, so that

$$\phi = \phi_w + \phi_s + \phi_f \tag{14.50}$$

and these must satisfy the boundary conditions at the body surface given by

$$\frac{\partial \phi_w}{\partial n} + \frac{\partial \phi_s}{\partial n} + \frac{\partial \phi_f}{\partial n} = V_n \tag{14.51}$$

where V_n is the velocity of the body surface in the direction n normal to the surface. This boundary condition can be applied at the mean body surface since the theory is applied for small motions. ϕ, together with its three components. It must also satisfy the Laplace equation and the free surface and sea-bed boundary conditions. Furthermore, ϕ_s and ϕ_f must satisfy the radiation conditions.

Boundary conditions for the scattering and radiation wave problems can be split up from equation (14.51) as

$$\left.\begin{aligned} &\frac{\partial \phi_w}{\partial n} + \frac{\partial \phi_s}{\partial n} = 0 \\ &\text{and} \\ &\frac{\partial \phi_f}{\partial n} = V_n \end{aligned}\right\} \tag{14.52}$$

respectively, both being applied on the body surface. The scattering problem is identical to the application of diffraction theory on fixed structures as described in Section 14.4. The radiation problem can also be solved by using either boundary-integral or boundary-element techniques. For brevity, only the solution using boundary-integral techniques is described here. As in Section 14.4, the analysis assumes inviscid, irrotational flow and that wave amplitudes are small. The unsteady flow around the floating vessel is calculated by introducing oscillating sources of unknown velocity potential on the vessel's submerged surface that is discretized by a mesh of facets with an oscillating source on the surface of each facet.

A Green's function is used to represent the velocity potential of each source which, because of the form of the Green's function, satisfies Laplace's equation, zero flow at the horizontal sea bed, the free surface and radiation boundary conditions. Now, the solution for scattered wave potential due to the stationary floating body, subjected to incident waves of potential, ϕ_2, is identical to that described in Section 14.5 for fixed structures. A set of linear simultaneous equations are obtained by equating the flow due to the local source plus the additional flow due to all other sources to the negative of the flow due to the undisturbed wave for each facet on the body surface. Solutions of these equations yields the unknown source strengths and, therefore, the velocity potential, ϕ_s, which is used to derive pressures and wave forces by integration over the body surface. Thus the wave force vector, **F**, of equation (14.46) may be obtained for an incident wave of specified frequency and direction.

The velocity potentials, ϕ_f, are obtained in a way similar to that above except for the use of a different boundary condition which reflects the fact that ϕ_f arises from body motions in otherwise still water. Thus, at all facets, the source strengths, ϕ_{fi}, are such that the flow due to the local source plus the flow due to all other sources equals the velocity component of the body along the facet normal. This velocity component will depend on the mode of motion (surge, sway, heave and so on) in which the body is moving. All of this can be represented by equating the normal velocity of the fluid and of the jth facet for the vessel moving in its kth mode of motion. This yields the equation

$$\sum_{\text{All } i} \frac{\partial \phi_{fi}}{\partial n_j} \sigma_{ik} = V_{jk} \tag{14.53}$$

where V_{jk} is the normal velocity of the jth facet with the vessel moving in its kth mode of motion. Furthermore, n_j is the normal to the jth facet, $\partial\phi_i/\partial n_j$ is the normal fluid velocity at the jth facet due to a unit source at the ith facet, and σ_{ik} are the unknown source strengths required in the kth mode. Application of equation (14.53) for all facets produces a system of complex equations to be solved for the source strengths. Once these are known, the pressures at the facets are evaluated and their effects integrated over the vessel surface to yield forces in each mode of motion to unit motion in the kth mode.

These forces may be written as a complex square matrix, $G(\omega)$ which can be decomposed into its real and imaginary parts through the equation

$$G(\omega) = \omega^2 \mathbf{M}_A(\omega) - i\omega \mathbf{B}_p(\omega) \tag{14.54}$$

to yield frequency-dependent added mass and damping matrices $\mathbf{M}_A(\omega)$ and $\mathbf{B}_p(\omega)$ which are required for equation (14.46).

The inclusion of physical mass, hydrostatic and mooring stiffness matrices, $\mathbf{M}$, $\mathbf{K}$ and $\mathbf{K}_m$ completes derivation of all of the coefficient matrices of equation (14.46). The hydrodynamic coefficient matrices are, however, frequency dependent and require carrying out a diffraction analysis at all frequencies at which motions are required. Equation (14.46) is linear and can readily be solved to yield the displacement vector $\mathbf{X}$. The exciting force vector $F(\omega)$ and the coefficient matrices $\mathbf{M}_A(\omega)$ and $\mathbf{B}_p(\omega)$ can also be derived using finite-element methods in a way analogous to that for the boundary-integral approach described above.

There is one further point of interest regarding the relationship between the scattered and forced wave potentials (ϕ_s and ϕ_f) for a floating vessel problem. The use of equations called Haskind relations (see Newman[32]) enables the scattered wave potential, ϕ_s, to be expressed in terms of the incident and forced wave potentials, ϕ_w and ϕ_f. Thus, once ϕ_f is calculated, ϕ_s need not be computed by diffraction analysis but can instead be derived using the Haskind relations.

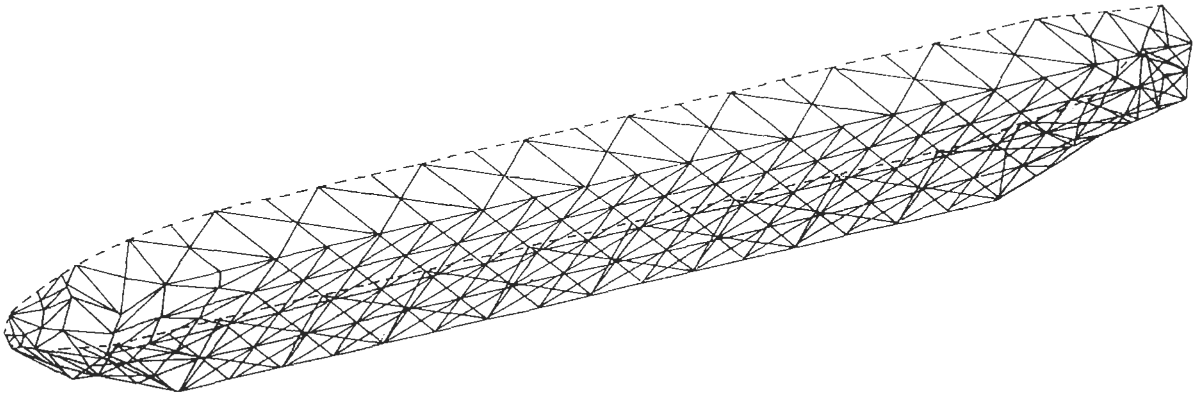

Figure 14.32 Facet discretization of a submerged ship hull for diffraction theory

Typical results of a boundary integral diffraction analysis for a ship-shaped hull are shown in Figure 14.33. The discretization of the submerged hull geometry is shown in Figure 14.32 using 277 triangular facets on the ship half-hull. The vessel is of 263.7 m overall length, 40.8 m beam and 145 937 t displacement with 14.80 m draught floating in deep water. Figure 14.33(a) presents the variation of added mass and radiation damping coefficients with frequency for heave and pitch motions. Note that the variation in added mass is relatively small but the radiation damping shows large changes with very small values at some wave periods. Wave-induced heave force and pitching moments and the resultant motion responses for head seas are presented in Figures 14.33(b) and 14.33(c).

14.7 Design considerations and certification

It is important to appreciate that the design procedures for jacket structures outlined in the previous three sections are

only a small part of the total design process. In order to illustrate this point, Figure 14.34 presents a flow chart showing the design procedures that need to be followed, from the initial specification through to commencing operation of a typical offshore structure. The jacket has to have sufficient strength, as it is assembled during the fabrication stage and loaded out of the yard. It has also to meet the naval architectural and structural requirements of tow-out, up-ending and installation as well as surviving for a 20–40-year life. Some of the supplementary design tasks not covered in this chapter include the response of the structure to earthquakes, the provision of corrosion protection and in-service structural monitoring. The design procedure for large jackets invariably contains a model test phase for critical operations such as up-ending during installation. The documentation of the material, structural and welding details of the design during its certification, fabrication and service life pose an engineering management problem.

Certifying authorities play a key role in the design procedure for an offshore structure. The major certifying authorities in the United Kingdom, Norway and the United States have built up extensive codes of practice which reflect research work, in-service experience and the results of failure investigations over many years of operation (see Lloyd's Register of Shipping,[33] Department of Energy,[34] Det Norske Veritas,[35] and American Bureau of Shipping[36]). Certifying authorities also provide an independent check of many of the calculations and decisions that need to be made during a typical design. There tends to be close technical collaboration between research establishments, designers and the operators of offshore structures.

15.1 Compressors, fans and pumps

15.1.1 Design principles

15.1.1.1 General

Compressors, fans and pumps are all devices for increasing the pressure energy of the fluid involved. Two basic types are used: rotodynamic, where flow is continuous, and positive displacement, where fluid is worked on in discrete packages defined by machine geometry. Compressors, fans and pumps may be rotodynamic, and compressors and pumps positive displacement. In general, the positive displacement machines give low mass flow and high pressure rise.

15.1.1.2 Rotodynamic machine principles

These can be discussed together as the Euler equation applies to all types, differences being due to the fluid involved and the flow path. Figure 15.1 illustrates flow path differences.

15.1.1.3 Forms of the Euler equation

Standard turbomachinery textbooks (see Turton[1]) derive this equation, so it will be applied here to centrifugal and axial machines. Considering Figure 15.2 (a simple centrifugal pump) the specific energy increase is given by the Euler equation

$$gH = u_2 Vu_2 - u_1 Vu_1 \qquad (15.1)$$

where u_1, u_2 are peripheral velocities ($=\omega r$) Vu_2, Vu_1 are the peripheral components of the absolute velocities V_2 and V_1, respectively (see Figure 15.3).

Vu_1 is usually considered as zero in design flow conditions, so

$$gH_{\mathrm{IDEAL}} = u_2\, Vu_2 \qquad (15.2)$$

or

$$gH_{\text{IDEAL}} = u_2^2 - \frac{Qu_2}{A_2}\cot\beta_2 \tag{15.3}$$

or when rotational speed is constant,

$$gH_{\text{IDEAL}} = K_1 - K_2Q \tag{15.4}$$

with K_2 depending on β_2. Figure 15.3 shows how varying β_2 affects both velocity diagrams and the gH to Q plot of performance plots, compressors being affected at lower flows by surge as discussed later.

A simple axial machine is shown in Figure 15.4, with typical general velocity diagrams, which define the geometry and terms used:

$$gH_{\text{IDEAL}} = u[Vu_2 - Vu_1] \tag{15.5}$$

or if $Vu_1 = 0$ (zero inlet whirl) as assumed for pumps of fans:

$$gH_{\text{IDEAL}} = uVu_2 \tag{15.6}$$

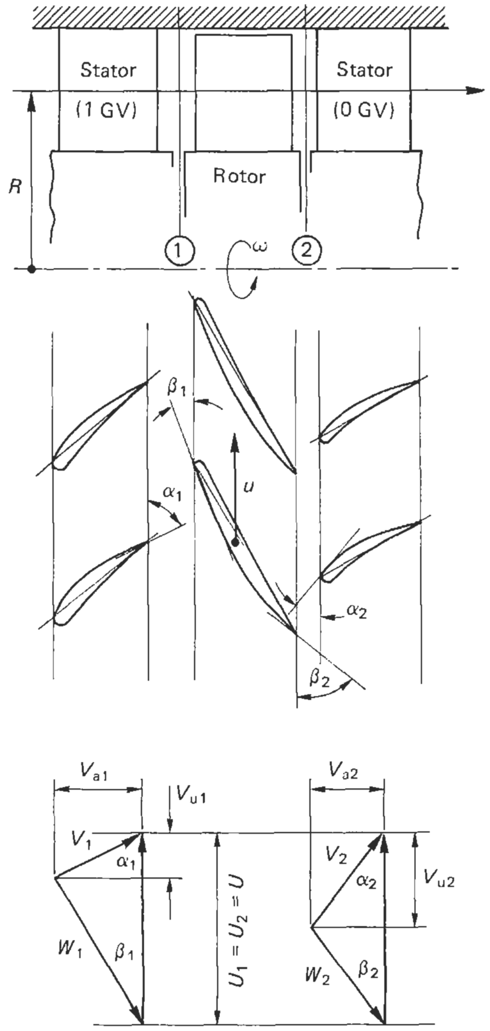

Figure 15.4 Axial flow pump or compressor stage and the 'ideal' velocity triangles

or

$$gH_{\text{IDEAL}} = uV_{A2}\cot\beta_2 \tag{15.7}$$

V_{A2} is a function of Q and flow area and β_2 is related to blade angles.

For compressors, as Horlock[2] and Turton[1] show,

$$gH = \frac{\Delta p}{\rho} = Cp\,\Delta T = (u_2\,Vu_2 - u_1\,Vu_1) \tag{15.8}$$

and for axial machines, this is usually written

$$\frac{\Delta p}{\rho} = Cp\,\Delta T = u\,(\Delta Vu) \tag{15.9}$$

and the velocity diagrams combine, as shown in Figure 15.5, on a common base.

15.1.1.4 Definitions of efficiency

In all these machines efficiency statements are used:

$$\text{Overall efficiency } \eta_0 = \frac{\text{Power to fluid}}{\text{Power to shaft}} \tag{15.10}$$

$$\text{Hydraulic efficiency } \eta_H = \frac{\text{Actual energy rise}}{\text{Euler energy rise}} \tag{15.11}$$

$$\text{Volumetric efficiency } \eta_V = \frac{\text{Delivered flow}}{\text{Flow passing through rotor}} \tag{15.12}$$

$$\text{Mechanical efficiency } \eta_M = \frac{\text{Fluid power}}{\text{Input shaft power}} \tag{15.13}$$

$$\text{Thus } \eta_0 = \eta_M \times \eta_V \times \eta_H \tag{15.14}$$

15.1.1.5 Reaction

This is defined for a compressor as:

$$R = \frac{\begin{array}{c}\text{Energy change due to or}\\ \text{resulting from static pressure}\\ \text{change in the rotor}\end{array}}{\text{Total change in the stage}} \tag{5.15}$$

For an axial compressor 50% reaction means a symmetrical velocity diagram as shown in Figure 15.5.

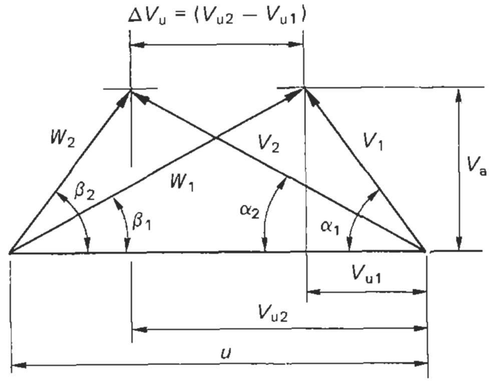

Figure 15.5 Axial velocity triangles based on a common base for an axial stage with 50% reaction ($V_1 = W_2$; $V_2 = W_1$)

If a simple pump is considered, it is possible to state that there must be a working relation between the power input P, the flow rate Q, energy rise gH, fluid properties ρ and μ, and size of the machine D. If a dimensional analysis is performed it can be shown that a working relation may exist between a group of non-dimensional quantities in the following equation:

$$\underset{(1)}{\frac{P}{\rho\omega^3D^5}} = f\left[\underset{(2)}{\frac{Q}{\omega D^3}} \cdot \underset{(3)}{\frac{gH}{\omega^2D^2}} \cdot \underset{(4)}{\frac{\rho\omega^2D^2}{\mu}} \cdot \underset{(5)}{\frac{\rho\omega^2D^2}{K}}\right] \tag{15.16}$$

Term (1) is a power coefficient which does not carry any conventional symbol. Term (2) can easily be shown to have the shape V/U and is called a flow coefficient, the usual symbol being θ. Term (3) similarly can be shown to be gH/U^2 and is usually known as a head coefficient (or specific coefficient) ψ. Term (4) is effectively a Reynolds number with the velocity the peripheral speed ωD and the characteristic dimension being usually the maximum impeller diameter. Term (5) is effectively a Mach number, since K is the fluid modulus.

Since these groups in the SI system are non-dimensional they can be used to present the results of tests of pumps in a family of pumps that are geometrically similar and dynamically similar. This may be done as shown in Figures 15.6 and 15.7 and Figure 15.8 shows how the effect of changing speed or diameter of a pump impeller may be predicted, using the scaling laws:

$$\left.\begin{aligned} \frac{P}{\rho\omega^3D^5} &= \text{Const} \\ \frac{Q}{\omega D^3} &= \text{Const} \\ \frac{gH}{\omega^2D^2} &= \text{Const} \end{aligned}\right\} \tag{15.17}$$

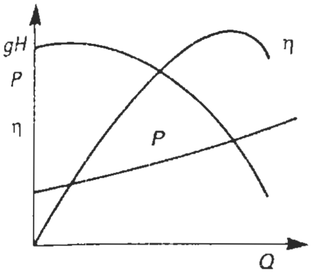

Figure 15.6 A pump characteristic for constant rotational speed

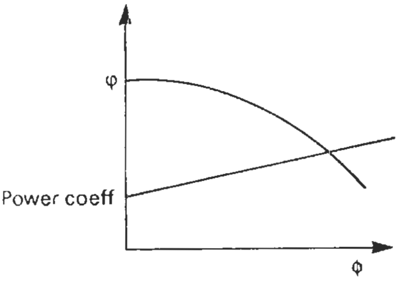

Figure 15.7 A non-dimensional plot for a pump

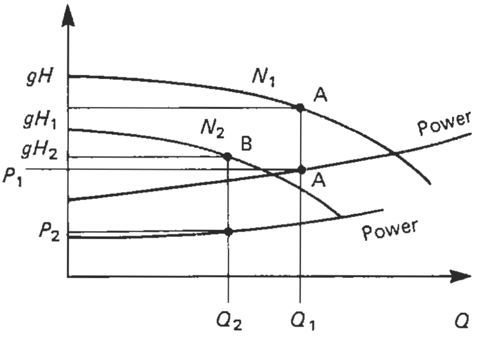

Figure 15.8 Prediction of speed change effect using equations (15.17)

In Figure 15.8 points A define the energy rise gH and power P_1 at a flow rate Q_1, when the pump is driven at speed ω_1. If equations (15.17) are applied, D and ρ being the same.

$Q_1/\omega_1D^3 = Q_2/\omega_2D^3$; hence Q_2

$gH_1/\omega_1^2D^2 = gH_2/\omega_2^2D^2$; hence gH_2

$P_1/\rho\omega_1^3D^5 = P_2/\rho\omega_2^3D^5$; hence P_2

This approximate approach needs to be modified in practice to give accurate results, for using model tests to predict full size power, as discussed by codes such as the American Hydraulic Institute Standards.[13]

The classical approach to the problem of characterizing the performance of a pump without including its dimensions was discussed by Addison,[3] who proposed that a pump of standardized size will deliver energy at the rate of one horsepower when generating a head of one foot when it is driven at a speed called the Specific Speed:

$$N_s = K\frac{N\sqrt{Q}}{H^{3/4}} \tag{15.18}$$

The constant K contains fluid density and a correction factor, and it has been customary to suppress K and use the equation:

$$N_s = \frac{N\sqrt{Q}}{H^{3/4}} \tag{15.19}$$

Caution is needed in using data as the units depend on the system of dimensions used, variations being litres/minute, cubic metres/second, gallons per minute or US gallons per minute as well a metres or feet. Plots of efficiency against specific speed are in all textbooks based upon the classic Worthington plot, and Figure 15.9, based on this information, has been prepared using a non-dimensional statement known as the characteristic number

$$k_s = \frac{\omega\sqrt{Q}}{(gH)^{3/4}} \tag{15.20}$$

This is based on the flow and specific energy produced by the pump at its best efficiency point of performance following the approach stated by Wislicenus:[4] 'Any fixed value of the specific speed describes a combination of operating conditions that permits similar flow conditions in geometrically similar hydrodynamic machines.'

Figure 15.10 presents, on the basis of the Characteristic number, the typical impeller profiles, velocity triangle shapes and characteristic curves to be expected from the machine flow paths shown. In the figure the characteristic ordinates are

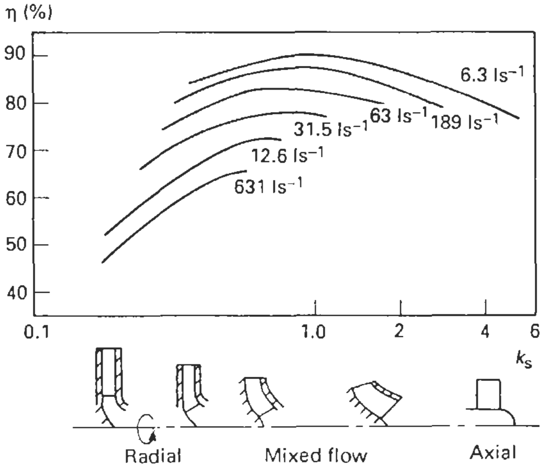

Figure 15.9 The variation of overall efficiency with non-dimensional characteristic number k_s for pumps (Turton[1])

are the ratios of actual head/design head and actual flow/design flow. This indicates the use of the number as a design tool for the pump engineer.

The scaling laws (equation (15.17)) may be used to predict the performance from change of speed as indicated in Figure 15.8. In many cases the pump engineer may wish to modify the performance of the pump by a small amount and Figure 15.11 illustrates how small changes in impeller diameter can affect the performance. The diagram in its original form appeared in the handbook by Karrasik *et al.*[5] and has been modified to appear in metric form, as can be seen. The rules used are often called the Scaling Laws, written in the form:

$$D_2/D_1 = \sqrt{g_2H_2/g_1H_1}$$
$$Q_2/Q_1 = \sqrt{(g_2H_2/g_1H_1)^{3/2}} \qquad (15.21)$$
$$P_2/P_1 = (g_2H_2/g_1H_1)^{5/2}$$

Other methods of adjusting the output while keeping the speed constant consist of modifying the profiles of the blades at the maximum diameter of the impeller. This technique has been used for a long time and is often used to obtain a small energy rise when the pump is down in performance when tested. (The reader is referred to Karassik *et al.*[5])

For compressors equation (15.16) could be employed but convention generally uses:

$$\frac{P_{02}}{P_{01}} = f\left[\frac{\omega D}{\sqrt{RT_{01}}} \cdot \frac{m\sqrt{RP_{01}}}{D^2\,P_{01}} \cdot R_E \cdot M_n\right] \qquad (15.22)$$

The temperature and pressure statements are conventionally stagnation values. Most compressor manufacturers use a dimensional form, and state the gas involved, so that equation (15.22) becomes:

$$\frac{P_{02}}{P_{01}} = f\left[\frac{\omega D}{\sqrt{T_{01}}} \cdot \frac{m\sqrt{T_{01}}}{D^2\,p_{01}} \cdot R_E \cdot M_n\right] \qquad (15.23)$$

Figure 15.12 presents a typical compressor plot.

15.1.1.6 *Positive displacement machine principles*

Whether the machine is of reciprocating or rotary design, fluid is transferred from inlet to outlet in discrete quantities defined by the geometry of the machine. For example, in a single-acting piston design (Figure 15.13) the swept volume created by piston movement is the quantity delivered by the pump for each piston stroke, and the total flow is related to the number

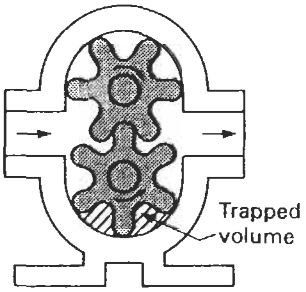
of strokes per unit time. Similarly, the spur-gear device (Figure 15.14) traps a fixed quantity in the space between adjacent teeth and the casing, and total flow rate is related to the rotational speed of the gear wheels.

The maximum possible flow rate

Q_0 = displacement × speed

as shown in Figure 15.15. The actual flow is reduced by leakage, flow Q_L:

$Q = Q_O - Q_L$



Trapped volume

Figure 15.14 An external gear pump

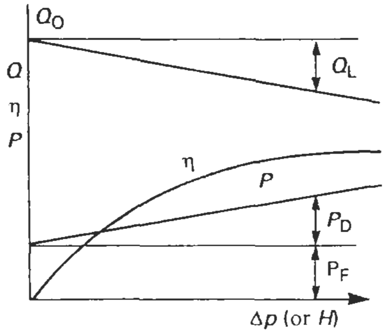


Figure 15.15 The typical characteristic of a positive displacement pump driven at constant speed

The volumetric efficiency

$$\eta_v = \frac{Q}{Q_O} = 1 - \frac{Q_L}{Q_O} \tag{15.24}$$

and

$$\eta_0 = \frac{\rho Q g H}{P_D + P_L} \tag{15.25}$$

P_D and P_L are defined in Figure 15.15. Table 15.1 gives typical values of η_v and η_0 for a number of pump types.

Since discrete quantities are trapped and transferred, the delivery pressure and flow vary as shown in Figure 15.16, which also illustrates how increasing the number of cylinders in a reciprocating pump reduces fluctuations. In the case of lobe and gear pumps the fluctuations are minimized by speed of rotation and increasing tooth number, but where, for control or process reasons, the ripple in pressure is still excessive a means of damping pulsations must be fitted. Often a damper to cope with this and pressure pulses due to valve closure is fitted, two types being shown in Figure 15.17. The capacity of the accumulator is important, and one formula based on experience for sudden valve closure is

$$Q_A = \frac{QP_2(0.016\ L - T)}{(P_2 - P_1)} \times 0.25 \tag{15.26}$$

Here Q_A is the accumulator volume (m^3); Q is flow rate (m^3/s); L is pipe length (m); T is valve closure time (seconds); P_1 is the pressure in the pipeline (N/m^2); and P_2 is the maximum pressure desired in the line (N/m^2) ($P_2 = 1.5P_1$ in many cases).

Axial – multi-piston	>98	>90

15.1.1.7 Limitations on performance

For pumps, performance is limited by cavitation, viscosity effects, gas entrainment and recirculation. Cavitation occurs in the suction zone of a pump due to the local pressure falling to around vapour pressure as Figure 15.18 illustrates.

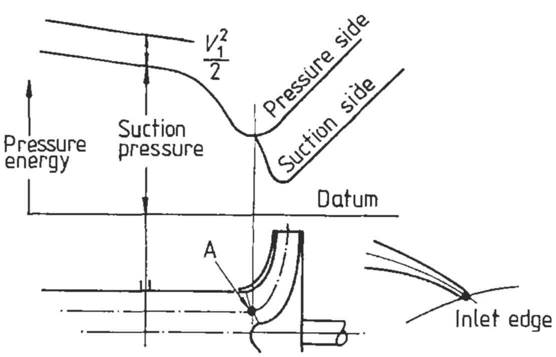

Figure 15.18 Pressure changes on a stream surface in the suction zone of a rotodynamic pump

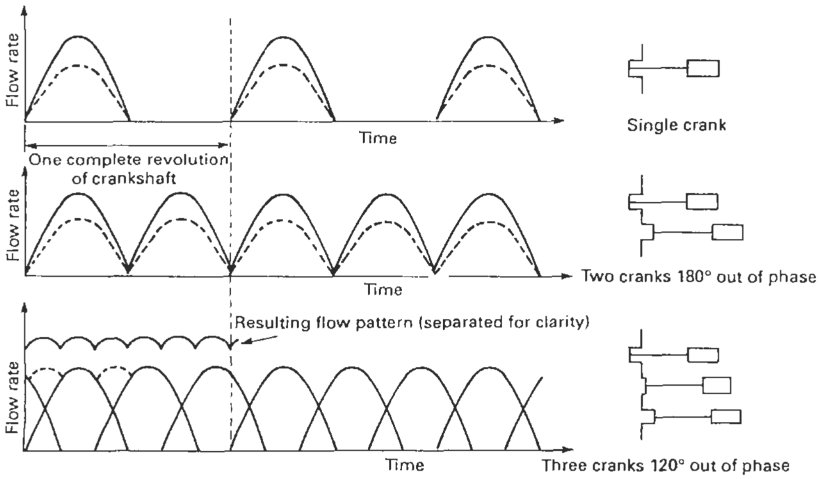

Figure 15.16 The variation in flow rate with numbers of cylinders caused by a reciprocating pump

The pump flow range is reduced as suction pressure reduces. Cavitation also causes considerable damage as bubbles of gas form and then collapse. Two criteria are used to judge whether a pump is in trouble from cavitation or not: one is the concept of NPSH (net positive suction head) and the other is the noise generated.

Net positive suction head is the margin of head at a point above the vapour pressure head. Two statements are used: NPSH available and NPSH required:

$\mathrm{NPSH_A}$ = Total head at suction flange − vapour pressure head

Figure 15.19 illustrates how system NPSH or $\mathrm{NPSH_{available}}$ is calculated for the usual suction systems shown.

For a centrifugal pump, the basic NPSH is calculated from

$$\mathrm{NPSH_A} = h_s - h_f \frac{10.2}{\rho}\left[\frac{B}{1000} + P_i - P_v\right] \tag{15.27}$$

where

h_s = static suction head at the pump suction (m)
h_f = flow losses in suction system (m)
B = minimum barometric pressure (mbar) (use 0.94 of mean barometer reading)
P_i = minimum pressure on free surface (bar gauge)
P_v = vapour pressure at maximum working temperature (bar absolute)

In the process industries h_f is calculated for the maximum flow rate and the NPSH at normal flow allowed for by using the formula

$$\mathrm{NPSH_A} = 0.8\,[\mathrm{NPSH_{basic}} - 1] \tag{15.28}$$

This gives a 'target' value to the pump supplier that is 'worst' condition. In general, for cold-water duties equation (15.28) can be used for the duty flow required. Equation (15.27) is used for reciprocating and rotary positive displacement machines, but allowance is made for acceleration effects.

In reciprocators h_f is calculated at peak instantaneous flow, including maximum loss through a dirty filter, and an additional head 'loss' to allow for pulsation acceleration is used:

$$h_A = \frac{700\,NQ}{2}\Sigma\frac{L}{d^2} \tag{15.29}$$

where

N = crankshaft rotational speed (rpm)
Q = flow rate, ($\mathrm{l\,s^{-1}}$)
L = length of line (m)
d = diameter of line (mm)

and

$$\mathrm{NPSH} = \mathrm{NPSH_A} - h_A \tag{15.30}$$

For metering pumps,

$$\mathrm{NPSH_{basic}} = h_s + \frac{10.2}{\rho}\left[\frac{B}{1000} + P_i - P_V\right] \tag{15.31}$$

h_f is as for the reciprocating pump based on peak instantaneous flow and

$$h_A = \frac{6\delta P_i}{\rho} \tag{15.32}$$

15.1.1.8 NPSH required ($\mathrm{NPSH_R}$)

This is a statement of the NPSH that the pump can sustain by its own operation, so that the operating requirement is that $\mathrm{NPSH_R} < \mathrm{NPSH_A}$ and Figure 15.20 indicates how the critical operating flow is related to $\mathrm{NPSH_A}$ and $\mathrm{NPSH_R}$. The usual operating criterion is based on a cavitation test (Figure 15.21). The critical $\mathrm{NPSH_R}$ is defined as the point at which the pump head falls by x% (3% is often used).

For the centrifugal pump two terms are in common use: the Thoma cavitation number σ and the suction specific speed S_N:

$$\sigma = \frac{\mathrm{NPSH_R}}{\text{Pump head rise}} \tag{15.33}$$

$\mathrm{NPSH_R}$ is defined as in Figure 15.22. This figure gives a typical plot of σ against k_s that may be used as a first 'design' estimate of $\mathrm{NPSH_R}$, but in many applications test data are required:

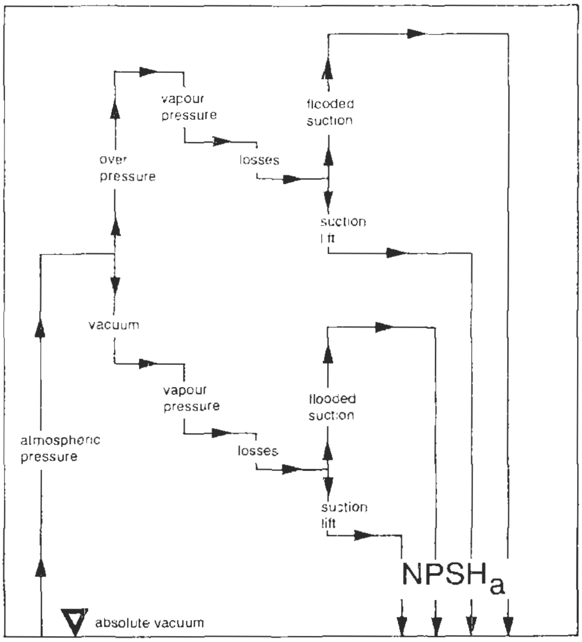

Figure 15.19 A visualization of the way NPSH $_{\text{available}}$ is calculated for a pump suction system. (Courtesy of Girdlestone Pumps Ltd)

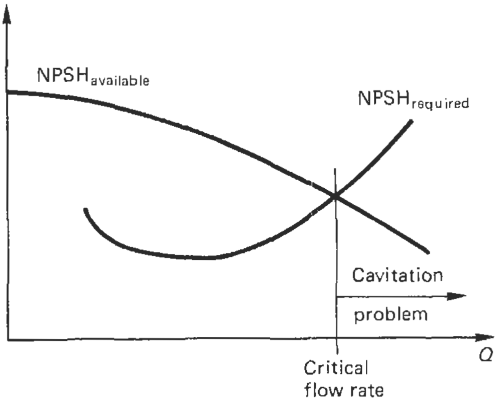

Figure 15.20 Critical flow rate determined by cavitation considerations

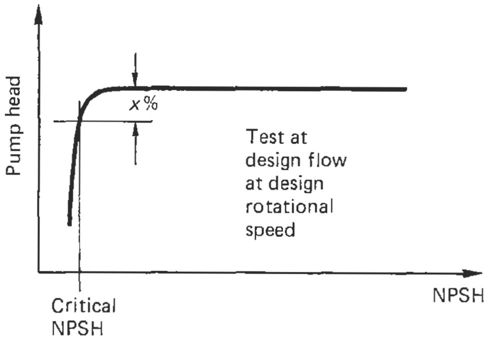

Figure 15.21 A conventional presentation of pump cavitation behaviour

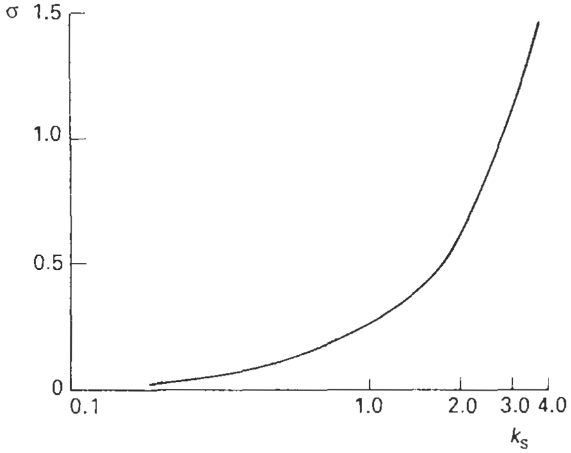

Figure 15.22 Variation of σ with k_s for rotodynamic pumps (Turton[1])

$$S_N = \frac{N\sqrt{Q}}{K(\text{NPSH}_R)^{3/4}} \qquad (15.34)$$

where K is a constant = 175 if $g = 9.81$ m s^{-2}, Q is in l/s, N in revolutions/second, and NPSH_R is m of liquid. A 'good' value of S_N for a centrifugal pump is around 10 000.

For reciprocating metering pumps NPSH_R is related to valve loading as shown in Figure 15.23:

$$A = \frac{24\nu Q\rho}{Zd_V{}^3} + 5 \times 10^5 \frac{\rho Q^2}{Z^2 d_V^4} \qquad (15.35)$$

where d_V = nominal valve size (mm) for single valves, and

$$A = \frac{80\nu Q\rho}{Zd_V^3} + 15 \times 10^5 \frac{\rho Q^2}{Z^2 d_V^4} \qquad (15.36)$$

for double valves. It is recommended that for hydraulically operated diaphragm pumps the extra losses imposed by the diaphragm and support plate are treated as a single unloaded valve.

For other reciprocators

$$\text{NPSH}_R = 5U^2 + \frac{0.12(P_d)^{0.75}}{\rho} \qquad (15.37)$$

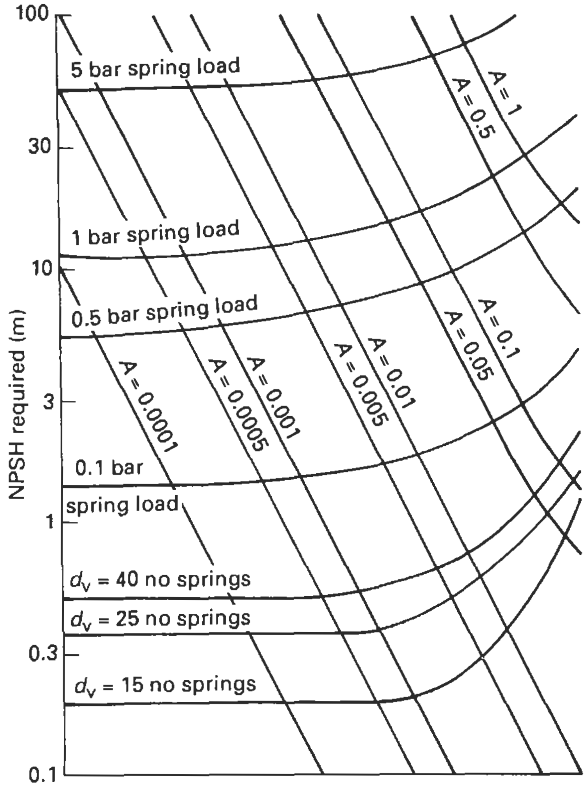

Figure 15.23 NPSH$_{\text{required}}$ for reciprocating metering pumps related to valve spring loading (equations (15.35) and (15.36)

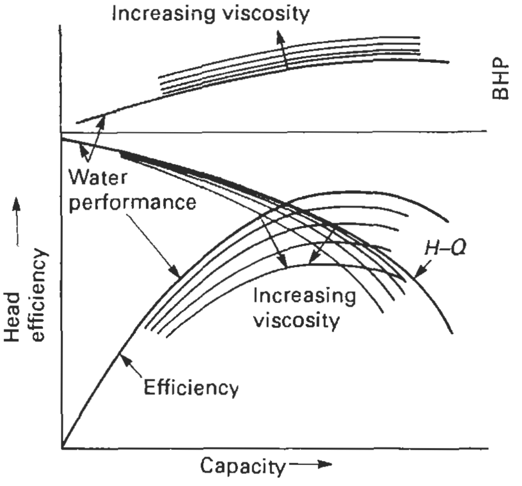

Figure 15.24 Effect of viscosity increase on centrifugal pump performance

where U = mean plunger speed (m s^{-1}) and P_d = discharge pressure bar absolute.

Viscosity affects pump performance by increasing flow losses. Figure 15.24 illustrates the deterioration as viscosity increases. If the kinematic viscosity is greater then 100 centistokes, water performance must be corrected as shown later in

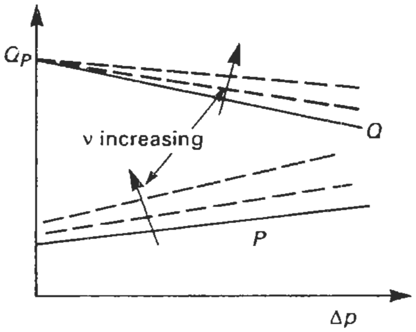

Figure 15.25 Effect of viscosity increase on positive displacement pump performance

Figure 15.27. Figure 15.25 indicates that in a positive displacement pump the volumetric efficiency improves and power requirement increases (with increasing viscosity).

Table 15.2 summarizes the effects of liquid changes (effectively, viscosity and density changes) on pump performance and Figure 15.26 presents material by Sterling[6] which illustrates how efficiency falls away with viscosity for two pumps working at the same duty point, graphically illustrating the rapid decay of efficiency as μ increases in a centrifugal pump.

Figure 15.27 demonstrates a well-known method of correcting for fluid change from water for a centrifugal pump. This allows an engineer to predict change in performance if the kinematic viscosity of the liquid to be pumped is known and the water test data are available.

Recirculation effects at low flow rates are now well documented, and can cause vibration and, in some cases, severe

Table 15.2 The effect of viscosity – a comparison

Type of pump	*Significant viscosity levels*[a]	*Effect of viscosity level*	*Treatment and/or notes*
Centrifugal	20	—	Performance maintained similar to water performance up to this level
	20–100	Lowering of *H–Q* curve increase in input hp	General lowering of efficiency but may be acceptable
	Above 100	Marked loss of head	Considerable reduction in efficiency, but high efficiencies may still be attainable from large pumps
Regenerative	Above 100	Marked loss of performance	Pumps of this type would not normally be considered for handling fluids with a viscosity greater than 100 centistokes
Reciprocating	Up to 100	Little	Performance generally maintained. Some reduction in speed may be advisable to reduce power input required
	Above 100	Performance maintained but power input increased	Speed is generally reduced to avoid excessive power inputs and fluid heating
	Above 1000	Flow through valves may become critical factor	Larger pump size selection run at reduced speed – e.g. 3 × size at 1000 centistokes running at one-third speed. Modification of valve design may be desirable for higher viscosities
Plunger	—	—	For very high-pressure deliveries only
Sliding vane	Above 100	Sliding action impaired: slip increased	Not generally suitable for use with other than light viscosity fluids
External gear	None	Power input and heat generated increases with increasing viscosity	May be suitable for handling viscosities up to 25 000 centistokes without modification. For high viscosities: (a) Clearances may be increased (b) Speed reduced (c) Number of gear teeth reduced
Internal gear	None	Power input and heat generated increases with increasing viscosity	For higher viscosities: (a) Speed may be reduced (b) Number of gear teeth reduced (c) Lobe-shaped gears employed
Lobe rotor	250	None	(a) Speed may have to be reduced
	Above 250	Cavitation may occur	(b) Modified rotor form may be preferred
Single-screw	None	—	Nitrile rubber stator used with oil fluids
Twin- or multiple-screw	Up to 500	Little or none	—
	Above 500	Increasing power input required	Speed may be reduced to improve efficiency

[a] Viscosity in centistokes.

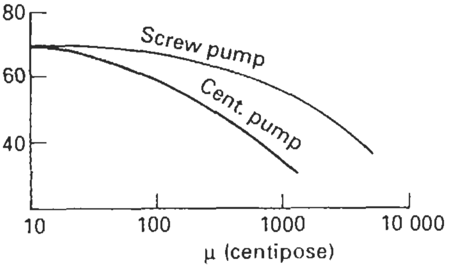

Figure 15.26 Comparison of efficiency reduction with viscosity increase for a screw pump and a centrifugal pump of similar duty

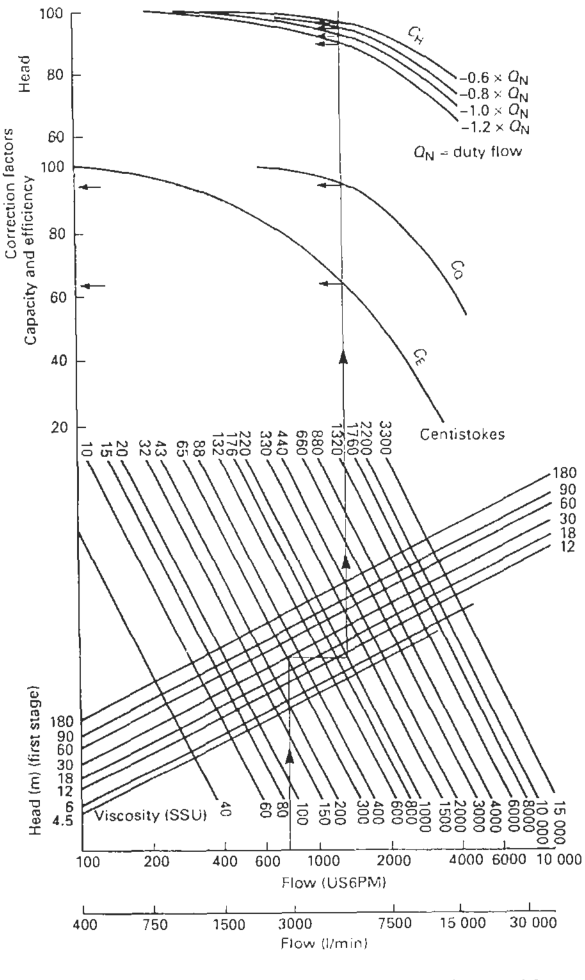

Figure 15.27 A method of correction for viscosity (adapted from American Hydraulic Standards[13]). Example: The pump is to handle 750 USGPM of 1000 SSU Liquid against a head of 30 m. From the diagram, $C_E = 0.64$; $C_Q = 0.95$; $C_M = 0.92$ at duty point ($1.0 \times Q_N$). To test on water needs tests at a flow rate of 789.5 USGPM and 32.6 m: if the test efficiency η is 75%, oil efficiency ≏ 0.75 × 0.64 = 48%

cavitation damage. Papers given at a recent conference[7] indicate the magnitude of the problem.

Gas content is another important effect. It is well known that centrifugal pumps will not pump high gas content mixtures, as flow breaks down (the pump loses 'prime') when the gas/liquid ratio rises beyond 15%. Figure 15.28 clearly shows how a centrifugal pump is affected particularly at low flow rates, and the behaviour is typical of conventional centrifugal pumps. Figures 15.29 and 15.30 present well-known information on the effects of dissolved and entrained gas on the volumetric efficiency of a positive displacement pump.

Fans are often used in near-ambient conditions, and density change is not significant, so that inlet density is used in power calculations. Care is needed in air-conditioning systems to correct for the temperature at the fan inlet. Axial fan performance is affected by blade stall as in compressors.

A compressor characteristic is shown in Figure 15.31. Flow is limited at the high mass flow end of the curve at any speed when local velocity in a passage (usually the last stage outlet guide vanes in an axial machine and the diffuser vane ring in a radial compressor) reaches sonic velocity and thus mass flow cannot increase further. The phenomenon of surge is more complicated as it is caused by flow instability. Its effects can be limited by reducing the pressure rise in an axial stage but not eliminated. Rotating stall occurs in both radial and axial machines and its action is shown in Figure 15.32. A vane stalls and affects flow round an adjacent vane which in turn stalls. This effect thus propagates round the blade row, in the opposite direction to rotation, at about half the rotational speed. Reference 2 gives more detailed discussion.

Figure 15.31 shows the total limitations on the compressor surge line and mass flow rate of stall and choking. For detailed discussion, textbooks such as those by Horlock[2] and Balje[10] may be consulted.

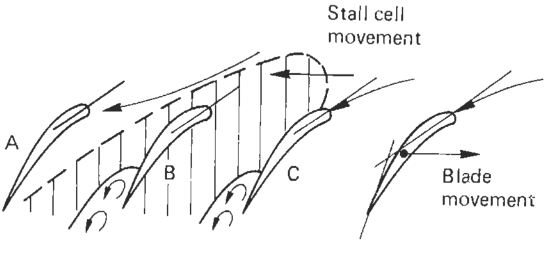

Figure 15.32 Rotating stall in an axial blade row

15.1.2 Machine selection

Although Balje[8] and Csanady[9] have proposed a common basis of performance presentations using a non-dimensionalized number resembling specific speed, each type of machine will be discussed separately. Engineers employed in water supply, the process industries and other spheres of activity have a formidable task when selecting equipment. If the equipment they select does not come up to specification the maximum claim on the supplier is the price paid. The cost to their company is that of plant downtime and lost production which is likely to exceed equipment costs by many times. 'Buyer beware' is thus a normal rule. To assist the buyer there are BS and ISO specifications and codes of practice such as the American Petroleum Industry (API) standards, but in many areas there are no such aids, and the buyer has to rely on advice, experience and, ultimately, engineering common sense.

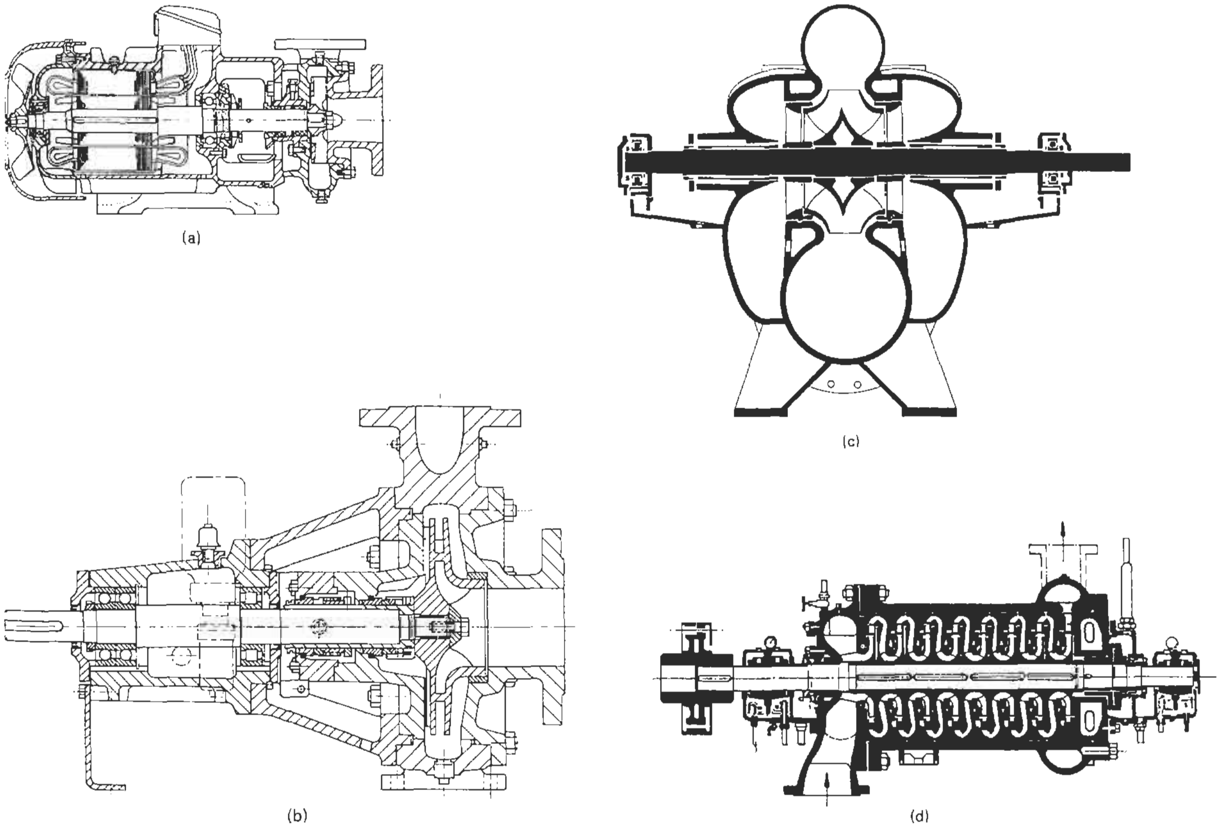
Any pump, fan or compressor selected must fulfil the specified duty (or duties) and be capable of operating safely and economically with a minimum of maintenance and downtime. The selector has therefore a challenging task. The first essential task is to prepare the technical brief which will become the tender document. This brief must state the entire operating envelope of the machine, with complete details of temperature, humidity, fluid properties and site variations, and detail the standards and codes which will apply, e.g. API 610[10] for refinery and petrochemical centrifugal pumps. This covers materials, bearing and seal systems, pressure testing of casings, vibration and noise limits, hydraulic performance, draft documents, shipping and installation in over 100 pages. In short it is a comprehensive document of mutual understanding between customer and supplier.

The project engineer needs data to decide which type of machine, likely size, rotational speed and drive system before submitting a detailed tender document. Some basic charts will therefore be discussed.

The principles of the two groups of pumps (rotodynamic and positive displacement) have been discussed, and Figures 15.33 and 15.34 illustrate the main types. A universal index of flow path and size for centrifugal pumps is the specific speed referred to above (Figure 15.10) which indicates the flow path shapes and probable characteristics. A useful pressure to flow rate envelope is shown in Figure 15.35. Once a type is decided, manufacturers' data may be consulted. Usually these are test data when pumping water for rotodynamic machines, and an approximate idea of performance can be obtained by converting water data using a conversion chart as described earlier.

When considering the selection of positive displacement pumps, Figure 15.36 is a useful range guide. Fan selection devolves into the choice of an axial or a centrifugal machine, and whether a single- or double-stage machine is required, but choice is usually determined by flow rate and pressure rise needed, and in some cases by the space available in which a machine will need to be installed. Table 15.3 gives a working basis for fan selection.

Figure 15.37 outlines the main types of compressor, and it must be said that when selecting turbo compressors the choice of machines is a function of delivery pressure and flow rate (as Figure 15.38 indicates). To extend consideration further, Figure 15.39, based on an article in a Sulzer Technical Review,



(a)

(b)

(c)

(d)

Figure 15.33 Some typical pump layouts. (a) A monobloc design with the impeller fixed on the motor shaft; (b) a modern back pull-out design; (c) a double-entry pump; (d) a multistage pump design

covers plant supplied by the company of both turbomachine and positive displacement, screw, vane, or diaphragm types. Most makers offer oil-lubricated and non-lubricated machines.

As Figures 15.38 and 15.39 indicate, the selection of compressor type depends on the pressure rise and flow rate required. Large compressors are supplied for a number of duties. About 20% are used for air compression, for factory services where usage is typically around 87 bar for energy storage, for other industrial duties, or in bottles. Industrial usage in the field of oxygen, nitrogen and medical gases accounts for a large sector. Natural gas transmission is also a substantial field of application. The industrial and process processes work on pressure up to about 400 bar. Polyethylene processes demand pressures up to 3500 bar. As the discussion on pumps indicated, when the duty could be met by a number of types, choice is often determined by experience in service, complexity or cost. The only positive attitude is probably to choose a turbomachine unless company policy dictates a positive displacement one. One factor with compressors is the temperature rise (over 150°C with a reciprocator). Cooling causes water and water vapour to accumulate with the consequent need for careful after cooling, intercooling between stages in multi-stage machines and water collection to prevent tools, instruments or equipment being damaged.

Oil injection is often used in screw and rotary vane machines to cool and to help eliminate water. Wear is also reduced. Oil injection at the rate of up to 20 mg m^{-3} of gas is used, and then filtered well below the contamination limit for factory air (5 mg m^{-3}). (An efficiency of recovery of 99.9999% has been claimed.)

Selection methods should reflect operating experience as well as being based on intelligent use of manufacturers' data, satisfactory performance results from rigorous adherence to company specifications as well as good selection.

15.1.3 Performance monitoring and prediction

Any pump, fan or compressor is supplied against a contract duty. In the case of many small pumps and fans which are quantity or batch produced makers will often quote against a typical performance which they check by routine testing, and will only do a full works test if a customer requires this. With larger pumps, fans and compressors, a full works test (usually witnessed) is required, and often check tests when installed in the systems will be needed; this latter point will be discussed together with routine monitoring.

15.1.3.1 Works tests

For back-pull out pumps ISO 5199[11] covers all aspects, including testing, seals, bearings, noise and vibration, and lists all the relevant ISO and related BS 5316 standards, among which Part 1 (for general-duty class C pumps) and Part 2 (for class B

pumps) detail test arrangements and procedures as well as instrumentation for pressure, flow, torque power and speed. Permissible bands of readings are specified as are alternative cavitation tests. In the case of BS 5316 it is stated in an annex that for mass-produced pumps the manufacturers, if they state that the standard is being satisfied, must be able to ensure that performance for any pump does not diverge from the published curve by more than ±6% for total head, ±8% for flow rate and ±8% for input power. This allows customers to have confidence in the published curves. Similar provisions will be found in the American Hydraulic Institute Standards.[13] If the pump is to follow API 610 these standards must be satisfied.

Where the liquid to be pumped is not water it is common practice to test on cold water and to predict the performance to be expected by using a chart such as Figure 15.36, which gives an example of how water test duty may be obtained if the duty is known.

For fans, standards also specify instrumentation and test rig layout. BS 848: Part 1[14] gives methods of standardized testing and also of prediction when models are used and of allowance for compressibility. Since fan noise is important in ventilation systems BS 848: Part 2[14] lays down noise-testing techniques and gives details of test chambers and site provisions. The two parts form an essential item of fan test provision, and give all the necessary equations required for test data presentation as well as for prediction of probable performance from model tests, and for correction for non-standard situations and air conditions.

A similar standard, BS 2009,[15] covers acceptance tests for turbo-type compressors and exhausters. This also states provisions for standardized rig layout and instrumentation and methods of presenting data in a standardized way. Corrections for compressibility and methods of performance prediction are all given.

BS 1571: Part 1[16] lays down provisions for testing positive displacement compressors of all the common types in use, both in packaged form and other installations.

All the standards give lists of British Standards which are relevant and quote ISO Standards which correspond. The reader is referred to the literature listed if test procedures and equipment are being planned and where standardized methods of performance are being sought for contract purposes. Performance prediction is covered in the standards and follows broadly the dimensionless quantities described here.

15.2 Seals and sealing

15.2.1 Compression packing

15.2.1.1 Introduction

Compared to the deterministic qualities of ferrous metals, for example, the essentially deformable nature of sealing materials has introduced a measure of variability that causes many commentators to regard fluid sealing technology as an art rather than a science. Seen as an anachronism in a period of high technological achievement, compression packings show no signs of losing significant ground in terms of production quantities as new and improved types proliferate in both Europe and elsewhere. To understand this situation requires some appreciation of the fundamental mode of operation of the adjustable gland or stuffing box shown in Figure 15.40.

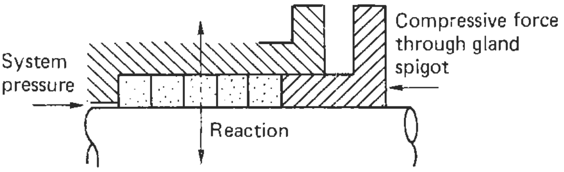

Figure 15.40 Compression packing

This may be filled with split packing rings chosen from a variety of materials and constructions, described elsewhere, which are persuaded to react against a shaft, whether rotary or reciprocating, to the extent that the radial force developed exceeds the pressure to be sealed. Packings in this category used for rotating or reciprocating equipment rely on a controlled leakage for long-term lubrication purposes if they are to survive for an adequate period. The continued justification for the compression packing might appear obscure against such a background but there can be no doubt that certain areas of application exist where no reasonable substitute is available.

Pumps Many reasoned and well-researched papers have been published to support mechanical seals against soft packing, and vice versa. There is no doubt that the former have supplanted packed glands as original equipment on the majority of rotodynamic pumps for a variety of process and service fluids, but there are operating parameters and cost considerations which will frequently dictate the choice of soft packing. Table 15.4 compares the relative attributes of the two contenders in basic terms.

In general, it may be said that, unless zero leakage is an absolute priority, compression packings will retain an important position wherever regular maintenance is available and the following considerations apply:

- Simplicity in gland design and ancillary equipment
- Ease of fitting
- Flexibility of supply and spares for plant utilizing many different types and sizes of pump handling a wide variety of fluids.
- Frequent ability to cater for adverse conditions without elaborate precautions

Valves If any doubt exists regarding selection on pumps then a much more obvious choice of soft packing applies to the valve scene. The relative lack of movement, ease of fitting and, in this case, lack of leakage requirement for lubrication purposes (plus the most decisive advantage of low cost) are factors which ideally relate to compression packings.

There are areas where moulded elastomeric seals present a reasonable alternative but even the most exotic compounds would seldom be used above 250°C – unless reinforced by asbestos fabric.

15.2.1.2 Operating principles

By comparison to the seal types described in the literature – particularly elastomeric lip and squeeze seals – compression packings respond to applied pressure in inverse proportion to the hardness of their construction and rely on an external force to produce the radial pressure required for effective sealing. The method of generating that force can vary but usually (and preferably) involves a bolted gland spigot as shown in Figure 15.40 where controlled axial movement is easily achieved by adjustment of the retaining nuts or studs. Spring loading is sometimes used in inaccessible situations but such a provision lacks the fine control demanded by some packing types and has a limited range of load capability.

While the sealing force can be adjusted to cater for service wear, care must be taken to avoid overcompression which will lead to excessive friction, shaft wear and premature packing failure.

To increase density and dissipate heat, soft packings invariably contain lubricants, loss of which, through excessive compression or overheating in service, will result in packing volume loss with subsequent reduction in the effective sealing reaction and correspondingly increasing leakage rates. By limiting compression to a point where slight controlled leakage is obtained, adequate lubrication of the dynamic surfaces is ensured and overcompression of the packing avoided. However, where lubrication is a problem – or a degree of gland cooling is required – a lantern ring can be incorporated into the gland area for the distribution of additional lubri-

Table 15.4

Comparison	*Soft packing*	*Mechanical seal*
Initial cost	Of the order of 10:1 in favour of soft packing depending on size and application	
	APPROXIMATELY EQUAL	
Reliability	Ample warning of impending failure with possibilities for correction	Little or no warning of end of useful life with possibility of sudden complete failure
Installation	Essentially simple – requiring no special skills if correct procedure adopted	Skilled fitting required – precisely defined environment and assembly
Maintenance	Regular and requiring experience	Zero
Spares	Facility for stocking length form material or complete pre-formed sets at relatively low cost	Spare seal components must be available – cost can be substantial
Shaft wear	Can be considerable; shaft sleeves reduce replacement costs Friction losses slightly higher with soft packing	Nil
Operating costs	Leakage losses zero with mechanical seals but positive with soft packing as lubrication of sealing rings is essential

(d)

Figure 15.41

cant/coolant (Figure 15.41(a)). The position of a lantern ring will depend on the nature of the application but, since the packing rings nearest to the gland spigot do most of the work, the additional fluid should usually be introduced near to that area.

If it is essential that the fluid being pumped does not escape to atmosphere (e.g. a toxic medium), the lantern ring may serve to introduce a barrier fluid at a pressure of 0.5–1 bar above that to be sealed (Figure 15.41(b)). Similarly, where there is a risk of severe abrasive wear to the packing, a flushing fluid may be introduced through the lantern ring (Figure 15.41(c)). For application with negative pump pressures (i.e. suction) a supply of the medium being sealed can be made through the lantern ring to prevent air-drawing (Figure 15.41(d)).

If extreme temperatures are to be encountered it is unlikely that cooling through the lantern ring will be sufficient and recourse must be made to internal cooling of the gland housing and shaft to reduce the temperature at the gland to a value within the packing's capabilities. Conversely, when dealing with media which crystallize or congeal when cool (e.g. sugars, tars, etc.), the packing will face rapid destruction unless gland heaters or a steam-jacketed arrangement are employed to restore the fluid state before starting up.

It should always be remembered that the inclusion of a lantern ring into the gland area invariably complicates assembly and can provide a possible source of shaft scoring. They should, therefore, only be considered when the nature of the application absolutely demands their presence.

15.2.1.3 Gland design

At this juncture, few international standards exist to define housing design for soft packings but the dimensions shown in Table 15.5 should be satisfactory for most applications. Housing depths will vary with individual circumstances, such as the inclusion of a lantern ring, but five rings of square-section

Table 15.5 Suggested housing widths in relation to shaft diameters (all dimensions in millimetres)

18–25	6.5	75–150	7.5
25–50	8	150 and above	10
50–90	10		
90–150	12.5		
150	15		

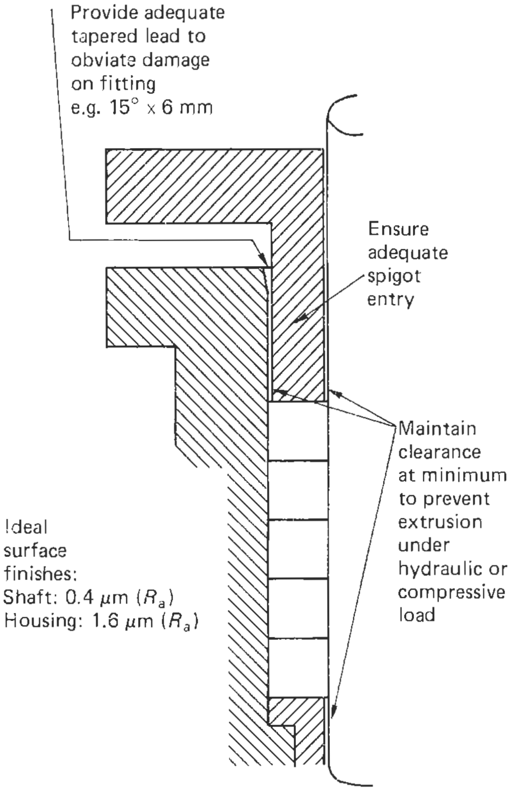

Figure 15.42

packings are usually recommended for the average, uncomplicated duty.

Other design considerations worthy of note, but often overlooked, are summarized as follows (see Figure 15.42):

1. The provision of an adequate tapered 'lead in' at the mouth of the gland to facilitate entry of the packing and to obviate the risk of damage in the assembly operation. A minimum of 15° × 6.5 mm usually represents good practice.
2. The provision of a reasonable surface finish on adjacent metal parts – particularly the dynamic surface. The better the finish, the less wear will occur; 0.4 μm (16 μ in) R_a on the shaft and 1.6 μm (64 μ in) R_a on the stuffing box bore should be ideal for most applications. The use of shaft sleeves can give considerable maintenance advantage when considering the question of surface finish.
3. The danger of extreme running clearances at the gland – particularly on the spigot side. In those exceptional cases where excessive clearance is unavoidable the packing should be protected by an independent ring of suitably robust material or construction which reduces the clearance to a minimum.
4. An allowance for entry of the gland spigot well into the gland area; certainly to an extent that exceeds substantially the depth of the tapered lead-in. The length of spigot selected must also cater for packing compression, resulting from gland adjustment. Typical entry lengths should be at least two times packing section. For packings of softer construction, maximum length should be provided. With modern packing materials, bevelled glands are seldom an advantage and can actually promote movement of the sealing ring on the spigot side into the live clearance.
5. The need to avoid excessive shaft misalignment or whip.
6. The provision of adequate shaft support. The packing must not be used as a bearing.

15.2.1.4 Packing construction and materials

	inconel wire
	stainless steel wire
Elastomers:	natural and synthetic

The principal forms of constructions for fibrous compression packings are (see Figure 15.43):

- *Braided* Individual yarns are braided tube over tube and squared off. The density of this type of construction is high and ideal for many valve applications.
- *Plaited* Multiple yarns are interwoven in plaited bundles in such a way that the direction of fibre follows the periphery of the packing ring. The natural characteristic of this construction is more suited to centrifugal pump applications than valve service although the inherent flexibility of the form is popular with some users.
- *Cross-plait* All the yarns are interlocking and pass diagonally through the packing to provide a firm construction of consistent density and shape. Used extensively for synthetic yarn packings for valves and pumps.
- *Composite asbestos plastic* This packing category is of fairly recent origin and includes those types based upon a braided and reinforced asbestos jacket enclosing a 'plastic' core. Although inaccurate in the scientific sense, the term 'plastic' conveniently describes those many mixtures of

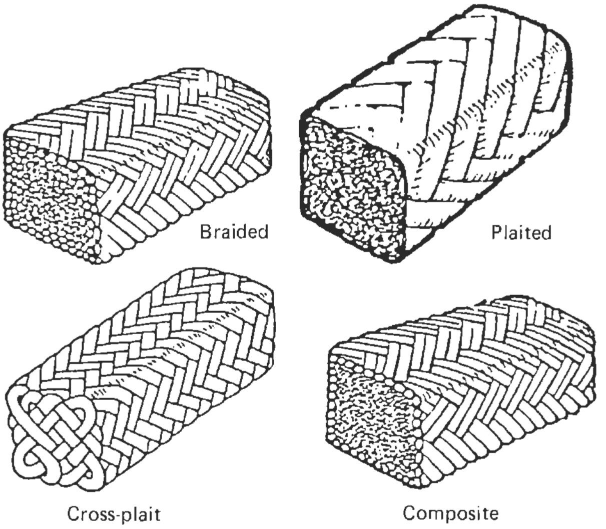

Figure 15.43 Basic packing constructions

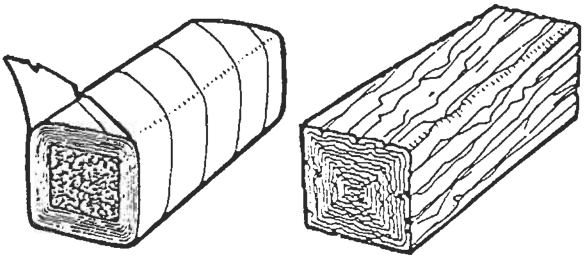
asbestos fibre and lubricant, both mineral and solid, from which readily deformable packing materials may be made. This packing is widely accepted for difficult valve-sealing duties.

All the fibre-based constructions described here are frequently reinforced with metal. This applies particularly to asbestos based products where the use of metal wire in the yarn can extend the service capability of the packing to 800°C and beyond. But for this feature, even the best quality non-metallic asbestos yarn packing would be restricted to temperatures of about 315°C maximum.

All the lubricants described above are used in conjunction with fibre packings of different sorts and are applied by dipping, coating, soaking, vacuum impregnation, dusting, etc. The prime object is maximum lubricant retention. Frequently, several treatments and repeat processes are employed to achieve this end.

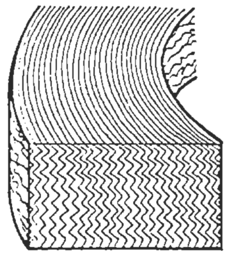
In the field of metallic packings there are many constructions available the three most popular being foil-wrapped resilient asbestos core, foil crinkled and folded upon itself, and corrugated foil, concertina wound (see Figure 15.44). These useful types are suitable for both reciprocating and rotary shafts and are widely used on pumps, valves, turbines, compressors and refrigeration plant. All are normally lubricated with mineral oil and graphite. Lead and aluminium alloys are the most popular foil materials.

In the field of compression packings, elastomers are not widely used although some braided packings do employ yarns that are treated with a rubber proofing to render them more suited to difficult wet applications such as condensate duty. Rings of square or rectangular section compression packing, manufactured from folded, rolled or laminated elastomer proofed cloth, are still popular for relatively slow-moving, lower-pressure reciprocating pumps handling water or LP steam. One particular design, with a moulded, double-bevelled section, made from semi-metallic rubberized yarn, is particularly effective on rotary applications dealing with viscous media which solidify when the pump is idle and cause damage to conventional plaited packings on restarting from cold. This moulded packing is also suitable for duties involving solids and abrasives (see Figure 15.45).



Foil-wrapped deformable asbestos core

Foil crinkled, twisted and folded upon itself



Corrugated foil, concertina wound

Figure 15.44 Typical metal foil-based packing construction

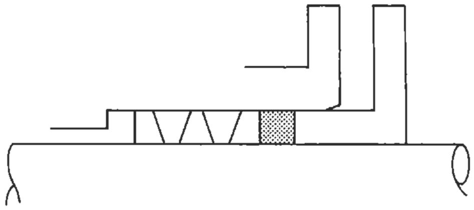


Figure 15.45 Double-bevelled, elastomer-proofed fabric packing for abrasive duties

15.2.1.5 Type of wear

Although a typical set will be five rings, experience has shown that there is not a linear pressure drop through/across the five rings. The majority of the effective sealing is done by the rings adjacent to the gland spigot, i.e. on the atmosphere side of the set – as indicated in Figure 15.46.

The two rings on the pressure side will often be virtually uncompressed and still contain ample lubricant. In contrast, the rings at the gland/atmosphere side will invariably have lost all lubricant, be very hard and probably have suffered around 50% compression – it is these rings which have been doing most of the sealing. In desperate situations replacement of these two – or possibly three – rings can often restore performance and leakage to an acceptable level.

The quantity of packing to use and its size for a given application relies largely on the experience of the user/manufacturer in the type of duty being performed, or in liaison with a packing supplier at the design stage. The latter course of action is always to be favoured if any doubt exists, since an exact knowledge of the capabilities and limitations of the material employed can be found only with those specialists responsible for compounding and production.

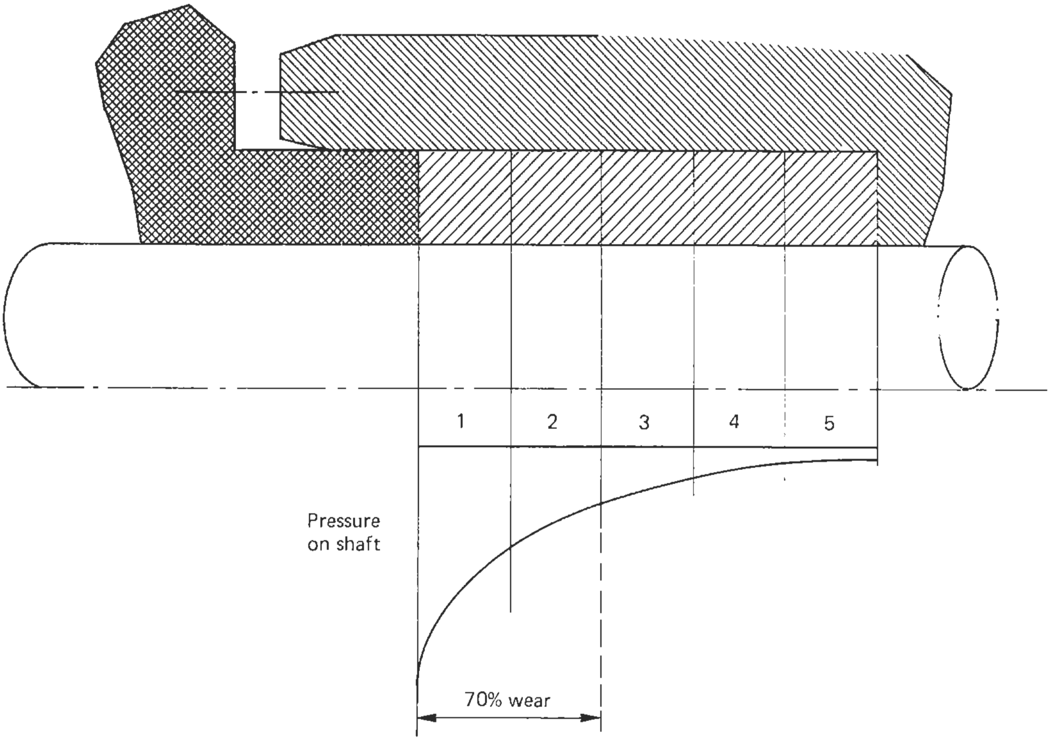

Figure 15.46

Five rings of square section packing are often accepted as a sufficient number for the average uncomplicated duty but there are many pump applications where the presence of a lantern ring or similar consideration may dictate a greater quantity.

The appropriate packing section to use in relation to diameter is open to a degree of individual preference but broad recommendations are shown in Table 15.5. To give an idea of the capabilities of the various materials and constructions of soft packings which are readily available, reference may be made to Table 15.6 (suitability in different media/speed and temperature limits). Table 15.7 (comparative speed performance), Table 15.8 (comparative temperature performance) and Table 15.9 (comparative cost indication). (*Note*: The statement of speed and temperature limits for a given material should not be construed as meaning that a packing will be suitable for duties where such maxima are jointly encountered.)

15.2.1.6 Reciprocating pumps' duties

Much of the above information also relates to reciprocating pumps. While many years ago compression packings were used on such pumps, many engineers today would automatically think of using a more modern multi-lip type seal. However, for the more difficult applications compression packings are now being used again.

The most important difference from rotary applications is that for these reciprocating duties the packing is generally subjected to far higher operating pressures, and so requires a proportionately greater degree of gland spigot loading/compression in order to develop sufficient sealing force. This extra compressive force combined with the frictional drag caused by the reciprocating movement means that extrusion of the packing into the gland bush clearance is often the main cause of seal failure. While the new synthetic yarns are extremely strong they are generally very small and so tend to extrude more easily. Once extrusion has occurred this will invariably stop any leakage completely and excessive temperatures are developed very quickly.

Often the operating clearance between the gland spigot and the ram is too wide to prevent extrusion and so some form of anti-extrusion element must be incorporated into the sealing arrangement. One very simple and very effective method is to use a hard fabric ring as is normally employed as the support ring of a typical set of multi-lip seals – as shown in Figure 15.47(a). Because the lip makes intimate contact with the ram and the wall of the stuffing box this contains the packing perfectly and prevents extrusion.

Many pumps are still fitted with multi-lip seals of the chevron type. Generally, these will operate well providing the conditions are within their capability. On many of the larger high-speed pumps, however, the frictional heat generated by the pressure and rubbing speed causes the rubber proofing of the seals to carbonize and soon the flexibility is completely lost and the set becomes virtually a solid mass which will not then respond to further gland adjustment. It is for these more arduous pump duties that a change back to compression packing is now occurring and is proving very successful.

On modern pumps, particularly of the smaller sizes, there is a trend towards non-adjustable glands. Compression packings cannot be considered for such applications unless some form of spring loading is incorporated. In this respect the arrangement as shown in Figure 15.47(b) has proved very successful.

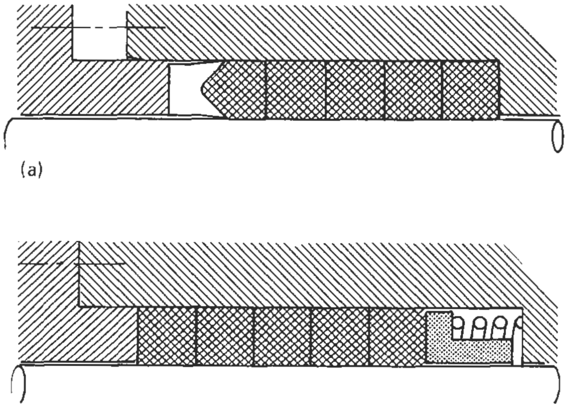

Figure 15.47 (a) Packing configuration with lip-profiled fabric anti-extrusion ring; (b) spring-loaded packing configuration for non-adjustable glands

Although the springs provide the basic force on the packing, during the pressure stroke the fluid acts over the full radial width of the metal ring and this then provides the extra 'hydraulic' force with which the conventional adjustable gland would have to be developed by appropriate gland loading.

15.2.1.7 Fitting

It is often assumed that unskilled labour can be used to repack pump glands but this is true only so long as 'unskilled' is not equated with 'unaware'. Familiarity with the following ideal procedure will be more than repaid in terms of trouble-free packing performance:

Where length form is used:

1. Spirally wrap the material around a rod of diameter equivalent to the pump shaft.
2. Cut the required number of rings cleanly to obtain good butt-joins (see *Figure 15.48*).
3. Proceed as for pre-formed split packing rings.

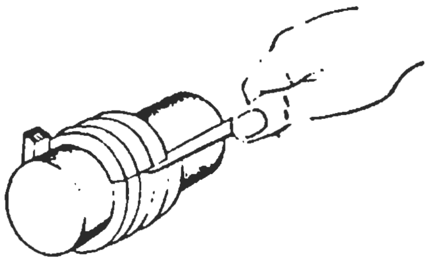

Figure 15.48

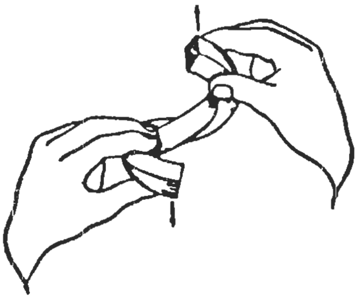

Figure 15.49

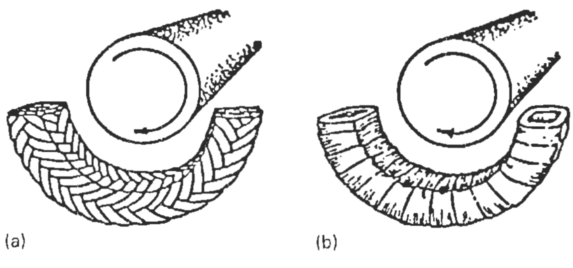
Where pre-formed split packing rings are used:

1. Carefully remove old packing (including, where appropriate, the packing on the far side of a lantern ring).
2. Thoroughly clean all surfaces that will contact the packing and, where permitted, smear with oil. Gland and neck bushes, shaft surface and bearings should also be checked for signs of wear and rectified as necessary.
3. Place first ring over the shaft by opening to an 'S' configuration to ensure that bending effects are spread over the whole ring (see *Figure 15.49*).
4. Insert first ring into stuffing box and lightly bed in with a split (wooden) distance piece and gland spigot. With plaited packing the 'V' formation on the outside diameter of the ring should be pointing in the direction of shaft rotation (see *Figure 15.50*).
5. Repeat (3) and (4) with remainder of rings ensuring that each ring is firmly seated and that the butt joins are staggered by at least 90°. (*Note*: The rings must be fitted individually and under no circumstances should complete sets be fitted as a unit.)
6. When the requisite number of rings have been fitted, tighten gland nuts until the shaft or spindle torque increases. Then slack off gland and pull up to finger tightness only. (If pump is to be stored before use leave gland slack so that packing resilience is not impaired.)
7. *Running-in pumps*
   Prime casing and run pump up to operating speed for 10–15 minutes. If pump is not fitted with gland cooling, a cold-water spray over the gland housing will avoid excessive heat build-up during this stage. If no leakage occurs, stop pump, vent casing pressure and slacken gland further. Repeat until leakage starts.
   The controlled leakage, essential for lubrication purposes, can then be obtained by running the pump and evenly tightening the gland nuts in increments of two flats until approximately one drop every few seconds is obtained. Approximately 15 minutes should be left between successive adjustments. *Do not overtighten.*
8. Where loose-form material is used for valves proceed as (1) and (2) and tamp packing into a dense homogeneous mass, progressively filling the housing to the required degree.
9. Because of the danger of corrosion through electrolytic action, packings containing graphite should be avoided on valves or pumps with stainless or chrome steel stems. This risk is most acute when the packing remains in the gland during storage and is particularly aggravated by the presence of moisture.



(a) (b)

Figure 15.50 (a) Plaited and (b) foil-wrapped packing

15.2.1.8 Fault finding

A major advantage of compression packings is that breakdown is rarely sudden or catastrophic but rather a matter of a gradual build-up of leakage until an unacceptable level is reached. Normally, considerable life can be achieved by controlling leakage with further tightening of the gland nuts. (*Note*: the seepage of fluid which acts as a lubricant for the packing on rotary applications should not be confused with leakage and the rate of one drop every few seconds should be maintained.) However, if other than routine maintenance or just plain 'fair wear and tear' are suspected as the cause of leakage and the need for repacking, then the following hints could well prove useful:

1. Confirm that the packing is rated as suitable for the application.
2. If one or more rings are missing from the set, check for excessive neck bush clearance allowing extrusion of rings into the system. If the top ring has extruded between the gland follower, anti-extrusion rings could avoid replacement of metal parts.
3. If the packing's radial thickness appears diminished in one or more places, check for an undersize shaft or badly worn bearings which could cause shaft whip or spindle wobble.
4. If radial section of packing directly beneath the shaft is reduced or premature leakage occurs along the top of the shaft, check for misalignment of shaft centre to stuffing box bore.
5. If the packing is worn on the outer diameter, check for loose rings or rings rotating with the shaft due to insufficient gland load.
6. If the packing rings have bulges on their radial faces, the adjacent ring was probably cut too short, causing packing under pressure to be forced into the gap at the joint.
7. If the packing nearest the gland spigot shows excessive deformation while other rings are in fair condition, the set was probably incorrectly installed and subjected to excessive gland tightening. (*Note*: Overtightening is usually the greatest single cause of premature packing failure.)
8. If the cause of your particular problem is still not apparent, give equal attention to i.d. and o.d. leakage and check for a rough stuffing box bore before seeking specialist advice.

15.2.1.9 Standardization

In the interests of stock control it is clearly an advantage to rationalize the variety of packings used in any plant to that minimum number which will effectively cater for all the conditions likely to be encountered. If cost is no object, then there are single, sophisticated materials and constructions that will go some way towards satisfying most demands, but it is doubtful if cost effectiveness could be justified. Far better to compromise on a small number of reputable products developed for the areas in question, e.g. pumps, valves, etc.

There are few standards applying to compression packings on a national or international basis, although many individual companies and organizations have domestic standards which have, in many cases, been the subject of collaboration between user and packing manufacturer. BS 4371: 1968 specifies minimum standards for lubricated plaited cotton, lubricated plaited flax, lubricated plaited or braided asbestos, dry white non-metallic plaited or braided asbestos, plaited or braided asbestos, metallic wire reinforced, indurated asbestos, and lubricated fibrous asbestos and gives guidance on limiting operating parameters for these constructions. There are other pump and valve British Standards which specify common stuffing box dimensions such as BS 1414: 1975, BS 1873: 1975 and BS 3808: 1964.

Where packings are required for service with potable water in the water authority distribution system (which covers reservoir to tap), only those materials which have gained a National Water Council Approval may be used. Such products have been tested to establish that they produce no colour, taste or turbidity, are non-toxic and will not support microbial growth.

Statutory Instruments 1978, No. 1927, The Materials and Articles in Contact with Food Regulations 1978 required that compression packing materials, for example,

> '......do not transfer their constituents to foods with which they are, or likely to be, in contact, in quantities which could –
>
> (1) endanger human health or
> (2) bring about a deterioration in the organoleptic [sensory] quality of such food or an unacceptable change in its nature, substance or quality.'

Such regulations inevitably restrict the range of available materials and lubricants. Consultation with the supplier is recommended to establish preferred grades.

15.2.1.10 Compression packings: material developments

Introduction The route to improve performance in most areas of sealing is generally in the use of new/improved materials – this is without doubt the case with compression packings. In recent years what can loosely be termed 'synthetic materials' have become available which have changed the overall attitude of the engineer regarding the use of the packed gland. These have three distinct advantages over the old-established materials:

1. The performance capabilities have been extended in terms of pressures, speed and temperature limitations.
2. Combined with these the resultant life has also been significantly increased.
3. The age-old problem of repeated gland adjustments has been reduced to the extent that on many applications it has been virtually eliminated – the 'non-adjustable' packed gland is now a reality.

Four materials have achieved these improvements and although not exactly new, PTFE is included, since by comparison with the natural fibres of asbestos and cotton, etc. it is relatively new and does occupy an important place in today's range of compression packings.

PTFE Polytetrafluoroethylene yarns provide soft packings for services where corrosive media are being handled or freedom from contamination is an essential requirement. A semi-rigid fluorocarbon plastic, PTFE is unique in possessing almost complete chemical resistance within its temperature range which, in this field of application, spans the cryogenic area to 250°C. Another major advantage refers to its very low coefficient of friction. Lubricated plaited PTFE yarn packings are suitable for rotary surface speeds up to 8 m s^{-1} and are also finding increasing acceptance on high-speed, high-pressure, multi-ram reciprocating pumps. In solid form this material is not acceptable as a compression packing due to poor creep properties and lack of resilience. However, solid junk rings or spacers in PTFE are often used to enhance packing performance on arduous pump duties.

Aramid fibre Packings made from aramid fibre, usually of a distinctive yellow colour, are becoming increasingly popular for a variety of pump and valve services hitherto satisfied by PTFE-lubricated asbestos packings. It has a high tensile strength, excellent resilience and thermal stability up to 250°C and is resistant to a wide range of chemicals. Experience has shown that while it is extremely resistant to abrasives, it is also extremely tough such that it can sometimes severely damage/wear the surface of a rotating pump shaft. However, the latest quality yarns combined with an improved lubricant have reduced this problem and speeds of 20 m s^{-1} have now been successfully achieved. It has also proved to be successful in high-pressure reciprocating pump applications, being used typically with arrangements as shown in Figures 15.47(a) and (b).

Graphite Without doubt, this material more than any other is responsible for extending the performance of the packed gland. It is available in various forms, each having advantages and, hence, specific areas of use:

Graphite yarn/filaments
Yarn packings in this material are a development for rotary pump applications and provide possibilities for extending the range of the packed gland beyond boundaries hitherto established. A high coefficient of thermal conductivity, low friction and resistance to chemical attack are the useful characteristics of this material. Temperatures up to 400°C may be considered. If a good performance is to be obtained, then close attention must be paid to mechanical conditions such as shaft run-out and finish. Care in fitting and running-in is also mandatory.
Expanded graphite foil is the most recent and significant application of graphite, particularly in the context of valve applications. Expanded graphite materials combine the well-established thermal and friction characteristics, long associated with the correctly developed use of carbon-based products, with a unique flexibility and resilience. The attributes of this exfoliated form of graphite bear recording.

- Excellent resistance to compression set resulting in little loss of radial gland force or flange seating stress over long periods (see Table 15.10)
- No loss of volatiles even at high temperature, thus minimizing frequency of gland adjustment
- Resistance to a wide range of chemicals
- High-temperature capability, particularly in non-oxidizing environments
- High thermal conductivity
- Low friction properties – self-lubricating
- Exceptionally low chloride content
- No adhesion or corrosion problems
- Fire-safe

Figure 15.51 shows an interesting comparison of performance on a test gland between half-rings of expanded graphite and a lubricated asbestos yarn packing. Not only did the former require fewer gland adjustments during the period of testing but the average leakage rate was much less – to the point of running virtually dry for protracted periods.

Table 15.10

Compressibility/recovery *ASTM F36-66 Procedure H* (Major load 7 N mm^{-2}) (1000 lbf in^{-2})	Expanded graphite 1 mm thick 1.0 g cm^{-3}	Expanded graphite 2 mm thick 1.0 g cm^{-3}
Compressibility	39%	33%
Recovery	20%	25%
Stress relaxation *BS 1832: 1972* Temperature 300°C for 16 h Initial stress of 40 N mm^{-2}		
Residual stress	40 N mm^{-2}	40 N mm^{-2}
NB: 10 N = 1 kgf 1 N mm^{-2} = 10 kgf cm^{-2} approx.		

Rather than use the tape form of expanded graphite which is primarily a useful maintenance expedient, moulded rings to a selected and controlled density should be the first choice. Although more costly than conventional packing materials, economies of radial width and number of rings used are feasible, quite apart from the performance advantage likely to be derived from the use of expanded graphite.

Hybrid graphite/PTFE yarn This latest material is a yarn combining PTFE and graphite; the PTFE is not added to the yarn as was the case with many other materials in the past. This proprietary blended yarn based on an exclusive process has achieved much success on high-speed rotating pump duties at speeds in excess of 25 ms^{-1}. Many manufacturers are now offering products based on this material, which is particularly insensitive to variations in fitting techniques, etc. Such packings bed-in easily and have characteristically lower leakage rates than many conventional variants.

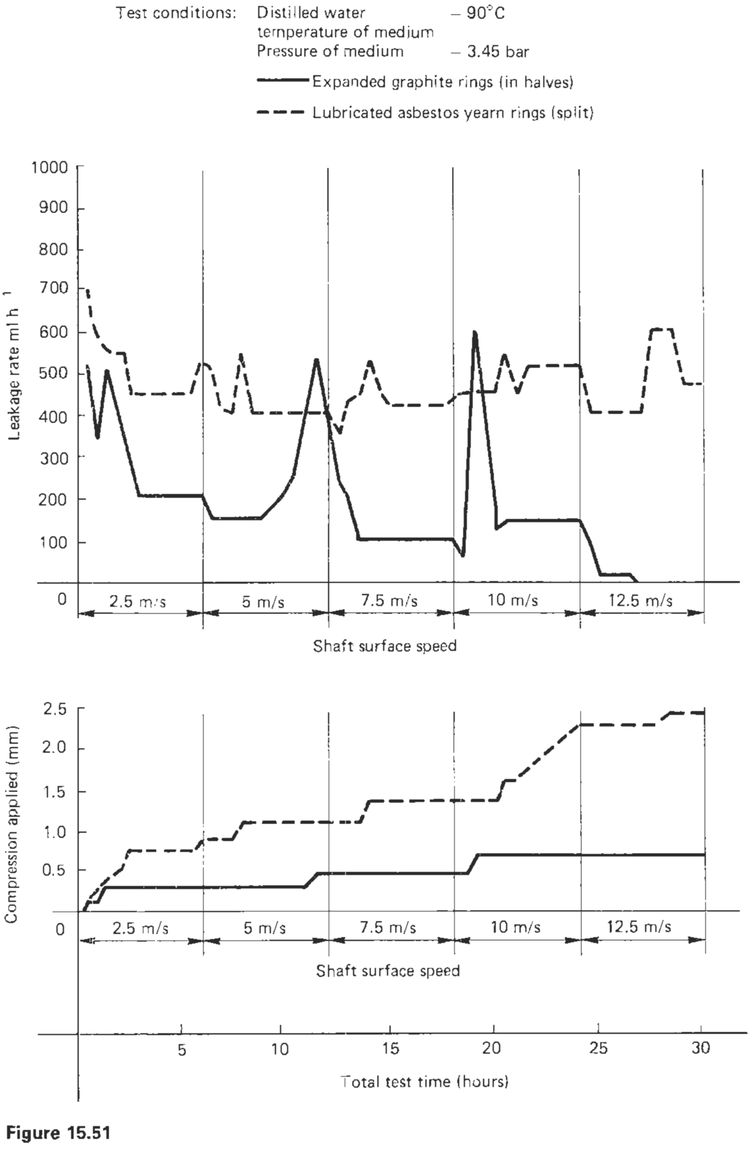


Figure 15.51

Since these yarns are extremely small in size, extrusion can occasionally be a problem. Hence when using these new products, extra attention should be given to the extrusion clearance of the gland and neck bushes.

Due to its PTFE content, service temperatures are limited to 260°C. However, this is well below the operational gland temperature of most rotary shaft applications.

One cannot leave materials without special reference to the vital role played by *asbestos* – a much-denigrated mineral fibre without which economic and practical solutions to many sealing problems would not be feasible. Although understandable, in an age of correct awareness of health and safety matters, the over-reaction against asbestos has revealed many inconsistencies. Motor manufacturers may prohibit its use as a plant-maintenance material but continue to use asbestos in a brake-lining and clutch-facing role where residual dust is evident. Some users may seek to limit its application in a safe form as a valve packing or gasket but perpetuate its specification for fireproof positions and roofing where the mineral is cut in a dry form.

Hazards exist but adherence to basic advice on handling asbestos will result in a sensible balance between prohibition and practicality. In this context, users of asbestos-based pump and valve packings, gaskets or allied components might heed, to advantage, the statement issued by the Asbestos Information Committee to the British Valve Manufacturers' Association.[18–22]

15.2.1.11 Selection

Selection is the most vexing question as, for many duties, so many reasonable alternatives exist. Much will depend on personal experience, frequency of maintenance, original cost level, contamination considerations, size, etc.

In the case of a manufacturer producing large quantities of valves or pumps to standard dimensions there is much to be said for purchasing sets or rings rather than length-form packing. With the techniques available, packing can be supplied ready for immediate fitting with substantial reduction in that overall cost represented by receiving length-form that must be cut to size by skilled personnel. This economy is not confined to the large manufacturers but it is they who will enjoy the greater advantage.

On the other hand, in many instances, the problem of stocking rings or sets tailormade for an assortment of valves varying in origin, type and dimensions can prove intolerable. For these cases, there is a clear need for the versatility of packing in length-form. Comparable with this solution is the expedient provided by those packings of plastic nature that are available in loose form but this advantage must be weighed against the labour cost in the careful fitting required.

15.2.1.12 Cross-plait construction/mixed yarns

Virtually all these new synthetic yarn/filament materials are manufactured into length-form packings using the 'cross-plait' construction as shown in Figure 15.43, which results in a far better and more uniform construction and it does have the distinct advantage of enabling two different yarns to be used in the manufacture of a packing. This technique has resulted in the development of a new generation of cross-plait mixed-yarn products, which can maximize the benefits of the individual constituents and minimize their shortfalls. Typical examples are packings deploying tough aramid (yellow) yarn at the corners and the high-speed thermally superior hybrid yarn just described to most of their rubbing face – these offer excellent extrusion resistance and a higher-speed capability than a plain aramid product. Also for chemical compatibility PTFE filaments can, of course, be combined with others as necessary.

15.2.1.13 Gland adjustment

The one disadvantage of the compression packing arrangement is that after installation subsequent periodic adjustment of the gland is normally required. The reason for this is that there has been a small loss of volume, either material or lubricant, which means that the density has been changed and so a reduction in the radial sealing force occurs, resulting in an increasing leakage. Gland adjustment, i.e. compression, then restores the density and the sealing force.

The new materials, particularly the graphite types, are self-lubricating and so very little lubricant is added to the packing. In consequence, because there is relatively no material or lubricant to be lost or forced out of the packing, the amount of subsequent gland adjustments are very much reduced, giving a longer life and reduced maintenance requirements. This aspect is demonstrated perfectly with the graphite foil used for valve sealing. The material is virtually pure graphite and is perfectly stable in size and density within the temperature range of −200 to +550°C, and once fitted and correctly adjusted it will usually provide years of trouble-free service.

15.2.1.14 Applications

Basically, the fundamental choice is generally that for a dynamic/rotary application the length-form cross-plaited yarn/filament product should be used and for valve spindles rings of expanded graphite are the first choice.

15.2.1.15 Valves

Expanded graphite is now the most common form of valve stem seal. It is the standard for virtually all valves in the power generation and nuclear industries, both in the UK and in Europe. Density of the material is very important and usually a density of 1.6 g/cm^3 is used. This is the value specified by CEGB in their specification for this material (No. 155701). For this reason, it is always preferable to use moulded rings for critical applications rather than the alternative 'tape' form of material. The rings are manufactured by winding tape coaxially around a rod until the required o.d. is obtained and then compressing these within a mould. The material is usually compressed in the order of approximately 60%.

Once installed and the optimum gland adjustment is applied, no further adjustments should be necessary. The only reason subsequent adjustments are necessary is because the sealing force has reduced – this can only happen if the density has changed, which in turn can only be the result of some loss of material, i.e. extrusion of the top or bottom rings.

It is therefore extremely important to have the minimum possible extrusion clearances. However, if extrusion proves to be a problem, then the use of end rings of graphite filament (i.e. cross-plaited type) have proved extremely successful in solving this problem. Indeed, the use of these 'combination sets' is now becoming far more common and in the power-generation industry in France it is virtually a standard approach.

Compared with the older materials, these new sets require negligible subsequent gland adjustments and the use of 'live' spring-loaded glands has now achieved the ultimate in long trouble-free operations. The reason 'live' glands can now be used is due to the small degree of compressibility of these graphite materials. Once fitted, these sets will probably only compress by about 8–10% at most, whereas the older sets in lubricated asbestos materials could well compress ultimately by perhaps 35% or 40%, rendering spring-loaded glands impractical.

15.2.1.16 Problems with expanded graphite

Occasionally a problem can occur which initially causes a significant increase in friction, then is usually followed by leakage. It is often referred to as graphite 'pick-up' and, for some reason, graphite from the inner surface of the rings adheres to the valve stem and is dragged through the set. Apart from the very noticeable increase in friction, depending upon the length of movement, the graphite deposit is often seen on the emerging valve stem.

At present there appears no clear explanation of why or when this will happen, although the number of instances are relatively low. However, although the mechanism of how it occurs is not fully understood, it has been found that the use of end rings of graphite filament – as used primarily to prevent extrusion – also seems to prevent this problem. A typical set is shown in Figure 15.52.

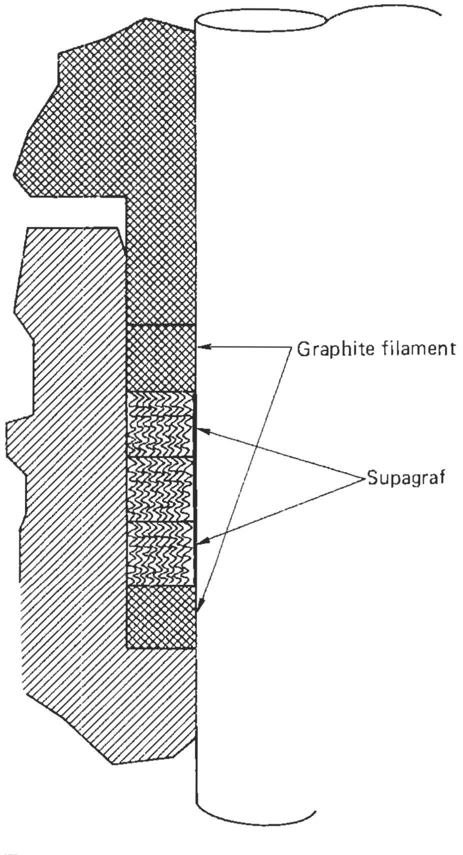

Figure 15.52

15.2.1.17 Corrosion

Corrosion is an aspect often associated with the use of graphite when used on stainless steel valve stems. However, this is normally not caused by the graphite itself but by other impurities used in the old-type seals – in particular, moisture that enters the seal when a valve is initially hydraulically tested which then remains there until such time that the valve is put into service. By using a different seal for this hydraulic testing, drying out the stuffing box and then fitting the graphite seals, no corrosion normally occurs. For those users still concerned, these materials can be supplied containing a corrosion inhibitor.

15.2.1.18 Length-form packing

If length-form packing is preferred (possibly for maintenance reasons) then within its operational limitations plaited-type packings can be used in valves, although their efficiency will rarely be equal to that of expanded graphite. However, for easier operating conditions, particularly those valves handling fluids, they can prove very successful. Non-asbestos length-form packings based on reinforced braided glass yarns combined with a graphite based core are now available for temperatures up to at least 500°C.

15.2.1.19 Rotary shafts (pumps, etc.)

Expanded graphite should not really be considered for dynamic rotary applications, since it does not have the flexibility to cater for the inevitable minute radial movements of the shaft that are usually present. Having said this, it has operated on equipment providing only the minimum of leakage, but the units in question did have double-ended bearing arrangements to the shaft, etc. – providing almost perfect mechanical conditions.

The cross-plaited types are therefore the first choice for any rotary application and the new materials discussed will normally give excellent results in terms of reduced leakage, extended life and infrequent adjustments. On boiler feed pumps the 'hybrid' PTFE/graphite yarn type is now giving exceptional results and after initial bedding-in periods of over 18 months without further adjustments are quite common – and then the packing is replaced purely as a scheduled maintenance requirement, not because it has failed.

15.2.1.20 Rubber core

A recent trend which is proving extremely successful is to incorporate an elastomeric core into the cross-plaited type packings. This then gives a degree of recovery to the rings and assists in reducing the subsequent gland adjustments. It is also extremely successful when there is radial movement of the shaft such as on mixing vessels and agitators, etc. Depending upon the operating conditions, the elastomer used is frequently fluorocarbon (Viton) or ethylene propylene. This approach is also being used for length-form valve packing – typically in the water industry and, obviously, for potable-water applications only approved materials must be used.

15.2.1.21 A new natural fibre

In contrast to the synthetic materials, packings manufactured from ramie yarns are now available and proving very successful. This is a natural material and is extremely tough and water resistant. Although it has a temperature limitation of only 120°C, it is a far more economical alternative for basically water applications, including rotary and reciprocating pumps and valves.

15.2.1.22 The future

The recently developed materials such as aramid, the hybrid graphite/PTFE and the natural ramie yarns will form the bulk of compression packings for both reciprocating and rotary applications. Not only do these materials overcome the health problems associated with using asbestos they have extended the performance capability of the packed gland. While they are initially more expensive than the asbestos products, the improvement in performance, reduced maintenance and extended life invariably make them cost effective.

Although these new materials can replace asbestos products for most dynamic applications, much development is still taking place with glass/PTFE/graphite or ceramic constructions mainly to satisfy the higher temperatures that are encountered in valve applications. However, many problems remain to be solved in producing a general-purpose product that can compete with asbestos in terms of lubricant retention, absorbency or durability at comparable costs.

There can be no doubt that graphite-based materials will see even greater acceptance despite the higher initial costs, and with the current rate of development, asbestos as a compression packing material will soon be a thing of the past. Despite its simple concept, there really is no alternative for the valve stem seal. Indeed, its performance now is such that the question must be asked, 'Is there a need for an alternative?'

For rotary shafts the improved performance in terms of less leakage, less shaft wear and longer life with fewer adjustments, must make the choice between a compression packing and the mechanical seal an even more difficult decision than it was in the past.

Finally, not including the spring-loaded lip seal, since this is really only suitable for very low pressures, the only choice for a rotating shaft seal has been either the mechanical seal or a packed gland. If a steady leakage is acceptable – as is normally experienced from a packed gland – there is now a third option of a rotalion, an automatic throttle device giving controlled leakage, irrespective of pressure and rubbing speed.

15.2.1.23 Guidelines for removal of asbestos from plant

1. Assess the amount of work involved.
2. Decide when the work is to be carried out.
3. Supervision to notify Safety Department Supervision, who will then notify the Health & Safety Executive (Asbestos Licensing Regulations 1983). Twenty-eight days' notice required except in cases of extreme emergency.
4. Permit to Work Certificate to be issued by Supervision with reference to protective clothing, respiratory protective equipment and electrical isolation.
5. The area is to be enclosed with polythene sheets where possible.
6. Asbestos warning notices are to be suitably placed in the area.
7. Disposable overalls must be worn, a new pair each day. If leaving the site is necessary, overalls must be vacuumed before removal and fitted again on-site when returning. On removal at the end of the day, place carefully into the plastic bag provided, having first vacuumed down as stated above. The bag should be sealed and placed in the notifiable waste container.
8. Rubber boots should be worn with the overall trouser outside the boots. The soles and outside of the boots are to be completely vacuumed clean and washed after use.
9. Dust masks *must* be worn throughout the asbestos-removal operation and *must* be the last piece of protective wear removed on completion of work. Masks should then be vacuumed, placed in the container provided and returned to source.
10. Thoroughly wet asbestos with water before removal.
11. Remove wetted asbestos with care and place into red notifiable waste bags and seal.
12. The whole area and screens must be carefully vacuumed with asbestos approved cleaner. Remove screens, bag, seal and place in notifiable waste container.
13. Vacuum overalls on-site before removal then place into plastic bag, seal and place in notifiable waste container with removed bagged asbestos.
14. Safety Department Supervision should inspect the area and, if found to be satisfactory and suitable for normal working, will endorse the Permit to Work Certificate to this effect.
15. Supervision will then complete the Permit to Work Certificate.
16. *The HSE Factory Inspector may call at any time to check that the correct procedure is being carried out.*

15.2.2 Reciprocating hydraulic seals

15.2.2.1 Introduction

Sealing devices, particularly in the field of hydraulics, are usually of an essentially deformable nature, and permit fluid power designers to work within economically sensible conditions of fit, surface finish and fluid cleanliness across the range of temperatures and pressures which they are likely to encounter. In the context of those seals specified for linear dynamic motion, a much axially shorter seal has evolved which allows hydraulic cylinders, for example, to be produced to more compact proportions with the consequent saving in raw material costs and in the overall bulk of fluid power subassemblies. This is clearly seen in Figure 15.53, which illustrates how the seal design can directly influence the size of the unit and still give the same performance in terms of power and stroke length.

A proliferation of seal designs and materials exists and those responsible for selection are required to make their choice with discretion to ensure that the most cost-effective solution is found. Selecting a seal which facilitates the achievement of the cheapest production costs for the component into which it fits is seldom the most reasonable basis for guaranteeing minimum leakage and maximum serviceability.

It is an unfortunate fact that most fluid leakages are attributed to a faulty seal whereas investigation will frequently show that the number of occasions of malfunction due to a faulty product are few. The real source of difficulty usually stems from incorrect seal selection, working conditions which differ from those considered to apply, seal containments outside specified tolerances in terms of dimension or finish, faulty fitting, contaminants in the fluid to be sealed or, importantly, personal interpretation of 'leakage' in quantitative terms.

To understand the limitations of fluid seal performance it is necesary to know a little of the materials most typically used, the origins of fundamental seal designs, how they function and their refinement to the present state of the art. Fortunately, the seal is no longer an afterthought but more often receives the attention it properly deserves as a vital interactive element in any complete fluid power system.

15.2.2.2 Materials

Within the scope of this section, attention will be centred on solid elastomeric seals, typified by the 'O' ring for static connections, elastomer-containing seals such as cylinder packings based on proofed textile and those designs which employ plastic components for various functions. Tables 15.11 and 15.12 and Figure 15.54 are taken from the British Rubber

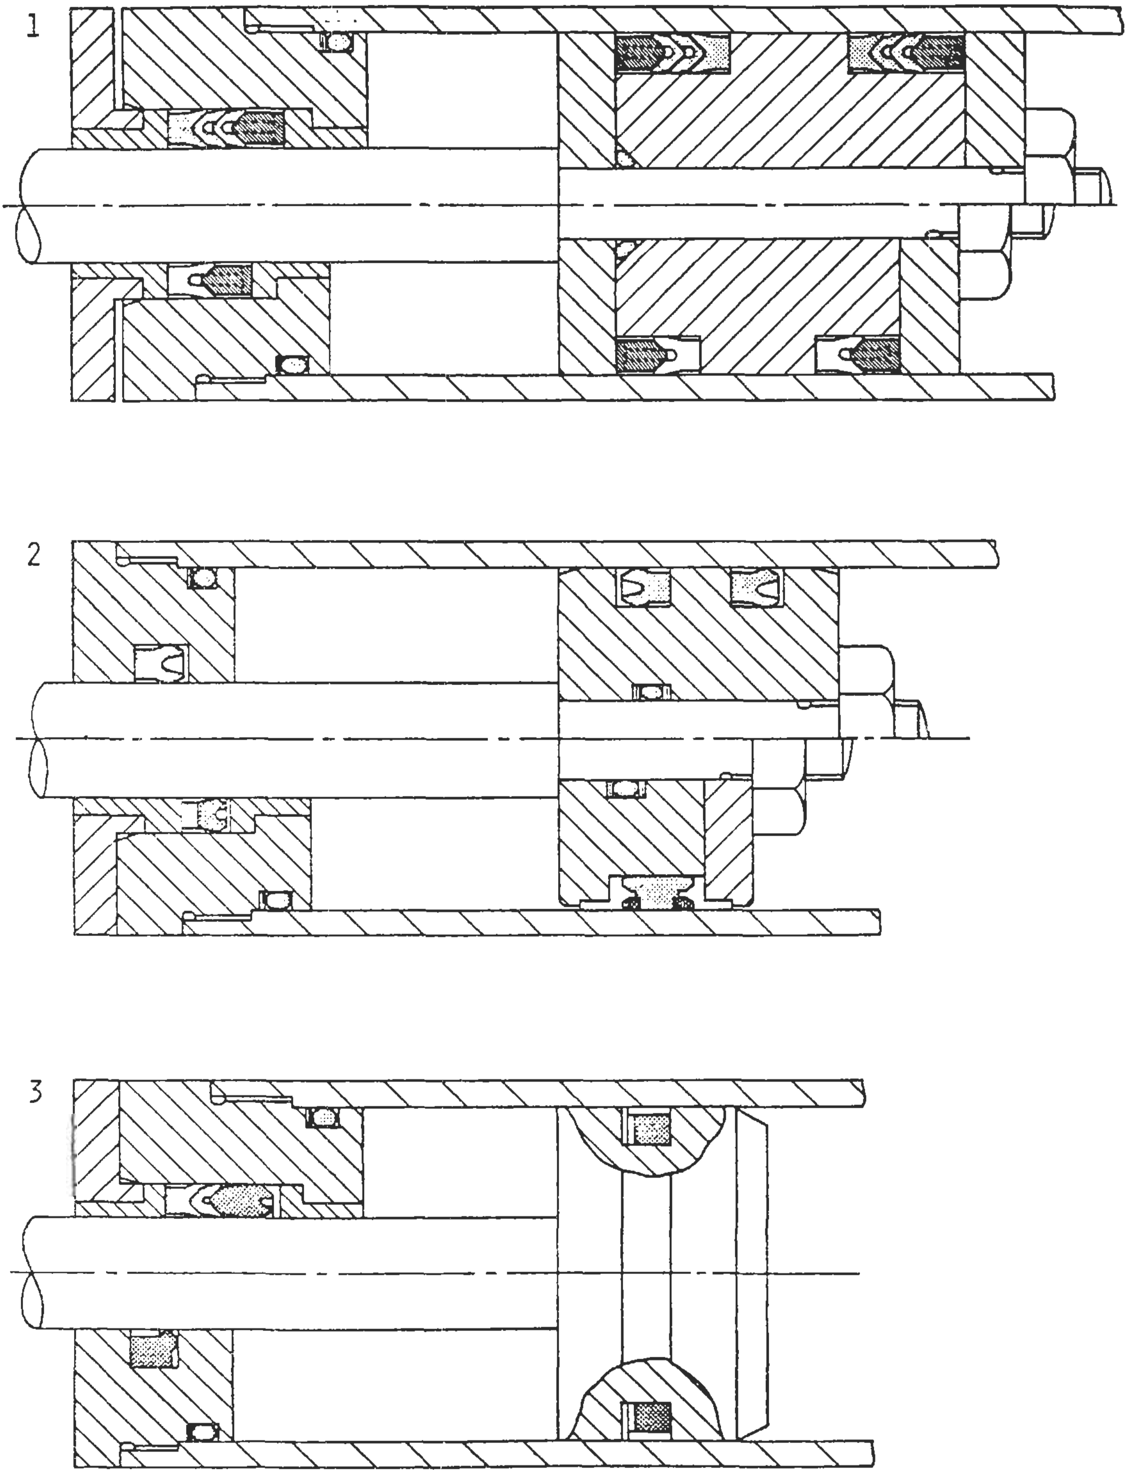

Figure 15.53

Table 15.11 Polymers – types and general properties

NATURAL POLYISOPRENE	(Natural Rubber-NR)
SYNTHETIC POLYISOPRENE	(Polyisoprene-IR)
Very good	General physical properties, in particular tear resistance, resistance to glycol-ether brake fluids and vegetable oils.
Poor resistance to	Heat, weather, ozone and mineral oil.
CHLOROPRENE (NEOPRENE-CR)	
Very good resistance to	Ozone, weathering and abrasion.
STYRENE-BUTADIENE (SBR)	
Very good resistance to	Abrasion, glycol-ether brake fluids and vegetable oil
Poor resistance to	Mineral oil and ozone.
ACRYLONITRILE-BUTADIENE (Nitrile-NBR)	
	Low, medium and high nitriles are available based on increasing acrylonitrile content which significantly affects low temperature and fluid swell properties.
Very good resistance to	Mineral oil, compression set and abrasion.
ISOBUTYLENE-ISOPRENE (Butyl-IIR)	
CHLORO-ISOBUTYLENE-ISOPRENE (Chloro-Butyl)	
Very good resistance to	Tear, weather and gas permeation.
Poor	Tensile properties and mineral oil resistance.
POLYBUTADIENE (Butadiene-BR)	
Very good resistance to	Tear, abrasion, low temperature, glycol-ether brake fluids and vegetable oils. Offers high resilience.
Poor resistance to	Water, ozone and mineral oil.
POLYSULPHIDE (Thiokol-T)	
Very good resistance to	Ozone, mineral oil, petroleum fuels and weather.
Poor	All other properties.
ETHYLENE PROPYLENE (EPR-EPM)	
ETHYLENE PROPYLENE TERPOLYMER (EPT-EPDM)	
Very good resistance to	Weather, ozone, heat, water, steam, glycol-ether brake fluids and vegetable oils.
Poor resistance to	Mineral oil.
CHLOROSULPHONATED POLYETHYLENE (Hypalon-CSM)	
Very good resistance to	Water, ozone, abrasion, acid and weather.
METHYL-VINYL SILOXANE (Silicone-VMQ)	
PHENYL-METHYL-VINYL SILOXANE (Silicone-PVMQ)	
Very good resistance to	High and low temperatures.
Poor resistance to	Abrasion, tear and tension.
TRIFLUOROPROPYL SILOXANE (Fluorosilicone-FMQ)	
Very good	Mineral oil and fuel resistance. All other properties as VMQ.
POLYURETHANE DI-ISOCYANATE (Urethane-AU)	
Very good resistance to	Mineral oil, abrasion, tear, ozone and weather. Offers high modulus and tensile properties.
Poor	Moist heat resistance.
FLUORINATED HYDROCARBON (Fluorocarbon-FKM)	
Very good resistance to	High temperature (in air and most oils), weather and petroleum fuel.
Poor	Tear strength.
POLYACRYLATE (Acrylic-ACM)	
Very good	Heat, weather, mineral oil and ozone resistance.
Poor	Water resistance.

Manufacturers' Association's *Guide to Elastomeric Seals* to give broad reference to most commonly used elastomers, their properties, fluid compatibility and temperature resistance. Of major interest to the fluid power industry are the following.

Acrylonitrile-butadiene (*nitrile – NBR*) Probably upwards of 80% of seals supplied to the fluid power industry are based on nitrile compositions. The balance of properties available from NBR in terms of good compression set qualities, abrasion resistance, mineral oil compatibility, ease of processing and low initial cost favour this choice. Nitrile compositions are not, however, compatible with fire-resistant fluids of the phosphate ester type.

Isobutylene-isoprene (*butyl – IIR*) Satisfactory in service with phosphate ester fluids but rather lifeless from a physical

R-recommended; A-acceptable; N-not recommended

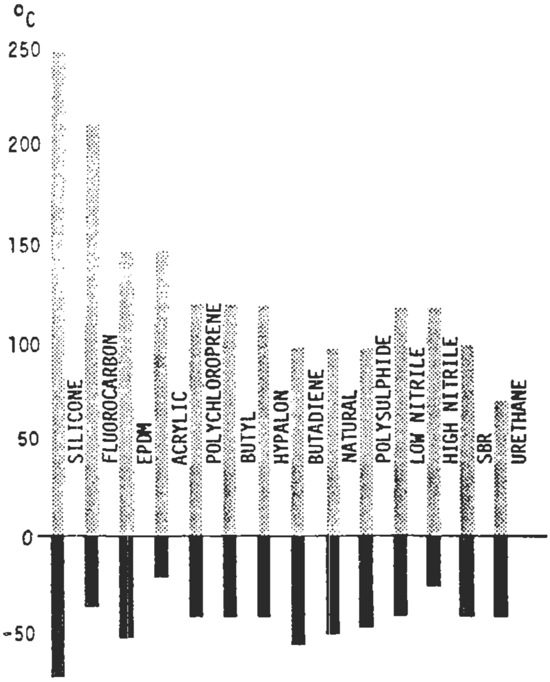

Figure 15.54 Temperature ranges for polymers

point of view. Not suitable for mineral oil service nor should butyl seals be smeared with mineral oil or grease on fitting.

Ethylene propylene (EPR – EPM) or ethylene propylene terpolymer (EPT – EPDM) Same service function and limitations as butyl but generally better physical properties.

Fluorinated hydrocarbon (fluorocarbon – FKM) The only usual selection where compatibility with mineral oil and phosphate ester is required.

Polyurethane (urethane – Au) Widely favoured as a dynamic seal material in the USA and in Germany, polyurethane exhibits excellent abrasion resistance and is very durable in situations which might adversely affect nitrile compositions or even proofed fabrics, e.g. passage of seal lips over ports in a cylinder wall. Poor low-temperature flexibility, hydrolysis in hot water and a lower operational temperature ceiling are limiting factors.

Other seal component materials worth mentioning are:

Textiles – woven cloth such as cotton, asbestos, terylene and nylon are used as the substratum in elastomer-proofed fabric packings for medium- and high-pressure duties. Non-woven materials such as polyester and polyamide are also available. The proofing elastomer can be varied to suit but will frequently be based on nitrile or fluorocarbon.

PTFE – employed as a back-up ring material for 'O' rings. Poor creep properties restrict its use as a seal material in its own right unless energized by an elastomeric component or spring.

Nylon and acetal – main function is heel support for dynamic seals or as component-bearing ring material.

Hytrel – the registered trade name of a Du Pont range of thermoplastic polyester materials which form a bridge between between elastomers and thermoplastics. Has similar properties to polyurethane but exhibits much better low-temperature flexibility. Used currently as an anti-extrusion element in certain spool type piston head seals.

It is important that seals are protected and stored in such a way that they will not deteriorate or become damaged before they are used. Recommendations for storage of seals, etc. are given in Section 15.2.2.19.

15.2.2.3 Seal designs

Within the boundaries set by fluid power systems the majority of seals employed can be categorized as 'lip' or 'squeeze' types, or indeed a combination of both. Figure 15.55 illustrates the simplest forms utilized for static or dynamic reciprocating situations – the 'U' ring and the 'O' seal – and indicates how both rely on interference stress for at least a component of their functional operation. Both are responsive to system pressure and will generate a radial stress greater than the pressure to be sealed. Neither rely on externally applied compression to any real degree as in the case of the soft-packed gland. This is particularly relevant to squeeze seals, which are usually intended to float axially in their housings.

The quality of the sealing contact area and the interference stress in the same zone will control low-pressure sealing efficiency. These factors plus overall seal geometry and composition will set the point at which time hydraulic response takes over from the manufactured interference condition. The hydraulic component may become significant at pressures of 40 bar for an elastomeric 'O' ring or as high as 200 bar for a rigid proofed fabric packing.

Sealing slack oil and low pressures is generally a function of seal integrity and is the more difficult condition. Preventing leakage at high pressures is a feature of seal containment, i.e. preventing extrusion or rapid wear if in a dynamic duty.

Figures 15.56 and 15.56 list typical lip and squeeze types in common and traditional usage. Some particular points to note on each category are as follows:

1. *Lip seals* are single-acting to applied pressure and must be separated by a fixed component in double-acting duties so that the hydraulic load from the element under pressure is not passed on to the trailing element. For maximum service life multi-ring packing sets are often preferred where the succession of sealing edges ensures that breakdown is not sudden. The use of split rings is also entirely feasible with most designs of this sort without sacrificing sealing performance to any critical degree. Savings in downtime will be obvious. Having said this, it will be shown later that for very arduous operating conditions multi-ring sets are not always the correct choice as they can in fact be self-destroying.

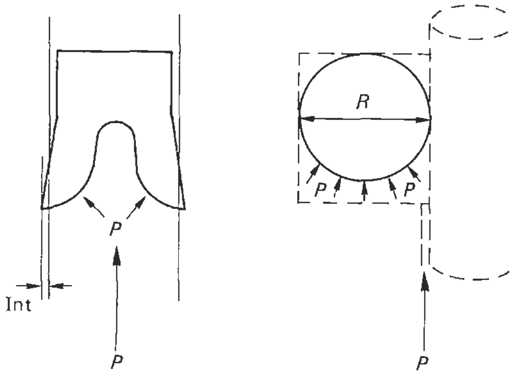

Figure 15.55 Lip and squeeze seals

2. *Squeeze seals* have the advantage of being double-acting and are usually housed more economically than their corresponding lip brethren. These seals all operate on the basic principle of the simple 'O' seal. For piston head or gland sealing, the 'O' seal should not ideally be used as a dynamic seal, since, due to the linear motion, it can suffer from rolling/spiral twist, which in turn leads to leakage. If, because of space restrictions a seal of 'O' seal proportions must be used, then either a 'D' section or 'quad' shape seal should be used – as seen in Figure 15.57. Remember that, as for static 'O' seals, if the pressures are in excess of, say, 100 bar these seals would also require some form of back-up/anti-extrusion washers. Most seals in this category use a single sealing zone and damage in service will be followed by more immediate breakdown than in the case of multi-lip packings.

Some of these seal types are discussed in more detail later. However, regardless of the seal design, it can only function correctly if the mechanical aspects of the housing are correct, therefore some fundamental requirements on this subject are now outlined.

15.2.2.4 Seal housings

The design of both gland and piston head arrangements will vary from one manufacturer to another and, particularly in the case of the piston head, this will be influenced by the actual seal, i.e. whether or not it incorporates bearing elements. Obviously, operating pressures, degree of knuckling/offset forces, etc. will also be taken into consideration.

Gland design A typical basic gland arrangement is as seen in Figure 15.58. The important aspects are that:

- The supporting bearing bush for the rod/ram is of sufficient axial length.
- This neck bush is positioned inboard of the seal and is therefore lubricated.
- While this bush requires to be a close fit to the rod, such bushes can cause fluid starvation to the seal or in certain conditions an intensification of fluid pressure at the seal. Such potential hazards can be easily avoided by providing a pressure relief through or across this inner bearing bush. (This is discussed later under 'Drag Flow'.)
- The gland follower should have the minimum possible clearance with the rod to prevent seal extrusion, but a wider clearance than the inner neck bush.

Piston heads Similar basic points apply for the piston head although, if the seal incorporates bearing elements, the fits, etc. should be as detailed by the seal manufacturer.

Tolerances Appropriate tolerances and/or limits are given in Figure 15.59 for both gland and piston head applications.

Extrusion clearances Table 15.13 shows extrusion clearances appropriate to an H9/f8 guidance fit of the neck bush.

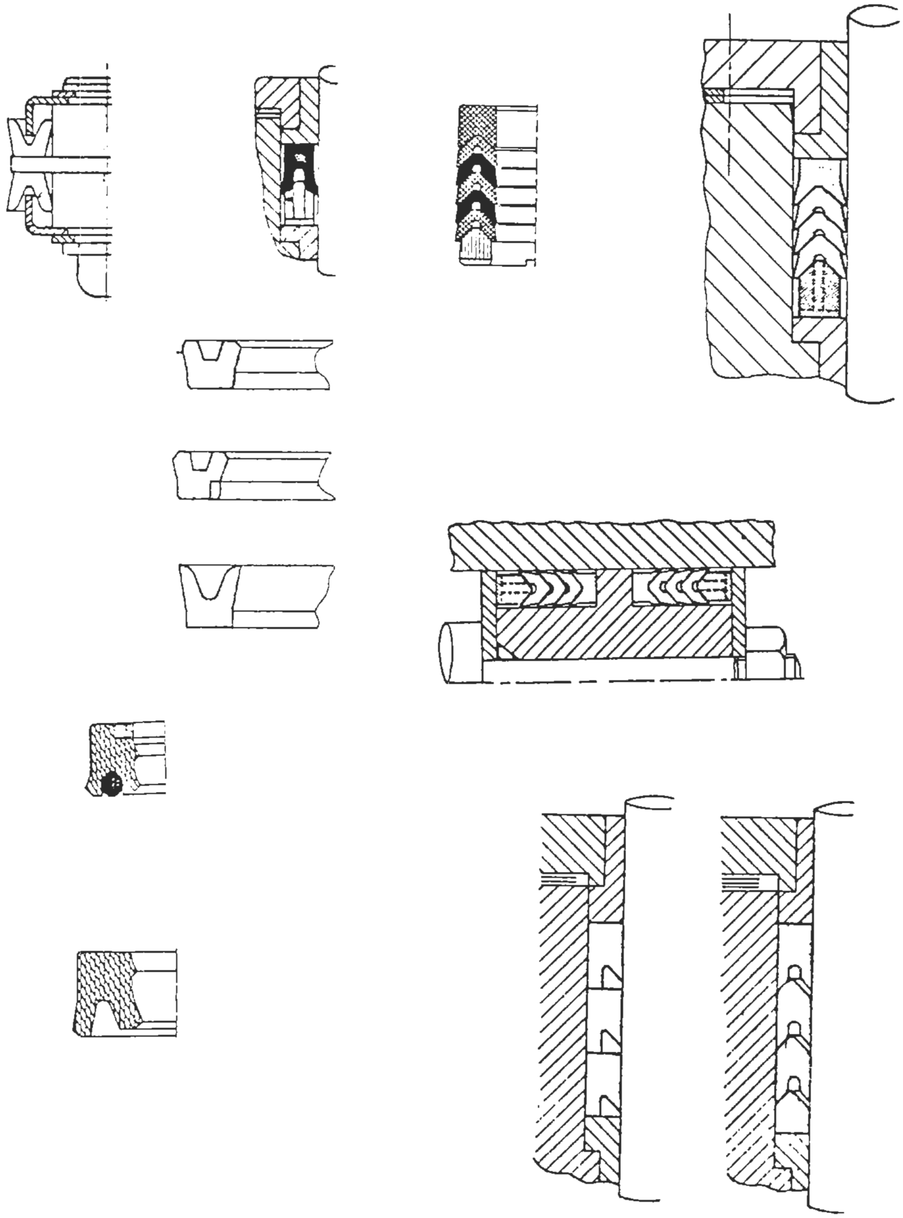

Figure 15.56 Lip seals

Lead-in chamfers To facilitate fitting of the seals both cylinder and piston rods should have an adequate lead-in/on. Suggested minimum values are given in Table 15.14 – these relate to an angle of 20°/30°.

Surface finish Piston rods and cylinder bores should be typically ground or honed and have a surface finish of 0.4 μm R_a or better, i.e. in accordance with BS 1134: Part 1. For critical applications this should be improved to 0.15/0.25 μm R_a. There is no advantage in trying to achieve a near-perfect finish, i.e. in the region of 0.05 μm R_a, as this will often prevent the establishment of a coherent fluid film under the seal. For the static seal contact surfaces, these should be better than 1.6 μm R_a.

Housing sizes Generally housing sizes will be taken from the seal suppliers' literature. However, for possible seal interchangeability housing sizes to an accepted standard should be used, i.e. ISO 5597/1. If there is a choice of seal sizes, the largest radial width/section seal should be chosen.

15.2.2.5 Type of fluid

As far as dynamic seals are concerned the great majority of mineral-based or phosphate ester fluids do not present lubricity problems. However, there is considerable development taking place to use water/soluble oil emulsions where seal performance can be directly influenced by the percentage of soluble oil.

One of the most demanding types of duty for any dynamic seal involves plain water at high pressure whether by design or by total loss of soluble oil content in a nominally lubricated

system. High speeds are particularly difficult to sustain unless a minimum soluble oil level of 2% is guaranteed.

Tests conducted on three-throw mining pumps operating at 250 bar, 0.6 m/s, have shown that for even a 2% soluble oil content, average seal life will be extended by a factor of four by comparison with untreated water. Equally, a separate lubricant feed will produce similarly notable improvements.

The temperature of hydraulic fluid should not exceed 60°C if at all possible, as significantly faster swell and softening of proofed fabrics and straight polymers will occur above this value. To illustrate the point, the following data are based on immersion testing for 7 days in Shell Tellus 27 mineral oil:

Nitrile proofed fabric –

room temperature	+ 0.7% volume increase
60°C	1.2%
90°C	2.6%
120°C	3.3%

Filtration For the bulk of elastomer proofed fabric and solid elastomer seals fluid filtration of 25 μm should be perfectly adequate from the sealing performance aspect. Special seals such as those embodying PTFE wear faces will benefit from 10 μm filtration or better. In either event, filtration equipment offering a finer cut-off will probably be specified to suit control valve functions on a given press or hydraulic component.

The majority of conventional hydraulic seals which are tested in-house work in conjunction with no more than a coarse wire strainer in any hydraulic system. However, modern filtration aids must be considered an advantage particularly if the operation of the plant involved produces aggressive residues.

Air entrainment As cycle speeds become faster due to increasing work demands, system pressures must fluctuate more quickly. In many situations, full working pressure must be exhausted in milliseconds (e.g. die-casting machines, plastics injection moulding presses, etc.). If air is entrained in the hydraulic fluid such rapid decompressions can be exceedingly dangerous if no automatic venting is available, and can cause rapid seal failure – as discussed later.

15.2.2.6 Tribological considerations

It is heartening to find the study of seal behaviour an essential part of tribology seminars, receiving as much attention, indeed, as bearings, lubricants and surface topography. In recent years much company research and independent study by organizations such as BHR Group, The Fluid Engineering Centre, has been expended on defining sealing mechanisms – particularly in relationship to reciprocating motion.

Film conditions All dynamic seals rely on a coherent fluid film under their contact area if they are to function consistently and predictably. Such films may stem from boundary

All dimensions in mm

lubrication in some modes and be truly hydrodynamic in others. The film will vary in thickness according to seal profile, interference stress, pressure, speed, surface finish, type of fluid employed and its temperature. On reciprocating duties it might typically vary from 0.25 to 3.0 μm in thickness. On rotary shafts, values of 0.6–1.0μm would usually apply.

Film conditions – rod/gland seals Leakage from rotary shaft lip seals is seldom evident unless seal weardown or under-lip cracking has taken place – all other features being equal. However, in reciprocating applications passage of the rod emerging out through the gland will carry/drag the oil film to the atmosphere side of the seal as indicated in Figure 15.61. Under normal conditions, unless the seal is severely physically damaged, leakage will only occur on the emerging stroke – no leakage will occur when the rod retracts although it is during this retracting stroke that leakage 'appears' to develop.

Figure 15.62 is a diagrammatic representation of the worst film transport situation involving an emerging cylinder rod with slack pressure to the gland which retracts with the sealing element under load. In this mode the heel of the seal will be energized and can prevent the return of the total quantity of film carried by the rod. The fitting of an effective wiper can aggravate the condition.

To combat the emergent film, careful attention is required to pressure side seal geometry. Designs such as that shown in Figure 15.63(a) with knife-cut sealing edges and a specific relationship between contact edge and groove heights have proved very successful despite their short axial length.

For greater security, the revised Chevron seal, incorporating a squeeze-type sealing header, as shown in Figure 15.63(b) has proved extremely successful.

Figure 15.63

Knuckling/offset conditions Experience has shown that many hydraulic cylinders are subjected to a knuckling condition which then causes wear in the bushes and so both the piston and, in particular, the rod seals are required to operate in a misaligned condition. Remembering that leakage typically occurs on the emerging stroke of the rod, often combined with low pressure at the seal, prevention of leakage is then a function of the seal's own retained residual sealing stress. Average lip seals will lose much of their original sealing force fairly quickly.

15.2.2.7 Friction

Many designers of hydraulic equipment will have experienced the reluctance of seal manufacturers to provide even approximate frictional values of their seals. This is not surprising when considering the many variables that will determine the resultant drag, such as: type of oil, degree of resultant sealing stress, whether it be as-moulded, or as the result of subsequent compression, surface finish of the rod/cylinder, direction of rod movement in relation to the pressure on the seal, and the speed of the rod or piston.

Variations in speed above 0.1 m/s (20 ft/min) will not have a noticeable influence on the frictional drag even at speeds of 25 m/s which is encountered in gun recuperator systems. However, at very slow speeds below approximately 0.02 m/s (4 ft/min) friction can vary and increase significantly – often experienced as 'stick-slip' – during which the actual movement is a constant start–stop sequence involving repeated breakout friction. Depending upon the characteristics of the equipment, this can often occur at a very high frequency resulting in noise and severe vibrations being set up. Whether or not this happens is also directly influenced by the function the hydraulic unit/actuator is performing in relation to the type of external force being exerted to the ram/cylinder. Determining the frictional drag of a seal is further complicated by the fact that many of today's seals incorporate two or three elements of different materials each having a different friction characteristic such as rubber; rubberized fabric; PTFE; nylon, etc.

In general, frictional drag is more of a problem with smaller actuators since the friction loss is proportional to the seal's diameter, whereas the thrust developed by the unit is, of course, directly related to the cylinder/piston rod area. However, when designing small actuators, low-friction seals should ideally be selected and if conventional seals in rubber/fabric materials are necessary the seals should be as short in axial length as possible since seal friction is also approximately a direct function of the seal's effective contact area. This point is shown in Figure 15.64.

Calculation of frictional drag Despite the many variables involved as discussed above, there are certain known factors which have a far greater influence on the result than others, such as fluid pressure, seal diameters and contact length and seal material. After much experimental work it has been established that a reasonable assessment of frictional drag is obtained by the following:

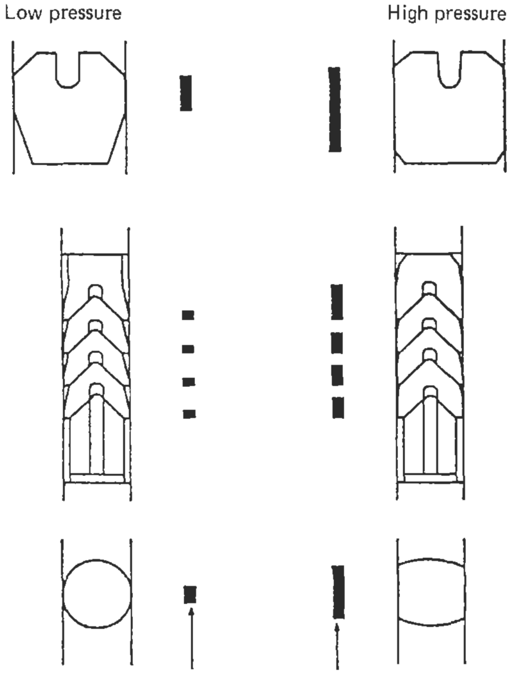

Figure 15.64 Seal contact band width

Fabric seals
Dynamic friction $F = DL\ [0.055 + (0.31R \times 10^{-3})]$

Rubber seals (i.e. 'O' seal or rubber contact seals)
Dynamic friction $F = Dd\ [0.092 + (0.465R \times 10^{-3})]$

PTFE contact seals
Dynamic friction $F = Dh\ [0.055 + (0.096R \times 10^{-3})]$

where
F = dynamic friction (kgf)
D = dynamic/sliding seal diameter (mm)
L = effective seal contact length (mm)
R = fluid pressure (bar)
d = 'O' seal cross-section or depth of rubber contact (mm)
h = effective seal contact length (mm)

It must be emphasized that the above gives only an approximate value since it will be appreciated that the result is dependent upon the accuracy of estimation of the contact length of the seal when under pressure. Also, these give 'dynamic' friction values, *not* break-out values, which will often be perhaps 20–30% higher. Break-out values are extremely difficult to predict because quite often the first actual movements will happen before the operating system pressure is reached. When considering seals containing a combination of materials each element must then be considered separately using the above formulae.

Low-friction seals If friction is a critical consideration then PTFE contact seals must be used. PTFE has many useful characteristics such as its low coefficient of friction but it does not possess any elastomeric properties and does suffer from what is commonly known as cold flow – this being more of a problem with flange gaskets.

For use as an hydraulic seal, regardless of the design of the seal, it will require some mechanical means of maintaining sufficient sealing stress to enable a seal to be maintained until the effect of the hydraulic pressure intensifies the sealing force. This can be achieved by using either springs or an elastomeric energizer. Typical spring-loaded designs are shown in Figure 15.65 and rubber-energized types do exist.

PTFE seals in general give excellent results, but there is always the possibility of a slight steady leakage developing. This is because the sealing face of the seal can be very easily damaged/scratched – perhaps during assembly – and eventually most rods or cylinders develop minute axial scores which can then cause a very small constant leakage.

A typical application where this has been a problem is when a PTFE piston seal is used on the double-acting piston of a down-stroking press typically as shown in Figure 15.66. When in the raised static position any minute leakage across the piston then causes the ram to creep downwards. Clearly, when considering the use of a PTFE contact seal it is useful to remember that these provide excellent dynamic seals. However, their use should be viewed with caution if the design/function of the equipment demands periods when a static pressurized condition exists such that even slight movement/creep of the rod/piston cannot be tolerated. For such applications an elastomeric rubber contact seal must then be considered preferable.

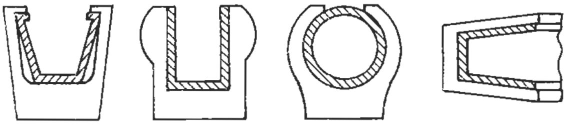

Figure 15.65

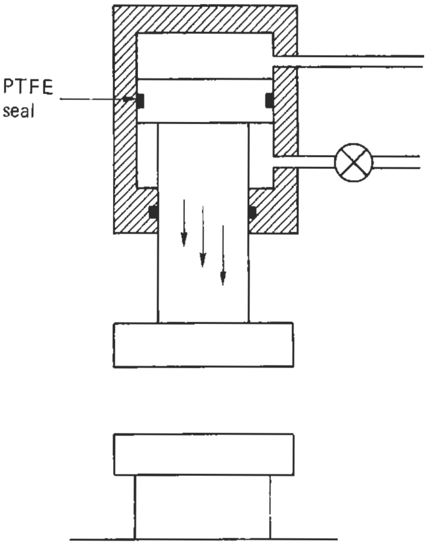

Figure 15.66

Because of the low friction, PTFE seals are required on equipment which demands very sensitive control. When used as a dynamic double-acting piston seal slight weepage across the seal is often not a problem – it is normally too small to be detectable and assists in lubricating the seal. However, when used as a rod/gland seal any eventual leakage is obviously undesirable. In such applications it is becoming more common to fit a secondary rubber seal outboard of the main PTFE seal with a leakage drain taken from between them. This arrangement is now proving very successful on even large 700 mm diameter ram extrusion presses (a typical arrangement is shown in Figure 15.67).

It will be appreciated that PTFE seals are only efficient in endless form, which is ideal for piston heads but may pose a replacement problem on rod positions, depending upon the overall design and accessibility of the equipment.

15.2.2.8 *Piston seals*

In the early days of hydraulics it made no difference whether a piston was single- or double-acting since the choice of seal was either a simple 'U' ring type or the multi V-ring Chevron type.

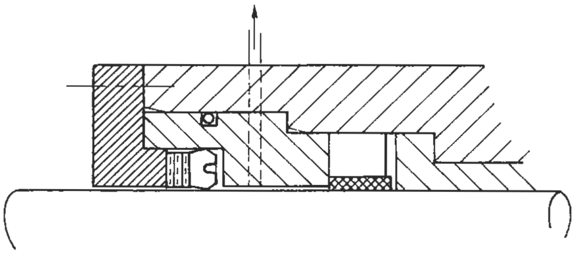

Figure 15.67

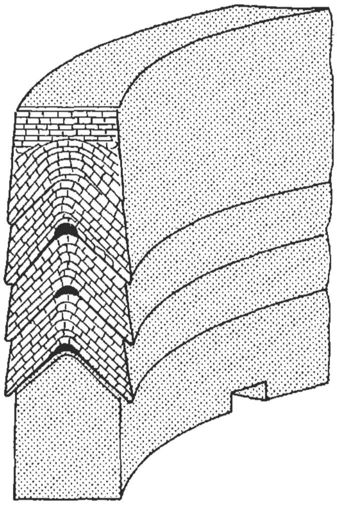

Conventional Chevron

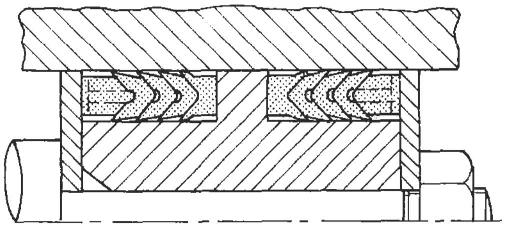

Figure 15.68 A typical double-acting piston seal assembly fitted with conventional Chevron

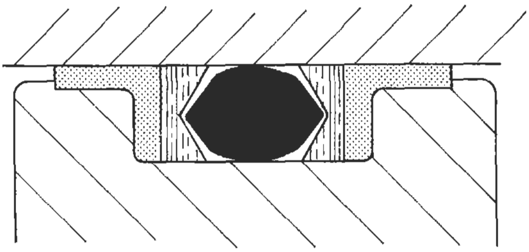

Figure 15.69

Single or opposed seals would be fitted as appropriate – typically as in Figure 15.68. Today the approach/choice is rather different. It is extremely rare now even to consider the double-opposed Chevron arrangement, which can cause excessive friction problems and demands a large/long piston which directly influences the overall size of the cylinder and therefore its manufacturing costs, etc.

For a single-acting piston the same type of seals would be considered as for use on a rod or gland position but, for a typical double-acting piston, a single double-acting seal would now normally be preferred of the types shown in Figure 15.60. Alternatively, two opposed single-acting seals could be considered if the minimum possible leakage across the piston was essential.

Most of the double-acting seals have radiused profile sealing areas and when dynamic they do allow a small weepage across the seal. On, say, a 100 mm diameter piston constantly reciprocating, a leakage of perhaps 30 ml h^{-1} may occur but this, in relation to the volume of fluid displaced, is negligible – the performance of the unit is not affected and the seal is well lubricated. These seals also perform a perfect static seal. As already mentioned, this can be important on certain applications.

The trend with new designs is influenced by commercial considerations so as to use the most economical piston design possible. This will obviously be a 'one-piece' component with a simple machined groove into which the seal must be stretched. The seal will usually also be required to incorporate integral bearing elements and one such design is shown in Figure 15.69. For such piston designs there are already two recognized standards, i.e. ISO Standard No. 6547 and BS 6241 which provide full housing details.

In general, piston seals can tolerate far more wear before replacement becomes necessary. It is only when their degree of leakage is such that the performance of the cylinder starts to become impaired that the seal is changed, whereas the same degree of wear on a gland seal would have caused far earlier excessive leakage out of the unit, which would be unacceptable.

15.2.2.9 Gland seals

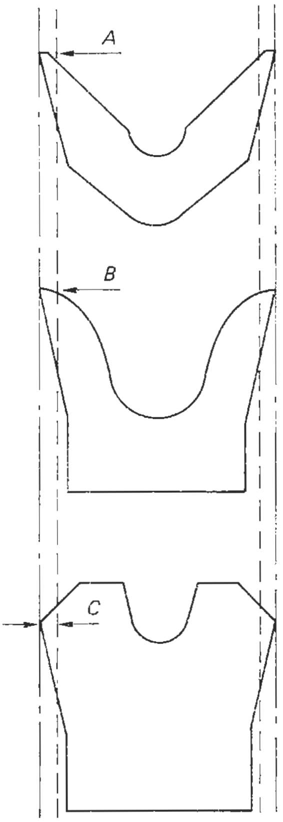
Overall, the sealing of a gland is a more difficult requirement since, unlike a piston seal, no leakage can normally be tolerated. Bearing in mind that to obtain even a reasonable service life the seal must operate on a fluid film, the resultant difference between essential film and acceptable leakage is extremely marginal – the emerging film conditions have already been discussed.

A gland seal is single-acting and therefore demands a different sealing contact profile to the piston seal. With 'U' rings and Chevron V-rings this is obvious but with the change from basic lip seals to the squeeze types the contact profile is somewhat different.

Many of these seals employ what is often termed a 'reverse rake' sealing edge, typically shown in Figure 15.63. To some minds this shape would appear to encourage leakage, but we must recall that most leakages occur at low pressures and what prevents leakage is the radial force the seal exerts on the rod and not the shape of the seal. In this context the lip profile is irrelevant since at pressures too low to energize the seal the lip shape has little or no effect. This point is shown in Figure 15.70. For the same degree of radial interference the rubber seal will normally exert and retain a significantly higher natural sealing force than the lip seals – even though these would be in a far harder material.

All seals which incorporate a rubber sealing element function on the basic 'O' seal principle which demands that, to respond to system pressure, the seal must be exposed to the pressure across its full radial width. The majority of these seals are therefore designed to float axially within the housing, or they may also be provided with ports across the full seal width so permitting the fluid to energize them. All these seals are therefore ideal for non-adjustable fixed-depth housings.

Depending on the installation of the equipment, seal replacement may demand that seals are in split form. Many of the latest shallow-gland seals are only supplied endless, and any seals that can function in split form will be of a multi-ring design requiring a deeper housing space. This aspect of subsequent seal replacement should therefore not be overlooked at the design stage.



Contact force *C* will be more than force *A* or *B*

Figure 15.70

So far, most of the emphasis has been around low pressures since this is the main cause of leakage. However, the high or operating pressures must not be overlooked. All the seals mentioned here are automatic, whether lip or squeeze type. They will be actuated by the pressure and so the critical element of the seal is its ability to resist extrusion at the side remote from the pressure source. This is achieved by various means – often the latest rubberized fabric compositions are themselves sufficiently strong, or nylon or PTFE heel elements will be used. In many designs the integral bearing elements also double as the anti-extrusion component.

Many seals use nylon/acetal elements that are in split form. This is primarily because of the high thermal expansion and water absorption characteristics of these materials which can significantly influence their sizes. While the change in radial section and depth will not be important, diametral changes can be considerable and a scarf split often allows this expansion to be resolved into a peripheral size change. If these components are not split they will usually have axial ports across them to provide unrestricted passage of the fluid to the seal.

For very high-pressure applications which can often incur expansion of the cylinder, anti-extrusion elements in phenolic resin-based materials are often employed and using a simple triangular shape is extremely successful since the pressure acting through the seal always ensures that this ring is forced directly into the area of the extrusion clearance. These materials are normally used as bearings and so do not suffer any effects of high radial loadings (they are also often supplied with a built-in lubricant). Furthermore, within their temperature range of around 100°C maximum they have a significantly higher resistance to shear than, say, nylon or PTFE.

Dirt excluders Ingress of dirt, etc. can cause both seal wear and, in particular, causes scoring of piston rods, hence all gland assemblies should ideally incorporate an efficient wiper. Typical shapes are as seen in Figure 15.71(a) – materials can be rubber, rubberized fabric, polyurethane or nylon.

Bearing elements Many units today, particularly the smaller sizes, employ synthetic bearing elements which can be in nylon, acetal, PTFE or, more often, phenolic resin. Most are simple rectangular section but 'T' section is also used, these being normally in nylon with axial pressure ports as shown in Figure 15.71(b). Regardless of the profile, it is important that these do not restrict the oil from reaching the seal – they must therefore always be split with a positive gap.

15.2.2.10 Seal selection

The ultimate question is: 'What is the best seal for a certain application?' This is a very difficult question and in most cases

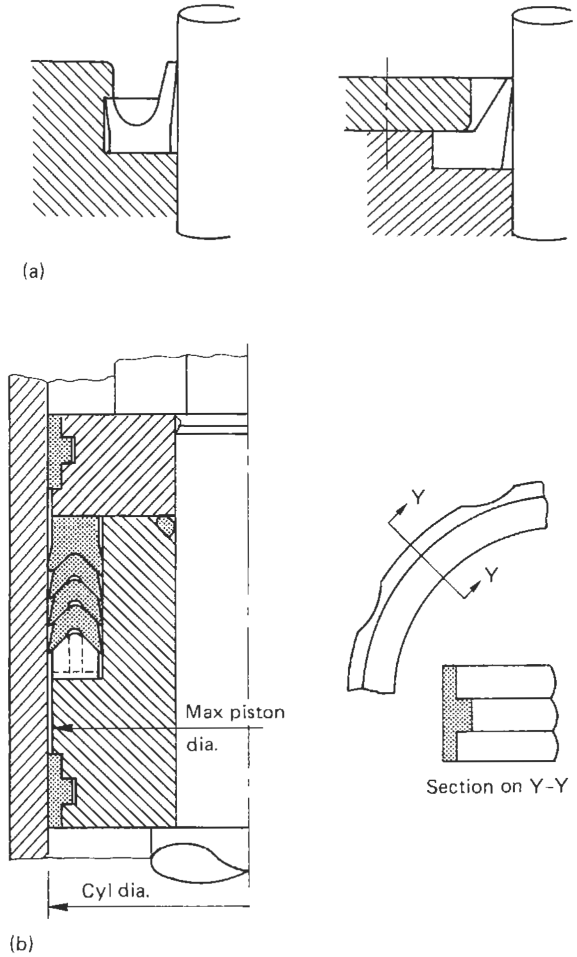


Figure 15.71

there will be many seal designs which will apparently meet the given conditions and yet appear significantly different in respect of material, size and price. The fluid power equipment designer can be forgiven for being confused.

The choice will often depend on the user's own experience and preference based on knowledge of the application. Schedule maintenance periods, accessibility, consequence of leakage, initial cost and availability will all play their part in steering the decision towards ultimate security or some other level of cost-effectiveness.

If in doubt or the application/conditions are unusual, then consult the seal manufacturers. If they are a reputable company they will express any reservations rather than offer a standard off-the-shelf product which will possibly experience premature failure. In recent times many applications have demanded a specially designed seal, but not all manufacturers are able to produce something special that is, to them, non-standard.

Having made a choice and being confronted with a range of overall sizes for a given diameter, the largest seal section available should be taken – not the smallest – other requirements allowing. The smaller the seal – whether lip or squeeze – the finer is the working tolerance band of interference and the lower is the capability for absorbing misalignment, vibration, adverse accumulative tolerances, etc. This applies equally to static and dynamic positions.

Even when the correct seal is selected, seals are, of course, prone to eventual failure – prior to failure of mechanical components. Most engineers and indeed end users accept this fact. However, 'correct' seals can fail prematurely through no fault of the seal and this can sometimes be associated with component failures. In many instances such failures can be avoided since the cause lies within the design of the equipment/unit. If the cause is known about in advance it can therefore be designed out of the unit.

15.2.2.11 Causes of seal failure

For many years most seal failures were attributed to either (or a combination of) extrusion of the seal, poor surface finish of the rods/cylinders, dirty fluids containing abrasives, etc. Combined with improved quality of machined metal parts, cleaner fluids are now used and seals are both superior in design and materials. These modes of failure are now far less common, but, with today's higher operating pressures and temperatures less obvious causes of seal failure are often encountered.

Air entrainment Within all hydraulic systems there will be some small percentage of air which, if trapped adjacent to a seal, can cause severe failures. Failure will not always occur and will be dependent upon the operating conditions, particularly the system pressure and the speed of the operating cycle. Seal failures can occur in the following two ways.

Explosive decompression Virtually all rubbers and rubberized fabrics are permeable to various degrees such that air under pressure can be forced into the seal material and will therefore be within the seal at system pressure – the longer the period at pressure, the greater the permeation into the material. The problem occurs when the system pressure is reduced, which will often be from e.g. 350 bar to atmosphere in perhaps a few milliseconds. At this point the air within the seal cannot slowly vent itself out but will expand rapidly such that the seal is severely damaged by splits or blisters. A simple analogy to this is the 'bends' suffered by divers when they are forced to surface too quickly.

The problem is more common with 'O' seals in valves used in multi-phase systems, primarily in the oil industries, but it has been experienced in hydraulic units. Much development work has taken place in the last few years and specialized elastomers are now available which have largely overcome the problem. These are based on fluorocarbon and are therefore suitable for both mineral oils and phosphate ester fluids. Should this mode of failure be encountered, a solution is now available.

With the rubberized fabric materials they tend to delaminate, but in developing harder materials primarily to resist extrusion these new fabrics are also less permeable, and so at least some of today's seals are less prone to this problem.

Dieseling This is a term often used to describe what happens when a pocket of air/oil mist self-ignites. It can occur when the rise in pressure is fast enough to cause a significant rise in temperature and hence ignition takes place. When this happens in the area of the seal it can cause severe localized damage and even melting of any nylon components. A typical case is in an inclined cylinder as shown in Figure 15.72, where air has become trapped adjacent to the piston seal, and possibly the gland seal, depending upon the position of the connecting ports.

Clearly, in any system serious attention should be given to eliminating the possible problems by trying to ensure that the minimum of air is present and that it can be vented if at all possible.

15.2.2.12 Axial length of seals

All seals fail in basically a similar way in that failure never occurs at the first point of contact with the fluid. With a 'U' ring or Chevron type seal the first lip is normally still in perfect condition since this will always be lubricated, and the failure happens beyond this towards the lower pressure side. This is because the subsequent lips and base of the seal still deform against the rod or cylinder under the hydraulic pressure but is often void of sufficient lubrication, and, obviously, the higher the pressure, the worse are the effects. The more modern squeeze seals do still fail eventually in a very similar way.

Many years ago, for higher-pressure applications the trend was to increase the depth of the seal, i.e. the number of rings, etc. but this is completely wrong, and many of today's most difficult applications are sealed perfectly with a shallow single-element seal. In principle, therefore, although it is sensible to opt for as wide a radial section seal as possible, the axial length must be carefully considered, as too deep a seal can in fact reduce seal life and cause premature failure.

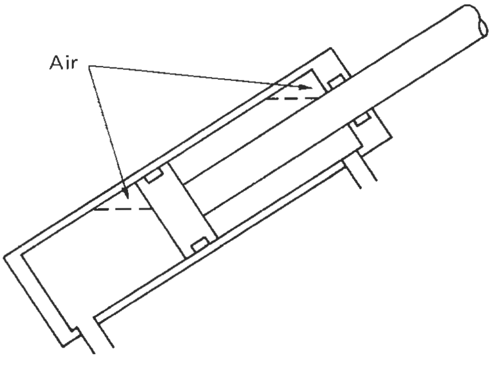

Figure 15.72

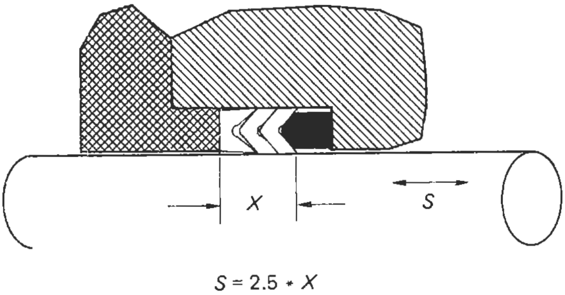

Figure 15.73 Short strokes

15.2.2.13 Short strokes

In a similar way, short-stroke applications can cause seal failures. Remembering that the vital fluid film is created by the movement of the rod through the seal, clearly a short stroke may not transport sufficient oil to the complete contact area of the seal. Also, a rod will not carry oil over the full length of its travel. With a seal length of, say, 50 mm a minimum stroke movement of perhaps 150 mm/200 mm will be necessary for oil to reach the full axial length of the seal. If this does not happen the seal may fail simply due to lack of lubrication. A typical sequence is that the 'dry' area towards the low-pressure side of the seal wears and particles of fabric are then dragged towards the forward sealing edge where they effectively become adhered to the seal and so create an uneven contact area and hence leakage. For short-stroke applications it is therefore important to use shallow seals, and a 'rule of thumb' is to ensure that the stroke length is at least two to three times that of the seal's contact area – as indicated in Figure 15.73.

15.2.2.14 Drag flow

This is a term often used to describe the effects of oil within a close clearance between a static and dynamic component. The first time the writer witnessed this was many years ago during tests to establish the friction characteristics of seals using a simple test rig as shown in Figure 15.74, where the right-hand seal had been replaced by a close-fitting bush. During the tests leakage through this bush would be expected, so providing a true friction value for the seal in the left-hand housing. During the tests leakage readily occurred with the rod moving to the right, but when moving to the left, no leakage developed, despite the system pressure of 350 bar!

The effect of this has been shown to be the cause of certain seal failures. A classic case is with a gland seal on a double-acting unit where, quite often, the gland seal will be subjected to exhausting oil when the rod emerges, and often only a relatively low pressure sufficient to return the rod on the inward stroke, i.e. a typical down-stroking press. Under such conditions seals have failed clearly as a result of being subjected to very high pressures, resulting in wear and extrusion, etc., although, according to the system, perhaps only 50 bar is used on the return stroke. With a close-fitting bush as shown in Figure 15.75 the following has been shown to happen.

On the emerging stroke (with low-pressure oil adjacent to the bush) oil is dragged by the movement of the rod towards the seal. On the inward return stroke slightly less oil is dragged back through the bush because of the return system pressure now acting adjacent to the inboard clearance between the rod and the bush. Therefore, during each cycle slightly more oil is transported towards the seal than is returned and, depending upon the frequency of operation, high pressures can be created at the seal. This then causes problems, since the seal is effectively under a constant energizing pressure which results in insufficient oil reaching the rear of the seal contact area. Hence possible failure occurs as described in earlier sections.

This possible mode of failure is easily prevented by simply ensuring that there is a 'hydraulic link' across the bearing

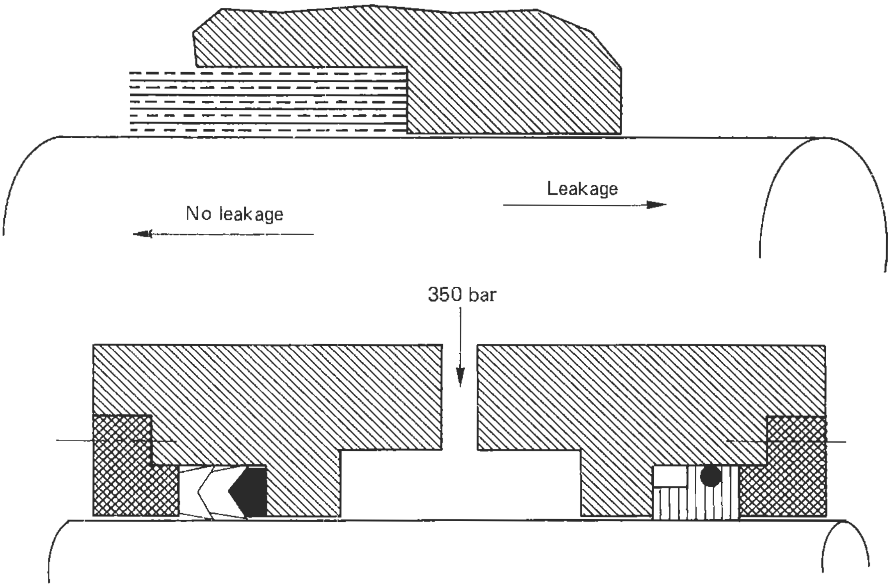

Figure 15.74 Drag flow

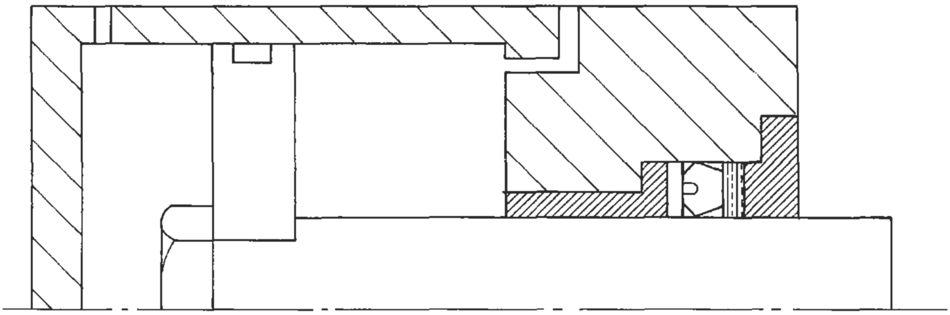

Figure 15.75

element either by holes through it or, more simply, by one or two small axial slots milled down the inside of the bush, or, if preferred, a spirally machined groove – all of which achieve the desired effect.

15.2.2.15 Pressure trapping

This is a situation that can develop between any two seals – it can cause seal failures and/or fracture of metal components of the gland or piston head. It can potentially develop if two seals are used which are of the type that can effectively be double-acting. In general, this applies to most of the more modern squeeze types even though they may appear supposedly as single-acting seals. There are various theories as to how this phenomenon develops but the writer's view is as follows.

Referring to Figure 15.76, i.e. using two simple 'O' rings on a double-acting piston, with the piston moving to the left, seal A is energized by the system pressure but seal B is relaxed and will therefore allow a minute degree of leakage across the seal into the centre space. Even if the centre space is full during this stroke, seal A, because it is pressurized, will not allow the same degree of leakage across it and therefore out from the centre position. On the reverse stroke, exactly the same thing happens, i.e. seal B is energized, but seal A, being relaxed, will allow a small leakage across it into the centre space. Hence, during each cycle, oil is forced into this centre position but never out of it, and so this space soon becomes permanently pressurized. As this happens the seals try to extrude outwards and, depending upon the seal type and profile, this in itself can encourage further movement of oil across the seals into this space.

In practice, this trapped pressure can become significantly higher than the system pressure such that piston components are under stress from the reverse direction and can fracture as shown in Figure 15.77.

Often there are symptoms revealed that indicate that this phenomenon is starting to develop. Because the *two* seals are now permanently under pressure, excessive friction is occurring. This may then cause the unit to become hot and if the seal incorporates nylon components the cylinders may emit squeaking noises. Also, the speed of the component may slow down and eventually stop. This is more likely the smaller is the diameter of the cylinder such that the developed thrust is lower in relation to the friction of the seals, than will be the case in a large diameter unit.

In cases where seizure has occurred the pistons have often required to be mechanically winched out of the cylinder. To prevent this possibility, two double-acting seals must never be used on the same component, i.e. piston (this should never be necessary since one such double-acting seal should be sufficient – but it has been known to happen!). If two opposed seals are essential, at least one of these must be a true single-acting type such that it can automatically vent any potential build-up of pressure between them. The same argument applies to a gland situation in cases where 100% leak-tightness is required by the fitting of a second (i.e. back-up) seal – the *inner* seal must be a single-acting type.

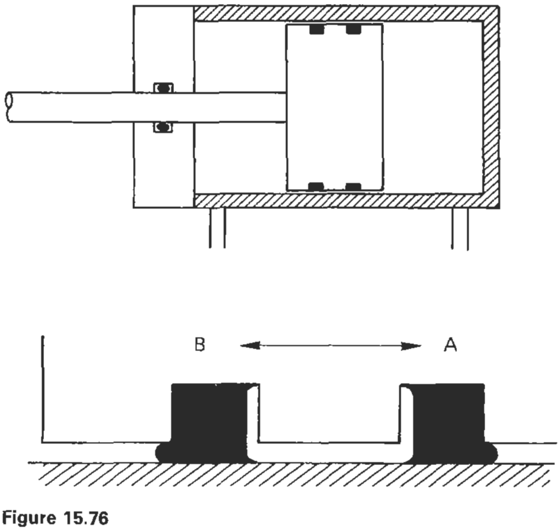

Figure 15.76

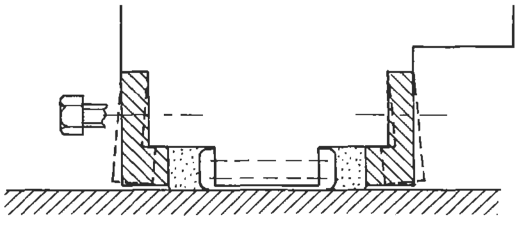

Figure 15.77

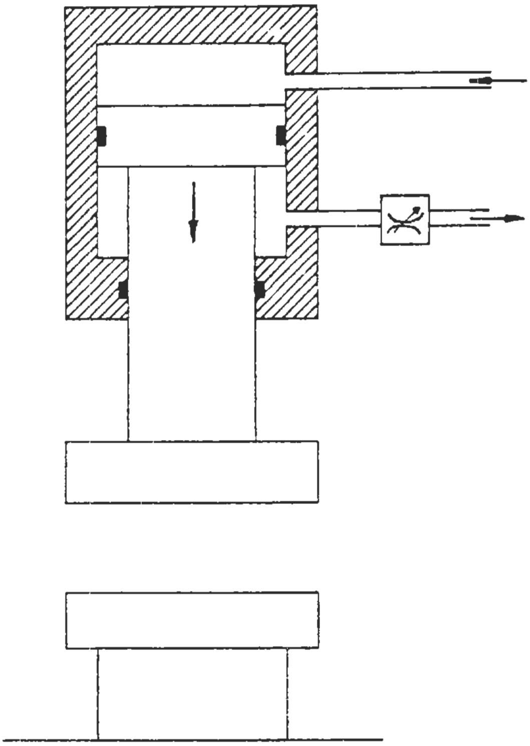

Figure 15.78

15.2.2.16 Exhaust pressures

Exhaust pressures from a double-acting cylinder can cause both seal and gland component failure. The typical way of controlling the speed of a unit is to use a flow control valve in the line so as to restrict the exhausting oil. This achieves a smooth and controlled speed of the unit.

By referring to Figure 15.78 it will be appreciated that during the emerging stroke, depending upon the difference in the diameters of the rod and cylinder, the resultant pressure in the exhausting annulus side can become higher than the inlet pressure to the full piston area. In most instances no apparent problems are encountered but in situations where the system can incorporate gas/oil accumulators, disastrous results have occurred.

In Figure 15.79 it is seen that *without* an accumulator in the system full system pressure will probably not develop until the press actually closes, but with an accumulator, the full system pressure will be applied *during* the closing/approach stroke. In many units the difference between the rod and cylinder diameters is quite small and therefore the developed pressure on the annulus side is equal to the system pressure × [AREA A]/AREA A − AREA B).

Normally the difference in cylinder area to rod area is quite small. Hence pressures during the emerging stroke can be in fact many times the system pressure but in the majority of systems this exhaust pressure is never monitored. Most systems only have gauges showing the system pressure being delivered by the pump. The effect of this extremely high pressure in the annulus side is to cause premature seal failure. This is bad enough, but the more serious effect is that the cylinder and the gland components are being subjected to

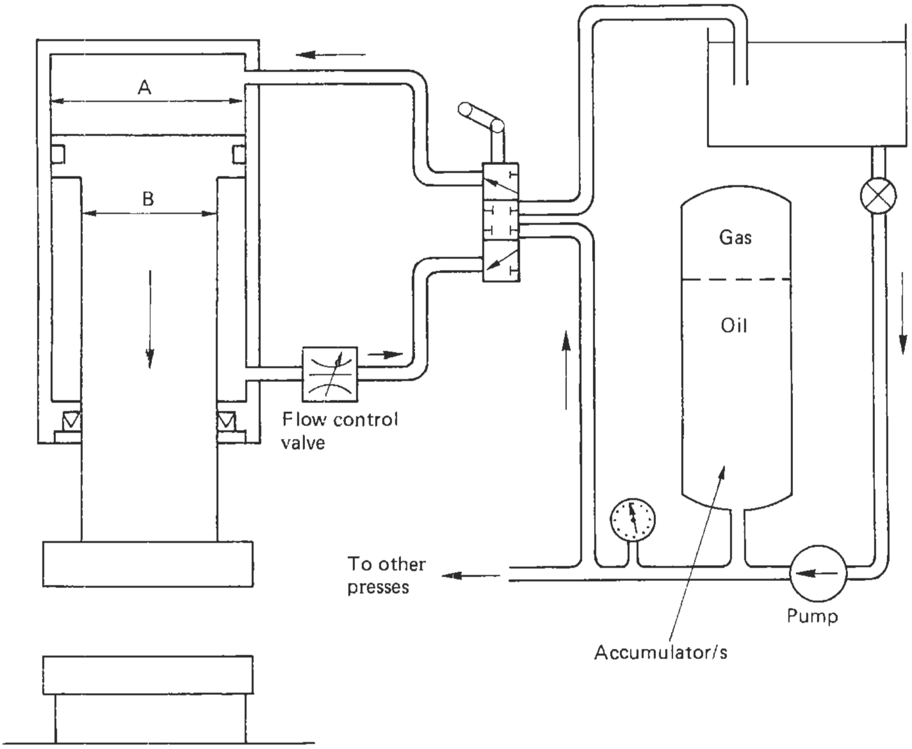

Figure 15.79

pressures far in excess of their design limits, and it is not uncommon to find that all the gland studs have sheared!

This 'unseen' problem can only be overcome by placing some form of flow control on the *inlet* to the piston side of the cylinder which then gives a 'comparable' flow rate in relation to the flow control of the exhaust side – which is often still necessary on larger down-stroking units.

15.2.2.17 Conclusions

This section has not attempted to identify the correct seal for any particular application but it is hoped that it may have at least pointed in the right direction in both the important aspects of the design of the seal housing, etc. and provided sufficient basic information for making a tentative selection of the most suitable seal type to use. It cannot be over-stressed that to consult a seal manufacturer regarding the final seal choice is well worth the cost of a telephone call or time involved in a discussion. It could save both you and your customer considerable time and expense at a later date.

Apart from the selection of the most suitable seal, applying the following rules should assist in obtaining the best out of your unit and may well prevent premature seal and/or component failure:

1. Pay careful attention to seal housing design, i.e. extrusion clearances, etc.
2. Use the widest radial width of seal rather than the narrowest.
3. Endeavour to prevent air entering the system and make provisions for venting – particularly during initial commissioning.
4. Ensure that bearings do not restrict fluid from reaching the seal – provide a positive hydraulic link across/through the bearings.
5. Be cautious when controlling actuator speeds by throttling of the exhausts – check whether excessive pressures are being created.

15.2.2.18 The future

It is unlikely that any radical new seal designs will suddenly emerge. Most so-called new designs are a modification of a well-established sealing concept although minor changes can, of course, give improved performance. The main area of change is in respect of seal materials to give improved properties, i.e. better resistance to extrusion and less friction and wear, etc. In this respect seals are now being manufactured in PTFE-loaded rubbers and rubberized fabric compositions with a PTFE-loaded proofing on the contact surfaces. These early tests are giving excellent results and such seals will become more common in the near future. Also, considerable development is taking place with polyurethane and future materials with a higher-temperature capability could significantly increase its use within the sealing industry.

15.2.2.19 Guidelines on storage

BS 3754: 1963 'Storage of vulcanized rubber' was prepared under the authority of the Rubber Industry Standards Committee and includes the following recommendations:

> 'Most vulcanized rubbers change in physical properties during storage and ultimately may become unserviceable, for example, because of excessive hardening, softening, cracking, crazing or other surface degradation. These changes may be the result of one particular factor or a combination of factors, namely, the action of oxygen, ozone, light, heat and humidity. The deleterious effects of these factors may, however, be minimized by careful choice of storage conditions.
>
> *Recommendations*
>
> Temperature
> The storage temperature should be below 25°C and preferably below 15°C. At temperatures exceeding 25°C certain forms of deterioration may be accelerated sufficiently to affect the ultimate service life. Sources of heat in storage rooms should be so arranged that the temperature of no stored article exceeds 25°C. The effects of low temperature are not permanently deleterious to vulcanized rubber articles but they may become stiffer if stored at low temperatures and care should be taken to avoid distorting them during handling at that temperature. When articles are taken from low-temperature storage for immediate use their temperature should be raised to approximately 30°C throughout before they are put into service.
>
> Humidity
> Moist conditions should be avoided; storage conditions should be such that condensation does not occur.
>
> Light
> Vulcanized rubber should be protected from light, in particular direct sunlight and strong artificial light with a high ultraviolet content. Unless the articles are packed in opaque containers, it is advisable to cover any windows of storage rooms with a red or orange coating or screen.
>
> Oxygen and ozone
> Where possible, vulcanized rubber should be protected from circulating air by wrapping, storage in airtight containers, or other suitable means; this particularly applies to articles with large surface area-to-volume ratios, e.g. proofed fabric, cellular rubber.
>
> As ozone is particularly deleterious, storage rooms should not contain any equipment that is capable of generating ozone, such as mercury vapour lamps, high-voltage electrical equipment, electric motors or other equipment which may give rise to electrical sparks or silent electrical discharges.
>
> Deformation
> Vulcanized rubber should, wherever possible, be stored in a relaxed condition free from tension, compression or other deformation.

High quality requirements for storage and periodic inspection such as those specified by the Aerospace industry are obtainable from BS 2F.68: 1963, 'Recommendations for the storage and inspection in store of vulcanized rubber items'.

15.2.3 Rotary shaft lip seals

15.2.3.1 Introduction

The spring-loaded rotary shaft lip seal, as shown in Figure 15.80, is widely used to retain operating media/system lubricants and to exclude foreign matter from within mechanical equipment with rotary shafts. This section explains important principles of operation with a review of basic seal types with materials in typical use and fluid compatibility being examined.

The nature of most designs precludes the use of this type of seal from operating at significant pressures unless the sealing lip is adequately supported by a shaped plate. For pressure conditions much in excess of 2.0–3.0 bar, combined with a rotary shaft, it would be preferable to consider the use of either a compression packing or a radial face mechanical seal.

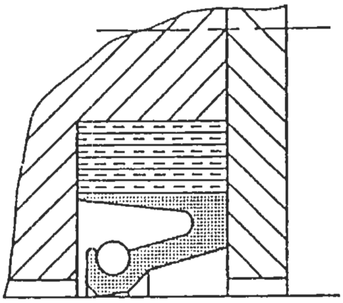

Figure 15.80 Standard fabric back seal with retaining plate

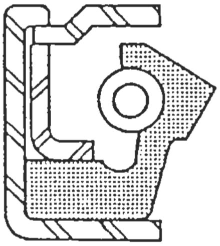

Figure 15.82 Typical metal-encased seal

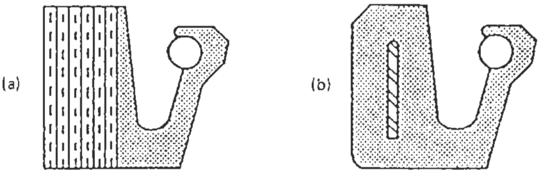

Figure 15.83 (a) Standard fabric back seal; (b) moulded-in flexible steel band self-retaining seal

15.2.3.2 Method of operation

The lip seal as we know it today has changed little in component parts and shape from its pre-war concepts. Originally, leather was the boundary-lubricated contact material but now elastomers predominate in a range of products that are intended for liquid/gas interfaces. The lip profile can be produced in as-moulded, ground or knife-cut condition – the last being demonstrably superior and the most common form of finishing used in contemporary products. In simple terms, the integrity of the seal leakage performance relies on the meniscus effect shown in Figure 15.81, which was first researched by Dr Ernest Jagger of the George Angus Company in Wallsend.

It should be remembered that this stable hydrodynamic film characteristic takes time to establish on start-up and diminishes to a boundary condition again when shaft rotation is being reduced towards stop. Most aggravated wear problems occur in the boundary regime and elastomers must be formulated to suit.

15.2.3.3 Design

A wide variety of lip seal designs is available in terms of overall construction, material and lip profile. Some are intended for fitting in housings which have no separate cover plate and may be supplied with a rigid metal case to which the seal is bonded – the unit being a force fit in the housing (Figure 15.82). Others have the advantage of flexibility by virtue of having a proofed fabric back (Figure 15.83) while requiring the provision of a retaining plate to nip axially the back of the seal to prevent leakage and obviate rotation. More recent developments combine the merits of flexibility and self-retention in a metal-supported all-rubber configuration (Figure 15.83(b)).

One of the several advantages of the fabric back seal is the facility with which split seals can be fitted without reducing performance which, in many cases, is of the same order of efficiency as an endless ring. A rubber inlay is frequently moulded into the back of such a seal through which the split is effected. The rubber abutment which results ensures good sealing across the split portion. Where shaft dynamics are encountered, this split seal may not provide the degree of sealability required – for such aplications on-site joining is necessary and one method is described later in this section.

The profile of the lip contact area is subject to each manufacturer's design philosophy. Some have a knife-edge contact band and rely on heavy as-moulded lip interference. Others depend on the spring tension to urge the lip into intimate shaft contact. In practice, a careful balance of interference, spring characteristics and contact band width must be allied to knowledge of the type of material being used, bearing type and condition and other environmental considerations such as temperature, fluid and, if any, pressure. A typical range of seal profiles is shown in Figure 15.84, which also illustrates the expedient used when insufficient space is available to accommodate a pair of seals, i.e. the so-called dust lip design.

Finite Element Analysis is extensively employed for the optimization of seal lip designs. This eliminates much costly physical testing and many sophisticated techniques are available for examining both hydrodynamic fluid film characteristics under given conditions and the non-linear properties of

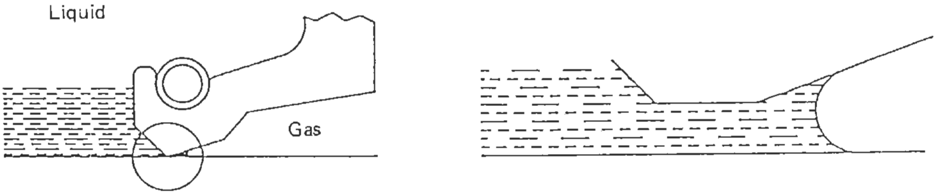

Figure 15.81

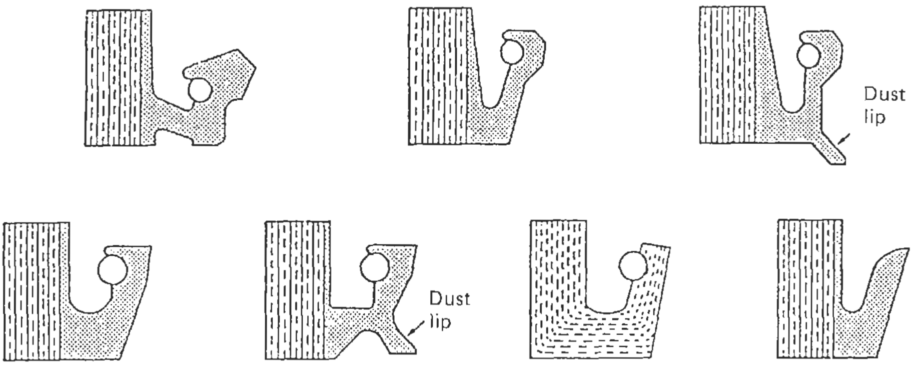

Figure 15.84

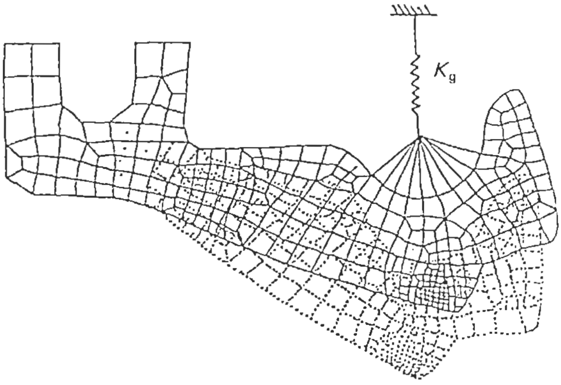

Figure 15.85

complex elastomer formulations which can contain sophisticated additive packages (Figure 15.85).

15.2.3.4 Material

Nitrile-base synthetic rubber compounds are widely employed as standard materials by reason of their compatibility with most lubricating oils and greases and their resistance to wear. There are, however, certain fluids which may cause excessive swelling or shrinkage of such polymers and a fluorocarbon rubber (e.g. Viton) may be a necessary selection. This is particularly true of some palm-oil solutions and other soluble types of oil.

Consideration for operational temperature is important and, in this respect, it is the condition at the lip of the seal which is paramount – not necessarily the environmental temperature. However, it may be said that nitriles are frequently used with success for intermittent service temperatures of 150°C and are continuously rated for 120°C in lubricated conditions. Above these values acrylic rubbers, fluorocarbon or silicone compounds would require investigation.

Many silicone and nitrile rubber shaft seals are fitted in automotive applications for crankshaft and gearbox sealing, in which areas much use is being made of grooved sealing surfaces that are designed to produce a hydrodynamic effect in the oil film being sealed, effectively causing the oil to be pumped away from the seal lip (see Figure 15.86).

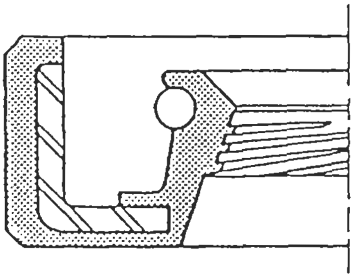

Figure 15.86

Table 15.15 gives a broad indication of cost to temperature and fluid performance. In the past, user selection judgement has been driven totally by cost considerations where an NBR seal would, for example, be selected for continuous running at 120°C. The right choice for much wider performance safety margins would have been a commercial FKM product rated to 180°C where the extra cost would be well justified in terms of operational lifetime and sustained reliability.

Another point worth flagging concerns low-temperature flexibility which can frequently be the Achilles' heel of a wide range of equipment involving working capabilities below −10°C. As temperatures approach the glass transition point of elastomers, stiffening of the material can produce significant changes in seal hysteresis effects in relation to shaft dynamics.

Out-of-phase frequencies that result can often lead to aggravated leakage conditions. Grades of VMQ (silicone) and low-nitrile versions of NBR elastomers are available for such duties. Low-temperature versions of FKM rubbers have become established in more recent times.

Table 15.15

Material	*Oil resistance*	*Temperature range (°C)*	*Price indicator*
NBR (nitrile)	Good	−20 to 120	1.0
ACM (polyacrylic)	Good	−10 to 130	1.5 to 2.0
VMQ (silicone)	Fair	−40 to 180	3.0
FKM (fluorocarbon)	Excellent	−25 to 180	5.0 to 10.0

In the overall sense, temperature has a more direct effect on seal materials than oil resistance (excluding fire-resistant fluids of the phosphate ester type). A reduction of even 10°C can produce disproportionate advantages in seal-lifetime terms for any given material. Greater attention to cooling and oil flow rates through equipment can have considerable benefits to actual under-lip temperatures which will frequently be 30–40°C higher than general sump temperatures.

Where systems cannot be changed and overheating has been identified, possible solutions can be found in highly developed liquid surface modifiers which are typically used in a ratio of 1:20 dilution with the specified lubricants. These surface modifiers are preferentially attracted to hot metallic dynamic interfaces and offer durable benefits.

15.2.3.5 Seal lubrication

In common with most other forms of dynamic seal, rotary shaft lip seals depend for their efficient and consistent performance upon the presence of a stable fluid film. The establishment of this film, which will typically be in the order of a few microns' thickness, may not occur immediately and it is not uncommon for a high percentage of wear to be observed on rotary shaft seal lips during this period before steady-state conditions are achieved. For this reason, it is always good practice to apply a lubricant to the seal lip and in the seal cavity before fitting.

Where single seals are housed at each end of the housing there is normally sufficient bearing lubricant in contact to provide adequate lubrication. Again, where two seals are housed together, it is often found that with bearing lubricant on one seal and fluid on the other, further lubrication is unnecessary. In all cases the liberal application of grease to the seals on assembly will ensure lubrication from the beginning, and in some instances this will be found sufficient to last from one fitting to the next.

However, there are many sealing arrangements in which two or more seals are fitted together in the same housing and there is the danger that at least one will run dry unless lubricant is supplied from an external source. This can be best accomplished by drilling a hole through which connects with an annular groove in the back of the seal housing, as shown in Figure 15.87, and using a special type of seal which has a series of radial ports in the base for passage of lubricant to the seal lip. When it is difficult or impossible to machine an annular groove in the back of the seal housing, this groove may be incorporated into the seals themselves as shown in Figure 15.88.

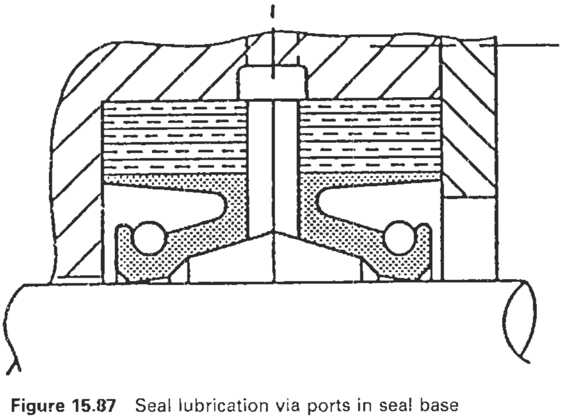

Figure 15.87 Seal lubrication via ports in seal base

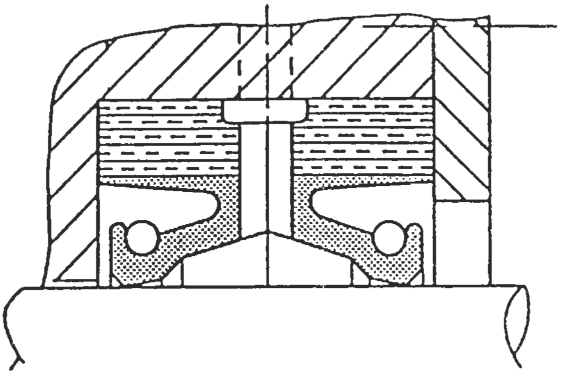

Figure 15.88 Seal lubrication via ports and annular groove in seal base

In general, a good-quality mineral oil or grease is suitable for seal lubrication, but molybdenized lubricants may be used to advantage where application is infrequent. Care should be taken to ensure that the grease or lubricant with which the seal is to come into contact is compatible. For example, where seals are being used with dilute mineral acids, butyl compositions may well be used. This material is likely to swell in contact with mineral oil or grease and an alternative lubricant will be essential.

15.2.3.6 Liquid/liquid interface

In submersible arrangements multiple seal assemblies are required to maintain oil and water separation. Figure 15.89 shows a typical marine stern gland where five seals are used to separate sea water from bearing lubricating oil. In this situation it is difficult to ensure the correct liquid/gas interface necessary for the establishment of stable hydrodynamic film conditions. Where liquid/liquid interfaces develop, the seal will see more contact with the shaft than intended and severe under-lip temperature hikes can result.

If the seal material has absorbed any liquid (usually water) vaporization can occur, leading to the formation of thin-skinned blisters. Rotation of the shaft removes this skin and pockmarking of the running face will result (see Figure 15.90).

Catastrophic failure can follow in the most severe cases. To resist these effects it is necessary to use a highly developed FKM compound which is an oil-industry benchmark standard to resist explosive decompression in 'O' rings and other seals subject to gas mixture absorption and subsequent rapid decompression. The mechanisms of explosive decompression and lip blistering are similar and can be resolved with the same FKM material.

15.2.3.7 Shaft surfaces

The sealing area of the shaft should be a fine ground finish of 0.4–0.8 μm R_a for most applications but, for the higher speed range, it is recommended that the surface finish be improved to 0.2–0.4 μm R_a In all cases it is important that the shaft sealing area be free from machining marks, dents, burrs and scratches. Where fluorocarbon or acrylic rubber seals are being employed, it is also advisable to use the finer level of finish indicated above in order to eliminate pick-up of the seal material. If lubrication is adequate and free from abrasive contact, unhardened mild steel shafts will generally give satisfactory results under normal operating conditions.

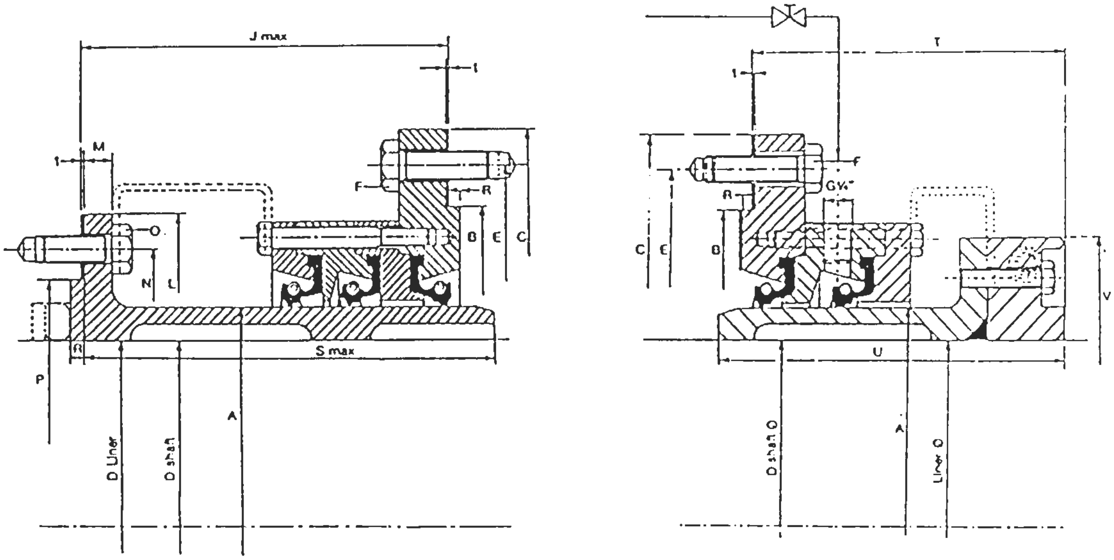

Figure 15.89

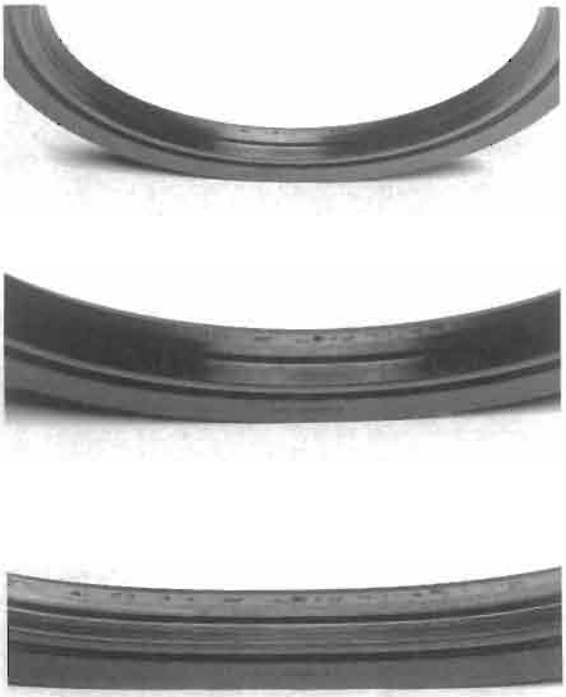

Figure 15.90

However, a harder shaft material is to be preferred for applications where lubrication is poor, abrasives are present, or speed and pressure conditions are particularly arduous. A fine machined finish is suitable for the housing bore.

Avoid methods of finishing shafts which produce unidirectional spiral patterns. These have frequently caused external 'pumped' leakage of the fluid being sealed.

15.2.3.8 Friction

The rubbing friction of the seal lip on the shaft material inevitably causes a higher local temperature than is present in the fluid being sealed. This effect will be due to the interference of the seal lip on the shaft material and may be aggravated by inadequate lubrication or speeds in excess of that for which a particular seal was designed. Assuming the system temperature to be well within the bounds of the material capability, a high differential between lip-tip temperature and fluid temperature will be manifested in many cases by hairline cracks in the seal lip co-axial with the shaft. Local carbonization of the rubber compound will also be evident.

Figure 15.91 indicates a set of curves derived by experiment, projecting frictional power loss against seal diameter for a conventional rotary lip seal design operating at 500 rpm in mineral lubricating oil at different system pressures.

15.2.3.9 Speeds

Many of the fabric-backed type of seals together with those of the metal-supported type are working satisfactorily on 400 mm shaft diameters at speeds of up to 25 m s^{-1} over sustained working periods. There are, however, many factors such as surface finish, eccentricity and lubrication which can limit the maximum speed for which any seal is suitable and manufacturers should be consulted in cases of doubt.

15.2.3.10 Eccentricity

Where plain metal or synthetic composition bearings are being employed, it is not uncommon to find that the shaft is not truly concentric with the seal housing owing to bearing clearance and wear. In this event, it is essential for efficient sealing that the seal lip be capable of following all shaft movement and, indeed, on many large comparatively slow-moving shafts, eccentricity values of 2.5 mm have been satisfactorily accommodated. Naturally, the seal performance in terms of eccentricity capability will be speed and shaft diameter dependent.

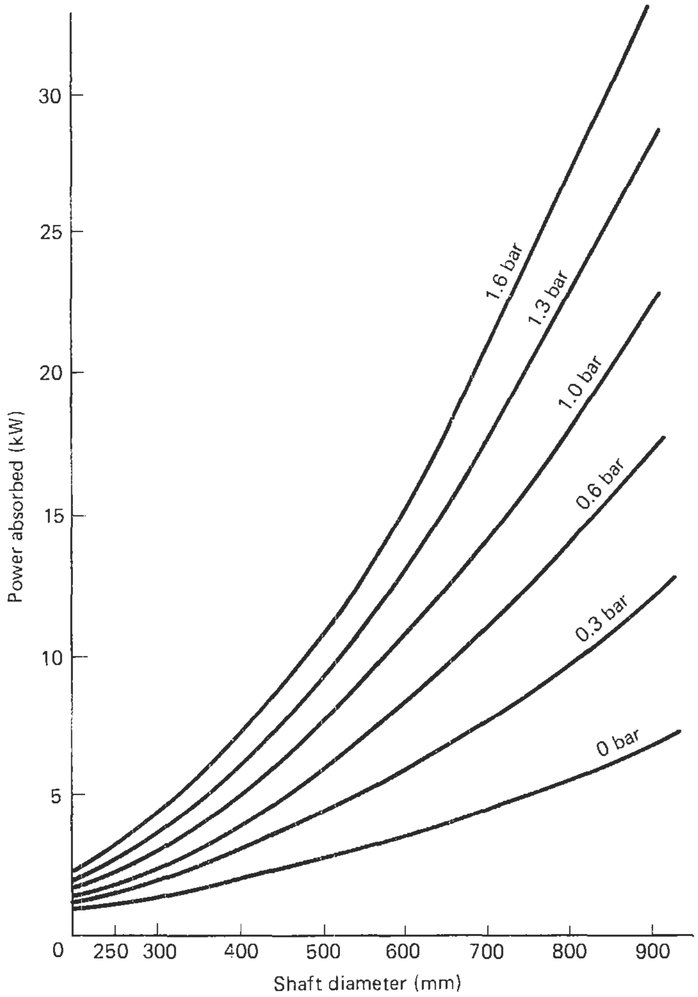

Figure 15.91 Frictional power absorbed rotary shaft lip seals, having conventional lip interference, operating at 500 rpm. (These values are conservative and are given as a worst-case guide)

Where split seals are fitted, then particular consideration is necessary to the problem of shaft eccentricity, since there may be a tendency for a split seal to open at the join. (See Section 15.2.3.14.)

15.2.3.11 Pressure

Although few rotary shaft lip seals are specifically designed as standard components to accept significant pressure, the use of metal supporting plates will extend the usefulness of this type of seal. A typical profile is shown in Figure 15.92. As a result of experimental work on the sealing of oil-filled marine stern glands and manoeuvring thrusters, a seal lip profile has been developed which satisfactorily sustains pressures up to 4.0 bar without the use of a shaped support plate. The base must be fully supported as indicated in Figure 15.93.

Where constant applied pressure is not anticipated it is frequently suggested that grease-lubricated bearings are equipped with relief holes and that oil-lubricated bearings have drains of adequate size. Drains taken from the ends of the bearing near the seals will help to dissipate any localized pressure build-up. Where possible, steps should be taken in bearing design to prevent escaping high-pressure oil impinging directly upon the seals.

In some cases, where the loss of a small amount of grease is unimportant, a simple relief system may be formed by facing seals away from the bearing and allowing the seal lip to be lifted under the influence of the lubricant pressure.

15.2.3.12 Flexible throttle bush

There is a unique and patented development which can throttle system pressure to lip seal positions in a wide variety of pressurized transmission arrangements. Operating on a simple pressure balance principle that tilts the bushing to give a minimum exit clearance on the fluid film beneath it (see Figure 15.94) the product is used in conjunction with a vertical drain to tank which leaves the lip seal functioning against slack pressure. This advantage has widespread implications to the PV capability of seals in high-speed gear trains at the expense of a small additional requirement in axial length of the total seal assembly. (See Figure 15.95.)

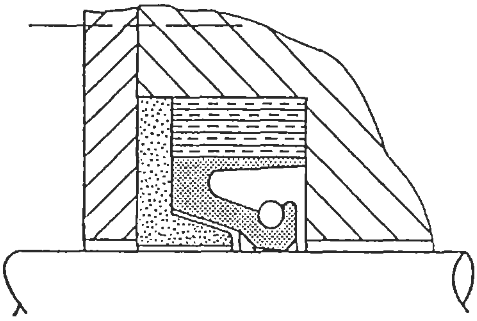

Figure 15.92 Seal with shaped support plate for pressures up to 3.0 bar

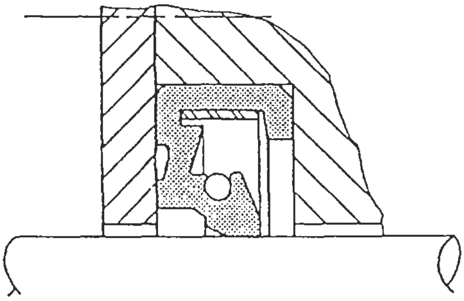

Figure 15.93 Seal development for pressures up to 4.0 bar without shaped support plate

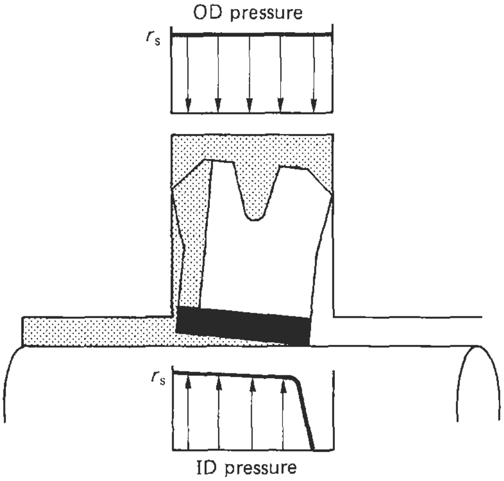

Figure 15.94

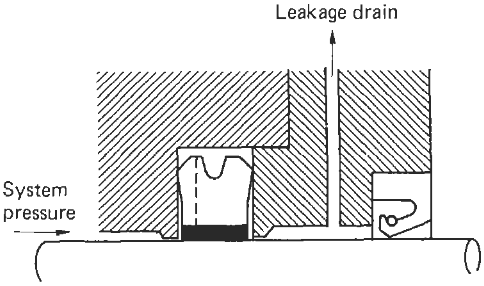

Figure 15.95

15.2.3.13 *Care and handling*

Fluid seals should be handled at all times with extreme care since the life of bearings or other costly machine parts may depend upon their efficiency. Attention to the following vital points will assist in ensuring trouble-free operation during service.

Storage

1. The store should have a cool, clean and dry atmosphere, free from dust and grit.
2. Whenever possible, seals should not be removed from the wrapping in which they were supplied as this provides protection and identification.
3. Avoid untidy stacking as the weight may distort the seals at the bottom of the stack.
4. Seals should never be threaded on wire or string as this will damage the lips.

Handling

1. It must be remembered that seal lips are extremely vulnerable to damage and the smallest nick provides a potential leak path.
2. Seal-reinforcing inserts, although adequate for their duty, may deform under adverse handling or stacking.
3. Seals having metal outside surfaces may damage other seals, especially if the metal edges contact the rubber parts of neighbouring seals.

Fitting A high proportion of failures and leakage of oil seals is due to incorrect fitting resulting in damage to both seal and sealing surface. Strict attention to the following matters is essential if best performance is to be obtained:

1. Before fitting, the seal should be examined to ensure that it is clean and undamaged.
2. The sealing lip should be smeared with suitable clean lubricant. Seals used as dust excluders should be packed with a compatible grease.
3. Normally, the sealing lip should face the fluid to be sealed.
4. When fitting, it is important to ensure that the sealing lip is not damaged even by the slightest nick, that the spring is correctly located when in position and that the seal is properly pressed home into the housing recess.
5. Examine the shaft, which should be free from all roughness and sharp edges and avoid passing the sealing lip over keyways, screw threads or shoulders. Shaft edges or shoulders should be well rounded or chamfered and where this is not practicable, a fitting sleeve slightly larger than the shaft with a lead-in taper should be used.
6. According to the type of assembly, it may be necessary either to press the seal first into the housing and subsequently on to the shaft, or alternatively, to pass the seal over the shaft and then press it into the housing. It is preferable first to mount the seal on the shaft where circumstances permit, since this allows observation of the lip during assembly.
7. The assembly should not be allowed to rest for any length of time at an incomplete state of fitting where the weight of

the shaft or housing may be borne by the seal, resulting in damage or distortion to the latter.

8. When pressing the seal into the housing a uniform pressure should be exerted, preferably by means of an arbor press in combination with a suitable tool. The diameter of the tool should be slightly smaller than the diameter of the housing by 0.1–0.4 mm. The outside surface of the seal can be smeared with a suitable lubricant in order to facilitate fitting. Care must be taken to ensure that the seal does not enter the housing recess in a tilted position since this will cause damage to the outer surface.

Figure 15.96 shows a range of typical fitting tools.

15.2.3.14 On-site joining technique

The advantages in terms of maintenance and downtime of having split and abutted lip seals is obvious, since extensive dismantling is avoided. The performance of these fabric backed split lip seals – where the abutment is located through a solid rubber inlay – is frequently acceptable. However, where shaft dynamics are severe, greater leakage may be encountered than with the fully moulded endless product.

Where such leakage is unacceptable but the benefits of assembling a split seal are also required, a new on-site joining method has been developed which precludes the need for costly and cumbersome vulcanizing methods. The kit comprises:

- A split fabric back seal adapted to incorporate a plastic circumferential insert at its join interface.
- Two-part epoxy adhesive in measured quantities. The epoxy cures to a semi-rigid state.
- A joining jig in silicone rubber precision moulded to the exact internal profile of the seal.
- A steel adjustable clamping band.

Full training in the use of the technique is made available by the manufacturers. See Figure 15.97.

The following two sections detail a number of fault-finding procedures which, if taken in sequence, should analyse the reason for a given difficulty.

15.2.3.15 Trouble-tracing

Unacceptable leakage This is almost always associated with oil-lubricating bearings, since grease is not a difficult lubricant to seal. The term 'unacceptable' can have wide interpretation since an occasional drop of oil might be disastrous if it resulted in contamination of the product being handled by the machine concerned in such spheres as the textile, paper or food industries, while it would probably remain unnoticed in a heavy industrial environment.

Cost and consideration for the environment have caused much greater sensitivity to oil losses in any form and leakage rates that hitherto have been ignored are now becoming regarded as unacceptable. When dealing with such complaints it is essential to discover the history of the equipment concerned and this broadly falls into three categories.

I New equipment recently commissioned, where sealing has been regarded as unsatisfactory from the start;
II Equipment that has been in operation for a period of time and only recently has developed leakage problems;
III Equipment that was satisfactory during its first term of operation but leakage has occurred after fitting replacement seals during routine maintenance or overhaul.

Since trouble tracing is basically a process of eliminating or substantiating suspected faults, the sequence of checks required would vary with each of the above categories.

In order to simplify the procedures and avoid irrelevant investigations, the recommended sequences for each of the above categories are defined by letter symbols to be used in conjunction with the fault-finding chart which follows.

Category I Full checks in order as A, B, C, D and E until fault is discovered.

Category II A, B, C(1), D(2), and D(3). If faults as C(1) or D(2) are exhibited, ascertain period of service with seals. This should be calculated in terms of hours of running and related to speed, temperature and other environmental conditions. A moderate speed with good clean lubrication conditions and ambient temperatures would normally anticipate a seal life of around 10 000 hours. High speeds, poor lubrication, elevated temperatures or partially abrasive media could reduce this to as little as 2000 hours. The problem may therefore be simply that of being due for seal replacement.

If faults as in D(3) are in evidence, obtain details of all media in contact with seal (including any cleaning fluids) as a change of lip material may be necessary to obtain compatibility. If seals display no faults check for mechanical defects as E(1) and E(2).

Category III A, B, C(1), C(3), D(1), D(3), D(4), E(1), E(3).

15.2.3.16 Fault-finding chart

(A) Is leakage actually occurring from the seal or does it stem from such sources as bearing cover flanges and is merely 'collected' by the seal housing, giving a false impression? Check by wiping clean all appropriate areas and run machine to ascertain leakage source.

(B) Is leakage from around seal back or from the lip along the shaft? Check by wiping both clean and observing while machine is running.

(C) If O/D leakage – check the following:

  (1) Is seal a good fit in housing or is it slack? (On split seals a slack seal will display a gap between seal ends.)
  (2) If housing bore is correct size then seal O/D dimension is suspect if slack in housing.
  (3) If seal is good fit in housing, check for damage on housing bore.
  (4) Check housing depth to ensure seal is being axially compressed – if applicable.

(D) If leakage along shaft check the following:

  (1) Shaft size, surface finish, shaft damage at contact area.
  (2) If (1) okay, check condition of sealing lip for hardening and/or cracking. If either in evidence, then speed or temperature conditions are probably incompatible with seal material.
  (3) If lip is soft or swollen this is usually an indication of chemical incompatibility with the media in contact with the seal.
  (4) If (2) and (3) okay, check section width of seal with spring fitted. This should be at least nominal section + 1% immediately on removal and increasing to nominal + 3% after 1 hour in free state. Spring may be shortened by up to 5% of its original length if section appears inadequate. Section measurement should be average of four equidistant readings.

(E) If checks (C) and (D) do not reveal any faults the problem may be due to mechanical conditions and the following should be checked:

(1) Shaft to housing concentricity – check by means of callipers between shaft and housing bore at four points around periphery. Variations of more than 0.3 mm require further investigation.
(2) If smallest calliper measurement occurs between bottom of shaft and housing this may indicate bearing wear with resultant dynamic eccentricity. (Applicable to horizontal shafts only.)
(3) If bearing is okay, then housing offset may be responsible. Seal housings are normally centralized with the shaft by means of a machined register with the bearing housing. Where this feature is not incorporated then it may be possible to centralize the housing by slackening the bolts and repositioning.
(4) If (1), (2) and (3) are blameless then the following requires investigation. If bearings are oil pressure lubricated, is there adequate drainage to prevent pressure build-up against the seal? If equipment operates on a constant oil level principle, are there gear-wheels or ball-journal bearings in close proximity to the seal causing oil turbulence or flooding? Where the latter situation exists, the housing lands should be only marginally larger than shaft diameter in order to form a baffle or, alternatively, a baffle plate fitted between bearing and seal housing. A temporary remedy can be made by using a 1.5 mm semi-rigid gasket at the bottom of the housing, the I/D of which should be shaft diameter plus 0.5 mm maximum. A further gasket of equal thickness should be fitted underneath the retaining plate to restore the correct amount of axial compression in the case of retained seals. (See Figures 15.98 and 15.99.)

15.2.4 Mechanical seals

15.2.4.1 Introduction

Lip seals cannot be used in many rotary shaft sealing applications. This is especially the case for fluids other than oil or when the sealed pressure is greater than 2 bar, but other factors can also be important. The most commonly used high-pressure rotary shaft seal is the mechanical seal, where the dynamic sealing occurs between the faces of a pair of very flat annular rings, one stationary and the other rotating against it. Mechanical seals are to be found in large numbers worldwide on rotary pumps (ranging from high-duty refinery applications to car-water and washing-maching pumps), compressors, mixers and ship stern-tubes. Mechanical seals have become an industry standard in many areas, frequently replacing other rotary seals such as soft packing and bushings. They have a deserved reputation for low leakage and low maintenance costs compared with other seal types. However, mechanical seals are precision devices which require certain actions on the part of the user to improve the chances of obtaining good performance on any given duty. Chief among these are: correct seal selection, careful installation by trained personnel, and an understanding of the effects of external factors out of the control of the seal manufacturer.

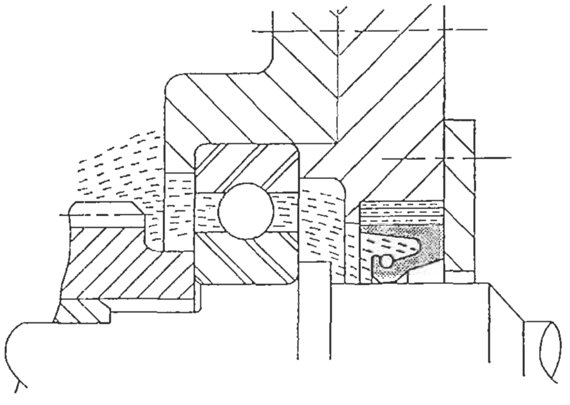

Figure 15.98 How too large a bore diameter of a seal housing land permits high-velocity oil impingement on a seal. A baffle plate between bearing and seal or a close-fitting land seal would reduce risk of oil leakage

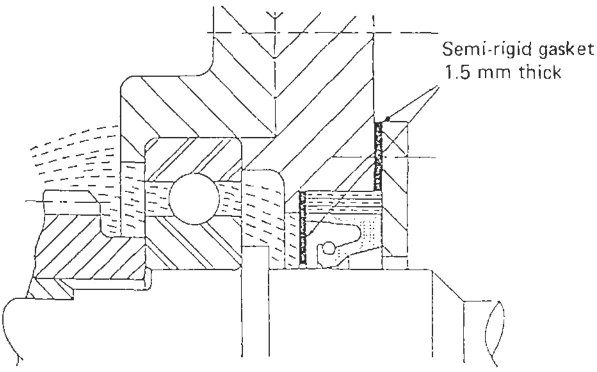

Figure 15.99 How the fitting of gaskets can provide a temporary remedy for the situation in Figure 15.98

A large number of seal types and variants are commercially available to the user – knowing where to start can be difficult. Most users would probably approach a reputable seal manufacturer, pass on what basic process data were available and let the manufacturer select a seal. Close liaison with seal manufacturers is to be encouraged and is usually the best way to enhance reliability in the field. However, it is also to the benefit of both manufacturer and user for the latter to understand the basic construction, operation, expected performance and requirements of the seal. The manufacturer will also be considerably aided in selection if the user is primed with appropriate data regarding the process, pump, ancillary equipment, installation procedures and any past failures. In particular, an awareness of the API 610 code of practice for centrifugal pumps will be helpful.[23] This document has been compiled by US oil producers for use on oil refineries but is widely regarded as a standard by the mechanical seal manufacturers. API 610 sets out requirements for subjects such as seal cooling, geometric envelopes, piping plans, inspection and testing, and pump data sheets.

It is the intention of the following text to equip the seal user with sufficient knowledge to enable effective liaison with seal manufacturers. Where further information is sought, the reader is referred to more detailed references pertaining to the subject. Reference 24 is particularly useful.

15.2.4.2 Seal design

Seal operation The function of a mechanical seal is to prevent the sealed process fluid escaping from the pump body at the point where the impeller drive-shaft enters. The seal is therefore required to operate under conditions of extreme

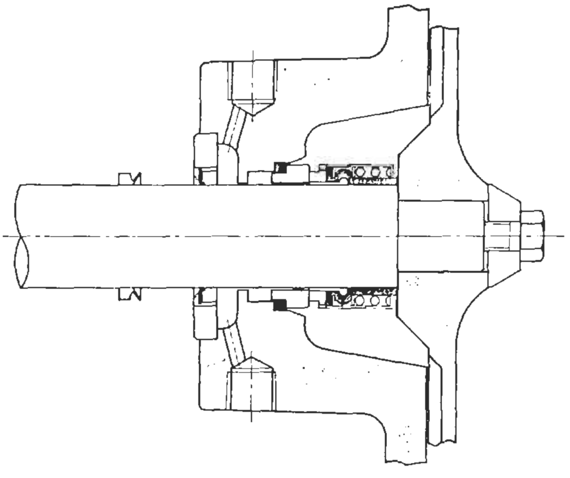

Figure 15.100 Typical mechanical seal installation. (Source: Girdlestone Pumps Ltd)

temperature (both high and low), and run on liquids which are possibly toxic, flammable and corrosive. Sealed pressures can commonly be up to 70 bar and occasionally higher. Often the actual conditions of pressure and temperature in the seal chamber are not known. Understandably, users expect virtually no leakage and reliable operation with predictable life typically in excess of 3 years.

A typical mechanical seal system as installed on a centrifugal pump is shown in Figure 15.100. The mechanical seal is, in essence, a plain annular thrust bearing. Despite the plethora of available seal types, the mechanical seal generally comprises the basic components shown in Figure 15.101. The dynamic sealing takes place in the sliding interface between the stator and the rotor, other leakage paths being sealed with stationary or pseudo-stationary seals. Unlike a conventional bearing, the mechanical seal usually has to run on the pumped fluid which encompasses a wide range of possibilities all with varying degrees of lubricating ability. Moreover, the interface lubricating film is very thin, generally in the order of a few microns. Consequently, the profiles, surface finish and materials of the seal faces are of crucial importance.

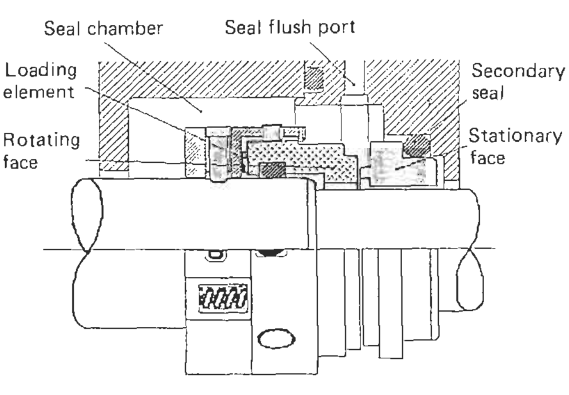

Figure 15.101 Basic features of a mechanical seal. (Copyright BHR Group Ltd)

Sealing interface The stability of the interface fluid film is vital to successful seal operation; should it disappear through vaporization and the seal run dry for any length of time, eventual failure is likely. This will be caused by face material distress, secondary seal degradation due to the high temperatures generated, or high face wear. Consequently, a large amount of research has been concentrated on understanding the behaviour of the sealing interface.

The faces of a mechanical face seal need to be flat to within a few tenths of a micron. This is achieved by lapping and their flatness checked using an optical flat. Surface roughness is normally in the range 0.05–0.20 μm R_a.

The faces are able to move axially and also cone inwards or outwards. The loading element provides a nominal closing force on the face when the seal is stationary. This force is usually designed to be small compared with the hydraulic loading of the seal in operation. Hydraulic forces can be controlled by the seal manufacturer by choice of 'hydraulic balance' or 'balance ratio'. These terms are explained with the aid of the diagrams in Figure 15.102. A seal with a balance ratio of 1 or greater is termed an 'unbalanced seal'. This means that the seal faces experience the full pressure of the pumped fluid. Unbalanced seals are simple and low-cost but cannot operate at pressures much in excess of 10 bar as the high interface loads cause vaporization of the interface film. Most process seals are of the 'balanced' type, that is, they have a balance ratio of less than 1; a ratio of 0.7 being not uncommon. By modifications to the geometry of the seal assembly the net interface area over which the system pressure acts can be reduced by balancing the pressure-induced forces on the seal as shown in Figure 15.102. The added complexity results in more expensive seals but extends the operating pressure envelope of the seal considerably. Choosing the optimum ratio for a particular application can be difficult and requires skill and judgement on the part of the seal manufacturer to obtain the best compromise of face loading and film thickness. Reducing the face loading allows the film thickness to increase and, consequently, the leakage will be greater. Conversely, increasing the face loading leads to thinner films, greater heat generation and an increased dependence on the tribological performance of the seal faces.

The hydraulic force generated by the sealed liquid not only loads the faces axially but also generates a turning moment about the cross-sectional centroid of the seal rings and causes them to cone. Where the sealed liquid is on the outside (the case with most seals) the moment tends to cone the faces inwards to cause contact at the outer edges as shown in Figure 15.103. This is denoted as 'positive' rotation and sets up a face taper which is divergent in the direction of leakage, thereby cutting off the interface film. Seals are also subject to thermal distortions, globally due to bulk warming of the surrounding pumped fluid and also locally due to heat generation at the interface. On most seals, the effect of heating distorts the seal faces to rotate 'negatively' to form a convergent taper as shown in Figure 15.104. Ideally, the pressure-induced and thermally induced rotations should be kept in balance so that the faces run as near parallel as possible. This can be achieved for steady-state running at a particular design condition, but tolerance to off-design or transient conditions is more difficult to engineer.

Face materials Most mechanical seals experience short periods of dry-running and boundary conditions during their lives, due either to the arduous nature of a duty or to transient conditions such as start-ups and process interruptions. The tribological compatibility of the face materials and their ability to survive when in rubbing contact is of paramount importance for long-term seal reliability. In the majority of cases this is

satisfied by using a high-quality carbon-graphite as the 'soft' face. Counterfaces are always harder and stiffer materials and include metals, ceramics and cermets. On duties where the pumped fluid is particularly abrasive, two hard faces may be run against each other, but such combinations are totally dependent on liquid lubrication.

The most commonly encountered seal face materials are summarized as follows:

1. *Carbon-graphite* This terms covers a broad spectrum of different carbon-based materials which, in the sealing industry, are referred to colloquially as 'carbons'. The base grade carbon-graphite has many properties which make it an excellent choice for mechanical seals. The most important are: good lubrication under boundary or dry conditions, tribological compliance, good chemical resistance, wide temperature range and low cost. To be impermeable to fluids, the carbon has to be impregnated – the impregnant chosen depends on the application being considered.
   - Resin-impregnated grades: wear resistant and good chemical resistance.
   - Metal-impregnated grades: better thermal conductivity and stronger than the plain grades. Enhanced running abilities. Metal impregnant limits chemical resistance.
   - Electro-graphite grades: high-temperature capability and good chemical resistance. Weaker and relatively soft.
2. *Ni-Resist* A generic term for particular nickel-alloy cast irons with enhanced chemical properties compared with cast iron. Ni-Resist material is popularly used in low- to medium-duty seals for which it is well suited. It is relatively low cost, easy to machine and fairly tolerant of transient and dry-running conditions. It is best run against resin-impregnated carbon. Ni-Resist is not a material to be used for physically or chemically arduous conditions.
3. *Alumina* Alumina ceramics are also widely used on low and some medium duties (typically at pressures less than 1.5 MPa) particularly where the duty involves aggressive or mildly abrasive or corrosive substances. It has very good wear resistance and performs well on aqueous duties. It is, however, rather intolerant of shock, transients and dry running. Its thermal conductivity is low which is a major drawback for more arduous and critical duties.
4. *Tungsten carbide* A cermet material known for its good performance under arduous and boundary conditions, tungsten carbide has been employed extensively on high-duty applications for many years. Its initial high cost is rapidly offset by its enhanced performance. Improvements in seal life have also encouraged its use on less severe applications. Because it includes a metallic binder, tungsten carbide does suffer from corrosion problems which tend to make it less suitable for acidic duties. Tribologically, it is very good when run against carbon even under boundary conditions but it has limited abilities when run against itself under similar conditions.
5. *Silicon carbide* Silicon carbide is a ceramic which is rapidly increasing in use due to its excellent performance. Initially, its high price precluded it from being used on any but the most arduous duties where cost-effectiveness could be easily demonstrated. The price has steadily fallen in recent years and it has gradually been effectively used on many medium- and low-duty applications. Of all the counterface materials it probably comes closest to being the 'industry standard'. The material itself is anything but standard as it is available in a number of grades, with each material within a grade varying between manufacturers. It does have some limitations particularly on strongly alkaline duties where certain grades are attacked. It has been widely used against itself for abrasive applications but again, choice of grades is important. Careful handling of silicon carbide is essential due to its brittleness.

Secondary seal materials The functions of the secondary seal are to seal the secondary leakage paths and, with the exception of metal bellows seals, to allow axial float of the seal faces. Secondary seal materials are usually polymeric, although other materials are employed for high-temperature applications. The choice of polymer depends on thermal and chemical compatibility. Strengths and weaknesses of selected polymeric materials are as follows:

Nitrile (*NBR*) Good physical properties. Resistant to many common chemicals. Should not be used on halogenated hydrocarbons, ketones, strong acids and some hydraulic fluids.
Ethylene propylene Good physical properties. Particularly good for hot-water duties. Do not use on petroleum-based fluids.
Fluorocarbons (*e.g. Viton, Fluorel*) Good for high temperatures. Wide range of chemical resistance available depending on the grade – correct matching of grade to duty is essential. Not recommended for hot water, ketones or alcohols. Relatively poor physical properties.
Perfluoroelastomer (*e.g. Kalrez*) Excellent high-temperature and chemical abilities. Relatively poor physical properties. Expensive.

Where elastomers cannot be used other options are available – generally these will have lower resilience and require superior surface finishes. The common alternatives are:

PTFE Outstanding chemical resistance and the ability to operate at cryogenic temperatures.
Exfoliated graphite Rapidly replacing compressed asbestos fibre. Excellent chemical resistance and capable of very high-temperature operation.

Design variants A considerable number of variations on the basic design (Figure 15.100) are available to the user. Each variant offers the user added benefits for a given application; optimizing the precise design and balancing their strengths and weaknesses is best done by the seal manufacturer. The user should be aware, however, of the principal variants available and their respective generic advantages and disadvantages; these are listed in Table 15.16.

1. *Cartridge seals* These are enjoying growing popularity despite their high initial cost. The cartridge comprises a self-contained mechanical seal which has been installed on the bench by the seal manufacturer; a typical cartridge is shown in Figure 15.109. The seal is set correctly by the manufacturer and is fitted directly to the user's machine without the need for any further adjustment. The cartridge seal offers a number of potential benefits to the user.
   - Option for pre-installation tests by the manufacturer;
   - Considerably reduces the risk of incorrect fitting or damage on-site;
   - Removes some out-of-square potential; this is particularly of benefit to rotating metal bellows seals.
2. *Tandem seals* A tandem seal comprises a pair of primary seals mounted head-to-tail as shown in Figure 15.110. This sealing arrangement may be operated in a number of ways. On some applications the outboard seal is simply used as a back-up to the inboard seal. In normal running the outboard seal merely contains any leakage from the inboard seal, but should the latter fail then the outboard seal will accept the full system pressure and seal the pump until a suitable maintenance window can be scheduled. Alterna-

Table 15.16

Variant	*Advantages*	*Disadvantages*
Externally mounted seal (Figure 15.105)	Easy installation and inspection. Minimal components in contact with pumped fluid, hence used on corrosive duties.	Not suited to high pressures. Face cooling more difficult. Leakage containment difficult. Space required outside housing.
Stationary floating seal (Figure 15.106)	Can be used at high speeds. More tolerant of misalignment. Suitable for liquids of higher viscosity.	Greater radial space required. Generally more expensive. Can become clogged by solid particles in product.
Non-metallic bellows seal (Figure 15.107)	Low cost. No hang-up or sleeve wear. PTFE bellows can be used for corrosive duties.	Less robust. Limited pressure capability. Not recommended for high temperatures and speeds.
Metal bellows seal (Figure 15.108)	No sliding secondary seal, hence no hang-up or sleeve wear. Can be used at high temperatures and speeds. Inherently balanced. Compact	Expensive. Less robust. Not generally recommended for highest pressures. More prone to fatigue failure especially with high vibration.

tively, the tandem seal can be used with a pressurized inter-stage or buffer fluid which reduces the pressure drop across each seal. In this way the seals are sharing the workload, thus permitting the sealing of very high product pressures.

3. *Double seals* A double seal also utilizes a pair of seals arranged in a back-to-back configuration as shown in Figure 15.111. The appropriately selected buffer fluid is pressurized externally at a pressure just above that of the process and, consequently, there is a slow leakage of buffer fluid into the process. The double seal is used when zero leakage is required; any product leakage into the buffer fluid can be dealt with using appropriate ancillary systems. Double seals offer enhanced reliability as the seal designer is able to select buffer fluids with good lubricating properties for the seals to run on – a rare luxury.

15.2.4.3 Seal performance

The two most important features of seal performance are leakage and life. The type of duty usually dictates the relative importance of the two although every user would ideally wish for low-cost leaktight seals which last, predictably, as long as the pump bearings. In general, this is unlikely to be achieved and it is worth noting that very few seals simply wear out – most 'seal failures' are due to excessive or unacceptable leakage.

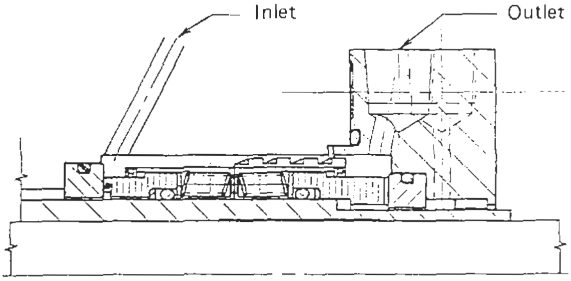

Figure 15.111 Double-seal arrangement. (Source: John Crane UK Ltd)

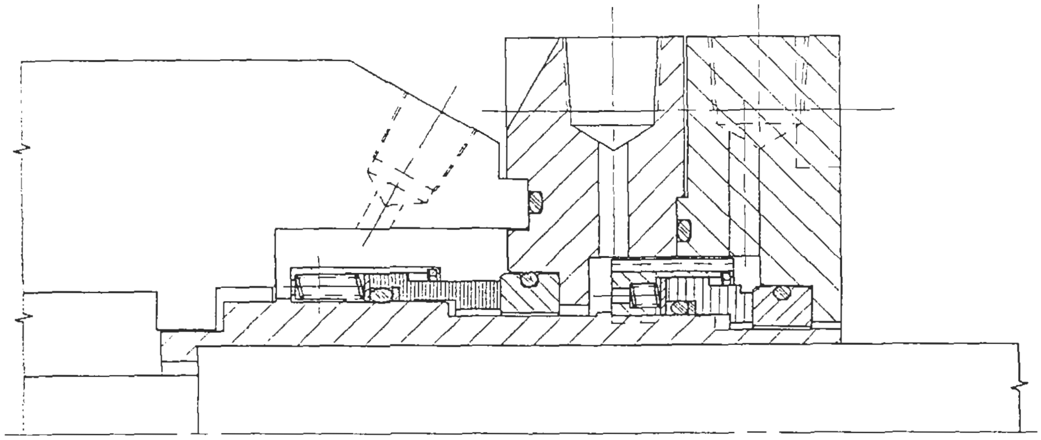

Figure 15.110 Tandem seal arrangement. (Source: John Crane UK Ltd)

Leakage All single mechanical seals leak to some extent, even if the leakage is in the form of invisible vapour. Indeed, vapour leakage can amount to quite high liquid equivalents which would be regarded as unacceptable on, for example, light hydrocarbon duties. Leakage can also be significant when the seal is at rest but still primed, as in the case of a stand-by unit. Typical leakage figures are difficult to give as seal design and size can be influential but, as a rule of thumb, values better than a few millilitres per hour can be achieved for a correctly functioning seal. On duties requiring truly zero leakage a double seal must be installed.

Life Seal life can be notoriously difficult to predict. Lives of thousands of hours are commonplace but cannot be guaranteed. The carbon wear rate on a correctly functioning seal will be of the order of 0.5 mm per year – a remarkable achievement giving the poor lubricating properties of many pumped fluids. There are, however, well-documented examples of a particular seal running successfully for many years and its identical replacement failing after only a few months for no apparent reason. Expected seal life varies depending on the duty, and the seal manufacturer should be able to give an idea of what to expect based on experience elsewhere. It should be emphasized that many factors affecting seal life are outside the direct control of the seal manufacturer. Principally, these are: the sealed fluid, seal cooling arrangements, pump design, and unforeseen process variations or disturbances.

Sealed fluid Apart from double-seal arrangements, the mechanical seal is required to run on the process fluid, however poor its lubricating capabilities. The sealed fluid can exert a major influence on seal performance by its effects on a number of processes inherent to the operation of the seal:

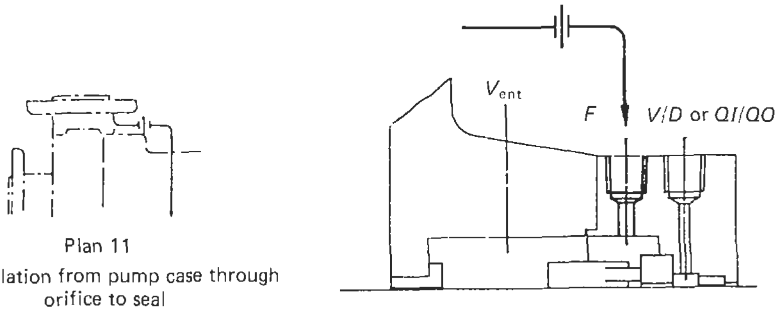
1. *Boundary lubrication of faces* Many process liquids have little or no boundary lubrication ability – the fact that the seal will often run successfully on these fluids is usually due to the careful choice of face materials. This contrasts strongly with bearing lubricants which are developed for optimum boundary performance by incorporating highly effective organic or inorganic additives. Thus, most aqueous duties are considered 'severe' in terms of the tribological performance expected of the seal.
2. *Volatility* In order to maintain a fully liquid film in the sealing interface, the liquid must not be allowed to evaporate. Vaporization of the film will allow solid contact between the faces which may experience thermal distress and high wear. The interface film is subject to local heating due to friction and liquid shear – its temperature is therefore above that of the bulk liquid surrounding the seal. It follows that a seal cannot run with a full liquid film when the temperature of the bulk fluid is within a certain margin of its boiling point or range; this margin is known as the 'Required Temperature Margin' or '$\Delta T_{\text{required}}$'. If the interface film is lost the seal can become unstable and will emit spurts of vapour leakage at regular intervals – this phenomenon is known as 'puffing'. A seal behaving in this way will often be obvious to the operator since the puffing is generally both visible and audible.
3. *Other properties* There are many other potential effects arising from properties of the sealed liquid, and the seal manufacturer will be in a position to take these into account. The more common ones are:
   - Dissolved solids can be deposited on the seal faces as the liquid evaporates. These particles can cause severe abrasive damage to the seal faces, particularly the carbon.
   - Liquid leakage can form crystals between the seal faces and on the atmospheric side of the seal faces. Unless these are continuously removed by a quench, hang-up of the floating member is possible.
   - The light ends of heavy hydrocarbons can evaporate as they reach the atmospheric side of the interface and leave a tarry residue; this must be removed by quenching.
   - Fine suspended solids may be drawn into the seal faces and cause severe abrasive damage.
   - Attack of elastomeric secondary seals.
   - Corrosion of seal components.
   - Solids clogging moving parts such as springs or bellows.

Seal cooling Removing heat from the interface of the seal is vital to its survival. A 50 mm seal running at 3000 rpm and 30 bar can easily generate heat at a rate of one kilowatt in the sealing interface. The volume of liquid in the interface itself is very small and instant vaporization would occur were the heat not removed efficiently. Given that one or both of the seal faces has high thermal conductivity, the fluid flow around the seal must be able to convect this conducted heat away faster than it is being generated. The process of convective heat transfer relies upon a good supply of relatively cool liquid circulating in the vicinity of the sealing interface. Sometimes this can be achieved by the flow behaviour inherent to a particular housing, especially if the duty is dissipating relatively low amounts of heat. This is known as a 'dead-ended' arrangement (API 610 – Plan 01) which may incorporate a water-cooled jacket (API 610 – Plan 02). Unfortunately, the cramped conditions of most seal chambers inhibit the self-flushing process and additional predictable cooling is often provided by flushing the seal chamber.

Flushing arrangements or plans are many and varied; the US petroleum industry pump standard API 610 gives many variants. Basic cooling methods are:

1. *Product recirculation (API 610 – Plan 11)* Product is tapped off from the pump discharge and recirculated through an orifice to the seal chamber, usually entering opposite the seal faces (Figure 15.112). This is a good arrangement providing that the bulk liquid temperature is low compared to its boiling point (i.e. the available ΔT is well in excess of the required ΔT). In addition, the duty should be relatively free of solids which could block the orifice and cause erosion of the softer seal face. The restriction on solids can be obviated in many cases by incorporating a hydro-cyclone in the recirculation line (API 610 – Plan 31).
2. *External injection to seal face (API 610 – Plan 32)* Clean, cool liquid is supplied to the seal faces from an independent external source (Figure 15.113). This allows the seal to operate on more severe applications and makes it less susceptible to process fluctuations. The external flush must be compatible with the pumped liquid; this presents few problems on aqueous duties where water may be used, but may be more difficult for hydrocarbon applications. Some duties, particularly where slurry is being pumped, may experience excessive dilution by external flushing. Removing the flush liquid downstream can be costly. In some industries, sourcing a supply of consistently clean water can be difficult. Finally, it should be borne in mind that external flushing systems are relatively expensive, require careful maintenance, and are more susceptible to operator error than the self-flushing and product recirculation arrangements.

Pump design The effects of pump design are not well understood but circumstantial evidence suggests that seal performance can be impaired by out-of-condition pumps. The seal is the most sensitive part of the pump assembly and any prob-



Plan 11

Plan 32
Injection to seal from external source of clean fluid

Figure 15.113 External injection. (Source: reference 23)

lems in this area are likely to lead to 'seal failures' even though the root of the problem lies elsewhere. The seal manufacturer should be consulted on the ideal requirements for pump condition and any information available from the user would be of use. In particular, the pump should be checked for:

- Tolerance stack-up which leads to out-of-square seal components or over-compression of the loading member;
- Shaft run-out due to a bent shaft or worn bearings;
- Pump operating away from the best efficiency point (BEP);
- Vibration at the pump due to coupling misalignment, impeller or motor imbalance, hydraulic effects or pipework-borne noise;
- Impeller design and its effect on seal chamber flows and pressures;
- Seal chamber geometry.

Process changes All seal manufacturers recognize that, at some point in the life of the seal, it will experience off-design running. Consequently, seal tolerance is a key area of development which has made significant advances in recent years. For example, it is often commented that the advent of silicon carbide as a counterface to carbon has improved seal reliability noticeably. It is not possible for the manufacturer to foresee, or design for, all fluctuations in the process and the user should be aware of the most common scenarios which can cause particular distress to the seal:

1. *Loss of lubricant* This can arise in a number of ways depending on the sealing arrangement, but usually will be due to the pump de-priming or failure of the seal-flushing system. Many seals are able to withstand short periods of dry running but hot running is inevitable after a while and this can lead to severe degradation of any polymeric secondary seals. Seal face materials may also experience thermal distress and in extreme cases the carbon may start burning. Many failures occur when the relatively cold process fluid returns as the thermal shock to the brittle seal faces may be sufficient to cause fracture.
2. *Running off BEP* Off-design point running, particularly the low-flow condition, is probably very common and the effects on the seal can be severe. It is most frequently caused by one or more of the following:
   - The over-specification of the pump
   - Changes in the plant throughput
   - The running of two pumps on a duty where one would be adequate.

   Cavitation associated with low flowrates can cause harmful vibrations – these can upset the seal directly by disturbing the interface film and by fatiguing metal bellows and elastomeric components. If the condition persists, the bearings may be damaged and this in turn can lead to eventual seal failure. Cavitation also generates gas or vapour bubbles which tend to be centrifuged onto the seal. In a dead-ended arrangement with a cramped seal chamber the seal may be starved of cooling and lubricating liquid. Another effect of the low flow condition is to deflect the pump shaft – this can be as much as half a millimetre at the seal.
3. *Transients* Process transients are inevitable and many are unavoidable. If particular transients are known to occur the seal manufacturer should be consulted as protective action for the seal may be possible by attention to seal design, face material combination, flushing arrangements, etc. It is worth reviewing whether some transients, e.g.

starting a pump against a closed valve, can be avoided or made less damaging – again the seal manufacturer may be able to help.

15.2.4.4 Seal selection

Selecting the most appropriate sealing system for a specified duty can be a difficult exercise which is best left in the hands of a reputable seal manufacturer unless particular company expertise and experience is available. In addition to the primary seal, secondary containment and ancillary equipment may be required and the manufacturer may also be able to make other suggestions for improving the reliability of the final design. The basic steps involved in seal selection are worth knowing and will aid the liaison betwen manufacturer and user.

The manufacturer will require the following data to make a primary seal selection:

- Precise and complete seal housing dimensions
- Running pressure including the seal chamber pressure, if known
- Running temperature
- Physical and chemical properties of the sealed fluid
- Expected life
- Required leakage

Specification of any secondary containment and ancillary systems will require further information regarding the sealed fluid (e.g. auto-ignition point, toxicity, flammability, tendency to decompose, tendency to crystallize, percentage of solids). Company or other regulations regarding permitted leakage levels should also be consulted. For a more extensive guide to seal selection the reader is referred to reference 24.

15.2.4.5 Seal installation

Training The fitting of mechanical seals is a skilled job and should be carried out by trained personnel. Site surveys indicate that between 25% and 40% of all seal failures may be attributable to incorrect fitting. Cartridge seals reduce the risk of fitting errors significantly and their use is to be encouraged. All reputable mechanical seal manufacturers offer training courses on seal installation and the investment of time and money for making use of these services will inevitably return dividends in reduced premature seal failures in the field.

Handling The rules for handling mechanical seals are:

- Obey any specific instructions in the literature enclosed with the seal.
- Avoid mechanical damage or shock as many seal components are brittle or fragile.
- Do not place the sealing faces down on dirty, unyielding surfaces.
- Unpack the seal carefully; shrunk-wrap packaging should be cut off carefully.
- Check that the seal supplied matches the seal specified for the duty.
- File all relevant technical information supplied by the seal manufacturer.
- Transfer fitting recommendations into company maintenance procedures.

Inspection While detailed checks cannot usually be made on-site, the seal should be inspected prior to installation for any superficial damage:

- Check materials specifications against duty (manufacturers provide references of material codes).
- Check all metal components for physical damage.
- Check seal faces for scratches, nicks or visible imperfections.
- Check secondary seals for cuts, nicks, tears, and chemical attack. Some elastomers are attacked by common fluids such as ozone, water and mineral oils.

Storage Mechanical seals should be stored in the protective packaging supplied by the manufacturer. The packaged seal should be kept in an area free from dirt, excessive moisture, high humidity and extreme cold. Good ventilation is also recommended.

Fitting Seal fitting is best carried out in a clean environment and, if possible, the pump should be removed in entirety to a workshop for stripping down and rebuilding. This practice has a number of attractions:

- The pump components, especially seals and bearings, are not exposed to the elements.
- The existing seal may be removed more carefully and inspected for damage.
- The relatively benign and clean conditions of a workshop are more conducive to good fitting practice.

Prior to fitting the seal the pump should be checked for misalignments which may be harmful to the seal. Checks should include: shaft balance, shaft run-out, seal chamber squareness, and concentricity of the shaft to the seal chamber. The seal manufacturer will be able to give a comprehensive list of recommended checks; alternatively, they are catalogued in Section 9.2 of reference 24.

Most mechanical seals are supplied with detailed fitting instructions and these should be carefully followed. There are some fitting requirements common to all seals:

- Check seal envelope dimensions carefully, particularly the components which dictate the compression length of the loading member. Over-compression of a seal will probably lead to premature failure.
- Avoid twists and kinks in any O-rings. PTFE O-rings should be softened in boiling water immediately prior to fitting.
- Seal faces must be kept clean. Any grease or foreign matter on the faces should be wiped off using lint-free tissue soaked in a suitable solvent such as propanol.
- Check that any ancillary equipment is cleaned and properly commissioned. Piping connections should be inspected for conformance to the seal manufacturer's drawing.
- Ensure adequate coupling alignment – this is very important for long seal life. The seal manufacturer will recommend appropriate tolerances.
- Avoid excessive pipe strains arising from misalignments between the pump flanges and pipework. Coupling alignment should be rechecked after connecting the pipework.
- Check that seal flushing systems are operating correctly and that valves are open.
- If possible, vent the seal chamber at start-up.

15.2.4.6 Seal failures

Defining seal failure is difficult and depends to large extent on the nature of the sealed fluid and the practice of the seal operator. Most seals are removed because of excessive leakage although sometimes it is necessary to inspect if the seal is running hot or squealing. A pump outage caused by a failing seal is obviously irritating to users but they should ensure that vital evidence, which may reveal the reasons for failure, is not lost when the failed seal is removed. Careful records of seal failures are valuable aids to effective troubleshooting and should be made systematically by the trained fitter as the seal is removed. Process conditions prevailing at the time of failure should be logged – many seal failures can be linked to changes causing the seal to experience off-design conditions; for example, low flow rates through the pump may cause cavitation and excessive vibration at the seal.

Leakage may be due to the failure of any of the seals including the secondary seals – these should be carefully inspected as they are removed. Do not handle the rubbing faces before visual inspection. Check the faces for obvious damage, including chemical attack. In addition, note any of the following if evident:

- Thermal distress including surface cracking and discoloration.
- Solids build-up both in the sealing interface and on the sides of the faces.
- Surface pitting and erosion – a magnifying glass can be a useful aid.

A summary of common failure modes and corrective action is given in Table 15.17 and further information can be found in references 25 and 26.

15.2.5 Clearance seals

15.2.5.1 Introduction

Clearance seals tend to be purpose-designed for use in particular rotary applications where it is not possible to use lip or mechanical seals. Their principal virtues are high reliability and long life compared to other rotary seal types. The price for these advantages is relatively high leakage for pressurized duties even when tight radial and axial tolerances are achieved. The principal areas of use are: steam and gas leakage control, especially for turbines and compressors, large water turbines, grease seals for bearings, high-pressure and/or high-speed reciprocating applications (e.g. diesel fuel injector pumps), and some high-pressure water pumps. Most high-duty clearance seals are built into the piece of machinery by the manufacturer; consequently there are few commercially available units. In terms of geometry the seals range from simple fixed and floating bushings to complex labyrinth and visco-seals. Clearance seals are used frequently as a secondary or back-up device (e.g. throttle bush) to limit leakage in the event of primary seal failure. In these cases the primary seal would often be a mechanical seal.

15.2.5.2 Characteristics

The high reliability and long life of clearance seals are important features. Given a correct initial set-up the life of the seal is usually only limited by wear caused by abrasives in the pumped fluid or contact between the rotating and stationary components due to shaft run-out. In most cases this process is very gradual.

Leakage from clearance seals is usually high compared with contact seals – very tight axial and radial tolerances are required to approach contact seal performance in this regard. However, tight-toleranced seals are more sensitive devices and may be adversely affected by deflections induced hydraulically and thermally in both seal and machine, and also by machine misalignment and external vibration. Tribologically compatible materials are required since contact is likely at some time. The unit cost is generally higher than more standardized seal types, an exception being grease retainers which are very low unit-cost items.

In general, the choice between individual types of seal will be a balance between cost, life and leakage. Table 15.18 outlines the four main types of clearance seal and their relative merits.

15.2.5.3 Seal types

Fixed bushing The fixed bushing, shown diagrammatically in Figure 15.114, is the simplest design of clearance seal. Its main virtue lies in its low cost. One-piece fixed bushings are mainly used as pump wear rings, as balance drums on multi-stage pumps and throttle bushes as a secondary back-up to other rotary seals. Tolerance requirements can be very tight, raising the true cost of an apparently low-cost seal. This problem is usually overcome by adopting multi-segment designs and/or a floating bush (see below).

The correct choice of materials is very important. Typically, for water duties bushes are segmented and may be manufactured from carbon-graphite and run on a bronze or carbon-steel shaft sleeve. On a clean process liquid the life of the bush may be between 5 and 10 years. If abrasives are present then a flame-hardened or nitrided stainless steel sleeve is recommended and possibly a compatible babbitt bush-lining.

The fixed bushing is characterized by high leakage, which is highly dependent on the radial clearance and relative eccentricity. The amount of leakage can be predicted for both laminar and turbulent flow conditions with compressible and incompressible fluids:

Laminar flow: Theoretical calculation as shown in Table 15.19
Turbulent flow: Empirical data as given in Figures 15.115 and 15.116

Fixed bushings are commonly used as an auxiliary seal on centrifugal pumps to minimize leakage in the event of primary seal failure. The diametral clearance to BS 6836 should be no greater than:

$$\frac{\text{Shaft diameter}}{100} + 0.2$$

Table 15.17 Mechanical seal failure modes (*copyright BHR Group Ltd*)

	Symptoms					
Special conditions	*High leak*	*Over-heat*	*High wear*	*Seize*	*Failure mechanism*	*Action*
Viscosity of fluid high		×	×	×	Excessive frictional heating, film vaporizes	Provide cooling
high	×	×	×	×	Excessive frictional heating, seal distorts	Provide cooling
low		×	×	×	Poor hydrodynamic lubrication, solid contact	Use faces with good boundary lubrication capacity
Low-lubricity fluid	×	×	×	×	Surface seize or 'pick-up'	Use faces with good boundary lubrication capacity Reduce face loading
Speed of sliding high		×	×	×	Excessive frictional heating, film vaporizes	Provide cooling
high	×				Thermal stress cracking of the face	Use material with higher conductivity or higher tensile strength
high	×	×	×	×	Thermal distortion of seal	Provide cooling
low		×	×	×	Poor hydrodynamic lubrication, solid contact	Use face with good boundary lubrication capacity
Pressure differential low	(×)				Fluid pumped by seal against pressure	Try reversing seal to redirect flow
high		×	×	×	Hydrodynamic film overloaded	Modify area ratio of seal to reduce load
high	×	×	×	×	Seal or housing distorting	Stiffen seal and/or housing
Fluid temperature high	×				Elastomer secondary seal overheated	Use a high-temperature rubber
high	×				Distortion of seal faces	Reduce thermal stresses, e.g. by cooling the seal
high	×				Thermal stress cracking of the faces	Avoid rapid temperature changes or large temperature gradients
Abrasives in fluid	×		×		Solids in interface film	Circulate clean fluid round seal
Crystallizable fluid	×		×		Crystals form at seal face, secondary seal jams	Raise temperature of flush fluid outside seal
Polymerizable fluid	×		×		Solids form at seal face, secondary seal jams	Raise temperature of flush fluid outside seal
Salt solutions Ionic fluid	×	×	×	×	Corrosion damages seal faces	Select resistant materials
Non-Newtonian fluids, suspensions, colloids, etc.	(×)				Fluid behaves unpredictably, leakage may be reversed	Try reversing seal to redirect flow in acceptable direction
Sterilization cycle Cleaning cycle	×				High temp. or solvents incompatible with seal materials, especially elastomer	Use compatible materials
Ozone, radiation exposure to sunlight	×				Seal materials (rubber) fail	Protect seal from exposure, consider other materials
Flushing etc. Auxiliary cooling	×	×	×	×	Stoppage in auxiliary circuit	Overhaul auxiliaries
Double seals	×	×	×	×	Pressure build-up between seals if there is no provision for pressure control	Provide pressure control
Seal faces rough	×	×	×	×	Asperities make solid contact	Lap or grind faces
Bellows type seal	×				Floating seal member vibrates	Fit damping device to bellows
Single-spring seal drive	×				Spring ineffective due to wrong shaft rotation direction	Reverse motor, or change spring
Vibration present	×		×	×	Face separation unstable	Try to reduce vibration, avoid bellows seals, fit damper
Housing flexes due to pressure or temperature changes	×	×	×	×	Seal faces out of alignment, non-uniform wear	Stiffen housing and/or mount seal flexibly
Seal flatness poor	×				Excessive seal gap	Lap faces flatter

Table 15.18 Types of clearance seal (*copyright BHR Group Limited*)

Seal type	*Advantages*	*Disadvantages*	*Application areas*
Labyrinth	High speed, high temperature. 'Zero' wear if shaft located correctly.	High cost. High precision, axially and radially. Static and dynamic leakage. Usually gas seal only.	Gas turbines Gas compressors Steam turbines
Visco-seal	High speed, high temperature. 'Zero' wear. Zero leakage at design speed. Gas or liquid seal.	High cost, high precision, radially. Uni-directional leaks when stopped. Gas ingestion can reduce effectiveness.	Specialized pumps and compressors. e.g., sodium pumps.
Fixed bush	Relatively low cost. Simple design.	High leakage.	Pump wear rings. Very low pressure water seals.
Floating bushing (most commonly segmented)	'Self-adjusting' clearance seal. Will wear in to shaft, so less precision required. Relatively low cost. Large diameters can be accommodated relatively economically.	Pressure/speed limited. Have 'finite' life compared with true clearance seals. Material choice limited to good bearing combinations: seal material generally, carbon, bronzes or babbitt.	Low-duty gas turbines and compressors. Water pumps and turbines (particularly large diameters)

Table 15.19 Leakage from a bushing seal – laminar flow

q ≡ volumetric flow rate/unit pressure gradient/unit periphery *η ≡ absolute viscosity*	*Fluid incompressible*	*Fluid compressible*[a]
$\left(\epsilon = \frac{\delta}{c}\right)$  Axial bush	$Q = \frac{2\pi a(P_s - P_a)}{l} \cdot q \quad m^3\,s^{-1}$	
	[b] $q = \frac{c^3}{12\eta} \cdot (1 + 1.5\epsilon^2)$	$q = \frac{c^3}{24\eta} \cdot \frac{(P_s + P_a)}{P_a}$
 Radial bush	$Q = \frac{2\pi a(P_s - P_a)}{(a - b)} q \quad m^3\,s^{-1}$	
	$q = \frac{c^3}{12\eta} \cdot \frac{(a - b)}{a \log_e \frac{a}{b}}$	$q = \frac{c^3}{24\eta} \cdot \frac{(a - b)}{a} \cdot \frac{(P_s + P_a)}{P_a}$

---

[a] For Mach number < 1.0, i.e. fluid velocity = local velocity of sound.

[b] If shaft rotates, onset of Taylor vortices limits validity of formula to $\frac{V}{\nu}\sqrt{\frac{c}{a}} < 41.3$ (where V = surface speed and ν = kinematic viscosity).

A variation on the fixed clearance seal is the centrifugal liquid barrier seal in which the centrifugal action of the rotating component is sufficient to create a pressure differential to oppose the leakage of sealed fluid. An example of a seal of this type is the hydrodynamic disk seal shown in Figure 15.117 which may be a single or multi-stage device. The performance of this seal type is reported in Merry and Thew.[27]

Floating bushing The floating bushing, shown in Figure 15.118, is a nominally self-aligning version of the fixed bush. It therefore requires less accurate precision in its installation. It is relatively low cost and, in segmented form, is particularly suited to large diameter seals. Its main areas of application are for low-duty gas turbines and compressors, low-pressure water pumps and water turbines. Leakage is relatively high compared with other seals unless very tight tolerances can be held. Estimates of leakage may be made using the figures given for fixed bushings. The floating bush is somewhat more limited in its pressure and speed capabilities and, as for fixed bushings, the choice of materials is vitally important.

Pressure

Figure 15.119 Bevel-section carbon gland. (Source: Morganite Special Carbons Ltd)

Floating bushing seals in the non-contacting gland-ring arrangement are commonly used on steam and gas applications. Typically the gland rings are manufactured from carbon-graphite which are often segmented. An example of a carbon gland is shown in Figure 15.119; in this case the rings are of bevel section and spring loaded to enable compensation for ring wear. The bore of the rings is designed to match the shaft diameter at the operating temperature in order to keep leakage to a minimum. Carbon gland rings can also be used in other arrangements for water turbines; typically the rings may be used in a tenon-jointed form, as opposed wedge rings or as hydrostatic radial face seals.

A special type of floating bush seal is the controlled clearance rotary seal shown in Figure 15.120. The seal is designed to be self-energizing and self-compensating. Hydrostatic and hydrodynamic forces resulting from the pressure of the sealed liquid and shaft rotation, respectively, are used to create a pressure wedge in the film between the flexible inner ring and the shaft. The result is a tapered film with a very small exit clearance, thus effecting a seal.

Labyrinth seal The labyrinth seal is the most widely used clearance seal type. In its basic forms it resembles the examples shown in Figure 15.121 but is also to be found in a plethora of different designs, some of which may be purchased 'off the shelf'. The leakage from labyrinth seals is typically about half that of bushing seals due to the increased flow resistance caused by the eddies which are set up in the grooves between the vanes. The vane axial spacing is commonly about twenty times the vane lip clearance – the compromise here is between achieving sufficiently large grooves to promote strong eddies and limiting the axial length of the seal to manageable

dimensions. Typical leakage performance is shown in Figure 15.122, which indicates the influence of blade spacing and the number of blades. For design purposes the user is referred to Figure 15.123.

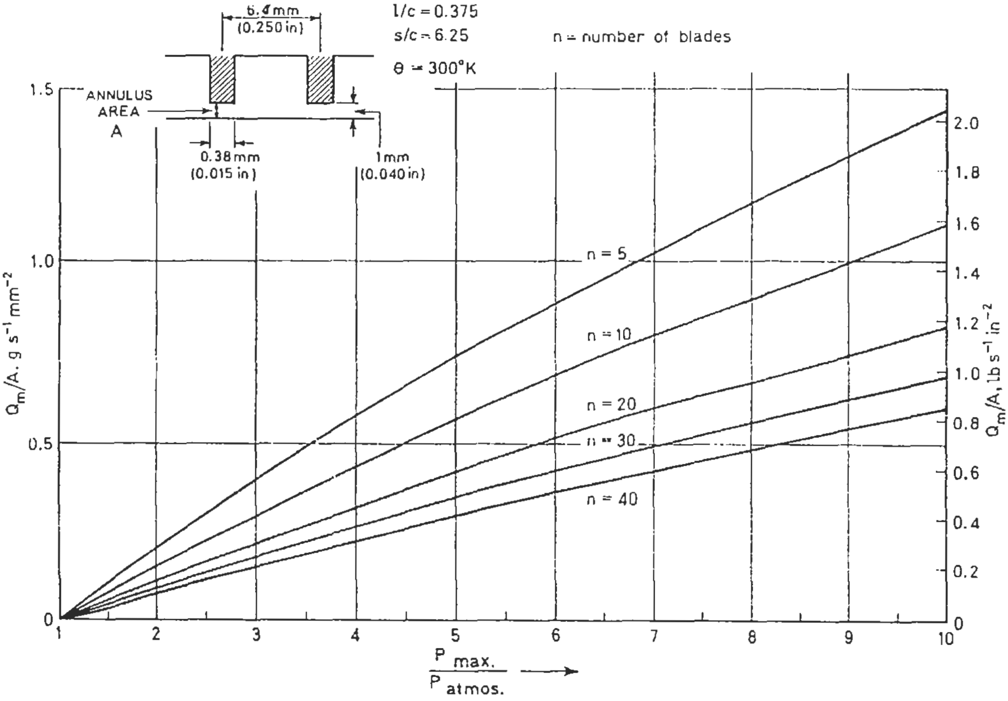
Labyrinth seals are capable of very high speeds and high temperatures with nominally unlimited life. Consequently, they are used on gas sealing duties, turbines and compressors, and for steam turbines. They are also available as bearing grease seals as an alternative to lip seals. Their main drawbacks are, in general, relatively high cost and the high axial and radial precision required in their installation and operation.

As for other clearance seals, the materials of construction should be tribologically compatible as a precaution against rubbing contact between the vanes and the rotor. An additional factor may also be creep, especially in high-speed turbines where stresses are large. A convenient material arrangement is to use metal fins and a carbon bush as shown in Figure 15.124. Alternatively, a metal foil honeycomb may be used made, for example, from stainless or Nimonic steels.

Visco-seal The visco-seal or wind-back seal is basically a fixed bush with a helical groove cut either into the shaft or the bore of the bush as shown in Figure 15.125. The effect of the helix is to pump the sealed fluid back into the sealed system as the shaft is rotated. The seal therefore works best for viscous fluids or for high rotational speeds.

The seal is essentially a single speed, uni-directional, device. It is designed to give inward pumping action perfectly matching the leakage flow with the net result of zero leakage at what is known as the *sealing pressure*. Excess pressure will result in leakage while at low pressures the seal runs partially dry and air may be pumped inwards. Typical performance and design criteria are summarized in Figure 15.126. There is no sealing action when the shaft is stationary and it may be necessary to fit an auxiliary static seal. This may lift off automatically when the shaft rotates.

A development of the visco-seal is the barrier visco-seal in which a pair of seals are installed back-to-back as shown in Figure 15.127. The resulting pressure barrier which builds up between the seals may be used to buffer the sealed fluid from atmosphere. Compatibility between sealed fluid (usually a gas) and buffer fluid (usually a liquid) must be established. In tests using grease as the barrier fluid a pressure of 10 bar was sealed by a 13 mm diameter seal running at 1000 rpm.

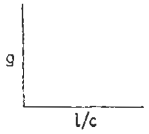


TEMPERATURE

For other temperatures multiply Q_m/A by $\frac{17.3}{\sqrt{\theta_K}}$

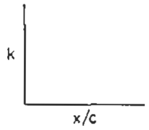
GEOMETRY

For other values of s/c or l/c multiply Q_m/A by g:



STEPPED LABYRINTH

For a stepped labyrinth use an 'effective' n value, kn:



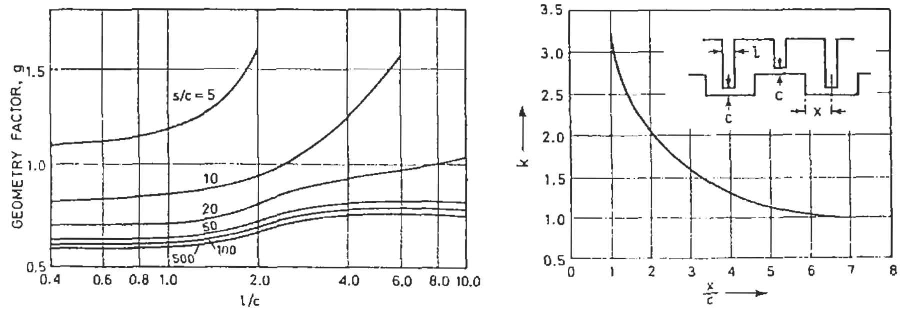


Figure 15.123 Calculation of leakage for a labyrinth seal

The visco-seal is suitable for high-temperature applications where the pressure is low to moderate. However, it requires a high degree of radial and axial precision and its initial cost is relatively high. Its main areas of application are for special-duty very long-life pumps or high-speed rotary compressors. Further information can be found in references 28 and 29.

15.3 Boilers and waste-heat recovery

15.3.1 Types of boilers

This section covers industrial boilers, therefore only units of 500 kg h^{-1} of steam, or equivalent hot water, and above will be considered. There are eight categories of boiler available. In order of rated output these are:

Cast iron sectional boilers
Steel boilers
Electrode boilers
Steam generators
Vertical shell boilers
Horizontal shell boilers
Water tube boilers
Fluid bed boilers

15.3.1.1 Cast iron sectional boilers

These are used for hot water services with a maximum operating pressure of 5 bar and a maximum output in the order of 1500 kW. Site assembly of the unit is necessary which will consist of a bank of cast iron sections. Each section has internal waterways.

The sections are assembled with screwed or taper nipples at top and bottom for water circulation and sealing between the sections to contain the products of combustion. Tie rods compress the sections together. A standard section may be used to give a range of outputs dependent upon the number of sections used. After assembly of the sections the mountings, insulation and combustion appliance are fitted. This system makes them suitable for locations where it is impractical to deliver a package unit. Models are available for use with liquid, gaseous and solid fuels.

15.3.1.2 Steel boilers

These are similar in rated outputs to the cast iron sectional boiler. Construction is of rolled steel annular drums for the pressure vessel. They may be in either a vertical or a horizontal configuration depending upon the manufacturer.

15.3.1.3 Electrode boilers

These are available for steam raising up to 3600 kg h^{-1}. Normal working pressure would be 10 bar but higher pressures are available. Construction is a vertical pattern pressure shell containing the electrodes.

The length of the electrodes controls the maximum and minimum water level. The electrical resistance of the water allows a current to flow through the water which in turn boils and releases steam. Since water has to be present within the electrode system, lack of water cannot burn out the boiler. The main advantage with these units is that they may be located at the point where steam is required and as no combustion fumes are produced, no chimney is required. Steam may also be raised relatively quickly as there is little thermal stressing to consider.

15.3.1.4 Steam generators

While the term 'steam generator' may apply to any vessel raising steam, this section is intended to cover coil type boilers in the evaporative range up to 3600 kg h^{-1} of steam. Because of the steam pressure being contained within the tubular coil, pressures of 35 bar and above are available although the majority are supplied to operate at up to 10 bar. They are suitable for firing with liquid and gaseous fuels although the use of heavy fuel oil is not common.

The coiled tube is contained within a pressurized combustion chamber and receives both radiant and convected heat. Feed water is pumped through the coil where it converts to steam. As the quantity of water is slightly more than the firing rate in order to protect the coil from damage a steam separator or steam manifold is required to produce an acceptable dryness fraction to the steam. Because there is no stored water in this type of unit they are lighter in weight and therefore suitable for siting on mezzanine or upper floors adjacent to the plant requiring steam. Also, as the water content is minimal, steam raising can be achieved very quickly and can respond to fluctuating demand within the capacity of the generator. Note that close control of suitable water treatment is essential to protect the coil against any build-up of deposits.

15.3.1.5 Vertical shell boilers

This is a cylindrical boiler where the shell axis is vertical to the firing floor. Originally it comprised a chamber at the lower end of the shell which contained the combustion appliance. The gases rose vertically through a flue surrounded by water. Large-diameter (100 mm) cross-tubes were fitted across this flue to help extract heat from the gases which then proceeded to the chimney. Later versions had the vertical flue replaced by one or two banks of small-bore tubes running horizontally before the gases discharged to the chimney. The steam was contained in a hemispherical chamber forming the top of the shell.

The present-day vertical boiler is generally used for heat recovery from exhaust gases from power generation or marine applications. The gases pass through small-bore vertical tube banks. The same shell may also contain an independently fired section to produce steam at such times as there is insufficient or no exhaust gas available.

15.3.1.6 Horizontal shell boilers

This is the most widely used type of boiler in industry. The construction of a single-flue three-pass wetback shell is illustrated in Figure 15.128. As a single-flue design boiler, evaporation rates of up to 16 300 kg h^{-1} F&A 100°C (see Section 15.3.4.7) are normal on oil and gas and 9000 kg h^{-1} F&A 100°C on coal.

In twin-flue design the above figures approximately double. Normal working pressures of 10–17 bar are available with a maximum working pressure for a shell boiler at 27 bar. The outputs of larger boilers will be reduced if high pressures are required.

The boilers are normally despatched to site as a packaged unit with the shell and smokeboxes fully insulated and painted and mounted on a base frame. The combustion appliance and control panel will be fitted together with the feed-water pump, water-level controls and gauges and a full complement of boiler valves. Additional equipment may be specified and incorporated during construction. Larger boilers may have certain items removed for transport, site restrictions or weight.

Some variations of the three-pass wet-back design exist. The most common is the reverse flame boiler and is shown in Figure 15.129. In this design the combustion appliance fires into a thimble-shaped chamber in which the gases reverse back to the front of the boiler around the flame core. The gases are then turned in a front smokebox to travel along a single pass of

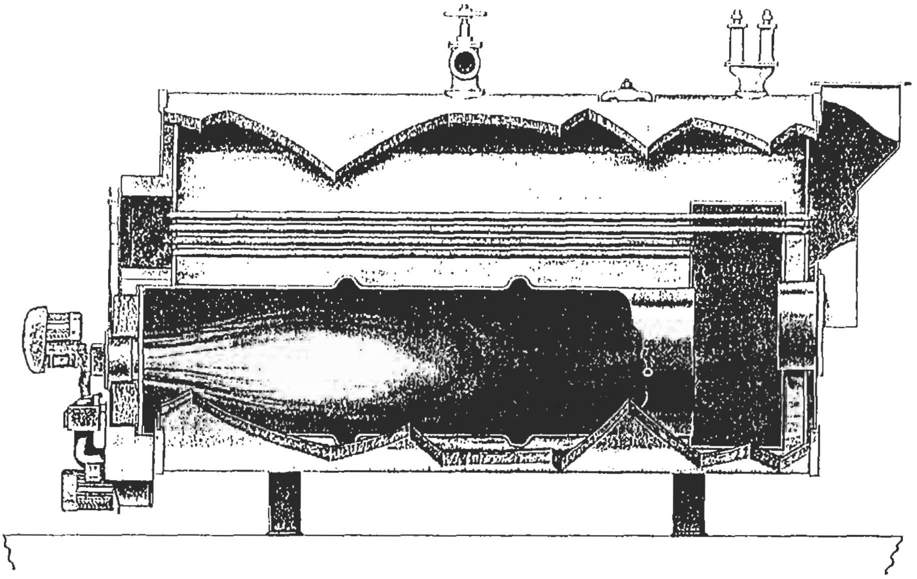

Figure 15.128 Three-pass wet-back shell

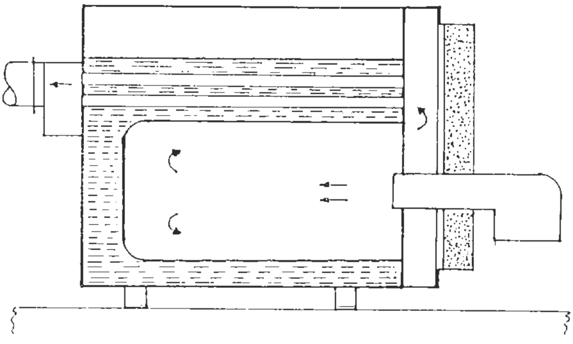

Figure 15.129 Reverse flame shell

smoketubes to the rear of the boiler and then to the chimney. In order to extract maximum heat, gas turbulators or retarders are fitted into these tubes to agitate the gases and help produce the required flue-gas outlet temperature. Evaporative outputs up to 4500 kg h^{-1} F&A 100°C using liquid and gaseous fuels are available.

Other variations of the three-pass wet-back design are the two-pass, where only one pass of smoketubes follows the combustion tube, and the four-pass, where three passes of smoketubes follow the combustion tube. Neither of these are as widely used as the three-pass design.

Dry-back boilers are still occasionally used when a high degree of superheat is required necessitating a rear chamber to house the superheater too large for a semi-wet-back chamber. A water-cooled membrane wall chamber would be an alternative to this.

With twin-flue design boilers it is usual to have completely separate gas passes through the boiler with twin wet-back chambers. It is then possible to operate the boiler on one flue only which effectively doubles its turndown ratio. For example, a boiler rated at 20 000 kg h^{-1} F&A 100°C may reasonably be expected to operate down to 2500 kg h^{-1} F&A 100°C on oil or gas providing suitable combustion equipment and control is incorporated. It would be good practice to alternate, on a planned time scale, which flue takes the single-flue load if prolonged periods of single-flue operation occur.

Shell boilers are supplied with controls making them suitable for unattended operation although certain operations such as blowdown of controls are called for by the insurance companies to comply with safety recommendations. Oil-, gas- and dual-fired boilers are available with a range of combustion appliances. The smaller units have pressure jet-type burners with a turndown of about 2:1, while larger boilers may have rotary cup, medium-pressure air (MPA) or steam-atomizing burners producing a turndown ratio of between 3:1 and 5:1 depending upon size and fuel. The majority have rotary cup-type burners while steam- or air-atomizing burners are used where it is essential that the burner firing is not interrupted even for the shortest period.

For coal-fired boilers, chain-grate stokers, coking stokers and underfeed stokers are supplied. An alternative to these is the fixed-grate and tipping-grate boiler with coal being fed through a drop tube in the crown of the boiler (Figure 15.130). With the fixed grate de-ashing is manual, while with the tipping grate a micro-sequence controller signals sections of the grate to tip, depositing the ash below the grate where it is removed to the front by a drag-link chain conveyor and then to a suitable ash-disposal system.

It is possible to design a boiler to operate on all or any combination of liquid, gaseous and solid fuel and waste heat sources, although its complexity may outweigh its flexibility in practical and commercial terms.

Access to both water- and fireside surfaces of the boiler is important. All boilers will have an inspection opening or manway on the top of the shell with inspection openings in the lower part. Some larger boilers will have a manway in the lower part of the shell or end plate. With a three-pass wet-back boiler all tube cleaning and maintenance is carried

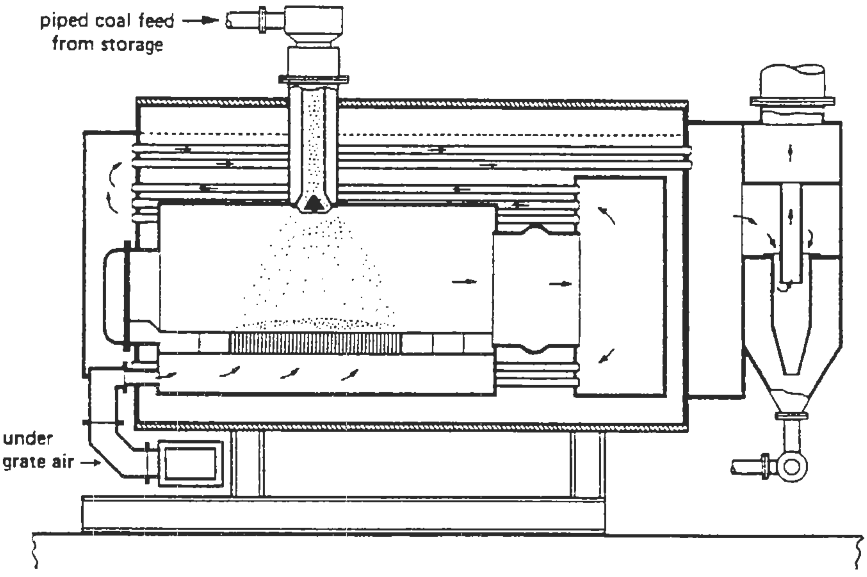

Figure 15.130 Fixed-grate coal-fired boiler

out from the front. The front smokebox doors will be hinged or fitted with davits. On most sizes of boilers bolted-on access panels are sufficient on the rear smokebox. As the majority of shell boilers operate under forced-draught pressurized combustion, steam raising is relatively quick. While good practice would require a cold boiler to come up to pressure over a period of several hours, once it is hot it may be brought up to pressure in minutes, not hours.

For hot water shell boilers the above still applies. The shells would be slightly smaller for equivalent duties due to the absence of steam space. There are three accepted operating bands for hot-water boilers. Low-temperature hot water (LTHW) refers to boilers having a mean water temperature (between flow and return) of below 95°C. Medium-temperature hot water (MTHW) would cover the range 95–150°C. High-temperature hot water (HTHW) covers applications above 150°C.

The flow and return connections will be designed to suit the flow rates and temperature differentials required. The water-return connection will be fitted with either an internal diffuser or a venturi nozzle to assist mixing of the water circulating within the shell and prevent water stratification. The flow connection will incorporate the temperature control stat to signal control of the firing rate for the burner.

Hot-water boilers are potentially more susceptible to gas-side corrosion than steam boilers due to the lower temperatures and pressures encountered on low- and medium-temperature hot-water boilers. With low-temperature hot-water the water-return temperature in particular may drop below the water dewpoint of 50°C, causing vapour in the products of combustion to condense. This, in turn, causes corrosion if it persists for long periods of time. The remedy is to ensure that adequate mixing of the return water maintains the water in the shell above 65°C at all times. Also, if medium or heavy fuel oil is to be used for low- or medium-temperature applications it is desirable to keep the heat transfer surfaces above 130°C, this being the approximate acid dewpoint temperature of the combustion gases. It may therefore be seen how important it is to match the unit or range of unit sizes to the expected load.

15.3.1.7 Water tube boilers

Originally, water tube boilers would have been installed for evaporation of 10 000 kg h^{-1} of steam with pressures as low as 10 bar. At that time this would have been the maximum evaporation expected from a shell-type boiler. Now shell boilers are available at much greater duties and pressures as described in Section 15.3.1.6. It may be appreciated that there will be an area where a water tube boiler is required because of its use on high pressure and then ultimately for the increased duty.

Figure 15.131 illustrates a stoker fired unit. Generally, an output of 60 MW from a single unit may be considered for industrial installations. Higher duties are available if required.

Water tube boilers supplied for national power generation will have outputs up to 900 MW, pressures of 140 bar and final steam temperatures of 500°C. Industrial units are usually supplied with pressures up to 65 bar and with a final steam temperature up to 500°C. This is the maximum temperature and pressure likely to be required for small turbine-driven generating units although turbines are available to operate at much lower pressures of, say, 17 bar.

Construction is a water-cooled wall combustion chamber connected to a steam drum at high level. The bottoms of the walls are connected to headers. Sometimes a bottom or mud drum is incorporated but improved water treatment now available does not always necessitate this.

The chamber is externally insulated and clad. Combustion equipment for solid fuel may be spreader or travelling-grate stokers or by pulverized fuel or fluid bed. Oil and gas burners may be fitted either as main or auxiliary firing equipment. The boilers will incorporate superheaters, economizers and, where necessary, air preheaters and grit arresters and gas-cleaning equipment to meet clean air legislation.

Where water tube boilers are used to recover waste heat (for example, exhaust gases from reciprocating engines) lower gas temperatures may be involved and this, in turn, could obviate the need for water-cooled walls. In this case tube banks may be contained within a gastight insulated chamber.

There are two basic types of water tube boilers: assisted and natural circulation. Assisted circulation might apply where heat is from a convection rather than a radiation source such as a waste-heat application. Natural circulation is more suited where radiant heat and high gas temperatures are present.

Depending upon the required duty and the site, units may be shop assembled or of modular construction. Site-erected units may be designed to have their main components arranged to fit in with the space available.

15.3.1.8 Fluid bed boilers

The name derives from the firebed produced by containing a mixture of silica sand and ash through which air is blown to maintain the particles in suspension. The beds are in three categories: shallow, deep and recirculating. Shallow beds are the most used and are about 150–250 mm in depth in their slumped condition and around twice that when fluidized. Heat is applied to this bed to raise its temperature to around 600°C by auxiliary oil or gas burners. At this temperature coal and/or waste is fed into the bed which is controlled to operate at 800–900°C. Water-cooling surfaces are incorporated into this bed connected to the water system of the boiler. As its name implies, the deep bed is similar to the shallow bed but in this case may be up to 3 m deep in its fluidized state, making it suitable only for large boilers. Similarly, the recirculating fluid bed is only applicable to large water-tube boilers.

Several applications of the shallow bed system are available for industrial boilers, the two most used being the open-bottom shell boiler and the composite boiler. With the open-bottom shell the combustor is sited below the shell and the gases then pass through two banks of horizontal tubes. In the composite boiler the combustion space housing the fluid bed is formed by a water-tube chamber directly connected to a single-pass shell boiler. In order to fluidize the bed, the fan power required will be greater than that with other forms of firing equipment.

To its advantage, the fluid bed may utilize fuels with a high ash content which affect the availability of other systems (see Section 15.3.4.9). It is also possible to control the acid emission by additions to the bed during combustion. They are also less selective in fuels and can cope with a wide range of solid fuel characteristics.

15.3.2 Application and selection

The graph shown in Figure 15.132 illustrates the selective bands for various types of boilers. The operating pressure will govern the steam temperature, except where superheaters are used. For hot-water units the required flow temperature will dictate the operating pressure. It is important that when arriving at the operating pressure for hot-water units due allowance is made for the head of the system, an anti-flash steam margin of 17°C, and a safety valve margin of 1.5 bar.

When deciding to install one or more boilers the following should be considered. The first choice, providing the load is

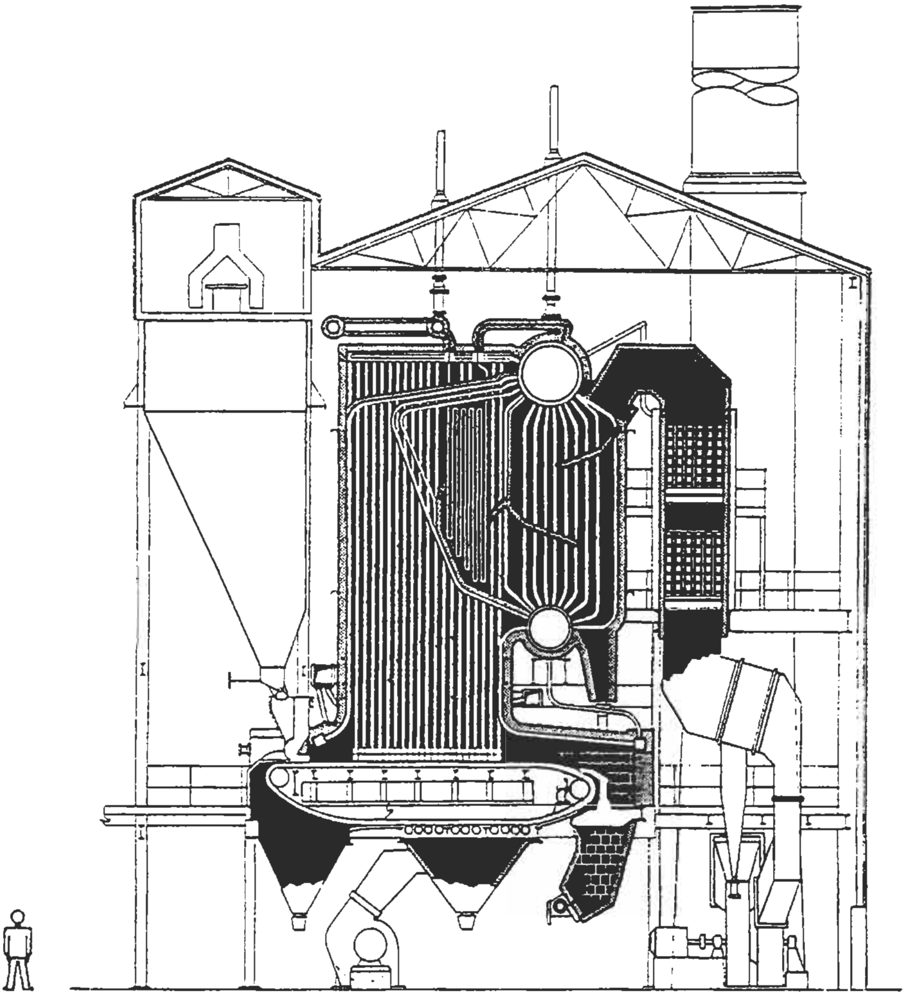

Figure 15.131 Stoker-fired water-tube boiler of 36 300 kg h^{-1} steam capacity at 28 bar and 385°C. (Source: the British Coal publication *Boiler House Design for Solid Fuel* (1980) and with kind permission from the College of Fuel Technology)

within the duty range of the boiler, will be a single unit. This is economically the most attractive providing account is taken of the following:

1. If there is a breakdown on the boiler will services be seriously affected immediately?
2. Will adequate spare parts for the boiler be held in stock or available within an acceptable time and will there be labour to carry out the repair work?
3. Will time be available to service the boiler?
4. The duty will preferably fall within the modulating firing rate of the burner.
5. Prolonged periods of intermittent operation should be avoided.
6. Is there an existing standby unit?

If any or all of these points are not accepted then the next consideration for a shell boiler could be a twin-flue unit suitable for single-flue operation. This has the advantage of using less space than two smaller boilers and having only one set of services.

Moving now to two boilers, the heat load may comprise two elements: one a production process where interruption would cause problems and the other, say, a heating load where any interruption would not be noticed immediately. Assuming that the two elements were of equal duty it would be reasonable to install two boilers each 50% of the total load. One boiler would then be able to cover the process load. An extension to this is to install two boilers each capable of handling the total combined load. Depending upon the boiler size, there may be only a relatively small difference in total capital cost between the above two schemes.

Further options involving three or more boilers must take into account minimum and maximum loads in order to run the plant efficiently. When considering hot water it may be advantageous to consider units in a range of outputs. This will help in operation so that a unit may be brought into duty to match the load and thus avoid low-load conditions and consequent danger of dewpoints. Also, should the plant be fired on solid fuel it will help in maintaining a more even firing rate and a clean stack.

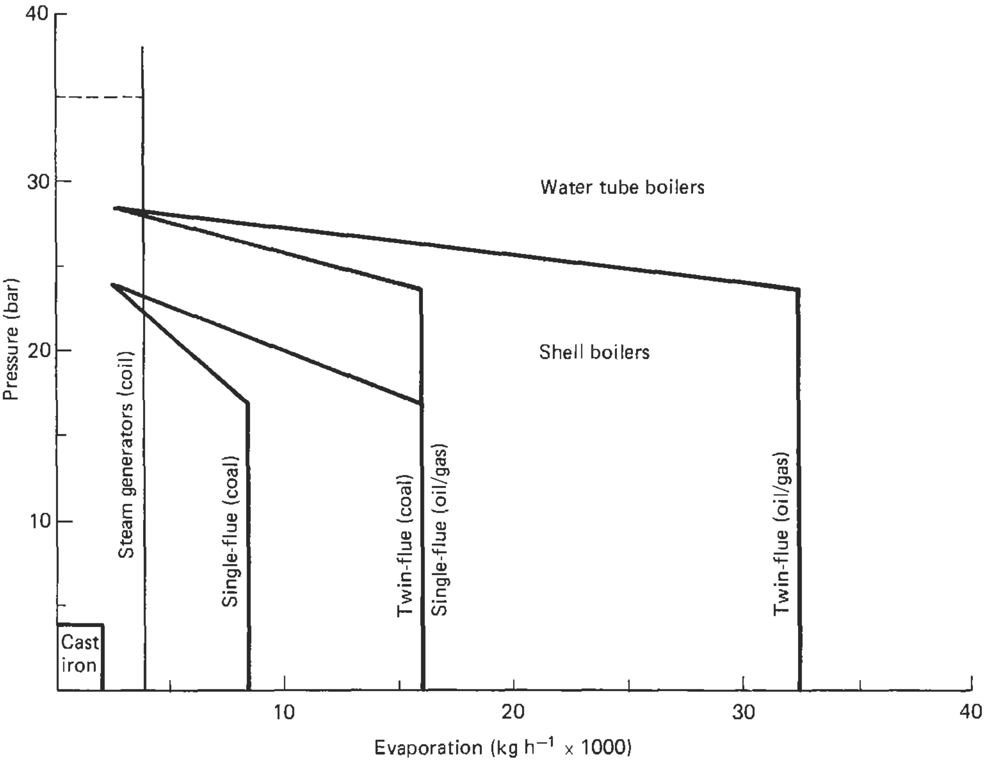

Figure 15.132 Guide to boiler capacities

15.3.3 Heat transfer in industrial boilers

Heat is transferred from the hot products of combustion to the boiler heating surfaces, through the plate and tube walls, and to the water by various mechanisms which involve conduction, radiation and convection.

15.3.3.1 Conduction

The rate at which heat is transferred by conduction through a substance without mass transfer is given by Fourier's Law. This states that the heat flow rate per unit area, or heat flux, is proportional to the temperature gradient in the direction of heat flow. The relationship between heat flux and temperature gradient is characterized by the thermal conductivity, which is a property of the substance. It is temperature dependent and is determined experimentally.

For a plate of area A (m^2), thickness e (m) and with hot and cold face temperatures of T_1 and T_2 (°C), respectively, the normal heat flux ϕ and heat transfer rate Q are given by:

$$\phi = \frac{Q}{A} = \frac{K(T_1 - T_2)}{e} \ (\text{W m}^{-2})$$

where K = thermal conductivity (W m^{-1} K^{-1}).

15.3.3.2 Radiation

Thermal radiation takes place by the emission of electromagnetic waves, at the velocity of light, from all bodies at temperatures above absolute zero. The heat flux from an ideal or 'black-body' radiating surface is proportional to the fourth power of the absolute temperature of the surface. The constant of proportionality is the Stefan–Boltzmann constant, which has a value of 5.6696×10^{-8} (W m^{-2} K^{-4}).

The heat flux radiated from a real surface is less than that from an ideal 'black-body' surface at the same temperature. The ratio of real to 'black-body' flux is the normal total emissivity. Emissivity, like thermal conductivity, is a property which must be determined experimentally.

Although the rate of emission from a surface is independent of the condition of the surroundings, the net overall exchange of radiant heat between surfaces at different temperatures depends on a number of factors. The continuous interchange of energy is a result of the reciprocal processes of radiation and absorption, and these are dependent on geometrical relationships, emissivity differences and the presence of any absorbing and emitting gases in the intervening space.

15.3.3.3 Convection

Convective heat transmission occurs within a fluid, and between a fluid and a surface, by virtue of relative movement of the fluid particles, that is, by mass transfer. Heat exchange between fluid particles in mixing and between fluid particles and a surface is by conduction. The overall rate of heat transfer in convection is, however, also dependent on the capacity of the fluid for energy storage and on its resistance to flow in mixing.

The fluid properties which characterize convective heat transfer are thus thermal conductivity, specific heat capacity and dynamic viscosity. Convection is classified according to the motivating flow. When the flow takes place as a result of density variations caused by temperature gradients the motion is called natural convection. When the flow is caused by an external agency such as a pump or a fan the process is called forced convection.

At a convection heat transfer surface the heat flux (heat transfer rate per unit area) is related to the temperature difference betweeen fluid and surface by a heat transfer coefficient. This is defined by Newton's law of cooling:

$$\phi = \frac{Q}{A} = h_c \Delta T_m$$

where

ϕ = heat flux (W m^{-2})
Q = heat transfer rate (W)
A = surface area (m^2)
ΔT_m = mean temperature difference between fluid and surface (K)
h_c = convective heat transfer coefficient (W m^{-2} K^{-1})

The heat transfer coefficient is correlated experimentally with the fluid transport properties (specific heat, viscosity, thermal conductivity and density), fluid velocity and the geometrical relationship between surface and fluid flow.

15.3.3.4 Furnace heat transfer

Heat transfer in the furnace is mainly by radiation, from the incandescent particles in the flame, and from hot radiating gases such as carbon dioxide and water vapour. The detailed theoretical prediction of overall radiation exchange is complicated by a number of factors such as carbon particle and dust distributions, and temperature variations in three-dimensional mixing. This is overcome by the use of simplified mathematical models or empirical relationships in various fields of application.

For industrial boilers the mean gas temperature at the furnace exit, or at the entrance to the convection section of the boiler, may be calculated using the relationship

$$T = k(H/A)^{0.25}$$

where

T = gas temperature (°C)
H = heat input rate (W) based on the net calorific value of the fuel
A = effective (projected) water-cooled absorption surface area (m^2)
k = a constant which depends on the fuel and the excess air in the combustion products.

The value of k is determined experimentally by gas-temperature measurement. The measurement error of a simple pyrometer can be 250–300 K, due to re-radiation to water-cooled surroundings, and the values given below are based on measurement by a 'Land' multi-shielded high-velocity suction pyrometer.

Typical values for normal excess air at or near full boiler load are:

natural gas	$k = 52.4$
gas oil	$k = 49.1$
heavy fuel oil	$k = 48.3$
coal	$k = 40.3$

In calculating the smoke tube inlet gas temperature of a shell boiler, A includes the effective water-cooled surface in the reversal chamber. In coal-fired boilers any water-cooled surface below the grate is excluded from A.

The total furnace heat absorption may be estimated by using the calculated furnace exit gas temperature and analysis to determine the enthalpy (excluding the latent heat of water vapour) and thus deducting the heat-rejection rate from the net heat input rate.

15.3.3.5 Boiler tube convection heat transfer

The radiant section of an industrial boiler may typically contain only 10% of the total heating surface yet, because of the large temperature difference, it can absorb 30–50% of the total heat exchange. The mean temperature difference available for heat transfer in the convective section is much smaller. To achieve a thermally efficient yet commercially viable design it is necessary to make full use of forced convection within the constraint of an acceptable pressure drop.

Forced convection heat transfer has been measured under widely differing conditions and correlation of the experimental results is made by using the dimensionless groups:

Nusselt number	$Nu = \dfrac{h_c D}{k}$
Reynolds number	$Re = \dfrac{GD}{\mu}$
Prandtl number	$Pr = \dfrac{C_p \mu}{k}$

where

h_c = heat transfer coefficient (W m^{-2} K^{-1})
D = characteristic dimension (m)
K = thermal conductivity (W m^{-1} K^{-1})
G = gas mass velocity (kg m^{-2} s^{-1})
μ = dynamic viscosity (kg m^{-1} s^{-1})
C_p = specific heat at constant pressure (J kg^{-1} K^{-1})

In applying the correlations use is made of the concept of logarithmic mean temperature difference across the boundary layer. For a boiler section, or pass, this is given by:

$$\Delta T_m = \frac{(T_1 - T_w) - (T_2 - T_w)}{\log_n((T_1 - T_w)/(T_2 - T_w))} \text{ (K)}$$

where

T_1 = inlet gas temperature (°C)
T_2 = outlet gas temperature (°C)
T_w = tube wall temperature (°C)

The difference in temperature between the tube wall and the water is small, typically less than 10 K in the convective section. Therefore little error is introduced by using the water temperature as T_w in the evaluation of the gas transport properties.

The representative gas temperatures used in the correlations are the bulk temperature and the film temperature. These are defined as:

Bulk temperature	$T_b = T_w + \Delta T_m$
Film temperature	$T_f = (T_b + T_w)/2$

For longitudinal flow in the tubes of shell boilers the mean heat transfer coefficient may be determined from:

$$Nu = 0.023 Re^{0.8} Pr^{0.4} (1 + (D/L)^{0.7})$$

where D/L is the tube inside diameter to length ratio and the characteristic dimension in Nu and Re is the tube inside diameter. Gas properties are evaluated at the film temperature.

Correlations for forced convection over tubes in cross-flow are complicated by the effect of the tube bank arrangement.

For the range of Reynolds numbers likely to be encountered in industrial boilers the following equations may be used:

In-line arrays $Nu = 0.211 Re^{0.651} Pr^{0.34} F_1 F_2$
Staggered arrays $Nu = 0.273 Re^{0.635} Pr^{0.34} F_1 F_2$

In these cases gas properties are evaluated at the bulk temperature, the characteristic dimension in *Nu* and *Re* is the tube outside diameter, and the Reynolds number is based on the mass velocity through the minimum area for flow between tubes. F_1 is a correction factor for wall-to-bulk property variation which can be calculated from the relationship:

$$F_1 = \frac{(Pr_b)^{0.26}}{(Pr_w)}$$

where Pr_b and Pr_w are Prandtl numbers at the bulk and wall temperatures, respectively. F_2 is a correction factor for the depth of the tube bank in the direction of flow. For bank depths of 10 rows or more $F_2 = 1$. For smaller bank depths the following values of F_2 may be used:

No. of rows	1	2	3	4	5	6	7	8	9
In-line tubes	0.64	0.8	0.87	0.9	0.92	0.94	0.96	0.98	0.99
Staggered tubes	0.68	0.75	0.83	0.89	0.92	0.95	0.97	0.98	0.99

Gas transport properties for the products of combustion of the common fuels, fired at normal excess air at or near full boiler load, may be obtained from Tables 15.20–15.23.

Non-luminous gas radiation has a small overall effect in the convective section, typically 2–5% of total convection. It may therefore be neglected for a conservative calculation.

15.3.3.6 Waterside conditions

In the radiant section of a boiler the fourth power of the wall temperature is typically less than 2% of the fourth power of the mean flame and gas temperature. The effect of waterside conditions and wall thickness on the heat transfer rate are therefore negligible. Even the presence of a dangerous layer of waterside scale reduces the heat flux only by a few per cent. Although this means that scale has little effect on radiant

section performance, it also indicates that the metal temperature escalation due to the presence of scale is not self-limiting but is almost proportional to scale thickness.

The thermal conductivity of an average boiler scale is 2.2($W\ m^{-1}\ K^{-1}$) and that of complex silicate scales is 0.2–0.7($W\ m^{-1}\ K^{-1}$). Since the furnace peak wall flux can be over 300 000 $W\ m^{-2}$ it may readily be seen that a small thickness of scale can raise the metal temperature into the creep region, resulting in very expensive repairs.

In the convective section the gas-side heat transfer coefficient controls the heat flux distribution since the waterside coefficient and the thermal conductance of the tube walls are very large in comparison. For this reason it is usually satisfactory to make an allowance by adding 10 K to the water temperature in steam boilers. In hot-water generators the allowance should be about 20 K because sub-cooled nucleate boiling generally takes place only on the radiant walls and, in shell boilers, on the reversal chamber tubeplate. Waterside heat transfer on the major part of the convective heating surface in these units is by convection without boiling.

15.3.3.7 Further reading

A good introduction to the vast literature on the science and technology of heat transfer, with 87 further references, is given in Rose, J. W. and Cooper, J. R., *Technical Data on Fuel*, 7th edn, British National Committee, World Energy Conference, London, p. 48 (1977).

15.3.4 Terminology

The following explain some of the more fundamental terms encountered when considering boilers.

15.3.4.1 Shell boiler

A boiler in which the products of combustion or hot gases pass through a series of tubes surrounded by water. All are contained in an outer shell.

15.3.4.2 Water tube boiler

A boiler where water circulates through small-bore tubes constructed in banks and connected to drums or headers. The external surfaces of the tubes are exposed to the products of combustion or hot gases.

15.3.4.3 Dry-back boiler

A horizontal shell boiler where the gas-reversal chamber from the combustion tube to the first pass of tubes is external to the rear tube plate and is formed by a refractory-lined steel chamber.

15.3.4.4 Wet-back boiler

A horizontal shell boiler where the gas-reversal chamber from the combustion tube to the first pass of tubes is integral within the boiler shell and is surrounded by water.

15.3.4.5 Economic boiler

A term applied to the early free-standing shell boilers of two- and three-pass construction. Originally they were dry-back and later wet-back. These boilers superseded the brickset Cornish and Lancashire boilers. The earliest economic boilers were also brickset, the gases from the front smokebox returning across the lower external part of the shell contained within the brick setting to form a third pass.

15.3.4.6 Packaged boiler

A concept of a factory-built and assembled shell boiler complete with its combustion appliance, feed-water pump and controls, valves, base frame and insulation. Before this the economic boiler was delivered to site as a bare shell and assembled *in situ*.
