PREFACE

INTRODUCTION

Since the publication of the second edition of *Handbook of Heat Transfer*, there have been many new and exciting developments in the field, covering both fundamentals and applications. As the role of technology has grown, so too has the importance of heat transfer engineering. For example, in the industrial sector heat transfer concerns are critical to the design of practically every process. The same is true of such vitally important areas as energy production, conversion, and the expanding field of environmental controls. In the generation of electrical power, whether by nuclear fission or combustion of fossil fuels, innumerable problems remain to be solved. Similarly, further miniaturization of advanced computers is limited by the capability of removing the heat generated in the microprocessors. Heat transfer problems at the macro scale, as exemplified by global warming, also offer tremendous challenges. As technology advances, engineers are constantly confronted by the need to maximize or minimize heat transfer rates while at the same time maintaining system integrity. The upper and lower boundaries—system size, pressure, and temperature—are constantly expanding, confronting the heat transfer engineer with new design challenges.

In preparing this third edition, the goal of the editors was to provide, in a single volume, up-to-date information needed by practicing engineers to deal with heat transfer problems encountered in their daily work. This new edition of the handbook contains information essential for design engineers, consultants, research engineers, university professors, students, and technicians involved with heat transfer technology.

COVERAGE

The third edition of *Handbook of Heat Transfer* provides expanded treatment of the fundamental topics covered in earlier editions. More than half of the authors of these basic chapters on conduction, convection, radiation, condensation, and boiling are new, reflecting the fact that there are new leaders in the field. Those chapters in the second edition dealing with applications related to the so-called energy crisis (solar energy, energy storage, cooling towers, etc.) have been replaced by new chapters treating heat transfer problems encountered in materials processing, porous media, and micro scale systems. Sections on the following topics were retained and updated: thermophysical properties, heat transfer enhancement, heat exchangers, heat pipes, fluidized beds, nonnewtonian fluids, and measurement techniques.

UNITS

It is recognized at this time that the English Engineering System of units cannot be completely replaced by the International System (SI). Transition from the English system of units to SI will proceed at a rational pace to accommodate the needs of the profession, industry, and the public. The transition period will be long and complex, and duality of units probably will

be demanded for at least one or two decades. Both SI and English units have been incorporated in this edition to the maximum extent possible, with the goal of making the handbook useful throughout the world. In general, numerical results, tables, figures, and equations in the handbook are given in both systems of units wherever presentation in dimensionless form is not given. In a few cases, some tables are presented in one system of units, mostly to save space, and conversion factors are printed at the end of such tables for the reader's convenience.

NOMENCLATURE

An attempt has been made by the editors to use a unified nomenclature throughout the handbook. Given the breadth of the technical coverage, some exceptions will be found. However, with few exceptions, one symbol has only one meaning within any given section. Each symbol is defined at the end of each section of the handbook. Both SI and English units are given for each symbol in the nomenclature lists.

INDEX

This edition provides a comprehensive alphabetical index designed to provide quick reference to information. Taken together with the Table of Contents, this index provides quick and easy access to any topic in the book.

ACKNOWLEDGMENTS

The editors acknowledge the outstanding performance of the contributing authors. Their cooperation on the contents and length of their manuscripts and in incorporating all of the previously mentioned specifications, coupled with the high quality of their work, has resulted in a handbook that we believe will fulfill the needs of the engineering community for many years to come. We also wish to thank the professional staff at McGraw-Hill Book Company, who were involved with the production of the handbook at various stages of the project, for their cooperation and continued support. The outstanding editorial work of Ms. Stephanie Landis of North Market Street Graphics is gratefully acknowledged.

The handbook is ultimately the responsibility of the editors. Care has been exercised to minimize errors, but it is impossible in a work of this magnitude to achieve an error-free publication. Accordingly, the editors would appreciate being informed of any errors so that these may be eliminated from subsequent printings. The editors would also appreciate suggestions from readers on possible improvements in the usefulness of the handbook so that these may be included in future editions.

W. M. Rohsenow
J. P. Hartnett

CONTENTS

Contributors xvii
Preface xix

Chapter 1. Basic Concepts of Heat Transfer **1.1**

Heat Transfer Mechanisms / 1.1
 Conduction / 1.1
 Radiation / 1.3
 Convection / 1.4
 Combined Heat Transfer Mechanisms / 1.10
Conservation Equations / 1.11
 The Equation of Continuity / 1.13
 The Equation of Motion (Momentum Equation) / 1.14
 The Energy Equation / 1.18
 The Conservation Equations for Species / 1.21
 Use of Conservation Equations to Set Up Problems / 1.22
Dimensionless Groups and Similarity in Heat Transfer / 1.23
Units and Conversion Factors / 1.29
Nomenclature / 1.31
References / 1.36

Chapter 2. Thermophysical Properties **2.1**

Conversion Factors / 2.1
Thermophysical Properties of Gases / 2.3
Thermophysical Properties of Liquids / 2.26
Thermophysical Properties of Solids / 2.46
Thermophysical Properties of Saturated Refrigerants / 2.69
Acknowledgment / 2.73
Nomenclature / 2.73
References / 2.73
Selected Additional Sources of Thermophysical Properties / 2.74

Chapter 3. Conduction and Thermal Contact Resistances (Conductances) **3.1**

Introduction / 3.1
Basic Equations, Definitions, and Relationships / 3.2
 Shape Factors / 3.3
 Shape Factors for Ellipsoids: Integral Form for Numerical Calculations / 3.11
 Shape Factors for Three-Dimensional Bodies in Unbounded Domains / 3.15
 Three-Dimensional Bodies with Layers: Langmuir Method / 3.19
 Shape Factors for Two-Dimensional Systems / 3.20
Transient Conduction / 3.23
 Introduction / 3.23
 Internal Transient Conduction / 3.23
 Lumped Capacitance Model / 3.24

Heisler and Grober Charts—Single-Term Approximations / 3.24	
Multidimensional Systems / 3.25	
Transient One-Dimensional Conduction in Half-Spaces / 3.26	
External Transient Conduction from Long Cylinders / 3.28	
Transient External Conduction from Spheres / 3.29	
Instantaneous Thermal Resistance / 3.30	
Transient External Conduction from Isothermal Convex Bodies / 3.31	
Spreading (Constriction) Resistance / 3.34	
Introduction / 3.34	
Definitions of Spreading Resistance / 3.34	
Spreading Resistance of Isoflux Arbitrary Areas on Half-Space / 3.35	
Circular Annular Contact Areas on Half-Space / 3.36	
Doubly Connected Isoflux Contact Areas on Half-Space / 3.37	
Effect of Contact Conductance on Spreading Resistance / 3.38	
Spreading Resistance in Flux Tubes and Channels / 3.39	
Effect of Flux Distribution on Circular Contact Area on Half-Space / 3.39	
Simple Correlation Equations of Spreading Resistance for Circular Contact Area / 3.40	
Accurate Correlation Equations for Various Combinations of Contact Area, Flux Tubes, and Boundary Condition / 3.40	
General Spreading Resistance Expression for Circular Annular Area on Circular Flux Tube / 3.41	
Spreading Resistance Within Two-Dimensional Channels / 3.41	
Effect of Single and Multiple Layers (Coatings) on Spreading Resistance / 3.43	
Circular Contact Area on Single Layer (Coating) on Half-Space / 3.46	
Circular Contact Area on Multiple Layers on Circular Flux Tube / 3.47	
Transient Spreading Resistance / 3.48	
Transient Spreading Resistance of Isoflux Hyperellipse Contact Area on Half-Space / 3.49	
Transient Spreading Resistance of Isoflux Regular Polygonal Contact Area on Half-Space / 3.50	
Transient Spreading Resistance Within Semi-Infinite Flux Tubes and Channels / 3.50	
Contact, Gap, and Joint Resistances and Contact Conductances / 3.51	
Point and Line Contact Models / 3.51	
Thermal Contact, Gap, and Joint Conductance Models / 3.55	
Gap Conductance Model and Integral / 3.59	
Acknowledgments / 3.60	
Nomenclature / 3.60	
References / 3.67	

Chapter 4. Natural Convection

4.1

Introduction / 4.1	
Basics / 4.1	
Equations of Motion and Their Simplification / 4.1	
Problem Classification / 4.5	
Heat Transfer Correlation Method / 4.6	
External Natural Convection / 4.12	
Flat Plates / 4.20	
Cylinders / 4.26	
Open Cavity Problems / 4.32	
Cooling Channels / 4.32	
Extended Surfaces / 4.36	
Natural Convection Within Enclosures / 4.40	
Introduction / 4.40	
Geometry and List of Parameters for Cavities Without Interior Solids / 4.40	
The Conduction Layer Model / 4.43	
Horizontal Rectangular Parallelepiped and Circular Cylinder Cavities / 4.44	
Heat Transfer in Vertical Rectangular Parallelepiped Cavities: $\theta = 90^\circ$ / 4.50	
Heat Transfer in Inclined Rectangular Cavities / 4.55	
Heat Transfer in Enclosures with Interior Solids at Prescribed Temperature / 4.58	
Partitioned Enclosures / 4.60	

Transient Natural Convection /	4.63
External Transient Convection /	4.63
Internal Transient Convection /	4.66
Natural Convection with Internal Generation /	4.68
Internal Problems /	4.68
Convection in Porous Media /	4.69
Properties and Dimensionless Groups /	4.69
External Heat Transfer Correlations /	4.71
Internal Heat Transfer Correlations /	4.72
Mixed Convection /	4.73
External Flows /	4.73
Internal Flows /	4.78
Acknowledgments /	4.80
Nomenclature /	4.80
References /	4.87

Chapter 5. Forced Convection, Internal Flow in Ducts

5.1

Introduction /	5.1
Scope of the Chapter /	5.1
Characteristics of Laminar Flow in Ducts /	5.1
Characteristics of Turbulent Flow in Ducts /	5.2
Hydraulic Diameter /	5.3
Fluid Flow Parameters /	5.3
Heat Transfer Parameters /	5.4
Thermal Boundary Conditions /	5.5
Circular Ducts /	5.5
Laminar Flow /	5.6
Turbulent Flow /	5.18
Transition Flow /	5.30
Concentric Annular Ducts /	5.32
Four Fundamental Thermal Boundary Conditions /	5.32
Laminar Flow /	5.33
Turbulent Flow /	5.50
Parallel Plate Ducts /	5.59
Laminar Flow /	5.59
Turbulent Flow /	5.65
Rectangular Ducts /	5.67
Laminar Flow /	5.67
Turbulent Flow /	5.72
Triangular Ducts /	5.73
Laminar Flow /	5.73
Turbulent Flow /	5.78
Elliptical Ducts /	5.82
Laminar Flow /	5.82
Turbulent Flow /	5.84
Curved Ducts and Helicoidal Pipes /	5.84
Fully Developed Laminar Flow /	5.85
Developing Laminar Flow /	5.90
Turbulent Flow in Coils with Circular Cross Sections /	5.90
Fully Developed Laminar Flow in Curved, Square, and Rectangular Ducts /	5.91
Fully Developed Turbulent Flow in Curved Rectangular and Square Ducts /	5.92
Laminar Flow in Coiled Annular Ducts /	5.92
Laminar Flow in Curved Ducts with Elliptic Cross Sections /	5.92
Longitudinal Flow Between Cylinders /	5.93
Laminar Flow /	5.93
Fully Developed Turbulent Flow /	5.97

Internally Finned Tubes / 5.99
Circular Ducts with Thin Longitudinal Fins / 5.100
Square Ducts with Thin Longitudinal Fins / 5.101
Rectangular Ducts with Longitudinal Fins from Opposite Walls / 5.101
Circular Ducts with Longitudinal Triangular Fins / 5.101
Circular Ducts with Twisted Tape / 5.102
Semicircular Ducts with Internal Fins / 5.104
Elliptical Ducts with Internal Longitudinal Fins / 5.104
Other Singly Connected Ducts / 5.105
Sine Ducts / 5.105
Trapezoidal Ducts / 5.106
Rhombic Ducts / 5.107
Quadrilateral Ducts / 5.107
Regular Polygonal Ducts / 5.107
Circular Sector Ducts / 5.108
Circular Segment Ducts / 5.108
Annular Sector Ducts / 5.110
Stadium-Shaped Ducts / 5.111
Moon-Shaped Ducts / 5.113
Corrugated Ducts / 5.113
Parallel Plate Ducts with Spanwise Periodic Corrugations at One Wall / 5.115
Cusped Ducts / 5.116
Cardioid Ducts / 5.117
Unusual Singly Connected Ducts / 5.117
Other Doubly Connected Ducts / 5.117
Confocal Elliptical Ducts / 5.117
Regular Polygonal Ducts with Centered Circular Cores / 5.118
Circular Ducts with Centered Regular Polygonal Cores / 5.118
Isosceles Triangular Ducts with Inscribed Circular Cores / 5.120
Elliptical Ducts with Centered Circular Cores / 5.120
Concluding Remarks / 5.120
Nomenclature / 5.120
References / 5.125

Chapter 6. Forced Convection, External Flows

6.1

Introduction / 6.1
Definition of Terms / 6.2
Two-Dimensional Laminar Boundary Layer / 6.2
Uniform Free-Stream Conditions / 6.2
Surface with Streamwise Pressure Gradient / 6.28
Two-Dimensional Turbulent Boundary Layer / 6.46
Turbulence Transport Mechanisms and Modeling / 6.46
Uniform Free-Stream Conditions / 6.54
Transitional Boundary Layers / 6.72
Transitional Boundary Layers for Uniform Free-Stream Velocity / 6.72
Complex Configurations / 6.74
Nomenclature / 6.75
References / 6.80

Chapter 7. Radiation

7.1

Introduction / 7.1
Radiation Intensity and Flux / 7.2
Blackbody Radiation / 7.3
Nonblack Surfaces and Materials / 7.6

Radiative Exchange: Enclosures Containing a Nonparticipating Medium / 7.12
Black Surfaces / 7.12
Exchange Among Gray Diffuse Surfaces / 7.16
Radiative Exchange with a Participating Medium / 7.19
Fundamentals and Definitions / 7.19
Solution Techniques for the RTE / 7.24
Solutions to Benchmark Problems / 7.43
Radiative Properties for Participating Media / 7.44
Radiative Properties of Gases / 7.44
Radiative Properties of Particulates / 7.55
Radiative Properties of Porous Materials / 7.66
Radiative Properties of Semitransparent Materials / 7.69
Combined Modes with Radiation / 7.70
The General Energy Equation / 7.70
Interaction with Conduction and Convection / 7.71
Interaction with Combustion and Turbulence / 7.71
Closing Remarks / 7.72
Appendix A: Radiative Property Tables / 7.73
Appendix B: Radiation Configuration Factors / 7.76
Nomenclature / 7.84
References / 7.86

Chapter 8. Microscale Transport Phenomena

8.1

Introduction / 8.1
Time and Length Scales / 8.2
Kinetic Theory / 8.3
Formulation / 8.3
Thermal Conductivity of Crystalline and Amorphous Solids / 8.5
Boltzmann Transport Theory / 8.9
General Formulation / 8.9
Fourier and Ohm's Laws / 8.11
Hyperbolic Heat Equation / 8.12
Mass, Momentum, and Energy Conservation—Hydrodynamic Equations / 8.12
Equation of Radiative Transfer for Photons and Phonons / 8.15
Nonequilibrium Energy Transfer / 8.16
Joule Heating in High-Field Electronic Devices / 8.17
Radiative Heating by Ultrashort Laser Pulses / 8.21
Summary / 8.23
Nomenclature / 8.24
References / 8.25

Chapter 9. Heat Transfer in Porous Media

9.1

Introduction / 9.1
Single-Phase Flow / 9.4
Conduction Heat Transfer / 9.4
Convection Heat Transfer / 9.7
Radiation Heat Transfer / 9.13
Two-Medium Treatment / 9.32
Two-Phase Flow / 9.35
Momentum Equations for Liquid-Gas Flow / 9.36
Local Volume Averaging of Energy Equation / 9.38
Effective Thermal Conductivity / 9.41
Thermal Dispersion / 9.42
Phase Change / 9.44
Condensation at Vertical Impermeable Bounding Surfaces / 9.44
Evaporation at Vertical Impermeable Bounding Surfaces / 9.51

Evaporation at Horizontal Impermeable Bounding Surfaces /	9.52
Evaporation at Thin Porous-Layer-Coated Surfaces /	9.58
Melting and Solidification /	9.60
Nomenclature /	9.68
Glossary /	9.72
References /	9.76

Chapter 10. Nonnewtonian Fluids

10.1

Introduction /	10.1
Overview /	10.1
Classification of Nonnewtonian Fluids /	10.1
Material Functions of Nonnewtonian Fluids /	10.2
Rheological Property Measurements /	10.3
Thermophysical Properties of Nonnewtonian Fluids /	10.7
Governing Equations of Nonnewtonian Fluids /	10.8
Use of Reynolds and Prandtl Numbers /	10.9
Use of the Weissenberg Number /	10.11
Laminar Nonnewtonian Flow in a Circular Tube /	10.11
Velocity Distribution and Friction Factor /	10.11
Fully Developed Heat Transfer /	10.13
Laminar Heat Transfer in the Thermal Entrance Region /	10.13
Laminar Nonnewtonian Flow in a Rectangular Duct /	10.14
Velocity Distribution and Friction Factor /	10.14
Fully Developed Heat Transfer—Purely Viscous Fluids /	10.17
Heat Transfer in the Thermal Entrance Region—Purely Viscous Fluids /	10.21
Laminar Heat Transfer to Viscoelastic Fluids in Rectangular Ducts /	10.23
Turbulent Flow of Purely Viscous Fluids in Circular Tubes /	10.29
Fully Established Friction Factor /	10.29
Heat Transfer /	10.30
Turbulent Flow of Viscoelastic Fluids in Circular Tubes /	10.31
Friction Factor and Velocity Distribution /	10.31
Heat Transfer /	10.35
Degradation /	10.38
Solvent Effects /	10.40
Failure of the Reynolds-Colburn Analogy /	10.41
Turbulent Flow of Purely Viscous Fluids in Rectangular Ducts /	10.42
Friction Factor /	10.42
Heat Transfer /	10.43
Turbulent Flow of Viscoelastic Fluids in Rectangular Ducts /	10.43
Friction Factor /	10.43
Heat Transfer /	10.44
Anomalous Behavior of Aqueous Polyacrylic Acid Solutions /	10.45
Flow over Surfaces; Free Convection; Boiling /	10.45
Flow over Surfaces /	10.45
Free Convection /	10.45
Boiling /	10.46
Suspensions and Surfactants /	10.46
Flow of Food Products /	10.46
Electrorheological Flows /	10.46
Nomenclature /	10.46
References /	10.49

Chapter 11. Techniques to Enhance Heat Transfer

11.1

Introduction /	11.1
General Background /	11.1
Classification of Heat Transfer Enhancement Techniques /	11.1
Performance Evaluation Criteria /	11.3

Treated and Structured Surfaces / 11.6	
Boiling / 11.6	
Condensing / 11.9	
Rough Surfaces / 11.9	
Single-Phase Flow / 11.9	
Boiling / 11.15	
Condensing / 11.15	
Extended Surfaces / 11.16	
Single-Phase Flow / 11.16	
Boiling / 11.21	
Condensing / 11.24	
Displaced Enhancement Devices / 11.29	
Single-Phase Flow / 11.29	
Flow Boiling / 11.32	
Condensing / 11.33	
Swirl-Flow Devices / 11.34	
Single-Phase Flow / 11.34	
Boiling / 11.38	
Condensing / 11.40	
Surface-Tension Devices / 11.41	
Additives for Liquids / 11.41	
Solid Particles in Single-Phase Flow / 11.41	
Gas Bubbles in Single-Phase Flow / 11.41	
Liquid Additives for Boiling / 11.42	
Additives for Gases / 11.44	
Solid Particles in Single-Phase Flow / 11.44	
Liquid Drops in Single-Phase Flow / 11.45	
Mechanical Aids / 11.45	
Stirring / 11.45	
Surface Scraping / 11.46	
Rotating Surfaces / 11.46	
Surface Vibration / 11.46	
Single-Phase Flow / 11.46	
Boiling / 11.49	
Condensing / 11.49	
Fluid Vibration / 11.49	
Single-Phase Flow / 11.49	
Boiling / 11.51	
Condensing / 11.52	
Electric and Magnetic Fields / 11.52	
Injection / 11.54	
Suction / 11.55	
Compound Enhancement / 11.55	
Prospects for the Future / 11.56	
Nomenclature / 11.57	
References / 11.60	

Chapter 12. Heat Pipes

12.1

Introduction / 12.1	
Fundamental Operating Principles / 12.2	
Capillary Limitation / 12.3	
Other Limitations / 12.8	
Design and Manufacturing Considerations / 12.10	
Working Fluid / 12.11	
Wicking Structures / 12.11	
Materials Compatibility / 12.12	
Heat Pipe Sizes and Shapes / 12.12	
Reliability and Life Tests / 12.13	

Heat Pipe Thermal Resistance	/ 12.14
Types of Heat Pipes	/ 12.15
Variable-Conductance Heat Pipes	/ 12.15
Micro-Heat Pipes	/ 12.16
Nomenclature	/ 12.17
References	/ 12.18

Chapter 13. Heat Transfer in Packed and Fluidized Beds

13.1

Introduction	/ 13.1
Hydrodynamics	/ 13.3

HEAT TRANSFER MECHANISMS

Heat is defined as energy transferred by virtue of a temperature difference. It flows from regions of higher temperature to regions of lower temperature. It is customary to refer to different types of heat transfer mechanisms as *modes*. The basic modes of heat transfer are *conduction*, *radiation*, and *convection*.

Conduction

Conduction is the transfer of heat from one part of a body at a higher temperature to another part of the same body at a lower temperature, or from one body at a higher temperature to another body in physical contact with it at a lower temperature. The conduction process takes place at the molecular level and involves the transfer of energy from the more energetic molecules to those with a lower energy level. This can be easily visualized within gases, where we note that the average kinetic energy of molecules in the higher-temperature regions is greater than that of those in the lower-temperature regions. The more energetic molecules, being in constant and random motion, periodically collide with molecules of a lower energy level and exchange energy and momentum. In this manner there is a continuous transport of energy from the high-temperature regions to those of lower temperature. In liquids the molecules are more closely spaced than in gases, but the molecular energy exchange process is qualitatively similar to that in gases. In solids that are nonconductors of electricity (dielectrics), heat is conducted by lattice waves caused by atomic motion. In solids that are good

conductors of electricity, this lattice vibration mechanism is only a small contribution to the energy transfer process, the principal contribution being that due to the motion of free electrons, which move in a similar way to molecules in a gas.

At the macroscopic level the heat flux (i.e., the heat transfer rate per unit area normal to the direction of heat flow) q'' is proportional to the temperature gradient:

$$q'' = -k \frac{dT}{dx} \tag{1.1}$$

where the proportionality constant k is a *transport* property known as the *thermal conductivity* and is a characteristic of the material. The minus sign is a consequence of the fact that heat is transferred in the direction of decreasing temperature. Equation 1.1 is the one-dimensional form of *Fourier's law* of heat conduction. Recognizing that the heat flux is a vector quantity, we can write a more general statement of Fourier's law (i.e., the conduction rate equation) as

$$\mathbf{q}'' = -k \nabla T \tag{1.2}$$

where ∇ is the three-dimensional del operator and T is the scalar temperature field. From Eq. 1.2 it is seen that the heat flux vector \mathbf{q}'' actually represents a current of heat (thermal energy) that flows in the direction of the steepest temperature gradient.

If we consider a one-dimensional heat flow along the x direction in the plane wall shown in Fig. 1.1a, direct application of Eq. 1.1 can be made, and then integration yields

$$q = \frac{kA}{\Delta x} (T_2 - T_1) \tag{1.3}$$

where the thermal conductivity is considered constant, Δx is the wall thickness, and T_1 and T_2 are the wall-face temperatures. Note that $q/A = q''$, where q is the heat transfer rate through an area A . Equation 1.3 can be written in the form

$$q = \frac{T_2 - T_1}{\Delta x/kA} = \frac{T_2 - T_1}{R_{th}} = \frac{\text{thermal potential difference}}{\text{thermal resistance}} \tag{1.4}$$

where $\Delta x/kA$ assumes the role of a *thermal resistance* R_{th} . The relation of Eq. 1.4 is quite like Ohm's law in electric circuit theory. The equivalent electric circuit for this case is shown in Fig. 1.1b.

The electrical analogy may be used to solve more complex problems involving both series and parallel resistances. Typical problems and their analogous electric circuits are given in many heat transfer textbooks [1-4].

In treating conduction problems it is often convenient to introduce another property that is related to the thermal conductivity, namely, the thermal diffusivity α ,

$$\alpha = \frac{k}{\rho c} \tag{1.5}$$

where ρ is the density and c_p is the specific heat at constant pressure.

As mentioned above, heat transfer will occur whenever there exists a temperature difference in a medium. Similarly, whenever there exists a difference in the concentration or density of some chemical species in a mixture, mass transfer must occur. Hence, just as a temperature gradient constitutes the driving potential for heat transfer, the existence of a concentration gradient for some species in a mixture provides the driving potential for transport of that species. Therefore,

FIGURE 1.1 One-dimensional heat conduction through a plane wall (a) and electric analog (b).

the term *mass transfer* describes the relative motion of species in a mixture due to the presence of concentration gradients.

Since the same physical mechanism is associated with heat transfer by conduction (i.e., heat diffusion) and mass transfer by diffusion, the corresponding rate equations are of the same form. The rate equation for mass diffusion is known as *Fick's law*, and for a transfer of species 1 in a binary mixture it may be expressed as

$$j_1 = -\mathbf{D} \frac{dC_1}{dx} \quad (1.6)$$

where C_1 is a mass concentration of species 1 in units of mass per unit volume. This expression is analogous to Fourier's law (Eq. 1.1). Moreover, just as Fourier's law serves to define one important transport property, the thermal conductivity, Fick's law defines a second important transport property, namely the *binary diffusion coefficient* or mass diffusivity \mathbf{D} . The quantity j_1 [mass/(time \times surface area)] is defined as the mass flux of species 1, i.e., the amount of species 1 that is transferred per unit time and per unit area perpendicular to the direction of transfer. In vector form Fick's law is given as

$$\mathbf{j}_1 = -\mathbf{D}\nabla C_1 \quad (1.7)$$

In general, the diffusion coefficient \mathbf{D} for gases at low pressure is almost composition independent; it increases with temperature and varies inversely with pressure. Diffusion coefficients are markedly concentration dependent and generally increase with temperature.

Radiation

Radiation, or more correctly *thermal radiation*, is electromagnetic radiation emitted by a body by virtue of its temperature and at the expense of its internal energy. Thus thermal radiation is of the same nature as visible light, x rays, and radio waves, the difference between them being in their wavelengths and the source of generation. The eye is sensitive to electromagnetic radiation in the region from 0.39 to 0.78 μm ; this is identified as the visible region of the spectrum. Radio waves have a wavelength of 1×10^3 to 2×10^{10} μm , and x rays have wavelengths of 1×10^{-5} to 2×10^{-2} μm , while the bulk of thermal radiation occurs in rays from approximately 0.1 to 100 μm . All heated solids and liquids, as well as some gases, emit thermal radiation. The transfer of energy by conduction requires the presence of a material medium, while radiation does not. In fact, radiation transfer occurs most efficiently in a vacuum. On the macroscopic level, the calculation of thermal radiation is based on the *Stefan-Boltzmann law*, which relates the energy flux emitted by an ideal radiator (or *blackbody*) to the fourth power of the absolute temperature:

$$e_b = \sigma T^4 \quad (1.8)$$

Here σ is the Stefan-Boltzmann constant, with a value of 5.669×10^{-8} $\text{W}/(\text{m}^2 \cdot \text{K}^4)$, or 1.714×10^{-9} $\text{Btu}/(\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{R}^4)$. Engineering surfaces in general do not perform as ideal radiators, and for real surfaces the above law is modified to read

$$e = \epsilon \sigma T^4 \quad (1.9)$$

The term ϵ is called the *emissivity* of the surface and has a value between 0 and 1. When two blackbodies exchange heat by radiation, the net heat exchange is then proportional to the difference in T^4 . If the first body "sees" only body 2, then the net heat exchange from body 1 to body 2 is given by

$$q = \sigma A_1 (T_1^4 - T_2^4) \quad (1.10)$$

When, because of the geometric arrangement, only a fraction of the energy leaving body 1 is intercepted by body 2,

$$q = \sigma A_1 F_{1-2} (T_1^4 - T_2^4) \tag{1.11}$$

where F_{1-2} (usually called a *shape factor* or a *view factor*) is the fraction of energy leaving body 1 that is intercepted by body 2. If the bodies are not black, then the view factor F_{1-2} must be replaced by a new factor \mathcal{F}_{1-2} which depends on the emissivity ϵ of the surfaces involved as well as the geometric view. Finally, if the bodies are separated by gases or liquids that impede the radiation of heat through them, a formulation of the heat exchange process becomes more involved (see Chap. 7).

Convection

Convection, sometimes identified as a separate mode of heat transfer, relates to the transfer of heat from a bounding surface to a fluid in motion, or to the heat transfer across a flow plane within the interior of the flowing fluid. If the fluid motion is induced by a pump, a blower, a fan, or some similar device, the process is called *forced convection*. If the fluid motion occurs as a result of the density difference produced by the temperature difference, the process is called *free* or *natural convection*.

Detailed inspection of the heat transfer process in these cases reveals that, although the bulk motion of the fluid gives rise to heat transfer, the basic heat transfer mechanism is *conduction*, i.e., the energy transfer is in the form of heat transfer by conduction within the moving fluid. More specifically, it is not *heat* that is being convected but *internal energy*.

However, there are convection processes for which there is, in addition, *latent heat exchange*. This latent heat exchange is generally associated with a phase change between the liquid and vapor states of the fluid. Two special cases are *boiling* and *condensation*.

Heat Transfer Coefficient. In convective processes involving heat transfer from a boundary surface exposed to a relatively low-velocity fluid stream, it is convenient to introduce a heat transfer coefficient h , defined by Eq. 1.12, which is known as *Newton's law of cooling*:

$$q'' = h(T_w - T_f) \tag{1.12}$$

Here T_w is the surface temperature and T_f is a characteristic fluid temperature.

For surfaces in unbounded convection, such as plates, tubes, bodies of revolution, etc., immersed in a large body of fluid, it is customary to define h in Eq. (1.12) with T_f as the temperature of the fluid far away from the surface, often identified as T_∞ (Fig. 1.2). For bounded convection, including such cases as fluids flowing in tubes or channels, across tubes in bundles, etc., T_f is usually taken as the enthalpy-mixed-mean temperature, customarily identified as T_m .

The heat transfer coefficient defined by Eq. 1.12 is sensitive to the geometry, to the physical properties of the fluid, and to the fluid velocity. However, there are some special situations in which h can depend on the temperature difference $\Delta T = T_w - T_f$. For example, if the surface is hot enough to boil a liquid surrounding it, h will typically vary as ΔT^2 ; or in the case of natural convection, h varies as some weak power of ΔT —typically as $\Delta T^{1/4}$ or $\Delta T^{1/3}$. It is important to note that Eq. 1.12 as a definition of h is valid in these cases too, although its usefulness may well be reduced.

As $q'' = q/A$, from Eq. 1.12 the thermal resistance in convection heat transfer is given by

$$R_{th} = \frac{1}{hA}$$

which is actually the resistance at a surface-to-fluid interface.

FIGURE 1.2 Velocity and temperature distributions in flow over a flat plate.

At the wall, the fluid velocity is zero, and the heat transfer takes place by conduction. Therefore, we may apply Fourier's law to the fluid at $y = 0$ (where y is the axis normal to the flow direction, Fig. 1.2):

$$q'' = -k \left. \frac{\partial T}{\partial y} \right|_{y=0} \quad (1.13)$$

where k is the thermal conductivity of fluid. By combining this equation with Newton's law of cooling (Eq. 1.12), we then obtain

$$h = \frac{q''}{T_w - T_f} = - \frac{k(\partial T/\partial y)|_{y=0}}{T_w - T_f} \quad (1.14)$$

so that we need to find the temperature gradient at the wall in order to evaluate the heat transfer coefficient.

Similar results may be obtained for *convective mass transfer*. If a fluid of species concentration $C_{1,\infty}$ flows over a surface at which the species concentration is maintained at some value $C_{1,w} \neq C_{1,\infty}$, transfer of the species by convection will occur. Species 1 is typically a vapor that is transferred into a gas stream by evaporation or sublimation at a liquid or solid surface, and we are interested in determining the rate at which this transfer occurs. As for the case of heat transfer, such a calculation may be based on the use of a convection coefficient [3, 5]. In particular we may relate the mass flux of species 1 to the product of a transfer coefficient and a concentration difference

$$j_1 = h_D(C_{1,w} - C_{1,\infty}) \quad (1.15)$$

Here h_D is the convection mass transfer coefficient and it has a dimension of L/t .

At the wall, $y = 0$, the fluid velocity is zero, and species transfer is due only to diffusion; hence

$$j_1 = -D \left. \frac{\partial C_1}{\partial y} \right|_{y=0} \quad (1.16)$$

Combining Eqs. 1.17 and 1.18, it follows that

$$h_D = - \frac{D(\partial C_1/\partial y)|_{y=0}}{C_{1,w} - C_{1,\infty}} \quad (1.17)$$

Therefore conditions that influence the surface concentration gradient $(\partial C_1/\partial y)_{y=0}$ will also influence the convection mass transfer coefficient and the rate of species transfer across the fluid layer near the wall.

For convective processes involving high-velocity gas flows (high subsonic or supersonic flows), a more meaningful and useful definition of the heat transfer coefficient is given by

$$q'' = h(T_w - T_{aw}) \quad (1.18)$$

Here T_{aw} , commonly called the adiabatic wall temperature or the recovery temperature, is the equilibrium temperature the surface would attain in the absence of any heat transfer to or from the surface and in the absence of radiation exchange between the surroundings and the surface. In general the adiabatic wall temperature is dependent on the fluid properties and the properties of the bounding wall. Generally, the adiabatic wall temperature is reported in terms of a dimensionless recovery factor r defined as

$$T_{aw} = T_f + r \frac{V^2}{2c_p} \quad (1.19)$$

The value of r for gases normally lies between 0.8 and 1.0. It can be seen that for low-velocity flows the recovery temperature is equal to the free-stream temperature T_f . In this case,

Eq. 1.15 reduces to Eq. 1.12. From this point of view, Eq. 1.18 can be taken as the generalized definition of the heat transfer coefficient.

Boundary Layer Concept. The transfer of heat between a solid body and a liquid or gas flow is a problem whose consideration involves the science of fluid motion. On the physical motion of the fluid there is superimposed a flow of heat, and the two fields interact. In order to determine the temperature distribution and then the heat transfer coefficient (Eq. 1.14) it is necessary to combine the equations of motion with the energy conservation equation. However, a complete solution for the flow of a viscous fluid about a body poses considerable mathematical difficulty for all but the most simple flow geometries. A great practical breakthrough was made when Prandtl discovered that for most applications the influence of viscosity is confined to an extremely thin region very close to the body and that the remainder of the flow field could to a good approximation be treated as inviscid, i.e., could be calculated by the method of potential flow theory.

FIGURE 1.3 Boundary layer flow past an external surface.

The thin region near the body surface, which is known as the *boundary layer*, lends itself to relatively simple analysis by the very fact of its thinness relative to the dimensions of the body. A fundamental assumption of the boundary layer approximation is that the fluid immediately adjacent to the body surface is at rest relative to the body, an assumption that appears to be valid except for very low-pressure gases, when the mean free path of the gas molecules is large relative to the body [6]. Thus the *hydrodynamic* or *velocity boundary layer* δ may be defined as the region in which the fluid velocity changes from its free-stream, or potential flow, value to zero at the body surface (Fig. 1.3). In reality there is no precise “thickness” to a boundary layer defined in this manner, since the velocity asymptotically approaches the free-stream value. In practice we simply imply that the

boundary layer thickness is the distance in which most of the velocity change takes place.

The viscous forces within the boundary layer region are described in terms of the shear stress τ between the fluid layers. If this stress is assumed to be proportional to the normal velocity gradient, we have the defining equation for viscosity

$$\tau = \mu \frac{du}{dy} \quad (1.20)$$

The constant of proportionality μ is called the *dynamic viscosity* (Pa·s), and Eq. 1.20 is sometimes referred to as Newton’s law of shear [7] for a simple flow in which only the velocity component u exists. The ratio of the viscosity μ to the density ρ is known as the *kinematic viscosity* (m^2/s) and is defined as

$$\nu = \frac{\mu}{\rho} \quad (1.21)$$

Flow inside a tube is a form of boundary layer problem in which, near the tube entrance, the boundary layer grows in much the same manner as over an external surface until its growth is stopped by symmetry at the centerline of the tube (Fig. 1.4). Thus the tube radius becomes the ultimate boundary layer thickness.

When there is heat transfer or mass transfer between the fluid and the surface, it is also found that in most practical applications the major temperature and concentration changes occur in a region very close to the surface. This gives rise to the concept of the *thermal boundary layer* δ_T and the *concentration boundary layer* δ_p . The influence of thermal conductivity k and mass diffusivity D is confined within these regions. Outside the boundary layer region the flow is essentially nonconducting and nondiffusing. The thermal (or concentration) boundary layer may be smaller than, larger than, or the same size as the velocity boundary layer. The development of the thermal boundary layer in the entrance region of a tube is shown in Fig. 1.5.

FIGURE 1.4 Velocity profile for laminar flow in a tube.

FIGURE 1.5 The development of temperature profile in the entrance region of a tube.

It is important to notice the similarity between Eqs. 1.1, 1.6, and 1.20. The heat conduction equation, Eq. 1.1, describes the transport of energy; the diffusion law, Eq. 1.6, describes the transport of mass; and the viscous shear equation, Eq. 1.20, describes the transport of momentum across fluid layers. We note also that the kinematic viscosity ν , the thermal diffusivity α , and the diffusion coefficient D all have the same dimensions L^2/t . As shown in Table 1.10, a dimensionless number can be formed from the ratio of any two of these quantities, which will give relative speeds at which momentum, energy, and mass diffuse through the medium.

Laminar and Turbulent Flows. There are basically two different types of fluid motion, identified as *laminar* and *turbulent* flow. In previous sections we referred basically to laminar flow.

In the case of flow over a flat plate (Fig. 1.6), the flow near the leading edge is smooth and streamlined. Locally within the boundary layer the velocity is constant and invariant with time. The boundary layer thickness grows with increasing distance from the leading edge, and at some critical distance the inertial effects become sufficiently large compared to the viscous damping action that small disturbances in the flow begin to grow. As these disturbances

FIGURE 1.6 Laminar, transition, and turbulent boundary layer flow regimes in flow over a flat plate.

FIGURE 1.7 Property variation with time at some point in a turbulent boundary layer.

become amplified, the regularity of the viscous flow is disturbed and a transition from laminar to turbulent flow takes place. (However, there still must be a very thin laminar sub-layer next to the wall, at least for a smooth plate.) These disturbances may originate from the free stream or may be induced by surface roughness.

In the turbulent flow region a very efficient mixing takes place, i.e., macroscopic chunks of fluid move across streamlines and transport energy and mass as well as momentum vigorously. The most essential feature of a turbulent flow is the fact that at a given point in it, the flow property X (e.g.,

velocity component, pressure, temperature, or a species concentration) is not constant with time but exhibits very irregular, high-frequency fluctuations (Fig. 1.7). At any instant, X may be represented as the sum of a *time-mean* value \bar{X} and a fluctuating component X' . The average is taken over a time that is large compared with the period of typical fluctuation, and if \bar{X} is independent of time, the time-mean flow is said to be *steady*.

The existence of turbulent flow can be advantageous in the sense of providing increased heat and mass transfer rates. However, the motion is extremely complicated and difficult to describe theoretically [3, 8]. In dealing with turbulent flow it is customary to speak of a *total* shear stress and *total* fluxes normal to the main flow direction (the main flow is in the x direction, and the y axis is normal to the flow direction), which are defined as

$$\tau_t = \mu \frac{\partial \bar{u}}{\partial y} - \rho \overline{u'v'} \quad (1.22)$$

$$q'' = -\left(k \frac{\partial \bar{T}}{\partial y} - \rho c_p \overline{v'T'} \right) \quad (1.23)$$

$$j_{1,i} = -\left(\mathbf{D} \frac{\partial \bar{C}_i}{\partial y} - \overline{v'C'_i} \right) \quad (1.24)$$

where the first term on the right side of Eqs. 1.22–1.24 is the contribution due to molecular diffusion and the second term is the contribution due to turbulent mixing. For example, $\overline{u'v'}$ is the time average of the product of u' and v' .

A simple conceptual model for turbulent flow deals with *eddies*, small portions of fluid in the boundary layer that move about for a short time before losing their identity [8]. The transport coefficient, which is defined as *eddy diffusivity for momentum transfer* ϵ_M , has the form

$$\epsilon_M \frac{\partial \bar{u}}{\partial y} = -\overline{u'v'} \quad (1.25)$$

Similarly, eddy diffusivities for heat and mass transfer, ϵ_H and ϵ_m , respectively, may be defined by the relations

$$\epsilon_H \frac{\partial \bar{T}}{\partial y} = -\overline{v'T'} \quad (1.26)$$

$$\epsilon_m \frac{\partial \bar{C}_i}{\partial y} = -\overline{v'C'_i} \quad (1.27)$$

Hence the total shear stress and total fluxes may be expressed, with the help of the relations of Eqs. 1.5 and 1.21, as

$$\tau_t = \rho(\nu + \epsilon_M) \frac{\partial \bar{u}}{\partial y} \quad (1.28)$$

$$q''_i = -\rho c_p (\alpha + \epsilon_H) \frac{\partial \bar{T}}{\partial y} \quad (1.29)$$

$$j_{1,c} = -(\mathbf{D} + \epsilon_m) \frac{\partial \bar{C}_1}{\partial y} \quad (1.30)$$

In the region of a turbulent boundary layer far from the surface (the core region), the eddy diffusivities are much larger than the molecular diffusivities. The enhanced mixing associated with this condition has the effect of making velocity, temperature, and concentration profiles more uniform in the core. This behavior is shown in Fig. 1.8, which gives the measured velocity distributions for laminar and turbulent flow where the mass flow is the same in both cases [7]. It is evident from Fig. 1.8 that the velocity gradient at the surface, and therefore the surface shear stress, is much larger for turbulent flow than for laminar flow. Following the same argument, the temperature or concentration gradient at the surface, and therefore the heat and mass transfer rates, are much larger for turbulent than for laminar flow. When the flow in the tube is turbulent, the mean velocity is about 83 percent of the center

FIGURE 1.8 Velocity distribution in a tube: (a) laminar; (b) turbulent.

velocity. For laminar flow, the profile has a parabolic shape and the mean velocity is one-half the value at the center.

A fundamental problem in performing a turbulent flow analysis involves determining the eddy diffusivities as a function of the mean properties of the flow. Unlike the molecular diffusivities, which are strictly fluid properties, the eddy diffusivities depend strongly on the nature of the flow; they can vary from point to point in a boundary layer, and the specific variation can be determined only from experimental data.

For flow in circular tubes, the numerical value of the Reynolds number (defined in Table 1.10), based on mean velocity at which transition from laminar to turbulent flow occurs, was established as being approximately 2300, i.e.,

$$\text{Re}_{cr} = \left(\frac{V_m D}{\nu} \right)_{cr} = 2300 \quad (1.31)$$

There exists, however, as demonstrated by numerous experiments [7], a lower value for Re_{cr} that is approximately at 2000. Below this value the flow remains laminar even in the presence of very strong disturbances. If the Reynolds number is greater than 10,000, the flow is considered to be fully turbulent. In the 2300 to 10,000 region, the flow is often described as transition flow. It is possible to shift these values by minimizing the disturbances in the inlet flow, but for general engineering application the numbers cited are representative.

For a flow over a flat plate, the transition to turbulent flow takes place at distance x , measured from the leading edge, as determined by

$$\text{Re}_{cr} = \left(\frac{V_\infty x}{\nu} \right)_{cr} = 3.5 \times 10^5 \text{ to } 10^6 \quad (1.32)$$

FIGURE 1.9 Velocity profile associated with separation on a circular cylinder in cross flow.

but the values are dependent on the level of turbulence in the main stream. Here V_∞ is the free-stream velocity.

A particularly interesting phenomenon connected with transition in the boundary layer occurs with blunt bodies, e.g., spheres or circular cylinders. In the region of adverse pressure gradient (i.e., $\partial P/\partial x > 0$ in Fig. 1.9) the boundary layer separates from the surface. At this location the shear stress goes to zero, and beyond this point there is a reversal of flow in the vicinity of the wall, as shown in Fig. 1.9. In this

separation region, the analysis of the flow is very difficult and emphasis is placed on the use of experimental methods to determine heat and mass transfer.

Nonnewtonian Fluids. In previous parts of this section we have mentioned only newtonian fluids. *Newtonian fluids* are those that have a linear relationship between the shear stress and the velocity gradient (or rate of strain), as in Eq. 1.20. The shear stress τ is equal to zero when *du/dy* equals zero. The viscosity, given by the ratio of shear stress to velocity gradient, is independent of the velocity gradient (or rate of strain), but may be a function of temperature and pressure.

Gases, and liquids such as water, usually exhibit newtonian behavior. However, many fluids, such as colloidal suspensions, polymeric solutions, paint, grease, blood, ketchup, slurry, etc., do not follow the linear shear stress–velocity gradient relation; these are called *nonnewtonian fluids*. Chapter 10 deals with the hydrodynamics and heat transfer of nonnewtonian fluids.

Combined Heat Transfer Mechanisms

In practice, heat transfer frequently occurs by two mechanisms in parallel. A typical example is shown in Fig. 1.10. In this case the heat conducted through the plate is removed from the plate surface by a combination of convection and radiation. An energy balance in this case gives

$$-k_s A \left. \frac{dT}{dy} \right|_w = hA(T_w - T_\infty) + \sigma A \epsilon (T_w^4 - T_a^4) \quad (1.33)$$

where T_a is the temperature of the surroundings, k_s is the thermal conductivity of the solid plate, and ϵ is the emissivity of the plate (i.e., in this special case $\mathcal{F}_{1-2} \equiv \epsilon$, as the area of the plate is much smaller than the area of the surroundings [3]). The plate and the surroundings are separated by a gas that has no effect on radiation.

There are many applications where radiation is combined with other modes of heat transfer, and the solution of such problems can often be simplified by using a thermal resistance R_{th} for radiation. The definition of R_{th} is similar to that of the thermal resistance for convection and conduction. If the heat transfer by radiation, for the example in Fig. 1.10, is written

$$q = \frac{T_w - T_a}{R_{th}} \quad (1.34)$$

FIGURE 1.10 Combination of conduction, convection, and radiation heat transfer.

the resistance is given by

$$R_{\text{th}} = \frac{T_w - T_a}{\sigma A \epsilon (T_w^4 - T_a^4)} \quad (1.35)$$

Also, a heat transfer coefficient h_r can be defined for radiation:

$$h_r = \frac{1}{R_{\text{th}} A} = \frac{\sigma \epsilon (T_w^4 - T_a^4)}{T_w - T_a} = \sigma \epsilon (T_w + T_a)(T_w^2 + T_a^2) \quad (1.36)$$

Here we have linearized the radiation rate equation, making the heat rate proportional to a temperature difference rather than to the difference between two temperatures to the fourth power. Note that h_r depends strongly on temperature, while the temperature dependence of the convection heat transfer coefficient h is generally weak.

CONSERVATION EQUATIONS

Each time we try to solve a new problem related to momentum, heat, and mass transfer in a fluid, it is convenient to start with a set of equations based on basic laws of conservation for physical systems. These equations include:

1. The continuity equation (conservation of mass)
2. The equation of motion (conservation of momentum)
3. The energy equation (conservation of energy, or the first law of thermodynamics)
4. The conservation equation for species (conservation of species)

These equations are sometimes called the *equations of change*, inasmuch as they describe the change of velocity, temperature, and concentration with respect to time and position in the system.

The first three equations are sufficient for problems involving a pure fluid (a *pure* substance is a single substance characterized by an unvarying chemical structure). The fourth equation is added for a mixture of chemical species, i.e., when mass diffusion with or without chemical reactions is present.

- *The control volume.* When deriving the conservation equations it is necessary to select a control volume. The derivation can be performed for a volume element of any shape in a given coordinate system, although the most convenient shape is usually assumed for simplicity (e.g., a rectangular shape in a rectangular coordinate system). For illustration purposes, different coordinate systems are shown in Fig. 1.11. In selecting a control volume we

FIGURE 1.11 Coordinate systems: (a) rectangular, (b) cylindrical, (c) spherical.

have the option of using a volume fixed in space, in which case the fluid flows through the boundaries, or a volume containing a fixed mass of fluid and moving with the fluid. The former is known as the eulerian viewpoint and the latter is the lagrangian viewpoint. Both approaches yield equivalent results.

- *The partial time derivative $\partial B/\partial t$.* The partial time derivative of $B(x, y, z, t)$, where B is any continuum property (e.g., density, velocity, temperature, concentration, etc.), represents the change of B with time at a fixed position in space. In other words, $\partial B/\partial t$ is the change of B with t as seen by a *stationary observer*.
- *Total time derivative dB/dt .* The total time derivative is related to the partial time derivative as follows:

$$\frac{dB}{dt} = \frac{\partial B}{\partial t} + \frac{dx}{dt} \frac{\partial B}{\partial x} + \frac{dy}{dt} \frac{\partial B}{\partial y} + \frac{dz}{dt} \frac{\partial B}{\partial z} \quad (1.37)$$

where dx/dt , dy/dt , and dz/dt are the components of the velocity of a moving observer. Therefore, dB/dt is the change of B with time as seen by the moving observer.

- *Substantial time derivative DB/Dt .* This derivative is a special kind of total time derivative where the velocity of the observer is just the same as the velocity of the stream, i.e., the observer drifts along with the current:

$$\frac{DB}{Dt} = \frac{\partial B}{\partial t} + u \frac{\partial B}{\partial x} + v \frac{\partial B}{\partial y} + w \frac{\partial B}{\partial z} \quad (1.38)$$

where u , v , and w are the components of the local fluid velocity \mathbf{V} . The substantial time derivative is also called the *derivative following the motion*. The sum of the last three terms on the right side of Eq. 1.38 is called the *convective contribution* because it represents the change in B due to translation.

The use of the operator D/Dt is always made when rearranging various conservation equations related to the volume element fixed in space to an element following the fluid motion. The operator D/Dt may also be expressed in vector form:

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + (\mathbf{V} \cdot \nabla) \quad (1.39)$$

Mathematical operations involving ∇ are given in many textbooks. Applications of ∇ in various operations involving the conservation equations are given in Refs. 6 and 10. Table 1.1 gives the expressions for D/Dt in different coordinate systems.

TABLE 1.1 Substantial Derivative in Different Coordinate Systems

Rectangular coordinates (x, y, z) :

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + u \frac{\partial}{\partial x} + v \frac{\partial}{\partial y} + w \frac{\partial}{\partial z}$$

Cylindrical coordinates (r, θ, z) :

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + v_r \frac{\partial}{\partial r} + \frac{v_\theta}{r} \frac{\partial}{\partial \theta} + v_z \frac{\partial}{\partial z}$$

Spherical coordinates (r, θ, ϕ) :

$$\frac{D}{Dt} = \frac{\partial}{\partial t} + v_r \frac{\partial}{\partial r} + \frac{v_\theta}{r} \frac{\partial}{\partial \theta} + \frac{v_\phi}{r \sin \theta} \frac{\partial}{\partial \phi}$$

The Equation of Continuity

For a volume element fixed in space,

$$\frac{\partial \rho}{\partial t} = -(\nabla \cdot \rho \mathbf{V}) \quad (1.40)$$

net rate of
mass efflux per
unit volume

The continuity equation in this form describes the rate of change of density at a fixed point in the fluid. By performing the indicated differentiation on the right side of Eq. 1.40 and collecting all derivatives of ρ on the left side, we obtain an equivalent form of the equation of continuity:

$$\frac{D\rho}{Dt} = -\rho(\nabla \cdot \mathbf{V}) \quad (1.41)$$

The continuity equation in this form describes the rate of change of density as seen by an observer "floating along" with the fluid.

For a fluid of constant density (incompressible fluid), the equation of continuity becomes:

$$\nabla \cdot \mathbf{V} = 0 \quad (1.42)$$

Table 1.2 gives the equation of continuity in different coordinate systems.

TABLE 1.2 Equation of Continuity in Different Coordinate Systems

Rectangular coordinates (x, y, z):

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x}(\rho u) + \frac{\partial}{\partial y}(\rho v) + \frac{\partial}{\partial z}(\rho w) = 0$$

Cylindrical coordinates (r, θ, z):

$$\frac{\partial \rho}{\partial t} + \frac{1}{r} \frac{\partial}{\partial r}(\rho r v_r) + \frac{1}{r} \frac{\partial}{\partial \theta}(\rho v_\theta) + \frac{\partial}{\partial z}(\rho v_z) = 0$$

Spherical coordinates (r, θ, ϕ):

$$\frac{\partial \rho}{\partial t} + \frac{1}{r^2} \frac{\partial}{\partial r}(\rho r^2 v_r) + \frac{1}{r \sin \theta} \frac{\partial}{\partial \theta}(\rho v_\theta \sin \theta) + \frac{1}{r \sin \theta} \frac{\partial}{\partial \phi}(\rho v_\phi) = 0$$

Incompressible flow

Rectangular coordinates (x, y, z):

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0$$

Cylindrical coordinates (r, θ, z):

$$\frac{1}{r} \frac{\partial}{\partial r}(r v_r) + \frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{\partial v_z}{\partial z} = 0$$

Spherical coordinates (r, θ, ϕ):

$$\frac{1}{r^2} \frac{\partial}{\partial r}(r^2 v_r) + \frac{1}{r \sin \theta} \frac{\partial}{\partial \theta}(v_\theta \sin \theta) + \frac{1}{r \sin \theta} \frac{\partial v_\phi}{\partial \phi} = 0$$

The Equation of Motion (Momentum Equation)

The momentum equation for a stationary volume element (i.e., a balance over a volume element fixed in space) with gravity as the only body force is given by

$$\frac{\partial \rho \mathbf{V}}{\partial t} = -(\nabla \cdot \rho \mathbf{V}) \mathbf{V} - \nabla P + \nabla \cdot \boldsymbol{\tau} + \rho \mathbf{g} \quad (1.43)$$

rate of increase of momentum per unit volume	=	rate of momentum gain by convection per unit volume	-	pressure force on element per unit volume	+	rate of momentum gain by viscous transfer per unit volume	+	gravitational force on element per unit volume
---	---	--	---	---	---	---	---	--

Equation 1.43 may be rearranged, with the help of the equation of continuity, to give

$$\rho \frac{D\mathbf{V}}{Dt} = -\nabla P + \nabla \cdot \boldsymbol{\tau} + \rho \mathbf{g} \quad (1.44)$$

The last equation is a statement of Newton’s second law of motion in the form *mass × acceleration = sum of forces*.

These two forms of the equation of motion (Eqs. 1.43 and 1.44), correspond to the two forms of the equation of continuity (Eqs. 1.40 and 1.41). As indicated, the only body force included in Eqs. 1.43 and 1.44 is gravity. In general, electromagnetic forces may also act on a fluid.

The scalar components of Eq. 1.44 are listed in Table 1.3 and the components of the stress tensor $\boldsymbol{\tau}$ are given in Table 1.4.

For the flow of a newtonian fluid with varying density but constant viscosity μ , Eq. 1.44 becomes

$$\rho \frac{D\mathbf{V}}{Dt} = -\nabla P + \frac{1}{3} \mu \nabla (\nabla \cdot \mathbf{V}) + \mu \nabla^2 \mathbf{V} + \rho \mathbf{g} \quad (1.45)$$

If ρ and μ are constant, Eq. 1.44 may be simplified by means of the equation of continuity ($\nabla \cdot \mathbf{V} = 0$) for a newtonian fluid to give

$$\rho \frac{D\mathbf{V}}{Dt} = -\nabla P + \mu \nabla^2 \mathbf{V} + \rho \mathbf{g} \quad (1.46)$$

This is the famous Navier-Stokes equation in vector form. The scalar components of Eq. 1.46 are given in Table 1.5.

For $\nabla \cdot \boldsymbol{\tau} = 0$, Eq. 1.44 reduces to Euler’s equation:

$$\rho \frac{D\mathbf{V}}{Dt} = -\nabla P + \rho \mathbf{g} \quad (1.47)$$

which is applicable for describing flow systems in which viscous effects are relatively unimportant.

As mentioned before, there is a subset of flow problems, called *natural convection*, where the flow pattern is due to buoyant forces caused by temperature differences. Such buoyant forces are proportional to the coefficient of thermal expansion β , defined as:

$$\beta = -\frac{1}{\rho} \left(\frac{\partial \rho}{\partial T} \right)_p \quad (1.48)$$

where T is absolute temperature. Using an approximation that applies to low fluid velocities and small temperature variations, it can be shown [9–11] that

$$\nabla P - \rho \mathbf{g} = \rho \beta \mathbf{g} (T - T_\infty) \quad (1.49)$$

Then Eq. 1.44 becomes

$$\rho \frac{D\mathbf{V}}{Dt} = \nabla \cdot \boldsymbol{\tau} - \rho\beta\mathbf{g}(T - T_\infty) \quad (1.50)$$

buoyant force
 on element per
 unit volume

The above equation of motion is used for setting up problems in natural convection when the ambient temperature T_∞ may be defined.

The Energy Equation

For a stationary volume element through which a pure fluid is flowing, the energy equation reads

$$\begin{aligned} \frac{\partial}{\partial t} \rho(\mathbf{u} + \frac{1}{2}V^2) = & -\nabla \cdot \rho\mathbf{V}(\mathbf{u} + \frac{1}{2}V^2) - \nabla \cdot \mathbf{q}'' + \rho(\mathbf{V} \cdot \mathbf{g}) \\ & - \nabla \cdot P\mathbf{V} + \nabla \cdot (\boldsymbol{\tau} \cdot \mathbf{V}) + q''' \end{aligned} \quad (1.51)$$

rate of gain of energy per unit volume rate of energy input per unit volume by convection rate of energy input per unit volume by conduction rate of work done on fluid per unit volume by gravitational forces
 rate of work done on fluid per unit volume by pressure forces rate of work done on fluid per unit volume by viscous forces rate of heat generation per unit volume ("source term")

where \mathbf{u} is the internal energy. The left side of this equation, which represents the rate of accumulation of internal and kinetic energy, does not include the potential energy of the fluid, since this form of energy is included in the work term on the right side. Equation 1.51 may be rearranged, with the aid of the equations of continuity and motion, to give [10, 19]

$$\rho \frac{D\mathbf{u}}{Dt} = -\nabla \cdot \mathbf{q}'' - P(\nabla \cdot \mathbf{V}) + \nabla\mathbf{V}:\boldsymbol{\tau} + q''' \quad (1.52)$$

A summary of $\nabla\mathbf{V}:\boldsymbol{\tau}$ in different coordinate systems is given in Table 1.6. For a newtonian fluid,

$$\nabla\mathbf{V}:\boldsymbol{\tau} = \mu\Phi \quad (1.53)$$

and values of dissipation function Φ in different coordinate systems are given in Table 1.7. Components of the heat flux vector $\mathbf{q}'' = -k\nabla T$ are given in Table 1.8 for different coordinate systems.

Often it is more convenient to work with enthalpy rather than internal energy. Using the definition of enthalpy, $i = \mathbf{u} + P/\rho$, and the mass conservation equation, Eq. 1.41, Eq. 1.52 can be rearranged to give

$$\rho \frac{Di}{Dt} = \nabla \cdot k\nabla T + \frac{DP}{Dt} + \mu\Phi + q''' \quad (1.54)$$

TABLE 1.3 Equation of Motion in Terms of Viscous Stresses (Eq. 1.44)*

Rectangular coordinates (x, y, z)	
x direction	$\rho \left(\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} \right) = -\frac{\partial P}{\partial x} + \left(\frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} + \frac{\partial \tau_{zx}}{\partial z} \right) + \rho g_x$
y direction	$\rho \left(\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} \right) = -\frac{\partial P}{\partial y} + \left(\frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \tau_{yy}}{\partial y} + \frac{\partial \tau_{zy}}{\partial z} \right) + \rho g_y$
z direction	$\rho \left(\frac{\partial w}{\partial t} + u \frac{\partial w}{\partial x} + v \frac{\partial w}{\partial y} + w \frac{\partial w}{\partial z} \right) = -\frac{\partial P}{\partial z} + \left(\frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} + \frac{\partial \tau_{zz}}{\partial z} \right) + \rho g_z$
Cylindrical coordinates (r, θ, z)	
r direction	$\rho \left(\frac{\partial v_r}{\partial t} + v_r \frac{\partial v_r}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_r}{\partial \theta} - \frac{v_\theta^2}{r} + v_z \frac{\partial v_r}{\partial z} \right) = -\frac{\partial P}{\partial r} + \left[\frac{1}{r} \frac{\partial}{\partial r} (r \tau_{rr}) + \frac{1}{r} \frac{\partial \tau_{\theta r}}{\partial \theta} - \frac{\tau_{\theta\theta}}{r} + \frac{\partial \tau_{zr}}{\partial z} \right] + \rho g_r$
θ direction	$\rho \left(\frac{\partial v_\theta}{\partial t} + v_r \frac{\partial v_\theta}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_r v_\theta}{r} + v_z \frac{\partial v_\theta}{\partial z} \right) = -\frac{1}{r} \frac{\partial P}{\partial \theta} + \left[\frac{1}{r^2} \frac{\partial}{\partial r} (r^2 \tau_{r\theta}) + \frac{1}{r} \frac{\partial \tau_{\theta\theta}}{\partial \theta} + \frac{\partial \tau_{z\theta}}{\partial z} \right] + \rho g_\theta$
z direction	$\rho \left(\frac{\partial v_z}{\partial t} + v_r \frac{\partial v_z}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_z}{\partial \theta} + v_z \frac{\partial v_z}{\partial z} \right) = -\frac{\partial P}{\partial z} + \left[\frac{1}{r} \frac{\partial}{\partial r} (r \tau_{rz}) + \frac{1}{r} \frac{\partial \tau_{\theta z}}{\partial \theta} + \frac{\partial \tau_{zz}}{\partial z} \right] + \rho g_z$
Spherical coordinates (r, θ, ϕ)	
r direction	$\rho \left(\frac{\partial v_r}{\partial t} + v_r \frac{\partial v_r}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_r}{\partial \theta} + \frac{v_\phi}{r \sin \theta} \frac{\partial v_r}{\partial \phi} - \frac{v_\theta^2 + v_\phi^2}{r} \right) = -\frac{\partial P}{\partial r} + \left[\frac{1}{r^2} \frac{\partial}{\partial r} (r^2 \tau_{rr}) + \frac{1}{r \sin \theta} \frac{\partial}{\partial \theta} (\tau_{\theta r} \sin \theta) + \frac{1}{r \sin \theta} \frac{\partial \tau_{\phi r}}{\partial \phi} - \frac{\tau_{\theta\theta} + \tau_{\phi\phi}}{r} \right] + \rho g_r$
θ direction	$\rho \left(\frac{\partial v_\theta}{\partial t} + v_r \frac{\partial v_\theta}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_\phi}{r \sin \theta} \frac{\partial v_\theta}{\partial \phi} + \frac{v_r v_\theta}{r} - \frac{v_\phi^2 \cot \theta}{r} \right) = -\frac{1}{r} \frac{\partial P}{\partial \theta} + \left[\frac{1}{r^2} \frac{\partial}{\partial r} (r^2 \tau_{r\theta}) + \frac{1}{r \sin \theta} \frac{\partial}{\partial \theta} (\tau_{\theta\theta} \sin \theta) + \frac{1}{r \sin \theta} \frac{\partial \tau_{\phi\theta}}{\partial \phi} + \frac{\tau_{r\theta}}{r} - \frac{\tau_{\phi\theta} \cot \theta}{r} \right] + \rho g_\theta$
ϕ direction	$\rho \left(\frac{\partial v_\phi}{\partial t} + v_r \frac{\partial v_\phi}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_\phi}{\partial \theta} + \frac{v_\phi}{r \sin \theta} \frac{\partial v_\phi}{\partial \phi} + \frac{v_\phi v_r}{r} + \frac{v_\theta v_\phi \cot \theta}{r} \right) = -\frac{1}{r \sin \theta} \frac{\partial P}{\partial \phi} + \left[\frac{1}{r^2} \frac{\partial}{\partial r} (r^2 \tau_{r\phi}) + \frac{1}{r} \frac{\partial \tau_{\theta\phi}}{\partial \theta} + \frac{1}{r \sin \theta} \frac{\partial \tau_{\phi\phi}}{\partial \phi} + \frac{\tau_{r\phi}}{r} + \frac{2\tau_{\theta\phi} \cot \theta}{r} \right] + \rho g_\phi$

* Components of the stress tensor (τ) for newtonian fluids are given in Table 1.4. This equation may also be used for describing nonnewtonian flow. However, we need relations between the components of τ and the various velocity gradients; in other words, we have to replace the expressions given in Table 1.4 with other relations appropriate for the nonnewtonian fluid of interest. The expressions for τ for some nonnewtonian fluid models are given in Ref. 10. See also Chap. 10.

$\tau_{rr} = \mu \left[2 \frac{\partial v_r}{\partial r} - \frac{2}{3} (\nabla \cdot \mathbf{V}) \right]$	
$\tau_{\theta\theta} = \mu \left[2 \left(\frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r} \right) - \frac{2}{3} (\nabla \cdot \mathbf{V}) \right]$	
$\tau_{\phi\phi} = \mu \left[2 \left(\frac{1}{r \sin \theta} \frac{\partial v_\phi}{\partial \phi} + \frac{v_r}{r} + \frac{v_\theta \cot \theta}{r} \right) - \frac{2}{3} (\nabla \cdot \mathbf{V}) \right]$	
$\tau_{r\theta} = \tau_{\theta r} = \mu \left[r \frac{\partial}{\partial r} \left(\frac{v_\theta}{r} \right) + \frac{1}{r} \frac{\partial v_r}{\partial \theta} \right]$	
$\tau_{\theta\phi} = \tau_{\phi\theta} = \mu \left[\frac{\sin \theta}{r} \frac{\partial}{\partial \theta} \left(\frac{v_\phi}{\sin \theta} \right) + \frac{1}{r \sin \theta} \frac{\partial v_\theta}{\partial \phi} \right]$	
$\tau_{\phi r} = \tau_{r\phi} = \mu \left[\frac{1}{r \sin \theta} \frac{\partial v_r}{\partial \phi} + r \frac{\partial}{\partial r} \left(\frac{v_\phi}{r} \right) \right]$	
$(\nabla \cdot \mathbf{V}) = \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 v_r) + \frac{1}{r \sin \theta} \frac{\partial}{\partial \theta} (v_\theta \sin \theta) + \frac{1}{r \sin \theta} \frac{\partial v_\phi}{\partial \phi}$	

* It should be noted that the sign convention adopted here for components of the stress tensor is consistent with that found in many fluid mechanics and heat transfer books; however, it is opposite to that found in some books on transport phenomena, e.g., Refs. 10, 11, and 14.

TABLE 1.5 Equation of Motion in Terms of Velocity Gradients for a Newtonian Fluid with Constant ρ and μ (Eq. 1.46)

Rectangular coordinates (x, y, z)	
x direction	$\rho \left(\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} \right) = -\frac{\partial P}{\partial x} + \mu \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} \right) + \rho g_x$
y direction	$\rho \left(\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} \right) = -\frac{\partial P}{\partial y} + \mu \left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} + \frac{\partial^2 v}{\partial z^2} \right) + \rho g_y$

r direction	$\rho \left(\frac{\partial v_r}{\partial t} + v_r \frac{\partial v_r}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_r}{\partial \theta} - \frac{v_\theta^2}{r} + v_z \frac{\partial v_r}{\partial z} \right) = -\frac{\partial P}{\partial r} + \mu \left[\frac{\partial}{\partial r} \left(\frac{1}{r} \frac{\partial}{\partial r} (rv_r) \right) + \frac{1}{r^2} \frac{\partial^2 v_r}{\partial \theta^2} - \frac{2}{r^2} \frac{\partial v_\theta}{\partial \theta} + \frac{\partial^2 v_r}{\partial z^2} \right] + \rho g_r$
θ direction	$\rho \left(\frac{\partial v_\theta}{\partial t} + v_r \frac{\partial v_\theta}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_r v_\theta}{r} + v_z \frac{\partial v_\theta}{\partial z} \right) = -\frac{1}{r} \frac{\partial P}{\partial \theta} + \mu \left[\frac{\partial}{\partial r} \left(\frac{1}{r} \frac{\partial}{\partial r} (rv_\theta) \right) + \frac{1}{r^2} \frac{\partial^2 v_\theta}{\partial \theta^2} + \frac{2}{r^2} \frac{\partial v_r}{\partial \theta} + \frac{\partial^2 v_\theta}{\partial z^2} \right] + \rho g_\theta$
z direction	$\rho \left(\frac{\partial v_z}{\partial t} + v_r \frac{\partial v_z}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_z}{\partial \theta} + v_z \frac{\partial v_z}{\partial z} \right) = -\frac{\partial P}{\partial z} + \mu \left[\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial v_z}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 v_z}{\partial \theta^2} + \frac{\partial^2 v_z}{\partial z^2} \right] + \rho g_z$
Spherical coordinates (r, θ, ϕ)*	
r direction	$\rho \left(\frac{\partial v_r}{\partial t} + v_r \frac{\partial v_r}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_r}{\partial \theta} + \frac{v_\phi}{r \sin \theta} \frac{\partial v_r}{\partial \phi} - \frac{v_\theta^2 + v_\phi^2}{r} \right) = -\frac{\partial P}{\partial r} + \mu \left(\nabla^2 v_r - \frac{2v_r}{r^2} - \frac{2}{r^2} \frac{\partial v_\theta}{\partial \theta} - \frac{2v_\theta \cot \theta}{r^2} - \frac{2}{r^2 \sin \theta} \frac{\partial v_\phi}{\partial \phi} \right) + \rho g_r$
θ direction	$\rho \left(\frac{\partial v_\theta}{\partial t} + v_r \frac{\partial v_\theta}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_\phi}{r \sin \theta} \frac{\partial v_\theta}{\partial \phi} + \frac{v_r v_\theta}{r} - \frac{v_\phi^2 \cot \theta}{r} \right) = -\frac{1}{r} \frac{\partial P}{\partial \theta} + \mu \left(\nabla^2 v_\theta + \frac{2}{r^2} \frac{\partial v_r}{\partial \theta} - \frac{v_\theta}{r^2 \sin^2 \theta} - \frac{2 \cos \theta}{r^2 \sin^2 \theta} \frac{\partial v_\phi}{\partial \phi} \right) + \rho g_\theta$
ϕ direction	$\rho \left(\frac{\partial v_\phi}{\partial t} + v_r \frac{\partial v_\phi}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_\phi}{\partial \theta} + \frac{v_\phi}{r \sin \theta} \frac{\partial v_\phi}{\partial \phi} + \frac{v_\theta v_r}{r} + \frac{v_\theta v_\phi}{r} \cot \theta \right) = -\frac{1}{r \sin \theta} \frac{\partial P}{\partial \phi} + \mu \left(\nabla^2 v_\phi - \frac{v_\phi}{r^2 \sin^2 \theta} + \frac{2}{r^2 \sin \theta} \frac{\partial v_r}{\partial \phi} + \frac{2 \cos \theta}{r^2 \sin^2 \theta} \frac{\partial v_\theta}{\partial \phi} \right) + \rho g_\phi$

* For spherical coordinates the laplacian is

$$\nabla^2 = \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial}{\partial r} \right) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \left(\frac{\partial^2}{\partial \phi^2} \right)$$

TABLE 1.6 Summary of Dissipation Term $\nabla \mathbf{V} : \boldsymbol{\tau}$ in Different Coordinate Systems

 Rectangular coordinates (x, y, z) :

$$\nabla \mathbf{V} : \boldsymbol{\tau} = \tau_{xx} \left(\frac{\partial u}{\partial x} \right) + \tau_{yy} \left(\frac{\partial v}{\partial y} \right) + \tau_{zz} \left(\frac{\partial w}{\partial z} \right) + \tau_{xy} \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) + \tau_{yz} \left(\frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} \right) + \tau_{zx} \left(\frac{\partial w}{\partial x} + \frac{\partial u}{\partial z} \right)$$

 Cylindrical coordinates (r, θ, z) :

$$\nabla \mathbf{V} : \boldsymbol{\tau} = \tau_{rr} \left(\frac{\partial v_r}{\partial r} \right) + \tau_{\theta\theta} \left(\frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r} \right) + \tau_{zz} \left(\frac{\partial v_z}{\partial z} \right) + \tau_{r\theta} \left[r \frac{\partial}{\partial r} \left(\frac{v_\theta}{r} \right) + \frac{1}{r} \frac{\partial v_r}{\partial \theta} \right] + \tau_{\theta z} \left(\frac{1}{r} \frac{\partial v_z}{\partial \theta} + \frac{\partial v_\theta}{\partial z} \right) + \tau_{rz} \left(\frac{\partial v_z}{\partial r} + \frac{\partial v_r}{\partial z} \right)$$

 Spherical coordinates (r, θ, ϕ) :

$$\begin{aligned} \nabla \mathbf{V} : \boldsymbol{\tau} = & \tau_{rr} \left(\frac{\partial v_r}{\partial r} \right) + \tau_{\theta\theta} \left(\frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r} \right) + \tau_{\phi\phi} \left(\frac{1}{r \sin \theta} \frac{\partial v_\phi}{\partial \phi} + \frac{v_r}{r} + \frac{v_\theta \cot \theta}{r} \right) + \tau_{r\theta} \left(\frac{\partial v_\theta}{\partial r} + \frac{1}{r} \frac{\partial v_r}{\partial \theta} - \frac{v_\theta}{r} \right) \\ & + \tau_{r\phi} \left(\frac{\partial v_\phi}{\partial r} + \frac{1}{r \sin \theta} \frac{\partial v_r}{\partial \phi} - \frac{v_\phi}{r} \right) + \tau_{\theta\phi} \left(\frac{1}{r} \frac{\partial v_\phi}{\partial \theta} + \frac{1}{r \sin \theta} \frac{\partial v_\theta}{\partial \phi} - \frac{v_\phi \cot \theta}{r} \right) \end{aligned}$$

TABLE 1.7 The Viscous Dissipation Function Φ

 Rectangular coordinates (x, y, z) :

$$\Phi = 2 \left[\left(\frac{\partial u}{\partial x} \right)^2 + \left(\frac{\partial v}{\partial y} \right)^2 + \left(\frac{\partial w}{\partial z} \right)^2 \right] + \left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \right)^2 + \left(\frac{\partial w}{\partial y} + \frac{\partial v}{\partial z} \right)^2 + \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right)^2 - \frac{2}{3} \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} \right)^2$$

 Cylindrical coordinates (r, θ, z) :

$$\begin{aligned} \Phi = & 2 \left[\left(\frac{\partial v_r}{\partial r} \right)^2 + \left(\frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r} \right)^2 + \left(\frac{\partial v_z}{\partial z} \right)^2 \right] + \left[r \frac{\partial}{\partial r} \left(\frac{v_\theta}{r} \right) + \frac{1}{r} \frac{\partial v_r}{\partial \theta} \right]^2 \\ & + \left[\frac{1}{r} \frac{\partial v_z}{\partial \theta} + \frac{\partial v_\theta}{\partial z} \right]^2 + \left(\frac{\partial v_r}{\partial z} + \frac{\partial v_z}{\partial r} \right)^2 - \frac{2}{3} \left[r \frac{\partial}{\partial r} (rv_r) + \frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{\partial v_z}{\partial z} \right]^2 \end{aligned}$$

 Spherical coordinates (r, θ, ϕ) :

$$\begin{aligned} \Phi = & 2 \left[\left(\frac{\partial v_r}{\partial r} \right)^2 + \left(\frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r} \right)^2 + \left(\frac{1}{r \sin \theta} \frac{\partial v_\phi}{\partial \phi} + \frac{v_r}{r} + \frac{v_\theta \cot \theta}{r} \right)^2 \right] \\ & + \left[r \frac{\partial}{\partial r} \left(\frac{v_\theta}{r} \right) + \frac{1}{r} \frac{\partial v_r}{\partial \theta} \right]^2 + \left[\frac{\sin \theta}{r} \frac{\partial}{\partial \theta} \left(\frac{v_\phi}{\sin \theta} \right) + \frac{1}{r \sin \theta} \frac{\partial v_\theta}{\partial \phi} \right]^2 + \left[\frac{1}{r \sin \theta} \frac{\partial v_r}{\partial \phi} + r \frac{\partial}{\partial r} \left(\frac{v_\phi}{r} \right) \right]^2 \\ & - \frac{2}{3} \left[\frac{1}{r^2} \frac{\partial}{\partial r} (r^2 v_r) + \frac{1}{r \sin \theta} \frac{\partial}{\partial \theta} (v_\theta \sin \theta) + \frac{1}{r \sin \theta} \frac{\partial v_\phi}{\partial \phi} \right]^2 \end{aligned}$$

TABLE 1.8 Scalar Components of the Heat Flux Vector \mathbf{q}''

Rectangular (x, y, z)	Cylindrical (r, θ, z)	Spherical (r, θ, ϕ)
$q''_x = -k \frac{\partial T}{\partial x}$	$q''_r = -k \frac{\partial T}{\partial r}$	$q''_r = -k \frac{\partial T}{\partial r}$
$q''_y = -k \frac{\partial T}{\partial y}$	$q''_\theta = -k \frac{1}{r} \frac{\partial T}{\partial \theta}$	$q''_\theta = -k \frac{1}{r} \frac{\partial T}{\partial \theta}$
$q''_z = -k \frac{\partial T}{\partial z}$	$q''_z = -k \frac{\partial T}{\partial z}$	$q''_\phi = -k \frac{1}{r \sin \theta} \frac{\partial T}{\partial \phi}$

For most engineering applications it is convenient to have the equation of thermal energy in terms of the fluid temperature and heat capacity rather than the internal energy or enthalpy. In general, for pure substances [11],

$$\frac{Di}{Dt} = \left(\frac{\partial i}{\partial P} \right)_T \frac{DP}{Dt} + \left(\frac{\partial i}{\partial T} \right)_P \frac{DT}{Dt} = \frac{1}{\rho} (1 - \beta T) \frac{DP}{Dt} + c_p \frac{DT}{Dt} \quad (1.55)$$

where β is defined by Eq. 1.48. Substituting this into Eq. 1.54 we have the following general relation:

$$\rho c_p \frac{DT}{Dt} = \nabla \cdot k \nabla T + T \beta \frac{DP}{Dt} + \mu \Phi + q''' \quad (1.56)$$

For an ideal gas, $\beta = 1/T$, and then

$$\rho c_p \frac{DT}{Dt} = \nabla \cdot k \nabla T + \frac{DP}{Dt} + \mu \Phi + q''' \quad (1.57)$$

Note that c_p need not be constant.

We could have obtained Eq. 1.57 directly from Eq. 1.54 by noting that for an ideal gas, $di = c_p dT$ where c_p is constant and thus

$$\frac{Di}{Dt} = c_p \frac{DT}{Dt}$$

For an incompressible fluid with specific heat $c = c_p = c_v$ we go back to Eq. 1.52 ($du = c dT$) to obtain

$$\rho c \frac{DT}{Dt} = \nabla \cdot k \nabla T + \mu \Phi + q''' \quad (1.58)$$

Equations 1.52, 1.54, and 1.56 can be easily written in terms of energy (heat) and momentum fluxes using relations for fluxes given in Tables 1.4, 1.6, and 1.8. The energy equation given by Eq. 1.58 (with $q''' = 0$ for simplicity) is given in Table 1.9 in different coordinate systems.

For *solids*, the density may usually be considered constant and we may set $\mathbf{V} = 0$, and Eq. 1.58 reduces to

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot k \nabla T + q''' \quad (1.59)$$

which is the starting point for most problems in heat conduction.

The Energy Equation for a Mixture. The energy equations in the previous section are applicable for pure fluids. A thermal energy equation valid for a mixture of chemical species is required for situations involving simultaneous heat and mass transfer. For a pure fluid, conduction is the only diffusive mechanism of heat flow; hence Fourier's law is used, resulting in the term $\nabla \cdot k \nabla T$. More generally this term may be written $-\nabla \cdot \mathbf{q}''$, where \mathbf{q}'' is the diffusive heat flux, i.e., the heat flux relative to the mass average velocity. More specifically, for a mixture, \mathbf{q}'' is now made from three contributions: (1) ordinary conduction, described by Fourier's law, $-k \nabla T$, where k is the *mixture* thermal conductivity; (2) the contribution due to interdiffusion of species, given by $\sum_i \mathbf{j}_i i$; and (3) diffusional conduction (also called the diffusion-thermo effect or Dufour effect [6, 12]). The third contribution is of the second order and is usually negligible:

$$\mathbf{q}'' = -k \nabla T + \sum_i \mathbf{j}_i i \quad (1.60)$$

TABLE 1.9 The Energy Equation* (for Newtonian Fluids of Constant ρ and k)

 Rectangular coordinates (x, y, z):

$$\rho c_p \left(\frac{\partial T}{\partial t} + u \frac{\partial T}{\partial x} + v \frac{\partial T}{\partial y} + w \frac{\partial T}{\partial z} \right) = k \left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \right) + 2\mu \left[\left(\frac{\partial u}{\partial x} \right)^2 + \left(\frac{\partial v}{\partial y} \right)^2 + \left(\frac{\partial w}{\partial z} \right)^2 \right] + \mu \left[\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right)^2 + \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right)^2 + \left(\frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} \right)^2 \right]$$

 Cylindrical coordinates (r, θ, z):

$$\rho c_p \left(\frac{\partial T}{\partial t} + v_r \frac{\partial T}{\partial r} + \frac{v_\theta}{r} \frac{\partial T}{\partial \theta} + v_z \frac{\partial T}{\partial z} \right) = k \left[\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial T}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 T}{\partial \theta^2} + \frac{\partial^2 T}{\partial z^2} \right] + 2\mu \left[\left(\frac{\partial v_r}{\partial r} \right)^2 + \left[\frac{1}{r} \left(\frac{\partial v_\theta}{\partial \theta} + v_r \right) \right]^2 + \left(\frac{\partial v_z}{\partial z} \right)^2 \right] + \mu \left[\left(\frac{\partial v_\theta}{\partial z} + \frac{1}{r} \frac{\partial v_z}{\partial \theta} \right)^2 + \left(\frac{\partial v_z}{\partial r} + \frac{\partial v_r}{\partial z} \right)^2 + \left[\frac{1}{r} \frac{\partial v_r}{\partial \theta} + r \frac{\partial}{\partial r} \left(\frac{v_\theta}{r} \right) \right]^2 \right]$$

 Spherical coordinates (r, θ, ϕ):

$$\rho c_p \left(\frac{\partial T}{\partial t} + v_r \frac{\partial T}{\partial r} + \frac{v_\theta}{r} \frac{\partial T}{\partial \theta} + \frac{v_\phi}{r \sin \theta} \frac{\partial T}{\partial \phi} \right) = k \left[\frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial T}{\partial r} \right) + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial T}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 T}{\partial \phi^2} \right] + 2\mu \left[\left(\frac{\partial v_r}{\partial r} \right)^2 + \left(\frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{v_r}{r} \right)^2 + \left(\frac{1}{r \sin \theta} \frac{\partial v_\phi}{\partial \phi} + \frac{v_r}{r} + \frac{v_\theta \cot \theta}{r} \right)^2 \right] + \mu \left[\left[r \frac{\partial}{\partial r} \left(\frac{v_\theta}{r} \right) + \frac{1}{r} \frac{\partial v_r}{\partial \theta} \right]^2 + \left[\frac{1}{r \sin \theta} \frac{\partial v_r}{\partial \phi} + r \frac{\partial}{\partial r} \left(\frac{v_\phi}{r} \right) \right]^2 + \left[\frac{\sin \theta}{r} \frac{\partial}{\partial \theta} \left(\frac{v_\phi}{\sin \theta} \right) + \frac{1}{r \sin \theta} \frac{\partial v_\theta}{\partial \phi} \right]^2 \right]$$

* The terms contained in braces { } are associated with viscous dissipation and may usually be neglected except in systems with large velocity gradients.

Here \mathbf{j}_i is a diffusive mass flux of species i , with units of mass/(area \times time), as mentioned before. Substituting Eq. 1.60 in, for example, Eq. 1.54, we obtain the energy equation for a mixture:

$$\rho \frac{Di}{Dt} = \frac{DP}{Dt} + \nabla \cdot k \nabla T - \nabla \cdot \left(\sum_i \mathbf{j}_i i \right) + \mu \Phi + q''' \quad (1.61)$$

For a nonreacting mixture the term $\nabla \cdot (\sum_i \mathbf{j}_i i)$ is often of minor importance. But when endothermic or exothermic reactions occur, this term can play a dominant role. For reacting mixtures the species enthalpies

$$i_i = i_i^0 + \int_{T^0}^T c_{p,i} dT$$

must be written with a consistent set of heats of formation i_i^0 at T^0 [13].

The Conservation Equation for Species

For a stationary control volume, the conservation equation for species is

$$\frac{\partial C_i}{\partial t} = -\nabla \cdot (C_i \mathbf{V}) - \nabla \cdot \mathbf{j}_i + r_i''' \quad (1.62)$$

rate of storage of species i per unit volume	net rate of convection of species i per unit volume	net rate of diffusion of species i per unit volume	production rate of species i per unit volume
--	---	--	--

Using the mass conservation equation, the above equation can be rearranged to obtain

$$\rho \frac{Dm_i}{Dt} = -\nabla \cdot \mathbf{j}_i + r_i''' \quad (1.63)$$

where m_i is mass fraction of species i , i.e., where $m_i = C_i/\rho$, where ρ is the density of the mixture, $\sum_i C_i = \rho$, and C_i is a partial density of species i (i.e., a mass concentration of species i).

The conservation equation for species can also be written in terms of mole concentration and mole fractions, as shown in Refs. 10, 12, and 13. The mole concentration of species i is $c_i = C_i/M_i$, where M_i is the molecular weight of the species. The mole fraction of species i is defined as $x_i = c_i/c$, where $c = \sum_i c_i$. As is obvious, $\sum_i m_i = 1$ and $\sum_i x_i = 1$.

Equations 1.62 and 1.63 written in different coordinate systems are given in Ref. 10.

Use of Conservation Equations to Set Up Problems

For a problem involving fluid flow and simultaneous heat and mass transfer, equations of continuity, momentum, energy, and chemical species (Eqs. 1.41, 1.44, 1.54, and 1.63) are a formidable set of partial differential equations. There are four *independent variables*: three space coordinates (say, x , y , z) and a time coordinate t .

If we consider a pure fluid, there are five equations: the continuity equation, three momentum equations, and the energy equation. The five accompanying *dependent variables* are pressure, three components of velocity, and temperature. Also, a thermodynamic equation of state serves to relate density to the pressure, temperature, and composition. (Notice that for natural convection flows the momentum and energy equations are coupled.)

For a mixture of n chemical species, there are n species conservation equations, but one is redundant, as the sum of mass fractions is equal to unity.

A complete mathematical statement of a problem requires specification of boundary and initial conditions. Boundary conditions are based on a physical statement or principle (for example: for viscous flow the component of velocity parallel to a stationary surface is zero at the wall; for an insulated wall the derivative of temperature normal to the wall is zero; etc.).

A general solution, even by numerical methods, of the full equations in the four independent variables is difficult to obtain. Fortunately, however, many problems of engineering interest are adequately described by simplified forms of the full conservation equations, and these forms can often be solved easily. The governing equations for simplified problems are obtained by deleting superfluous terms in the full conservation equations. This applies directly to laminar flows only. In the case of turbulent flows, some caution must be exercised. For example, on an average basis a flow may be two-dimensional and steady, but if it is unstable and as a result turbulent, fluctuations in the three components of velocity may be occurring with respect to time and the three spatial coordinates. Then the remarks about dropping terms apply only to the time-averaged equations [7, 12].

When simplifying the conservation equation given in a full form, we have to rely on physical intuition or on experimental evidence to judge which terms are negligibly small. Typical resulting classes of simplified problems are:

- Constant transport properties
- Constant density
- Timewise steady flow (or quasi-steady flow)
- Two-dimensional flow
- One-dimensional flow
- Fully developed flow (no dependence on the streamwise coordinate)
- Stagnant fluid or rigid body

Terms may also be shown to be negligibly small by order-of-magnitude estimates [7, 12]. Some classes of flow that result are:

Creeping flows: inertia terms are negligible.

Forced flows: gravity forces are negligible.

Natural convection: gravity forces predominate.

Low-speed gas flows: viscous dissipation and compressibility terms are negligible.

Boundary-layer flows: streamwise diffusion terms are negligible.

DIMENSIONLESS GROUPS AND SIMILARITY IN HEAT TRANSFER

Modern engineering practice in the field of heat transfer is based on a combination of theoretical analysis and experimental data. Often the engineer is faced with the necessity of obtaining practical results in situations where, for various reasons, physical phenomena cannot be described mathematically or the differential equations describing the problem are too difficult to solve. An experimental program must be considered in such cases. However, in carrying the experimental program the engineer should know how to relate the experimental data (i.e., data obtained on the model under consideration) to the actual, usually larger, system (prototype). A determination of the relevant dimensionless parameters (groups) provides a powerful tool for that purpose.

The generation of such dimensionless groups in heat transfer (known generally as *dimensional analysis*) is basically done (1) by using differential equations and their boundary conditions (this method is sometimes called a *differential similarity*) and (2) by applying the dimensional analysis in the form of the Buckingham pi theorem.

The first method (differential similarity) is used when the governing equations and their boundary conditions describing the problem are known. The equations are first made dimensionless. For demonstration purposes, let us consider the relatively simple problem of a binary mixture with constant properties and density flowing at low speed, where body forces, heat source term, and chemical reactions are neglected. The conservation equations are, from Eqs. 1.42, 1.46, 1.58, and 1.63,

$$\text{Mass} \quad \nabla \cdot \mathbf{V} = 0 \quad (1.64)$$

$$\text{Momentum} \quad \rho \frac{D\mathbf{V}}{Dt} = -\nabla P + \mu \nabla^2 \mathbf{V} \quad (1.65)$$

$$\text{Thermal energy} \quad \rho c \frac{DT}{Dt} = k \nabla^2 T + \mu \Phi \quad (1.66)$$

$$\text{Species} \quad \frac{Dm_1}{Dt} = \mathbf{D} \nabla^2 m_1 \quad (1.67)$$

Using L and V as characteristic length and velocity, respectively, we define the dimensionless variables

$$x^* = \frac{x}{L} \quad y^* = \frac{y}{L} \quad z^* = \frac{z}{L} \quad (1.68)$$

$$\mathbf{V}^* = \frac{\mathbf{V}}{V} \quad (1.69)$$

$$t^* = \frac{t}{LV} \quad (1.70)$$

$$P^* = \frac{P}{\rho V^2} \quad (1.71)$$

and also

$$T^* = \frac{T - T_w}{T_\infty - T_w} \quad (1.72)$$

$$m^* = \frac{m_1 - m_{1,w}}{m_{1,\infty} - m_{1,w}} \quad (1.73)$$

where the subscript ∞ refers to the external free-stream condition or some average condition and the subscript w refers to conditions adjacent to a bounding surface across which transfer of heat and mass occurs. If we introduce the dimensionless quantities (Eqs. 1.68–1.73), into Eqs. 1.64–1.67, we obtain, respectively,

$$\nabla^* \cdot \mathbf{V}^* = 0 \quad (1.74)$$

$$\frac{D\mathbf{V}^*}{Dt^*} = -\nabla^* P^* + \frac{1}{\text{Re}} \nabla^{*2} \mathbf{V}^* \quad (1.75)$$

$$\frac{DT^*}{Dt^*} = \frac{1}{\text{Re Pr}} \nabla^{*2} T^* + \frac{2 \text{Ec}}{\text{Re}} \Phi^* \quad (1.76)$$

$$\frac{Dm^*}{Dt^*} = \frac{1}{\text{Re Sc}} \nabla^{*2} m^* \quad (1.77)$$

Obviously, the solutions of Eqs. 1.74–1.77 depend on the coefficients that appear in these equations. Solutions of Eqs. 1.74–1.77 are equally applicable to the model and prototype (where the model and prototype are geometrically similar systems of different linear dimensions in streams of different velocities, temperatures, and concentration), if the coefficients in these equations are the same for both model and prototype. These coefficients, Pr, Re, Sc, and Ec (called dimensionless parameters or similarity parameters), are defined in Table 1.10.

Focusing attention now on heat transfer, from Eq. 1.14, using the dimensionless quantities, the heat transfer coefficient is given as

$$h = \frac{k}{L} \left. \frac{\partial T^*}{\partial y^*} \right|_{y^*=0} \quad (1.78)$$

or, in dimensionless form,

$$\frac{hL}{k} = \left. \frac{\partial T^*}{\partial y^*} \right|_{y^*=0} = \text{Nu} \quad (1.79)$$

where the dimensionless group Nu is known as the Nusselt number. Since Nu is the dimensionless temperature gradient at the surface, according to Eq. 1.76 it must therefore depend on the dimensionless groups that appear in this equation; hence

$$\text{Nu} = f_1(\text{Re}, \text{Pr}, \text{Ec}) \quad (1.80)$$

For processes in which viscous dissipation and compressibility are negligible, which is the case in many industrial applications, we have

$$\text{Nu} = f_2(\text{Re}, \text{Pr}) \quad (\text{forced convection}) \quad (1.81)$$

TABLE 1.10 Summary of the Chief Dimensionless Groups*

Group	Symbol	Definition	Physical significance (interpretation)	Main area of use
Biot number	Bi	$\frac{hL}{k_s}$	Ratio of internal thermal resistance of solid to fluid thermal resistance	Heat transfer between fluid and solid
Biot number [†] (mass transfer)	Bi _D	$\frac{h_D L}{D}$	Ratio of the internal species transfer resistance to the boundary layer species transfer resistance	Mass transfer between fluid and solid
Coefficient of friction (skin friction coefficient)	c_f	$\frac{\tau_w}{\rho V^2/2}$	Dimensionless surface shear stress	Flow resistance
Eckert number	Ec	$\frac{V_w^2}{c_p(T_w - T_\infty)}$	Kinetic energy of the flow relative to the boundary layer enthalpy difference	Forced convection (compressible flow)
Euler number	Eu	$\frac{\Delta P}{\rho V^2}$	Ratio of friction to velocity head	Fluid friction
Fourier number	Fo	$\frac{\alpha t}{L^2}$	Ratio of the heat conduction rate to the rate of thermal energy storage in a solid	Unsteady-state heat transfer
Fourier number (mass transfer)	Fo _D	$\frac{D t}{L^2}$	Ratio of the species diffusion rate to the rate of species storage	Unsteady-state mass transfer
Froude number	Fr	$\frac{V^2}{gL}$	Ratio of inertial to gravitational force	Wave and surface behavior (mixed natural and forced convection)
Graetz number	Gz	$\text{Re Pr} \frac{D}{L} = \frac{\rho c_p V D^2}{kL}$	Ratio of the fluid stream thermal capacity to convective heat transfer	Forced convection
Grashof number	Gr	$\frac{g\beta\Delta T L^3}{\nu^2}$	Ratio of buoyancy to viscous forces	Natural convection
Colburn <i>j</i> factor (heat transfer)	j_H	$\text{St Pr}^{2/3}$	Dimensionless heat transfer coefficient	Forced convection (heat, mass, and momentum transfer analogy)
Colburn <i>j</i> factor (mass transfer)	j_D	$\text{St}_D \text{Sc}^{2/3}$	Dimensionless mass transfer coefficient	Forced convection (heat, mass, and momentum transfer analogy)
Jakob number	Ja	$\frac{\rho_l c_{pl}(T_w - T_{\text{sat}})}{\rho_g i_{fg}}$	Ratio of sensible heat absorbed by the liquid to the latent heat absorbed	Boiling

TABLE 1.10 Summary of the Chief Dimensionless Groups* (*Continued*)

Group	Symbol	Definition	Physical significance (interpretation)	Main area of use
Knudsen number	Kn	$\frac{\lambda}{L}$	Ratio of molecular mean free path to characteristic dimension	Low-pressure (low-density) gas flow
Lewis number	Le	$\frac{\alpha}{\mathbf{D}} = \frac{Sc}{Pr}$	Ratio of molecular thermal and mass diffusivities	Combined heat and mass transfer
Mach number	Ma	$\frac{V}{a}$	Ratio of the velocity of flow to the velocity of sound	Compressible flow
Nusselt number	Nu	$\frac{hL}{k}$	Basic dimensionless convective heat transfer coefficient (ratio of convection heat transfer to conduction in a fluid slab of thickness L)	Convective heat transfer
Péclet number	Pe	$Re Pr = \frac{\rho c_p VL}{k}$	Dimensionless independent heat transfer parameter (ratio of heat transfer by convection to conduction)	Forced convection
Péclet number (mass transfer)	Pe _D	$Re Sc = \frac{VL}{\mathbf{D}}$	Dimensionless independent mass transfer coefficient (ratio of bulk mass transfer to diffusive mass transfer)	Mass transfer
Prandtl number	Pr	$\frac{\mu c_p}{k} = \frac{\nu}{\alpha}$	Ratio of molecular momentum and thermal diffusivities	Forced and natural convection
Rayleigh number	Ra	$Gr Pr = \frac{\rho g \beta \Delta T L^3}{\mu \alpha}$	Modified Grashof number (see interpretations for Gr and Pr)	Natural convection
Reynolds number	Re	$\frac{\rho VL}{\mu}$	Ratio of inertia to viscous forces	Forced convection; dynamic similarity
Schmidt number	Sc	$\frac{\nu}{\mathbf{D}}$	Ratio of molecular momentum and mass diffusivities	Mass transfer
Sherwood number	Sh	$\frac{h_D L}{\mathbf{D}}$	Ratio of convection mass transfer to diffusion in a slab of thickness L	Convective mass transfer

Strouhal number [†]	Sr	$\frac{Lf}{V}$	Ratio of the velocity of vibration Lf to the velocity of the fluid	Flow past tube (shedding of eddies)
Stanton number	St	$\frac{Nu}{Re Pr} = \frac{h}{\rho c_p V}$	Dimensionless heat transfer coefficient (ratio of heat transfer at the surface to that transported by fluid by its thermal capacity)	Forced convection
Stanton number (mass transfer)	St _D	$\frac{Sh}{Re Sc} = \frac{h_D}{V}$	Dimensionless mass transfer coefficient	Convective mass transfer
Weber number	We	$\frac{\rho V^2 L}{\sigma}$	Ratio of inertia force to surface tension force	Droplet breakup; thin-film flow

* In these dimensionless groups L designates characteristic dimension (e.g., tube diameter, hydraulic diameter, length of the tube or plate, slab thickness, radius of a cylinder or sphere, droplet diameter, thin-film thickness, etc.). Physical properties are usually evaluated at mean temperature unless otherwise specified.

[†] Note: $\mathbf{D} = \mathbf{D}_{12}$ (\mathbf{D}_{12} is also a commonly used symbol for binary diffusion coefficient; \mathbf{D}_i is the multicomponent diffusion coefficient). When species 1 is in very small concentration the symbol \mathbf{D}_{1m} is occasionally used [12], representing an effective binary diffusion coefficient for species 1 diffusing through the mixture.

[‡] In some engineering texts the symbol St is also used for this group.

In the case of buoyancy-induced flow, Eq. 1.65 should be replaced with the simplified version [16] of Eq. 1.50, and, following a similar procedure, we should obtain

$$\text{Nu} = f_3(\text{Gr}, \text{Pr}) \quad (\text{natural convection}) \quad (1.82)$$

where Gr is the Grashof number, defined in Table 1.10. Also, using the relation of Eq. 1.17 and dimensionless quantities,

$$h_D = \frac{D}{L} \left. \frac{\partial m^*}{\partial y^*} \right|_{y^*=0} \quad (1.83)$$

or

$$h_D \frac{L}{D} = \left. \frac{\partial m^*}{\partial y^*} \right|_{y^*=0} = \text{Sh} \quad (1.84)$$

This parameter, termed the Sherwood number, is equal to the dimensionless mass fraction (i.e., concentration) gradient at the surface, and it provides a measure of the convection mass transfer occurring at the surface. Following the same argument as before (but now for Eq. 1.77), we have

$$\text{Sh} = f_4(\text{Re}, \text{Sc}) \quad (\text{forced convection, mass transfer}) \quad (1.85)$$

The significance of expressions such as Eqs. 1.80–1.82 and 1.85 should be appreciated. For example, Eq. 1.81 states that convection heat transfer results, whether obtained theoretically or experimentally, can be represented in terms of three dimensionless groups instead of seven parameters (h , L , V , k , c_p , μ , and ρ). The convenience is evident. Once the form of the functional dependence of Eq. 1.81 is obtained for a particular surface geometry (e.g., from laboratory experiments on a small model), it is known to be universally applicable, i.e., it may be applied to different fluids, velocities, temperatures, and length scales, as long as the assumptions associated with the original equations are satisfied (e.g., negligible viscous dissipation and body forces). Note that the relations of Eqs. 1.80 and 1.85 are derived without actually solving the system of Eqs. 1.64–1.67. References 3, 7, 12, 15, 16, and 18 cover the above procedure in more detail and also include many different cases.

It is important to mention here that once the conservation equations are put in dimensionless form it is also convenient to make an order-of-magnitude assessment of all terms in the equations. Often a problem can be simplified by discovering that a term that would be very difficult to handle if large is in fact negligibly small [7, 12]. Even if the primary thrust of the investigation is experimental, making the equations dimensionless and estimating the orders of magnitude of the terms is good practice. It is usually not possible for an experimental test to include (simulate) all conditions exactly; a good engineer will focus on the most important conditions. The same applies to performing an order-of-magnitude analysis. For example, for boundary-layer flows, allowance is made for the fact that lengths transverse to the main flow scale with a much shorter length than those measured in the direction of main flow. References 7, 12, and 17 cover many examples of the order-of-magnitude analysis.

When the governing equations of a problem are unknown, an alternative approach of deriving dimensionless groups is based on use of dimensional analysis in the form of the Buckingham pi theorem [9, 11, 14, 16, 18]. The success of this method depends on our ability to select, largely from intuition, the parameters that influence the problem. For example, knowing in advance that the heat transfer coefficient in fully developed forced convection in a tube is a function of certain variables, that is, $h = f(V, \rho, \mu, c_p, k, D)$, we can use the Buckingham pi theorem to obtain Eq. 1.81, as shown in Ref. 11. However, this method is carried out without any consideration of the physical nature of the process in question, i.e., there is no way to ensure that all essential variables have been included. However, as shown above, starting with the differential form of the conservation equations we have derived the similarity parameters (dimensionless groups) in rigorous fashion.

In Table 1.10 those dimensionless groups that appear frequently in the heat and mass transfer literature have been listed. The list includes groups already mentioned above as well as those found in special fields of heat transfer. Note that, although similar in form, the Nusselt and Biot numbers differ in both definition and interpretation. The Nusselt number is defined in terms of thermal conductivity of the fluid; the Biot number is based on the solid thermal conductivity.

UNITS AND CONVERSION FACTORS

The dimensions that are used consistently in the field of heat transfer are length, mass, force, energy, temperature, and time. We should avoid using both force and mass dimensions in the same equation, since force is always expressible in dimensions of mass, length, and time, and vice versa. We do not make a practice of eliminating energy in terms of force times length, because the accounting of work and heat is practically always kept separate in heat transfer problems.

In this handbook both *SI* (the accepted abbreviation for *Système International d'Unités*, or International System of Units) and *English engineering units** are used simultaneously throughout. The base units for the English engineering units are given in the second column of Table 1.11. The unit of force in English units is the *pound force* (lb_f). However, the use of the *pound mass* (lb_m) and pound force in engineering work causes considerable confusion in the proper use of these two fundamentally different units.

TABLE 1.11 Conversion Factor g_c for the Common Unit Systems

Quantity	SI	English engineering*	cgs [†]	Metric engineering
Mass	kilogram, kg	pound mass, lb_m	gram, g	kilogram mass, kg
Length	meter, m	foot, ft	centimeter, cm	meter, m
Time	second, s	second, s, or hour, h	second, s	second, s
Force	newton, N	pound force, lb_f	dyne, dyn	kilogram force, kg_f
g_c	$1 \text{ kg}\cdot\text{m}/(\text{N}\cdot\text{s}^2)^\ddagger$	$32.174 \text{ lb}_m\cdot\text{ft}/(\text{lb}_f\cdot\text{s}^2)$	$1 \text{ g}\cdot\text{cm}/(\text{dyn}\cdot\text{s}^2)$	$9.80665 \text{ kg}\cdot\text{m}/(\text{kg}_f\cdot\text{s}^2)$

* In this system of units the temperature is given in degrees Fahrenheit ($^\circ\text{F}$).

[†] Centimeter-gram-second: this system of units has been used mostly in scientific work.

[‡] Since $1 \text{ kg}\cdot\text{m}/\text{s}^2 = 1 \text{ N}$, then $g_c = 1$ in the SI system of units.

The two can be related as

$$1 \text{ lb}_f = \frac{1 \text{ lb}_m \times 32.174 \text{ ft}/\text{s}^2}{g_c}$$

whence

$$g_c = 32.174 \text{ lb}_m\cdot\text{ft}/(\text{lb}_f\cdot\text{s}^2)$$

Thus, g_c is merely a conversion factor and it should not be confused with the gravitational acceleration g . The numerical value of g_c is a constant depending only on the system of units involved and not on the value of the gravitational acceleration at a particular location. Values

* Also associated with this system of units are such names as *U.S. Customary Units*, *British engineering units*, *engineering units*, and *foot-pound-second system of units*. The name *English engineering units*, or, for short, *English units*, is selected in this handbook because it has been used by practicing engineers more frequently than the other names mentioned.

TABLE 1.12 SI Base and Supplementary Units

Quantity	Unit
Length	meter (m)
Mass	kilogram (kg)
Time	second (s)

Amount of substance	mole (mol)
Luminous intensity	candela (cd)
Plane angle*	radian (rad)
Solid angle*	steradian (sr)

* Supplementary units.

of g_c corresponding to different systems of units found in engineering literature are given in Table 1.11.

The SI base units are summarized in Table 1.12. The SI units comprise a rigorously coherent form of the metric system, i.e., all remaining units may be derived from the base units using formulas that do not involve any numerical factors. For example, the unit of force is the newton (N); a 1-N force will accelerate a 1-kg mass at 1 m/s^2 . Hence $1 \text{ N} = 1 \text{ kg}\cdot\text{m/s}^2$. The unit of pressure is the N/m^2 , often referred to as the pascal. In the SI system there is one unit of energy (thermal, mechanical, or electrical), the joule (J); $1 \text{ J} = 1 \text{ N}\cdot\text{m}$. The unit for energy rate, or power, is joules per second (J/s), where one J/s is equivalent to one watt ($1 \text{ J/s} = 1 \text{ W}$).

In the English system of units it is necessary to relate thermal and mechanical energy via the mechanical equivalent of heat J_c . Thus

$$J_c \times \text{thermal energy} = \text{mechanical energy}$$

The unit of heat in the English system is the British thermal unit (Btu). When the unit of mechanical energy is the pound-force-foot (lb_fft), then

$$J_c = 778.16 \text{ lb}_f\text{ft/Btu}$$

as $1 \text{ Btu} = 778.16 \text{ lb}_f\text{ft}$. Happily, in the SI system the units of heat and work are identical and J_c is unity.

Since it is frequently necessary to work with extremely large or small numbers, a set of standard prefixes has been introduced to simplify matters (Table 1.13). Symbols and names for all units used in the handbook are given in Table 1.14. Conversion factors for commonly

† Definition of the units of energy based on thermal phenomena:

1 Btu = energy required to raise 1 lb_m of water 1°F at 68°F

1 cal = energy required to raise 1 g of water 1°C at 20°C

‡ The SI unit for the quantity pressure is the pascal (Pa); 1 Pa = 1 N/m².

§ Also expressed in equivalent units of kg/(s·m).

NOMENCLATURE

Symbol, Definition, SI Units, English Units

<i>A</i>	heat transfer area: m ² , ft ²
<i>a</i>	acceleration: m/s ² , ft/s ²
<i>a</i>	speed of sound: m/s, ft/s
<i>C</i>	mass concentration of species: kg/m ³ , lb _m /ft ³
<i>c</i>	specific heat: J/(kg·K), Btu/(lb _m ·°F)
<i>c_p</i>	specific heat at constant pressure: J/(kg·K), Btu/(lb _m ·°F)
<i>c_v</i>	specific heat at constant volume: J/(kg·K), Btu/(lb _m ·°F)
<i>D</i>	tube inside diameter, diameter: m, ft
D	diffusion coefficient: m ² /s, ft ² /s
<i>Ec</i>	Eckert number (see Table 1.10)
<i>e</i>	emissive power: W/m ² , Btu/(h·ft ²)
<i>e_b</i>	blackbody emissive power: W/m ² , Btu/(h·ft ²)
<i>F</i>	force: N, lb _f
<i>F₁₋₂</i>	view factor (geometric shape factor for radiation from one blackbody to another)
<i>ℱ₁₋₂</i>	real body view factor (geometric shape and emissivity factor for radiation from one gray body to another)
<i>f</i>	frequency of vibration (see Table 1.10): s ⁻¹
<i>f₁, f₂, f₃, f₄</i>	denotes function of Eqs. 1.80–1.82 and 1.85

Gr	Grashof number (see Table 1.10)
g	gravitational acceleration: m/s^2 , ft/s^2
\mathbf{g}	gravitational acceleration (vector): m/s^2 , ft/s^2
g_c	conversion factor (see Table 1.11): $\text{lb}_m \cdot \text{ft}/(\text{lb}_f \cdot \text{s}^2)$
h	heat transfer coefficient: $\text{W}/(\text{m}^2 \cdot \text{K})$, $\text{Btu}/(\text{h} \cdot \text{ft}^2 \cdot ^\circ\text{F})$
h_D	mass transfer coefficient: m/s , ft/s
i	enthalpy per unit mass: J/kg , Btu/lb_m
i_g	latent heat of evaporation: J/kg , Btu/lb_m
i^0	heat of formation: J/kg , Btu/lb_m
j	mass diffusion flux of species: $\text{kg}/(\text{s} \cdot \text{m}^2)$, $\text{lb}_m/(\text{h} \cdot \text{ft}^2)$
\mathbf{j}	mass diffusion flux of species (vector): $\text{kg}/(\text{s} \cdot \text{m}^2)$, $\text{lb}_m/(\text{h} \cdot \text{ft}^2)$
k	thermal conductivity: $\text{W}/(\text{m} \cdot \text{K})$, $\text{Btu}/(\text{h} \cdot \text{ft} \cdot ^\circ\text{F})$
L	length: m , ft
M	mass: kg , lb_m
m	mass fraction of species (Eq. 1.63)
Nu	Nusselt number (see Table 1.10)
P	pressure: Pa (N/m^2), lb_f/ft^2
Pr	Prandtl number (see Table 1.10)
ΔP	pressure drop: Pa (N/m^2), lb_f/ft^2
q	heat transfer rate: W , Btu/h
\mathbf{q}''	heat flux (vector): W/m^2 , $\text{Btu}/(\text{h} \cdot \text{ft}^2)$
q''	heat flux: W/m^2 , $\text{Btu}/(\text{h} \cdot \text{ft}^2)$
q'''	volumetric heat generation: W/m^3 , $\text{Btu}/(\text{h} \cdot \text{ft}^3)$
R_{th}	thermal resistance: K/W , $\text{h} \cdot ^\circ\text{F}/\text{Btu}$
Re	Reynolds number (see Table 1.10)
r	radial distance in cylindrical or spherical coordinate: m , ft
\mathbf{r}	recovery factor (Eq. 1.19)
r'''	volumetric generation rate of species: $\text{kg}/(\text{s} \cdot \text{m}^3)$, $\text{lb}_m/(\text{h} \cdot \text{ft}^3)$
Sc	Schmidt number (see Table 1.10)
Sh	Sherwood number (see Table 1.10)
St	Stanton number (see Table 1.10)
T	temperature: $^\circ\text{C}$, K , $^\circ\text{F}$, $^\circ\text{R}$
ΔT	temperature difference: $^\circ\text{C}$, $^\circ\text{F}$
t	time: s
u	velocity component in the axial direction (x direction) in rectangular coordinates: m/s , ft/s
\mathbf{u}	internal energy per unit mass: J/kg , Btu/lb_m
V	velocity: m/s , ft/s
\mathbf{V}	velocity (vector): m/s , ft/s
v	velocity component in the y direction in rectangular coordinates: m/s , ft/s
v_r	velocity component in the r direction: m/s , ft/s
v_z	velocity component in the z direction: m/s , ft/s

v_θ	velocity component in the θ direction: m/s, ft/s
v_ϕ	velocity component in the ϕ direction: m/s, ft/s
w	velocity component in the z direction in rectangular coordinates: m/s, ft/s
x	rectangular coordinate: m, ft
y	rectangular coordinate: m, ft
z	rectangular or cylindrical coordinate: m, ft

Greek

α	thermal diffusivity: m^2/s , ft^2/s
β	coefficient of thermal expansion: K^{-1} , $^\circ\text{R}^{-1}$
δ	hydrodynamic boundary layer thickness: m, ft
δ_D	concentration boundary layer thickness: m, ft
δ_T	thermal boundary layer thickness: m, ft
ϵ	emissivity
ϵ_H	eddy diffusivity of heat: m^2/s , ft^2/s
ϵ_M	eddy diffusivity of momentum: m^2/s , ft^2/s
ϵ_m	eddy diffusivity of mass: m^2/s , ft^2/s
θ	angle in cylindrical and spherical coordinates: rad, deg
λ	molecular mean free path: m, ft
μ	dynamic viscosity: $\text{Pa}\cdot\text{s}$, $\text{lb}_m/(\text{s}\cdot\text{ft})$
ν	kinematic viscosity: m^2/s , ft^2/s
ρ	density: kg/m^3 , lb_m/ft^3
σ	surface tension (see Table 1.10): N/m , lb_f/ft
σ	Stefan-Boltzmann radiation constant: $\text{W}/(\text{m}^2\cdot\text{K}^4)$, $\text{Btu}/(\text{h}\cdot\text{ft}^2\cdot^\circ\text{R}^4)$
τ	shear stress: N/m^2 , lb_f/ft^2
τ	shear stress tensor: N/m^2 , lb_f/ft^2
Φ	dissipation function (see Table 1.7): s^{-2}
ϕ	angle in spherical coordinate system: rad, deg

Subscripts

a	surroundings
aw	adiabatic wall
cr	critical
f	fluid
g	gas (vapor)
i	species i
l	liquid
m	mean
r	radiation (Eq. 1.36)
s	solid
sat	saturation
t	total
w	wall

x	x component
y	y component
z	z component
θ	θ component
ϕ	ϕ component

Miscellaneous Subscripts

1	species 1 in binary mixture of 1 and 2
∞	free-stream condition

Superscripts

'	fluctuating component (for example, X' is the fluctuating component of X)
–	time average (for example, \bar{X} is the time average of X)

Mathematical Operation Symbols

d/dx	derivative with respect to x : m^{-1} , ft^{-1}
$\partial/\partial t$	partial time derivative operator: s^{-1}
d/dt	total time derivative operator: s^{-1} (Eq. 1.37)
D/Dt	substantial time derivative operator: s^{-1} (Eq. 1.38)
∇	del operator (vector): m^{-1} , ft^{-1}
∇^2	laplacian operator: m^{-2} , ft^{-2}

CHAPTER 2

THERMOPHYSICAL PROPERTIES

Thomas F. Irvine Jr.
State University of New York at Stony Brook

When organizing a chapter of thermophysical properties with limited space, some difficult decisions have to be made. Since this is a handbook for heat transfer practitioners, emphasis has been placed on transport rather than thermodynamic properties. The primary exception has been the inclusion of densities and isobaric specific heats, which are needed for the calculation of Prandtl numbers and thermal diffusivities.

In the spirit of today's computer usage, a number of gas properties are given in equation rather than tabular form. However, they are accompanied by skeleton tables to allow for program checks.

Because new refrigerants are being considered and used in technical applications, a number of transport and thermodynamic property tables are included for these substances.

Whenever possible, the properties in this chapter are divided into those for gases, liquids, and solids. There are unavoidable overlaps to this arrangement when the tables account for phase changes such as in the case of water.

ft ² /s	3.600	929.03	334.45	1	0.09290
m ² /s	38,750	10,000	3600	10.7639	1

The notation 2.581.-5 signifies 2.581×10^{-5} .

1 stoke = 1 cm²/s.

THERMOPHYSICAL PROPERTIES OF GASES

Table 2.10 treats the specific heats, dynamic viscosities, and thermal conductivities as functions of temperature only. To obtain the density of a gas, the perfect gas law may be used, i.e.,

$$P = \rho RT$$

From the specific heat and density and using other given properties, the thermal diffusivity and Prandtl number may be calculated.

For each gas, skeleton tables of the properties are given at several temperatures so that computer program checks can be made.

TABLE 2.10 Thermophysical Properties of Thirteen Common Gases Using Computer Equations

* Calculated from values of pressure, volume (or density), and temperature in A. A. Vasserman, Y. Z. Kazavchinskii, and V. A. Rabinovich, *Thermophysical Properties of Air and Air Components*, Nauka, Moscow, 1966, and NBS-NSF Trans. TT 70-50095, 1971; and A. A. Vasserman and V. A. Rabinovich, *Thermophysical Properties of Liquid Air and Its Components*, Moscow, 1968, and NBS-NSF Trans. 69-55092, 1970.

† Calculated from P - v - T values tabulated in A. A. Vasserman and V. A. Rabinovich, *Thermophysical Properties of Liquid Air and Its Components*, Israeli Program for Scientific Translations TT 69-55092, 235 pp., 1970; A. A. Vasserman, Y. Z. Kazavchinskii, and V. A. Rabinovich, *Thermophysical Properties of Air and Air Components*, IPST TT 70-50095, 383 pp., 1971.

‡ Calculated from density-pressure-temperature data in Vukalovitch and Altunin, *Thermophysical Properties of Carbon Dioxide*, Atomizdat, Moscow, 1965, and Collet's, London, 1968, trans.

§ Computed from pressure-volume-temperature tables in Zagoruchenko and Zhuravlev, *Thermophysical Properties of Gaseous and Liquid Methane*, Moscow, 1969, and NBS-NSF TT 70-50097, 1970 translation.

¶ Computed from tables in A. A. Vasserman, Y. Z. Kazavchinskii, and V. A. Rabinovich, *Thermophysical Properties of Air and Air Components*, Nauka, Moscow, 1966, and NBS-NSF Trans. TT 70-50095, 1971.

** Computed from tables in A. A. Vasserman, Y. Z. Kazavchinskii, and V. A. Rabinovich, *Thermophysical Properties of Air and Air Components*, Nauka, Moscow, 1966, and NBS-NSF Trans. TT 70-50095, 1971.

†† Calculated from P - v - T tables of D. M. Vashchenko, Y. F. Voinov, et al., Standartov, Moscow, Monograph 8, 1971; NBS IR 75-763, NTIS COM-75-11276, 203 pp., 1972; republished 1975.

		453	0.2477	1680	3.50	378.0	0.0900
		483	0.2892				

All the D_{ij} values are in (m²/s) × 10⁻⁴. For example, at 276.2 K the interdiffusion coefficient for the air-carbon dioxide mixture is 1.420 × 10⁻⁵ m²/s.

For an extensive review with formula fits but no data tables, see Marroero and Mason, *J. Phys. Chem. Ref. Data*, **1**:3-118 (1972). Interpolation from a graph of log D_{ij} versus log T is often simple.

ACKNOWLEDGMENT

The author gratefully acknowledges the use of a number of thermophysical property tables from previous editions of *Handbook of Heat Transfer*. These include Table 12 from the first edition, prepared by Professor Warren Ibele of the University of Minnesota, and Tables 11, 12, 14, 16, 21, 29, 30, and 33, prepared by Professor Peter Liley of Purdue University.

NOMENCLATURE

Symbol, Definition, SI Units, English Units

c_p	specific heat at constant pressure: kJ/(kg·K), Btu/(lb _m ·°F)
c_{pf}	specific heat at constant pressure of saturated liquid: kJ/(kg·K), Btu/(lb _m ·°F)
c_v	specific heat at constant volume: kJ/(kg·K), Btu/(lb _m ·°F)
D_{ij}	diffusion coefficient: m ² /s, ft ² /s
g	gravitational acceleration: m/s ² , ft/s ²
k	thermal conductivity: W/(m·K), Btu/(h·ft·°F)
k_f	thermal conductivity of saturated liquid: W/(m·K), Btu/(h·ft·°F)
M	molecular weight: kg/(kilogram-mole), lb _m /(pound-mole)
P	pressure: bar, lb _f /in ² (psi)
Pr	Prandtl number, $\mu c_p/k$, dimensionless
R	gas constant: kJ/(kg·K), Btu/(lb _m ·°R)
T	temperature: K, °R, °C
v	specific volume: m ³ /kg, ft ³ /lb _m
Z	compressibility factor, Pv/RT , dimensionless

Greek Symbols

α	thermal diffusivity: m ² /s, ft ² /s
β	coefficient of volumetric thermal expansion: K ⁻¹ , °R ⁻¹
λ or κ	thermal conductivity: W/mK, Btu/h·ft·°F
η or μ	dynamic viscosity: Pa·s, lb _m /(h·ft)
ν	kinematic viscosity: m ² /s, ft ² /s
ρ	density: kg/m ³ , lb _m /ft ³
σ	surface tension: N/m, lb _f /ft

CHAPTER 3

CONDUCTION AND THERMAL CONTACT RESISTANCES (CONDUCTANCES)

M. M. Yovanovich

University of Waterloo

INTRODUCTION

When steady-state conduction occurs within and outside solids, or between two contacting solids, it is frequently handled by means of conduction shape factors and thermal contact conductances (or contact resistances), respectively. This chapter covers the basic equations, definitions, and relationships that define shape factors and the thermal contact, gap, and joint conductances for conforming, rough surfaces, and nonconforming, smooth surfaces.

Shape factors for two- and three-dimensional systems are presented. General expressions formulated in orthogonal curvilinear coordinates are developed. The general expression is used to develop numerous general expressions in several important coordinate systems such as (1) circular, elliptical, and bicylinder coordinates and (2) spheroidal coordinates (spherical, oblate spheroidal, and prolate spheroidal). The integral form of the shape factor for an ellipsoid is presented and then used to obtain analytical expressions and numerical values for the shape factors of several isothermal geometries (spheres, oblate and prolate spheroids, circular and elliptical disks). It is demonstrated that the dimensionless shape factor is a weak function of the geometry (shape and aspect ratio) provided that the square root of the total *active* surface area is selected as the characteristic body length. A general dimensionless expression is proposed for accurate estimations of shape factors of three-dimensional bodies such as cuboids. Shape factor expressions are presented for two-dimensional systems bounded by isothermal coaxial (1) regular polygons, (2) internal circles and outer regular polygons, and (3) internal regular polygons and outer circles. A method is given for estimating the shape factors of systems bounded by two isothermal cubes and other combinations of internal and external geometries. The shape factor results of this chapter are used in the chapter on natural convection to model heat transfer from isothermal bodies of arbitrary shape.

Transient conduction within solids and into full and half-spaces is presented for a wide range of two- and three-dimensional geometries.

Steady-state and transient constriction (spreading) resistances for a range of geometries for isothermal and isoflux boundary conditions are given. Analytical solutions for half-spaces and heat flux tubes and channels are reported.

Elastoconstriction resistance and gap and joint resistances for line and point contacts are presented. Contact conductances of conforming rough surfaces that undergo (1) elastic, (2)

plastic, and (3) elastoplastic deformation are reported. The gap conductance integral is presented. The overall joint conductance is considered.

Analytical solutions and correlation equations are presented rather than graphic results. The availability of many computer algebra systems such as *Macsyma*, *MathCad*, *Maple*, *MATLAB*, and *Mathematica*, as well as spreadsheets such as *Excel* and *Quattro Pro* that provide symbolic, numerical, and plotting capabilities, makes the analytical solutions amenable to quick, accurate computations. All equations and correlations reported in this chapter have been verified in *Maple* worksheets and *Mathematica* notebooks. These worksheets and notebooks will be available on my home page on the Internet. Some spreadsheet solutions will also be developed and made available on the Internet.*

BASIC EQUATIONS, DEFINITIONS, AND RELATIONSHIPS

Shape factors of isothermal, three-dimensional convex bodies having complex shapes and small to large aspect ratios are of considerable interest for applications in the nuclear, aerospace, microelectronic, and telecommunication industries. The shape factor S also has applications in such diverse areas as antenna design, electron optics, electrostatics, fluid mechanics, and plasma dynamics [27].

In electrostatics, for example, the capacitance C is the total charge Q_e required to raise the potential ϕ_e of an isolated body to the electrical potential V_e and the relationship between them is (e.g., Greenspan [27], Morse and Feshbach [68, 69], Smythe [98], and Stratton [111])

$$C = \frac{Q_e}{V_e} = \iint_A -\epsilon \frac{\partial \phi_e}{\partial n} dA$$

where ϵ is the permittivity of the surrounding space, ϕ_e is the nondimensional electric potential, n is the outward-directed normal on the surface, and A is the total surface area of the body.

Mathematicians prefer to deal with the capacity C^* of a body, which they [81, 113] define as

$$C^* = \frac{1}{4\pi} \iint_A -\frac{\partial \phi_e}{\partial n} dA$$

Shape Factor, Thermal Resistance, and Diffusion Length. The shape factor S , the thermal resistance R , and the thermal diffusion length Δ are three useful and related thermal parameters.

They are defined by the following relationships:

$$S = \frac{1}{kR} = \frac{A}{\Delta} = \frac{Q}{k(T_0 - T_\infty)} = \iint_A -\frac{\partial \phi}{\partial n} dA \quad (3.1)$$

where k is the thermal conductivity, T_0 is the temperature of the isothermal body, T_∞ is the temperature of points remote from the body, and ϕ is the dimensionless temperature $(T(\vec{r}) - T_\infty)/(T_0 - T_\infty)$.

The relationships between the shape factor S , the capacitance C , and the capacity C^* are

$$S = \frac{C}{\epsilon} = 4\pi C^* \quad (3.2)$$

The three parameters have units of length.

Analytical solutions are available for a small number of geometries such as the family of geometries related to the ellipsoid (e.g., sphere, oblate and prolate spheroids, elliptical and circular disks). Precise numerical values of S for other axisymmetric convex bodies have been obtained by various numerical methods such as that proposed by Greenspan [27] and that proposed by Wang and Yovanovich [123].

* The Internet address is mmyovemh1.uwaterloo.ca.

Chow and Yovanovich [15] showed, by analytical and numerical methods, that the capacitance is a slowly changing function of the conductor shape and aspect ratio provided the total area of the conductor is held constant.

Wang and Yovanovich [123] showed that the dimensionless shape factor

$$S_{\sqrt{A}}^* = \frac{S\mathcal{L}}{A} = \frac{\mathcal{L}}{A} \iint_A \frac{-\partial\phi}{\partial n} dA \quad (3.3)$$

where the characteristic scale length \mathcal{L} was chosen to be \sqrt{A} as recommended by Yovanovich [133], Yovanovich and Burde [134], and Yovanovich [144–146], when applied to a range of axisymmetric, convex bodies is a weak function of the body shape and its aspect ratios.

This chapter reports and demonstrates, through inclusion of additional accurate numerical results of Greenspan [27] for complex body shapes such as cubes, ellipsoids, and circular and elliptical toroids, a lens that is formed by the intersection of two spheres such that $S_{\sqrt{A}}^*$ is a relatively weak function of the body shape and its aspect ratios.

This chapter also introduces the geometric length Δ , called the diffusion length, and shows that this physical length scale is closely related to the square root of the total body surface area when the body is convex.

The dimensionless geometric parameter \sqrt{A}/Δ is proposed as an alternate parameter for determination of shape factors of complex convex bodies.

Shape Factors

Formulation of the Problem in General Coordinates. Consider the steady flow of heat Q from an isothermal surface A_1 at temperature T_1 through a homogeneous medium of thermal conductivity k to a second isothermal surface A_2 at temperature T_2 ($T_1 > T_2$). The stationary temperature field depends on the geometry of the isothermal boundary surfaces. When these isothermal surfaces can be made coincident with a coordinate surface by a judicious choice of coordinates, then the temperature field will be one-dimensional in that coordinate system. In other words, heat conduction occurs across two surfaces of an orthogonal curvilinear parallelepiped (Fig. 3.1a), and the remaining four coordinate surfaces are adiabatic.

Let the general coordinates u_1, u_2, u_3 be so chosen that $T = T(u_1)$ and, therefore, $\partial T/\partial u_2 = \partial T/\partial u_3 = 0$. Under these conditions, the heat flux vector will have one component in the u_1 direction:

$$q_1 = -k(dT/ds) = -k(dT/\sqrt{g_1} du_1)$$

where $\sqrt{g_1}$ is the metric coefficient in the u_1 direction. The metric coefficients are defined by the general line element ds expressed in terms of the differentials of arc lengths on the coordinate lines [67]

$$(ds)^2 = g_1(du_1)^2 + g_2(du_2)^2 + g_3(du_3)^2$$

The product terms such as $du_i du_j$ ($i \neq j$) do not appear because of the orthogonality property of the chosen coordinate system. These metric coefficients can also be generated by means of the following formula [67]:

$$g_i \equiv (\partial x/\partial u_i)^2 + (\partial y/\partial u_i)^2 + (\partial z/\partial u_i)^2 \quad i = 1, 2, 3$$

provided that the Cartesian coordinates x, y, z can be expressed in terms of the new coordinates u_1, u_2, u_3 by the equations

$$x = x(u_1, u_2, u_3), \quad y = y(u_1, u_2, u_3), \quad z = z(u_1, u_2, u_3)$$

FIGURE 3.1a Orthogonal curvilinear parallelepiped.

The elemental coordinate surface located at u_1 , which is orthogonal to the u_1 direction, is therefore

$$dA_1 = ds_2 ds_3 = \sqrt{g_2 g_3} du_2 du_3$$

and the heat flow per unit time through this surface into the volume element is, according to Fourier's law of conduction,

$$Q_1 = -k dA_1 (dT/ds_1) = -k(\sqrt{g}/g_1)(dT/du_1) du_2 du_3$$

where $g \equiv g_1 g_2 g_3$ [67]. The heat flow rate out of the volume element is

$$Q_1 + (dQ_1/ds_1) ds_1 = Q_1 + (dQ_1/du_1) du_1$$

neglecting the higher-order terms of the Taylor series expansion of Q_1 about u_1 .

The net rate of heat conduction out of the volume element in the u_1 direction is

$$(d/du_1)[k(\sqrt{g}/g_1)(dT/du_1)] du_1 du_2 du_3$$

For steady-state conditions with no heat sources within the volume element, the Laplace equation in general coordinates is obtained by dividing by the elemental volume $\sqrt{g} du_1 du_2 du_3$ and equating to zero. Therefore,

$$(1/\sqrt{g})(d/du_1)[k(\sqrt{g}/g_1)(dT/du_1)] = 0$$

The above equation is the governing differential equation and it is nonlinear when k is a function of temperature.

The isothermal temperature boundary conditions are

$$\begin{aligned} u_1 = a, & \quad T = T_1 \\ u_1 = b, & \quad T = T_2 \end{aligned}$$

The above equation can be reduced to a linear differential equation by the introduction of a new temperature θ related to the temperature T by the Kirchoff transformation [4, 11]:

$$\theta = (1/k_0) \int_0^{T_0} k dT$$

where k_0 denotes the value of the thermal conductivity at some convenient reference temperature, say $T = 0$. It follows that

$$d\theta/du_1 = (k/k_0)(dT/du_1)$$

and, therefore, we have

$$(d/du_1)[(\sqrt{g}/g_1)(d\theta/du_1)] = 0$$

after multiplying through by \sqrt{g}/k_0 . The boundary conditions become

$$\begin{aligned} u_1 = a, & \quad \theta = \theta_1 = (1/k_0) \int_0^{T_1} k dT \\ u_1 = b, & \quad \theta = \theta_2 = (1/k_0) \int_0^{T_2} k dT \end{aligned}$$

The solution of the linear equation is

$$\theta = C_1 \int_0^{u_1} (g_1/\sqrt{g}) du_1 + C_2$$

where the constants C_1 and C_2 are obtained from

$$C_1 = -(\theta_1 - \theta_2) \int_a^b (g_1/\sqrt{g}) du_1$$

and

$$C_2 = \theta_1 - C_1 \int_0^a (g_1/\sqrt{g}) du_1$$

Temperature Distribution in Orthogonal Curvilinear Coordinates. The temperature distribution in orthogonal curvilinear coordinates is

$$\frac{\theta_1 - \theta}{\theta_1 - \theta_2} = \frac{\int_a^{u_1} (g_1/\sqrt{g}) du_1}{\int_a^b (g_1/\sqrt{g}) du_1}, \quad a < u_1 < b \quad (3.4)$$

The local heat flux in the u_1 direction is

$$q_1 = \frac{-k_0}{\sqrt{g_1}} \frac{d\theta}{du_1} = \frac{k_0(\theta_1 - \theta_2)}{\sqrt{g_2 g_3} \int_a^b (g_1/\sqrt{g}) du_1} \quad (3.5)$$

The heat flow rate through the elemental surface dA_1 is

$$q_1 dA_1 = \frac{k_0(\theta_1 - \theta_2)}{\int_a^b (g_1/\sqrt{g}) du_1} du_2 du_3 \quad (3.6)$$

The total heat flow rate through the thermal system can be obtained by integration between the appropriate limits. Therefore,

$$Q = k_0(\theta_1 - \theta_2) \int_{u_3} \int_{u_2} \frac{du_2 du_3}{\int_a^b (g_1/\sqrt{g}) du_1} \quad (3.7)$$

An examination of the above equation shows that

$$k_0(\theta_1 - \theta_2) = \int_{T_2}^{T_1} k dT = k_a(T_1 - T_2) \quad (3.8)$$

where k_a , the average value of the thermal conductivity, is given by

$$k_a = k_0[1 + (\beta/2)(T_1 + T_2)] \quad (3.9)$$

if $k = k_0(1 + \beta T)$.

Shape Factor and Thermal Resistance in Orthogonal Curvilinear Coordinates. The definition of thermal resistance of a system (total temperature drop across the system divided by the total heat flow rate) yields the following general expression for the thermal resistance R and the conduction shape factor S :

$$S = (Rk_a)^{-1} = \int_{u_3} \int_{u_2} \frac{du_2 du_3}{\int_a^b (g_1/\sqrt{g}) du_1} \quad (3.10)$$

The right side of the previous equation has units of length and depends on the geometry of the body only. There are several very important and useful coordinate systems that can be used to solve many seemingly complex conduction problems. Since each coordinate system

FIGURE 3.1b Circular cylinder coordinates.

has three principal directions, there are three sets of shape factors corresponding to each of these directions. The conduction shape factors for several coordinate systems are given in the following section. This section by no means represents the total number of coordinate systems that are amenable to this type of analysis. It does, however, contain the most frequently used coordinate systems.

General Expressions for Conduction Shape Factors

Circular Cylinder Coordinates (r, ψ, z): Fig. 3.1b

r direction. Let $u_1 = r$; therefore, $u_2 = \psi$, $u_3 = z$, and $g_1/\sqrt{g} = 1/r$. If

$$\begin{aligned} a < r < b \\ 0 < \psi < \beta & \quad \beta_{\max} = 2\pi \\ 0 < z < L \end{aligned}$$

then
$$S^{-1} = Rk_a = \frac{\ln(b/a)}{\beta L} \tag{3.11}$$

ψ direction. Let $u_1 = \psi$; therefore, $u_2 = z$, $u_3 = r$, and $g_1/\sqrt{g} = r$. Limits of integration are given just previously.

$$S^{-1} = Rk_a = \frac{\beta}{L \ln(b/a)} \tag{3.12}$$

z direction. Let $u_1 = z$; therefore, $u_2 = r$, $u_3 = \psi$, and $g_1/\sqrt{g} = 1/r$. Limits of integration were given previously.

$$S^{-1} = Rk_a = \frac{2L}{\beta(b^2 - a^2)} \tag{3.13}$$

Spherical Coordinates (r, θ, ψ): Fig. 3.1c

$$(ds)^2 = (dr)^2 + r^2(d\theta)^2 + r^2 \sin^2 \theta (d\psi)^2$$

$$g_r = 1, \quad g_\theta = r^2, \quad g_\psi = r^2 \sin^2 \theta, \quad \sqrt{g} = r^2 \sin \theta$$

r direction. Let $u_1 = r$; therefore, $u_2 = \theta$, $u_3 = \psi$, and $g_1/\sqrt{g} = 1/(r^2 \sin \theta)$. If

$$\begin{aligned} a < r < b \\ \beta_1 < \theta < \beta_2 & \quad \beta_{\min} = 0 \quad \text{and} \quad \beta_{\max} = \pi \\ 0 < \psi < \gamma & \quad \gamma_{\max} = 2\pi \end{aligned}$$

then
$$S^{-1} = Rk_a = \frac{[(1/a) - (1/b)]}{\gamma(\cos \beta_1 - \cos \beta_2)} \tag{3.14}$$

θ direction. Let $u_1 = \theta$; therefore, $u_2 = \psi$, $u_3 = r$, and $g_1/\sqrt{g} = 1/(\sin \theta)$. Limits of integration are given just previously.

$$S^{-1} = Rk_a = \frac{\ln[\tan(\beta_2/2)] - \ln[\tan(\beta_1/2)]}{\gamma(b - a)} \tag{3.15}$$

FIGURE 3.1c Spherical coordinates.

FIGURE 3.1d Elliptical cylinder coordinates.

ψ direction. Let $u_1 = \psi$; therefore, $u_2 = r$, $u_3 = \theta$, and $g_1/\sqrt{g} = \sin \theta$. Limits of integration were given previously.

$$S^{-1} = Rk_a = \frac{\gamma}{(b-a) \{ \ln [\tan (\beta_2/2)] - \ln [\tan (\beta_1/2)] \}} \quad (3.16)$$

Elliptical Cylinder Coordinates (η, ψ, z): Fig. 3.1d

$$(ds)^2 = a^2(\cosh^2 \eta - \cos^2 \psi)[(d\eta)^2 + (d\psi)^2] + (dz)^2$$

$$g_\eta = g_\psi = a^2(\cosh^2 \eta - \cos^2 \psi), \quad g_z = 1,$$

$$\sqrt{g} = a^2(\cosh^2 \eta - \cos^2 \psi)$$

η direction. Let $u_1 = \eta$; therefore, $u_2 = \psi$, $u_3 = z$, and $g_1/\sqrt{g} = 1$. If

$$\begin{aligned} \eta_1 < \eta < \eta_2 & \quad \eta_{\min} = 0, & \quad \eta_{\max} = \infty \\ 0 < \psi < \beta & \quad \beta_{\max} = 2\pi \\ 0 < z < L & \end{aligned}$$

then

$$S^{-1} = Rk_a = \frac{(\eta_2 - \eta_1)}{L\beta} \quad (3.17)$$

where

$$\eta_1 = \frac{1}{2} \ln \left[\frac{b_1 + c_1}{b_1 - c_1} \right], \quad \eta_2 = \frac{1}{2} \ln \left[\frac{b_2 + c_2}{b_2 - c_2} \right]$$

and

$$a = \sqrt{b_1^2 - c_1^2} = \sqrt{b_2^2 - c_2^2}$$

ψ direction. Let $u_1 = \psi$; therefore, $u_2 = z$, $u_3 = \eta$, and $g_1/\sqrt{g} = 1$. Limits of integration were given previously.

$$S^{-1} = Rk_a = \frac{\beta}{L(\eta_2 - \eta_1)} \quad (3.18)$$

z direction. Let $u_1 = z$; therefore, $u_2 = r$, $u_3 = \psi$, and

$$\frac{g_1}{\sqrt{g}} = \frac{1}{a^2(\cosh^2 \eta - \cos^2 \psi)}$$

Limits of integration were given previously.

$$S^{-1} = Rk_a = \frac{L}{a \int_{\eta_1}^{\beta} \int_{\eta_1}^{\eta_2} (\cosh^2 \eta - \cos^2 \psi) d\eta d\psi} \quad (3.19)$$

Bicylinder Coordinates (η, ψ, z): Fig. 3.1e

$$(ds)^2 = \frac{a^2}{(\cosh \eta - \cos \psi)^2} [(d\eta)^2 + (d\psi)^2] + (dz)^2$$

$$g_\eta = g_\psi = \frac{a^2}{(\cosh \eta - \cos \psi)^2}, \quad g_z = 1, \quad \sqrt{g} = \frac{a^2}{(\cosh \eta - \cos \psi)^2}$$

η direction. Let $u_1 = \eta$; therefore, $u_2 = \psi$, $u_3 = z$, and $g_1/\sqrt{g} = 1$. If

$$\begin{aligned} \eta_1 > \eta > \eta_2 & \quad \eta_{\min} = -\infty, & \quad \eta_{\max} = +\infty \\ 0 < \psi < \beta & \quad \beta_{\max} = 2\pi \\ 0 < z < L & \end{aligned}$$

FIGURE 3.1e Bicycylinder coordinates.

then
$$S^{-1} = Rk_a = \frac{(\eta_2 - \eta_1)}{L\beta} \tag{3.20}$$

where
$$|\eta_1| = \sinh^{-1} \sqrt{\left(\frac{w_1}{r_1}\right)^2 - 1} \quad \text{and} \quad |\eta_2| = \sinh^{-1} \sqrt{\left(\frac{w_2}{r_2}\right)^2 - 1}$$

ψ direction. Let $u_1 = \psi$; therefore, $u_2 = z$, $u_3 = \eta$, and $g_1/\sqrt{g} = 1$. Limits of integration were given previously.

$$S^{-1} = Rk_a = \frac{\beta}{L(\eta_2 - \eta_1)} \tag{3.21}$$

z direction. Let $u_1 = z$; therefore, $u_2 = \eta$, $u_3 = \psi$, and

$$\frac{g_1}{\sqrt{g}} = \frac{(\cosh \eta - \cos \psi)^2}{a^2}$$

Limits of integration were given previously.

$$S^{-1} = Rk_a = \frac{L}{a^2 \int_0^\beta \int_{\eta_2}^{\eta_1} [d\eta d\psi / (\cosh \eta - \cos \psi)^2]} \tag{3.22}$$

where
$$a = \sqrt{w_1^2 - r_1^2} = \sqrt{w_2^2 - r_2^2}$$

Oblate Spheroidal Coordinates (η, θ, ψ): Fig. 3.1f

$$(ds)^2 = a^2(\cosh^2 \eta - \sin^2 \theta)[(d\eta)^2 + (d\theta)^2] + a^2 \cosh^2 \eta \sin^2 \theta (d\psi)^2$$

$$g_\eta = g_\theta = a^2(\cosh^2 \eta - \sin^2 \theta)$$

$$g_\psi = a^2 \cosh^2 \eta \sin^2 \theta$$

$$\sqrt{g} = a^3(\cosh^2 \eta - \sin^2 \theta) \cosh \eta \sin \theta$$

η direction. Let $u_1 = \eta$; therefore, $u_2 = \theta$, $u_3 = \psi$, and

$$\frac{g_1}{\sqrt{g}} = \frac{1}{a \cosh \eta \sin \theta}$$

$$\text{If} \quad \begin{array}{lll} \eta_1 < \eta < \eta_2 & \eta_{\min} = 0, & \eta_{\max} = \infty \\ \beta_1 < \theta < \beta_2 & \beta_{\min} = 0, & \beta_{\max} = \pi \\ 0 < \psi < \gamma & \gamma_{\max} = 2\pi & \end{array}$$

$$\text{then} \quad S^{-1} = Rk_a = \frac{\tan^{-1}(\sinh \eta_2) - \tan^{-1}(\sinh \eta_1)}{a\gamma[\cos \beta_1 - \cos \beta_2]} \quad (3.23)$$

where

$$a = \sqrt{b_1^2 - c_1^2} = \sqrt{b_2^2 - c_2^2}$$

and

$$\eta_1 = \tanh^{-1}(c_1/b_1), \quad \eta_2 = \tanh^{-1}(c_2/b_2)$$

θ direction. Let $u_1 = \theta$; therefore, $u_2 = \psi$, $u_3 = \eta$, and

$$\frac{g_1}{\sqrt{g}} = \frac{1}{a \cosh \eta \sin \theta}$$

Limits of integration were given previously:

$$S^{-1} = Rk_a = \frac{\ln [\tan (\beta_2/2)] - \ln [\tan (\beta_1/2)]}{a\gamma(\sinh \eta_2 - \sinh \eta_1)} \quad (3.24)$$

ψ direction. Let $u_1 = \psi$; therefore, $u_2 = \eta$, $u_3 = \theta$, and

$$\frac{g_1}{\sqrt{g}} = \frac{\cosh \eta \sin \theta}{a(\cosh^2 \eta - \sin^2 \theta)}$$

Limits of integration were given previously.

$$S^{-1} = Rk_a = \frac{\gamma}{a \int_{\eta_1}^{\eta_2} \int_{\beta_1}^{\beta_2} [(\cosh^2 \eta - \sin^2 \theta) / \cosh \eta \sin \theta] d\theta d\eta} \quad (3.25)$$

Prolate Spheroidal Coordinates (η, θ, ψ): Fig. 3.1g

$$(ds)^2 = a^2(\sinh^2 \eta + \sin^2 \theta)[(d\eta)^2 + (d\theta)^2] + a^2 \sinh^2 \eta \sin^2 \theta (d\psi)^2$$

$$g_\eta = g_\theta = a^2(\sinh^2 \eta + \sin^2 \theta)$$

$$g_\psi = a^2 \sinh^2 \eta \sin^2 \theta$$

$$\sqrt{g} = a^3(\sinh^2 \eta + \sin^2 \theta) \sinh \eta \sin \theta$$

FIGURE 3.1f Oblate spheroidal coordinates.

FIGURE 3.1g Prolate spheroidal coordinates.

η direction. Let $u_1 = \eta$; therefore, $u_2 = \theta$, $u_3 = \psi$, and

$$\frac{g_1}{\sqrt{g}} = \frac{1}{a \sinh \eta \sin \theta}$$

If
$$\begin{aligned} \eta_1 < \eta < \eta_2 & \quad \eta_{\min} = 0, & \quad \eta_{\max} = \infty \\ \beta_1 < \theta < \beta_2 & \quad \beta_{\min} = 0, & \quad \beta_{\max} = \pi \\ 0 < \psi < \gamma & \quad \gamma_{\max} = 2\pi \end{aligned}$$

then
$$S^{-1} = Rk_a = \frac{\ln [\tanh (\eta_2/2)] - \ln [\tanh (\eta_1/2)]}{a\gamma(\cos \beta_1 - \cos \beta_2)} \tag{3.26}$$

where
$$a = \sqrt{b_1^2 - c_1^2} = \sqrt{b_2^2 - c_2^2}$$

and
$$\eta_1 = \frac{1}{2} \ln \left[\frac{b_1 + c_1}{b_1 - c_1} \right], \quad \eta_2 = \frac{1}{2} \ln \left[\frac{b_2 + c_2}{b_2 - c_2} \right]$$

θ direction. Let $u_1 = \theta$; therefore, $u_2 = \psi$, $u_3 = \eta$, and

$$\frac{g_1}{\sqrt{g}} = \frac{1}{a \sinh \eta \sin \theta}$$

Limits of integration were given previously.

$$S^{-1} = Rk_a = \frac{\ln [\tan (\beta_2/2)] - \ln [\tan (\beta_1/2)]}{a\gamma(\cosh \eta_2 - \cosh \eta_1)} \tag{3.27}$$

ψ direction. Let $u_1 = \psi$; therefore, $u_2 = \eta$, $u_3 = \theta$, and

$$\frac{g_1}{\sqrt{g}} = \frac{\sinh \eta \sin \theta}{a(\sinh^2 \eta + \sin^2 \theta)}$$

Limits of integration were given previously.

$$S^{-1} = Rk_a = \frac{\gamma}{a \int_{\eta_1}^{\eta_2} \int_{\beta_1}^{\beta_2} [(\sinh^2 \eta - \sin^2 \theta) / \sinh \eta \sin \theta] d\theta d\eta} \tag{3.28}$$

The basic relations given above for several curvilinear coordinates can be used to obtain expressions for the shape factor for many problems of interest to thermal analysts. Several typical two- and three-dimensional examples are presented in Fig. 3.2. The material in the following section provides shape factors for three-dimensional isothermal bodies in full space.

Shape Factors for Ellipsoids: Integral Form for Numerical Calculations

The capacity and/or the capacitance of an isopotential ellipsoid are presented in several texts and handbooks such as those by Flugge [22], Jeans [40], Kellogg [43], Mason and Weaver [62], Morse and Feshbach [68, 69], Smythe [98], and Stratton [111]. The results presented in these texts are used to develop expressions for the shape factors of several bodies: spheres, oblate and prolate spheroids (see Fig. 3.3), circular and elliptical disks, and ellipsoids. The shape factor for the ellipsoid is general; it reduces to the shape factor for the other bodies.

The capacity of an isopotential ellipsoid having semiaxes $a \geq b \geq c$ was given in the integral form [113]:

$$\frac{1}{C^*} = \frac{1}{2} \int_0^\infty \frac{dv}{\sqrt{(a^2 + v)(b^2 + v)(c^2 + v)}} \quad (3.29)$$

where v is a dummy variable. This expression is used to develop the expression for the dimensionless shape factor of isothermal ellipsoids. Since $S = 4\pi C^*$, one can set the space variable $v = a^2 t$, where t is a dimensionless variable. Next we normalize the two smaller axes b, c of the ellipsoid with respect to the largest semiaxis a such that $\beta = b/a$ and $\gamma = c/a$. This leads to the following dimensionless integral [150]:

$$\frac{8\pi a}{S} = I(\beta, \gamma) = \int_0^\infty \frac{dt}{\sqrt{(1+t)(\beta^2+t)(\gamma^2+t)}}, \quad 0 \leq \gamma \leq \beta \leq 1 \quad (3.30)$$

FIGURE 3.3 Three-dimensional bodies.

The ellipsoidal integral can be expressed in terms of the incomplete elliptical integral of the first kind $F(\kappa, \phi)$ [10, 60]:

$$I(\beta, \gamma) = \frac{2}{\sqrt{1-\gamma^2}} F\left(\sin^{-1} \sqrt{1-\gamma^2}, \sqrt{\frac{1-\beta^2}{1-\gamma^2}}\right) \quad (3.31)$$

where κ and ϕ are the modulus and amplitude angle, respectively. Computer algebra systems can be used to evaluate the above special function accurately and quickly.

The ellipsoidal integral reduces to several special cases, which are presented next.

Sphere. $a = b = c; \beta = \gamma = 1.$

$$I(1, 1) = \int_0^\infty \frac{dt}{(1+t)^{3/2}} = 2 \quad (3.32)$$

which gives $S = 4\pi a$, a well-known result.

Circular disk. $a = b, c = 0; \beta = 1, \gamma = 0.$

$$I(1, 0) = \int_0^\infty \frac{dt}{(1+t)\sqrt{t}} = \pi \quad (3.33)$$

which gives $S = 8a$, also a well-known result.

Elliptical disk. $a \geq b, c = 0; 0 < \beta \leq 1, \gamma = 0.$

$$I(\beta, 0) = \int_0^\infty \frac{dt}{\sqrt{(1+t)(\beta^2+t)t}} = 2K(\sqrt{1-\beta^2}) \tag{3.34}$$

where $K(\kappa)$ is the complete elliptical integral of the first kind of modulus $\kappa = \sqrt{1-\beta^2}$. There are several methods available to compute accurately the complete elliptical integral [1]. Here are two simple approximations:

$$K(\sqrt{1-\beta^2}) \approx \frac{2\pi}{(1+\sqrt{\beta})^2}, \quad 0.2 < \beta \leq 1 \tag{3.35}$$

and
$$K(\sqrt{1-\beta^2}) \approx \ln\left(\frac{4}{\beta}\right), \quad 0 < \beta < 0.2 \tag{3.36}$$

Oblate spheroid. $a = b > c; \beta = 1, 0 \geq \gamma < 1.$

$$I(1, \gamma) = \int_0^\infty \frac{dt}{(1+t)\sqrt{\gamma^2+t}} = \frac{2}{\sqrt{1-\gamma^2}} \cos^{-1} \gamma \tag{3.37}$$

Prolate spheroid. $a > b = c; \beta = \gamma \leq 1.$

$$I(\gamma, \gamma) = \int_0^\infty \frac{dt}{(\gamma^2+t)\sqrt{1+t}} = \frac{1}{\sqrt{1-\gamma^2}} \ln \left[\frac{1+\sqrt{1-\gamma^2}}{1-\sqrt{1-\gamma^2}} \right] \tag{3.38}$$

The above results correspond to an important family of axisymmetric, convex geometries. The results presented in dimensional form or in nondimensional form as given above do not reveal an important property presented by this family of geometries and other geometries when the appropriate physical characteristic scale length is used for the nondimensionalization.

The numerical values S_a^* for oblate spheroids ($\beta = 1, 0 \leq \gamma \leq 1$), prolate spheroids ($\beta = \gamma, 1 \geq \gamma \geq 10$), and elliptical disks ($0 \leq \beta \leq 1, \gamma = 0$) are presented in Tables 3.1–3.3.

The range of dimensionless shape factor for the oblate spheroids is $8 \leq S_a^* \leq 4\pi$. The highest and lowest values correspond to the sphere and the circular disk, respectively. The radii of the disk and sphere are set to one unit.

The dimensionless shape factor range for the prolate spheroids is approximately $4.177 \leq S_a^* \leq 4\pi$ for the aspect ratio range $1 \leq a/b \leq 10$, and the major axis is set to $2a = 2$.

The dimensionless shape factor range for the elliptical disks is approximately $3.4 \leq S_a^* \leq 8$. The highest value corresponds to a circular disk of unit radius, and the lowest value corresponds to an elliptical disk with a 10 to 1 aspect ratio.

The range of all values of S_a^* presented in the three tables is quite large. The ratio of the largest and smallest values is approximately 3.7. These values correspond to the sphere and the elliptical disks of large aspect.

In the next section the range of the dimensionless shape factors will be reduced significantly by the introduction of a scale length based on the square root of the total surface area.

Surface Area of Ellipsoids. The expression for the total surface area of an ellipsoid is written as [150]:

$$\frac{A}{2\pi a^2} = \gamma^2 + \frac{\beta}{\sin \phi} [\gamma^2 F(\phi, \kappa) + (1 - \gamma^2) E(\phi, \kappa)] = \mathcal{A}(\beta, \gamma) \quad (3.39)$$

with $\phi = \cos^{-1} \gamma$ and $\kappa = \left(\frac{1 - (\gamma/\beta)^2}{1 - \gamma^2} \right)^{1/2}$

The total surface area related to the semimajor axis is a function of the two aspect ratios β and γ . The special functions $F(\phi, \kappa)$ and $E(\phi, \kappa)$ are incomplete elliptical integrals of the first and second kind, respectively. They depend on the amplitude angle ϕ and the modulus κ . These special functions can be computed quickly and accurately by means of computer algebra systems such as *Mathematica* [153]. Their properties are given in Abramowitz and Stegun [1].

The relationship between the square root of the total surface area and the semimajor axis is [150]:

$$\frac{\sqrt{A}}{a} = \sqrt{2\pi \mathcal{A}(\beta, \gamma)} \quad (3.40)$$

Dimensionless Shape Factor and Diffusion Length of Ellipsoids. The dimensionless shape factor $S_{\sqrt{A}}^*$ and the proposed dimensionless diffusion length \sqrt{A}/Δ for isothermal ellipsoids can be obtained from the shape factor integral $I(\beta, \gamma)$ and the relationship \sqrt{A}/a given previously. The equation is

$$S_{\sqrt{A}}^* = \frac{\sqrt{A}}{\Delta} = \frac{4\sqrt{2\pi}}{I(\beta, \gamma)\sqrt{\mathcal{A}(\beta, \gamma)}} \quad (3.41)$$

The functions that appear in this expression were computed quickly and accurately using *Mathematica*. The numerical values for oblate spheroids are presented in the third column of

Table 3.1. The range of values has been significantly reduced. The ratio of the values for the sphere $a/c = 1$ and the circular disk $a/c \rightarrow \infty$ has been reduced from 1.57 to 1.11.

The numerical values for prolate spheroids are presented in the third column of Table 3.2. Here the reduction in the range is much greater. The ratio of the values for the sphere $a/b = 1$ and the long prolate spheroid $a/b = 10$ has been reduced from 3.0 to 1.18.

The numerical values for elliptical disks are presented in the third column of Table 3.3. Here, also, we observe that the reduction in the range is much greater. The ratio of the values for the circular disk $a/b = 1$ and the long elliptical disk $a/b = 10$ has been reduced from 2.35 to 1.34.

There is another benefit when $\mathcal{L} = \sqrt{A}$ is used as the characteristic body length. The differences between the values for the elliptical disks and the prolate spheroids are greatly reduced, becoming negligible for large aspect ratios. The largest difference of approximately 11 percent occurs when the aspect ratio is 1, i.e., when a sphere and a circular disk are compared.

This shows that elliptical disks (zero-thickness bodies) and prolate spheroids that have identical total surface areas and similar aspect ratios possess shape factors that are close in magnitude.

This important finding is demonstrated further in the subsequent sections, where a wide range of body shapes is considered.

Raithby and Hollands, in the chapter on natural convection, have developed correlation equations for external convection from isothermal bodies. In the correlation equations, the conduction Nusselt number is based on the shape factors developed in these sections.

Shape Factors for Three-Dimensional Bodies in Unbounded Domains

The shape factors for steady conduction within two- and three-dimensional systems that are bounded by isothermal surfaces are available. Dimensionless shape factors for several three-dimensional bodies are presented next. The results are based on analytical and numerical techniques.

Circular Toroid. The circular toroid is characterized by the ring diameter d and the toroid diameter D (Fig. 3.4a). The analytical solution [94] for the shape factor is written as an infinite series in which each term consists of toroidal or ring functions [1]:

$$S_{\sqrt{A}}^* = \frac{\sqrt{A}}{\Delta} = \frac{4}{\pi} \sqrt{\xi - 1/\xi} \left\{ \frac{Q_{-1/2}(\xi)}{P_{-1/2}(\xi)} + 2 \sum_{n=1}^{\infty} \frac{Q_{n-1/2}(\xi)}{P_{n-1/2}(\xi)} \right\} \quad (3.42)$$

with $\xi = D/d > 1$. The special functions are accurately computed using *Mathematica*. The series converges very slowly for $D/d \rightarrow 1$, which corresponds to toroids with small inner diameters. When $D/d = 1$, $S_{\sqrt{A}}^* = 3.482761$, which is approximately 1.8 percent smaller than the value for the sphere. In the narrow range: $1 \leq D/d \leq 2$, $S_{\sqrt{A}}^* = 3.449$ to within 1 percent.

FIGURE 3.4 (a) Circular toroid; (b) square toroid; (c) finite circular cylinder; (d) finite square cylinder.

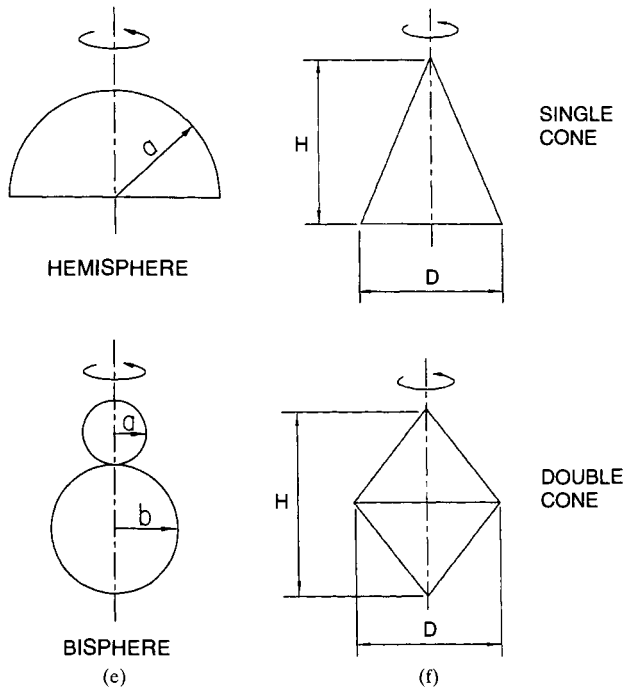

FIGURE 3.4 (Continued) (e) bisphere and hemisphere; (f) single and double cones.

For $D/d > 5$, the dimensionless shape factor for the toroid approaches the asymptote:

$$S_{\sqrt{A}}^* = \frac{\sqrt{A}}{\Delta} = 2\pi \frac{\sqrt{D/d}}{\ln(8D/d)} \quad (3.43)$$

For the practical range $2 \leq D/d \leq 10$, the shape factor is approximated with a maximum error of about 0.7 percent by multiplying the asymptotic expression by the empirical correlation equation:

$$C_{CT} = \frac{81}{80} + \frac{e^{-D/d}}{\sqrt{4.5}}$$

Square Toroid. The accurate numerical values of shape factors for square toroids, which are characterized by the inner and outer diameters D_i and D_o , respectively (Fig. 3.4b), were reported by Wang [122] for a wide range of the diameter ratio D_i/D_o . The dimensionless results were found to be in close agreement with the analytical results for the equivalent circular toroid defined by

$$\frac{D}{d} = \frac{\pi}{4} \frac{1 + D_i/D_o}{1 - D_i/D_o}, \quad \frac{D_i}{D_o} > 0.1 \quad (3.44)$$

The above relationship was obtained by the application of two geometric rules: (1) set the surface area and (2) set the mean perimeter of the equivalent circular toroid equal to the surface area and the mean perimeter of the square toroid. When the circular toroid asymptotic expression given above is multiplied by the empirical correlation equation

$$C_{ST} = \frac{161}{160} + \frac{e^{-D/d}}{\sqrt{18}}$$

with D/d defined by the previous equation, the numerical values and the predicted values differ by less than 0.8 percent.

Finite Circular Cylinder. The dimensionless shape factor for an isothermal right circular cylinder of length L and diameter d (Fig. 3.4c) was obtained from the analytical solution for the capacitance [96, 97]. Using the square root of the total surface area, the result is recast as

$$S_{\sqrt{A}}^* = \frac{\sqrt{A}}{\Delta} = \frac{3.1915 + 2.7726(L/d)^{0.76}}{\sqrt{1 + 2L/d}}, \quad 0 \leq L/d \leq 8 \quad (3.45)$$

The dimensionless shape factor for the right circular cylinder is in very close agreement with the values for the oblate spheroid in the range $0 \leq L/d \leq 1$ and with the values for the prolate spheroid in the range $1 \leq L/d \leq 8$. The difference when $L/d = 1$ is less than 1 percent. This shows that the results for the sphere and a finite circular cylinder of unit aspect ratio are very close. The simple expression obtained from the Smythe solution can be used to estimate the shape factors of circular disks, oblate spheroids, and prolate spheroids in the range $0 \leq L/d \leq 8$. For $L/d > 8$, the prolate spheroid asymptotic result can be used to provide accurate results for long circular cylinders and other equivalent bodies.

Finite Square Cylinder. The dimensionless shape factors for finite square cylinders of length L and side dimension W (Fig. 3.4d) can be calculated using the finite circular expression by means of the equivalent aspect ratio

$$\frac{L}{d} = \frac{1}{2^{1/4}} \frac{L}{W} \quad (3.46)$$

which was obtained by the following rule: take the geometric mean of the aspect ratios obtained by (1) inscribing and (2) circumscribing the square cylinder with circular cylinders. This procedure produces results that are in close agreement with reported numerical results in the range $0 \leq L/W \leq 10$.

Cube, Bisphere, and Hemisphere. The dimensionless shape factors are as follows: for the cube (Fig. 3.3), $S_{\sqrt{A}}^* = 3.391$, for the bisphere (Fig. 3.4e), $S_{\sqrt{A}}^* = 3.4749$, and for the hemisphere (Fig. 3.4e), $S_{\sqrt{A}}^* = 3.4601$. These numerical and analytical results are approximately 4.5 percent, 2 percent, and 2.5 percent smaller than the value for the sphere.

Single and Double Cones. The single and double cones (Fig. 3.4f) are characterized by the height dimension H and the maximum diameter D . The dimensionless shape factors were obtained by means of an accurate numerical technique [122].

Single cone. The single cone numerical results for the shape factor are predicted by the following two correlation equations.

for $0.001 \leq x = H/D \leq 1$:

$$S_{\sqrt{A}}^* = 3.19399 + 0.629823x - 0.933731x^2 + 0.862597x^3 - 0.312459x^4 \quad (3.47)$$

for $1 \leq x = H/D \leq 8$:

$$S_{\sqrt{A}}^* = 3.280967 + 1.61022(x/10) - 0.047366(x/10)^2 - 0.30067(x/10)^3 + 2.99117 \times 10^{-3}(x/10)^4 \quad (3.48)$$

Double Cone. The double cone numerical data for the shape factors are correlated by the following two polynomials.

for $0.001 \leq x = H/D \leq 1$:

$$S_{\sqrt{A}}^* = 3.194264 + 0.626604x - 0.477791x^2 + 0.0751056x^3 + 0.0531827x^4 \quad (3.49)$$

and for $1 \leq x = H/D \leq 10$:

$$S_{\sqrt{A}}^* = 3.41318 + 0.419048(x/10) + 2.02734(x/10)^2 - 2.23961(x/10)^3 + 0.80661(x/10)^4 \quad (3.50)$$

Circular and Rectangular Annulus. The dimensionless shape factors of isothermal circular and rectangular annuli are presented next.

Circular annulus. The circular annulus has inner and outer radii a and b , respectively. The two capacitance analytical solutions of Smythe [95] are recast into the following two expressions, which relate the dimensionless shape factor to the radii ratio $\epsilon = a/b$:

$$S_{\sqrt{A}}^* = \frac{\sqrt{A}}{\Delta} = \pi\sqrt{2\pi} \sqrt{\frac{1+\epsilon}{1-\epsilon}} \cdot \frac{1}{\ln 16 + \ln [(1+\epsilon)/(1-\epsilon)]} \quad (3.51)$$

which is restricted to the range $1.000 < 1/\epsilon < 1.1$; and

$$S_{\sqrt{A}}^* = \frac{\sqrt{A}}{\Delta} = \frac{8}{\pi} \sqrt{\frac{2}{\pi}} \frac{1}{\sqrt{1-\epsilon^2}} [\cos^{-1} \epsilon + \sqrt{1-\epsilon^2} \tanh^{-1} \epsilon] [1 + 0.0143\epsilon^{-1} \tan^3 (1.28\epsilon)] \quad (3.52)$$

which is valid in the range $0 < \epsilon < 1/1.1$.

Rectangular annulus. The rectangular annulus is characterized by its outer length L and outer width W . The width ${}^{\circ}W$ of the annular area is uniform. The interior open region has dimensions $L - 2{}^{\circ}W$ by $W - 2{}^{\circ}W$.

The dimensionless shape factor for the isothermal rectangular annulus is derived from the correlation equation of Schneider [89], who obtained accurate numerical values of the thermal constriction resistance of doubly connected rectangular contact areas by means of the boundary integral equation method:

$$S_{\sqrt{A}}^* = \frac{\sqrt{A}}{\Delta} = \frac{\sqrt{2}}{[C_1({}^{\circ}W/2W)^{C_2} + C_3]} \cdot \left[\frac{{}^{\circ}W}{W} + \frac{L}{W} - 2\left(\frac{{}^{\circ}W}{W}\right)^2 \right]^{-1/2} \quad (3.53)$$

with the recommended correlation coefficients

$$C_1 = -0.00232 \frac{L}{W} + 0.03128$$

$$C_2 = 0.2927 \left(\frac{L}{W} + 0.7463 \right)^{-1} + 0.4316$$

$$C_3 = 0.6786 \left(\frac{L}{W} + 0.8145 \right)^{-1} + 0.0346$$

The correlation equation is restricted to the ranges $1 \leq L/W \leq 4$ and $0.01 \leq {}^{\circ}W/W \leq 0.5$, with a maximum error of 1.45 percent between the correlation predictions and the numerical values. Selected values of the dimensionless diffusion length \sqrt{A}/Δ are given in Table 3.4.

The dimensionless diffusion length is a weak function of the two parameters L/W and ${}^{\circ}W/W$ over a practical range of these parameters. The values are close to the circular and elliptical disk values reported earlier.

TABLE 3.4 Dimensionless Diffusion Length for Rectangular Annulus

L/W	W/W	\sqrt{A}/Δ	L/W	W/W	\sqrt{A}/Δ
1	0.1	3.2918	3	0.1	3.7001
	0.3	3.1978		0.3	3.6106
	0.5	3.3575		0.5	3.6370
2	0.1	3.4893	4	0.1	3.8774
	0.3	3.4044		0.3	3.7829
	0.5	3.4681		0.5	3.7884

Rectangular Plate. The dimensionless shape factor for isothermal rectangular plates of length L and width W , where $L \geq W$, is calculated by means of the following two semianalytical expressions:

$$S_{\sqrt{A}}^* = 0.8 \frac{(1 + \sqrt{L/W})^2}{\sqrt{L/W}}, \quad 1 \leq L/W \leq 5 \quad (3.54)$$

$$S_{\sqrt{A}}^* = \frac{\sqrt{8\pi L/W}}{\ln(4L/W)}, \quad 5 < L/W < \infty \quad (3.55)$$

The maximum difference between the predicted values and the numerical values for the range $1 \leq L/W \leq 4$ is less than 1 percent.

Cuboid. The dimensionless shape factor of cuboids with side dimensions $L_1 \geq L_2 \geq L_3$ is approximated by the expression [150]

$$S_{\sqrt{A}}^* = [S_{\sqrt{A}}^*]_{\text{rect}} \frac{(1 + 0.8688(L_1/D_{\text{GM}})^{0.76})}{\sqrt{1 + 2L_1/D_{\text{GM}}}} \quad (3.56)$$

where the equivalent circular cylinder diameter is based on the cuboid lengths L_2 and L_3 :

$$D_{\text{GM}} = \sqrt{\frac{2}{\pi} (L_2 + L_3) \sqrt{L_2^2 + L_3^2}}$$

The values for $[S_{\sqrt{A}}^*]_{\text{rect}}$ are obtained from the expressions for the rectangular plates given above. This parameter depends on the cuboid lengths L_2 and L_3 . The proposed expression for cuboids predicts the dimensionless shape factor to within ± 5 percent.

Three-Dimensional Bodies With Layers: Langmuir Method

Shape factors for three-dimensional systems such as regions bounded by isothermal concentric spheres or concentric cubes; inner sphere and outer cube; and inner cube and outer sphere are presented in this section. The systems fall into two categories: (1) uniform thickness layers, and (2) nonuniform thickness layers. Warrington et al. [124] reported in graphic form numerical results for the cube-in-cube, sphere-in-cube, and cube-in-sphere systems. The numerical results for the shape factors were normalized with respect to the classical sphere-in-sphere solution and plotted against the ratio D_i/D_o , where D_i and D_o are the inner and outer equivalent diameters, respectively. Hassani and Hollands [33] proposed an approximate method for calculating shape factors for a region of uniform thickness surrounding an isothermal convex body of arbitrary shape. The proposed method is based on the asymptotic results corresponding to very thin layers where the shape factor is given by

$$S_0(\Delta) = \frac{A_i}{\Delta} \quad (3.57)$$

where A_i and Δ are the surface area of the inner body and the layer thickness, respectively, and the result corresponding to *infinitely* thick layers

$$S_\infty = C_\infty \sqrt{A_i} \tag{3.58}$$

where C_∞ is a constant that is close to the value $2\sqrt{\pi}$ for many body shapes [15] as shown in the sections on transient one-dimensional conduction in half-spaces and external transient conduction from long cylinders. Hassani and Hollands [33] set $C_\infty = 3.51$ for all bodies and proposed the following equation, which accurately interpolates between the two asymptotic solutions:

$$S^n(\Delta) = [S_0^n + S_\infty^n]^{1/n} \tag{3.59}$$

where n is a constant that is a function of the body shape. By trial and error, Hassani and Hollands found the following empirical formula:

$$n = \left[1.26 - \frac{(2 - \sqrt{A_i/L_s})}{9\sqrt{1.0 - 4.79V_i^{2/3}/A_i}}, 1.0 \right]_{\max} \tag{3.60}$$

where V_i and A_i are the volume and surface area of the inner body, and L_s is the longest straight line passing through the inner body. They gave the following rule: $Y = [x_1, x_2]_{\max}$ means that $Y = x_1$ if $x_1 > x_2$ and $Y = x_2$ if $x_2 > x_1$. The shape parameter n was found to lie in the range $1 \leq n \leq 1.2$ for a very wide range of body shapes. The results obtained through this method show agreement to within about 5 percent with those obtained from numerical or existing analytical techniques.

Shape Factors for Two-Dimensional Systems

The shape factors for two-dimensional systems are available for (1) long cylinders bounded by homologous, regular polygons having N sides (Fig. 3.5), (2) long cylinders bounded internally by circles and bounded externally by regular polygons (Fig. 3.6), and (3) long cylinders bounded internally by regular polygons and bounded externally by circles (Fig. 3.7). In all three cases, as the number of sides N of the regular polygon becomes large ($N > 10$), the shape factor approaches the shape factor for the system bounded by two coaxial circular cylinders.

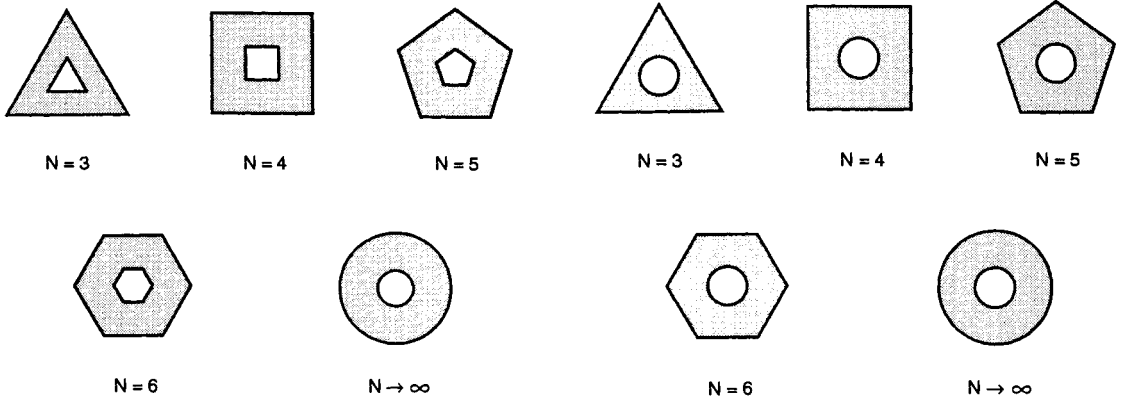

FIGURE 3.5 Regions bounded by regular polygons.

FIGURE 3.6 Regions bounded by inner circles and outer regular polygons.

FIGURE 3.7 Regions bounded by inner regular polygons and outer circles.

Regular Polygon Inside a Regular Polygon. The shape factor of two-dimensional regions bounded internally and externally by isothermal regular polygons of sides $N \geq 3$ (Fig. 3.5) is obtained by means of the general expression

$$\frac{S}{L} = \frac{4\pi}{\ln \left[1 + \frac{(D/d)^2 - 1}{(N/\pi) \tan(\pi/N)} \right]}, \quad N \geq 3 \quad (3.61)$$

where d and D are the diameters of the inscribed circles of the inner and outer polygons, respectively. For the region bounded by two squares ($N = 4$), the general expression reduces to

$$\frac{S}{L} = \frac{4\pi}{\ln [1 + (\pi/4)[(D/d)^2 - 1]]} \quad (3.62)$$

The square/square problem has a complex analytical solution that requires the numerical computation of complete elliptical integrals of the first kind (see Ref. 8). For a large range of the parameter d/D , the analytical solution provides an accurate asymptotic expression:

$$\frac{S}{L} = 4 \frac{[1 + (d/D)]}{[1 - (d/D)]} - \frac{8}{\pi} \ln 2, \quad 0.3 \leq d/D \leq 1 \quad (3.63)$$

Two correlation equations based on electrical measurements were reported by Smith et al. [93]:

$$\frac{S}{L} = \frac{2\pi}{0.93 \ln [0.947(D/d)]}, \quad \frac{D}{d} > 1.4 \quad (3.64)$$

and

$$\frac{S}{L} = \frac{2\pi}{0.785 \ln (D/d)}, \quad \frac{D}{d} < 1.4 \quad (3.65)$$

Circle Inside a Regular Polygon. Several expressions have been developed for this system (Fig. 3.6). Two relationships that give results to within a fraction of 1 percent are given. The first is [52]

$$\frac{S}{L} = \frac{2\pi}{\ln [A, \beta]} \quad (3.66)$$

where $\beta = b/a > 1$ is the ratio of the radius of the inner circle to the radius of the inscribed circle. The parameter A_s is obtained by means of a numerical integration of the integral

$$A_s = \left[\int_0^1 (1 + u^N)^{-2/N} du \right]^{-1}, \quad N \geq 3 \tag{3.67}$$

Laura and Susemihl [52] gave several values of the parameter A_s for several values of N . The alternate relationship [91] is

$$\frac{S}{L} = \frac{4N}{A\sqrt{A^2 + 1}} \tan^{-1} \left[\frac{\sqrt{A^2 + 1}}{A} \tan \frac{\pi}{N} \right], \quad N \geq 3 \tag{3.68}$$

where the parameter $A = \sqrt{2 \ln \beta}$. The second relationship does not require a numerical integration.

Regular Polygon Inside a Circle. Numerous analytical, numerical, and experimental studies have produced results for shape factors and resistances for regions bounded internally by isothermal regular polygons of N sides where $N \geq 3$ and externally by an isothermal circle (Fig. 3.7). Lewis [55] gave the following general analytical result

$$\frac{S}{L} = \frac{2\pi}{\ln [A_N(D/d)]} \tag{3.69}$$

where the coefficients are given by

$$A_N = [(\sqrt{N} - \sqrt{N - 2})]^{2/N} (N - 2)^{1/N}, \quad N \geq 3 \tag{3.70}$$

The above relationship is limited to the range $0 < d/D < \cos \pi/N$, where d and D are the diameters of the inscribed circle and the outer circle, respectively. The relationship gives accurate values of S for small values of d/D and for all values of N . The accuracy decreases for values of $d/D \rightarrow \cos \pi/N$ for small values of N . Ramachandra Murthy and Ramachandran [82] obtained two empirical correlation equations for regions bounded by squares and hexagons. Their correlation equations were developed from electrical measurements and have been shown to be in good agreement with the above relationship for a limited range of values of d/D .

Polygons With Layers. Hassani et al. [34] presented a procedure for obtaining a close upper bound for shape factors for a uniform thickness two-dimensional layer on cylinders having cross sections of the following forms: an equilateral triangle, a square, a rhombus, and a rectangle (Fig. 3.8). The shape factor per unit length of the inner cylinder is obtained from

$$\frac{S}{L} = \frac{2\pi}{\ln [1 + (2\pi B/P_i)]} \tag{3.71}$$

FIGURE 3.8 Polygons with uniform thickness layers.

where B is the layer thickness and P_i is the perimeter of the inner boundary. The accuracy of the above relationship was verified by comparison of the predicted values against numerical values for the layer thickness-to-side dimension range $0.10 \leq B/L \leq 3.00$. The proposed relationship overpredicts the shape factor by approximately 1–3 percent.

TRANSIENT CONDUCTION

Introduction

Transient conduction internal and external to various bodies subjected to the boundary conditions of the (1) first kind (Dirichlet), (2) second kind (Neumann), and (3) third kind (Robin) are presented in this section. Analytical solutions are presented in the form of series or integrals. Since these analytical solutions can be computed quickly and accurately using computer algebra systems, the solutions are not presented in graphic form.

Internal Transient Conduction

Internal one-dimensional transient conduction within infinite plates, infinite circular cylinders, and spheres is the subject of this section. The dimensionless temperature $\phi = \theta/\theta_i$ is a function of three dimensionless parameters: (1) dimensionless position $\zeta = x/L$, (2) dimensionless time $Fo = \alpha t/L^2$, and (3) the Biot number $Bi = hL/k$, which depends on the convective boundary condition. The characteristic length L is the half-thickness L of the plate and the radius a of the cylinder or the sphere. The thermophysical properties k , α , the thermal conductivity and the thermal diffusivity, are constant.

The basic solutions for the plate and the cylinder can be used to obtain solutions within rectangular plates, cuboids, and finite circular cylinders. The equations and the initial and boundary conditions are well known [4, 11, 23, 28, 29, 38, 49, 56, 80, 87]. The solutions presented below follow the recent review of Yovanovich [151]. The Heisler [36] cooling charts for dimensionless temperature are obtained from the series solution:

$$\phi = \sum_{n=1}^{\infty} A_n \exp(-\delta_n^2 Fo) S_n(\delta_n \zeta) \quad (3.72)$$

with the temperature Fourier coefficients A_n for the plate, cylinder, and sphere, respectively, given in Table 3.5. The spatial functions for the three basic geometries are given in Table 3.6. The eigenvalues δ_n are the positive roots of the characteristic equations found in Table 3.6 where Bi , the physical parameter, ranges between 0 and ∞ .

TABLE 3.5 Fourier Coefficients for Temperature and Heat Loss

Geometry	A_n	B_n
Plate	$\frac{2 \sin \delta_n}{\delta_n + \sin \delta_n \cos \delta_n}$	$\frac{2Bi^2}{\delta_n^2(Bi^2 + Bi + \delta_n^2)}$
Cylinder	$\frac{2J_1(\delta_n)}{\delta_n[J_0(\delta_n) + J_2(\delta_n)]}$	$\frac{4Bi^2}{\delta_n^2(\delta_n^2 + Bi^2)}$
Sphere	$(-1)^{n+1} \frac{2Bi [\delta_n^2 + (Bi - 1)^2]^{1/2}}{(\delta_n^2 + Bi^2 - Bi)}$	$\frac{6Bi^2}{\delta_n^2(\delta_n^2 + Bi^2 - Bi)}$

TABLE 3.6 Space Functions and Characteristic Equations

Geometry	S_n	Characteristic equation
Plate	$\cos(\delta_n \zeta)$	$x \sin x = \text{Bi} \cos x$
Cylinder	$J_0(\delta_n \zeta)$	$x J_1(x) = \text{Bi} J_0(x)$
Sphere	$\frac{\sin(\delta_n \zeta)}{(\delta_n \zeta)}$	$(1 - \text{Bi}) \sin x = x \cos x$

The Grober charts [29] for the heat loss fraction Q/Q_i , where $Q_i = \rho c_p V \theta_i$ is the initial total internal energy, are obtained from the series solution:

$$\frac{Q}{Q_i} = 1 - \sum_{n=1}^{\infty} B_n \exp(-\delta_n^2 \text{Fo}) \tag{3.73}$$

The Fourier coefficients B_n are given in Table 3.5 for the three geometries. These coefficients depend on the Biot number.

Lumped Capacitance Model

When the Biot number is sufficiently small ($\text{Bi} < 0.2$), the series solutions converge to the first term for all values of $\text{Fo} > 0$. The values of the Fourier coefficients A_1 and B_1 approach 1, and the dimensionless temperature and the heat loss fraction approach the general lumped capacitance solutions

$$\phi = e^{-(hS/\rho c_p V)t}$$

and

$$\frac{Q}{Q_i} = 1 - e^{-(hS/\rho c_p V)t}$$

where S and V are the total active surface area and the volume. The lumped capacitance solutions for the three geometries are given in Table 3.7.

TABLE 3.7 Lumped Capacitance Solutions $\text{Bi} < 0.2$

Geometry	ϕ	Q/Q_i
Plate	$e^{-\text{Bi} \text{Fo}}$	$1 - e^{-\text{Bi} \text{Fo}}$
Cylinder	$e^{-2\text{Bi} \text{Fo}}$	$1 - e^{-2\text{Bi} \text{Fo}}$
Sphere	$e^{-3\text{Bi} \text{Fo}}$	$1 - e^{-3\text{Bi} \text{Fo}}$

Heisler and Grober Charts—Single-Term Approximations

The Heisler [36] cooling charts and the Grober [29] heat loss fraction charts for the three geometries can be calculated accurately by the single-term approximations [28, 56]

$$\frac{\theta}{\theta_i} = A_1 \exp(-\delta_1^2 \text{Fo}) S_1(\delta_1 \zeta)$$

and

$$\frac{Q}{Q_i} = 1 - B_1 \exp(-\delta_1^2 \text{Fo})$$

TABLE 3.8 Asymptotic Values of First Eigenvalues, Correlation Parameter n , and Critical Fourier Number

Geometry	$Bi \rightarrow 0$	$Bi \rightarrow \infty$	n	Fo_c
Plate	$\delta_1 \rightarrow \sqrt{Bi}$	$\delta_1 \rightarrow \pi/2$	2.139	0.24
Cylinder	$\delta_1 \rightarrow \sqrt{2Bi}$	$\delta_1 \rightarrow 2.4048255$	2.238	0.21
Sphere	$\delta_1 \rightarrow \sqrt{3Bi}$	$\delta_1 \rightarrow \pi$	2.314	0.18

for all values of the Biot number, provided $Fo \geq Fo_c$. The critical values of the Fourier number for the three geometries are given in Table 3.8. The first eigenvalue can be computed accurately by means of the correlation [151]

$$\delta_1 = \frac{\delta_{1,\infty}}{[1 + (\delta_{1,\infty}/\delta_{1,0})^n]^{1/n}}$$

which is valid for all values of Bi . The asymptotic values of the first eigenvalues corresponding to very small and very large values of Bi are given in Table 3.8. The correlation parameter n is also given in Table 3.8. The correlation equation predicts values of δ_1 that differ from the exact values by less than 0.4 percent.

For $Fo < Fo_c$, additional terms in the series solutions must be included. It is therefore necessary to use numerical methods to compute the higher-order eigenvalues δ_n that lie in the intervals $n\pi < \delta_n < (n + 1/2)\pi$ for the plate and $(n - 1)\pi < \delta_n < n\pi$ for the cylinder and the sphere. Computer algebra systems are very effective in computing the eigenvalues.

Chen and Kuo [12] have presented approximate solutions of θ/θ_i and Q/Q_i for the plates and long cylinders. The accuracy of these solutions is acceptable for engineering calculations.

Multidimensional Systems

The basic solutions for the infinite plates and infinitely long cylinders can be used to obtain solutions for multidimensional systems such as long rectangular plates, cuboids, and finite circular cylinders with end cooling. The texts on conduction heat transfer [4, 11, 23, 29, 38, 49, 56, 87] should be consulted for the proofs of the method and other examples.

Langston [51] showed how to obtain the heat loss from multidimensional systems using the one-dimensional solutions given above. Two-dimensional systems such as long rectangular plates and finite circular cylinders are characterized by two Biot numbers, two Fourier numbers, and two dimensionless position parameters. Three-dimensional systems such as cuboids are characterized by three sets of values of Bi , Fo , and ζ corresponding to the three cartesian coordinates. When the two or three sets of Fourier numbers are greater than the critical values given in Table 3.8, then the first-term approximate solutions discussed above can be used to develop composite solutions. Yovanovich [151] has discussed the application of the basic solutions to long rectangular plates, cuboids, and finite-length circular cylinders.

FIGURE 3.9 Circular cylinder of finite length.

When the two or three sets of Fourier numbers are greater than the critical values given in Table 3.8, then the first-term approximate solutions discussed above can be used to develop composite solutions. Yovanovich [151] has discussed the application of the basic solutions to long rectangular plates, cuboids, and finite-length circular cylinders.

Dimensionless Temperature and Heat Loss Fraction for Finite-Length Cylinders. The finite-length circular cylinder of radius R and length $2X$, shown in Fig. 3.9, has constant properties and is cooled through the sides and the two ends by uniform film coefficients h_r and h_x , respectively. The sys-

tem is characterized by four physical parameters: $Bi_x = h_x X/k$, $Bi_c = h_r R/k$, $Fo_x = \alpha t/X^2$, and $Fo_r = \alpha t/R^2$. The dimensionless temperature within the cylinder is obtained from the product solution:

$$\phi_{xr} = \phi_x \phi_r$$

where ϕ_x and ϕ_r are the solutions corresponding to the x and r coordinates, respectively. According to Langston [51], the heat loss fraction can be obtained from

$$\left(\frac{Q}{Q_i}\right)_{xr} = \left(\frac{Q}{Q_i}\right)_x + \left(\frac{Q}{Q_i}\right)_r - \left(\frac{Q}{Q_i}\right)_x \cdot \left(\frac{Q}{Q_i}\right)_r$$

where $Q_i = \rho c_p 2\pi X R^2 \theta_i$. The subscripts x and r denote solutions corresponding to the x and r coordinates, respectively.

Transient One-Dimensional Conduction in Half-Spaces

The analytical solutions for transient one-dimensional conduction in half-spaces $x \geq 0$ are well known and appear in most heat transfer texts. The solutions are given here for completeness and to review important characteristics of the solutions.

Equation and Initial and Boundary Conditions. The diffusion equation and the initial and boundary conditions are presented first, followed by the solutions with some important relationships.

$$\frac{\partial^2 \theta}{\partial x^2} = \frac{1}{\alpha} \frac{\partial \theta}{\partial t}, \quad t > 0, \quad x > 0 \quad (3.74)$$

where $\theta = T(x, t) - T_i$ is the instantaneous temperature rise within the half-space. The initial condition is

$$\theta = 0, \quad t = 0, \quad x > 0 \quad (3.75)$$

and the boundary condition at remote points in the half-space is

$$\theta \rightarrow 0, \quad t > 0, \quad x \rightarrow \infty \quad (3.76)$$

There are three options for the boundary condition at $x = 0$.

Dirichlet Condition

$$\theta = T_0 - T_i, \quad t > 0 \quad (3.77)$$

where T_0 is the fixed temperature on the surface.

Neumann Condition

$$\frac{\partial \theta}{\partial x} = -\frac{q_0}{k}, \quad t > 0 \quad (3.78)$$

where q_0 is the constant heat flux imposed on the surface.

Robin Condition

$$\frac{\partial \theta}{\partial x} = -\frac{h}{k} (\theta_f - \theta), \quad t > 0 \quad (3.79)$$

where h is the constant film or contact conductance that connects the surface to the heat source and $\theta_f = T_f - T_i$ is the constant temperature difference between the heat source temperature and the initial temperature. The solutions have been obtained by several analytical methods. Introducing the dimensionless parameters $\phi = (T(x, t) - T_i)/(T_0 - T_i)$, $\eta = x/(2\sqrt{\alpha t})$, and $\text{Bi} = (h/k)\sqrt{\alpha t}$, the three solutions are given below.

Dirichlet Solution

$$\phi = \text{erfc}(\eta), \quad \eta > 0 \quad (3.80)$$

which gives the instantaneous and time-average surface fluxes

$$q_0(t) = \frac{1}{\sqrt{\pi}} \frac{k(T_0 - T_i)}{\sqrt{\alpha t}} \quad (3.81)$$

and

$$\bar{q}_0(t) = \frac{2}{\sqrt{\pi}} \frac{k(T_0 - T_i)}{\sqrt{\alpha t}} \quad (3.82)$$

The time average value of any function $f(t)$ is defined as $\bar{f}(t) = (1/t) \int_0^t f(t) dt$.

Neumann Solution

$$\frac{k[T(x, t) - T_i]}{2q_0\sqrt{\alpha t}} = \frac{1}{\sqrt{\pi}} \exp(-\eta^2) - \eta \text{erfc}(\eta) \quad (3.83)$$

which gives the following relationships for the instantaneous and time-average surface temperatures

$$\frac{k[T(0, t) - T_i]}{2q_0\sqrt{\alpha t}} = \frac{1}{\sqrt{\pi}} \quad (3.84)$$

and

$$\frac{k[\bar{T}(0) - T_i]}{2q_0\sqrt{\alpha t}} = \frac{2}{3\sqrt{\pi}} \quad (3.85)$$

Robin Solution

$$\frac{T(x, t) - T_i}{T_f - T_i} = \text{erfc}(\eta) - \exp(2\eta \text{Bi} + \text{Bi}^2) \text{erfc}(\eta + \text{Bi}) \quad (3.86)$$

which yields the following two relationships for the instantaneous surface temperature and the surface heat flux:

$$\frac{T(0, t) - T_i}{T_f - T_i} = 1 - \exp(\text{Bi}^2) \text{erfc}(\text{Bi}) \quad (3.87)$$

and

$$\frac{q_0(t)\sqrt{\alpha t}}{k(T_f - T_i)} = \text{Bi} \exp(\text{Bi}^2) \text{erfc}(\text{Bi}) \quad (3.88)$$

For large values of the parameter $\text{Bi} \geq 100$, the Robin solution approaches the Dirichlet solution.

The three one-dimensional solutions presented above give important *short-time* results that appear in other solutions such as the external transient three-dimensional conduction from isothermal bodies of arbitrary shape into large regions. These solutions are presented in the next section.

External Transient Conduction From Long Cylinders

Introduction. Transient one-dimensional conduction external to long circular cylinders is considered in this section. The conduction equation, the boundary and initial conditions, and the solutions for the Dirichlet and Neumann conditions are presented. The conduction equation for the instantaneous temperature rise $\theta(r, t) - T_i$ in the region external to a long circular cylinder of radius a is

$$\frac{\partial^2 \theta}{\partial r^2} + \frac{1}{r} \frac{\partial \theta}{\partial r} = \frac{1}{\alpha} \frac{\partial \theta}{\partial t}, \quad t > 0, \quad r > a \quad (3.89)$$

The initial condition is

$$\theta = 0, \quad t = 0$$

and the boundary condition at remote points in the full space is

$$\theta \rightarrow 0, \quad r \rightarrow \infty$$

Two types of boundary conditions at the cylinder boundary $r = a$ will be considered: (1) Dirichlet and (2) Neumann.

Dirichlet Condition

$$\theta = T_0 - T_i, \quad t > 0$$

where T_0 is the fixed surface temperature.

Neumann Condition

$$\frac{\partial \theta}{\partial r} = -\frac{q_0}{k}, \quad t > 0$$

where q_0 is the constant heat flux on the cylinder surface.

The solutions for the two boundary conditions are reported in Carslaw and Jaeger [11]. The solutions were obtained by means of the Laplace transform method. The solutions are given as infinite integrals and the integrand consists of Bessel functions of the first and second kinds of order zero.

Dirichlet Solution

$$\frac{\theta}{\theta_i} = 1 + \frac{2}{\pi} \int_0^\infty e^{-Fo \beta^2} \frac{J_0(\beta r/a) Y_0(\beta) - Y_0(\beta r/a) J_0(\beta)}{J_0^2(\beta) + Y_0^2(\beta)} \frac{d\beta}{\beta} \quad (3.90)$$

with $Fo \equiv \alpha t/a^2 > 0$. The integral can be evaluated accurately and easily for all dimensionless times using computer algebra systems.

Instantaneous Surface Heat Flux. The instantaneous surface flux, defined as $q(t) = -k\partial\theta/\partial r$ at $r = a$, is given by the integral

$$\frac{aq(t)}{k\theta_i} = \frac{4}{\pi^2} \int_0^\infty e^{-Fo \beta^2} \frac{d\beta}{[J_0^2(\beta) + Y_0^2(\beta)]\beta} \quad (3.91)$$

Carslaw and Jaeger [11] presented short-time expressions for the instantaneous temperature rise and the surface heat flux.

Short-Time Temperature Rise

$$\frac{\theta}{\theta_i} = \frac{1}{\sqrt{\rho}} \operatorname{erfc} \left[\frac{\rho - 1}{2\sqrt{Fo}} \right] + \frac{(\rho - 1)\sqrt{Fo}}{4\rho^{3/2}} \operatorname{ierfc} \left[\frac{\rho - 1}{2\sqrt{Fo}} \right] + \frac{(9 - 2\rho - 7\rho^2)}{32\rho^{5/2}} i^2 \operatorname{erfc} \left[\frac{\rho - 1}{2\sqrt{Fo}} \right]$$

with $\rho \equiv r/a \geq 1$. The special functions $\text{ierfc}(x)$ and $\text{i}^2\text{erfc}(x)$ are integrals of the complementary error function and are defined in Carslaw and Jaeger [11].

Short-Time Surface Heat Flux. The instantaneous surface heat flux is given by

$$\frac{aq(t)}{k\theta_i} = \frac{1}{\sqrt{\pi}\sqrt{\text{Fo}}} + \frac{1}{2} - \frac{1}{4} \left(\frac{\text{Fo}}{\pi} \right)^{1/2} + \frac{1}{8} \text{Fo}$$

The first term corresponds to the half-space solution when the dimensionless time is very small, i.e., $\text{Fo} < 10^{-3}$.

Neumann Solution. The instantaneous temperature rise for arbitrary dimensionless time $\text{Fo} > 0$ at arbitrary radius $r/a \geq 1$ is given by the integral solution:

$$\frac{k\theta}{q_0} = -\frac{2}{\pi} \int_0^{\infty} (1 - e^{-\text{Fo}\beta^2}) \frac{J_0(\beta r/a)Y_1(\beta) - Y_0(\beta r/a)J_1(\beta)}{J_1^2(\beta) + Y_1^2(\beta)} \frac{d\beta}{\beta^2}$$

Carslaw and Jaeger [11] presented an approximate short-time solution for arbitrary radius:

$$\frac{k\theta}{q_0} = \frac{2}{\sqrt{\rho}} \sqrt{\text{Fo}} \left\{ \text{ierfc} \left[\frac{\rho - 1}{2\sqrt{\text{Fo}}} \right] - \frac{(3\rho + 1)}{4\rho} \text{i}^2\text{erfc} \left[\frac{\rho - 1}{2\sqrt{\text{Fo}}} \right] \right\}$$

with $\rho = r/a \geq 1$ and $\text{Fo} = \alpha t/a^2$. The instantaneous surface temperature rise θ_0 for short times is given by

$$\frac{k\theta_0}{q_0} = \frac{2}{\sqrt{\pi}} \sqrt{\text{Fo}} - \frac{1}{2}$$

Transient External Conduction From Spheres

Introduction. Solutions of transient conduction from a sphere of radius a into an isotropic space whose properties are constant and whose initial temperature T_i is constant are considered here. The dimensionless equation is

$$\frac{\partial^2 \phi}{\partial \rho^2} + \frac{2}{\rho} \frac{\partial \phi}{\partial \rho} = \frac{\partial \phi}{\partial \text{Fo}}, \quad \text{Fo} > 0, \quad \rho > 1 \quad (3.92)$$

where ϕ is the dimensionless temperature, $\rho = r/a$, and $\text{Fo} = \alpha t/a^2$ is the dimensionless time defined with respect to the sphere radius. Solutions are available in Carslaw and Jaeger [11] for three boundary conditions: (1) the Dirichlet condition where $T(a, t) = T_0$, (2) the Neumann condition where $\partial T(a, t)/\partial r = -q_0/k$, and (3) the Robin condition where $\partial T(a, t)/\partial r = -(h/k)[T_i - T(a, t)]$. The thermophysical parameters T_0 , T_i , q_0 , and h are constants. These boundary conditions in dimensionless form are $\phi = 1$, $\partial\phi/\partial\rho = -1$, and $\partial\phi/\partial\rho = -\text{Bi}(1 - \phi)$ with $\text{Bi} = h/k$ for the three boundary conditions, respectively. The three definitions of dimensionless temperature are presented below.

The three dimensionless solutions [11] are:

Dirichlet Solution

$$\phi = \frac{1}{\rho} \text{erfc} \left(\frac{\rho - 1}{2\sqrt{\text{Fo}}} \right) \quad (3.93)$$

where $\phi = (T(r, t) - T_i)/(T_0 - T_i)$.

Neumann Solution

$$\phi = \frac{1}{\rho} \operatorname{erfc} \left(\frac{\rho - 1}{2\sqrt{Fo}} \right) - \frac{1}{\rho} \exp(\rho - 1 + Fo) \operatorname{erfc} \left(\frac{\rho - 1}{2\sqrt{Fo}} + \sqrt{Fo} \right) \quad (3.94)$$

where $\phi = k(T(r, t) - T_i)/(aq_0)$.

Robin Solution

$$\begin{aligned} \phi = & \frac{Bi}{Bi + 1} \frac{1}{\rho} \operatorname{erfc} \left(\frac{\rho - 1}{2\sqrt{Fo}} \right) \\ & - \frac{Bi}{Bi + 1} \frac{1}{\rho} \exp[(Bi + 1)(\rho - 1) + (Bi + 1)^2 Fo] \operatorname{erfc} \left[\frac{\rho - 1}{2\sqrt{Fo}} + (Bi + 1)\sqrt{Fo} \right] \end{aligned} \quad (3.95)$$

where $\phi = (T(r, t) - T_i)/(T_f - T_i)$.

Instantaneous Surface Temperature and Heat Flux. The previous solutions give the following important results for the instantaneous surface temperature and surface heat flux.

Dirichlet Condition. The instantaneous surface heat flux is given by

$$\frac{aq(a, t)}{k(T_0 - T_i)} = 1 + \frac{1}{\sqrt{\pi}\sqrt{Fo}} \quad (3.96)$$

Neumann Condition. The instantaneous surface temperature is given by

$$\frac{k(T(a, t) - T_i)}{aq_0} = 1 - e^{Fo} \operatorname{erfc}(\sqrt{Fo}) \quad (3.97)$$

Robin Condition. The Robin solution given above yields expressions for the instantaneous surface temperature and the instantaneous surface heat flux. They are as follows:

$$\frac{(T(a, t) - T_i)}{(T_f - T_i)} = \frac{Bi}{Bi + 1} \{1 - e^{(Bi + 1)^2 Fo} \operatorname{erfc}[(Bi + 1)\sqrt{Fo}]\} \quad (3.98)$$

and

$$\frac{aq(a, t)}{k(T_f - T_i)} = \frac{Bi}{Bi + 1} \{1 + e^{(Bi + 1)^2 Fo} \operatorname{erfc}[(Bi + 1)\sqrt{Fo}]\} \quad (3.99)$$

Instantaneous Thermal Resistance

Resistance Definition. The instantaneous thermal resistance for the three boundary conditions is defined as $R = (T(a, t) - T_i)/Q$ where $Q = q(a, t)4\pi a^2$. The results given above yield the following expressions.

Dirichlet Condition Resistance

$$4\pi kaR_D = \frac{1}{[1 + (1/\sqrt{\pi}\sqrt{Fo})]} \quad (3.100)$$

Neumann Condition Resistance

$$4\pi kaR_N = 1 - e^{Fo} \operatorname{erfc}(\sqrt{Fo}) \quad (3.101)$$

Robin Condition Resistance

$$4\pi kaR_R = \frac{1 - e^{z^2} \operatorname{erfc}(z)}{1 + e^{z^2} \operatorname{erfc}(z)} \quad (3.102)$$

where $z = (\text{Bi} + 1)\sqrt{\text{Fo}}$.

The three previous expressions approach the steady-state result $4\pi kaR = 1$ for large dimensionless time.

The previous expression for the Robin condition can be calculated by the following rational approximation with a maximum error of less than 1.2 percent:

$$4\pi kaR_R = \frac{1 - a_1s - a_2s^2 - a_3s^3}{1 + a_1s + a_2s^2 + a_3s^3} \quad (3.103)$$

where $s = 1/(1 + pz)$ and the coefficients are $a_1 = 0.3480242$, $a_2 = -0.0958798$, $a_3 = 0.7478556$, $p = 0.47047$.

The three solutions corresponding to the three boundary conditions can be used to obtain approximate solutions for other convex bodies, such as a cube, for which there are no analytical solutions available. The dimensionless parameters Bi and Fo are defined with respect to the equivalent sphere radius, which is obtained by setting the surface area of the sphere equal to the surface area of the given body, i.e., $a = \sqrt{A/(4\pi)}$. This will be considered in the following section, which covers transient external conduction from isothermal convex bodies.

Transient External Conduction From Isothermal Convex Bodies

External transient conduction from an isothermal convex body into a surrounding space has been solved numerically (Yovanovich et al. [149]) for several axisymmetric bodies: circular disks, oblate and prolate spheroids, and cuboids such as square disks, cubes, and tall square cuboids (Fig. 3.10). The sphere has a complete analytical solution [11] that is applicable for all dimensionless times $\text{Fo}_{\sqrt{A}} = \alpha t/A$. The dimensionless instantaneous heat transfer rate is $Q_{\sqrt{A}}^* = Q\sqrt{A}/(kA\theta_0)$, where k is the thermal conductivity of the surrounding space, A is the total area of the convex body, and $\theta_0 = T_0 - T_i$ is the temperature excess of the body relative to the initial temperature of the surrounding space. The analytical solution for the sphere is given by

$$Q_{\sqrt{A}}^* = 2\sqrt{\pi} + \frac{1}{\sqrt{\pi} \sqrt{\text{Fo}_{\sqrt{A}}}} \quad (3.104)$$

which consists of the linear superposition of the steady-state solution (dimensionless shape factor) and the small-time solution (half-space solution). This observation was used to propose a simple approximate solution for all body shapes of the form

$$Q_{\sqrt{A}}^* = S_{\sqrt{A}}^* + \frac{1}{\sqrt{\pi} \sqrt{\text{Fo}_{\sqrt{A}}}} \quad (3.105)$$

where $S_{\sqrt{A}}^*$ is the dimensionless shape factor for isothermal convex bodies in full space. This parameter is a relatively weak function of shape and aspect ratio; its values lie in the range $3.192 \leq S_{\sqrt{A}}^* \leq 4.195$ for the wide range of bodies examined (Fig. 3.10). The simple model predicts values with RMS and maximum differences between the predicted and numerical values in the ranges 0.40–6.31 percent and 0.98–11.52 percent, respectively, as shown in Table 3.9. The maximum differences lie in the intermediate range of dimensionless time: $10^{-3} < \text{Fo}_{\sqrt{A}} < 10^{-1}$.

A more accurate model based on the method of Churchill and Usagi [13] was proposed for all bodies:

$$Q_{\sqrt{A}}^* = \left[(S_{\sqrt{A}}^*)^n + \left(\frac{1}{\sqrt{\pi} \sqrt{\text{Fo}_{\sqrt{A}}}} \right)^n \right]^{1/n} \quad (3.106)$$

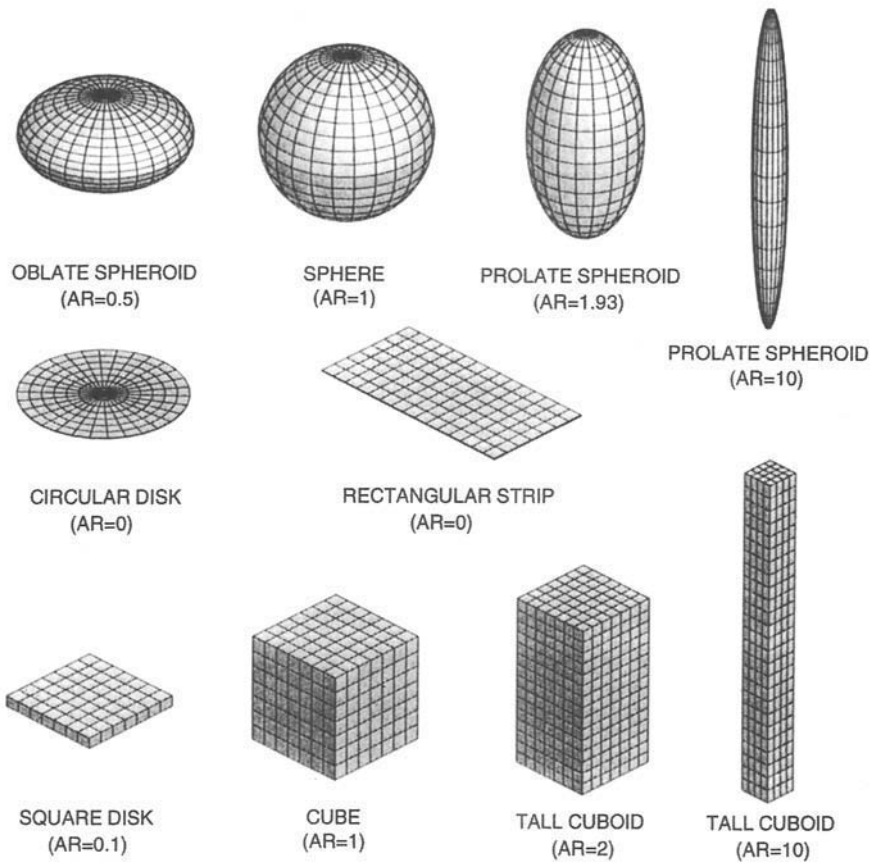

FIGURE 3.10 Various convex bodies.

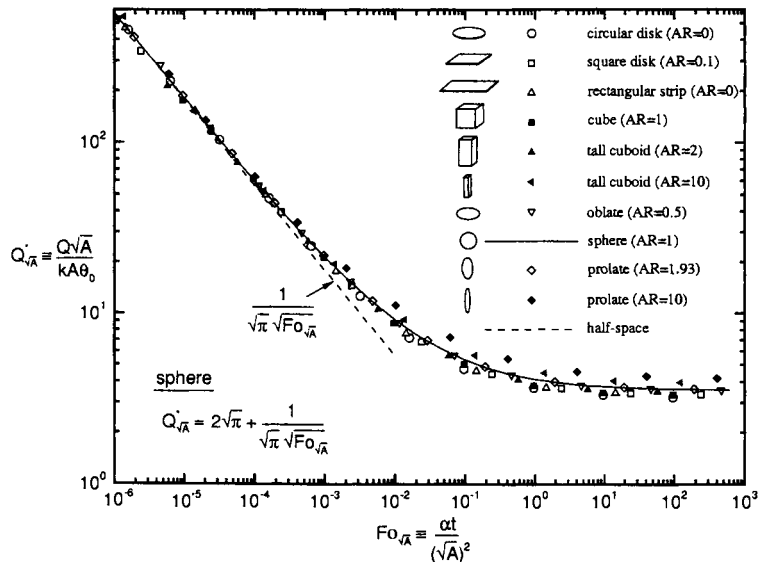

FIGURE 3.11 Comparison of numerical results and proposed model.

TABLE 3.9 Comparison of Superposition Model and Numerical Results

Body	$S^*_{\sqrt{A}}$	Max. % diff.	RMS % diff.
Circular disk ($AR = 0$)	3.192	7.05	3.36
Rectangular strip ($AR = 0$)	3.303	4.99	2.94
Square disk ($AR = 0.1$)	3.343	2.60	1.91
Cube ($AR = 1$)	3.388	3.78	2.52
Tall cuboid ($AR = 2$)	3.406	2.77	1.87
Oblate spheroid ($AR = 0.5$)	3.529	0.98	0.40
Prolate spheroid ($AR = 1.93$)	3.564	1.65	0.73
Tall cuboid ($AR = 10$)	3.945	3.15	1.63
Prolate spheroid ($AR = 10$)	4.195	11.52	6.31

The values of the parameter n that reduce the RMS and maximum differences between the model and the numerical data were found by trial and error to lie in the range $0.87 \leq n \leq 1.10$ for RMS and maximum differences less than 1.34 percent and 2.06 percent, respectively. The largest values of n were required for the thin bodies and the smallest values were required for the tallest bodies. For bodies having aspect ratios close to unity, the values of n were found to lie close to unity like the sphere. The values of n , and the corresponding values of the maximum and RMS percent differences for the various bodies are given in Table 3.10. The numerical data and the model predictions are shown in Fig. 3.11.

Table 3.11 gives recommended values of n for axisymmetric bodies (spheroids) and cuboids for various aspect ratios.

TABLE 3.10 Comparison of Blended Model and Numerical Results

Body	n	Max. % diff.	RMS % diff.

SPREADING (CONSTRICTION) RESISTANCE

Introduction

Spreading (constriction) resistance is an important thermal parameter that depends on several factors such as (1) geometry (singly or doubly connected areas, shape, aspect ratio), (2) domain (half-space, flux tube), (3) boundary condition (Dirichlet, Neumann, Robin), and (4) time (steady-state, transient). The results are presented in the form of infinite series and integrals that can be computed quickly and accurately by means of computer algebra systems. Accurate correlation equations are also provided.

Definitions of Spreading Resistance

Half-Space Spreading Resistance. When conduction occurs in a region whose dimensions are two or more orders of magnitude larger than the largest dimension of the source area (Fig. 3.12), the spreading resistance is defined as the difference between the heat source temperature and the heat sink temperature divided by the total heat transfer rate from the heat source. If the flux over the heat source area is uniform, the source temperature may be based on the area-average source temperature or the centroid temperature, which is the maximum temperature or close to it. If the heat sink temperature is spatially variable, then the area-average temperature is used in the definition. Thus

$$R_s = \frac{\bar{T}_{\text{source}} - \bar{T}_{\text{sink}}}{Q} \quad (3.107)$$

Flux Tube or Channel Spreading Resistance. When conduction occurs in a confined region such as a finite or an infinitely long flux tube or flux channel (Fig. 3.13), then the one-dimensional conduction resistance and other resistances must be accounted for. The definition proposed by Mikic and Rohsenow [65] can be used to define the spreading resistance. It is as follows:

$$R_s = \frac{\bar{T}_{\text{source}} - \bar{T}_{\text{contact plane}}}{Q} \quad (3.108)$$

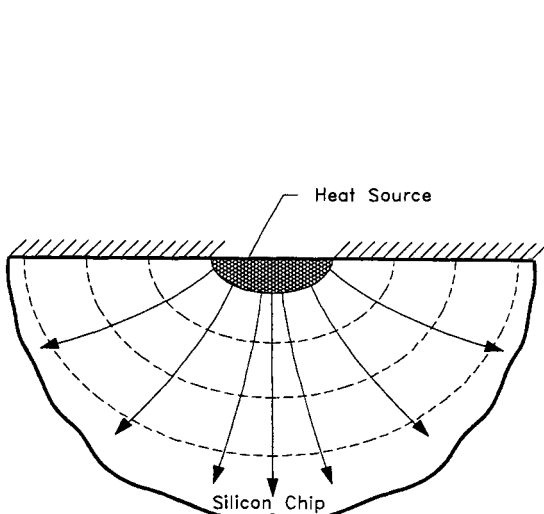

FIGURE 3.12 Spreading in a half-space.

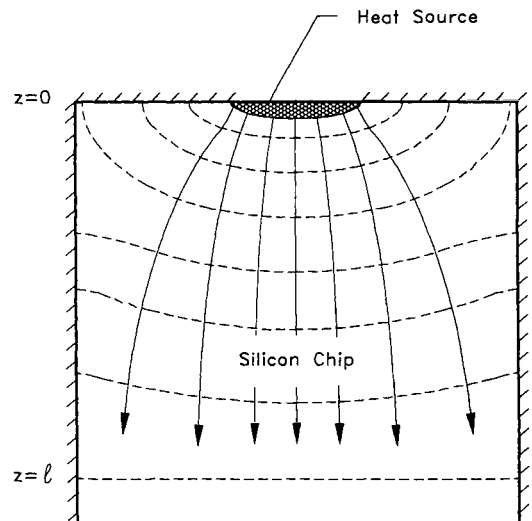

FIGURE 3.13 Spreading in a flux tube or channel.

Dimensionless Spreading Resistance. Whichever definition is used, the dimensionless spreading resistance is generally defined as $R_s^* = k\mathcal{L}R_s$, where k is the thermal conductivity of the region and \mathcal{L} is some length scale related to the contact area. It will be shown for arbitrary, singly connected contact areas that $\mathcal{L} = \sqrt{A}$, where A is the active area of the heat source and \mathcal{L} is the appropriate length scale.

Spreading Resistance of Isoflux Arbitrary Areas on Half-Space

Circular, Rectangular, and Square Areas. The discussion of spreading resistance in isotropic half-spaces begins with the circular area, which has analytical solutions for the isothermal and isoflux boundary conditions, and the rectangular contact, which has an isoflux solution. The solutions are reported in Carslaw and Jaeger [11]. From the circular contact solutions, one finds that the spreading resistance (1) for the isothermal condition is $R_s = 1/(4ka)$, where a is the contact radius, (2) for the isoflux condition is $R_s = 8/(3\pi^2ka)$ based on the area-average temperature, and (3) for the isoflux condition is $R_s = 1/(\pi ka)$ based on the centroid temperature.

This geometry establishes the effect of boundary condition and the choice of source temperature used in the definition of the spreading resistance. The spreading resistances are related as follows:

$$kaR_s(\text{centroid}) > kaR_s(\text{area average}) > kaR_s(\text{isothermal}) \quad (3.109)$$

The temperature ratios are $T_0/\bar{T} = 1.1781$ and $\bar{T}/T(\text{isothermal}) = 1.0807$. These relationships are approximately valid for other geometries.

The centroid and area-average temperatures of the rectangular contact area of length $2a$ and width $2b$ with $a \geq b$ are given in Carslaw and Jaeger [11]. The centroid temperature is

$$T_0 = \frac{2}{\pi} \frac{qa}{k} \left[\sinh^{-1} \frac{1}{\epsilon} + \epsilon \sinh^{-1} \epsilon \right] \quad (3.110)$$

where the aspect ratio parameter is $\epsilon = a/b \geq 1$. The area-average temperature is

$$\bar{T} = \frac{2}{\pi} \frac{qa}{k} \left\{ \sinh^{-1} \frac{1}{\epsilon} + \frac{1}{\epsilon} \sinh^{-1} \epsilon + \frac{\epsilon}{3} \left[1 + \frac{1}{\epsilon^3} - \left(1 + \frac{1}{\epsilon^2} \right)^{3/2} \right] \right\} \quad (3.111)$$

The two expressions for the rectangular area give the results $kaR_s = 0.2806$ and $kaR_s = 0.2366$ for the spreading resistance of a square contact area based on the centroid and area-average temperatures, respectively. The ratio of centroid temperature to area-average temperature is $T_0/\bar{T} = 1.1857$. The differences between the results for the circle and those for the square are very small when the spreading resistances are based on $\mathcal{L} = \sqrt{A}$. The dimensionless spreading resistances become $k\sqrt{A}R_0 = 0.5611$ and $k\sqrt{A}R_0 = 0.5642$ for the square and circle, respectively, and $k\sqrt{A}\bar{R} = 0.4728$ and $k\sqrt{A}\bar{R} = 0.4787$ for the square and circle, respectively, where \bar{R} is based on the area average temperature.

Regular Polygonal Areas. The equilateral triangle, square, pentagon, and hexagon and the circle are members of the regular polygonal contact family as shown in Fig. 3.14. The dimensionless spreading resistance based on the centroid temperature is obtained from the integral [132].

$$k\sqrt{A}R_0 = \frac{1}{\pi} \sqrt{\frac{N}{\tan(\pi/N)}} \ln \left[\frac{1 + \sin(\pi/N)}{\cos(\pi/N)} \right], \quad N \geq 3 \quad (3.112)$$

The above expression gives $k\sqrt{A}R_0 = 0.5516$ for the triangle ($N = 3$), which is approximately 2.3 percent smaller than the value for the circle where ($N = \infty$). The corresponding value for the area-average basis was reported by Yovanovich and Burde [134] to be $k\sqrt{A}\bar{R} = 0.4600$, which is approximately 4 percent smaller than the value for the circle.

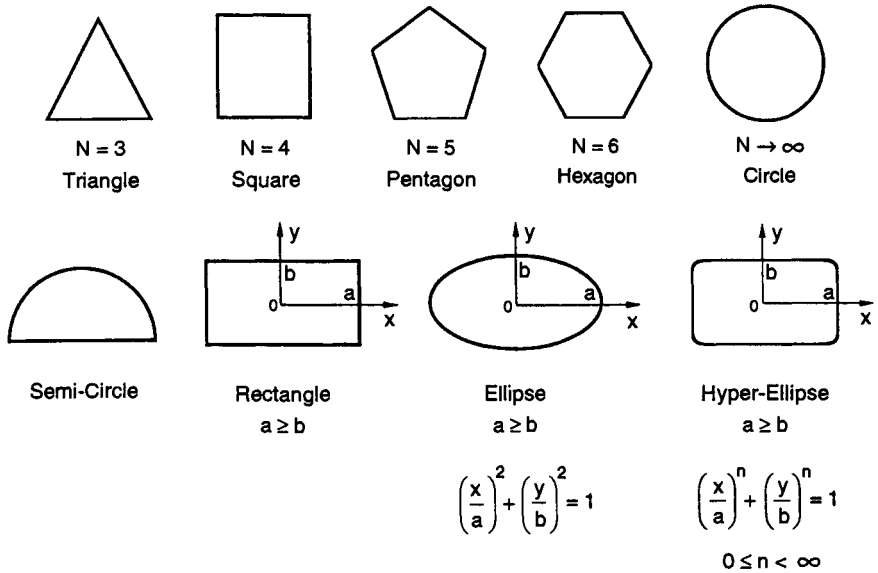

FIGURE 3.14 Singly connected planar areas.

Hyperellipse Contact Areas. The family of contact areas defined by the hyperellipse $(x/a)^n + (y/b)^n = 1$ with $b \leq a$ is shown in Fig. 3.14. Yovanovich et al. [137] used a numerical technique to determine the spreading resistances for several values of the shape parameter $n = 0.5, 1, 2, 4, \infty$ and for a range of the aspect ratio $0.1 \leq \alpha = b/a \leq 1$.

The centroid temperature-based spreading resistance is obtained from the integral [137]

$$k\sqrt{A}R_0 = \frac{1}{\pi} \sqrt{\alpha} \sqrt{\frac{n}{B}} \int_0^{\pi/2} \frac{d\omega}{[\sin^n \omega + \alpha^n \cos^n \omega]^{1/n}} \quad (3.113)$$

where $\alpha = b/a$ is the aspect ratio parameter and B is the beta function [1], which depends on the shape parameter n :

$$B = B\left(1 + \frac{1}{n}, \frac{1}{n}\right)$$

Nonsymmetric Contact Areas. Yovanovich and Burde [134] reported centroidal and area-average spreading resistances of several nonsymmetric contact areas such as semicircles, isosceles triangles of different aspect ratios, and squares with corners removed. For these contact areas Yovanovich and Burde reported that all numerical results lie in the ranges $0.4424 \leq k\sqrt{A}R_0 \leq 0.4733$ and $0.5197 \leq k\sqrt{A}R_0 \leq 0.5614$, and that $\bar{T}/T_0 = 0.84 \pm 1.7$ percent.

Circular Annular Contact Areas on Half-Space

Isoflux Annulus. Yovanovich and Schneider [135] reported the temperature distribution within a circular annular contact $a \leq r \leq b$ subject to a uniform flux q :

$$T(r) = \frac{2}{\pi} \frac{qb}{k} \left\{ E\left(\frac{r}{b}\right) - \left(\frac{r}{b}\right) E\left(\frac{a}{r}\right) + \left(\frac{r}{b}\right) \left[1 - \left(\frac{a}{r}\right)^2 \right] K\left(\frac{a}{r}\right) \right\} \quad (3.114)$$

where k is the thermal conductivity of the half-space. The special functions that appear in the preceding expression, $K(x)$ and $E(x)$, are complete elliptical integrals of the first and second kinds, respectively [1, 10]. The heat sink temperature was set to zero for convenience. The thermal spreading resistance is based on the area-average temperature:

$$\bar{T} = \frac{1}{\pi(b^2 - a^2)} \int_a^b T(r) 2\pi r dr$$

The dimensionless thermal spreading resistance with $\epsilon = a/b < 1$ is given by

$$4kbR_s = \frac{32}{3\pi^2} \frac{1}{(1 - \epsilon^2)^2} [1 + \epsilon^3 - (1 + \epsilon^2)E(\epsilon) + (1 - \epsilon^2)K(\epsilon)] \quad (3.115)$$

The above result reduces to the case of a circular contact area $\epsilon = 0$ on a half-space where $4kbR_s = 32/(3\pi^2)$.

Isothermal Annulus. Smythe [95] obtained the solution for the capacitance of a thin circular annulus. The solutions were recast [135] into the following dimensionless thermal spreading resistance expressions:

$$4kbR_s = \frac{4}{\pi^2} \left[\frac{\ln 16 + \ln [(1 + \epsilon)/(1 - \epsilon)]}{(1 + \epsilon)} \right] \quad (3.116)$$

for $1.000 < 1/\epsilon < 1.10$, and

$$4kbR_s = \frac{\pi/2}{[\cos^{-1} \epsilon + \sqrt{1 - \epsilon^2} \tanh^{-1} \epsilon][1 + 0.0143\epsilon^{-1} \tan^3(1.28\epsilon)]} \quad (3.117)$$

for $1.1 < 1/\epsilon < \infty$.

Doubly Connected Isoflux Contact Areas on Half-Space

The numerical data of Martin [154] for the dimensionless thermal spreading resistance $k\sqrt{A_c}R_s$ for three doubly connected regular polygons (Fig. 3.15)—equilateral triangle, square, and circle—are functions of $\epsilon = \sqrt{A_i/A_o}$, where A_i and A_o are the inner and outer projected areas of the polygons (Fig. 3.15). The contact area is $A_c = A_o - A_i$. Accurate correlation equations with a maximum relative error of 0.6 percent were given for the range $0 \leq \epsilon \leq 0.995$:

$$k\sqrt{A_c}R_s = a_0 \left[1 - \left(\frac{\epsilon}{a_1} \right)^{a_2} \right]^{a_3} \quad (3.118)$$

FIGURE 3.15 Doubly connected regular polygonal areas.

and for the range $0.995 \leq \epsilon \leq 0.9999$:

$$kP_o R_s = a_5 \ln \left[\frac{a_4}{(1/\epsilon) - 1} \right] \quad (3.119)$$

where P_o is the outer perimeter of the polygons, and the correlation coefficients a_0 through a_5 are given in Table 3.12.

TABLE 3.12 Coefficients for Doubly Connected Polygons

	Circle	Square	Triangle
a_0	0.4789	0.4732	0.4602
a_1	0.99957	0.99980	1.00010
a_2	1.5056	1.5150	1.5101
a_3	0.35931	0.37302	0.38637
a_4	39.66	68.59	115.91
a_5	0.31604	0.31538	0.31529

The correlation coefficient a_0 represents the dimensionless spreading resistance of the full contact area, in agreement with results presented previously. Since the results for the square and the circle are very close for all values of the parameter ϵ , the correlation equations for the square or the circle may be used for other doubly connected regular polygons such as pentagons, hexagons, etc.

Effect of Contact Conductance on Spreading Resistance

Martin et al. [61] used a numerical technique to determine the effect of a uniform contact conductance h on the spreading resistance of square and circular contact areas. The dimensionless spreading resistance values were correlated with an accuracy of 0.1 percent by the following expression:

$$k\sqrt{A}R_s = c_1 - c_2 \tanh(c_3 \ln \text{Bi} - c_4), \quad 0 \leq \text{Bi} < \infty \quad (3.120)$$

with $\text{Bi} = h\sqrt{A}/k$. The correlation coefficients c_1 through c_4 are presented in Table 3.13.

TABLE 3.13 Coefficients for Square and Circle

	Circle	Square
c_1	0.46159	0.45733
c_2	0.017499	0.016463
c_3	0.43900	0.47035
c_4	1.1624	1.1311

When $\text{Bi} \leq 0.1$, the values predicted by the expression approach the values corresponding to the isoflux boundary condition; and when $\text{Bi} \geq 100$, the predicted values are within 0.1 percent of the values obtained for the isothermal boundary condition. The transition from the isoflux values to the isothermal values occurs in the range $0.1 \leq \text{Bi} \leq 100$.

Spreading Resistance in Flux Tubes and Channels

General Expression for Circular Contact Area With Arbitrary Flux on Circular Flux Tube.

The general expression for the dimensionless spreading (constriction) resistance $4kaR_s$ for a circular contact subjected to an arbitrary axisymmetric flux distribution $f(u)$ [131–133] is obtained from the series

$$4kaR_s = \frac{(8/\pi)}{\int_0^1 uf(u) du} \sum_{n=1}^{\infty} \frac{J_1(\delta_n \epsilon)}{\delta_n^2 J_0^2(\delta_n)} \int_0^1 uf(u) J_0(\delta_n \epsilon u) du \quad (3.121)$$

where δ_n are the roots of $J_1(\cdot) = 0$ and $\epsilon = a/b$ is the relative size of the contact area.

General Expression for Flux Distributions of the Form $(1 - u^2)^\mu$. Yovanovich [131–133] reported the following general solution for axisymmetric flux distributions of the form $f(u) = (1 - u^2)^\mu$, where the parameter μ accounts for the shape of the flux distribution. The above general expression reduces to the following general expression:

$$4kaR_s = \frac{16}{\pi} (\mu + 1) 2^\mu \Gamma(\mu + 1) \frac{1}{\epsilon} \sum_{n=1}^{\infty} \frac{J_1(\delta_n \epsilon) J_{\mu+1}(\delta_n \epsilon)}{\delta_n^3 J_0(\delta_n) (\delta_n \epsilon)^\mu} \quad (3.122)$$

where $\Gamma(x)$ is the gamma function [1] and $J_\nu(x)$ is the Bessel function of arbitrary order ν .

The above general expression can be used to obtain specific solutions for various values of the flux distribution parameter μ . Three particular solutions are considered next.

Equivalent Isothermal Contact Area: $\mu = -1/2$. The isothermal contact area requires the solution of a difficult mathematical problem that has received much attention from numerous researchers [24, 42, 65, 70, 71, 84, 132, 133].

Mikic and Rohsenow [65] proposed the use of the flux distribution corresponding to $\mu = -1/2$ to approximate an isothermal contact area for small relative contact areas: $0 < \epsilon < 0.5$. The general expression becomes

$$4kaR_s = \frac{8}{\pi} \frac{1}{\epsilon} \sum_{n=1}^{\infty} \frac{J_1(\delta_n \epsilon) \sin(\delta_n \epsilon)}{\delta_n^3 J_0^2(\delta_n)} \quad (3.123)$$

An accurate correlation equation of this series solution is given later.

Isolfux Contact Area: $\mu = 0$. The preceding general solution with $\mu = 0$ yields the isolfux solution reported by Mikic and Rohsenow [65]:

$$4kaR_s = \frac{16}{\pi} \frac{1}{\epsilon} \sum_{n=1}^{\infty} \frac{J_1^2(\delta_n \epsilon)}{\delta_n^3 J_0^2(\delta_n)} \quad (3.124)$$

An accurate correlation equation of this series solution is given later.

Parabolic Flux Distribution: $\mu = 1/2$. Yovanovich [131–133] reported the solution for the parabolic flux distribution corresponding to $\mu = 1/2$.

$$4kaR_s = \frac{24}{\pi} \frac{1}{\epsilon} \sum_{n=1}^{\infty} \frac{J_1(\delta_n \epsilon) \sin(\delta_n \epsilon)}{\delta_n^3 J_0^2(\delta_n)} \left\{ \frac{1}{(\delta_n \epsilon)^2} - \frac{1}{\delta_n \epsilon \tan(\delta_n \epsilon)} \right\} \quad (3.125)$$

Effect of Flux Distribution on Circular Contact Area on Half-Space

The three series solutions just given converge very slowly as $\epsilon \rightarrow 0$, which corresponds to the case of a circular contact area on a half-space. The corresponding half-space results are given by Strong et al. [112]: $4kaR_s$, ($\mu = -1/2$) = 1, $4kaR_s$, ($\mu = 0$) = $32/(3\pi^2)$, $4kaR_s$, ($\mu = 1/2$) = 1.1252.

Simple Correlation Equations of Spreading Resistance for Circular Contact Area

Yovanovich [131–133] recommended the following simple correlations for the three flux distributions:

$$4kaR_s = a_1(1 - a_2\epsilon) \tag{3.126}$$

in the range $0 < \epsilon \leq 0.1$ with a maximum error of 0.1 percent and

$$4kaR_s = a_1(1 - \epsilon)^{a_3} \tag{3.127}$$

in the range $0 < \epsilon \leq 0.3$ with a maximum error of 1 percent. The correlation coefficients for the three flux distributions are given in Table 3.14.

TABLE 3.14 Correlation Coefficients for $\mu = -1/2, 0, 1/2$

μ	$-1/2$	0	$1/2$
a_1	1	1.0808	1.1252
a_2	1.4197	1.4111	1.4098
a_3	1.50	1.35	1.30

Accurate Correlation Equations for Various Combinations of Contact Area, Flux Tubes, and Boundary Condition

General Accurate Correlation Equation. Solutions are also available for various combinations of contact areas and flux tubes such as circle/circle and circle/square for the uniform flux, true isothermal, and equivalent isothermal boundary conditions [71].

Numerical results were correlated using the polynomial

$$4kaR_s = C_0 + C_1\epsilon + C_3\epsilon^3 + C_5\epsilon^5 + C_7\epsilon^7 \tag{3.128}$$

The dimensionless spreading (constriction) resistance coefficient C_0 is the half-space value, and the correlation coefficients C_1 through C_7 are given in Table 3.15.

General Approximate Correlation Equation for Applications. For microelectronic applications, an accurate engineering approximation [74] that is valid for a circular contact on a circular or square flux tube or a square contact on a square flux tube is

$$k\sqrt{A_c}R_s = 0.475 - 0.62\epsilon + 0.13\epsilon^3 \tag{3.129}$$

where $\epsilon = \sqrt{A_c/A_t}$, and A_c, A_t are the contact and flux tube areas, respectively. The maximum error with respect to the exact solution is less than 2 percent for $0 \leq \epsilon \leq 0.5$ and less than 4 percent for $0 \leq \epsilon \leq 0.7$.

TABLE 3.15 Coefficients for Correlations of Dimensionless Spreading Resistance $4kaR_s$

Flux tube geometry and contact boundary condition	C_0	C_1	C_3	C_5	C_7
Circle/circle, uniform flux	1.08076	-1.41042	0.26604	-0.00016	0.058266
Circle/circle, true isothermal	1.00000	-1.40978	0.34406	0.04305	0.02271
Circle/square, uniform flux	1.08076	-1.24110	0.18210	0.00825	0.038916
Circle/square, equivalent isothermal flux	1.00000	-1.24142	0.20988	0.02715	0.02768

Square Contact Area on Square Flux Tube. Mikic and Rohsenow [65] reported the solution for an isoflux square contact area on the end of a semi-infinite square flux tube. The solution was recast [74] to give the dimensionless spreading resistance:

$$k\sqrt{A_c}R_s = \frac{2}{\pi^3\epsilon} \left[\sum_{m=1}^{\infty} \frac{\sin^2(m\pi\epsilon)}{m^3} + \frac{1}{\pi^2\epsilon^2} \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{\sin^2(m\pi\epsilon) \sin^2(n\pi\epsilon)}{m^2n^2\sqrt{m^2+n^2}} \right] \quad (3.130)$$

Circular Contact Area on Square Flux Tube. Sadhal [155] reported the general solution for an isoflux or equivalent isothermal elliptical contact area on a rectangular flux tube. His general solution gives the dimensionless spreading resistance for an isoflux square contact area on a circular flux tube that has the form

$$k\sqrt{A_c}R_s = \frac{2}{\pi^3\epsilon} \left[\sum_{n=1}^{\infty} \frac{J_1^2(2n\sqrt{\pi\epsilon})}{n^3} + \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{J_1^2(2\sqrt{\pi\epsilon}\sqrt{m^2+n^2})}{(m^2+n^2)^{3/2}} \right] \quad (3.131)$$

with the relative size parameter defined as $\epsilon = \sqrt{A_c/A_t} = (\sqrt{\pi}/2)a/b$. The dimensionless isoflux spreading resistance $k\sqrt{A_c}R_s$ has the half-space values 0.47890 and 0.47320 for the circular and square contact areas, respectively, as $\epsilon \rightarrow 0$. Negus et al. [74] reported accurate correlations for the circle/circle, circle/square, and square/square combinations corresponding to the preceding series solutions given by Eq. 3.128.

General Spreading Resistance Expression for Circular Annular Area on Circular Flux Tube

General Expression for Arbitrary Flux. The spreading resistance of a circular annulus of inner and outer radii a and b , respectively, on one end of a semi-infinite circular flux tube of radius c and thermal conductivity k is considered here.

The general expression for the dimensionless spreading resistance $4kbbR_s$ for a circular annular contact subjected to an arbitrary axisymmetric flux distribution $f(u)$ is given by [131]

$$4kbbR_s = \frac{(8/\pi)}{(1-\epsilon^2) \int_{\epsilon}^1 uf(u) du} \sum_{n=1}^{\infty} \frac{J_1(\beta\delta_n) \{1 - \epsilon [J_1(\beta\epsilon\delta_n)] / [J_1(\beta\delta_n)]\}}{\delta_n^3 J_0^2(\delta_n)} \int_{\epsilon}^1 uf(u) J_0(\beta\delta_n u) du \quad (3.132)$$

Spreading Resistance of Isoflux Annular Contact on Circular Flux Tube. The previous general expression reduces for the isoflux case that corresponds to $f(u) = 1$ to the following series [128, 131–133]:

$$4kbbR_s = \frac{16}{\pi\beta(1-\epsilon^2)^2} \sum_{n=1}^{\infty} \frac{J_1^2(\beta\delta_n)}{\delta_n^3 J_0^2(\delta_n)} \left[1 - \epsilon \frac{J_1(\beta\epsilon\delta_n)}{J_1(\beta\delta_n)} \right]^2 \quad (3.133)$$

with the parameters $0 < \beta = b/c < 1$ and $0 \leq \epsilon < 1$. The eigenvalues δ_n are the roots of $J_1(\cdot) = 0$. This solution reduces to the solution for the isoflux circular contact area on the end of a circular flux tube when $\beta = 0$. For small values of β and $0 < \epsilon < 1$ one can use the closed-form solution reported previously for a circular annular contact on a half-space.

Spreading Resistance Within Two-Dimensional Channels

General Expression for Arbitrary Flux. The steady-state spreading resistance due to conduction through a strip of width $2a$ on one end of an infinitely long two-dimensional channel of width $2b$ and thermal conductivity k (Fig. 3.16) has solutions reported by Smythe [98], Mikic and Rohsenow [65], Veziroglu and Chandra [119], and SEXT and Burkhard [90]. Solu-

FIGURE 3.16 Two-dimensional flux channel.

tions have been obtained for the isothermal strip, the isoflux strip, and a general solution developed for arbitrary flux distribution over the strip. Yovanovich [130] reported the following general solution:

$$kR_s = \frac{1}{\pi^2} \frac{1}{\int_0^1 f(u) du} \left(\frac{1}{\epsilon} \right) \sum_{n=1}^{\infty} \frac{\sin(n\pi\epsilon)}{n^2} \int_0^1 f(u) \cos(n\pi\epsilon u) du \quad (3.134)$$

where $f(u)$ with $0 \leq u = x/a < 1$ represents the arbitrary flux distribution over the contact strip, and $\epsilon = a/b < 1$ is the relative size of the contact strip.

General Expression for Flux Distribution of the Form $(1 - u^2)^\mu$. Yovanovich [130] chose the general flux function $f(u) = (1 - u^2)^\mu$ with parameter μ , which gives (1) the isoflux contact when $\mu = 0$, (2) the equivalent isothermal strip when $\mu = -1/2$, and (3) the parabolic flux distribution when $\mu = 1/2$ to develop another general solution:

$$kR_s = \frac{1}{\pi^2} \Gamma\left(\mu + \frac{3}{2}\right) \left(\frac{1}{\epsilon}\right) \sum_{n=1}^{\infty} \frac{\sin(n\pi\epsilon)}{n^2} \left[\frac{2}{n\pi\epsilon}\right]^{\mu+(1/2)} J_{\mu+(1/2)}(n\pi\epsilon) \quad (3.135)$$

Setting $\mu = -1/2$ and $\mu = 0$ in the above general solution gives the two solutions reported by Mikic and Rohsenow [65].

Equivalent Isothermal Contact Area: $\mu = -1/2$. For $\mu = -1/2$

$$kR_s = \frac{1}{\pi^2} \left(\frac{1}{\epsilon}\right) \sum_{n=1}^{\infty} \frac{\sin(n\pi\epsilon)}{n^2} J_0(n\pi\epsilon) \quad (3.136)$$

Isoflux Contact Area: $\mu = 0$. For $\mu = 0$

$$kR_s = \frac{1}{\pi^3} \left(\frac{1}{\epsilon}\right)^2 \sum_{n=1}^{\infty} \frac{\sin^2(n\pi\epsilon)}{n^3} \quad (3.137)$$

Parabolic Flux Distribution: $\mu = 1/2$. The parabolic flux distribution $\mu = 1/2$ gives

$$kR_s = \frac{2}{\pi^3} \left(\frac{1}{\epsilon}\right)^2 \sum_{n=1}^{\infty} \frac{\sin(n\pi\epsilon)}{n^3} J_1(n\pi\epsilon) \quad (3.138)$$

True Isothermal Contact Area. Veziroglu and Chandra [119] used a conformal mapping technique to obtain the closed-form solution for the true isothermal strip:

$$kR_s = \frac{1}{\pi} \ln \left\{ \frac{1}{\sin[(\pi/2)\epsilon]} \right\} \quad (3.139)$$

The true isothermal strip solution and the equivalent isothermal flux solution predict values of the dimensionless spreading resistance that are in close agreement provided $\epsilon < 0.4$. The parabolic flux distribution gives the greatest values of the spreading resistance, followed by the isoflux values, which are greater than the values for the isothermal strip.

FIGURE 3.17 Two-dimensional flux channel with area change.

Effect of Area Change. Smythe [98] reported the analytical solution for the spreading resistance for the case of two coaxial channels of widths $2a$ and $2b$ where $a < b$ are in perfect contact of width $2a$ (Fig. 3.17):

$$kR_s = \frac{1}{2\pi} \left\{ \left(\epsilon + \frac{1}{\epsilon} \right) \ln \left[\frac{1+\epsilon}{1-\epsilon} \right] + 2 \ln \left[\frac{1-\epsilon^2}{4\epsilon} \right] \right\} \quad (3.140)$$

Effect of Single and Multiple Layers (Coatings) on Spreading Resistance

The influence of single and multiple layers of different thermal conductivities and thicknesses is of great interest. The solutions given below can be used to determine the effect of oxide layers and coatings on the spreading resistance. Solutions are available for semi-infinite flux tubes and finite systems such as circular disks.

Spreading Resistance Within Compound Disks With Conductance. The compound disk is shown in Fig. 3.18. The disk consists of two isotropic materials of thicknesses t_1 , t_2 and thermal conductivities k_1 , k_2 that are in perfect contact. The radius of the compound disk is denoted b and its thickness is denoted $t = t_1 + t_2$. The lateral boundary $r = b$ is adiabatic;

the face at $z = t$ is either cooled by a fluid through the film conductance h or in contact with a heat sink through a contact conductance h . In either case h is assumed to be uniform. The face at $z = 0$ consists of the heat source area of radius a , and the remainder of that face $a < r \leq b$ is adiabatic. The boundary condition over the contact area can be modeled as (1) uniform heat flux or (2) isothermal. The complete solution for these two boundary conditions has been reported by Yovanovich et al. [138]. The general solution for the dimensionless constriction parameter $4k_1aR_c$ depends on several dimensionless geometric and thermophysical parameters: $\tau = t/b$, $\tau_1 = t_1/b$, $\tau_2 = t_2/b$, $\epsilon = a/b$, $\kappa = k_1/k_2$, $Bi = hb/k_2$, μ . The parameter μ describes

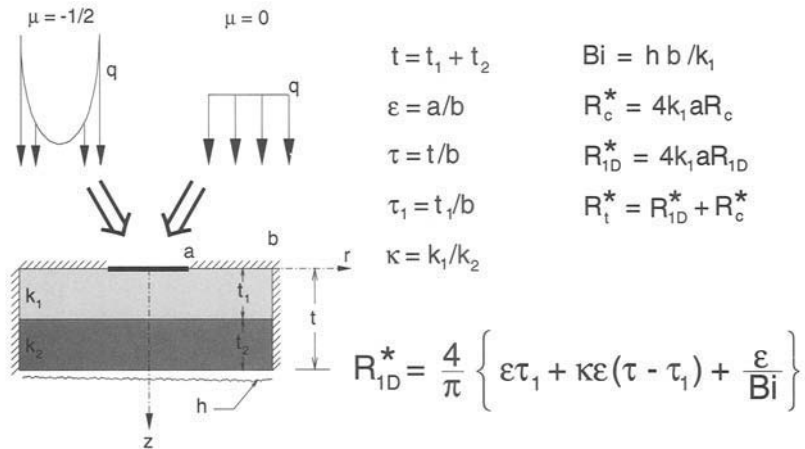

FIGURE 3.18 Compound circular disk with conductance.

the heat flux distribution over the contact area. When $\mu = 0$, the heat flux is uniform, and when $\mu = -1/2$, this heat flux distribution is called the equivalent isothermal distribution because it produces an *almost* isothermal contact area provided $a/b < 0.6$.

The general solution is given as

$$4k_1aR_s = \frac{8(\mu + 1)}{\pi\epsilon} \sum_{n=1}^{\infty} A_n(n, \epsilon) B_n(n, \tau, \tau_1) \frac{J_1(\delta_n\epsilon)}{\delta_n\epsilon} \quad (3.141)$$

The coefficients A_n are functions of the heat flux parameter μ . They become, for $\mu = -1/2$:

$$A_n = \frac{-2\epsilon \sin \delta_n\epsilon}{\delta_n^2 J_0^2(\delta_n)}$$

and for $\mu = 0$:

$$A_n = \frac{-2\epsilon J_1(\delta_n\epsilon)}{\delta_n^2 J_0^2(\delta_n)}$$

The function B_n is defined as

$$B_n = \frac{\phi_n \tanh(\delta_n\tau_1) - \phi_n}{1 - \phi_n} \quad (3.142)$$

and the two functions that appear in the above relationship are defined as

$$\phi_n = \frac{\kappa - 1}{\kappa} \cosh(\delta_n\tau_1) [\cosh(\delta_n\tau_1) - \phi_n \sinh(\delta_n\tau_1)] \quad (3.143)$$

and

$$\phi_n = \frac{\delta_n + \text{Bi} \tanh(\delta_n\tau)}{\delta_n \tanh(\delta_n\tau) + \text{Bi}} \quad (3.144)$$

The eigenvalues δ_n are the positive roots of $J_1(\cdot) = 0$.

Characteristics of ϕ_n . This function accounts for the effects of the parameters δ_n , τ , and Bi. For limiting values of the parameter Bi it reduces to

$$\phi_n = \tanh(\delta_n\tau) \quad \text{Bi} \rightarrow \infty$$

and

$$\phi_n = \coth(\delta_n\tau) \quad \text{Bi} \rightarrow 0$$

For all $0 < \text{Bi} < \infty$ and for all values $\tau > 0.72$, $\tanh(\delta_n\tau) = 1$ for all $n \geq 1$. Therefore $\phi_n = 1$ for $n \geq 1$.

Characteristics of B_n . When $\tau_1 > 0.72$, $\tanh(\delta_n\tau) = 1$, $\phi_n = 1$ for all $0 < \text{Bi} < \infty$, therefore $B_n = 1$ for $n \geq 1$. These characteristics lead to the previously discussed flux tube solutions.

The general solution for the compound disk can be used to obtain the spreading resistances for the several cases shown in Figs. 3.19 and 3.20.

Spreading Resistance Within Isotropic Finite Disks With Conductance. The dimensionless constriction resistance for isotropic ($\kappa = 1$) finite disks ($\tau_1 < 0.72$) with negligible thermal resistance at the heat sink interface ($\text{Bi} = \infty$) is given by the following solutions.

$$\text{For } \mu = -1/2: \quad 4kaR_s = \frac{8}{\pi\epsilon} \sum_{n=1}^{\infty} \frac{J_1(\delta_n\epsilon) \sin(\delta_n\epsilon)}{\delta_n^3 J_0^2(\delta_n)} \tanh(\delta_n\tau) \quad (3.145)$$

$$\text{For } \mu = 0: \quad 4kaR_s = \frac{16}{\pi\epsilon} \sum_{n=1}^{\infty} \frac{J_1^2(\delta_n\epsilon)}{\delta_n^3 J_0^2(\delta_n)} \tanh(\delta_n\tau) \quad (3.146)$$

If the external resistance is negligible ($\text{Bi} \rightarrow \infty$), the temperature at the lower face of the disk is assumed to be isothermal. The solutions for isoflux $\mu = 0$ heat source and isothermal base temperature were given by Kennedy [42] for (1) the centroid temperature and (2) the area-average contact area temperature.

FIGURE 3.19 Special cases of the compound disk with $\kappa \neq 1$.

FIGURE 3.20 Special cases of the compound disk with $\kappa = 1$.

Correlation Equation for Spreading Resistance Within Finite Disk With Conductance.

The solution for the isoflux boundary condition and with external thermal resistance was recently reexamined by Song et al. [156] and Lee et al. [157]. These researchers nondimensionalized the constriction resistance based on the centroid and area-average temperatures using the square root of the contact area as recommended by Chow and Yovanovich [15] and Yovanovich [132, 137, 144–146, 150], and compared the analytical results against the numerical results reported by Nelson and Sayers [158] over the full range of the independent parameters Bi , ϵ , and τ . Nelson and Sayers [158] also chose the square root of the contact area to report their numerical results. The analytical and numerical results were reported to be in excellent agreement.

Lee et al. [157] recommended a simple closed-form expression for the dimensionless constriction resistance based on the area-average and centroid temperatures. They defined the dimensionless spreading resistance parameter as $\psi = \sqrt{\pi}kaR_c$ and recommended the following approximations.

For the area-average temperature:
$$\psi_{\text{ave}} = 1/2(1 - \epsilon)^{3/2}\phi_c \tag{3.147}$$

For the centroid temperature:
$$\psi_{\text{max}} = \frac{1}{\sqrt{\pi}}(1 - \epsilon)\phi_c \tag{3.148}$$

with
$$\phi_c = \frac{Bi \tanh(\delta_c \tau) + \delta_c}{Bi + \delta_c \tanh(\delta_c \tau)}$$

and
$$\delta_c = \pi + \frac{1}{\sqrt{\pi\epsilon}}$$

The above approximations are within ± 10 percent of the analytical results [156, 157] and the numerical results [158]. They do not, however, indicate where the maximum errors occur.

Circular Contact Area on Single Layer (Coating) on Half-Space

Equivalent Isothermal Circular Contact. Dryden [16] obtained the solution for an equivalent isothermal circular contact of radius a that is in perfect contact with an isotropic layer of thermal conductivity k_1 and thickness t_1 that is also in perfect thermal contact with a substrate of thermal conductivity k_2 . This system is shown in Fig. 3.21. Dryden based his solution on the axisymmetric flux distribution:

$$q(r) = \frac{Q}{2\pi a(a^2 - r^2)^{1/2}}$$

where Q is the heat transfer rate through the contact area. The spreading resistance, based on the area-average temperature, is obtained from the integral:

$$R_s = \frac{1}{\pi k_1 a} \int_0^\infty \left[\frac{\lambda_2 \exp(\zeta t_1/a) + \lambda_1 \exp(-\zeta t_1/a)}{\lambda_2 \exp(\zeta t_1/a) - \lambda_1 \exp(-\zeta t_1/a)} \right] \frac{J_1(\zeta) \sin \zeta}{\zeta^2} d\zeta \tag{3.149}$$

with $\lambda_1 = (1 - k_2/k_1)/2$ and $\lambda_2 = (1 + k_2/k_1)/2$. The parameter ζ is a dummy variable of integration. The constriction resistance depends on the thermal conductivity ratio k_1/k_2 and

FIGURE 3.21 Circular contact area on single layer (coating) on half-space.

the relative layer thickness t_1/a . Dryden gave simple asymptotes for the constrictions for thin layers ($t_1/a \leq 0.1$) and thick layers ($t_1/a \geq 10$). These asymptotes were also presented as dimensionless spreading resistances defined as $4k_2aR_s$. They are as follows.

Thin-Layer Asymptote

$$(4k_2aR_s)_{\text{thin}} = 1 + \left(\frac{4}{\pi}\right)\left(\frac{t_1}{a}\right)\left[\frac{k_2}{k_1} - \frac{k_1}{k_2}\right] \quad (3.150)$$

Thick-Layer Asymptote

$$(4k_2aR_s)_{\text{thick}} = \frac{k_2}{k_1} - \left(\frac{2}{\pi}\right)\left(\frac{a}{t_1}\right)\left(\frac{k_2}{k_1}\right) \ln\left(\frac{2}{1+k_1/k_2}\right) \quad (3.151)$$

These asymptotes provide results that are within 1 percent of the full solution for relative layer thickness $t_1/a < 0.5$ and $t_1/a > 2$.

The dimensionless constriction is based on the substrate thermal conductivity k_2 . The preceding general solution is valid for conductive layers where $k_1/k_2 > 1$ as well as for resistive layers where $k_1/k_2 < 1$. The infinite integral can be evaluated numerically by means of computer algebra systems, which provide accurate results.

Isoflux Circular Contact. Hui and Tan [39] gave the solution for a circular contact of radius a that is subjected to a uniform and steady heat flux q and that is in perfect contact with an isotropic layer of thermal conductivity k_1 and thickness t_1 that is also in perfect thermal contact with a substrate of thermal conductivity k_2 . This system is shown in Fig. 3.21.

Hui and Tan [39] reported the following integral solution for the dimensionless spreading resistance:

$$4k_2aR_s = \frac{32}{3\pi^2} \left(\frac{k_2}{k_1}\right)^2 + \frac{8}{\pi} \left[1 - \left(\frac{k_2}{k_1}\right)^2\right] \int_0^\infty \frac{J_1^2(\zeta) d\zeta}{[1 + (k_1/k_2) \tanh(\zeta t_1/a)] \zeta^2} \quad (3.152)$$

which depends on the thermal conductivity ratio k_1/k_2 and the relative layer thickness t_1/a . The dimensionless constriction is based on the substrate thermal conductivity k_2 . The above general solution is valid for conductive layers where $k_1/k_2 > 1$ as well as for resistive layers where $k_1/k_2 < 1$.

Circular Contact Area on Multiple Layers on Circular Flux Tube

The effect of single and multiple isotropic layers or coatings on the end of a circular flux tube has been determined by Antonetti [2] and Sridhar et al. [107]. The heat enters the end of the circular flux tube of radius b and thermal conductivity k_3 through a coaxial, circular contact area that is in perfect thermal contact with an isotropic layer of thermal conductivity k_1 and thickness t_1 . This layer is in perfect contact with a second layer of thermal conductivity k_2 and thickness t_2 that is in perfect contact with the flux tube having thermal conductivity k_3 (Fig. 3.22). The lateral boundary of the flux tube is adiabatic and the contact plane outside the contact area is also adiabatic. The boundary condition over the contact area may be (1) isoflux or (2) isothermal. The dimensionless constriction resistance $\Psi_{2 \text{ layers}} = 4k_3aR_c$ is defined with respect to the thermal conductivity of the flux

FIGURE 3.22 Flux tube with two layers.

tube, which is often referred to as the substrate. This constriction resistance depends on several dimensionless parameters: relative contact size $\epsilon = a/b$ where $0 < \epsilon < 1$; two conductivity ratios, $\kappa_{21} = k_2/k_1$ and $\kappa_{32} = k_3/k_2$; two relative layer thicknesses, $\tau_1 = t_1/a$ and $\tau_2 = t_2/a$; and the boundary condition over the contact area. The solution for two layers is given as

$$\Psi_{2 \text{ layers}} = \frac{16}{\pi} \frac{1}{\epsilon} \sum_{n=1}^{\infty} \phi_{n,\epsilon} \kappa_{21} \kappa_{32} \frac{\vartheta^+}{\vartheta^-} \quad (3.153)$$

where

$$\phi_{n,\epsilon} = \frac{J_1^2(\delta_n \epsilon)}{\delta_n^2 J_0^2(\delta_n)} \rho_{n,\epsilon} \quad (3.154)$$

and the boundary condition parameter is defined as

$$\rho_{n,\epsilon} = \begin{cases} \frac{\sin(\delta_n \epsilon)}{2J_1(\delta_n \epsilon)} & \text{isothermal contact} \\ 1 & \text{isoflux contact} \end{cases} \quad (3.155)$$

The thermal conductivity ratios are defined above. The layer parameters ϑ^+ and ϑ^- come from the following general function:

$$\vartheta^\pm = (1 + \kappa_{21})(1 + \kappa_{32}) \pm (1 - \kappa_{21})(1 + \kappa_{32}) \exp(-2\delta_n \epsilon \tau_1) \\ + (1 - \kappa_{21})(1 - \kappa_{32}) \exp(-2\delta_n \epsilon \tau_2) \pm (1 + \kappa_{21})(1 + \kappa_{32}) \exp(-2\delta_n \epsilon (\tau_1 + \tau_2))$$

The eigenvalues δ_n that appear in the solution are the roots of $J_1(\cdot) = 0$.

The two-layer solution can be used to obtain the solution for a single layer of thermal conductivity k_1 and thickness t_1 in perfect contact with a flux tube of thermal conductivity k_2 . In this case the dimensionless constriction resistance $\psi_{1 \text{ layer}}$ depends on the relative contact size ϵ , the conductivity ratio κ_{21} , and the relative layer thickness τ_1 :

$$\Psi_{1 \text{ layer}} = \frac{16}{\pi} \frac{1}{\epsilon} \sum_{n=1}^{\infty} \phi_{n,\epsilon} \kappa_{21} \frac{\vartheta^+}{\vartheta^-} \quad (3.156)$$

and the general layer function reduces to

$$\vartheta^\pm = 2[(1 + \kappa_{21})(1 - \kappa_{21})] \exp(-2\delta_n \epsilon \tau_1)$$

Transient Spreading Resistance

Introduction. Transient spreading resistance occurs during startup and is important in certain micro-electronic systems. The spreading resistance can be defined with respect to the area-average temperature as a single point temperature such as the centroid. Solutions have been reported for isoflux contact areas on half-spaces, circular contact areas on circular flux tubes, and strips on channels.

Spreading Resistance of Isoflux Circular Contact Area on Half-Space. Beck [6] reported the following integral solution for a circular area of radius a that is subjected to a uniform and constant flux q for $t > 0$:

$$4kaR_s = \frac{8}{\pi} \int_0^\infty J_1^2(\zeta) \operatorname{erf}(\zeta \sqrt{\text{Fo}}) \frac{d\zeta}{\zeta^2} \quad (3.157)$$

where the dimensionless time is defined as $\text{Fo} = \alpha t/a^2$. The spreading resistance is based on the area average temperature. Steady state is obtained when $\text{Fo} \rightarrow \infty$ and the solution goes to $4kaR_s = 32/(3\pi^2)$.

Beck gave approximate solutions for short and long times. For short times ($Fo < 0.6$),

$$4kaR_s = \frac{8}{\pi} \left[\sqrt{\frac{Fo}{\pi}} - \frac{Fo}{\pi} + \frac{Fo^2}{8\pi} + \frac{Fo^3}{32\pi} + \frac{15Fo^4}{512\pi} \right] \quad (3.158)$$

and for long times ($Fo \geq 0.6$),

$$4kaR_s = \frac{32}{3\pi^2} - \frac{2}{\pi^{3/2}\sqrt{Fo}} \left[1 - \frac{1}{3(4Fo)} + \frac{1}{6(4Fo)^2} - \frac{1}{12(4Fo)^3} \right] \quad (3.159)$$

The maximum errors of about 0.18 percent and 0.07 percent occur at $Fo = 0.6$ for the short- and long-time expressions, respectively.

Transient Spreading Resistance of Isoflux Hyperellipse Contact Area on Half-Space

The hyperellipse is defined by $(x/a)^n + (y/b)^n = 1$ with $b \leq a$, where n is the shape parameter and a and b are the axes along the x and y axes, respectively, as shown in Fig. 3.14. The hyperellipse reduces to many special cases by setting the values of n and the aspect ratio parameter $\gamma = b/a$, which lies in the range $0 \leq \gamma \leq 1$. Therefore the solution developed for the hyperellipse can be used to obtain solutions for many other geometries, such as ellipses and circles, rectangles and squares, diamondlike geometries, etc. The transient dimensionless centroid constriction resistance $k\sqrt{A}R_0$ where $R_0 = T_0/Q$ is given by the double-integral solution [152]:

$$k\sqrt{A}R_0 = \frac{2}{\pi\sqrt{A}} \int_0^{\pi/2} \int_0^{r_0} \operatorname{erfc} \left(\frac{r}{2\sqrt{A}\sqrt{Fo_{\sqrt{A}}}} \right) dr d\omega \quad (3.160)$$

where the area of the hyperellipse is given by $A = (4\gamma/n)B(1 + 1/n, 1/n)$ and $B(x, y)$ is the beta function. The dimensionless time is defined as $Fo_{\sqrt{A}} = \alpha t/A$. The upper limit of the radius is given by $r_0 = \gamma/[(\sin \omega)^n + \gamma^n(\cos \omega)^n]^{1/n}$ and the aspect ratio parameter $\gamma = b/a$. The preceding solution has the following characteristics: (1) for small dimensionless times, $Fo_{\sqrt{A}} \leq 4 \times 10^{-2}$ and $k\sqrt{A}R_0 = (2/\sqrt{\pi})\sqrt{Fo_{\sqrt{A}}}$ for all values of n and γ ; (2) for long dimensionless times $Fo_{\sqrt{A}} \geq 10^3$. The results are within 1 percent of the steady-state values, which are given by the single integral:

$$k\sqrt{A}R_0 = \frac{2\gamma}{\pi\sqrt{A}} \int_0^{\pi/2} \frac{d\omega}{[(\sin \omega)^n + \gamma^n(\cos \omega)^n]^{1/n}} \quad (3.161)$$

which depends on the aspect ratio γ and the shape parameter n . The dimensionless spreading resistance depends on the three parameters $Fo_{\sqrt{A}}$, γ , and n in the transition region: $4 \times 10^{-2} \leq Fo_{\sqrt{A}} \leq 10^3$ in some complicated manner that can be deduced from the solution for the circular area. For this axisymmetric shape we put $\gamma = 1$, $n = 2$ into the hyperellipse double integral, which yields the following closed-form result valid for all dimensionless time [152]:

$$k\sqrt{A}R_0 = \sqrt{Fo_{\sqrt{A}}} \left[\frac{1}{\sqrt{\pi}} - \frac{1}{\sqrt{\pi}} \exp(-1/(4\pi Fo_{\sqrt{A}})) + \frac{1}{2\sqrt{\pi}\sqrt{Fo_{\sqrt{A}}}} \operatorname{erfc} \left(\frac{1}{2\sqrt{\pi}\sqrt{Fo_{\sqrt{A}}}} \right) \right] \quad (3.162)$$

where the dimensionless time for the circle of radius a is $Fo_{\sqrt{A}} = \alpha t/(\pi a^2)$.

Transient Spreading Resistance of Isoflux Regular Polygonal Contact Area on Half-Space

For regular polygons having sides $N \geq 3$ as depicted in Fig. 3.14, the area is $A = Nr_i^2 \tan \pi/N$, where r_i is the radius of the inscribed circle. The dimensionless constriction resistance based on the centroid temperature $k\sqrt{A}R_0$ is given by the following double integral [152]:

$$k\sqrt{A}R_0 = 2\sqrt{\frac{N}{\tan(\pi/N)}} \int_0^{\pi/N} \int_0^{1/\cos\omega} \operatorname{erfc}\left(\frac{r}{2\sqrt{N \tan(\pi/N)} \sqrt{\operatorname{Fo}_{\sqrt{A}}}}\right) dr d\omega \quad (3.163)$$

where the polygonal area is expressed in terms of the number of sides N and for convenience the inscribed radius has been set to unity. This double-integral solution has identical characteristics to those of the double-integral solution given above for the hyperellipse, i.e., for small dimensionless time, $\operatorname{Fo}_{\sqrt{A}} \leq 4 \times 10^{-2}$ and $k\sqrt{A}R_0 = (2/\sqrt{\pi})\sqrt{\operatorname{Fo}_{\sqrt{A}}}$ for all polygons $N \geq 3$; for long dimensionless time, $\operatorname{Fo}_{\sqrt{A}} \geq 10^3$. The results are within 1 percent of the steady-state values given by the following closed-form expression [152]:

$$k\sqrt{A}R_0 = \frac{1}{\pi} \sqrt{\frac{N}{\tan(\pi/N)}} \ln \left[\frac{1 + \sin(\pi/N)}{\cos(\pi/N)} \right] \quad (3.164)$$

The dimensionless spreading resistance $k\sqrt{A}R_0$ depends on the parameters $\operatorname{Fo}_{\sqrt{A}}$ and N in the transition region $4 \times 10^{-2} \leq \operatorname{Fo}_{\sqrt{A}} \leq 10^3$ in some complicated manner that, as described above, can be deduced from the solution for the circular area. The steady-state solution yields ψ_0 values of 0.5617, 0.5611, and 0.5642 for the equilateral triangle ($N=3$), the square ($N=4$), and the circle ($N \rightarrow \infty$). The difference between the values for the triangle and the circle is approximately 2.2 percent, whereas the difference between the values for the square and the circle is less than 0.6 percent. The following procedure is proposed for computation of the centroid-based transient spreading resistance for the range $4 \times 10^{-2} \leq \operatorname{Fo}_{\sqrt{A}} \leq 10^6$. The closed-form solution for the circle is the basis of the proposed method. For any planar, singly connected contact area subjected to a uniform heat flux take, $\psi_0 = k\sqrt{A}R_0$.

$$\frac{\psi_0}{\psi_0(\operatorname{Fo}_{\sqrt{A}} \rightarrow \infty)} = 2\sqrt{\operatorname{Fo}_{\sqrt{A}}} \left[1 - \exp(-1/(4\pi \operatorname{Fo}_{\sqrt{A}})) + \frac{1}{2\sqrt{\operatorname{Fo}_{\sqrt{A}}}} \operatorname{erfc}\left(\frac{1}{2\sqrt{\pi} \sqrt{\operatorname{Fo}_{\sqrt{A}}}}\right) \right] \quad (3.165)$$

The right side of the above equation can be considered to be a *universal* dimensionless time function that accounts for the transition from small times to near steady state. The proposed procedure should provide quite accurate results for any planar, singly connected area. A simpler expression based on the Greene approximation [25] of the complementary error function is proposed [152]:

$$\frac{\psi_0}{\psi_0(\operatorname{Fo}_{\sqrt{A}} \rightarrow \infty)} = \frac{1}{z\sqrt{\pi}} [1 - e^{-z^2} + a_1\sqrt{\pi}ze^{-a_2(z+a_3)^2}] \quad (3.166)$$

where $z = 1/(2\sqrt{\pi}\sqrt{\operatorname{Fo}_{\sqrt{A}}})$ and the three correlation coefficients are $a_1 = 1.5577$, $a_2 = 0.7182$, $a_3 = 0.7856$. This approximation provides values of ψ_0 with maximum errors of less than 0.5 percent for $\operatorname{Fo}_{\sqrt{A}} \geq 4 \times 10^{-2}$.

Transient Spreading Resistance Within Semi-Infinite Flux Tubes and Channels

Isoflux Circular Contact Area on Circular Flux Tube. Turyk and Yovanovich [118] reported the analytical solutions for transient spreading resistance within semi-infinite circular

flux tubes and two-dimensional channels. The circular contact and the rectangular strip are subjected to uniform and constant heat fluxes. The dimensionless spreading resistance for the flux tube is given by the series solution

$$4kaR_s = \frac{16}{\pi} \frac{1}{\epsilon} \sum_{n=1}^{\infty} \frac{J_1^2(\delta_n \epsilon) \operatorname{erf}(\delta_n \epsilon \sqrt{Fo})}{\delta_n^3 J_0^2(\delta_n)} \quad (3.167)$$

where $\epsilon = a/b < 1$, $Fo = \alpha t/a^2$, and δ_n are the roots of $J_1(x) = 0$. The series solution approaches the steady-state solution presented in an earlier section when the dimensionless time satisfies the criterion $Fo \geq 1/\epsilon^2$ or when the real time satisfies the criterion $t \geq a^2/(\alpha \epsilon^2)$.

Isoflux Strip on Two-Dimensional Channel. The dimensionless spreading resistance within a two-dimensional channel of width $2b$ and thermal conductivity k was reported as

$$kR_s = \frac{1}{\pi^3 \epsilon} \sum_{m=1}^{\infty} \frac{\sin^2(m\pi\epsilon) \operatorname{erf}(m\pi\epsilon\sqrt{Fo})}{m^3} \quad (3.168)$$

where $\epsilon = a/b < 1$ is the relative size of the contact strip, and the dimensionless time is defined as $Fo = \alpha t/a^2$. There is no half-space solution for the two-dimensional channel. The transient solution is within 1 percent of the steady-state solution when the dimensionless time satisfies the criterion $Fo \geq 1.46/\epsilon^2$.

CONTACT, GAP, AND JOINT RESISTANCES AND CONTACT CONDUCTANCES

Point and Line Contact Models

The thermal resistance models for steady-state conduction through contact areas and gaps formed when nonconforming smooth surfaces are placed in contact are based on the Hertz elastic deformation model [37, 41, 117, 121] and the thermal spreading (constriction) results presented previously. The general elastoconstriction models for point and line contacts are reviewed by Yovanovich [143]. In the general case the contact area is elliptical and its dimensions are much smaller than the dimensions of the contacting bodies. The gap that is formed is a function of the shape of the contacting bodies, and in general the local gap thickness is described by complex integrals and special functions called elliptical integrals [8, 10]. Two important special cases are considered in the following sections: sphere-flat and circular cylinder-flat contacts. The review of Yovanovich [143] can be consulted for the general case.

FIGURE 3.23 Sphere-flat contact with gap.

Elastoconstriction Resistance of Sphere-Flat Contacts.

The contact resistance of the sphere-flat contact shown in Fig. 3.23 is discussed in this section. The thermal conductivities of the sphere and flux tube are k_1 and k_2 , respectively. The total contact resistance is the sum of the constriction resistance in the sphere and the spreading resistance within the flux tube. The contact radius a is much smaller than the sphere diameter D and the tube diameter. Assuming isothermal contact area, the general elastoconstriction resistance model [143] becomes:

$$R_c = \frac{1}{2k_2 a} \quad (3.169)$$

where $k_s = 2k_1k_2/(k_1 + k_2)$ is the harmonic mean thermal conductivity of the contact, and the contact radius is obtained from the Hertz elastic model [117]:

$$\frac{2a}{D} = \left[\frac{3F\Delta}{D^2} \right]^{1/3} \quad (3.170)$$

where F is the mechanical load at the contact, and the physical parameter is defined as

$$\Delta = \frac{1}{2} \left[\frac{(1 - \nu_1^2)}{E_1} + \frac{(1 - \nu_2^2)}{E_2} \right] \quad (3.171)$$

where ν_1 and ν_2 are the Poisson's ratio and E_1 and E_2 are the elastic modulus of the sphere and flat contacts, respectively.

Elastoconstriction Resistance of Cylinder-Flat Contacts. The thermal contact resistance model for the contact formed by a smooth circular cylinder of diameter D and thermal conductivity k_1 , and a smooth flat of thermal conductivity k_2 , was reported by McGee et al. [63] to be

$$k_s R_c = \frac{1}{2\pi} \frac{k_s}{k_1} \ln \left(\frac{\pi}{F^*} \right) - \frac{k_s}{2k_2} - \frac{1}{2\pi} \frac{k_s}{k_2} \ln (4\pi F^*) \quad (3.172)$$

where k_s is the harmonic mean thermal conductivity and Δ is the Hertz physical parameter defined above. The dimensionless mechanical load is defined as $F^* = F\Delta/(DL)$, where F is the total load at the contact strip and L is the length of the cylinder and the flat.

Gap Resistance Model of Sphere-Flat Contacts. The general elastogap resistance model for point contacts [143] reduces for the sphere-flat contact to

$$\frac{1}{R_g} = \left(\frac{D}{L} \right) k_{g,0} I_{g,p} \quad (3.173)$$

where $L = D/(2a)$ is the relative contact size defined previously. The gap integral for point contacts proposed by Kitscha and Yovanovich [46] is defined as

$$I_{g,p} = \int_1^L \frac{2x \tan^{-1} \sqrt{x^2 - 1}}{(2\delta/D) + (2M/D)} dx \quad (3.174)$$

The local gap thickness δ is obtained from

$$\frac{2\delta}{D} = 1 - \left(1 - \left(\frac{x}{L} \right)^2 \right)^{1/2} + \frac{1}{\pi L^2} \left[(2 - x^2) \sin^{-1} \left(\frac{1}{x} \right) + \sqrt{x^2 - 1} \right] - \frac{1}{L^2} \quad (3.175)$$

where $L = D/(2a)$, $x = r/a$, and $1 \leq x \leq L$. The gap gas rarefaction parameter is defined as

$$M = \alpha\beta\Lambda \quad (3.176)$$

with $\alpha = (2 - \alpha_1)/\alpha_1 + (2 - \alpha_2)/\alpha_2$, where α_1 and α_2 are the accommodation coefficients at the gas-solid interfaces, respectively. The gas parameter $\beta = (2\gamma)/[(\gamma + 1)/Pr]$, where $\gamma = C_p/C_v$, and Pr is the Prandtl number. The mean free path Λ of the gas molecules is given in terms of $\Lambda_{g,0}$, the mean free path at some reference gas temperature T_0 and reference gas pressure P_0 , as follows:

$$\Lambda = \Lambda_{g,0} \frac{T_g}{T_{g,0}} \frac{P_{g,0}}{P_g}$$

Gap Resistance Model of Cylinder-Flat Contacts. The general elastogap resistance model for line contacts [143] reduces for the circular cylinder-flat contact to

$$\frac{1}{R_g} = \frac{4aL_{\text{cyl}}}{D} k_{g,0} I_{g,l} \quad (3.177)$$

where D and L are the diameter and length of the cylinder, and a is the half-width of the contact strip. The gap integral for line contacts [63] is

$$I_{g,l} = \frac{2}{\pi} \int_1^L \frac{\cosh^{-1}(\zeta)}{(2\delta/D) + (2M/D)} d\zeta \quad (3.178)$$

The local gap thickness for line contacts [121] is

$$\frac{2\delta}{D} = \left(1 - \frac{1}{L^2}\right)^{1/2} - \left(1 - \frac{\zeta^2}{L^2}\right)^{1/2} + \frac{1}{2L} [\zeta(\zeta^2 - 1)^{1/2} - \cosh^{-1}(\zeta) - \zeta^2 + 1] \quad (3.179)$$

where $L = D/(2a)$, $\zeta = x/L$ and $1 \leq x \leq L$. The dimensionless contact strip width is obtained from the Hertz theory [117]

$$\frac{2a}{D} = 4 \sqrt{\frac{F\Delta}{\pi D L_{\text{cyl}}}} \quad (3.180)$$

where F is the total load at the contact and Δ is the physical parameter defined earlier.

Radiative Resistance Model of Sphere-Flat Contacts. The radiative resistance of a gap formed by two bodies in elastic contact, such as a sphere-flat or cylinder-flat contact, respectively, is complex because it depends on the geometry of the gap—the surface emissivities of the boundaries, which includes the side walls that form the enclosure.

Kitscha and Yovanovich [46] and Kitscha [47] proposed the following radiative resistance model for a sphere-disk contact with bounding side walls. All surfaces were assumed to be gray with constant emissivity values ϵ_1 , ϵ_2 , and ϵ_3 for the sphere, disk, and side walls, respectively. The sphere and disk were assumed to be isothermal at temperatures T_1 and T_2 , respectively. The following expression was proposed:

$$R_r = \frac{1}{A_2 \bar{F}_{12} 4\sigma T_m^3} \quad (3.181)$$

where A_2 is the surface area of the disk, σ is the Stefan-Boltzmann constant, and $T_m = (T_1 + T_2)/2$ is the mean absolute temperature of the contact. The radiative parameter \bar{F}_{12} is defined as

$$\frac{1}{\bar{F}_{12}} = \frac{1 - \epsilon_1}{2\epsilon_1} + \frac{1 - \epsilon_2}{\epsilon_2} + 1.104 \quad (3.182)$$

Joint Resistance Model of Sphere-Flat Contacts. The joint thermal resistance of a contact formed by elastic bodies, such as a sphere-flat contact is obtained from the model proposed by Kitscha and Yovanovich [46] and Kitscha [47]:

$$\frac{1}{R_j} = \frac{1}{R_c} + \frac{1}{R_g} + \frac{1}{R_r} \quad (3.183)$$

which is a function of the constriction resistance R_c , the gap resistance R_g , and the radiative resistance R_r , which are in parallel. The accuracy of the proposed model was verified by numerous experiments.

Experimental Verification of Elastoconstriction and Elastogap Models. Experimental data have been obtained for the elastoconstriction resistance of point contacts [47] and line contacts [63] for a range of sphere and cylinder diameters, material properties, and mechanical loads. Data were obtained for the verification of the elastogap model for the point contact [46] and line contact [63]. The elastogap models have been tested with air, argon, helium, and nitrogen as the gap fluid at gas pressures from 10^{-6} torr to atmospheric pressure.

Some representative test data for the elastoconstriction and elastogap resistances compared with the theoretical values are given in the following sections.

Sphere-Flat Test Results. Kitscha [47] performed experiments on steady heat conduction through 25.4- and 50.8-mm sphere-flat contacts in an air and argon environment at pressures between 10^{-5} torr and atmospheric pressure. He obtained vacuum data for the 25.4-mm-diameter smooth sphere in contact with a polished flat having a surface roughness of approximately 0.13 μm RMS. The mechanical load ranged from 16 to 46 N. The mean contact temperature ranged between 321 and 316 K. The harmonic mean thermal conductivity of the sphere-flat contact was found to be 51.5 W/mK. The emissivities of the sphere and flat were estimated to be $\epsilon_1 = 0.2$ and $\epsilon_2 = 0.8$, respectively.

The contact, gap, radiative, and joint resistances were nondimensionalized as $R^* = Dk_c R$.

The dimensionless radiative resistance for the sphere-flat contact given above becomes

$$R_r^* = \frac{3.82 \times 10^{10}}{T_m^3}$$

The dimensionless constriction resistance is $R_c^* = L$ and the dimensionless joint resistance in a vacuum is

$$\frac{1}{R_j^*} = \frac{1}{L} + \frac{1}{R_r^*} \tag{3.184}$$

The model predictions and the vacuum experimental results are compared in Table 3.16.

TABLE 3.16 Dimensionless Load, Constriction, Radiative, and Joint Resistances [47]

N, newtons	L, D/2a	T_m , K	R_c^*	R_r^*	R_j^* test
16.0	115.1	321	1155	104.7	107.0
22.2	103.2	321	1155	94.7	99.4
55.6	76.0	321	1155	71.3	70.9
87.2	65.4	320	1164	61.9	61.9
195.7	50.0	319	1177	48.0	48.8
266.9	45.1	318	1188	43.4	42.6
467.0	37.4	316	1211	36.4	35.4

The radiative resistance was approximately 10 times the constriction resistance at the lightest load and 30 times at the highest load. The largest difference between the theory and experiments is approximately -4.7 percent, within the probable experimental error. These and other vacuum tests [47] verified the accuracy of the elastoconstriction and the radiation models.

The elastogap model for a point contact was verified by Kitscha [47] and Ogniewicz [159]. For air, the gas parameter M depends on T_m, P_g as follows:

$$M = 1.373 \times 10^{-4} \frac{T_m}{DP_g} \tag{3.185}$$

where D is in cm, T_m in K and P_g in mmHg. The numerical value M is based on air properties at $T_{g,0} = 288\text{K}$ and $P_{g,0} = 760\text{ mmHg}$.

TABLE 3.17 Elastogap Resistance Theory and Air Data [47]:
 $D = 25.4 \text{ mm}$, $D/(2a) = 115.1$

321	Vacuum	∞	1155	104.7	107.0

The elastogap model and the experimental results are compared over a range of gas pressures in Table 3.17. Although tests were conducted at smaller values of the dimensionless parameter L over a range of gas pressures, sphere diameters, and gases, the results given in Table 3.17 are representative of the other data and they also correspond to the case that challenges the validity of the proposed elastoconstriction and elastogap models. First note that the radiative resistance is approximately 10 times the constriction resistance. Second, observe that the gap resistance is approximately $\frac{2}{3}$ of the constriction resistance at the highest gas pressure, approximately equal to the constriction resistance at a gas pressure between 4 and 40 mmHg, and finally 3 times the constriction resistance at $P_g = 0.2 \text{ mmHg}$. The agreement between the theory and the tests is very good to excellent.

The largest difference occurs at the highest gas pressures, where the theory predicts lower joint resistances by approximately 5 percent. The agreement between theory and experiment improves with decreasing gas pressure.

It can also be seen in Table 3.17 that the air within the sphere-flat gap significantly decreases the joint resistance when compared with the vacuum result.

Thermal Contact, Gap, and Joint Conductance Models

Thermal contact, gap, and joint conductance models developed by many researchers over the past five decades are reviewed and summarized in several articles [20, 23, 50, 58, 143, 147, 148] and in the recent text of Madhusudana [59]. The models are, in general, based on the assumption that the contacting surfaces are conforming (or flat) and that the surface asperities have particular height and asperity slope distributions [26, 116, 125]. The models assume either plastic or elastic deformation of the contacting asperities, and require the thermal spreading (constriction) resistance results presented above.

Plastic Contact Conductance Model of Cooper, Mikic, and Yovanovich. The thermal contact conductance models are based on three fundamental models: (1) the metrology model (surface roughness and asperity slope), (2) the contact mechanics model (deformation of the softer contacting surface asperities), and (3) the thermal constriction (spreading) resistance model for the microcontact areas. Cooper et al. [14] presented the contact conductance model, which is based on the Gaussian distribution of the asperity heights and slopes, the plastic deformation of the contacting asperities, and the constriction resistance, which is based on the isothermal circular contact area on a circular flux tube result. The development of the dimensionless contact conductance model for conforming rough surfaces has been presented in several publications [14, 65, 139, 143, 147, 148]. The theoretical dimensionless contact conductance has the form

$$C_c = \frac{\sigma}{m} \frac{h_c}{k_s} = \frac{1}{2\sqrt{2\pi}} \frac{\exp(-x^2)}{(1-\epsilon)^{1.5}} \quad (3.186)$$

FIGURE 3.24 Conforming rough surface geometric parameters.

with $x = \operatorname{erfc}^{-1}(2P/H_c)$ and $\epsilon = \sqrt{P/H_c}$, where P is the contact pressure and H_c is the flow pressure at the plastically deformed surface asperities. The surface parameters are $\sigma = \sqrt{\sigma_1^2 + \sigma_2^2}$ and $m = \sqrt{m_1^2 + m_2^2}$, where σ_1 and σ_2 represent the RMS surface roughness of the two contacting surfaces and m_1 and m_2 represent the absolute mean slopes of the surface asperities of the contacting surfaces (Fig. 3.24). The interface effective thermal conductivity is defined as $k_i = 2k_1k_2/(k_1 + k_2)$. The metrology model also gives the following geometric relationships [139–141].

Relative Real Contact Area.

$$\epsilon^2 \equiv \frac{A_r}{A_a} = \frac{1}{2} \operatorname{erfc}(x)$$

where A_r is the total real contact area and A_a is the corresponding total apparent area.

Contact Spot Density.

$$n = \frac{1}{16} \left(\frac{m}{\sigma} \right)^2 \frac{\exp(-2x^2)}{\operatorname{erfc}(x)}$$

Mean Contact Spot Radius.

$$a = \sqrt{\frac{8}{\pi}} \left(\frac{\sigma}{m} \right) \exp(x^2) \operatorname{erfc}(x)$$

where $x = (1/\sqrt{2})(Y/\sigma)$ and Y is the mean plane separation (Fig. 3.24). The relative mean plane separation is obtained from

$$\frac{Y}{\sigma} = \sqrt{2} \operatorname{erfc}^{-1} \left(\frac{2P}{H_c} \right)$$

which is approximated by [139–141]

$$\frac{Y}{\sigma} = 1.184 \left[-\ln \left(3.132 \frac{P}{H_c} \right) \right]^{0.547}$$

which is valid in the ranges $4.75 \geq Y/\sigma \geq 2.0$ and $10^{-6} \leq P/H_c \leq 2 \times 10^{-2}$, and it has a maximum error of approximately 1 percent. The relative mean plane separation appears in the gap conductance model.

Yovanovich [139] proposed the correlation equation for the contact conductance model:

$$C_c = 1.25 \left(\frac{P}{H_c} \right)^{0.95} \tag{3.187}$$

which is valid for the wide range $10^{-6} \leq P/H_c \leq 2 \times 10^{-2}$ and has a maximum error of approximately 1.5 percent.

Yovanovich et al. [140] and Hegazy [35] recognized the importance of the effect of work-hardened layers on the deformation of the contacting asperities. They proposed an iterative procedure to obtain the appropriate value of the contact microhardness H_c from Vickers microhardness H_v measurements [41, 114]. Song and Yovanovich [102] reported the explicit expression for calculating the relative contact pressure:

$$\frac{P}{H_c} = \left[\frac{0.9272P}{c_1(1.62\sigma/m)^{c_2}} \right]^{1/(1+0.071c_2)} \tag{3.188}$$

where the correlation coefficients c_1 and c_2 are obtained from Vickers microhardness measurements. Sridhar and Yovanovich [108] developed correlation equations for the Vickers coefficients:

$$\frac{c_1}{3178} = [4.0 - 5.77H_B^* + 4.0(H_B^*)^2 - 0.61(H_B^*)^3]$$

and

$$c_2 = -0.370 + 0.442\left(\frac{H_B}{c_1}\right)$$

where H_B is the Brinell hardness [41, 114] and $H_B^* = H_B/3178$. The correlation equations are valid for the Brinell hardness range of 1300–7600 MPa. The above correlation equations were developed for a range of metals: Ni200, SS304, Zr alloys, Ti alloys, and tool steel. Sridhar and Yovanovich [108] also reported a correlation equation that relates the Brinell hardness number to the Rockwell C hardness number:

$$BHN = 43.7 + 10.92HRC - \frac{HRC^2}{5.18} + \frac{HRC^3}{340.26}$$

for the range $20 \leq HRC \leq 65$. It has been demonstrated that the above plastic contact conductance model predicts accurate values of h_c for a range of surface roughness σ/m , a range of metals (SS304, Ni200, Zr alloys, etc.), and a range of relative contact pressure P/H_c [2, 35, 105, 106, 109].

Plastic Contact Conductance Model of Greenwood and Williamson. Sridhar and Yovanovich [109] developed correlation equations for the contact conductance of conforming rough surfaces based on the Greenwood and Williamson [26] surface model using the plastic deformation model described above. The dimensionless contact conductance correlation is

$$C_c \equiv \frac{\sigma}{m} \frac{h_c}{k_s} = 0.91\alpha^{0.31} \left\{ \frac{0.9272P}{c_1[(2.47/\alpha^{0.269})(\sigma/m)]^{c_2}} \right\}^{(0.971\alpha^{1/251.93})/(1 + 0.038c_2)} \quad (3.189)$$

which is valid in the relative contact pressure range $10^{-5} \leq P/H_c \leq 10^{-2}$. The surface parameter α is the bandwidth parameter, which depends on the variance of surface heights, the variance of surface slopes, and the variance of the second derivative of surface heights. The correlation is valid for the range $5 \leq \alpha \leq 100$. σ and m are the surface roughness and the surface slope as defined previously. The parameters c_1 and c_2 are the Vickers microhardness correlation coefficients, which can be determined by means of the relationships just presented.

Sridhar and Yovanovich [109] found that the Greenwood and Williamson (GW) model [26] and the Cooper, Mikic, and Yovanovich (CMY) model [14] are in very good agreement when $\alpha > 5$. For all values of $\alpha > 5$, the GW model predicts values of C_c that are greater than those predicted by the CMY model.

Elastic Contact Conductance Models of Mikic and Greenwood and Williamson. Sridhar and Yovanovich [106] reviewed the elastic contact models proposed by Greenwood and Williamson [26] and Mikic [66] and compared the correlation equation with data obtained for five different metals. The models were developed for conforming rough surfaces; they differ in the description of the surface metrology and the contact mechanics. The thermal model developed by Cooper et al. [14] was used. The details of the development of the models and the correlation equations are reviewed by Sridhar and Yovanovich [106]. The correlation equation derived from the Mikic [66] surface and asperity contact models is

$$C_c \equiv \frac{\sigma}{m} \frac{h_c}{k_s} = 1.54 \left(\frac{\sqrt{2P}}{mE'} \right)^{0.94} \quad (3.190)$$

where σ and m are the contact surface roughness and slope. The equivalent modulus is defined as $E' = [(1 - \nu_1^2)/E_1 + (1 - \nu_2^2)/E_2]^{-1}$ where ν_1 and ν_2 are the Poisson's ratio, and E_1 and E_2 are the elastic modulus of the contacting asperities.

The correlation equation derived from the Greenwood and Williamson [26] surface and asperity contact models is

$$C_c \equiv \frac{\sigma}{m} \frac{h_c}{k_s} = (1.18 + 0.161 \ln \alpha) \left(\frac{\sqrt{2}P}{mE'} \right)^{0.922\alpha^{1/205.54}} \quad (3.191)$$

where α is the bandwidth parameter discussed above.

The two elastic contact correlation equations [106] were developed for the ranges $10^{-5} \leq \sqrt{2}P/mE' \leq 10^{-2}$ and $5 \leq \alpha \leq 100$. The two correlation equations predict values of C_c that are in close agreement when $\alpha = 5$ and for the largest value of α the difference between the predicted values is approximately 35 percent.

The correlation equation developed from the Mikic [66] models is simpler; therefore it is recommended for predicting contact conductance for elastic contacts.

Elastoplastic Contact Model and Relationships. Sridhar and Yovanovich [106] developed an elastoplastic contact conductance model that is summarized below in terms of the geometric parameters (1) A_r/A_a , the real to apparent area ratio; (2) n , the contact spot density; (3) a , the mean contact spot radius; and (4) λ , which is the dimensionless mean plane separation:

$$\begin{aligned} \frac{A_r}{A_a} &= \frac{f_{ep}}{2} \operatorname{erfc}(\lambda/\sqrt{2}) \\ n &= \frac{1}{16} \left(\frac{m}{\sigma} \right)^2 \frac{\exp(-\lambda^2)}{\operatorname{erfc}(\lambda/\sqrt{2})} \\ a &= \sqrt{\frac{8}{\pi}} \cdot \sqrt{f_{ep}} \cdot \frac{\sigma}{m} \exp(\lambda^2/2) \operatorname{erfc}(\lambda/\sqrt{2}) \\ h_c &= \frac{k_s}{2\sqrt{2}\pi} \frac{m}{\sigma} \frac{\sqrt{f_{ep}} \cdot \exp(-\lambda^2/2)}{[1 - \sqrt{(f_{ep}/2)} \operatorname{erfc}(\lambda/\sqrt{2})]^{1.5}} \\ \lambda &\equiv \frac{Y}{\sigma} = \sqrt{2} \operatorname{erfc}^{-1} \left(\frac{1}{f_{ep}} \cdot \frac{2P}{H_{ep}} \right) \end{aligned}$$

The elastoplastic parameter f_{ep} is a function of the dimensionless contact strain ϵ_c^* , which depends on the amount of work hardening. This physical parameter lies in the range $0.5 \leq f_{ep} \leq 1.0$. The smallest and largest values correspond to zero and infinitely large contact strain, respectively. The dimensionless contact strain is defined as

$$\epsilon_c^* = 1.67 \left(\frac{mE'}{S_f} \right)$$

where S_f is the material yield or flow stress [41], which is a complex physical parameter that must be determined by experiment for each metal. The elastoplastic microhardness H_{ep} can be determined by means of an iterative procedure that requires the following relationship:

$$H_{ep} = \frac{2.76S_f}{[1 + (6.5/\epsilon_c^*)^2]^{1/2}} \quad (3.192)$$

The proposed elastoplastic contact conductance model moves smoothly between the elastic contact model of Mikic [66] and the plastic contact conductance model of Cooper, Mikic, and

Yovanovich [14], which was modified by Yovanovich and co-workers [102, 139, 140] to include the effect of work-hardened layers on the deformation of the contacting asperities.

Gap Conductance Model and Integral

The gap conductance model for conforming rough surfaces was developed, modified, and verified by Yovanovich and co-workers [35, 73, 100–104]. The gap contact model is based on surfaces having Gaussian height distributions. It also accounts for the mechanical deformation of the contacting surface asperities. The development of the gap conductance model appears in several papers [139, 143, 147].

The gap conductance model is expressed in terms of an integral:

$$h_g = \frac{k_g}{\sigma} \frac{1}{\sqrt{2\pi}} \int_0^{\infty} \frac{\exp[-(Y/\sigma - u)^2/2]}{u + M/\sigma} du \quad (3.193)$$

where k_g is the thermal conductivity of the gas trapped in the gap, σ is the effective surface roughness of the interface, and $u = t/\sigma$ is the dimensionless local gap thickness. The integral depends on two parameters: Y/σ , which is the mean plane separation, and M/σ , which is the relative gas rarefaction parameter defined and discussed previously. The gas rarefaction parameter $M = \alpha\beta\Lambda$ has also been defined and discussed previously.

Accommodation Coefficients. The accommodation coefficient α accounts for the efficiency of gas-surface energy exchange. There is a large body of research dealing with experimental and theoretical aspects of α for different gases in contact with metallic surfaces under various surface conditions and temperatures [32, 92, 120, 126]. Song and Yovanovich [100] and Song et al. [101, 104] examined the gap conductance models available in the literature, the experimental data, and the models for the accommodation coefficients. Song and Yovanovich [100] developed a correlation for the accommodation coefficient for “engineering” surfaces (i.e., surfaces with adsorbed layers of gases and oxides). They proposed a correlation based on experimental results of numerous investigators for monatomic gases. The relation was extended by the introduction of a “monatomic equivalent molecular weight” to diatomic and polyatomic gases. The correlation equation has the form

$$\alpha = \exp(C_0 T) [M_g / (C_1 + M_g) + \{1 - \exp(C_0 T)\} \{2.4\mu / (1 + \mu)^2\}]$$

where $C_0 = -0.57$

$$T = (T_s - T_0) / T_0$$

$$M_g = M_g \text{ for monatomic gases}$$

$$= 1.4 M_g \text{ for diatomic and polyatomic gases}$$

$$C_1 = 6.8, \text{ units of } M_g \text{ [g/mole]}$$

$$\mu = M_g / M_s$$

where T_s and T_0 are the absolute temperatures of the surface and the gas, and M_g and M_s are the molecular weights of the gas and the solid, respectively. The agreement between the predictions according to this correlation and the published data for diatomic and polyatomic gases was within ± 25 percent.

Wesley and Yovanovich [127] compared the predictions of the proposed gap conductance model and experimental measurements of gaseous gap conductance between the fuel and clad of a nuclear fuel rod. The agreement was very good and the model was recommended for fuel pin analysis codes.

Gap Conductance Correlation Equations. Although the gap integral can be computed accurately and easily by means of computer algebra systems, Negus and Yovanovich [73] proposed the following correlation equations for the gap integral:

$$I_g = \frac{f_g}{(Y/\sigma) + (M/\sigma)}$$

with $f_g = 1.063 + 0.0471(4 - Y/\sigma)^{1.68}[\ln(\sigma/M)]^{0.84}$ for $2 \leq Y/\sigma \leq 4$ and $0.01 \leq M/\sigma \leq 1$
and $f_g = 1 + 0.06(\sigma/M)^{0.8}$ for $2 \leq Y/\sigma \leq 4$ and $1 \leq M/\sigma \leq \infty$

The correlations have a maximum error of approximately 2 percent.

ACKNOWLEDGMENTS

The author is grateful to the Natural Science and Engineering Research Council for its continued financial support of the research for the preparation of this chapter. Thanks to P. Teertstra, J. R. Culham, Y. S. Muzychka and M. Stevanovic for help with the figures and other assistance.

NOMENCLATURE

Symbol, Definition, SI Units

A, A_c, A_t	area, contact, and flux tube areas: m ²
A_a, A_r	apparent and real contact areas, $A_r/A_a < 1$: m ²
A_s, A_N	shape factor parameters
A_m, B_n	Fourier coefficients for temperature and heat loss
AR	aspect ratio of bodies
$\mathcal{A}(\beta, \gamma)$	dimensionless ellipsoid area function = $A/(2\pi a^2)$
a	semimajor axis of ellipse, hyperellipse, rectangle: m
a	point contact radius, line contact half-width: m
a, b, c	semiaxes of ellipsoid: m
a, b	radii of bisphere: m
a_1, a_2, a_3, a_4, a_5	correlation coefficients
$B(x, y)$	beta function
B	layer thickness
Bi	Biot number = hL/k (typical)
$Bi_{\sqrt{A}}$	Biot number based on square root of area
BHN	Brinell hardness number
C	capacitance: coulomb/volt
C^*	capacity: m
C_c	dimensionless contact conductance = $\sigma h_c/(mk_s)$
C_p, C_v	specific heat at constant pressure and volume: J/(kg·°C)
C_0, C_1, C_3, C_5, C_7	correlation coefficients
C_{CT}, C_{ST}	correlation coefficients for circular and square toroids
C_1, C_2, C_3	correlation coefficients
c	specific heat: J/(kg·°C)
c_1, c_2	Vickers microhardness correlation coefficients

D	diameter of cylinders, spheres, and toroids: m
D_i, D_o	inner and outer diameters of circular and square toroids
D_{GM}	geometric mean diameter: m
d	diameter of cylinders and toroids: m
E	modulus of elasticity: N/m^2
$E(\kappa)$	complete elliptic integral of the second kind
$E(\phi, \kappa)$	incomplete elliptic integral of second kind
E'	equivalent modulus = $[(1 - \nu_1^2)/E_1 + (1 - \nu_2^2)/E_2]^{-1}$
erf, erfc	error and complementary error functions
$erfc^{-1}$	inverse complementary error function
F	contact load: N
F^*	dimensionless line contact load = $F\Delta/(DL)$
$F(\phi, \kappa)$	incomplete elliptic integral of the first kind
Fo	Fourier number = $\alpha t/L^2$ (typical)
$Fo_{\sqrt{A}}$	Fourier number based on square root of area
Fo_c	critical value of Fourier number
\bar{F}_{12}	radiative parameter for point contact
f_{ep}	elastoplastic contact parameter
f_g	gap conductance correlation equation
g_i, \sqrt{g}	metric coefficients, jacobian
H	height of single and double cones
HRC	Rockwell C hardness number
H_B	Brinell hardness
H_c	surface contact microhardness: MPa
H_{ep}	elastoplastic microhardness: MPa
H_V	Vickers microhardness: MPa
h, h_c, h_g, h_j	heat transfer coefficient and contact, gap and joint conductances: $W/(m^2 \cdot K)$
$I(\beta, \gamma)$	shape factor integral
I_n	n th-order modified Bessel function of first kind
I_g	gap conductance integral = $f_g/(Y/\sigma + M/\sigma)$
$I_{g,p}$	point contact gap integral
$I_{g,l}$	line contact gap integral
$i^n erfc$	integrals of complementary error function
J_n	n th-order Bessel function of first kind
$K(\kappa)$	complete elliptic integral of first kind of modulus κ
K_n	n th-order modified Bessel function of first kind
k	thermal conductivity: $W/(m \cdot K)$
k_1, k_2	layer and substrate conductivities: $W/(m \cdot K)$
k_a	conductivity at average temperature: $W/(m \cdot K)$
k_0	conductivity at reference temperature: $W/(m \cdot K)$
k_s	harmonic mean conductivity = $2k_1 k_2 / (k_1 + k_2)$: $W/(m \cdot K)$
L	length of circular and square cylinders and rectangular plate: m

L	dimensionless point contact parameter: $D/(2a)$
L_{cyl}	cylinder length: m
L_1, L_2, L_3	side dimensions of cuboid: m
\mathcal{L}	arbitrary length scale: m
M	gap gas parameter = $\alpha\beta\Lambda$: m
M_g, M_s	gas and solid molecular weights: g/mole
m	effective surface asperity slope = $\sqrt{m_1^2 + m_2^2}$
m_1, m_2	surface mean asperity slope of contacting rough surfaces
N	number sides of regular polygons
n	outward directed normal, shape parameter
n	interpolation parameter
n	contact spot density: m^{-2}
O	area
P, P_i, P_o	perimeter, inner, and outer perimeters: m
P	contact pressure: MPa
P_g	gas pressure: kPa
$P_{g,0}$	reference gas pressure: kPa
Pr	Prandtl number = $\mu c/k$
$P_{n-1/2}(\zeta)$	toroidal function
p	correlation coefficient
Q	heat flow rate: W
$Q_{\mathcal{L}}^*$	dimensionless heat flow rate = $(Q\mathcal{L})/(kA\theta_0)$ (typical)
Q_i	initial internal energy = $\rho cV\theta_i$ (typical): J
Q_e	total electrical charge
$Q_{n-1/2}(\zeta)$	toroidal function
q	heat flux: W/m^2
q_0	surface heat flux: W/m^2
R	thermal resistance, spreading resistance = $(\bar{T}_{\text{source}} - \bar{T}_{\text{sink}})/Q$ (typical): K/W
R_0	spreading resistance based on centroid temperature: K/W
R_c, R_s	constriction and spreading resistances: K/W
R_r	gap resistance: K/W
R_j	joint or overall resistance = $(1/R_c + 1/R_g + 1/R_r)^{-1}$: K/W
R_r	radiation resistance: K/W
R^*	dimensionless resistance = $k\mathcal{L}R$ (typical)
R_s^*	dimensionless spreading resistance = $4k\mathcal{L}R_s$ (typical)
R^*	dimensionless contact, gap, or radiation resistance = k_rDR (typical)
R_c^*	dimensionless point contact resistance = L
R_g^*	dimensionless gap resistance
R_r^*	dimensionless radiative resistance = $(3.82 \times 10^{10})/T_m^3$
R_j^*	dimensionless joint resistance = $(1/L + 1/R_r^*)^{-1}$
r	radius, polar, and spherical coordinates: m
\vec{r}	radius vector: m

r_0	radius for hyperellipse: m
S	shape factor: m
$S_{\sqrt{A}}^*$	dimensionless shape factor
S_f	material yield or flow stress: MPa
S_0, S_∞	shape factors for thin and thick conduction layers: m
$S_{\mathcal{L}}^*$	dimensionless shape factor = $(S\mathcal{L})/A$
S	active surface area: m ²
s	dimensionless parameter = $1/(1 + pz)$
s	dummy variable
T, \bar{T}	temperature, area average temperature: K
T_f	fluid temperature: K
T_i	initial solid temperature: K
T_m	mean temperature = $(T_1 + T_2)/2$: K
$T_{g,0}$	reference gas temperature: K
t	time: s
t	variable gap thickness: m
t_1, t_2	coating or layer thicknesses: m
u	dimensionless position variable
u	dimensionless variable gap thickness = t/σ
u_i	curvilinear coordinates
V	volume: m ³
V_e	electrical potential: V
W	width of annular area: m
W	width of rectangular plate: m
x, y, z	cartesian coordinates: m
x	dimensionless parameter for single and double cones
x	dimensionless mean plane separation = $(1/\sqrt{2})(Y/\sigma)$
Y	mean plane separation = $\sigma\sqrt{2} \operatorname{erfc}^{-1}(2P/H_c)$: m
Y_n	n th-order Bessel function of second kind
z	dimensionless parameter = $(Bi + 1)\sqrt{Fo}$
z	dimensionless time parameter = $1/(2\sqrt{\pi}\sqrt{Fo_{\sqrt{A}}})$

Greek Symbols

α	thermal diffusivity = $k/(\rho c)$: m ² /s
α	accommodation coefficient = $(2 - \alpha_1)/\alpha_1 + (2 - \alpha_2)/\alpha_2$
α_1, α_2	accommodation coefficients for gap
α	bandwidth surface roughness parameter $5 \leq \alpha \leq 100$
β	gas parameter = $(2\gamma)/[(\gamma + 1)/Pr]$
β	dimensionless parameter in ellipsoidal integral = b/a
β	thermal conductivity temperature coefficient
β_1, β_2	integration limits
β	dimensionless parameter in ellipsoidal integral = b/a

β	dimensionless parameter in ellipsoidal integral = b/a
$\Gamma(x)$	gamma function
γ	dimensionless parameter in ellipsoidal integral = c/a
γ	specific heat ratio = C_p/C_v
γ	aspect ratio parameter = $b/a \leq 1$
Δ	diffusion thickness = A/S : m
Δ	elastic parameter = $[(1 - \nu_1^2)/E_1 + (1 - \nu_2^2)/E_2]/2$: (MPa) ⁻¹
δ_n	n th eigenvalue
δ_1	first eigenvalue
$\delta_{1,0}$	first eigenvalue for $Bi \rightarrow 0$
$\delta_{1,\infty}$	first eigenvalue for $Bi \rightarrow \infty$
δ_c	approximate first eigenvalue = $\pi + 1/(\sqrt{\pi\epsilon})$
ϵ	permittivity of space: farad
ϵ	relative size = a/b (typical)
ϵ_c	contact strain
ϵ_c^*	dimensionless contact strain = $1.67(mE'/S_f)$
ζ	arguments of toroidal functions = D/d
ζ	dimensionless position = x/L (typical)
ζ	dummy variable
η	elliptic cylinder, bicylinder, oblate and prolate spheroidal coordinate
η_1, η_2	integration limits
η_{\min}, η_{\max}	minimum and maximum integration limits
θ	steady or transient temperature excess = $[T(\vec{r}, t) - T_\infty]$ (typical): K
θ_f	maximum system temperature excess = $T_f - T_i$ (typical): K
θ_i	initial temperature excess = $T_f - T_i$ (typical): K
θ	Kirchhoff temperature = $1/k_0 \int_0^{T_0} k dT$ (typical): K
θ	spherical, oblate, and prolate spheroidal coordinate
ϑ^\pm	multiple layer thickness and conductivity parameter
κ	modulus of complete and incomplete elliptic integrals of first and second kind
κ	thermal conductivity ratio = k_1/k_2 (typical)
κ_{21}	conductivity ratio = k_2/k_1
κ_{32}	conductivity ratio = k_3/k_2
Λ	molecular mean free path: m
$\Lambda_{g,0}$	molecular mean free path at reference conditions: m
λ	relative gap thickness = Y/σ
λ_1	conductivity ratio parameter = $(1 - k_2/k_1)/2$
λ_2	conductivity ratio parameter = $(1 + k_2/k_1)/2$
μ	heat flux distribution parameter $q^* = (1 - u^2)^\mu$
μ	order of Bessel function of the first kind $J_{\mu + (1/2)}(n\pi\epsilon)$
μ	ratio of molecular weights = M_g/M_s
ν_1, ν_2	Poisson's ratios

v	elliptic cylinder, bicylinder, oblate and prolate spheroidal coordinate
v	dummy variable in ellipsoidal integral
ρ	mass density: kg/m^3
ρ	dimensionless position in cylindrical and spherical coordinates = r/a (typical)
$\rho_{n,\epsilon}$	heat flux parameter = 1, isothermal; = $\sin(\delta_r, \epsilon)/[2J_1(\delta_r, \epsilon)]$, isoflux
σ_1, σ_2	RMS surface rough of contacting surfaces: m
σ	effective RMS surface rough of interface: m
τ	relative layer thickness = t/a (typical)
v	
ϕ	dimensionless temperature = $[T(\bar{r}) - T_\infty]/(T_0 - T_\infty)$
ϕ_e	nondimensional electrical potential
ϕ_x, ϕ_r	dimensionless temperatures for plate and cylinder
ϕ_c	approximation function for compound cylinder
ϕ_n	compound cylinder function
φ_n	compound cylinder function
ψ	dimensionless spreading resistance = $4k\mathcal{L}R$ (typical)
ψ	dimensionless spreading resistance = $\sqrt{\pi}kaR_c$
ψ_{ave}	dimensionless spreading resistance = $(1 - \epsilon)^{3/2}k\phi_c/2$
ψ_{max}	dimensionless spreading resistance = $(1 - \epsilon)k\phi_c/\sqrt{\pi}$
ψ_0	dimensionless centroid based spreading resistance = $k\sqrt{A}R_0$
ω	angle

Subscripts

\sqrt{A}	scale length is square root of the area
a	apparent
ave	based on average temperature
c	contact, constriction, critical
cyl	cylinder
contact plane	apparent
CT, ST	circular and square toroids
e	electrical
ep	elastoplastic
f	fluid
f	flow stress
D	Dirichlet condition solution
GM	geometric mean
g	gap, gas
$g, 0$	at reference gas temperature and pressure
g, l	gap for line contact
g, p	gap for point contact
i	initial value
i, o	inner and outer

i	inner body volume and area
j	joint
L	longest straight line through inner body
l	line contact
m	mean value
max	based on centroid temperature
min	based on area average temperature
N	Neumann condition solution
n	n th
p	point contact
p	constant pressure condition
R	Robin condition solution
r	radiative
rect	rectangular area
s	spreading
s	based on harmonic mean value
source	based on source temperature
sink	based on sink temperature
thick	thick layer
thin	thin layer
v	constant volume condition
r, ψ, z	cylindrical coordinates
r, ψ, θ	spherical coordinates
η, ψ, z	elliptical cylinder coordinates
η, ψ, z	bicylinder coordinates
η, θ, ψ	oblate and spheroidal coordinates
0	zero thickness limit
0	based on centroid temperature
0, 1	zeroeth order, first order
0, ∞	value on the surface and at infinity
∞	infinite thickness limit
1, 0	first eigenvalue value at zero Biot number limit
1, ∞	first eigenvalue value at infinite Biot number limit
1, 2	solids 1 and 2; surfaces 1 and 2
1, 2, 3	cubeoid side dimensions
12	net radiative transfer
1D	one-dimensional conduction

Superscripts

*	dimensionless value
'	effective value of parameter
\pm	parameter with positive or negative terms

Overscores

-	mean value

CHAPTER 4

NATURAL CONVECTION

G. D. Raithby and K. G. T. Hollands

University of Waterloo

INTRODUCTION

Natural convection is the motion that results from the interaction of gravity with density differences within a fluid. The differences may result from gradients in temperature, concentration, or composition. This chapter deals with the heat transfer associated with natural convection driven by temperature gradients in a newtonian fluid.

The first section presents some fundamental ideas that are frequently referred to in the remainder of the chapter. The next three sections deal with the major topics in natural convection. The first of these addresses problems of heat exchange between a body and an extensive quiescent ambient fluid, such as that depicted in Fig. 4.1*a*. Open cavity problems, such as natural convection in fin arrays or through cooling slots (Fig. 4.1*b*), are considered next. The last major section deals with natural convection in enclosures, such as in the annulus between cylinders (Fig. 4.1*c*). The remaining sections present results for special topics including transient convection, natural convection with internal heat generation, mixed convection, and natural convection in porous media.

In response to the main needs of engineers, this chapter focuses on the average (rather than the local) heat transfer, and it provides correlation equations in preference to tabulated data. The advantage is that even complex equations are easy to program into computer codes used for design.

The forms of the correlation equations are based, whenever possible, on general principles and an approximate solution method, both briefly discussed in the section on basics. Confidence in the use of the equations will be enhanced by reading that section. Where accuracy is important, the underlying assumptions and experimental validation should be understood, and where accuracy is critical, no equation should be used beyond its range of experimental validation.

BASICS

Equations of Motion and Their Simplification

In this section the full equations of motion for the external problem sketched in Fig. 4.1*a* are simplified by using approximations appropriate to natural convection, and the resulting equations are nondimensionalized to bring to light the important dimensionless groups. Although

FIGURE 4.1 Natural convection on external surfaces (a), through open cavities (b), and in enclosures (c).

this development is written around the external problem, similar developments may be made for the open cavity and internal problems (Fig. 4.1b and c).

Full Equations of Motion. The complete equations of motion in cartesian coordinates and for a newtonian fluid are presented in Chap. 1. The coordinate z will be used to represent the upward vertical direction as shown in Fig. 1a.

Simplified Equations of Motion. The local pressure in the fluid can (for convenience) be broken into three terms:

$$P \equiv P_{\text{ref}} - \int_{z_{\text{ref}}}^z g \rho_\infty(z) dz + P_d \tag{4.1}$$

The first term is the pressure at some reference point $(x_{\text{ref}}, y_{\text{ref}}, z_{\text{ref}})$ in the ambient fluid far from the body; the second term is the hydrostatic pressure of this ambient fluid; and the third term, P_d is the pressure component associated with dynamics of the flow. Substituting Eq. 4.1 for P into the full equations of motion, we find that P_d simply replaces P in the x and y momentum equations. But in the z momentum equation there arises the additional term $\rho_\infty(z)g$, representing the hydrostatic pressure gradient force. The local gravitational body force ρg also appears in the z momentum equation, and the imbalance between these two forces, represented by the difference $\rho_\infty(z)g - \rho g$, is the driving force of natural convection. By introducing $\beta = -(1/\rho)(\partial\rho/\partial T)_p$ and $\gamma = 1/\rho(\partial\rho/\partial P)_T$, this imbalance, called the buoyancy force, can be expressed by

$$(\rho_\infty(z) - \rho)g = \rho g \left[\exp\left(-\int_T^{T_\infty(z)} \beta dT + \int_P^{P_\infty(z)} \gamma dP\right) - 1 \right] \tag{4.2}$$

where T and P (like ρ) are local values at x, y, z , and $T_\infty(z)$ and $P_\infty(z)$, like $\rho_\infty(z)$, are values in the ambient fluid at the same z .

Equation 4.2 may be simplified. Because the difference between $P(x, y, z)$ and $P_\infty(z)$ is small, the term involving γ may be dropped. Further simplifications are different for gases and liquids. For gases (assumed ideal), $\beta = 1/T$ and Eq. 4.2 reduces to

$$(\rho_\infty(z) - \rho)g = \rho g \frac{1}{T_\infty} (T - T_\infty) \approx \rho_0 g \beta_\infty (T - T_\infty) \tag{4.3}$$

where $\beta_\infty = 1/\bar{T}_\infty$ and ρ_0 is evaluated at a mean film temperature T_f : $T_f = 0.5(\bar{T}_w + \bar{T}_\infty)$. [\bar{T}_w and \bar{T}_∞ are T_w and $T_\infty(z)$ averaged over the vertical height of the body.] The replacement of ρ by

ρ_0 in the third term in Eq. 4.3 has assumed that changes in density are small compared to density itself. For liquids Eq. 4.2 is approximated as follows:

$$(\rho_\infty(z) - \rho)g \approx \rho g \{\exp[-\beta_0(T_\infty - T)] - 1\} \approx \rho g \beta_0(T - T_\infty) \approx \rho_0 g \beta_0(T - T_\infty) \quad (4.4)$$

where both β_0 and ρ_0 are evaluated at T_f . Thus, except for the reference temperature at which β is evaluated, the final expression for the buoyancy force is the same for liquids and gases. An extra degree of approximation was, however, required in Eq. 4.4 as compared to Eq. 4.3, and the temperature range over which Eq. 4.4 is valid will be considerably less than that for Eq. 4.3. For water near 4°C (40°F), the range of validity is so small that, for practical problems, Eq. 4.4 must be replaced by a nonlinear relation between ρ and T [110].

Thus the appropriate equations of motion for natural convection [107] are produced by introducing Eq. 4.1 for P into the full equations of motion and then introducing Eq. 4.3 or 4.4 for the term $(\rho_\infty - \rho)g$. These equations are then further simplified by taking each of the properties ρ , μ , c_p , and k as constant at their respective values, ρ_0 , μ_0 , c_{p0} , and k_0 , evaluated at T_f .

The resulting equations are nondimensionalized by substituting $x = x^*L$, $y = y^*L$, $z = z^*L$, $T = \bar{T}_\infty + \theta\Delta T$, $u = v_0u^*$, $v = v_0v^*$, $w = v_0w^*$, $P_d = 1/2\rho_0v_0^2P_d^*$, and $t = (L/v_0)t^*$, where L is a characteristic dimension of the body, $\Delta T = \bar{T}_w - \bar{T}_\infty$, and $v_0 = \sqrt{g\beta_1\Delta T L/(1 + v_0/\alpha_0)}$, with $\beta_1 = \beta_\infty$ for gases and β_0 for liquids. With the assumption that $T_\infty(z)$ and T_w are constant, the resulting equations for mass, z momentum, and energy become

$$\frac{\partial u^*}{\partial x^*} + \frac{\partial u^*}{\partial y^*} + \frac{\partial w^*}{\partial z^*} = 0 \quad (4.5)$$

$$\begin{array}{cccc} \text{I} & \text{II} & \text{III} & \text{IV} \\ \frac{Dw^*}{Dt^*} = -\frac{\partial P_d^*}{\partial z^*} + \sqrt{\frac{\text{Pr}(1 + \text{Pr})}{\text{Ra}}} \nabla^{*2}w^* + (1 + \text{Pr})\theta & & & \end{array} \quad (4.6)$$

$$\begin{array}{ccccc} \text{I} & \text{II} & \text{III} & \text{IV} & \text{V} \\ \frac{D\theta}{Dt^*} = \sqrt{\frac{1 + \text{Pr}}{\text{Ra Pr}}} \nabla^{*2}\theta - \frac{\beta T g L}{c_{p0} \Delta T} + \beta_1 T \text{Ec} \frac{DP_d^*}{Dt^*} + \frac{\text{Ec}}{\text{Re}} \left[\left(\frac{\partial w^*}{\partial z^*} \right)^2 + \dots \right] & & & & \end{array} \quad (4.7)$$

where, with $\alpha_0 = k_0/\rho_0c_{p0}$ and $v_0 = \mu_0/\rho_0$, Ra (the Rayleigh number) = $g\beta_1\Delta T L^3/v_0\alpha_0$, Pr (the Prandtl number) = v_0/α_0 , Re (the Reynolds number) = Lv_0/v_0 , and Ec (the Eckert number) = $v_0^2/(c_{p0}\Delta T)$. See the end of the nomenclature list for the definition of the operators D/Dt^* and ∇^{*2} . The nondimensional x momentum equation is identical to Eq. 4.6 except that u^* replaces w^* , $\partial P_d^*/\partial x^*$ replaces $\partial P_d^*/\partial z^*$, and the term in θ does not occur; an analogous description applies to the nondimensional y momentum equation. The subscripts 0 and 1 on the properties will, for simplicity, be dropped in the rest of this chapter.

Terms III–V in Eq. 4.7 often have only minor influence and can usually be dropped. Term III reflects the fact that the pressure of the ambient fluid decreases with elevation so that, if the fluid moves upward, it does work on expanding at the expense of internal energy and this produces a cooling effect; since $\beta T g/c_p$ (the adiabatic lapse rate) is usually small (0.01°C/m or 0.006°F/ft for gases) compared to $\Delta T/L$, this term can be safely dropped. Term IV represents a similar effect, this time due to dynamic pressure changes, and can likewise be neglected. Term V represents viscous heating and has a negligible effect.

With terms III–V in Eq. 4.7 deleted, Eqs. 4.5–4.7, together with the x and y momentum equations, constitute the “simplified equations of motion” appropriate to natural convection problems. For constant T_w and T_∞ , the boundary conditions on these equations are $\theta = 1$ and $u^* = v^* = w^* = 0$ on the body and $\theta = 0$ far from the body. *Steady-state laminar* solutions to these equations are those that are obtained after setting the time partials (i.e., terms containing partial derivatives with respect to t^*) in the equations equal to zero. *Steady-state turbulent*

solutions are those that are obtained after setting time partials of *mean* quantities equal to zero but that incorporate the effect of the unsteady (turbulent) motion.

Important Dimensionless Groups. The average Nusselt number for steady-state heat transfer from the body shown in Fig. 4.1a depends on the dimensionless groups that arise in the nondimensionalized equations of motion and their boundary conditions [78]. With T_w and T_∞ constant, the only dimensionless groups that appear in the boundary conditions are those associated with the body shape. Provided the simplified equations (Eqs. 4.5–4.7) are valid, the only other dimensionless groups are the Rayleigh and Prandtl numbers. Thus, for a given body shape,

$$Nu = \frac{qL}{A\Delta Tk} = f(Ra, Pr) \tag{4.8}$$

where A is the surface area transferring the total heat rate q .

The role of the Prandtl number and its relative importance can be surmised by inspecting Eqs. 4.6 and 4.7. For $Pr \gg 1$, the buoyancy force that drives the motion (term IV in Eq. 4.6) can be seen to be balanced almost exclusively by the viscous force (term III). With this approximation, and because, for $Pr \gg 1$, Pr disappears from Eq. 4.7, Ra is the only remaining dimensionless group in the simplified equations. For $Pr \ll 1$ the viscous force is unimportant, and the buoyancy force must be balanced by the dynamic pressure and inertial terms; in this case the product $Ra Pr$ remains as the only dimensionless group. It is therefore concluded that

$$Nu = f(Ra) \quad \text{for } Pr \gg 1 \tag{4.9a}$$

$$Nu = f(Ra Pr) \quad \text{for } Pr \ll 1 \tag{4.9b}$$

and the Prandtl number governs the relative importance of viscous and inertial forces in the problem.

Validation of the Simplified Equations. Steady-state laminar solutions to the simplified equations for flow around a long horizontal circular cylinder immersed in air with both T_∞ and T_w constant have been obtained by Kuehn and Goldstein [165] and Fujii et al. [101], using numerical methods. Their results, in terms of the Nusselt number, are plotted in Fig. 4.2,

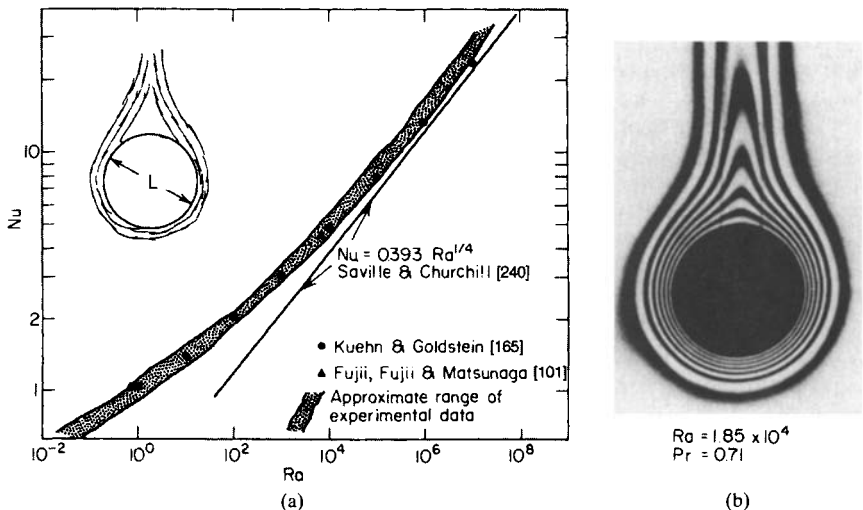

FIGURE 4.2 Measurements and predictions for a circular cylinder (a). (b) shows isotherms for natural convection around a horizontal cylinder. (Courtesy of ERG Eckert.)

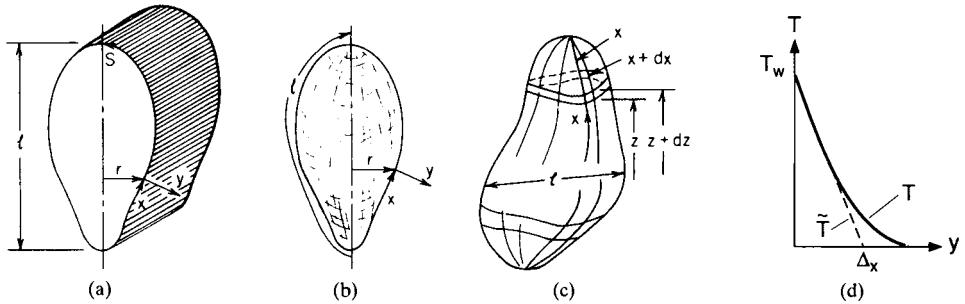

FIGURE 4.3 Surface coordinate systems for two-dimensional (a), axisymmetric (b), and three-dimensional (c) natural convection flows; (d) is a schematic of the temperature distribution near the boundary.

together with the band in which the experimental data for this problem lie. The agreement is good; the differences for $Ra \geq 10^6$ are believed to be due to turbulence, which is not included in their steady-state laminar solution. This comparison lends support to the approximations inherent in the simplified equations of motion.

Thin-Layer Approximation. Laminar analyses often make the further approximation that the boundary layer is so thin that when the simplified equations of motion are rewritten in terms of local surface coordinates, i.e., in terms of the x and y of Fig. 4.3a, several terms normally associated with curvature effects can be dropped. The Nusselt number equation, based on solutions to such laminar “thin-layer” equation sets, always takes the form

$$Nu = c Ra^{1/4} \quad (4.10)$$

where c is independent of Ra but does depend on geometry and Prandtl number. For example, $c = 0.393$ for the horizontal circular cylinder in air ($Pr \approx 0.71$) [240]. Plotted in Fig. 4.2, Eq. 4.10 with this value of c falls consistently below the experimental data; also (since no single power law can fit the data) its functional form is incorrect. At high Ra it approaches Kuehn and Goldstein’s laminar solution to the complete simplified equations of motion, but, as already discussed, the presence of turbulence has rendered laminar solution invalid in this range.

The thin-layer approximation fails because natural convective boundary layers are not thin. From the interferometric fringes in Fig. 4.2b (which are essentially isotherms), the thermal boundary layer around a circular cylinder is seen to be nearly 30 percent of the cylinder diameter. For such thick boundary layers, curvature effects are important. Despite this failure, thin-layer solutions provide an important foundation for the development of correlation equations, as explained in the section on heat transfer correlation method.

Problem Classification

Classification of Flow. The flow near bodies like that in Fig. 4.1a can be classified into one of three types: two-dimensional (2D), axisymmetric, and three-dimensional (3D). The flow is 2D if the body is invariant in cross-sectional shape along a long horizontal axis (e.g., a long horizontal circular cylinder). An axisymmetric flow takes place near a body (Fig. 4.3b) whose shape can be generated by revolving a body contour about a vertical line; for example, a sphere is generated by rotating a semicircle. If the body meets neither the 2D or axisymmetric requirements, its flow is classified as 3D; this class includes the flow around 2D and axisymmetric bodies whose axes have been tilted.

In addition to this geometric classification, the flow can be classified as fully laminar (i.e., laminar over the entire body), fully turbulent (turbulent over the entire body), or laminar and

turbulent (i.e., laminar over one portion and turbulent over the other). Laminar flow is confined to a boundary layer, but turbulent flow may be either attached or detached, as discussed in the section on turbulent Nusselt number.

Thermal Boundary Conditions. The simplest thermal boundary conditions are T_w and T_∞ , both specified constants. If T_∞ varies, it is assumed to be a function only of the elevation z ; also, dT_∞/dz is always positive, since, with β positive, a situation where dT_∞/dz is negative is always unstable and cannot be maintained in an extensive fluid. Either T_w or q'' may be specified on the body surface. The difference between the temperature at a given point on the body and T_∞ at the same elevation is denoted ΔT ; $\overline{\Delta T}$ is the area-weighted average value of ΔT over the surface, and ΔT_0 is an arbitrary reference temperature difference, usually set equal to $\overline{\Delta T}$. If ΔT is positive over the lower part of the body and negative over the upper part, the surface flows over each part are in opposite directions, and these two flows meet and detach from the body near the line on the surface where $\Delta T = 0$.

Direction of Heat Transfer (Cooling versus Heating). The relationship of Nu to Ra and Pr for a heated body is precisely the same as when the body is inverted and cooled, except that $T_w - T_\infty$ is replaced by $T_\infty - T_w$. This principle implies, for example, that the relationship for the heated triangular cylinder in Fig. 4.4a is identical to that for the inverted cooled triangular cylinder in Fig. 4.4b. In this chapter it is normally assumed that the surface is heated, and the results for a cooled surface can be inferred from results for a corresponding heated surface by using the above principle.

FIGURE 4.4 The Nusselt number for a heated body (a) is the same if the same body is cooled and inverted (b).

Definition of Surface Angle ζ . Let $\hat{\mathbf{b}}$ be the unit vector in the direction of the buoyancy force as follows. For $T_w > T_\infty$, $\hat{\mathbf{b}}$ is directed vertically upward as shown in Fig. 4.5a and c, and for $T_w < T_\infty$, $\hat{\mathbf{b}}$ is directed vertically downward (Fig. 4.5b and d). The unit outward normal from the surface is $\hat{\mathbf{n}}$, and the angle between $\hat{\mathbf{n}}$ and $\hat{\mathbf{b}}$ is defined as the surface angle ζ . For $0^\circ \leq \zeta < 90^\circ$, as in Fig. 4.5c and d, the buoyancy force has components along and away from the surface. For $90^\circ < \zeta \leq 180^\circ$, Fig. 4.5a and b, the buoyancy force is directed along and into the surface. Clearly, ζ varies locally over a curved surface.

Heat Transfer Correlation Method

Overview. The heat transfer correlations given in subsequent sections draw on a certain paradigm, which is outlined in this section. Strictly, the reader need not be aware of this

FIGURE 4.5 Definition of surface angle ζ for heated and cooled surfaces. For $90^\circ \leq \zeta \leq 180^\circ$ the flow remains attached, while it may detach if $0^\circ \leq \zeta < 90^\circ$.

paradigm to use the equations. On the other hand, knowing something of it will assist the reader in interpreting the results and in extending the results to shapes not mentioned. Briefly, the idea is to obtain an equation for the laminar Nusselt number Nu_l that would be valid for the hypothetical situation where the flow is always fully laminar over the entire surface, to obtain an equation for the turbulent Nusselt number, Nu_t , that would be valid for the hypothetical situation where the flow is always fully turbulent at all surface locations, and to combine the equations for Nu_l and Nu_t to obtain an expression for Nu that is valid for all cases: wholly laminar, wholly turbulent, or partly laminar and partly turbulent.

The equation for the laminar Nusselt number Nu_l is obtained in a two-step procedure. In the first step, not only is the flow idealized as everywhere laminar, but the boundary layer is treated as thin. There results from this idealization the equation for the laminar thin-layer Nusselt number Nu^T . As already explained, natural convection boundary layers are generally not thin, so the second step is to correct Nu^T to account for thick boundary layers. This correction uses the method of Langmuir [175]. The corrected Nusselt number is the laminar Nusselt number Nu_l .

Conduction Nusselt Number Nu_{COND} . It is the aim of the method to give expressions for Nu (defined by Eq. 4.8, where L is any convenient length scale) that cover the entire range in Ra from zero to infinity, so one needs to consider the Nusselt number in the limit where $Ra \rightarrow 0$. For $Ra \rightarrow 0$, there is no fluid motion, and (with the possible exception of radiation) heat transfer is by conduction only. The Nusselt number that applies in this limit is therefore called the conduction Nusselt number Nu_{COND} . Nu_{COND} is zero for 2D flows and nonzero for 3D flows. For a sphere of radius D , for example, $Nu_{COND} = 2L/D$. Except for simple body shapes—for which values of Nu_{COND} may be available in the literature (see, for example, Ref. 292)—a detailed conduction analysis may be required to determine Nu_{COND} . On the other hand, the work of Chow and Yovanovich [296] and, later, of Yovanovich [292] has shown that the quantity $(\sqrt{A}/L) Nu_{COND}$ is highly insensitive to the body shape, ranging from 3.391 to 3.609 over a very wide range of shapes, including cubes, lenses, ellipsoids, and toroids; for an ellipsoid, $(\sqrt{A}/L) Nu_{COND}$ ranges from 3.55 to 3.19 as the ratio of major to minor axis ranges from 1 to 10^6 . In the absence of a conduction analysis for a particular body shape, the Yovanovich method provides a quick method for estimating Nu_{COND} .

Laminar Thin-Layer Nusselt Number Nu^T . Raithby and Hollands [223] derived the following equation (similar to Eq. 4.10) as a close approximation to the full solution of the thin-layer equations:

$$\text{Nu}^T = G \bar{C}_\ell \text{Ra}^{1/4} \tag{4.11}$$

where

$$\text{Ra} = \frac{g\beta\Delta T_0 L^3}{\nu\alpha} \tag{4.12}$$

and L is any convenient reference length (the dependence on this length cancels out of the equations). G is a ratio of integrals (both of which can often be evaluated in closed form) that depend on the shape of the body and on thermal boundary conditions, and \bar{C}_ℓ is an approximately universal function of Prandtl number Pr given by Churchill and Usagi [54]

$$\bar{C}_\ell = \frac{0.671}{[1 + (0.492/\text{Pr})^{9/16}]^{4/9}} \tag{4.13}$$

\bar{C}_ℓ is tabulated in Table 4.1. For the special case of a heated body with constant T_w and T_∞ , the G ratio is given for both 2D and axisymmetric flows by

$$G = \frac{L^{1/4}}{\int_0^S r^i dx} \left[\int_0^S r^{4i/3} \sin^{1/3} \zeta dx \right]^{3/4} \tag{4.14}$$

where index $i = 0$ if the flow is 2D and $i = 1$ if the flow is axisymmetric (see the section on classification of flow). The body coordinates r and x in Eq. (4.14) are defined in Fig. 4.3, x being the distance measured along the surface of the body from the lowest point on the body, and S is the value of x at the highest point on the body. The angle ζ in the integral is the surface angle explained previously and in Fig. 4.5. Raithby and Hollands [225–227] and (for the special case of $\text{Pr} \rightarrow \infty$) Stewart [264] have given more general expressions covering the cases of 3D flows and nonuniform T_w and T_∞ . Hassani and Hollands [126, 127] gave the following approximate equation for G for 3D flows: $G = (L_f L \mathcal{P}^2 / A^2)^{1/4}$, where L_f is the vertical distance from the lowest point on the body to the highest, and \mathcal{P} is the vertically averaged perimeter of the body defined by

$$\mathcal{P} = \frac{1}{L_f} \int_0^{L_f} \mathcal{P}(z) dz \tag{4.15}$$

where $\mathcal{P}(z)$ is the local perimeter of the body at elevation z above the lowest point on the body. [A horizontal plane at height z will intersect the surface of the body at a flat curve; $\mathcal{P}(z)$ is the circumference of this curve.] For 2D flow, this equation for G reduces to $G = (4L_f L / P_i^2)^{1/4}$, where P_i is the perimeter of the cylinder’s cross section.

To further characterize the laminar thin-layer heat transfer, it is helpful to introduce the idea of the local and average conduction layer thicknesses, Δ_x and Δ , respectively: Δ_x is defined in Fig. 4.3d as the local distance from the wall at which the linear \tilde{T} profile intersects T_∞ , it being understood that the \tilde{T} profile is a hypothetical linear temperature profile that has the same value at the surface and the same slope at the surface as the true temperature profile. Stated differently, Δ_x is the local thickness of stationary fluid that would offer the same ther-

mal resistance as the thin boundary layer. The average conduction layer thickness $\bar{\Delta}$ is an area-weighted harmonic-mean average of Δ_x taken over the whole body surface. One can show that $\bar{\Delta}$ is related to the thin-layer average Nusselt number by

$$\bar{\Delta} = \frac{L}{\text{Nu}^T} \quad (4.16)$$

Fully Laminar Nusselt Number Nu_ℓ . As the next step in the correlation method, the thin-layer solution is corrected to account for thick-layer effects [175, 223]. The body is surrounded by a uniform layer of stationary fluid of thickness $\bar{\Delta}$, and outside that thickness the fluid temperature is taken to be T_∞ . The heat transfer that would occur across this layer is determined by a conduction analysis and converted to a Nusselt number, and this Nusselt number is Nu_ℓ .

For example, to determine Nu_ℓ for the case where the body is a very long horizontal isothermal circular cylinder of diameter D , the relevant heat transfer would then be that by heat conduction across a cylindrical annulus of inner diameter D , inner temperature T_w , outer diameter $D + 2\bar{\Delta}$, and outer temperature T_∞ (assumed constant). Calculating this heat transfer by standard methods, substituting Eq. 4.16, and converting to a Nusselt number yields

$$\text{Nu}_\ell = \frac{C_1}{\ln(1 + C_1/\text{Nu}^T)}; \quad C_1 = \frac{2\pi L}{P_i} \quad (4.17)$$

where the reference length L is equated to the diameter D , and P_i is the perimeter of the cylinder. The work of Hassani et al. [129] on conduction across layers of uniform thickness on very long cylinders of various cross section, has shown, in effect, that Eq. 4.17 applies to triangular, rectangular, and trapezoidal cross sections as well, and by implication to cylinders of almost any convex cross section.

As a second example, which also will be extended to a more general case, consider the case where the body is an isothermal sphere and, again, T_∞ is uniform. The relevant conduction heat transfer in this case is that between two concentric spheres of diameters D and $D + 2\bar{\Delta}$, respectively. Solving this elementary problem in heat conduction, recasting in terms of the Nusselt number, substituting from Eq. 4.16, and then recognizing that the $2L/D$ is the conduction Nusselt number Nu_{COND} , one obtains

$$\text{Nu}_\ell = \text{Nu}_{\text{COND}} + \text{Nu}^T \quad (4.18)$$

The work of Hassani and Hollands [128] on conduction across layers of uniform thickness applied to 3D bodies of various shape has shown that Eq. 4.18 applies approximately to other 3D body shapes as well. (Note that the actual Nu_{COND} for the body at hand must be used.) The work of Hassani and Hollands also shows that slightly better results for such nonspherical bodies would be obtained if Eq. 4.18 is modified as follows:

$$\text{Nu}_\ell = ((\text{Nu}_{\text{COND}})^n + (\text{Nu}^T)^n)^{1/n} \quad (4.19)$$

where n is a parameter best determined by fitting to experimental data. If data are not available, $n \approx 1.07$ can be used as a rough approximation; alternatively, a more accurate value can be obtained by using a formula proposed by Hassani and Hollands [128].

A special case arises when the length of a horizontal cylinder greatly exceeds its diameter. If the cylinder is treated as infinite, Eq. 4.17 would yield the result $\text{Nu}_\ell \rightarrow 0$ as $\text{Ra} \rightarrow 0$. Nu_ℓ should, however, approach Nu_{COND} as $\text{Ra} \rightarrow 0$, where Nu_{COND} is small but nonzero because the cylinder length is not truly infinite. As a rough approximation for this case:

$$\text{Nu}_\ell = \left[\frac{C_1}{\ln(1 + C_1/\text{Nu}^T)}, \text{Nu}_{\text{COND}} \right]_{\text{max}}; \quad C_1 = \frac{2\pi L}{P_i} \quad (4.20)$$

where $[x, y]_{\text{max}}$ requires that the maximum of x and y is to be taken.

Turbulent Nusselt Number Nu_t . This section presents a model for the Nusselt number-Rayleigh number relation applying in the limiting case where the flow is turbulent at all locations on the surface, i.e., in the asymptote $Ra \rightarrow \infty$.

Model Description. The chief characteristic of turbulent heat transfer is that (for a given Prandtl number and Rayleigh number) the heat transfer at a point on the surface depends only on the local surface angle ζ (Fig. 4.5), and is independent of how far the point is from the leading edge. It follows that

$$Nu_{t,x} = C_t(\zeta) Ra_x^{1/3} \quad (4.21)$$

where $Nu_{t,x}$ is the local Nusselt number and the function $C_t(\zeta)$ depends only on the Prandtl number. (The appearance of x in this equation is an artifact of the nomenclature; when $Nu_{t,x}$ and Ra_x are replaced by their definitions, the x on each side of the equation cancels out.) If one integrates this local Nusselt number over the entire body surface to get the total heat transfer, one obtains

$$Nu_t = \bar{C}_t Ra^{1/3} \quad (4.22)$$

where

$$\bar{C}_t = \frac{1}{A} \int_A C_t(\zeta) \left(\frac{T_w - T_\infty}{\Delta T_0} \right)^{4/3} dA \quad (4.23)$$

Equation for C_t . A number of experiments at different Prandtl numbers (mostly on tilted plates) have been carried out that permit the function $C_t(\zeta)$ to be modeled. Observation has also revealed that there are two patterns of turbulent flow: detached and attached. Attached flow, where the flow sticks to the body contour, is best exemplified by the flow on a vertical plate, and the $C_t(\zeta) = C_t(90^\circ)$ applying in this situation is denoted C_t^V . Detached flow, where turbulent eddies rise away from the heated surface, is best exemplified by the flow on a horizontal upward-facing (heated) plate, and the $C_t(\zeta) = C_t(0^\circ)$ applying in this situation is denoted C_t^U . The first step in establishing the $C_t(\zeta)$ function has been to model how C_t^U and C_t^V depend on the Prandtl number; the equations for these quantities (justified later) that have been found to best fit currently available data are

$$C_t^V = \frac{0.13 Pr^{0.22}}{(1 + 0.61 Pr^{0.81})^{0.42}} \quad (4.24)$$

and

$$C_t^U = 0.14 \left(\frac{1 + 0.0107 Pr}{1 + 0.01 Pr} \right) \quad (4.25)$$

C_t^V and C_t^U are tabulated in Table 4.1.

For other angles, we can make use of the fact that the attached flow on an inclined plate would look just like the corresponding flow on the vertical plate if the gravity on the vertical plate were changed from g to $g \sin \zeta$; in other words, the flow is driven by the component of the buoyancy force that is directed along the surface. Since (from Eq. 4.22) $Nu_x \propto Ra_x^{1/3}$, it follows that, in attached flow,

$$C_t = C_t^V \sin^{1/3} \zeta \quad (4.26)$$

In detached flow, the mixing of the boundary layer fluid and the ambient fluid is driven by the component of gravity normal to the surface. Since this mixing dominates the heat exchange, the heat transfer from a tilted upward-facing plate can be obtained from the equation for a horizontal plate by replacing g by $g \cos \zeta$. For the flow to remain detached, however, $g \cos \zeta$ must remain positive. Since $Nu_x \propto Ra_x^{1/3}$, it follows directly that, in detached flow,

$$C_t = C_t^U [\cos \zeta, 0]_{\max}^{1/3} \quad (4.27)$$

Equation 4.26 applies for attached flow and Eq. 4.27 for detached flow. Experience has indicated that the flow pattern actually observed at a given location on the body will be the one that maximizes the local heat transfer. From this it follows that

$$C_i = [C_i^U [\cos \zeta, 0]^{1/3}_{\max}, C_i^V \sin^{1/3} \zeta]_{\max} \quad (4.28)$$

Equation 4.28 for C_i is substituted into Eq. 4.23 to obtain \bar{C}_i . This requires an integration over the surface. The values of \bar{C}_i in the equations provided in this chapter were obtained in this way.

For geometries not covered in this chapter, it may be more convenient to use the following approximate equation for \bar{C}_i [128], which applies for $0.7 \text{ Pr} < 2000$:

$$\bar{C}_i = 0.0972 - (0.0157 + 0.462C_i^V) \frac{A_h}{A} + (0.615C_i^V - 0.0548 - 6 \times 10^{-6} \text{ Pr}) \frac{L_f \mathcal{P}}{A} \quad (4.29)$$

A_h is the area of any horizontal downward-facing heated parts (or upward-facing horizontal cooled parts) of the body's surface.

The recommended equation for $C_i(\zeta)$ is provisional because of the lack of data and the disagreement among different sets of measurements. Since the recommended $C_i(\zeta)$ affects many of the correlations in this chapter, the user of these correlations should understand the experimental foundation for Eq. 4.24 for C_i^V and Eq. 4.25 for C_i^U . The following paragraphs provide the necessary background.

Discussion of C_i^V Equation. Equation 4.24 for C_i^V has been forced to pass through 0.103 for gases ($\text{Pr} = 0.71$), and through the value of 0.064 measured by Lloyd et al. [187] for $\text{Pr} = 2000$. There is no experimental confirmation of Eq. 4.24 for $\text{Pr} < 0.7$. The data for gases ($\text{Pr} \approx 0.7$) are tightly clustered around 0.103, provided $\Delta T/T \ll 1$. For water, the measurements of Fujii and Fujii [99] yield $C_i^V \approx 0.13$, compared to 0.11 by Vliet and Liu [275]; the equation passes near the lower of these values. The equation agrees with values obtained from the data of Fujii and Fujii [99] for oils ($\text{Pr} = 20\text{--}200$) if all properties are evaluated at a reference temperature of $T_e = 0.75T_w + 0.25T_\infty$. For $\text{Pr} = 2000$, the value obtained from the data of Moran and Lloyd [197] falls about 15 percent below the benchmark value of 0.064 obtained by Lloyd et al. [187] using the same technique.

The form of Eq. 4.24 is surprising since, based on Eq. 4.9a and b, one would expect C_i^V to increase monotonically with increasing Pr and approach the $\text{Pr} \rightarrow \infty$ asymptote from below. It is therefore not clear why the high-quality data of Lloyd et al. [187] at $\text{Pr} \approx 2000$ give a C_i^V value less than that for water and air. The apparent corroboration by Fujii and Fujii [99] for oils is also highly uncertain because of the extreme sensitivity to the reference temperature used. Using $T_f = 0.5T_w + 0.5T_\infty$ as the reference temperature, instead of T_e , raises the value of C_i^V by about 20 percent, to almost the same value as for water.

The C_i^V values for gases given by Eq. 4.24 assume that for $\Delta T/T_\infty \ll 1$, or $T_w/T_\infty \rightarrow 1$. If this condition is not met for a vertical plate, Eq. 4.21 should be rewritten as

$$\text{Nu}_{L,x} = C_i^V f \left(\frac{T_w}{T_\infty} \right) \text{Ra}_x^{1/3} \quad (4.30)$$

Measurements by Pirovano et al. [220, 221], Siebers et al. [251], and Clausing et al. [61, 63] suggest quite different values of f . Until further data become available, the recommended equation for f in Eq. 4.30 is

$$f \left(\frac{T_w}{T_\infty} \right) = 1.0 + 0.078 \left(\frac{T_w}{T_\infty} - 1 \right) \quad (4.31)$$

The equations provided in this chapter assume that $\Delta T/T_\infty \rightarrow 0$. For large ΔT , the equation for C_i^V should be replaced by fC_i^V , where f is given by Eq. 4.31. It is concluded that there is considerable uncertainty in the recommended equation for C_i^V for $\text{Pr} > 1$ and for large T_w/T_∞ . This is perhaps the most important unresolved fundamental issue in the equations used to estimate natural convection heat transfer.

Discussion of C_i^U Equation. Equation 4.25 for C_i^U has been forced to agree with the value 0.15 measured by Lloyd and Moran [297] at $\text{Pr} \approx 2000$, and forced to pass through $C_i^U = 0.14$ for air ($\text{Pr} = 0.71$) and water ($\text{Pr} = 6$). The latter values are deduced from measurements of heat transfer across horizontal fluid layers (see the section on natural convection within

enclosures) that, for $Ra \rightarrow \infty$, are correlated by $Nu = c Ra^{1/3}$; in this limit the relation between c and C_i^U is $C_i^U = c2^{4/3}$. $C_i^U = 0.14$ for air and water agrees to within experimental scatter with measurements of heat transfer from horizontal upward-facing plates obtained by Yousef et al. [290], Bovy and Woelk [23], Clausing and Berton [62], Grober et al. [119], Hassan and Mohamed [123], Fishenden and Saunders [98], Al-Arabi and El-Riedy [4], Weiss [282], and Fujii and Imura [103]. The single data point for mercury ($Pr = 0.024$), deduced from the horizontal layer measurements of Globe and Dropkin [114], is $C_i^U = 0.13$, which compares well with 0.14 from Eq. 4.25.

Blending of Laminar and Turbulent Nusselt Numbers. The previous two sections provided heat transfer equations for the cases where there is laminar heat transfer from the entire body, (Nu_l), and turbulent heat transfer from the entire body, (Nu_t). To obtain a fit to heat transfer data over the entire range of Ra , the blending equation of Churchill and Usagi [54] is used:

$$Nu = (Nu_l^m + Nu_t^m)^{1/m} \quad (4.32)$$

The appropriate value of m , which generally lies in the range from 4 to 20, is chosen so as to give the best fit to the experimental data. Where no data for the body shape at hand are available, the value for a known body of similar shape is tentatively recommended; Tables 4.2 (found on page 4.24) and 4.3 (found on pages 4.26–4.31) give values of m for a range of shapes. Minor modifications to this prescription are sometimes implemented in order to more accurately represent the dependence of heat transfer on Ra through the transition.

The aim of the correlation method has been to give an equation for Nu (Ra) that covers the entire range of Ra from zero to infinity. On the other hand, the Rayleigh number range of interest in the particular problem at hand may be low enough to ensure that laminar heat transfer dominates. In this case it may be preferable to simplify the equation by assuming that the turbulent term in Eq. 4.32 does not contribute appreciably, and take Nu as being equal to Nu_l . This is allowable if, at the highest Rayleigh number of interest, the difference between the calculated values of Nu and Nu_l is acceptably small.

Although certain of the steps in the development of the Nu (Ra) function given in this section have assumed that the body is convex, in practice, a minor degree of concavity has not been found to compromise its usefulness. For example, it has been applied to long cylinders with an “apple core” cross section and to 3D bodies in the shape of an apple core. A test is to examine the degree to which the conduction layer on one part of the surface overlaps with that on another part; if the degree of overlap is modest, the method should be useful. An extreme case of concavity is the case of a body with a vertical hole passing through it. Provided the conduction layer thickness Δ (Eq. 4.16) is thinner than, say, about $1/5$ the hole radius, the method should continue to work satisfactorily. If not, the hole should be treated separately as an open cavity, using methods explained in the section on open cavity problems.

EXTERNAL NATURAL CONVECTION

Equations are presented in this section for evaluating the heat transfer by natural convection from the external surfaces of bodies of various shapes. The correlation equations are of the form described in the section on the heat transfer correlation method, and the orientation of the surface is given by the surface angle ζ defined in Fig. 4.4. Supporting experimental evidence for each such equation set is outlined after each equation tabulation. The correlations are in terms of Nu , Ra , and Pr , parameters that involve physical properties, a length scale, and a reference temperature difference. Rules for the evaluation of property values are provided in the nomenclature, and the relevant length scale and reference temperature difference are provided in a separate definition sketch for each problem.

$$\text{Nu} = \frac{\bar{q}''L}{\Delta T_k} \quad \text{Nu}_x = \frac{q''_x x}{\Delta T_k} \quad \text{Ra} = \frac{g\beta\Delta T L^3}{\nu\alpha} \quad \text{Ra}_x = \frac{g\beta\Delta T x^3}{\nu\alpha}$$

$$\text{Ra}^* = \frac{g\beta q'' L^4}{\nu\alpha k} = \text{Ra Nu} \quad \text{Ra}_x^* = \frac{g\beta q'' x^4}{\nu\alpha k} = \text{Ra}_x \text{Nu}_x$$

FIGURE 4.6 Definition sketch for natural convection on a vertical plate with uniform wall temperature or uniform heat flux.

Flat Plates

Vertical Flat Plate with Uniform T_w and T_∞ , $\zeta = 90^\circ$

Correlation. In terms of quantities defined in Fig. 4.6 and the nomenclature, the total heat transfer from a wide ($W \gg L$) vertical isothermal plate can be estimated from the following equations:

$$\text{Nu}^T = \bar{C}_\ell \text{Ra}^{1/4} \quad (4.33a)$$

$$\text{Nu}_\ell = \frac{2.0}{\ln(1 + 2.0/\text{Nu}^T)} \quad (4.33b)$$

$$\text{Nu}_t = C_t^V \text{Ra}^{1/3} / (1 + 1.4 \times 10^9 \text{Pr}/\text{Ra}) \quad (4.33c)$$

$$\text{Nu} = [(\text{Nu}_\ell)^m + (\text{Nu}_t)^m]^{1/m} \quad m = 6 \quad (4.33d)$$

For large $\Delta T/T$, C_t^V should be replaced by $C_t^V f$, where f is given by Eq. 4.31.

Comparison With Data. Figure 4.7 compares Eq. 4.33 to four sets of measurements for gases for small $\Delta T/T$. The range of experimental data is $10^{-1} < \text{Ra} < 10^{12}$, and the RMS deviation of the data from the equation is 5 percent. The data of Saunders [239] have been reevaluated using more accurate property values. The data of Pirovano et al. [220, 221] are for their lowest T_w/T_∞ ratio, and only the laminar data of Clausing and Kempka [63] are shown. Equation 4.33 also closely fits the data for other fluids compiled by Churchill [56].

Outstanding Issues. There are no data at low Ra for $\text{Pr} < 0.7$. There is also uncertainty surrounding the expression for C_t^V (Eq. 4.24) for both $\text{Pr} \ll 1$ and $\text{Pr} \gg 1$. The transition in Eq. 4.33 is assumed to depend exclusively on Ra/Pr ; in fact, the transition appears to also depend on the vertical stratification within the ambient medium and on the size of ΔT .

FIGURE 4.7 Comparison of Eq. 4.33 with data for an isothermal, vertical flat plate in air.

Vertical Plate With Uniform Surface Heat Flux and Constant T_∞ . When the surface heat flux, q''_w , is uniform and known, values of Nu_x and Nu are used respectively to compute the local temperature difference ΔT and the average temperature difference $\overline{\Delta T}$. Parameters related to this problem are defined in Fig. 4.6 and in the nomenclature.

Calculation of Local ΔT . The local ΔT can be found from the value of Nu_x calculated from the following equation for $Ra^* \geq 0.1$.

$$Nu_x^T = H_\ell (Ra_x^*)^{1/5} \quad H_\ell = \left(\frac{Pr}{4 + 9\sqrt{Pr} + 10 Pr} \right)^{1/5} \quad (4.34a)$$

$$Nu_{\ell,x} = 0.4 / \ln(1 + 0.4 / Nu_x^T) \quad (4.34b)$$

$$Nu_{t,x} = \frac{(C_1^V)^{3/4} (Ra_x^*)^{1/4}}{1 + (C_2 Pr / Ra_x^*)^3} \quad \begin{matrix} 10^{12} < C_2 < 2 \times 10^{13} \\ C_2 = 7 \times 10^{12} \quad (\text{nominal}) \end{matrix} \quad (4.34c)$$

$$Nu_x = ((Nu_{\ell,x})^m + (Nu_{t,x})^m)^{1/m} \quad m = 3.0 \quad (4.34d)$$

The value of C_2 determines the transition between laminar and turbulent heat transfer. A nominal value is $C_2 = 7 \times 10^{12}$.

Comparison With Data. Equation 4.34 is in excellent agreement with the data of Humphreys and Welty [147] and Chang and Akins [40] for $Pr = 0.023$ (mercury), but the data lie only in the laminar regime. There is also good agreement with measurements of Goldstein and Eckert [115], Vliet and Liu [275], and Qureshi and Gebhart [222] for water, although the observed transition depends on the level of heat flux. By choosing an appropriate value for C_2 for each q'' , Fig. 4.8 shows that Eq. 4.34 can be made to fit each data set. For a nominal value

FIGURE 4.8 Comparison of local heat transfer measurements of Qureshi and Gebhart [222] with Eq. 4.34 for a uniform heat flux, vertical flat plate in water.

by $C_2 = 7 \times 10^{12}$, Eq. 4.34 gives good agreement with measurements for oils, $Pr \approx 60$ and $Pr \approx 140$, except in the transition region. Fujii and Fujii [99] have shown that strong vertical temperature gradient in the ambient fluid also affects the value of Nu_x in the transition regime.

Calculation of $\overline{\Delta T}$. In some cases involving uniform q'' , it is sufficient to know the average temperature difference, defined as

$$\overline{\Delta T} = \frac{1}{A} \int_A (T_w - T_\infty) dA \tag{4.35}$$

This is obtained from the average Nusselt number Nu defined in Fig. 4.6. A rough estimate of Nu can be obtained for $Ra \geq 10^5$ by using the equations in the section on vertical flat plates with uniform T_w and T_∞ , $\zeta = 90^\circ$, with ΔT replaced by $\overline{\Delta T}$. For higher accuracy, and for convenience since Ra^* is used in place of Ra , use the following equation set:

$$Nu^T = \overline{H}_\ell Ra^{*1/5} \quad \overline{H}_\ell = \frac{6}{5} \left(\frac{Pr}{4 + 9\sqrt{Pr} + 10 Pr} \right)^{1/5} \tag{4.36a}$$

$$Nu_\ell = \frac{1.0}{\ln(1 + 1.0/Nu^T)} \tag{4.36b}$$

$$Nu_t = (C_1')^{3/4} Ra^{*1/4} \left/ \left(1 + \left(\frac{C_2 Pr}{Ra^*} \right)^{0.4} \right) \right. \quad C_2 \approx 7 \times 10^{12} \tag{4.36c}$$

$$Nu = (Nu_t^m + Nu_\ell^m)^{1/m} \quad m = 6.0 \tag{4.36d}$$

\overline{H}_ℓ is tabulated in Table 4.1.

Vertical Plates of Various Planforms. There is a class of vertical plates, such as shown in Fig. 4.9, for which any vertical line on the plate intersects the edge only twice. When such plates are isothermal, the thin-layer laminar Nusselt number Nu^T can be calculated [225] by dividing the surface into strips of width Δx and length $S(x)$, applying Eq. 4.33a to compute the heat transfer from each strip, adding these to obtain the total (thin-layer) heat transfer, and using this heat transfer to calculate Nu^T . The result can be expressed as

$$Nu^T = G \overline{C}_\ell Ra^{1/4} \quad G = \frac{\ell^{1/4} \int_0^w S^{3/4} dx}{A} \tag{4.37a}$$

where ℓ is any characteristic dimension of the surface. This also results from the application of Eq. 4.14. Figure 4.9 shows examples of the constants G for three body shapes.

FIGURE 4.9 Definition sketch for natural convection from plates of various planform.

For laminar heat transfer, the correlations for such disks have been given by Eq. 4.18 [227]:

$$Nu_\ell = Nu_{COND} + Nu^T \tag{4.37b}$$

Yovanovich and Jafarpur [294] have shown that, for the length scales in Fig. 4.9,

$$Nu_{COND} = \frac{\ell}{\sqrt{A}} Nu_{\sqrt{A},COND} \tag{4.37c}$$

If the plate is heated on one side only, but is immersed in a full space $Nu_{\sqrt{A},COND} \approx 3.55$, if the plate is heated on one side and immersed in a half-space (i.e., the heated plate is embedded in an infinite adiabatic surface) $Nu_{\sqrt{A},COND} \approx 2.26$, and if the plate is heated on both sides and immersed in a full space $Nu_{\sqrt{A},COND} \approx 3.19$. In all cases A is the surface area that is active. For a general equation for Nu : substitute Eqs. 4.37a and c into Eq. 4.37b to obtain the equation for Nu_ℓ , use Eq. 4.33 for Nu_ℓ , and substitute these equations for Nu_ℓ and Nu , into Eq. 4.33 to obtain the equation for Nu .

The isothermal surface correlation just provided can also be used to estimate Nu for a uniform flux boundary by replacing ΔT by $\Delta \bar{T}$. For higher accuracy, use Eq. 4.36a to find the thin-layer $\Delta \bar{T}$ for each strip, find $\Delta \bar{T}$ for the entire surface by area weighting the $\Delta \bar{T}$ for each strip (Eq. 4.35), and calculate Nu^T from the area weighted $\Delta \bar{T}$. This results in

$$Nu^T = C_2 \bar{H}_\ell Ra^{*1/5} \quad C_2 = \frac{A \ell^{1/5}}{\int_0^w S^{6/5} dx} \tag{4.38}$$

where ℓ is again any characteristic dimension of the surface, and terms are defined in Fig. 4.9. To find Nu , substitute Eq. 4.38 for Nu^T and Eq. 4.37c for Nu_{COND} into Eq. 4.37b to obtain an expression for Nu_ℓ . Use this Nu_ℓ and Eq. 4.36c for Nu , in Eq. 4.36d to obtain Nu .

Horizontal Heated Upward-Facing Plates ($\zeta = 0^\circ$) With Uniform T_w and T_∞

Correlation. For horizontal isothermal plates of various planforms with unrestricted inflow at the edges as shown in Fig. 4.10, the heat transfer is correlated for $1 < Ra < 10^{10}$ by the equation:

$$Nu^T = 0.835 \bar{C}_\ell Ra^{1/4} \tag{4.39a}$$

$$Nu_\ell = \frac{1.4}{\ln(1 + 1.4/Nu^T)} \tag{4.39b}$$

$$Nu_\ell = C_\ell^U Ra^{1/3} \tag{4.39c}$$

$$Nu = ((Nu_\ell)^m + (Nu_i)^m)^{1/m} \quad m = 10 \tag{4.39d}$$

Use of the length scale L^* [116], defined in Fig. 4.10c, is intended to remove explicit dependence on the planform from the correlation.

FIGURE 4.10 Definition sketch for natural convection on a horizontal upward-facing plate of arbitrary planform. Only the top heated surface of area A is heated.

FIGURE 4.11 Comparison of Eq. 4.39 to data for upward-facing heated plates of various planform in air.

Comparison With Data. Figure 4.11 shows that Eq. (39) is in good agreement with measurements for gases ($Pr \approx 0.7$). The Clausing and Berton [62] data shown in the figure have been extrapolated to $T_w/T_\infty = 1$ using their correlation. The scatter in the data of Yousef et al. [290] is due to temporal changes in the heat transfer. Excellent agreement was also found with the data of Goldstein et al. [116] for $1.9 < Pr < 2.5$ for a variety of shapes, but the data of Sahraoui et al. [237] for a disk and flat annular ring, $1 < Ra < 10^3$, fall below this equation. For $Pr > 100$, Eq. 4.39 is in excellent agreement with the measurements of Lloyd and Moran [297] for $10^7 < Ra < 10^9$, and agrees, within the experimental scatter, with the measurements of Lewandowski et al. [179] for $10^2 < Ra < 10^4$.

Horizontal Heated Upward-Facing Plates ($\zeta = 0^\circ$) With Uniform Heat Flux

Correlation. The nomenclature for this problem is also given in Fig. 4.10, where $\overline{\Delta T}$ is the surface average temperature difference. Equation 4.39 should also be used for this case, where the calculated Nu value provides the average temperature difference $\overline{\Delta T}$.

Comparison With Data. Equation 4.39 agrees to within about 10 percent with the data of Fujii and Imura [103] and Kitamura and Kimura [161], for heat transfer in water ($Pr \approx 6$), for $10^4 < Ra < 10^{11}$. Both these experiments were performed using effectively infinite strips of finite width.

Horizontal Isothermal Heated Downward-Facing Plates ($\zeta = 180^\circ$)

Correlation. Definitions and a typical flow pattern for this problem are shown in Fig. 4.12. The heat transfer relations given here assume that the downward-facing surface is substantially all heated; if the heated surface is set into a larger surface, the heat transfer will be reduced. Since the buoyancy force is mainly into the surface, laminar flow prevails up to very high Rayleigh numbers. The following equation can be used for $10^3 < Ra \leq 10^{10}$:

FIGURE 4.12 Definition sketch for natural convection on a downward-facing plate. Only the bottom surface of area A is heated.

$$Nu^T = \frac{0.527}{(1 + (1.9/Pr)^{9/10})^{2/9}} Ra^{1/5} \tag{4.40a}$$

$$Nu_c = \frac{2.5}{\ln(1 + 2.5/Nu^T)} \tag{4.40b}$$

The coefficient in Eq. 4.40a was obtained by fitting the results of the integral analysis of Fujii et al. [102].

Comparison With Data. Measurements for isothermal plates in air are compared to Eq. 4.40 in Fig. 4.13 for rectangular plates. Data lie within about ± 20 percent of the correlation. Measurements have also been done using water, but only with a uniform heat flux boundary condition. For water, the data of Fujii and Imura [103] for a simulated 2D strip lie about 30 percent below Eq. 4.40, but the data of Birkebak and Abdulkadir [20] lie about 3 percent

FIGURE 4.13 Comparison of Eq. 4.40 to data for downward-facing heated plates of various planform in air.

above the correlation. The importance of the heat transfer from the outer edge of the plate is believed to be the cause of such large discrepancies.

Plates at Arbitrary Angle of Tilt. The previous sections provide equations from which to compute the total heat transfer from vertical plates ($\zeta = 90^\circ$), horizontal upward-facing plates ($\zeta = 0^\circ$), and horizontal downward-facing surfaces ($\zeta = 180^\circ$). These equations are the basis for obtaining the heat transfer from tilted plates.

For a wide isothermal plate at any angle of tilt, first compute the heat transfer from Eq. 4.33 (vertical plate) but with g replaced by $g \sin \zeta$, then compute the heat transfer from Eq. 4.40 (downward-facing plate) with g replaced by $g(0, -\cos \zeta)_{\max}$, then compute the heat transfer from Eq. 4.39 (upward-facing plate) with g replaced by $g(0, \cos \zeta)_{\max}$, and take the maximum of the three heat transfer rates. It is important to take maximum heat transfer rather than the maximum Nusselt number, because the Nusselt numbers are based on different length scales.

For plates with small aspect ratio, such as shown in Fig. 4.9, follow the same procedure except use Eq. 4.37b in place of Eq. 4.33b.

Vertical Isothermal Plate in Stably Stratified Ambient

Correlation. For an isothermal vertical plate (see Fig. 4.6) in an ambient fluid whose temperature T_∞ increases linearly with height x , the heat transfer depends on the stratification parameter S , defined by

$$S = \frac{L}{\Delta T} \frac{dT_\infty}{dx} \quad (4.41)$$

where the mean temperature difference $\overline{\Delta T}$ is also the value of $T_w - T_\infty$ at the mid-height of the surface. For $0 \leq S < 2$, $T_w - T_\infty$ is positive over the entire plate; for $S = 2$, $T_w = T_\infty$ at $x = L$; and for $S \rightarrow \infty$ the plate temperature is lower than T_∞ over the top half of the plate and greater than T_∞ over the bottom half.

From laminar thin-layer analysis [41, 225, 226] the value of Nu^T , corrected for stratification effects, is

$$Nu^T = (1 + S/a)^b \overline{C}_\ell Ra^{1/4} \quad S \leq 2 \quad (4.42a)$$

$$= cS^{1/4} \overline{C}_\ell Ra^{1/4} \quad S \geq 2 \quad (4.42b)$$

For gases: $a = 1$, $b = 0.38$, and $c = 1.28$; for water ($Pr \approx 6$): $a = 2$, $b = 0.5$, and $c = 1.19$. For turbulent flow everywhere on the plate and for $S \leq 2$, Nu , is given by

$$Nu_\ell \approx \frac{3}{7S} \left[\left(1 + \frac{S}{2}\right)^{7/3} - \left(1 - \frac{S}{2}\right)^{7/3} \right] \frac{C_\ell^V Ra^{1/3}}{(1 + 1.4 \times 10^9 Pr/Ra)}; \quad S \leq 2 \quad (4.43)$$

To estimate Nu at intermediate Ra for $S \leq 2$, substitute Eq. 4.42 for Nu^T into Eq. 4.33b to obtain Nu_ℓ and use this Nu_ℓ and Nu , from Eq. 4.43 in Eq. 4.33d to find the Nusselt number.

Confirmation of Procedure. This procedure leads to good agreement with the data of Chen and Eichhorn [41] for water, for $2 \times 10^6 < Ra < 3 \times 10^7$, but it is unconfirmed outside this range. The accuracy of Eq. 4.43 is particularly questionable through transition since the transition to turbulence depends on S .

Cylinders

Long Vertical Cylinders, Circular or Noncircular

Correlation. The objective is to calculate the heat transfer from the lateral surface of the long vertical cylinder or wire, where heat transfer from the ends is ignored. See Fig. 4.14 for relevant nomenclature.

$$Nu = \frac{qL}{A\Delta T k}$$

$$Ra = \frac{g\beta\Delta T L^3}{\nu\alpha}$$

$$Nu_\ell = \frac{\zeta}{\ln(1 + \zeta)} Nu_{\ell, Plate}; \quad \zeta = \frac{1.8L/D}{Nu_{Plate}^T} \quad (4.44)$$

$$Ra^* = \frac{g\beta q^* L^4}{\nu\alpha k}$$

$$Nu_{Plate} = \left(\frac{qL}{A\Delta T k} \right)_{Plate}$$

FIGURE 4.14 Definition sketch for natural convection from long vertical cylinders.

For a vertical cylinder of length L and diameter D , first calculate the Nusselt number Nu^T and Nu_ℓ for a vertical flat plate of height L , using Eq. 4.33 if the cylinder is isothermal and Eq. 4.36 if it has uniform heat flux. These Nusselt numbers are based on the length L of the plate (see Fig. 4.6) and are renamed Nu_{Plate}^T and $Nu_{\ell, Plate}$ here. The laminar Nusselt number for the vertical cylinder (defined in Fig. 4.14), Nu_ℓ , is then calculated from

For an isothermal boundary, calculate Nu_i from Eq. 4.33c and substitute this Nu_i and Eq. 4.44 for Nu_ℓ into Eq. 4.33d to obtain Nu . For an isoflux boundary, calculate Nu_i from Eq. 4.36c, calculate Nu_ℓ from Eq. 4.44, and find Nu by substituting these values of Nu_i and Nu_ℓ into Eq. 4.36d.

For a cylinder of noncircular convex cross section, such as the triangular cylinder shown in Fig. 4.14, follow the same procedure but replace D in Eq. 4.44 by $D_{eff} = P_i/\pi$, where P_i is the perimeter of the cylinder.

Discussion. This procedure is compared to available measurements in Fig. 4.15. The predictions fall about 10 percent higher than the measurements of Nagendra et al. [203] for a uniform flux into water. There is excellent agreement with the measurements of Li and Tarasuk [180] for $14 < L/D < 21$ for a uniform wall temperature in air, and predictions fall slightly below the measurements of Al-Arabi and Salman [6], also for air. There is also good agreement with the data of Kyte et al. [172] for a vertical wire of extremely small diameter ($D = 0.08$ mm, $L/D = 5430$) in air where the transverse curvature correction in Eq. 4.44 is very large (the measured Nu values in Fig. 4.15 fall below the predictions at the low end of the Nu range because of rarefied gas effects).

FIGURE 4.15 Comparison of recommended procedure for calculating heat transfer to data for vertical cylinders in air and water.

FIGURE 4.16 Definition sketch for long horizontal cylinder in an isothermal medium (a), in a stratified medium (b), and for a tilted cylinder (c).

The present recommendation leads to good agreement with existing data, but none of these data lie in the turbulent range, and the tested range of Pr and L/D is also limited.

A correlation for short vertical cylinders, including heat transfer from the ends, is provided in the section on bodies with small aspect ratios.

Long Horizontal Circular Cylinders

Correlation. For a long isothermal horizontal circular cylinder in an isothermal environment, and using the nomenclature in Fig. 4.16, Nu is obtained from the following equations:

$$\text{Nu}^T = 0.772 \bar{C}_\ell \text{Ra}^{1/4} \quad (4.45a)$$

$$\text{Nu}_\ell = \frac{2f}{\ln(1 + 2f/\text{Nu}^T)} \quad f = 1 - \frac{0.13}{(\text{Nu}^T)^{0.16}} \quad (4.45b)$$

$$\text{Nu}_\ell = \bar{C}_\ell \text{Ra}^{1/3} \quad (4.45c)$$

$$\text{Nu} = [(\text{Nu}_\ell)^m + (\text{Nu}_\ell)^m]^{1/m} \quad m \approx 10 \quad (4.45d)$$

\bar{C}_ℓ can be found from Table 4.2 (elliptical cylinders, $C/L = 1.0$). If $\text{Ra} \geq 10^{-4}$, the expression for f in Eq. 4.45b can be replaced by $f = 0.8$.

Discussion. Equation 4.45 follows the recommendation of Raithby and Hollands [227] except that the value of m has been improved. There is a large body of data for this problem, because the shape is so frequently encountered in practice. Five sets of data, thought to be especially reliable, are compared to Eq. 4.45 in Fig. 4.17 for air. The RMS deviation from the equation is less than 5 percent for $10^{-10} < \text{Ra} < 10^7$. Similar agreement is found with the data of Chen and Eichhorn [42] for water and with the data of Schütz [300] for Pr ≈ 2000 . High Rayleigh number data are still needed to confirm the value of \bar{C}_ℓ in Eq. 4.45c and Table 4.2.

For a uniform heat flux condition, apply Eq. 4.45 to obtain the average temperature difference $\Delta \bar{T}$.

Stratified Medium. For a long horizontal circular cylinder in a thermally stratified environment in which the temperature increases linearly with height (see Fig. 4.16b for nomenclature), $\Delta \bar{T}$ is the temperature difference at the mid-height of the cylinder. First calculate the laminar isothermal Nusselt number Nu_ℓ from Eq. 4.45 with $\Delta T = \Delta \bar{T}$ and rename it $\text{Nu}_{\ell,\text{iso}}$; the corresponding calculated heat flow is q_{iso} . The laminar Nusselt number Nu_ℓ corrected to account for the stratification is then estimated from

$$\frac{q}{q_{\text{iso}}} = \frac{\text{Nu}_\ell}{\text{Nu}_{\ell,\text{iso}}} = \left(1 + \frac{S}{a}\right)^b \quad S \leq 2 \quad (4.46a)$$

$$= cS^{1/4} \quad S \geq 2 \quad (4.46b)$$

For gases: $a = 1$, $b = 0.39$, and $c = 1.29$. For water (Pr ≈ 6): $a = 2$, $b = 0.53$, and $c = 1.21$.

FIGURE 4.17 Comparison of Eq. 4.45 to data for long, horizontal, isothermal cylinders in air.

Discussion of Stratified Medium. Equation 4.46 was obtained by fitting the analytical results of Chen and Eichhorn [42]. There is agreement with their measurements of Nu/Nu_{iso} to within about 10 percent. All their data were obtained for $2 \times 10^5 < Ra < 3 \times 10^7$. Use of Eq. 4.46 is not recommended for Ra much outside this range, because turbulent heat transfer will not be properly accounted for at larger Ra and because thick boundary layer effects may be poorly approximated for smaller Ra .

Long Inclined Circular Cylinder, Laminar Flow. See Fig. 4.16c for nomenclature. The cylinder axis is inclined from the horizontal at an angle θ . The heat transfer from the ends is ignored, which will be valid for insulated ends or for $L/D \geq 5$. The analysis of Raithby and Hollands [225, 226] led to the following correlation:

$$Nu^T = \left\{ 0.772 + \frac{0.228}{1 + 0.676p^{1.23}} \right\} \left(\cos \theta + \frac{D}{L} \sin \theta \right)^{1/4} \bar{C}_\epsilon Ra^{1/4} \quad (4.47a)$$

$$Nu_\epsilon = \frac{1.8}{\ln(1 + 1.8/Nu^T)} \quad p = 2 \frac{L}{D} \cot \theta \quad (4.47b)$$

Equation 4.47a can be shown to reduce exactly to Eqs. 4.33a and 4.45a for the vertical ($\theta = 90^\circ$) and horizontal ($\theta = 0^\circ$) orientation, respectively.

Discussion. Equation 4.47 agrees with the data of Oosthuizen [213] and Li and Tarasuk [180] to within RMS and maximum errors of 6 and 12 percent, respectively. The data range is $2.0 \times 10^4 \leq Ra \leq 2.5 \times 10^5$, $Pr = 0.71$, $8 < LD < 21$, and $0^\circ \leq \theta \leq 90^\circ$, and the fluid is air. Figure 4.18 presents a comparison for one case, and shows that the heat transfer falls as the cylinder is rotated from the horizontal ($\theta = 0^\circ$) to the vertical ($\theta = 90^\circ$) orientation.

FIGURE 4.18 Dependence of heat transfer on the inclination angle of a cylinder (defined in Fig. 4.16c): comparison of Eq. 4.47 with the data of Oosthuizen [213].

Long Horizontal Noncircular Cylinders

Correlation for Specific Shapes. For the four shapes shown in Table 4.2, the heat transfer is calculated from the following equation:

$$Nu^T = G \bar{C}_\ell Ra^{1/4} \quad (4.48a)$$

$$Nu_\ell = \frac{C_2}{\ln(1 + C_2/Nu^T)} \quad (4.48b)$$

$$Nu_s = \bar{C}_s Ra^{1/3} \quad (4.48c)$$

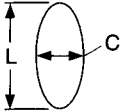

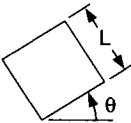

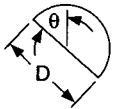

$$Nu = [(Nu_\ell)^m + (Nu_s)^m]^{1/m} \quad (4.48d)$$

The constants G , C_2 , \bar{C}_s , and m are tabulated in Table 4.2, which also gives the definitions of Nu and Ra for each cylinder shape in addition to the equation for the perimeter P that is required to find the surface area.

Discussion of Correlation for Specific Shapes. The equation for elliptical cylinders fits the approximate analysis of Raithby and Hollands [224] but has not been verified by experiment except in the limiting cases of a vertical plate ($C/L = 0$) and a circular cylinder ($C/L = 1.0$). The vertical plate predictions by Eq. 4.48 are slightly different than those based on the more accurate specialized equations given in the section on external natural convection in flat plates.

Equation 4.48 agrees with the measurements by Clemes et al. [64] for square cylinders at angles of rotation of 0° , 15° , 30° , and 45° in air ($Pr = 0.71$) for $10^1 < Ra < 10^7$ to an RMS deviation of less than 3 percent and a maximum error of 8 percent. Similar comparisons for the semicircular cylinder at $\theta = 0^\circ$, 45° , 90° , -45° , and -90° give RMS and maximum deviations from the measurements of Clemes et al. [64] of 2.5 and 5 percent, respectively. For the slotted cylinder, the RMS and maximum deviations were 2 and 5 percent, respectively.

$$a = 0.0972 \quad b = 0.0815 - 0.462C_2^Y$$

$$e = 0.615C_2^Y - 0.0548 - 6 \times 10^{-9} \text{Pr} C_2^Y$$

FIGURE 4.19 Definition sketch for long horizontal convex cylinder of arbitrary shape. The constants G , C_2 , and \bar{C}_i are for use in Eq. 4.48.

There appears to be no verification of Eq. 4.48 for these shapes for fluids other than air, and for Rayleigh numbers (defined in Table 4.2) outside the range $10^1 < \text{Ra} < 10^8$. The turbulent asymptote of the equations has therefore not been verified for any fluid.

General Correlation for Convex Horizontal Cylinders. For cylinders of arbitrary convex shape, such as shown in Fig. 4.19, Eq. 4.48 can be used to find the Nusselt number, provided the coefficients G , C_2 , and \bar{C}_i are known. General expressions for these coefficients, based on the recommendations of Clemes et al. [64] and Hassani [125], are given in Fig. 4.19. Note that Nu and Ra in Fig. 4.19 are based on the perimeter of the cylinder, P . Z_f is the height of the cylinder, \bar{C}_i is given by Eq. 4.24, and P_h/P is the fraction of the perimeter that lies in the horizontal plane and faces downward for a heated cylinder (it is the fraction that is horizontal and upward-facing for a cooled cylinder). This correlation gives results in close agreement with Eq. 4.48 (using the constants in Table 4.2 and allowing for the different definitions of

Nu and Ra). There is also agreement to within about 12 percent with the data of Nakamura and Asako [204] for cylinders of modified square and triangular cross section in the range $3 \leq \text{Pr} \leq 8$.

Bodies with Small Aspect Ratios

Correlations for 3D and Axisymmetric Flows. For bodies of “small aspect ratio,” there is no single dimension that greatly exceeds all other dimensions. Examples are shown in Table 4.3a. For these bodies, the correlation equation has the form

$$\text{Nu}^T = G \bar{C}_i \text{Ra}^{1/4} \quad (4.49a)$$

$$\text{Nu}_t = [(\text{Nu}_{\text{COND}})^n + (\text{Nu}^T)^n]^{1/n} \quad (4.49b)$$

$$\text{Nu}_t = \bar{C}_i \text{Ra}^{1/3} \quad (4.49d)$$

$$\text{Nu} = [\text{Nu}_t^m + \text{Nu}^m]^{1/m} \quad (4.49c)$$

The length scales on which Nu and Ra are based, and values of the constants, are provided in Table 4.3a. The basis for these relations was discussed in the section on heat transfer correlation method.

In the rightmost column in Table 4.3a, NA is an abbreviation for *none available*, meaning that the correlation is based entirely on the approximate method [227]. Values of $n = 1.07$, recommended by Hassani and Hollands [126, 127], and $m = 10$ are used for these cases. When data are available, the values of G have been adjusted to provide a best fit of the data. Except for the thin oblate spheroid, $C/D = 0.1$, the value G was never adjusted by more than a few percent from the value predicted by the approximate method. \bar{C}_i was never adjusted, mainly because so few of the available data fall in the turbulent regime. Table 4.3b provides references to all data used, and the RMS error (E_{RMS}) and maximum error (E_{MAX}) from Eq. 4.49 fit using the constants in Table 4.3a. The range of Ra and Pr covered by the data is also noted.

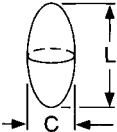

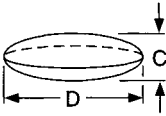

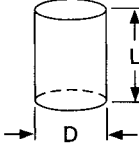

The Nusselt number in the $\text{Ra} \rightarrow 0$ limit is the conduction Nusselt number Nu_{COND} . This was calculated in all cases using the recommendations of Yovanovich et al. [291–294].

Table 4.3b shows that Eq. 4.49 fits the data very closely. The range of data is, however, limited.

For body shapes not treated in Table 4.3, the general correlation of Hassani and Hollands [126, 127] is recommended.

Correlations for Spheres in a Thermally Stratified Medium. Consider the case of an isothermal sphere in a thermally stratified medium with constant vertical temperature gradient dT_∞/dz and with a temperature difference at the mid-height of the sphere of ΔT . A Nusselt number Nu_{iso} is first calculated for an isothermal sphere in an isothermal environment

(use Eq. 4.49) with the constants in Table 4.3a and with a temperature difference of $\overline{\Delta T}$. The corresponding total heat flow is q_{iso} . The actual heat flow q is corrected to account for the stratification as follows:

$$\frac{q}{q_{iso}} = \frac{Nu}{Nu_{iso}} = \left(1 + \frac{S}{a}\right)^b \quad S \leq 2 \quad (4.50a)$$

$$= cS^{1/4} \quad S \geq 2 \quad (4.50b)$$

For gases: $a = 1$, $b = 0.36$, and $c = 1.25$. For water ($Pr \approx 6$): $a = 2.0$, $b = 0.47$, and $c = 1.17$.

Equation 4.50 was obtained by fitting the analytical results of Chen and Eichhorn [42]. They also obtained measurements for $0 < S < 3.5$, $Pr \approx 6$, and $10^6 < Ra < 10^8$, and Eq. 4.50 agrees with these data to within about 10 percent. Extrapolation beyond the range of the experimental data is not recommended.

OPEN CAVITY PROBLEMS

In open cavity problems, buoyancy generated by heat exchange with the enclosure walls drives flow through the cavity (Fig. 4.20a). Either the wall temperature or the heat flux can be specified on the cavity walls, and cavities may take a variety of forms (Fig. 4.20). The fluid temperature far from the cavity is assumed constant at T_∞ . The cooling of electronic equipment and the augmentation of heat transfer using finned surfaces are two important areas where open cavity problems arise.

FIGURE 4.20 Various configurations in which “open cavity” natural convection occurs.

In the equations presented in this section, the characteristic temperature difference appearing in the Nusselt and Rayleigh numbers is $(\overline{T}_w - T_\infty)$, where \overline{T}_w is the average wall temperature of the cavity. Properties are to be evaluated at the film temperature $T_f = 0.5(\overline{T}_w + T_\infty)$ unless otherwise specified.

Cooling Channels

Cooling channels of the type depicted in Fig. 4.20b and c will first be discussed. For channels that are very long relative to the spacing of the vertical surfaces, the flow and heat transfer become fully developed (i.e., velocity and temperature profiles become invariant with distance along the channel) and are described by simple equations. For short channels or widely spaced vertical surfaces, a boundary layer regime is observed in which the boundary layers on the vertical walls remain well separated. In the latter case the heat transfer relation is similar

in form to that for a vertical plate but the heat transfer is usually found to be slightly higher. This augmentation results from the flow induced through the cavity by the chimney effect.

Parallel Isothermal Plates. For parallel isothermal plates of either equal or different temperatures (see Fig. 4.21), Aung [11] has shown that the Nusselt number in the fully developed regime is given by

$$Nu_{fd} = \frac{4T^{*2} + 7T^* + 4}{90(1 + T^*)^2} Ra \approx \frac{Ra}{24} \quad Ra \leq 10 \quad (4.51)$$

Both plate temperatures are assumed in the analysis to be equal to or greater than T_∞ , and q in the definition of Nu in Fig. 4.21 is the total heat delivered to the fluid from both plates; the remaining symbols are defined in the figure.

FIGURE 4.21 Geometry and nomenclature for natural convection heat transfer from a wide ($W \gg S$) rectangular cooling slot with heat flux or temperature-specified conditions on the walls.

For $Ra > 10$, the observed values of Nu depart from the value of Nu_{fd} given in Eq. 4.51 and beyond $Ra \approx 10^3$ follow a relation of the form

$$Nu = c\bar{C}_\ell Ra^{1/4} \quad (4.52)$$

where \bar{C}_ℓ is given by Eq. 4.13 and Table 4.1. This is called the laminar boundary layer regime. For air, measurements of Elenbaas [88, 89] and Aung et al. [12] indicate that $c \approx 1.20$, which gives 20 percent higher heat transfer than a vertical isolated plate. The analysis of Aung et al. [12] and Bodoia and Osterle [21] yielded a value of $c \approx 1.32$. The measurements of Novotny [210] for $Pr = 6$ and the analysis of Miyatake and Fujii [196] for $Pr = 10$ suggest that c approaches 1.0 at higher Pr .

For all Ra up to $Ra \approx 10^5$, the following heat transfer equation is recommended:

$$Nu = [(Nu_{fd})^m + (c\bar{C}_\ell Ra^{1/4})^m]^{1/m} \quad m = -1.9 \quad (4.53)$$

While property values are normally evaluated at $0.5(\bar{T}_w + T_\infty)$, for large temperature differences and small Ra better agreement between Eq. 4.53 and measurements is obtained (e.g., Ref. 178) by evaluating the properties at \bar{T}_w .

The heat transfer per unit surface area, and the heat transfer coefficient, are relatively insensitive to the plate spacing until the spacing is reduced to the point at which the thermal boundary layers begin to interfere. If the objective is to transfer the maximum heat from a given volume of height H , adding more channels proportionately increases the heat transfer by adding surface area, until the boundary layers begin to interfere. The addition of still more

channels decreases the spacing of each channel, so that the heat transfer coefficient falls, but the total heat transfer continues to increase because the product of heat transfer coefficient and surface area, or equivalently the heat transfer per unit cross-sectional area of the channel q/A_x , increases. As the plate spacing decreases still further, q/A_x passes through a maximum and then falls. Levy et al. [178] and Raithby and Hollands [223] have shown that the boundary layers begin to interfere at $400 < Ra < 800$. From Eq. 4.53, q/A_x can be shown to pass through a maximum at

$$Ra = Ra_{\max} = (24c\bar{C}_t 2^{-(1/m)})^{4/3} \approx 60 \quad (4.54)$$

Given Ra_{\max} , the spacing S can be found that corresponds to this maximum q/A_x .

In a related problem, Sparrow and Prakash [261] have shown that the heat transfer from a series of parallel-plate channels can be substantially increased, for the same surface area, by breaking the continuous vertical plates into a staggered array of discrete vertical plates.

Uniform Heat Flux Parallel Plates. If the heat fluxes are specified as q''_1 and q''_2 , respectively, on the surfaces of the vertical plates (where $q''_1 > q''_2$ and both q''_1 and q''_2 are positive, denoting heat transfer from the plate to the fluid), the Nusselt number for the fully developed regime for air is given by [11]

$$Nu_{fd} = 0.29(Ra^*)^{1/2} \quad Ra^* \leq 5 \quad (4.55)$$

where the terms are defined in Fig. 4.21. The temperature difference that appears in Nu is, in this case, $\bar{T}_{w(1/2)} - T_\infty$, where $\bar{T}_{w(1/2)}$ is the average wall temperature at the channel mid-height.

In the laminar boundary layer regime, the Nusselt number relation is of the form of that for a vertical flat plate

$$Nu = c\bar{H}_t(Ra^*)^{1/5} \quad 10^2 \leq Ra^* \leq 10^4 \quad (4.56)$$

where \bar{H}_t is given by Eq. 4.36a and Table 4.1 and c is given in the following text. Equation 4.56 may apply well past the upper limit indicated. The following equation satisfactorily fits the results of Aung et al. [12] obtained for $Ra^* < 10^4$:

$$Nu = [(Nu_{fd})^m + (c\bar{H}_t(Ra^*)^{1/5})^m]^{1/m} \quad m = -3.5 \quad (4.57)$$

The Nu value calculated from Eq. 4.57 provides the average temperature at the mid-height of the channel. For air, the analysis suggests $c = 1.15$, while the data of Sobel et al. [254] yield $c = 1.07$; the latter value is recommended. These values may be compared to $c = 1.00$ for an isolated vertical plate in air (i.e., Eq. 4.36a).

Bar-Cohen and Rohsenow [14] provide a relation, similar in form to Eq. 4.57, for the local Nusselt number, from which the maximum plate temperature can be calculated.

Extensive measurements for mercury ($Pr \approx 0.022$) have been reported by Colwell and Welty [68] and Humphreys and Welty [147]. The data at this Prandtl number do not support Eq. 4.57, and the original references should be consulted.

Sobel et al. [254] showed through measurements that the heat transfer from an array of uniform heat flux parallel plates could be substantially increased by interrupting and staggering the plate surfaces.

Isothermal Circular Channels. Measurements and analyses by Elenbaas [88, 89] and Dyer [77] show that the heat transfer from isothermal cylindrical cooling channels (Fig. 4.20c) can be represented by

$$Nu = \left[\left(\frac{Ra}{16} \right)^m + (c\bar{C}_t Ra^{1/4})^m \right]^{1/m} \quad m = -1.03 \quad (4.58)$$

The nomenclature is defined in Fig. 4.22. The experiments for $Pr = 0.71$ (air) indicate $c \approx 1.17$, while analysis gives 1.22. The value of Ra for the maximum heat transfer per unit of cross-

FIGURE 4.22 Natural convection through a cylindrical cooling channel.

sectional area of the tube (for a given height H and temperature difference) is given by Eq. 4.54 with 24 replaced by 16; this yields $Ra_{\max} \approx 50$ for air.

Dyer [77] also presents results for air for the case when an unheated entry length H_i is added to the tube as shown in Fig. 4.22. For fully developed flow, the 16 in Eqs. 4.54 and 4.58 is, in this case, replaced by $16(1 + H_i/H)$. The heat flow is also reduced in the boundary layer regime by increasing H_i , and if H_i becomes sufficiently large, the throughflow is reduced and a large portion of the wall cooling is provided by a downward flow through the central portion of the top of the tube and a return flow upward along the tube walls (thermosiphon exchange).

Uniform Flux Cylindrical Channels. The heat flow results from the analysis of Dyer [76] for air and for vertical circular cooling channels with uniform heat flux at the boundary can be represented closely by

$$Nu = \left\{ \left(\sqrt{\frac{Ra^*}{8}} \right)^m + (0.67(Ra^*)^{1/5})^m \right\}^{1/m} \quad 0.1 < Ra^* < 10^5 \quad (4.59)$$

where $m = -1.7$, $Pr = 0.71$ (air), and the remaining symbols are defined in Fig. 4.22. From the definition of Nu , the Nu value obtained from Eq. 4.59 provides the average wall temperature. Data from experiments in the range $5 < Ra^* \leq 5 \times 10^3$ agree well with Eq. 4.59.

Isothermal Channels of Other Shapes. For isothermal cooling channels of other shapes,

$$Nu = \left[\left(\frac{Ra}{fRe} \right)^m + (c\bar{C}_t Ra^{1.4})^m \right]^{1/m} \quad Ra \leq 10^4 \quad m \approx -1.5 \quad (4.60)$$

where the nomenclature is defined in Fig. 4.22, fRe is the friction factor–Reynolds number product in Table 4.4, and c has a value of about 1.20 for air and should decrease toward 1.0 with increasing Pr . Equation 4.54 with 24 replaced by fRe yields Ra_{\max} , the Rayleigh number for maximum heat transfer per unit of cross-sectional area for a channel of given length H and given $T_w - T_\infty$. The relationship of the fully developed Nusselt number to fRe was originally pointed out by Elenbaas [88, 89].

Extended Surfaces

Heat transfer from each of the extended surfaces (fins), shown in Fig. 4.23, is now discussed. The prediction of the heat transfer requires a solution for complex 3D motion, so few analyses are as yet available. Experimental data have been obtained exclusively using air.

In many practical applications there is a significant temperature drop between the base of the fin and its tip, and this affects both the natural convection flow and heat transfer. Very little information is available on the coupling between fin conduction and fluid convection, so that attention is restricted to isothermal fins. As a first approximation, the heat transfer coefficient for isothermal fins can be used for the case where the fins are not isothermal, because there is such a weak dependence on the temperature difference. Property values are to be evaluated at $0.5(T_w + T_\infty)$ unless otherwise indicated.

Rectangular Isothermal Fins on Vertical Surfaces. Vertical rectangular fins, such as shown in Fig. 4.23a, are often used as heat sinks. If $W/S \geq 5$, Aihara [1] has shown that the heat transfer coefficient is essentially the same as for the parallel-plate channel (see the section on parallel isothermal plates). Also, as $W/S \rightarrow 0$, the heat transfer should approach that for a vertical flat plate. Van De Pol and Tierney [270] proposed the following modification to the Elenbaas equation [88, 89] to fit the data of Welling and Wooldridge [283] in the range $0.6 < Ra < 100$, $Pr = 0.71$, $0.33 < W/S < 4.0$, and $42 < H/S < 10.6$:

$$Nu = \frac{Ra}{\Psi} \left\{ 1 - \exp \left[-\Psi \left(\frac{0.5}{Ra} \right)^{3/4} \right] \right\} \quad (4.61a)$$

where

$$\Psi = \frac{24(1 - 0.483e^{-0.17/\alpha^*})}{\left\{ (1 + \alpha^*/2) [1 + (1 - e^{-0.83\alpha^*}) (9.14\sqrt{\alpha^*} e^{\alpha^*} - 0.61)] \right\}^3} \quad (4.61b)$$

$$r = \frac{2WS}{2W + S}; \alpha^* = S/W$$

$$Nu = \frac{q'' r}{(T_w - T_\infty) k}$$

$$Ra = \frac{g\beta (T_w - T_\infty) r^3}{\nu\alpha} \frac{r}{L} \quad (a)$$

$$Nu = \frac{q'' S}{(T_w - T_\infty) k}$$

$$Ra = \frac{g\beta (T_w - T_\infty) S^3}{\nu\alpha} \quad (b)$$

$$Nu = \frac{q'' L}{(T_w - T_\infty) k}$$

$$Ra = \frac{g\beta (T_w - T_\infty) L^3}{\nu\alpha} \quad (c)$$

$$Nu = \frac{q'' \bar{S}}{(T_w - T_\infty) k}$$

$$Ra = \frac{g\beta (T_w - T_\infty) \bar{S}^3}{\nu\alpha} \frac{\bar{S}}{H} \quad (d)$$

$$Nu = \frac{q'' S}{(T_w - T_\infty) k}; Ra = \frac{g\beta (T_w - T_\infty) S^3}{\nu\alpha} \frac{S}{H} \quad (e)$$

$$Nu = \frac{q'' S}{(T_w - T_\infty) k}; \zeta = \frac{d}{D}; Ra = \frac{g\beta (T_w - T_\infty) S^3}{\nu\alpha} \frac{S}{D} \quad (f)$$

FIGURE 4.23 Flow configurations and nomenclature for various open cavity problems.

and where \bar{S} is dimensionless and equal to $-4.65S$ (for S in cm) or $-11.8S$ (for S in inches). Other nomenclature is defined in Fig. 4.23a.

For a given base plate area there are two fin spacings, S_1 and S_2 , of particular interest. If the fin spacing is decreased, starting from a large value, the heat transfer coefficient remains relatively constant until the spacing S_1 (which corresponds to $Ra = Ra_1$) is reached, at which it begins to fall rapidly because of fin interference. As the spacing is decreased within a specified volume, more fins are added to the base plate, thereby increasing the total surface area for heat transfer. Since total heat flow is proportional to the product of heat transfer coefficient and surface area, decreasing the spacing below S_1 still improves the total heat transfer until the spacing S_2 (which corresponds to $Ra = Ra_{\max}$) is reached; below S_2 , the total heat transfer falls. For long fins ($\alpha^* \ll 1$), S_1 and S_2 will fall to roughly the same values as for parallel-plate channels: $Ra_1 \approx 600$, $Ra_{\max} \approx 60$. For short fins, these spacings can be established from Eq. 4.61.

Rectangular Isothermal Fins on Horizontal Surfaces. The heat transfer from rectangular finned surfaces such as shown in Fig. 4.23b (upward-facing for $T_w > T_\infty$ or downward-facing for $T_w < T_\infty$) has been measured by Jones and Smith [150], Starner and McManus [263], and Harahap and McManus [120]. For a given fin width, $W = 0.254$ m (0.833 ft), Jones and Smith were able to correlate their measured heat transfer to within about ± 25 percent on an Nu - Ra plot. The following equation closely represents this correlation over the data range $2 \times 10^2 < Ra < 6 \times 10^5$, $Pr = 0.71$, $0.026 \leq H/W \leq 0.19$, and $0.016 \leq S/W \leq 0.20$:

$$Nu = \left[\left(\frac{Ra}{1500} \right)^m + (0.081 Ra^{0.39})^m \right]^{1/m} \quad m = -2 \quad (4.62)$$

This simple equation ignores the effect of the geometric parameters H/S and H/W . While H/S does not appear to play a strong role, H/W is known to have significant effect.

A parametric study using Eq. 4.62 shows that, for a given base area and temperature difference, the curve of total heat transfer versus fin spacing displays a sharp maximum for high fins (large H) and a less well-defined peak for short fins. This results from the rapid increase in total surface area with decreasing fin spacing (i.e., as fins are added to the base plate) for high fins. Because the total heat transfer falls off very sharply for spacings below the optimum, a conservative design would use spacings larger than the optimum S_2 (defined in the section on rectangular isothermal fins on vertical surfaces) calculated from Eq. 4.62.

Horizontal Corrugated Surfaces. A heated horizontal isothermal corrugated surface, such as that shown in Fig. 4.23c, can also be considered a finned surface. The heat transfer is from the top surface only. Al-Arabi and El-Refaee [3] have measured heat transfer rates to air ($Pr = 0.71$) over the range $1.8 \times 10^4 < Ra < 1.4 \times 10^7$ (the nomenclature is defined in Fig. 4.23c), and have provided the following correlations:

$$Nu = \left(\frac{0.46}{\sin(\Psi/2)} - 0.32 \right) Ra^m \quad \text{for } 1.8 \times 10^4 < Ra < Ra_c \quad (4.63)$$

where $Ra_c = (15.8 - 14.0 \sin(\Psi/2)) \times 10^5$

$$m = 0.148 \sin(\Psi/2) + 0.187$$

and $Nu = \left(0.090 + \frac{0.054}{\sin(\Psi/2)} \right) Ra^{1/3} \quad \text{for } Ra_c < Ra < 1.4 \times 10^7 \quad (4.64)$

The measurements and the above correlation were intended to represent the case where W is asymptotically large. The dependence of the heat transfer on W remains to be determined.

Vertical Triangular Fins. For the vertical fin array in Fig. 4.23d, \bar{S} is the fin spacing measured at the mid-height of the fin, so that $\bar{S}W$ is the cross-sectional area of the flow channel formed by the sides of adjacent fins, the base of width S , and the vertical plane passing

through the fin tips. Nu and Ra are defined in the figure. The correlation of Karagiozis et al. [152] is

$$Nu = Nu_{COND} + \bar{C}_\ell Ra^{1/4} \left[1 + \left(\frac{3.26}{Ra^{0.21}} \right)^3 \right]^{-(1/3)} + \delta Nu \quad (4.65a)$$

$$\delta Nu = [(0.147 Ra^{0.39} - 0.158 Ra^{0.46}), 0]_{\max} \quad (4.65b)$$

where Nu_{COND} is the (conduction) Nusselt number for the entire fin array in the limit as $Ra \rightarrow 0$. A conservative design (i.e., the heat transfer is underestimated) results if $Nu_{COND} = 0$ is used.

Otherwise, to estimate Nu_{COND} , suppose that triangular fins are mounted on a rectangular base plate of dimension L_1 and H , where the base plate entirely covers the vertical surface on which it is mounted. The surface and base plate therefore have area $A_b = L_1 \times H$. Suppose further that the fin height is small compared to the base plate dimensions (i.e., $W \ll L_1$ and $W \ll H$), and that there are no adjacent cool surfaces to which heat can be directly conducted.

The lower bound on Nu_{COND} (see Refs. 293 and 294) can be found from

$$Nu_{COND} = \frac{\bar{S}(1 + \sqrt{r})^2}{\sqrt{\pi A_b r}} \quad r \leq 5 \quad (4.66a)$$

$$= \bar{S} \frac{\sqrt{4\pi r}}{\sqrt{A_b} \ln(4r)} \quad r \geq 5 \quad (4.66b)$$

where $r = (L_1/H, H/L_1)_{\max}$. The upper bound for Nu_{COND} is roughly 1.57 times the value calculated from Eq. 4.66; this factor is obtained by extrapolating the recommendation of Yovanovich and Jafarpur [293], intended for $r \approx 1$. In the absence of better information, use the average of these two values.

If the base plate of the fins is attached to a vertical isothermal surface whose dimensions are much larger than both H and L_1 , Nu_{COND} will approach zero. If, however, there is a nearby cool surface to which heat can be transferred, Nu_{COND} can be larger than the upper bound just described; this effect becomes important when the nearest distance to the cool surface is less than $\bar{S}/(Nu - Nu_{COND})$ and where $(Nu - Nu_{COND})$ is obtained from Eq. 4.65.

Figure 4.24 compares Eq. 4.65, shown by the solid line, to the data of Karagiozis et al. [152, 153]. The data approach the asymptote for laminar heat transfer from a vertical flat plate (dotted line) at high Ra . The dashed line shows Eq. 4.65a with no correction (i.e., $\delta Nu = 0$); this correction is seen to be significant only at low Ra .

Finned surfaces are often installed on a vertical surface with the fin tips running horizontally (instead of vertically). Karagiozis [153] has shown that this reduces the heat transfer by up to a factor of 2, and the use of this orientation is not recommended.

Square Isothermal Fins on a Horizontal Tube. Square fins attached to a horizontal tube, as shown in Fig. 4.23e, are commonly used in heat exchangers. The experimental data of Elenbaas [88, 89] for square plates, without the tube, covered the range $0.2 < Ra < 4 \times 10^4$, for $Pr = 0.71$. These data are closely correlated by

$$Nu = \left[\left(\frac{Ra^{0.89}}{18} \right)^m + (0.62 Ra^{1/4})^m \right]^{1/m} \quad m = -2.7 \quad (4.67)$$

Recent heat transfer measurements by Sparrow and Bahrami [256, 257] lie about a factor of 10 higher than those of Elenbaas near the lower end of the Ra range. Tsubouchi and Masuda [269] recommended that the heat transfer from square fins be calculated from their equations for circular fins using an equivalent diameter $D = 1.23H$. Their procedure for circular fins is outlined in the following section.

$$\text{where} \quad \beta = 0.17\zeta + e^{-4.8\zeta}; \quad \zeta = d/D$$

$$C_1 = \left[\frac{23.7 - 1.1(1 + 152\zeta^2)^{1/2}}{1 + \beta} \right]^{4/3} \quad (4.69b)$$

Properties are based on the wall temperature. This equation is in excellent agreement with Tsubouchi and Masuda's data over the measurement range $3 < Ra < 10^4$.

For shorter fins, $1.67 \geq D/d \geq 1.0$, Eq. 4.69a is replaced by

$$Nu = C_0 Ra_0^p \left\{ 1 - \exp \left[- \left(\frac{C_1}{Ra_0} \right)^{C_2} \right] \right\}^{C_3} \quad (4.70a)$$

$$\text{where} \quad C_0 = -0.15 + 0.3\zeta + 0.32\zeta^{16} \quad C_1 = -180 + 480\zeta - 1.4\zeta^{-8}$$

$$C_2 = 0.04 + 0.9\zeta \quad C_3 = 1.3(1 - \zeta) + 0.0017\zeta^{-12} \quad (4.70b)$$

$$p = 1/4 + C_2 C_3 \quad Ra_0 = Ra/\zeta = Ra D/d$$

Properties are again evaluated at the wall temperature.

Edwards and Chaddock [81] correlated their data for heat transfer from the entire surface, including the tip, for $D/d = 1.94$, $5 < Ra < 10^4$, by

$$Nu = 0.125 Ra^{0.55} \left[1 - \exp \left(- \frac{137}{Ra} \right) \right]^{0.294} \quad (4.71)$$

where properties are evaluated at $T_\infty + 0.62(T_w + T_\infty)$. The measurements of Jones and Nwizu [151] fall slightly below Eq. 4.71. The fact that these equations do not have the expected fully developed behavior ($Nu \propto Ra$) as $Ra \rightarrow 0$ has been attributed [269] to tip effects.

NATURAL CONVECTION WITHIN ENCLOSURES

Introduction

Enclosure problems (Fig. 4.1c) arise when a solid surface completely envelops a cavity containing a fluid and, possibly, interior solids. This section is concerned with heat transfer by natural convection within such enclosures. Problems without interior solids include the heat transfer between the various surfaces of a rectangular cavity or a cylindrical cavity. These problems, along with problems with interior solids including heat transfer between concentric or eccentric cylinders and spheres and enclosures with partitions, are discussed in the following sections. Property values (including β) in this section are to be taken at $T_m = (T_h + T_c)/2$.

Geometry and List of Parameters for Cavities Without Interior Solids

The problem of natural convection in a cavity without interior solids is exemplified by the two situations sketched in Fig. 4.25. In both situations, the fluid-filled cavity is bounded by two isothermal parallel "plates" that are inclined at angle θ from horizontal, spaced at distance L , and held at different temperatures. The temperature T_h is assumed to be larger than T_c , so cavities with $\theta = 0^\circ$ are described as horizontal with heating from below, those with $\theta = 90^\circ$ are described as vertical with heating from the side, and those with $\theta = 180^\circ$ are described as horizontal with heating from above.

FIGURE 4.25 The (a) rectangular parallelepiped and (b) truncated circular cylinder cavities. Angle θ is measured from the horizontal.

In Fig. 4.25a the cavity is a rectangular parallelepiped, in Fig. 4.25b a truncated circular cylinder; the area over which the fluid contacts each plate is $A_f = HW$ for the first, and $A_f = \pi D^2/4$ for the second. The “wall” (as distinct from the plates) bounding the fluid on the sides is of uniform thickness b and thermal conductivity k_w . The upper and lower plates extend over the wall as shown, and each therefore contacts the wall over an area $A_w = (2b + H)(2b + W) - HW$ for the first shape, and $A_w = (\pi/4)[(D + 2b)^2 - D^2]$ for the second. The thermal boundary condition on the outside faces of the wall (i.e., those faces not bounded by either the fluid or the plates) is adiabatic. The fluid is assumed to be either completely transparent or completely opaque to thermal radiation. Usually liquids are opaque and gases transparent. When the fluid is transparent, radiant exchange can affect the free convection by altering the wall temperature distribution: hemispherical emissivities ϵ_h , ϵ_c , and ϵ_w are assigned to the surfaces of the hot plate, the cold plate, and the walls, respectively.

Two different Nusselt numbers can be assigned for both cavity problems. The first is defined by

$$\text{Nu} = 1 + \frac{(q_f - q_{f0})L}{k(T_h - T_c)A_f} \quad (4.72)$$

and the second by

$$\text{Nu} = 1 + \frac{[q_f + q_r + q_w - (q_{f0} + q_{r0} + q_{w0})]L}{k(T_h - T_c)A_f} \quad (4.73)$$

where q_f is the nonradiative heat transfer rate from the inner area A_f of the hot plate, q_r is the net radiant heat transfer from that same area into the cavity, and q_w is the heat transfer conducted from the area A_w of the hot plate and into the wall. The heat transfers q_{f0} , q_{r0} , and q_{w0} are the respective values of q_f , q_r , and q_w when the fluid is completely stationary and therefore behaves thermally like a solid—a situation reached in the limit $\text{Ra} \rightarrow 0$. For fluids that are radiantly opaque,

$$q_r = q_{r0} = 0 \quad q_{f0} = \frac{kA_f(T_h - T_c)}{L} \quad q_{w0} = \frac{k_w A_w (T_h - T_c)}{L}$$

If the fluid is transparent, $q_{r0} + q_{f0} + q_{w0}$ must be determined from a combined radiative-conductive analysis—see, for example, Hollands et al. [143]. Such an analysis is beyond the scope of this chapter, whose function is to report the additional heat transfer associated with free convective motion. This motion usually alters the temperature distribution in the wall

from that which exists when the fluid is stationary. In so doing, it alters not only q_f but also q_w and q_r ; the alteration in q_r and q_w is not incorporated into Nu as defined by Eq. 4.72, but it is incorporated into Nu as defined by Eq. 4.73. Thus the latter (Eq. 4.73) is to be preferred, and it will therefore be the meaning of Nu used in this section.

A dimensional analysis reveals that, in the most general case,

$$\text{Nu} = \text{Nu} \left(\text{Ra}, \text{Pr}, \theta, \frac{H}{L}, \frac{W}{H}, \frac{b}{L}, \frac{k_w}{k}, \frac{\sigma T_m^3 L}{k}, \epsilon_w, \epsilon_h, \epsilon_c, \frac{T_h}{T_c} \right) \quad (4.74)$$

for the rectangular parallelepiped cavity, and that for the circular cylinder cavity,

$$\text{Nu} = \text{Nu} \left(\text{Ra}, \text{Pr}, \theta, \frac{D}{L}, \frac{b}{L}, \frac{k_w}{k}, \frac{\sigma T_m^3 L}{k}, \epsilon_w, \epsilon_h, \epsilon_c, \frac{T_h}{T_c} \right) \quad (4.75)$$

The Rayleigh number is based on dimension L :

$$\text{Ra} = \frac{g\beta(T_h - T_c)L^3}{\nu\alpha} \quad (4.76)$$

Under certain (and probably most) conditions, the parameter lists given by Eqs. 4.74 and 4.75 can be considerably shortened. Table 4.6 lists some of the more common conditions and the shortening each permits. Of particular interest are the adiabatic wall and the perfectly conducting wall. The latter imposes a linear temperature rise from the cold plate to the hot plate, regardless of the convective strength.

TABLE 4.6 Conditions Under Which the List of Parameters in Eq. 4.74 or 4.75 Can Be Shortened

Entry	Condition	Changes in parameter list permitted	Name of condition or comment
1.	Fluid is opaque	Can drop $\sigma T_m^3 L/k$, ϵ_w , ϵ_h , ϵ_c , and T_h/T_c	Opaque field
2.	Fluid is opaque and $k_w/k \ll 1$ or $b = 0$	Can drop $\sigma T_m^3 L/k$, ϵ_w , ϵ_h , ϵ_c , T_h/T_c , k_w/k , and b/L	Adiabatic walls
3.	$k_w/k \gg 1$	Can drop $\sigma T_m^3 L/k$, ϵ_w , ϵ_h , ϵ_c , T_h/T_c , k_w/k , and b/L	Perfectly conducting walls
4.	$b/D \leq 0.05$	b/L and k_w/k , and b/L can be dropped, but the single group $k_w b/kD$ must be added	Finlike walls on a cylinder
5.	$b/H \leq 0.05$ and $b/W \leq 0.05$	b/L and k_w/k , and b/L can be dropped, but the single group $k_w b/(kH)$ must be added	Finlike walls on a rectangular parallelepiped
6.	Walls behave like fins and $k_w/(kL) > 25 \text{ Nu}$	Can drop $\sigma T_m^3 L/k$, ϵ_w , ϵ_h , ϵ_c , T_h/T_c , and $k_w b/kD$	Perfectly conducting walls (obtained with finlike walls)
7.	$k_w/k < \text{Nu}/5$ and $b/L > 0.75$	Can drop b/L	Very thick walls (which behave like $b = \infty$)
8.	$T_h/T_c \approx 1$	Can drop T_h/T_c	Radiation effects can be linearized
9.	$H/L \geq 10$ and $W/L \geq 10$	Can drop k_w/k , b/L , $\sigma T_m^3 L/k$, ϵ_w , ϵ_h , ϵ_c , and T_h/T_c	Extensive plates (for which heat transfer between walls and fluid is unimportant)
10.	$D/L \geq 40$, or $W/L \geq 10$ and $H/L \geq 40$	Can drop k_w/k , b/L , $\sigma T_m^3 L/k$, ϵ_w , ϵ_h , ϵ_c , T_h/T_c , and either D/L or W/L and H/L	Very extensive plates (for which extent of walls is unimportant)

The Conduction Layer Model

The concept of surrounding the surfaces by a layer of stationary fluid, called the conduction layer, is useful for the present enclosure problem as well as for the external and open cavity problems. Unless the conduction layer thickness is greater than the cavity dimensions, a central region is produced (Fig. 4.26*a* and *b*), which experience has shown takes up a nearly uniform temperature; this region can therefore be modeled as isothermal. Once the thicknesses of the conduction layers have been specified, finding the heat transfer and the temperature T_{cr} of this central region is a relatively straightforward heat conduction problem.

The conduction layer thickness Δ on each individual surface of the enclosure may be calculated using the equation $\Delta = X/\text{Nu}_X$, where X is the characteristic dimension used for that surface and Nu_X is the Nusselt number on that surface calculated using the methods previously discussed; that is, in calculating the Nusselt number for a particular surface, one assumes that the surface is immersed in an infinite fluid of uniform temperature T_{cr} . Since T_{cr} depends on the conduction layer thickness, the method will, in fact, require some iteration to find T_{cr} ; an initial guess for T_{cr} is required. For the side walls (as opposed to the plates), we take for the surface temperature the average of T_h and T_c . Once calculated, the appropriate conduction layers are applied to all the surfaces, where they are all treated as solids of conductivity equal to the fluid conductivity. The remaining core fluid is treated as material of infinite conductivity.

FIGURE 4.26 The conduction layer model: (a) conduction layer growth on plates and wall for a cavity without interior solids; (b) similar growth for a cavity with an interior solid; (c) conduction layer model applied to a horizontal cavity having $\theta = 0$ and $D \gg L$.

ity, and from a simple conduction solution, the resultant heat transfer on each plate can be calculated, as required. (Also calculated from the conduction analysis is a new value of T_{cr} , to be compared to the previously assumed value in the iterative scheme.) If the conduction layers overlap to the degree that the central region disappears, the heat transfer may simply be equated to that for pure conduction across the fluid.

These ideas can be illustrated by considering a cylindrical cavity with $D \gg L$ and $\theta = 0$ (Fig. 4.26c). The conduction layer thicknesses on the plates are found to be $\Delta_h = [\nu\alpha\{g\beta(T_h - T_{cr})\}]^{1/3}/C_i^U$ on the hot plate and $\Delta_c = [\nu\alpha\{g\beta(T_{cr} - T_c)\}]^{1/3}/C_i^U$ on the cold plate. By symmetry, $T_{cr} = (T_h + T_c)/2$, so that each conduction layer is in fact of equal thickness $\Delta = 2^{1/3}[\nu\alpha\{g\beta(T_h - T_c)\}]^{1/3}/C_i^U$. Since the central core offers no thermal resistance and since $D \gg L$, the combined unit area thermal resistance of the fluid is $2\Delta/k$, so that $q'' = k(T_h - T_c)/2\Delta$ and Nu is found to be given by $Nu = C_i^U 2^{-4/3} Ra^{1/3}$. As Ra is decreased, the conduction layers thicken until at some particular value of Ra they touch in the middle of the layer (that is, until $2\Delta = L$) and Nu becomes unity. According to the model, Nu remains at unity for smaller values of Ra. Thus the conduction layer model prediction for this problem is

$$Nu = [1, C_i^U 2^{-4/3} Ra^{1/3}]_{\max} \quad (4.77)$$

This prediction will be compared with measurement in the next section.

As yet, the conduction layer approach has only been tested quantitatively on those problems in which the influence of the side walls is unimportant. Even for these problems the model has met with only mixed success in closely predicting the heat transfer. However, it does predict the correct trends and the correct asymptotes, it is useful in correlating experimental data, and does afford a simple physical understanding to problems that, when viewed from a different perspective, often appear very complex. The practitioner may find it useful for problems for which there is insufficient information from other sources.

Horizontal Rectangular Parallelepiped and Circular Cylinder Cavities

Cavities Extensive in the Horizontal Direction ($H \gg L$ and $W \gg L$, or $D \gg L$). This section deals with situations covered by entry 10 in Table 4.6, with the additional proviso that either $\theta = 0$ or $\theta = 180^\circ$.

When $\theta = 180^\circ$, the hot, light fluid lies above the cold, heavy fluid, so the stationary fluid layer (in which there is no fluid motion) is inherently stable, and $Nu = 1$ for all Ra. (In terms of the conduction layer model, for $\theta = 180^\circ$ both the conduction layers are infinite, so the conduction layers always overlap, and $Nu = 1$.)

In the $\theta = 0^\circ$ orientation, hot, light fluid lies below the cold, heavy fluid, so the stationary fluid layer is inherently unstable. Despite this inherent instability, the fluid remains stationary provided Ra is less than a "critical Rayleigh number" denoted by Ra_c . The value of Ra_c for this particular geometry is 1708. For $Ra > Ra_c$, the instability leads to a steady-state convective motion, the form and strength of which depends on both Ra and Pr. For Ra only slightly greater than Ra_c , it consists of steady rolls of order L in size, but as Ra is further increased, more complex flow patterns are observed, and eventually the flow becomes unsteady. At very high Ra it becomes fully turbulent. The heat transfer characteristics reflect the existence of these various flow regimes: for $Ra < Ra_c$ the fluid is stationary, so Nu is unity; the cellular motion initiated at Ra_c produces a sharp rise in Nu with Ra, which ultimately becomes asymptotic to the relation $Nu \propto Ra^{1/3}$ at very large Ra.

For $\theta = 0^\circ$, the recommended equation [140] for Nu is:

$$Nu = 1 + \left[1 - \frac{1708}{Ra} \right] \cdot \left[k_1 + 2 \left(\frac{Ra^{1/3}}{k_2} \right)^{1 - \ln(Ra^{1/3}/k_2)} \right] + \left[\left(\frac{Ra}{5803} \right)^{1/3} - 1 \right] \quad (4.78)$$

where square brackets with dots indicate that only positive values of the argument are to be taken, i.e.,

$$[X]^* = \left(\frac{|X| + X}{2} \right) \quad (4.79)$$

X being any quantity. Values of the parameters k_1 and k_2 , both functions of Pr , are tabulated in Table 4.7 for several values of Pr . This table also cites the experiments from which the values were inferred, and gives the range in Ra over which Eq. 4.78 has been tested for each Pr . The following equations fit the dependence of k_1 and k_2 on Pr exhibited in Table 4.7.

$$k_1 = \frac{1.44}{1 + 0.018/Pr + 0.00136/Pr^2} \quad (4.80)$$

$$k_2 = 75 \exp(1.5 Pr^{-1/2}) \quad (4.81)$$

The form of Eq. 4.80 resulted from an approximate analysis [118], but the constants in the denominator have been chosen to fit the values given in Table 4.7 for $Pr = 0.7$ and $Pr = 0.024$, and they are therefore based on limited data. Caution is advised in using this equation when $Pr < 0.7$, except when $Pr \approx 0.024$. Also, for some values of Pr , the narrow range of Ra over which Eq. 4.78 has been tested should be noted. The data of Kek and Müller's [158] recent experiments using liquid sodium with $Pr = 0.0058$ are fit reasonably well by Eqs. 4.78–4.81, but the fit is improved considerably if k_1 is set equal to 0.087 and the power on $(Ra/5830)$ is changed from $1/3$ to $1/4$.

TABLE 4.7 Values of k_1 and k_2 to Be Used in Eq. 4.78

Pr (approximate)	k_1	k_2	Range of Ra tested	Reference
0.02	0.35	>200	$10^3 \leq Ra \leq 10^8$	233
0.7	1.40	>400	$10^3 \leq Ra \leq 10^{11}$	See 142 for list.
6	1.44	140	$10^3 \leq Ra \leq 2 \times 10^5$	See 142 for list; also 117
34	1.44	100	$10^3 \leq Ra \leq 10^5$	243
100	1.44	~85	$10^3 \leq Ra \leq 3 \times 10^6$	243
200	1.44	85	$10^3 \leq Ra \leq 5 \times 10^5$	233
3000	1.44	~75	$10^3 \leq Ra \leq 3 \times 10^4$	243

Equation 4.78 with k_1 and k_2 having values appropriate to water at moderate temperatures ($Pr \approx 6$) is plotted in Fig. 4.27, together with relevant data for water. Figure 4.28 shows a plot of Eq. 4.78 for various values of Pr , covering only those ranges in Ra at which the equation has been tested. Also plotted are the predictions of the conduction layer model given by Eq. 4.77. This model is seen to be correct only in the limit of small Ra ($Ra < 1708$) and large Ra

FIGURE 4.27 Comparison of Eq. 4.78 (solid curve) and the data of Garon and Goldstein [104], Chu and Goldstein [53], and Rossby [233] for water ($Pr \approx 6$).

FIGURE 4.28 Plot of Eq. 4.78 for various values of Prandtl numbers, describing the heat transfer across a horizontal cavity with $D/L \geq 10$ and heating from below; also shown is the heat transfer predicted by the conduction layer model (Eq. 4.77).

($Ra \geq 10^8$). The maximum error, which occurs near $Ra = 5830$, varies from 20 percent for $Pr = 0.024$ to 50 percent for $Pr \geq 0.7$.

Critical Rayleigh Numbers for Horizontal Cavities Restricted in the Horizontal Direction.

A critical Rayleigh number Ra_c governs the initiation of convective motion in the horizontal cavity that is restricted in the horizontal direction, just as in the extensive cavity discussed in the previous section. In restricted cavities, Ra_c depends on the geometric parameters describing the cavity and on the thermal properties of the wall, but not on the Prandtl number. For $\theta = 180^\circ$, $Ra_c = \infty$, as for horizontally extensive cavities. For $\theta = 0^\circ$, Ra_c is bounded between two values, Ra_{cp} and Ra_{ci} . Evaluated by Catton [31–33], and Buell and Catton [27], these bounds are tabulated in Table 4.8 for rectangular parallelepiped cavities and in Table 4.9 for circular cylinder cavities. The greater of the two, Ra_{cp} , applies to the perfectly conducting wall case (Table 4.6, entry 3 or 5); and the lesser, Ra_{ci} , applies to the adiabatic wall case (see Table 4.6, entry 2; note that because of radiation, a wall with $k_w = 0$ is not necessarily adiabatic). Interpolation and extrapolation in Tables 4.8 and 4.9 may be assisted by knowledge of certain asymptotes: for the circular cylinder,

$$\text{as } \frac{D}{L} \rightarrow \infty, \quad Ra_{cp} \rightarrow 1708 \quad \text{and} \quad Ra_{ci} \rightarrow 1708$$

and [216, 289]

$$\text{as } \frac{D}{L} \rightarrow 0, \quad Ra_{cp} \left(\frac{D}{L} \right)^4 \rightarrow 3456 \quad \text{and} \quad Ra_{ci} \left(\frac{D}{L} \right)^4 \rightarrow 1086.4$$

For the rectangular parallelepiped,

$$\text{as } \frac{H}{L} \text{ and } \frac{W}{L} \rightarrow \infty, \quad Ra_{cp} \rightarrow 1708 \quad \text{and} \quad Ra_{ci} \rightarrow 1708$$

For the rectangular parallelepiped having $W/H = \infty$ [285],

$$\text{as } \frac{H}{L} \rightarrow 0, \quad Ra_{cp} \left(\frac{H}{L} \right)^4 \rightarrow 97.4 \quad \text{and} \quad Ra_{ci} \left(\frac{H}{L} \right)^2 \rightarrow 473.7$$

The asymptotic relations for the cylinder suggest that for the square-section ($H/W = 1$) rectangular parallelepiped, $Ra_{cp} (H/L)^4$ and $Ra_{ci} (H/L)^4$ should approach constant values as $H/L \rightarrow 0$. Extrapolating the values in Table 4.8 gives the following estimates for these asymptotes:

TABLE 4.8 Critical Rayleigh Numbers Ra_{cp} and Ra_{ci} for Horizontal Rectangular Parallelepiped Cavities Having a Perfectly Conducting Wall (Ra_{cp}) or an Adiabatic Wall (Ra_{ci}) [31–33]

TABLE 4.9 Critical Rayleigh Numbers Ra_{cp} and Ra_{ci} at Different Values of D/L for Horizontal Circular Cavities Having a Perfectly Conducting Wall (Ra_{cp}) or an Adiabatic Wall (Ra_{ci}) [27]

	0.4	0.5	0.7	1.0	1.4	2	3	4	∞
Ra_{cp}	151,200	66,600	21,300	8010	4350	2540	2010	1880	1708
Ra_{ci}	51,800	23,800	8,420	3770	2650	2260	1900	1830	1708

$$\text{as } \frac{H}{L} \rightarrow 0, \quad Ra_{cp} \left(\frac{H}{L}\right)^4 \rightarrow 2350 \quad \text{and} \quad Ra_{ci} \left(\frac{H}{L}\right)^4 \rightarrow 710$$

For the limit H/L equal to infinity, Daniels and Ong [70] have obtained the following values for Ra_{cp} : 8955 at $W/L = 0.5$; 2944 at $W/L = 1$; 1870 at $W/L = 2$; and 1719 at $W/L = 4$.

For opaque fluids contained in rectangular parallelepiped cavities with finlike walls (see Table 4.6, entry 5), Catton [32, 33] has calculated Ra_c as a function of L/H , L/W , and the wall thermal admittance C_{ar} , defined by

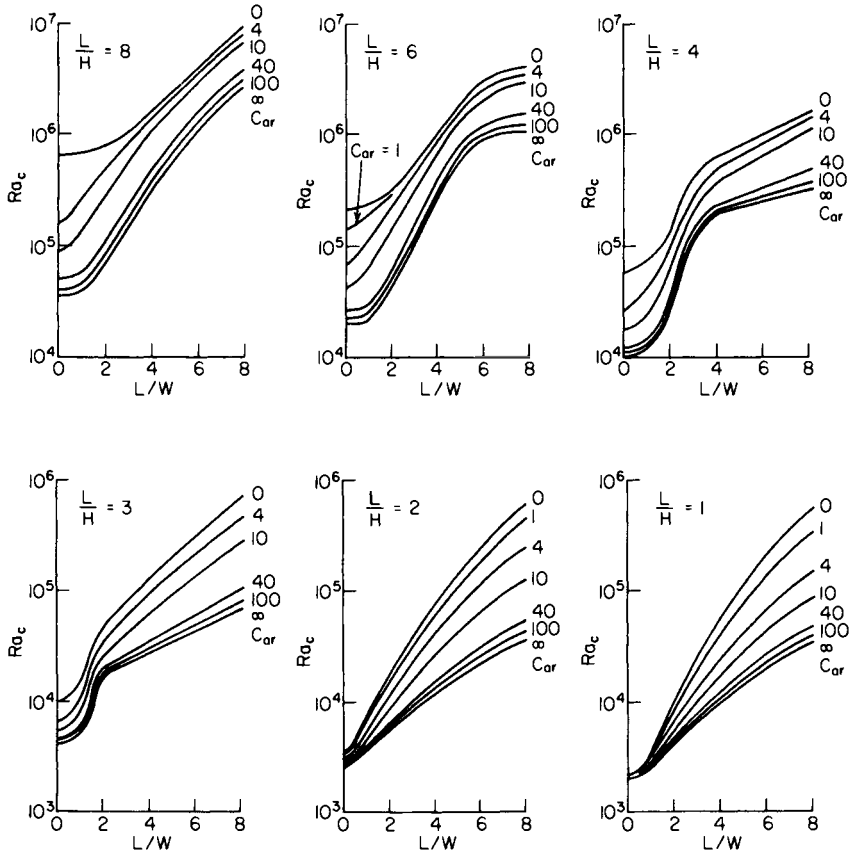

FIGURE 4.29 Catton's [32, 33] plots of Ra_c as a function of L/H , L/W , and C_{ar} for horizontal rectangular parallelepiped cavities with finlike walls of arbitrary conductivity.

$$C_{ar} = \frac{kL}{k_w b} \tag{4.82}$$

The results are plotted in Fig. 4.29. Note that $Ra_c \rightarrow Ra_{ci}$ as $C_{ar} \rightarrow \infty$, and $Ra_c \rightarrow Ra_{cp}$ as $C_{ar} \rightarrow 0$. (Values of Ra_c for cases when opposing walls have different admittances are also available [32, 33].) Figure 4.30 gives similar plots taken from the data of Buell and Catton [27] for the circular cylinder with a finlike wall (Table 4.6, entry 4), for which the wall thermal admittance C_{ac} is defined by

$$C_{ac} = \frac{kD}{2k_{wr}^* b} \tag{4.83}$$

where (for the finlike wall and an opaque fluid) $k_{wr}^* = k_w$.

No exact solutions for Ra_c are available when the walls are not finlike and L is finite. But for circular cylinder cavities with thick walls and for $L/D \rightarrow \infty$, Ostroumov [216] showed that Fig. 4.30 is valid, provided k_{wr}^* in Eq. 4.83 is equated to k_{wr} , where k_{wr} (the equivalent finlike wall conductivity of a very thick wall material—see Table 4.6, entry 7) is defined by

$$k_{wr} = \frac{k_w D}{2b} \frac{(D + 2b)^2 - D^2}{(D + 2b)^2 + D^2} \tag{4.84}$$

FIGURE 4.30 Buell's [26] plots of Ra_c as a function of D/L and C_{ar} for horizontal cylindrical cavities with finlike walls of arbitrary conductivity.

The effect of the radiant exchange in a cavity containing a transparent fluid is similar to that of an increase in wall conductivity. For circular cylinders in which $T_h/T_c \approx 1$, Edwards and Sun [83] showed that for large L/D the results of Fig. 4.30 apply to radiantly transparent fluids if k_{wr}^* in Eq. 4.83 is given by

$$k_{wr}^* = k_{wr} + \frac{8\sigma T_m^3 D \epsilon_w}{4 - \epsilon_w} \quad (4.85)$$

where $T_m = (T_h + T_c)/2$. Thus the effect of radiation is to raise the apparent conductivity of the walls and thereby raise Ra_c . Experiments by Hollands [141] and Cane et al. [29] confirmed that, although technically correct only in the limit $L/D \rightarrow \infty$, Eq. 4.85 can be applied with little error for L/D as small as unity. They also showed that Eq. 4.85 can be applied to square-celled ($H/W = 1$) rectangular parallelepiped cavities with finlike walls if D is set equal to H ; that is, by redefining C_{ar} for transparent fluids contained in square cavities as

$$C_{ar} = \frac{kL}{b[k_w + 8\sigma T_m^3 H \epsilon_w / (4 - \epsilon_w)]} \quad (4.86)$$

the points on Fig. 4.29 pertaining to $H/W = 1$ are made valid for both transparent and opaque fluids. For rectangular parallelepiped gas-filled cavities in which $W \gg H$ and $T_h/T_c \approx 1$, Edwards and Sun [82] and Sun [265] showed that for large L/H the results of Fig. 4.29 pertaining to $W \gg H$ are valid, provided C_{ar} is redefined as

$$C_{ar} = \frac{kL}{bk_w} \left(1 + \frac{\sigma T_m^3 L^2 \epsilon (1 - S_k)}{8b[1 - (1 - \epsilon)S_k]} \right)^{-1} \quad (4.87)$$

where, for $L/H > 2$, S_k is given by [253]:

$$S_k = 1.0102 - 1.4388 \frac{H}{L} - 9.4653 \left(\frac{H}{L} \right)^2 + 31.44 \left(\frac{H}{L} \right)^3 - 27.515 \left(\frac{H}{L} \right)^4 \quad (4.88)$$

This method has been found [253] to predict Ra_c with reasonable accuracy for L/H at least as small as 3.

Heat Transfer Across Horizontal Cavities Restricted in the Horizontal Direction. The recommended equation [140] for the heat transfer across horizontally nonextensive cavities is

$$\text{Nu} = 1 + \left[1 - \frac{\text{Ra}_c}{\text{Ra}} \right] \left[k_1 + 2 \left(\frac{\text{Ra}^{1/3}}{k_2} \right)^{1 - \ln(\text{Ra}^{1/3}/k_2)} \right] + \left[\left(\frac{\text{Ra}}{5830} \right)^{1/3} - 1 \right] \left(1 - \exp \left\{ -0.95 \left[\left(\frac{\text{Ra}}{\text{Ra}_c} \right)^{1/3} - 1 \right] \right\} \right) \quad (4.89)$$

where Ra_c is the critical Rayleigh number appropriate to the particular cavity, calculated by methods outlined in the previous section, and k_1 and k_2 are as given by Eqs. 4.80 and 4.81. This largely empirical equation has been tested against experimental data for gases [29, 141, 253], and liquids of various Prandtl numbers [36, 265, 266] (but not liquid metals) using circular cylinder cavities (as approximated by hexagons) with $0.2 \leq D/L \leq 5$, and rectangular parallelepiped cavities with $1 \leq H/L \leq 10$ and planforms ranging from square ($H/W = 1$) to long ($W/H \gg 1$). For circular cylinder, and for rectangular parallelepiped, cavities with $W = H$, Eq. 4.89 generally agrees with measurements to within 10 percent, but for rectangular parallelepiped cavities with $W \gg H$, differences of up to 25 percent occur. The equation from Smart et al. [253]

$$\text{Nu} = 1 + 0.131 \text{Ra}^{1/3} \left(1 - \exp \left\{ -0.18 \left[\left(\frac{\text{Ra}}{\text{Ra}_c} \right)^{0.513} - 1 \right] \right\} \right) \quad (4.90)$$

fits the data for $W \gg H$ better than Eq. 4.89, but in contrast to Eq. 4.89, it does not have the proper asymptote, as $\text{Ra} \rightarrow \infty$. Equation 4.90 agrees well with data for $\text{Ra} < 100 \text{Ra}_c$ and $L/H = 3, 5$, and 10. It is not recommended for $\text{Ra} > 100 \text{Ra}_c$.

Figure 4.31 shows a plot of Eq. 4.89 for a circular cylinder cavity with perfectly conducting walls and various values of D/L . As is clear from the graph, the Nusselt number rises very steeply with Ra after initiation of convection, and very rapidly approaches the value of Nu for the horizontally extensive cavity. This behavior is consistent with the conduction layer model: at high Ra , the conduction layers on the walls at the sides are so thin that they have no effect on the heat transfer; at sufficiently low Ra , they are so thick that they overlap (even though those on the horizontal plates do not), so that their presence governs the condition for a stationary fluid.

Heat Transfer in Vertical Rectangular Parallelepiped Cavities: $\theta = 90^\circ$

Cavities with $H/L \geq 5$ and $W/L \geq 5$. In contrast to the horizontal cavity, for which there is flow only when $\text{Ra} > \text{Ra}_c$, the vertical cavity experiences flow for any finite Ra . At small Ra ,

FIGURE 4.31 Relation between Nu and Ra for horizontal cylindrical cavities with perfectly conducting walls, for various values of D/L , as given by Eq. 4.89 with $\text{Pr} = 6.0$.

however, the velocities are small and essentially parallel to the plates, so that they contribute little to the heat transfer, and for all practical purposes, $Nu = 1$. These conditions constitute the conduction regime. The development of the flow as Ra increases beyond this regime depends on H/L .

If $H/L \geq 40$, the conduction regime becomes unstable at a critical Rayleigh number Ra_c , which is plotted as a function of Pr in Fig. 4.32 (from Ref. 162). Increases in Ra past Ra_c lead through a turbulent transition regime and finally into a fully developed turbulent boundary layer regime characterized by turbulent boundary layers on each plate and a well-mixed core between them in which there is a vertical temperature gradient of about $0.36(T_h - T_c)/H$ [170]. If $H/L \leq 40$, the flow enters a laminar boundary layer regime before becoming unstable and entering the turbulent transition regime. This laminar boundary layer regime [112] is characterized by laminar boundary layers on each plate with an essentially stationary core between them: this core is nearly isothermal in the horizontal direction, but it has a positive gradient in the vertical direction of approximately $0.5(T_h - T_c)/H$. The stability analyses [17] of the laminar boundary layer regime predict higher critical Rayleigh numbers than for the conduction regime plotted in Fig. 4.32. In summary, for $H/L \geq 40$, the regimes encountered as Ra increases are first conduction, then turbulent transition, and then turbulent boundary layer; for $H/L \leq 40$ they are conduction, then laminar boundary layer, then turbulent boundary layer.

FIGURE 4.32 Korpela's [162] plot of Ra_c governing the stability of the conduction regime in a vertical rectangular parallelepiped cavity with $W/L \geq 5$ and $H/L \geq 40$. For $Pr < 12.7$, the instability leads to stationary, horizontal axis rolls; for $Pr > 12.7$, it leads to unsteady, vertically traveling waves.

The recommended correlation equations for the Nusselt number relation are based on experimental data. For $Pr \approx 0.7$ (gases), and $H/L > 40$, the equation of Shewen et al. [250] is recommended:

$$Nu = \left[1 + \left[\frac{0.0665 Ra^{1/3}}{1 + (9000/Ra)^{1.4}} \right]^2 \right]^{1/2} \quad (4.91)$$

This equation has been validated for $Ra < 10^6$ and $40 < H/L < 110$. For $5 < H/L < 40$, the equation of ElSherbiny et al. [84, 85] equates Nu to the maximum of three Nusselt numbers as follows:

$$Nu = [Nu_{cr}, Nu_l, Nu_t]_{\max} \quad (4.92)$$

where

$$Nu_{cr} = \left[1 + \left\{ \frac{0.104 Ra^{0.293}}{1 + (6310/Ra)^{1.36}} \right\}^3 \right]^{1/3} \quad (4.93)$$

$$\text{Nu}_t = 0.242 \left(\frac{\text{Ra} L}{H} \right)^{0.273} \quad (4.94)$$

$$\text{Nu}_r = 0.0605 \text{Ra}^{1/3} \quad (4.95)$$

Nu_{cr} applies to the conduction and the turbulent transition regime, Nu_r to the laminar boundary layer regime, and Nu_t to the turbulent boundary layer regime. Equation 4.92 fits the data with a maximum deviation of about 10 percent and mean deviation of about 4 percent. It compares well with computer simulations [177]. A more accurate but also more complex set of equations is also available in [84, 85]. Equation 4.92 has been validated up to $\text{Ra} (H/L)^3 = 1.5 \times 10^{10}$ for $H/L = 5, 20, \text{ and } 40$. Equation 4.92 is based on data for perfectly conducting walls, but for $H/L \geq 10$ the effect of wall properties is not expected to be important (see Table 4.6, entry 9).

For fluids with $\text{Pr} \geq 4$, the recommended equations are based on the proposals of Seki et al. [248]. For $\text{Ra} (H/L)^3 < 4 \times 10^{12}$,

$$\text{Nu} = \left[1, 0.36 \text{Pr}^{0.051} \left(\frac{L}{H} \right)^{0.36} \text{Ra}^{0.25}, 0.084 \text{Pr}^{0.051} \left(\frac{L}{H} \right)^{0.1} \text{Ra}^{0.3} \right]_{\max} \quad (4.96)$$

and for $\text{Ra} (H/L)^3 > 4 \times 10^{12}$,

$$\text{Nu} = 0.039 \text{Ra}^{1/3} \quad (4.97)$$

These equations have been tested for values of H/L ranging from 5 to 47.5. The middle term in Eq. 4.96 has been tested for $3 < \text{Pr} < 40,000$, and the last term for $3 \leq \text{Pr} \leq 200$. Equation 4.97 has been tested only for $\text{Pr} \approx 5$, and may underpredict measurements by as much as 20 percent. For $5 \leq H/L < 10$, the equations should be most accurate for adiabatic walls. For $H/L \geq 10$, the plates are extensive (Table 4.6, entry 9), and the wall thermal properties are not important.

Vertical Cavities ($\theta = 90^\circ$) with $L/H \geq 2$ and $W/L \geq 5$. Except in an end region immediately adjacent to the two vertical plates, the flow in a cavity with $L \gg H$ is everywhere parallel to the horizontal walls, with hot fluid in the upper half of the cavity streaming toward the cold plate and cold fluid in the lower half streaming toward the hot plate (only at very high Rayleigh numbers, where turbulent eddies of a scale smaller than H are possible, will this simple flow pattern break down). The plates at temperatures T_h and T_c deflect the streams into boundary layers on each vertical surface. The predictions of Bejan and Tien [16] for *adiabatic walls* are correlated to within 8 percent by their equation

$$\text{Nu} = 1 + \left\{ \left[\gamma_1 \text{Ra}^2 \left(\frac{H}{L} \right)^8 \right]^m + \left[\gamma_2 \text{Ra}^{1/5} \left(\frac{L}{H} \right)^{2/5} \right]^m \right\}^{1/m} \quad (4.98)$$

in which $m = -0.386$, $\gamma_1 = 2.756 \times 10^{-6}$, and $\gamma_2 = 0.623$. The analysis is for laminar flow and hence this equation is not recommended for large $\text{Ra} (H/L)^3$. Because of the dominance of the walls in this problem, departures from the adiabatic wall conditions can be expected to have a marked effect on Nu .

Rectangular cavities of practical interest are very often not isolated cells but rather members of a multicellular array, such as that sketched in Fig. 4.33. When $\theta = 0$, the central plane of each partition forms an adiabatic plane of symmetry, so that each cell behaves like an isolated cell (of the type defined in the section on geometry and parameters for cavities without interior solids) having wall thickness b equal to one-half the partition thickness. When $\theta \neq 0$, there is usually heat transfer between cells, the magnitude of which is established by the coupling parameter $k_w L/kb$.

Smart et al. [253] carried out an experimental study on multicellular arrays with air as the fluid and $\theta = 90^\circ$ and found that for Ra at least as high as 10^7 , Eq. 4.98 fit their data provided

FIGURE 4.33 Sketch of a multicellular array in which many rectangular parallelepiped cavities such as sketched in Fig. 4.25 may be contained.

the values of γ_1 and γ_2 were slightly altered. The altered values of γ_1 and γ_2 , tabulated in Table 4.10, depended on the conductive and radiative wall properties, as noted in the table. Whether the changes in γ_1 and γ_2 were attributable to the multicellular array effect, the radiative effect, or both, cannot be resolved from the data.

Vertical Cavities with $0.5 < H/L < 5$ and $W/L \geq 5$. In this intermediate range of H/L , the low-to-moderate Rayleigh number flow consists of a two-dimensional roll. The problem, particularly with $L/H = 1$, has been the subject of many numerical studies, and indeed for the adiabatic wall case with $Pr = 0.7$, it has formed the basis of a “benchmark problem” [72] for computational fluid dynamic (CFD) codes (even though it is virtually impossible to duplicate this situation in the real world because real fluids with $Pr = 0.7$ can never be properly insulated). For both the perfectly conducting and the adiabatic boundary conditions, Table 4.11 gives a tabulation of Nu as a function of Ra for values of H/L of 0.5, 1, 2, and 5, as calculated by Catton et al. [35] (and reported by Catton [34]) for very large Pr , by Wong and Raithby [284] and Raithby and Wong [230] for $Pr = 0.7$, and by Le Quére [176]. The effect of Pr over

TABLE 4.10 Values of γ_1 and γ_2 to Be Used in Eq. 4.98 for Air-Filled Cavities in Multicellular Arrays [253]

L/H	ϵ_w	ϵ_h	ϵ_c	$kL/k_w b$	$\gamma_1 \times 10^6$	γ_2
3	0.13	0.065	0.065	100	1.274	0.415
5	0.13	0.065	0.065	166	1.324	0.474
5	0.9	0.065	0.065	42	0.970	0.594
5	0.9	0.9	0.065	42	1.524	0.430
5	0.9	0.9	0.9	42	4.76	0.511
10	0.13	0.065	0.065	332	3.952	0.502

See Fig. 4.33 for the meaning of b .

the range $0.7 < Pr < \infty$ is seen to be quite modest. But for $Pr < 0.7$, the effect of Pr has been found to be stronger: the effect of low Prandtl number on cavities with adiabatic walls and $H/L = 1$ was investigated, using a CFD code, by Lage and Bejan [173]. They found that at $Ra = 1 \times 10^5$, Nu went from 4.9 at $Pr = 1$, to 3.35 at $Pr = 0.1$, and to 2.77 at $Pr = 0.01$. These workers also give a criterion to establish whether the flow is laminar or turbulent. Extension to Table 4.11 to higher Ra appears only to have been made for the “benchmark” configuration (i.e., adiabatic walls, $Pr = 0.7$). Thus Kuyper et al. [171] correlated their CFD results by the equations

$$Nu = 0.171 Ra^{0.282} \quad \text{for } 10^4 < Ra < 10^8 \quad (4.99a)$$

$$Nu = 0.050 Ra^{0.341} \quad \text{for } 10^8 < Ra < 10^{12} \quad (4.99b)$$

Equation 4.99b fits predictions obtained using a turbulence model. Hsieh and Wang [146] correlated their high Rayleigh number experimental results on adiabatic-walled cavities by the equations

$$Nu = 0.321 Ra^{0.241} (H/L)^{-0.095} Pr^{0.053} \quad \text{for } 10^6 < Ra < 1.4 \times 10^7 \quad (4.100)$$

and
$$Nu = 0.133 Ra^{0.301} (H/L)^{-0.095} Pr^{0.053} \quad \text{for } Ra > 1.4 \times 10^7 \leq Ra \leq 2 \times 10^9 \quad (4.101)$$

This equation pair was derived from data covering the range $0.7 < Pr < 464$ and $3 < H/L < 5$.

Heat Transfer in Vertical Cavities With $W/L \geq 5$: An Overview. Figure 4.34 presents a compilation of some of the data of the previous three sections in terms of Nu versus H/L , with Ra as a parameter, for adiabatic walls with $\epsilon_w = 0$ and $Pr = 0.7$. The figure shows a peak that moves to lower values of H/L as Ra is increased.

FIGURE 4.34 Nu as a function of H/L for various values of Ra for a vertical rectangular parallelepiped cavity with $W/L \geq 5$, $Pr = 0.7$, and $\epsilon_w = 0$ (no radiation effects). For $H/L < 0.5$, the plot is based on Eq. 4.98; for $0.5 \leq H/L \leq 5$, it is based on Table 4.11; for $H/L > 5$, it is based on Eq. 4.92.

Effect of W/L on the Heat Transfer in Vertical Cavities. For $L/H = 4$, and for cavities with adiabatic walls, Arnold et al. [9] showed experimentally that Nu is unaffected when W/H is decreased from essentially infinity to 2. On the other hand, Edwards et al. [80] demonstrated that when W/H is further reduced to unity, a very substantial reduction in Nu results. For cavities with $2 \leq L/H \leq 10$ within a multicellular array (Fig. 4.33), the experimental data of Cane et al. [29] with $W/H = 1$ show a constant reduction factor in $Nu - 1$ of about 2.2 when compared to the $W/H \rightarrow \infty$ data of Smart et al. [253]. That is, for all other factors (including Ra) constant,

$$\frac{(Nu - 1)_{W/H=1}}{(Nu - 1)_{W/H \rightarrow \infty}} = 0.45 \pm 0.05 \quad (4.102)$$

The reduction relation given by Eq. 4.102 has been tested for $Ra \leq 10^6$ with $L/H = 2, 3, 4$, and 5, and for $Ra \leq 3 \times 10^6$ for $L/H = 10$.

Very little information exists on the effect of W on Nu at moderate to high values of H/L . Edwards et al. [80] indicate that when $H/L \geq 0.5$, provided $W/L \geq 2$, Nu is insensitive to W . A somewhat similar insensitivity to W/L was found in the CFD study of Fusegi et al. [298] for adiabatic-walled cavities; they found that changing W/L from ∞ to 1 decreased Nu by only 8.3 percent at most. At higher Ra an even smaller decrease in Nu would be expected. More work is required to sort out the effect of W/L .

Heat Transfer in Inclined Rectangular Cavities

Angular Scaling. Depending on the inclination θ , flow in an inclined cavity with $W/H > 8$ can resemble that in the corresponding horizontal cavity or that in the corresponding vertical cavity; it rarely combines the characteristics of both. Consequently, with few exceptions, the Nusselt number in the inclined cavity can be determined, to a reasonable approximation, from either the vertical or the horizontal Nusselt number relation, by means of simple angular scaling laws.

In this section $Nu_H(Ra)$ will refer to the Nusselt number–Rayleigh number relation for a horizontal cavity (as determined by methods given in the section on natural convection in these cavities) having the same values for all the other relevant dimensionless groups as the inclined cavity at hand. Similarly, $Nu_V(Ra)$ will refer to the $Nu(Ra)$ relation for the corresponding cavity at $\theta = 90^\circ$ (as determined by methods given in the section on heat transfer in vertical rectangular parallelepiped cavities), while $Nu_\theta(Ra)$ will be the sought $Nu(Ra)$ relation at the angle θ .

The scaling laws are found to be slightly dependent on the Prandtl number; the laws will first be reported for $Pr \geq 4$ (nonmetallic liquids), then for $Pr \approx 0.7$ (gases).

Cavities with $Pr \geq 4$ and $W/H \geq 8$. For $90^\circ < \theta < 180^\circ$, i.e., cavities heated from above, the scaling law suggested by Arnold et al. [7],

$$Nu_\theta (Ra) = 1 + (Nu_V (Ra) - 1) \sin \theta \tag{4.103}$$

has been experimentally validated by Arnold et al. [8] for cavities with $H/L = 1, 3, 6,$ and 12 . For $0 < \theta < 90^\circ$ (heating from below), two scaling laws are particularly useful: the horizontal scaling law of Clever [65],

$$Nu_\theta (Ra) = Nu_H (Ra \cos \theta) \tag{4.104}$$

and the vertical scaling law,

$$Nu_\theta (Ra) = Nu_V (Ra \sin \theta) \tag{4.105}$$

for $H/L \geq 6$, the maximum of the values of Nu_θ given by each is recommended, i.e.,

$$Nu_\theta (Ra) = [Nu_H (Ra \cos \theta), Nu_V (Ra \sin \theta)]_{\max} \tag{4.106}$$

FIGURE 4.35 Plot of the crossover angle θ_c governing the transition from horizontal-like flow to vertical-like flow in an inclined cavity containing nonmetallic liquids. Adapted from Arnold et al. [8]. θ_c is in degrees.

Equation 4.106 yields a single value of the crossover angle θ_c , defined so that for $\theta < \theta_c$ the horizontal scaling law applies and for $\theta > \theta_c$ the vertical scaling law applies. Angle θ_c is obtained by equating $Nu_H (Ra \cos \theta)$ to $Nu_V (Ra \sin \theta)$ and solving for θ . This angle (which also locates a minimum in Nu_θ when Nu_θ is plotted against θ with Ra held constant) is plotted as a function of H/L in Fig. 4.35, as given by Arnold et al. [8]. Equation 4.106, with a different but very similar vertical scaling law, was validated by Arnold et al. [8] for $H/L = 6$ and 12 and for $10^4 \leq Ra \leq 10^6$.

For $1 < H/L \leq 6$, the variation of Nu_θ over the range $0 < \theta < 90^\circ$ is found to be quite modest, and the horizontal scaling law breaks down. For this regime in H/L the following relations, similar to those proposed by Catton [34], are recommended:

$$Nu_\theta (Ra) = Nu_V (Ra \sin \theta) \quad \theta_c < \theta < 90^\circ \tag{4.107}$$

$$Nu_\theta (Ra) = Nu_H (Ra) \left[\frac{Nu_V (Ra \sin \theta_c)}{Nu_H (Ra)} \right]^{0.6} \quad 0 < \theta < \theta_c \tag{4.108}$$

where θ_c is obtained from Fig. 4.35. Equations 4.107 and 4.108 are in agreement with the data of Arnold et al. [8] for $H/L = 1$ and 3 . Agreement with the data and theory of Ozoe et al. [217] is not so satisfactory, but the differences are mostly within 10 percent. For $1 \leq H/L \leq 6$, and for $10^4 < Ra < 5 \times 10^5$, the $Nu_V (Ra)$ relation can be approximated by a $1/4$ -power law so that for this range Eq. 4.107 can be approximated by [35]

$$Nu_\theta (Ra) = Nu_V (Ra) \sin^{1/4} \theta \tag{4.109}$$

For $H/L \leq 0.25$, Eq. 4.106 is again recommended; when $Nu_H (Ra \cos \theta)$ is equated to $Nu_V (Ra \sin \theta)$ to find the crossover angle θ_c , this angle is generally found to be greater than 60° . Equation 4.106 agrees within about 10 percent with the data of Arnold et al. [9] for $H/L = 0.25$, and Edwards et al. [80] for $H/L = 0.25$ and $H/L = 0.14$. No data on which to base scaling laws seem to be available for $0.25 \leq H/L \leq 1$.

Cavities with $Pr \approx 0.7$ and $W/H \geq 8$. For $H/L > 5$ and $0 \leq \theta \leq 60^\circ$, direct application of the horizontal scaling law (Eq. 4.104) introduces significant errors when $Pr \approx 0.7$ and $Ra \approx 10^4$ [144]; these errors have been shown [66, 235] to result from a secondary instability that appears at a Rayleigh number only slightly greater than that for the primary instability discussed in the section on horizontal rectangular parallelepiped and circular cylinder cavities. A modified scaling relation, taken from Hollands et al. [144], is recommended for $0 \leq \theta \leq 60^\circ$:

$$Nu_\theta (Ra) = 1 + 1.44 \left[1 - \frac{1708}{Ra \cos \theta} \right] \cdot \left[1 - \frac{1708 (\sin 1.8\theta)^{1.6}}{Ra \cos \theta} \right] + \left[\left(\frac{Ra \cos \theta}{5830} \right)^{1/3} - 1 \right] \quad (4.110)$$

This equation agrees well with data up to $Ra \approx 10^5$; for $Ra = 10^6$ it underestimates the measurements of ElSherbiny et al. [84, 85] by 10 percent. (See Eq. 4.79 for meaning of dots.)

For $\theta = 60^\circ$ the recommended relation, taken from ElSherbiny et al. [84, 85], is

$$Nu_{60} (Ra) = [Nu_{60}^1, Nu_{60}^2]_{\max} \quad (4.111)$$

$$\text{where} \quad Nu_{60}^1 = \left[1 + \frac{(0.0936 Ra^{0.314})^7}{1 + G} \right]^{1/7} \quad G = \frac{0.5}{[1 + (Ra/3165)^{20.61}]^{0.1}} \quad (4.112)$$

$$\text{and} \quad Nu_{60}^2 = \left(0.1044 + 0.1750 \frac{L}{H} \right) Ra^{0.283} \quad (4.113)$$

For $60^\circ \leq \theta \leq 90^\circ$, linear interpolation between the 60° and 90° relations is recommended:

$$Nu_\theta (Ra) = \frac{90^\circ - \theta}{30^\circ} Nu_{60} (Ra) + \frac{\theta - 60^\circ}{30^\circ} Nu_{90} (Ra) \quad (4.114)$$

The tested range of validity of Eqs. 4.111–4.114 is the same as that for Eq. 4.92.

For $0.5 \leq H/L \leq 5$ and $45^\circ \leq \theta \leq 90^\circ$, Meyer et al. [191] recommend a relation that can be fitted by

$$Nu_\theta (Ra) = 1.06 Nu_{90} (Ra) \quad 45^\circ \leq \theta \leq 60^\circ \quad (4.115)$$

$$Nu_\theta (Ra) = \left[1 + \frac{0.06(90^\circ - \theta)}{30^\circ} \right] Nu_{90} (Ra) \quad 60^\circ \leq \theta \leq 90^\circ \quad (4.116)$$

For $3 \leq L/H \leq 10$ and $0 \leq \theta \leq 75^\circ$, Smart et al. [253] found that the horizontal scaling law (Eq. 4.99) is valid. For ranges of θ not covered in this section, the relevant scaling laws for $Pr \geq 4$ are tentatively recommended (see the preceding section).

Effect of W/H on Nu for Inclined Cavities. The data of Edwards et al. [80] indicate that for $L/H = 4$, horizontal scaling (which had been found valid for $0 \leq \theta \leq 60^\circ$ when $W/H = 24$ and 8) becomes invalid for $W/H = 4$. The data of Cane et al. [29], for which $W/H = 1$, agree well with the following relation:

$$Nu = 1 + 1.15 [Nu_{90} (Ra) - 1] \cos (\theta - 60^\circ) \left(\frac{Ra H^4}{2840 L^4} \right)^{1.64(1 - \sin \theta)} \quad (4.117)$$

provided $\theta \geq 30^\circ$ and $Ra H^4/L^4 \leq 6000$. Equation 4.117 was validated for $L/H = 2, 3, 4$, and 5. Plotted experimental data for a number of combinations of W/H , H/W , and θ are given by Edwards et al. [80].

Heat Transfer in Enclosures with Interior Solids at Prescribed Temperature

Region between Concentric or Eccentric Cylinders. The geometry and dimensions are as shown in cross section in Fig. 4.36a, the two cylinders being assumed to have parallel axes. The dimension E represents the perpendicular distance from the axis of the inner cylinder to the axis of the outer cylinder. Thus, for concentric cylinders, $E = 0$. Each cylinder is taken to be isothermal but at a different temperature.

FIGURE 4.36 Sketch of concentric and eccentric cylinder and sphere problems.

The stages of flow development with increasing Ra parallel those in the vertical rectangular parallelepiped cavity. For small Ra , the fluid flow (which is present for any finite Ra) is sufficiently feeble that the heat transfer is, for all practical purposes, by conduction only. As Ra is increased, a laminar boundary layer regime is established wherein the flow is largely restricted to boundary layers on each of the cylinders. The central region in the regime is stably stratified and almost stationary: it generally contains one or two large, slowly rotating eddies on each side of the cavity, but the details of this flow structure have little effect on the heat transfer. At high Ra the boundary layers can be expected to become turbulent.

The Nusselt number for this problem is defined by

$$Nu = \frac{q' \ln (D_o/D_i)}{2\pi(T_i - T_o)k} \quad (4.118)$$

where q' is the heat transfer by conduction and convection from the inner cylinder to the outer one per unit axial length of cylinder. The temperatures T_i and T_o correspond to the inside diameter D_i and the outside diameter D_o . By Nu_{COND} we mean the Nusselt number that applies when the fluid is stationary and so there is no convection. The definition for Nu prescribed by Eq. 4.118 makes $Nu_{COND} = 1$ when the cylinders are concentric ($E = 0$), and

$$Nu_{COND} = \frac{\ln (D_o/D_i)}{\cosh^{-1} [(D_o^2 + D_i^2 - 4E^2)/2D_oD_i]} \quad (4.119)$$

when $0 \leq E < L$.

Figure 4.36b shows conduction layers applied to each cylinder. Both conduction layer thicknesses are shown as being much less than the spacing L so that they do not touch—this situation will always occur if Ra is large enough to make $\Delta_o + \Delta_i < L - E$. Since, according to the conduction layer model, the central region is isothermal, this model predicts that, provided the conduction layers do not touch, Nu will be independent of E . In fact, this is what is

observed; for cylinders with vertical axes and for $Ra = 4.8 \times 10^4$, $D_o/D_i = 2.5$, and $Pr = 0.7$, Kuehn and Goldstein [164] found that Nu changed by no more than 10 percent when E was varied from 0 to $\frac{2}{3}L$, regardless of the direction of displacement of this inner cylinder. (Calculations indicate that for this Ra , $\Delta_i \approx \Delta_o \approx L/4$, so a slight overlap of conduction layers would have occurred at $E = \frac{2}{3}L$.)

Cylinders With Horizontal Axes. The conduction layer model has been shown to accurately predict the heat transfer for horizontal cylinders [164, 223], but because of the need to iteratively solve for the central region temperature it does not yield an explicit expression for Nu . However, by making additional approximations Raithby and Hollands [223] were able to derive an explicit relation for the heat transfer when the (assumed laminar) conduction layers do not overlap:

$$Nu_i = 0.603 \bar{C}_i \frac{\ln(D_o/D_i) Ra^{1/4}}{[(L/D_i)^{3/5} + (L/D_o)^{3/5}]^{5/4}} \quad (4.120)$$

For $E = 0$, the conduction layers just touch when Ra falls to the value at which Eq. 4.120 predicts $Nu_i = Nu_{COND} = 1$; for still smaller values of Ra , Nu remains at Nu_{COND} , so that for the conduction *and* laminar flow regimes

$$Nu = [Nu_{COND}, Nu_i]_{\max} \quad (4.121)$$

where Nu_i is given by Eq. 4.120 and Nu_{COND} is equal to unity. For $E \neq 0$, Eq. 4.121 can still be used, with Eq. 4.119 being used for Nu_{COND} ; however, since the conduction layers do not touch uniformly as Ra decreases toward the conduction regime, some error must be expected around $Nu_i \approx Nu_{COND}$. Well removed from this region, the equation should be accurate.

Equation 4.121 was tested against earlier (i.e. prior to 1975) data with $E = 0$ over the ranges $2 \times 10^2 \leq Ra \leq 8 \times 10^7$, $0.7 \leq Pr \leq 6000$, and $1.15 \leq D_o/D_i \leq 8$; agreement was almost invariably within 10 percent. The more recent data of Kuehn and Goldstein [164] at $D_o/D_i = 2.6$ and at $Pr = 0.7$, which covered the range $2 \times 10^2 \leq Ra \leq 8 \times 10^7$, agree with Eq. 4.116 with a mean deviation of 2.1 percent and a maximum error, occurring when $Nu \approx 1$, of 8 percent. The equation also agrees very well with the numerical solutions of Farouk and Güçeri [96], which were for $D_o/D_i = 2.6$ and ranged in Ra from 10^3 to 10^7 . For $Ra > 10^8$, turbulence effects neglected in the derivation of Eq. 4.115 may become important, and the nonexplicit conduction layer model, expanded on by Kuehn and Goldstein [163, 164], should be adopted. Also, the equation may not be accurate at very low Prandtl numbers. An equation with a wider Prandtl number range has been recommended by Hessami et al. [136] on the basis of their own data (which covered the ranges $0.023 < Pr < 10,000$ and $1.15 < D_o/D_i < 11.4$) as well as those of some other workers. Their equation is

$$Nu = 0.265 [\ln(D_o/D_i)] [Ra (D_i/L)^3 (1 - D_i/D_o)/(1 + 0.952/Pr)]^{1/4} \quad (4.122)$$

Cylinders With Vertical Axes. In the case of vertical cylinders, the height H of the cylinders also plays a role, and so do the two flat end faces, which are assumed to be adiabatic surfaces. Several studies have been done on this problem; Kumar and Kalam [169] have provided a summary of much of that work. For laminar flow and outside the conduction regime, they recommend the equation

$$Nu_i = 0.09 Ra^{0.278} (D_o/D_i)^{0.34 + 0.329 D_i/D_o} (L/H)^{0.122} (D_i/L) \ln(D_o/D_i) \quad (4.123)$$

Once Nu_i has been calculated from this equation, Eq. 4.121 should then be applied. The range of validity of this approach should extend at least over the following ranges: $Ra < 10^6$, $2 < (D_o/D_i) < 15$, $1 < H/L < 10$.

Region Between Concentric and Eccentric Spheres. The geometry, dimensions, and Rayleigh number definition are as sketched in Fig. 4.36a, the centers of the (isothermal)

spheres being distance E apart. The flow regimes and heat transfer relations closely parallel those for the circular cylinder. The Nusselt number is defined by

$$\text{Nu} = \frac{qL}{\pi D_i D_o (T_i - T_o) k} \quad (4.124)$$

which makes the Nu_{COND} (i.e., the Nu for a stationary fluid) equal to unity when $E = 0$. Nu_{COND} for $0 < E < L$ is found by conduction analysis to be [M. M. Yovanovich, personal communication]

$$\text{Nu}_{\text{COND}} = \frac{D_o - D_i}{\Phi(\eta_i) D_o - \Phi(\eta_o) D_i} \quad (4.125)$$

$$\Phi(\eta) = \left[1 + \sum_{n=1}^{\infty} \frac{\sinh \eta}{\sinh (n+1)\eta} \right]^{-1} \quad (4.126)$$

$$\eta_i = \cosh^{-1} \sqrt{\frac{D_o^2 - D_i^2 - 4E^2}{4D_i E}}, \quad \eta_o = \cosh^{-1} \left(\frac{2E}{D_o} + \frac{D_i}{D_o} \sqrt{\frac{D_o^2 - D_i^2 - 4E^2}{4D_i E}} \right) \quad (4.127)$$

When $0.3 \leq \eta \leq 1.2$, Eq. 4.126 can be approximated to within 1 percent by $\Phi(\eta) = 0.659\eta^{0.42}$; when $\eta \geq 1.2$, it can be similarly approximated by $\Phi(\eta) = (2 \cosh \eta - 1)/(2 \cosh \eta)$. As was the case for cylinders, Nu is expected to be independent of E when Ra is large enough to make $\Delta_i + \Delta_o < L - E$. Using a modified conduction layer method, Raithby and Hollands [223] obtained an explicit relation for the Nusselt number Nu: namely Eq. 4.121 with Nu_{COND} given by Eqs. 4.125–4.127 (or given by unity if $E = 0$) and Nu_i given by

$$\text{Nu}_i = 1.16 \bar{C}_i \left(\frac{L}{D_i} \right)^{1/4} \frac{\text{Ra}^{1/4}}{[(D_i/D_o)^{3/5} + (D_o/D_i)^{4/5}]^{5/4}} \quad (4.128)$$

This equation was shown to closely fit the $E = 0$ data of Scanlan et al. [241], which covered the ranges $1.3 \times 10^3 \leq \text{Ra} \leq 6 \times 10^8$, $5 \leq \text{Pr} \leq 4000$, and $1.25 \leq D_o/D_i \leq 2.5$. The measurements of Weber et al. [281] for eccentric spheres, where the displacement of the concentric position is vertically up or down, showed that for downward displacement E had little effect on Nu for $0 \leq E/L \leq 0.75$, but for upward displacement with $0.25 \leq E/L \leq 0.75$, the Nusselt number was observed to be about 10 percent higher than that given by Eq. 4.128. The same reservations as discussed for the cylinder when $\text{Nu}_{\text{COND}} \approx \text{Nu}_i$ apply here.

Other 3D Enclosures With Interior Solids. Warrington and Powe [278] showed that so far as the heat transfer is concerned, cubes and stubby cylinders behave similarly to equivalent spheres of the same volume. This appears to be the case for both the inner and outer body shape. So Eqs. 4.121, 4.124, and 4.128 appear to be applicable to other inner and outer body shapes as well, it being understood that $D_o = (6V_o/\pi)^{1/3}$ and $D_i = (6V_i/\pi)^{1/3}$, where V_o and V_i are the inner and outer body volumes, respectively. Sparrow and Charmichi [258], using stubby cylinders for the inner and outer body shapes, confirmed the conduction layer model prediction that the heat transfer is independent of eccentricity E when Ra (based on inner cylinder diameter) is greater than about 1500.

Partitioned Enclosures

Classification of Partitions. Partitions are relatively thin, solid walls mounted inside the enclosure, as for example in Fig. 4.33. The partitions are “passive” in the sense that neither their temperature nor heat flux is prescribed. Depending on their extent and orientation, such partitions can have profound effect on the heat transfer. Partitions can be classified in various ways. *Complete partitions* run continuously from one side to another; *partial partitions* have

breaks, or *windows*. Referring to Fig. 4.25, *parallel partitions* run parallel to the hot and cold plates; *perpendicular partitions* run perpendicular to these plates, or parallel to the side walls as shown in Fig. 4.33. Partitions can also be either *single* (one partition only) or *multiple* (more than one partition).

Complete, Parallel Partitions. We first consider a single parallel partition. Such a partition will divide the enclosure into two *subenclosures*. Usually it is a fair approximation to treat each subenclosure as a regular enclosure of the type discussed in the previous parts of this section. Such a strategy requires the determination of the partition's temperature, and this can generally be found by trial and error through an energy balance on the partition itself. (If the fluid is a gas it is very important to include radiation in the heat balance—for a sample of such calculations, see Hollands and Wright [145].) The problem with such a strategy is that it inherently assumes that the partition is isothermal. Under certain conditions, for example at very high Rayleigh numbers or in the triple-paned vertical windows [287], the assumption would appear to introduce little or essentially zero error. On the other hand, it is known to introduce substantial error in at least one case: the horizontal layer at near-critical conditions.

Thus consider the rectangular parallelepiped of Fig. 4.25a with $\theta = 0$ and with a thin partition running parallel to the plates and extending the whole H by W distance between the walls. It is further assumed that the cavity is extensive in the horizontal direction, i.e., $W \gg L$ and $H \gg L$, and (for the moment) that the fluid is opaque to thermal radiation. Catton and Lienhard [37] have treated the problem of predicting the critical Rayleigh number in such a situation, for arbitrary thickness L_B and conductivity k_B of the partition and for arbitrary spacings L_1 and L_2 between the lower plate and the partition and between the upper plate and the partition, respectively. (Note that $L = L_1 + L_2 + L_B$.) For $L_1 = L_2$ they found that the critical Rayleigh number for each layer varied with k/k_B , from 1708 at $k/k_B = 0$ to very close to 1296 at large values of k/k_B . (The isothermal partition model described in the previous paragraph would predict a critical Rayleigh number of 1708.) Keeping to the restriction that $L_1 = L_2$, and for thin partitions (implying in this case that $L_B/L < 0.2$), their predicted critical Rayleigh number Ra_c for each layer was found to vary with the group $k(L_1 + L_2)/(k_B L_B)$ as follows: for $k(L_1 + L_2)/(k_B L_B) = 1$, $Ra_c \approx 1580$; for $k(L_1 + L_2)/(k_B L_B) = 3$, $Ra_c \approx 1480$; for $k(L_1 + L_2)/(k_B L_B) = 10$, $Ra_c \approx 1375$; and for $k(L_1 + L_2)/(k_B L_B) = 100$, $Ra_c \approx 1305$. When $L_1 \neq L_2$, they found that the critical Rayleigh number for the thicker fluid layer is always bounded between 1708 and 1296. Lienhard [182] extended these results to layers of fluids (like gases) that are transparent to thermal radiation, where the partition is opaque. In the case where $L_1 = L_2$, the effect of radiation is to raise the upper-layer Ra_c , applying for the case of the limit of large k/k_B , from the value of 1296 that applied for no radiation to a value intermediate between 1296 and 1708, given by

$$Ra_c = 1502 - 206 \tanh \left(\ln \left[1.636 \left(\frac{T_c}{T_h} \right)^{0.5331} \left(\frac{k}{4\sigma T_h^4 L_1} \right)^{0.46511} \right] \right) \quad (4.129)$$

Once convection starts in either of the two layers, it drives a fluid motion in the other. Using a certain model (the Landau model), Lienhard and Catton [299] predicted the heat transfer in the Rayleigh number range slightly greater than critical. Use of Eq. 4.78 for both layers, with the Ra_c the one relevant to thicker layer, is also tentatively recommended.

Like the single-partition enclosure, the multipartitioned enclosure may be treated by analyzing each subenclosure separately, assuming isothermal partitions, and then making energy balances on the individual partitions to determine the partition temperatures (e.g., see Hollands and Wright [145]). But, as for the single-partition case, substantial errors can arise around the critical condition at $\theta = 0$. Finding the critical Rayleigh numbers for each layer has been treated by Hieber [139] and Lienhard [181] for some special cases. For the case where the spacing between partitions is constant, the Ra_c at the limit of diminishingly small k_B is found to be only 720 for the inner layers and 1296 for the layers that are next to the hot and cold plates. These should be compared to an expected value of 1708 on the basis of the isothermal partition. For further details the interested reader is referred to these papers.

Complete Perpendicular Partitions. For this case, where the partition(s) are perpendicular to the plates (as illustrated in Fig. 4.33), two or more subenclosures are formed, the partitions themselves constituting at least part of the side walls of these subenclosures. In the conceptual process of forming these subenclosures, the partitions' thickness should be split down the middle, with half of the partition being inside each of the adjacent subenclosures. With certain reservations, the heat transfer across these subenclosures can then be determined using the methods for unpartitioned enclosures described in previous sections. The reservations concern the boundary conditions applying on the outside faces of the side walls. In the section on geometry and parameters for cavities without interior solids (which refers to Fig. 4.25), these outside faces were prescribed as being adiabatic surfaces. Thus, strictly speaking, for the methods of previous sections to apply, the central faces of the split partitions should be treatable as adiabatic. Under certain conditions—for example, because of symmetry—this may be realistic, although because of the possibility of corotating cells in adjacent subenclosures, even then the adiabatic assumption may not be strictly correct. On the other hand, the errors associated with the nonadiabatic conditions should be acceptably small. If the thermal analyst is not satisfied with the uncertainties associated with this approximation, more refined analyses do exist (e.g., see Asako et al. [10]) and experimental data are available (e.g., see Cane et al. [29], Smart et al. [253]), but these will be only for certain limited methods of partitioning that may or may not match those of interest to the analyst.

Partial Parallel Partitions. In a number of studies researchers have investigated the rectangular parallelepiped cavity of Fig. 4.25a, at $\theta = 90^\circ$, in which a partial partition is inserted parallel to and midway between the plates. In most of the experimental work, the Rayleigh number was on the order of 10^{10} (so the conduction boundary layers on the vertical walls are very much smaller than the cavity dimensions) and the Prandtl number was close to 6. However, when expressed in terms of the equations below, the results should have wider applicability. In the early studies, the partition projected some vertical distance, say H_p , either down from the ceiling or up from the floor, and it ran the entire width W of the cavity. For the situation in which the partition runs up from the floor, Lin and Bejan [186] found that the part of the cold side of the cavity that is below the top of the partition in elevation contains only a very weak circulation cell that hardly contributes to the heat transfer, whereas a strong circulatory cell runs—in a single boundary layer—up the hot plate, across the ceiling to the cold plate, down the cold plate to the elevation of the top of the partition, across the cavity to the top of the partition, down the partition on the hot side, across the floor, and back to the hot plate. Unless the opening is very small, this cell carries almost the entire heat transfer observed, which means that only the upper part of the cold plate receives significant heat transfer. When the partition projects down from the ceiling, an analogous pair of cells is produced. On the basis of this model Lin and Bejan developed a quantitative heat transfer model that fit their data and those of other workers. After some reworking, their model can be expressed as

$$\text{Nu} = \text{Nu}_{np} - (\text{Nu}_{np} - \text{Nu}_{fp}) \left(1 - \frac{1.5H^{-3/4}}{(H_0 + H_{\text{MIN}})^{-3/4} + 0.5(H_0 + H_{\text{MAX}})^{-3/4}} \right) \left(1 - \frac{1.5H^{-3/4}}{H_{\text{MIN}}^{3/4} + 0.5H_{\text{MAX}}^{3/4}} \right)^{-1} \quad (4.130)$$

where $H_0 = H - H_p$ is the height of the “window” left in the partition, $H_{\text{MAX}} = H_p$, and for the moment $H_{\text{MIN}} = 0$. To apply this equation, one must first evaluate the Nusselt number Nu with the partition fully removed; this is the Nu_{np} (or Nu for no partition) in Eq. 4.130. Next one evaluates the Nu with the full partition in place, i.e., with $H_p = H$; this is the Nu_{fp} (or Nu for full partition) in Eq. 4.130. Both Nu_{np} and Nu_{fp} can be evaluated using the methods of previous sections. Equation 4.130 provides an interpolation scheme to be used between these two limiting values for Nu . The work of Nansteel and Greif [205] showed that moving the partition—so that it is no longer central but is closer to either the hot plate or the cold plate—has only a minor effect on the heat transfer provided the movement is $H/4$ or less.

An extension can be made to Lin and Bejan's analysis to allow for there being both an upper and a lower partition, the upper partition extending down, say, distance H_U from the ceiling, and the lower partition extending upward, say, distance H_L from the floor, leaving an opening of height $H_0 = H - H_L - H_U$. The result of such an analysis is again expressed by Eq. 4.130, provided one now interprets H_{MAX} as the maximum of H_U and H_L and H_{MIN} as the minimum of H_U and H_L .

It may be that the opening in the partition does not extend the full width W of the cavity shown in Fig. 4.25. Say it only extends over a width W_0 , leaving widths W_L and W_R on the left and right, respectively. The flow in the parts of the cavity on the right and left of the opening should be very similar to the flow in the corresponding complete cavity with the full partition, while the flows in the part having the opening should be very similar to the flow in the corresponding complete cavity with the opening extending the full width. Thus it is recommended that one determine the Nusselt number from a weighted average of the Nu_{fp} (giving it weight $(W_L + W_R)/W$) and the Nu calculated from Eq. 4.130 (giving it weight W_0/W). Karki et al. [154] have numerically investigated such enclosure in the low Rayleigh number range: $10^4 < \text{Ra} < 10^7$.

TRANSIENT NATURAL CONVECTION

External Transient Convection

Overview. Suppose a body, such as that shown in Fig. 4.37a, is initially in equilibrium with its surroundings at T_∞ , but at time $t = 0$ its surface temperature is changed impulsively to T_w . The surface heat flux rises to infinity (theoretically) and then falls off quickly with increasing t as shown in Fig. 4.37b. Since there is a delay in initiating the fluid motion, the heat flow into the fluid is initially by conduction, and the surface average heat flux \bar{q}'' follows the conduction curve in Fig. 4.37b to the departure time t_D . At a later time ($t > t_\infty$), steady-state convection is achieved. These two regimes are called the conduction regime ($0 \leq t \leq t_D$) and the steady-state regime ($t \geq t_\infty$). The transition regime lies in the range $t_D < t < t_\infty$.

At time t_i , the heat flow by conduction matches the steady-state convective heat transfer from the body. If conditions are met to initiate convection before t_i (this will depend on Pr and Ra), the heat flow falls monotonically in the transition regime, as along path A in Fig. 4.37b. Otherwise convection will not be initiated until $t_D > t_i$, so the heat flow will have fallen below the steady-state value and must therefore recover from the undershoot in the transition regime as shown by path B.

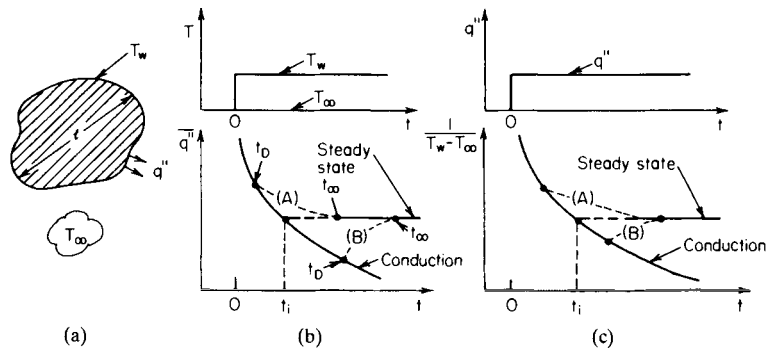

FIGURE 4.37 Transient response of heat flow from a surface (a) following a step change in wall temperature (b), and of the wall temperature following a suddenly applied heat flux (c).

The correct order of magnitude of the time constant for the transient response of the fluid is given by t_i . For a flat plate (or for any body shape up to the time that the penetration distance of the heat conduction from the boundary is small compared to the radius of curvature of the body), the conduction heat transfer is given by [244]

$$q'' = \frac{k(T_w - T_\infty)}{\sqrt{\pi\alpha t}} \quad (4.131)$$

The value of t_i is found by equating this value of q'' to the steady-state average heat transfer q''_s . For example, for a vertical flat plate 0.1 m (0.32 ft) long that is subjected to an impulsive 10°C (16°F) temperature change and is immersed in various fluids at 20°C (68°F), the values of t_i are as follows: for air, $t_i = 0.5$ s; for water, $t_i = 5$ s; for oil ($\text{Pr} = 10^4$), $t_i = 80$ s; for mercury, $t_i = 2$ s.

An imposed temporal change of T_w , other than the step change, is also of interest. In fact, because the heat capacity of any body or wall is finite, a step change could never be achieved. If the time constant associated with the prescribed change in T_w is much larger than t_i , the heat transfer at each instant in the transient can be accurately calculated from the steady-state natural convection equation; this is called a quasi-static transient. From the above estimates of t_i it will be appreciated that the quasi-static approximation will usually be valid for gases.

The analogous problem of response to a step change in surface heat flux is depicted in Fig. 4.37c. The inverse of $T_w - T_\infty$ (proportional to the heat transfer coefficient) again either may fall monotonically to its steady-state value or may undershoot; the possibility of an undershoot, which corresponds to a temperature overshoot, may have serious ramifications in practical problems and has provided much of the incentive for studying the external transient problem. As before, a step change in surface heat flux could never be achieved in practice because of finite surface heat capacitance. If the time constant for changes in surface heat flux at the surface is large compared to t_i , either because of body heat capacitance or because heating is only gradually applied, the quasi-static approximation will again be accurate.

Vertical Surfaces. Analyses and measurements related to transient heat transfer on vertical surfaces have been reviewed by Ede [79]. For negligible solid heat capacitance, results of analyses are discussed for step changes in wall temperature and in surface heat flux, and for periodic specified temperature or flux, as well as for other prescribed variations. Most recent analyses have confirmed the estimate of Siegel [252] that the local time for departure from the conduction regime at distance position x from the leading of a vertical flat plate after a step change in wall temperature is

$$t_D = 1.8(1.5 + \text{Pr})^{1/2} \left\{ \frac{x}{[g\beta(T_w - T_\infty)]} \right\}^{1/2} \quad (4.132a)$$

The steady-state regime is attained in time t_∞ , where

$$t_\infty = 5.24(0.952 + \text{Pr})^{1/2} \left\{ \frac{x}{[g\beta(T_w - T_\infty)]} \right\}^{1/2} \quad (4.132b)$$

Gebhart and Adams [105, 106, 108] have predicted the average wall temperature response of a vertical flat plate following a sudden application of internal heating to the wall (applied by switching on a current). The plate was assumed to be isothermal in any horizontal plane, and the average (over the length of the plate) wall temperature was reported. The predictions and measurements for air and water are reproduced in Fig. 4.38. In Fig. 4.38, ψ , τ^* , and \mathbf{Q} are dimensionless average surface temperature, time, and thermal capacitance defined in Fig. 4.38 by Gebhart and Adams. In these relations \mathbf{b} and M are Prandtl-number-dependent parameters given in Table 4.12, \bar{T}_w is the average wall temperature (the unknown), \mathbf{P}'' in the definition of Ra^* is the rate of internal generation of energy per unit heat transfer surface area A , and C_w'' in the definition of \mathbf{Q} is the total heat capacitance of the wall per unit of heat

FIGURE 4.38 Temperature response of a vertical plate to a step heat input including the effects of thermal capacitance (from Gebhart and Adams [108]).

transfer surface area. All the data collapse into a single curve for $Q \geq 1$ because the quasi-static approximation applies in this range of Q .

Horizontal Wires. Attention is restricted to horizontal cylinders (see Fig. 4.39 for nomenclature) that are nearly isothermal on any plane perpendicular to the axis of the cylinder (this will occur if $\bar{h}D/k_w \leq 0.1$, where \bar{h} is the average heat transfer coefficient on the outside surface and k_w is the thermal conductivity of the wire). If the wire is suddenly heated by switching on a current, its temperature response in the conduction regime for a given heat capacity ratio $(\rho c_p)_w/\rho c_p$ can be found [30, 218]. The trends are schematically illustrated in Fig. 4.39 for different values of Ra^* .

The end of the conduction regime at time τ_D (see Fig. 4.39 for definition of τ) is associated with the top-heavy instability (see the section on horizontal rectangular parallelepiped and circular cylinder cavities) that occurs along the separation line on the top of the cylinder [272]. The dimensionless time τ_D for air, water, and alcohol was adequately correlated by

$$\tau_D = 80.2(Ra^*)^{-2/3} \tag{4.133}$$

where P'' , which appears in the definition of Ra^* in Fig. 4.39, is the internal generation rate per unit surface area.

In the transition regime ($\tau_D < \tau < \tau_\infty$), if the conduction heat transfer at τ_D exceeds the steady-state heat transfer for high Ra^* , Nu falls monotonically as shown in Fig. 4.39. For small

FIGURE 4.39 Temporal response of the Nusselt number to suddenly applied internal heating in a horizontal wire.

Ra^* the heat transfer at τ_D falls below the steady-state value, causing the wall temperature to overshoot its steady-state value. The value of Ra^* at which the steady-state heat transfer is the same as the heat transfer at the departure time τ_D is defined as Ra_0^* , and the corresponding τ_D is denoted in the figure as τ_0 ; in this case the transition regime is virtually nonexistent.

Because the existence of an overshoot in the wall temperature is of crucial concern, it is desirable to know both Ra_0^* and τ_0 . The value of Ra_0^* can be calculated from the following equation, which fits the prediction of Parsons and Mulligan [218] for intermediate values of Pr (air, water, alcohol):

$$Ra_0^* = [20, 20c^{3/2}]_{\min} \quad c = \frac{2\rho c_p}{(\rho c_p)_w} \tag{4.134}$$

where the minimum of the two quantities in brackets is to be used. Subscript w refers to the wire, and ρc_p is the volumetric heat capacitance of the fluid. τ_0 is the value of τ_D evaluated from Eq. 4.133 at $Ra = Ra_0^*$.

Parsons and Mulligan [218] have correlated the time to reach steady state, τ_∞ , by the equation

$$(\tau_\infty - \tau_0) = 2.5|\tau_D - \tau_0| \tag{4.135}$$

Internal Transient Convection

Overview. This section deals with the transient heating or cooling of a fluid in an enclosure, such as a tank. Applications include storage of cryogenic fluids and transients in startup or shutdown of operating systems. Literature reviews by Clark [59] and Hess and Miller [135] are available.

Response to Step Change in Wall Temperature. Following a sudden change in wall temperature there is an initial transient in which conduction dominates, as described in the previous section. This heat transfer depends on the shape of the enclosure but is given roughly by Eq. 4.131 at small enough time.

Following the conduction regime there is a transition period, during which convection becomes established, to a quasi-steady regime in which the bulk temperature of the fluid in the enclosure gradually approaches the wall temperature. It is heat transfer in this quasi-steady regime that is the subject of this section.

Spheres. Schmidt [242] measured heat transfer to the fluid inside a sphere following what was essentially a step change in wall temperature. Fluids tested were water and three alcohols: methyl, ethyl, and butyl. For $2 \times 10^8 < Ra < 5 \times 10^{11}$ the Nusselt number was correlated by

$$Nu = \frac{q''D}{(T_w - \bar{T})k} = 0.098 Ra^{0.345} \quad Ra = \frac{g\beta(T_w - \bar{T})D^3}{\nu\alpha} \quad (4.136)$$

where T_w is the wall temperature and \bar{T} is the average temperature of the fluid within the sphere. Properties are to be evaluated at \bar{T} . This equation (with \bar{T} replaced by T_∞) agrees to within 18 percent with Eq. 4.49, with constants in Table 4.3a, for steady turbulent heat transfer from the external surface of a sphere. No corresponding data seem to be available for the laminar flow regime.

Cylinders. Evans and Stefany [92] measured the heat transfer to fluids in short cylindrical enclosures and, with length-to-diameter ratios $0.75 < L/D < 2.0$, following an abrupt increase or decrease in wall temperature. Measurements were obtained for both horizontally and vertically oriented cans, $7 < Pr < 7000$ and $6 \times 10^5 < Ra < 6 \times 10^9$, and all the data in the quasi-steady regime were correlated to within about 10 percent by

$$Nu = \frac{q''L}{(T_w - \bar{T})k} = 0.55 Ra^{1/4} \quad Ra = \frac{g\beta(T_w - T_i)L^3}{\nu\alpha} \quad (4.137)$$

In this equation \bar{T} is the mean fluid temperature at any time, T_w is the wall temperature, T_i is the mean temperature of the quiescent fluid before the transient is initiated, and L is the length of the cylinder. All physical properties are evaluated at T_w . The length scales L and D were not sufficiently different to affect the correlation much, and L was arbitrarily chosen. The heat transfer coefficient $q''/(T_w - \bar{T})$ remained constant throughout the quasi-steady period. Hiddink et al. [138] found that Eq. 4.137 also correlated data for heating only the bottom and side walls of vertical cylinders provided the cylinder diameter replaced L , and a coefficient of 0.52 rather than 0.55 was used. Their experiments were performed for length-to-diameter ratios of 0.25 to 2.0 and for $5 \leq Pr \leq 83,000$.

Hauf and Grigull [133–135] precisely measured the natural convection heat transfer inside a tube following a step change in the temperature of a fluid in forced convection over the outside of the tube. In this case the heat transfer coefficient on the outer surface is constant throughout the transient, and the heat capacity of the wall plays an important role. Cheng et al. [50] have studied conditions leading to the formation of ice inside horizontal tubes (without throughflow), also with uniform heat transfer coefficient between the outside boundary and a cold environment.

Uniform Flux or Linear Rise in Boundary Temperature. If there is a uniform heat flux to the fluid in the enclosure, all temperatures increase linearly with time in the quasi-steady regime, but velocities and spatial gradients become virtually independent of time. A similar quasi-steady regime also exists when the boundary temperature is isothermal but increases linearly with time.

The equations governing the fluid motion and heat transfer in these quasi-steady regimes are (if the property values and boundary conditions are the same) identical to those for steady-state convection in the same geometry with a uniform internal generation of energy [73]. The heat transfer equations from one situation can therefore be readily transferred to the other by replacing the constant $\rho c_p \partial T/\partial t$ by the internal generation rate q''' (in W/m^3 or $Btu/h \cdot ft^3$).

Heat transfer to water in a long cylindrical tube subjected to a linearly increasing wall temperature was measured by Deaver and Eckert [73]. Their data in the laminar quasi-steady regime can be closely represented by

$$Nu = 8 + 3 \left/ \ln \left(\frac{Nu^T + 2\epsilon}{((Nu^T - 3), \epsilon)_{\max}} \right) \right. \quad (4.138)$$

where Nu^T is given by Eq. 4.45a and where diameter and the difference between the wall temperature and the mean fluid temperature ($T_w - \bar{T}$) are the length scale and temperature difference used in Nu and Ra , and $\epsilon \approx 10^{-30}$. The first term in Eq. 4.138 represents the conduction solution, while the second term is the laminar Nusselt number for a cylinder corrected for curvature effects. For any selected rate of increase of temperature with time, an energy balance gives the heat that must be added through the boundaries, and Eq. 4.138 gives the corresponding wall-to-fluid temperature difference.

A number of studies [50, 91, 247] have discussed the thermal development of the flow prior to the quasi-steady state under uniform flux conditions. Quasi-steady results for a uniform flux applied to the side wall of a short vertical cylinder are described by Hess and Miller [135].

NATURAL CONVECTION WITH INTERNAL GENERATION

Internal Problems

Background. Natural convection driven by internal heat sources is of interest in geophysics, and the heat transfer associated with such motion is important in the design of tanks in which fermentation or other chemical reactions occur and in the safety analysis of nuclear reactors where a core meltdown is postulated. The last of these applications has led to the intensive study of internally generating horizontal fluid layers.

The connection between internal generation problems and the quasi-steady transient problems described in the previous section permits data obtained in one area to be applied in the other.

Horizontal Fluid Layers. A uniform volumetric heat production q''' in a horizontal layer bounded above by an isothermal surface and on the sides and bottom by adiabatic surfaces is depicted in Fig. 4.40. For a stationary fluid, the Nusselt number defined in the figure is $Nu = 2$, and the temperature difference used to construct the Rayleigh number is $T_0 - T_1 = q'''L^2/2k$. As Ra increases from zero, the layer remains stable and heat flow is by conduction until a critical Rayleigh number of 1386 is reached [167]. Thereafter convection promotes a monotonic increase in Nu with Ra . For water ($2.5 \leq Pr \leq 7$), and for $Ra \leq 10^{12}$, the heat transfer data of Kulacki et al. [166–168] are accurately represented by

$$Nu = [2.0, 0.389 Ra^{0.228}]_{\max} \quad (4.139)$$

The lateral extent of the layer and the boundary shape appear to play a small role in this problem until the smallest horizontal dimension of the fluid cavity is equal to or smaller than the depth of the layer [174].

FIGURE 4.40 Geometry and nomenclature for some natural problems where motion is driven by internal heat generation within the fluid.

The transient thermal response of the horizontal layer after turning on or shutting off of the internal generation has been studied extensively also by Kulacki et al. [166–168] and Keyhani and Kulacki [159].

When both bottom and top surfaces are maintained at constant temperatures and there is internal generation, there is a superposition of the horizontal layer problem discussed in the section on natural convection within enclosures and the internal generation problem previously described. These are characterized by the “external” Rayleigh number defined in the section on natural convection within enclosures and the “internal” Rayleigh number defined in Fig. 4.40a. The dependence of the layer stability on these parameters has been discussed by Ning et al. [208]. The heat transfer at the top and bottom surfaces has been estimated for these conditions by Baker et al. [13], Suo-Anttila and Catton [276], and Cheung [51].

Other Enclosure Geometries. The steady and transient heat transfer in internally generating fluid layers bounded above by an isothermal flat surface, below by an adiabatic spherical segment, and on the sides by an adiabatic cylinder, as shown in Fig. 4.40b, has been measured by Min and Kulacki [192, 193]. Kee et al. [157] present numerical heat transfer predictions for a heat-generating fluid within an isothermal sphere. Murgatroyd and Watson [202] and Watson [279] have examined the corresponding problem for closed vertical cylinders, and Bergholz [18] has presented an approximate analysis for a rectangular enclosure. The quasi-steady data of Deaver and Eckert [73] for convection in a long cylinder can be converted to the corresponding internal generation problem, as already described.

Convective heat transfer across two immiscible stably stratified layers, bounded above by an isothermal plate and below by an adiabatic plate, and with the bottom layer heated internally, has been measured by Nguyen and Kulacki [206]. A similar problem was earlier studied by Schramm and Reineke [245].

CONVECTION IN POROUS MEDIA

A porous medium consists of a packed bed of solid particles in which the fluid in the pores between particles is free to move. The superficial fluid velocity \vec{V} is defined as the volumetric flow rate of the fluid per unit of cross-sectional area normal to the motion. It is the imbalance between the pressure gradient ($\vec{\nabla}P$) and the hydrostatic pressure gradient ($\rho\vec{g}$) that drives the fluid motion. The relation that includes both viscous and inertial effects is the Forchheimer equation [47]

$$-\vec{\nabla}P' \equiv -(\vec{\nabla}P - \rho\vec{g}) = \frac{\mu}{K} \vec{V} + \frac{\rho\chi}{K} |\vec{V}| \vec{V} \quad (4.140)$$

where ρ and μ are the fluid properties, K is the permeability of the medium, and χ is the Forchheimer coefficient. The coefficients K and χ are approximated by [90]

$$K = \frac{d^2\phi^3}{150(1-\phi)^2} \quad \chi = \frac{1.75d}{150(1-\phi)} \quad (4.141)$$

where d is the average particle diameter and ϕ is the medium porosity, or volume fraction occupied by the fluid. For $\text{Re}_p/(1-\phi) \leq 10$, where $\text{Re}_p = \rho d |\vec{V}|/\mu$ is the particle Reynolds number, the Forchheimer term, the term with coefficient χ , in Eq. 4.140 can be dropped, and the resulting linear relation between velocity and pressure gradient is Darcy's equation. The relations in the chapter are restricted to Darcy flow.

Properties and Dimensionless Groups

Heat transfer in a porous medium depends on the thermal properties of both the fluid and the solid. For porous media k_m is the thermal conductivity of the medium (fluid and solid) in the

absence of no fluid motion. Relations here are from Kaviany [155]. If the heat transfer through the solid and fluid are assumed to act in parallel,

$$k_m = \phi k_f + (1 - \phi)k_s \tag{4.142}$$

whereas in series

$$\frac{1}{k_m} = \frac{\phi}{k_f} + \frac{(1 - \phi)}{k_s} \tag{4.143}$$

The true value of k_m will lie somewhere above that given by Eq. 4.143 and below that from Eq. 4.142. Provided k_f is not very much greater than k_s , k_m can be approximated by

$$k_m = k_s^{1-\phi} k_f^\phi \tag{4.144}$$

Properties α_m and σ are the thermal diffusivity and heat capacity ratio of the medium defined by

$$\alpha_m = \frac{k_m}{\phi(\rho C_p)_f + (1 - \phi)(\rho C_p)_s} \quad \sigma = \frac{\phi(\rho C_p)_f + (1 - \phi)(\rho C_p)_s}{(\rho C_p)_f} \tag{4.145}$$

where subscripts f and s refer to the fluid and solid, respectively. Typical values of porosity are given in Table 4.13.

Siltstone	0.097

The Darcy-modified Rayleigh number, based on characteristic dimension L , is defined as follows

$$\tilde{Ra} = Ra \times Da = \frac{\rho g \beta \Delta T L^3}{\mu \alpha_m} \times \frac{K}{L^2} = \frac{\rho g \beta \Delta T K L}{\mu \alpha_m} \quad (4.146)$$

where $Da = K/L^2$ is the Darcy number. The heat transfer rate can be recovered from the Nusselt number, defined in Figs. 4.41 and 4.42 for the problems considered in this section.

External Heat Transfer Correlations

Vertical Flat Plate (Fig. 4.41a). Based on a similarity solution [49] for Darcian flow, for an isothermal plate,

$$Nu = 0.89 \tilde{Ra}^{1/2} \quad (4.147)$$

This relation fits the data of Kaviany and Mittal [156] over the range of their data, $1 < \tilde{Ra} < 10^2$, for polyurethane foams with $\phi \approx 0.98$ and 0.4 to 4 pores per millimeter.

Horizontal Upward-Facing Plate (Fig. 4.41b). Based on the similarity solution of Cheng and Chang [48], the average heat transfer from an isothermal plate in Darcian flow is given by

$$Nu = 1.26 \tilde{Ra}^{1/2} \quad (4.148)$$

There appears to be no experimental validation.

Horizontal Cylinder (Fig. 4.41c). The boundary layer solution of Cheng, as reported by Fand et al. [94], yields

$$Nu = 0.565 \tilde{Ra}^{1/2} \quad (4.149)$$

This is found to correlate their data to within about 30 percent for $0.5 < \tilde{Ra} < 10^2$. Departures from Eq. 4.149 in the low Ra region occur for oils (high Pr) because the boundary layer approximations become invalid, and in the high Ra region because the flow is no longer in the Darcy regime. Fand et al. [94] give correlations that fit their data more precisely, but the generality of these equations is unknown.

Spheres (Fig. 4.41c). Cheng [46] reports the similarity solution for heat transfer from an isothermal sphere to be

$$Nu = 0.362 \tilde{Ra}_D^{1/2} \quad (4.150)$$

There appears to be no experimental validation of this relation.

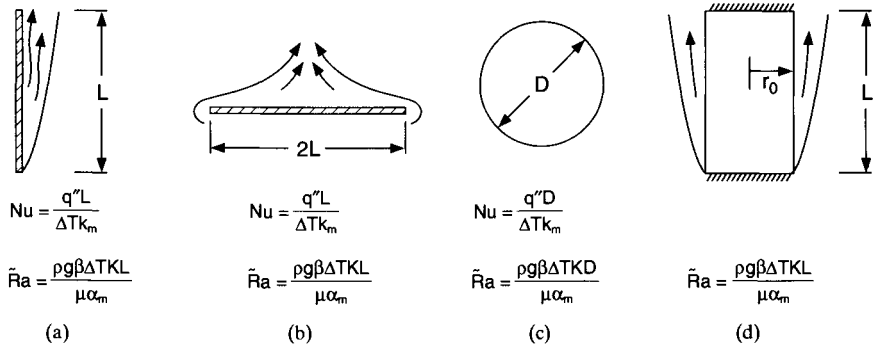

FIGURE 4.41 Definition sketch for vertical plate (a), long horizontal strip (b), long horizontal circular cylinder (c), and short vertical cylinder with insulated ends (d), all in an isothermal porous medium.

FIGURE 4.42 Definition sketch for heat transfer between extensive horizontal plates (a) and in long cavity with isothermal side walls and insulated top and bottom. The medium is porous.

Vertical Cylinder With Adiabatic Ends (Fig. 4.41d). The heat transfer q_c from the curved boundary of the vertical cylinder in Fig. 4.41d is related to the heat transfer from a vertical plate (q_p) of the same height and surface area by [194]

$$\frac{q_c}{q_p} = 1 + 0.26 \zeta_L \quad \zeta_L = \frac{2L}{r_0 \bar{Ra}^{1/2}} \quad (4.151)$$

q_c/q_p increases as Ra falls, similar to that for a continuous fluid medium. There is apparently no experimental validation of Eq. 4.151.

Internal Heat Transfer Correlations

Horizontal Layer, Heated from Below (Fig. 4.42a). For an extensive horizontal layer heated from below, the Nusselt number is approximately given by [87]

$$Nu = \left[1, \frac{\bar{Ra}}{40} \right]_{\max} \quad (4.152)$$

There is a very large scatter of experimental data from this relation [46] that has been attributed to the effect of Prandtl number and the ratio of bead diameter to the depth of the porous layer being too large for the analysis to hold.

Rectangular Cavity, Heated From the Side (Fig. 4.42). The rectangular cavity of width w and height H in Fig. 4.42b has side boundaries held at different temperatures, T_1 and T_2 , and is insulated on the top and bottom. The cavity is considered to be extensive in the third dimension. Bejan [15] compiled heat transfer calculations for aspect ratios $0.1 < A < 30$, and this is reproduced in Fig. 4.43.

FIGURE 4.43 Summary of heat transfer calculation for a cavity filled with a fluid-saturated porous medium, from Bejan [15]. (Reprinted by permission of Pergamon Press.)

MIXED CONVECTION

Mixed convection occurs when both natural convection and forced convection play significant roles in the transfer of heat. In applications it is important to first establish whether satisfactory predictions will result by ignoring either one, or if the combined effects must be considered. Guidelines for delineating the forced, natural, and mixed convection regimes are reported for external and internal flows in the sections that follow. Some design equations and graphs for heat transfer in the mixed convection regime are also given. Attention is focused on laminar flows, in which mixed convection effects are most frequently important.

External Flow

Introduction. For the problem depicted in Fig. 4.44, the heat transfer by “pure” forced convection would increase monotonically with Reynolds number along the curve shown. The heat transfer by pure natural convection from the same surface for various Ra is denoted by the horizontal lines in the figure. If Re is slowly increased from zero in the real problem, the measured values of Nu would at first follow the natural convection curve, since the superimposed forced convection velocities are too feeble to affect the heat transfer. If the forced convection “assists” the natural convection, the Nu curve in Fig. 4.44 will break upward along path A at larger Re and approach the pure forced convection curve from above. If the flows are “opposed,” Nu passes through a minimum along path B in Fig. 4.44 and approaches the forced convection curve from below. Mixed convection occurs when the heat transfer is significantly different from that for either pure natural convection or pure forced convection.

From the Nusselt number for pure natural convection, Nu_N , and that for pure forced convection, Nu_F , a rough estimate of the actual Nusselt number for a given problem is

$$Nu = [Nu_N, Nu_F]_{\max} \quad (4.153)$$

That is, the maximum of the two Nusselt numbers is used. The error in this equation is often less than 25 percent, with the maximum deviation near the intersection point of the curves, denoted by the dot in Fig. 4.44.

FIGURE 4.44 Definition of terms relating to mixed convection in opposed and assisting flows.

The intersection points of the pure natural convection and pure forced convection equation also provide valuable information on the conditions for which forced and natural convection are equally important. For example, for laminar flow along the heated isothermal vertical plate in Fig. 4.6 if Eq. 4.33a for Nu_N is equated to the forced convection Nusselt number given by

$$Nu_F = 0.664Re^{1/2} Pr^{1/3} \tag{4.154}$$

This yields the following relation between Gr_i and Re_i^2 :

$$Gr_i = \left(\frac{0.664Pr^{1/2}}{C_i} \right)^4 Re_i^2 \tag{4.155}$$

where i refers to the intersection point. For a 0.30-m (1-ft) vertical plate at 60°C (140°F) immersed in air at 20°C (68°F), the superimposed forced convection velocity that satisfies Eq. 4.155 is 0.25 m/s (0.82 ft/s); under the same conditions but in water, this velocity is 0.084 m/s (0.28 ft/s).

The intersection relation (see, for example, Eq. 4.155) also permits one to roughly estimate when mixed convection should be considered. If, for a given Reynolds number, the value of Rayleigh number Ra for a laminar problem greatly exceeds the intersection Rayleigh number Ra_i , forced convection effects can be ignored. If Ra is much less than Ra_i , natural convection effects may be ignored. The change from the natural convection regime to the forced convection regime occurs over a smaller range of Ra , for a given Re , for turbulent flow than for laminar.

Vertical Plates. If Eq. 4.33a (Eq. 4.33b should be used if $Ra \leq 10^4$ is of interest) and Eq. 4.33c are used for laminar and turbulent natural convection, respectively, and if Eq. 4.154 and $Nu_F = (0.037Re^{0.8} - 871.3) Pr^{1/3}$ are used, respectively, for laminar and turbulent forced convection, then Eq. 4.155 gives the laminar-laminar (i.e., laminar forced convection and laminar natural convection) intersection, while the laminar-turbulent intersection is given by

$$Gr_i = \frac{0.664}{C_i^V} Re_i^{3/2} \tag{4.156}$$

and the turbulent-turbulent intersection by

$$Gr_i = \left[\frac{0.037 - 871.3/Re_i^{0.8}}{C_i^V} \right]^3 Re_i^{2.4} \tag{4.157}$$

These are plotted in Fig. 4.45 as a solid line. The dashed curves are drawn at $Ra = 10$ Ra_i and $Ra = 0.1$ Ra_i as estimates of the bounds on the mixed convection regime.

FIGURE 4.45 Regimes of forced, mixed, and natural convection for flow along a vertical plate.

Sparrow and Gregg [260] established by a perturbation analysis that the forced convection Nusselt number was altered by less than 5 percent by either an assisting or opposing natural convection if

$$|\text{Gr}| \leq 0.225\text{Re}^2 \quad (4.158)$$

for $0.01 \leq \text{Pr} \leq 10$. The curve representing this equation in Fig. 4.45 agrees closely with the estimate given by the dashed lines of the forced convection boundary of the mixed convection regime.

The mean heat transfer in the mixed convection regime for assisting flows has been correlated by Churchill [55] using the equation

$$\text{Nu} = [(\text{Nu}_F)^m + (\text{Nu}_N)^m]^{1/m} \quad (4.159)$$

$m = 3$ was found to best fit the results of laminar boundary layer analyses. The same equation was found to apply to both isothermal and uniform heat flux plates. Oosthuizen and Bassey [214] also correlated their data with Eq. 4.159, but with $m = 4$; the Reynolds and Grashof numbers in their experiments were below the ranges where boundary layer theory holds, and they also provide measurements (but no correlation) for opposed mixed convection. Churchill [55] reviews other available data.

The authors of most experimental studies and analyses have focused their attention on the local values defined in Fig. 4.44. Churchill [55] fitted the local Nu_x values for assisting flow using Eq. 4.159 with $m = 3$ and with each average value on the right side of the equation replaced by its local value counterpart. Mucoglu and Chen [201] have solved the inclined flat plate problem for uniform wall temperature and heat flux and have presented local heat transfer results for mixed convection.

Horizontal Flow. For laminar flow over the upper surface of a horizontal heated plate (or over the bottom surface of a cooled plate), the center of the mixed convection regime can again be estimated by equating the forced convection Nusselt number from Eq. 4.154 to that for natural convection from Eq. 4.39c (for detached turbulent convection). This results in

$$\text{Gr}_l = \left(\frac{0.664}{C_l^U} \right)^3 \text{Re}_l^{3/2} \approx 107\text{Re}_l^{3/2} \quad (4.160)$$

where the terms are defined in Fig. 4.46. As a rough approximation, one would expect that for $\text{Gr} \leq 11\text{Re}^{3/2}$ forced convection dominates, and for $\text{Gr} \geq 1100\text{Re}^{3/2}$ natural convection dominates.

The details of the flow in the mixed convection regime have been clarified by Gilpin et al. [113]. After an initial development of the laminar forced convection boundary layer, rolls with axes aligned with the flow appear at the location marked *Onset* in Fig. 4.6. These persist until the end of the transition regime, marked *Breakup*, after which the motion appears as fully detached turbulent natural convection flow.

The experiments for water, $7 \leq \text{Pr} \leq 10$, revealed that the rolls first become visible at the x location at which

$$\text{Gr} \left(\frac{x}{L} \right)^{3/2} = K \text{Re}^{3/2} \quad (4.161)$$

FIGURE 4.46 Mixed convection on a heated horizontal plate.

where $K \approx 100$. The stability analysis for longitudinal rolls by Wu and Cheng [288] is in good agreement with these observations and also predicts a Prandtl number dependence of K , but Chen and Mucoglu [44] have questioned the validity of these predictions. Despite the uncertainties that still exist, there is general agreement that buoyancy effects can greatly decrease the value of Re_x at which the first instability appears.

To obtain an average heat transfer equation, the flow is modeled as purely forced convection up to x_c and purely natural convection for $x > x_c$; from the experiments [148] for water, x_c is given roughly by Eq. 4.161 with $K \approx 155$. Integrating the local heat transfer relations results in the following expression for average heat transfer:

$$Nu = \sqrt{\zeta} 0.664 Re^{1/2} Pr^{1/3} + (1 - \zeta) C_f^U Ra^{1/3} \tag{4.162a}$$

$$\zeta = \left[\frac{29 Re}{Gr^{2/3}}, 1 \right]_{\min} \quad Ra = Gr Pr \tag{4.162b}$$

where the minimum of the two quantities in brackets is to be used in Eq. 4.162b. The coefficient 29 in Eq. 4.162b will likely be somewhat dependent on Prandtl number, but data are not available to resolve this dependence.

For laminar flow above a cooled surface or below a heated surface, the presence of buoyancy forces stabilizes the flow (inhibits transition) and tends to diminish the heat transfer. The analysis of Chen et al. [43] predicts that natural convection will alter the local convective heat transfer by less than 5 percent if $|Gr|(x/L)^{3/2}/Re^{5/2} \leq 0.03$ for $Pr = 0.7$. Robertson et al. [232] show that for $|Gr|/Re^{5/2} > 0.8$ and $Pr = 0.7$, buoyancy may inhibit the flow so strongly that a separation bubble may form over the surface.

In turbulent flow, stable stratification significantly damps turbulence and reduces heat transfer in the vertical direction.

$$Nu = \frac{q'' D}{(T_w - T_\infty) k}$$

$$Re = \frac{DV}{\nu}$$

$$Ra = \frac{g\beta (T_w - T_\infty) D^3}{\nu\alpha}$$

$$Gr = \frac{Ra}{Pr}$$

Horizontal Cylinders. For a heated horizontal cylinder in perpendicular cross flow, the angle of the approaching stream, ϕ in Fig. 4.47, greatly affects the heat flow in the mixed convection regime. For $\phi = 0$ the forced flow assists the natural convection and the dependence of the average Nusselt number on Re resembles path A in Fig. 4.44. For $\phi = 90^\circ$ there is a sharper transition from natural to forced convection than when $\phi = 0$, while for opposed flow ($\phi = 180^\circ$) there is a minimum as shown by path B in Fig. 4.44. For a cooled cylinder the same description applies except that ϕ is measured from the vertical axis extending upward from the cylinder.

Equating the Nusselt numbers for pure natural convection and pure forced convection provides a good estimate of the Ra - Re curve along which mixed convection effects are most important, as already discussed. After a careful study

FIGURE 4.47 Perpendicular flow across a horizontal circular cylinder in mixed convection.

of available data, Morgan [198] proposed the following equation for forced convection heat transfer from a cylinder for cross flow in a low-turbulence airstream:

$$Nu_F = a Re^n \tag{4.163}$$

where a and n are given in Table 4.14. This equation can also be used as a first approximation for other fluids if the right side is multiplied by the factor $(Pr/0.71)^{1/3}$. If Eq. 4.163 is equated to Eq. 4.45 for Nu_N , the Re_i versus Gr_i relation indicated by the solid curve in Fig. 4.48 is obtained, which denotes the approximate center of the mixed convection regime. The approximate bounds of this regime, based on a 5 percent deviation in heat transfer from pure forced convection and from pure natural convection, respectively, have been estimated by Morgan [198] to lie in the shaded bands.

TABLE 4.14 Constants for Forced Convection [Over a Circular Cylinder (Eq. 4.163)

	Re range						
	10 ⁻⁴ to 4 × 10 ⁻³	4 × 10 ⁻³ to 9 × 10 ⁻²	9 × 10 ⁻² to 1.0	1.0 to 35	35 to 5 × 10 ³	5 × 10 ³ to 5 × 10 ⁴	5 × 10 ⁴ to 2 × 10 ⁵
<i>a</i>	0.437	0.565	0.800	0.795	0.583	0.148	0.0208
<i>n</i>	0.0895	0.136	0.280	0.384	0.471	0.633	0.814

A procedure for calculating the heat transfer in the mixed convection regime for the problem has also been proposed by Morgan [198] on the basis of work of Börner [22] and Hatton et al. [131]. For a given Ra and Re, the value of Nu_N is computed from Eq. 4.45. For the given Re, the constants *a* and *n* are chosen from Table 4.14. The value of Re_{*i*} is then found from Eq. 4.163 with Nu_{*F*} = Nu_{*N*}; that is,

$$Re_i = \left[\frac{Nu_N}{a(Pr/0.71)^{1/3}} \right]^{1/n} \tag{4.164}$$

An effective Reynolds number Re_{eff} is then calculated from

$$Re_{eff} = [(Re_i + Re \cos \phi)^2 + (Re \sin \phi)^2]^{1/2} \tag{4.165}$$

and Nu is computed by insertion of Re_{eff} into Eq. 4.163 to obtain

$$Nu = a Re_{eff}^n \left(\frac{Pr}{0.71} \right)^{1/3}$$

It will be seen that if Re_{*i*} >> Re, the natural convection result is recovered, while if Re_{*i*} << Re, Nu ≈ Nu_{*F*}. Morgan showed that this calculation procedure gave good agreement with experiments for air and water for φ = 90°. For assisting flow (φ = 0°) the agreement was poorer, and it was still poorer for opposed flow (φ = 180°).

Gebhart et al. [109, 111] have provided accurate heat transfer measurements spanning the mixed convection zone for extremely fine wires for Pr = 0.7, 6.3, and 63, and have also provided equations for the bounds of the mixed convection zone.

FIGURE 4.48 Regimes of forced, mixed, and natural convection for assisting flow over a horizontal circular cylinder.

Other Shapes. Churchill [55] proposed that Eq. (4.159) with $m = 3$ be used also for assisting mixed convection flow around other surface shapes, such as spheres and cylinders. The appropriate expressions for Nu_F and Nu_N for the body shape of interest must be used.

Internal Flows

Horizontal Tubes

Uniform Heat Flux. For laminar flow in a horizontal tube where uniform heat flux is applied at the outer boundary of the tube, the bulk temperature T_b , increases linearly in the axial direction. To maintain the heat flow to the fluid, the wall temperature must remain higher than the fluid temperature, and under these conditions a fully developed natural convection motion becomes established in which velocity and temperature gradients become independent of the axial location. Because the fully developed Nusselt number for laminar pure forced convection is small ($Nu_F \rightarrow 4.36$), the buoyancy-induced mixing motion can greatly enhance the heat transfer.

Marcos and Bergles [189] correlated their data for fully developed heat transfer for water and ethylene glycol in glass and metal tubes by the equation

$$Nu_{fd} = \left\{ 4.36^2 + \left[0.055 \left(\frac{Ra Pr^{0.35}}{P_w^{1/4}} \right)^{0.4} \right]^2 \right\}^{1/2} \tag{4.166}$$

where the nomenclature is defined in Fig. 4.49. The P_w term accounts for the redistribution by circumferential conduction of the uniform heat flux on the outside surface of the tube before entering the fluid. Fluid properties are to be evaluated at the mean film temperature, $0.5(\bar{T}_{wi} + T_b)$. The data are in the range $3 \times 10^4 < Ra < 10^6$, $4 < Pr < 175$, $2 < P_w < 66$.

The heat transfer immediately downstream of the location where heating begins will be dominated by forced convection and will depend on the velocity profile. For a parabolic inlet profile, the forced convection Nusselt number can be approximated by [249]:

$$Nu_F = 1.30 \left(\frac{Re Pr}{x/D} \right)^{1/3} \quad \frac{x/D}{Re Pr} \leq 0.01 \tag{4.167}$$

For $Ra \leq 5 \times 10^5$ the transition from forced (Eq. 4.167) to natural convection (Eq. 4.166) is very sharp [249] but it becomes more rounded with increasing Ra . To find the total heat trans-

FIGURE 4.49 Geometry and definition of terms for mixed convection inside a horizontal tube.

fer over some length of tube, numerically integrate from the inlet of the tube using, at each location, the maximum value of local heat transfer given by Eqs. 4.166 and 4.167, and using the energy balance at each step to update the bulk temperature T_b .

As a result of natural convection, the fully developed condition is reached much farther upstream than for pure forced convection. For example, for $Ra \approx 10^6$, Nu_{fd} is reached at roughly $x/D = 0.001 Re Pr$ as opposed to $x/D \approx 0.06 Re Pr$ for pure forced convection (i.e., 1 diameter as opposed to 60 diameters for $Re Pr = 1000$).

When circular tubes subjected to a uniform heat flux are tilted upward, the Nusselt number has been shown to monotonically decrease with increasing angle for air [236].

Isothermal Wall. Natural convection also affects the laminar thermal development in a tube with an isothermal wall. In this case the temperature differences in the fluid near the tube inlet initiate a natural convection motion, but as the fluid temperature approaches the wall temperature far downstream, the motion slows and the fully developed Nusselt number ($Nu_F = 3.66$) is approached.

On the basis of data available up to 1964, Metais and Eckert [190] established the forced convection boundary of the mixed convection regime, and their results are presented in Fig. 4.50. The line was drawn where natural convection was thought to alter the heat transfer from that for pure forced convection by 10 percent. Figure 4.49 defines the nomenclature for this problem.

FIGURE 4.50 Regimes of forced and mixed convection for flow through horizontal tubes with uniform wall temperature, for $10^{-2} < (Pr D/L) < 1$. From Metais and Eckert [190].

Heat transfer relations in the mixed convection regime have been proposed by several investigators, but the equation proposed by Depew and August [74] appears to be most successful. This relation agrees with their measurements for water ($Pr = 6.5$), ethyl alcohol ($Pr \approx 15$), and a glycerol-water mixture ($Pr = 375$), as well as with the data from other authors, to about ± 40 percent:

$$Nu = 1.75 \left(\frac{\mu_b}{\mu_w} \right)^{1/4} [Gz + 0.12(Gz Ra^{1/3} Pr^{0.03})^{0.88}]^{1/3} \quad (4.168)$$

where b and w refer to average bulk and wall conditions, Nu , Gz , and Ra are defined in Fig. 4.49, and \bar{T}_b is obtained by arithmetically averaging the inlet and outlet temperature. All physical properties are to be evaluated at \bar{T}_b . The data on which this equation was derived lie in the following ranges: $28 < L/D < 193$, $10 < Gz < 456$, and $30 < Gr < 2 \times 10^7$.

Vertical Tubes. The flow regime chart for vertical tube flow shown in Fig. 4.51 was prepared by Metais and Eckert [190] for either a uniform-heat-flux or uniform-wall-temperature boundary condition. The two boundaries of the mixed convection are defined in such a way

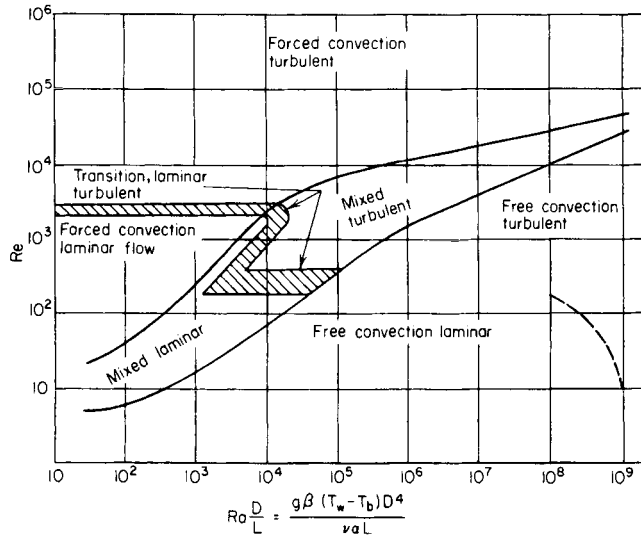

FIGURE 4.51 Regimes of natural, forced, and mixed convection for flow through vertical tubes with uniform wall temperature of heat flux, for $10^{-2} < (Pr D/L) < 1$. From Metais and Eckert [190].

that the Nusselt number at these locations does not deviate by more than 10 percent from the values for pure natural convection and pure forced convection.

ACKNOWLEDGMENTS

The authors are grateful to the Natural Science and Engineering Research Council of Canada for financial support of the research required to prepare this chapter. Thanks to Andrew Woronko and Skye Legon for digitizing and analyzing data, and to Anita Fonn for typing the manuscript.

NOMENCLATURE

Symbol, Definition, SI Units, English Units

<i>A</i>	heat transfer surface area of body: m ² , ft ²
<i>A_f</i>	area over which fluid contacts each plate in enclosure problem (Fig. 4.25): m ² , ft ²
<i>A_h</i>	flat horizontal heated area that faces downward (or cooled horizontal area that faces upward on a cold body): m ² , ft ²
<i>A_w</i>	area over which wall contacts each plate in enclosure problem (Fig. 4.25): m ² , ft ²
<i>a</i>	proportionality constant in Morgan's law (Eq. 4.163) for forced convection heat transfer from cylinders (see Table 4.14)
<i>a</i>	constant in stratified medium (Eqs. 4.42, 4.46, and 4.50)
<i>b</i>	wall thickness (Fig. 4.25): m, ft

b	constant in stratified medium (Eqs. 4.42, 4.46, and 4.50)
b	function of Pr given in Table 4.12 and used in Fig. 4.38
$\hat{\mathbf{b}}$	unit vector in direction of buoyancy force (Fig. 4.5)
C	minor axis of elliptical cylinder or spheroid (Tables 4.2 and 4.3a): m, ft
C_1	constant (Eq. 4.20)
C_1	constant, defined separately for different problems
C_2	functions of C/L for elliptical cylinders and spheroids, tabulated in Tables 4.2 and 4.3a
C_2	constant (e.g., Eqs. 4.34c and 4.38)
C_{ac}	wall admittance parameter for circular cylinder enclosures, given by Eq. 4.83.
C_{ar}	wall admittance parameter for rectangular parallelepiped enclosures, given by Eq. 4.82 for opaque fluids and (approximately) by Eq. 4.86 for transparent fluids
\overline{C}_l	function of Pr (Eq. 4.13 and Table 4.1)
C_l	function of Pr and ζ , given by Eq. 4.28
\overline{C}_l	average value of C_l over a body, defined by Eq. 4.23 (see Tables 4.2 and 4.3 for \overline{C}_l for various body shapes)
C_l^U	function of Pr given by Eq. 4.25; see Table 4.1
C_l^V	function of Pr given by Eq. 4.24; see Table 4.1
c	constant, defined separately for each problem
c	constant in stratified medium equations (Eqs. 4.42, 4.46, and 4.50)
c_p, c_{p0}	specific heat of fluid evaluated at T_f : J/(kg·K), Btu/(lb _m ·°F)
D	diameter of sphere, cylinder, or disk: m, ft
Da	Darcy number (Eq. 4.146)
D_i	for a pair of eccentric or concentric spheres or cylinders, the diameter of the inner one (Fig. 4.36): m, ft
D_o	for a pair of eccentric or concentric spheres or cylinders, the diameter of the outer one (Fig. 4.36): m, ft
d	tube diameter (Fig. 4.23): m, ft
d	average particle diameter in porous medium: m, ft
E	perpendicular distance between axes of eccentric cylinders, or distance between centers of eccentric spheres (Fig. 4.36): m, ft
Ec	Eckert number, $v_0^2/(c_p \Delta T)$
fRe	friction factor–Reynolds number product for forced flow in a duct (Table 4.4)
f	quantity defined by Eq. 4.45b
G	geometry-dependent constant (Eqs. 4.11, 4.14, and 4.37a and Tables 4.2 and 4.3)
Gr	Grashof number, Ra/Pr
Gr_i	Grashof number at which $Nu_F = Nu_N$
Gz	Graetz number, defined in Fig. 4.49
g	acceleration of gravity: m/s ² , ft/s ²
H	height, defined by Figs. 4.21–4.23 and 4.25: m, ft
H_L	function of Prandtl number (Eq. 4.34a)
H_L	height of partition extending up from the floor of a cavity: m, ft

H_U	height of partition hanging down from the ceiling of a cavity: m, ft
\overline{H}_L	function of Prandtl number (Eq. 4.36a, Table 4.1)
H_p	partition height: m, ft
$H_{\text{MIN}}, H_{\text{MAX}}$	minimum and maximum, respectively, of H_U and H_L : m, ft
i	flow index: $i = 0$ for 2D flow problems and $i = 1$ for axisymmetric flow problems
k	thermal conductivity of fluid, evaluated at T_f for external and open cavity problems and at T_m for enclosure problems (unless otherwise specifically directed): $\text{W}/(\text{m}\cdot\text{K})$, $\text{Btu}/\text{h}\cdot\text{ft}\cdot^\circ\text{F}$
k_1, k_2	constants in Hollands equation (Eq. 4.78); given by Eqs. 4.80–4.81 and Table 4.7
k_m	effective thermal conductivity of porous medium: W/mK , $\text{Btu}/\text{hr ft}\cdot^\circ\text{F}$
k_f	thermal conductivity of fluid in a porous medium: W/mK , $\text{Btu}/\text{hr ft}\cdot^\circ\text{F}$
k_s	thermal conductivity of solid in a porous medium: W/mK , $\text{Btu}/\text{hr ft}\cdot^\circ\text{F}$
k_w	thermal conductivity of wall: $\text{W}/(\text{m}\cdot\text{K})$, $\text{Btu}/\text{h}\cdot\text{ft}\cdot^\circ\text{F}$
k_{wt}	equivalent enclosure wall thermal conductivity, given by Eq. 4.84: $\text{W}/(\text{m}\cdot\text{K})$, $\text{Btu}/\text{h}\cdot\text{ft}\cdot^\circ\text{F}$
k_{wt}^*	special wall conductivity, equal to k_w for enclosures with finlike walls and opaque fluids, and given by Eq. 4.85 (approximately) for enclosures with thick walls and transparent fluids: $\text{W}/(\text{m}\cdot\text{K})$, $\text{Btu}/\text{h}\cdot\text{ft}\cdot^\circ\text{F}$
L	characteristic length, chosen separately for each problem: m, ft
L	spacing between isothermal surfaces (Figs. 4.25 and 4.26), or length of a plate or a cylinder (Figs. 4.6 and 4.14): m, ft
L_f	vertical distance between lowest and highest points on a body: m, ft
L^*	characteristic length for a horizontal plate, equal to A/p (Fig. 4.10): m, ft
l	characteristic dimension of body or enclosure: m, ft
m	exponent used in the Churchill-Usagi fit (Eqs. 4.32, 4.34d, 4.36d, etc.)
\hat{n}	unit vector normal to the surface (Fig. 4.5)
Nu	Nusselt number, usually given by $qL/(A \Delta T k)$, but see separate defining sketch for each problem
Nu_{COND}	Nusselt number when fluid is stationary and transfer is by conduction only
Nu_F	Nusselt number for pure forced convection
Nu_{fd}	Nusselt number for fully developed flow
Nu_H (Ra)	Nu-Ra relation which results when a given inclined cavity is rotated to the horizontal position
Nu_{iso}	Nusselt number that is obtained for constant T_w and T_∞ with $T_w - T_\infty = \Delta T_m$
Nu_{np}	Nusselt number for a cavity with no partition
Nu_{fp}	Nusselt number for a cavity with full interior partition
Nu_l	average Nusselt number taken over entire body, assuming laminar flow prevails over entire body
Nu_N	Nusselt number for pure natural convection
Nu_t	average Nusselt number taken over entire body, assuming turbulent heat transfer prevails over whole body
$\text{Nu}_{t,x}$	local Nusselt number for turbulent heat transfer at location x , $q''x/\Delta T k$

Nu_v (Ra)	Nu-Ra relation that results when a given inclined cavity is rotated to the vertical position
Nu'_x	local Nusselt number for a turbulent boundary layer at point x
Nu^T	average "thin-layer-solution" Nusselt number for laminar flow
Nu_θ (Ra)	Nu-Ra relation for a cavity inclined at angle θ
n	Churchill usage constant used to determine Nu_ℓ (Eq. 4.19, Table 4.3)
n	exponent in Eq. 4.163 for forced convection heat transfer over cylinders (Table 4.14)
P	pressure: Pa, lb _f /ft ²
P_d	pressure component associated with dynamics of flow (Eq. 4.1): Pa, lb _f /ft ²
P_i	perimeter of a cylinder at the intersection of its surface with the plane normal to its axis: m, ft
P_{ref}	reference pressure, equal to pressure at $z = z_{ref}$ far from solid surface: Pa, lb _f /ft ²
P_∞	pressure at height z and far from solid surface or wall: Pa, lb _f /ft ²
P_w	"circumferential heat flux" dimensionless group for internal mixed convection problems (Fig. 4.49)
P''	rate of internal generation of energy in a wall per unit of heat transfer surface area of the wall: W/m ² , Btu/(h·ft ²)
Pr	Prandtl number, equal to ν/α , evaluated at T_f (or T_m for enclosure problems) unless otherwise specifically directed
p	perimeter of plate (Fig. 4.10 <i>b</i>): m, ft
p	tilt parameter for long tilted cylinder (Eq. 4.47 <i>b</i>)
$\mathcal{P}(z)$	perimeter of body along the intersection with a horizontal plane at elevation z : m, ft
\mathcal{P}	average body perimeter, defined by Eq. 4.15
Q	dimensionless thermal capacity rate (Fig. 4.38)
q	heat transfer rate, total heat delivered to fluid moving through an open cavity: W, Btu/h
q^*	heat flux ratio for rectangular open cavity, equal to q_2/q_1 (Fig. 4.21)
q'	heat flow per unit length of surface: W/m, Btu (h·ft)
q''	heat flow per unit area of surface: W/m ² , Btu (h·ft ²)
$\overline{q''}$	average heat flux over surface, equals q/A : W/m ² , Btu (h·ft ²)
q'''	rate of internal generation of heat within the fluid: W/m ³ , Btu (h·ft ³)
q_f	heat transfer from hot plate to fluid in enclosure problem: W, Btu/h
q_{f0}	value of q_f when fluid is stationary: W, Btu/h
q_r	radiative heat transfer from hot plate in enclosure problem: W, Btu/h
q_{r0}	value of q_r when fluid is stationary: W, Btu/h
q_w	heat transfer over A_w from plate to wall in enclosure problem (see Fig. 4.25 for definition of plate and wall): W, Btu/h
q_{w0}	value of q_w when fluid is stationary: W, Btu/h
q''_x	local heat flux at location x : W/m ² , Btu/(h·ft ²)
Δq	heat flow through area ΔA : W, Btu/h
Ra	Rayleigh number in terms of the reference temperature difference ΔT_0 , usually given by $g\beta\Delta T_0 L^3/\nu\alpha$ (but see separate definition sketch for each problem discussed)

Ra_c	critical Rayleigh number governing the initiation of small eddy convective motion in a fluid
Ra_{ci}, Ra_{cp}	critical Rayleigh numbers for cavities with adiabatic and perfectly conducting walls, respectively
Ra_x	local value of Ra based on local temperature difference, given by $g\beta\Delta Tx^3/\nu\alpha$
Ra_{max}	value of Ra at which the heat transfer per unit volume of vertical channels is maximum for a given channel height H
\tilde{Ra}	Rayleigh number for porous medium (Eq. 4.146)
Ra^*	Rayleigh number in terms of surface flux q'' , usually given by $g\beta\bar{q}''L^4/\nu\alpha k$ (but see separate definition sketch for each problem)
Ra_x^*	local value of Ra^* defined in separate definition sketch for each problem (e.g., Fig. 4.6)
Re	Reynolds number, usually equal to Lv_0/ν (but see separate definition sketch for each problem)
Re_{fd}	Reynolds number when flow and heat transfer are fully developed
Re_i	Reynolds number at which $Nu_F = Nu_N$
Re_p	Reynolds number based on particle diameter in a porous medium
r	radius of axisymmetric body in horizontal plane measured from vertical axis characteristic dimension (Fig. 4.3b): m, ft
S	spacing between fins or width of open cavity (Fig. 4.21 or 4.23): m, ft
\bar{S}	average spacing between vertical triangular fins (Fig. 4.23d)
S	stratification number, given by Eq. 4.41, with $L = D$ for cylinders, spheres
$S(\chi)$	vertical height of plate at location χ (Fig. 4.9): m, ft
T	local fluid temperature: K, °F
\bar{T}	mean fluid temperature: K, °F
T^*	wall temperature ratio for open rectangular cavity (Fig. 4.21)
\bar{T}_b	average of inlet and outlet bulk fluid temperatures for internal tube flow: K, °F
T_c	temperature of cold plate of enclosure (Figs. 4.25 and 4.26): K, °F
T_{cr}	temperature of the central region in a cavity (Fig. 4.26): K, °F
T_f	film temperature $(T_\infty + T_w)/2$, unless specifically given another meaning in section of interest: K, °F
T_h	temperature of hot plate in enclosure (Figs. 4.25 and 4.26): K, °F
T_i	initial temperature of quiescent fluid before transient is initiated: K, °F
T_m	$(T_h + T_c)/2$: K, °F
T_w	temperature of solid surface of body or wall: K, °F
\bar{T}_w	mean value of T_w taken over surface of body: K, °F
T_{wi}	temperature of inside of tube wall (Fig. 4.49): K, °F
$\bar{T}_{w(1/2)}$	mean wall temperature halfway up the rectangular open cavity (Fig. 4.21): K, °F
T_∞	fluid temperature far from solid surface or wall at a given elevation z : K, °F
\bar{T}_∞	mean value of T_∞ taken over vertical height of body
t	time: s
t_D	time period over which the fluid near a wall subjected to a step change in temperature or heat flux behaves like a stationary fluid (Figs. 4.37 and 4.39): s

t_i	time after the initiation of a transient at which the purely conductive heat transfer solution matches the steady-state convective heat transfer (Figs. 4.37 and 4.39): s
t_0	value of t_D when Nu at t_D is equal to Nu at t_∞ (Fig. 4.39): s
t_∞	time after the initiation of a transient at which the heat transfer at the wall is essentially the steady-state value (Fig. 4.37): s
t^*	dimensionless time, tv_0/L
u	fluid velocity in the x direction: m/s, ft/s
V, \bar{V}	fluid velocity and mean fluid velocity in tube: m/s, ft/s
v	fluid velocity in the y direction: m/s, ft/s
v_0	reference velocity, $\sqrt{g\beta\Delta TL(1 + Pr)}$: m/s, ft/s
W	width of plate (Fig. 4.6), of cavity (Figs. 4.25 and 4.33), or of open cavity (Fig. 4.23): m, ft
w	fluid velocity in the z direction: m/s, ft/s
x	spatial coordinate (Fig. 4.1); distance measured along a surface streamline starting from the beginning of the streamline (Fig. 4.3): m, ft
x^*	x/L
x_f	value of x at trailing edge of body: m, ft
y	spatial coordinate (Fig. 4.1); coordinate measured normal to surface of body and into the fluid (Fig. 4.3): m, ft
y^*	y/L
z	spatial coordinate (Fig. 4.1): m, ft; elevation of a point above reference level (Fig. 4.3c): m, ft
z_f	elevation of end of streamline passing through a particular point on a body
z_i	elevation of start of streamline passing through a particular point on a body: m, ft
z_{ref}	z at reference level: m, ft
z^*	z/L

Greek Symbols

α	thermal diffusivity evaluated at T_f (or at T_m for enclosure problems) unless specifically otherwise directed: m^2/s , ft^2/s
α_m	thermal diffusivity at porous medium (Eq. 4.145): m^2/s , ft^2/s
α^*	aspect ratio, S/W in Fig. 4.23a
β	coefficient of thermal expansion; evaluate β at T_f for liquids and T_∞ for gases, except for enclosure problems, where β is evaluated at T_m (unless otherwise specifically directed): K^{-1} , $^\circ\text{R}^{-1}$
β_0	β evaluated at T_f : K^{-1} , $^\circ\text{R}^{-1}$
β_1	equals β_0 for liquids and β_∞ for gases
β_∞	β evaluated at T_∞ : K^{-1} , $^\circ\text{R}^{-1}$
γ	pressure coefficient of expansion: Pa^{-1} , ft^2/lb_f
γ_1, γ_2	constants in the Bejan-Tien correlation equation (Eq. 4.98)
Δ_c	conduction layer thickness on the cold plate (Fig. 4.26): m, ft
Δ_{tx}	local turbulent conduction layer thickness on cold plate: m, ft
Δ_h	conduction layer thickness on hot plate (Fig. 4.26): m, ft

Δ_x	local conduction layer thickness for a laminar or turbulent boundary layer; $\Delta_x = k(T_w - T_\infty)/q''$: m, ft
ΔT	temperature difference $ T_w - T_\infty , T_h - T_c , T_i - T_o $, and so on: K or °C, °F
$\bar{\Delta}$	average conduction layer thickness around body (Eq. 4.16)
$\overline{\Delta T}$	area-weighted average value of $ T_w - T_\infty $ over the surface (or part of the surface) of body (Eq. 4.35): K, °F
ΔT_m	ΔT evaluated at the mid-height of a plate, cylinder, or sphere
ΔT_0	reference temperature difference, defined separately for each problem: K, °F
Δx	segment of length in x direction: m, ft
δ	thickness of tube wall (Fig. 4.49): m, ft
ϵ_c	emissivity of cold plate in enclosure problem (Fig. 4.25)
ϵ_h	emissivity of hot plate in enclosure problem (Fig. 4.25)
ϵ_w	emissivity of wall in enclosure problem (Fig. 4.25)
ζ	d/D (Fig. 4.23f)
ζ	local surface angle (Fig. 4.5)
ζ	parameter that accounts for transverse curvature of vertical cylinder (Eq. 4.44)
θ	angle of inclination from horizontal (Figs. 4.9, 4.16, and 4.25): rad, deg
θ_c	for enclosure problem, the crossover value of θ defined so that for $\theta < \theta_c$, Eq. 4.107 applies and for $\theta_c \leq \theta \leq 90^\circ$, Eq. 4.108 applies: rad, deg
θ	dimensionless temperature, $(T - T_\infty)/(T_w - T_\infty)$
μ	dynamic viscosity, evaluated at T_f (or T_m for enclosure problems) unless specifically directed otherwise: Pa·s, lb _m /(s·ft)
μ_b	viscosity of fluid evaluated at bulk temperature: Pa·s, lb _m /(s·ft)
ν	kinematic viscosity, evaluated at T_f (or T_m for enclosure problems) unless specifically directed otherwise: m ² /s, ft ² /s
ρ	local density of fluid: kg/m ³ , lb _m /ft ³
ρ_0	reference density, evaluated at film temperature T_f and P_{ref} : kg/m ³ , lb _m /ft ³
ρ_∞	density of fluid at $T = T_\infty, P = P_{ref}$: kg/m ³ , lb _m /ft ³
$(\rho c_p)_f$	heat capacity per unit volume for fluid: kJ/(m ³ ·K), Btu/(ft ³ ·°F)
$(\rho c_p)_w$	heat capacity per unit volume for wall adjacent to fluid: kJ/(m ³ ·K), Btu/(ft ³ ·°F)
σ	Stefan-Boltzman constant: W/m ² K ⁴ , Btu/(h·ft ² ·°R ⁴)
σ	heat capacitance ratio for a porous medium (Eq. 4.145)
$\tau, \tau_D, \tau_0, \tau_\infty$	dimensionless time, $4\alpha t/D^2, 4\alpha t_D/D^2, 4\alpha t_0/D^2, 4\alpha t_\infty/D^2$, respectively
ϕ	volume fraction occupied by fluid for a porous medium
Ψ	function of α^* , given by Eq. 4.61b
ψ	angle of opening of V-corrugated surface (Fig. 4.23c): rad, deg
χ	Forscheimer coefficient (Eq. 4.141)

Special Brackets

$[]'$	indicates that only positive values of quantities in brackets are to be taken: $[X]' = (X + X)/2$
$[x_1, x_2, \dots, x_n]_{\min}$	indicates that the minimum member of set $\{x_i\}$ is to be taken
$[x_1, x_2, \dots, x_n]_{\max}$	indicates that the maximum member of the set $\{x_i\}$ is to be taken

Operators

$$\frac{DX}{Dt^*} = \frac{\partial X}{\partial t^*} + u^* \frac{\partial X}{\partial x^*} + v^* \frac{\partial X}{\partial y^*} + w^* \frac{\partial X}{\partial z^*}$$

$$\nabla^{*2} X = \frac{\partial^2 X}{\partial x^{*2}} + \frac{\partial^2 X}{\partial y^{*2}} + \frac{\partial^2 X}{\partial z^{*2}}$$

CHAPTER 5

FORCED CONVECTION, INTERNAL FLOW IN DUCTS

M. A. Ebadian and Z. F. Dong

Florida International University

INTRODUCTION

Scope of the Chapter

This chapter deals with internal flow and heat transfer in ducts such as circular pipes, rectangular pipes, and other pipes with irregular cross sections. The scope of the chapter is restricted to the study of the steady, incompressible flow of newtonian fluids. The effects of natural convection, phase change, mass transfer, and chemical reactions have been ignored. This chapter is organized according to duct geometry. Hydrodynamics and heat transfer characteristics will be presented for each duct in terms of mathematical expressions, tables, and graphs in the corresponding sections. To the authors' knowledge, the most accurate and updated correlations and data for the friction factor and Nusselt number are provided for use in practical calculations.

Characteristics of Laminar Flow in Ducts

As a result of the development of the hydrodynamic and thermal boundary layers, four types of laminar flows occur in ducts, namely, fully developed, hydrodynamically developing, thermally developing (hydrodynamically developed and thermally developing), and simultaneously developing (hydrodynamically and thermally developing). In this chapter, the term *fully developed flow* refers to fluid flow in which both the velocity profile and temperature profile are fully developed (i.e., hydrodynamically and thermally developed flow). In such cases, the velocity profile and dimensionless temperature profile are constant along the flow direction. The friction factor and Nusselt number are also constant.

Hydrodynamically developing flow is isothermal fluid flow in which the velocity profile varies in the flow direction. Fluid flow from the entrance of the duct to the location at which the fully developed velocity profile forms is referred to as hydrodynamically developing flow. The distance over which the velocity distribution changes and the hydrodynamic boundary layer develops is referred to as the *hydrodynamic entrance length*. The friction factor in the hydrodynamic entrance is a function of the axial location.

The term *thermally developing flow* refers to fluid flow in which the temperature profile is developing and the velocity profile has already developed (i.e., the velocity distribution is invariant with axial length, and the nondimensional temperature profile changes with axial length). In other words, the hydrodynamic boundary layer is already developed while the thermal boundary is developing. This kind of flow is alternately termed *thermal entrance flow*. The distance over which the nondimensional temperature distribution changes or the thermal boundary layer develops is termed *thermal entrance length*, corresponding to hydrodynamic entrance length in hydrodynamically developing flow. The Nusselt number for thermally developing flow changes with axial location.

Simultaneously developing flow is fluid flow in which both the velocity and the temperature profiles are developing. The hydrodynamic and thermal boundary layers are developing in the entrance region of the duct. Both the friction factor and Nusselt number vary in the flow direction. Detailed descriptions of fully developed, hydrodynamically developing, thermally developing, and simultaneously developing flows can be found in Shah and London [1] and Shah and Bhatti [2].

Characteristics of Turbulent Flow in Ducts

In turbulent flow, the fluid particles do not travel in a well-ordered pattern. These particles possess velocities with macroscopic fluctuations at any point in the flow field. Even in steady turbulent flow, the local velocity components transverse to the main flow direction change in magnitude with respect to time. Instantaneous velocity consists of time-average velocity and its fluctuating component. When heat transfer is involved in turbulent flow, the instantaneous temperature is composed of the time-average temperature and its fluctuating components.

Similar to laminar flow in ducts, turbulent flow can be divided into four types—fully developed, hydrodynamically developing, thermally developing, and simultaneously developing. Nevertheless, the hydrodynamic and thermal entrance lengths in turbulent duct flow are characteristically much shorter than their corresponding lengths in laminar duct flow. Consequently, the results of fully developed turbulent flow and heat transfer are frequently used in design calculations without reference to the hydrodynamic and thermal entrance regions. However, caution must be taken in using the fully developed results for low Prandtl number fluids such as liquid metals inasmuch as entrance effects are very important for these fluids. Table 5.1 illustrates the relationships between the types of flow, boundary layers, velocity and temperature distributions, the friction factor, and the Nusselt number.

TABLE 5.1 Terminology for Flow Types

Flow type	Hydrodynamic boundary layer	Velocity distribution in the flow direction	Friction factor	Thermal boundary layer	Dimensionless temperature distribution in the flow	Nusselt number
Fully developed flow	Developed	Invariant	Constant	Developed	Invariant	Constant
Hydrodynamically developing flow	Developing	Variants	Variants	—	—	—
Thermally developing flow	Developed	Invariant	Constant	Developing	Variants	Variants
Simultaneously developing flow	Developing	Variants	Variants	Developing	Variants	Variants

Hydraulic Diameter

For fluid flow and heat transfer inside a duct, various dimensionless parameters are used. In these parameters, a characteristic length of the duct is commonly involved. The hydraulic diameter D_h of the duct serves this purpose. It is defined as follows:

$$D_h = 4A_c/P \quad (5.1)$$

where A_c is the flow cross-sectional area and P is the wetted perimeter of the duct.

For a circular duct, the hydraulic diameter is equal to its physical diameter. For a noncircular duct, it is convenient to use the hydraulic diameter to substitute for the characteristic physical dimension. However, for ducts with very sharp corners (e.g., triangular and cusped ducts), the use of the hydraulic diameter results in unacceptably large errors in the turbulent flow friction and heat transfer coefficients determined from the circular duct correlation. Other dimensions have been proposed as substitutes for hydraulic diameter. These equivalent diameters, provided for specific ducts only, will be presented elsewhere in this chapter.

Fluid Flow Parameters

One of the flow parameters most commonly used in practice is the friction factor, also referred to as the *Fanning friction factor* f , which is defined as follows:

$$f = \frac{\tau_w}{\rho u_m^2/2} \quad (5.2)$$

where τ_w is wall shear stress, u_m is the mean velocity, and ρ is the density of fluid.

The Reynolds number Re , the parameter that represents the status of the flow, is defined as

$$Re = \frac{u_m D_h}{\nu} \quad (5.3)$$

The hydrodynamic entrance length L_{hy} is defined as the axial distance required to attain 99 percent of the ultimate fully developed maximum velocity when the entering flow is uniform. The dimensionless hydrodynamic entrance length is expressed as $L_{hy}^+ = L_{hy}/D_h Re$.

In this hydrodynamic entrance region, the apparent friction factor f_{app} is employed to incorporate the combined effects of wall shear and the change in momentum flow rate due to the developing velocity profile. Based on the total axial pressure drop from the duct inlet ($x = 0$) to the point of interest, the apparent friction factor is defined as follows:

$$\Delta p^* = \frac{p_0 - p}{\rho u_m^2/2} = f_{app} \frac{2x}{D_h} \quad (5.4)$$

The incremental pressure drop number $K(x)$ in the hydrodynamic entrance region is expressed as

$$K(x) = (f_{app} - f_{fd}) \frac{2x}{D_h} \quad (5.5)$$

where f_{fd} is the friction factor for fully developed laminar flow. $K(x)$ is sometimes referred to as the incremental pressure defect. It increases from a value of zero at $x = 0$ to a constant value $K(\infty)$ in the hydrodynamically developed region at $x > L_{hy}$.

The relationship between the friction factor, axial pressure drop, and incremental pressure drop number is the following:

$$\Delta p^* = (f_{\text{app}} \text{Re})(4x^+) = K(x) + (f \text{Re})(4x^+) \quad (5.6)$$

where x^+ is the dimensionless axial length, defined as $x/(D_h \text{Re})$.

Heat Transfer Parameters

The most useful parameters for heat transfer are the fluid bulk mean temperature and the heat transfer coefficient. The fluid bulk mean temperature T_m , also known as the mixing cup or flow average temperature, is defined as

$$T_m = \frac{1}{A_c u_m} \int_{A_c} uT \, dA_c \quad (5.7)$$

The circumferentially averaged but axial local heat transfer coefficient h_x is defined by

$$q_x'' = h_x(T_{w,m} - T_m) \quad (5.8)$$

where $T_{w,m}$ is the wall mean temperature and T_m is the fluid bulk mean temperature given by Eq. 5.7. In Eq. 5.8, the heat flux q_x'' and the temperature difference $T_{w,m} - T_m$ are vector quantities. The direction in which the heat is transferred is from the wall to the fluid, and the temperature consistently drops from the wall to the fluid.

The average circumferential and axial heat transfer coefficient can be obtained by means of the following expression:

$$h_m = \frac{1}{x} \int_0^x h_x \, dx \quad (5.9)$$

Correspondingly, the circumferentially averaged but axially local Nusselt number is defined as

$$\text{Nu}_x = \frac{h_x D_h}{k} \quad (5.10)$$

The mean Nusselt number based on h_m in the thermal entrance region is defined as

$$\text{Nu}_m = \frac{1}{x} \int_0^x \text{Nu}_x \, dx = \frac{h_m D_h}{k} \quad (5.11)$$

Two dimensionless axial distances will be used in this chapter. The term x^+ , which denotes hydrodynamically developing flow, is defined as

$$x^+ = \frac{x/D_h}{\text{Re}} \quad (5.12)$$

The term x^* , denoting thermally and simultaneously developing flows, is expressed as:

$$x^* = \frac{x/D_h}{\text{Pe}} = \frac{x/D_h}{\text{Re Pr}} \quad (5.13)$$

where Pe is the Péclet number, defined as Re Pr. The relationship between x^+ and x^* is simply given by

$$x^* = x^+/\text{Pr} \quad (5.14)$$

Corresponding to the hydrodynamic entrance length, the thermal entrance length L_{th} is defined as the axial distance needed to achieve a value of the local Nusselt number Nu_x , which is 1.05 times the fully developed Nusselt number value. The dimensionless thermal entrance length is expressed as $L_{th}^+ = L_{th}/(D_h Pe)$.

Thermal Boundary Conditions

The following thermal boundary conditions are the most important and frequently encountered in practical use:

1. Uniform wall temperature, denoted by ①. This boundary condition is present when the duct has a constant wall temperature in both the circumferential and axial directions. Uniform wall temperature has frequent application in condensers, evaporators, and automotive radiators with high flow rates.
2. Convective boundary condition, denoted by ③. The convection between the duct wall and the environment is taken into consideration in the ③ boundary condition. The duct wall temperature is considered to be uniform in the axial direction. The practical applications are the same as those in the ① boundary condition, except for the case of finite thermal resistance in the wall.
3. Radiative boundary condition, denoted by ④. This boundary condition involves radiative heat transfer from the duct to the environment. The wall heat flux is proportional to the fourth power of the absolute wall temperature, and the environment temperature is uniform in the axial direction. This boundary condition can be found in high-temperature systems such as space radiators, liquid-metal exchangers, and heat exchangers involving heat-radiating gases.
4. Uniform wall heat flux axially, but uniform wall temperature circumferentially, denoted by ⑥. This boundary condition is found in electric resistance heating, nuclear heating, and counterflow heat exchangers, in which two fluids have nearly the same fluid capacity rates and the wall is highly conductive.
5. Uniform wall heat flux axially and circumferentially, denoted by ⑦. This boundary condition has applications that are similar to those listed for the ⑥ boundary condition except that the thermal conductivity of the wall material is low and the wall thickness is uniform.
6. Conductive boundary condition, denoted by ⑧. This boundary condition refers to the axial uniform wall heat flux and finite heat condition along the wall circumference. The same applications can be found as those for the ⑥ boundary condition except for the existence of heat conduction in the circumferential direction.
7. Exponential wall heat flux, denoted by ⑨. This boundary condition represents a duct with circumferentially constant wall temperature and exponentially varying wall heat flux along the axial direction. Exponential wall heat flux can be seen in parallel and counterflow heat exchangers with an appropriate value of m .

The preceding boundary conditions are applicable to both singly connected and doubly connected ducts. Detailed descriptions of the various boundary conditions are available in Shah and London [1] and Shah and Bhatti [2].

CIRCULAR DUCTS

In industry, circular ducts are widely used in various applications. Fluid and heat transfer inside circular ducts have been analyzed in great detail. A discussion of laminar and turbulent flows and heat transfer in circular ducts is presented in the following sections.

Laminar Flow

For a circular duct with a diameter of $2a$, the characteristics of laminar flow and heat transfer for four kinds of flows, namely, fully developed, hydrodynamically developing, thermally developing, and simultaneously developing, are outlined in the following sections.

Fully Developed Flow

Velocity Profile and Friction Factor. The velocity profile of fully developed laminar flow of a constant-property fluid in a circular duct with an origin at the duct axis is given by the Hagen-Poiseuille parabolic profile, as follows:

$$\frac{u}{u_m} = 2 \left[1 - \left(\frac{r}{a} \right)^2 \right] \quad (5.15)$$

where u_m can be obtained by the following equation:

$$u_m = - \frac{1}{8\mu} \left(\frac{dp}{dx} \right) a^2 \quad (5.16)$$

The product of the friction factor and the Reynolds number for fully developed flow in a circular duct is found to be constant. This is obtained from Eq. 5.15 as:

$$f \text{ Re} = 16 \quad (5.17)$$

Heat Transfer on Walls With Uniform Temperature. For this boundary condition, denoted as \textcircled{U} , temperature distribution in a circular duct for fully developed laminar flow in the absence of flow work, thermal energy sources, and fluid axial conduction has been solved by Bhatti [3] and presented by Shah and Bhatti [2], as follows:

$$\frac{T_w - T}{T_w - T_m} = \sum_{n=0}^{\infty} C_{2n} \left(\frac{r}{a} \right)^{2n} \quad (5.18)$$

where the coefficients C_{2n} are given by

$$C_0 = 1 \quad C_2 = - \frac{\lambda_0^2}{2^2} = -1.828397$$

$$C_{2n} = \frac{\lambda_0^2}{(2n)^2} (C_{2n-4} - C_{2n-2}) \quad \lambda_0 = 2.7043644199 \quad (5.19)$$

The bulk mean temperature of the fluid can be obtained by:

$$\frac{T_w - T_m}{T_w - T_e} = 0.819048 \exp(-2\lambda_0^2 x^*) \quad (5.20)$$

It should be noted that Eq. 5.20 is valid for $x^* > 0.0335$ [3].

The Nusselt number corresponding to Eq. 5.18 is as follows:

$$\text{Nu}_T = \frac{\lambda_0}{2} = 3.657 \quad (5.21)$$

The Péclet number is introduced to consider the effect of fluid axial conduction. It has been found that the axial conduction of fluid can be ignored when the Péclet number is

greater than 10. For a small Péclet number, the following formulas by Michelsen and Villadsen [4] are recommended:

$$\text{Nu}_T = \begin{cases} 4.1807(1 - 0.0439\text{Pe} + \dots) & \text{Pe} < 1.5 \\ 3.6568(1 + 1.227/\text{Pe}^2 + \dots) & \text{Pe} > 5 \end{cases} \quad (5.22)$$

The Brinkmann number $\text{Br} = (\mu u_m^2)/[k(T_{w,m} - T_e)]$ is introduced to account for the influence of viscous dissipation, such as heating or cooling of the fluid due to internal friction in high-velocity flow, highly viscous fluid, or in cases in which viscous dissipation cannot be ignored. When viscous dissipation is considered, the asymptotic Nusselt number in a very long pipe, found by Ou and Cheng [5], is 9.6 and independent of the Brinkmann number.

Heat Transfer on Walls With Uniform Heat Flux. For circular ducts with symmetrical heating, the same heat transfer results for fully developed flow and developing flow are obtained for boundary conditions ⑥ through ⑧. Therefore, the uniform wall heat flux boundary conditions are simply designated as the ⑥ boundary condition. Shah and Bhatti [2] have derived the temperature distribution and Nusselt number by recasting the results reported by Tyagi [6] for heat transfer in circular ducts. These follow:

$$\frac{T_w - T}{T_w - T_m} = 6 \left[1 - \left(\frac{r}{a} \right)^2 \right] \left[\frac{(12 + \gamma) - (4 + \gamma)(r/a)^2}{44 + 3\gamma} \right] \quad (5.23)$$

$$\text{Nu}_H = \frac{q_w'' D_h}{k(T_w - T_m)} = \frac{192}{44 + 3\gamma} \quad \gamma = S^* + 64 \text{Br}' \quad (5.24)$$

where S^* is the dimensionless thermal energy source number ($S^* = SD_h/q_w''$) and Br' is the dimensionless Brinkmann number, defined as $\text{Br}' = \mu u_m^2/q_w'' D_h$, for the uniform wall heat flux boundary condition. For the case of negligible viscous dissipation and no thermal energy sources ($\gamma = 0$), the Nusselt number can be obtained from Eq. 5.24:

$$\text{Nu}_H = 4.364 \quad (5.25)$$

Eq. 5.24 can also be applied in the case of finite axial fluid conduction.

Heat Transfer on Convection Duct Walls. For this boundary condition, denoted as ⑨, the wall temperature is considered to be constant in the axial direction, and the duct has convection with the environment. An external heat transfer coefficient is incorporated to represent this case. The dimensionless Biot number, defined as $\text{Bi} = h_e D_h/k_w$, reflects the effect of the wall thermal resistance, induced by external convection.

For cases in which the external heat transfer coefficient h_e is constant, Hickman [7] developed the following formula to calculate the Nusselt number:

$$\text{Nu}_{T3} = \frac{4.3636 + \text{Bi}}{1 + 0.2682\text{Bi}} \quad (5.26)$$

From the preceding equation, the uniform wall heat flux and uniform wall temperature can be obtained when $\text{Bi} = 0$ and $\text{Bi} = \infty$, respectively.

Heat Transfer on Radiative Duct Walls. Heat transfer on radiative duct walls is of the ⑩ boundary condition type. Kadaner et al. [8] obtained the following equation for the fully developed Nusselt number under the ⑩ boundary condition:

$$\text{Nu}_{T4} = \frac{8.728 + 3.66\text{Sk} (T_a/T_e)^3}{2 + \text{Sk} (T_a/T_e)^3} \quad (5.27)$$

where Sk is the dimensionless Stark number, defined as $\text{Sk} = \epsilon_w \sigma T_e^3 D_h/k$, and T_a and T_e are the absolute temperatures of the external environment and the internal fluid at the location of

the impingement of the radiation flux, respectively. In Eq. 5.27, when $Sk = 0$ and $Sk = \infty$, Nu_{T4} reduces to Nu_H and Nu_T .

Heat Transfer on the Walls With Exponentially Varying Heat Flux. Exponentially varying wall heat flux is delineated by the \textcircled{B} boundary condition and represented by $q_w'' = q_0'' \exp(mx^*)$, where the exponent m can have both positive and negative values corresponding to the exponential growth or decay of the wall heat flux.

Shah and London [1] have obtained the Nusselt number for $-51.36 \leq m \leq 100$ as the following correlation with a maximum error of 3 percent:

$$Nu_{HS} = 4.3573 + 0.0424m - 2.8368 \times 10^{-8}m^2 + 3.6250 \times 10^{-6}m^3 - 7.6497 \times 10^{-8}m^4 + 9.1222 \times 10^{-4}m^5 - 3.8446 \times 10^{-12}m^6 \quad (5.28)$$

When $m = 0$ and $m = -14.627$, the \textcircled{B} boundary condition corresponds to uniform wall heat flux and uniform wall temperature, respectively. Recently, Piva [9] obtained the fully developed Nusselt number for the \textcircled{B} boundary condition based on confluent hypergeometric functions. The Nusselt number for very large m can be found in Piva [9].

Hydrodynamically Developing Flow. Solutions for three different flow conditions are provided as follows.

Solutions for Very Large Reynolds Number Flows. For very large Reynolds number flow, boundary layer theory simplifications are involved in the solutions. The numerical solution found by Hornbeck [10] is the most accurate of the various solutions reviewed by Shah and London [1]. The dimensionless axial velocity and pressure drop obtained by Hornbeck [10] are presented in Table 5.2.

Based on these results, the hydrodynamic entrance length was found to be:

$$L_{hy}^+ = 0.0565 \quad K(\infty) = 1.28 \quad (5.29)$$

It should be noted, however, that the solutions for very large Reynolds numbers are inaccurate in the duct inlet. For practical computations, the following correlation proposed by Shah

TABLE 5.2 Axial Velocity and Pressure Drop in the Hydrodynamic Entrance Region of a Circular Duct [10]

∞	2.0000	1.9800	1.9200	1.8200	1.6800	1.5000	1.2800	1.0200	0.7200	0.3800	0	—

and London [1] can be used to calculate the dimensionless axial pressure drop in the hydrodynamic entrance region:

$$\Delta p^* = 13.74(x^*)^{1/2} + \frac{1.25 + 64x^* - 13.74(x^*)^{1/2}}{1 + 0.00021(x^*)^{-2}} \quad (5.30)$$

Solutions for the Flow with $Re < 400$. It has been found that the effects of axial momentum diffusion and radial pressure variation are significant only in the duct inlet of $x^* < 0.005$. Chen [11] obtained the dimensionless hydrodynamic entrance length L_{hy}^* and the fully developed incremental pressure drop number $K(\infty)$, which are given by

$$L_{hy}^* = 0.056 + \frac{0.60}{Re(1 + 0.035Re)} \quad (5.31)$$

$$K(\infty) = 1.20 + \frac{38}{Re} \quad (5.32)$$

For $x^* > 0.005$, the solutions proposed by Hornbeck [10] are quite satisfactory.

Solutions for Small Reynolds Number ($Re \rightarrow 0$) Flows. For small Reynolds number flows, such as creeping flow, in which viscous forces completely overwhelm the inertia forces, the hydrodynamic entrance length L_{hy}^* has been found to approach the value of 0.60 as $Re \rightarrow 0$ with the uniform flow at the inlet of the circular duct [1].

The following expression, proposed by Weissberg [12] and verified experimentally by Linehan and Hirsch [13], can be used to compute pressure drop in the entrance region of a circular duct with a very small Reynolds number flow:

$$\Delta p^* = 64 \left(x^* + \frac{3\pi}{16Re} \right) \quad (5.33)$$

Thermally Developing Flow

Heat Transfer on Walls With Uniform Wall Temperature. Heat transfer in a duct with uniform wall temperature is known as the Graetz or Graetz-Nusselt problem. In this case, a fluid with a fully developed velocity distribution (Eq. 5.15) and a uniform temperature flows into the entrance, and the fluid axial conduction, viscous dissipation flow work, and energy resources are negligible. Graetz [14] and Nusselt [15] solved this problem as follows:

$$\theta = \frac{T_w - T}{T_w - T_e} = \sum_{n=0}^{\infty} C_n R_n \left(\frac{r}{a} \right) \exp(-2\lambda_n^2 x^*) \quad (5.34)$$

$$\theta_m = \frac{T_w - T_m}{T_w - T_e} = 8 \sum_{n=0}^{\infty} \frac{G_n}{\lambda_n^2} \exp(-2\lambda_n^2 x^*) \quad (5.35)$$

$$Nu_{x,T} = \frac{\sum_{n=0}^{\infty} G_n \exp(-2\lambda_n^2 x^*)}{2 \sum_{n=0}^{\infty} (G_n/\lambda_n^2) \exp(-2\lambda_n^2 x^*)} \quad (5.36)$$

$$Nu_{m,T} = - \frac{\ln \theta_m}{4x^*} \quad (5.37)$$

where λ_n , $R_n(r/a)$, and C_n denote the eigenvalues, eigenfunctions, and constants, respectively, and $G_n = -(C_n/2)R'_n(1)$, where $R'_n(1)$ is the derivative of $R_n(r/a)$ evaluated at $r/a = 1$.

The eigenvalues and constants in Eqs. 5.34–5.36 are listed in Table 5.3, while those for $R_n(r/a)$ are given in Table 5.4. When n is greater than 10, the following correlations are used to calculate the λ_n and G_n [16]:

$$\lambda_n = \lambda + S_1\lambda^{-4/3} + S_2\lambda^{-8/3} + S_3\lambda^{-10/3} + S_4\lambda^{-11/3} + o(\lambda^{-14/3}) \tag{5.38}$$

$$G_n = \frac{C}{\lambda^{1/3}} \left[1 + \frac{L_1}{\lambda^{4/3}} + \frac{L_2}{\lambda^{6/3}} + \frac{L_3}{\lambda^{7/3}} + \frac{L_4}{\lambda^{10/3}} + \frac{L_5}{\lambda^{11/3}} + o(\lambda^{-4}) \right] \tag{5.39}$$

where $\lambda = 4n + 8/3 \quad n = 0, 1, 2, \dots$ (5.40)

$$\begin{aligned} S_1 = 0.159152288 \quad S_2 = 0.0114856354 \quad S_3 = -0.224731440 \\ S_4 = -0.033772601 \quad C = 1.012787288 \end{aligned} \tag{5.41}$$

and $L_1 = 0.144335160 \quad L_2 = 0.115555556 \quad L_3 = -0.21220305$
 $L_4 = -0.187130142 \quad L_5 = 0.0918850832$ (5.42)

FIGURE 5.1 Local and mean Nusselt numbers $Nu_{x,T}$ and $Nu_{m,T}$ for thermal developing flow in a circular duct.

The local Nusselt number and mean Nusselt number computed from Eqs. 5.36 and 5.37 are shown in Fig. 5.1. The data corresponding to this figure can be found in Shah and London [1].

The thermal entrance length for thermally developing flow in circular ducts can be obtained using the following expression:

$$L_{th,T}^* = 0.0335 \quad (5.43)$$

It should be noted that the solutions derived from Eqs. 5.34 through 5.36 are inaccurate when $x^* < 10^{-4}$. Therefore, L  v  que's [19] asymptotic solution is introduced. The local and mean Nusselt numbers can be computed from the following formulas [1]:

$$Nu_{x,T} = \begin{cases} 1.077x^{*-1/3} - 0.7 & \text{for } x^* \leq 0.01 \\ 3.657 + 6.874(10^3x^*)^{-0.488}e^{-57.2x^*} & \text{for } x^* > 0.01 \end{cases} \quad (5.44)$$

$$Nu_{m,T} = \begin{cases} 1.615x^{*-1/3} - 0.7 & \text{for } x^* \leq 0.005 \\ 1.615x^{*-1/3} - 0.2 & \text{for } 0.005 < x^* < 0.03 \\ 3.657 + (0.0499/x^*) & \text{for } x^* \geq 0.03 \end{cases} \quad (5.45)$$

Shah and Bhatti [2] and Hausen [20] have obtained the following correlations for the local and mean Nusselt numbers for the entire x^* .

$$Nu_{x,T} = 3.66 + \frac{0.0018}{x^{*1/3}(0.04 + x^{*2/3})^2} \quad (5.46)$$

$$Nu_{m,T} = 3.66 + \frac{0.0668}{x^{*1/3}(0.04 + x^{*2/3})} \quad (5.47)$$

The effects of fluid axial conduction on the Graetz solution have been reviewed extensively by Shah and London [1]. Furthermore, Laohakul et al. [21], Ebadian and Zhang [22],

and Nguyen [23] have investigated this extended Graetz problem with axial heat conduction. For $Pe < 50$, $Nu_{m,T}$ can be calculated with the following expression [4]:

$$Nu_{m,T} = \begin{cases} 3.6508 \left(1 + \frac{1.227}{Pe^2} + \dots \right) & \text{for } Pe > 5 \\ 4.1807(1 - 0.0439Pe + \dots) & \text{for } Pe < 1.5 \end{cases} \quad (5.48)$$

It has been confirmed that the effect of fluid axial conduction can be neglected for $Pe > 50$ [24]. However, the thermal entrance length $L_{th,T}^*$ varies with the Péclet number. Nguyen [23] expresses $L_{th,T}^*$ as follows:

$$L_{th,T}^* = \begin{cases} -0.003079 + 0.4663/Pe & \text{for } 1 \leq Pe \leq 5 \\ 0.02020 + 0.3550/Pe & \text{for } 5 \leq Pe \leq 20 \\ 0.03258 + 0.1295/Pe & \text{for } 20 \leq Pe \leq 1000 \end{cases} \quad (5.49)$$

Other extended Graetz problems in which the effect of viscous dissipation, inlet velocity, and temperature profiles are considered are reviewed in detail by Shah and London [1].

Heat Transfer on Walls With Uniform Heat Flux. The temperature profile and the local and mean Nusselt numbers for thermally developing flow in a circular duct with uniform wall heat flux are provided by Siegel et al. [25] as follows:

$$\Theta = \frac{T - T_e}{q_w''(D_h/k)} = 4x^* + \frac{1}{2} \left(\frac{r}{a} \right)^2 - \frac{1}{8} \left(\frac{r}{a} \right)^4 - \frac{7}{48} + \frac{1}{2} \sum_{n=1}^{\infty} C_n R_n \left(\frac{r}{a} \right) \exp(-2\beta_n^2 x^*) \quad (5.50)$$

$$\Theta_m = \frac{T_m - T_e}{q_w''(D_h/k)} = 4x^* \quad (5.51)$$

$$Nu_{x,H} = \left(\frac{11}{48} + \frac{1}{2} \sum_{n=1}^{\infty} C_n R_n(1) \exp(-2\beta_n^2 x^*) \right)^{-1} \quad (5.52)$$

$$Nu_{m,H} = \left(\frac{11}{48} + \frac{1}{2} \sum_{n=1}^{\infty} C_n R_n(1) \frac{1 - \exp(-2\beta_n^2 x^*)}{2\beta_n^2 x^*} \right)^{-1} \quad (5.53)$$

where β_n , $R_n(r/a)$, and C_n are eigenvalues, eigenfunctions, and constants, respectively.

Hsu [26] extended the work conducted by Siegel et al. [25] and reported the first 20 values for β_n^2 , $R_n(1)$, and C_n . These are listed in Table 5.5. In addition, Hsu [26] presented approximate formulas for higher eigenvalues and constants. The following are of particular interest:

$$\beta_n = 4n + 4/3 \quad (5.54)$$

$$R_n(1) = (-1)^n 0.774759003 \beta_n^{-1/3} \quad (5.55)$$

$$C_n = (-1)^n 3.099036005 \beta_n^{-4/3} \quad (5.56)$$

The local and mean Nusselt numbers for the Θ boundary condition are displayed in Fig. 5.2. For the inlet of the circular duct, the local and mean Nusselt numbers can be computed by

$$Nu_{x,H} = \begin{cases} 1.302x^{*-1/3} - 1 & \text{for } x^* \leq 0.00005 \\ 1.302x^{*-1/3} - 0.5 & \text{for } 0.00005 \leq x^* \leq 0.0015 \\ 4.364 + 8.68(10^3 x^*)^{-0.506} e^{-41x^*} & \text{for } x^* \geq 0.0015 \end{cases} \quad (5.57)$$

$$Nu_{m,H} = \begin{cases} 1.953x^{*-1/3} - 1 & \text{for } x^* \leq 0.03 \\ 4.364 + 0.0722/x^* & \text{for } x^* > 0.03 \end{cases} \quad (5.58)$$

The thermal entrance length for thermally developing flow under the uniform wall heat flux boundary condition is equal to the following:

$$L_{th,H}^* = 0.0430 \quad (5.59)$$

The effects of fluid axial conduction on the thermal entrance problem with uniform wall heat flux are negligible for $Pe > 10$ when $x^* \geq 0.005$ [24]. However, the thermal entrance length $L_{th,H}^*$ obtained by Nguyen [23] is expressed in terms of Pe :

$$L_{th,H}^* = \begin{cases} -0.000518 + 0.4686/Pe & \text{for } 1 \leq Pe \leq 5 \\ 0.03263 + 0.3090/Pe & \text{for } 5 \leq Pe \leq 20 \\ 0.04217 + 0.1309/Pe & \text{for } 20 \leq Pe \leq 1000 \end{cases} \quad (5.60)$$

The effects of viscous dissipation on the thermal entrance problem with the uniform wall heat flux boundary condition can be found in Brinkman [27], Tyagi [6], Ou and Cheng [28], and Basu and Roy [29]. Other effects, such as inlet temperature, internal heat source, and wall heat flux variation, are reviewed by Shah and London [1] in detail.

Heat Transfer on the Walls With Exponential Heat Flux. Heat transfer on walls with exponential wall heat flux is denoted as the $\textcircled{\oplus}$ boundary condition. According to the analysis by Siegel et al. [25], the local Nusselt number for a circular duct with exponential variation of the wall heat flux, as represented by $q_w'' = q_0'' \exp(mx^*)$, can be determined using the following formula:

$$Nu_{x,H5} = \left(\sum_{n=1}^{\infty} \frac{-C_n R_n(1) \beta_n^2}{m + 2\beta_n^2} [1 - \exp[-(m + 2\beta_n^2)x^*]] \right)^{-1} \quad (5.61)$$

The constants C_n , $R_n(1)$, and β_n^2 in Eq. 5.61 can be obtained from Table 5.5 and Eqs. 5.54 through 5.55.

FIGURE 5.2 Local and mean Nusselt numbers $Nu_{x,H}$ and $Nu_{m,H}$ for thermal developing flow in a circular duct.

Heat Transfer on Walls With External Convection. Figure 5.3 presents the results obtained by Hsu [30] for the thermal entrance problem with the convective duct wall boundary condition \textcircled{C} without consideration of viscous dissipation, fluid axial conduction, flow work, or internal heat sources. As limiting cases of the \textcircled{C} boundary condition, the curves corresponding to $Bi = 0$ and $Bi = \infty$ are identical to $Nu_{x,H}$ and $Nu_{x,T}$, respectively. Significant viscous dissipation effects have been found by Lin et al. [31] for larger Bi values.

Heat Transfer on Walls With Radiation. The local Nusselt numbers normalized with respect to $Nu_{x,H}$ have been obtained by Kadaner et al. [8] for thermally developing flow with the radioactive duct wall boundary condition \textcircled{D} . This is expressed as:

$$\frac{Nu_{x,T4}}{Nu_{x,H}} = 0.94 - \frac{0.0061 - 0.0053 \ln x^*}{1 + 0.0242 \ln x^*} \ln \left(\frac{Sk}{2} \right) \quad (5.62)$$

Equation 5.62 is valid in the ranges $0.001 < x^* < 0.2$ and $0.2 < Sk < 100$ for zero ambient temperature. It should be noted that Nusselt numbers $Nu_{x,T4}$ with $Sk = 0$ and $Sk = \infty$ are identical to $Nu_{x,H}$ and $Nu_{x,T}$, respectively.

Simultaneously Developing Flow. Simultaneously developing flow usually occurs when the fluid exhibits a moderate Prandtl number. In such a flow, the velocity and the temperature profiles develop simultaneously along the flow direction. Therefore, the heat transfer rate strongly depends on the Prandtl number of the fluid and the thermal boundary condition.

Heat Transfer on Walls With Uniform Temperature. The local and mean Nusselt numbers $Nu_{x,T}$ and $Nu_{m,T}$ are shown in Figs. 5.4 and 5.5, respectively. The data corresponding to these figures can be found in Jensen [32] and Shah and London [1]. It can be observed that for fluids with a large Prandtl number ($Pr \rightarrow \infty$), the solution for simultaneously developing flow corresponds to the solution for thermally developing flow because the velocity profile develops before the temperature profile begins developing. However, for a fluid with a very small Prandtl number ($Pr = 0$), the temperature profile develops much more quickly than the velocity profile, while the velocity remains uniform. This is termed *slug flow*. The local and mean Nusselt numbers for slug flow ($Pr = 0$) and for $Pr \rightarrow \infty$ are shown in Figs. 5.4 and 5.5, respectively.

FIGURE 5.3 Local Nusselt number $Nu_{x,T3}$ for thermally developing flow in a circular duct [30].

FIGURE 5.4 Local Nusselt number $Nu_{x,T}$ for simultaneously developing flow in a circular duct [1].

FIGURE 5.5 Mean Nusselt number $Nu_{m,T}$ for simultaneously developing flow in a circular duct [1].

The thermal entrance lengths for simultaneously developing flow with the thermal boundary condition of uniform wall temperature provided by Shah and London [1] are as follows:

$$L_{th,T}^* = \begin{cases} 0.028 & \text{for } Pr = 0 \\ 0.037 & \text{for } Pr = 0.7 \\ 0.033 & \text{for } Pr = \infty \end{cases} \quad (5.63)$$

Heat Transfer on the Walls With Uniform Heat Flux. The solutions for simultaneously developing flow in circular ducts with uniform wall heat flux $\textcircled{\oplus}$ are reviewed by Shah and London [1]. Recently, a new integral or boundary layer solution has been obtained by Al-Ali and Selim [33] for the same problem. However, the most accurate results for the local Nusselt numbers [1] are presented in Table 5.6.

The thermal entrance lengths for simultaneously developing flow with the thermal boundary condition of uniform wall heat flux [1, 34] can be obtained by

$$L_{th,T}^* = \begin{cases} 0.042 & \text{for } Pr = 0 \\ 0.053 & \text{for } Pr = 0.7 \\ 0.043 & \text{for } Pr = \infty \end{cases} \quad (5.64)$$

The axial diffusions of heat and momentum were considered by Pagliarini [35] for simultaneously developing flow, whereas the viscous dissipation effect has been taken into account by Barletta [36].

Heat Transfer With the Convective Boundary Condition. The solution for simultaneously developing flow with the convective boundary condition $\textcircled{\ominus}$ has been obtained by Javeri [37]. The results are listed in Table 5.6. It should be noted that when $Bi = \infty$, $Nu_{x,T3}$ is identical to $Nu_{x,T}$. When $Bi = 0$, $Nu_{x,T3}$ is the same as $Nu_{x,H}$.

Conjugate Problem. To this point, uniform wall thickness has been assumed, and no heat conduction in the wall has been involved, meaning that the wall has infinite heat conductivity. If heat conduction in the wall is considered, forced convection and conduction in the wall must be analyzed simultaneously. The solution for this combined problem, referred to as a *conjugate problem*, entails several additional parameters. An extensive review has been per-

FIGURE 5.6 Local Nusselt number $Nu_{x,H}$ for simultaneously developing flow in a circular duct [1].

formed by Barozzi and Pagliarini [38] for fully developed flow. The reader can also refer to Kuo and Lin [39] and Pagliarini [40] for developing flow.

Turbulent Flow

In this section, turbulent flow and heat transfer in a circular duct with a diameter of $2a$ is discussed for fully developed and developing flow.

Critical Reynolds Number. The Reynolds number, defined as $u_m D_h / \nu$, is widely adopted to identify flow status such as laminar, turbulent, and transition flows. A great number of experimental investigations have been performed to ascertain the critical Reynolds number at which laminar flow transits to turbulent flow. It has been found that the transition from laminar flow to fully developed turbulent flow occurs in the range of $2300 \leq Re < 10^4$ for circular ducts [41]. Correspondingly, flow in this region is termed *transition flow*. More conservatively, the lower end of the critical Reynolds number is set at 2100 in most applications.

Generally, the duct inlet configuration and surface roughness have significant effects on the value of Re_{crit} . Other factors, such as noise, vibration, and flow pulsation, affect Re_{crit} as well. Caution should be taken to choose Re_{crit} for the particular application. On the other hand, flow and heat transfer characteristics are difficult to predict in transition flow. The reader is encouraged to consult the literature for the cases not mentioned in this chapter.

Fully Developed Flow. In this section, the characteristics of the fully developed turbulent flow and heat transfer are presented for both a smooth and a rough circular duct with a diameter of $2a$.

The Power Law Velocity Distribution. The solution for the power law velocity distribution is introduced in Prandtl [42] in the following form:

$$\frac{u}{u_{\max}} = \left(\frac{y}{a}\right)^{1/n} \quad \frac{u}{u_{\max}} = \frac{2n^2}{(n+1)(2n+1)} \quad (5.65)$$

where $y = a - r$ represents the radial distance measured from the wall. The exponent n varies with the Reynolds number. The values of n are listed in Table 5.7; these were obtained from the measurements by Nikuradse [43].

Universal Velocity-Defect Law. Figure 5.7 shows the velocity profile computed from Eq. 5.65 together with Nikuradse's [43] measurement data. It can be observed that the velocity profile becomes flatter over most of the duct section, and the exponent $1/n$ of the power law of the velocity distribution, Eq. 5.65, decreases as Re increases. This observation led to the derivation of another form for velocity distribution, the universal velocity-defect law. The for-

FIGURE 5.7 Power law distribution for fully developed turbulent flow in a smooth circular duct [45].

mula, which follows, was discovered by Prandtl [44] and can be used in high Reynolds number flow, applicable in the turbulent core:

$$\frac{u_{\max} - u}{u_t} = 2.5 \ln \frac{a}{y} \quad (5.66)$$

where

$$u_t = \sqrt{\frac{\tau_w}{\rho}} = u_m \sqrt{\frac{f}{2}} \quad (5.67)$$

denotes friction velocity.

Von Kármán [46] derived the following form for the universal velocity-defect law:

$$\frac{u_{\max} - u}{u_t} = -2.5 \left[\ln \left(1 - \sqrt{1 - \frac{y}{a}} \right) + \sqrt{1 - \frac{y}{a}} \right] \quad (5.68)$$

Wang [47] proposed a third form for the universal velocity-defect law. It follows:

$$\begin{aligned} \frac{u_{\max} - u}{u_t} = 2.5 \left[\ln \frac{1 + \sqrt{1 - y/a}}{1 - \sqrt{1 - y/a}} - 2 \tan^{-1} \sqrt{1 - \frac{y}{a}} - 0.572 \ln \frac{2.53 - y/a + 1.75\sqrt{1 - y/a}}{2.53 - y/a - 1.75\sqrt{1 - y/a}} \right] \\ + 1.43 \tan^{-1} \frac{1.75\sqrt{1 - y/a}}{0.53 + y/a} \end{aligned} \quad (5.69)$$

Darcy's [48] experimental measurements led to the following formula for the velocity-defect law:

$$\frac{u_{\max} - u}{u_t} = 5.08 \left(1 - \frac{y}{a} \right)^{3/2} \quad (5.70)$$

Figure 5.8 displays the velocity distributions in terms of the velocity defect obtained from Eqs. 5.66, 5.68, 5.69, and 5.70. When compared to the experimental data presented by Nikuradse [43], it can be observed that the Eq. 5.69 is in overall best accord with the data; however, it is too complicated to be used. Equation 5.70 agrees well with the data except near the wall, $y/a < 0.25$.

Friction Factor. From the power law velocity distribution of Eq. 5.65, the friction factor can be expressed as:

$$f = \frac{C}{\text{Re}^{1/m}} \quad (5.71)$$

where C is an experimentally determined constant and m is related to the n in Eq. 5.66 as follows:

$$m = \frac{n + 1}{2} \quad (5.72)$$

The constants n , m , and C have been determined based on Nikuradse's [43] measurements, as is shown in Table 5.7.

Several friction factor correlations for fully developed turbulent flow in smooth, circular ducts are listed in Table 5.8. According to Bhatti and Shah [45], these formulas were derived from highly accurate experimental data for a certain Reynolds number range.

The Prandtl-Kármán-Nikuradse (PKN) correlation is based on the universal velocity-defect law with the coefficients slightly modified to fit the highly accurate experimental data reported by Nikuradse [43], which is known to be the most accurate. This correlation is also referred to as the universal law of friction. However, since the PKN formula gives f values

FIGURE 5.8 Universal velocity-defect law distribution for fully developed turbulent flow in a smooth circular duct [45].

implicitly, the explicit formulas by Colebrook [54] and Techo et al. [56], which are close approximations to the PKN formula, may be used.

Velocity Distribution and the Friction Factor for Rough Circular Ducts. Fully developed velocity distribution in a completely rough circular duct has been expressed by Schlichting [57] as follows:

$$u^+ = 2.5 \ln \frac{y^+}{Re_\epsilon} + 8.5 \quad (5.73)$$

where

$$u^+ = \frac{u}{u_t} = \frac{u}{\sqrt{\tau_w/\rho}}; \quad y^+ = \frac{yu_t}{\nu} = \frac{y\sqrt{\tau_w/\rho}}{\nu} \quad (5.74)$$

and Re_ϵ is the roughness Reynolds number, defined as $Re_\epsilon = \epsilon u_t/\nu$. The term ϵ denotes the surface-roughness element height. The value $Re_\epsilon < 5$ corresponds to the hydraulically smooth regime; $5 \leq Re_\epsilon \leq 70$ corresponds to the transition from the hydraulically smooth to the completely rough regime; and $Re_\epsilon > 70$ corresponds to the completely rough regime. Furthermore, $y^+ < 5$ corresponds to the laminar sublayer region, whereas $y^+ > 70$ is the fully turbulent region and $5 < y^+ < 70$ is the transition region.

The friction factor correlations for fully developed turbulent flow in a rough circular duct are summarized in Table 5.9. The friction factor for turbulent flow in an artificially roughened circular duct can be found in Rao [59].

Moody's [58] plot, shown in Fig. 5.9, gives the friction factor for laminar and turbulent flow in both smooth and rough circular ducts. Relative roughness ϵ/D_h is used as a parameter for

TABLE 5.8 Fully Developed Turbulent Flow Friction Factor in Smooth, Circular Ducts [45]

Investigators	Correlation	Recommended Re range	Remarks
Blasius [49]	$f = 0.0791 \text{ Re}^{-0.25}$	4×10^3 to 10^5	Within +2.6 and -1.3% of PKN (see the following)
McAdams [50]	$f = 0.46 \text{ Re}^{-0.2}$ $f = 0.036 \text{ Re}^{-0.1818}$	3×10^4 to 10^6 4×10^4 to 10^7	Within +2.6 and -0.4% of PKN
Bhatti and Shah [45]	$f = 0.0366 \text{ Re}^{-0.1818}$	4×10^4 to 10^7	Within +2.4 and -3% of PKN
Nikuradse [43]	$f = 0.0008 + 0.0553 \text{ Re}^{-0.237}$	10^5 to 10^7	Within -2% of PKN
Drew et al. [51]	$f = 0.00128 + 0.1143 \text{ Re}^{-0.311}$ $f = 0.0014 + 0.125 \text{ Re}^{-0.32}$	4×10^3 to 5×10^6 4×10^3 to 10^7	Within +3% of PKN
Bhatti and Shah [45]	$f = 0.00128 + 0.1143 \text{ Re}^{-0.311}$	4×10^3 to 10^7	Within +1.2 and -2% of PKN
Prandtl [52]	$\frac{1}{\sqrt{f}} = 1.7272 \ln(\text{Re} \sqrt{f}) - 0.3946$	4×10^3 to 10^7	Classical correlation, here called PKN, has a theoretical basis and is valid for arbitrarily large Re. Its predictions agree with extensive experimental measurements within $\pm 2\%$.
von Kármán [53]			
Nikuradse [43]			
Colebrook [54]	$\frac{1}{\sqrt{f}} = 1.5635 \ln\left(\frac{\text{Re}}{7}\right)$	4×10^3 to 10^7	Mathematical approximation to PKN, yielding numerical values within $\pm 1\%$ of PKN.
Filonenko [55]	$\frac{1}{\sqrt{f}} = 1.58 \ln \text{Re} - 3.28$	10^4 to 10^7	Within $\pm 1.8\%$ of PKN
Techo et al. [56]	$\frac{1}{\sqrt{f}} = 1.7372 \ln \frac{\text{Re}}{1.964 \ln \text{Re} - 3.8215}$	10^4 to 10^7	Explicit form of PKN;

turbulent curves. The broken line demarcating fully turbulent flow and transition flow, obtained by Moody [58], is as follows:

$$\sqrt{f} = \frac{100}{\text{Re}(\epsilon/D_h)} \quad (5.75)$$

It should be noted that the horizontal portions of the curves to the right of the broken line are represented by Nikuradse's [60] correlation, which is presented in Table 5.9. The downward-sloping line for the smooth turbulent flow is represented by the PKN correlation shown in Table 5.8. The downward-sloping line for laminar flow is represented by Eq. 5.17. Relative roughness ϵ can be obtained from Table 5.10 for a variety of commercial pipes.

Heat Transfer in Smooth Circular Ducts. For gases and liquids ($\text{Pr} > 0.5$), very little difference exists between the Nusselt number for uniform wall temperature and the Nusselt number for uniform wall heat flux in smooth circular ducts. However, for $\text{Pr} < 0.1$, there is a difference between Nu_T and Nu_H . Table 5.11 presents the fully developed turbulent flow Nusselt number in a smooth circular duct for $\text{Pr} > 0.5$. The correlation proposed by Gnielinski [69] is recommended for $\text{Pr} > 0.5$, as are those suggested by Bhatti and Shah [45]. In this table, the f in the equation is calculated using the Prandtl [52]-von Kármán [53]-Nikuradse [43]; Colebrook [54]; Filonenko [55]; or Techo et al. [56] correlations shown in Table 5.8.

FIGURE 5.9 Moody's [58] friction factor diagram for fully developed flow in a rough circular duct [45].

For liquid metal ($Pr < 0.1$), the most accurate correlations for Nu_T and Nu_H are those put forth by Notter and Sleicher [80]:

$$Nu_T = 4.8 + 0.0156Re^{0.85} Pr^{0.93} \quad (5.76)$$

$$Nu_H = 6.3 + 0.0167Re^{0.85} Pr^{0.93} \quad (5.77)$$

These equations are valid for $0.004 < Pr < 0.1$ and $10^4 < Re < 10^6$.

Heat Transfer in Rough Circular Ducts. The Nusselt number for a complete, rough flow regime in a circular duct is given in Table 5.12. The term f in this table denotes the friction factor for fully rough flow. It is given by the Nikuradse [60] correlation shown in Table 5.9. The recommended equations for practical calculations are those correlations by Bhatti and Shah [45] shown in Table 5.12.

Artificially roughed circular ducts are also often used to enhance heat transfer. The Nusselt numbers for artificially roughed ducts have been reviewed by Rao [59].

Hydrodynamically Developing Flow. An analytical, close-form solution for hydrodynamically developing flow in rough circular ducts has been obtained by Zhiqing [87]. The velocity distribution in the hydrodynamic entrance region is given as

$$\frac{u}{u_{\max}} = \begin{cases} (y/\delta)^{1/7} & \text{for } 0 \leq y \leq \delta \\ 1 & \text{for } \delta \leq y \leq a \end{cases} \quad (5.78)$$

$$\frac{u}{u_{\max}} = 1 - \frac{1}{4} \left(\frac{\delta}{a} \right) + \frac{1}{15} \left(\frac{\delta}{a} \right)^2 \quad (5.79)$$

where δ is the hydrodynamic boundary layer thickness, which varies with axial coordinate x in accordance with the following relation:

TABLE 5.9 Fully Developed Turbulent Flow Friction Factor Correlations for a Rough Circular Duct [48]
(a = tube radius)

Investigators	Correlations	Remarks
von Kármán [46]	$\frac{1}{\sqrt{f}} = 3.36 - 1.763 \ln \frac{\epsilon}{a}$	This explicit theoretical formula is applicable for $Re_\epsilon > 70$.
Nikuradse [60]	$\frac{1}{\sqrt{f}} = 3.48 - 1.737 \ln \frac{\epsilon}{a}$	This experimentally derived formula renders very nearly the same results as the von Kármán [46] formula.
Colebrook [54]	$\frac{1}{\sqrt{f}} = 3.48 - 1.7372 \ln \left(\frac{\epsilon}{a} + \frac{9.35}{Re\sqrt{f}} \right)$	This implicit formula is applicable for $5 \leq Re_\epsilon \leq 70$, spanning the transition, hydraulically smooth, and completely rough flow regimes.
Moody [58]	$f = 1.375 \times 10^{-3} \left[1 + 21.544 \left(\frac{\epsilon}{a} + \frac{100}{Re} \right)^{1/3} \right]$	Shows a maximum deviation of -15.78% from the Colebrook-White equation for $4000 \leq Re \leq 10^8$ and $2 \times 10^{-8} \leq \epsilon/a \leq 0.1$.
Wood [61]	$f = 0.08 \left(\frac{\epsilon}{a} \right)^{0.225} + 0.265 \left(\frac{\epsilon}{a} \right) + 66.69 \left(\frac{\epsilon}{a} \right)^{0.4} Re^{-n}$ where $n = 1.778 \left(\frac{\epsilon}{a} \right)^{0.134}$	Applicable only for $\epsilon/a \geq 2 \times 10^{-5}$; shows a maximum deviation of 6.16% from the Colebrook-White equation for $4000 \leq Re \leq 10^8$ and $2 \times 10^{-8} \leq \epsilon/a \leq 0.1$.
Swamee and Jain [62]	$\frac{1}{\sqrt{f}} = 3.4769 - 1.7372 \ln \left[\frac{\epsilon}{a} + \frac{42.48}{Re^{0.9}} \right]$	Shows a maximum deviation of 3.19% from the Colebrook-White equation for $4000 \leq Re \leq 10^8$ and $2 \times 10^{-8} \leq \epsilon/a \leq 0.1$.
Churchill [63]	$f = 2 \left[\left(\frac{8}{Re} \right)^{12} + \frac{1}{(A_1 + B_1)^{3/2}} \right]^{1/12}$ where $A_1 = \left\{ 2.2088 + 2.457 \ln \left[\frac{\epsilon}{a} + \frac{42.683}{Re^{0.9}} \right] \right\}^{16}$ $B_1 = \left(\frac{37.530}{Re} \right)^{16}$	Unlike other equations in the table, this equation applies to all three flow regimes—laminar, transition, and turbulent. Its predictions for laminar flow are in agreement with $f = 16/Re$. The predictions for transition flow are subject to some uncertainty. However, the predictions for turbulent flow are comparable with those rendered by the preceding equation.
Chen [64]	$\frac{1}{\sqrt{f}} = 3.48 - 1.7372 \ln \left[\frac{\epsilon}{a} - \frac{16.2446}{Re} \ln A_2 \right]$ where $A_2 = \frac{(\epsilon/a)^{1.1098}}{6.0983} + \left(\frac{7.149}{Re} \right)^{0.8981}$	This explicit equation is consistently in good agreement with the Colebrook-White equation for $4000 \leq Re \leq 10^8$ and $2 \times 10^{-8} \leq \epsilon/a \leq 0.1$, the maximum deviation being -0.39% .
Round [65]	$\frac{1}{\sqrt{f}} = 4.2146 - 1.5635 \ln \left[\frac{\epsilon}{a} + \frac{96.2963}{Re} \right]$	Comparable with Moody's equation.
Zigrang and Sylvester [66]	$\frac{1}{\sqrt{f}} = 3.4769 - 1.7372 \ln \left[\frac{\epsilon}{a} - \frac{16.1332}{Re} \ln A_3 \right]$ where $A_3 = \frac{\epsilon/a}{7.4} - 2.1802 \ln \left[\frac{\epsilon}{a} - 16.1332 \ln A_3 \right]$	Shows a maximum deviation of $+0.96\%$ from the Colebrook-White equation for $4000 \leq Re \leq 10^8$ and $2 \times 10^{-8} \leq \epsilon/a \leq 0.1$.
Zigrang and Sylvester [66]	$\frac{1}{\sqrt{f}} = 3.4769 - 1.7372 \ln \left[\frac{\epsilon}{a} - 16.1332 \ln A_4 \right]$ where $A_4 = \frac{\epsilon/a}{7.4} - 2.1802 \ln \left[\frac{\epsilon/a}{7.4} + \frac{13}{Re} \right]$	Predictions not substantially different from those of the preceding equation.

TABLE 5.9 Fully Developed Turbulent Flow Friction Factor Correlations for a Rough Circular Duct [48] (*Continued*)

Investigators	Correlations	Remarks
Haaland [67]	$\frac{1}{\sqrt{f}} = 3.4735 - 1.5635 \ln \left[\left(\frac{\epsilon}{a} \right)^{1.11} + \frac{63.6350}{\text{Re}} \right]$	Shows a maximum deviation of +1.21% from the Colebrook-White equation for $4000 \leq \text{Re} \leq 10^8$ and $2 \times 10^{-8} \leq \epsilon/a \leq 0.1$.
Serghides [68]	$\frac{1}{\sqrt{f}} = A_5 - \frac{(A_5 - B_2)^2}{A_5 - 2B_2 + C_1}$ where $A_5 = -0.8686 \ln \left(\frac{\epsilon/a}{7.4} + \frac{12}{\text{Re}} \right)$ $B_2 = -0.86868 \ln \left(\frac{\epsilon/a}{7.4} \right) + \frac{2.5A_5}{\text{Re}}$ $C_1 = -0.8686 \ln \left(\frac{\epsilon/a}{7.4} + \frac{2.51B_2}{\text{Re}} \right)$	Shows a maximum deviation of +0.14% from the Colebrook-White equation for $4000 \leq \text{Re} \leq 10^8$ and $2 \times 10^{-8} \leq \epsilon/a \leq 0.1$.
Serghides [68]	$\frac{1}{\sqrt{f}} = 4.781 - \frac{(A_5 - 4.781)^2}{(4.781 - 2A_5 - B_2)}$	Shows a maximum deviation of -0.45% from the Colebrook-White equation for $4000 \leq \text{Re} \leq 10^8$ and $2 \times 10^{-8} \leq \epsilon/a \leq 0.1$.

$$\frac{x/D_h}{\text{Re}^{1/4}} = 1.4039 \left(\frac{\delta}{a} \right)^{5/4} \left[1 + 0.1577 \left(\frac{\delta}{a} \right) - 0.1793 \left(\frac{\delta}{a} \right)^2 - 0.0168 \left(\frac{\delta}{a} \right)^3 + 0.0064 \left(\frac{\delta}{a} \right)^4 \right] \quad (5.80)$$

The axial pressure drop Δp^* , the incremental pressure drop number $K(x)$, and the apparent Fanning friction factor f_{app} are given as follows [87]:

$$\Delta p^* = \left(\frac{u_{\text{max}}}{u_m} \right)^2 - 1 \quad (5.81)$$

$$K(x) = \Delta p^* - 0.316 \frac{x/D_h}{\text{Re}^{1/4}} \quad (5.82)$$

$$f_{\text{app}} \text{Re}^{1/4} = \frac{\Delta p^*}{4x/(D_h \text{Re}^{0.25})} \quad (5.83)$$

TABLE 5.10 Average Roughness of Commercial Pipes

Colburn [71]	$Nu = (f/2) Re Pr^{1/3}$ $Nu = 0.023 Re^{0.8} Pr^{1/3}$	$0.5 \leq Pr \leq 3$ and $10^4 \leq Re \leq 10^5$
von Kármán [72]	$Nu = \frac{(f/2) Re Pr}{1 + 5(f/2)^{1/2} \left[Pr - 1 + \ln \left(\frac{5 Pr + 1}{6} \right) \right]}$	$0.5 \leq Pr \leq 10$ and $10^4 \leq Re \leq 5 \times 10^6$
Prandtl [52]	$Nu = \frac{(f/2) Re Pr}{1 + 8.7(f/2)^{1/2}(Pr - 1)}$	$0.5 \leq Pr \leq 5$ and $10^4 \leq Re \leq 5 \times 10^6$
Drexel and McAdams [73]	$Nu = 0.021 Re^{0.8} Pr^{0.4}$	$Pr \leq 0.7$ and $10^4 \leq Re \leq 5 \times 10^6$
Friend and Metzner [74]	$Nu = \frac{(f/2) Re Pr}{1.2 + 11.8(f/2)^{1/2}(Pr - 1) Pr^{-1/3}}$	$50 < Pr < 600$ and $5 \times 10^4 \leq Re \leq 5 \times 10^6$
Petukhov, Kirillov, and Popov [75]	$Nu = \frac{(f/2) Re Pr}{C + 12.7(f/2)^{1/2}(Pr^{2/3} - 1)}$ where $C = 1.07 + 900/Re - [0.63/(1 + 10 Pr)]$	$0.5 < Pr < 10^6$ and $4000 \leq Re \leq 5 \times 10^6$
Hausen [76]	$Nu = 0.037(Re^{0.75} - 180) Pr^{0.42} [1 + (x/D)^{-2/3}]$	$0.7 \leq Pr \leq 3$ and $10^4 \leq Re \leq 10^5$
Webb [77]	$Nu = \frac{(f/2) Re Pr}{1.07 + 9(f/2)^{1/2}(Pr - 1) Pr^{1/4}}$	$0.5 \leq Pr \leq 100$ and $10^4 \leq Re \leq 5 \times 10^6$
Gnielinski [69]	$Nu = \frac{(f/2)(Re - 1000) Pr}{1 + 12.7(f/2)^{1/2}(Pr^{2/3} - 1)}$ $Nu = 0.0214(Re^{0.8} - 100) Pr^{0.4}$ $Nu = 0.012(Re^{0.87} - 280) Pr^{0.4}$	$0.5 \leq Pr \leq 2000$ and $2300 \leq Re \leq 5 \times 10^6$, $0.5 \leq Pr \leq 1.5$ and $10^4 \leq Re \leq 5 \times 10^6$ $1.5 \leq Pr \leq 500$ and $3 \times 10^3 \leq Re \leq 10^6$
Sieder and Tate [78]	$Nu = 0.027 Re^{4/5} Pr^{1/3} \left(\frac{\mu}{\mu_w} \right)^{0.14}$	$0.7 < Pr < 16,700$ and $Re > 10^4$
Sandall et al. [79]	$Nu = \frac{\sqrt{f/2} Re Pr}{12.48 Pr^{2/3} - 7.853 Pr^{1/3} + 3.613 \ln Pr + 5.8 + C}$ where $C = 2.78 \ln(\sqrt{f/2} Re/45)$	$0.5 \leq Pr < 2000$ and $10^4 \leq Re \leq 5 \times 10^6$

The hydrodynamic entrance length L_{hy}/D_h can be calculated by the following equation [87]:

$$\frac{L_{hy}}{D_h} = 1.3590 Re^{1/4} \tag{5.84}$$

The results from Eq. 5.84 agree fairly well with experimental data [88].

Thermally Developing Flow. Numerous investigators [80, 89–94] have carried out the investigation of turbulent thermally developing flow in a smooth circular duct with uniform wall temperature and uniform wall heat flux boundary conditions. It has been found that the dimensionless temperature and the Nusselt number for thermally developing turbulent flow have the same formats as those for laminar thermally developing flow (i.e., Eqs. 5.34–5.37 and Eqs. 5.50–5.53). The only differences are the eigenvalues and constants in the equations.

TABLE 5.12 Nusselt Numbers for Fully Developed Turbulent Flow in the Fully Rough Flow Regime of a Circular Duct [45]

Investigators	Correlations	Remarks
Martinelli [81]	$\text{Nu} = \frac{\text{Re Pr} \sqrt{f/2}}{5[\text{Pr} + \ln(1 + 5 \text{Pr}) + 0.5 \ln(\text{Re} \sqrt{f/2}/60)]}$	This equation differs from that derived by Martinelli [81] for a smooth duct by the omission of the temperature ratio $(T_w - T_c)/(T_w - T_m)$.
Nunner [82]	$\text{Nu} = \frac{\text{Re Pr} (f/2)}{1 + 1.5 \text{Re}^{-1/8} \text{Pr}^{-1/6} [\text{Pr} (f/f_s) - 1]}$	This correlation is valid for $\text{Pr} \approx 0.7$; it does not give satisfactory results for $\text{Pr} > 1$.
Dipprey and Sabersky [83]	$\text{Nu} = \frac{\text{Re Pr} (f/2)}{1 + \sqrt{f/2}[5.19 \text{Re}_e^{0.2} \text{Pr}^{0.44} - 8.48]}$	This correlation is valid for $0.0024 \leq \varepsilon/D_h \leq 0.049$, $1.2 \leq \text{Pr} \leq 5.94$, and $1.4 \times 10^4 \leq \text{Re} \leq 5 \times 10^5$.
Gowen and Smith [84]	$\text{Nu} = \frac{\text{Re Pr} \sqrt{f/2}}{4.5 + [0.155(\text{Re} \sqrt{f/2})^{0.54} + \sqrt{2/f}]\sqrt{\text{Pr}}}$	This correlation is valid for $0.0021 \leq \varepsilon/D_h \leq 0.095$, $0.7 \leq \text{Pr} \leq 14.3$, and $10^4 \leq \text{Re} \leq 5 \times 10^4$.
Kawase and Ulbrecht [85]	$\text{Nu} = 0.0523 \text{Re} \sqrt{\text{Pr}} \sqrt{f}$	The predictions of this correlation are somewhat lower than those of the following correlation.
Kawase and De [86]	$\text{Nu} = 0.0471 \text{Re} \sqrt{\text{Pr}} \sqrt{f} (1.11 + 0.44 \text{Pr}^{-1/3} - 0.7 \text{Pr}^{-1/6})$	The predictions of this correlation are in reasonable agreement with the experimental data for $0.0024 \leq \varepsilon/D_h \leq 0.165$, $5.1 < \text{Pr} < 390$, and $5000 < \text{Re} < 5 \times 10^5$.
Bhatti and Shah [45]	$\text{Nu} = \frac{(\text{Re Pr} (f/2))}{1 + \sqrt{f/2}(4.5 \text{Re}_e^{0.2} \text{Pr}^{0.5} - 8.48)}$	This correlation is valid for $0.5 < \text{Pr} < 10$, $0.002 < 0.002 < \varepsilon/D_h < 0.05$, and $\text{Re} > 10^4$. Its predictions are within $\pm 5\%$ of the available measurements.
Bhatti and Shah [45]	$\text{Nu} = \frac{(\text{Re} - 1000) \text{Pr} (f/2)}{1 + \sqrt{f/2}[(17.42 - 13.77 \text{Pr}_t^{0.8}) \text{Re}_e^{0.5} - 8.48]}$	This correlation is valid for $0.5 < \text{Pr} < 5000$, $0.001 < 0.002 < \varepsilon/D_h < 0.05$, and $\text{Re} > 2300$. Its predictions are within $\pm 15\%$ of the available measurements.

Bhatti and Shah [45] listed these eigenvalues and constants. On the other hand, the local Nusselt numbers for uniform wall temperature and uniform wall heat flux $\text{Nu}_{x,T}$ and $\text{Nu}_{x,H}$ in turbulent developing flow are nearly identical for $\text{Pr} > 0.2$. Therefore, the subscripts T or H are dropped in the equations in this section.

The mean Nusselt number Nu_m for thermally developing flow with uniform wall temperature or uniform wall heat flux conditions can be calculated using Al-Arabi's [95] correlation:

$$\frac{\text{Nu}_m}{\text{Nu}_\infty} = 1 + \frac{C}{x/D_h} \quad (5.85)$$

where Nu_∞ stands for the fully developed Nusselt number Nu_T or Nu_H and

$$C = \frac{(x/D_h)^{0.1}}{\text{Pr}^{1/6}} \left(0.68 + \frac{3000}{\text{Re}^{0.81}} \right) \quad (5.86)$$

However, the thermal entrance lengths for uniform wall temperature and uniform wall heat flux are much different. These are shown in Figs. 5.10 and 5.11, respectively.

FIGURE 5.10 Thermal entrance lengths for the turbulent Graetz problem for a smooth circular duct [80].

FIGURE 5.11 Thermal entrance lengths for the turbulent thermal entrance problem for a smooth circular duct with uniform wall heat flux [80].

For liquid metals ($Pr < 0.03$), when $x/D_h > 2$ and $Pe > 500$, the local and mean Nusselt numbers for the uniform wall temperature boundary condition have been proposed by Chen and Chiou [96] as follows:

$$\frac{Nu_{x,T}}{Nu_T} = 1 + \frac{2.4}{x/D_h} - \frac{1}{(x/D_h)^2} \quad (5.87)$$

$$\frac{Nu_{m,T}}{Nu_T} = 1 + \frac{7}{x/D_h} + \frac{2.8}{x/D_h} \ln \left(\frac{x/D_h}{10} \right) \quad (5.88)$$

$$Nu_T = 4.5 + 0.0156Re^{0.85} Pr^{0.86} \quad (5.89)$$

When the uniform heat flux condition is applied to the duct wall, Eqs. 5.87 and 5.88 are still used, but with $Nu_{x,H}$, $Nu_{m,H}$, and Nu_H replacing $Nu_{x,T}$, $Nu_{m,T}$, and Nu_T , respectively, while Nu_H can be obtained from:

$$Nu_H = 5.6 + 0.0165Re^{0.85} Pr^{0.86} \quad (5.90)$$

The thermal entrance length $L_{th,H}$ for liquid metals has been found by Genin et al. [97]:

$$\frac{L_{th,H}}{D_h} = \frac{0.04Pe}{1 + 0.002Pe} \quad (5.91)$$

Simultaneously Developing Flow. The local Nusselt numbers obtained theoretically by Deissler [92] for simultaneously developing velocity and temperature fields in a smooth circular duct subject to uniform wall temperature and the uniform heat flux for $Pr = 0.73$ are plotted in Fig. 5.12. It can be seen from this figure that the Nusselt numbers for two different thermal boundary conditions are identical for $x/D_h > 8$.

It is worth noting that the duct entrance configuration affects simultaneously developing flow [98, 99]. The local Nusselt number is different for each duct entrance configuration. For practice usage, Bhatti and Shah [45] suggest the following formula for the calculation of the mean Nusselt number:

$$\frac{Nu_m}{Nu_\infty} = 1 + \frac{C}{(x/D_h)^n} \quad (5.92)$$

where Nu_∞ denotes the fully developed Nusselt number Nu_H or Nu_T . The terms C and n have been determined from the $Nu_{m,H}$ measurement given by Mills [99] for air ($Pr = 0.7$). Table 5.13 lists the resulting C and n of Eq. 5.92 for each configuration. Equation 5.92 may be used in the case of the uniform wall temperature and uniform wall heat flux boundary conditions.

For liquid metals ($Pr < 0.03$), Chen and Chiou [95] have obtained the correlations for simultaneously developing flow in a smooth circular duct with a uniform velocity profile at the inlet. These follow:

$$\frac{Nu_x}{Nu_\infty} = 0.88 + \frac{2.4}{x/D_h} - \frac{1.25}{(x/D_h)^2} - A \quad (5.93)$$

$$\frac{Nu_x}{Nu_\infty} = 1 + \frac{5}{x/D_h} + \frac{1.86}{x/D_h} \ln \left(\frac{x/D_h}{10} \right) - B \quad (5.94)$$

where for the uniform wall temperature boundary condition,

$$A = \frac{40 - x/D_h}{190}, \quad B = 0.09 \quad (5.95)$$

FIGURE 5.12 Local Nusselt numbers $Nu_{x,T}$ and $Nu_{x,H}$ for simultaneously developing turbulent flow in a smooth circular duct for $Pr = 0.73$ [92].

and for the uniform wall heat flux boundary condition,

$$A = B = 0 \tag{5.96}$$

The Nu_x in Eqs. 5.93 and 5.94 denotes the local Nusselt number $Nu_{x,T}$ or $Nu_{x,H}$, and Nu_∞ represents the fully developed Nu_T or Nu_H . Equations 5.93 and 5.94 are valid for $2 \leq x/D_h < 35$ and $Pe > 500$.

Transition Flow

As seen in the previous section, flow is considered to be laminar when $Re < 2300$ and turbulent when $Re > 10^4$. Transition flow occurs in the range of $2300 < Re < 10^4$. Few correlations or formulas for computing the friction factor and heat transfer coefficient in transition flow are available. In this section, the formula developed by Bhatti and Shah [45] is presented to compute the friction factor. It follows:

$$f = A + \frac{B}{Re^{1/m}} \tag{5.97}$$

Equation 5.97 is applicable to the laminar, transition, and turbulent flow regions. For laminar flow ($Re < 2100$), $A = 0$, $B = 16$, and $m = 1$. For transition flow, $2100 < Re \leq 4000$, $A = 0.0054$, $B = 2.3 \times 10^{-8}$, and $m = -2/3$. For turbulent flow, ($Re > 4000$) $A = 1.28 \times 10^{-3}$, $B = 0.1143$, and $m = 3.2154$. Blasius's [49] formula (see Table 5.8) is also applicable for calculating the friction factor in the range of $4000 \leq Re \leq 10^5$.

TABLE 5.13 Nusselt Number Ratios for a Smooth Circular Duct with Various Entrance Configurations for $Pr = 0.7$ [2]

Entrance configurations	Schematics	C	n
Long calming section		0.9756	0.760
Square entrance		2.4254	0.676
180° Round bend		0.9759	0.700
90° Round bend		1.0517	0.629
90° Elbow		2.0152	0.614

Heat transfer results for transition flow are rather uncertain due to the fact that so many parameters are needed to characterize heat-affected flow. In the range of $0 < Pr < \infty$ and $2100 \leq Re \leq 10^6$, Churchill [100] recommends that the following equations be used to calculate the Nusselt number for the laminar, transition, and turbulent regimes:

$$Nu^{10} = Nu_l^{10} + \left\{ \frac{\exp[(2200 - Re)/365]}{Nu_l^2} + \frac{1}{Nu_t^2} \right\}^{-5} \quad (5.98)$$

$$Nu_t = \begin{cases} 3.657 & \text{for the uniform wall temperature boundary condition} \\ 4.364 & \text{for the uniform wall heat flux boundary condition} \end{cases} \quad (5.99)$$

$$Nu_t = Nu_0 + \frac{0.079(f/2)^{1/2} Re Pr}{(1 + Pr^{4/5})^{5/6}} \quad (5.100)$$

$$Nu_0 = \begin{cases} 4.8 & \text{for the uniform wall temperature boundary condition} \\ 6.3 & \text{for the uniform wall heat flux boundary condition} \end{cases} \quad (5.101)$$

where superscript 10 indicates transition region and Nu_0 denotes an overall Nusselt number associated with the convection boundary condition.

Kaupas et al. [101] experimentally investigated heat transfer in transition gas flow in a circular duct at high heat flux in the range of $2 \times 10^3 \leq Re \leq 3 \times 10^4$.

More research is needed to determine reliable friction factors and Nusselt numbers for transition flow.

CONCENTRIC ANNULAR DUCTS

Concentric annular ducts are a common and important geometry for fluid flow and heat transfer devices. The double pipe heat exchanger is a simple example. In this device, one fluid flows through an inside pipe, while the other flows through the concentric annular passages. The friction factor and the heat transfer coefficient are essential for the design of such heat transfer devices.

Four Fundamental Thermal Boundary Conditions

As shown in Fig. 5.13, there are two walls in concentric annular ducts. Either or both of them can be involved in heat transfer to a flowing fluid in the annulus. Four fundamental thermal boundary conditions, which follow, can be used to define any other desired boundary condition. Correspondingly, the solutions for these four fundamental boundary conditions can be adopted to obtain the solutions for other boundary conditions using superposition techniques.

The four fundamental thermal boundary conditions are as follows:

First kind. Uniform temperature (different from the entering fluid temperature) at one wall; the other wall at the uniform entering fluid temperature

Second kind. Uniform wall heat flux at one wall; the other wall insulated (i.e., adiabatic with zero heat flux)

Third kind. Uniform temperature (different from the entering fluid temperature) at one wall; the other wall insulated

Fourth kind. Uniform wall heat flux at one wall; the other wall maintained at the entering fluid temperature.

The previously mentioned boundary conditions can be applied in both laminar and turbulent flow.

FIGURE 5.13 Fully developed Nusselt numbers for uniform temperatures at both walls in concentric annular ducts [1].

Laminar Flow

In this section, the characteristics of laminar flow and heat transfer in concentric annular ducts are presented, and the effect of eccentricity is discussed.

Fully Developed Flow. Velocity distribution, the friction factor, and heat transfer for fully developed laminar flow in concentric annular ducts are described sequentially.

Velocity Distribution and the Friction Factor. For a concentric annular duct with inner radius r_i and outer radius r_o , the velocity distribution and friction factor for fully developed flow in a concentric annular duct are as follows [1]:

$$u = -\frac{1}{4\mu} \left(\frac{dp}{dx} \right) r_o^2 \left[1 - \left(\frac{r}{r_o} \right) + 2r_m^{*2} \ln \left(\frac{r}{r_o} \right) \right] \quad (5.102)$$

$$u_m = -\frac{1}{8\mu} \left(\frac{dp}{dx} \right) r_o^2 (1 + r^{*2} - 2r_m^{*2}) \quad (5.103)$$

$$\frac{u_{\max}}{u_m} = \frac{2(1 - r_m^{*2} + 2r_m^{*2} \ln r_m^*)}{1 + r^{*2} - 2r_m^{*2}} \quad (5.104)$$

$$f_i \text{Re} = -\frac{1}{\mu} \left(\frac{dp}{dx} \right) \frac{D_h}{u_m} \left(\frac{r_m^2 - r_i^2}{r_i} \right), \quad D_h = 2(r_o - r_i) \quad (5.105)$$

$$f_o \text{Re} = -\frac{1}{\mu} \left(\frac{dp}{dx} \right) \frac{D_h}{u_m} \left(\frac{r_o^2 - r_m^2}{r_o} \right) \quad (5.106)$$

$$f \text{Re} = \frac{16(1 - r^*)^2}{1 + r^{*2} - 2r_m^{*2}} \quad (5.107)$$

where r_m in the preceding equations is the radius where the maximum velocity achieves $[(\partial u/\partial r) = 0]$, and r_m^* is its dimensionless form, which is defined as

$$r_m^* = \frac{r_m}{r_o} = \left(\frac{1 - r^{*2}}{2 \ln(1/r^*)} \right)^{1/2} \quad (5.108)$$

The terms f_i and f_o represent the friction factor at the inner and the outer walls, respectively. The circumferentially averaged friction factor is related to f_i and f_o as follows:

$$f = \frac{f_i r_i + f_o r_o}{r_i + r_o} \quad (5.109)$$

Natarajan and Lakshmanan [102] present a simple equation for $f \text{Re}$ that is easy to use. This equation agrees with the values calculated from Eq. 5.107 within ± 2 percent for $r^* \geq 0.005$. It follows:

$$f \text{Re} = 24r^{*0.035} \quad (5.110)$$

Heat Transfer. Fundamental solutions for boundary conditions of the first, second, and third kinds for fully developed flow in concentric annular ducts are given in Table 5.14. The nomenclature used in describing the corresponding solutions can best be explained with reference to the specific heat transfer parameters $\theta_{ij}^{(k)}$ and $\theta_{mj}^{(k)}$, which are the dimensionless duct wall and fluid bulk mean temperature, respectively. The superscript k denotes the type of the fundamental solution according to the four types of boundary conditions described in the section entitled "Four Fundamental Thermal Boundary Conditions." Thus, $k = 1, 2, 3,$ or 4 . The subscript l in $\theta_{ij}^{(k)}$ refers to the particular wall at which the temperature is evaluated; $l = i$ or o when the temperature is evaluated at the inner or the outer wall. The subscript j in $\theta_{ij}^{(k)}$ refers

to the wall at which $T \neq T_e$ or $q_w'' \neq 0$ (i.e., the active wall that participates in the heat transfer with flowing fluid). The role of k and j in the $\theta_{mj}^{(k)}$ is the same as in $\theta_{ij}^{(k)}$, while m represents fluid bulk mean temperature.

The other heat transfer results related to the four fundamental solutions can be obtained using the following equations in conjunction with Table 5.14 [1]:

$$\Phi_{oo}^{(1)} = -\Phi_{oi}^{(1)} = r^* \Phi_{ii}^{(1)} = -r^* \Phi_{io}^{(1)} \quad (5.111)$$

$$\theta_{mi}^{(1)} = 1 - \theta_{mo}^{(1)} \quad (5.112)$$

$$\text{Nu}_{io}^{(1)} = \text{Nu}_{ii}^{(1)} = \frac{\Phi_{ii}^{(1)}}{1 - \theta_{mi}^{(1)}} = \frac{\Phi_{ii}^{(1)}}{\theta_{mo}^{(1)}} \quad (5.113)$$

$$\text{Nu}_{io}^{(1)} = \text{Nu}_{oo}^{(1)} = \frac{\Phi_{ii}^{(1)}}{1 - \theta_{mo}^{(1)}} = \frac{r^* \Phi_{ii}^{(1)}}{\theta_{mi}^{(1)}} \quad (5.114)$$

$$\theta_{oi}^{(2)} - \theta_{mi}^{(2)} = r^* [\theta_{io}^{(2)} - \theta_{mo}^{(2)}] \quad (5.115)$$

$$\text{Nu}_{ii}^{(2)} = \frac{1}{\theta_{ii}^{(2)} - \theta_{mi}^{(2)}} \quad (5.116)$$

$$\text{Nu}_{oo}^{(2)} = \frac{1}{\theta_{oo}^{(2)} - \theta_{mo}^{(2)}} \quad (5.117)$$

$$\text{Nu}_{oi}^{(2)} = \text{Nu}_{io}^{(2)} = 0 \quad (5.118)$$

$$\Phi_{ii}^{(3)} = \Phi_{oo}^{(3)} = 0 \quad (5.119)$$

$$\theta_{oi}^{(3)} = \theta_{io}^{(3)} = \theta_{mi}^{(3)} = \theta_{mo}^{(3)} = 1 \quad (5.120)$$

$$\Phi_{oi}^{(4)} = \frac{1}{\Phi_{io}^{(4)}} = -r^* \quad (5.121)$$

$$\theta_{ii}^{(4)} = r^* \theta_{oo}^{(4)} = \frac{1}{\text{Nu}_{ii}^{(1)}} + \frac{r^*}{\text{Nu}_{oo}^{(1)}} \quad (5.122)$$

$$\text{Nu}_{oo}^{(4)} = \text{Nu}_{io}^{(4)} = \frac{1}{\theta_{ii}^{(4)} - \theta_{mi}^{(4)}} = \frac{1}{r^* \theta_{mo}^{(4)}} \quad (5.123)$$

$$\text{Nu}_{oo}^{(4)} = \text{Nu}_{oi}^{(4)} = \frac{1}{\theta_{oo}^{(4)} - \theta_{mo}^{(4)}} = \frac{r^*}{\theta_{mi}^{(4)}} = \text{Nu}_{oo}^{(1)} \quad (5.124)$$

The direct use of these four fundamental solutions is rare in engineering applications. The solutions for practical problems must be developed. The following examples should be of great interest with respect to the application of these fundamental solutions.

Uniform Temperature at Both Walls. When $T_i \neq T_o$, the problem is designated as 1a, and the fully developed Nusselt numbers at the two walls are designated as $\text{Nu}_i^{(1a)}$ and $\text{Nu}_o^{(1a)}$. When $T_i = T_o$, the problem is designated as 1b, and the fully developed Nusselt numbers at the two walls are designated as $\text{Nu}_i^{(1b)}$ and $\text{Nu}_o^{(1b)}$. These are presented in Fig. 5.13. Tabulated values for these and the subsequent solutions are available in Shah and London [1].

A circumferentially averaged Nusselt number in the case of $T_i = T_o$, designated as Nu_T , can be obtained from $\text{Nu}_i^{(1b)}$ and $\text{Nu}_o^{(1b)}$ by means of the following relation [1]:

$$\text{Nu}_T = \frac{\text{Nu}_o^{(1b)} + r^* \text{Nu}_i^{(1b)}}{1 + r^*} \quad (5.125)$$

FIGURE 5.14 Fully developed friction factor and Nusselt numbers for concentric annular ducts [2].

The Nu_T values for Eq. 5.125 are presented in Fig. 5.14, in which Nu_H , described later, and $f Re$, calculated from Eq. 5.107, are also displayed.

Uniform Heat Fluxes at Both Walls. When $q_i'' = q_o''$ the problem is designated as 2a, and the fully developed Nusselt numbers at the two walls are designated as $Nu_i^{(2a)}$ and $Nu_o^{(2a)}$. When $q_i'' \neq q_o''$ the problem is designated as 2b and the fully developed Nusselt numbers at the two walls are denoted $Nu_i^{(2b)}$ and $Nu_o^{(2b)}$. These Nusselt numbers are shown in Fig. 5.15. In the case of $q_i'' = q_o''$ the circumferentially averaged Nusselt number Nu_H can be obtained from $Nu_i^{(2b)}$ and $Nu_o^{(2b)}$ via Eq. 5.125 by replacing subscript T with H and superscript 1 with 2. The Nu_H obtained in this way is shown in Fig. 5.14.

It should be noted that the heat flux is positive if the heat transfer occurs from the wall to the fluid. Therefore, a negative Nusselt number like those shown in Fig. 5.15 signifies that heat transfer has taken place in the opposite direction (i.e., from the fluid to the wall). In both aforementioned cases, $T_w - T_m$ is considered positive. Therefore, the infinite Nusselt numbers in Figs. 5.13 and 5.15 indicate that $T_w = T_m$, not infinite heat flux.

Uniform Temperature at One Wall and Uniform Heat Flux at the Other. The subscripts 1 and 2 refer to either the inside or the outside wall. When $T_1 \neq T_2$, the problem is known as 4a, and when $T_1 = T_2$ it is known as 4b. It has been shown by Shah and London [1] that

$$Nu_i^{(4a)} = Nu_i^{(4b)} = Nu_i^{(1a)} \tag{5.126}$$

$$Nu_o^{(4a)} = Nu_o^{(4b)} = Nu_o^{(1a)} \tag{5.127}$$

Hydrodynamically Developing Flow. Shah and London [1] summarize the solutions for the hydrodynamic development of laminar flow in concentric annuli. The apparent friction factor in the hydrodynamic entrance region, derived by Shah [103], is expressed as:

$$f_{app} Re = 3.44(x^+)^{-0.05} + \frac{K(\infty)/(4x^+) + f Re - 3.44(x^+)^{-0.5}}{1 + C(x^+)^{-2}} \tag{5.128}$$

The values of $K(\infty)$, $f Re$, and C in Eq. 5.128 are given in Table 5.15. A very good agreement, within ± 3 percent, with the various analytical predictions has been achieved using Eq. 5.128.

FIGURE 5.15 Fully developed Nusselt numbers for uniform axial heat fluxes at both walls in concentric annular ducts [1].

In addition, the hydrodynamic entrance length L_{hy}^+ , recommended by Shah and London [1], is given in Table 5.15.

Thermally Developing Flow. The solutions for thermally developing flow in concentric annular ducts under each of the four fundamental thermal boundary conditions are tabulated in Tables 5.16, 5.17, 5.18, and 5.19. These results have been taken from Shah and London [1]. Additional quantities can be determined from the correlations listed at the bottom of each table using the data presented.

The thermal entrance lengths for thermally developing flow with these four fundamental thermal boundary conditions are given in Table 5.20.

Using the four fundamental solutions presented in Tables 5.16–5.19, thermally developing flow with thermal boundary conditions different from the fundamental conditions presented in the section entitled “Four Fundamental Thermal Boundary Conditions” can be obtained by the superposition method. Three examples are detailed in the following sections.

Uniform Temperatures at Both Walls. As mentioned in the section “Fully Developed Flow,” when $T_i \neq T_o$, the problem is designated as 1a, and its solution is expressed in terms of the following equations [1]:

$$T_{x,m}^{(1a)} = T_e + (T_i - T_e)\theta_{x,mi}^{(1)} + (T_o - T_e)\theta_{x,mo}^{(1)} \quad (5.129)$$

$$q_{x,i}^{(1a)} = \frac{k}{D_h} [(T_i - T_e)\Phi_{x,ii}^{(1)} + (T_o - T_e)\Phi_{x,io}^{(1)}] \quad (5.130)$$

$$q_{x,o}^{(1a)} = \frac{k}{D_h} [(T_i - T_e)\Phi_{x,oi}^{(1)} + (T_o - T_e)\Phi_{x,oo}^{(1)}] \quad (5.131)$$

$$Nu_{x,i}^{1a} = \frac{(T_i - T_e)\Phi_{x,ii}^{(1)} + (T_o - T_e)\Phi_{x,io}^{(1)}}{(T_o - T_e)(1 - \theta_{x,mo}^{(1)}) - (T_i - T_e)\theta_{x,mi}^{(1)}} \quad (5.132)$$

$$Nu_{x,o}^{1a} = \frac{(T_o - T_e)\Phi_{x,oo}^{(1)} + (T_i - T_e)\Phi_{x,oi}^{(1)}}{(T_o - T_e)(1 - \theta_{x,mo}^{(1)}) - (T_i - T_e)\theta_{x,mi}^{(1)}} \quad (5.133)$$

		$\theta_{x,mi}^{(2)} = \left(\frac{4r^*}{1+r^*} \right) x^*$		$\Phi_{x,ii}^{(2)} = 1$	$\Phi_{x,oi}^{(2)} = 0$		
		$\theta_{x,mo}^{(2)} = \left(\frac{4r^*}{1+r^*} \right) x^*$		$\Phi_{x,oo}^{(2)} = 1$	$\Phi_{x,oi}^{(2)} = 0$		

When $T_i = T_o$, the problem is designated as 1*b*. The solutions for this problem can be obtained from Eqs. 5.129 through 5.133 with $T_o = T_i$. The circumferentially averaged Nusselt number for this problem can be determined with the following expression:

$$Nu_{x,T} = \frac{Nu_{x,o}^{(1b)} + r^* Nu_{x,i}^{(1b)}}{1 + r^*} \quad (5.134)$$

Uniform Heat Fluxes at Both Walls. As is mentioned in the section “Fully Developed Flow,” when $q_i'' \neq q_o''$, the problem is designated as 2*a*. The solution to this problem is expressed in terms of the following equations [1]:

$$T_{x,i}^{(2a)} = T_e + \frac{D_h}{k} [q_i'' \theta_{x,ii}^{(2)} + q_o'' \theta_{x,io}^{(2)}] \quad (5.135)$$

$$T_{x,o}^{(2a)} = T_e + \frac{D_h}{k} [q_i'' \theta_{x,oi}^{(2)} + q_o'' \theta_{x,oo}^{(2)}] \quad (5.136)$$

$$T_{x,m}^{(2a)} = T_e + \frac{D_h}{k} [q_i'' \theta_{x,mi}^{(2)} + q_o'' \theta_{x,mo}^{(2)}] \quad (5.137)$$

$$Nu_{x,i}^{(2a)} = \frac{q_i''}{q_i'' [\theta_{x,oo}^{(2)} - \theta_{x,mi}^{(2)}] - q_o'' [\theta_{x,mo}^{(2)} - \theta_{x,io}^{(2)}]} \quad (5.138)$$

Uniform Temperature at One Wall and Uniform Heat Flux at the Other. In this case, the subscripts 1 and 2 refer to either the inside or the outside wall. The thermal entrance length solution to this problem is expressible in terms of the following equations [1]:

$$T_{x,2} = T_e + (T_1 - T_e)\theta_{x,21}^{(3)} + \frac{D_h}{k} q_2'' \theta_{x,22}^{(4)} \quad (5.140)$$

$$T_{x,m} = T_e + (T_1 - T_e)\theta_{x,m1}^{(3)} + \frac{D_h}{k} q_2'' \theta_{x,m2}^{(4)} \quad (5.141)$$

$$q_{w,1}'' = \frac{k}{D_h} (T_1 - T_e)\Phi_{x,11}^{(3)} + q_2'' \Phi_{x,12}^{(4)} \quad (5.142)$$

$$\text{Nu}_{x,1} = \frac{(T_1 - T_e)\theta_{x,11}^{(3)}(q_2'' D_h/k)\Phi_{x,12}^{(4)}}{(T_1 - T_e)(1 - \theta_{x,m1}^{(3)})(q_2'' D_h/k)\theta_{x,m2}^{(4)}} \quad (5.143)$$

$$\text{Nu}_{x,2} = \frac{1}{(\theta_{x,22}^{(4)} - \theta_{x,m2}^{(4)}) + [(T_1 - T_e)k/q_2'' D_h](\theta_{x,21}^{(3)}\theta_{x,m1}^{(3)})} \quad (5.144)$$

In Eqs. 5.129 through 5.144, the coefficients θ and Φ in various combinations of subscripts and superscripts can be found in Tables 5.16 through 5.19.

Simultaneously Developing Flow. For the four fundamental thermal boundary conditions, the solutions to simultaneously developing velocity and temperature fields in concentric annuli with $r^* = 0.1, 0.25, 0.50,$ and 1.0 and $\text{Pr} = 0.01, 0.7,$ and 10 have been obtained by Kakaç and Yücel [104]. Presented in Tables 5.21 to 5.23 are the results for $\text{Pr} = 0.7$. The results for $\text{Pr} = 0.01$ and $\text{Pr} = 10$ have also been tabulated in Kakaç and Yücel [104].

Unlike thermally developing flow, the superposition method cannot be applied directly to the simultaneously developing flow because of the dependence of the velocity profile on the axial locations. However, certain influence coefficients are introduced to determine the local Nusselt number for simultaneous developing flow in concentric annuli with thermal boundary conditions that are different from the four fundamental conditions; the influence coefficients θ_1^* through θ_{12}^* , determined by Kakaç and Yücel [104] are listed in Tables 5.24 and 5.25.

Several examples of the application of the influence coefficients and fundamental solutions are detailed in the following paragraphs.

The fundamental solution of the first kind, presented in Table 5.21, is only valid if one of the duct walls is at the same temperature as the entering fluid. When the duct walls are maintained at uniform and equal or unequal temperatures T_i and T_o , the local Nusselt numbers $\text{Nu}_{x,i}$ and $\text{Nu}_{x,o}$ at the two walls can be determined from the following [1]:

$$\frac{\text{Nu}_{x,i}}{\text{Nu}_{x,ii}^{(1)}} = \frac{1 - [(T_o - T_e)/(T_i - T_e)]\theta_1^*}{1 - [(T_o - T_e)/(T_i - T_e)]\theta_2^*} \quad (5.145)$$

$$\frac{Nu_{x,o}}{Nu_{x,oo}^{(1)}} = \frac{1 - [(T_i - T_e)/(T_o - T_e)]\theta_3^*}{1 - [(T_i - T_e)/(T_o - T_e)]\theta_4^*} \quad (5.146)$$

where $Nu_{x,ii}^{(1)}$ and $Nu_{x,oo}^{(1)}$ are available in Table 5.21 and θ_1^* , θ_2^* , θ_3^* , and θ_4^* are listed in Table 5.24.

The fundamental solution of the second kind presented in Table 5.22 is valid in the case of one duct wall's being adiabatic, that is, either $q_i'' = 0$ or $q_o'' = 0$. However, for both duct walls subjected to uniform and equal or unequal wall fluxes q_i'' and q_o'' , the local Nusselt numbers $Nu_{x,i}$ and $Nu_{x,o}$ at the two walls can be determined from the following expression [1]:

$$\frac{Nu_{x,i}}{Nu_{x,ii}^{(2)}} = \frac{1}{1 - (q_o''/q_i'')\theta_5^*} \quad (5.147)$$

$$\frac{Nu_{x,o}}{Nu_{x,oo}^{(2)}} = \frac{1}{1 - (q_i''/q_o'')\theta_6^*} \quad (5.148)$$

where $Nu_{x,ii}^{(2)}$ and $Nu_{x,oo}^{(2)}$ are taken from Table 5.22 and θ_1^* , θ_2^* , θ_3^* , and θ_4^* are listed in Table 5.24.

The third example is for the case of uniform heat flux at the outer wall and uniform temperature on the inner wall, that is, $q_w'' = q_o''$ at $r = r_o$ and $T_w = T_i$ at $r = r_i$. The local Nusselt numbers at the two walls are determined from the fundamental solutions of the third and fourth kinds from Tables 5.22 and 5.23 and the influence coefficients from Table 5.25, which are given as

$$\frac{Nu_{x,i}}{Nu_{x,ii}^{(3)}} = \frac{1 - [(q_o'' D_h/k)/(T_i - T_e)]\theta_7^*}{1 - [(T_i - T_e)/(T_o - T_e)]\theta_8^*} \quad (5.149)$$

$$\frac{Nu_{x,o}}{Nu_{x,oo}^{(4)}} = \frac{1}{1 - [(T_i - T_e)/(q_o'' D_h/k)]\theta_{12}^*} \quad (5.150)$$

If $T_w = T_o$ at $r = r_o$ and $q_w'' = q_i''$ at $r = r_i$, the local Nusselt numbers $Nu_{x,i}$ and $Nu_{x,o}$ at the two walls are given by

the other adiabatic. The fundamental solution of the fourth kind (Table 5.23) is valid when one wall is at uniform temperature ($\neq T_c$) and the other wall has a uniform temperature equal to T_c . The reader should therefore exercise caution when using Tables 5.21–5.25.

Effects of Eccentricity. In practice, a perfect concentric annular duct cannot be achieved because of manufacturer tolerances, installation, and so forth. Therefore, eccentric annular ducts are frequently encountered. The velocity profile for fully developed flow in an eccentric annulus has been analyzed by Piercy et al. [105]. Based on Piercy's solution, Shah and London [1] have derived the friction factor formula, as follows:

$$f Re = 16(1 - r^{*2})(1 - r^*)^2 \times \left(1 - r^{*4} + Z - 8e^{*2}(1 - r^*)^2 S^2 \sum_{n=1}^{\infty} \frac{n \exp[-n(\alpha + \beta)]}{\sinh [n(\beta - \alpha)]} \right) \quad (5.153)$$

$$\text{where } S = \frac{1-r^*}{2e^*} (1-e^{*2})^{1/2} \left[\left(\frac{1+r^*}{1-r^*} \right)^2 - e^{*2} \right]^{1/2} \quad (5.154)$$

$$\alpha = \sinh^{-1} S \quad \beta = \sinh^{-1} (S/r^*)$$

$$Z = \frac{4e^{*2}(1-r^*)^2}{\alpha - \beta} S^2$$

where $r^* = r_i/r_o$ and $e^* = \varepsilon/(r_o - r_i)$. The term ε denotes the distance between the centers of the two circular walls. Equation 5.153 is valid for $0 < e^* < 1$ and $0 \leq r^* < 1$.

For $e^* = 1$ and $0 \leq r^* < 1$, the following equation obtained by Tiedt [106] can be applied:

$$fRe = \frac{16(1-r^{*2})(1-r^*)^2}{1-r^{*4} - 4r^{*2}\psi'[1/(1-r^*)]} \quad (5.155)$$

where ψ' is the so-called trigamma function with the argument $1/(1-r^*)$. This is given by

$$\psi' \left(\frac{1}{1-r^*} \right) = \sum_{n=0}^{\infty} \left(\frac{1}{n + [1/(1-r^*)]} \right)^2 \quad (5.156)$$

From the results obtained by Becker [107] for $0 \leq e^* \leq 1$ and $r^* \rightarrow 1$, Tiedt [106] also demonstrated that

$$fRe = \frac{24}{1 + 1.5e^{*2}} \quad (5.157)$$

It should be noted that when $e^* = 0$, the eccentric annular duct is reduced to a concentric annular duct.

Cheng and Hwang [108] analyzed the heat transfer problem in eccentric annular ducts. The Nusselt numbers for fully developed flow in eccentric annular ducts with the \textcircled{H} and \textcircled{C} thermal boundary conditions are given in Table 5.26. For eccentric annular ducts with boundary conditions different from the four described in the section entitled "Four Fundamental

Thermal Boundary Conditions,” caution must be taken in using the superposition technique. The reader is strongly recommended to consult the literature.

Turbulent Flow

Presented in this section are the friction factor and Nusselt number for turbulent flow and heat transfer in concentric annular ducts. The effects of eccentricity on the friction factor and Nusselt number are also discussed.

Critical Reynolds Number. For concentric annular ducts, the critical Reynolds number at which turbulent flow occurs varies with the radius ratio. Hanks [109] has determined the lower limit of Re_{crit} for concentric annular ducts from a theoretical perspective for the case of a uniform flow at the duct inlet. This is shown in Fig. 5.16. The critical Reynolds number is within ± 3 percent of the selected measurements for air and water [109].

Fully Developed Flow. Knudsen and Katz [110] obtained the following velocity distributions for fully developed turbulent flow in a smooth concentric annular duct in terms of wall coordinates u^+ and y^+ :

$$u_o^+ = 3.0 + 2.6492 \ln y_o^+ \quad \text{for } r_m \leq r \leq r_o \quad (5.158)$$

$$u_i^+ = 6.2 + 1.9109 \ln y_i^+ \quad \text{for } r_i \leq r \leq r_m \quad (5.159)$$

FIGURE 5.16 Lower limits of the critical Reynolds numbers for concentric annular ducts with uniform velocity at the inlet [109].

where

$$\begin{aligned} u_o^* &= \frac{u}{u_{t,o}} & u_i^* &= \frac{u}{u_{t,i}} \\ y_o^* &= \frac{u_{t,o}(r_o - r)}{\nu} & y_i^* &= \frac{u_{t,i}(r - r_i)}{\nu} \end{aligned} \quad (5.160)$$

and

$$u_{t,o} = \sqrt{\frac{\tau_o}{\rho}} \quad u_{t,i} = \sqrt{\frac{\tau_i}{\rho}}$$

The radius of maximum velocity r_m^* in Eqs. 5.158 and 5.159 can be determined by the formula obtained by Kays and Leung [111]. It follows:

$$r_m^* = \frac{r_m}{r_o} = r^*{}^{0.343} (1 + r^*{}^{0.657} - r^*) \quad (5.161)$$

A critical review of the extensive friction factor data has been made by Jones and Leung [112]. The researchers recommend that the fully developed friction factor formulas for smooth circular ducts given in Table 5.8 be used for calculating the friction factor for concentric annular ducts by replacing $2a$ with the laminar equivalent diameter D_l for concentric annular ducts. The term D_l is defined by

$$D_l = D_h \frac{1 + r^{*2} + (1 - r^{*2})/\ln r^*}{(1 - r^*)^2} \quad (5.162)$$

where $r^* = r_i/r_o$, $D_h = 2(r_o - r_i)$ and r_i and r_o are the radii of the inner and outer tubes, respectively.

The fully developed Nusselt numbers Nu_o and Nu_i at the outer and inner walls of a smooth concentric annular duct can be determined from the following relations for uniform wall heat fluxes q_o'' and q_i'' at the outer and inner walls:

$$Nu_o = \frac{h_o D_h}{k} = \frac{Nu_{oo}}{1 - (q_i''/q_o'')\theta_o^*} \quad (5.163)$$

$$Nu_i = \frac{h_i D_h}{k} = \frac{Nu_{ii}}{1 - (q_o''/q_i'')\theta_i^*} \quad (5.164)$$

where

$$q_o'' = h_o(T_o - T_m), \quad q_i'' = h_i(T_i - T_m) \quad (5.165)$$

The terms T_o and T_i denote the duct wall temperatures at the outer and inner walls. The temperature difference $T_o - T_i$ is given by

$$T_o - T_i = \frac{D_h}{k} \left[q_o'' \left(\frac{1}{Nu_{oo}} + \frac{\theta_i^*}{Nu_{ii}} \right) - q_i'' \left(\frac{1}{Nu_{ii}} + \frac{\theta_o^*}{Nu_{oo}} \right) \right] \quad (5.166)$$

The Nusselt numbers Nu_{oo} and Nu_{ii} as well as the influence coefficients θ_o^* and θ_i^* in Eqs. 5.163, 5.164, and 5.166 are provided by Kays and Leung [111]. These are given in Table 5.27 for wide ranges of Re and Pr and for $r^* = 0.1, 0.2, 0.5$, and 0.8 .

For $r^* = 1$, the concentric annular duct is reduced to a parallel plate duct. The applicable results are given in Table 5.28, the simple Nu being used for the Nusselt number at the heated wall.

It should be noted that for laminar flow ($Re < 2300$) in parallel plate ducts, Nu is equal to 5.385 and θ^* is equal to 0.346 for all values of Pr.

Dwyer [113] has developed semiempirical equations for liquid metal flow ($Pr < 0.03$) in a concentric annular duct ($0 < r^* \leq 1$) with one wall subjected to uniform heat flux and the other

wall insulated. For the case of the outer wall's being heated, the semiempirical equations are as follows:

$$\text{Nu}_{oo} = A_o + B_o(\beta \text{Pe})^{n_o} \quad (5.167)$$

where

$$A_o = 5.26 + \frac{0.05}{r^*} \quad (5.168)$$

$$B_o = 0.01848 + \frac{0.003154}{r^*} - \frac{0.0001333}{r^{*2}} \quad (5.169)$$

$$n_o = 0.78 - \frac{0.01333}{r^*} + \frac{0.000833}{r^{*2}} \quad (5.170)$$

$$\beta = 1 - \frac{1.82}{\text{Pr} (\epsilon_m/v)_{\max}^{1.4}} \quad (5.171)$$

where $(\epsilon_m/v)_{\max}$ can be calculated from the relation

$$\left(\frac{\epsilon_m}{v}\right)_{\max} = \frac{1}{2} \left(\frac{\epsilon_m}{v}\right)_{\max,c} \quad (5.172)$$

An expression for $(\epsilon_m/v)_{\max,c}$ applicable to a circular duct ($r^* = 0$) was developed by Bhatti and Shah [45]. It is given by

$$\left(\frac{\epsilon_m}{v}\right)_{\max,c} = 0.037 \text{Re} \sqrt{f} \quad (5.173)$$

In Eq. 5.173, the friction factor f can be calculated from the explicit formula given by Techo et al. [56], which is shown in Table 5.8.

For a concentric annular duct with the inner wall heated, the semiempirical equations developed by Dwyer [113] are applicable:

$$\text{Nu}_{ii} = A_i + B_i(\beta \text{Pe})^{n_i} \quad (5.174)$$

where

$$A_i = 4.63 + \frac{0.686}{r^*} \quad (5.175)$$

$$B_i = 0.02154 - \frac{0.000043}{r^*} \quad (5.176)$$

$$n_i = 0.752 + \frac{0.01657}{r^*} - \frac{0.000883}{r^{*2}} \quad (5.177)$$

The values of β for this case can also be calculated from Eqs. 5.171 to 5.173. Both Eqs. 5.166 and 5.173 are valid for Pe values above the critical values. For Pr = 0.005, 0.01, 0.02, and 0.03, the critical Pe values are 270, 300, 330, and 345, respectively. For liquid metals, only the heat transfer mode for Pe < Pe_{crit} is molecular conduction.

Hydrodynamically Developing Flow. Hydrodynamically developing turbulent flow in concentric annular ducts has been investigated by Rothfus et al. [114], Olson and Sparrow [115], and Okiishi and Serouy [116]. The measured apparent friction factors at the inner wall of two concentric annuli ($r^* = 0.3367$ and $r^* = 0.5618$) with a square entrance are shown in Fig. 5.17 ($r^* = 0.5618$), where f_i is the fully developed friction factor at the inner wall. The values of f_i equal 0.01, 0.008, and 0.0066 for Re = 6000, 1.5×10^4 , and 3×10^4 , respectively [114].

FIGURE 5.17 Normalized apparent friction factors for turbulent flow in the hydrodynamic entrance region of a smooth concentric annular duct ($r^* = 0.5168$) [114].

Having determined $f_{app,i}$ from Fig. 5.17, the apparent friction factor $f_{app,o}$ at the outer wall can be determined from

$$\frac{f_{app,o}}{f_{app,i}} = \frac{r^*(1 - r_m^{*2})}{r_m^{*2} - r^{*2}} \quad (5.178)$$

where r_m^* is given by

$$r_m^* = r^{*0.343}(1 + r^{*0.657} - r^*) \quad (5.179)$$

Having identified both $f_{app,o}$ and $f_{app,i}$, the circumferentially averaged friction factor can be calculated as follows:

$$f_{app} = \frac{f_{app,o}r_o + f_{app,i}r_i}{r_o + r_i} \quad (5.180)$$

Thermally Developing Flow. Kays and Leung [111] present experimental results for thermally developing turbulent flow in four concentric annular ducts, $r^* = 0.192, 0.255, 0.376,$ and 0.500 , with the boundary condition of one wall at uniform heat flux and the other insulated, that is, the fundamental solution of the second kind. In accordance with this solution, the local Nusselt numbers $Nu_{x,o}$ and $Nu_{x,i}$ at the outer and inner walls are expressed as

$$Nu_{x,o} = \frac{Nu_{x,oo}}{1 - \theta_{x,o}^* q_i'' / q_o''}, \quad Nu_{x,i} = \frac{1}{1 - \theta_{x,ii} - \theta_{x,mi}} \quad (5.181)$$

where q_o'' and q_i'' are the uniform heat fluxes at the outer and inner walls. Both q_o'' and q_i'' are positive whenever heat is added to the fluid and negative whenever heat is transferred out of

the fluid. The Nusselt numbers $Nu_{x,oo}$ and $Nu_{x,ii}$ and the influence coefficients $\theta_{x,o}^*$ and $\theta_{x,i}^*$ are given by:

$$Nu_{x,oo} = \frac{1}{\theta_{x,oo} - \theta_{x,mo}} \quad Nu_{x,ii} = \frac{1}{\theta_{x,ii} - \theta_{x,mi}} \quad (5.182)$$

$$\theta_{x,o}^* = \frac{\theta_{x,mi} - \theta_{x,mo}}{\theta_{x,oo} - \theta_{x,mo}} \quad \theta_{x,i}^* = \frac{\theta_{x,mo} - \theta_{x,io}}{\theta_{x,ii} - \theta_{x,mi}} \quad (5.183)$$

and

$$\theta_{x,mo} = \frac{4(x/D_h)}{Re Pr (1 + r^*)} \quad \theta_{x,mi} = \frac{4r^*(x/D_h)}{Re Pr (1 + r^*)} \quad (5.184)$$

The nondimensional temperatures $\theta_{x,oo}$, $\theta_{x,ii}$, $\theta_{x,oi}$, and $\theta_{x,io}$ for $r^* = 0.192$ and 0.5 are presented in Fig. 5.18 as an example. Additional graphical results for $r^* = 0.192, 0.255,$ and 0.376 are available in Kays and Leung [111].

FIGURE 5.18 $\theta_{x,oo}$, $\theta_{x,ii}$, $\theta_{x,oi}$, $\theta_{x,io}$ for use with Eqs. 5.182 and 5.183 for thermally developing flow in a smooth concentric annular duct with $r^* = 0.5$ and $Pr = 0.7$ [111].

The preceding solution is restricted to a fluid with $Pr = 0.7$, $10^4 < Re < 1.61 \times 10^5$, and $0.192 < r^* < 0.5$. Cross plotting and interpolation can be employed to increase the application range of the results in terms of Re and r^* . For $Pr = 0.01$ and $Pr = 1000$, an eigenvalue solution to the fundamental problem of the second kind for four concentric annular ducts ($r^* = 0.02, 0.1067, 0.1778,$ and 0.3422) can be found in Quarmby and Anand [117].

Simultaneously Developing Flow. Little information is available on simultaneously developing turbulent flow in concentric annular ducts. However, the theoretical and experimental studies by Roberts and Barrow [118] indicate that the Nusselt numbers for simultaneously developing flow are not significantly different from those for thermally developing flow.

Effects of Eccentricity. Jonsson and Sparrow [119] have conducted a careful experimental investigation of fully developed turbulent flow in smooth, eccentric annular ducts. The researchers have provided the velocity measurements graphically in terms of the wall coordinate u^+ as well as the velocity-defect representation. From their results, the circumferentially averaged fully developed friction factor is correlated by a power-law relationship of the following type:

$$f = \frac{C}{Re^n} \quad (5.185)$$

where C is a strong function of e^* , a relatively weak function of r^* , and independent of the Reynolds number, which is given in Fig. 5.19. A single value, $n = 0.18$, has been suggested by Jonsson and Sparrow [119] for all r^* , e^* , and Re . More details regarding the friction factors f_i and f_o for each of the two surfaces are also available [120]. Other investigations of fully developed turbulent flow in eccentric annular ducts have been conducted by Lee and Barrow [121], Deissler and Taylor [122], Yu and Dwyer [123], and Ricker et al. [124].

FIGURE 5.19 Empirical constant C in Eq. 5.185 [119].

The effects of the eccentricity on turbulent heat transfer in eccentric annular ducts have been investigated by Judd and Wade [125], Leung et al. [126], Lee and Barrow [121], and Yu and Dwyer [123] for the boundary condition of a uniform wall heat flux on the inner or outer surfaces while the other wall is insulated. The results were obtained under specific conditions. Further details can be found in the previously mentioned references.

Few investigations have been conducted on hydrodynamically developing flow in eccentric annular ducts. Jonsson [120] has obtained experimental information on the pressure gradient in hydrodynamically developing flow and provided the hydrodynamic lengths L_{hy}/D_h for $1.8 \times 10^4 < Re < 1.8 \times 10^5$. These are presented in Table 5.29.

TABLE 5.29 Turbulent Flow Hydrodynamic Entrance Lengths for Smooth, Eccentric Annular Ducts [120]

r^*	L_{hy}/D_h			
	$e^* = 0$	0.5	0.9	1.0
0.281	29	32	38	38
0.561	26	38	59	78
0.750	28	50	69	91

Few results that can be used in practice are available for thermally developing flow and simultaneously developing flow in eccentric annuli. According to the discussion in Bhatti and Shah [45], the Nusselt numbers may be estimated from the corresponding results for concentric annuli ($e^* = 0$).

PARALLEL PLATE DUCTS

Parallel plate ducts, also referred to as *flat ducts* or *parallel plates*, possess the simplest duct geometry. This is also the limiting geometry for the family of rectangular ducts and concentric annular ducts. For most cases, the friction factor and Nusselt number for parallel plate ducts are the maximum values for the friction factor and the Nusselt number for rectangular ducts and concentric annular ducts.

Laminar Flow

Laminar flow and heat transfer in parallel plate ducts are described in this section. The friction factor and Nusselt number are given for practical calculations.

Fully Developed Flow. For a parallel plate duct with hydraulic diameter $D_h = 4b$ (b being the half-distance between the plates) and the origin at the duct axis, the velocity distribution and friction factor are given by the following expression:

$$\frac{u}{u_m} = \frac{3}{2} \left[1 - \left(\frac{y}{b} \right)^2 \right] \quad (5.186)$$

$$u_m = -\frac{1}{3\mu} \left(\frac{dp}{dx} \right) b^2, \quad f \text{Re} = 24 \quad (5.187)$$

Similar to the four fundamental thermal boundary conditions for concentric annuli, the four kinds of fundamental conditions for parallel plate ducts are shown in Fig. 5.20. The fully developed Nusselt numbers for the four boundary conditions follow [1]:

$$\text{First kind:} \quad \text{Nu}_1 = \text{Nu}_2 = 4 \quad (5.188)$$

$$\text{Second kind:} \quad \text{Nu}_1 = 0 \quad \text{Nu}_2 = 5.385 \quad (5.189)$$

$$\text{Third kind:} \quad \text{Nu}_1 = 0 \quad \text{Nu}_2 = 4.861 \quad (5.190)$$

$$\text{Fourth kind:} \quad \text{Nu}_1 = \text{Nu}_2 = 4 \quad (5.191)$$

FIGURE 5.20 Four fundamental boundary conditions for a parallel plate duct [2].

Examples of the application of these fundamental solutions to obtain the fully developed Nusselt number for a duct with three different boundary conditions follow. The Nusselt numbers are defined as

$$Nu_j = \frac{q''_{wj} D_h}{k(T_j - T_m)} \tag{5.192}$$

where j denotes wall 1 or 2, and T_j is the temperature of the j th wall.

Uniform Temperature at Each Wall. When the temperatures on two walls are equal, $T_{w1} = T_{w2}$, then $Nu_1 = Nu_2 = Nu_T$. The value of Nu_T is given by Shah and London [1] as follows:

$$Nu_T = 7.541 \tag{5.193}$$

When the temperatures on two walls are different, $T_{w1} \neq T_{w2}$, then $Nu_1 = Nu_2 = 4$, as shown in Eq. 5.188.

When the effect of viscous dissipation is considered, the following formulas developed by Cheng and Wu [127] for the case $T_{w1} > T_{w2}$ are used to compute the Nusselt numbers:

$$Nu_1 = \frac{4(1 - 6Br)}{1 - 48/35Br} \quad Nu_2 = \frac{4(1 + 6Br)}{1 + 48/35Br} \tag{5.194}$$

When the effects of viscous dissipation and flow work are considered together for the case of $T_{w1} = T_{w2}$, Ou and Cheng [128] have shown that for fully developed flow, $Nu_T = 0$ and the dimensionless temperature distribution is as follows:

$$\frac{T_w - T}{T_w - T_e} = \frac{9}{8} Br \left[1 - \left(\frac{y}{b} \right)^2 \right]^2, \quad \frac{T_w - T_m}{T_w - T_e} = \frac{27}{35} Br \tag{5.195}$$

Taking the fluid axial condition into account, Pahor and Strand [129] and Grosjean et al. [130] have obtained the following asymptotic formulas for the Nusselt number in the case of $T_{w1} = T_{w2}$:

$$\text{Nu}_T = \begin{cases} 7.540(1 + 3.79/\text{Pe}^2 + \dots) & \text{for } \text{Pe} \gg 1 \\ 8.11742(1 - 0.030859\text{Pe} + 0.0069436\text{Pe}^2 - \dots) & \text{for } \text{Pe} \ll 1 \end{cases} \quad (5.196)$$

Uniform Heat Flux at Each Wall. When the heat fluxes on the two walls of parallel plate ducts are equal, $q''_{w1} = q''_{w2}$, the temperature distribution of fully developed laminar flow is given by:

$$\frac{T_w - T_H}{T_w - T_{m,H}} = \frac{35}{136} \left[5 - 6 \left(\frac{y}{b} \right)^2 + \left(\frac{y}{b} \right)^4 \right], \quad \frac{T_w - T_{m,H}}{q''_w D_h / k} = \frac{17}{140} \quad (5.197)$$

and the Nusselt number is obtained as:

$$\text{Nu}_1 = \text{Nu}_2 = \text{Nu}_H = 8.235 \quad (5.198)$$

When $q''_{w1} \neq q''_{w2}$, then

$$\text{Nu}_1 = \frac{140}{26 - 9(q''_{w2}/q''_{w1})}, \quad \text{Nu}_2 = \frac{140}{26 - 9(q''_{w1}/q''_{w2})} \quad (5.199)$$

To consider the effect of internal energy generation and viscous dissipation, the following formula obtained by Tyagi [6] is recommended:

$$\text{Nu}_H = \frac{140}{17 + \frac{3}{4}S^* + 108\text{Br}'} \quad (5.200)$$

Uniform Temperature at One Wall and Uniform Heat Flux at the Other. When the two walls of a parallel plate duct are subject to a thermal boundary condition such as uniform temperature at one wall and uniform heat flux at the other, the Nusselt numbers for fully developed laminar flow for $q''_w = 0$ and $q''_w \neq 0$ are determined to be:

$$\text{Nu}_1 = 4.8608 \quad \text{Nu}_2 = 0 \quad \text{for } q''_w = 0 \quad (5.201)$$

$$\text{Nu}_1 = \text{Nu}_2 = 4 \quad \text{for } q''_w \neq 0 \quad (5.202)$$

The Convective Boundary Condition \textcircled{B} . The fully developed Nusselt number with the convective boundary condition at both walls can be computed from Hickman's [7] analysis:

$$\text{Nu}_{T3} = \frac{4620 + 561\text{Bi}}{561 + 74\text{Bi}} \quad (5.203)$$

The Exponential Wall Heat Flux Boundary Condition \textcircled{C} . When both walls of parallel plate duct are subjected to the exponential heat flux of $q''_w = q''_0 \exp(mx^*)$, the fully developed Nusselt number can be obtained as follows [2]:

$$\text{Nu}_{H5} = 8.24 + 2.1611 \times 10^{-3}m - 4.4397 \times 10^{-5}m^2 + 1.2856 \times 10^{-7}m^3 - 2.7035 \times 10^{-10}m^4 \quad (5.204)$$

When $m = -30.16$, then $\text{Nu}_{H5} = \text{Nu}_T$, and when $m = 0$, then $\text{Nu}_{H5} = \text{Nu}_H$.

Hydrodynamically Developing Flow. For hydrodynamically developing flow in parallel plate ducts, Shah and London [1] obtained the apparent friction factor f_{app} and Chen [11] has obtained L_{hy} , $K(\infty)$ as the function of x^+ and Re , respectively, as shown in the following equations:

$$f_{\text{app}} \text{Re} = \frac{3.44}{(x^*)^{1/2}} + \frac{24 + 0.674/(4x^*) - 3.44/(x^*)^{1/2}}{1 + 0.000029(x^*)^{-2}} \quad (5.205)$$

$$\frac{L_{hy}}{D_h} = 0.011 \text{ Re} + \frac{0.315}{1 + 0.0175 \text{ Re}} \tag{5.206}$$

$$K(\infty) = 0.64 + \frac{38}{\text{Re}} \tag{5.207}$$

Thermally Developing Flow. The results for thermally developing flow in parallel plate ducts are presented for the following practical thermal boundary conditions of interest.

Equal and Uniform Temperatures on Both Walls. The local and mean Nusselt numbers for parallel plate ducts with equal and uniform temperatures on both walls can be computed from Nusselt's [131] solution, which is displayed in Fig. 5.21. The tabulated values for Fig. 5.21 are available in Shah and London [1].

FIGURE 5.21 Local and mean Nusselt numbers in the thermal entrance region of a parallel plate duct with the $\textcircled{1}$ and $\textcircled{2}$ boundary conditions [1].

From these results, the dimensionless thermal entrance length can be determined as follows:

$$L_{th,T}^* = 0.00797 \tag{5.208}$$

It is also suggested that the following set of empirical equations proposed by Shah and London [1] be used for the practical calculation of the local Nusselt number:

$$\text{Nu}_{x,T} = \begin{cases} 1.233x^{*-1/3} + 0.4 & \text{for } x^* < 0.001 \\ 7.541 + 6.874(10^3x^*)^{-0.488}e^{-245x^*} & \text{for } x^* > 0.001 \end{cases} \tag{5.209}$$

$$\text{Nu}_{m,T} = \begin{cases} 1.849x^{*-1/3} & \text{for } x^* \leq 0.0005 \\ 1.849x^{*-1/3} + 0.6 & \text{for } 0.0005 < x^* \leq 0.006 \\ 7.541 + 0.0235/x^* & \text{for } x^* > 0.006 \end{cases} \tag{5.210}$$

Uniform and Equal Heat Flux at Both Walls. Thermally developing flow in a parallel plate duct with uniform and equal heat flux at both walls has been investigated by Cess and Shaffer [132] and Sparrow et al. [133] in terms of a series format for the local and mean Nusselt numbers. The dimensionless thermal entrance length for this problem has been found by Shah and London [1] to be as follows:

$$L_{th,H} = 0.01154 \quad (5.211)$$

The local and mean Nusselt numbers are also displayed in Fig. 5.21.

The following set of equations are recommended for practical computations without loss of accuracy [1]:

$$\text{Nu}_{x,H} = \begin{cases} 1.490x^{*-1/3} & \text{for } x^* \leq 0.0002 \\ 1.490x^{*-1/3} - 0.4 & \text{for } 0.0002 < x^* \leq 0.001 \\ 8.235 + 8.68(10^3x^*)^{-0.506}e^{-164x^*} & \text{for } x^* \geq 0.001 \end{cases} \quad (5.212)$$

$$\text{Nu}_{m,H} = \begin{cases} 2.236x^{*-1/3} & \text{for } x^* \leq 0.001 \\ 2.236x^{*-1/3} + 0.9 & \text{for } 0.001 < x^* \leq 0.01 \\ 8.235 + 0.0364/x^* & \text{for } x^* \geq 0.01 \end{cases} \quad (5.213)$$

It has been concluded that except in the neighborhood of the duct inlet ($x^* < 10^{-2}$), the effect of the fluid axial conduction is negligible for $Pe > 50$ [134, 135].

Convective Boundary Condition at Both Walls or One Wall. The solutions for the convective boundary condition on both walls or one wall are reviewed in Shah and London [1], where more detailed descriptions are available.

Simultaneously Developing Flow. The results for simultaneously developing flow in parallel plate ducts are provided for the following thermal boundary conditions.

Equal and Uniform Temperatures at Both Walls. For simultaneously developing flow in a parallel plate duct with fluids of $0.1 < Pr < 1000$, the following equations are recommended for the computation of the local and mean Nusselt numbers [2, 136, 137]:

$$\text{Nu}_{x,T} = 7.55 + \frac{0.024x^{*-1.14}[0.0179Pr^{0.17}x^{*-0.64} - 0.14]}{[1 + 0.0358Pr^{0.17}x^{*-0.64}]^2} \quad (5.214)$$

$$\text{Nu}_{m,T} = 7.55 + \frac{0.024x^{*-1.14}}{1 + 0.0358Pr^{0.17}x^{*-0.64}} \quad (5.215)$$

The thermal entrance length $L_{th,T}^*$ has been found to be 0.0064 for $0.01 < Pr < 10,000$ [138, 139]. A detailed description can be found in Shah and London [1] for the solutions for $Pr = \infty$ and $Pr = 0$.

When one duct wall is insulated and the other is at a uniform temperature, the local and mean Nusselt numbers for simultaneously developing flow have been obtained for fluids of $0.1 \leq Pr \leq 10$. These follow [1]:

$$\text{Nu}_{x,T} = 4.86 + \frac{0.0606x^{*-1.2}[0.0455Pr^{0.17}x^{*-0.7} - 0.2]}{[1 + 0.0909Pr^{0.17}x^{*-0.7}]^2} \quad (5.216)$$

$$\text{Nu}_{m,T} = 4.86 + \frac{0.0606x^{*-1.2}}{1 + 0.0909Pr^{0.17}x^{*-0.7}} \quad (5.217)$$

Uniform and Equal Heat Flux at Both Walls. The local Nusselt number for heat transfer of laminar flow in a parallel plate duct with uniform and equal heat flux at both walls is displayed in Fig. 5.22 for different Prandtl numbers, $Pr = 0$ [34] and $Pr = 0.01, 0.7, 1, 10$, and ∞ [136]. The thermal entrance lengths obtained from the results presented in this figure are 0.016, 0.030, 0.017, 0.014, 0.012, and 0.0115, for $Pr = 0, 0.01, 0.7, 1, 10$, and ∞ , respectively.

FIGURE 5.22 Local and mean Nusselt numbers for simultaneously developing flow in a parallel plate duct with the Θ boundary condition [34, 136].

The local Nusselt number is displayed in Fig. 5.23 for $Pr = 0.0, 0.01, 0.7, 10,$ and ∞ when one wall of the parallel plate duct is insulated and the other wall is subjected to uniform heat flux heating [140]. Included in Fig. 5.23 are the results for $Pr = \infty$, obtained from the concentric annular duct corresponding to $r^* = 1$. The local and mean Nusselt numbers for $Pr = 0$ were obtained by Bhatti [34].

In addition, Nguyen [141] has obtained the apparent friction factor and Nusselt numbers for low Reynolds number simultaneously developing flow in a parallel plate duct with a con-

FIGURE 5.23 Local and mean Nusselt numbers for simultaneously developing flow in a flat duct with uniform heat flux at one wall and the other wall insulated [34, 140].

stant temperature and constant wall heat flux thermal boundary conditions. Results are presented for $Pr = 0.7$ and Reynolds numbers between 1 and 20. The results for $Pr = 0.2, 0.7, 2, 7, 10,$ and 100 as well as for the Reynolds numbers between 40 and 200 have been numerically determined by Nguyen and Maclaine-Cross [142].

Turbulent Flow

The characteristics of turbulent flow and heat transfer in parallel plate ducts are discussed in this section. The friction factor for transition flow is also addressed.

Transition Flow. The lower limit of the critical Reynolds number Re_{crit} for a parallel plate duct is reported to be between 2200 and 3400, depending on the entrance configurations and disturbance sources [143]. The following friction factor formula developed by Hrycak and Andrushkiw [144] is recommended for transition flow in the range of $2200 \leq Re \leq 4000$:

$$f = -2.56 \times 10^{-3} + 4.085 \times 10^{-6} Re - 5.5 \times 10^{-10} Re^2 \quad (5.218)$$

The mean Nusselt number in the thermal entrance region of a parallel plate duct with uniform wall temperature at both walls in the range of $2300 < Re < 6000$ is given by Hausen [20] as follows:

$$Nu_{m,T} = 0.116(Re^{2/3} - 160) Pr^{1/3} \left[1 + \left(\frac{x}{D_h} \right)^{-2/3} \right] \quad (5.219)$$

Fully Developed Flow. Beavers et al. [145] obtained the following friction factor for fully developed turbulent flow in a parallel plate duct for $5000 < Re < 1.2 \times 10^6$ from very accurate experimental data:

$$f = \frac{0.1268}{Re^{0.3}} \quad (5.220)$$

For $1.2 \times 10^4 < Re < 1.2 \times 10^6$, Dean [146] has developed the following equation based on a comprehensive survey of the available data:

$$f = \frac{0.0868}{Re^{1/4}} \quad (5.221)$$

Comparisons of precision using Eqs. 5.220 and 5.221 and Blasius's formula (Table 5.8) in which the diameter of circular duct $2a$ is replaced by hydraulic diameter $4b$, b being the half-space between two plates, have been conducted by Bhatti and Shah [45]. In the range of $5000 \leq Re \leq 3 \times 10^4$, Eq. 5.220 is recommended; otherwise, Eq. 5.221 should be used to obtain the friction factor for fully developed turbulent flow in a parallel plate duct. However, use of the hydraulic diameter to substitute for the circular duct diameter in the Blasius equation is reasonable for the prediction of the friction factor [45].

Kays and Leung [111] analyzed turbulent heat transfer in a parallel flat plate duct for arbitrarily prescribed heat flux on the two duct walls. The fully developed Nusselt number Nu_H can be obtained from the following expression:

$$Nu_H = \frac{Nu}{1 - \gamma\theta^*} \quad (5.222)$$

where γ is the ratio of the prescribed heat fluxes on the two duct walls. The Nusselt number Nu and the influence coefficient θ^* in Eq. 5.222 are given in Table 5.28 for different Re and Pr numbers. It should be noted that $\gamma = 0$ signifies that one wall is heated and the other is insulated; $\gamma = 1$ indicates that uniform heat fluxes of equal magnitudes are applied to both walls;

and $\gamma = -1$ refers to heat transfer into one wall and out of the other wall, while the absolute values of the heat fluxes at both walls are the same.

Bhatti and Shah [45] and Sparrow and Lin [133] have performed a comparison of Nusselt numbers predicted using Eq. 5.222 or other equations for parallel plate ducts and the Nusselt number calculated using the equation for circular ducts replacing $2a$ with the hydraulic diameter of the parallel plate duct. It was concluded that the Nusselt number for parallel plate ducts can be determined using the circular duct correlations.

Analogous to circular ducts, the fully developed turbulent Nusselt numbers for uniform wall temperature and uniform wall heat flux boundary conditions in parallel plate ducts are nearly identical for $Pr > 0.7$ and $Re > 10^5$. This is also true for the Nusselt number of turbulent thermally developing flow in a parallel plate duct [147].

For liquid metal, when one wall of the parallel plate duct is heated and the other is adiabatic, the following empirical equation is recommended for $Pr < 0.03$ by Duchatelle and Vautrey [148]:

$$Nu_H = 5.14 + 0.0127 Pe^{0.8} \quad (5.223)$$

Fully developed fluid flow and heat transfer results for rough parallel plate ducts can be predicted using the results for rough circular ducts with the use of hydraulic diameter [45].

Hydrodynamically Developing Flow. Hydrodynamically developing flow in smooth parallel plate ducts with uniform velocity at the duct inlet has been analyzed by Deissler [92] by means of an integral method. The apparent friction factors f_{app} in the hydrodynamic entrance are presented in Fig. 5.24.

FIGURE 5.24 Turbulent flow apparent friction factors in the hydrodynamic entrance region of a parallel plate duct with uniform inlet velocity [45].

Thermally Developing and Simultaneously Developing Flow. Thermally developing turbulent flow in a parallel plate duct with uniform and equal temperatures at both walls has been solved by Sakakibara and Endo [149] and by Shibani and Özisik [150]. A discussion of the solution can be found in Bhatti and Shah [45]. Hatton and Quarmby [151] and Sakakibara and Endo [149] have obtained the solution for a thermally developing turbulent flow problem in a flat duct with one wall at uniform temperature and the outer wall insulated (i.e., the fundamental solution of the third kind). Hatton and Quarmby [151], Hatton et al. [152], and Sakakibara [153] have analyzed thermally developing turbulent flow in a flat duct with uniform heat flux at one wall and the other insulated (i.e., the fundamental solution of the second kind). Özisik et al. [154] have obtained the solution of the thermal entry region heat transfer of turbulent developing flow in a parallel plate duct with uniform wall temperature. Detailed discussions of these solutions can be found in the previously mentioned references.

Few investigations have been conducted for simultaneously developing flow in parallel plate ducts. Therefore, no correlations are provided for practical usage.

RECTANGULAR DUCTS

Rectangular ducts are also often used in the design of heat transfer devices such as compact heat exchangers. Unlike circular and parallel plate ducts, two-dimensional analysis is required to obtain the friction factors and Nusselt numbers for rectangular ducts.

Laminar Flow

In this section, the friction factors and Nusselt numbers for fully developed, hydrodynamically developing, thermally developing, and simultaneously developing laminar flows in rectangular ducts are presented.

Fully Developed Flow

Velocity Distribution and the Friction Factor. Marco and Han [155] have obtained the fully developed velocity distribution in a rectangular duct with cross-sectional dimensions $2a$ and $2b$. It follows:

$$u = -\frac{16}{\pi^3} \left(\frac{dp}{dx} \right) \frac{a^2}{\mu} \sum_{n=1,3,\dots}^{\infty} \frac{(-1)^{(n-1)/2}}{n^3} \left(1 - \frac{\cosh(n\pi y/2a)}{\cosh(n\pi b/2a)} \right) \cos\left(\frac{n\pi z}{2a}\right) \quad (5.224)$$

where the pressure gradient dp/dx is related to u_m as follows:

$$u_m = -\frac{1}{3} \left(\frac{dp}{dx} \right) \frac{a^2}{\mu} \left[1 - \frac{192}{\pi^5} \left(\frac{a}{b} \right) \sum_{n=1,3,\dots}^{\infty} \frac{1}{n^5} \tanh\left(\frac{n\pi b}{2a}\right) \right] \quad (5.225)$$

The origin of the Cartesian coordinate is at the center of the rectangular duct. To avoid computational complexity, the following simple approximations have been suggested [156]:

$$\frac{u}{u_{\max}} = \left[1 - \left(\frac{y}{b} \right)^n \right] \left[1 - \left(\frac{z}{a} \right)^m \right] \quad (5.226)$$

$$\frac{u_{\max}}{u_m} = \left(\frac{m+1}{m} \right) \left(\frac{n+1}{n} \right) \quad (5.227)$$

Natarajan and Lakshmanan [157] have provided the relation for the values of m and n :

$$m = 1.7 + 0.5\alpha^{*-1.4} \quad (5.228)$$

$$n = \begin{cases} 2 & \text{for } \alpha^* \leq 1/3 \\ 2 + 0.3(\alpha^* - 1/3) & \text{for } \alpha^* \geq 1/3 \end{cases} \quad (5.229)$$

where $\alpha^* = b/a$ is the aspect ratio. The exact expression for the fully developed friction factor is

$$f Re = \frac{24}{\left(1 + \frac{1}{\alpha^*}\right)^2 \left(1 - \frac{192}{\pi^5 \alpha^*} \sum_{n=1,3,\dots}^{\infty} \frac{\tanh(n\pi\alpha^*/2)}{n^5}\right)} \quad (5.230)$$

However, for ease in practical calculations, the following empirical equation suggested by Shah and London [1] is used to approximate Eq. 5.230:

$$f Re = 24(1 - 1.3553\alpha^* + 1.9467\alpha^{*2} - 1.7012\alpha^{*3} + 0.9564\alpha^{*4} - 0.2537\alpha^{*5}) \quad (5.231)$$

Heat Transfer. The fully developed Nusselt numbers Nu_T for the case of the uniform temperature at four walls are approximated by the following formula [1]:

$$Nu_T = 7.541(1 - 2.610\alpha^* + 4.970\alpha^{*2} - 5.119\alpha^{*3} + 2.702\alpha^{*4} + 0.548\alpha^{*5}) \quad (5.232)$$

For rectangular ducts with uniform temperature at one or more walls, the Nusselt numbers, available in Shah and London [1], are displayed in Table 5.30.

For rectangular ducts with a uniform wall heat flux at four walls under the Ⓢ boundary condition, the fully developed Nusselt numbers Nu_{HI} can be computed with the following formula [1]:

$$Nu_{HI} = 8.235(1 - 2.0421\alpha^* + 3.0853\alpha^{*2} - 2.4765\alpha^{*3} + 1.0578\alpha^{*4} - 0.1861\alpha^{*5}) \quad (5.233)$$

For rectangular ducts with one or more walls subjected to the Ⓢ boundary condition with the other wall insulated, the fully developed Nusselt numbers Nu_{HI} are displayed in Table 5.30.

For rectangular ducts with four walls heated under the $\textcircled{\ominus}$ thermal boundary condition, the fully developed Nu_{H2} can be determined from Table 5.31 [1]. The $f Re$, Nu_T , and Nu_{H1} are also given in Table 5.31 for convenience of usage.

Hydrodynamically Developing Flow. Shah and London [1] have reviewed and compared several analytical and experimental investigations of hydrodynamically developing flow in rectangular ducts. They concluded that the numerical results reported by Curr et al. [158] and the analytical results reported by Tachibana and Iemoto [159] best fit the experimental data. The apparent friction factors obtained by Curr et al. [158] are shown in Fig. 5.25.

FIGURE 5.25 Apparent Fanning friction factors for hydrodynamically developing flow in rectangular ducts [158].

Thermally Developing Flow. Wibulswas [160] and Aparecido and Cotta [161] have solved the thermal entrance problem for rectangular ducts with the thermal boundary condition of uniform temperature and uniform heat flux at four walls. However, the effects of viscous dissipation, fluid axial conduction, and thermal energy sources in the fluid are neglected in their analyses. The local and mean Nusselt numbers $Nu_{x,T}$, $Nu_{m,T}$, and $Nu_{x,H1}$ and $Nu_{m,H1}$ obtained by Wibulswas [160] are presented in Tables 5.32 and 5.33.

For square ducts, $\alpha^* = 1$, the Nusselt numbers for the \textcircled{T} , \textcircled{H} , and \textcircled{H} thermal boundary conditions have been obtained by Chandrupatla and Sastri [162]. As recommended by Shah and London [1], the results obtained by Chandrupatla and Sastri [162], shown in Table 5.34, are more accurate than those presented by Wibulswas [160].

The thermal entrance lengths for rectangular ducts in the \textcircled{T} boundary condition $L_{th,T}^*$ are determined to be 0.008, 0.054, 0.049, and 0.041 for $\alpha^* = 0, 0.25, 0.5$, and 1, respectively [1]. The thermal entrance lengths in the \textcircled{H} boundary condition $L_{th,H1}^*$ are found to be 0.0115, 0.042,

0.048, 0.057, and 0.066 for $\alpha^* = 0, 0.25, \frac{1}{3}, 0.5,$ and $1,$ respectively [1]. Thermally developing flow in rectangular ducts with one wall or more insulated is reviewed in Shah and London [1].

Simultaneously Developing Flow. Table 5.35 presents the results for simultaneously developing flow in rectangular ducts; these were obtained by Wibulswas [160] for the $\text{\textcircled{T}}$ and $\text{\textcircled{H}}$ boundary conditions for air ($Pr = 0.72$). Transverse velocity is neglected in this analysis. However, Chandrupatla and Sastri [163] include transverse velocity in their analysis for a square duct with the $\text{\textcircled{H}}$ boundary condition.

The $Nu_{x,H1}$ and $Nu_{m,H1}$ obtained by Chandrupatla and Sastri [163] are illustrated in Table 5.36. It should be noted that in Table 5.36, $Pr = 0$ corresponds to slug flow, whereas $Pr = \infty$ corresponds to hydrodynamically developed flow.

Turbulent Flow

Entrance configuration is the key factor affecting flow transition in rectangular ducts. The lower limit of the critical Reynolds numbers Re_{crit} along with entrance configuration has been investigated by Davies and White [164], Allen and Grunberg [165], Cornish [166], and Hartnett et al. [167]. The lower limits of the critical Reynolds numbers for a smooth rectangular duct with two entrance configurations are given in Table 5.37.

For most engineering calculations of friction factors and Nusselt numbers for fully developed flow in rectangular ducts, it is sufficiently accurate to use the circular duct correlations by replacing the circular duct diameter $2a$ with the hydraulic diameter $D_h = 4ab/(a + b)$ or with D_i , defined by the following equations to consider the shape effect [168]:

$$D_i = \frac{2}{3} D_h (1 + \alpha^*)^2 \left(1 - \frac{192\alpha^*}{\pi^5} \sum_{n=0}^{\infty} \frac{1}{(2n+1)^5} \tanh \frac{(2n+1)\pi\alpha^*}{2} \right) \quad (5.234)$$

An approximate expression for D_i is:

$$D_i = \frac{2}{3} D_h + \frac{11}{24} \alpha^* (2 - \alpha^*) \quad (5.235)$$

which yields D_i values within ± 2 percent of those given by Eq. 5.234.

TABLE 5.37 Lower Limits of the Critical Reynolds Numbers for Smooth Rectangular Ducts

		0.2	2500
		0.2555	2400
		0.3425	2360
		1.0	2200

The fully developed friction factor and heat transfer coefficients for turbulent flow in an asymmetrically heated rectangular duct have been reported by Rao [59]. In this investigation, the experimental region of the Reynolds number was from 10^4 to 5×10^4 .

For fully developed Nusselt numbers for the turbulent flow of liquid metals in rectangular ducts, a simple correlation has been derived for the \textcircled{T} and \textcircled{H} boundary conditions [169]. This correlation follows:

$$Nu = \frac{2}{3}Nu_{\text{slug}} + 0.015Pe^{0.8} \quad (5.236)$$

where Nu_{slug} is the Nusselt number corresponding to slug flow ($Pr = 0$) through rectangular ducts, which is given in Fig. 5.26 as a function of α^* for rectangular ducts under the \textcircled{T} and \textcircled{H} boundary conditions.

FIGURE 5.26 Slug flow Nusselt numbers for rectangular ducts [169].

TRIANGULAR DUCTS

The flow and heat transfer characteristics of triangular ducts, as shown in Fig. 5.27, are explained in this section. The coordinates shown in Fig. 5.27 are used in the presentation of the results.

Laminar Flow

In this section, the laminar flow and heat transfer characteristics are explained for different triangular ducts.

FIGURE 5.27 Triangular ducts: (a) equilateral; (b) equilateral with rounded corners; (c) isosceles; (d) and (e) right; and (f) arbitrary.

Fully Developed Flow

Equilateral Triangular Ducts. For equilateral triangle ducts as shown in Fig. 5.27a, the fully developed laminar flow velocity profile and friction factor have been obtained by Marco and Han [155]:

$$\frac{u}{u_m} = \frac{15}{8} \left[\left(\frac{y}{b}\right)^3 - 3\left(\frac{y}{b}\right)\left(\frac{z}{b}\right)^2 - 2\left(\frac{y}{b}\right)^2 - 2\left(\frac{z}{b}\right)^2 + \frac{32}{37} \right] \tag{5.237}$$

$$u_m = -\frac{b^2}{15\mu} \left(\frac{dp}{dx}\right), \quad f Re = \frac{40}{3} = 13.333 \tag{5.238}$$

When the three walls of the equilateral triangles are subjected to the uniform wall temperature boundary condition $\textcircled{1}$, the fully developed Nusselt number Nu_T is equal to 2.49 [170]. However, when the uniform wall heat flux with the uniform circumferential wall temperature boundary condition $\textcircled{2}$ is applied, the Nusselt number Nu_{H1} is determined by the following equation [6]:

$$Nu_{H1} = \frac{28/9}{1 + 1/12 S^* + 40/11 Br'} \tag{5.239}$$

The internal heat source and viscous dissipation effects are considered in Eq. 5.239.

The Nusselt number for uniform wall heat flux in both the axial and circumferential directions under the $\textcircled{2}$ boundary condition Nu_{H2} is found to be 1.892 [171].

Since sharp triangular ducts are rarely seen in practical use, triangular ducts with rounded corners, such as that presented in Fig. 5.27b, have been investigated by Shah [172]. His results are presented in Table 5.38, in which the y and y_{max} refer to the distances measured from the duct base to the centroid and to the point of maximum fluid velocity, respectively.

TABLE 5.38 Fully Developed Laminar Flow and Heat Transfer Characteristics of Equilateral Triangular Ducts With Rounded Corners [172]

	No rounded corners	One rounded corner	Two rounded corners	Three rounded corners
$D_h/2a$	0.57735	0.59745	0.62115	0.64953

$y_{\max}/2a$	0.28868	0.28627	0.29117	0.28868
u_{\max}/u_m	2.222	2.172	2.115	2.064
$K(\infty)$	1.818	1.698	1.567	1.441
L_{hy}^+	0.0398	0.0659	0.0319	0.0284
$f Re$	13.333	14.057	14.899	15.993
Nu_{H1}	3.111	3.401	3.756	4.205
Nu_{H2}	1.892	2.196	2.715	3.780

Isosceles Triangular Ducts. For isosceles triangular ducts like those shown in Fig. 5.27c, the velocity distribution and friction factors for fully developed laminar flow are expressed by the following set of equations suggested by Migay [173]:

$$u = -\frac{1}{2\mu} \left(\frac{dp}{dx} \right) \frac{y^2 - z^2 \tan^2 \phi}{1 - \tan^2 \phi} \left[\left(\frac{z}{2b} \right)^{B-2} - 1 \right] \quad (5.240)$$

$$u_m = -\frac{2b^2}{3\mu} \left(\frac{dp}{dx} \right) \frac{(B-2) \tan^2 \phi}{(B+2)(1 - \tan^2 \phi)} \quad (5.241)$$

$$f Re = \frac{12(B+2)(1 - \tan^2 \phi)}{(B-2)[\tan \phi + (1 + \tan^2 \phi)^{1/2}]^2} \quad (5.242)$$

$$B = [4 + \sqrt{2}(\cot^2 \phi - 1)]^{1/2} \quad (5.243)$$

Apparently, when $2\phi = 90^\circ$, $f Re$ is indeterminate from Eq. 5.242. Migay [173] obtained another relation for $2\phi = 90^\circ$, as follows:

$$f Re = \frac{12(B+2)(1 - 3 \tan^2 \phi)}{[\sqrt{2} \tan \phi [4 \tan^2 \phi + \sqrt{2}(1 - \tan^2 \phi)]^{-1/2} - 2][\tan \phi + (1 + \tan^2 \phi)^{1/2}]^2} \quad (5.244)$$

The remaining flow and heat transfer characteristics, represented by $K(\infty)$, L_{hy}^+ , Nu_T , Nu_{H1} , and Nu_{H2} , together with $f Re$, are given in Table 5.39 [1].

The fully developed Nusselt numbers Nu_T and Nu_{H1} for laminar flow in isosceles triangular ducts with one wall or more heated are given in Table 5.40.

Right Triangular Ducts. For right triangular ducts, shown in Fig. 5.27d and e, the fully laminar developed flow and heat transfer characteristics $f Re$, $K(\infty)$, Nu_{H1} , and Nu_{H2} are given in Fig. 5.28 [2]. The data for this figure were taken from Haji-Sheikh et al. [170], Sparrow and Haji-Sheikh [174], and Iqbal et al. [175].

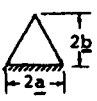

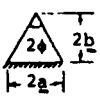

Arbitrary Triangular Ducts. For triangular ducts with arbitrary angles such as that shown in Fig. 5.27f, the fully developed friction factors and Nusselt numbers are presented for fully developed laminar flow in Figs. 5.29 and 5.30 [2].

Thermally and Simultaneously Developing Flows. Hydrodynamically developing laminar flow in triangular ducts has been solved by different investigators as is reviewed by Shah and London [1]. Wibulswas [160] obtained a numerical solution for the problem of simultaneously

developing laminar flow for equilateral triangular and right-angled isosceles triangular ducts for $Pr = 0, 0.72,$ and ∞ . His results for uniform wall temperature and axial uniform wall heat flux with circumferential uniform wall temperature boundary conditions are presented in Tables 5.41 and 5.42. Since $Pr = \infty$ implies that the flow is hydrodynamically developed, the results for $Pr = \infty$ can be applied to all fluids in thermally developing laminar flow.

FIGURE 5.30 Fully developed Nusselt numbers for arbitrary triangular ducts [2].

Turbulent Flow

The lower limit of Re_{crit} is considered to be approximately 2000 in triangular ducts [45]. No reliable results for the friction factor and Nusselt number are available for transition flow in triangular ducts. In this section, the turbulent flow and heat transfer characteristics for equilateral, isosceles, and right triangular ducts are presented.

Fully Developed Flow

Equilateral Triangular Ducts. The friction factor for an equilateral triangular duct has been measured by Altemani and Sparrow [176]. Their data are fitted by the following equation in the region of $4000 < Re < 8 \times 10^4$:

$$f = \frac{0.0425}{Re^{0.2}} \quad (5.245)$$

These researchers have also obtained the fully developed Nusselt numbers for air ($Pr = 0.7$) in the range of $4000 < Re < 8 \times 10^4$ in an equilateral triangular duct with the \textcircled{H} boundary condition on two walls and the third wall insulated as follows:

$$Nu_{HI} = 0.019Re^{0.781} \quad (5.246)$$

Isosceles Triangular Ducts. Bhatti and Shah [45] recommended that the friction factor for fully developed turbulent flow in isosceles triangular ducts can be determined using different correlations. For $0 < 2\phi < 60^\circ$, the circular duct correlations in Table 5.8 can be used with D_h replaced by D_g , as defined by Bandopadhyay and Ambrose [177]:

$$D_g = \frac{D_h}{2\pi} \left[3 \ln \cot \frac{\theta}{2} - 2 \ln \tan \frac{\phi}{2} - \ln \tan \frac{\phi}{2} \right] \quad (5.247)$$

where $\theta = (90^\circ - \phi)/2$. For $2\phi = 60^\circ$, the circular duct correlations in Table 5.8 should be used with D_h replaced by D_h , which is equal to $\sqrt{3}a$. For $60^\circ < 2\phi < 90^\circ$, the use of circular duct correlations with D_h is probably accurate enough. For $2\phi = 90^\circ$, the circular duct correlations in Table 5.8 can be used. For $2\phi > 90^\circ$, no definite recommendation can be made at this moment.

Right Triangular Ducts. The fully developed turbulent friction factor for two right-angled triangular ducts and an equilateral triangular duct are shown in Fig. 5.31 [45]. The data are from Nikuradse [178] and Schiller [179]. Also provided in this figure are the correlations for computing the friction factor for each triangular duct.

Thermally Developing Flow. Altemani and Sparrow [176] have conducted experimental measurements of the thermally developing flow of air ($Pr = 0.7$) in an equilateral triangular duct with the \textcircled{H} boundary condition on two walls and the third wall insulated. The local Nusselt numbers $Nu_{x,HI}$ and the thermal entrance lengths from their results are given in Figs. 5.32 and 5.33, respectively.

FIGURE 5.31 Fully developed friction factor for turbulent flow in smooth right-angled and equilateral triangular ducts [45].

FIGURE 5.32 Local Nusselt numbers $Nu_{x,H1}$ for thermally developing and hydrodynamically developing turbulent airflow ($Pr = 0.7$) in a smooth equilateral triangular duct [176].

FIGURE 5.33 Thermal entrance lengths for thermally developing and hydrodynamically developing turbulent airflow ($Pr = 0.7$) in a smooth equilateral triangular duct [176].

For equilateral triangular ducts having rounded corners with a ratio of the corner radius of curvature to the hydraulic diameter of 0.15, Campbell and Perkins [180] have measured the local friction factor and heat transfer coefficients with the \oplus boundary condition on all three walls over the range $6000 < Re < 4 \times 10^4$. The results are reported in terms of the hydrodynamically developed flow friction factor in the thermal entrance region with the local wall (T_w) to fluid bulk mean (T_m) temperature ratio in the range $1.1 < T_w/T_m < 2.11$, $6000 < Re < 4 \times 10^4$, and $7.45 < x/D_h < 72$. These data were correlated by

$$\frac{f}{f_{iso}} = \left(\frac{T_w}{T_m} \right)^{-0.40 + (x/D_h)^{-0.67}} \quad (5.248)$$

where f_{iso} denotes the friction factor for isothermal flow, which can be calculated from either the Blasius formula or the PKN formula presented in Table 5.8. In these calculations, kinematic viscosity ν entering $Re = u_m D_h / \nu$ must be evaluated at the duct wall temperature T_w .

The following correlation has been obtained by Campbell and Perkins [180] from their measurements for local Nusselt numbers:

$$Nu_{x,H1} = 0.021 Re^{0.8} Pr^{0.4} \left(\frac{T_w}{T_m} \right)^{0.7} \Phi \quad (5.249)$$

For $6 < x/D_h \leq 50$, the correction factor Φ is given by

$$\Phi = \left[1 + \left(\frac{x}{D_h} \right)^{-0.7} \left(\frac{T_w}{T_m} \right)^{0.7} \right] \quad (5.250)$$

and for $x/D_h > 50$, $\Phi = 1$. Equation 5.249 is valid for $6 < x/D_h < 123$ and $1.10 < T_w/T_m < 2.11$. The fluid properties ν , α , and k entering Eq. 5.249 must be taken at the fluid bulk mean temperature T_m .

ELLIPTICAL DUCTS

Elliptical ducts can be thought as a family of ducts, including geometries ranging from lenticular to circular ducts. The major and minor axes lengths are represented by $2a$ and $2b$, respectively, in this section. The origin of the coordinate is the intersection of the major and minor axes.

Laminar Flow

Presented in this section are the friction factors and Nusselt numbers for laminar flow in elliptical ducts.

Fully Developed Flow. The velocity distribution for fully developed laminar flow in elliptical ducts with major axis $2a$ and minor axis $2b$ is given by Shah and London [1] as follows:

$$\frac{u}{u_m} = 2 \left[1 - \left(\frac{z}{a} \right)^2 - \left(\frac{y}{b} \right)^2 \right] \quad (5.251)$$

$$u_m = -\frac{1}{4\mu} \left(\frac{dp}{dx} \right) \left(\frac{b^2}{1 + \alpha^{*2}} \right), \quad f \text{Re} = 2(1 + \alpha^{*2}) \left(\frac{\pi}{E(m)} \right)^2 \quad (5.252)$$

In the preceding equations, $m = 1 + \alpha^{*2}$, and $E(m)$ is the complete elliptic integral of the second kind. The hydraulic diameter of the elliptical duct is $D_h = \pi b/E(m)$, and the cross-sectional area is $A_c = \pi ab$.

The expression for hydrodynamic entrance length L_{hy}^+ developed by Bhatti [181] is as follows:

$$L_{hy}^+ = \frac{0.5132}{1 + \alpha^{*2}} \left(\frac{E(m)}{\pi} \right)^2 \quad (5.253)$$

The fully developed incremental pressure drop number $K(\infty)$ for elliptical ducts has been found to be independent of the duct aspect ratio $\alpha^* = 2b/2a$ [187]. The value of $K(\infty)$ is recommended to be 1.26 for practical calculations [2].

The fully developed Nusselt numbers Nu_T , Nu_{H1} , Nu_{H2} are displayed in Fig. 5.34. The values of the data used in this figure are derived from the results by Tyagi [6], Tao [182], Iqbal et al. [175], and Dunwoody [183].

FIGURE 5.34 Fully developed Nusselt numbers for elliptical ducts [2].

Hydrodynamically Developing Flow. Bhatti [181] has analyzed hydrodynamically developing flow in elliptic ducts. The apparent friction factors and incremental pressure drop numbers can be expressed as:

$$f_{\text{app}} \text{Re} = \frac{\Delta p^*}{4x^*}, \quad \Delta p^* = \frac{2(1-\eta)(1+3\eta) - (1+\eta)^2 \ln \eta^3}{3(1+\eta)^2} \quad (5.254)$$

$$K(x) = \frac{(3\eta^3 + 9\eta^2 + 21\eta + 7)(1-\eta)}{6(1+\eta)^2} \quad (5.255)$$

where η is a boundary layer parameter that refers to the fraction of the duct cross section carrying inviscid flow. The term η is determined from the following equation implicitly as a function of x^* :

$$16(1 + \alpha^{*2}) \left(\frac{\pi}{E(m)} \right)^2 x^* = \eta^2 - 1 - \ln \eta^2 \quad (5.256)$$

Thermally Developing Flow. The local Nusselt number for thermally developing flow in elliptic ducts with uniform wall temperature $\text{Nu}_{x,T}$ was obtained by Dunwoody [183] in terms of a double infinite series. These results are considered the most accurate as $x^* > 0.005$. Dunwoody's formula for calculating the mean Nusselt number is as follows:

$$\text{Nu}_{m,T} = \frac{\lambda}{4} \left(1 + \frac{C}{x^*} \right) \quad (5.257)$$

The λ and C values for Eq. 5.257 are given in Table 5.43.

TABLE 5.43 The Constants λ and C for Eq. 5.257 [183]

α^*	λ	C
0.0625	14.59	0.0578
0.125	14.90	0.0388
0.25	15.17	0.0239
0.5	14.97	0.0158
0.8	14.67	0.0138

For $x^* < 0.005$, the following formula obtained by Richardson [184] is recommended:

$$\text{Nu}_{m,T} = \frac{3}{\Gamma(4/3)(9x^*)^{1/3}} \left(1 + \frac{(1-\alpha^*)^2 + (1-\alpha^*)^3}{36} \right) \quad (5.258)$$

For elliptic ducts subjected to the \oplus thermal boundary condition, Someswara et al. [185] have solved thermally developing flow. The mean Nusselt number $\text{Nu}_{m,HI}$ can be computed using the following expression:

$$\text{Nu}_{m,HI} = \frac{2.61F}{x^{*1/3}} \quad (5.259)$$

where factor F is a function of α^* and can be calculated by the following [2]:

$$F = 1.2089 - 0.795\alpha^* - 4.3011\alpha^{*2} + 23.8465\alpha^{*3} - 44.7053\alpha^{*4} + 37.0874\alpha^{*5} - 11.4809\alpha^{*6} \quad (5.260)$$

Equation 5.260 is accurate within ± 3 percent error to the original data given by Someswara et al. [185].

Turbulent Flow

The friction factors for fully developed turbulent flow have been measured by Barrow and Roberts [186] in elliptical ducts with $\alpha^* = 0.316$ and 0.415 in the range of $10^3 < \text{Re} < 3.10^5$ and by Cain and Duffy [187] in elliptical ducts with $\alpha^* = 0.5$ and 0.667 in the range $2 \times 10^4 < \text{Re} < 1.3 \times 10^5$. Based on the data presented by Barrow and Roberts [186] and Cain and Duffy [187], Bhatti and Shah [45] have derived the following correlation to calculate the friction factor:

$$\frac{f}{f_c} = 0.4443 + 2.2168\alpha^* - 2.0431\alpha^{*2} + 0.3821\alpha^{*3} \quad (5.261)$$

where f_c is the friction factor for a smooth circular duct ($\alpha^* = 1$), which can be obtained from the Blasius equation in Table 5.8. It should be noted that Eq. 5.261 is valid for $0.136 < \alpha^* < 1$.

Heat transfer in fully developed turbulent flow in elliptical ducts has been determined in several investigations. A comparison of the different results has been presented by Bhatti and Shah [45]. It was concluded that the Gnielinski correlation for circular ducts can confidently be used to calculate the fully developed Nusselt number for elliptical ducts for fluids of $\text{Pr} \geq 0.5$.

For liquid metals, the fully developed Nusselt numbers can be determined using Eq. 5.236 for elliptical ducts with the $\textcircled{\ominus}$ boundary condition. The values of Nu_{slug} required in Eq. 5.236 are given in Fig. 5.35.

FIGURE 5.35 Slug flow Nusselt numbers for elliptical ducts with the $\textcircled{\ominus}$ boundary condition [169].

CURVED DUCTS AND HELICOIDAL PIPES

The most prominent characteristic of flow in curved ducts and helicoidal pipes is the secondary flow induced by centrifugal force due to the curvature of the pipe. Consequently, the friction factor is higher in curved pipes than that in straight pipes for the same Reynolds number. The pitch of the helicoidal pipe also has an effect on the flow. As a result, the heat trans-

fer rate is higher in curved or helicoidal pipes than in straight pipes. Therefore, curved or helicoidal pipes are widely used in engineering applications.

Spiral coils are curved ducts with varying curvature. The friction factor and heat transfer rate for spiral coils are also included in this section. In addition to the dimensionless parameters used in straight pipes, the following parameters are particularly useful in the case of curved ducts or helicoidal pipes: the Dean number De ; the helical number He , and the effective radius of curvature R_c . These are defined as follows:

$$De = Re \left(\frac{a}{R} \right)^{1/2} \quad (5.262)$$

$$He = Re \left(\frac{a}{R_c} \right)^{1/2} = De \left[1 + \left(\frac{b}{2\pi R} \right)^2 \right]^{1/2} \quad (5.263)$$

$$R_c = R \left[1 + \left(\frac{b}{2\pi R} \right)^2 \right] \quad (5.264)$$

where a denotes the radius of a circular pipe, b represents the coil pitch, and R is the radius of the coil.

In this section, emphasis will be given to the correlations used for calculating the friction factors and Nusselt numbers for laminar and turbulent flows in curved ducts, helicoidal pipes, and spiral ducts. These will be presented as the ratio of the friction factor in curved ducts to the friction factor in straight ducts f_c/f_s , and the ratio of the Nusselt number in curved ducts to the Nusselt number in straight ducts Nu_c/Nu_s , in most cases. The subscript c represents curved ducts or helicoidal pipes, while the subscript s denotes straight pipes of the same shape.

Fully Developed Laminar Flow

Dean [188, 189] first studied the velocity profile of flow in helicoidal pipes using perturbation analysis. His result is valid only for $De < 20$, where the velocity distribution is almost identical to that found in straight ducts. Mori and Nakayama [190] have obtained the solution for $De > 100$ for a coil with $R > a$. Their results are in agreement with the experimental data reported by Mori and Nakayama [190] and Adler [191] and numerical simulations [192].

The friction factors for fully developed flow in helicoidal pipe proposed by Srinivasan et al. [193] in the range of $7 < R/a < 104$ follow:

$$\frac{f_c}{f_s} = \begin{cases} 1 & \text{for } De < 30 \\ 0.419De^{0.275} & \text{for } 30 < De < 300 \\ 0.1125De^{0.5} & \text{for } De > 300 \end{cases} \quad (5.265)$$

However, after reviewing the available experimental data and theoretical predications, Manlapaz and Churchill [194] recommended the following correlations, which contain both the Dean number De and radius ratio of R/a :

$$\frac{f_c}{f_s} = \left[\left(1.0 - \frac{0.18}{[1 + (35/De)^2]^{0.5}} \right)^m + \left(1.0 + \frac{a/R}{3} \right)^2 \left(\frac{De}{88.33} \right) \right]^{0.5} \quad (5.266)$$

where $m = 2$ for $De < 20$; $m = 1$ for $20 < De < 40$; and $m = 0$ for $De > 40$. It can be observed that Eq. 5.265 does not include the parameter R/a and will not be used for all the range of R/a . After a comparison of Eq. 5.266 with experimental data, Shah and Joshi [195] suggested that Eq. 5.265 be used for the coils with $R/a < 3$ and that either Eq. 5.265 or Eq. 5.266 be used for coils with $R/a > 3$.

The friction factors for spiral coils can be obtained using the following correlation [193], which is valid for $500 < \text{Re} (b/a)^{0.5} < 20,000$ and $7.3 < b/a < 15.5$.

$$f_c = \frac{0.62(n_2^{0.7} - n_1^{0.7})^2}{\text{Re}^{0.6} (b/a)^{0.3}} \quad (5.267)$$

where n_1 and n_2 represent the numbers of turns from the origin to the start and the end of a spiral.

The critical Reynolds number, which is used to identify the transition from laminar to turbulent flow in curved or helicoidal pipes, has been recommended for design purposes by Srinivasan et al. [193]:

$$\text{Re}_{\text{crit}} = 2100 \left[1 + 12 \left(\frac{R}{a} \right)^{-0.5} \right] \quad (5.268)$$

However, for spiral pipes, no single Re_{crit} exists because of varying curvature. The minimum value of Re_{crit} can be obtained using R_{max} to replace R in Eq. 5.268, and the maximum value of Re_{crit} can be determined using R_{min} to replace the R in Eq. 5.268.

The fully developed Nusselt numbers for laminar flow in helicoidal pipes subjected to the uniform wall temperature have been obtained theoretically and experimentally by Mori and Nakayama [196], Tarbell and Samuels [197], Dravid et al. [198], Akiyama and Cheng [199], and Kalb and Seader [200]. A comparison of these results has been made using the Manlapaz-Churchill [201] correlation.

In Fig. 5.36, experimental and theoretical results [196–200] are compared with the following Manlapaz-Churchill [201] correlation based on a regression analysis of the available data:

$$\text{Nu}_T = \left[\left(3.657 + \frac{4.343}{x_1} \right)^3 + 1.158 \left(\frac{\text{De}}{x_2} \right)^{3/2} \right]^{1/3} \quad (5.269)$$

$$\text{where} \quad x_3 = \left(1.0 + \frac{957}{\text{De}^2 \text{Pr}} \right)^2, \quad x_2 = 1.0 + \frac{0.477}{\text{Pr}} \quad (5.270)$$

It can be seen that the prediction calculated from Eq. 5.269 agrees well with the experimental data in most cases, except for $\text{Pr} = 0.01$ and 0.1 at intermediate He values.

The fully developed Nusselt numbers for spiral coils with uniform wall temperature are suggested by Kubair and Kuldor [202, 203], as follows:

$$\text{Nu}_T = \left(1.98 + 1.8 \frac{a}{R_{\text{ave}}} \right) \text{Gz}^{0.7} \quad (5.271)$$

which is valid in the ranges of $9 \leq \text{Gz} \leq 1000$, $80 < \text{Re} < 6000$, and $20 < \text{Pr} < 100$. Although this equation can be used to obtain the Nusselt number in the thermal entrance region, the fully developed Nusselt number may be calculated by substituting $\text{Gz} = 20$.

For helicoidal pipes with the \textcircled{H} thermal boundary condition, the Nusselt number has been developed by Manlapaz and Churchill [201]:

$$\text{Nu}_{\text{HI}} = \left[\left(4.364 + \frac{4.636}{x_3} \right)^3 + 1.816 \left(\frac{\text{De}}{x_4} \right)^{3/2} \right]^{1/3} \quad (5.272)$$

$$\text{where} \quad x_3 = \left(1.0 + \frac{1342}{\text{De}^2 \text{Pr}} \right)^2 \quad x_4 = 1.0 + \frac{1.15}{\text{Pr}} \quad (5.273)$$

Figure 5.37 compares Eq. 5.272 with some of the available theoretical predictions [204, 205] and experimental Nusselt number data [190, 198]. The figure indicates a fairly good agreement between the correlation and most of the available data.

FIGURE 5.36 A comparison of the recommended design correlation (Eq. 5.268, solid line) with theoretical and experimental Nusselt numbers for the $\overline{\nu}$ boundary condition [201].

FIGURE 5.37 A comparison of the recommended design correlation (Eq. 5.271, solid line) with theoretical and experimental Nusselt numbers for the ⊗ boundary condition [201].

The fully developed Nusselt numbers Nu_{H_2} for helicoidal pipes have been obtained numerically by Manlapaz and Churchill [201]. Their results are listed in Table 5.44.

In Table 5.44, it can be seen that the pitch of the helicoidal coil has almost no influence on the Nusselt number. However, the studies by Yang et al. [206, 207] have shown a positive effect of the pitch on the Nusselt number when $Pr > 1$. In addition, the experiments conducted by Austen and Soliman [208] indicated that the Nusselt number for the laminar flow of water ($3 < Pr < 6$) in the uniformly heated helicoidal pipe is in good agreement with the prediction from Manlapaz and Churchill [201].

To consider the effect of variable viscosity, the viscosity ratio $(\mu_m/\mu_w)^{0.14}$ is applied. The use of Eqs. 5.269 and 5.272 with their right sides multiplied by $(\mu_m/\mu_w)^{0.14}$ is recommended. The density change of fluids leads to natural convection; consequently, heat transfer is normally enhanced.

An experimental correlation has been obtained by Abul-Hamayel and Bell [209] to account for the density and viscosity variations in helicoidal pipe. Experiments with water, ethylene glycol, and *n*-butyl alcohol in a helicoidal pipe with the Ⓢ boundary condition were conducted. The following equation was derived from the measurement data:

$$Nu_{HI} = \left[4.36 + 2.84 \left(\frac{Gr}{Re^2} \right)^{3.94} \right] \left[1 + 0.9348 \left(\frac{Gr}{Re^2} \right)^{2.78} x_5 \right] \left[1 + 0.0276 De^{0.75} Pr^{0.197} \left(\frac{u_m}{u_w} \right)^{0.14} \right] \quad (5.274)$$

$$\text{where} \quad x_5 = \exp\left(-\frac{1.33 Gr'}{De^2}\right) \quad (5.275)$$

This correlation is valid for $92 < Re < 5500$, $2.2 < Pr < 101$ and $760 < Gr' < 10^6$. It reduces to the straight circular duct forced convection Nusselt number value of 4.36 upon neglecting the coil

effect ($De \rightarrow 0$). Equation 5.274 is recommended for those fluids whose densities are strongly dependent on temperature.

Developing Laminar Flow

Hydrodynamically developing laminar flow, thermally developing laminar flow, and simultaneously developing laminar flow in helical coils are still under investigation [210–212]. Accurate formulas for engineering applications are limited. However, the entrance region of a helical coil is approximately 20 to 50 percent shorter than that of a straight tube. For most engineering applications, when $De \geq 200$, the design can be based on fully developed values without significant errors [195].

Turbulent Flow in Coils With Circular Cross Sections

The research conducted by Hogg [213] has indicated that turbulent flow entrance length in coils with circular cross sections is much shorter than that for laminar flow. Turbulent flow can become fully developed within the first half-turn of the coil. Therefore, most of the turbulent flow and heat transfer analyses concentrate on the fully developed region.

Ito [214] has proposed the following correlation to calculate the friction factor for turbulent flow in helicoidal coils:

$$f_c \left(\frac{R}{a} \right)^{0.5} = 0.00725 + 0.076 \left[\text{Re} \left(\frac{R}{a} \right)^{-2} \right]^{-0.25} \quad \text{for } 0.034 < \text{Re} \left(\frac{R}{a} \right) < 300 \quad (5.276)$$

However, Srinivasan et al. [193] has obtained another formula for the turbulent friction factor, as follows:

$$f_c \left(\frac{R}{a} \right)^{0.5} = 0.084 \left[\text{Re} \left(\frac{R}{a} \right)^{-2} \right]^{-0.2} \quad \text{for } \text{Re} \left(\frac{R}{a} \right) < 700 \quad \text{and} \quad 7 < \frac{R}{a} < 104 \quad (5.277)$$

Either Eq. 5.276 or Eq. 5.277 can be used for design purposes since they are very similar and agree quite well (within ± 10 percent) with the experimental data for air [215] and water [216] and with the numerical predictions by Patankar et al. [217].

The friction factor for spiral coils can be obtained using the following experimental correlation [193]:

$$f_c = \frac{0.0074(n_2^{0.9} - n_1^{0.9})^{1.5}}{[\text{Re} (b/a)^{0.5}]^{0.2}} \quad (5.278)$$

Equation 5.278 is valid for $40,000 < \text{Re} (b/a)^{0.5} < 150,000$ and $7.3 < b/a < 15.5$.

Since the turbulent Nusselt numbers are independent of the thermal boundary condition for $Pr \geq 0.7$, the Nusselt numbers that appear in this section will not be specified with thermal boundary conditions.

The following correlation, developed by Schmidt [218] to calculate the turbulent Nusselt number, is suggested for $2 \times 10^4 < \text{Re} < 1.5 \times 10^5$ and $5 < R/a < 84$:

$$\frac{\text{Nu}_c}{\text{Nu}_s} = 1.0 + 3.6 \left[1 - \left(\frac{a}{R} \right) \right] \left(\frac{a}{R} \right)^{0.8} \quad (5.279)$$

Equation 5.279 was obtained using air and water flow in coils. For low Reynolds numbers, Pratt's [219] correlation is recommended:

$$\frac{\text{Nu}_c}{\text{Nu}_s} = 1 + 3.4 \frac{a}{R} \quad \text{for } 1.5 \times 10^3 < \text{Re} < 2 \times 10^4 \quad (5.280)$$

This correlation was obtained from experiments using water and isopropyl alcohol.

When the variable thermal properties of the fluid are considered, Orlov and Tselishchev [220] recommend the following correlation:

$$\frac{\text{Nu}_c}{\text{Nu}_s} = \left(1 + 3.54 \frac{a}{R} \right) \left(\frac{\text{Pr}_m}{\text{Pr}_w} \right)^{0.025} \quad \text{for } \frac{R}{a} > 6 \quad (5.281)$$

The pitch effect in helicoidal circular pipe has been considered in the investigation conducted by Yang and Ebdian [221]. These researchers have concluded that the effect of pitch is minimum on heat transfer.

Fully Developed Laminar Flow in Curved, Square, and Rectangular Ducts

The following formulas are suggested by Shah and Joshi [195] to compute the friction factor for fully developed laminar flow in curved square ducts:

$$\frac{(f \text{Re})_c}{(f \text{Re})_s} = 0.1520 \text{De}^{0.5} (1.0 - 0.216 \text{De}^{0.5} + 0.473 \text{De}^{-1} + 111.6 \text{De}^{-1.5} - 256.1 \text{De}^{-2}) \quad \text{for } \text{De} < 100 \quad (5.282)$$

$$\frac{(f \text{Re})_c}{(f \text{Re})_s} = 0.2576 \text{De}^{0.39} \quad \text{for } 100 < \text{De} < 1500 \quad (5.283)$$

$$\frac{(f \text{Re})_c}{(f \text{Re})_s} = 0.1115 \text{De}^{0.5} \quad \text{for } \text{De} > 1500 \quad (5.284)$$

The preceding three equations were obtained through the comparison of theoretical investigations [222–224] and experimental measurement [225]. The influence of the pitch of coil on the friction factor has been found to be negligible [226, 227]. Friction factors for curved rectangular ducts are provided by Cheng et al. [222], as follows:

$$\frac{f_c}{f_s} = \mathbf{C}_0 \text{De}^{*0.5} (1.0 + \mathbf{C}_1 \text{De}^{-1/2} + \mathbf{C}_2 \text{De}^{-1} + \mathbf{C}_3 \text{De}^{-3/2} + \mathbf{C}_4 \text{De}^{-2}) \quad (5.285)$$

Equation 5.284 is valid for $\text{De} \leq 700$. \mathbf{C}_0 , \mathbf{C}_1 , \mathbf{C}_2 , \mathbf{C}_3 , and \mathbf{C}_4 in Eq. 5.284 are constants given in Table 5.45 and De is defined as $\text{Re} (D_h/R)^{1/2}$.

The following correlation, obtained by Cheng et al. [228], is recommended for curved square ducts:

$$\text{Nu}_{\text{H}_2} = \text{Nu}_{\text{T}} = 0.152 + 0.627(1.414 \text{De})^{0.5} \text{Pr}^{0.25} \quad (5.286)$$

Equation 5.286 is valid for $0.7 \leq \text{Pr} \leq 5$ and $20 \leq \text{De} \leq 705$. This correlation agrees quite well with the experimental data for air for the $\textcircled{\ominus}$ boundary condition [224]. It also represents the Nusselt number for the $\textcircled{\omin�}$ boundary condition [229] quite well.

TABLE 5.45 Constants for Eq. 5.285 [222]

α^*	\mathbf{C}_0	\mathbf{C}_1	\mathbf{C}_2	\mathbf{C}_3	\mathbf{C}_4
0.5	0.0974	4.366	-13.56	131.8	-182.6
1.0	0.1278	-0.257	0.699	187.7	-512.2
2.0	0.2736	-24.79	325.2	-1591.0	2728.0
5.0	0.0805	-5.217	104.4	-202.8	0.0

It should be noted again that the effect of the wall thermal boundary condition on the Nusselt number for coils is not significant for the fluids with $Pr \geq 0.7$. Equation 5.286 can also be used for the \textcircled{T} , $\textcircled{\oplus}$, and $\textcircled{\otimes}$ thermal boundary conditions. Furthermore, the appropriate correlation for circular cross section coiled tubes can be adopted with the substitution of the appropriate hydraulic diameter for $2a$ to calculate the Nusselt number when the parameters are out of the application range as is the case in Eq. 5.286.

Fully Developed Turbulent Flow in Curved Rectangular and Square Ducts

For curved rectangular ducts as well as square ducts, when $Re^* < 8000$, the fully developed friction factors can be computed from the following correlation obtained by Butuzov et al. [230] and Kadambi [231]:

$$\frac{f_c}{f_s} = 0.435 \times 10^{-3} Re^{*0.96} \left(\frac{R}{d^*} \right)^{0.22} \quad (5.287)$$

where d^* is the short-side length of the rectangular duct and Re^* is defined as $u_m d^*/\nu$. The term f_s refers to the friction factor in a straight duct with the same aspect ratio as that of curved coil. For $Re^* \geq 8000$, Eq. 5.276 or Eq. 5.277 for circular ducts can be used with a replaced by $0.5D_h$, where D_h is the hydraulic diameter of the rectangular duct.

The Nusselt numbers for turbulent flow in curved rectangular ducts have been studied by Butuzov et al. [230] and Kadambi [231]. The correlation suggested by Butuzov et al. [230] is as follows:

$$\frac{Nu_c}{Nu_s} = 0.117 \times 10^{-2} Re^{*0.93} \left(\frac{R}{d^*} \right)^{0.24} \quad (5.288)$$

This correlation is valid for $450 \leq Re^* (R/d^*)^{0.5} \leq 7500$ and $25 \leq R/d^* \leq 164$. The term Nu_s in Eq. 5.288 is fully developed Nusselt number for a straight duct.

Laminar Flow in Coiled Annular Ducts

Xin et al. [232] experimentally investigated the laminar flow and turbulent flow in coiled annular ducts. The pressure drop was measured for air and water flows. Based on these experimental measurements, the friction factor data can be correlated for laminar and turbulent flow as follows:

$$f = 0.02985 + 75.89 \left[0.5 - a \tan \left(\frac{De - 39.88}{77.56} \right) \right] / \pi \left[\left(\frac{d_o - d_i}{D} \right)^{1.45} \right] \quad (5.289)$$

where D is coil diameter. This equation is valid in the region of $De = 35-20,000$, $d_o/d_i = 1.61-1.67$, and $D/(d_o - d_i) = 21-32$.

For the heat transfer in laminar flow in coiled annular ducts, Garimella et al. [233] experimentally obtained the following correlation to calculate the heat transfer coefficient:

$$Nu = 0.027De^{0.94} Pr^{0.69} \left(\frac{d_o - d_i}{D} \right)^{0.01} \quad (5.290)$$

This equation indeed shows that the Dean number represents the heat transfer in laminar flow; the coil ratio $(d_o - d_i)/D$ is another factor to affect the heat transfer.

Laminar Flow in Curved Ducts With Elliptic Cross Sections

Dong and Ebadian [234] numerically obtained the friction factor for laminar flow in curved elliptic ducts. The friction factor ratio f_c/f_s is represented by the following expression:

$$\frac{f_c}{f_s} = 1 + 0.0031\alpha^{*3} De^{1.07} \quad (5.291)$$

where f_s is the friction factor for straight elliptic ducts and α^* is the ratio of the minor axis to the major axis of the elliptic duct.

In subsequent research [235], thermally developing flow in curved elliptic ducts is analyzed for different α^* and Prandtl numbers. The local Nusselt numbers along the flow direction are shown in graph form, and the asymptotic values of the Nusselt numbers have been obtained, as is shown in Table 5.46. In a related study, the effects of buoyancy on laminar flow in curved elliptic ducts are discussed by Dong and Ebadian [236].

TABLE 5.46 The Asymptotic Values of the Nusselt Number for Curved Elliptic Ducts [235]

LONGITUDINAL FLOW BETWEEN CYLINDERS

Longitudinal flow between cylinders is encountered in the fuel elements of nuclear power reactors, shell-and-tube heat exchangers, boilers, and condensers, among other applications. A *cylinder* is considered to be a long circular pipe or rod. The flow and heat transfer characteristics between the cylinders are dependent on their arrangement (e.g., triangular array, square array, etc.) as well as the Reynolds number. In this section, the fully developed friction factor and Nusselt number for longitudinal flow between the cylinders in triangular and square arrays are introduced. For longitudinal flow in other channels formed by the cylinders and the walls, the reader is encouraged to refer to Shah and London [1] and Rehme [237].

Laminar Flow

The friction factor and Nusselt number for longitudinal laminar flow between a triangular array and a square array are discussed in this section.

Triangular Array. A triangular array is shown in Fig. 5.38. The fluid longitudinally flows in the virtual channel formed by the triangular array. The friction factor for fully developed laminar flow in this configuration has been proposed by Rehme [237] as follows:

$$f Re = \begin{cases} 5.1777(P/D - 1)^{0.404} & \text{for } 1.02 \leq P/D < 1.12 & (5.292) \\ 36.713(P/D - 1)^{0.24} & \text{for } 1.12 \leq P/D < 1.6 & (5.293) \\ 36.947(P/D - 1)^{0.372} & \text{for } 1.6 \leq P/D < 2.0 & (5.294) \\ \frac{16(r_*^2 - 1)^3}{4r_*^2 \ln r_* - 3r_*^4 + 4r_*^2 - 1} & \text{for } P/D > 2.1 & (5.295) \end{cases}$$

FIGURE 5.38 Fully developed $f Re$ and Nusselt numbers for longitudinal laminar flow between cylinders in a triangular array [237].

where
$$r_* = \frac{P}{D} \sqrt{\frac{2\sqrt{3}}{\pi}} \approx 1.05 \frac{P}{D} \tag{5.296}$$

Equations 5.292 through 5.295 were obtained as a result of comparison with numerous investigations such as those by Rosenberg [239], Sparrow and Loeffler [240], Axford [241, 242], Shih [243], Rehme [244, 245], Johannsen [246], Malák et al. [247], Ramachandra [238], Mikhailov [248], Subbotin et al. [249], Dwyer and Berry [250], Rehme [251], and Cheng and Todreas [252]. The $f Re$ calculated from Eqs. 5.292 through 5.294 is shown in Fig. 5.38.

The fully developed Nusselt number for longitudinal flow in a triangular array with uniform cylinder temperature has been analyzed by Ramachandra [238] and is shown in Fig. 5.38. The fully developed Nusselt numbers for the \oplus and \ominus boundary conditions have been studied by Sparrow et al. [253], Dwyer and Berry [250], Hsu [254], and Ramachandra [238]. The differences for Nu_{H1} and Nu_{H2} reported by these investigators are small (1 percent). The fully developed Nu_{H1} and Nu_{H2} are shown in Fig. 5.38.

Miyatake and Iwashita [255] conducted a numerical analysis to determine the characteristics of developing laminar flow between a triangular array of cylinders with a uniform wall temperature and various ratios of pitch to diameter (P/D). The relationships between the local Nusselt number $Nu_{x,T}$ and local Graetz number Gz_x and between the logarithmic mean Nusselt number $Nu_{m,T}$ and Graetz number Gz were obtained as follows:

for $P/D = 1.0-1.1$:
$$Nu_{x,T} = 9.26(1 + 0.0022Gz_x^{1.46})^{1/4} \tag{5.297}$$

$$Nu_{m,T} = 9.26(1 + 0.0179Gz^{1.46})^{1/4} \tag{5.298}$$

for $P/D = 1.1-4.0$
$$Nu_{x,T} = (a^2 + b^2 Gz_x^{2/3})^{1/2} \tag{5.299}$$

$$Nu_{m,T} = [a^2 + (3b/2)^2 Gz^{2/3}]^{1/2} \tag{5.300}$$

where

$$a = \frac{8.92[1 + 2.82(P/D - 1)]}{1 + 6.86(P/D - 1)^{5/3}} \quad (5.301)$$

$$b = \frac{2.34[1 + 24(P/D - 1)]}{[1 + 36.5(P/D - 1)^{5/4}][2\sqrt{3}(P/D - 1)^2 - \pi]^{1/3}} \quad (5.302)$$

$$Gz_x = \dot{m}c_p/kx \quad (5.303)$$

$$Gz = \dot{m}c_p/kL \quad (5.304)$$

$$Nu_{x,T} = h_x D/k \quad (5.305)$$

$$Nu_{lm,T} = h_m D/k = \frac{\dot{m}c_p(T_b - T_0)_{x=L}}{\pi L \Delta T_{lm}} \quad (5.306)$$

$$\Delta T_{lm} = \frac{(T_w - T_0)(T_w - T_b)_{x=L}}{\ln [(T_w - T_0)/(T_w - T_b)_{x=L}]} \quad (5.307)$$

In Eqs. 5.306 and 5.307, T_0 , T_w , and T_b are the inlet, wall, and fluid bulk temperatures, respectively; L is the length of the cylinder. It is noted that the fully developed Nusselt number can be calculated using $Gz \rightarrow 0$ ($L \rightarrow \infty$) in the corresponding equations.

In the study of Miyatake and Iwashita [256], the relationship of local Nusselt number and Graetz number is formulated for developing longitudinal flow between a triangular array of cylinders with a uniform heat flux and various pitch-to-diameter ratios. For $P/D = 1.01$ – 1.1 :

$$Nu_{x,H2} = \frac{b Gz_x^{1/3} - a}{1 + 451 Gz_x^{-[15.4P/D - 14.937]}} + 1 \quad \text{when } Gz_x \geq (ab)^3 \quad (5.308)$$

$$Nu_{x,H2} = a; \quad \text{when } Gz_x < (ab)^3 \quad (5.309)$$

For $P/D = 1.1$ – 4.0 :

$$Nu_{x,H2} = (a^2 + b^2 Gz_x^{2/3})^{1/2} \quad (5.310)$$

where

$$a = \frac{3.1(P/D - 1)^{0.1} + 324(P/D - 1)^{1.6}}{1 + 69.5(P/D - 1)^{2.4}} \quad (5.311)$$

$$b = \frac{1.536[1 + 8.24(P/D - 1)^{0.39}]}{[2\sqrt{3}(P/D - 1)^2 - \pi]^{1/3}[1 + 6.37(P/D - 1)^{0.73}]} \quad (5.311)$$

Square Array. A square array is displayed in Fig. 5.39. The fully developed friction factor for longitudinal flow in such a virtual channel has been investigated by Sparrow and Loeffler [240], Shih [243], Rehme [244, 245], Malák et al. [247], Meyder [257], Kim [258], Ramachandra [238], and Ohnemus [259]. The $f Re$ is given in Fig. 5.39. It can be approximated by the following equation [237]:

$$f Re = 40.70 \left(\frac{P}{D} - 1 \right)^{0.435} \quad (5.312)$$

Equation 5.312 is valid in the range of $1.05 \leq P/D \leq 2.0$.

The fully developed Nusselt numbers for the \textcircled{H} and \textcircled{B} boundary conditions in square arrays have been analyzed by Kim [258], Ramachandra [238], Ohnemus [259], and Chen et al. [260]. The fully developed Nu_{H1} and Nu_{H2} are shown in Fig. 5.39.

Miyatake and Iwashita [255] also investigated the developing longitudinal laminar flow between a square array of cylinders with uniform wall temperature. The local and logarithmic Nusselt number can be obtained using the following correlations:

FIGURE 5.39 Fully developed $f Re$ and Nusselt numbers for longitudinal laminar flow in a square array [237].

For $P/D = 1.0-1.2$:
$$Nu_{x,T} = 4.08(1 + 0.0058Gz_x^{1.46})^{1/4} \tag{5.313}$$

$$Nu_{m,T} = 4.08(1 + 0.0349Gz_x^{1.46})^{1/4} \tag{5.314}$$

For $P/D = 1.2-4.0$, the same equations as Eqs. 5.299 and 5.300 are used, but the a and b are different:

$$a = \frac{4.00[1 + 0.509(P/D - 1)]}{1 + 0.765(P/D - 1)^{5/3}} \tag{5.315}$$

$$b = \frac{1.69[1 + 9.1(P/D - 1)]}{[1 + 10.8(P/D - 1)^{5/4}][4(P/D - 1)^2 - 2]^{1/3}} \tag{5.316}$$

For developing longitudinal laminar flow between a square array of cylinders with a uniform wall heat flux, the local Nusselt number correlations were made by Miyatake and Iwashita [256] as follows:

For $P/D = 1.01-1.2$:
$$Nu_{x,H2} = \frac{b Gz_x^{1/3} - a}{1 + 94Gz_x^{-[7.66P/D - 7.379]}} + a \quad \text{when } Gz_x \geq (ab)^3 \tag{5.317}$$

$$Nu_{x,H2} = a \quad \text{when } Gz_x < (ab)^3 \tag{5.318}$$

For $P/D = 1.2-4.0$:
$$Nu_{x,H2} = (a^2 + b^2 Gz_x^{2/3})^{1/2} \tag{5.319}$$

where

$$a = \frac{3.6(P/D - 1)^{0.2} + 32.2(P/D - 1)^{1.5}}{1 + 9.1(P/D - 1)^{2.2}} \quad (5.320)$$

$$b = \frac{1.224[1 + 4.40(P/D - 1)^{0.39}]}{[4(P/D - 1)^2 - \pi]^{1/3}[1 + 2.66(P/D - 1)^{0.73}]} \quad (5.321)$$

Fully Developed Turbulent Flow

Fully developed turbulent flow and heat transfer in triangular and square arrays have been analyzed by Deissler and Taylor [261, 262]. The friction factors for longitudinal flow between the cylinders in a triangular and a square array are given in Fig. 5.40. Correspondingly, the Nusselt numbers, in terms of the Stanton number, defined as $Nu/(Re Pr)$, are given in Fig. 5.41, where the cylinders are considered to be uniformly heated.

FIGURE 5.40 Fully developed friction factor for longitudinal turbulent flow between a triangular and a rectangular array [261].

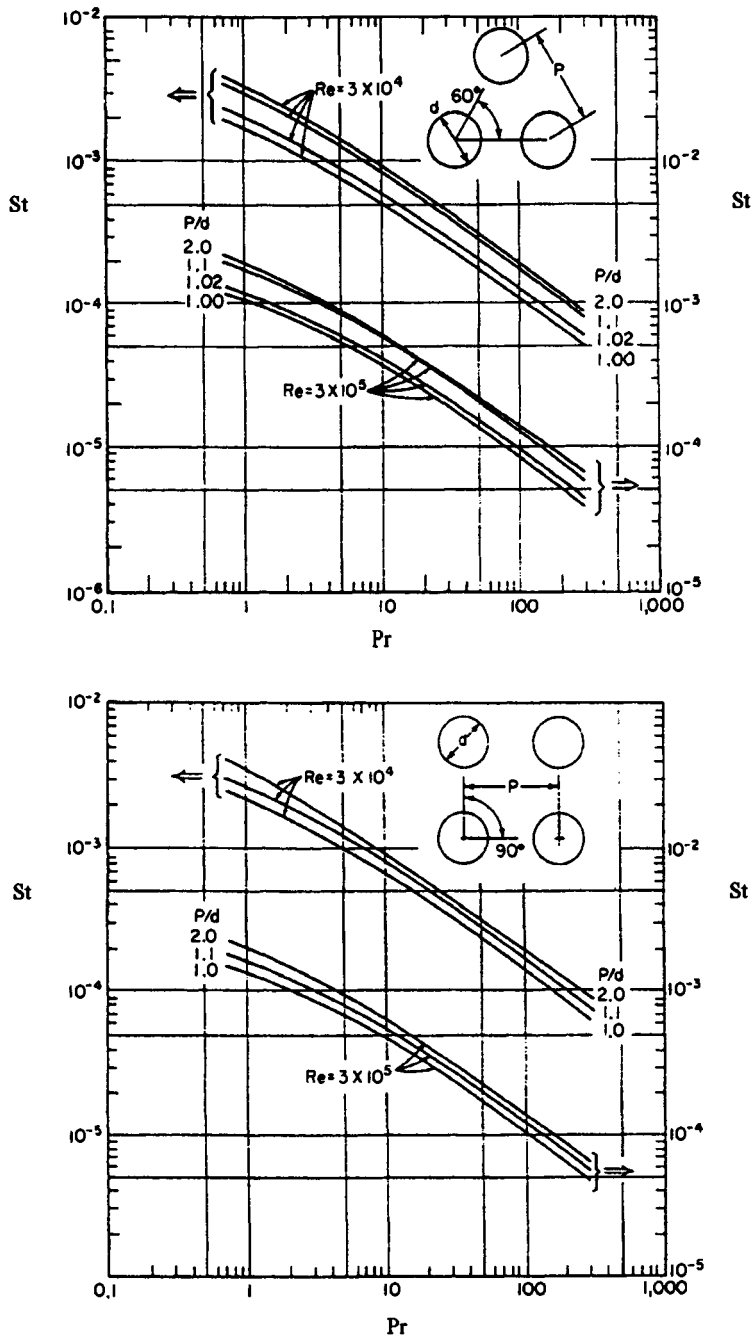

FIGURE 5.41 Fully developed heat transfer characteristics for longitudinal turbulent flow between a triangular array and a square array [261].

FIGURE 5.42 Nusselt numbers for fully developed longitudinal flow between cylinders in a triangular array [263].

Maresca and Dwyer [264] have analyzed the heat transfer of liquid metal flow in a triangular array with uniform longitudinal heat flux. The Nusselt number resulting from their analysis is given in Fig. 5.42.

INTERNALLY FINNED TUBES

Internally finned tubes are ducts with internal longitudinal fins. These tubes are widely used in compact heat exchangers. The friction factor–Reynolds number product and the Nusselt number for such internally finned tubes, designated as $(f Re)_d$ and $Nu_{bc,d}$, respectively, are computed from the following definitions:

$$f_d = \Delta p^* \left(\frac{D_{h,finless}}{4L} \right) = \left(\frac{\rho \Delta p}{2LW^2} \right) (A_c^2 D_h)_{finless} \quad (5.322)$$

$$Re_d = \frac{GD_{h,finless}}{\mu} = \left(\frac{u_m}{\mu} \right) \left(\frac{D_h}{A_c} \right)_{finless} \quad (5.323)$$

$$Nu_{bc,d} = \frac{q'' D_{h,finless}}{k(t_w - t_m)} = \frac{q'}{4k(t_w - t_m)} \left(\frac{D_h^2}{A_c} \right)_{finless} \quad (5.324)$$

where $D_{h,finless}$ is the hydraulic diameter corresponding to finless ducts. Based on actual geometry, the $D_{h,finned}$ is used in the $f Re$ and Nu_{bc} . The relationships between $(f Re)_d$, $Nu_{bc,d}$, and $f Re$, Nu_{bc} are given in the following expressions:

$$(f Re)_d = (f Re) \left(\frac{D_{h,finless}}{D_{h,finned}} \right)^2 \left(\frac{A_{c,finless}}{A_{c,finned}} \right) \quad (5.325)$$

$$Nu_{bc,d} = Nu_{bc} \left(\frac{D_{h,finless}}{D_{h,finned}} \right)^2 \left(\frac{A_{c,finned}}{A_{c,finless}} \right) \quad (5.326)$$

Circular Ducts With Thin Longitudinal Fins

Hu and Chang [265] have obtained the friction factors and Nusselt numbers for fully developed laminar flow through a circular duct having longitudinal rectangular fins equally spaced along the wall. The fin's efficiency was treated as 100 percent, while its thickness was treated as zero. The fully developed $(f Re)_d$ and $Nu_{H2,d}$ for laminar flow in a circular duct with longitudinal fins are given in Table 5.47, in which l^* and n are relative fin length and the number of fins, respectively.

Prakash and Liu [266] have numerically analyzed laminar flow and heat transfer in the entrance region of an internally finned circular duct. In this study, the fully developed $f Re$ is compared with those reported by Hu and Chang [265] and Masliyah and Nandakumar [267]. The incremental pressure drop $K(\infty)$ and hydrodynamic entrance length L_{hy}^+ together with $f Re$ are given in Table 5.48, in which the term n refers to the number of fins, while l^* denotes the relative length of the fins.

The fully developed Nusselt numbers for the thermal boundary conditions of uniform wall temperature and axial uniform wall heat flux with circumferential uniform temperature obtained by Prakash and Liu [266] are given in Table 5.49, along with the corresponding thermal entrance lengths. The term n in Table 5.49 denotes the number of fins, whereas l^* represents the relative length of the fins.

Square Ducts With Thin Longitudinal Fins

Gangal and Aggarwala [268] have analytically obtained the fRe and Nu_{HI} for fully developed flow in a square duct with four equal internal fins, as that shown in Fig. 5.43. The fins were treated as having zero thickness and 100 percent efficiency. The results of fRe and $Nu_{HI,d}$ for fully developed flow are provided in Table 5.50.

Rectangular Ducts With Longitudinal Thin Fins from Opposite Walls

The fully developed $(fRe)_d$ and $Nu_{HI,d}$ for rectangular ducts with two fins and four fins on opposite walls have been obtained by Aggarwala and Gangal [269] and Gangal [270]. These are shown in Fig. 5.44.

Circular Ducts With Longitudinal Triangular Fins

Nandakumar and Masliyah [271] and Masliyah and Nandakumar [267] have analyzed fully developed laminar flow in a circular duct with equally spaced triangular fins, as shown in the inset in Fig. 5.45. The flow area and wetted perimeter for this type of duct are given by

$$A_{c,finned} = \pi a^2 - n[a^2\phi - a(a-l)\sin\phi] \quad (5.327)$$

$$P_{finned} = 2\pi a + 2nl' - 2n\phi a \quad (5.328)$$

FIGURE 5.44 Friction factor and Nusselt number for fully developed laminar flow in rectangular ducts with longitudinal thin fins from opposite walls [1].

$$l' = [a^2 + (a - l)^2 - 2a(a - l) \cos \phi]^{1/2} \quad (5.329)$$

The hydraulic diameter can be calculated from $D_{h,finned} = 4(A_c/P)_{finned}$. The results of $(fRe)_d$ and $Nu_{HL,d}$ are provided and Figs. 5.45 and 5.46, in which the case of $2\phi = 0^\circ$ represents longitudinal fins of zero thickness.

Circular Ducts With Twisted Tape

The enhancement of heat transfer inside a circular duct is often achieved by inserting a thin, metal tape in such a way that the tape is twisted about its longitudinal axis, as indicated in Fig. 5.47. Swirl flow is created in this manner. The width of the tape is usually the same as the internal diameter of the duct. The tape twist ratio X_L is defined as H/d . When X_L approaches infinity, the circular straight duct with the twisted tape becomes two semicircular straight ducts separated by the tape.

Manglik and Bergles [272, 273] made an extensive review on the study of laminar and turbulent flow in circular ducts with inserted tape. For laminar flow, the dimensional swirl parameter Sw was incorporated in the correlation of friction factor. This parameter considers the thickness of inserted tape δ ,

FIGURE 5.45 Friction factors for fully developed laminar flow in a circular duct with longitudinal triangular fins [1].

FIGURE 5.46 Nusselt numbers for fully developed laminar flow in a circular duct with longitudinal triangular fins [1].

FIGURE 5.47 A circular tube with a twisted tape inserted [1].

the twist ratio X_L , and the helicoidally twisting flow velocity. The definition of dimensional swirl parameter Sw is given as:

$$Sw = Re_{sw} / \sqrt{X_L} \left(\frac{\pi}{\pi - 4\delta/d} \right) \left(1 + \frac{\pi^2}{4X_L^2} \right) \quad (5.330)$$

For most applications, the following equation is recommended for the calculation of friction factor in laminar flow in circular ducts with inserted tape:

$$f Re = 15.767\pi \left(\pi + 2 - \frac{2\delta}{d} \right)^2 \left(\pi - 4 \frac{\delta}{d} \right)^{-3} \left(1 + \frac{\pi}{2X_L} \right) (1 + 10^{-6} Sw^{2.55})^{1/6} \quad (5.331)$$

where $f Re$ is based on the empty tube diameter d . The above equation can be applied in the range $0 < (\delta/d) < 0.1$ and $300 \leq Sw \leq 1400$.

The mean Nusselt number for the laminar flow in isothermal circular ducts with inserted tape can be obtained from the following equation suggested by Manglik and Bergles [272]:

$$Nu_m = 4.612 \left[\left((1 + 0.0951 Gz^{0.894})^{2.5} + 6.413 \times 10^{-9} (Sw \cdot Pr^{0.391})^{3.853} \right)^{0.2} + 2.132 \times 10^{-14} (Re_{ax} \cdot Ra)^{2.23} \right]^{0.1} \left(\frac{\mu_m}{\mu_w} \right)^{0.14} \quad (5.332)$$

Where Gz , Re_{ax} , and Ra are the Graetz number, the Reynolds number based on axial velocity, and the Rayleigh number, respectively. Their definitions are expressed as follows:

$$Gz = mc_p / KL \quad (5.333)$$

$$Re_{ax} = \frac{m\mu}{\pi d/4 - \delta\lambda} \quad (5.334)$$

$$Ra = \frac{\rho g d^3 \beta \Delta T w}{\mu a} \quad (5.335)$$

For the turbulent flow in circular duct with inserted tape, it was proposed by Manglik and Bergles [273] that the friction factor can be calculated by the following equation:

$$f = \frac{0.0791}{Re^{0.25}} \left(\frac{\pi}{\pi - 4\delta/d} \right)^{1.75} \left(1 + \frac{2.752}{X_L^{1.29}} \right) \quad (5.336)$$

It was found that the flow rates with $Re \geq 10^4$ can be considered as fully developed turbulent flow. Therefore, the above equation is a more generalized correlation that covers a broad database of available empirical data for turbulent flow [273].

A generalized correlation of mean Nusselt number for turbulent heat transfer in an isothermal circular duct with inserted tape was developed by Manglik and Bergles [273] based on the experimental data. It is expressed as:

$$Nu = 0.023(1 + 0.769/X_L) Re^{0.8} Pr^{0.4} \left(\frac{\pi}{\pi - 4\delta/d} \right)^{0.8} \left(\frac{\pi + 2 + 2\delta/d}{\pi - 4\delta/d} \right)^{0.2} \phi \quad (5.337)$$

where
$$\phi = \left(\frac{\mu_m}{\mu_w} \right)^n \text{ or } \left(\frac{T_m}{T_w} \right)^m \quad (5.338)$$

n = 0.18 for liquid heating and 0.30 for liquid cooling; *m* = 0.45 for gas heating and 0.15 for gas cooling.

Semicircular Ducts With Internal Fins

Dong and Ebdian [274] have used a very fine grid to perform a numerical analysis of fully developed laminar flow in a semicircular duct with internal longitudinal fins. The fins are considered to have zero thickness, and the number of fins *n* and relative fin length $l^* = l/a$ are taken into account. The \oplus thermal boundary condition is applied. Their results are given in Table 5.51.

FIGURE 5.48 An elliptical duct with internal fins.

Elliptical Ducts With Internal Longitudinal Fins

An elliptical duct with four internal longitudinal fins mounted on the major and minor axes, as shown in Fig. 5.48, has been analyzed by Dong and Ebdian [275] for fully developed laminar flow and heat transfer. In this analysis, the fins are considered to have zero thickness. The \oplus thermal boundary condition is applied to the duct wall, and l^* is defined as a ratio of $H_a/a = H_b/b$. The friction factors and Nusselt numbers for fully developed laminar flow are given in Table 5.52.

OTHER SINGLY CONNECTED DUCTS**FIGURE 5.49** A sine duct.

The fluid flow and heat transfer characteristics for 14 types of singly connected ducts are described in this section.

Sine Ducts

A sine duct with associated coordinates is shown in Fig. 5.49. The characteristics of fully developed laminar flow and heat transfer in such a duct are given in Table 5.53. These results are based on the analysis by Shah [172].

Trapezoidal Ducts

A trapezoidal duct is displayed in the inset of Fig. 5.50. Fully developed laminar flow and the heat transfer characteristics of trapezoidal ducts have been analyzed by Shah [172]. The fully developed $f Re$, Nu_{H1} , and Nu_{H2} are given in Figs. 5.50 and 5.51. Farhanieh and Sunden [276] numerically investigated the laminar flow and heat transfer in the entrance region of trapezoidal ducts. The fully developed values of $f Re$, $K(\infty)$, and Nu were in accordance with the results from Shah [172].

FIGURE 5.50 Fully developed $f Re$ and $K(\infty)$ for laminar flow in a trapezoidal duct [172].

FIGURE 5.51 Fully developed Nusselt numbers for laminar flow in a trapezoidal pipe [172].

Chiranjivi and Rao [277] experimentally obtained a correlation for laminar and turbulent flow in trapezoidal ducts with one side heated, which is expressed as:

$$Nu = a Re^b Pr^{0.52} \left(\frac{\mu_w}{\mu} \right) \quad (5.339)$$

where $a = 6.27$ and $b = 0.14$ for laminar flow, and $a = 0.79$ and $b = 0.4$ for turbulent flow of Reynolds number from 3000 to 15,000.

FIGURE 5.52 A rhombic duct.

Rhombic Ducts

A rhombic duct is depicted in Fig. 5.52. The fully developed flow and heat transfer characteristics of rhombic ducts obtained by Shah [172] are shown in Table 5.54.

FIGURE 5.53 A schematic drawing of a quadrilateral duct.

Quadrilateral Ducts

A quadrilateral duct is shown schematically in Fig. 5.53. Nakamura et al. [278] analyzed fully developed laminar flow and heat transfer in arbitrary polygonal ducts. Their results are presented in Table 5.55.

Regular Polygonal Ducts

Fully developed flow and heat transfer in a regular polygonal duct with n equal sides, each subtending an angle of $360^\circ/n$ at the duct center, have been reviewed by Shah and London [1]. The fRe and Nu are given in Table 5.56.

For practical calculations, Schenkel [279] proposed the following formula to compute the $f Re$ in regular polygonal ducts:

$$f Re = 16 \left(\frac{n^2}{0.44 + n^2} \right)^4 \quad (5.340)$$

The values of the predictions from Eq. 5.337 agree well (within ± 1 percent) with the tabulated values in Table 5.56.

FIGURE 5.54 A circular sector duct.

Circular Sector Ducts

A schematic drawing of a circular sector duct is presented in Fig. 5.54. The fully developed $f Re$ and Nu for circular sector ducts have been obtained by Eckert and Irvine [280], Sparrow and Haji-Sheikh [174], Hu and Chang [265], and Ben-Ali et al. [281]. The results are summarized in Table 5.57.

Soliman et al. [282] numerically analyzed the problem of laminar flow development in circular sector ducts. Their $f_{app} Re$ and L_{hy}^* results for $2\phi = 11.25, 22.5, 45,$ and 90° are presented in Table 5.58. Furthermore, the hydrodynamic entrance lengths are 0.235, 0.144, 0.108, and 0.0786 for hydrodynamically developing flow in circular sector ducts with $2\phi = 11.25, 22.5, 45,$ and 90° , respectively.

FIGURE 5.55 A circular segment duct.

Circular Segment Ducts

A circular segment duct is depicted in Fig. 5.55. The fully developed flow and heat transfer characteristics obtained by Sparrow and Haji-Sheikh [283] are given in Table 5.59.

Hong and Bergles [284] have analyzed the thermal entrance solution of heat transfer for a circular segment duct with $2\phi = 180^\circ$ (i.e., a semicircular duct). Two kinds of thermal boundary conditions are used: (1) a constant wall heat flux along the axial flow direction with a constant wall temperature along the duct circumference, and (2) a constant wall heat flux along the axial flow direction and a constant wall temperature along the semicircular arc, with zero heat

flux along the diameter. The local Nusselt numbers for these two boundary conditions are presented in Table 5.60. The terms BC1 and BC2 in Table 5.60 refer to the previously mentioned first and second boundary conditions.

Annular Sector Ducts

An annular sector duct is displayed in the inset of Fig. 5.56. Shah and London [1] have calculated the $f Re$ value to a high degree of accuracy using the analytical solution proposed by Sparrow et al. [285]. The results of $f Re$ are presented in Fig. 5.56.

FIGURE 5.56 Fully developed friction factor for laminar flow in an annular sector duct [1].

Schenkel [279] has developed the following approximate equation for $f Re$ in an annular sector duct:

$$f Re = \frac{24}{\left[1 - \frac{0.63}{\phi} \left(\frac{1-r^*}{1+r^*}\right)\right] \left[1 + \frac{1}{\phi} \left(\frac{1-r^*}{1+r^*}\right)\right]^2} \quad (5.341)$$

This equation is valid for $\phi \geq \phi_{\min}(r^*)$. The values of ϕ_{\min} for $r^* = 0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8,$ and 0.9 are $60^\circ, 50^\circ, 42^\circ, 35^\circ, 28.5^\circ, 22.5^\circ, 17.5^\circ, 13^\circ, 8.5^\circ,$ and 4° , respectively. For $\phi \geq \phi_{\min}(r^*)$, the predictions of Eq. 5.341 are in excellent accord with the results presented in Fig. 5.56.

Ben-Ali et al. [281] and Soliman [286] have investigated fully developed flow and heat transfer in annular sector ducts with the \textcircled{T} , \textcircled{H} , and \textcircled{B} boundary conditions. The Nusselt numbers obtained by those investigators can be found in Table 5.61.

Simultaneously developing flow in annular sector ducts for air ($Pr = 0.7$) has been analyzed by Renzoni and Prakash [287]. In their analysis, the outer curved wall is treated as adiabatic, and the \textcircled{H} boundary condition is imposed on the inner curved wall as well as on the two straight walls of the sector. The fully developed friction factors, incremental pressure drop numbers, hydrodynamic entrance lengths, and thermal entrance lengths are presented in Table 5.62. The term L_{hy}^+ used in Table 5.62 is defined as the dimensionless axial distance at which $f_{app} Re = 1.05 f Re$. The fully developed Nusselt numbers are represented by Nu_{fd} in order not to confuse the reader since the thermal boundary condition applied in Renzoni and Prakash [287] is different from those defined in the section.

Stadium-Shaped Ducts

A stadium-shaped duct and a modified stadium-shaped duct are displayed in the insets of Fig. 5.57. Zarling [288] has obtained the $f Re$ and Nu_{HI} for fully developed laminar flow in stadium-shaped ducts. Cheng and Jamil [289] have determined the $f Re$ and Nu for the mod-

ified stadium-shaped ducts. The $f Re$ and Nu_{H1} for fully developed laminar flow in rectangular ducts are also included for the purpose of comparison.

FIGURE 5.58 A moon-shaped duct.

Moon-Shaped Ducts

A moon-shaped duct is depicted in Fig. 5.58. Shah and London [1] have determined the fully developed $f Re$ and the velocity profile for moon-shaped ducts. These follow:

$$u = \frac{c_1}{4} (r^2 - b^2) \left(1 - \frac{2a \cos \theta}{r} \right) \quad (5.342)$$

$$f Re = - \frac{c_1 D_h^2}{2u_m} \quad (5.343)$$

where
$$D_h = 2a \left[\frac{(2 - \alpha^{*2})\phi + \sin 2\phi}{(2 + \alpha^*)\phi} \right] \quad (5.344)$$

$$u_m = \frac{c_1 a^2}{4} \frac{(\frac{1}{2}\alpha^{*4} + 2\alpha^{*2} - 1)\phi - \frac{8}{3}\alpha^{*3} \sin \phi + (\alpha^{*2} - \frac{2}{3}) \sin 2\phi - \frac{1}{12} \sin 4\phi}{(2 - \alpha^{*2})\phi + \sin 2\phi} \quad (5.345)$$

In the preceding equations, $\alpha^* = b/a$ and $c_1 = \mu dp/dx$.

Corrugated Ducts

Three corrugated ducts are schematically shown in the insets of Fig. 5.59. Hu and Chang [265] have analyzed the $f Re$ for fully developed laminar flow in circumferentially corrugated circular ducts with n sinusoidal corrugations over the circumference as shown in Fig. 5.59, inset a , for $e^* = e/a = 0.06$. The perimeter and hydraulic diameter of these ducts must be evaluated numerically. However, their free flow area A_c is given by $A_c = \pi \alpha^2 (1 + 0.5e^2)$.

The $f Re$, Nu_{H1} , and Nu_{H2} values determined by Hu and Chang [265] for circumferentially corrugated circular ducts with sinusoidal corrugations are presented in Table 5.63 as functions

FIGURE 5.59 Fully developed friction factors for circumferentially corrugated circular ducts [2].

of n and e^* , which are defined in Fig. 5.59. Angle 2ϕ in Fig. 5.59 is related to n simply as $2\phi = 360^\circ/n$.

Schenkel [279] has determined the fully developed friction factors for circular ducts with semicircular corrugations, as that shown in Fig. 5.59, inset *b*. For this kind of duct,

$$A_c = \pi a^2 \frac{\sin \phi}{\phi} \left[\frac{\pi}{2} \sin \phi + \cos \phi \right], \quad P = \pi^2 a \frac{\sin \phi}{\phi} \tag{5.346}$$

	0.06	12.872	3.231	3.219	0.8583

The radius of the semicircular corrugation is $a \sin \phi$. The $f Re$ values for ducts with semicircular corrugations can be determined using the following expression given by Schenkel [279]:

$$f Re = 6.4537 + 0.8350\phi - 3.6909 \times 10^{-2}\phi^2 + 8.6674 \times 10^{-4}\phi^3 - 1.0588 \times 10^{-5}\phi^4 + 6.2094 \times 10^{-8}\phi^5 - 1.3261 \times 10^{-4}\phi^6 \quad (5.347)$$

where ϕ is in degrees. Equation 5.347 is valid for $0 \leq 2\phi \leq 180^\circ$. When $2\phi = 180$, this geometry reduces to a circular duct. The prediction of $f Re = 16$ was obtained from Eq. 5.347 for circular ducts.

Schenkel [279] has also determined the fully developed friction factors for laminar flow in circular ducts having triangular corrugations with an angle of 60° , as shown in Fig. 5.59, inset c. For this type of duct, the cross section of the fluid flow area A_c and wetted perimeter P can be calculated as follows:

$$A_c = \pi a^2 \frac{\cos \phi + \sqrt{3} \sin \phi}{\phi}, \quad P = 4\pi a \frac{\sin \phi}{\phi} \quad (5.348)$$

The $f Re$ values for ducts with triangular corrugations can be obtained with the following expression [279]:

$$f Re = 3.8952 + 0.3692\phi - 3.2483 \times 10^{-3}\phi^2 - 3.3187 \times 10^{-5}\phi^3 + 4.5962 \times 10^{-7}\phi^4 \quad (5.349)$$

where ϕ is in degrees. Equation 5.349 is valid for $0 \leq 2\phi \leq 120^\circ$.

A comparison of $f Re$ for these three types of corrugated ducts with $e^* = 0.06$ is displayed in Fig. 5.59.

Parallel Plate Ducts With Spanwise Periodic Corrugations at One Wall

Two types of corrugations (triangular and rectangular) in parallel plate ducts are displayed in the insets of Figs. 5.60 and 5.61, respectively. Sparrow and Charmchi [290] have obtained the solutions for fully developed laminar flow in these ducts. The flow in the duct is considered to be perpendicular to the plane of the paper. Both ducts are assumed to be infinite in the span-

FIGURE 5.60 Fully developed friction factors and Nusselt numbers for flat ducts with spanwise-periodic triangular corrugations at one wall [290].

FIGURE 5.61 Fully developed friction factors and Nusselt numbers for flat ducts with spanwise-periodic rectangular corrugations at one wall [291].

wise direction; therefore, the end effects due to the short bounding walls are neglected. The corrugated wall is subjected to the \textcircled{H} thermal boundary condition, while the flat wall is considered to be adiabatic.

The cross-sectional area and perimeter of a flat duct with spanwise triangular corrugation can be found by:

$$A_c = n(b^2 - a^2) \tan \phi, \quad P = 2n(b - a) \frac{1 + \sin \phi}{1 + \cos \phi} \quad (5.350)$$

where n represents the number of triangular corrugations and 2ϕ is the angle of the top vertex of the triangle.

The fully developed $f Re$ and Nu_{HI} values obtained by Sparrow and Charmchi [290] are shown in Fig. 5.60, which is taken from Shah and Bhatti [2]. If $a/b = 0$, the duct with triangular corrugations reduces to an array of isosceles triangles. The $f Re$ and Nu_{HI} values from Fig. 5.60 agree well with the values obtained from the corresponding figures in the section concerning triangular ducts.

Fully developed laminar flow and heat transfer in a parallel plate duct with spanwise-periodic rectangular corrugations at one wall have been investigated by Sparrow and Chukaev [291]. The end effect is also ignored in their analysis. The fully developed $f Re$ is shown in Fig. 5.61, which is based on the results reported by Sparrow and Chukaev [291] and the extension by Shah and Bhatti [2]. The heat transfer characteristics for the three pairs of geometric parameters can be found in Sparrow and Chukaev [291].

Cusped Ducts

A *cusped duct*, also referred to as a *star-shaped duct*, such as the one shown in Fig. 5.62, is made up of concave circular arcs. The fully developed $f Re$, Nu_{HI} , and Nu_T , in laminar flow are given in Table 5.64, in which n is the number of the concave circular arcs in the cusped ducts. The values for $f Re$, Nu_T , and Nu_{HI} are taken from Shah and London [1], Dong et al. [292], and

TABLE 5.64 Fully Developed $f Re$, Nu_T , and Nu_{HI} for Laminar Flow in Cusped Ducts

FIGURE 5.62 A cusped duct with four concave walls.

FIGURE 5.63 A cardioid duct.

Dong and Ebdian [293]. An analysis of thermally developing laminar flow in cusped ducts can be found in Dong et al. [292].

Cardioid Ducts

A cardioid duct is shown in Fig. 5.63. Fully developed laminar flow and heat transfer under the $\textcircled{\ominus}$ boundary condition have been analyzed by Tyagi [294]. The $f Re$ and Nu_{HI} values derived from this analysis are 5.675 and 4.208, respectively. The Nusselt number for the $\textcircled{\oplus}$ thermal boundary condition was found to be 4.097 [1].

Unusual Singly Connected Ducts

For the fully developed friction factors for laminar flow in unusual singly connected ducts, interested readers are encouraged to consult Shah and Bhatti [2].

OTHER DOUBLY CONNECTED DUCTS

Fully developed laminar flow and heat transfer in several doubly connected ducts are discussed in the following sections.

Confocal Elliptical Ducts

A confocal elliptical duct is shown in Fig. 5.64. According to the analysis by Topakoglu and Arnas [295], the friction factor for fully developed laminar flow in confocal elliptical ducts can be computed by

$$f Re = \frac{256A_c^3}{\pi I_{oo} P^2 (a_o + b_o)^4} \tag{5.351}$$

where
$$I_{oo} = \frac{1}{4} (1 - \omega^4) \left(1 + \frac{m^8}{\omega^4} \right) - 2m^4 \frac{1 - \omega^2}{1 + \omega^2} + \frac{1}{4 \ln \omega} (1 - \omega^2)^2 \left(1 - \frac{m^4}{\omega^2} \right)^2 \tag{5.352}$$

FIGURE 5.64 A confocal elliptical duct.

$$\frac{A_c}{(a_o + b_o)^2} = \frac{\pi}{4} (1 - \omega^2) \left(1 + \frac{m^4}{\omega^2} \right) \tag{5.353}$$

$$\frac{P}{a_o + b_o} = 2 \left[(1 + m^2) E_1 + \left(1 + \frac{m^2}{\omega^2} \right) \omega E_\omega \right] \tag{5.354}$$

$$\omega = \left(\frac{a_i + b_i}{a_o + b_o} \right) = \frac{\alpha^* r^* + [1 - \alpha^{*2} (1 - r^*)^2]^{1/2}}{1 + \alpha^*} \tag{5.355}$$

$$m = \left(\frac{1 - \alpha^*}{1 + \alpha^*} \right)^{1/2}, \quad \alpha^* = \frac{b_o}{a_o}, \quad r^* = \frac{b_i}{b_o} \tag{5.356}$$

E_1 and E_ω are the complete elliptical integrals of the second kind. These are evaluated using the arguments $1 - b_o^2/a_o^2$ and $1 - b_i^2/a_i^2$, respectively. In addition, b_i/a_i is related to ω and m by means of the following:

$$\frac{b_i}{a_i} = \frac{1 - (m^2/\omega^2)}{1 + (m^2/\omega^2)} \tag{5.357}$$

The fully developed Nusselt numbers Nu_{H1} determined from the analysis of Topakoglu and Arnas [295], together with the $f Re$ calculated from Eq. 5.351, are displayed in Table 5.65.

Regular Polygonal Ducts With Centered Circular Cores

The product of fully developed friction factor and Reynolds number in laminar flow $f Re$ obtained by Ratkowsky and Epstein [296] for polygonal ducts with centered circular cores (see the inset in Fig. 5.65) are shown in Fig. 5.65. The fully developed Nu_{H1} obtained by Cheng and Jamil [297] are given in Fig. 5.66. It can be observed that as $n \rightarrow \infty$, the value of $f Re$ approaches 6.222 for $\alpha^* = 1$ (annular duct); $f Re$ approaches 16 for $\alpha^* = 0$ (circular duct).

Circular Ducts With Centered Regular Polygonal Cores

nal cores (see inset in Fig. 5.65) is shown in Fig. 5.65. Corresponding fully developed Nu_{HI} obtained by Cheng and Jamil [289] are depicted in Fig. 5.66. The $f Re$ and Nu_{HI} for concentric circular annular ducts are shown in Figs. 5.65 and 5.66 for the purpose of comparison.

Isosceles Triangular Ducts With Inscribed Circular Cores

An isosceles triangular duct with an inscribed circular core is shown in Fig. 5.67. The $f Re$ obtained for fully developed laminar flow in such a duct by Bowen [299] can be expressed in terms of ϕ , as follows:

$$f Re = 12.0000 - 0.1605\phi + 4.2883 \times 10^{-3}\phi^2 - 1.0566 \times 10^{-4}\phi^3 + 1.6251 \times 10^{-6}\phi^4 - 1.04821 \times 10^{-8}\phi^5 \quad (5.358)$$

where ϕ is in degrees.

Elliptical Ducts With Centered Circular Cores

For elliptical ducts with centered circular cores, fully developed laminar flow has been analyzed by Shivakumar [300]. The $f Re$ values are given in Table 5.66, in which α^* denotes the ratio of the length of the minor axis to the length of the major axis of the ellipse and r^* is the ratio of the diameter of the circular core to the length of the minor axis.

CONCLUDING REMARKS

This chapter discusses forced convection in various ducts. The formulas, correlations, equations, tables, and figures included in this chapter are given for the purpose of practical calculations. However, the following effects are not considered: a detailed discussion of heat source and dissipation effects, non-newtonian fluids, varying thermal property effects, porous wall ducts, unsteady-state effects, rotating ducts, combined radiation, and convection. The interested reader can consult Kays and Perkins [263] and Kakaç, Shah, and Aung [301] for further information regarding these effects.

NOMENCLATURE

- A_c flow cross-sectional area, m^2
- a radius of a circular duct, m; half-length of major axis of an elliptic duct, m; half-length of the width of a rectangular duct, m

Bi	Biot number = $h_e D_h / k$
Br	Brinkmann number for the \textcircled{T} boundary condition, = $\mu u_m^2 / k (T_{w,m} - T_e)$
Br'	Brinkmann number for the \textcircled{H} boundary condition, = $\mu u_m^2 / q'' D_h$
b	half-spacing of a parallel plate duct, m; coil spacing, m; half length of minor axis of an elliptic duct, m; half length of height of a rectangular duct, m
C	constant
C_p	specific heat of the fluid at constant pressure, J/(kg·K)
D	diameter of a circular cylinder, m
De	Dean number = $\text{Re} \sqrt{a/R}$
De*	modified Dean number = $\text{Re} \sqrt{D_h/R}$
D_g	general length
D_h	hydraulic diameter of the duct = $4A_c/P$, m
D_l	laminar equivalent diameter, m
$E(m)$	complete elliptic integral of the second kind with argument m , which is defined by Eq. 2.252
e^*	eccentricity of the eccentric annular duct = $\varepsilon/(r_o - r_i)$; amplitude of the circular duct with sinusoidal corrugation = ε/a
F	a multiplicative factor entering various expressions
f	circumferentially averaged fully developed friction factor = $\tau_w / (\rho u_m^2 / 2)$
f_{app}	apparent Fanning friction factor = $\Delta p^* / (2x/D_h)$
f_c	friction factor for curved ducts = $\tau_w / (\rho u_m^2 / 2)$
f_s	friction factor for straight ducts
$G_n()$	eigenfunctions
Gr	Grashof number = $\beta g a^3 \Delta T / \nu^2$
Gr'	modified Grashof number = $\beta g a^4 q'' / k \nu$
Gz	Graetz number = $m c p / k L = p / (4 D_h x^*)$
\textcircled{H}	uniform wall heat flux boundary conditions
$\textcircled{H1}$	thermal boundary condition referring to uniform axial wall heat flux with uniform peripheral wall temperature
$\textcircled{H2}$	thermal boundary condition referring to axially and circumferentially uniform wall heat flux
$\textcircled{H4}$	conductive thermal boundary condition
$\textcircled{H6}$	thermal boundary condition referring to exponential wall heat flux
He	helical coil number
H_a	length of the fin on the major axis in an elliptic duct, m
H_b	length of the fin on the minor axis in an elliptic duct, m
h	convective heat transfer coefficient, W/(m ² ·K)
h_e	convective heat transfer coefficient for the duct exterior, W/(m ² ·K)
$J_i()$	Bessel functions of the first kind and orders 0 or 1 corresponding to $i = 0$ or 1
K	wall conductivity parameter = $ks/k_w \delta_w$
$K(x)$	incremental pressure drop number, defined by Eq. 5.5
k	thermal conductivity, W/(m·K)
l	length of fin, m
l^*	relative length of fins = l/a

L	length of the duct, m
L_{hy}	hydrodynamic entrance length, m
L_{hy}^+	dimensionless hydrodynamic entrance length = L_{hy}/D_h Re
L_{th}	thermal entrance length, m
L_{th}^*	dimensionless thermal entrance length = L_{th}/D_h Pe
m	argument of complete integral of the second kind; an exponent; a constant
n	number of sides of a duct; a dimensionless constant
n_1	number of coil turns at the beginning of the spiral = $L/(2\pi bN) - N/2$
n_2	number of coil turns at the end of the spiral = $L/(2\pi bN) + N/2$
N	number of spiral coil turns = $n_2 - n_1$
Nu	Nusselt number = hD_h/k
Nu_{bc}	circumferentially averaged mean Nusselt number in the fully developed region for a given boundary condition
$Nu_{x,bc}$	circumferentially averaged but axially local Nusselt number
$Nu_{m,bc}$	mean Nusselt number for the thermal entrance region for the specified thermal boundary condition
$Nu_{x,lj}^{(k)}$	local Nusselt number for a doubly connected duct = $\Phi_{ij}^{(k)}/(\theta_{ij}^{(k)} - \theta_{mj}^{(k)})$
$Nu_{x,i}^{(k)}, Nu_{x,o}^{(k)}$	local Nusselt number at inner and outer walls of a concentric or eccentric annular duct
Nu_o	overall Nusselt number associated with the $\textcircled{3}$ boundary condition
$Nu_{p,bc}$	peripherally local Nusselt number in the fully developed region for a given boundary condition
P	wetted perimeter of the duct, m; distance between circular cylinders, m
Pe	Péclet number = $u_m D_h/\alpha = \text{Re Pr}$
Pr	Prandtl number = ν/α
p	fluid static pressure, Pa
Δp	fluid static pressure drop in the flow direction between two cross sections of interest, Pa
Δp^*	dimensionless fluid static pressure drop = $\Delta p/(\rho u_m^2/2)$
q''_w	wall heat flux, heat transfer rate per unit heat transfer area of the duct (average value with respect to perimeter), W/m^2
q	heat transfer rate, W
q'	heat transfer rate per unit length, W/m
q''	heat flux, W/m^2
Re	Reynolds number = $u_m D_h/\nu$
Re_{crit}	critical Reynolds number
Re_ϵ	roughness Reynolds number
$R_n(\)$	eigenfunctions
r	radial coordinate in the cylindrical coordinate system, m
r_i, r_o	inner and outer tube radii of a concentric annular duct, m
r^*	aspect ratio r_i/r_o of a concentric or eccentric annular duct
r_m^*	radius in annular ducts where maximum velocity is achieved, m
R	radius of curvature, m

S	dimensionless parameter for eccentric annular duct; thermal energy source function, rate of thermal energy generated per unit volume of the fluid, W/m^3
s	duct dimension, m
S^*	thermal energy source number, $= SD_h^2/k(T_{w,m} - T_e)$ for \textcircled{T} boundary condition; $= SD_h/q''$ for $\textcircled{\oplus}$ boundary conditions
Sk	Stark number $= \epsilon_w \sigma T^3 D_h/k$
T	fluid temperature, K
T_a	ambient fluid temperature, K,
T_m	fluid bulk mean temperature, K
T_w	wall temperature at the inside duct periphery, K
$T_{w,m}$	circumferentially averaged wall temperature, K
$T_{w,\max}^*$	dimensionless maximum wall temperature
$T_{w,\min}^*$	dimensionless minimum wall temperature
\textcircled{T}	uniform wall temperature boundary condition
$\textcircled{\text{B}}$	convection boundary condition
$\textcircled{\text{R}}$	radiative boundary condition
u	fluid velocity, fluid axial velocity in x direction, m/s
u_m	fluid mean axial velocity, m/s
u_{\max}	fluid maximum axial velocity for fully developed flow, m/s
u_t	turbulent friction or shear velocity $= \sqrt{\tau_w/\rho}$, m/s
u^+	wall coordinate $= u/u_t$, dimensionless
v	fluid velocity component in y or r direction, m/s
w	fluid velocity component in the z or θ direction, m/s
x	axial (streamwise) coordinate in the Cartesian or cylindrical coordinate system, m
x^+	dimensionless axial coordinate for the hydrodynamic entrance region, $= x/D_h \text{ Re}$
x^*	dimensionless axial coordinate for the thermal entrance region, $= x/D_h \text{ Pe}$
X_L	twist ratio
y	Cartesian coordinate across the flow cross section, m; distance measured from the duct wall, m
y^+	wall coordinate $= yu_t/\nu$
\bar{y}	distance of the centroid of the duct cross section measured from the base, m
y_{\max}	normal distance from the base to the point where u_{\max} occurs in the duct cross section, m
z	Cartesian coordinates across the flow cross section, m; distance from the apex of a triangle, m

Greek Symbols

α	fluid thermal diffusivity $= k/\rho c_p$, m^2/s
α^*	aspect ratio of a rectangular channel $= 2b/2a$; ratio of the minor axis to the major axis of an elliptic duct, $2b/2a$
β	coefficient of thermal expansion, $1/\text{K}$
β_n	eigenvalues

$\Gamma()$	gamma function
γ	dimensionless parameter defined by Eq. 5.24; ratio of heat fluxes at two walls of a parallel plate duct
δ	hydrodynamic boundary layer thickness, m; thickness of a twisted tape, m
δ_w	duct wall thickness, m
ϵ	distance between centers of two circles of an eccentric annular duct, m; amplitude of a circular duct with sinusoidal corrugations, m; roughness of duct wall, m
ϵ_w	emissivity of the duct wall material; eddy diffusivity, m^2/s
Θ	dimensionless fluid temperature for the boundary condition of axially constant wall heat flux, $= (T - T_e)/q''_w D_h/k$
θ_m	dimensionless fluid bulk mean temperature $= (T_m - T_w)/(T_e - T_w)$
$\theta_j^{(k)}$	dimensionless fluid temperature for a doubly connected duct, defined in Shah and London [1]
$\theta_{ij}^{(k)}$	dimensionless circumferentially averaged wall temperature ($l = i$ for the inner wall, $l = o$ for outer wall) for the fundamental boundary condition of kind k when the inner or outer wall ($j = i$ or o) is heated or cooled; dimensionless fluid bulk mean temperature if $l = m$
$\theta_{mj}^{(k)}$	fluid bulk mean temperature for the fundamental boundary condition of kind k when the inner wall ($j = i$) or outer wall ($j = o$) is heated or cooled
θ_i^*	influence coefficients derived from the fundamental solutions of the second kind, $= (\theta_{mo}^{(2)} - \theta_{io}^{(2)})/(\theta_{ii}^{(2)} - \theta_{mi}^{(2)})$
θ_o^*	influence coefficients derived from the fundamental solutions of the second kind, $= (\theta_{mi}^{(2)} - \theta_{oi}^{(2)})/(\theta_{oo}^{(2)} - \theta_{mo}^{(2)})$
μ	fluid dynamic viscosity coefficient, Pa·s
ν	fluid kinematic viscosity coefficient $= \mu/\rho$, m^2/s
ρ	fluid density, kg/m^3
σ	Stefan-Boltzmann constant $= 5.6697 \times 10^{-8} \text{ W}/(m^2 \cdot K^4)$
τ	wall shear stress, Pa
$\Phi_j^{(k)}$	dimensionless heat flux at a point in the flow field for the j th wall of a doubly connected duct, defined in Ref. 1
$\Phi_{ij}^{(k)}$	dimensionless wall heat flow defined in a manner similar to $\theta_{ij}^{(k)} = q''_i D_h/k(T_j - T_e)$ for $k = 1, 3$; $= q''_i/q''_j$ for $k = 2, 4$
$\Phi_{m,T}$	dimensionless mean wall heat flux for boundary condition of axially constant wall temperature, $= q'' D_h/k(T_w - T_e)$
$\Phi_{x,T}$	dimensionless local wall heat flux for boundary condition of axially constant wall temperature, $= q''_x D_h/k(T_w - T_e)$
$\Phi_i^{(k)}, \Phi_o^{(k)}$	dimensionless heat flux at a point in the flow field for the inner or outer wall of a concentric or eccentric annular duct
ϕ	apex angle or half-apex angle of a duct; angle of tube curvature
Φ	coefficient, defined by Eq. 5.250

Subscripts

bc	thermal boundary condition
c	center, centroid, or curved
d	finned duct
e	initial value at the entrance of the duct or where the heat transfer begins

f	fluid
fd	fully developed flow
finless	finless duct
H	Ⓜ boundary condition
H1	Ⓜ ¹ boundary condition
H2	Ⓜ ² boundary condition
H4	Ⓜ ⁴ boundary condition
H5	Ⓜ ⁵ boundary condition
hy	hydrodynamic
i	inner surface of a doubly connected duct
in	inlet
j	heated wall of a doubly connected duct, = i or o
l	laminar flow
m	mean
max	maximum
min	minimum
o	outer surface of a doubly connected duct
p	peripheral value
s	smooth, straight duct
slug	slug flow
T	Ⓣ boundary condition
T3	Ⓣ ³ boundary condition
T4	Ⓣ ⁴ boundary conditions
t	turbulent
th	thermal
x	an arbitrary section along the duct length; a local value as opposed to a mean value; axial
w	wall or fluid at the wall
∞	fully developed value at $x = \infty$

INTRODUCTION

In the current era of large electronic computers, many complex problems in convection are being solved precisely by numerical solution of equations expressing basic principles. Keen insight into the fine points of such problems, however, requires extensive parametric studies that consume computer time, and therefore the numerical approach is usually applied only to a few examples. Further, these numerical programs may occupy so much computer storage space that their use as subroutines within generalized systems studies becomes impractical. Thus there still exists a need for general formulas and data correlations that can be used in preliminary design, in systems studies where convection is only one of many inputs, in creative design where inventiveness is based on understanding the influences of the variables of a problem, and in verifying computer codes for convective heat transfer to complex bodies. This chapter provides many of these tools for the case of forced convection over simple bodies.

Specifically, theoretical equations and correlations of data are presented for evaluating the local rate of heat transfer between the surface of a body and an encompassing fluid at different temperatures and in relative motion. *Forced convection* requires either that the fluid be pumped past the body, as for a model in a wind tunnel, or the body be propelled through the fluid, as an aircraft in the atmosphere. The methods presented apply equally to either situation when velocities are expressed relative to the body. Gravity forces are usually negligible under these conditions. Further, the contents of this chapter are confined to those conditions where the fluid behaves as a continuum.

The evaluation of forced convection to bodies has become a major problem in many aspects of modern technology. A few examples of applications include the following: thermally de-icing aircraft surfaces; turbine blade cooling; furnace tube bundles; and protecting high-performance aircraft, missile nose cones, and reentry bodies from intense aerodynamic heating. Formulas for evaluating convective heat transfer rates are generally established through a combination of theoretical analysis and experimentation. Analysis is almost universally based on *boundary*

layer theory—the mathematical solution of conservation equations of individual species, overall mass, momentum, and energy that are applicable to the thin region of fluid adjacent to the surfaces of bodies where the effects of shear, heat conduction, and species diffusion are controlling. Separated flows are not considered here. The experimentation involves the measurement of solid and fluid temperatures and of heat flux in a multitude of ways.

DEFINITION OF TERMS

The local convective heat flux from a point on a body is often expressed through Newton's law of cooling, generalized as

$$q''_w = \rho_e u_e St (i_w - i_{e,\text{eff}}) \quad (6.1)$$

Enthalpy is used as the measure of the thermal driving potential to broaden the application of Eq. 6.1 to thermally perfect gases with temperature-dependent specific heats where

$$i = \int c_p(T) dT \quad (6.2)$$

With bodies having constant surface temperatures, at low speeds

$$i_{e,\text{eff}} = i_e = c_p T_e \quad (6.3)$$

At high speeds where frictional heating takes place,

$$i_{e,\text{eff}} = i_e + r(0)(u_e^2/2) = i_{aw} \quad (6.4)$$

where $r(0)$ is the recovery factor, having approximate values for air of 0.85 and 0.9 for laminar and turbulent flow, respectively.

For bodies with nonuniform surface temperature distributions, $i_{e,\text{eff}}$ depends not only on the conditions at the boundary layer edge but also on the distribution of the surface temperature upstream of the location being considered.

For constant fluid properties, Eq. 6.1 correlates both theoretical and experimental results for a wide range of flow and temperature conditions through the single parameter Stanton number St . As will be seen in subsequent sections, this correlation is even useful when St is dependent on i_e or $i_{e,\text{eff}}$ and the equation is nonlinear.

The Reynolds analogy, defined as the ratio of the Stanton number to the local skin friction coefficient $St/(c_f/2)$ is a function of the Prandtl number and is extremely useful for estimating heat transfer. Pressure drop can be used to predict heat transfer in pipes, and the skin friction can be used to predict Stanton number for external flows.

When mass transfer of a foreign gas occurs at a surface, an equation similar to Eq. 6.1 is employed to define the local mass flux of the species i of a binary mixture as

$$j_{iw} = \rho_e u_e c_{mi} (K_{iw} - K_{ie}) \quad (6.5)$$

The Reynolds analogy can be extended to express $c_{mi}/(c_f/2)$ as a function of the Lewis number.

TWO-DIMENSIONAL LAMINAR BOUNDARY LAYER

Uniform Free-Stream Conditions

The most studied configuration for forced convection has been the “flat plate,” a surface at constant pressure with a sharp leading edge. The simplicity of this configuration so facilitates

the solution of the boundary layer equations, even for a variety of surface boundary conditions, that the bulk of heuristic theoretical boundary layer research is identified with the flat plate. These results are useful because much that is learned can be extended to more realistic body shapes using computer codes and applied directly to platelike surfaces (e.g., supersonic aircraft wings or fins having wedge cross sections and attached shock waves).

Uniform Surface Temperature

Governing Differential Equations. For a fluid as general as a gas in chemical equilibrium, the boundary layer equations for laminar flow over a flat plate are:

$$\frac{\partial}{\partial x}(\rho u) + \frac{\partial}{\partial y}(\rho v) = 0 \quad (6.6)$$

$$\rho u \frac{\partial u}{\partial x} + \rho v \frac{\partial u}{\partial y} = \frac{\partial}{\partial y} \left(\mu \frac{\partial u}{\partial y} \right) \quad (6.7)$$

$$\rho u \frac{\partial I}{\partial x} + \rho v \frac{\partial I}{\partial y} = \frac{\partial}{\partial y} \left[\frac{\mu}{\text{Pr}_T} \frac{\partial I}{\partial y} + \mu \left(1 - \frac{1}{\text{Pr}_T} \right) \frac{\partial(u^2/2)}{\partial y} \right] \quad (6.8)$$

with the boundary conditions

$$\left. \begin{array}{l} x=0 \quad y>0; \quad u=u_e \quad I=I_e \\ x>0 \quad y \rightarrow \infty; \quad u \rightarrow u_e \quad I \rightarrow I_e \\ y=0; \quad u=0 \quad v=0 \\ I=i_w = \text{constant} \quad \text{or} \quad \frac{\partial i}{\partial y} = 0 \quad \text{for} \quad I=i_w \end{array} \right\} \quad (6.9)$$

The leading edge of the plate is located at $x = 0$. The surface boundary conditions at $y = 0$ reflect the assumed conditions of zero mass transfer, a prescribed uniform temperature including the case of zero heat flux and an implied condition of a smooth surface.

A stream function ψ defined as

$$\rho u = \rho_e \frac{\partial \psi}{\partial y} \quad \rho v = -\rho_e \frac{\partial \psi}{\partial x} \quad (6.10)$$

immediately satisfies Eq. 6.6.

Fluid With Constant Properties. When the density and viscosity in Eqs. 6.6 and 6.7 are constant, the velocity field is independent of the temperature field. Blasius [1] collapsed the partial differential equations (Eqs. 6.6 and 6.7) to a single ordinary differential equation by transforming the coordinate system from x and y to ζ and η , defined as

$$\zeta = x \quad \eta = \sqrt{y u_e / \nu_e} x \quad (6.11)$$

The stream function defined by Eq. (6.10) is expressed as

$$\psi = m(\zeta) f(\eta)$$

where $m(\zeta) = \sqrt{u_e \nu_e \zeta}$

and the velocity components are expressed in terms of the similarity variable η

$$\frac{u}{u_e} = f'(\eta) \quad \frac{v}{u_e} = \frac{1}{2} \frac{[\eta f'(\eta) - f(\eta)]}{\sqrt{\text{Re}_{x_e}}} \quad (6.12)$$

where $f(\eta)$ is the solution of the ordinary differential equation

$$f''' + \frac{1}{2}ff'' = 0 \tag{6.13}$$

with the boundary conditions

$$\begin{aligned} \eta = 0 & \quad f = 0, f' = 0 \\ \eta \rightarrow \infty & \quad f' \rightarrow 1 \end{aligned} \tag{6.14}$$

The u velocity profile is shown in Fig. 6.1. The velocity ratio reaches a value of 0.99 at a boundary layer thickness of

$$\frac{\delta}{x} = \frac{5}{\sqrt{\text{Re}_x}} \tag{6.15}$$

FIGURE 6.1 Similar velocity profile in the laminar boundary layer on a flat plate—constant fluid properties.

The local skin friction coefficient is

$$\frac{c_f}{2} = \frac{f''(0)}{\sqrt{\rho_e \mu_e x / \mu_e}} = \frac{0.332}{\sqrt{\text{Re}_x}} \tag{6.16}$$

The average skin friction coefficient for the length of the plate up to x is defined as

$$\frac{\bar{c}_f}{2} = \frac{1}{x} \int_0^x \frac{c_f}{2} dx = \frac{0.664}{\sqrt{\text{Re}_x}} \tag{6.17}$$

Equation 6.17 indicates that on a flat plate the average skin friction coefficient is equal to twice the local skin friction coefficient at the trailing edge.

Experimental verification of the Blasius theory has been hindered by the difficulty in reproducing the ideal flat plate boundary conditions in the laboratory. Whenever uniform pressure was attained and the effects of a real leading edge were accounted for, however, it was found that the preceding calculated results were always verified to within the accuracy of the experiment.

Pohlhausen [2] utilized the Blasius coordinate system and velocity distribution to evaluate the convective heating processes within the constant-property boundary layer on a flat plate. He solved two problems:

1. The convective heat transfer rate to a plate with uniform surface temperature for fluid speeds sufficiently low to make viscous dissipation negligible
2. The temperature attained by an insulated plate (zero surface heat transfer) when exposed to a high-speed stream where viscous dissipation is important

The latter is the *plate thermometer* or *adiabatic wall problem*. Eckert and Drewitz [3] showed that the general problem of heat transfer to a uniform-surface-temperature plate in constant-property high-speed flow is merely the superposition of the two Pohlhausen solutions.

For a uniform-surface-temperature plate in a low-speed flow ($u^2 \ll 2c_p T$), Eq. 6.8 simplifies to

$$\rho u \frac{\partial T}{\partial x} + \rho v \frac{\partial T}{\partial y} = \frac{\mu}{\text{Pr}} \frac{\partial^2 T}{\partial y^2} \quad (6.18)$$

with the boundary conditions

$$\begin{aligned} x = 0 \quad y > 0; \quad T &= T_e \\ x > 0 \quad y = 0; \quad T &= T_w \\ y \rightarrow \infty; \quad T &\rightarrow T_e \end{aligned}$$

When Eq. 6.18 is transformed to the independent variables (Eq. 6.11) and the new normalized dependent variable

$$Y_0(\eta) = \frac{T - T_e}{T_w - T_e} \quad (6.19)$$

is introduced, the ordinary homogeneous differential equation that results is

$$Y_0'' + \frac{1}{2} \text{Pr} f Y_0' = 0 \quad (6.20)$$

where f is the Blasius stream function. The transformed boundary conditions are

$$\left. \begin{aligned} \eta = 0 \quad Y_0 &= 1 \\ \eta \rightarrow \infty \quad Y_0 &\rightarrow 0 \end{aligned} \right\} \quad (6.21)$$

Solutions for $\text{Pr} = 0.5$ and 1.0 are shown in Fig. 6.2 as solid curves. The abscissa of this figure is the thermal boundary layer thickness parameter η_H , consisting of the Blasius boundary layer similarity parameter multiplied by $\text{Pr}^{1/3}$. The close agreement of the two solid curves suggests for Pr near unity that the thermal boundary layer thickness where $Y_0 = 0.01$ is inversely proportional to approximately $\text{Pr}^{1/3}$ or

$$\frac{\delta_T}{x} = \frac{5\text{Pr}^{-1/3}}{\sqrt{\text{Re}_{x_e}}} = \frac{\delta}{x} \text{Pr}^{-1/3} \quad (6.22)$$

Thus, fluids with Pr less than unity have thermal boundary layers that are thick relative to their flow boundary layers. Conversely, fluids with Pr greater than unity have relatively thin thermal boundary layers.

This latter condition suggests a particularly simple solution of Eq. 6.20 for very large Pr [4] because the temperature variations occur where the velocity distribution is still linear in η (see Fig. 6.1 for $\eta < 2.0$). The linear velocity condition in Eq. 6.20 permits expressing Y_0 explicitly in terms of η_H . The solution for this case of large Pr is shown as a dashed line in Fig. 6.2 and agrees quite well with the calculations based on the more exact velocity distributions for Pr near unity. This agreement indicates that Eq. 6.22 is applicable over a large range of Pr from values characteristic of gases to those for heavy oils.

The local Stanton number found by Pohlhausen is represented very well by

$$\text{St} = \frac{0.332\text{Pr}^{-2/3}}{\sqrt{\text{Re}_{x_e}}} \quad (6.23)$$

a form consistent with the parameter η_H .

FIGURE 6.2 Temperature distributions in the laminar boundary layer on a flat plate at uniform temperature—constant property, low-speed flow.

The modified Reynolds analogy from Eqs. 6.16 and 6.23 is

$$St = \frac{C_f}{2} Pr^{-2/3} \tag{6.24}$$

The excellent agreement of this formula with the precise numerical results of Pohlhausen [2] over a large range of Pr is shown graphically in Fig. 6.4 (solid curves are the numerical results). The dashed line, labeled $1.02 Pr^{-2/3}$, results from the analysis employing a linear velocity distribution throughout the boundary layer [5]. Equation 6.24 has been shown to be consistent with experimental results through a successive series of data correlations dating back to Colburn [6].

The average Stanton number up to station x is

$$\bar{St} = \frac{1}{x} \int_0^x St \, dx = 2St \tag{6.25}$$

For an insulated plate in high-speed flow with constant properties, Eq. 6.8 combined with Eq. 6.7 reduces to

$$\rho u \frac{\partial T}{\partial x} + \rho v \frac{\partial T}{\partial y} = \frac{\mu}{Pr} \frac{\partial^2 T}{\partial y^2} + \frac{\mu}{c_p} \left(\frac{\partial u}{\partial y} \right)^2 \tag{6.26}$$

with boundary conditions

$$\left. \begin{aligned} x = 0 \quad y > 0; \quad T = T_e \\ x > 0 \quad y \rightarrow \infty; \quad T \rightarrow T_e \\ y = 0; \quad \frac{\partial T}{\partial y} = 0 \end{aligned} \right\} \tag{6.27}$$

When the independent variables are transformed to the Blasius variables and a new dependent variable

$$\mathbf{r}(\eta) = \frac{T - T_e}{u_e^2 / 2c_p} \quad (6.28)$$

is introduced into Eq. 6.26, the ordinary inhomogeneous equation that results is

$$\mathbf{r}'' + \frac{1}{2}\text{Pr} f \mathbf{r}' = -2\text{Pr} f''^2 \quad (6.29)$$

with boundary conditions

$$\left. \begin{array}{l} \eta = 0 \quad \mathbf{r}' = 0 \\ \eta \rightarrow \infty \quad \mathbf{r} \rightarrow 0 \end{array} \right\} \quad (6.30)$$

The solutions of this problem are indicated in Fig. 6.3. The temperature distributions shown are based on calculations employing exact velocity distributions for Pr near unity and a linear velocity distribution for very large Pr. These temperatures have been normalized by the temperature rise at the surface, and the abscissa is the η_H utilized in Fig. 6.2.

FIGURE 6.3 Temperature profiles in the laminar boundary layer on an insulated plate—constant-property, high-speed flow.

Figure 6.3 shows less correlation for different Pr than was exhibited for the uniform-surface-temperature case in Fig. 6.2. The implication here is that the thermal boundary layer produced by viscous dissipation grows at a rate different from $\text{Pr}^{-1/3}$ for all but the very large values of Pr. For Pr near unity, the growth factor is closer to $\text{Pr}^{-0.28}$.

The adiabatic wall temperature (recovery temperature) is given by

$$T_{aw} = T_e + \mathbf{r}(0) \frac{u_e^2}{2c_p} \quad (6.31)$$

Figure 6.4 shows the dependence of the recovery factor $\mathbf{r}(0)$ on Pr as given by Refs. 2 and 5 (solid line). In the region $0.5 < \text{Pr} < 2$, the formula

$$\mathbf{r}(0) = \text{Pr}^{1/2} \quad (6.32)$$

FIGURE 6.4 Influence of Prandtl number on the recovery factor and modified Reynolds analogy for a laminar boundary layer on a flat plate.

represents the calculated values to within 1 percent. For $Pr = 7$, Eq. 6.32 yields results high by 5.4 percent. The dashed line labeled A in Fig. 6.4 represents an extrapolation of the exact numerical results for $Pr < 15$ to approach asymptotically the limiting value

$$r(0) = 1.92Pr^{1/3} \tag{6.33}$$

resulting explicitly when a linear velocity distribution exists throughout the thermal boundary layer.

For a uniform-surface-temperature plate in high-speed flow, the temperature distribution within the boundary layer is expressed by a superposition of the two Pohlhausen solutions [3]. This is permissible because the energy equation (Eq. 6.8) with constant properties is linear in temperature. The general solution of the energy equation is the sum of the general solution of the homogeneous equation (Eq. 6.18) and a particular solution of the inhomogeneous equation (Eq. 6.26):

$$T - T_e = (T_w - T_{aw})Y_0(\eta) + \frac{u_e^2}{2c_p} r(\eta) \tag{6.34}$$

$Y_0(\eta)$ and $r(\eta)$ (Eqs. 6.19 and 6.28) are indicated in Figs. 6.2 and 6.3, respectively. The local heat flux is expressed as

$$q_w'' = P_e/\rho_e \mu_e c_p St (T_w - T_{aw}) \tag{6.35}$$

The appropriate Stanton number is again represented by Eq. 6.23, T_{aw} is given by Eq. 6.31, and $r(0)$ is given by Eq. 6.32 or Fig. 6.4.

Liquids With Variable Viscosity. When the temperature difference between a liquid and a surface becomes significant, it is necessary to consider the temperature dependence of the viscosity across the boundary layer. Calculations of convective heating were made [7] for a liquid whose viscosity varies as

$$\frac{\mu}{\mu_w} = \left(\frac{T_w + T_c}{T + T_c} \right)^b$$

where b and T_c are constants. The boundary layer equations are solved through a transformation of independent variables identical in form with Eq. 6.11, but with the kinematic viscosity ν evaluated at the surface temperature. The resulting transformed momentum equation is

$$\left(\frac{\mu}{\mu_w} f''\right)' + \frac{1}{2} ff'' = 0$$

and the energy equation, where viscous dissipation has been neglected, is identical with Eq. 6.20, but with Pr evaluated at the wall temperature. In Ref. 7 the form of the solution requires a choice of the constant b ($b = 3$ in most of the examples) but avoids the necessity of predetermining an explicit value of the constant T_c . The skin friction and heat transfer are expressed directly in terms of the viscosity ratio across the boundary layer μ_w/μ_e and the Prandtl number at the surface.

Figure 6.5 shows the velocity distributions in a boundary layer of a liquid with $Pr_w = 100$ (e.g., sulfuric acid at room temperature). For this Prandtl number, the thermal boundary layer penetration into the liquid is much less than the flow boundary layer, and the regions where viscosity variations occur are confined close to the surface. The curve corresponding to $\mu_w/\mu_e = 1$ is the Blasius solution (see Fig. 6.1). The curve labeled $\mu_w/\mu_e = 0.23$ corresponds to a heated surface where the low viscosity near the surface requires steeper velocity gradients to maintain a continuity of shear with the outer portion of the boundary layer. The heated free-stream cases reveal the opposite effects. In general, the outer portions of the flow boundary layers act similarly to the velocity distribution of the Blasius case except for their being displaced in or out by the effects that have taken place in the thermal boundary layer.

FIGURE 6.5 Velocity profiles in the laminar boundary layer of a liquid, $Pr_w = 100$ [7].

The temperature profiles for different Pr_w and μ_w/μ_e are indicated in Fig. 6.6. Note that the curves for $Pr_w = 10$ apply equally well for greater Prandtl numbers because of the use of the thermal boundary layer thickness parameter as the abscissa (see Fig. 6.2).

The effects of the viscosity variation across the boundary layer on the surface shear stress and heat flux are shown in Fig. 6.7. The shear stress is normalized by the value obtained from the Bla-

FIGURE 6.6 Temperature profiles in the laminar boundary layer of a liquid [7].

sus solution with the same free-stream properties. The heat flux is normalized by the Pohlhausen value with the viscosity and Prandtl number evaluated at the wall temperature. Note that at the higher Prandtl numbers the wall shear becomes less dependent on the fluid properties.

Ideal Gases at High Temperatures. The speeds of modern military aircraft, missiles, or reentry bodies are so high that the resulting recovery temperatures are several times to orders of

FIGURE 6.7 Effects of viscosity changes across a laminar liquid boundary layer on surface shear and heat flux—reference shear from Blasius solution with free-stream properties, reference heat flux from Pohlhausen solution with wall properties [7].

magnitude larger than the ambient atmospheric temperatures. Under these conditions, the behavior of atmospheric gases within the boundary layer changes from that of an ideal gas to that of a real gas, including the physical effects of rotational and vibrational excitation, dissociation, and even ionization. The real-gas behavior is so complex that numerical analysis is the only means of introducing it into boundary layer problems. Because the cases of simpler gas behavior are directly applicable to many aircraft problems and are guides for correlating the numerical results of the real-gas computations, examples of ideal-gas solutions will be presented first.

Equations 6.6–6.8 are converted to a convenient form through the Howarth-Dorodnitsyn transformation of the independent variables [8] from x, y to ζ, η as follows:

$$\begin{aligned}\zeta &= u_e \mu_r \rho_r x \\ \eta &= \sqrt{\frac{u_e}{\nu_e x}} \int_0^y \frac{\rho}{\rho_r} dy\end{aligned}\quad (6.36)$$

The subscript r represents a reference condition for the properties, usually the conditions at the edge of the boundary layer or at the surface.

The transformed momentum and energy equations for a uniform-temperature flat plate are

$$(C_r f'')' + \frac{1}{2} f f'' = 0 \quad (6.37)$$

$$\left(\frac{C_r \bar{I}'}{\text{Pr}} \right)' + \frac{1}{2} f \bar{I}' + \frac{u_e^2}{I_e} \left[C_r \left(1 - \frac{1}{\text{Pr}} \right) f' f'' \right]' = 0 \quad (6.38)$$

where

$$f' = \frac{u}{u_e} \quad \bar{I} = \frac{I}{I_e} \quad C_r = \frac{\mu \rho}{\mu_r \rho_r} \quad \frac{\partial}{\partial \eta} = ()' \quad (6.39)$$

with the boundary conditions

$$\begin{aligned}\eta = 0 \quad f = f' = 0 \quad \bar{I} &= \frac{i_w}{I_e} \\ \eta \rightarrow \infty \quad f' &\rightarrow 1, \quad \bar{I} \rightarrow 1\end{aligned}$$

The fluid properties are introduced into these equations only through C_r and Pr , which involve combinations of individual physical properties. Certain values of C_r and Pr permit simplifications that lead to useful general relationships.

Prandtl Number Equal to Unity. If $\text{Pr} = 1$, considerable simplification results. Equation 6.38 acquires a form identical with Eq. 6.37, \bar{I} being analogous to f' . A solution of the energy equation, therefore, is directly expressible in terms of the velocity distribution as

$$\bar{I} = \left(1 - \frac{i_w}{I_e} \right) f' + \frac{i_w}{I_e} \quad (6.40)$$

after the boundary conditions at the surface and boundary layer edge have been introduced. When the wall enthalpy equals the total enthalpy, Eq. 6.40 indicates that $\bar{I} = 1$, i.e., the total enthalpy is constant throughout the boundary layer. For other wall enthalpies, the local total enthalpy is linearly dependent on the local velocity. The corresponding static enthalpy distribution is

$$\frac{i}{i_e} = 1 + \frac{i_w - I_e}{i_e} (1 - f') + \frac{u_e^2}{2i_e} (1 - f'^2) \quad (6.41)$$

The Reynolds analogy is given by

$$\text{St} = \frac{C_f}{2} \quad (6.42)$$

with the requirement that the recovery enthalpy be

$$i_{aw} = I_e \quad \text{or} \quad \mathbf{r}(0) = 1$$

Note that $c_f/2$ in Eq. 6.42 differs in magnitude from that given by Eq. 6.16 because of the departure from the Blasius solution by the existence of $C_r(\eta)$ in Eq. 6.37.

Viscosity-Density Product Equal to a Constant. If $C_r = \bar{C}$ and Pr are constant, a natural transformation suggests itself [9], where η is replaced by

$$\eta_c = \frac{\eta}{\sqrt{\bar{C}}} \quad (6.43)$$

and

$$F'(\eta_c) = f'(\eta) \quad (6.44)$$

$$\mathbf{I}(\eta_c) = \bar{\mathbf{I}}(\eta) \quad (6.45)$$

Equations 6.37 and 6.38 become

$$F''' + \frac{1}{2}FF'' = 0 \quad (6.46)$$

$$\mathbf{I}'' + \frac{1}{2}\text{Pr} F\mathbf{I}' + \frac{u_e^2}{I_e} (\text{Pr} - 1)(F'F'')' = 0 \quad (6.47)$$

with boundary conditions

$$\begin{aligned} \eta_c = 0 & \quad F = F' = 0, \quad \mathbf{I} = \bar{\mathbf{I}}_w \\ \eta_c \rightarrow \infty & \quad F' \rightarrow 1, \quad \mathbf{I} \rightarrow 1 \end{aligned}$$

The assumption of constant C_r , therefore, permits separation of the momentum equation from its dependence on the energy equation and results in an energy equation that is linear in \mathbf{I} so that general solutions can be obtained from a superposition of individual solutions.

Equation 6.46 with its boundary conditions is the Blasius problem again. The energy equation is satisfied by

$$\frac{i}{i_e} = \frac{i_w - i_{aw}}{i_e} Y_0(\eta_c) + \frac{u_e^2}{2i_e} \mathbf{r}(\eta_c) + 1 \quad (6.48)$$

where Y_0 and \mathbf{r} are obtainable from Figs. 6.2 and 6.3 when η_H is adjusted according to Eq. 6.43. The recovery factor $\mathbf{r}(0)$ is independent of \bar{C} and therefore is identical to the constant-property value given in Fig. 6.4 and Eq. 6.32.

$$\frac{c_f}{2} = \frac{0.332}{\sqrt{\text{Re}_{x_e}}} \frac{\mu_w \rho_w / \mu_e \rho_e}{\sqrt{\bar{C}}} = \left(\frac{c_f}{2} \right)_i \frac{\mu_w \rho_w / \mu_e \rho_e}{\sqrt{\bar{C}}} \quad (6.49)$$

The term $(c_f/2)_i$ represents the skin friction coefficient corresponding to a constant-property boundary layer at the same local length Reynolds number. Similarly, the Stanton number is given by

$$\text{St} = \frac{0.332}{\sqrt{\text{Re}_{x_e}}} \frac{\mu_w \rho_w / \mu_e \rho_e}{\sqrt{\bar{C}}} \text{Pr}^{-2/3} = \text{St}_i \frac{\mu_w \rho_w / \mu_e \rho_e}{\sqrt{\bar{C}}} \quad (6.50)$$

where St_i is the corresponding constant-property Stanton number.

For a gas that satisfies the perfect gas equation of state and whose viscosity obeys the equation

$$\frac{\mu}{\mu_e} = \frac{T}{T_e} \quad (6.51)$$

where T_e is the reference condition, the constant \bar{C} becomes

$$\bar{C} = C_e = \frac{\mu \rho}{\mu_e \rho_e} = \frac{\mu_w \rho_w}{\mu_e \rho_e} \equiv 1 \quad (6.52)$$

Thus, Eqs. 6.49 and 6.50 indicate that the skin friction coefficient and Stanton number remain equal to their constant-property values. In terms of these dimensionless transfer coefficients, the effects of the linear dependence of viscosity on temperature just cancel those of the perfect gas variation of the density. It should be noted, however, that the density variation itself still affects the boundary layer thickness.

For a constant-temperature plate, Chapman and Rubesin [9] modified Eq. 6.51

$$\frac{\mu}{\mu_e} = C_{ew} \frac{T}{T_e} \quad (6.53)$$

in order to approximate better the actual viscosity distribution near the surface. Equation 6.53 with the perfect gas equation of state yields

$$\bar{C} = C_{ew} = \frac{\mu_w \rho_w}{\mu_e \rho_e}$$

and Eqs. 6.49 and 6.50 become

$$\frac{c_f}{2} = \left(\frac{c_f}{2} \right)_i \sqrt{\frac{\mu_w \rho_w}{\mu_e \rho_e}} \quad (6.54)$$

$$\text{St} = \frac{c_f}{2} \text{Pr}^{-2/3} \quad (6.55)$$

$$\text{St} = \text{St}_i \sqrt{\frac{\mu_w \rho_w}{\mu_e \rho_e}} \quad (6.56)$$

The above skin friction relationship was deduced intuitively many years earlier by von Kármán [10], who assumed local wall properties would control the skin friction law when property variations occur. Thus, Eq. 6.54 is equivalent to

$$\left(\frac{c_f}{2} \right)_w = \frac{0.332}{\sqrt{\rho_w u_e x / \mu_w}}$$

where

$$\tau_w = \rho_w u_e^2 \left(\frac{c_f}{2} \right)_w$$

Similarly, since Pr has been assumed constant in Eq. 6.47, the modified Reynolds analogy also applies under these conditions with

$$\text{St}_w = \left(\frac{c_f}{2} \right)_w \text{Pr}^{-2/3}$$

where

$$q_w'' = \text{St}_w \rho_w u_e (i_w - i_{aw})$$

Sutherland Law Viscosity. Crocco [5] solved equations equivalent to Eqs. 6.37 and 6.38 utilizing the rather accurate Sutherland viscosity relationship and a constant value of Pr other than unity. For a gas that satisfies the ideal equation of state, the quantity C_r , referred to free-stream conditions, becomes

$$C_r = \frac{\mu \rho}{\mu_e \rho_e} = \sqrt{\frac{T}{T_e}} \left(\frac{1 + \theta_0}{T/T_e + \theta_0} \right) \quad (6.57)$$

where $\theta_0 = T_{sc}/T_e$ and T_{sc} is the Sutherland constant corresponding to the specific gas. Values of θ_0 are indicated in Table 6.1 for a variety of gases and boundary layer edge temperatures characteristic of those occurring in the stratosphere, under room conditions, and in products of combustion. Crocco obtained numerical results for $\theta_0 = 0, 1/3, 1,$ and 3 . Because enthalpy is employed as the thermodynamic dependent variable in Eq. 6.38 to account for specific heat variations, it is necessary to express C_e in terms of enthalpy rather than temperature as in Eq. 6.57. This is no problem when attention is confined to a specific gas where the enthalpy and temperature are uniquely related at specified pressures. Crocco, however, chose to avoid this approach because it would confine his results to specific gases and thermodynamic conditions. To retain generality, he made the assumption that the temperature ratio in Eq. 6.57 can be replaced by the enthalpy ratio i/i_e without introducing serious errors.

TABLE 6.1 Prandtl Number and Sutherland Constant for Gases [5]

Gas	Pr, $T = 230$ K	Sutherland constant $T_{sc},$ K	$\theta_0 = T_{sc}/T_e$		
			T_e 218 K	T_e 300 K	T_e 3000 K
H ₂	0.717	90	0.413	0.300	0.030
CO	0.765	104	0.477	0.347	0.035
N ₂	0.739	112	0.514	0.373	0.037
Air	0.725	116	0.532	0.387	0.039
O ₂	0.731	131	0.601	0.437	0.044
CO ₂	0.805	266	1.220	0.887	0.089
H ₂ O	1.08	673	3.09	2.24	0.224

A major result of Crocco's numerical solutions was the discovery that the functional dependence of the local enthalpy on the local velocity is independent of the particular law of viscosity employed. Thus, $i(f')$ found for the simplified case of $C_e \equiv 1$ applies for all values of θ . The conclusions deduced from this discovery are that the modified Reynolds analogy of Eq. 6.24 or Fig. 6.4 and the recovery factor expression of Eq. 6.32 or Fig. 6.4 apply to all gases, regardless of their viscosity laws, as long as Prandtl number is constant. Another significant consequence of this discovery is that it simplifies the solution of Eqs. 6.37 and 6.38 by avoiding either a simultaneous solution of two differential equations or a sequential iteration process. The simpler process uses Eq. 6.48 and the Blasius solution to relate i and f' . Then C_e is evaluated in terms of f' through Eq. 6.57 with T/T_e replaced by i/i_e and with the proper θ_0 , and Eq. 6.37 is solved to yield the final velocity distribution. The local enthalpy distribution in terms of the local velocity is given by

$$\frac{i}{i_e} = 1 + \frac{i_w - i_{aw}}{i_e} Y_0(f') + \frac{u_e^2}{2i_e} \mathbf{r}(0) \frac{\mathbf{r}(f')}{\mathbf{r}(0)} \quad (6.58)$$

where the enthalpy profile functions Y_0 and $\mathbf{r}/\mathbf{r}(0)$ are plotted in Figs. 6.8 and 6.9 for several Prandtl numbers. Many authors have argued that Eq. 6.41 can be modified to account for Prandtl number deviations from unity by replacing I_e by i_{aw} and multiplying the last term by $\mathbf{r}(0)$. A comparison with Eq. 6.58 reveals that this suggestion is equivalent to retaining Y_0 and $\mathbf{r}/\mathbf{r}(0)$ characteristic of $\text{Pr} = 1$ for all Prandtl numbers. Reference to Figs. 6.8 and 6.9 indicates the errors introduced by this procedure. For example, on a plate at constant temperature, the local temperature at $f' = u/u_e = 0.5$ is 10 percent higher at $\text{Pr} = 0.725$ from Fig. 6.8 than would be given by the aforementioned rule.

Correlation equations that fit these results within 0.015 of the ordinates are

$$Y_0 = 1 - \text{Pr}^{1/2} \frac{u}{u_e} - (1 - \text{Pr}^{1/3}) \left(\frac{u}{u_e} \right)^{6.3\text{Pr}^{-1/2}} \quad (6.59)$$

FIGURE 6.8 Laminar boundary layer enthalpy profile function on a uniform-temperature flat plate, $C_e = 1$ [5].

FIGURE 6.9 Laminar boundary layer enthalpy profile function on an insulated flat plate, $C_e = 1$ [5].

and

$$\frac{r}{r(0)} = 1 - \text{Pr}^{1/2} \left(\frac{u}{u_e} \right)^2 - (1 - \text{Pr}^{1/2}) \left(\frac{u}{u_e} \right)^{7.3\text{Pr}-0.38} \quad (6.60)$$

An example of the skin friction results obtained by Crocco for the case of $\theta_0 = 3$ is shown in Fig. 6.10. The individual curves represent values for constant surface temperatures where $i_w/i_e = 0.25, 0.50, 1.0, 1.5,$ and 2.0 , and for an insulated plate.

For slender aircraft flying in the stratosphere, the temperature at the edge of the boundary layer is 218 K (-67.6°F) and the value of θ_0 for air based on the Sutherland constant is 0.505. Van Driest [11] repeated Crocco's analysis for these conditions and $\text{Pr} = 0.75$. Graphs of the

FIGURE 6.10 Local laminar boundary layer skin friction coefficient on a flat plate at uniform temperature, $Pr = 0.725$ and $\theta_0 = 3$ [5].

local velocity, temperature, and Mach number profiles for an extensive range of conditions are presented in Ref. 11. The local skin friction coefficient is indicated in Fig. 6.11 for Ma_e up to 20, for wall temperatures $0.25 \leq i_w/i_e \leq 6$, and for an insulated plate. Two examples of the solutions based on a constant value of $C_e = C_{ew}$ are indicated for comparison with the insulated plate curve (circled points). Note that the use of wall properties underestimates the skin friction here by about 5 percent.

Air as a Real Gas in Chemical Equilibrium. At reentry speeds, the high enthalpies introduce Prandtl number variations and the nonideal effects of dissociation and ionization in the behavior of equilibrium air. Several studies [12–17] have determined the effects of these property variations on the behavior of the laminar boundary layer for successively increasing speeds. A characteristic common to these theories because of the complexity of the behavior of air at elevated enthalpies is the reliance on completely numerical computation of a relatively limited number of examples. The results, however, are not markedly different from the

FIGURE 6.11 Local skin friction coefficient for air flowing in a laminar boundary layer on a flat plate, $Pr = 0.75$, $\theta_0 = 0.505$ [11].

ideal-gas cases. The variations in Pr_T cause the recovery factor to be dependent on the surface temperature and Mach number at the edge of the boundary layer. When this relatively small effect is taken into account, the skin friction and heat transfer coefficients exceed the van Driest results of the previous section by less than 15 percent for enthalpies characteristic of flight speeds less than 25,000 ft/s (7620 m/s) and wall temperatures below the sublimation temperature of carbon (6000°R or 3333 K). When ionization takes place, however, a marked increase occurs in both the skin friction and heat transfer.

Errors are inherent in the above solutions because of the uncertainties in the transport properties of air at very high temperatures. The theories of Refs. 15 and 17 employed total properties from different sources, while Ref. 16 accounted for equilibrium air by using frozen properties and $Le = 1$ in the diffusional heat flux contribution. A comparison of skin friction and heat transfer coefficients reveals differences of less than 10 percent between the results of Refs. 15 and 16 and only a few percent between the results of Refs. 16 and 17. Thus, prior to ionization the errors in convective heating predictions caused by property uncertainties are rather small. With the onset of ionization, large errors may have been introduced because of the large uncertainty of the thermal conductivity of ionized air as influenced primarily by the charge-transfer cross section of atomic nitrogen. Hence, the marked increase in heat transfer rate with the presence of ionization [17] can only be considered qualitatively correct.

A technique for correlating the results for the convective heating behavior of any ideal gas and real air is given in the following section.

Reference Enthalpy Method. The behavior of the skin friction coefficient indicated in Figs. 6.10 and 6.11 can be correlated to a very good approximation by the modified incompressible formula

$$\frac{c_f}{2} = \frac{0.332}{\sqrt{Re_{x_e}}} \sqrt{\frac{\rho' \mu'}{\rho_e \mu_e}} \quad (6.61)$$

where the properties designated with the prime are evaluated at a reference enthalpy i' and the boundary layer edge pressure. This correlation technique was expressed originally in terms of a reference temperature T' [12, 18–20] and later as a reference enthalpy i' to account for variations in specific heat [14, 21].

A convenient form of the reference enthalpy is

$$\frac{i'}{i_e} = \mathbf{a}^* + \mathbf{b}^* \frac{i_w}{i_e} + \mathbf{c}^* \frac{i_{aw}}{i_e}$$

On evaluation of the coefficients \mathbf{a}^* , \mathbf{b}^* , and \mathbf{c}^* based on the van Driest values of skin friction in Fig. 6.11, it is found that they differ from those given in the earlier references. Therefore, the following formula is adopted:

$$\frac{i'}{i_e} = 0.32 + 0.50 \frac{i_w}{i_e} + 0.18 \frac{i_{aw}}{i_e} \quad (6.62)$$

A convenient form of the skin friction coefficient compatible with the Crocco and van Driest formulations is

$$\frac{c_f}{2} = \frac{0.332}{\sqrt{Re_{x_e}}} \sqrt{\left(\frac{i'}{i_e}\right)^{1/2} \frac{1 + \theta_0}{i'/i_e + \theta_0}} \quad (6.63)$$

Note that Eq. 6.62 differs slightly from the popular Eckert relationship

$$\frac{i'}{i_e} = 0.28 + 0.50 \frac{i_w}{i_e} + 0.22 \frac{i_{aw}}{i_e} \quad (6.64)$$

The relative accuracies of these formulations are indicated in Table 6.2 for the skin friction coefficients shown in Figs. 6.10 and 6.11.

TABLE 6.2 Comparison of Skin Friction Coefficients From Reference Enthalpy Methods

Source	% RMS error [11]		% RMS error [5]			
	Air		$\theta_0 = 0$	$\theta_0 = 1/3$	$\theta_0 = 1$	$\theta_0 = 3$
Eq. 6.64	2.0		2.3	1.1	0.65	0.83
Eq. 6.62	0.64		1.2	0.30	0.50	0.64

The figures of merit indicated in this table represent the RMS errors of the formulas at the matrix of points $Ma_e = 0$ and 5, $i_w/i_e = 0.25, 2.0$, and i_{ow}/i_e in Fig. 6.10 for $\theta_0 = 3$ and for similar points for the other values of θ_0 ; and at $Ma_e = 0, 5$, and 10, $i_w/i_e = 0.25, 6$, and i_{ow}/i_e in Fig. 6.11 for $\theta_0 = 0.505$.

From Table 6.2 for air, it can be seen that Eq. 6.62 gives some improvement in comparison with the van Driest results over the older formulas. At the high speeds where air behaves as a real gas, Wilson [15] shows that equations equivalent to Eqs. 6.61 and 6.62 yield skin friction coefficients that agree with those found from numerical integrations of the boundary layer equations to within 5 percent for total enthalpies corresponding to free-stream speeds up to 25,000 ft/s (7620 m/s). Similar close agreement is achieved between the use of the Eckert reference enthalpy and results of Cohen [16].

For real air, the total Prandtl number varies in an oscillating manner with enthalpy distribution across the boundary layer. In view of this behavior, it would not be expected a priori that evaluation of Pr_T at the reference enthalpy would be appropriate for evaluating the recovery factor from Eq. 6.32 or the modified Reynolds analogy from Eq. 6.24. Comparison with the numerical results of Refs. 12, 13, and 15, however, reveals that this interpretation of the reference enthalpy technique yields results for the recovery factor correct to within 2.5 percent, and for the Reynolds analogy correct to within 5 percent. Note that Wilson [15] suggests the use of Pr_{Tw} evaluated at wall enthalpy in the Reynolds analogy. Comparison of this method with the use of Pr_T evaluated at the reference enthalpy for surface temperatures below the sublimation temperature of carbon reveals little difference. Because Pr_T rather than Pr_w or Pr_e yields better agreement with the modified Reynolds analogy of van Driest [13], the consistent use of Pr_T in both the recovery factor and Reynolds analogy as suggested by Eckert is still appropriate. Further, when the assumption that $Le = 1$ in Ref. 16 is interpreted as equivalent to the assumption that $Pr_F = Pr_T$, the use of Pr_T based on the reference enthalpy for the recovery factor and Reynolds analogy is again borne out by these independent calculations to the accuracies quoted previously.

With the onset of ionization, the reference enthalpy technique yields results that begin to depart from the exact calculations, and recourse to the latter [16, 17] is recommended for accurate predictions.

Nonuniform Surface Temperature. The previous section was devoted to uniform-temperature plates. In practice, however, this ideal condition seldom occurs, and it is necessary to account for the effects of surface temperature variations along the plate on the local and average convective heat transfer rates. This is required especially in the regions directly downstream of surface temperature discontinuities, e.g., at seams between dissimilar structural elements in poor thermal contact. These effects cannot be accounted for by merely utilizing heat transfer coefficients corresponding to a uniform surface temperature coupled with the local enthalpy or temperature potentials. Such an approach not only leads to serious errors in magnitude of the local heat flux, but can yield the wrong direction, i.e., whether the heat flow is into or out of the surface.

It has been shown that, for property variations for which superposition of solutions is permitted, a series of solutions corresponding to a step in surface temperature can be utilized to represent an arbitrary surface temperature [22]. This approach is identical with the Duhamel method used in heat conduction problems to satisfy time-dependent boundary conditions

with a series of solutions involving sudden changes in surface boundary conditions [23]. The resulting convective heat flux distribution expressed in terms of the surface enthalpy distribution is

$$q_w''(x) = \rho_e u_e \text{St}(x, 0) \left\{ [i_w(0) - i_{aw}] + \int_0^x \frac{\text{St}(x, s)}{\text{St}(x, 0)} \frac{d[i_w(s) - i_{aw}]}{ds} ds + \sum_{j=1}^k \frac{\text{St}(x, s_j)}{\text{St}(x, 0)} [i_w(s_j^+) - i_w(s_j^-)] \right\} \quad (6.65)$$

Here, $\text{St}(x, s)$ represents the local Stanton number on a plate at a uniform temperature for $x > s$ preceded by an unheated portion of length s , and $\text{St}(x, 0)$ is the Stanton number on a plate with a uniform temperature over its entire length. The first term in parentheses in the enthalpy potential arises from the difference between the leading-edge enthalpy of the plate and the recovery enthalpy. The integral term accounts for the portions where continuous surface enthalpy variations occur. The last term sums over a k number of discontinuous jumps in surface enthalpy that may occur downstream of the leading edge. The terms $i_w(s_j^-)$ and $i_w(s_j^+)$ represent the surface enthalpy just upstream and downstream of s_j where the j th jump in enthalpy occurs.

The effect of a stepwise discontinuity in surface temperature on a flat plate can be expressed as

$$\frac{\text{St}(x, s)}{\text{St}(x, 0)} = \left[1 - \left(\frac{s}{x} \right)^{3/4} \right]^{-1/3} \quad (6.66)$$

This closed-form equation was obtained through similarity solutions of the energy equation by investigators who assumed that the velocity profile in the boundary layer is linear in η_c for the case of constant C_e and Pr_T or in y for the case of constant fluid properties [24, 25]. Note that the right side does not contain terms involving the fluid properties, a direct consequence of C_e and Pr_T being assumed constant throughout the boundary layer. Again, an intuitive approach to include property variations is to use the local surface enthalpy in the reference enthalpy technique for evaluating $\text{St}(x, 0)$. The stepwise discontinuous-surface-temperature solutions are used solely to define the functional form of the enthalpy potential appropriate to an arbitrary surface temperature. A plot of Eq. 6.66 is given in Fig. 6.12 ($\beta_p = 0$ for a flat plate).

The preceding theory has been verified by several experiments. For example, in Ref. 26, local heat transfer rates were measured in the presence of ramplike temperature distributions that began downstream of the leading edge (see inset in Fig. 6.13). The data shown in Fig. 6.13 agree with the theory (solid line) to within ± 10 percent, the estimated accuracy of the data. The dot-dashed line in the figure represents the use of a local temperature potential in estimating the heat flux and yields large errors for this particular form of the surface temperature distribution. Had the leading edge been raised above the recovery temperature, the error in neglecting the variable-surface-temperature effects would have diminished. In general, if continuous variations in the surface temperature or enthalpy are large compared to the overall driving potential, the variable-surface-temperature methods must be utilized. For discontinuous surface temperatures, much smaller variations are important.

Stepwise and Arbitrary Heat Flux Distribution. It is often necessary to evaluate the surface temperatures resulting from a prescribed heat flux distribution. The superposition of solutions yields the surface enthalpy distribution as

$$i_w(x) - i_{aw} = \frac{0.207}{\rho_e u_e \text{St}(x, 0)x} \int_0^x \frac{q_w''(x')}{[1 - (x'/x)^{3/4}]^{2/3}} dx' \quad (6.67)$$

Surface With Mass Transfer. An effective method of alleviating the intense convective heating of surfaces exposed to very-high-enthalpy streams is by means of mass transfer cooling systems. The coolant is introduced, usually in gaseous form, into the hot boundary

FIGURE 6.12 Effect of a stepwise surface temperature discontinuity on the local Stanton number—Eq. 6.66 for a flat plate ($\beta_p = 0$) and Eq. 6.124 for a surface with a pressure gradient ($\beta_p > 0$)

FIGURE 6.13 Comparison of data and theory for a flat plate with a delayed ramp surface temperature distribution [26].

layer through the surface being protected. Mass transfer cooling is particularly applicable to leading edges of wings, fins, and nose tips of aircraft; turbine blades; and reentry capsules and missile nose cones. The types of systems include transpiration, ablation, and film cooling.

A *transpiration cooling system* is characterized by a porous surface material that remains intact while the coolant is being pumped through the pores toward the hot boundary layer. The coolant may be a gas or a liquid that changes phase within the porous surface or after it emerges from the surface. This system operates best when pore sizes are so small that the coolant leaves at the surface temperature of the porous solid. These systems are complicated in that they require coolant storage vessels, pumps, controls, distribution ducts, and filters to avoid pore clogging. It is also difficult to fabricate strong, aerodynamically smooth porous surfaces. Another drawback of these systems is that they are unstable because a clogged pore resulting from local overheating seals off the flow of coolant and causes local failure. The advantages of transpiration cooling systems are their versatility in the choice of coolant and coolant distribution, the reusability of the system, and the retention of intact aerodynamically contoured surfaces.

An *ablation cooling system* is one where the gas entering the boundary layer has been generated by the thermal destruction of a sacrificial solid thermally protecting an underlying structure. The simplest ablation mechanism is the sublimation of a homogeneous material. More complex ablation involves the thermal degradation of composite materials such as reinforced plastics where a heat-absorbing pyrolysis occurs below the surface. The gaseous products of pyrolysis pass through a carbonaceous char, gaining additional sensible heat or chemical heat through endothermic reactions, and then pass into the boundary layer to absorb additional heat. Ablation cooling has the enormous advantage of being self-controlled and requiring no active elements. The disadvantages are that surface dimensions are usually altered, part of the char is eroded mechanically by shear forces rather than through heat-absorbing phase change, and often the heavy gaseous products are not as effective in blocking the incoming convective heat as light gases. Furthermore, ablation systems are generally not reusable. For short-time applications, dimensional stability has been achieved in ablation systems by employing porous refractory metal surfaces that have been impregnated with lower-melting-temperature metals that absorb heat by melting, vaporizing, and transpiring through the porous refractory matrix.

A *film cooling system* is one where a surface is protected by a film of coolant introduced into the boundary layer from either a finite length of porous surface or a slot upstream. A liquid can be used as the coolant to absorb heat by vaporization as it is drawn along the surface by the main stream gas. A severe limitation on such systems is the requirement that gravity or inertial forces act in a direction that will keep the liquid film stable and against the surface. In addition, a film cooling system requires all the active elements of a transpiration cooling system. Its main advantage over the latter is in the simpler construction of limited areas of porous surfaces or slots and in localized ducting.

The boundary layer behavior over a continuously transpiration-cooled surface and an ablation-cooled surface is generally the same, differing only as a result of the specific chemical identity of the coolant. The effects of a porous surface when the pore size is below some threshold dimension that is a small fraction of the local boundary layer thickness, and of the flow of liquid char over ablating surfaces, do not appreciably alter the behavior of the boundary layer and can be neglected in design considerations. Thus, boundary layer theory with continuous mass injection is applicable to both types of cooling systems. Further, results of experiments involving transpiration systems can be utilized in the prediction of the behavior of ablation systems. In film cooling systems, because of the discontinuities formed by slots or limited porous regions, the boundary-layer profiles at various stations along the surface are dissimilar so that prediction methods are quite complex and rely on experimental data or rather complicated numerical analyses.

Uniform Surface Temperature, Air as Coolant. When the boundary layer and coolant gases are the same, the equations controlling boundary layer behavior are Eqs. 6.6–6.8. The mass injection at the surface simply alters the boundary conditions (Eq. 6.9) at the wall to be

$$x > 0, y = 0 \quad u = 0, v = v_w(x)$$

$$I = \text{constant} = i_w \text{ or } i_{aw}, \text{ i.e., } \frac{\partial i}{\partial y} = 0$$

where

$$f(0) = - \frac{2\rho_w v_w}{\rho_e \mu_e} \sqrt{\frac{\rho_e \mu_e x}{\mu_e}} \tag{6.68}$$

As boundary layer similarity requires $f(0)$ to be independent of x , $\rho_w v_w$ must be proportional to $x^{-1/2}$. A simple heat balance on an element of a porous surface with a transpired gas, or of a subliming surface, reveals that this distribution of gaseous injection is uniquely compatible with the requirements of a constant surface temperature. Thus, $\rho_w = \text{constant}$, and $v_w \sim x^{-1/2}$. This mass injection distribution has practical importance because the porous surface can operate at its maximum allowable temperature everywhere, thereby minimizing the coolant required.

The boundary layer equations, together with these boundary conditions, were solved in a series of similarity theories such as those described in the section on the two-dimensional laminar boundary layer, beginning with solutions for constant properties and progressing to ideal gases with variable properties. A rather complete bibliography of these theories and corroborating experiments is given in Ref. 27. The assumption of constant $C_e = \mu\rho/\mu_e\rho_e$ proved equally useful in this problem as with the impervious plate in extending constant-property solutions to high Mach number cases where air still behaves as an ideal gas. The results shown here are predominantly from Refs. 28–30.

It is found in these analyses that blowing, i.e., negative values of $f(0)$, thickens both the flow and thermal boundary layers. In addition, the velocity profiles take on an S shape characteristic of boundary layers approaching separation (see Fig. 6.19). Separation, $(\partial u/\partial y)_w = 0$, occurs when $f(0) = -1.238$ [28]. These S-shaped profiles are less stable, thereby decreasing transition Reynolds numbers with increased blowing rates. Near the surface, blowing reduces the velocity and temperature gradients and the corresponding shear and heat transfer rates, respectively. The heat transfer does not drop as rapidly as the shear and, consequently, Reynolds analogy becomes dependent on the blowing rate. The recovery factor, $r(0)$, also depends on the blowing rate when Pr does not equal unity. For the case of a slender body where $r(0)u_e^2/2 \gg I_w - I_e$, the reduction in the heat flux q_w is dependent on the product of the reduction in Stanton number and the recovery factor. This is shown in Fig. 6.14 by the line labeled Air-Air.

FIGURE 6.14 Reduction of the local heat flux by surface mass transfer of a foreign gas, $T_w - T_e < r(0)u_e^2/2c_{p1}$ [31].

Uniform Surface Temperature, Foreign Gas as Coolant. The effectiveness of air injection in reducing convective heat flux stimulated investigations into the use of other coolants. With the introduction of a foreign species into the boundary layer, the boundary layer equations reduce to the continuity equation (Eq. 6.6), the momentum equation (Eq. 6.7), the energy equation

$$\rho u \frac{\partial I}{\partial x} + \rho v \frac{\partial I}{\partial y} = \frac{\partial}{\partial y} \left\{ \frac{\mu}{Pr_F} \left[\frac{\partial I}{\partial y} - (i_1 - i_2)(1 - Le) \frac{\partial K_1}{\partial y} \right] + \left[\mu \left(1 - \frac{1}{Pr_F} \right) \frac{\partial (u^2/2)}{\partial y} \right] \right\} \quad (6.69)$$

and the diffusion equation

$$\rho u \frac{\partial K_1}{\partial x} + \rho v \frac{\partial K_1}{\partial y} = \frac{\partial}{\partial y} \left(\frac{\mu Le}{Pr_F} \frac{\partial K_1}{\partial y} \right) \quad (6.70)$$

Here, $Pr_F/Le = Sc$ is the Schmidt number, K_1 is the coolant mass concentration, and i_1 and i_2 are the coolant and air enthalpies, respectively. These equations are the bases for the bulk of the analyses involving foreign gas transpiration.

The boundary conditions for Eqs. 6.69 and 6.70 are

$$\begin{aligned} x = 0, y \geq 0 & \quad K_1 = 0 \\ x > 0, y \rightarrow \infty & \quad K_1 \rightarrow 0 \\ y = 0 & \quad K_1 = K_{1w} \end{aligned}$$

The value of K_{1w} is dependent on the blowing rate, and some hypothesis is required to establish this dependency. Most authors have assumed a zero net mass transfer of air into the surface. This requires that the air carried away from the surface by the mass motion normal to the surface be balanced by the diffusion of air toward the surface. Since $K_1 = 1 - K_2$ and $j_1 = -j_2$, this balance of air motion can be expressed directly in terms of the coolant properties as

$$\rho_w v_w = - \frac{\rho_w \mathcal{D}_{12}}{1 - K_{1w}} \left(\frac{\partial K_1}{\partial y} \right)_w = \frac{j_{1w}}{1 - K_{1w}} \quad (6.71)$$

Equation 6.71 is the required relationship between the blowing rate of the coolant and its concentration at the wall. When the diffusion flux is expressed in terms of the mass transfer coefficient, the concentration of the coolant at the wall is given by

$$K_{1w} = \frac{1}{1 + (\rho_e \mathcal{U}_e / \rho_w v_w) c_{m1}} \quad (6.72)$$

Note that the mass transfer coefficient is defined differently in Ref. 31.

Although the total heat flux at the surface in a binary gas is composed of the sum of a conduction term and a diffusion term, the results of analyses are expressed solely in terms of the heat conduction term. The reason is that this term is equal to the heat gained by the coolant in passing from its reservoir to the surface in contact with the boundary layer. This simple heat balance is

$$k_w \left(\frac{\partial T}{\partial y} \right)_w = \rho_w v_w (i_{1w} - i_{1c}) \quad (6.73)$$

where the subscript c represents the initial coolant condition in the reservoir. Further, the recovery factor is defined in terms of the surface temperature that results in zero heat conduction at the surface for a given mass transfer rate. This adiabatic condition is achieved in experiments by setting $T_{1c} = T_w$ for a given mass flow rate so that the coolant gains no heat. In terms of the Stanton number, the heat balance indicated by Eq. 6.73 can be expressed as

$$\frac{q_w''}{q_w''_{w0}} = \frac{\rho_w v_w}{\rho_e \mathcal{U}_e St_0} \frac{i_{1w} - i_{1c}}{i_{2aw0} - i_{2w}} \quad (6.74)$$

The subscript 0 in this equation signifies zero mass transfer at the surface ($f(0) = 0$). The subscript 2 indicates that the enthalpy potential contributing to the heat flux by conduction alone is dependent only on the specific heat of the air and not that of the coolant.

The effect of mass transfer on heat flux from slender bodies is shown in Fig. 6.14 for a variety of coolant gases. The corresponding mass transfer coefficients are shown in Fig. 6.15.

FIGURE 6.15 Reduction of the local mass transfer coefficient by surface mass transfer of a foreign gas [31]. (Reprinted by permission of Pergamon Press.)

An important result from these figures is that lighter gases are more effective in reducing the transport coefficients and surface heat flux. For a range of calculations including Mach numbers as high as 12 and surface temperatures from free-stream (392°R; 218 K) to recovery temperatures, the maximum departure from these correlation lines of individual solutions is ± 15 percent for q_w'' and ± 25 percent for c_{m_i} . The bulk of the discrete numerical results lie within about one-third of these bandwidths. The maximum spread of results is obtained with the mass transfer of hydrogen, and the spread is smaller with helium and much smaller with the heavier gases. The differences in results from different calculations with the light gases are due primarily to the use of different gas properties [32].

Figures 6.14 and 6.15 are particularly useful for obtaining the mass transfer rate required in a transpiration cooling system. Usually the following quantities are specified: the coolant and its reservoir conditions, the porous surface material and its maximum allowable surface temperature, and the inviscid flow conditions outside the boundary layer. For cases where the difference between the surface temperature and the boundary layer edge temperature is small compared to the temperature rise by frictional heating, Fig. 6.14 can be used directly. For the specified conditions, the factor $(i_{1w} - i_{1c}) / (i_{2aw_0} - i_{2w})$ can be readily established from the thermodynamic properties of the coolant and air and $i_{2aw_0} = i_{aw}$. This factor is used as the slope of a straight line that represents Eq. 6.74 and passes through the origin of Fig. 6.14. The intercept of this line with the appropriate heat blockage curve on the figure is the operating condition required to yield the specified surface temperature. The abscissa of this point yields the required local mass transfer rate.

The behavior of a coolant composed of mixtures of He, Ar, Xe, and N₂ injected into a nitrogen boundary layer has been analyzed in Ref. 33. Examination of the results reveals that

at a given mass transfer rate the skin friction coefficient is correlated for different coolants within ± 5 percent using the mean molecular weight of the coolant. Thus, for a coolant composed of a mixture of n gases, the average molecular weight of the coolant at reservoir conditions defined as

$$M_{\text{avg}} = \frac{1}{\sum_i^n (K_{ic}/M_i)} \quad (6.75)$$

can be used to interpolate between the curves of Figs. 6.14 and 6.15.

Uniform Surface Injection. Although a mass transfer distribution yielding a uniform surface temperature is most efficient, it is much easier to construct a porous surface with a uniform mass transfer distribution. Libby and Chen [34] have considered the effects of uniform foreign gas injection on the temperature distribution of a porous flat plate. For these conditions, however, boundary layer similarity does not hold. Libby and Chen extended the work of Iglisch [35] and Lew and Fanucci [36], where direct numerical solutions of the partial differential equations were employed. An example of the nonuniform surface enthalpy and coolant concentrations resulting from these calculations is shown in Fig. 6.16.

FIGURE 6.16 Surface temperature and coolant concentration distribution along a plate with uniform foreign gas injection, $Le = Pr = C_r = 1$, all binary diffusion coefficients equal [34]. (Reprinted by permission from *The Physics of Fluids*.)

Film Cooling With Upstream Transpiration. Film cooling systems provide protection to a surface exposed to high-enthalpy streams by injecting a coolant into the hot boundary layer upstream of the surface. Injection can take place through local porous sections or slots at various angles to the surface. The coolant may be the same gas as in the boundary layer, a foreign gas, or a liquid. In the upstream porous section, more coolant is provided than is required to maintain safe surface temperatures. The excess coolant is entrained in the boundary layer close to the surface and is carried downstream, providing an insulating layer between the hot free-stream gas and the surface. This layer is dissipated by laminar mixing while flowing with the boundary layer in such a way that protection is afforded over a limited distance. Because of the discontinuous nature of the surface injection, the boundary layer downstream of the

discontinuity is far from similar. Numerical solutions of higher-order integral equations [37] or of finite difference forms of the partial differential equations [38] have been used for evaluating the local convection to the surface.

Examples of thermal protection offered by an upstream transpiration system are indicated in Fig. 6.17 (see Ref. 37). The figure shows the temperature rise that occurs on an insulated surface downstream of a transpiration-cooled section for two amounts of blowing. Also indicated are the corresponding surface temperatures for the case where the upstream section was cooled internally, i.e., $f(0) = 0$. The quantity T_{wL} is the upstream surface temperature in either case. The differences between the curves labeled $f(0) = -0.5$ and $f(0) = -1$ and the $f(0)$ curve show how the presence of the transpired coolant within the downstream boundary layer distorts the temperature profiles so as to afford greater downstream protection depending on the amount of blowing.

FIGURE 6.17 Effect of upstream transpiration cooling on the temperature distribution of the impervious portion of a flat plate.

Cone in Supersonic Flow. The preceding solutions for a flat plate may be applied to a cone in supersonic flow through the Mangler transformation [39], which in its most general form relates the boundary layer flow over an arbitrary axisymmetric body to an equivalent flow over a two-dimensional body. This transformation is contained in Eq. 6.89, which results in transformed axisymmetric momentum and energy equations equivalent to the two-dimensional equations (Eqs. 6.95 and 6.97). Hence, solutions of these equations are applicable to either a two-dimensional or an axisymmetric flow, the differences being contained solely in the coordinate transformations.

For the case of an arbitrary pressure distribution, it is just as convenient to solve the axisymmetric problem directly. When the solution for the equivalent two-dimensional flow already exists, however, as for a flat plate, then the results for the corresponding axisymmetric problem can be obtained by direct comparison. This correspondence exists for a cone in supersonic flow when the surface pressure is constant. Solutions of Eqs. 6.95 and 6.97 for a flat plate expressed in terms of ζ and η may then be applied to a cone. Illustrative examples are presented in the following subsections.

Uniform Surface Temperature. Transformations (see Eq. 6.89) for a flat plate ($\mathbf{k} = 0$) or a cone ($\mathbf{k} = 1$) become

$$\left. \begin{aligned} \zeta &= \frac{\rho_w \mu_w u_e}{\mu_r^2} \left(\frac{\sin \theta_c}{L} \right)^{2\mathbf{k}} \frac{x^{2\mathbf{k}+1}}{2\mathbf{k}+1} \\ \eta &= \sqrt{\frac{(2\mathbf{k}+1)u_e}{2\rho_w \mu_w x}} \int_0^y \rho \, dy \end{aligned} \right\} \quad (6.76)$$

with ρ_w , μ_w , and u_e equal to constants, $\bar{\zeta} = 0$, and $r = x \sin \theta_c$. The transformed momentum and energy equations (Eqs. 6.95 and 6.97) are essentially the same as Eqs. 6.37 and 6.38 for a flat plate. For the same wall and boundary layer edge conditions, then, the solutions for $f(\eta)$ and $\bar{T}(\eta)$ are the same for a flat plate or a cone. These results may be expressed in terms of physical variables as

$$y = \sqrt{\frac{2\rho_w \mu_w x}{(2\mathbf{k}+1)u_e}} \int_0^\eta \frac{1}{\rho} \, d\eta \quad (6.77)$$

$$\tau_w = \mu_w \left(\frac{\partial u}{\partial y} \right)_w = \rho_e u_e^2 \sqrt{\frac{(2\mathbf{k}+1)\mu_e}{2\rho_e \mu_e x}} \frac{\mu_w \rho_w}{\mu_e \rho_e} f''(0) \quad (6.78)$$

$$q_w'' = -k_w \left(\frac{\partial T}{\partial y} \right)_w = -\frac{k_w I_e}{\mu_w c_{p_w}} \sqrt{\frac{(2\mathbf{k}+1)\mu_e}{2\rho_e \mu_e x}} \frac{\mu_w \rho_w}{\mu_e \rho_e} \bar{T}'(0) \quad (6.79)$$

For a given value of x and the same flow properties, the boundary layer on a cone ($\mathbf{k} = 1$) is thinner by a factor of $1/\sqrt{3}$, and the surface shear stress and heat transfer are larger by a factor of $\sqrt{3}$. The local skin friction and heat transfer coefficients are related similarly:

$$\frac{(c_f)_{\text{cone}}}{(c_f)_{\text{flat plate}}} = \frac{\text{St}_{\text{cone}}}{\text{St}_{\text{flat plate}}} = \sqrt{3} \quad (6.80)$$

The local and average coefficients for a cone are related as follows:

$$\left(\frac{\bar{c}_f}{c_f} \right)_{\text{cone}} = \left(\frac{\bar{\text{St}}}{\text{St}} \right)_{\text{cone}} = \frac{4}{3} \quad (6.81)$$

These relationships may be used to obtain cone flow results from the flat-plate results of the section on uniform free-stream conditions. Real-gas solutions for air obtained in this manner are given in Ref. 17.

Nonuniform Surface Temperature. Transformations (Eq. 6.76) are applicable to flows with nonuniform surface temperature provided a linear viscosity law is assumed ($\mu\rho = \text{constant}$). The flat-plate results given previously for constant Pr_T may be applied to a cone with the requirement that the surface boundary conditions be the same in terms of ζ . For a flat plate, $\zeta \sim x$, and for a cone, $\zeta \sim x^3$. Therefore, the flat-plate results must be modified in such a way that lengths in the x direction are replaced by x^3 to obtain the cone results. For example, Eq. 6.66, which expresses the effect of a stepwise surface temperature for a flat plate, becomes for a cone

$$\left[\frac{\text{St}(x, s)}{\text{St}(x, 0)} \right]_{\text{cone}} = \left[1 - \left(\frac{s}{x} \right)^{9/4} \right]^{-1/3} \quad (6.82)$$

Similar expressions may be derived for the effect of an arbitrary heat flux distribution.

Mass Transfer, Uniform Surface Temperature. The uniform-surface-temperature results above may be extended to include mass transfer. Similarity requires that $f(0)$ be constant,

which determines the blowing distribution along the surface. The normal velocity component from Eq. 6.99 is

$$\frac{v_w}{u_e} = -\sqrt{\frac{(2\mathbf{k} + 1)\mu_w}{2\rho_w u_e x}} f(0) \tag{6.83}$$

For a cone, $v_w \sim x^{-1/2}$ as for a flat plate, but is larger by the factor $\sqrt{3}$ for given values of x and $f(0)$ (thus, the blowing parameter $\rho_w v_w / \rho_e u_e St_0$ remains unchanged). With this difference, the flat-plate results may be applied to a cone according to the equations above.

For a nonsimilar blowing distribution, for example, $v_w = \text{constant}$, Eq. 6.83 is not applicable. Solutions to this problem may be found in Ref. 40.

Surface With Streamwise Pressure Gradient

Gas With Uniform Elemental Composition in Chemical Equilibrium. Except for a few configurations such as a flat plate and wedges or cones in supersonic flow, the pressure varies over the body surface as determined by inviscid flow theory. The influence of pressure gradients on forced convection in laminar boundary layers is presented in this section. Axisymmetric bodies at zero angle of attack and yawed cylinders of infinite length will be treated together to illustrate their close relationship (see Fig. 6.18). Because boundary layer theory requires negligible pressure gradients across the boundary layer, the techniques presented here apply only to those bodies whose local surface radius of curvature (r_n in Fig. 6.18) is large compared with the boundary layer thickness, thereby minimizing centrifugal forces.

Governing Differential Equations. In the absence of foreign gas injection, the boundary layer can be considered to have uniform elemental composition and be in chemical equilibrium, and is governed by the following equations:

$$\frac{\partial}{\partial x} (\rho u r^k) + \frac{\partial}{\partial y} (\rho v r^k) = 0 \tag{6.84}$$

$$\rho u \frac{\partial u}{\partial x} + \rho v \frac{\partial u}{\partial y} = -\frac{dP}{dx} + \frac{\partial}{\partial y} \left(\mu \frac{\partial u}{\partial y} \right) \tag{6.85}$$

$$\rho u \frac{\partial w}{\partial x} + \rho v \frac{\partial w}{\partial y} = \frac{\partial}{\partial y} \left(\mu \frac{\partial w}{\partial y} \right) \quad (\text{for } \mathbf{k} = 0 \text{ only}) \tag{6.86}$$

$$\rho u \frac{\partial I}{\partial x} + \rho v \frac{\partial I}{\partial y} = \frac{\partial}{\partial y} \left[\frac{\mu}{Pr_T} \frac{\partial I}{\partial y} + \mu \left(1 - \frac{1}{Pr_T} \right) \frac{\partial}{\partial y} \left(\frac{u^2 + w^2}{2} \right) \right] \tag{6.87}$$

where $\mathbf{k} = 1$ for the axisymmetric body and $\mathbf{k} = 0$ for the yawed cylinder.

FIGURE 6.18 Sketch of coordinates employed for related two-dimensional flows. (a) axisymmetric body; (b) yawed cylinder of infinite length.

The boundary conditions are

$$\left. \begin{aligned}
 x=0, y>0 \quad & u = u_e(0) \\
 & I = I_e \\
 & w = w_e = V_\infty \sin \Lambda \quad \text{for } k=0 \\
 x>0, y \rightarrow \infty \quad & u \rightarrow u_e(x) \\
 & I \rightarrow I_e \\
 & w \rightarrow w_e = V_\infty \sin \Lambda \quad \text{for } k=0 \\
 y=0 \quad & u = w = 0 \\
 & v = 0 \text{ for an impervious surface or } v_w(x) \text{ with transpiration} \\
 & I = i_w(x) \quad \text{for } q_w'' \neq 0 \quad \text{or} \quad \frac{\partial I}{\partial y} = 0 \quad \text{for } I = i_{aw}(x)
 \end{aligned} \right\} \quad (6.88)$$

The yaw angle Λ is the complement of the angle between the free-stream direction and the cylinder axis (see Fig. 6.18).

Transformation of Variables and Equations. The extensions of transformations Eq. 6.36 to include the effects of pressure gradients are

$$\begin{aligned}
 \zeta &= \frac{1}{\mu_r^2} \int_0^x \rho_w \mu_w u_e \left(\frac{r}{\mathbf{L}} \right)^{2k} dx = \zeta(x) \\
 \eta &= \frac{u_e(r/\mathbf{L})^k}{\mu_r \sqrt{2(\zeta - \bar{\zeta})}} \int_0^y \rho dy
 \end{aligned} \quad (6.89)$$

where μ_r is a reference viscosity and \mathbf{L} is a reference length introduced to make ζ and η dimensionless [16, 41]. The function $\bar{\zeta}(\zeta)$ is yet to be determined and is a key element in the extension of similarity solutions to flows where the inviscid boundary conditions do not permit boundary layer similarity. (Note the change in symbols employed here from those of Refs. 16 and 41.)

The dependent variables are defined as

$$f_\eta = \frac{u}{u_e(x)} \quad \bar{I} = \frac{I}{I_e} \quad \bar{w} = \frac{w}{w_e} \quad (\text{for } \mathbf{k} = 0 \text{ only}) \quad (6.90)$$

Additional parameters that enter the equations are

$$\bar{i} = \frac{i}{I_e} = \bar{I} - (1 - \bar{i}_s) \bar{w}^2 - (\bar{i}_s - \bar{i}_e) f_\eta^2 \quad (6.91)$$

where
$$\bar{i}_s = 1 - \frac{w_e^2}{2I_e} \quad (6.92)$$

and
$$\bar{i}_e = 1 - \frac{u_e^2 + w_e^2}{2I_e} \quad (6.93)$$

The pressure gradient parameter is defined as

$$\beta_p = \frac{2(\zeta - \bar{\zeta})}{u_e} \frac{\bar{i}_s}{\bar{i}_e} \frac{du_e}{d\zeta} \quad (6.94)$$

Both \bar{i}_e and β_p are functions of x through their dependence on $u_e(x)$.

The transformed partial differential equations of momentum and energy are

$$(C_w f_{\eta\eta})_{\eta} + \left(1 - \frac{d\bar{\zeta}}{d\zeta}\right) f f_{\eta\eta} = \beta_p \left[f_{\eta}^2 - \frac{\bar{I}}{\bar{t}_s} + \frac{1 - \bar{t}_s}{\bar{t}_s} \bar{w}^2 - \frac{\bar{t}_e}{\bar{t}_s} \left(\frac{\rho_e}{\rho} - \frac{\bar{t}}{\bar{t}_e} \right) \right] + 2(\zeta - \bar{\zeta})(f_{\eta} f_{\eta\zeta} - f_{\zeta} f_{\eta\eta}) \quad (6.95)$$

$$(C_w \bar{w}_{\eta})_{\eta} + \left(1 - \frac{d\bar{\zeta}}{d\zeta}\right) f \bar{w}_{\eta} = 2(\zeta - \bar{\zeta})(f_{\eta} \bar{w}_{\zeta} - f_{\zeta} \bar{w}_{\eta}) \quad (6.96)$$

$$\left(\frac{C_w}{\text{Pr}_T} \bar{I}_{\eta} \right)_{\eta} + \left(1 - \frac{d\bar{\zeta}}{d\zeta}\right) f \bar{I}_{\eta} = \left\{ C_w \left(\frac{1}{\text{Pr}_T} - 1 \right) [(\bar{t}_s - \bar{t}_e)(f_{\eta}^2)_{\eta} + (1 - \bar{t}_s)(\bar{w}^2)_{\eta}] \right\} + 2(\zeta - \bar{\zeta})(f_{\eta} \bar{I}_{\zeta} - f_{\zeta} \bar{I}_{\eta}) \quad (6.97)$$

The boundary conditions for zero mass transfer are

$$\left. \begin{aligned} \eta = 0 \quad & f(\zeta, 0) = f_{\eta}(\zeta, 0) = \bar{w}(\zeta, 0) = 0 \\ & \bar{I}(\zeta, 0) = \bar{I}_w(\zeta) = \bar{t}_w(\zeta) \quad \text{for } q_w'' \neq 0 \\ \text{and} \quad & \bar{I}_{\eta}(\zeta, 0) = 0 \quad \text{for } q_w'' = 0 \\ \eta \rightarrow \infty \quad & f_{\eta}(\zeta, \infty) = \bar{w}(\zeta, \infty) = \bar{I}(\zeta, \infty) \rightarrow 1 \end{aligned} \right\} \quad (6.98)$$

With mass transfer, $f(\zeta, 0)$ depends on $v_w(x)$ as follows:

$$\frac{v_w(x)}{u_e(x)} = - \frac{\mu_w}{\mu_r} \left(\frac{r}{L} \right)^{1/2} \left[\frac{f(\zeta, 0)}{\sqrt{2\zeta}} + \sqrt{2\zeta} f_{\zeta}(\zeta, 0) \right] \quad (6.99)$$

Similar Solutions

Similarity Criteria and Reduced Equations. The partial differential equations (Eqs. 6.95–6.97) are not amenable to solution except by numerical methods utilizing high-speed computers. Considerable simplifications can result, as in the case of the flat plate, if these equations are reduced to ordinary differential equations through the similarity concept where the dependent variables f , \bar{w} , and \bar{I} are assumed functions of η alone. Equations 6.95–6.97 become, for $\bar{\zeta} = \text{constant}$

$$(C_w f''')' + f f'' = \beta_p \left[f'^2 - \frac{\bar{I}}{\bar{t}_s} + \frac{1 - \bar{t}_s}{\bar{t}_s} \bar{w}^2 - \frac{\bar{t}_e}{\bar{t}_s} \left(\frac{\rho_e}{\rho} - \frac{\bar{t}}{\bar{t}_e} \right) \right] \quad (6.100)$$

$$(C_w \bar{w}')' + f \bar{w}' = 0 \quad (6.101)$$

$$\left(\frac{C_w}{\text{Pr}_T} \bar{I}' \right)' + f \bar{I}' = \left\{ C_w \left(\frac{1}{\text{Pr}_T} - 1 \right) [(\bar{t}_s - \bar{t}_e)(f'^2)' + (1 - \bar{t}_s)(\bar{w}^2)'] \right\} \quad (6.102)$$

Consistent with the similarity assumption, none of the terms that appear in these equations or in the related boundary conditions can be dependent on x or ζ ; that is, β_p , \bar{t}_e , and \bar{I}_w , as well as $\bar{\zeta}$, must be constant. The parameter \bar{t}_e , defined by Eq. 6.93, however, violates this requirement when u_e varies with x . The similarity assumption is also violated by the terms that contain \bar{t}_e explicitly in Eqs. 6.100 and 6.102 and by the gas properties C_w , Pr_T , ρ_e/ρ , which can be expressed in terms of \bar{t} , which in turn depends on \bar{t}_e through Eq. 6.91. Consequently, exact similar solutions are not possible under general stagnation region flow conditions.

Exact similar solutions are possible for stagnation regions where $u_e \approx 0$ and \bar{t}_e is a constant and equal to unity for an axisymmetric body and to \bar{t}_s for a yawed cylinder. The terms involving \bar{t}_e drop out of Eqs. 6.100–6.102, and similarity occurs for constant \bar{t}_w and β_p .

For similar flows, the pressure gradient parameter expressed as follows must be constant:

$$\beta_p = \frac{2}{u_e} \frac{\bar{i}_s}{\bar{i}_e} \frac{du_e}{dx} \frac{\int_0^x \rho_w \mu_w u_e \left(\frac{r}{L}\right)^{2k} dx}{\rho_w \mu_w u_e \left(\frac{r}{L}\right)^{2k}} \quad (6.103)$$

In a stagnation region, the fluid properties are nearly constant, and $u_e \sim x$; also $r \approx x$. Thus, $\beta_p = 1/2$ for an axisymmetric body, and $\beta_p = 1$ for a yawed cylinder.

The skin friction coefficient and Stanton number are defined under the conditions of similarity on axisymmetric and two-dimensional bodies as follows. The components of the shear stress in the x_i direction are given by

$$\tau_{wi} = \sqrt{\frac{\mu_w \rho_w \bar{i}_s u_e^2}{\beta_p \bar{i}_e} \frac{du_e}{dx}} \frac{\partial}{\partial \eta} \left(\frac{u_i}{u_{ie}} \right) \Big|_w \quad (6.104)$$

where the subscript $i = 1$ or 3 represents the x or z direction, respectively. The skin friction coefficient is defined as

$$\frac{c_{f_i}}{2} = \frac{\tau_{v_i}}{\rho_w u_e u_{ie}} \quad (6.105)$$

with

$$\frac{c_{f_1}}{2} \sqrt{\frac{\rho_w u_e x}{\mu_w}} = \sqrt{\frac{\bar{i}_s}{\beta_p \bar{i}_e} \frac{x}{u_e} \frac{du_e}{dx}} f_w'' \quad (6.106)$$

$$\frac{c_{f_3}}{2} \sqrt{\frac{\rho_w u_e x}{\mu_w}} = \sqrt{\frac{\bar{i}_s}{\beta_p \bar{i}_e} \frac{x}{u_e} \frac{du_e}{dx}} \bar{w}'_w \quad (6.107)$$

Alternative forms of these equations that are sometimes more convenient are

$$\frac{c_{f_1}}{2} \sqrt{\frac{\rho_w u_e x_{eff}}{\mu_w}} = \frac{1}{\sqrt{2}} f_w'' \quad (6.108)$$

$$\frac{c_{f_3}}{2} \sqrt{\frac{\rho_w u_e x_{eff}}{\mu_w}} = \frac{1}{\sqrt{2}} \bar{w}'_w \quad (6.109)$$

where

$$x_{eff} = \frac{\int_0^x \rho_w \mu_w u_e \left(\frac{r}{L}\right)^{2k} dx}{\rho_w \mu_w u_e \left(\frac{r}{L}\right)^{2k}} \quad (6.110)$$

The corresponding Stanton number expressions for a surface at constant temperature are

$$St \sqrt{\frac{\rho_w u_e x}{\mu_w}} = \sqrt{\frac{\bar{i}_s}{\beta_p \bar{i}_e} \frac{x}{u_e} \frac{du_e}{dx}} \frac{1}{Pr_{T_w}} \frac{\bar{I}'_w}{\bar{I}_w - \bar{I}_{aw}} \quad (6.111)$$

$$St \sqrt{\frac{\rho_w u_e x_{eff}}{\mu_w}} = \frac{1}{\sqrt{2}} \frac{1}{Pr_{T_w}} \frac{\bar{I}'_w}{\bar{I}_w - \bar{I}_{aw}} \quad (6.112)$$

Uniform Surface Temperature, Ideal Gas With Viscosity-Density Product and Prandtl Number Equal to Unity. For the case of an ideal gas with $C_w = Pr = 1$, similarity is possible away from the stagnation region of a body. Equations 6.100 and 6.102 for an axisymmetric body or a cylinder normal to the free stream reduce to

$$f''' + ff'' = \beta_p(f'^2 - \bar{I}) \quad (6.113)$$

$$\bar{I}'' + f\bar{I}' = 0 \quad (6.114)$$

when u_e satisfies

$$\frac{u_e}{\sqrt{t_e}} = A\zeta^{\beta_p/2} \quad (6.115)$$

These equations are equivalent to those solved in Ref. 42 for a uniform surface temperature. Examples of the extensive solutions in Refs. 16 and 42 are presented in this section.

Figure 6.19 shows the velocity distribution in the boundary layer of an axisymmetric body or an unswept cylinder for a cold wall ($\bar{I}_w = 0$). (Note that the value of η used here is a factor of $\sqrt{2}$ smaller than the one employed in sections on the flat plate.) An accelerating free stream ($\beta_p > 0$, u_e increasing) reduces the flow boundary layer thickness and increases the velocity gradient rather uniformly through the boundary layer. A decelerating free stream ($\beta_p < 0$) thickens the flow boundary layer rather severely and causes the velocity distribution to acquire an S shape. Eventually, the boundary layer will separate; that is, $f_w'' = 0$. For the boundary conditions of Fig. 6.19, two solutions are possible for negative values of β_p near separation. It is argued in Ref. 42 that true similarity with negative β_p cannot occur physically because Eq. 6.115 would require $u_e \rightarrow \infty$ as $\zeta \rightarrow 0$. Thus, similar solutions with negative β_p can only be approached after a period of nonsimilar flow, and depending on the conditions, one or the other of the similar solutions for a given β_p can be attained. In Ref. 42, experimental evidence from Ref. 43 for turbulent flow is cited for the possible existence of double-valued flow-field behavior. The velocity profiles shown are characteristic of those for either a cooled surface or one at the total enthalpy of the fluid. For a heated surface and $\beta_p > 0$, it is possible for the velocity ratio f' in the outer portion of the boundary layer to attain a value greater than unity before approaching unity at the outer edge. The physical reason for this is that the acceleration of lower-density fluid by the favorable pressure gradient exceeds the retardation by the viscous forces.

FIGURE 6.19 Similar velocity distributions for body with surface pressure gradient β_p defined by Eq. 6.103, $\bar{I}_w = 0$, $\bar{I}_e = 1$ [42].

The total enthalpy distribution in terms of the velocity is shown in Fig. 6.20 for $\bar{T}_w = 0$ and $\bar{i}_s = 1$. A pressure gradient can cause significant departures from the Crocco relationship (Eq. 6.40), represented by the straight line labeled $\beta_p = 0$). The latter is often used for approximate calculations even when pressure gradients are present.

FIGURE 6.20 Enthalpy and velocity relationship within similar boundary layers on a body with pressure gradient β_p defined by Eq. 6.103, $\bar{T}_w = 0$, $\bar{i}_s = 1$ [42].

Figure 6.21 shows the wall shear parameter f_w'' required to evaluate the local skin friction coefficients by Eq. 6.106 or 6.108. These curves apply for the case where $\bar{i}_s = 1$. The double-valued nature of f_w'' for a cooled surface ($\bar{T}_w = 0$) for β_p near separation ($f_w'' = 0$) is evident. Generally, f_w'' is more sensitive to variations in β_p for a hot surface. In fact, for cold wall conditions ($\bar{T}_w = 0$), the variation of f_w'' with β_p for $\beta_p > 0$ is quite modest. Also, a cooled surface tends to retard separation; that is, $f_w'' = 0$ at a smaller value of β_p .

FIGURE 6.21 Effect of pressure gradient on the skin friction parameter f_w'' for various wall temperature levels, $\bar{i}_s = 1$ [42].

FIGURE 6.22 Effect of pressure gradient on the heat transfer parameter \bar{I}'_w for various wall temperature levels, $\bar{t}_s = 1$, $Pr = 1$ [42].

The heat transfer parameter required in Eq. 6.111 or 6.112 to calculate Stanton number is shown in Fig. 6.22 for $\bar{t}_s = 1$. It should be noted that because of the similarity of Eqs. 6.101 and 6.102 for $Pr = 1$,

$$\bar{w}'_w = \frac{\bar{I}'_w}{\bar{I}_w - \bar{I}'_{aw}} \tag{6.116}$$

Hence, the ordinate in Fig. 6.22 can also be used in conjunction with Eq. 6.107 or 6.109 to calculate the cross flow skin friction coefficient for cases of very small yaw angles ($\bar{t}_s \approx 1$). Note that \bar{I}'_{aw} is equal to unity because the solution of Eq. 6.102 with $Pr = 1$ and an insulated surface is $\bar{I} \equiv 1$. Although the trends exhibited in Figs. 6.21 and 6.22 are generally similar, it must be cautioned that such large variations in the Reynolds analogy factor occur that the latter is no longer a useful concept. The heat transfer parameter for a cooled surface shows a rather small variation with β_p for $\beta_p \geq 1/2$, a fact first utilized in Ref. 44 to obtain relatively simple expressions for the local heat flux to blunt bodies in hypersonic flow.

Cylinder Normal to the Free Stream, Fluid With Constant Properties. For constant fluid properties, Eqs. 6.100 and 6.102 reduce to

$$f''' + ff'' = \beta_p (f'^2 - 1) \tag{6.117}$$

$$\bar{I}'' + Pr f \bar{I}' = 2Pr \zeta f' \bar{I}'_\zeta \tag{6.118}$$

For a cylinder normal to the free stream, the inviscid velocity distribution is given by

$$u_e = Ax^m \tag{6.119}$$

with

$$\beta_p = \frac{2m}{1+m} \tag{6.120}$$

The term on the right side of Eq. 6.118 has been added to account for a nonuniform surface temperature.

Similar solutions for Prandtl numbers other than unity may be obtained from Eqs. 6.117 and 6.118 or their equivalent. A major simplification is the independence of the momentum equation (Eq. 6.117), from the energy equation (Eq. 6.118), which makes f independent of \bar{I} . Also, the linear form of the energy equation in \bar{I} permits handling arbitrary surface temperature distributions as in the case of the flat plate. (See the section on the two-dimensional laminar boundary layer.)

Solutions of the momentum equation (Eq. 6.117) [45] yield velocity distributions generally similar to those of Fig. 6.19, and the skin friction parameter f_w'' shown by the line labeled 1 in Fig. 6.21. The skin friction coefficient is given by

$$\frac{c_f}{2} \sqrt{\frac{\rho_e \mu_e x}{\mu_e}} = \frac{f_w''}{\sqrt{2 - \beta_p}} \quad (6.121)$$

For a uniform surface temperature, solutions of the energy equation (Eq. 6.118) [46, 47] can be expressed as

$$\text{St}(x, 0) \sqrt{\frac{\rho_e \mu_e x}{\mu_e}} = \frac{\text{Pr}^{-a}}{\sqrt{2 - \beta_p}} \left(\frac{\bar{I}'_w}{\bar{I}_w - \bar{I}_{aw}} \right)_{\text{Pr}=1} \quad (6.122)$$

where the heat transfer parameter in parentheses on the right is given by the line labeled 1 in Fig. 6.22. The exponent a for the Prandtl number is given in Table 6.3 as a function of β_p .

TABLE 6.3 Exponent of Pr in Eq. 6.122

β_p	-0.199	0	1	1.6
a	0.746	0.673	0.645	0.633

In Ref. 46, an ingenious set of transformations is employed to evaluate the recovery factor away from the stagnation line. The results for $\beta_p = 1$ show a significant departure (≈ -10 percent for $\text{Pr} = 0.7$) from $\mathbf{r}(0) = \text{Pr}^{1/2}$. These values, however, do not agree with calculations performed in Ref. 49. Perhaps the discrepancy is due to the evaluation of $\mathbf{r}(0)$ in Ref. 46 by taking the derivative of a function. Slight errors in the function itself could easily account for a 10 percent error in the derivative. For accuracies of $\mathbf{r}(0)$ within a few percent [48], it is recommended that

$$\mathbf{r}(0) = \text{Pr}^{1/2} \quad (6.123)$$

be employed for all β_p .

For a stepwise and arbitrary surface temperature distribution, the local heat flux distribution is given by Eq. 6.65. The term $\text{St}(x, 0)$ represents the Stanton number for the same flow conditions but with a uniform surface temperature. Equation 6.65 was derived formally with the assumption that i_{aw} is uniform along the surface; however, small continuous variations in i_{aw} or T_{aw} are permissible. The value of i_{aw} at $x = 0$ is used in the first term on the right side of Eq. 6.65, and the local value of i_{aw} is employed within the integral. Although Eq. 6.65 appears to be reciprocal in variations of i_w and i_{aw} , this is not the case. Changes in the same direction of both i_w and i_{aw} do not necessarily cancel, because a change in i_{aw} takes effect gradually downstream.

The kernel function $\text{St}(x, s)/[\text{St}(x, 0)]$ in Eq. 6.65 represents the behavior of the heat transfer coefficient after a jump in wall temperature at $x = s$. This function was obtained in Refs. 24 and 25 by solving the energy equation with the assumption of a linear velocity profile and is given by

$$\frac{\text{St}(x, s)}{\text{St}(x, 0)} = \left[1 - \left(\frac{s}{x} \right)^{a^*} \right]^{-b^*} \quad (6.124)$$

$$a^* = \frac{3}{2(2 - \beta_p)} \quad b^* = \frac{1}{3} \quad (6.125)$$

The analogous function for a flat plate is given by Eq. 6.66. These results were improved upon in Ref. 49, where a power-law velocity profile was assumed, $u/u_e = (y/y_e)^{d^*}$, with d^* found to best fit Hartree's calculations [45] as listed in Table 6.4. The form of the kernel function (Eq. 6.124) is the same, but the exponents are changed to

$$a^* = \frac{2 + d^*}{(1 + d^*)(2 - \beta_p)} \quad b^* = \frac{1}{2 + d^*} \quad (6.126)$$

TABLE 6.4 Exponent d^* for Velocity Function, $u/u_e = (y/y_e)^{d^*}$

m	0	1/9	1/3	1	4
β_p	0	0.2	0.5	1	1.6
d^*	0.88	0.86	0.80	0.76	0.66

Use of these values to calculate the heat flux distribution from Eqs. 6.65 and 6.124 yields excellent agreement with the exact solutions of Refs. 9, 47, and 50. Hence, for $m \geq 0$, values of a^* and b^* given by Eq. 6.126 are preferred to those given by Eq. 6.125. For $m = 0$, there is little difference between the kernel functions (Eq. 6.124) based on the two different sets of exponents. Values of the kernel function Eq. 6.124 are shown in Fig. 6.12 for $\beta_p = 0.5$ and 1. The effect of the upstream temperature jump decays more rapidly with increasing β_p . As $\beta_p \rightarrow 2$, the kernel function becomes unity for all $s/x < 1$, as is seen directly from the functional form of Eqs. 6.124 and 6.126.

Axisymmetric Stagnation Point, High-Speed Flow. The axisymmetric stagnation point has received attention from many investigators because of its importance in the assessment of the convective heat load of missile nose cones and atmospheric entry vehicles. The speeds involved in these applications produce stagnation enthalpies where real-gas behavior must be considered in the evaluation of the forced convection. Because of the very complex behavior of the physical properties of real gases, a characteristic common to all the studies is the reliance on numerical solutions followed by correlations of the results in terms of parameters involving the fluid properties. In addition to air, other gases have been treated because of the current interest in the exploration of the planetary neighbors of Earth. The contents of this section are confined to gases in chemical equilibrium with uniform elemental composition and to flows where boundary layer similarity occurs—namely, the immediate vicinity of the stagnation point—and where there is a uniform surface temperature. The effects of surface mass transfer of the same gas as exists in the free stream are also included.

Equations 6.100 and 6.102 with $t_s = t_e = 1$, $t = I$ have been solved for real air in Ref. 16 and in Refs. 51–55, with the latter references utilizing the concept of total properties k_T , c_{pT} , Pr_T . The air properties of Ref. 56 were employed in all the studies except that of Ref. 55, which employed properties evaluated in Refs. 57 and 58, where careful consideration was given to the effect of dominant resonant charge exchange cross sections in establishing the thermal conductivity of ionized nitrogen.

For speeds under 30,000 ft/s (9144 m/s), which represent relatively moderate entry conditions into the earth's atmosphere without appreciable ionization, the numerical results of Ref. 16 for $10^{-4} \text{ atm} < P_{st} < 10^2 \text{ atm}$ and $540^\circ\text{R} (300 \text{ K}) < T_w < 3100^\circ\text{R} (1722 \text{ K})$ are correlated by

$$\frac{\text{Nu}_w}{\text{Pr}_w^{0.4} \text{Re}_w^{0.5}} = 0.767 \left(\frac{\mu_e \rho_e}{\mu_w \rho_w} \right)^{0.43} \quad (6.127)$$

$$\text{where } Nu_w = \frac{q_w'' c_{pw} L}{(i_w - I_e) k_w}$$

$$Re_w = \frac{(du_e/dx) L^2 \rho_w}{\mu_w}$$

At the stagnation point (where $u_e = 0$) the recovery enthalpy is identical to the stagnation enthalpy even for $Pr_T \neq 1$. Thus, from the definition of Nu_w and Re_w , the local heat flux at the stagnation point in airflow for the speed range up to 30,000 ft/s (9144 m/s) can be expressed as

$$q_w'' = \left(\frac{Nu_w}{\sqrt{Re_w}} \right) \frac{I_e(\bar{I}_w - 1)}{Pr_{T_w}} \sqrt{\mu_w \rho_w} \sqrt{\frac{du_e}{dx}} \quad (6.128)$$

or from Eq. 6.127 as

$$q_w'' = 0.767 Pr_{T_w}^{-0.6} (\mu_e \rho_e)^{0.43} (\mu_w \rho_w)^{0.07} \sqrt{\frac{du_e}{dx}} I_e(\bar{I}_w - 1) \quad (6.129)$$

Here, a negative value of q_w'' represents heat flux toward the body.

At speeds greater than 10,000 ft/s (3048 m/s), where $I_e \approx V_\infty^2/2$, Eq. 6.129 can be represented in much simpler form when a relatively cold surface temperature (below dissociation temperature) is assumed:

$$q_w'' \sqrt{\frac{r_n}{P_{st}}} = 121 \left(\sqrt{\frac{T_w}{492}} \frac{1.38}{T_w/492 + 0.38} \right)^{0.07} \sqrt{\frac{r_n}{V_\infty}} \frac{du_e}{dx} \bar{U}^{2.21} (\bar{I}_w - 1) \quad (6.130a)$$

For the heat flux expressed in Btu/(s·ft²), the dimensionless velocity is expressed as $\bar{U} = V_\infty/10,000$ ft/s, T_w is expressed in °R, and P_{st} is expressed in atm. In SI units, Eq. 6.130a becomes

$$q_w'' \sqrt{\frac{r_n}{P_{st}}} = 2382 \left(\sqrt{\frac{T_w}{273}} \frac{1.38}{T_w/273 + 0.38} \right)^{0.07} \sqrt{\frac{r_n}{V_\infty}} \frac{du_e}{dx} \bar{U}^{2.21} (\bar{I}_w - 1) \quad (6.130b)$$

where $\bar{U} = V_\infty/(3048$ m/s), q_w'' is in W/m², T_w is expressed in K, and P_{st} is in N/m². Note that

$$\frac{r_n}{V_\infty} = \frac{1.54}{V_\infty} \sqrt{\frac{P_{st} - P_\infty}{\rho_{st}}} \quad (6.131)$$

For stagnation-point heating in gases other than air, correlations similar to Eq. 6.128 were obtained in Ref. 53 for speeds up to 30,000 ft/s (9144 m/s). The correlation is of the form

$$\frac{Nu_w}{\sqrt{Re_w}} = A^* \left(\frac{\mu_e \rho_e}{\mu_w \rho_w} \right)^{B^*} \quad (6.132)$$

with coefficients A^* and B^* given in Table 6.5 for the various gases considered. There is rather close agreement between Eqs. 6.127 and 6.132 for air. The heat flux is obtained from Eq. 6.128.

TABLE 6.5 Coefficients for Eq. 6.132 [53]

Gas	A^*	B^*
Air	0.718	0.475
N ₂	0.645	0.398
H ₂	0.675	0.358
CO ₂	0.649	0.332
A	0.515	0.110

For speeds above 30,000 ft/s (9144 m/s), where the total enthalpy reaches values where ionization significantly lowers the viscosity μ_e , the correlation for air (Eq. 6.127) from Ref. 16 begins to break down. Similar behavior was observed on pointed cones in Ref. 17. Similarly, it was found for argon in Ref. 53 that only the solutions for the lowest wall temperatures were correlated well by the property parameter $\mu_e \rho_e / \mu_w \rho_w$. Thus, extrapolation of the Nusselt number relations beyond the range of $\mu_e \rho_e / \mu_w \rho_w$ actually used in the correlations could yield significant errors. Two alternate approaches avoid this problem. In Ref. 52 the intermediate Nusselt number correlation was bypassed, and a correlation for air was achieved directly in terms of the heat flux for speeds up to 50,000 ft/s (15,200 m/s) in English units as follows:

$$q_w'' \sqrt{\frac{r_n}{P_{st}}} = 119 \sqrt{\frac{r_n}{V_\infty} \frac{du_e}{dx}} \bar{U}^{2.19} (\bar{I}_w - 1) \quad (6.133)$$

(In SI units, the coefficient is 2342.) It will be noted that this equation is quite similar to Eq. 6.130. The implication of this similarity is that the large variations in μ_e associated with ionization, which is not present in the range of velocities for which Eq. 6.130 is valid, can be ignored in the evaluation of heat flux. In fact, it is systematically demonstrated in Ref. 53 that the surface heat flux is quite insensitive to variations of the gas properties at the boundary layer edge and is controlled instead by the gradients of these properties near the surface. Apparently, correlations such as Eq. 6.127 or 6.132 result because in the speed range where they are applicable, the physical properties vary monotonically through the boundary layer, and their derivatives in the inner portion of the boundary layer are related to the ratio of properties across the boundary layer. For a variety of gases, the resulting heat flux expression, using strong shock relationships, is given by

$$q_w'' \sqrt{\frac{r_n}{P_{st}}} = F_0 \sqrt{\frac{r_n}{V_\infty} \frac{du_e}{dx}} \bar{U}^{2.2} (\bar{I}_w - 1) \quad (6.134)$$

where the units are the same as in Eqs. 6.130a and 6.130b, and F_0 is given in Table 6.6.

From the value of F_0 for air in Table 6.6 and the form of Eq. 6.134, it is apparent that the correlation of Ref. 53 yields results essentially identical to those of Eq. 6.133 taken from Ref. 52 and to Eq. 6.130 derived by directly extrapolating the lower-speed range equation of Ref. 16. Thus, it is recommended that Eq. 6.134 with the coefficients of Table 6.6 be utilized to predict stagnation-point heat flux at speeds greater than 10,000 ft/s (3048 m/s). At lower speeds, Eqs. 6.128 and 6.132 with the coefficients of Table 6.5 are appropriate. A comparison of these techniques with existing stagnation-point measurements is shown in Fig. 6.23. It should be noted that convection predominated over radiation in these measurements despite speeds up to 50,000 ft/s (15,200 m/s) because of the small nose radii for the models. For body dimensions exceeding a few feet, shock layer radiation begins to compete with convection at speeds of about 25,000 ft/s (7620 m/s) and becomes the predominant heating mechanism at higher speeds.

Stagnation Line on a Cylinder in High-Speed Flow. The stagnation line on a uniform-temperature cylinder of infinite length with its axis either normal to the free stream or swept back at angle Λ is characterized by boundary layer similarity solutions with $\beta_p = 1$. The solution in Ref. 16 of Eqs. 6.100–6.102 for $\beta_p = 1$ yields the correlation

$$\frac{\text{Nu}_w}{\text{Pr}_{T_w}^{0.4} \text{Re}_w^{0.5}} = 0.57 \left(\frac{\mu_e \rho_e}{\mu_w \rho_w} \right)^{0.45} \quad (6.135)$$

for $i_w/I_e < \bar{i}_s$ (see Eq. 6.92 for definition of \bar{i}_s) and $V_\infty \cos \Lambda < 29,000 \text{ ft/s}$ (8840 m/s). Although Eq. 6.135 was established from calculations that employed real-air properties, the resulting coefficient and exponents are consistent with those for low-speed calculations for either constant properties or ideal gases. In terms of heat flux, Eq. 6.135 becomes

$$q''_w = 0.57 \text{Pr}_{T_w}^{-0.6} (\mu_e \rho_e)^{0.45} (\mu_w \rho_w)^{0.05} \sqrt{\frac{du_e}{dx}} (i_w - I_{aw}) \quad (6.136)$$

where the recovery enthalpy I_{aw} is given by

$$I_{aw} = I_e - (1 - \text{Pr}_{T_w}^{0.5}) \frac{w_e^2}{2} = I_e - (1 - \text{Pr}_{T_w}^{0.5}) \frac{V_\infty^2 \sin^2 \Lambda}{2} \quad (6.137)$$

and a negative q_w'' represents heat flow into the body. An alternate form of Eq. 6.136, valid for $V_\infty > 10,000$ ft/s (3048 m/s) and having the same form as Eq. 6.130 for an axisymmetric stagnation point in airflow, is

$$q_w'' \sqrt{\frac{r_n}{P_{st}}} = 87.3 \left[\left(\frac{T_w}{492} \right)^{1/2} \frac{1.38}{T_w/492 + 0.38} \right]^{0.05} \sqrt{\frac{r_n}{V_\infty} \frac{du_e}{dx}} \bar{U}^{2.2} (\bar{I}_w + 0.15 \sin^2 \Lambda - 1) \quad (6.138a)$$

with the following units: q_w'' , Btu/(s·ft²); r_n , ft; P_{st} , atm; T_w , °R; V_∞ , ft/s; and $\bar{U} = V_\infty/(10,000$ ft/s). In SI units, this equation is

$$q_w'' \sqrt{\frac{r_n}{P_{st}}} = 1718 \left[\left(\frac{T_w}{273} \right)^{1/2} \frac{1.38}{(T_w/273) + 0.38} \right]^{0.05} \sqrt{\frac{r_n}{V_\infty} \frac{du_e}{dx}} \bar{U}^{2.2} (\bar{I}_w + 0.15 \sin^2 \Lambda - 1) \quad (6.138b)$$

with q_w'' , W/m²; r_n , m; P_{st} , N/m²; T_w , K; V_∞ , m/s; and $\bar{U} = V_\infty/(3048$ m/s).

The velocity gradient in Eq. 6.138 is obtained from Eq. 6.131, but with 1.54 changed to 1.43. In these equations, P_{st} and ρ_{st} are the inviscid flow conditions on the stagnation line of the swept cylinder. For an ideal gas in hypersonic flow, the inviscid flow relationships are particularly simple, and Eq. 6.138 shows that the heat flux is reduced with sweep by approximately $\cos^{3/2} \Lambda$. Equation 6.138 may be extended to gases other than air by setting the quantity in brackets equal to unity and replacing the coefficient 87.3 by $0.72F_0$, where F_0 is given in Table 6.6.

Mass Transfer in Stagnation Region. As on a flat plate, surface mass transfer is an effective means for alleviating convective heating in the stagnation regions of axisymmetric bodies and cylinders. The effect of surface mass transfer of a gas with the same elemental composition as the free stream will be treated initially. Consistent with the similarity requirements following Eqs. 6.100–6.102, the surface mass transfer rate is given by

$$\rho_w v_w = -f(0) \sqrt{\frac{\mu_w \rho_w \bar{t}_s}{\beta_p \bar{t}_e}} \frac{du_e}{dx} \quad (6.139)$$

In the vicinity of the stagnation region and with a uniform surface temperature, the terms under the radical sign are constants. Thus, boundary layer similarity, that is, $f(0)$ being independent of x , requires a uniform mass injection rate along the surface rather than one varying as $x^{-1/2}$ as on a flat plate. A convenient correlation parameter, as in the case of the flat plate, is

$$B_m = \frac{\rho_w v_w}{\rho_e \mu_e \text{St}_0} = \frac{\rho_w v_w (i_w - I_{aw})}{q_w''} = - \frac{f(0) \text{Pr}_{T_w}}{\sqrt{\beta_p (\text{Nu}_w / \sqrt{\text{Re}_w)}}} \quad (6.140)$$

where the subscript 0 denotes zero surface mass transfer.

The effect of surface mass transfer in reducing the Stanton number is indicated in Fig. 6.24. Note that for the stagnation point on a body of revolution or an unswept cylinder, the recovery enthalpy is equal to the total enthalpy. Hence, $q_w'' \sim \text{St}$ so that Fig. 6.24 indicates the reduction of the heat flux as well as the Stanton number. The line representing the axisymmetric stagnation point correlates all the gases listed in Table 6.5 to within a few percent [54]. Although the curves for the cylinder are based on air calculations, the correlation for the various gases for the axisymmetric stagnation point implies that the cylinder results can be applied to other gases when the injected and free-stream gas are the same. Note that in the coordinate system of Fig. 6.24, the effect of sweep is quite small.

Along the stagnation line of a swept cylinder, the recovery enthalpy is less than the stagnation enthalpy. Thus, the effect of surface mass transfer on the recovery factor, as shown in Fig. 6.25, should be considered in establishing the proper driving potential for the

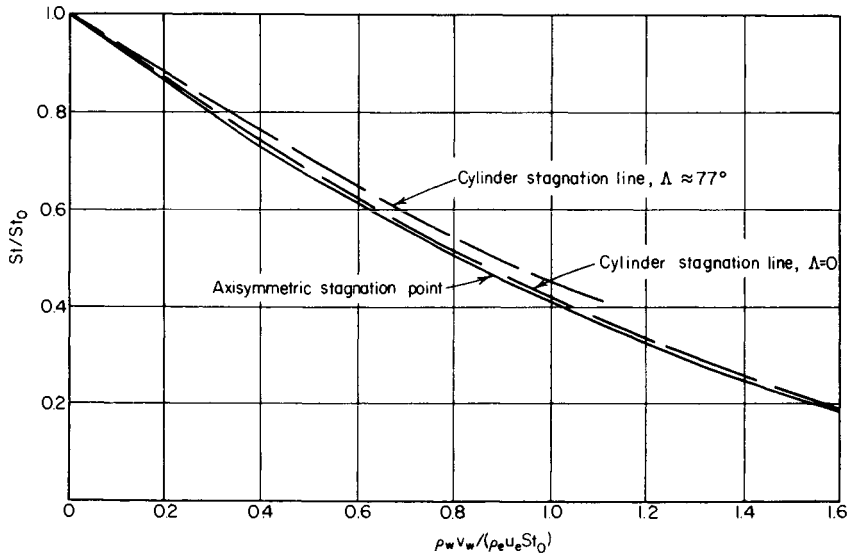

FIGURE 6.24 The reduction of Stanton number in stagnation regions by surface mass transfer.

FIGURE 6.25 The effect of surface mass transfer on the recovery factor on the stagnation line of a yawed cylinder of infinite length [48].

heat flux [48]. The heat flux for a swept cylinder normalized by its value with zero mass transfer is

$$\frac{q''_w}{q''_{w_0}} = \frac{St}{St_0} \left[\frac{1 - (1 - r(0)) \sin^2 \Lambda - \bar{I}_w}{1 - (1 - r_0(0)) \sin^2 \Lambda - \bar{I}_w} \right] \quad (6.141)$$

Because the term containing the recovery factor depends on $\sin^2 \Lambda$, modification of the recovery factor to account for surface mass transfer need be made only for large sweep angles. The graphic procedure for using these figures in establishing the required mass flow rate to yield a prescribed surface temperature was described on page 6.24.

The evaluation of the effectiveness of a transpiration cooling system utilizing a foreign gas is quite formidable and requires the use of complex computer codes.

Heat Transfer Over a Single Cylinder and Arrays of Cylinders in Low-Speed Cross Flow.

A boundary layer subjected to a significant static pressure increase in the streamwise direction thickens considerably and may eventually separate from the surface of the body. For steady separation, the velocity gradient normal to the surface vanishes at the separation point, and downstream the flow direction is reversed. Although the skin friction vanishes, significant amounts of heat transfer can occur at the point of separation. Separation is commonly encountered in cross flow over blunt bodies such as circular cylinders. The flow pattern downstream of separation is very complex and is often accompanied by unsteadiness and vortex shedding. Theoretical treatment of such flows is still in an early stage of development [63], and heat transfer predictions must rely on experimental data. The following sections summarize the experimental data available on heat transfer rates from single cylinders and arrays of cylinders in cross flow.

Single Cylinder. The classic experiments on the average heat transfer rates from a cylinder in cross flow were performed by Hilpert [64] for a wide range of Reynolds numbers in air. Hilpert's results are shown in Fig. 6.26 as average Nusselt number versus the cross flow Reynolds number.

In Ref. 66, Morgan made an extensive review of more recent heat transfer data obtained on a cylinder in cross flow. He found that the average Nusselt number could be correlated as

$$\overline{Nu}_d = (A + B Re_d^{n*}) Pr^{m*} \quad (6.142)$$

FIGURE 6.26 Nusselt number for average heat transfer from circular cylinder in cross flow of air [64]. (Reprinted from Ref. 65 by permission of McGraw-Hill.)

where A , B , n^* , and m^* are constants. The value of the exponent m^* found in various experiments lies between 0.3 and 0.4; Zukauskas [67] recommends a value of 0.37. The data were obtained mostly in air. Depending on the Reynolds number, the scatter in Nusselt numbers calculated from Eq. 6.142, using constants from various investigations, ranges from 10 percent to 29 percent. Other types of correlations were proposed and tested by Morgan and found to be less accurate than the above. Morgan attributed the scatter in the heat transfer data to three factors: (1) aspect ratio (length/diameter) of the cylinder, (2) free-stream turbulence level, and (3) wind tunnel blockage effects.

Corrections by Morgan [66] for the combined effects of free-stream turbulence and wind tunnel blockage on Nusselt numbers measured in air are shown in Fig. 6.27. Here, d/d_T is the ratio of the cylinder diameter to the wind tunnel height or diameter, δNu_d is the increase in the Nusselt number over Hilpert's measurements (Fig. 6.26), and Tu is the intensity of the longitudinal turbulent fluctuations in the free stream. In addition to these corrections, Morgan also proposed the Nusselt number correlations shown in Table 6.7 that are applicable to an extremely wide range of Reynolds numbers in air. At the higher Reynolds numbers, these Nusselt numbers are quite consistent with those of Fig. 6.26.

FIGURE 6.27 Correction factors to Nusselt numbers for combined effects of wind tunnel blockage and free-stream turbulence [66]. (Reprinted by permission of Academic Press.)

Local heat transfer rates from the surface of a cylinder in cross flow in air were measured by Schmidt and Wenner [68] and are shown in Fig. 6.28. The local Nusselt number is based on the local heat transfer coefficient and the cylinder diameter. Note that for subcritical Reynolds numbers ($Re_d < 170,000$), the local Nusselt number decreases initially along the surface from the forward stagnation point to a minimum at the separation point and subsequently reaches high values again in the separated portion of the flow on the back surface. For

TABLE 6.7 Correlation of Cross-Flow Forced Convection From Cylinders in Air [66]

$\overline{Nu}_d = D_2 Re_d^{n_1}$

9×10^{-2}	1	0.800	0.280
1	35	0.795	0.384
35	5×10^3	0.583	0.471
5×10^3	5×10^4	0.148	0.633
5×10^4	2×10^5	0.0208	0.814

Reynolds numbers above the critical value, transition from laminar to turbulent flow in the upstream attached boundary layer causes a dramatic increase in the local heat transfer, followed by a sharp decrease in the separated flow region.

The local heat transfer distribution is extremely sensitive to the free-stream turbulence intensity according to the measurements of Kestin and Maeder [69]; this is reflected in the correction terms shown in Fig. 6.27 for the average Nusselt number.

Arrays of Cylinders. The heat transfer behavior of a tube in a bank differs considerably from that of a single tube immersed in a flow of infinite extent. The presence of adjacent tubes in an array and the turbulence and unsteadiness generated by upstream tubes generally tend to increase the overall heat transfer from a particular tube. After the flow has passed through several rows of tubes, however, the heat transfer from individual tubes becomes independent of their location and just a function of the Reynolds number with a parametric dependence on the array geometry. Average and local heat transfer data for tube banks have been summarized by Zukauskas [67].

FIGURE 6.28 Distribution of local heat transfer on the surface of a circular cylinder in cross flow in air [66]. (Reprinted from Ref. 65 by permission of McGraw-Hill.)

The overall heat transfer data for a tube in an infinite array are correlated by Kays and London [70] as:

$$\overline{St} = c_h Pr^{-2/3} Re_d^{-0.4} \quad (6.143)$$

or

$$\overline{Nu}_d = c_h Pr^{-1/3} Re_d^{0.6} \quad (6.144)$$

The Reynolds number in this correlation is based on the flow velocity at the minimum area section normal to the flow direction.

A typical correlation for c_h is shown in Fig. 6.29 for the case of a staggered array. For effects of array geometry, Refs. 67 and 70 should be consulted.

FIGURE 6.29 Correlation of coefficient in Eq. 6.143 or 6.144 for an infinite bank of staggered array, $300 < Re_d < 15,000$ [70]. (Reprinted by permission of McGraw-Hill.)

For a tube located near the front of the bank, the overall or average heat transfer is lower than that predicted by correlations for infinite arrays. The necessary correction factor as a function of row number in an array as presented by Kays and London [70] is shown in Fig. 6.30.

TWO-DIMENSIONAL TURBULENT BOUNDARY LAYER

Turbulence Transport Mechanisms and Modeling

In turbulent flows, the transport of momentum, heat, and/or individual species within gradients of velocity, temperature, and concentration is caused predominantly by the chaotic motion of elements of fluid (eddies). This mixing process transports properties much more effectively than the molecular processes identified with viscosity, thermal conductivity, and diffusion. A rather complete description of these processes is given in Refs. 71–73.

Currently there exist computers with sufficient storage capacity and speed to allow computation of these time-dependent motions for rather simple flows with finite difference meshes sufficiently fine to resolve the larger eddies of the motion. Even with such computations, however, it is necessary to model the effects of the eddies that are too small to be resolved. It is believed that since the transport of properties is governed by the larger eddies, the modeling process is less critical in these computations than where the entire turbulence is modeled. These “turbulence simulations” are still too costly for routine engineering computations and are used primarily to study the “physics” of particular turbulent flows. In fact, the results provide much more information than an engineer may ever want or need.

In engineering computations, the turbulent transport of properties is usually treated in a statistical manner, where computations are concerned with the *mean* velocities, temperatures, and/or concentrations. This statistical approach, however, masks many of the actual physical processes in the dynamic flow field, which must be recovered by the modeling at some level of the turbulence statistics. This modeling was originally guided by the results from experiments, but currently this guidance can rely on “simulations” as well.

The statistical turbulence models generally employed at present are based on time-averaging, at a single point in space, the instantaneous dynamic equations representing the conservation of mass, momentum components, energy, and species concentrations. These equations, in their most general form, apply to compressible, viscous, heat-conducting, and diffusing fluids. The statistical representation is initiated by expressing the dependent variables as the sum of a mean and fluctuating quantity, e.g.,

$$\begin{aligned}u &= \bar{u} + u' \\ \rho &= \bar{\rho} + \rho' \\ K_i &= \bar{K}_i + K'_i\end{aligned}$$

Substitution of such a decomposition of the dependent variables into the basic conservation equations is then followed by time-averaging the equations according to the following definition:

$$\bar{f} = \lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t f(t') dt'$$

It is seen that this definition of mean quantities eliminates terms that are linear in the fluctuating quantities. Moments of the fluctuating quantities that are retained in a boundary layer are $\overline{\rho'v'}$, $\overline{(\rho v)'u'}$, $\overline{(\rho v)'w'}$, $\overline{(\rho v)'i'}$, and $\overline{(\rho v)'K'_i}$, which represent the turbulent flux of mass, momentum, heat, and species concentration in the direction normal to a surface. These quantities are added to their molecular counterparts. Details of these derivations can be found in several sources, e.g., Refs. 65, 71, 74, and 75.

The evaluation of these statistical second moments is the goal of turbulence models. These models fall into two categories. First are models in which the turbulent fluxes are expressed in the same functional form as their laminar counterparts, but in which the molecular properties of viscosity, thermal conductivity, and diffusion coefficient are supplemented by corresponding eddy viscosities, conductivities, and diffusivities. The primary distinction is the recognition that the eddy coefficients are properties of the turbulent flow field, not the

physical properties of the fluid. The second category of turbulence models includes those that express the turbulent moments in terms of partial differential field equations. When this is done, new moments (some of higher order, others involving pressure fluctuations, and still others involving space derivatives of the fluctuating quantities) appear in these equations. The number of moments grows faster than the number of the additional moment equations; thus, the set of equations cannot be closed. References 73 and 76 demonstrate this closure problem in detail.

The classical turbulence models express the eddy viscosity algebraically in terms of a turbulence scale and intensity that are related, respectively, to the characteristic length dimensions of the flow field and the local mean velocity gradients. This implies an equilibrium between the local turbulence and the mean motion. This requirement of equilibrium has been relaxed in some eddy viscosity models where the intensity and scale of turbulence used to evaluate the eddy viscosity are expressed by partial differential equations for the turbulence kinetic energy and its dissipation rate. This latter class of models is presented in detail, for example, in Refs. 76 and 77.

A 1982 conference held at Stanford University [63] was devoted to assessing the merits of existing turbulence models in the prediction of the mean velocity fields for both simple and complex turbulent flows. The flow fields employed as standards for comparison were selected on the basis of their being well-documented experimentally. It was found that the field models of turbulence, the second-order closure of the Reynolds stress equations or the two-equation eddy viscosity models, while having a broader range of application than particular algebraic eddy viscosity models, did not show dramatic improvement in accuracy over the simpler models for flow situations similar to those experiments on which the simpler models were based. In view of these observations, and the analytical advantages of the simpler models in the analysis of convection, classical algebraic eddy viscosity models will be used to represent turbulent transport in this chapter.

The turbulent flux vector for the local shear stress is given by

$$\tau_i = \bar{\rho} \epsilon_M \frac{\partial \bar{u}}{\partial y} = -\overline{(\rho v)' u'} \quad (6.145)$$

and the heat flux by

$$q_i'' = -\bar{\rho} c_p \epsilon_H \frac{\partial \bar{T}}{\partial y} = \overline{(\rho v)' T'} \quad (6.146)$$

The quantity ϵ_M is called the eddy diffusivity for momentum, and ϵ_H is the eddy diffusivity for heat. They are related through the turbulent Prandtl number $Pr_t = \epsilon_M / \epsilon_H$.

Although these eddy diffusivities act in the same manner as the kinematic viscosity and thermal diffusivity in laminar flow, the critical difference is that the eddy diffusivities are not properties of the fluid but are dependent largely on the dynamic behavior of the fluid motion. In this section the fluid dynamic bases for evaluating these eddy diffusivities are given. They will then be used in a variety of convective heating situations to yield formulas useful in engineering computations.

Mean Velocity Characteristics for Constant Fluid Properties. Mean velocity distributions measured in turbulent boundary layers when the fluid properties are uniform (low speeds and small temperature differences between the free stream and surface) are described in the reviews of Refs. 78 and 79. At a given station, the turbulent boundary layer is composed of two regions with velocity profiles described by the “law of the wall” and the “law of the wake” after Coles [80, 81].

Wall Region. The region near the wall possesses a universal velocity profile when the data are correlated in terms of the coordinates $u^+ = u/u^*$ and $y^+ = u^*y/\nu$. The quantity $u^* = \sqrt{\tau_w/\rho}$ is called the friction velocity and is the appropriate characteristic velocity in this region. The corresponding characteristic length is ν/u^* .

The near-wall region is composed of three layers as shown in Fig. 6.31. The layer immediately adjacent to the surface ($y^+ \leq 5$) is called the laminar sublayer where, because of the presence of the surface, the turbulence has been damped into a fluctuating laminar flow. In this layer, viscosity predominates over the eddy viscosity, and the velocity distribution may be approximated by

$$u^+ = y^+ \quad (6.147)$$

FIGURE 6.31 Universal velocity profile for an incompressible turbulent boundary layer near the surface (“law of the wall”) [79]. (Reprinted by permission of Academic Press.)

For $y^+ > 50$, the turbulent processes completely dominate the local shear, and the resulting correlation can be represented by

$$u^+ = \frac{1}{\kappa} \ln y^+ + \mathbf{B} \quad (6.148)$$

The parameter κ is called the von Kármán constant, and the value that fits most of the data is 0.41. The corresponding value of \mathbf{B} is 5.0. Intermediate between these layers is the buffer layer, where both shear mechanisms are important. The essential feature of this data correlation is that the wall shear completely controls the turbulent boundary layer velocity distribution in the vicinity of the wall. So dominant is the effect of the wall shear that even when pressure gradients along the surface are present, the velocity distributions near the surface are essentially coincident with the data obtained on plates with uniform surface pressure [82]. Within this region for a flat plate, the local shear stress remains within about 10 percent of the surface shear stress. It is noted that this shear variation is often ignored in turbulent boundary layer theory.

Wake Region. The experimental data toward the outer edge of the boundary layer do not correlate in a plot of $u^+(y^+)$. Correlation of these data can be achieved by utilizing the boundary layer thickness δ as the characteristic dimension and expressing the velocity as a decrement relative to its value at the boundary layer edge. Such a “wake” correlation is shown in Fig. 6.32 for a plate with uniform pressure. Although δ is rather arbitrary because of the asymptotic approach of the velocity to its free-stream value, no serious error results in these correlations if a consistent definition such as $u(\delta) = 0.995u_e$ is adopted. The velocity distribution for the combined wall and wake region of a fully developed turbulent boundary layer was formulated by Coles [81] as

$$u^+ = \frac{1}{\kappa} \ln y^+ + \mathbf{B} + \frac{\tilde{\pi}}{\kappa} \mathbf{w}\left(\frac{y}{\delta}\right) \quad (6.149)$$

where $\mathbf{w}(y/\delta)$ is the wake function indicated in Fig. 6.33. This function is approximated quite well by $1 - \cos(\pi y/\delta)$. Equation 6.149 applies to equilibrium boundary layers, as defined by Clauser [79], where $(\delta^*/\tau_w) dP/dx$ is constant along the surface. Under these conditions and at large Reynolds numbers, the parameter $\tilde{\pi}$ in Eq. 6.149 is independent of position.

FIGURE 6.32 Velocity decrement for an incompressible turbulent boundary layer away from the surface (“law of the wake”) [83].

Coles [84] used Eq. 6.149, with $\kappa = 0.41$ and $\mathbf{B} = 5.0$, to evaluate $c_f/2$, δ , and $\tilde{\pi}$ from a large set of equilibrium boundary layer data. In this evaluation, Coles excluded data for $y^+ < 50$, where Eq. 6.149 does not apply, and data for values of y near the boundary layer edge, where Eq. 6.149 provides poor values of the slope du^+/dy^+ .

For flat plates with uniform free-stream velocities, Coles found agreement with the data when $\tilde{\pi} = 0.62$. On the other hand, if experimental skin friction data obtained at very high Reynolds numbers are used to define $\tilde{\pi}$, a value of 0.55 is favored. The use of these different values of $\tilde{\pi}$ produces differences of only a few percent in the skin friction and boundary layer integral parameters, such as the displacement thickness

$$\delta^* = \int_0^\delta \left(1 - \frac{\rho u}{\rho_e u_e}\right) dy \quad (6.150)$$

and the momentum thickness

$$\theta = \int_0^\delta \frac{\rho u}{\rho_e u_e} \left(1 - \frac{\rho u}{\rho_e u_e}\right) dy \quad (6.151)$$

The value of $\tilde{\pi}$ recommended in regions of zero or positive pressure gradients is

FIGURE 6.33 Coles’ “law of the wake” function in Eq. 6.149 [81].

$$\bar{\pi} = 0.55 + 0.47 \frac{\delta^*}{\tau_w} \frac{dP}{dx} \quad (6.152)$$

In regions of negative pressure gradients, $\bar{\pi}$ can be estimated by doubling the constant 0.47 in Eq. 6.152.

The parameter $\bar{\pi}$ is influenced by low Reynolds numbers even when the boundary layer is fully turbulent. In zero-pressure-gradient flow, $\bar{\pi}$ can be represented approximately by

$$\bar{\pi} = 0.6 \left(\frac{\text{Re}_\theta - 470}{\text{Re}_\theta} \right)^{0.85} \quad (6.153)$$

for $\text{Re}_\theta \leq 5000$; $\bar{\pi} = 0.55$ for $\text{Re}_\theta > 5000$.

If Eq. 6.149 is used throughout the boundary layer to define the integral parameters, the displacement thickness becomes

$$\frac{\delta^*}{\delta} = \frac{1 + \bar{\pi}}{\kappa} \sqrt{\frac{c_f}{2}} \quad (6.154)$$

and the shape factor is

$$H = \frac{\delta^*}{\theta} = \left(1 - \frac{2 + 3.179\bar{\pi} + 1.5\bar{\pi}^2}{1 + \bar{\pi}} \frac{\sqrt{c_f/2}}{\kappa} \right)^{-1} \quad (6.155)$$

The approximations introduced in the integrations leading to these equations, that is, utilizing Eq. 6.149 throughout the sublayer and buffer layer and ignoring the nonzero value of $\partial u^+/\partial y^+$ near the outer edge of the boundary layer, are valid at Reynolds numbers of practical interest.

Equation (6.149) also leads directly to the skin friction expression

$$\frac{1}{\sqrt{c_f/2}} = \frac{1}{\kappa} \ln \text{Re}_{\delta^*} + \frac{1}{\kappa} \ln \frac{\kappa}{1 + \bar{\pi}} + \mathbf{B} + \frac{2\bar{\pi}}{\kappa} \quad (6.156)$$

For $2000 < \text{Re}_\theta < 50,000$ and $0.55 < \bar{\pi} < 2.0$ and with $\kappa = 0.41$ and $\mathbf{B} = 5.0$, Eqs. 6.155 and 6.156 yield skin friction coefficients within ± 10 percent of the well-established Ludwig-Tillman correlation equation [82]

$$\frac{c_f}{2} = 0.123 \times 10^{-0.678H} \text{Re}_\theta^{-0.268} \quad (6.157)$$

Given the momentum thickness at some location on a body with streamwise pressure gradients, the evaluation of the local skin friction coefficient from Eq. 6.157 requires knowledge of the shape factor H . Alternatively, the same input information can be used to evaluate both the skin friction coefficient and the shape factor by solving Eqs. 6.152–6.156 iteratively.

Clausner [79] made two observations regarding turbulent boundary layer velocity profiles that have direct influence on convective heating analyses. First, he noted that the region characterized by the “law of the wall” equilibrates very quickly after it is disturbed by some external force. Thus, this region is nearly in equilibrium with its local surface boundary conditions. In contrast, the region characterized by the “law of the wake” possesses a long memory of the upstream events. Clausner also found that the eddy diffusivity in the wake region is essentially independent of the distance from the surface y and is related to the local boundary layer thickness, which reflects the growth of the boundary layer from the leading edge. The resulting expression for the eddy diffusivity in the wake region on a flat plate or a surface with an equilibrium turbulent boundary layer ($(\delta^*/\tau_w)(dP/dx) = \text{constant}$) is

$$\frac{\bar{\epsilon}}{\nu} = 0.018 \frac{u_e \delta^*}{\nu} \quad (6.158)$$

where $\bar{\epsilon} = \nu + \epsilon_M$.

Flat Plate With Zero Pressure Gradient. With values of $\kappa = 0.41$, $\mathbf{B} = 5.0$, and $\bar{\pi} = 0.55$, Eqs. 6.154 and 6.155 reduce to

$$\frac{\delta^*}{\delta} = 3.8 \sqrt{\frac{c_f}{2}} \quad (6.159)$$

and

$$H = \frac{\delta^*}{\theta} = \left(1 - 6.6 \sqrt{\frac{c_f}{2}}\right)^{-1} \quad (6.160)$$

The skin friction in the range $5000 < Re_\theta < 50,000$ can be expressed as

$$\sqrt{\frac{2}{c_f}} = 2.44 \ln Re_{\theta^*} + 4.4 \quad (6.161)$$

A convenient relationship expressed explicitly in terms of the momentum-thickness Reynolds number that agrees with Eqs. 6.160 and 6.161 within a few percent in the range $5000 < Re_\theta < 50,000$ is given by

$$\frac{c_f}{2} = \frac{1}{(2.43 \ln Re_{\theta^*} + 5.0)^2} \quad (6.162)$$

This form of equation originated with von Kármán; however, the coefficients appearing here are slightly different because they are based on more recent data.

It is often convenient to evaluate the local skin friction coefficient with the following simple equations:

$$\frac{c_f}{2} = \frac{0.0128}{Re_{\theta^*}^{1/4}} \quad Re_{\theta^*} < 4000 \quad (6.163)$$

$$\frac{c_f}{2} = \frac{0.0065}{Re_{\theta^*}^{1/6}} \quad Re_{\theta^*} > 4000 \quad (6.164)$$

after Blasius and Falkner [85], respectively. Equations 6.162–6.164 are compared with high-Reynolds number data [86] in Fig. 6.34.

FIGURE 6.34 Comparison of local skin friction coefficients predicted by Eqs. 6.162–6.164 with the experimental data of Ref. 86.

On an impervious flat plate with uniform pressure, the momentum integral equation is

$$\frac{\tau_w}{\rho_e u_e^2} = \frac{d\theta}{dx} \quad (6.165)$$

This equation leads directly to an expression for the local length Reynolds number,

$$\text{Re}_{x_e} = \int_0^{\text{Re}_{\theta_e}} \frac{d \text{Re}_{\theta_e}}{c_f/2} \quad (6.166)$$

If the laminar and transitional zones are short, the turbulent boundary layer can be assumed to begin at the leading edge of the plate. In this case, for surface length Reynolds number of a few million, Eq. 6.163 can be employed in Eq. 6.166 to establish the following simple relationship:

$$\frac{c_f}{2} = \frac{0.0296}{\text{Re}_{x_e}^{1/5}} \quad (6.167)$$

For length Reynolds numbers in the tens of millions, the upstream portion of the boundary layer is not significant, and Eq. 6.164 may be used in Eq. 6.166 all the way from $\text{Re}_{\theta_e} = 0$ to yield

$$\frac{c_f}{2} = \frac{0.0131}{\text{Re}_{x_e}^{1/7}} \quad (6.168)$$

A more general equation proposed by Schultz-Grunow [83] that covers the full Reynolds number range is given by

$$\frac{c_f}{2} = \frac{0.185}{(\log \text{Re}_{x_e})^{2.584}} \quad (6.169)$$

Eddy Diffusivity Models. The mean velocity data described in the previous section provide the bases for evaluating the eddy diffusivity for momentum (eddy viscosity) in heat transfer analyses of turbulent boundary layers. These analyses also require values of the turbulent Prandtl number for use with the eddy viscosity to define the eddy diffusivity of heat. The turbulent Prandtl number is usually treated as a constant that is determined from comparisons of predicted results with experimental heat transfer data.

The presence of “wall” and “wake” regions in the turbulent boundary layer is reflected in the distribution of the eddy viscosity. In the outer wake region, Clauser’s empirical form (Eq. 6.158), has been adopted for finite-difference boundary layer computations, although Ref. 87 suggests that the constant in Eq. 6.158 be altered to 0.0168. In analyses, however, the need for defining the wake region eddy viscosity has not been critical, largely because of the nearness of the value of the turbulent Prandtl number to unity and the use of the Crocco transformation, as demonstrated in the next section.

Evaluation of the wall region eddy viscosity has been facilitated by the fact that the shear stress remains essentially constant across the wall layer. On a flat plate with uniform free-stream conditions, the shear stress drops less than 10 percent from its wall value across the wall layer. The equation governing low-speed flow on a flat plate in the absence of a pressure gradient is

$$u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = \frac{\partial}{\partial y} \left[(\nu + \epsilon_M) \frac{\partial u}{\partial y} \right] \quad (6.170)$$

If the shear is equal to the wall shear throughout the region of interest, Eq. 6.170 reduces to the Couette flow approximation

$$(\nu + \epsilon_M) \frac{du}{dy} = \frac{\tau_w}{\rho} \quad (6.171)$$

Expressed in near-wall coordinates, $u^+ = u/u^*$ and $y^+ = u^*y/\nu$, Eq. 6.171 becomes

$$\frac{\epsilon_M}{\nu} = \frac{1}{du^+/dy^+} - 1 \quad (6.172)$$

Equation 6.172 directly relates the mean velocity data to the eddy viscosity.

From Eqs. 6.147 and 6.172, it is seen that the sublayer is physically identified with zero eddy viscosity or no turbulent transport. Beyond $y^+ = 50$, Eqs. 6.148 and 6.172 indicate

$$\frac{\epsilon_M}{\nu} = \kappa y^+ - 1 \quad (6.173)$$

For $5 \leq y^+ \leq 30$, von Kármán [88] fitted the buffer layer velocity data with a semi-logarithmic relationship, $u^+ = 5[1 + \ln(y^+/5)]$, that provided

$$\frac{\epsilon_M}{\nu} = \frac{y^+}{5} - 1 \quad (6.174)$$

Spalding [89] defined a simple expression for the eddy viscosity applicable to the entire law of the wall region as

$$\frac{\epsilon_M}{\nu} = \frac{\kappa}{E} \left[e^{\kappa u^+} - 1 - \kappa u^+ - \frac{(\kappa u^+)^2}{2!} - \frac{(\kappa u^+)^3}{3!} \right] \quad (6.175)$$

where $\kappa = 0.4$ and $9 < E < 10$. For consistency with Eq. 6.148, it is necessary to set $\kappa = 0.41$ and $E = 7.8$. Another form of ϵ_M/ν , recommended by van Driest [90] and currently popular in finite difference calculations of turbulent boundary layers, is

$$\frac{\epsilon_M}{\nu} = l^{*2} \left| \frac{du^+}{dy^+} \right| \quad (6.176)$$

with

$$l^* = \kappa y^+ \left[1 - \exp\left(-\frac{y^+}{A^+}\right) \right] \quad (6.177)$$

When $\kappa = 0.41$, it is required that $A^+ = 24.7$ for consistency with Eq. 6.148. Finite difference calculations favor $A^+ = 26$ on a flat plate, and Refs. 87 and 91 give corrections to A^+ required in regions with pressure gradients and when mass transfer occurs at the surface. With a pressure gradient, the A^+ in a constant-property fluid becomes, according to Ref. 87,

$$A^+ = \frac{26}{[1 - 11.8(\nu u_e/u^*{}^3)(du_e/dx)]^{0.5}} \quad (6.178)$$

This modification is rather small, e.g., even where $\tilde{\pi}$ has risen to 10, A^+ is decreased by only 6 percent. This behavior is consistent with the observed insensitivity of the law of the wall to pressure gradients.

The behavior of the alternate forms of ϵ_M/ν in the near-wall region of a turbulent boundary layer is shown in Fig. 6.35. The classical Prandtl-Taylor model assumes a sudden change from laminar flow ($\epsilon_M/\nu = 0$) to fully turbulent flow (Eq. 6.173) at $y^+ = 10.8$. The von Kármán model [88] allows for the buffer region and interposes Eq. 6.174 between these two regions. The continuous models depart from the fully laminar conditions of the sublayer around $y^+ = 5$ and asymptotically approach limiting values represented by Eq. 6.173. In finite difference calculations, ϵ_M/ν is allowed to increase until it reaches the value given by Eq. 6.158 and then is either kept constant at this value or diminished by an intermittency factor found experimentally by Klebanoff [92].

FIGURE 6.35 Near-wall eddy viscosity models.

Uniform Free-Stream Conditions

Uniform Surface Temperature

Low-Speed Flow. Heat transfer is best found from the Reynolds analogy, the relationship between heat transfer and skin friction evaluated through analyses utilizing the empirical velocity distributions cited earlier. Knowledge of the flow field, which is independent of the temperature field when the fluid properties are constant, can be used directly to define the temperature field for a variety of thermal conditions and to evaluate the resulting convective heat transfer rates. For low-speed, constant-property flow, the energy equation is

$$\rho c_p u \frac{\partial T}{\partial x} + \rho c_p v \frac{\partial T}{\partial y} = \frac{\partial}{\partial y} \left[\left(\frac{\mu}{Pr_T} + \frac{\rho \epsilon_M}{Pr_t} \right) c_p \frac{\partial T}{\partial y} \right] \quad (6.179)$$

When this equation (Eq. 6.170) and the continuity equation are transformed from the x, y coordinate system to one with x and u as independent variables (the Crocco transformation), a formal solution results for the temperature field expressed in terms of the velocity field. This expression for the temperature, developed by van Driest [93], is

$$\frac{T}{T_e} = \frac{T_w}{T_e} - \left(\frac{T_w}{T_e} - 1 \right) \frac{\mathbf{S}(u/u_e)}{\mathbf{S}(1)} \quad (6.180)$$

$$\text{where} \quad \mathbf{S}(u/u_e) = \int_0^{u/u_e} \text{Pr}_M \exp\left(-\int_{\tau_w}^{\tau} \frac{1 - \text{Pr}_M}{\tau} d\tau\right) d\left(\frac{u}{u_e}\right) \quad (6.181)$$

$$\text{and} \quad \text{Pr}_M = \frac{1 + \epsilon_M/\nu}{1/\text{Pr}_T + (1/\text{Pr}_i)(\epsilon_M/\nu)} \quad (6.182)$$

It follows directly that

$$\frac{\text{St}}{c_f/2} = \frac{1}{\mathbf{S}(1)} \quad (6.183)$$

In terms of wall layer coordinates, the temperature distribution can be expressed from Eqs. 6.180–6.183 as

$$t^+ = \frac{\sqrt{c_f/2}}{\text{St}} \frac{T_w - T}{T_w - T_e} = \int_0^{u^+} \text{Pr}_M \exp\left(-\int_{\tau_w}^{\tau} \frac{1 - \text{Pr}_M}{\tau} d\tau\right) du^+ \quad (6.184)$$

Reference [78] gives an excellent review of the hypotheses employed by various analysts to empirically define the integrand and the intermediate limits of integration in Eq. 6.181 for the different regions within the turbulent boundary layer.

The most widely used formula resulting from integrating Eq. 6.181 was due to von Kármán [88]. In effect, he eliminated the exponential term in Eq. 6.181 by setting the shear stress equal to its wall value near the surface and utilizing $\text{Pr}_i = 1$ in the fully turbulent region. This truncated form of $\mathbf{S}(u/u_e)$ was integrated in the sublayer ($0 \leq y^+ \leq 5$) with $\text{Pr}_M = \text{Pr}_T$ in the buffer layer ($5 \leq y^+ \leq 30$) with Pr_M evaluated using the ϵ_M/ν indicated in Fig. 6.35, and in the outer portion of the boundary layer with $\text{Pr}_M = \text{Pr}_i = 1.0$. Deissler [94] extended this analysis by replacing the discontinuous formulations of ϵ_M/ν in the sublayer and buffer layer with $\epsilon_M/\nu = n_D^2 u^+ y^+$ where n_D is an empirical constant. When this value of ϵ_M/ν reaches that given by Eq. 6.173, the latter is used through the rest of the boundary layer. Deissler retained the assumption that $\text{Pr}_i = 1$ in this fully turbulent region.

Because the wake region encompasses more of the boundary layer as the Reynolds number is increased, later analyses attempted to account for the wake region in different ways. Van Driest [93] permitted the shear in the boundary layer to approach zero at the outer edge. He also introduced nonunity turbulent Prandtl numbers to permit his recovery factor expression for air to agree with data, consistent with the findings of an earlier analysis [95]. The van Driest expression is

$$\frac{c_f/2}{\text{St}} = \text{Pr}_i \left(1 + 5 \sqrt{\frac{c_f}{2}} \left\{ \frac{1 - \text{Pr}_i}{5\kappa} \left[\frac{\pi^2}{6} + \frac{3}{2} (1 - \text{Pr}_i) \right] + \left(\frac{\text{Pr}_T}{\text{Pr}_i} - 1 \right) + \ln \left[1 + \frac{5}{6} \left(\frac{\text{Pr}_T}{\text{Pr}_i} - 1 \right) \right] \right\} \right) \quad (6.185)$$

where $0.7 \leq \text{Pr}_i \leq 1$ and $\kappa = 0.4$. Equation 6.185 reduces to the von Kármán analogy for $\text{Pr}_i = 1$.

Spalding [89] abandoned the Couette flow hypothesis and solved Eq. 6.179 through the use of the von Mises transformation obtaining

$$\frac{\partial T}{\partial x^+} = \frac{1}{\epsilon_M^+ u^+} \frac{\partial}{\partial u^+} \left(\frac{\epsilon_H^+}{\epsilon_M^+} \frac{\partial T}{\partial u^+} \right) \quad (6.186)$$

$$\text{where} \quad x^+ = \int_0^{\text{Re}_{x^+}} \sqrt{\frac{c_f}{2}} d \text{Re}_{x^+}$$

$$\epsilon_M^+ = 1 + \frac{\epsilon_M}{\nu} \quad (6.187)$$

$$\epsilon_H^+ = \frac{1}{\text{Pr}_T} + \frac{1}{\text{Pr}_i} \frac{\epsilon_M}{\nu}$$

Spalding used Eq. 6.175 for ϵ_M/ν throughout the boundary layer.

Ferrari [96] also solved the von Mises form of the energy equation, but with the velocity distributions in the inner and outer portions of the boundary layer represented by polynomials of a velocity potential function. This analysis is applicable to gases in that it accounts for compressibility, but the solutions may be in error for high Prandtl numbers because of the rather approximate fit to the law of the wall.

Spalding [97] examined the results of other investigators who followed his approach and deduced that Pr_t must differ from unity to yield agreement with experimental data that show a Reynolds number dependence of the Reynolds analogy factor. The requirement of a nonunity turbulent Prandtl number for gases seems to be independent of the details of the analyses used to define the Reynolds analogy factor. From velocity distributions in gases, Spalding suggested $Pr_t = 0.9$. He showed, further, how previous solutions can be adjusted to accommodate nonunity Pr_t and found that the numerical results can be fitted with the interpolation formula

$$\frac{c_f/2}{St} = Pr_t \sqrt{\frac{c_f}{2}} \left\{ 6.76 \left(\frac{x^+}{Pr_t} \right)^{1/9} + 11.57 \left[\left(\frac{Pr_t}{Pr_t} \right)^{3/4} - 1 \right] \right\} \quad (6.188)$$

Later, Spalding [98] extended his analysis to include the wake region of the boundary layer. The numerical results for heat transfer rates to a plate agree with those given by Eq. 6.188 to a few percent. This would be expected because at high Prandtl numbers the thermal boundary layer is confined to the inner portion of the flow boundary layer and is insensitive to the flow characteristics in the outer portion of the flow boundary layer.

The numerical results of the various Reynolds analogy factors are compared in Fig. 6.36 for laminar Prandtl numbers ranging from those characteristic of gases to those of oils and for $Re_{x_c} = 10^7$. Results for very low laminar Prandtl numbers, characteristic of liquid metals, are not shown because the assumptions for the velocity distributions in the various analyses are

FIGURE 6.36 Reynolds analogy factor for incompressible turbulent boundary layer.

not valid when the thermal boundary layer is much thicker than the flow boundary layer. A comparison of the von Kármán analogy with the van Driest results indicates that use of $Pr_t = 0.89$ rather than $Pr_t = 1$ affects the results only for laminar Prandtl numbers less than about 10 and causes the Reynolds analogy factor to exceed unity when $Pr_T = 1$. These observations are also evident from the form of Eq. 6.188. The Deissler and Spalding results, although crossing in the vicinity of $Pr_T = 1$, both approach an asymptotic limit proportional to $Pr_T^{-3/4}$ for very large Prandtl numbers. Most significant is the departure of all the analyses from the Colburn analogy $Pr_T^{-2/3}$. An explanation of this can be deduced from the Deissler analysis [94], where the Reynolds analogy is also applied to the case of pipe flow through the calculation of bulk-mean properties. Here the analytical results agree reasonably well with the Colburn analogy. Thus, a deductive extension of the behavior of turbulent pipe flow data and laminar boundary layer theory on a flat plate, both of which yield a Reynolds analogy factor of $Pr_T^{-2/3}$, to the turbulent boundary layer on a flat plate yields erroneous results, particularly for $Pr_T \leq 10$.

If Eq. 6.184, restricted to a constant value of shear, is used to evaluate the temperature profile in a heated boundary layer, there results

$$t^* = \frac{Pr_t}{\kappa} \ln y^* + 5Pr_t \ln \left(1 + 5 \frac{Pr_T}{Pr_t} \right) + 5Pr_T - 8.5Pr_t \quad (6.189)$$

This formula agrees very well with the near-wall temperature profile data of Blackwell et al. [99] obtained in air if $Pr_T = 0.7$ and $Pr_t = 0.88$. It should be noted that good agreement with the data was achieved here without consideration of near-wall turbulent Prandtl number variations observed by some investigators [100].

Kader [101] presented an empirical correlation formula for boundary layer temperature profiles that were demonstrated to fit experimental data in fluids with Prandtl numbers in the range from 0.7 to 60. The formula is

$$t^* = Pr_T y^* \exp(-\bar{\Gamma}) + \left\{ 2.12 \ln \left[(1 + y^*) \frac{2.5(2 - y/\delta)}{1 + 4(1 - y/\delta)^2} \right] + \bar{\beta}(Pr_T) \right\} \exp\left(-\frac{1}{\bar{\Gamma}}\right) \quad (6.190)$$

$$\text{where} \quad \bar{\beta}(Pr_T) = (3.85Pr_T^{1/3} - 1.3)^2 + 2.12 \ln Pr_T \quad (6.191)$$

$$\text{and} \quad \bar{\Gamma} = \frac{10^{-2}(Pr_T y^*)^4}{1 + 5Pr_T^3 y^*} \quad (6.192)$$

The Reynolds analogy factor corresponding to these relationships can be written as

$$\frac{St}{c_f/2} = \frac{1}{\sqrt{c_f/2} \left[2.12 \ln \left(2.5Pr_T Re_{\delta^*} \frac{\kappa}{1 + \bar{\pi}} \right) + (3.85Pr_T^{1/3} - 1.3)^2 \right]} \quad (6.193)$$

When Eq. 6.193 is evaluated on a flat plate at $Re_x = 10^7$, it essentially coincides with the line attributed to the Deissler theory shown in Fig. 6.36 for Pr_T up to 100. It is recommended that Eq. 6.193 be used for Prandtl numbers considerably greater than unity.

For Prandtl numbers slightly less than unity (gases), it is quite obvious that the Colburn analogy is at variance with the analytical results. For $Pr_T = 0.7$, excellent low-speed data [102] indicate values of $2St/c_f \approx Pr_T^{-0.4} \approx 1.15$. Other data in air at higher speeds [103], though less accurate and sometimes containing disturbances such as small pressure gradients, favor the value $2St/c_f = 1.2$. Since these data were obtained over a small Prandtl number range, it is difficult to ascertain empirically the influence of Pr_t and the functional dependence on Pr_T . Accordingly, it is recommended that the Spalding and van Driest results, represented by Eqs. 6.188 and 6.185, be utilized for $Pr_T \approx 1$ in view of their general agreement with the data cited. These conclusions are supported further by the agreement of Eq. 6.188 with the data of Ref. 99.

High-Speed Flow. Frictional dissipation occurs in the turbulent boundary layer for high-speed flow because of combined viscous and turbulent shear mechanisms. To account for variations in the specific heat of the fluid, it is best to express the heat potential as enthalpy rather than temperature. It was shown by van Driest [93] that under high-speed conditions, Eq. 6.180 is replaced by

$$\frac{i}{i_e} = \frac{i_w}{i_e} - \left(\frac{i_w}{i_e} - 1 \right) \frac{\mathbf{S}(u/u_e)}{\mathbf{S}(1)} + \frac{u_e^2}{i_e} \left[\frac{\mathbf{S}(u/u_e)}{\mathbf{S}(1)} \bar{R}(1) - \bar{R}\left(\frac{u}{u_e}\right) \right] \quad (6.194)$$

The function $\mathbf{S}(u/u_e)$ is still represented by Eq. 6.181. The function $\bar{R}(u/u_e)$ is

$$\bar{R}\left(\frac{u}{u_e}\right) = \int_0^{u/u_e} \text{Pr}_M \exp\left(-\int_{\tau(0)}^{\tau} \frac{1 - \text{Pr}_M}{\tau} d\tau\right) \left\{ \int_0^{u/u_e} \exp\left[\int_{\tau(0)}^{\tau} \frac{1 - \text{Pr}_M}{\tau} d\tau\right] d\left(\frac{u}{u_e}\right) \right\} d\left(\frac{u}{u_e}\right) \quad (6.195)$$

As with a laminar boundary layer, the local surface heat flux can be written as

$$q_w'' = \rho_e u_e \text{St} (i_w - i_{aw}) \quad (6.196)$$

$$\text{where} \quad i_{aw} = i_e + \mathbf{r}(0) \frac{u_e^2}{2} \quad (6.197)$$

It is found from Eq. 6.194 that the recovery factor is

$$\mathbf{r}(0) = 2\bar{R}(1) \quad (6.198a)$$

When Eq. 6.195 is solved under the same assumptions employed in Eq. 6.181 [93, 95, 96], it is found that the recovery factor for air ($\text{Pr}_T = 0.7$, $\text{Pr}_i = 1$) experiences a marked Reynolds number dependence, contrary to a rather profuse accumulation of data that yield values of $\mathbf{r}(0)$ between 0.87 and 0.89. Thus, solutions of Eq. 6.198a, rather than yielding values of $\mathbf{r}(0)$, have been used to estimate the turbulent Prandtl number necessary to eliminate the dependence of $\mathbf{r}(0)$ on Re_{x_e} . It is in this manner that van Driest found $\text{Pr}_i = 0.89$ for use in Eq. 6.183. Values of $\mathbf{r}(0)$ within a percent of most existing data in air can be obtained by using

$$\mathbf{r}(0) = \text{Pr}_T^{1/3} \quad (6.198b)$$

Liquids With Variable Viscosity. Deissler [94] considered a fluid where the viscosity is temperature dependent but all the other fluid properties remain constant. Solutions for $\text{Pr}_T = 10$ and

$$\frac{\mu}{\mu_w} = \left(\frac{T}{T_w} \right)^4 \quad (6.199)$$

are shown in Figs. 6.37 and 6.38. The ordinate in Fig. 6.38 is defined as

$$t^* = \frac{\sqrt{c_f/2}}{\text{St}} \frac{T_w - T}{T_w - T_e}$$

and the parameter

$$\beta_T = \frac{\text{St}}{\sqrt{c_f/2}} \frac{T_w - T_e}{T_w} = \frac{1}{t_e^*} \frac{T_w - T_e}{T_w} \quad (6.200)$$

It is noted in Fig. 6.37 that the effects of variable viscosity cause the velocity distributions outside the buffer layer to displace while remaining essentially parallel, so that

$$\frac{u}{\sqrt{\tau_w/\rho}} = A \ln \left(\frac{\sqrt{\tau_w/\rho} \rho y}{\mu_w} \right) + B(\beta_T) \quad (6.201)$$

FIGURE 6.37 Universal velocity profiles for a liquid with $\mu/\mu_w = (T/T_w)^{-1}$; $\beta_T = (St\sqrt{c_f/2})[(T_w - T_c)/T_w]$ [94].

FIGURE 6.38 Universal temperature profiles for a liquid with velocity profiles as in Fig. 6.37.

where $B(\beta_T)$ is shown in Fig. 6.39. The parallel curves lead to the conclusion that $c_f/2$ can be computed from $c_f(Re_{x'})$ relationships, e.g., Eq. 6.167 or 6.168, if the Reynolds number employed is replaced by

$$Re_{\text{eff}} \approx \frac{\rho_e t_e x}{\mu_w} e^{B(\beta_T) - B(0)} \quad (6.202)$$

FIGURE 6.39 Displacement function of Eq. 6.201.

A simple iterative procedure for evaluating the local heat transfer rate is begun by assuming a value of β_T . The effective Reynolds number is evaluated from Fig. 6.39 and Eq. 6.202. Equation 6.167 or 6.168 yields $c_f/2$. The ordinate in Fig. 6.37 set equal to $\sqrt{2/c_f}$ yields the limiting value at the edge of the boundary layer of $\rho\delta\sqrt{\tau_w/\rho}/\mu_w$ that is then used in Fig. 6.38 to obtain a value of t_e^* . This value of t_e^* and the wall and boundary layer edge temperatures are substituted in Eq. 6.200 to yield the next approximation for β_T . The procedure is repeated until convergence on a value of β_T is achieved. The local heat flux is then found from

$$q_w'' = \rho c_p u_e T_w \beta_T \sqrt{\frac{c_f}{2}} \quad (6.203)$$

Ideal Gases at High Temperature. Three fundamentally different approaches have been applied to the treatment of the turbulent boundary layer with variable fluid properties; all are restricted to air behaving as an ideal, calorically perfect gas. First, the Couette flow solutions have been extended to permit variations in viscosity and density. Second, mathematical transformations, analogous to Eq. 6.36 for a laminar boundary layer, have been used to transform the variable-property turbulent boundary layer differential equations into constant-property equations in order to provide a direct link between the low-speed boundary layer and its high-speed counterpart. Third, empirical correlations have been found that directly relate the variable-property results to incompressible skin friction and Stanton number relationships. Examples of the latter are reference temperature or enthalpy methods analogous to those used for the laminar boundary layer, and the method of Spalding and Chi [104].

Generalized Coordinate Transformation. The coordinate transformation rules for extending constant-property skin friction and Stanton number formulas to account for property variations as performed by Spalding and Chi [104] can be expressed functionally as

$$\tilde{c}_f = f_1(\tilde{Re}_\theta) \quad (6.204)$$

and

$$\tilde{c}_f = f_2(\tilde{Re}_x) \quad (6.205)$$

the generalized formulas are

$$c_f F_c = f_1(F_{R\theta} Re_\theta) \quad (6.206)$$

$$c_f F_c = f_2(F_{R_x} Re_x) \quad (6.207)$$

In general, the coordinate transformation factors F_c , $F_{R\theta}$, F_{R_x} are functions of Ma_e , T_w/T_e , Re_{x_e} , and T_e . (If the viscosity is expressed as a power-law function of temperature, the dependence on T_e can be eliminated.) From the von Kármán momentum integral equation for a flat plate,

$$\frac{c_f}{2} = \frac{d Re_\theta}{d Re_x} \quad (6.208)$$

it follows that

$$F_{R_x} = \frac{F_{R\theta}}{F_c} \quad (6.209)$$

The expressions for F_c and $F_{R\theta}$ given by the various methods are presented in Table 6.8. Values of these functions obtained from the van Driest theory [105] are shown in Figs. 6.40 and 6.41 for $T_e = 400 \text{ R (222 K)}$, $0 < Ma_e < 10$, and $T_w/T_e = 1, 2, 3, 5$, T_{aw}/T_e . It is noted that only the Coles method allows F_c and $F_{R\theta}$ to depend on the Reynolds number (through the parameter \tilde{c}_f).

TABLE 6.8 Expressions for F_c and F_{R0} for Air as an Ideal Gas

Method	F_c	F_{R0}	Supplemental formulas and notes
Eckert [20]	ρ_e/ρ'	μ_e/μ'	$\frac{T'}{T_e} = 0.28 + 0.50 \frac{T_w}{T_e} + 0.22 \frac{T_{aw}}{T_e}$
Sommer and Short [107]	ρ_e/ρ'	μ_e/μ'	$\frac{T'}{T_e} = 0.36 + 0.45 \frac{T_w}{T_e} + 0.19 \frac{T_{aw}}{T_e}$
van Driest (von Kármán mixing length) [105]	$\frac{T_{aw}/T_e - 1}{(\sin^{-1} \alpha + \sin^{-1} \beta)^2}$	μ_e/μ_w	$\alpha = \frac{T_{aw}/T_e + T_w/T_e - 2}{\sqrt{(T_{aw}/T_e - T_w/T_e)^2 + 4(T_w/T_e)(T_{aw}/T_e - 1)}}$ $\beta = \frac{T_{aw}/T_e - T_w/T_e}{\sqrt{(T_{aw}/T_e - T_w/T_e)^2 + 4(T_w/T_e)(T_{aw}/T_e - 1)}}$
Coles [106]	$\frac{\mu_e \rho_e}{\mu_w \rho_w} \frac{\mu_{ss}}{\mu_e}$	μ_e/μ_{ss}	$\frac{T_{ss}}{T_e} = \frac{T_w}{T_e} + 17.2 \sqrt{\frac{\tilde{c}_f}{2} \left(\frac{T_{aw}}{T_e} - \frac{T_w}{T_e} \right)} - 305 \frac{\tilde{c}_f}{2} \left(\frac{T_{aw}}{T_e} - 1 \right)$
Spalding and Chi [104]	$\frac{T_{aw}/T_e - 1}{(\sin^{-1} \alpha + \sin^{-1} \beta)^2}$	$\frac{(T_{aw}/T_e)^{0.772}}{(T_w/T_e)^{1.474}}$	α, β , same as van Driest $\mu \sim T^{0.76}$ assumed in empirical exponent of F_{R0}

The recommended design method for Mach numbers up to supersonic ($Ma_e < 4$) and adiabatic wall conditions ($T_w = T_{aw}$) is arbitrary since all the methods yield essentially the same results. The design methods for hypersonic Mach numbers ($Ma_e > 4$) and cold wall conditions ($T_w < T_{aw}$) should be based on conservatism. Comparison of the available skin friction data reveals differences of ± 20 percent on surfaces near adiabatic wall temperature and as much as a factor of 2 for highly cooled walls ($T_w \sim 0.2T_{aw}$). If only the most recent skin friction data for

FIGURE 6.40 Compressible turbulent boundary layer transformation parameter for skin friction coefficient, $r(0) = 0.9$, $T_e = 400$ R (222 K).

FIGURE 6.41 Compressible turbulent boundary layer transformation parameter for momentum-thickness Reynolds number, $r(0) = 0.9$, $T_e = 400$ R (222 K).

$0.3 < T_w/T_{aw} < 1.0$ are considered, particularly those where Re_{θ} was obtained from boundary-layer surveys, a recent evaluation [108] favors the Coles and van Driest methods. The Sommer and Short method and the Spalding and Chi method may underpredict the skin friction as much as 30 percent. For very cold walls ($T_w < 0.3T_{aw}$), none of the methods predict the effect of wall temperature ratio in the available skin friction data. The van Driest skin friction predictions are shown in Fig. 6.42 for $T_e = 400$ R (222 K), $0 < Ma_e < 10$, and $T_w/T_e = 1, 2, 3, 5, T_{aw}/T_e$.

FIGURE 6.42 Local skin friction coefficient for a compressible turbulent boundary layer on a flat plate, $r(0) = 0.9$, $T_e = 400$ R (222 K).

The heat transfer is obtained by using a Reynolds analogy factor in combination with a skin friction prediction. For Mach numbers up to supersonic and near-adiabatic wall conditions, the recommended Reynolds analogy factor is the same as for low-speed flow, namely, 1.16. Any of the previously discussed skin friction theories may be used. For hypersonic Mach numbers and cold wall conditions, there are indications that the Reynolds analogy factor is more nearly equal to unity [108]. Use of this value and either the van Driest or the Coles theory for skin friction results in heat transfer predictions within ± 10 percent of the data for $5 < Ma_e < 7.5$ and $0.1 < T_w/T_{aw} < 0.6$ [108]. Alternatively, to similar accuracy one can use the usually accepted Reynolds analogy factor of 1.16 and the Spalding and Chi skin friction theory.

Nonuniform Surface Temperature. Nonuniform surface temperatures affect the convective heat transfer in a turbulent boundary layer similarly as in a laminar case except that the turbulent boundary layer responds in shorter downstream distances. The heat transfer to surfaces with arbitrary temperature variations is obtained by superposition of solutions for convective heating to a uniform-temperature surface preceded by a surface at the recovery temperature of the fluid (Eq. 6.65). For the superposition to be valid, it is necessary that the energy equation be linear in T or i , which imposes restrictions on the types of fluid property variations that are permitted. In the turbulent boundary layer, it is generally required that the fluid properties remain constant; however, under the assumption that boundary layer velocity distributions are expressible in terms of the local stream function rather than y for ideal gases, the energy equation is also linear in T [96].

The effect of a stepwise discontinuity in surface temperature on a flat plate is expressible as

$$\frac{St(x, s)}{St(x, 0)} = \left[1 - \left(\frac{s}{x} \right)^{9/10} \right]^{-1/9} \quad (6.210)$$

For fluids other than gases, use of the Spalding relationship (Eq. 6.188) results in

$$\frac{St(x, s)}{St(x, 0)} = \frac{\frac{5.62Re_{x_e}^{1/10}}{Pr_t^{1/9}} + 11.57 \left[\left(\frac{Pr}{Pr_t} \right)^{3/4} - 1 \right]}{\frac{5.62Re_{x_e}^{1/10}}{Pr_t^{1/9}} \left[1 - \left(\frac{s}{x} \right)^{9/10} \right]^{1/9} + 11.57 \left[\left(\frac{Pr}{Pr_t} \right)^{3/4} - 1 \right]} \quad (6.211)$$

A short distance downstream from the step in surface temperature, for $Pr = 0.7$ and $Pr_t = 0.9$, the second term in both the numerator and denominator of Eq. 6.211 becomes comparatively small, and Eq. 6.211 reduces to Eq. 6.210. For very high Prandtl numbers, the Stanton number behind a step in surface temperature is essentially the same as on a uniform-temperature surface.

The intuitive approach for including variable fluid properties is to evaluate the local $St(x, 0)$ from the variable-property techniques of the previous section, employing the local surface temperature or enthalpy as a parameter. Equations 6.210 and 6.211 are used primarily to define the form of the enthalpy potential appropriate to an arbitrary surface temperature. (See Eq. 6.65).

Stepwise and Arbitrary Heat Flux Distribution. A corollary of the problem treated in the previous section is the problem of finding the surface temperature distribution (or enthalpy distribution) resulting from a prescribed heat flux distribution. The superposition of solutions based on Eq. 6.210 yields

$$i_w(x) - i_{aw} = \frac{0.0979}{\rho_e \mu_e St(x, 0)} \int_0^1 \frac{q_w''(s/x)}{[1 - (s/x)^{9/10}]^{8/9}} d\left(\frac{s}{x}\right) \quad (6.212)$$

Surface With Mass Transfer. The advantages of mass transfer cooling systems in certain applications were discussed in the section on two-dimensional laminar boundary layers beginning on page 6.19. Reference 109 should be consulted for a complete description of the per-

formance of different forms of mass transfer cooling systems. This section highlights the evaluation of turbulent boundary layer behavior in transpiration cooling systems.

Uniform Fluid Properties. Analyses of turbulent boundary layers experiencing surface transpiration employ a hierarchy of increasingly complex models of the turbulent transport mechanisms. Most of the analyses, supported by complementary experiments, have emphasized the transpiration of air into low-speed airstreams [110–112]. Under these conditions, the fluid properties in the boundary layer are essentially constant, and the turbulent boundary layer can be described mathematically with Eqs. 6.170 and 6.179. In addition, when small quantities of a foreign species are introduced into the boundary layer for diagnostic purposes or by evaporation, the local foreign species concentration in the absence of thermal diffusion is given by

$$\rho u \frac{\partial K_1}{\partial x} + \rho v \frac{\partial K_1}{\partial y} = \frac{\partial}{\partial y} \left[\left(\frac{\mu}{Sc} + \frac{\rho \epsilon_M}{Sc_t} \right) \frac{\partial K_1}{\partial y} \right] \quad (6.213)$$

where the laminar and turbulent Schmidt numbers are $Sc = \nu/\mathcal{D}$ and $Sc_t = \epsilon_M/\epsilon_D$, respectively. The boundary conditions at the surface are $v = v_w(x)$ and $T = T_w(x)$, where one of these is specified and the other is determined from the heat balance represented by Eq. 6.74.

The simpler analyses reduce the boundary layer equations to ordinary differential equations, with the distance normal to the surface as the independent variable. This results from the assumption of Couette flow, where changes of the dependent variables in the streamwise direction may be neglected. The continuity and momentum equations then become

$$\frac{dv}{dy} = 0 \quad (6.214)$$

$$v \frac{du}{dy} = \frac{d}{dy} \left[(v + \epsilon_M) \frac{du}{dy} \right] \quad (6.215)$$

Solved simultaneously, these equations yield

$$v = v_w \quad (6.216)$$

and

$$\frac{c_f}{2} = \frac{\ln(1 + B_f)}{B_f} \frac{1}{u_e} \left(\int_0^\delta \frac{dy}{v + \epsilon_M} \right)^{-1} \quad (6.217)$$

where

$$B_f = \frac{v_w}{u_e} \frac{1}{c_f/2} \quad (6.218)$$

The simplest analyses, e.g., Ref. 110, assume that the value of the integral in Eq. 6.217 is independent of the amount of surface mass transfer at a given location or Re_x . This implies that mass transfer affects the boundary layer thickness and the eddy viscosity equally, thus compensating for the change in the limit of integration with a proportionate change in the reciprocal of the integrand. The resulting simple expression

$$\frac{c_f}{c_{f0}} \Big|_{Re_x} = \frac{\ln(1 + B_f)}{B_f} \quad (6.219)$$

predicts experimental data surprisingly well [113].

Sometimes it is more convenient to scale the transpiration rate to c_{f0} , the skin friction coefficient in the absence of surface mass transfer. With

$$b_f = \frac{v_w}{u_e} \frac{1}{c_{f0}/2} \quad (6.220)$$

Eq. 6.219 becomes
$$\frac{c_f}{c_{f0}} \Big|_{\text{Re}_x} = \frac{b_f}{\exp(b_f) - 1} \quad (6.221)$$

The quantity c_{f0} in Eqs. 6.219 and 6.221 is found from the equations given in the section on uniform free-stream conditions. For example, at moderate Reynolds numbers on a flat plate, the skin friction coefficient is given by

$$\frac{c_f}{2} = 0.0296 \text{Re}_x^{-0.2} \frac{\ln(1 + B_f)}{B_f} \quad (6.222)$$

Expressions based on Re_θ are found through the use of the integral momentum equation for a flat plate,

$$\frac{d \text{Re}_\theta}{d \text{Re}_x} = \frac{c_f}{2} (1 + B_f) \quad (6.223)$$

and yield
$$\frac{c_f}{2} = 0.0129 \left[\frac{\ln(1 + B_f)}{B_f} \right]^{1.25} (1 + B_f)^{0.25} \text{Re}_\theta^{0.25} \quad (6.224)$$

A Couette flow analysis of the energy equation leads to an expression similar to Eq. 6.219 for the reduction in Stanton number due to blowing:

$$\frac{\text{St}}{\text{St}_0} \Big|_{\text{Re}_x} = \frac{\ln(1 + B_h)}{B_h} \quad (6.225)$$

where
$$B_h = \frac{v_w}{u_e \text{St}} \quad (6.226)$$

At moderate Reynolds numbers and with an empirical Reynolds analogy factor independent of blowing, the Stanton number on a flat plate can be expressed as

$$\text{St Pr}^{0.4} = 0.0296 \text{Re}_x^{-0.2} \frac{\ln(1 + B_h)}{B_h} \quad (6.227)$$

The energy integral equation reduces for low-speed flow over a flat plate to

$$\text{St} + \frac{v_w}{u_e} = \frac{d \text{Re}_\Gamma}{d \text{Re}_x} \quad (6.228a)$$

where
$$\Gamma = \int_0^{\delta^*} \frac{\rho u}{\rho_c u_e} = \left(\frac{I - I_c}{i_w - I_c} \right) dy \quad (6.228b)$$

Equation 6.227 can then be expressed as

$$\text{St Pr}^{0.4} = 0.0129 \text{Re}_\Gamma - 0.25 \left[\frac{\ln(1 + B_h)}{B_h} \right]^{1.25} (1 + B_h)^{0.25} \quad (6.229)$$

Figure 6.43 shows Eqs. 6.224 and 6.229, based on local boundary layer thicknesses, to be applicable locally to boundary layers experiencing acceleration, deceleration, and moderate variations in blowing along the surface.

While the analysis described above is useful to define the surface parameters c_f , St , and, by inference, c_{mi} , more detailed analysis is required to define the velocity, temperature, and species concentration profiles in the boundary layer (see Refs. [112] and [113]).

Variable Fluid Properties. The fluid properties within a boundary layer may vary because of large temperature differences caused by frictional dissipation at high Mach numbers or because the coolant introduced through the surface possesses properties quite different from those of the main stream.

FIGURE 6.43 Effect of transpiration at the surface on skin friction and heat transfer [113]. (Reprinted from Ref. 74 by permission of McGraw-Hill.)

Early theories for transpiration of air into air [114, 115] were based on the Couette flow approximation. Reference 114 extended the Reynolds analogy to include mass transfer by defining a two-part boundary layer consisting of a laminar sublayer and a fully turbulent core. Here, $l^* = 0$ in the sublayer ($y^+ < y_a^+$), and $l^* = 0.4y^+$ and $\mu = 0$ in the fully turbulent region. The density was permitted to vary with temperature. The effect of foreign gas injection in a low-speed boundary layer was studied in Ref. 116, and all these theories were improved upon in Ref. 117.

The aforementioned theories show very small effects of Mach number on the normalized skin friction and heat transfer data c_f/c_{f_0} and St/St_0 , respectively. Some experiments [118] support these results, while others [119, 120, 121] show surface mass transfer to be less effective in reducing skin friction and heat transfer as Mach number increases. In view of these differences, it is necessary to rely on the aggregate of data presented in Ref. 109 to assess the uncertainties involved in a particular approach.

For preliminary design of ablation systems, in particular, it has been found convenient to use a figure such as Fig. 6.44, which represents a composite of experimental results with air injection [122, 123–126]. This figure reflects a conservative choice of a fixed recovery factor equal to 0.9 even in the presence of light gas injection, and introduces the effects of foreign gas injection by empirically adjusting the blowing parameter. The modified parameter is $(\rho_w v_w / \rho_e \mu_e St_0)(M_2/M_1)^{a_m}$, where the subscripts 1 and 2 refer to the coolant and air, respectively, and $a_m = 0.35$ when $M_1 > M_2$, $a_m = 0.6$ when $M_1 < M_2$. The graphic technique for using this figure to establish $\rho_w v_w$ is to determine the intersection of the curves in Fig. 6.44 with a straight line drawn from the origin with slope

$$\frac{i_{1w} - i_{1c}}{i_{2w} - i_{2c}} \left(\frac{M_1}{M_2} \right)^{a_m}$$

In an ablating system, the change in the enthalpy of the coolant, $i_{1w} - i_{1c}$, includes the effective heat of ablation, the heat absorbed by phase change, and the chemical processes that take place in the char, if present. In evaporating systems, $i_{1w} - i_{1c}$ includes the heat of vaporization.

Surface Roughness. Up to this point, the turbulent boundary layer has been assumed to form on a surface that is aerodynamically smooth, namely, a surface whose roughness elements are small compared with the thickness of the viscous sublayer. As many surfaces in practical appli-

FIGURE 6.44 Compressibility effects on the reduction of the Stanton number by surface mass transfer on bodies with zero axial pressure gradient and including effects of foreign gas injection.

cations are not aerodynamically smooth, the effects of surface roughness must be accounted for in describing the hydrodynamic and thermal behavior of turbulent boundary layers.

Skin Friction. The earliest investigation of the effects of surface roughness was conducted by Nikuradse [127], who determined the friction factors for flow through artificially roughened pipes. The pipes were coated with various sizes of sand grains in dense arrays. Nikuradse found that the friction factor could be correlated with two parameters, Re_d and k_s/d , where k_s is the size of the sand grains. For a given roughness, the friction factor becomes independent of the Reynolds number when the latter is sufficiently large.

Similar behavior is observed in a turbulent boundary layer over a rough flat plate, where Prandtl and Schlichting [128] showed that the important parameter is k_s/x . The local skin friction coefficient is shown in Fig. 6.45 as a function of Re_x with x/k_s as a parameter.

The lowest curve represents the skin friction for a smooth flat plate (Eq. 6.167). The other curves apply for rough plates with $u_e k_s/\nu$ and x/k_s as parameters. The region above the dashed line is defined to be “fully rough.” At a point on a moderately rough surface where x and x/k_s are fixed and the Reynolds number is low, the skin friction coefficient is the same as on a smooth surface. An increase in velocity or Reynolds number causes the skin friction coefficient at that point to rise from its smooth-surface value. When the Reynolds number reaches a critical high value, the skin friction coefficient increases asymptotically to a constant value. The dashed line defines the critical Reynolds numbers, above which fully rough conditions exist. With uniform roughness and fixed unit Reynolds number, the skin friction coefficient along the plate behaves as indicated by the curves generally parallel to, but higher than, the smooth-plate curve.

Schlichting [65] gives the following correlations for local and average skin friction coefficients in the fully rough regime:

$$c_f = \left(2.87 + 1.58 \ln \frac{x}{k_s} \right)^{-2.5} \quad (6.230)$$

$$\bar{c}_f = \left(1.89 + 1.62 \ln \frac{x}{k_s} \right)^{-2.5} \quad (6.231)$$

FIGURE 6.45 Variation of local skin friction coefficient along a sand-roughened flat plate [65]. (Reprinted by permission of McGraw-Hill.)

Effects of surface roughness are also evident in the boundary layer mean velocity profiles shown in Fig. 6.46. The profiles still exhibit a near-wall logarithmic behavior, but with a dependence on the roughness Reynolds number $k^+ = k_s u_e^+ / \nu$. The law of the wall for a rough surface may be written as

$$u^+ = \frac{1}{\kappa} \ln y^+ + 5.0 - \Delta u^+ \tag{6.232}$$

FIGURE 6.46 Velocity profiles in wall coordinates on a rough plate with u_e constant [129]. (Reprinted by permission of the authors.)

where Δu^+ is a function of k^+ . This functional relationship is shown in Fig. 6.47 for various roughness geometries. For a uniform particle distribution, Δu^+ approaches zero for $k^+ < 5.0$. This value of k^+ defines an aerodynamically smooth surface consistent with Nikuradse's definition. The surface is transitionally rough for $5 < k^+ < 70$ and fully rough for $k^+ > 70$. For surfaces having a wide distribution of particle size, Δu^+ remains nonzero even for small k^+ based on average particle size. For this geometry, even a small number of large particles disturbs significantly the near-wall flow. For larger values of k^+ , Δu^+ becomes proportional to $\ln k^+$ with the proportionality constant nearly equal to $1/\kappa$. The law of the wall then becomes

$$u^+ = \frac{1}{\kappa} \ln \frac{y}{k_s} + \mathbf{B}^* \quad (6.233)$$

FIGURE 6.47 Effect of roughness size and type on universal velocity profiles in a turbulent boundary layer over a rough flat plate [130]. (Reprinted by permission of Hemisphere Publishing.)

where \mathbf{B}^* is a function of the surface geometry but independent of k^+ provided $k^+ > 70$. The behavior of the velocity profile (Eq. 6.233) and the constant value of the skin friction coefficient in the fully rough regime suggest that the integral parameters also attain unique values. Based on the data of Ref. 131, Kays and Crawford [74] recommend the following correlation for the skin friction coefficient on a fully rough flat plate:

$$\frac{c_f}{2} = \frac{0.168}{[\ln(864 \theta/k_s)]^2} \quad (6.234)$$

where θ is the momentum thickness.

Heat Transfer. The Stanton number over a rough surface behaves similarly to the skin friction coefficient; at sufficiently high roughness Reynolds numbers k^+ , the Stanton number becomes independent of the free-stream velocity. At a given Re_x or Re_δ , roughness causes an increase in local Stanton number over the smooth-plate value. These effects are shown in Fig. 6.48 for five values of the free-stream velocity. The geometry of the rough surface used in these experiments was the densest array of spheres of radius r as shown in Fig.

FIGURE 6.48 Rough-surface Stanton number versus energy-thickness Reynolds number [129]. (Reprinted by permission of the authors.)

20.24 of Schlichting [65]. For a smooth plate, data for all five velocities collapse on a single correlation:

$$\begin{aligned}
 St &= 0.0129 Re_\Gamma^{-0.25} Pr^{-0.4} \\
 &\approx 0.0153 Re_\Gamma^{-0.25} \quad \text{for air at room temperature} \quad (6.235)
 \end{aligned}$$

The effect of roughness is seen as an increase in the local Stanton number with increasing u_e at a fixed value of the Reynolds number based on energy thickness Re_{Γ_E} . The roughness Reynolds number range corresponding to the five values of u_e is also shown in Fig. 6.48. The same data plotted as St against Γ_E/r in Fig. 6.49, however, follow a single correlation showing no dependence on u_e . The Stanton number data of Ref. 131 in the fully rough regime on the same test surface can be correlated as

$$St = 0.00317 \left(\frac{\Gamma}{r} \right)^{-0.175} \quad (6.236)$$

in the range $1.5 < \Gamma/r < 10.0$.

Streamwise Curvature. Streamwise surface curvature, e.g., on a highly cambered turbine blade, has a significant effect on the local rate of convection. Convex surfaces tend to reduce convection rates from those on a flat surface experiencing boundary layers with the same thickness and edge conditions, whereas concave surfaces tend to increase convection rates. In laminar boundary layers, these effects can be evaluated by transforming the cartesian coordinates of the analysis to an orthogonal set with x representing the distance along the curved surface and y locally normal to the surface. The principal change in the governing equations is that

$$\frac{\partial(\)}{\partial y} \text{ is replaced by } \frac{1}{1 + y/r_c} \cdot \frac{\partial(\)}{\partial y},$$

where r_c is the local streamwise radius of curvature of the surface. Here, it is assumed that the boundary layer is very thin compared with r_c , which is positive for a convex surface and negative for a concave one. At sufficiently small values of δ/r_c , the instabilities inherent in flow over a concave surface do not generate Taylor-Görtler vortices, and the change in convection, or skin friction, for positive or negative r_c is similar but of opposite sign. For boundary layers that are somewhat thicker, the next level of approximation requires additional terms identified with second-order boundary layer theory; see Ref. 132, where it is shown that the skin friction coefficient for a laminar boundary layer on a curved surface is related to its flat-plate counterpart by

$$\frac{c_f}{c_{f\text{flat plate}}} = 1 - \frac{0.87\delta}{r_c} \quad (6.237)$$

When Taylor-Görtler vortices develop, the boundary layer on a concave surface possesses an additional mixing mechanism and is capable of transferring heat and momentum at a greater rate than suggested by Eq. 6.237.

The early heat transfer experiments by Thomann [133] demonstrated that a turbulent boundary layer behaves qualitatively the same as a laminar boundary layer, but that the magnitude of the curvature effect is about an order of magnitude greater. Bradshaw's careful review [134] of this topic identified the relatively large effect of the streamwise curvature in a turbulent boundary layer as not due to the geometric effects on the mean motion but due to extra rates of strain on the turbulence production. In this view, as the surface curvature changes, the local turbulence and mean motion are out of equilibrium, which implies a breakdown of the eddy viscosity concept. Others [135, 136] have retained the eddy viscosity approach by modifying it empirically to alter its magnitude—a new mixing length form—and allowing for nonequilibrium of the mean motion and the turbulence through an empirical lag equation. This approach employs finite difference calculations of the boundary layer equations in partial differential form. It has been shown [137] that finite difference computations of the mean conservation equations that utilize the transport equations for the components of Reynolds stress lead to solutions for skin friction that represent curvature effects without model modifications but merely through geometric changes appropriate to thin layers.

Free-Stream Turbulence and Unsteadiness. It was shown in Fig. 6.27 that the free-stream turbulence level significantly affects local and overall heat transfer from single cylinders in cross flow. This is caused primarily by early transition of the laminar boundary layer on the forward portion of the cylinder and subsequently by delayed separation of the turbulent boundary layer from the surface of the cylinder. Free-stream turbulence and unsteadiness also affect, to varying degrees, the heat transfer behavior of a turbulent boundary layer in the absence of transition-point shift and separation.

A summary of the available experimental data on the effects of free-stream turbulence on heat transfer was presented by Kestin [138]. The experiments of Refs. 139–141 showed that for free-stream turbulence intensities ranging from 0.75 percent to about 4 percent, the skin friction and heat transfer coefficients at a fixed Re_x remained practically unchanged.

A later study by Hancock [142] revealed a significant dependence of the boundary layer momentum thickness on the free-stream turbulence level. Consequently, significant effects were observed when skin friction data were compared at the same momentum-thickness

Reynolds number Re_θ . The correlated data are shown in Fig. 6.50, where the increase in the skin friction is plotted versus a parameter that accounts for both the intensity and the scale of the free-stream turbulence. The effect of free-stream turbulence is primarily in the outer region of the boundary layer, where the law of the wake is modified, and, hence, the boundary layer integral thicknesses are modified.

FIGURE 6.50 Effect of free-stream turbulence on skin friction for a flat-plate turbulent boundary layer [142]. (All details about different data points are given in Ref. 142.) (Reprinted by permission of the authors.)

The problem of turbulent boundary layers with an oscillatory free stream has received considerable attention recently. Such flows are encountered with turbine blades, reciprocating cylinder walls, and helicopter rotor blades. The experiments of Refs. 143–146 have shown that even at amplitudes as large as 40 percent of the mean and frequencies ranging from quasi-steady to twice the bursting frequency, approximately $\frac{1}{3} u/\delta$, the mean velocity and turbulence intensity profiles in the boundary layer remain unaffected and are indeed the same as those measured with free-stream velocity distributions held steady at the mean value. This shows that there is apparently no energy transfer between the imposed organized oscillations and the random turbulent fluctuations in the boundary layer. This being the case, the behavior of unsteady turbulent boundary layers can be predicted satisfactorily using turbulence models developed for steady flows [145].

TRANSITIONAL BOUNDARY LAYERS

Transitional Boundary Layers for Uniform Free-Stream Velocity

Because the transition zone from a laminar to a turbulent boundary layer often covers a major portion of the exposed surface of a body, it is necessary to be able to predict the rapidly

changing convection rate in this zone. The position of the onset of turbulence and the extent of the transition zone for a specific configuration depend on many factors such as the scale and spectral content of the free-stream turbulence and sound field, the free stream Mach number, and the surface characteristics of smoothness, waviness, temperature, compliance, and mass transfer. To date, there is no universal correlation of these factors that will permit the prediction of the position and extent of the transition zone. What is presented here is a technique for predicting transitional boundary layer convection on a plate, given the position of the transition region. If the transition zone is not well known, one design approach is to arbitrarily assign a series of positions of the onset of turbulence and to set the length of the transition zone equal to the length of the fully laminar boundary layer. The sensitivity of the final design to changes in the position of transition must be determined; a high degree of sensitivity suggests the need for careful experimentation with prototype models.

The contents of this section are an extension of the work of Ref. 147 to include the effects of variable fluid properties. The ideas employed are based on the observations of Ref. 148 that on a flat plate the distribution of β , the fraction of time a surface point is covered by a fully turbulent boundary layer, is closely approximated by a Gaussian integral curve throughout the transition zone, i.e.,

$$\beta(x) = \int_0^x P(s_i) \frac{ds_i}{\bar{\sigma}} \quad (6.238)$$

where $\bar{\sigma}$ is the standard deviation of the transition location about its mean \bar{s}_i , and $P(s_i)$ is the probability that transition initiates between s_i and $s_i + ds_i$:

$$P(s_i) = \frac{1}{\sqrt{2\pi}} \exp\left[-\frac{1}{2} \left(\frac{s_i - \bar{s}_i}{\bar{\sigma}}\right)^2\right] \quad (6.239)$$

Use of Eq. 6.239 requires that the transition take place sufficiently downstream so that the boundary layer is fully laminar at all times near the leading edge ($\bar{s}_i > 2\sigma$).

If the term $q''_{wl}(x, s_i)$ is defined as the heat flux at point x in a turbulent boundary layer with instantaneous transition from laminar to turbulent flow at s_i , and $q''_{wl}(x)$ is defined as the heat flux at point x with a laminar boundary layer beginning at the leading edge, the heat flux caused by the intermittency of turbulence in the transition zone is then

$$q''_w(x) = [1 - \beta(x)]q''_{wl}(x) + \int_0^x P(s_i)q''_{wl}(x, s_i) \frac{ds_i}{\bar{\sigma}} \quad (6.240)$$

The first term is the product of the laminar heat flux and the fraction of time the boundary layer is laminar at x . The second term accounts for both the fraction of time the boundary layer is turbulent and the effect of the moving transition location. The term $q''_{wl}(x, s_i)$ is sufficiently complex mathematically that Eq. 6.240 is normally solved by numerical integration. If it is assumed that the energy thickness remains unchanged as the laminar boundary layer changes instantaneously into a turbulent boundary layer, then

$$\frac{q''_{wl}(x, s_i)}{q''_{wl}(x, 0)} = \left\{ 1 - \frac{s_i}{x} \left[1 - \frac{36.9}{\text{Pr}^{1/3}} \left(\frac{z_l}{z_i}\right)^{5/4} \frac{F_c F_{R0}^{1/4}}{\left(\frac{\mu' \rho'}{\mu_e \rho_e}\right)^{5/8} \left(\frac{\rho_e \mu_e s_i}{\mu_e}\right)^{3/8}} \right] \right\}^{-1/5} \quad (6.241)$$

where

$$\frac{\bar{z}_l}{\bar{z}_i} = \frac{i_e + \text{Pr}^{1/2} (u_e^2/2) - i_w}{i_e + \text{Pr}^{1/3} (u_e^2/2) - i_w} \quad (6.242)$$

The form of Eq. 6.241 applies for $\text{Re}_{x,c} < 4 \times 10^6$, where the Blasius skin friction equation (Eq. 6.16) is reasonably accurate and $2 \text{St}/c_f = \text{Pr}^{-2/3}$ and $\text{Pr}^{-0.4}$ for laminar and turbulent flow, respectively. It also uses the laminar reference enthalpy approach to define $\mu' \rho' / \mu_e \rho_e$ (see the section on uniform free-stream conditions) and uses the turbulent boundary layer transfor-

mations F_c and F_{R0} , which are assumed insensitive to Reynolds number variations (see the section on ideal gases at high temperature). Thus, given Ma_e , T_e , T_w , \bar{s}_e , σ , Eq. 6.240 provides the distribution of heat flux in the prescribed transition zone by techniques consistent with those for the fully laminar and fully turbulent boundary layers given previously.

COMPLEX CONFIGURATIONS

The material presented earlier was confined to steady-state flows over simply shaped bodies such as flat plates, with and without pressure gradients in the streamwise direction, or stagnation regions on blunt bodies. The simplicity of these flow configurations allows reduction of the problems to the solution of steady-state ordinary differential equations. The evaluation of convective heat transfer to more complex three-dimensional configurations, characteristic of real aerodynamic vehicles, involves the solution of partial differential equations. Even when the latter are confined to steady-state problems, they require extensive use of computers in the solution of finite difference or finite element formulations. Nonsteady flows further complicate the problems by introducing another dimension, namely, time.

Recent years have shown considerable progress in the development of methods for solving these more complex problems. Larger and faster computers have become more accessible and solution algorithms are more efficient. Complex flow fields undergoing chemical reactions between many species are being performed routinely. For simpler configurations, time-dependent calculations of the dynamic behavior of chaotic turbulent flows have been performed to provide numerical experiments with much more detail than can be provided by physical experiments.

With regard to accuracy, laminar flows can be solved accurately provided care is given to specifying a computational mesh that can resolve shock waves and/or the regions very near surfaces. The introduction of surface mass transfer or nonuniform streamwise surface temperatures is straightforward. With transitional or turbulent boundary layers, however, the state of the art is less satisfactory. A truly predictive method of computing the flow over practical three-dimensional shapes, where the laminar, transitional, and turbulent boundary portions of the flow have been computed in a time-dependent manner and with mesh spacing that resolves all the significant eddies, is not currently available and is likely to be too expensive for general engineering use far into the foreseeable future. Practical mainstream studies of turbulent flows have been confined to steady-state computations dealing only with mean motions. Experimental guidance has been used to define the transition regions and the turbulent regions have been computed with a hierarchy of turbulence models ranging from the simple algebraic eddy viscosity models presented here to second-order models where the concept of the eddy viscosity can be dropped and the Reynolds stresses themselves are evaluated with field equations.

Second-order turbulence models depend on partial differential equations describing measures of the turbulence, i.e., the kinetic energy, the dissipation rate, and/or the individual Reynolds stresses. Thus the number of field equations defining a flow field is increased significantly. Two-equation models that define the eddy viscosity in terms of the turbulence kinetic energy and the dissipation rate (or a dissipation rate per unit kinetic energy) add two partial differential equations to the system and represent a 20 to 40 percent increase in computer storage needs; in addition, these models often reduce convergence rates because of their stiffness. Reynolds stress computations more than double computational costs for similar reasons. Despite their complexity and cost, the second-order models become advantageous for flows involving steep pressure gradients, separated boundary layers, or surface curvature. The models also often lack universality, working very well for one or more flows but then failing when applied to some other type of flow. As a consequence, codes with particular turbulence models must be verified by comparing their results with data from physical or numerical experiments for similar flow fields. Only when an algorithm, a mesh field, and a

turbulence model have been verified for a particular shape and set of flow conditions can the technique be applied with confidence to other generally similar configurations and free-stream flow conditions. In their early stages of development, these codes should be applied to flat plates and stagnation regions and compared to the time-tested methods shown in the previous sections as a first step in the code verification process. Also, because computations with these codes are costly, they are used sparingly. For example, in the computation of the total heat transferred to a body on a trajectory, standard practice is to employ these codes at specific, but widely separated, intervals and then to interpolate for the times between these solutions with guidance for the influence of various parameters from formulas such as those presented earlier.

NOMENCLATURE

Symbol, Definition, SI Units, English Units

A	constant, Eqs. 6.119, 6.142, and 6.201
A^*	coefficient, Eq. 6.132, Table 6.5
A^+	van Driest wall damping parameter, Eq. 6.178
a^*	coefficient, Eq. 6.124
\mathbf{a}^*	constant in reference enthalpy method
\mathbf{a}	exponent, Eq. 6.122, Table 6.3
a_m	molecular weight ratio exponent, Fig. 6.44
B	constant, Eq. 6.142
$B(\beta_T)$	function, Eq. 6.201, Fig. 6.39
B^*	coefficient, Eq. 6.132, Table 6.5
\mathbf{B}	coefficient in law of the wall, Eq. 6.148
\mathbf{B}^*	surface geometry function, Eq. 6.233
B_f	blowing function, Eq. 6.218
B_h	blowing function, Eq. 6.225
B_m	blowing function, compressible flow, Eq. 6.140
b	exponent in viscosity law for liquids
b^*	coefficient, Eq. 6.124
\mathbf{b}^*	constant in reference enthalpy equation
b_f	blowing function, Eq. 6.220
\bar{C}	constant value of C_r , Eq. 6.43
C_e	normalized viscosity-density product referred to boundary layer edge conditions
C_{ew}	Chapman-Rubens constant, Eq. 6.53
C_r	normalized viscosity-density product referred to conditions at r , Eq. 6.39
\mathbf{c}^*	constant in reference enthalpy equation
c_f	local skin friction coefficient
\bar{c}_f	average skin friction coefficient
c_{fw}	local skin friction coefficient in terms of wall properties, Eq. 6.105
c_h	coefficient, Eqs. 6.143 and 6.144
c_{mi}	mass transfer coefficient for species i

c_p	specific heat at constant pressure: J/(kg·K), Btu/(lb _m ·°F)
c_v	specific heat at constant volume: J/(kg·K), Btu/(lb _m ·°F)
D_2	cross flow forced convection coefficient, Table 6.7
\mathcal{D}	diffusion coefficient: m ² /s, ft ² /s
\mathcal{D}_{ij}	binary diffusion coefficient: m ² /s, ft ² /s
d	body or tube diameter: m, ft
d^*	exponent in power-law velocity profile, Table 6.4
d_T	wind tunnel diameter or height: m, ft
E	coefficient for turbulent boundary layer, Eq. 6.175
Ec	Eckert number, $V^2/2i$
F	dimensionless boundary layer stream function, Eq. 6.41
F_c	turbulent boundary layer transformation function, \tilde{c}_f/c_f , Table 6.8
F_{R_x}	turbulent boundary layer transformation function, \tilde{R}_{e_x}/Re_x , Eq. 6.209
$F_{R\theta}$	turbulent boundary layer transformation function, $\tilde{R}_{e_\theta}/Re_\theta$, Table 6.8
F_0	function, Table 6.6: (W/m ²)[m/(N·m ²)] ^{1/2} , [Btu/(s·ft ²)](ft/atm) ^{1/2} , Eq. 6.134
f	Blasius stream function, Eq. 6.12
$f(x)$	denotes function of x
H	form factor in two-dimensional flow, δ^*/θ
h	local heat transfer coefficient: W/(m ² ·K), Btu/(h·ft ² ·°F)
\bar{h}	average heat transfer coefficient for row of tubes: W/(m ² ·K), Btu/(h·ft ² ·°F)
\bar{h}_∞	average heat transfer coefficient for infinite array of tubes: W/(m ² ·K), Btu/(h·ft ² ·°F)
I	total enthalpy per unit mass: J/kg, Btu/lb _m , $I = i + (u^2 + v^2 + w^2)/2$
\bar{I}	normalized total enthalpy, Eq. 6.39
I	normalized total enthalpy, Eq. 6.45
i	enthalpy per unit mass: J/kg, Btu/lb _m
j	diffusion flux: kg/(m ² ·s), lb _m /(ft ² ·s)
K_i	mass concentration of species i
k	thermal conductivity: W/(m·K), Btu/(s·ft·°R)
k^+	roughness Reynolds number, wall layer coordinates
k	index, Eq. 6.76
k_s	roughness size: m, ft
L	length of porous section in film cooling: m, ft
L	reference length, e.g., Eq. 6.76 and Eq. 6.89: m, ft
L_t	free-stream turbulence length scale, Fig. 6.50: m, ft
Le	Lewis number, $\rho\mathcal{D}c_p/k$, or ϵ_D/ϵ_H
l	mixing length: m, ft
l^*	normalized mixing length, lu^*/ν
M	molecular weight: kg/kmol, lb _m /lb _m -mol
M_c	mean molecular weight of coolant: kg/kmol, lb _m /lb _m -mol
Ma	Mach number
m	exponent, Eq. 6.119
m^*	constant, Eq. 6.142

Nu	Nusselt number, $St Re_L Pr$
\overline{Nu}	mean or average Nusselt number, $\overline{St} Re_L Pr$
n	number of species
n^*	constant, Eq. 6.142
n_D	Deissler empirical constant
n_1	exponent, Table 6.7
P	pressure: N/m^2 , lb_f/ft^2 (atm)
$P(\)$	probability function of transition, Eq. 6.239
Pr	Prandtl number, $\mu c_p/k$, single gas or liquid
Pr_F	frozen Prandtl number, gas properties weighted over all species present
Pr_M	effective Prandtl number, Eq. 6.182
Pr_T	Prandtl number based on total properties for gas in chemical equilibrium
Pr_t	turbulent Prandtl number, ϵ_M/ϵ_H
q''	heat flux: W/m^2 , $Btu/(s \cdot ft^2)$
$\overline{q''}$	average heat flux (over space): W/m^2 , $Btu/(s \cdot ft^2)$
\overline{R}	enthalpy profile function, Eq. 6.195
R	universal gas constant: $m^2/(s^2 \cdot K)$ or $J \cdot kmol^{-1} \cdot K^{-1}$, $ft^2/(s^2 \cdot ^\circ R)$
Re_d	Reynolds number based on diameter d
Re_{eff}	effective Reynolds number, Eq. 6.202
Re_L	Reynolds number based on length L ; $L = x$, θ , δ^* , δ , or Γ
r	radius of spherical roughness: m, ft
\mathbf{r}	dimensionless temperature variable, Eq. 6.28
$r(0)$	recovery factor
r_c	streamwise radius of curvature: m, ft
r_n	nose radius: m, ft
S	enthalpy profile function, Eq. 6.181
St	local Stanton number, $h/\rho c_p u_e$
\overline{St}	average Stanton number, $\overline{h}/\rho c_p u_e$
$St(x, s)$	local Stanton number on a plate with a temperature jump at $x = s$
s	distance to location of surface temperature discontinuity: m, ft
s_j^+	downstream of surface temperature jump: m, ft
s_j^-	upstream of surface temperature jump: m, ft
s_t	distance from leading edge to transition from laminar to turbulent flow: m, ft
T	temperature: K, $^\circ R$
T_c	constant in viscosity law for liquids: K, $^\circ R$
T_{sc}	Sutherland constant: K
Tu	intensity of turbulence, u'/v_e
T_{wL}	porous section temperature
t	time: s
\bar{t}	normalized local enthalpy, Eq. 6.91
t^+	normalized temperature parameter, Eq. 6.184
\bar{t}_e	normalized free-stream enthalpy, Eq. 6.93

\bar{h}_s	normalized free-stream enthalpy, Eq. 6.92
U_∞	velocity component normal to leading edge of yawed cylinder, Fig. 6.18
\bar{U}	normalized free-stream velocity: $V_\infty/(10,000 \text{ ft/s})$, $V_\infty/(3048 \text{ m/s})$
u	velocity component in x direction: m/s, ft/s
u^*	friction velocity, $\sqrt{\tau_w/\rho}$: m/s, ft/s
u^+	normalized velocity, u/u^*
Δu^+	shift in normalized velocity due to roughness
u	internal energy per unit mass: J/kg, Btu/lb _m
u_e	free-stream velocity component in the x direction: m/s, ft/s
u'_e	free-stream RMS fluctuation of velocity: m/s, ft/s
u_i	velocity component in the x_i direction: m/s, ft/s
V_∞	free-stream velocity: m/s, ft/s
v	velocity component in the y direction: m/s, ft/s
v_0^+	velocity component in the y direction at surface normalized by u^*
w	velocity component in the z direction: m/s, ft/s
\bar{w}	normalized cross flow velocity, Eq. 6.90
w	Coles wake function, Fig. 6.33
x	rectangular coordinate: m, ft
\bar{x}	dimensionless tube spacing in the free-stream direction
x_{eff}	effective distance, laminar flow, Eq. 6.110
x_i	generalized orthogonal coordinate: m, ft
\bar{x}_i	dimensionless tube spacing normal to the free-stream direction
x^+	normalized x_1 distance, Eq. 6.187
$Y_0(\eta)$	dimensionless temperature function, Eq. 6.19
y	rectangular coordinate, normal to surface: m, ft
y^+	normalized distance from wall, u^*y/ν

η	transformed boundary layer variable, Eqs. 6.11, 6.36, and 6.89
η_c	modified transformed boundary layer variable, Eq. 6.43
η_H	thermal boundary layer thickness parameter, Figs. 6.2 and 6.3
θ	momentum thickness, two-dimensional flow, Eq. 6.151: m , ft
θ_c	cone angle: rad , deg
θ_0	ratio of Sutherland constant to edge temperature
κ	von Kármán mixing length constant, Eq. 6.148
Λ	sweepback angle: rad , deg
μ	dynamic viscosity: $\text{kg}/(\text{m}\cdot\text{s})$, $\text{lb}_m/(\text{ft}\cdot\text{s})$
ν	kinematic viscosity: m^2/s , ft^2/s
$\tilde{\pi}$	parameter in Coles wake velocity distribution, Eq. 6.149
ρ	density: kg/m^3 , lb_m/ft^3
$\bar{\sigma}$	standard deviation of transition location about its mean
τ	shear stress between fluid layers: N/m^2 , lb_f/ft^2
τ_w	shear stress at wall: N/m^2 , lb_f/ft^2
ψ	stream function: m^2/s , ft^2/s , Eq. 6.10

Subscripts

aw	adiabatic wall conditions
c	initial coolant condition in reservoir
d	diameter
e	evaluated at the boundary layer edge
eff	effective value
F	frozen properties
i	component i of a mixture
i	constant-property case
i	defining orthogonal direction, Eq. 6.104
j	component j of a mixture
l	laminar
r, ref	reference condition
st	stagnation point on body
T	total properties
t	turbulent
w	wall
0	zero mass transfer

- 1 component 1 (coolant) of mixture
- 2 component 2 (air) of mixture
- ∞ free-stream conditions

Superscripts

- mean value
- ' random fluctuating value; dummy variable, reference property, ordinary derivative
- * properties to be evaluated at reference enthalpy or temperature condition
- constant-property case

INTRODUCTION

The field of radiative transfer is undergoing major advances in the capability to analyze complex problems. A well-developed theoretical base exists that can be applied to the solution of most (but not all) engineering problems. Major increases in computational speed and capacity have opened the way to solutions of problems that include complex geometries, spectral effects, and inhomogeneous properties. The need for such a capability is driven by applications that include high-temperature manufacturing processes and materials processing, improved efficiency, and more accurate design methods necessary for energy conversion devices, the use of new materials, hypersonic flow analysis, and others.

Some areas of radiative transfer analysis that had seen sparse research for some time have undergone a renaissance. This is true for radiative transfer among surfaces with no participating medium. The need to provide fast and accurate computer visualization for use in data depiction, virtual reality, real-time animation, and other areas requiring accurate modeling of radiative transfer has revived research on surface radiative transfer algorithms. These same needs have brought forth new research on surface property measurement and modeling so that accurate spectral and directional effects can be included in computer visualization.

Other areas of radiative transfer have been driven by increased capability of analysis due to the great strides in computer capability. Just a few years ago, two-dimensional problems of radiative transfer in enclosures with a participating medium were at the edge of computational capability. Now, these are routine, and many three-dimensional cases have been analyzed. Because of the need in applications such as utility steam generator design to analyze three-dimensional geometries with up to tens of thousands of surface and volume computational elements, much research is now focused on further increases in computational speed. Massively parallel computers may well provide the required computational capability for such problems.

In this chapter, we present the fundamentals of radiative transfer analysis. We begin with a review of the properties of the ideal radiating body, the *blackbody*, by describing radiative exchange among ideal (black) surfaces and then extending the analysis to surfaces with real radiative properties. We further extend the analysis to the case of a medium between the bounding surfaces that can absorb, emit, and scatter radiation. We provide information on the radiative properties of such participating media and conclude with a discussion of methods

for treating combined-mode heat transfer problems in which radiative transfer is important. We present the bounds of applicability of the theory based on current state-of-the-art and available data.

Additional information can be found in the recent texts by Siegel and Howell [1], Brewster [2], and Modest [3].

Radiation Intensity and Flux

Any substance at a finite temperature emits electromagnetic energy in discrete energy quanta called *photons*. The energy of each photon is equal to $h\nu = hc/\lambda$, where h is the Planck constant, c is the speed of light, and ν and λ are the frequency and wavelength of the emitted energy, respectively. As it will be outlined below, with decreasing wavelength, or increasing frequency, the energy associated with photons increases.

Thermal radiation is associated with a temperature range of approximately 30 to 30,000 K and wavelength range of 0.1 to 100 μm . For most practical purposes, however, we are interested in a wavelength range of 0.4 (near-UV) to about 15 μm (near-IR). The photons whose energies correspond to this wavelength/temperature range are capable of changing the discrete vibrational, rotational, and electronic energy states of atoms and molecules of the material on which they are incident, and this, in turn, changes the internal energy and the corresponding temperature of the material. As a result of this, energy is transferred from a hot object to a colder one via thermal radiation as opposed to transfer by phonons when the objects are in contact.

Radiative heat transfer from one small volume or surface element to another is determined by accounting for the energies of photons of all wavelengths, emitted in all directions over a certain time interval. Depending on the location of each element and its orientation with respect to others, the amount of radiant energy exchange between elements will vary. In order to determine the contribution of each element to the radiation balance, we introduce a fundamental and mathematically convenient quantity termed *radiation intensity*.

By definition, the fractional radiant energy de_λ propagating through (or originating from) an infinitesimally small area dA_n in the direction $\hat{\Omega}(\theta, \phi)$, confined within an infinitesimally small solid angle $d\Omega$ around $\hat{\Omega}(\theta, \phi)$, within a wavelength interval $d\lambda$ around the wavelength of λ , and within a time interval of dt is called the *radiation intensity*:

$$I_\lambda(\hat{\Omega}) = I_\lambda(\theta, \phi) = \lim_{(dA_n, d\Omega, d\lambda, dt) \rightarrow 0} \frac{de_\lambda(\theta, \phi)}{dA_n d\Omega d\lambda dt} \quad (7.1)$$

FIGURE 7.1 Definition of radiative intensity.

The direction of propagation $\hat{\Omega}$ is defined in spherical coordinates in terms of the zenith angle θ and azimuthal angle ϕ (see Fig. 7.1). dA_n is the area normal to the direction of propagation $\hat{\Omega}$ and is equal to $dA \cos \theta$, with θ being the zenith angle (i.e., the angle between the surface normal \hat{n} and $\hat{\Omega}$).

The solid angle is defined as the ratio of infinitesimal area normal to $\hat{\Omega}$, to the square of the distance between two infinitesimal surface elements exchanging radiation (see Fig. 7.2). Note that radiation intensity may vary as a function of location $\vec{r} = \vec{r}(x, y, z)$, direction $\hat{\Omega} = \hat{\Omega}(\theta, \phi)$, time t , and wavelength λ ; therefore, it is a function of seven independent parameters. For most calculations of interest, the transient nature of radiation intensity is not critical. Recently, however, with the advances in femto- and picosecond pulsed lasers, the transient radiative transfer applications have started becoming important (see, e.g., Ref. 4); nevertheless, we will not cover these advances in this chapter.

FIGURE 7.2 Definition of solid angle.

For heat transfer predictions, the radiative heat flux through a surface (with normal \hat{n}) is required, which is determined by integrating the radiation intensity incident from all directions (i.e., 4π steradians) as

$$\tilde{q}_\lambda(\vec{r}) = \int_{\Omega=4\pi} I_\lambda(\vec{r}, \hat{\Omega}) \hat{n} \cdot \hat{\Omega} d\Omega \quad (7.2)$$

where \hat{n} is the unit vector normal to the surface (see Fig. 7.1). Note that by replacing $\hat{\Omega}$ with $\hat{n} \cdot \hat{\Omega}$, which is equivalent to the direction cosine for a given surface, the flux across the surface is obtained. Radiative flux on an opaque (i.e., nontransmitting) surface element is obtained by evaluating the integral over a single hemisphere (i.e., $\Omega = 2\pi$ steradians). The total radiative flux is determined by integrating $\tilde{q}_\lambda(\vec{r})$ over the entire wavelength spectrum.

Blackbody Radiation

The blackbody is the standard against which the behavior of all real radiating materials is gauged. It has well-defined characteristics that are firmly based in theory and experiment. Here, these characteristics will be outlined, as understanding them is paramount to conceptualizing the radiative transfer phenomenon.

General Definitions and Characteristics. The most important attributes of a blackbody can be listed as:

- A blackbody is defined as a surface or volume that absorbs all incident radiation. This includes radiation at every wavelength and from every direction.
- The blackbody is the best possible emitter of radiation at every wavelength and in every direction.
- Radiation emitted by a blackbody increases monotonically at every wavelength with absolute temperature.
- Radiation within an isothermal enclosure with blackbody boundaries is isotropic; that is, uniform in all directions.

With such qualities, the blackbody is seen to be a convenient standard for comparing the properties of real materials. All real materials will reflect some incident radiant energy and are thus not perfect absorbers. Because they do not absorb as much as the ideal blackbody, they must emit less than an ideal blackbody to remain in thermal equilibrium with their surroundings. A real surface thus emits less than the blackbody (again, at every wavelength and in every direction).

It is possible to construct a nearly ideal blackbody by the artifice of defining the surface over the small entrance to a deep cavity as the blackbody. Little of the radiation crossing this fictitious “black” surface reflects back through the cavity opening, especially if the internal cavity surfaces are made as nonreflecting as possible and are oriented so as not to face the cavity opening directly. If the interior cavity surfaces are maintained at a uniform constant temperature and the cavity opening is small, then the radiation within the cavity is isotropic and the energy leaving the cavity opening will be quite close to that of a blackbody at the cavity temperature. These observations are the basis for producing experimental blackbodies used in making comparisons of radiation from real material surfaces for property measurements. To analyze radiative heat transfer, quantitative measures of the blackbody characteristics described in this section must be provided.

Blackbody Intensity, Emissive Power. It can be shown that the intensity leaving a black surface is independent of θ and ϕ ; that is, the blackbody emitted intensity is isotropic [1]. This fact provides another convenient benchmark for comparing the behavior of real surfaces.

For a blackbody, the spectral intensity is given by the *Planck distribution of blackbody intensity* [5]:

$$I_{\lambda b} = \frac{2C_1}{n^2 \lambda^5 (e^{C_2/n\lambda T} - 1)} \quad (7.3)$$

where T is the absolute temperature (in K) and C_1 and C_2 are constants with values

$$C_1 = hc_o^2 = 0.59552 \cdot 10^8 \text{ W } \mu\text{m}^4/\text{m}^2$$

$$C_2 = hc_o/k = 14,388 \text{ } \mu\text{mK} \quad (7.4)$$

with $h = 6.626075 \cdot 10^{-34} \text{ Js}$ (Planck constant) (7.5)

$$k = 1.380658 \cdot 10^{-23} \text{ J/K}$$
 (Boltzmann constant) (7.6)

$$c_o = 2.99792458 \cdot 10^8 \text{ m/s}$$
 (speed of light in vacuum) (7.7)

and n is the index of refraction of the medium. To determine the energy leaving a black surface in all directions, $I_{\lambda b}$ is integrated over the hemisphere of solid angles $d\Omega = \sin \theta d\theta d\phi$ to give the *spectral emissive power of a blackbody* $e_{\lambda b}$:

$$e_{\lambda b} = \int_{\theta=0}^{\pi} \int_{\phi=0}^{2\pi} I_{\lambda b} \cos \theta \sin \theta d\theta d\phi = \frac{2\pi C_1}{n^2 \lambda^5 (e^{C_2/n\lambda T} - 1)} = \pi I_{\lambda b} \quad (7.8)$$

Figure 7.3 depicts the blackbody function for different temperatures, including the solar temperature of 5762 K. Equation 7.8 can be simplified by dividing by $n^3 T^5$ to give

$$\frac{e_{\lambda b}}{n^3 T^5} = \frac{2\pi C_1}{(n\lambda T)^5 (e^{C_2/n\lambda T} - 1)} \quad (7.9)$$

This relation is plotted in Fig. 7.4.

FIGURE 7.3 The Planck distribution of blackbody emissive power.

FIGURE 7.4 Normalized and fractional blackbody emission distributions.

Note that, with decreasing temperature, the area under the curve (i.e., the *total* energy emitted by the blackbody) decreases. The maximum value of the curve shown in Fig. 7.4 can be found mathematically by taking the partial derivative of Eq. 7.9 with respect to wavelength and setting the result equal to zero. The maximum of the curve occurs at a fixed value of

$$C_3 = (n\lambda T)_{\max} = 2897.8 \mu\text{mK} \quad (7.10)$$

This relation is known as *Wien's displacement law*, and it provides a convenient means of determining where the wavelength of peak radiated energy occurs for a given temperature. For example, the solar radiation spectrum has a peak at about $\lambda = 0.5 \mu\text{m}$, as $T_{\text{sun}} = 5762 \text{ K}$. On the other hand, an object at room temperature ($T_{\text{room}} = 300 \text{ K}$) would emit maximum energy at about $\lambda \approx 10 \mu\text{m}$. It is obvious that, as absolute temperature increases, the wavelength at which the maximum emissive power occurs becomes smaller.

Values of $e_{\lambda b}/n^3T^5$ are tabulated in many sources (usually for $n = 1$; see Refs. 1, 2, 3, and 6) and easily computed from Eq. 7.9. If $\exp(C_2/n\lambda T) \gg 1$, the Planck blackbody distribution can be simplified to

$$e_{\lambda b} = \frac{2\pi C_1}{n^2 \lambda^5} e^{-C_2/n\lambda T} \quad (7.11)$$

This expression, known as *Wien's distribution of blackbody radiation*, is accurate over a wide range of wavelengths and temperatures.

Equation 7.9 can be integrated with respect to wavelength to obtain the total blackbody emissive power (i.e., the rate of energy emitted by a blackbody into all directions at all wavelengths):

$$e_b = \int_{\lambda=0}^{\infty} e_{\lambda b} d\lambda = n^2 \sigma T^4 \quad (7.12)$$

Equation 7.12 is known as the *Stefan-Boltzmann equation*, and σ is the Stefan-Boltzmann constant, which has the value

$$\sigma = 2C_1\pi^5/15C_2^4 = 2\pi^5 k^4/(15h^3 c_0^2) = 5.6705 \cdot 10^{-8} \text{ W}/(\text{m}^2\text{K}^4) \quad (7.13)$$

The value of σ calculated from the accepted values of Planck's constant h , the Boltzmann constant k , and the speed of light in a vacuum c_0 agrees with experimentally determined values within experimental error of 1.4 parts in 10^4 [7].

Equation 7.12 shows that the rate of energy emitted by a blackbody increases in proportion to the absolute temperature to the fourth power, so that radiation will generally be the dominating heat transfer mode at high absolute temperatures.

For many practical applications, the blackbody emission is needed within finite, relatively narrow wavelength intervals, rather than the entire spectrum. To calculate the blackbody energy between wavelengths λ_1 and λ_2 , we write

$$\int_{\lambda_1}^{\lambda_2} e_{\lambda b} d\lambda = \frac{C_1}{C_2^4} \int_{\xi_1}^{\xi_2} n^2 T^4 \frac{\xi^3 d\xi}{e^\xi - 1} \quad (7.14)$$

$$= \frac{C_1}{C_2^4} \left[\int_0^{\xi_2} n^2 T^4 \frac{\xi^3 d\xi}{e^\xi - 1} - \int_0^{\xi_1} n^2 T^4 \frac{\xi^3 d\xi}{e^\xi - 1} \right] \quad (7.15)$$

$$= (F_{0-n\lambda_2 T} - F_{0-n\lambda_1 T}) E_b(T) \quad (7.16)$$

where $\xi = C_2/n\lambda T$. Here, $F_{0-n\lambda T}$ is the fraction of the energy in the blackbody distribution that lies below some given $n\lambda T$ value and is called the fractional blackbody function of the first kind. This fraction is defined as

$$F_{0-n\lambda T} = \frac{\int_0^{\lambda T} (e_{\lambda b}/T^5) d(\lambda T)}{\int_0^\infty (e_{\lambda b}/T^5) d(\lambda T)} = \frac{\int_0^\lambda e_{\lambda b} d\lambda}{\int_0^\infty e_{\lambda b} d\lambda} \quad (7.17)$$

where the F fraction can be evaluated numerically and is listed in most textbooks. An analytical formulation for this integral was suggested [8], resulting in

$$F_{0-n\lambda T} = \frac{15}{\pi^4} \sum_{j=1}^{\infty} \left[\frac{e^{-j\xi}}{j} \left(\xi^3 + \frac{3\xi^2}{j} + \frac{6\xi}{j^2} + \frac{6}{j^3} \right) \right] \quad (7.18)$$

This relation converges very quickly, usually within three terms of the series except at very large values of ξ . Figure 7.4 also depicts the fractional blackbody function versus $n\lambda T$ product.

Nonblack Surfaces and Materials

No real materials act as blackbodies, so measures of their deviation from blackbody behavior are used to define the spectral, directional, and temperature dependence of real surfaces relative to those of a blackbody.

The notation used is to denote a spectrally dependent property with a λ subscript as before, and to denote a directionally dependent property with a prime ($'$). These symbols are omitted when the property in question has been averaged over one or both of the dependencies.

Emissivity. The ability of a surface to emit radiation in comparison with the ideal emission by a blackbody is defined as the emissivity of the surface. The emissivity can be defined on a spectral, directional, or total basis.

*Directional Spectral Emissivity**

$$\epsilon'_\lambda = \frac{I_\lambda}{I_{\lambda b}} \quad (7.19)$$

* The prime denotes the directional quantity. Note that the radiation intensity I is directional by definition.

FIGURE 7.5 Schematic of angular intensity distributions leaving an ideal blackbody ($I_{\lambda b}$) and a real surface (I_{λ}).

Figure 7.5 depicts the angular distribution of $I_{\lambda b}$ and I_{λ} schematically for an ideal blackbody and a typical real surface. Note that only the azimuthal angle (θ) dependence is shown for the sake of clarity. Integrating the emitted energy over all wavelengths at a particular direction results in the directional total emissivity.

Directional Total Emissivity

$$\epsilon' = \frac{I}{I_b} = \frac{\pi \int_{\lambda=0}^{\infty} I_{\lambda} d\lambda}{\sigma T^4} = \frac{\pi \int_{\lambda=0}^{\infty} \epsilon'_{\lambda} I_{\lambda b} d\lambda}{\sigma T^4} = \frac{\pi I}{\sigma T^4} \quad (7.20)$$

Integrating the energy emitted over all directions at a particular wavelength gives hemispherical-spectral emissivity.

Hemispherical-Spectral Emissivity

$$\epsilon_{\lambda} = \frac{e_{\lambda}}{e_{\lambda b}} = \frac{1}{\pi} \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} \epsilon'_{\lambda} \cos \theta \sin \theta d\theta d\phi \quad (7.21)$$

Integrating the emitted energy over both wavelength and direction and comparing with the similar integrated quantity for a blackbody yields hemispherical total emissivity.

Hemispherical Total Emissivity

$$\begin{aligned} \epsilon = \frac{e}{e_b} &= \frac{\int_{\lambda=0}^{\infty} \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} \epsilon'_{\lambda} I_{\lambda b} \cos \theta \sin \theta d\theta d\phi d\lambda}{\sigma T^4} \\ &= \frac{\pi \int_{\lambda=0}^{\infty} \epsilon_{\lambda} I_{\lambda b} d\lambda}{\sigma T^4} = \frac{\int_{\lambda=0}^{\infty} \epsilon_{\lambda} e_{\lambda b} d\lambda}{\sigma T^4} \end{aligned} \quad (7.22)$$

The various integrated emissivities allow calculation using data for the detailed emissivities.

Absorptivity. The absorptivity is the property that defines the fraction of the incident energy that is absorbed by a surface. This property may also be dependent upon the direction and wavelength of the incident radiation. These properties will usually depend on the temperature of the absorbing surface (T_s); however, notation to indicate this fact is omitted.

Directional Spectral Absorptivity

$$\alpha'_{\lambda} = \frac{d^3 q_{\lambda,a}}{d^3 q_{\lambda,i}} = \frac{d^3 q_{\lambda,a}}{I_{\lambda,i} \cos \theta d\Omega d\lambda} \quad (7.23)$$

where the superscript 3 indicates that the flux q is a dependent function of three variables: wavelength λ , direction (θ, ϕ), and location $r(x, y, z)$. Integrating the absorbed energy over all wavelengths at a particular direction of incidence results in directional total absorptivity.

Directional Total Absorptivity

$$\alpha' = \frac{d^2 q_a}{d^2 q_i} = \frac{\pi \int_{\lambda=0}^{\infty} \alpha'_{\lambda} I_{\lambda,i} d\lambda}{\int_{\lambda=0}^{\infty} I_{\lambda,i} d\lambda} \quad (7.24)$$

By integrating Eq. 7.23 over all incident directions, the energy absorbed from all directions at a particular wavelength is obtained as hemispherical-spectral absorptivity.

Hemispherical-Spectral Absorptivity

$$\alpha_\lambda = \frac{d^2 q_{\lambda,a}}{d^2 q_{\lambda,i}} = \frac{\int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} \alpha'_\lambda I_{\lambda,i} \cos \theta \sin \theta \, d\theta \, d\phi}{\int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} I_{\lambda,i} \cos \theta \sin \theta \, d\theta \, d\phi} \quad (7.25)$$

Finally, integrating the absorbed energy over both wavelength and direction and comparing with the integrated incident energy gives hemispherical total absorptivity.

Hemispherical Total Absorptivity

$$\alpha = \frac{dq_a}{dq_i} = \frac{\int_{\lambda=0}^{\infty} \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} \alpha'_\lambda I_{\lambda,i} \cos \theta \sin \theta \, d\theta \, d\phi \, d\lambda}{\int_{\lambda=0}^{\infty} \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} I_{\lambda,i} \cos \theta \sin \theta \, d\theta \, d\phi \, d\lambda} = \frac{\int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} \alpha'_i I_i \cos \theta \sin \theta \, d\theta \, d\phi}{\int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} I_i \cos \theta \sin \theta \, d\theta \, d\phi} \quad (7.26)$$

Kirchhoff's Law. Through an energy balance at thermodynamic equilibrium, it can be shown that the directional-spectral emissivity is always equal to the directional-spectral absorptivity of a surface, or

$$\alpha'_\lambda = \epsilon'_\lambda \quad (7.27)$$

This relation is known as Kirchhoff's law. Equation 7.27 may be substituted into the various relationships for the integrated emissivity or absorptivity. However, it does not follow that such quantities as directional total, hemispherical-spectral, or hemispherical total emissivity and absorptivity are necessarily equal. In fact, the integrated properties are only equal if certain restrictions are met. These are given in Table 7.1.

TABLE 7.1 Requirements for Application of Kirchhoff's Law

Relation	Restrictions
I: $\alpha'_\lambda = \epsilon'_\lambda$	None
II: $\alpha_\lambda = \epsilon_\lambda$	Incident radiation has equal intensity from all angles, or $\alpha'_\lambda = \epsilon'_\lambda$ are independent of angle
III: $\alpha' = \epsilon'$	Incident radiation has a spectral distribution proportional to that of a blackbody at the temperature of the surface, or $\alpha'_\lambda = \epsilon'_\lambda$ are independent of wavelength
IV: $\alpha = \epsilon$	One restriction each from II and III above

Reflectivity. Reflectivity is the property of a surface that defines the fraction of incident energy that is reflected by the surface. This property depends not only on the wavelength and directional characteristics, but it must also describe the directional distribution of the reflected radiation. It therefore has more independent variables than the properties discussed so far. Integrated properties are defined by integration over incident angle, reflected angle, wavelength, and combinations of these. Many of the reflectivities are rarely used in practice; the most useful ones are defined here. Note that the same notation is used as for absorptivity and emissivity, except that a double prime indicates a reflectivity that depends on both direction of incidence and direction of reflection.

The most fundamental reflectivity defines the intensity reflected into a particular direction resulting from energy incident from a given direction. At a particular wavelength, this is as follows.

Bidirectional Spectral Reflectivity

$$\rho''_\lambda = \frac{I_{\lambda,r}}{I_{\lambda,i} \cos \theta_i \sin \theta_i \, d\theta_i \, d\phi_i} \quad (7.28)$$

where double prime (") indicates the directional nature of both incident and reflected radiant energy.

Integrating ρ''_{λ} over all angles of reflection gives:
Directional-Hemispherical Spectral Reflectivity

$$\rho'_{\lambda i} = \frac{\int_{\phi_r=0}^{2\pi} \int_{\theta_r=0}^{\pi/2} I_{\lambda,r} \cos \theta_r \sin \theta_r d\theta_r d\phi_r}{I_{\lambda,i} \cos \theta_i \sin \theta_i d\theta_i d\phi_i} = \int_{\phi_r=0}^{2\pi} \int_{\theta_r=0}^{\pi/2} \rho''_{\lambda} \cos \theta_r \sin \theta_r d\theta_r d\phi_r \quad (7.29)$$

Because of the reciprocity of the bidirectional reflectivity ρ''_{λ} , the hemispherical-directional spectral reflectivity for isotropic incident intensity $\rho'_{\lambda r}$ is equal to the directional-hemispherical reflectivity $\rho'_{\lambda i}$. Here, a single prime (') is used to denote the directional nature of incident radiation.

The fraction of the incident energy from all directions that is reflected into all directions at a particular wavelength is written as hemispherical spectral reflectivity.

Hemispherical Spectral Reflectivity

$$\rho_{\lambda} = \frac{\int_{\phi_i=0}^{2\pi} \int_{\theta_i=0}^{\pi/2} \rho'_{\lambda i} I'_{\lambda,i} \cos \theta_i \sin \theta_i d\theta_i d\phi_i}{\int_{\phi_i=0}^{2\pi} \int_{\theta_i=0}^{\pi/2} I'_{\lambda,i} \cos \theta_i \sin \theta_i d\theta_i d\phi_i} \quad (7.30)$$

By integrating over all wavelengths, the reflectivities defined above become total values and are given as follows.

Bidirectional Total Reflectivity

$$\rho'' = \frac{\int_{\lambda=0}^{\infty} I_{\lambda,r} d\lambda}{\cos \theta_i \sin \theta_i d\theta_i d\phi_i \int_{\lambda=0}^{\infty} I_{\lambda,r} d\lambda} = \frac{\int_{\lambda=0}^{\infty} \rho''_{\lambda} I_{\lambda,i} d\lambda}{\int_{\lambda=0}^{\infty} I_{\lambda,i} d\lambda} \quad (7.31)$$

Directional-Hemispherical Total Reflectivity

$$\rho'_i = \frac{\int_{\lambda=0}^{\infty} \rho_{\lambda,i} I_{\lambda,i} d\lambda}{\int_{\lambda=0}^{\infty} I_{\lambda,i} d\lambda} \quad (7.32)$$

Hemispherical Total Reflectivity

$$\rho = \frac{\int_{\lambda=0}^{\infty} \int_{\phi_j=0}^{2\pi} \int_{\theta_j=0}^{\pi/2} \rho'_{\lambda,i} I'_{\lambda,i} \cos \theta_i \sin \theta_i d\theta_i d\phi_i d\lambda}{\int_{\lambda=0}^{\infty} \int_{\phi_i=0}^{2\pi} \int_{\theta_i=0}^{\pi/2} I'_{\lambda,i} \cos \theta_i \sin \theta_i d\theta_i d\phi_i d\lambda} = \frac{\int_{\phi_i=0}^{2\pi} \int_{\theta_i=0}^{\pi/2} \rho'_i I'_i \cos \theta_i \sin \theta_i d\theta_i d\phi_i}{\int_{\phi_i=0}^{2\pi} \int_{\theta_i=0}^{\pi/2} I'_i \cos \theta_i \sin \theta_i d\theta_i d\phi_i} \quad (7.33)$$

Relations among Surface Properties. Because incident energy onto an opaque surface is either reflected or absorbed by the surface, it follows that one unit of radiant energy incident on an opaque surface at a given wavelength and from a given direction will have a fraction absorbed and the remainder reflected, or

$$1 = \alpha'_{\lambda} + \rho'_{\lambda} \quad (7.34)$$

Similarly, for radiation at all wavelengths, it follows that

$$1 = \alpha' + \rho' \quad (7.35)$$

Total radiation onto a surface at all wavelengths and from all directions follows a similar conservation relation,

$$1 = \alpha + \rho \tag{7.36}$$

Kirchhoff's law (Eq. 7.27) may be used to replace the absorptivity in these relations with emissivity if the restrictions of Table 7.1 are observed. Thus, data on one of the radiative properties can often be used to generate the others, although care must be used to avoid violating the restrictions of Table 7.1.

If the surface is not opaque but semitransparent, then Eqs. 7.34–7.36 need to include transmissivity τ and be replaced by the following equations:

$$1 = \alpha'_\lambda + \rho'_\lambda + \tau'_\lambda \tag{7.37}$$

$$1 = \alpha' + \rho' + \tau' \tag{7.38}$$

$$1 = \alpha + \rho + \tau \tag{7.39}$$

where τ'_λ , τ' , and τ are defined similar to the corresponding α equations (see Eqs. 7.23, 7.24, and 7.25).

Values for Surface Properties. In solving radiative transfer problems involving surfaces, property values must be available. Radiative surface properties given in the literature show wide variations, because the values are altered greatly by the presence of surface contaminants (oxidation, fingerprints, etc.), the presence of surface texture or roughness (machining marks, grain structure), and tailored surface characteristics such as coatings, films, or geometric structures specifically designed to affect spectral or directional characteristics. Thus, tabulated values serve at best as rough guidelines to the properties of engineering surfaces. Tabulated property values for selected substances are given in the first two tables in App. A (Tables A.7.1 and A.7.2).

The available data for radiative properties of metallic and nonmetallic surfaces can be found in a number of data bases [9, 10]; they are too extensive to be included in this chapter. Also, the reader is referred to a number of recent handbooks and reviews for more detailed data [11–17].

In the absence of tabulated or measured properties for a given surface, various options are available. The behavior of a surface can be computed based on fundamental theories, such as Maxwell's electromagnetic wave theory; the surface characteristics can be assumed based on extrapolation from the behavior of similar surfaces; a model of the surface behavior can be constructed based on simplified assumed surface characteristics; or greatly simplified characteristics can be assumed to be accurate enough for use. In the third table in App. A (Table A.7.3), the spectral complex index of refraction data for a number of metals are listed (from Ref. 16), which can be used to determine the surface absorption, reflection, and transmission characteristics as discussed below.

Computed Properties. For perfect dielectric materials and for highly conducting materials, electromagnetic wave theory can be used to predict radiative properties [1, 18]. These predictions are based on the assumption that the surface is *optically smooth*; that is, the surface roughness is small compared with the wavelength of the radiation (otherwise, the problem may be numerically intractable). In addition, the composition of the material must be well known so that necessary properties such as the simple refractive index n and the attenuation coefficient k that comprise the complex refractive index $m = n - ik$ can be assigned (Fig. 7.6); this implies that the surface is not contaminated by oxide films or other impurities. If these restrictions are met, then properties can be computed with reasonable accuracy from the following relations, which apply for radiation from medium 1, assumed to be non- or weakly absorbing (i.e., $n_1 \approx 1$ and $k_1 \approx 0$), onto the surface of absorbing/reflecting surface of medium 2:

FIGURE 7.6 Definition of radiative properties at the interfaces.

surface roughness is small compared with the wavelength of the radiation (otherwise, the problem may be numerically intractable). In addition, the composition of the material must be well known so that necessary properties such as the simple refractive index n and the attenuation coefficient k that comprise the complex refractive index $m = n - ik$ can be assigned (Fig. 7.6); this implies that the surface is not contaminated by oxide films or other impurities. If these restrictions are met, then properties can be computed with reasonable accuracy from the following relations, which apply for radiation from medium 1, assumed to be non- or weakly absorbing (i.e., $n_1 \approx 1$ and $k_1 \approx 0$), onto the surface of absorbing/reflecting surface of medium 2:

- Dielectrics (insulating materials, with $n = n_2/n_1$ and $k_1 = k_2 = 0$)

—Normal-hemispherical total or spectral reflectivity

$$\rho'_n = \frac{(n-1)^2}{(n+1)^2} \quad (7.40)$$

—Directional-hemispherical total or spectral reflectivity

$$\rho' = \frac{1}{2} \left[\frac{(n^2 \cos \theta - [n^2 - \sin^2 \theta]^{1/2})^2}{n^2 \cos \theta + [n^2 - \sin^2 \theta]^{1/2}} + \frac{([n^2 - \sin^2 \theta]^{1/2} - \cos \theta)^2}{[n^2 - \sin^2 \theta]^{1/2} + \cos \theta} \right] \quad (7.41)$$

—Normal total emissivity

$$\epsilon'_n = \frac{4n}{(n+1)^2} \quad (7.42)$$

—Hemispherical total emissivity

$$\epsilon = \frac{1}{2} - \frac{(3n+1)(n-1)}{6(n+1)^2} - \frac{n^2(n^2-1)^2}{(n^2+1)^3} \ln \left(\frac{n-1}{n+1} \right) + \frac{2n^3(n^2+2n-1)}{(n^2+1)(n^4-1)} - \frac{8n^4(n^4+1)}{(n^2+1)(n^4-1)^2} \ln n \quad (7.43)$$

- Metals (electromagnetically attenuating materials; for incidence on a surface through most gases, $n_1 = 1$ and $k_1 = 0$):

—Normal hemispherical reflectivity

$$\rho'_n = \frac{(n_2 - n_1)^2 + (k_2 - k_1)^2}{(n_2 + n_1)^2 + (k_2 + k_1)^2} = \frac{(n_2 - 1)^2 + (k_2)^2}{(n_2 + 1)^2 + (k_2)^2} \quad (7.44)$$

—Normal spectral emissivity ($n_1 = 1$ and $k_1 = 0$),

$$\epsilon'_{\lambda,n} = 36.5 \left(\frac{r_e}{\lambda} \right)^{1/2} - 464 \frac{r_e}{\lambda} \quad (7.45)$$

where r_e is the electrical resistivity of the metal in ohm-cm and λ is in μm

—Normal total emissivity ($n_1 = 1$ and $k_1 = 0$)

$$\epsilon' = 0.578(r_e T)^{1/2} - 0.178r_e T + 0.0584(r_e T)^{3/2} \quad (7.46)$$

—Hemispherical total emissivity ($n_1 = 1$ and $k_1 = 0$)

$$\epsilon = 0.766(r_e T)^{1/2} - [0.309 - 0.0889 \ln(r_e T)]r_e T - 0.0175(r_e T)^{3/2} \quad (7.47)$$

The relations of Eqs. 7.40–7.47 as well as Kirchhoff's law (with the restrictions of Table 7.1) may be used to find other properties from the electromagnetic theory relations.

The relations given for both dielectrics and metals are for unpolarized incident radiation; if polarization is important, then more detailed analysis must be used (see Refs. 1, 3, 18, 19). Also, the refractive index and absorption index may show spectral dependence, in which case the computed radiative properties will also be spectral in nature.

Property Approximations. Because of the lack of accurate radiative properties in many situations, it is common practice to invoke certain approximations for the property behavior. The most common assumptions are that the surface properties are independent of wavelength (a gray surface), independent of direction (a diffuse surface), that the surface behaves as an ideal mirror (a specular surface), or that the surface is black. The assumption of a gray-diffuse surface is the most commonly invoked. For a surface that is truly both gray and diffuse, Kirchhoff's law applies for all of the property sets; that is, $\alpha = \epsilon$, and the computation of radia-

tive exchange among surfaces and in enclosures is considerably simplified. However, for surfaces with directional or spectral property variations, these assumptions can introduce considerable error into the energy exchange calculations, particularly when radiation is the dominant heat transfer mode.

RADIATIVE EXCHANGE: ENCLOSURES CONTAINING A NONPARTICIPATING MEDIUM

In this section, we deal with energy exchange among surfaces and in enclosures when no medium is present between the surfaces that affects the transfer; that is, no scattering, absorption, or emission occurs within the medium. Such effects are covered in the next major section of this chapter.

Black Surfaces

The radiative exchange between two black surfaces depends only on the absolute temperatures of the surfaces and their shapes and relative positions. If the fraction of blackbody energy leaving area element dA_j and incident on area element dA_k is defined as dF_{dj-dk} , then the energy emitted in wavelength interval $d\lambda$ around λ by black element j and incident on element k is $d^3q_{\lambda,dj-dk}$ and given by (see Fig. 7.7)

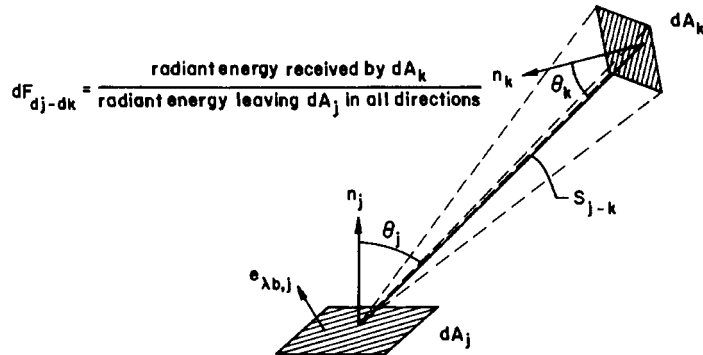

FIGURE 7.7 Nomenclature and schematic for radiative exchange between two surfaces.

$$d^3q_{\lambda,dj \rightarrow dk} = e_{\lambda b,j} dA_j dF_{dj-dk} d\lambda \quad (7.48)$$

where, again, the superscript 3 means that the flux is a function of three independent parameters, wavelength, direction, and spatial coordinate. The dF_{dj-dk} is called the configuration factor, shape factor, view factor, or angle factor. It is independent of wavelength because for black surfaces, the directional distribution of emission from a surface does not depend on wavelength but is diffuse at every wavelength.

Equation 7.48 gives the energy leaving surface j that is incident upon (and therefore absorbed by) black surface k . The energy leaving k and absorbed by j is given by a similar equation:

$$d^3q_{\lambda,dk \rightarrow dj} = e_{\lambda b,k} dA_k dF_{dk-dj} d\lambda \quad (7.49)$$

The net exchange between the two surface elements $d^3q_{\lambda,dj-dk}$ (instead of $d^3q_{\lambda,dj \rightarrow dk}$) is then

$$d^3q_{\lambda,dj-dk} = d^3q_{\lambda,dj \rightarrow dk} - d^3q_{\lambda,dk \rightarrow dj} = e_{\lambda,b,j} dA_j dF_{dj-dk} d\lambda - e_{\lambda,b,k} dA_k dF_{dk-dj} d\lambda \quad (7.50)$$

If surfaces j and k are at the same temperature, then the net energy exchange must be zero, and it follows from Eq. 7.50 that

$$dA_k dF_{dk-dj} = dA_j dF_{dj-dk} \quad (7.51)$$

Substituting this reciprocity relation into Eq. 7.50 results in

$$d^3q_{\lambda,dj-dk} = (e_{\lambda,b,j} - e_{\lambda,b,k}) dA_j dF_{dj-dk} d\lambda \quad (7.52)$$

Integrating over all wavelengths gives

$$dq_{dj-dk} = (e_{b,j} - e_{b,k}) dA_j dF_{dj-dk} = \sigma(T_j^4 - T_k^4) dA_j dF_{dj-dk} \quad (7.53)$$

If surface k is finite in extent and dA_k is an element of that surface, then Eq. 7.53 can be integrated over the entire area of surface k to find the net energy exchange of surface element j with surface k :

$$dq_{dj-k} = \sigma \int_{A_k} [T_j^4 - T_k^4] dF_{dj-dk} dA_j \quad (7.54)$$

Isothermal Surfaces. If surface k is isothermal, Eq. 7.54 can be easily integrated to obtain

$$dq_{dj-k} = \sigma[T_j^4 - T_k^4] F_{dj-k} dA_j \quad (7.55)$$

where

$$F_{dj-k} = \int_{A_k} dF_{dj-dk} \quad (7.56)$$

If surface j is also isothermal, then Eq. 7.55 can be integrated to give

$$dq_{j-k} = \sigma[T_j^4 - T_k^4] \int_{A_j} dF_{dj-k} dA_j = \sigma[T_j^4 - T_k^4] F_{j-k} A_j \quad (7.57)$$

where

$$F_{j-k} = \frac{1}{A_j} \int_{A_j} F_{dj-k} dA_j \quad (7.58)$$

By writing the net radiative energy flux on surface k (rather than j), it is easily found that

$$\begin{aligned} A_j dF_{j-dk} &= dA_k F_{dk-j} \\ A_k dF_{k-dj} &= dA_j F_{dj-k} \\ A_k F_{k-j} &= A_j F_{j-k} \end{aligned} \quad (7.59)$$

These *reciprocity* relations will be used in later sections.

If there are N surfaces forming an enclosure, then the net radiative energy flux on surface j is given by summing the contributions from all surfaces forming the interior of the enclosure:

$$dq_j = \sigma \sum_{k=1}^N (T_j^4 - T_k^4) dF_{dj-k} dA_j \quad (7.60)$$

A total of N temperatures and radiative energy fluxes must be known to solve for the others. If the temperatures of all of the N surfaces are available, then the radiative fluxes at all surfaces are easily computed from Eq. 7.60. If radiative energy fluxes are given at M of the N surfaces, and temperatures are given at the others, then the set of M linear equations must be

solved for the unknown temperatures. The methods given in the section “Exchange among Gray Diffuse Surfaces” can be used.

Nonisothermal Surfaces. If the temperature of a surface varies, determination of the radiative energy flux or temperature profile on all surfaces of an enclosure requires the solution of integral equations (see Eq. 7.54). For the general case of all surfaces having varying temperatures, the relation for an element on surface j becomes

$$dq(r_j)_{dj-k} = \sigma \int_{A_k} [T_j^4(r_j) - T_k^4(r_k)] dF_{dj-dk} dA_j \tag{7.61}$$

and, summing over all surfaces in the enclosure,

$$dq(r_j)_{dj} = \sigma \sum_{k=1}^N \int_{A_k} [T_j^4(r_j) - T_k^4(r_k)] dF_{dj-dk} dA_j \tag{7.62}$$

Configuration Factors. To solve for the radiative transfer among surfaces using the previous black-surface equations, expressions for the configuration factors must be available. Many factors for common geometries have been derived and presented in the literature. Compilations are given in Siegel and Howell [1] (42 factors and references to 234 factors available in the literature); Brewster [2] (13 factors); Modest [3] (51 factors); and Howell [20] (over 278 factors with an annotated bibliography). Some useful factors are illustrated in App. B.

Configuration Factor Algebra. When the configuration factor F_{A-B} between two surfaces is known, the reciprocity relation (Eq. 7.59) can be used to find F_{B-A} . Other relations can also be developed that allow simple calculations of new factors from known factors.

If surface B can be subdivided into N nonoverlapping surfaces that completely cover surface B , then

$$F_{A-B} = F_{A-1} + F_{A-2} + F_{A-3} + \dots + F_{A-N} = \sum_{n=1}^N F_{A-n} \tag{7.63}$$

because all energy fractions from surface A to parts of surface B must equal the fraction of the total energy leaving A that is incident on all of B .

Suppose that surface 1 is completely enclosed by a set of M surfaces. In that case, all energy leaving surface A must strike some other surface forming the enclosure. In terms of configuration factors:

$$F_{1-1} + F_{1-2} + F_{1-3} + \dots + F_{1-M} = \sum_{m=1}^M F_{1-m} = 1 \tag{7.64}$$

FIGURE 7.8 Perpendicular right isosceles triangles joined along their short sides.

Note the term F_{1-1} must be included in the summation if surface A is concave to account for the fraction of energy leaving surface A which is incident on itself.

The reciprocity relations plus Eqs. 7.63 and 7.64 form the basis of what is called *configuration factor algebra*. Using these relations, new factors can be computed from a set of known factors; sometimes, factors can be generated from the algebra alone. The procedure is best illustrated by example.

Consider two right isosceles triangles that are joined along a short side, as shown in Fig. 7.8. The triangles are perpendicular to one another. To find F_{1-2} , note that an enclosure can be formed by first joining the free corners of the triangles by a line of length l as shown in Fig. 7.9. This forms a corner cavity with the third congruent triangle. The enclosure is completed by placing an equilateral triangle of side l

FIGURE 7.9 Construction of corner cavity by addition of line connecting free corners of triangle.

FIGURE 7.10 Completion of enclosure by addition of equilateral triangle, surface 4.

(and area A_4) over the cavity formed by the three isosceles triangles, which have equal areas A_1 , A_2 , and A_3 . This is shown in Fig. 7.10.

Now, apply configuration factor algebra. Eq. 7.64 gives

$$F_{1-1} + F_{1-2} + F_{1-3} + F_{1-4} = 1 \quad (7.65)$$

Because surface 1 is planar, $F_{1-1} = 0$. By symmetry, $F_{1-2} = F_{1-3}$. Thus, Eq. 7.65 reduces to

$$2F_{1-2} + F_{1-4} = 1 \quad (7.66)$$

For surface 4 of the enclosure, Eq. 7.64 plus the use of symmetry gives

$$F_{4-1} + F_{4-2} + F_{4-3} + F_{4-4} = 3F_{4-1} = 1 \quad (7.67)$$

Using reciprocity, Eq. 7.59 results in

$$F_{1-4} = \frac{A_4}{A_1} F_{4-1} = \frac{A_4}{3A_1} \quad (7.68)$$

Substituting into Eq. 7.66 results in

$$F_{1-2} = \frac{1 - F_{1-4}}{2} = \frac{1 - (A_4/3A_1)}{2} \quad (7.69)$$

Using geometry, $A_1 = h^2/2$ and $A_4 = \sqrt{3}l^2/4 = \sqrt{3}h^2/2$, giving

$$F_{1-2} = \frac{1 - (1/\sqrt{3})}{2} \approx 0.21132 \quad (7.70)$$

This is the desired answer. The other configuration factors can be determined in a similar manner.

Siegel and Howell [1] note on p. 220 that, for an N -surfaced enclosure of all planar or convex surfaces (i.e., $F_{i-i} = 0$ for all i), $N(N-3)/2$ factors must be found from a catalog of factors or by calculation. The remaining factors can then be determined by configuration factor algebra. If M of the surfaces ($M < N$) are concave (i.e., have $F_{i-i} \geq 0$), then $[N(N-3)/2] + M$ factors must be known before configuration factor algebra can determine the remaining factors. The presence of symmetry may further reduce the number of factors that must be known before the rest can be determined.

When the values of certain factors are known only approximately, then the constraints imposed on the factors by reciprocity and conservation in an enclosure can be used to refine the known values. Methods for this purpose have been proposed in Refs. 21–24.

Exchange Among Gray Diffuse Surfaces

When an enclosure can be assumed to be made up of a set of black or gray diffuse surfaces, well-developed techniques are available for determining the exchange among the surfaces.

In general, one boundary condition (either surface temperature or heat flux) must be specified for every surface of the enclosure. It is possible by more advanced techniques to obtain solutions for the case when some surfaces have both conditions prescribed and others have neither condition specified. This situation causes the solution methods described here to fail, as the equation set is then ill-conditioned. So-called *inverse solution methods* must be invoked. Methods of handling such a problem are given for black-surfaced enclosures in Ref. 25 and for enclosures with black or gray diffuse surfaces in Refs. 26, 27, and 28.

Use of Configuration Factors. For diffuse nonblack surfaces, the radiation leaving the surface is made up of both diffusely emitted and diffusely reflected energy. Thus, the directional distribution of all radiation is diffuse. It follows that we can continue to use the concept of configuration factors to determine the fraction of the leaving radiation that strikes another surface. Thus, all of the information generated about configuration factors for black surfaces also applies to the more general case of diffusely reflecting and emitting surfaces. If the surfaces are diffuse and have wavelength-dependent properties, the methods to be outlined here will apply for energy exchange at each wavelength; a final summation or integration over all wavelengths will then be necessary to compute total radiant exchange.

The outgoing radiation energy flux from a given location on surface k , $q_{o,k}$ is made up of the emitted and reflected flux from that surface, or

$$q_{o,k} = \epsilon_k \sigma T_k^4 + \rho_k q_{i,k} \quad (7.71)$$

where all quantities are evaluated at a particular location on surface k . The quantity $q_{i,k}$ is the radiation flux incident at the given location from all other surfaces in the enclosure, including surface k itself, if it is concave. The quantity $q_{o,k}$ is often called the *radiosity* of the surface, and $q_{i,k}$, the *irradiance*. Note that, contrary to the practice in most of heat transfer, these energy fluxes carry a *directionality*—the radiosity is the portion of the radiant energy flux with the component *away* from the surface, while the irradiance is the portion directed *toward* the surface.

The *net* radiative heat flux *leaving* surface k (q_k) is the difference between the radiosity and the irradiance, or

$$q_k = q_{o,k} - q_{i,k} \quad (7.72)$$

This flux corresponds to the usual concept used in heat transfer, as the net energy flux is taken as positive if in the direction parallel to the surface normal of the position on k .

The final equation for energy transfer quantifies the irradiance as the sum of the radiant energies reaching a location on surface k from all other areas on the enclosure surface. This relation can have various forms depending on the degree of approximation used in the analysis.

Circuit Analogy. Simple problems in radiant transfer can be diagrammed and formulated in analogy with a simple electrical circuit [29]. This is done by observing that Eq. 7.57 for black surfaces is in the form of Ohm's Law if dq_{j-k} is analogous to the current and $(T_j^4 - T_k^4)$ is analogous to the driving potential difference. In this case, the corresponding resistance is $1/(\sigma F_{j-k} A_j)$. The analogy can also be extended to gray diffuse surfaces. In making this analogy, all of the usual assumptions are still present: all surfaces are gray and diffuse, and the

radiosity leaving each surface is uniform over the surface (implying that the temperature, heat flux, and incident radiation are uniform over each surface). The circuit analogy is not a useful approach when more than about four surfaces are treated, and it will not be elaborated here. For more details, see Refs. 1 and 3.

Net Radiation Method. A more powerful method for describing radiative transfer is the net radiation method. In this method, radiative energy balances are constructed for each surface, and the resulting set of equations is then solved. (Some equations as written may fail in the limit of black surfaces and must be slightly modified starting from the original relations.)

Uniform Surface Radiosity. Here, first, we limit consideration to gray diffuse surfaces with uniform radiosity. In that case, Eqs. 7.71 and 7.72 apply. Because of the assumption of gray diffuse surfaces, Eq. 7.71 can be rewritten as

$$q_{\alpha k} = \epsilon_k \sigma T_k^4 + (1 - \epsilon_k) q_{i,k} \quad (7.73)$$

An additional equation for the radiative energy incident on surface k is

$$q_{i,k} A_k = \sum_{j=1}^N q_{\alpha,j} A_j F_{j-k} = A_k \sum q_{\alpha,j} F_{k-j} \quad (7.74)$$

The three equations, 7.72–7.74, can be written for each of the N surfaces in the enclosure. If either T_k or q_k is prescribed for each surface, this results in $3N$ equations in $3N$ unknowns: the unknowns being $q_{i,k}$, $q_{\alpha,k}$, and either q_k or T_k values for each surface.

For m of the N surfaces in the enclosure having specified temperatures and the remaining $N - m$ surfaces having specified heat flux, $q_{i,k}$ can be eliminated to give the useful forms

$$\sum_{j=1}^N [\delta_{kj} - (1 - \epsilon_k) F_{k-j}] q_{\alpha,j} = \epsilon_k \sigma T_k^4 \quad 1 \leq k \leq m \quad (7.75)$$

and

$$\sum_{j=1}^N (\delta_{kj} - F_{k-j}) q_{\alpha,j} = q_k \quad m + 1 \leq k \leq N \quad (7.76)$$

where δ_{kj} is the Kronecker delta function, defined such that if $k = j$, $\delta_{kj} = 1$ and if $k \neq j$, $\delta_{kj} = 0$. This results in a set of N equations in N unknowns that can be solved directly for the $q_{\alpha,k}$ of each surface. Once $q_{\alpha,k}$ is known for each surface, the unknown q_k or T_k for each surface is found from the relation

$$q_k = \frac{\epsilon_k}{1 - \epsilon_k} (\sigma T_k^4 - q_{\alpha,k}) \quad (7.77)$$

This approach is useful when values of the radiosity $q_{\alpha,k}$ are needed, for example, to predict or interpret the readings observed by radiometric devices such as pyrometers.

If values of the radiosity are not needed, an alternative method is to eliminate both $q_{\alpha,k}$ and $q_{i,k}$ from Eqs. 7.75, 7.76, and 7.77. The result can be put in the form

$$\sum_{j=1}^N \left(\frac{\delta_{kj}}{\epsilon_j} - F_{k-j} \frac{1 - \epsilon_j}{\epsilon_j} \right) q_j = \sum_{j=1}^N (\delta_{kj} - F_{k-j}) \sigma T_j^4 \quad (7.78)$$

Surfaces with Nonuniform Radiosity. If the radiosity across a given surface does not meet the assumption of uniformity, then the surface may be subdivided into subsurfaces, each of which approximates the condition of uniformity. In the limit, this reduces to relations in the form of integral equations. In this case, the net radiation method can be extended. Note that Eqs. 7.72 and 7.73 still apply to every position on surface k , but Eq. 7.74 must be modified to remove the assumption of uniform radiosity. The third equation for the net radiation method is the relation for incident radiation onto a particular location on surface k from all other surfaces, each of which can have a variable radiosity. The resulting relations are

$$q_{\alpha k}(\bar{r}_k) = \epsilon_k(\bar{r}_k)\sigma T_k^4(\bar{r}_k) + [1 - \epsilon_k(\bar{r}_k)]q_{i,k}(\bar{r}_k) \quad (7.79)$$

$$q_k(\bar{r}_k) = q_{\alpha k}(\bar{r}_k) - q_{i,k}(\bar{r}_k) \quad (7.80)$$

$$q_{i,k}(\bar{r}_k) = \sum_{j=1}^N \int_{A_j} q_{\alpha j}(\bar{r}_j) dF_{dk-dj}(\bar{r}_k, \bar{r}_j) \quad (7.81)$$

These can be combined to eliminate $q_{i,k}$ as for the uniform radiosity case to provide equations for the radiosity of the surfaces 1 to m (with known temperature distributions) and surfaces $m+1$ to N (with known heat flux distributions) as

$$q_{\alpha k}(\bar{r}_k) - [1 - \epsilon_k(\bar{r}_k)] \sum_{j=1}^N \int_{A_j} q_{\alpha j}(\bar{r}_j) dF_{dk-dj}(\bar{r}_k, \bar{r}_j) = \epsilon_k(\bar{r}_k)\sigma T_k^4(\bar{r}_k) \quad 1 \leq k \leq m \quad (7.82)$$

$$q_{\alpha k}(\bar{r}_k) - \sum_{j=1}^N \int_{A_j} q_{\alpha j}(\bar{r}_j) dF_{dk-dj}(\bar{r}_k, \bar{r}_j) = q_k(\bar{r}_k) \quad m+1 \leq k \leq N \quad (7.83)$$

The relation between radiosity and the unknown local net radiative flux or temperature is found from Eqs. 7.84 and 7.85:

$$q_k(\bar{r}_k) = \frac{\epsilon_k(\bar{r}_k)}{1 - \epsilon_k(\bar{r}_k)} [\sigma T_k^4(\bar{r}_k) - q_{\alpha k}(\bar{r}_k)] \quad 1 \leq k \leq m \quad (7.84)$$

$$\sigma T_k^4(\bar{r}_k) = \frac{1 - \epsilon_k(\bar{r}_k)}{\epsilon_k(\bar{r}_k)} q_k(\bar{r}_k) + q_{\alpha k}(\bar{r}_k) \quad m+1 \leq k \leq N \quad (7.85)$$

An alternative form is found by eliminating both $q_{i,k}$ and $q_{\alpha k}$ from Eqs. 7.79 through 7.81 to obtain

$$\frac{q_k(\bar{r}_k)}{\epsilon_k} - \sum_{j=1}^N \frac{1 - \epsilon_j(\bar{r}_j)}{\epsilon_j(\bar{r}_j)} \int_{A_j} q_j(\bar{r}_j) dF_{dk-dj}(\bar{r}_k, \bar{r}_j) = \sigma T_k^4(\bar{r}_k) - \sum_{j=1}^N \int_{A_j} \sigma T_j^4(\bar{r}_j) dF_{dk-dj}(\bar{r}_k, \bar{r}_j) \quad (7.86)$$

Solution Techniques

Surfaces with Uniform Radiosity. For the case of gray diffuse surfaces with uniform radiosities, the solution of either Eq. 7.82 or 7.83 for $q_{\alpha k}$ or Eq. 7.86 for the unknown temperatures and heat fluxes requires the solution of a set of simultaneous equations. These are of the form

$$[a_{kj}][x_j] = [C_k] \quad (7.87)$$

For determining $x_j = q_{\alpha j}$ using Eqs. 7.82 and 7.83, the matrix coefficients are given by

$$\begin{aligned} a_{kj} &= \delta_{kj} - (1 - \epsilon_k)F_{k-j} & 1 \leq k \leq m \\ a_{kj} &= \delta_{kj} - F_{k-j} & m+1 \leq k \leq N \end{aligned} \quad (7.88)$$

and the right-hand-side vector elements are given by

$$\begin{aligned} C_k &= \epsilon_k \sigma T_k^4 & 1 \leq k \leq m \\ C_k &= q_k & m+1 \leq k \leq N \end{aligned} \quad (7.89)$$

For finding the unknown q_k or T_k using Eq. 7.86, the values of the unknowns can be rearranged so that the unknown m values of q_k are given by $x_j = q_j$ for $1 \leq k \leq m$ and $x_j = T_j$ for $m+1 \leq k \leq N$. The matrix coefficients in this case are given for row k by

$$\begin{aligned} a_{kj} &= \frac{\delta_{jk}}{\epsilon_j} - F_{k-j} \frac{1 - \epsilon_j}{\epsilon_j} & 1 \leq k \leq m \\ a_{kj} &= \sigma(\delta_{jk} - F_{k-j}) & m+1 \leq k \leq N \end{aligned} \quad (7.90)$$

and the elements for the $[C_k]$ vector are given for all k by

$$C_k = \sum_{j=1}^m (\delta_{kj} - F_{k-j}) \sigma T_j^4 \quad 1 \leq j \leq m \quad (7.91)$$

$$C_k = \sum_{j=m+1}^N \left(\frac{\delta_{kj}}{\epsilon_j} - F_{k-j} \frac{1 - \epsilon_j}{\epsilon_j} \right) q_j \quad m+1 \leq j \leq N \quad (7.92)$$

Equation 7.87 for either solution method is now solved using standard matrix inversion routines to find the inverse of the matrix $[a_{kj}]$, denoted by $[a_{kj}]^{-1}$, and then using standard matrix multiplication routines to solve for the unknown elements of the $[x_j]$ vector by

$$[x_j] = [a_{kj}]^{-1} [a_{kj}] [x_j] = [a_{kj}]^{-1} [C_k] \quad (7.93)$$

Solutions for nonuniform radiosity relations: analytical solution of radiative transfer is possible for only the simplest cases. In general, a numerical solution is necessary.

RADIATIVE EXCHANGE WITH A PARTICIPATING MEDIUM

Fundamentals and Definitions

Absorption, Extinction, and Scattering Coefficients. If a beam of radiation of intensity $I_\lambda(\vec{r}, \hat{\Omega})$ propagates within a participating media along the direction $\hat{\Omega}$, it will lose its energy due to absorption and scattering. In mathematical terms, the changes in radiation intensity due to the absorption and scattering of the radiation beam within a small length element ds along the direction $\hat{\Omega}$ are proportional to the local intensity, and are expressed as

$$\text{absorption: } -\kappa_\lambda I_\lambda(\hat{\Omega}) ds \quad (7.94)$$

and

$$\text{scattering: } -\sigma_\lambda I_\lambda(\hat{\Omega}) ds \quad (7.95)$$

Here, κ_λ and σ_λ are the spectral absorption and scattering coefficients, respectively. The attenuation of radiation intensity by the medium is proportional to both of these coefficients. The spectral attenuation (or extinction) coefficient is expressed by the sum of the absorption and scattering coefficients, as

$$\text{extinction coefficient: } \beta_\lambda = \kappa_\lambda + \sigma_\lambda \quad (7.96)$$

The single scattering albedo is defined as the fraction of energy attenuated due to scattering:

$$\text{single scattering albedo: } \omega_\lambda = \sigma_\lambda / \beta_\lambda \quad (7.97)$$

Scattering Phase Function. Energy absorbed is converted primarily to thermal energy, whereas scattered radiant energy is redistributed in the medium. The directional distribution of scattered energy is expressed by the phase function, $\Phi_\lambda(\hat{\Omega}', \hat{\Omega})$, which represents the fraction of energy incident in direction $\hat{\Omega}'$ and scattered into direction $\hat{\Omega}$. The angle between the directions of the incident beam ($\hat{\Omega}'$) and the scattered beam ($\hat{\Omega}$) is called as the scattering angle Θ . It is related to the azimuthal and zenith angles via the following equation:

$$\cos \Theta = \cos \theta \cos \theta' + \sin \theta \sin \theta' \cos(\phi - \phi') \quad (7.98)$$

Figure 7.11 shows the relation between the incident and scattered intensities schematically.

The phase function is normalized so that the sum of scattered light in all directions adds up to 100 percent:

$$\frac{1}{4\pi} \int_{\Omega=4\pi} \Phi_\lambda(\hat{\Omega}', \hat{\Omega}) d\Omega' = \frac{1}{4\pi} \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} \Phi_\lambda(\theta', \phi'; \theta, \phi) \sin \theta d\theta d\phi = 1 \quad (7.99)$$

FIGURE 7.11 Relation between the incident and scattered intensities and the definition of scattering angle.

Examples of phase functions for spherical particles of different sizes are depicted in Fig. 7.12 as computed using electromagnetic wave theory (so-called Mie scattering). In Fig. 7.12(a), the real part of the index of refraction is 1.8, and the imaginary part is 0.8. The size parameter $x = \pi D/\lambda$, which is the scaling parameter relating the particle diameter D and the radiation wavelength λ , is changing from 0.01 to 10. It is obvious that, with increasing x , the particles become more forward-scattering. In Fig. 7.12(b), the size parameter x is kept constant, and the index of refraction is varied. For this particular size parameter, the effects of n and k on the phase function are not large. For nonhomogeneous spheres, especially if there is a size distribution, the small variation on the complex index of refraction does not affect the phase function significantly. However, for particle characterization studies based on laser/light diagnostic techniques, more accurate information about the spectral complex index of refraction data is needed.

For numerical computations, an explicit form of the phase function is required. A Legendre polynomial expansion of the phase function is the most common form. For an azimuthally symmetric medium (i.e., independent of azimuthal angle ϕ), the phase function is written as:

$$\Phi_{\lambda}(\mu', \mu) = \sum_{i=0}^N a_i P_i(\mu') P_i(\mu) \quad (7.100)$$

where $a_0 = 1$, P_i are the i th order Legendre polynomials, and $\mu = \cos \theta$ and $\mu' = \cos \theta'$ are the direction cosines for the directions of the scattered and the incident beams, respectively.

Isotropic scattering indicates that the radiant energy incident on a volume element is uniformly distributed to all directions. For an isotropically scattering medium, all a_i coefficients of the phase function are zero, except a_0 . If only a_0 and the first coefficient a_1 are considered, then one obtains the linearly anisotropic phase function, which means that the phase function is a linear function of $\cos \Theta$ (or, in the case of an azimuthally symmetric medium, a linear function of $\mu = \cos \theta$).

If the size parameter is small ($x \leq 0.05$), then the phase function can be approximated by the Rayleigh phase function, which reads as

$$\Phi_{\lambda} = \frac{3}{4} (1 + \cos \Theta) \quad (7.101)$$

On the other hand, for particles with diameters much larger than the wavelength of radiation (that is, for large-size parameters), several terms of the series expansion need to be considered to account for the strong forward-scattering peak. This yields a significant increase in computational effort. To avoid this, it is possible to use a δ -Eddington phase function [30, 31, 32], which is given as:

$$\Phi_{\lambda}(\theta', \phi'; \theta, \phi) = 2f\delta(1 - \cos \Theta) + (1 - f)(1 + 3g \cos \Theta) \quad (7.102)$$

where δ represents the Dirac delta function, Θ is the scattering angle, and the f and g parameters are related to the coefficients of the Legendre polynomial expansion of the phase function as

$$g = (a_1 - a_2)/(1 - a_2), \quad f = a_2 \quad (7.103)$$

This approximation divides the directional distribution of scattered energy into two components: one highly peaked component in the forward direction, and an isotropic distribution for all other directions. Improvement of this phase function is possible if the second term on the right-hand side of Eq. 7.102 is comprised of more than a single term. Crosbie and David-

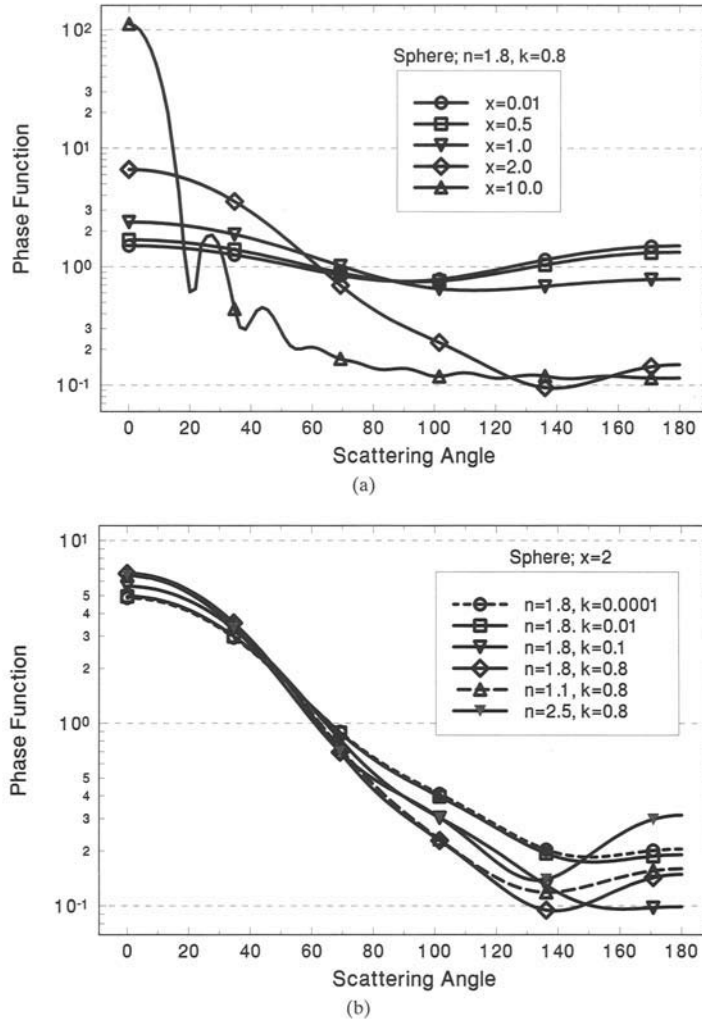

FIGURE 7.12 Scattering phase functions: (a) For different size parameters $x = \pi D/\lambda$; (b) for a fixed size parameter of $x = 2$ and different complex index of refraction values.

son [31] showed that, if a full phase function is expressed as a sum of a Dirac-delta term and series expansion, the number of terms required in the series of the new expression is usually an order of magnitude smaller than that required for the original phase function.

Lambert-Beer Law. The radiation intensity of a beam propagating through an absorbing slab is reduced exponentially, as a function of slab thickness y and slab absorption coefficient κ_λ :

$$I_\lambda(y, \hat{\Omega}) = I_{0,\lambda}(y, \hat{\Omega}) \exp(-\kappa_\lambda y) = I_{0,\lambda}(y, \hat{\Omega}) \exp(-\tau_\lambda) \quad (7.104)$$

where $I_{0,\lambda}(y, \hat{\Omega})$ is the intensity of the incident beam at the slab boundary, and $\tau_\lambda = \kappa_\lambda y$ is the optical thickness. According to the Lambert law, the intensity exiting the slab would be the same if the absorption coefficient is doubled and the slab thickness is reduced by one half.

The Beer law is similar to the Lambert law with the exception that the absorption coefficient is expressed as the product of a unit absorption coefficient and the concentration of particles. In general, this definition is more fundamental and appropriate for application to dispersed media, where the concentration can be directly measured. If there are particles in the medium, depending on their size with respect to the wavelength of the incident radiation, they scatter as well as absorb the incident radiation. With increasing concentration, the multiple scattering effect becomes significant, and the Beer law deviates from the experimental measurements, especially if the size of the particles is comparable to the wavelength of radiation. Under these conditions, the complete radiative transfer equation should be solved. For solid materials, the Beer and Lambert laws are identical.

Radiative Transfer Equation. Although the theoretical basis for radiative transfer is well established for most problems of engineering interest, there are problems that cannot be accurately handled. The radiative transfer equation (RTE) describes the spatial dependence of radiation on absorption, scattering, and emission by a surrounding medium. This equation is the foundation for almost all radiative transfer analysis, and all of the standard techniques assume that the equation is valid. However, some common engineering systems do not conform to the assumptions buried in this equation.

The RTE is a simplified form of the complete Maxwell equations describing the propagation of an electromagnetic wave in an attenuating medium. The simplified RTE does not include the effects of polarization of the radiation or the influence of nearby particles on the radiation scattered or absorbed by other particles (dependent scattering or absorption). For example, if polarization effects are present (as they are when reflections occur at off-normal incidence from polished surfaces or in reflections from embedded interfaces), then the analyst should revert to complete solution of the Maxwell equations, which is a formidable task in complex geometries! Delineating the bounds of applicability of the radiative transfer equation is an area of active research.

The RTE is based on the conservation of radiant energy* along a direction $\hat{\Omega}$ in a small absorbing, emitting, and scattering volume element dV . Intuitively, it is written by following the graphical representation shown in Fig. 7.13 as:

(Change in energy of a pencil of radiation along a direction $\hat{\Omega}$ and pathlength of ds within a volume element dV) = +① (Contribution of emitted radiant energy by dV along $\hat{\Omega}$) – ② (Energy absorbed by dV along $\hat{\Omega}$) + ③ (Contribution of energy emitted/scattered from all volume/surface elements in the medium which is incident on dV and scattered in the direction $\hat{\Omega}$) – ④ (Energy scattered out of the direction $\hat{\Omega}$ by dV)

* Note that *conservation of radiant energy* should not be confused with *conservation of energy*; any *loss* in radiant energy within a control volume via the absorption mechanism is a *gain* for the overall energy balance and vice versa.

FIGURE 7.13 Conservation of radiant energy principle.

where circled numbers correspond to the physical phenomena depicted in the figure. After some manipulation, the radiative energy balance is expressed in terms of intensity as:

$$\frac{1}{c} \frac{\partial I_\lambda}{\partial t} + \vec{\nabla} \cdot \hat{\Omega} I_\lambda + \beta_\lambda I_\lambda = \kappa_\lambda I_{b\lambda}(T) + \frac{\sigma_\lambda}{4\pi} \int_{\Omega' = 4\pi} \Phi_\lambda(\hat{\Omega}', \hat{\Omega}) I_\lambda(\hat{\Omega}') d\Omega' \quad (7.105)$$

where c is the speed of light. For most practical applications, the transient behavior of the radiation intensity is negligibly small and the first term is omitted. The $\vec{\nabla} \cdot \hat{\Omega}$ operator is to denote the incremental change in intensity along the direction $\hat{\Omega}$ and is expressed as a function of the coordinate system chosen for a specific geometry. For one-dimensional media, $\vec{\nabla} \cdot \hat{\Omega} = d/ds$, where s is the coordinate along the propagation direction of the beam. Specific expressions of $\vec{\nabla} \cdot \hat{\Omega}$ for other geometries are available in the literature [33, 34]. Note that the radiation originating from every volume/surface element in the medium directed to the control volume may be rescattered in the direction of interest; the integral term at the right-hand side of Eq. 7.105 is to account for this contribution to the radiation intensity in the direction $\hat{\Omega}$.

If the medium is neither emitting (cold) nor scattering, the RTE, as given by Eq. 7.105, is simplified to:

$$\vec{\nabla} \cdot \hat{\Omega} I_\lambda = -\kappa_\lambda I_\lambda \quad (7.106)$$

Integration of this equation along the line of sight gives the Lambert law, Eq. 7.104.

Boundary Conditions for the RTE. The solution of the radiative transfer equation in a given geometry is subject to boundary conditions, which give the radiation intensity distribution on the boundaries. The boundary intensity is comprised of two components: (1) contribution due to emission at the boundary surfaces and (2) contribution due to diffuse and specular reflection of radiation intensity incident on the boundaries. The radiation incident on the boundary is due to intensity emitted from all volume and surface elements in the medium. In mathematical terms, the general boundary condition on any surface element is written as [1, 6]:

$$I_\lambda^+(y, \hat{\Omega}) = \epsilon_\lambda I_{b\lambda}(T) + \frac{\rho_\lambda^d}{\pi} \int_{\Omega' = 2\pi} I_\lambda^-(y, \hat{\Omega}') \hat{\Omega} \cdot \hat{n} d\Omega' + \rho_\lambda^s I_\lambda^-(y, -\hat{\Omega}) \quad (7.107)$$

where ϵ_λ , ρ_λ^d and ρ_λ^s are the diffuse emissivity and the diffuse and specular reflectivity of the surface, respectively. T is the surface temperature, and $-\hat{\Omega}$ is to denote the direction of specular (mirrorlike) reflection. In most radiative transfer applications, boundaries are assumed to emit and reflect diffusely only.

Conservation of Radiant Energy Equation. The radiative transfer equation represents the change in radiation intensity for a single beam in the direction $\hat{\Omega}$ along an infinitesimal path length ds within a small control volume dV in the medium. As discussed before, the net change in radiation intensity along a given direction is the difference between emission and in-scattering gains and absorption and out-scattering losses. Absorption loss and emission gain directly affect the temperature of volume element dV . The scattered radiant energy, however, has no direct impact on the energy balance of dV , although the scattered photons may be absorbed by the medium later and ultimately influence the energy balance. The control volume temperature is affected by the absorption/emission of radiation incident on dV from all possible directions. The net contribution of radiative transfer to the energy balance of dV can be determined by integrating the RTE over the entire solid angle range of $\Omega = 4\pi$, for all possible wavelengths, which yields

$$\vec{\nabla} \cdot \vec{q} = \int_0^\infty \kappa_\lambda [4\pi I_{b\lambda}(T) - G_\lambda] d\lambda \quad (7.108)$$

where the incident radiation G_λ is defined as

$$G_\lambda = \int_{\Omega = 4\pi} I_\lambda d\Omega \quad (7.109)$$

Equation 7.108 describes the conservation of radiative transfer in a unit volume (includes the radiative energy incident from *all* directions), and $\vec{\nabla} \cdot \vec{q}$ is the radiative flux divergence. The scattering coefficient does not appear in Eq. 7.108, because scattering does not directly contribute to the local energy balance in the medium. However, scattering of thermal radiation has an indirect effect via the G_λ term. Also note that the sign of $\vec{\nabla} \cdot \vec{q}$ is a function of the difference between total emission $\int_0^\infty 4\pi\kappa_\lambda I_{\lambda b} d\lambda$ and total absorption of incident radiation $\int_0^\infty \kappa_\lambda G_\lambda d\lambda$. The difference in the spectral emission and absorption, however, may be positive in certain bands of the wavelength spectrum and negative in others, and the distribution of spectral absorption coefficient and radiation intensity in the medium must be known to calculate $\vec{\nabla} \cdot \vec{q}$ accurately.

If $\vec{\nabla} \cdot \vec{q}$ is positive, then the control volume dV is emitting more energy than it is absorbing; therefore it is radiatively cooling. If $\vec{\nabla} \cdot \vec{q}$ is negative, then the medium is heated due to the absorption of radiation incident on it. In other words, the $\vec{\nabla} \cdot \vec{q}$ term determines the effect of radiation on the total energy balance of dV , and the negative of it appears as a radiation source term in the conservation of total energy equation. The intimate coupling between the radiative transfer equation and the total energy equation is obvious.

Solution Techniques for the RTE

The radiative transfer equation (RTE) is an integro-differential equation; it is difficult to develop a closed-form solution to it in general multidimensional and nonhomogeneous media. After introducing a number of approximations, however, reasonably accurate models of the RTE can be obtained. In all models, the objective is to solve the RTE, or a modified form of it, in terms of radiation intensity or its moments (such as flux) and then calculate the distribution of the divergence of radiative flux $\vec{\nabla} \cdot \vec{q}$ everywhere in the medium. In this section, we will discuss the approximate models of the RTE which can be extended to multidimensional geometries.

The dependent variable in the RTE is the radiation intensity, which is, as stated earlier, a function of seven independent variables: three spatial coordinates (x , y , and z , in Cartesian coordinates, or r , z , and θ_r , in cylindrical coordinates), two angular coordinates (θ , ϕ), wavelength (λ) or frequency (ν) of radiation, and time (t). Although the intensity is also a function of local temperature, local absorption and scattering coefficients, and scattering phase function, they are not written explicitly, but implied through the \vec{r} -dependence. For most practical problems, a transient analysis of radiative transfer is not required. (Transient dependence enters through the coupling with the energy equation.) The wavelength dependency of radiation intensity, on the other hand, is extremely important and needs special consideration. Given the fact that the spectral variation of intensity arises primarily due to wavelength-dependent radiative properties, we can delay the discussion of this effect until the next section. It is sufficient to say that, if a radiative transfer model is developed for monochromatic (single-wavelength) radiation, then the same model can be used in sequence at all wavelengths of significance, and then the total effect is determined.

In most radiative transfer models, the objective is to reduce the number of geometric independent parameters to a minimum. The simplest model can be obtained if the spatial and angular dependency of radiation intensity can be neglected. In this case, it is assumed that the gas inside an enclosure (for example, a combustion system) has uniform distribution and constant temperature. Then the radiative heat transfer from a source (e.g., flame) to sink (e.g., refractories and combustion gases) can be calculated from a single expression called the total radiation exchange area [35]. Although this expression is a complicated function of geometry

and gas and surface radiative properties, it needs to be calculated only once. This approach is known as a stirred-vessel model, and its usefulness lies in its simplicity and capability of estimating global furnace performance [35]. However, the spatial distribution of radiative flux cannot be predicted using this approach, and, because of this, it should be used with caution.

More accurate radiative transfer models can be obtained by separating the angular variation of radiation intensity from its spatial variation. Next, the angular distribution is simplified further by considering only a finite number of directions found either deterministically or statistically, and, in each of these angular subdivisions, the intensity is assumed to be invariant with angle. In theory, if the number of subdivisions increases, the accuracy of the model also increases; however, both the numerical difficulty and computational cost of the solution escalate. Brief discussions of several different radiative transfer models developed over the years using this type of independent variable separation technique are given in the following subsections.

Zonal Method. The zonal method is one of the most widely employed models for calculating the radiative transfer in combustion chambers [35]. The basic idea behind this approach is similar to that of radiation exchange between finite size surfaces of an enclosure containing a nonparticipating medium (see the previous section). In its most simple version, the walls of an enclosure are divided into many uniform-property, uniform-temperature surface elements. This division determines the spatial distribution of the radiation field (intensity). The net radiation exchange between these elements is determined using a radiosity-irradiation approach along with appropriate radiation configuration factors where radiosities at all surface elements are determined simultaneously. The radiation configuration factor between arbitrary surfaces i and j is determined by considering the fraction of radiative energy leaving surface i that arrives at surface j and is a purely geometric parameter (see Fig. 7.7) [1]. Each surface element sees others within a hemispherical solid angle. The relative orientation of all i surfaces with respect to the j surface divides the hemispherical solid angle to many small discrete solid angles. This discretization implicitly represents the angular subdivision of the radiation field for the j surface within the medium.

For an absorbing, but nonemitting (cold) medium, the amount of radiation energy emanating from surface i and reaching surface j is reduced because of the attenuation of the beam by the medium along the line of sight joining the two surfaces. This energy loss can be accounted for in the model easily. Here, the entire volume is divided into many elements, each presumed to have uniform and constant properties. Then, the interaction of each volume and surface element is written explicitly and cast into a matrix form, and the required radiosities are determined computationally.

For an emitting medium, however, a more fundamental modification of the method is needed. In this case, the emission contribution of each small-volume element to the radiative flux distribution on every surface and volume element is to be determined.

For nonparticipating media, either Poljak's (see Chap. 8 of Ref. 1) or Gebhart's (see App. D of Ref. 1) formulation can be followed to develop the required equations to determine the radiative flux distribution on the walls. If the medium is absorbing and emitting, then Hottel's zonal method can be followed (Chap. 11 of Ref. 35). Originally, the zonal method was developed for nonscattering media. Later, Noble [36] extended the methodology to include scattering by the medium. Smith and his coworkers presented a numerical study in which they showed the feasibility of including isotropic scattering by the volume elements [37]. Byun and Smith extended this formulation to include anisotropically scattering media, although their formulation was only for a one-dimensional geometry [38].

An alternative zonal method, which includes the isotropic scattering effects, was given by Larsen and Howell [22, 39]. Another variation of the zonal method was proposed by Naraghi and Chung [40], who developed an explicit matrix formulation. Later Naraghi et al. [41] presented a continuous exchange method for the solution of the RTE. The exchange factor definitions given in these works are different from Hottel's or Larsen's formulations. A modified form of this method was also suggested by Naraghi et al. [42, 43]. They called it the *discrete*

exchange method, where the integral equations of the continuous exchange method are discretized using a numerical integration scheme. The method yields accurate results in both two- and three-dimensional enclosures, especially if a Gaussian quadrature integration is performed.

Differential and Moment Methods. The radiative transfer equation can be approximated using the moments of radiation intensity instead of intensity itself. A moment is defined as the integral of intensity multiplied by a power of a direction cosine over a predetermined solid angle division. For example,

$$I_n(\vec{r}) = \int_{4\pi} I(\vec{r}, \hat{\Omega}) \mu^n d\Omega \quad (7.110)$$

is the n th moment of intensity in the z -direction, and $\mu = \cos \theta$ is the corresponding direction cosine. The first moment of intensity ($n = 1$) is the radiative flux in x , y , and z directions for Cartesian direction cosines, which are defined, respectively, as:

$$\xi = \sin \theta \cos \phi \quad \eta = \sin \theta \sin \phi \quad \mu = \cos \theta \quad (7.111)$$

Here, θ and ϕ are the spherical polar components, used to define the angular dependency of direction of propagation of radiation intensity.

A classical moment formulation of radiative transfer is obtained by multiplying the entire RTE by a single direction cosine or a multiplicative combination of different direction cosines, and then by integrating over a solid angle range. This procedure eliminates the integral in the RTE (the last term on the right-hand side of Eq. 7.105), and yields a series of equations in terms of different orders of moments. Using a closure condition, which is an approximation between the highest moment used and the lower-order ones, the number of unknowns is equated to that of available equations. As one may guess, if the order of the highest moment being considered is large, then this approximation for the closure condition yields a smaller error, and the predictions of the approximate radiation model approaches those obtained from exact models.

In order to take advantage of moment methods, the radiation intensity is expressed as a series of products of angular and spatial functions. If the angular dependence is expressed using a simple power series, the *moment method (MM)* is obtained; if spherical harmonics are employed to express the intensity, then the method is called the *spherical harmonics (SH) approximation*. In principle, the first-order moment and the first-order spherical harmonics approximations are identical to each other, as well as to the lowest order *discrete ordinates (DO) approximation* [34].

The spherical harmonics approximation to the RTE in multidimensional geometries has been formulated and solved by several different researchers. Liou and Ou [44] gave the formulation for the first-order P_1 approximation for modeling cuboidal clouds; Bayazitoglu and Higenyi [45] presented analyses for both P_1 and P_3 approximations for a nonscattering medium in Cartesian, cylindrical, and spherical geometries; Higenyi and Bayazitoglu [46] and Ahluwalia and Im [47] included isotropic scattering in the formulation for a cylindrical medium; Ratzel and Howell [48] developed the solution for the P_1 and P_3 approximations in two-dimensional rectangular enclosures, and they accounted for isotropic scattering. Mengüç and Viskanta [49, 50] developed the general equations for the solution of both P_1 and P_3 approximations in absorbing, emitting, and anisotropically scattering cylindrical and three-dimensional rectangular enclosures.

The first-order spherical harmonics (P_1) approximation is one of the most simple RTE models, as it can be cast into a single second-order differential equation. In general, it does not yield very accurate results, and the error in radiative flux predictions can be as large as 50 percent for low optical thicknesses. It can, however, be modeled with little effort, and, therefore, its use is strongly recommended if the alternative is not to account for the radiation effects in a comprehensive heat transfer model or to use a simple zero-dimensional stirred-vessel method.

The P_3 -approximation is more difficult to solve in multidimensional geometries. It yields improved predictions over those obtained from the P_1 -approximation, and its accuracy is comparable to the similar-order discrete ordinates approximation (S_4), which is computationally more efficient. For one-dimensional systems, it is possible to develop higher-order P_N approximations [51, 52]; however, for multidimensional geometries, even the P_5 -approximation is extremely complicated.

Instead of using higher-order spherical harmonics approximations, reasonably accurate RTE models can be developed by modifying the relatively simple P_1 approximation. Modest [53] presented such a modified differential approximation based on the formulation given by Olfe [54]. He divided the intensity into two components to separate the medium contribution from the wall contribution and then assumed that the medium contribution can be accounted for, roughly, using the P_1 approximation. The results show significant improvement over the classical P_1 approximation and have a possible use for more complicated geometries. However, if the phase function is highly forward- or backward-scattering, or if there are large temperature gradients in the medium, this method may not yield accurate solutions.

Another improvement of the P_1 approximation is obtained by defining moments not in the entire solid angle range but within predetermined solid angle divisions [55, 56]. In this approach, the number of resulting moment equations is proportional to the number of solid angle divisions used. For planar systems, the 4π solid angle domain is divided into two hemispheres, and the double P_1 (DP_1) approximation is obtained. For a two-dimensional rectangular geometry, a similar derivation yields a quadruple P_1 (QP_1) approximation. Both approximations yield better predictions than the P_3 approximation.

DP_1 Model for Planar Geometries. Here, the formulation of a relatively simple model for plane parallel media is presented. This hybrid model was introduced and evaluated by Mengüç and Iyer [55]. It is a much better alternative to regular flux approximations or moment methods, and it is simpler to use than more accurate F_N method or higher-order DO and SH approximations. It can be considered as a hybrid between the first-order SH (P_1) method and a two-flux approximation.

Let us assume that, in a plane-parallel and azimuthally symmetric medium, the intensities in positive and negative z -directions are given as (see Fig. 7.14):

$$M^+(\tau, \mu) = A_0 + A_1\mu \quad (7.112)$$

$$M^-(\tau, \mu) = B_0 + B_1\mu \quad (7.113)$$

The zeroth and the first-order moments of intensity can be obtained by multiplying the M^+ and M^- by 1 and μ and integrating over the corresponding hemispheres. For M^+ , this yields:

$$M_0^+ = \int_{\phi=0}^{2\pi} \int_{\mu=0}^1 M^+ d\Omega = 2\pi A_0 + \pi A_1 \quad (7.114)$$

$$M_1^+ = \int_{\phi=0}^{2\pi} \int_{\mu=0}^1 \mu M^+ d\Omega = \pi A_0 + (2\pi/3)A_1 \quad (7.115)$$

Equations 7.114 and 7.115 can be solved for the A_0 and A_1 coefficients and substituted back into Eq. 7.112 to obtain

$$M^+(\tau, \mu) = \frac{1}{\pi} [(2M_0^+ - 3M_1^+) + (-3M_0^+ + 6M_1^+)\mu] \quad (7.116)$$

The second order moment of intensity is obtained by multiplying Eq. 7.116 by μ^2 and integrating over the upper hemisphere:

FIGURE 7.14 Representation of angular division of intensity for DP_1 approximation [55].

$$M_{11}^+ = \int_{\phi=0}^{2\pi} \int_{\mu=0}^1 \mu^2 M^+ d\Omega = -(1/6)M_0^+ + M_1^+ \quad (7.117)$$

Following the same procedure, the intensity and second-order moment for the lower hemisphere are found as:

$$M^-(\tau, \mu) = \frac{1}{\pi} [(2M_0^- + 3M_1^-) + (3M_0^- + 6M_1^-)\mu] \quad (7.118)$$

$$M_{11}^- = \int_{\phi=0}^{2\pi} \int_{\mu=-1}^0 \mu^2 M^- d\Omega = -(1/6)M_0^- - M_1^- \quad (7.119)$$

If the phase function is approximated as a linearly anisotropic one (there is no justification for the use of a more elaborate one since the method itself will not pick the resolution), such as:

$$\phi(\mu, \mu') = 1 + a_1 \mu \mu' \quad (7.120)$$

then, the RTE for each domain becomes

$$\frac{\mu}{\tau_0} \frac{\partial M^+}{\partial \tau} + M^+ = (1 - \omega)I_b(T) + \frac{\omega}{4\pi} [(M_0^+ + M_0^-) + a_1 \mu (M_1^+ + M_1^-)] \quad (7.121)$$

$$\frac{\mu}{\tau_0} \frac{\partial M^-}{\partial \tau} + M^- = (1 - \omega)I_b(T) + \frac{\omega}{4\pi} [(M_0^+ + M_0^-) + a_1 \mu (M_1^+ + M_1^-)] \quad (7.122)$$

As it is performed for regular P_1 approximations, these equations are multiplied by 1 and μ and integrated over corresponding hemispheres to obtain the four first-order differential equations:

$$\frac{1}{\tau_0} \frac{\partial M_1^+}{\partial \tau} = 2\pi(1 - \omega)I_b + \left(\frac{\omega}{2} - 1\right)M_0^+ + \frac{\omega}{2}M_0^- + \frac{\omega a_1}{4}M_1^+ + \frac{\omega a_1}{4}M_1^- \quad (7.123)$$

$$\frac{1}{\tau_0} \frac{\partial M_0^+}{\partial \tau} = 6\pi(1 - \omega)I_b + \left(\frac{3\omega}{2} - 6\right)M_0^+ + \frac{3\omega}{2}M_0^- + \left(\frac{\omega a_1}{2} + 6\right)M_1^+ + \frac{\omega a_1}{2}M_1^- \quad (7.124)$$

$$\frac{1}{\tau_0} \frac{\partial M_1^-}{\partial \tau} = 2\pi(1 - \omega)I_b + \frac{\omega}{2}M_0^+ + \left(\frac{\omega}{2} - 1\right)M_0^- - \frac{\omega a_1}{4}M_1^+ - \frac{\omega a_1}{4}M_1^- \quad (7.125)$$

$$\frac{1}{\tau_0} \frac{\partial M_0^-}{\partial \tau} = -6\pi(1 - \omega)I_b - \frac{3\omega}{2}M_0^+ + \left(6 - \frac{3\omega}{2}\right)M_0^- + \frac{\omega a_1}{2}M_1^+ + \left(6 + \frac{\omega a_1}{2}\right)M_1^- \quad (7.126)$$

For the boundary conditions, Marshak's boundary relations are imposed. This means that the moments of the intensity at each of the boundaries are determined from:

$$\int_{\Omega_j} I(\tau, \mu) l d\Omega_j = \int_{\Omega_j} I^* l d\Omega_j \quad (j = 1, 2) \quad (7.127)$$

where l is the direction cosine, and the I^* for a diffusely emitting and reflecting surface is given as (see Eq. 7.108):

$$I^* = \epsilon_w I_b(T_w) + (\rho^d/\pi) \int_{\Omega'=2\pi} I(\tau, \mu') l d\Omega' \quad (7.128)$$

or, for each surface:

$$I_1^* = \epsilon I_b(T_1) - (\rho_1^d/\pi)M_1^- \quad I_2^* = \epsilon_2 I_b(T_2) + (\rho_2^d/\pi)M_1^+ \quad (7.129)$$

After substituting Eqs. 7.129 into Eq. 7.127 and carrying out the integration for $l=1$ and $l=\mu$, we obtain the necessary boundary conditions:

$$M_0^+ = 2\pi I_1^+, \quad M_1^+ = \pi I_1^+, \quad M_0^- = 2\pi I_2^+, \quad M_1^- = -\pi I_2^+ \quad (7.130)$$

The radiative flux at any given point in the medium is found from

$$q = \int_{4\pi} I \mu \, d\Omega = \int_{\phi=0}^{2\pi} \int_{\mu=-1}^1 I \mu \, d\Omega = M_1^+ + M_1^- \quad (7.131)$$

Figure 7.15 shows the accuracy of this approach compared to the more accurate P_9 approximation. Note that for the P_9 , a nine-term phase function was used, and it can be considered as exact (see Ref. 55 for comparisons). Additional calculations showed that, even for nonuniform media, the DP_1 approximation yields accurate results [55].

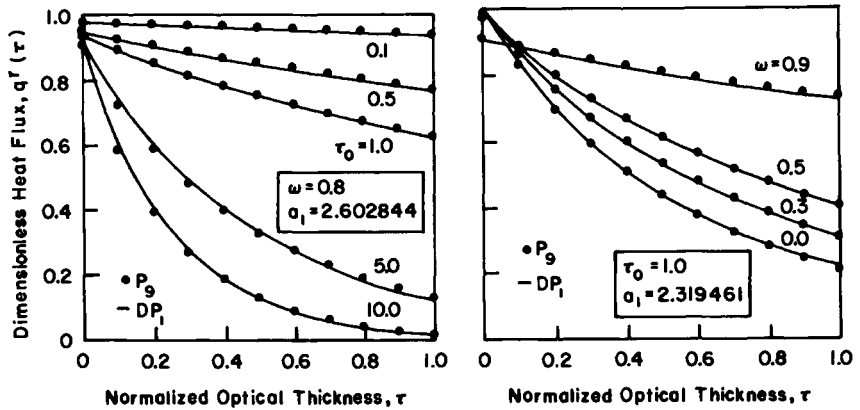

FIGURE 7.15 Comparison of DP_1 approximation predictions with those of the exact P_9 approximation [55].

Multiflux and Discrete Ordinates Approximations. In order to solve the radiative transfer equations, the spatial and angular variations of intensity are usually expressed in two different functional forms. The entire angular domain is divided into several subdomains, and the radiation intensity in each is considered to be uniform. Then the intensities in each angular domain are related and solved for as functions of position. In principle, this is the same approach followed in the zonal method; however, in deriving the flux methods, the angular subdomains are obtained by following a mathematical reasoning rather than using the relative orientation of the different surfaces with respect to each other. These angular divisions are fixed and do not change as a function of spatial coordinates.

The simplest multiflux model can be developed for a one-dimensional planar medium or a one-dimensional axisymmetric cylindrical geometry by dividing the entire solid angle range (4π sr) into two components: one in the forward and the other in the backward hemisphere. It is assumed that the incident radiation and flux are proportional to each other in each of these hemispheres. Then, the question is finding a closure condition, or, in other words, a proportionality factor between flux and integrated intensity in each half-sphere. This choice yields different two-flux methods, such as Schuster-Hamaker, Schuster-Schwarzschild or modified two-flux models [1, 19, 51].

In multidimensional geometries, the number of angular subdomains needs to be increased. A natural extension of the two-flux method in two- and three-dimensional systems would be four- and six-flux methods, respectively. However, these straightforward extensions to multi-

dimensional systems do not yield acceptable accuracy in radiative transfer predictions. Extensive lists of various multiflux approximations proposed in the past are available in the literature (see, e.g., Refs. 1, 3, and 34). Because the intuitive flux approximations are inferior to the mathematically rigorous multiflux models, they will not be discussed here.

The discrete ordinates (DO) approximation is also a multiflux model. The discrete ordinates approximation was originally suggested by Chandrasekhar [19] for astrophysical applications, and a detailed derivation of the related equations was discussed by several researchers for application to neutron transport problems [33, 57–61]. During the last two decades, the method has been applied to various heat transfer problems [62–81].

In DO models, a Gaussian or Lobatto quadrature scheme is used in the integration of in-scattered radiation, and, for a three-dimensional system, the entire solid angle range is divided into $N(N+2)$ angular subdomains, where N is determined by the order of quadrature scheme used. Such a DO approximation is referred to as the S_N approximation [61]. For axisymmetric systems, the number of angular subdivisions required is reduced by one-half. The intensity is assumed to remain uniform within each of these angular domains whose extent is obtained from the weights of the quadrature scheme employed. For one-dimensional planar media, the simplest DO approximation is identical to the modified two-flux method. Higher-order DO approximations can easily be used for a plane-parallel medium if the exact solution to the RTE is needed [82].

The DO methods are better than the well-known multiflux methods, which usually cannot couple angular divisions adequately. The DO methods avoid this by discretizing the angular domain such that no direction lies on a coordinate direction. In general, the DO approximation yields acceptable results with an increasing number of directions considered. However, if there are strong local sinks and sources or discontinuous boundary conditions, then the ray effects begin to affect the accuracy of the results [61]. Even with increasing order of the S_N approximation, these ray effects show an oscillatory behavior on the boundary fluxes. Therefore, care should be exercised in interpreting the S_N method predictions especially near flame zones or boundaries with discontinuities in temperature or heat flux. In the following section, we will give the formulation of the DO approximation for cylindrical geometries.

Fiveland and Jessee [77] and Krebs et al. [79] have recently discussed a modified formulation of the DO approximation. They adapted the even-parity formulation originally discussed by Lewis and Miller [61]. They showed that this formulation yields parabolic equations; therefore, a boundary value problem is to be solved instead of an initial value problem. Given that several solution techniques are available for the solution of governing equations (particularly in the field of computational fluid dynamics [CFD]), a solution to the RTE can be obtained with little difficulty. This formulation does not necessarily produce more accurate results, and the ray effects still persist.

Also, an adaptive mesh refinement (AMR) algorithm was developed by Jessee et al. [83]. The results showed that the AMR algorithm did not necessarily produce any improvement over single-grid algorithms. Recently, the accuracy of the discrete ordinates approximation in three-dimensional rectangular enclosures were evaluated carefully [77, 84, 85]. Selçuk and Kayakol [85] have observed that the standard S_N quadrature scheme as well as the ones suggested by Fiveland [65] yield more accurate results than the Gaussian quadrature scheme.

Tan [86, 87] and Hsu et al. [88, 89, 90] have proposed and explored the YIX method. This technique uses the discrete ordinate formulation for angular discretization but precalculates and stores the kernel functions for the distance integration along each ordinate direction. The resulting computational grid is not uniform, but it makes each unequal distance increment along a given ordinate direction contribute an approximately equal amount to the flux at the origin element. This approach allows the path integrations along each ordinate direction to be replaced with fast summations.

The YIX method requires precomputation of the kernel functions but makes the actual radiative transfer computation very efficient. For problems with constant absorption and scattering coefficient, or for problems with known fixed distributions of these properties, the YIX method is an improvement over the standard DO method. If, however, the properties

are temperature-dependent, then the kernel functions will change at every iteration, and much of the benefit of the method is lost.

S₂ and S₄ Models for Cylindrical Geometries. For the solution of the RTE in cylindrical media, the formulations for the *S₂* and *S₄* discrete ordinates (DO) approximations (based on Ref. 69) will be presented here. Note that, in a more recent study, Jendoubi et al. [75] used a similar DO approximation in cylindrical geometry and evaluated the effect of anisotropic phase function on the accuracy of the model.

As discussed before, the idea in the DO approximation is to solve the RTE (Eq. 7.105) in a finite number of directions. If these directions are chosen using the values of the Gaussian quadrature points, then the number of directions considered (*N_m*) will be related to the order *N* of Gaussian quadratures as *N_m* = *N(N + 2)*. Here, *N* is also the order of the DO approximation *S_N*. Each direction chosen is uniquely determined by the Gaussian quadratures and corresponds to a point on a surface of a unit sphere (see Fig. 7.16). It is assumed that the solution is valid for an angular range, which corresponds to an area *w_m* on the surface of the unit sphere. The *w_m* values are nothing but the weights corresponding to the Gaussian quadratures. They satisfy the requirement:

FIGURE 7.16 Representation of the division of spherical domain by a Gaussian quadrature scheme.

$$\sum_m w_m = 4\pi \quad (7.132)$$

Using this nomenclature, the RTE in each of the Gaussian quadrature directions is written as

$$\frac{\xi_m}{r} \frac{\partial(rI_m)}{\partial r} - \frac{1}{r} \frac{\partial(\eta_m I_m)}{\partial \phi} + \mu_m \frac{\partial I_m}{\partial z} = -(\kappa + \sigma)I_m + \kappa I_b + \frac{\sigma}{4\pi} \int_{4\pi} \Phi(\Omega, \Omega') I_m d\Omega' \quad (7.133)$$

where, the direction cosines ξ_m , η_m , and μ_m are written in terms of zenith and azimuthal angles, θ and ϕ (see Fig. 7.1).

Considering diffusely emitting and reflecting cylindrical boundaries, the corresponding boundary conditions are:

$$\text{at } r = R: \quad I_m = \varepsilon_w I_{bw} + (1 - \varepsilon_w) \frac{q_r^+}{\pi}; \quad \xi_m < 0$$

$$\text{at } r = 0: \quad I_m = I'_m; \quad \xi'_m = \xi_m$$

$$\text{at } z = 0: \quad I_m = \varepsilon_w I_{bw} + (1 - \varepsilon_w) \frac{q_z^-}{\pi}; \quad \mu_m > 0$$

$$\text{at } z = L: \quad I_m = \varepsilon_w I_{bw} + (1 - \varepsilon_w) \frac{q_z^+}{\pi}; \quad \mu_m < 0 \quad (7.134)$$

Radiative fluxes in $\pm r$ and $\pm z$ directions become (see Eq. 7.2):

$$q_r^+ = \sum_m w_m \xi_m I_m; \quad \xi_m > 0$$

$$q_r^- = \sum_m w_m |\xi_m| I_m; \quad \xi_m < 0$$

$$q_z^+ = \sum_m w_m \mu_m I_m; \quad \mu_m > 0$$

$$q_z^- = \sum_m w_m |\mu_m| I_m; \quad \mu_m < 0 \quad (7.135)$$

In this formulation, the angular derivative term (i.e., the second term in Eq. 7.133) is the most difficult to evaluate. Since the original work of Carlson and Lathrop [33], a direct differencing procedure has been used to simplify this term, such as:

$$\frac{1}{r} \frac{\delta(\eta_m I_m)}{\delta\phi} = \frac{1}{r} \frac{\alpha_{m+1/2} I_{m+1/2} - \alpha_{m-1/2} I_{m-1/2}}{w_m} \quad (7.136)$$

As mentioned by Jamaluddin and Smith [69], the $m \pm 1/2$ directions correspond to the angular range of w_m . An explicit relation can be obtained assuming a uniform radiation field in the corresponding angular domain:

$$\alpha_{m+1/2} - \alpha_{m-1/2} = w_m \xi_m \quad (7.137)$$

If Eq. 7.133 is multiplied by $2\pi r dr dz$ and integrated over the ring-shaped volume element, a difference formulation of the RTE is obtained:

$$\xi_m (A_{i+1} I_{i+1} - A_i I_i) - (A_{i+1} - A_i) [(\alpha_{m+1/2} I_{m+1/2} - \alpha_{m-1/2} I_{m-1/2}) / w_m] + \mu_m (B_{j+1} I_{j+1} - B_j I_j)$$

$$= -(\kappa + \sigma) V_p I_m + \kappa V_p I_b + \frac{\sigma V_p}{4\pi} \sum_m \Phi(\Omega, \Omega') w_m I_m \quad (7.138)$$

Here, let us assume that the phase function is a linearly-anisotropic one, expressed as:

$$\Phi(\Omega, \Omega') = 1 + a_0 \cos \phi = 1 + a_0 (\xi_m \xi'_m + \mu_m \mu'_m) \quad (7.139)$$

Using a central-differencing scheme, the intensities can be related to I_m

$$I_i + I_{i+1} = I_{m+1/2} + I_{m-1/2} = I_j + I_{j+1} = 2I_m \quad (7.140)$$

where I_m is the intensity at the center of the volume element:

$$I_m = \frac{\xi_m A I_i + \beta_m I_{m-1/2} + \mu_m B I_j + V_p (\kappa I_b + \sigma I_s)}{\xi_m A + \beta_m + \mu_m B + V_p (\kappa + \sigma)} \quad (7.141)$$

with

$$A = A_i + A_{i+1}$$

$$B = B_j + B_{j+1}$$

$$\beta_m = -(\alpha_{m+1/2} + \alpha_{m-1/2})(A_{i+1} - A_i) / w_m$$

$$I_s = \sum_m w_m I_m \left[\frac{1 + a_0 (\xi_m \xi'_m + \mu_m \mu'_m)}{4\pi} \right]$$

Equation 7.141 is written for positive ξ_m and μ_m values. For other combinations, similar equations need to be developed. Note that V_p is the volume of the computational cell.

For the solution of the governing equations, an iterative scheme is followed [69]. After determining the intensity at a cell center (see Eq. 7.141), the intensity downstream of the surface element can be determined via extrapolation using Eq. 7.140. The central differencing used in Eq. 7.140 may result in negative intensities, particularly if the change in the radiative field is steep. A numerical solution to this problem was recommended by Truelove [67], where a mixture of central and upward differencing is used:

$$I_{i+1} = (1 + f)I_m - fI_i \quad (7.142)$$

where $0 \leq f \leq 1$ and $\xi_{mm}\mu_m > 0$. If f is 1.0, it is central differencing, and if $f=0.0$, it is upwind differencing, and the intensity is always positive.

For a scattering medium, the first solution excludes the in- and out-scattering terms; they are included in further iterations. Tables 7.2 and 7.3 list the quadratures used for the S_2 and S_4 approximations.

Figure 7.17 depicts the comparison of S_2 and S_4 DO approximation predictions [69] with Monte Carlo calculations [91] in an absorbing, emitting, and scattering medium. Overall, the accuracy of the agreement is acceptable, for a wide range of optical thicknesses and single scattering albedo values considered.

Note that the extension of the DO approximation to three-dimensional rectangular enclosures was attempted by a number of researchers (see, e.g., Refs. 65 and 85). Even though the formulation of the three-dimensional model will not be given here, its governing equations can be derived with little difficulty. As shown in Refs. 65 and 85, the original S_N quadratures yield accurate results in three-dimensional solutions; they are listed in Table 7.4 for S_2 , S_4 , S_6 , and S_8 approximations.

Statistical Models. By the Lambert-Beer law, the radiative transfer equation is derived from a macroscopic point of view using the principle of the conservation of radiative energy. In order to solve the RTE using any of the available methods, certain mathematical assumptions are introduced, and the physics of the problem are retained. If the assumptions are correct, then the RTE model yields physically acceptable results.

FIGURE 7.17 Comparison of S_2 and S_4 predictions with the Monte Carlo results in cylindrical geometry (adapted from Ref. 69).

On the other hand, it is possible to determine the radiative energy balance everywhere in the medium by considering a large number of photons, which originate from each volume/surface element, propagate in all directions, and are absorbed and scattered. The radiative energy gain or loss in each element is calculated by considering the effect of an infinitely large number of photons, as each photon affects the total energy balance. In doing so, the direction and the path length of each photon bundle are determined statistically. This procedure, called

a statistical or Monte-Carlo approach, is straightforward to implement, although, computationally, it may be expensive.

The Monte Carlo method seeks to replace mathematical descriptions of radiative transfer such as those described in the subsections on the zonal method and the differential and moment method with a simulation of the physical processes that are occurring. The method simulates radiative transfer by following the histories of small amounts of radiative energy, often called energy *bundles*. The bundles are followed throughout the series of events such as emission, reflection, scattering, and absorption that occur over the bundle lifetime. By following a sufficiently large number of bundles, the radiative flux or flux divergence distributions can be found over surfaces or within volumes of participating media.

The Monte Carlo method results in statistically averaged results. The accuracy of the results depends upon the number of sample bundles chosen for study in the same way that experimental accuracy depends upon the number of replications of the experiment. This dependence on the number of samples is the greatest drawback of the method, as it requires a tradeoff between computer time and statistical accuracy of the results.

Brief Outline of the Monte Carlo Method. Monte Carlo is based on determining the probability of a particular event in the history of an energy bundle. Whenever such an event occurs based on the physics of the problem, a choice is made such that, after many such events, the choices have the correct distribution. This is done by relating the variable being chosen to a random number R , where $0 \leq R \leq 1$, through a cumulative distribution function, or CDF. For example, the direction of emission from a diffuse surface is determined by the two angles (θ, ϕ) . For a particular energy bundle being emitted from the surface, these angles are determined from Table 7.5 to be

$$\sin \theta = R^{1/2} \quad (7.143)$$

$$\phi = 2\pi R \quad (7.144)$$

A separate random number must be chosen for each of these relations, so that they will be independent of one another. Each event will have a different CDF. Derivations of the statistical relations necessary to determine the CDF relations needed to implement the Monte Carlo technique are given in Refs. 1, 2, and 3 and are not repeated here; however, the resulting relations for implementing the method are given in Table 7.5.

These relations are based on the assumption that wavelength and directional dependence are independent of one another; for example, the directional distribution of emitted energy is independent of the wavelength of emission. When this is not the case, somewhat more complex relations are necessary [1, 92]. For use in a Monte Carlo calculation, we need a relation of the form $\mu = F(R)$ rather than $R = G(\mu)$. These inversions can be generated from the integral forms shown in the table by substituting the required properties, carrying out the integrations, and then curve-fitting the results. Haji-Sheikh [93] has provided such a relation for $\lambda = F(R)$ for black or gray surfaces that is reproduced in Siegel and Howell [1].

Examples. To illustrate the Monte Carlo method, two radiative transfer examples are presented.

First, take the case of determining the radiative transfer between two infinite parallel gray diffuse directly opposed plates separated by a distance D and of width W , with known temperatures T_1 and T_2 and equal emissivities ϵ (Fig. 7.18). No attenuating medium is present between the surfaces.

FIGURE 7.18 Geometry for the Monte Carlo example problem.

To begin the model, consider radiant energy that is initiated by emission from surface 1. The first choice in the history of emission will be the position x along plate 1, at which point emission occurs. This can be chosen at random as $x = RW$, or it can be chosen in sequence such that for sample number n of the N bundles, we let $x = (n/N)W$. Either method will provide uniform emission along the constant temperature plate, but the latter method avoids repetitive

TABLE 7.5 Monte Carlo Relations for Surface-Surface and Participating Media Radiative Exchange

Phenomenon	Variable	Relation
Emission or reflection from diffuse gray or black surface	Cone angle θ	$\sin \theta = R^{1/2}$
	Circumferential angle ϕ	$\phi = 2\pi R$
	Wavelength λ	$F_{0-\lambda} = R$
Emission from gray θ -directional surface	Cone angle θ	$R = \frac{2 \int_0^\theta \epsilon(\theta^*) \sin \theta^* \cos \theta^* d\theta^*}{\epsilon}$
Emission from nongray θ -directional surface	Cone angle θ	$R = \frac{2\pi \int_0^\theta \int_0^\infty \epsilon(\lambda, \theta^*) i_{\lambda b}(\lambda) \sin \theta^* \cos \theta^* d\lambda d\theta^*}{\epsilon \sigma T^4}$
Emission from diffuse nongray surface	Wavelength λ	$R = \frac{\pi \int_0^\lambda \epsilon(\lambda^*) i_{\lambda b}(\lambda^*) d\lambda^*}{\epsilon \sigma T^4}$
Emission from nongray θ -directional surface	Wavelength λ	$R = \frac{2\pi \int_0^\lambda \int_0^{\pi/2} \epsilon(\lambda^*, \theta) i_{\lambda b}(\lambda^*) \sin \theta \cos \theta d\theta d\lambda^*}{\epsilon \sigma T^4}$
Emission from a volume element	Cone angle θ	$\cos \theta = 1 - 2R$
	Circumferential angle ϕ	$\phi = 2\pi R$
	Wavelength λ	Gray medium: $F_{0-\lambda} = R$
	Wavelength λ	Nongray medium: $R = \frac{\int_0^\lambda a_\lambda(\lambda^*) i_{\lambda b}(\lambda^*) d\lambda^*}{\int_0^\infty a_\lambda(\lambda^*) i_{\lambda b}(\lambda^*) d\lambda^*}$
Attenuation by medium	Path length s	Uniform properties: $s = -\frac{1}{K_\lambda} \ln R$
		Nonuniform properties: $\ln R = -\int_0^s K_\lambda(s^*) ds^*$
Isotropic scattering	Cone angle θ	$\cos \theta = 1 - 2R$
	Circumferential angle ϕ	$\phi = 2\pi R$
Anisotropic scattering	Cone angle θ	$R = \frac{1}{2} \int_0^\theta \Phi(\theta^*) \sin \theta^* d\theta^*$
	Circumferential angle ϕ	$\phi = 2\pi R$

calls of the random number generator and is usually both faster and introduces less statistical variation.

The rate of energy emission per unit area can be broken into N bundles of energy per unit time and area, each carrying an amount of energy w . Therefore,

$$e = wN_1 = \epsilon \sigma T_1^4 \tag{7.145}$$

The programmer can choose the value of N to provide the desired degree of accuracy in the final solution.

The direction of emission at point x is chosen using Eqs. 7.143 and 7.144. Now we determine whether the bundle intersects the opposing plate by determining the x -position at which the bundle intersects the plane containing plate 2; in other words, $0 \leq x_2 \leq W$, where

$$x_2 = x_1 + L \tan \theta \cos \phi \tag{7.146}$$

If the bundle misses plate 2, then we choose another bundle; if it strikes plate 2, then we know the position where it strikes, x_2 , from Eq. 7.146. At this position, we need to see how much energy is absorbed. Two common strategies are employed for this. In the first, we choose

a new random number and see whether $R \geq \alpha = \epsilon$. If the answer is yes, then the bundle is completely reflected from surface 2. If the answer is no, then the entire energy of the bundle is absorbed on surface 2 at x_2 . In the second strategy, we simply absorb an amount of energy $\omega\alpha$ at x_2 and reflect a bundle with remaining energy $(1 - \alpha)\omega$. In this strategy, the bundle energy is diminished at each reflection, and the process is usually ended by depositing all remaining energy when the bundle energy has been reduced to some small fraction of the original value.

The first of these strategies requires somewhat less bookkeeping but has larger statistical uncertainty. The second method is probably more efficient for most cases, where efficiency is the product of CPU time and solution variance.

If the bundle is reflected from diffuse surface 2, then angles of reflection are chosen by Eqs. 7.143 and 7.144, and trigonometry is again applied to determine whether the reflected bundle strikes surface 1, and, if so, at what location. This procedure of reflections is continued until the bundle misses the opposite surface, or it is either absorbed or its energy is reduced below the given threshold value. If some or all of the energy is absorbed, the amount absorbed is tallied at the position of incidence.

To complete the solution, bundles must be emitted from surface 2. If they have the same energy per bundle as those emitted from surface 1, then we must emit $N_2 = \epsilon\sigma T_2^4/\omega = (\epsilon_2 T_2^4/\epsilon_1 T_1^4)N_1$ bundles from surface 2. The histories follow the same sequence of emission and reflection as before, except that the bundle histories are initiated at surface 2.

A flow chart for this process is shown in Fig. 7.19. In this case, the plates are assumed to be black, and the environment is at $T_e = 0$. The S_k and S_n are counters used to tally the number of

FIGURE 7.19 Flowchart for the Monte Carlo solution.

absorptions at positions on surfaces 1 and 2, respectively, and M is the number of Δx increments on the surfaces.

For a second example, consider a gray absorbing medium with uniform properties contained between black infinite parallel plates at different temperatures. Find the heat transfer between the plates and the temperature distribution in the medium, assuming radiative equilibrium (i.e., no sources or sinks in the medium).

Energy bundles are followed through their histories after emission from each surface until absorption at a boundary. Because of the assumption of radiative equilibrium, any bundles absorbed within a medium volume element must be balanced by an emission from that element; this is simulated by simply reemitting an absorbed bundle in a new direction and continuing the history until final absorption at a boundary. The medium temperature distribution is computed by equating the emission from the element to the absorption. The flow chart for this case is shown in Fig. 7.20.

Table 7.6 gives the results for the net radiative flux between the plates at an optical thickness of 1.0 for various numbers of energy bundles, compared with the exact solution of this problem, which is 0.5532. The solution was programmed according to the flow chart in Fig. 7.20.

Discussion of Monte Carlo methods for radiative transfer calculations have been given in Refs. 61, 93, and 94. It was used to model radiative heat transfer in large scale furnaces by, among others, Taniguchi and Funazu [95], Xu [96], Gupta et al. [91], and Richter [97]. In general, Monte Carlo techniques do yield reliable results if certain precautions are taken and sufficient numbers of photon bundles are utilized and biasing techniques are applied [61]. As mentioned by Howell [94], one of the main drawbacks of a Monte Carlo technique is the grid

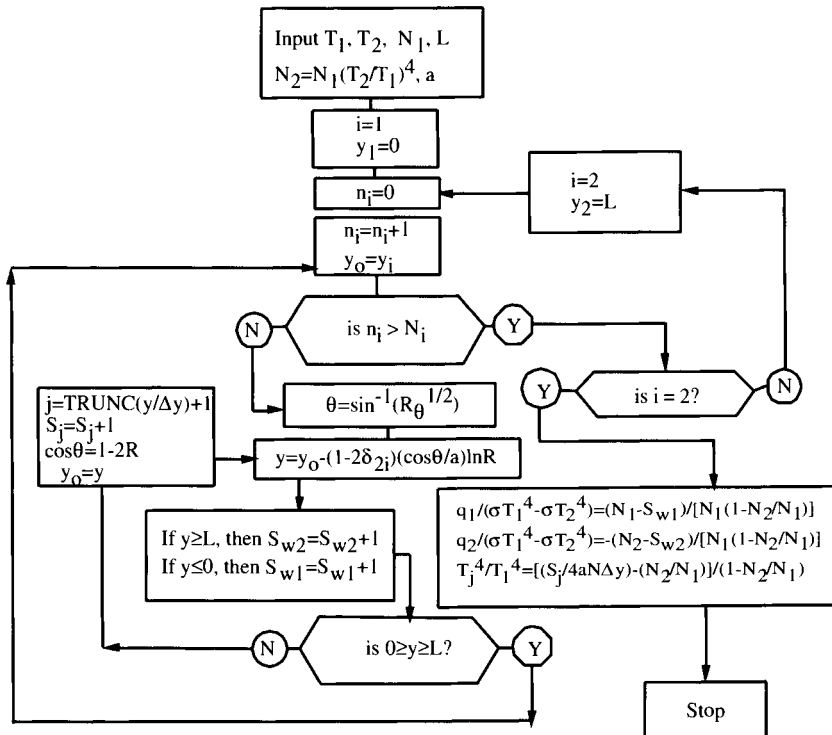

FIGURE 7.20 Monte Carlo flowchart for radiative exchange between opposed black plates of finite width.

TABLE 7.6 Results of Monte Carlo Example Problem; Normalized Radiative Flux at Surface 1 for Various Sample Sizes

N_1 , bundles emitted by surface 1	Radiative flux at surface 1, $q_1/\sigma T_1^4$
100	0.592
500	0.542
1000	0.553
5000	0.561
10,000	0.567
50,000	0.5564

incompatibility with the conservation of mass and energy equations. This problem, however, is likely to be eliminated with increasing computational power of computers. The main advantage of the Monte Carlo techniques is its possible application to any complex geometry.

Recent work on the Monte Carlo technique includes that by Farmer and Howell [98–101], who investigated the optimal strategies for implementing the Monte Carlo technique on both serial and parallel computers. For up to 32 parallel processors, the CPU time on the parallel machines was very nearly inversely proportional to the number of processors, indicating that the method is very well suited to parallel machines.

Numerical Models. With the advancement of computers, it is theoretically possible to solve any differential or integral equation using an appropriate numerical discretization scheme. The challenge here is to devise a scheme such that the physics of the problem are retained. All the radiative transfer models developed in the past attempt to do this; however, they also take advantage of different analytical techniques to reduce the complexity of equations and the required computational power as much as possible. In numerical solution techniques, the computational requirements may be decreased by using certain numerical simplifications and/or by choosing coarser grids. In general, it is safe to say that, with the availability of supercomputers, finer grids compatible with the grid scheme used for the solution of the other conservation equations can be used with little difficulty and computational penalty. Therefore, numerical techniques are likely to have wide acceptance in the future to model the radiative heat transfer in complicated geometries, especially for nonscattering media (see Refs. 102 and 103).

Raithby and Chui [103] suggested a finite volume formulation of the RTE in one-dimensional planar and two-dimensional rectangular enclosures. The model is capable of handling scattering by the medium and yields very good agreement with the exact solutions. In principle, it is very similar to the discrete ordinates approximation, the main difference being the selection of the angular discretization to be used. In DO approximations, this selection is analytically determined, whereas Raithby and Chui use an arbitrary criterion for the selection. Therefore, a trial-and-error approach is required to determine the optimum angular discretization.

The finite element techniques have been used to model radiative heat transfer in multidimensional enclosures. Razzaque et al. [104, 105] considered the combined conduction-radiation problem in an absorbing/emitting medium. Chung and Kim [106] and Sökmen and Razzaque [107] allowed for isotropic scattering in the medium. Tan [108] introduced a product integration method, which is similar to the finite element technique. This approach requires much less computational time than the other finite element solution techniques. Burns et al. [109, 110] formulated a detailed finite element radiative transfer code that uses grids generated by commercial FEM grid generators. The code computes the local radiative flux divergence based on a given temperature distribution in the medium; the computed divergence can then be used in the energy equation in a commercial FEM code for treating

combined-mode problems. Note that the finite element approach was also used for the solution of the reduced equations of the DO approximations [73, 74, 76].

Hybrid Techniques. Almost all the methods discussed before have certain disadvantages. It is sometimes possible to combine the features of two or more methods to develop a more efficient technique to model radiative heat transfer in furnaces. For example, if the furnace geometry is very complicated, the zone method cannot be used effectively, as it is quite difficult to determine all the required exchange factors. Here, a Monte Carlo technique can be adopted, as done by Vercammen and Froment [111], to calculate the exchange factors between volume and surface elements, and then the radiative heat transfer between each element is calculated using the zonal method. Edwards [112] also suggested a similar approach where he obtained the exchange factors using a Monte Carlo technique and calculated the radiative flux distribution using a radiosity-irradiosity approach. With this hybrid approach, exchange factors in most complicated geometries can be calculated with little difficulty. Also, a significant amount of time is saved by using the zone method instead of a Monte Carlo technique to determine the radiative heat flux distribution in the medium. In addition to that, possible statistical errors due to a Monte Carlo technique are avoided.

The basic principles of Monte Carlo techniques have been used by Lockwood and Shah [113] in developing the so-called *discrete transfer method*. Instead of choosing the direction of the intensities originating (due to emission, scattering, or reflection) from each volume/surface element randomly, they suggested a deterministic approach. Although the method was shown to be accurate and computationally efficient for nonscattering media, it did not yield accurate results if scattering particles were present. Recently, Selçuk and Kayakol [114] evaluated this approach and outlined the problems related to its implementation. They noted that, for relatively simple, homogeneous, and nonscattering media, this approach yielded about 10 percent error for the radiative source term near the corners, even if 64 rays were considered. Additionally, it required three times more CPU time than the S_4 approximation to converge in three-dimensional rectangular enclosures [85].

An alternative approach similar to the discrete transfer method was reported by Taniguchi et al. [115, 116, 117]. They showed that, for nonscattering media, the method yields very good results with significant computational time savings over standard Monte Carlo techniques.

Richter [97] suggested a similar semistochastic approach, where he developed a solution scheme based on the principles of a Monte Carlo technique, yet the directions of photons emitted by each volume/surface element were predetermined. He applied this approach to several large-scale furnaces and showed that, if the scattering is not accounted for, the model yields reasonable results even if as few as 10,000 photons are considered.

Another hybrid approach is to combine the diffusion approximation for optically thick media with the Monte Carlo technique. The diffusion method can be applied in geometric or spectral regions that are optically thick with good accuracy; Monte Carlo is used in geometric or spectral regions with intermediate or thin optical depth and near boundaries. Farmer and Howell [98, 99] have implemented two forms of such a hybrid, finding good accuracy and greatly reduced computer time over conventional Monte Carlo.

Strategies for Choosing a Radiative Transfer Model. One of the most important decisions an engineer has to make regarding the modeling of radiative heat transfer in large-scale furnaces is the choice of an appropriate radiative transfer model. Considering the fact that the solution of the RTE requires information about the temperature and spatial distribution of radiative properties in the medium, the radiative transfer model is to be coupled with the models for flow, chemical kinetics, turbulence, and so on. Therefore, the design engineer must choose a model that will be compatible with the solution techniques for the other governing equations. The model should also be reliable and able to predict accurately the radiative flux and the divergence of radiative flux distributions in the medium. In addition, the model should be computationally efficient.

It is not always necessary or desirable to choose the most accurate radiative transfer model available. If the accuracy of the radiative property data used in predictions is not as good as the accuracy of the model itself, it is difficult to justify the extra computational effort required by a refined model. A simpler approximate model may be more appropriate.

It is important to ask the following questions before a specific model is chosen. (1) Is the medium geometry simple? (2) Are there steep temperature and species concentration distributions in the medium? (3) Are there anisotropically scattering particles? (4) If there are, what kind of scattering phase function approximations can be used for them? Having some approximate answers to these questions will help to expedite the selection process.

For the solution of the radiative transfer equation, there are several different models available in the literature, as summarized in the foregoing sections. None of these models, however, can be used on a universal basis and applied to all different types of practical problems. It is up to the researcher to decide which model should be used for what type of application. In order to make such a choice, he or she should know the advantages, disadvantages, range of applicability, and versatility of each model. In this section, we will attempt to introduce some simple guidelines to make the selection procedure less time-consuming. For this purpose, the advantages and disadvantages of different models are listed in Table 7.7 to help the reader in choosing an appropriate model.

As discussed previously, the radiative transfer equation is written in terms of radiation intensity, which is a function of seven independent parameters. The RTE is developed phenomenologically and is a mathematical expression of a physical model (i.e., the conservation of the radiative energy). It is a complicated integro-differential equation. There is no available analytical solution to the RTE in its general form. In order to solve it, physical and mathematical approximations are to be introduced individually or in tandem.

We can consider possible approximations under three different types of broad categories: (1) simplification of the spectral nature of properties; (2) angular discretization of the intensity field; and (3) spatial discretization of the medium (for all parameters).

It is important to realize that the solution of the radiative transfer equation is required only to obtain the divergence of the radiative flux vector that is a total quantity (i.e., inte-

grated over the entire wavelength range spectrum). Since eventually we need to obtain a spectrally integrated quantity, one natural way to simplify the problem is by using spectrally averaged radiative properties. The averaging over the wavelength spectrum can be performed over predefined narrow ranges or over the entire wavelength spectrum.

The radiative flux itself is an integrated quantity over a predetermined hemispherical angular domain. After solving the radiative transfer equation in terms of intensity in all directions, the radiative flux is calculated. If a radiative heat transfer model based on fluxes or similar integrated quantities is developed, then the required mathematical complexity will be greatly reduced. The disadvantage of this approach is the eventual suppression of directional variations of intensity. In other words, if there are localized sinks or sources that contribute to radiative transfer, their effect cannot be predicted accurately by such an approximate model. If smaller angular divisions are employed, then the accuracy is increased.

Finally, the medium is to be discretized spatially to perform the numerical calculations. It is preferable to employ the same discretization for radiative transfer calculations as for flow and other scalar field calculations. This is a very time-consuming approach if, for example, the zonal method is used. The multiflux approximations are more useful for this type of discretization.

After this brief background, we can start discussing a logical procedure for selecting a radiative transfer model. If the physical system being considered is not large and has relatively simple geometry, and if a high degree of accuracy is required, then a very narrow discretization of angular radiation field can be chosen, and computations can be carried out by considering the RTE over each of these directions. If the medium is not scattering, then the integral term in Eq. 7.105 vanishes, and the problem becomes relatively straightforward and significantly simpler. This approach is likely to yield a highly accurate solution for radiation intensity.

To be able to take advantage of such a detailed solution scheme, one must model the radiative property variations very accurately, and the effect of temperature on these properties should be considered. Once the divergence of the radiative flux is determined, it enters into the energy equation as a source term, which affects the temperature profile in the medium directly and the concentration distributions indirectly. Since the medium properties are dependent on the temperature and concentration distributions, the radiative properties need to be updated before each iteration in a comprehensive model.

If the medium is scattering, and if the scattering phase function is not mathematically simple, then direct simulation of the radiative transfer equation becomes extremely prohibitive. There are basically two exceptions to this case. If the scattering particles are highly forward-scattering (i.e., most of the energy scattered is in the same direction as the incident beam), then the phase function may be modeled using a δ -Eddington approximation. After introducing appropriate scaling laws, the scattering is modeled with isotropic or linearly anisotropic phase functions. In this case, the problem is still tractable, although not simple. This complication is greatly reduced if the optical thickness is small (i.e., the maximum value of the integral of path-length extinction coefficient product in the medium is less than 0.1 so that a single scattering assumption can be made).

The second exception is if we are interested in the propagation of a collimated light source (i.e., a laser). In this case, since only one incident direction is to be considered, the problem can be modeled by direct simulation, even for multiple scattering media up to intermediate optical thicknesses ($\tau \approx 1$). In general, the direct simulation of the radiative transfer equation is to be chosen if a fundamental understanding of radiation-combustion or radiation-turbulence interactions is required.

If the level of accuracy required is not so high, then a Monte Carlo (MC) simulation of the radiative transfer equation can be considered. The MC technique can be effectively used for complex geometries, and it is possible to account for spectral property variations in detail. Its main drawback is the requirement for extensive computational time, which, probably, will not be an important issue in the near future.

For comprehensive modeling of combustion systems, a relatively less detailed multiframe or moment method is preferable to the statistical MC approach. For example, the S_4 discrete ordinates approximation has been successfully used by several researchers for both cylindrical and rectangular systems. The method allows the user to account for sufficient detail in spectral properties of combustion products and reasonably accurate discretization of the angular radiation field, and it is compatible with the finite difference schemes used for flow and energy equations. The S_6 approximation yields slightly better results, and its advantage is more visible if there are large temperature gradients and scattering particles in the medium. Of course, its use can be justified only if the properties are known with good accuracy. It is computationally more costly than the S_4 approximation. Because of this, an innovative strategy is to be devised to avoid computational difficulties. For example, the S_2 or S_4 approximation can be used for the initial calculations of the radiative flux distribution, and S_6 can be used only for the final iterations. This approach is likely to yield more accurate predictions with little computational penalty. For systems with uniform or fixed distributions of properties, the YIX modification of the S_N method should be considered [87–90].

On the other hand, the use of even higher-order DO approximations is not warranted given the current level of the accuracy and availability of radiative properties. In multidimensional systems, moment, spherical harmonics, and hybrid multiframe approximations usually do not yield results with the accuracy or efficiency of the DO approximations.

For nonscattering media, the zone method yields accurate results; however, it may not be directly compatible with the flow and energy equations. This problem has been solved by considering two separate finite difference schemes: one for radiation calculations and the other for flow and energy equations [118]. Another alternative is to solve the RTE using a finite difference or finite element scheme. This approach will guarantee the compatibility of the equations [103, 109]. Also worth consideration is the semistochastic model suggested by Richter [97], which is very fast for nonscattering media, and can easily be extended to account for scattering.

Solutions to Benchmark Problems

The choice of modeling method, particularly when a participating medium is present, is not yet a clear one. Each method discussed above has drawbacks as well as positive attributes. In an effort to clarify the choice of methods, the American Society of Mechanical Engineers has sponsored a series of workshops in the form of technical sessions and discussions. A particular series of problems was proposed by the workshop organizers, Professor Timothy Tong of Colorado State University and Dr. Russ Skocypec of Sandia, Albuquerque. Contributors were asked to provide solutions to the benchmark problems at the first workshop. The problems were simple geometries in one, two, and three dimensions. A participating medium was specified with given spectrally dependent anisotropic scattering properties and a given model for spectral band absorbance. (Edward's exponential wideband approximation for a given mole fraction of CO_2 in nitrogen was specified.) A temperature distribution within the medium was given, and the bounding surfaces were specified as cold and black. Researchers were asked to apply their favorite method of solution and provide the workshop with numerical values of boundary heat flux distributions and the divergence of the radiative flux at various locations within the medium.

Solutions were presented based on a generalized zonal method, three Monte Carlo solutions, a modified discrete ordinates method (the YIX method), and two specialized approaches. The conclusions noted by Tong and Skocypec [119] are that the boundary heat flux values were in better agreement than were the flux divergence values, but even the boundary fluxes varied by as much as 40 percent among investigators for two-dimensional geometries and as much as a factor of 2 for the three-dimensional geometries. The poor agreement found in this exercise has led to continued dialogue among all of those concerned. Solutions have

been reexamined and modified among many of the researchers, and the conclusions at this time are that the major methods provide good agreement (within a few percent) for two- and three-dimensional geometries for the case of a gray medium with and without anisotropic scattering, but there remain considerable differences in the solutions when spectral effects are included. It is not clear as yet why this is the case.

Recently, benchmarking attempts have been extended to more complicated L-shaped configurations [90, 120, 121, 122]. Hsu and Tan [90] have also presented comparisons between different approaches and suggested that the ray effects could be minimized by increasing the order of angular quadrature used.

There are not many exact solutions to the RTE in multidimensional enclosures. The few exceptions include those by Cheng [123] and Crosbie and Lee [124] for inhomogeneous media and Selçuk [125] and Selçuk and Tahiroglu [126] for homogeneous systems, although they are all related to “simple” geometries. Benchmarking studies against the “real” data, as those obtained from careful experiments, are still lacking!

RADIATIVE PROPERTIES FOR PARTICIPATING MEDIA

The medium that interacts with radiation may contain particles and gases which absorb and scatter the radiant energy. In combustion chambers, for example, soot, char, fly-ash, coal particles and spray droplets affect the propagation of radiant energy. Among various gases, carbon dioxide and water vapor are the major participants to radiative transfer, both in combustion chambers and in the atmosphere.

In this section, we will give a short review for the radiative properties of gases and then present some easy-to-use formulations.

Radiative Properties of Gases

If an electromagnetic wave is incident on a gas cloud, it interacts with the individual molecules. This interaction can be considered as a radiative transition and results in a change of energy level in each molecule. If the molecule absorbs the energy from the EM wave, there may be a transition between the nondissociated molecular states (bound-bound transition), between the nondissociated and dissociated states (bound-free transition), or within the dissociated states. For most radiative heat transfer applications, the energy level of interest is such that, when the EM wave is incident on a molecule, it results in a bound-bound transition, if any. According to quantum mechanics, this means that, for an EM wave being absorbed by a molecule, it has to have just the right amount of energy to raise the molecular energy state to higher levels.

It is also possible to consider this transition as the absorption of a photon (energy quantum). The energy of a photon is expressed as $E = h\nu$, where h is the Planck constant and ν is the frequency of the wave, which is related to the wavelength via the speed of light: $c = c_o/n = \nu\lambda = \nu\lambda_o/n = \nu/\eta$. Here, subscript o is used to denote the vacuum, and n is the real part of the complex index of refraction of the medium. It is obvious that a molecule can absorb the energy in discrete amounts of $h\nu$ or hc/λ , which results in a bound-bound transition. This suggests that, if a beam of radiation spanning a wavelength interval is incident on a gas cloud, it will lose its energy at certain wavelengths but will not be affected at others.

For most gas molecules, there are several hundreds, even thousands, of possible molecular energy states. Therefore, one expects to find a large number of wavelengths at which the molecules absorb the incident energy, which makes the prediction of gas absorption a very difficult problem. Additionally, each of these absorption wavelengths can be broadened because of pressure and temperature as well as the uncertainty principle of Heisenberg. It is obvious that exact consideration of all these active frequencies/wavelengths may not be

desirable for most engineering applications, although it will be within the realm of possibility with increasing availability of high-speed, large-memory computers.

Even though most of the discussion given above refers only to gas absorption, it can be readily extended to emission. It should be understood, however, that the emission is related to the gas temperature, whereas absorption depends on both gas temperature and the temperature of the source.

Line Radiation. As briefly mentioned under ideal conditions above, a molecule absorbs or emits radiation at a fixed wavelength. Then, the change in the energy of the beam incident along path s within the gas cloud is written as (Eq. 7.105 with scattering neglected):

$$\frac{dI_\eta}{ds} = \kappa_\eta(I_{b\eta} - I_\eta) \quad (7.147)$$

where I_η is the spectral radiation intensity and η ($=1/\lambda$) is the wavenumber (usually expressed in units of cm^{-1}). The absorption coefficient κ_η is equal to the emission coefficient based on Kirchhoff's law.

The absorption and emission by gas molecules are realized not at a single frequency but over a very narrow band of frequencies. The reason for this is mainly the change in the energy level of molecular states due to molecular collisions, temperature, pressure, or relative motion of molecules with respect to the beam of radiation. The result is the broadening of absorption/emission lines; the most well known are the collision, natural line, and Doppler broadenings. The shape of these narrow spectral lines is exponential, peaked at the center, with rapid decay away from the center frequency. The corresponding line width is in the order of $d\eta = 0.05 \text{ cm}^{-1}$. Here, $\eta = 1/\lambda$ is the wavenumber corresponding to the wavelength λ ; the unit cm^{-1} is read as "wavenumbers." For example, at wavelength of $\lambda = 1 \text{ }\mu\text{m}$, $\eta = 10,000 \text{ cm}^{-1}$, and for $d\eta = 0.05 \text{ cm}^{-1}$, $d\lambda = -d\eta/\eta^2 = 0.001 \text{ }\mu\text{m}$.

The shape and width of each absorption line are functions of temperature and pressure of the medium. The Lorentz profile is usually used to define the shape of these lines at moderate temperatures under local thermodynamic equilibrium conditions. Although other profiles, such as Doppler or Stark profiles, can also be used to define the line shapes, the Lorentz profile, which adequately describes collision-broadened lines, is more appropriate for most applications, including those in combustion systems. For more details, the reader is referred to Siegel and Howell [1] or Modest [3].

Narrowband Models. Given that detailed spectral calculations with wavelength resolution on the order of $10^{-3} \text{ }\mu\text{m}$ is neither computationally efficient nor justifiable for many engineering applications, it is better to develop more affordable models. A close look at the broadened absorption lines depicts that several of them are positioned very close to each other and may overlap, especially for the vibration-rotation transitions of diatomic and polyatomic molecules. The absorption coefficients of individual lines can be added to find the absorption coefficient of the narrowband:

$$\kappa_\eta = \sum_j \kappa_{\eta j} \quad (7.148)$$

Two of the best-known models used for this purpose are the Elsasser and the statistical Goody models, both of which employ the Lorentz profile for description of individual line shapes. These models give very accurate predictions over a bandwidth of approximately 50 cm^{-1} , which is considered narrow for most practical purposes. (At $\lambda = 1 \text{ }\mu\text{m}$, this bandwidth translates to about $\Delta\lambda = 0.05 \text{ }\mu\text{m}$.) Because of this, the model is called the *narrowband model*. Although this technique is significantly simpler than the line-by-line models, it still requires an extensive database about the species considered and significant computational effort. Such a detailed model can be considered useful only if the species concentration distribution is known very accurately, which is usually not the case.

Detailed discussions of narrowband models were given by Tien [127], Ludwig et al. [128], Edwards [129], and Tiwari [130]. The discussion of these approaches can also be found in standard texts [1, 2, 3].

Wideband Models. The narrowband models introduce significant simplification over the line-by-line calculations; however, the accurate predictions depend not only on the rigor of the model but also on the accuracy of input data, such as the local temperature, the temperature profile, the partial pressures of the radiating gases, and so on. In most practical systems, these data are not available with good accuracy. This suggests that even simpler approximations may be more appropriate for calculation of gas properties in practical systems.

Water vapor, carbon dioxide, and carbon monoxide are the most important contributors to nonluminous radiation in combustion systems. They are the byproducts of any hydrocarbon combustion and absorb and emit radiation selectively only at certain wavelengths. Although there are other gases such as NO_x and SO_2 present in the combustion products, their partial pressures are very small, and their contributions can be safely neglected in radiative transfer predictions. Among these, SO_2 is more important, as it has usually an order of magnitude higher concentration in large-scale furnaces than that of NO . The emissivity of SO_2 is about the same order of magnitude as the H_2O , and, therefore, it is possible to account for the SO_2 contribution easily by adding its partial pressure to that of H_2O and considering only the CO_2 and H_2O contributions in the calculations [131].

For combustion gases such as water vapor, carbon dioxide, and carbon monoxide, the number of wavelength ranges important for thermal radiation calculations is not excessive. Figure 7.21 shows the important absorption bands of the CO_2 and H_2O gases at two different temperatures [132]. For H_2O , there are four important widebands centered at wavelengths of 1.38, 1.84, 2.7, and 6.3 μm . For CO_2 , there are bands at 2.7 and 4.3 μm , and, for CO , there is one band centered at 4.4 μm . The width of each of these so-called widebands is an adjustable parameter that is determined by assuming the absorption and emission of radiation in the wideband is equal to the effective absorption and emission of several narrowbands present within the band. Therefore, the shape of the band chosen determines the width.

Edwards and his coworkers first developed basic concepts of wideband models (see Ref. 129). There are different variations of the model, such as the box or exponential wideband models. The underlying idea in these approaches is to represent the gas absorption over a relatively wide spectral band (about 0.1 to 0.5 μm) with a simple function. If this function is an exponential, the resulting model is called as the *exponential wideband model* [129, 133], which is the most well-known and successful of all different models. It is possible to simplify this even further by assuming absorption remains constant over a prescribed wavelength interval. This yields the box model, which is not as good as the former one, as expected.

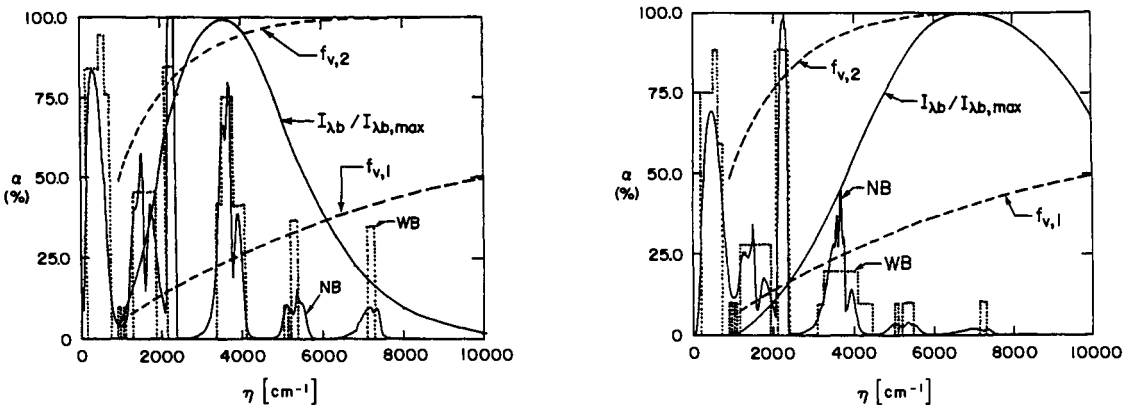

FIGURE 7.21 The important absorption/emission bands of combustion gases at different temperatures [132].

In this section, we will outline the formulation of the Edwards-Menard model, as it can be readily used for different applications.

Formulation of the Exponential Wideband Models. In exponential wideband models, the band strength parameter, or an integrated absorption coefficient of a given wideband, is defined as:

$$\alpha \equiv \int_0^{\infty} \kappa_{\eta} d\eta \quad (7.149)$$

where κ_{η} is the spectral absorption coefficient, based on either line-by-line calculations or narrowband models. Note that the integration is evaluated from 0 to ∞ , even though the band itself is finite in size. The Edwards-Menard model assumes an exponentially decaying function for the smoothed absorption coefficient (sometimes written as $\bar{\kappa}_{\eta} = (S/d)_{\eta}$, where S and d are parameters defined similar to those used for individual absorption lines).

The exponential wideband model assumes that for a symmetric band, $\bar{\kappa}_{\eta}$ is given as:

$$\bar{\kappa}_{\eta} = \frac{\alpha}{\omega} e^{-f(\eta)/\omega} = \frac{\alpha}{\omega} e^{-2|\eta_c - \eta|/\omega} \quad (7.150)$$

where α is defined by Eq. (149) and ω is the so-called bandwidth parameter, which is the width of the band at $1/e$ of the maximum intensity. Most of the absorption bands of the gases of engineering interest are symmetric, and the corresponding η_c wavenumbers are listed in Table 7.8 (adapted from Ref. 3). If the bands are not symmetric, the $f(\eta)$ function is slightly modified to represent a cut band shape, which simulates the real profile more accurately. Then, either an upper limit η_u or lower limit η_l is used, and $f(\eta)$ is defined as $(\eta_u - \eta)$ or $(\eta - \eta_l)$. Note that, for only a few bands (η_u or η_l), values are reported in Table 7.9. (Even though these correlations were developed more than three decades ago, they are still the most convenient and accurate of all wideband model expressions, see Refs. 1 and 3 for details.)

The total band absorption is defined as

$$A \equiv \int_{\text{band}} \epsilon_{\eta} d\eta = \int_0^{\infty} (1 - e^{-\kappa_{\eta}x}) d\eta \quad (7.151)$$

with x being the path length. The normalized total band absorbance is:

$$A^* = A/\omega = A^*(\alpha, \beta, \tau_0) \quad (7.152)$$

Here, $\tau_0 = \kappa_{\eta_c}x$ is the optical thickness at the band center. Table 7.8 lists all the exponential wideband model correlations as derived by Edwards and Menard for an isothermal gas. They are calculated using the equations given below:

$$\alpha(T) = \alpha_0 \frac{\Psi^*(T)}{\Psi^*(T_0)} = \alpha_0 \frac{\left[1 - \exp\left(-\sum_{k=1}^m u_k \delta_k\right)\right] \Psi(T)}{\left[1 - \exp\left(-\sum_{k=1}^m u_{0,k} \delta_k\right)\right] \Psi(T_0)} \quad (7.153)$$

$$\beta(t) = \gamma P_e = \gamma_0 \sqrt{\frac{T_0}{T}} \frac{\Phi(T)}{\Phi(T_0)} P_e \quad (7.154)$$

$$\omega(T) = \omega_0 \sqrt{T/T_0} \quad (7.155)$$

where

$$\Psi(T) = \frac{\prod_{k=1}^m \sum_{\nu_k=\nu_{0,k}}^{\infty} [(v_k + g_k + \delta_k - 1)/(g_k - 1)! \nu_k!]}{\prod_{k=1}^m \sum_{\nu_k=0}^{\infty} [(v_k + g_k - 1)/(g_k - 1)! \nu_k!]} e^{-u_k \nu_k} \quad (7.156)$$

TABLE 7.8 Exponential Wide Band Correlations for an Isothermal Gas [133]

$\beta \leq 1$	$0 \leq \tau_0 \leq \beta$	$A^* = \tau_0$	Linear regime
	$\beta \leq \tau_0 \leq 1/\beta$	$A^* = 2\sqrt{\tau_0\beta} - \beta$	Square root regime
	$1/\beta \leq \tau_0 \leq \infty$	$A^* = \ln(\tau_0\beta) + 2 - \beta$	Logarithmic regime
$\beta \geq 1$	$0 \leq \tau_0 \leq 1$	$A^* = \tau_0$	Linear regime
	$1 \leq \tau_0 \leq \infty$	$A^* = \ln(\tau_0) + 1$	Logarithmic regime

* For the rotational band $\alpha = \alpha_0 \exp(-9\sqrt{T_0/T})$, $\gamma = \gamma_0 \sqrt{T_0/T}$.

† Combination of three bands, all but weak (0,2,0) band are fundamental bands, $\alpha_0 = 25.9 \text{ cm}^{-1}$.

‡ Line overlap for overlapping bands from Eqs. (7.163, 7.164).

§ $B = 8.6\sqrt{T_0/T}$.

$$\Phi(T) = \frac{\left[\prod_{k=1}^m \sum_{\nu_k = \nu_{0,k}}^{\infty} \frac{[(\nu_k + g_k + \delta_k - 1)! / (g_k - 1)! \nu_k!]}{e^{-u_k \nu_k}} \right]^{1/2}}{\prod_{k=1}^m \sum_{\nu_k = \nu_{0,k}}^{\infty} \frac{[(\nu_k + g_k + \delta_k - 1)! / (g_k - 1)! \nu_k!]}{e^{-u_k \nu_k}}} \quad (7.157)$$

and

$$u_k = hc\eta_k/kT, \quad u_{0,k} = hc\eta_k/kT_0 \quad (7.158)$$

where $T_0 = 100$ K.

$$\nu_{0,k} = \begin{cases} 0 & \text{for } \delta_k \geq 0 \\ |\delta_k| & \text{for } \delta_k \leq 0 \end{cases} \quad (7.159)$$

$$P_e = \left[\frac{p}{p_0} \left(1 + (b-1) \frac{p_a}{p} \right) \right]^n, \quad (p_0 = 1 \text{ atm}) \quad (7.160)$$

The parameters required for these calculations are listed in Table 7.9 for six common gases. Here, ν_k is the vibrational quantum number, δ_k is the change in ν_k during transition, and g_k is the statistical weight for the corresponding transition. Most of the absorption bands of the gases given in Table 7.9 have nonnegative δ_k values, and, for most, $\nu_{0,k}$ is zero. Under these conditions, the denominator of Eq. 7.157 for Φ , which is identical to the numerator of Eq. 7.156 for Ψ , becomes:

$$\sum_{\nu_k=0}^{\infty} \frac{(\nu_k + g_k + \delta_k - 1)!}{(g_k - 1)!} e^{-u_k \nu_k} = \frac{(g_k + \delta_k - 1)!}{(g_k - 1)!} (1 - e^{-u_k})^{-g_k - \delta_k} \quad (7.161)$$

If the values for $\nu_{0,k}$ are not zero, corresponding values should be subtracted from the above expression [3].

The reference values $\Psi(T_0) = \Psi_0$ and $\Phi(T_0) = \Phi_0$ are obtained at a very low temperature of $T_0 = 100$ K:

$$\Psi_0 \approx \prod_{k=1}^m \frac{(g_k + \delta_k - 1)!}{(g_k - 1)!}, \quad \Phi_0 \approx 1 \quad (7.162)$$

Note that the Ψ and Φ expressions given in Eqs. 7.156 and 7.157 have infinite-summation terms. Recently, Lallemand and Weber [134] suggested a simplified formulation based on polynomial expression of the Φ functions, which reduces the required computational time significantly.

Sometimes, the absorption bands of different species overlap. For these cases, the band parameters are calculated as:

$$\alpha = \sum_{j=1}^J \alpha_j \quad (7.163)$$

$$\beta = \frac{1}{\alpha} \left[\sum_{j=1}^J \sqrt{\alpha_j \beta_j} \right]^2 \quad (7.164)$$

where J is the number of overlapping bands.

Felske and Tien [135] presented a relatively simple correlation for the band absorption A^* as:

$$A^* = 2E_1 \left(\sqrt{\frac{\tau_0 \beta}{1 + \beta/\tau_0}} \right) + E_1 \left(\frac{1}{2} \sqrt{\frac{\tau_0/\beta}{1 + \beta/\tau_0}} \right) - E_1 \left(\frac{1 + 2\beta}{2} \sqrt{\frac{\tau_0/\beta}{1 + \beta/\tau_0}} \right) + \ln \left(\frac{\tau_0}{(1 + \beta/\tau_0)(1 + 2\beta)} \right) + 2\gamma_E \quad (7.165)$$

where E_1 is the exponential integral function and $\gamma_E = 0.57221 \dots$ is the Euler constant [136].

Nonisothermal Gases. The spectral emissivity for a nonisothermal path within a gas cloud is expressed as:

$$\varepsilon_\eta = 1 - \exp\left(-\int_0^X \kappa_\eta dX\right) \quad (7.166)$$

Using this expression, the total band absorptance can be determined:

$$A = \int_0^\infty \varepsilon_\eta d\eta = \int_0^\infty \left[1 - \exp\left(-\int_0^X \kappa_\eta dX\right)\right] d\eta \quad (7.167)$$

If a simple wideband model is going to be used, the path-averaged values of α , β , and ω are needed. The correlations for these values were listed in Refs. 129 and 137. If a weak line limit is considered, the following simple relations yield acceptable accuracy in predictions [137]:

$$\bar{\alpha} \equiv \frac{1}{X} \int_0^X \int_0^\infty \kappa_\eta d\eta dX = \frac{1}{X} \int_0^X \alpha dX \quad (7.168)$$

$$\bar{\omega} \equiv \frac{1}{\bar{\alpha}X} \int_0^X \omega \alpha dX \quad (7.169)$$

$$\bar{\beta} \equiv \frac{1}{\bar{\omega}\bar{\alpha}X} \int_0^X \beta \omega \alpha dX \quad (7.170)$$

Total Emissivity and Absorptivity Models. For many engineering applications, spectrally integrated gas emission and absorption are needed. The total emissivity is defined as the ratio of the total radiation emitted from a path of length X to the maximum possible emission:

$$\begin{aligned} \varepsilon &\equiv \frac{\int_0^\infty I_{b\eta} \varepsilon_\eta d\eta}{\int_0^\infty I_{b\eta} d\eta} = \frac{\int_0^\infty I_{b\eta} (1 - e^{-\kappa_\eta X}) d\eta}{\int_0^\infty I_{b\eta} d\eta} \\ &= \sum_{i=1}^N \left(\frac{\pi I_{b\eta 0}}{\sigma T^4} \right)_i \int_{\Delta\eta_{\text{band}}} (1 - e^{-\kappa_\eta X}) d\eta = \sum_{i=1}^N \left(\frac{\pi I_{b\eta 0}}{\sigma T^4} \right)_i A_i \end{aligned} \quad (7.171)$$

The last expression can be easily calculated using the data supplied before. In the derivation of this expression, there are two implicit assumptions: (1) the spectral wideband is still very narrow, such that the Planck blackbody emission does not vary over the spectral interval of the band; and (2) there are no overlapping bands. Even though the first assumption is easy to justify, the second is not. For example, at about $\lambda = 2.7 \mu\text{m}$, both H_2O and CO_2 have strong absorption bands, which contribute significantly to their emission. For completely overlapped bands, the total emissivity is expressed as:

$$\varepsilon_{a+b} = \varepsilon_a + \varepsilon_b - \varepsilon_a \varepsilon_b \quad (7.172)$$

If the bands overlap only partially, the calculations become more cumbersome and will not be given here (see Refs. 1 and 3 for further discussion).

Most textbooks present the total emissivity and absorptivity in charts, an approach first introduced by Hottel [35]. These charts are based on the following expressions:

$$\varepsilon = \varepsilon(p_a L, p, T_g) \quad (7.173)$$

$$\alpha = \alpha(p_a L, p, T_g, T_s) \approx \left(\frac{T_g}{T_s} \right)^{1/2} \varepsilon\left(p_a L \frac{T_g}{T_s}, p, T_s\right) \quad (7.174)$$

where T_g is the gas temperature and T_s is the temperature of the source (for absorption calculations).

Figures 7.22 and 7.23 depict the gas emissivity ϵ for H_2O and CO_2 , the most common combustion gases. These values are valid for individual gases and mixtures with a total pressure of 1 atm. If the pressure is higher and/or if both H_2O and CO_2 are present, then the total emissivity is to be corrected according to the relation:

$$\epsilon_{\text{total}} = C_{\text{H}_2\text{O}}\epsilon_{\text{H}_2\text{O}} + C_{\text{CO}_2}\epsilon_{\text{CO}_2} - \Delta\epsilon \quad (7.175)$$

Figure 7.24 shows the correction factor $\Delta\epsilon$ for the overlap of CO_2 and H_2O bands for different pressures and path lengths.

Absorption Coefficient Based Gas Properties. In the gas models discussed above, the final product is the band absorbance and total emissivity or absorptivity. For most radiative transfer models, however, the absorption coefficient is the desired input. For this purpose, either polynomial expressions or the weighted-sum-of-gray-gases (WSGG) models are developed, which are usually based on the pseudo absorption coefficient concept [35]:

$$\epsilon = \sum_{i=0}^I b_{\epsilon,i} \{1 - e^{-K_i p_i L}\} \quad (7.176)$$

where $b_{\epsilon,i}$ and K_i are the parameters used to fit this polynomial to radiative properties predicted by the narrow or wideband models, and they are usually functions of pressure and temperature. Here L is the physical length of the gas cloud and p_i is the partial pressure of the i th species. It is obvious that K_i , by definition, is similar to the absorption coefficient. This suggests that the RTE can be solved N times for different values of the K_i using any standard formulation, such as the DO, SH, or MC techniques. Note that if $i = 0$, $b_{\epsilon,i}$ is also set to zero to account for the transparent window of the wavelength range.

Polynomial gas property models [139, 140, 141] as well as the weighted-sum-of-gray-gas models [142–155] have been studied extensively. All of these models are for predicting the gas radiation along a homogeneous line of sight (i.e., constant pressure and temperature).

One of the most elaborate of these approaches is that developed by Denison and Webb [147–153]. Instead of fitting the parameters of the WSGG model to the total emissivity data (as done for all other models), they used the high resolution transmission molecular absorption database of Rothman et al. [156]. By doing so, they replaced the spectral integration over wavenumber by a quadrature over an absorption cross section. Their approach is also known as the correlated k -distribution method.

Detailed comparison of different WSGG models are available in the literature. Spectral calculations in a medium with homogeneous absorption coefficient profile are given by Modest [146]. Song [157] compared the WSGG model predictions against wideband model results in a planar medium. Denison and Webb [147, 148] evaluated their model against the detailed line-by-line calculations for water-vapor in planar media. Comparisons of WSGG against a statistical narrowband model were given for both planar and axisymmetric combustion chambers by Soufiani and Djavdan [158]. Pierrot et al. [159] presented detailed comparisons for a planar medium containing an H_2O - N_2 mixture. Their results indicated that WSGG models are very time-efficient yet may yield inaccurate predictions. The most significant weakness of these models is realized if there is a large difference between the temperatures of the radiation source and the absorbing gases. Also, if particle and wall properties considered are not gray, the model becomes quite cumbersome. Several different WSGG models need to be used at different wavelength intervals over the spectrum, as the model properties lose their universality [159].

Tang and Brewster [160] used the correlated k -distribution method proposed in [161] to account for nongray gas contribution when absorbing, emitting, and anisotropically scattering particles are present. They obtained very good accuracy, and showed that this approach is compatible with the discrete ordinates and Monte Carlo techniques. Marin and Buckius [162] also used a correlated- k distribution method based on wideband formulation for absorbing, emitting, and scattering media and reported reasonable accuracy.

In a recent study, Lallemand and Weber [134] compared the performance of various WSGG models with their simplified exponential wideband model. These results indicate that,

FIGURE 7.22 (a) Total emissivity ϵ_{H_2O} for water vapor as a function of T_{gas} and $p_{H_2O} L_e$ product; (b) the corresponding correction factor C_{H_2O} for different total pressures.

(a)

(b)

FIGURE 7.23 Total emissivity ϵ_{CO_2} for carbon dioxide as a function of T_{gas} and $p_{CO_2} L_e$ product; (b) the corresponding correction factor C_{CO_2} for different total pressures.

FIGURE 7.24 $\Delta\epsilon$ band overlap correction factors for water vapor and carbon dioxide total emissivities (see Eq. 7.175). (a) $T_{\text{gas}} = 400 \text{ K}$ (720 R); (b) $T_{\text{gas}} = 810 \text{ K}$ (1460 R); (c) $T_{\text{gas}} \geq 1200 \text{ K}$ (2160 R).

after the introduction of suggested modifications, the model given in Ref. 134 yields more accurate results, although it requires slightly more CPU time.

For most combustion chamber applications, pressure, temperature, and concentration along the line of sight of radiation do change. Under these circumstances, one should exercise care in using total emissivity and absorptivity models. For inhomogeneous paths, either the equivalent line model [163, 164] or total transmittance nonhomogeneous method [165] can be used. These models are quite complicated and computer-intensive and can therefore be efficiently used only for simple systems (such as the interpretation of results obtained from optical diagnostic techniques) rather than for multidimensional systems. Also, they can be coupled with particle properties, as suggested by Grosshandler and Modak [166].

Denison and Webb [150, 151] applied the spectral line WSGG (SLW) model to inhomogeneous paths. They reported that, compared to line-by-line calculations, the SLW model was off about 15 to 20 percent; yet, the computational savings were significant. Another simple and effective model was developed by Parthasarathy et al. [154] and applied to different media with both uniform and nonuniform temperature profiles.

Planck and Rosseland Mean Absorption Coefficients. Two of the most common *mean absorption* coefficient expressions are the Planck and Rosseland coefficients, κ_p and κ_R , respectively, which are defined as [1, 3, 34]:

$$\kappa_p = \frac{\int_0^\infty I_{b\eta} \kappa_\eta d\eta}{\int_0^\infty I_{b\eta} d\eta} = \frac{\pi}{\sigma T^4} \int_0^\infty I_{b\eta} \kappa_\eta d\eta = \sum_{i=1}^N \left(\frac{\pi I_{b\eta 0}}{\sigma T^4} \right)_i \alpha_i \quad (7.177)$$

$$\frac{1}{\kappa_R} = \frac{\int_0^\infty (1/\kappa_\eta)(dI_{b\eta}/dT) d\eta}{\int_0^\infty (dI_{b\eta}/dT) d\eta} = \frac{\pi}{4\sigma T^3} \int_0^\infty \frac{1}{\kappa_\eta} \frac{dI_{b\eta}}{dT} d\eta \quad (7.178)$$

Note that these coefficients are obtained over the entire wavelength range; therefore, the spectral details are lost. For practical applications where the spectral structure of radiation field is important, the use of these mean coefficients is not recommended. The Planck coefficient yields acceptable results if the medium optical thickness is small (less than unity), whereas the Rosseland coefficient is more useful at large optical thicknesses (i.e., larger than five over the entire spectrum).

Radiative Properties of Particulates

In many engineering applications, the radiative properties of particles are much more important than those of combustion gases because particles absorb, emit, and scatter radiation continuously across the entire wavelength spectrum. By contrast, combustion gases participate radiatively only in narrow bands centered around discrete wavelengths. The radiative properties required for typical radiative transfer calculations are absorption and scattering coefficients and scattering phase function. These properties are dependent on the partial pressures and chemical composition of combustion gases, material and physical structure of the particles, particle size and volume fraction distributions in the medium, and the wavelength of radiation.

The material structure of the particulate matter determines its complex index of refraction, which is considered to be the most fundamental property. The real part of the complex refractive index is the ratio of the speed of light in vacuum to that within the particle for light at normal incidence. In this case, the imaginary part, which is also termed the attenuation, extinction, or absorption index, is directly related to the rate of attenuation of radiation with depth within the material. For other than normal incidence, the relations between the complex index of refraction, speed of light, and attenuation within the particle are complicated and require rigorous solution of the electromagnetic (EM) wave equations (i.e., Maxwell's equations) within the medium of interest with appropriate boundary conditions.

As one may expect, if the shape of the particle is simple (i.e., mathematically tractable), then the solution to the problem can be obtained relatively easily. An analytical solution to the propagation of electromagnetic waves in spherical particles was first given by Lorenz in 1890 and Mie in 1903 (see Ref. 167 for historical discussion and Refs. 167 and 168 for the detailed formulations). The theory, which is widely referred to as the Lorenz-Mie theory, is used to determine how the incident wave is absorbed and scattered by a homogeneous spherical obstacle, provided that the diameter of the sphere, the wavelength of the incident electromagnetic wave, and the complex index of refraction of particle and surroundings are available. For spherical particles, there is a natural scaling factor:

$$x = \pi D/\lambda \quad (7.179)$$

which is called the *size parameter*. Two particles of different sizes but with the same refractive index absorb and scatter the EM wave similarly, if they have the same size parameter (i.e., if the ratio of their diameter to the wavelength of the incident radiation is the same).

The Lorenz-Mie theory yields information about the absorption and scattering of an incident EM wave by an isolated single spherical particle. It predicts the rate at which the energy is absorbed and scattered by the particle as a function of its complex index of refraction. The ratio of this rate to the incident irradiance gives the absorption and scattering cross sections, C_{abs} and C_{sca} , respectively. These cross sections have the units of area, and indicate the size of an imaginary surface which extracts the same amount of energy from the incident beam. It is preferable to express these parameters in dimensionless form. If we consider the ratio of the absorption/scattering cross section to the geometric area cross section of a particle, we obtain the efficiency factors:

$$Q_{\text{abs}} = \frac{C_{\text{abs}}}{\pi D^2/4}; \quad Q_{\text{sca}} = \frac{C_{\text{sca}}}{\pi D^2/4} \quad (7.180)$$

and

$$Q_{\text{ext}} = Q_{\text{abs}} + Q_{\text{sca}} \quad (7.181)$$

The extinction efficiency factor Q_{ext} approaches a constant asymptotic value of 2 with increasing size parameter. It means that a large particle attenuates (absorbs and scatters) twice as much energy from an incident beam as characterized by its own geometric area. The additional attenuation is because of diffraction of the EM waves by the particle. This phenomenon

is known as the *extinction paradox*. Note that, at the large particle limit, the values of Q_{abs} and Q_{sca} are not necessarily equal to 1 (i.e., one half of the value of Q_{ext}); rather, their asymptotic limits are dependent on their complex index of refraction.

The volumetric absorption, scattering, and extinction coefficients of polydispersions are related to efficiency factors as

$$\eta_\lambda = \int_0^\infty Q_{\eta_\lambda} \frac{\pi D^2}{4} dN(D) \quad (7.182)$$

where η_λ is either κ_λ , σ_λ , or β_λ , Q_{η_λ} is the corresponding spectral efficiency factor Q_{abs} , Q_{sca} , or Q_{ext} ; and $dN(D)$ is the particle size distribution (number of particles of diameter D per unit volume).

Wiscombe and Mugnai [169] showed that differences exist in the scattering properties of irregularly shaped particles when compared to the Lorenz-Mie theory calculations. For irregularly shaped particles, the oscillations in the efficiency factors versus size parameter are damped out, and more side-scattering and less back-scattering are observed. The agreement with the Lorenz-Mie theory calculations becomes worse for radiative properties as the size parameter increases past $x = \pi D/\lambda = 5$. It is stated that the spherical shape is a singularity in nature rather than a norm, and using a single effective diameter may yield erroneous results in radiative property predictions [170].

Analytical expressions similar to those for spherical particles have been derived for infinite-length cylinders in perpendicular incidence as well as in oblique incidence, for elliptic cylinders, and for spheroids (see Refs. 168 and 169). With increasing complexity of the shape of the particle, even with as little change as from sphere to spheroid, the analytical solution to the problem becomes formidable. Then, the use of numerical solution techniques may be preferable to analytical techniques.

The numerical techniques used to determine the particle absorption and scattering characteristics can be divided into two subgroups [169]: (1) integral equation methods and (2) differential equation approaches. Integral equation methods use Green's functions in the formulation of the vector in the Helmholtz equations, and the boundary conditions between the obstacle and the surrounding medium are accounted for directly in the formulation. The extended boundary condition method (EBCM) which is also known as the T-matrix method is the most successful integral equation method [169, 170, 171]; a recent detailed review is available in the literature [171]. Differential equation methods, on the other hand, were developed employing finite element methods and can be extended to inhomogeneous obstacles. They are simpler in concept compared to integral equation methods; however, they require significantly more computational time.

Another method was suggested by Purcell and Pennypacker [172]. They replaced the scattering obstacle by a cubic array of point dipoles spaced no farther than $\lambda/4\pi$ apart and considered mutual dipole-dipole interactions exactly. This technique provides a highly general prediction of scattering cross sections of irregularly shaped and nonhomogeneous particles. Later extensions of this approach were given by Draine [173]. Currently, the only drawback of this technique appears to be the maximum size parameter that can be considered; because of convergence problems, results obtained are not reliable beyond $\pi D/\lambda \geq 4$. A recent review of these techniques has been given by Manickavasagam and Mengüç [174].

Although most particles in combustion chambers are nonspherical, because of large uncertainties in particle shape and material structure (which affects the complex index of refraction), the use of more sophisticated models to determine particle radiative properties is not always warranted. There are special applications where the exact shape and composition of the particle may be very critical to the understanding of the physical phenomena. For example, it is important to know the soot agglomerate structure to determine the soot formation mechanism in flames using laser/light diagnostics. Also important is the effect of pores and material inhomogeneity in pulverized coal particles on the radiation-combustion interaction. In other words, particle shape and structure are very critical in understanding the

microscale phenomena being observed in flames; however, for predicting the average radiative properties for radiative heat transfer calculations, the use of simpler models may be sufficient.

Simple engineering models for coal/char particles were suggested by Buckius and Hwang [175], Viskanta et al. [176], and Mengüç and Viskanta [177]. In Ref. 175, the coal/char radiative properties were calculated from the Lorenz-Mie theory for different size distributions and complex index of refraction values, and then a curve-fitting technique was employed to obtain simple engineering equations. It was shown that these “empirical” equations are valid for a wide variety of size distributions. The same conclusion was also drawn in Ref. 177, where analytical expressions were developed starting from anomalous diffraction theory. More recently, Im and Ahluwalia [178] and Kim et al. [179] presented a series of approximations for pulverized-coal and particulate-gas mixtures. Any of these models can be easily incorporated into complicated global computer algorithms.

Skocypec and Buckius [180, 181] presented an analytical formulation to obtain the radiation heat transfer from a mixture of combustion gases and scattering particles. They considered band models for the gases and accounted for the absorption and scattering by particles. They developed charts similar to Hottel charts for combustion gases. The results presented can be used to obtain the average radiative properties if the particle loading information is not known accurately. (See also Refs. 182–184 for a discussion on the limits of this formulation.)

In the following sections, we will present simple techniques to calculate the optical/radiative properties of soot, fly ash, and coal/char particles. Also, the necessary physical parameters will be summarized.

Soot Particles/Agglomerates. Soot is one of the most important contributors to radiative transfer in combustion chambers. It is formed during the combustion of almost all hydrocarbons, and in combustion chambers it exists almost everywhere. Unlike combustion gases such as H₂O or CO₂, which absorb and emit only at certain wavelengths, soot participates in radiative transfer at all wavelengths. Therefore, the radiant energy emitted from a sooty flame is significantly more than, for example, a clean-burning natural gas flame. Although this can be considered as an advantage, having unburned carbon particles emitted in the exhaust is a major drawback. In order to predict the contribution of soot to overall radiative transfer phenomena in combustion chambers, one must know the soot shape, size, size distribution, and optical properties.

In a combustion chamber, soot volume fraction or number densities are usually not known. It is generally accepted that the primary soot particles are spherical in shape and about 20–60 nm in diameter (see the review by Charalampopoulos [185]). However, depending on the flow and combustion characteristics of the system, they agglomerate to form irregularly shaped large particles. The shape can be clusters of spheres or cylindrical long tails attached to burning coal particles.

If the agglomeration is not considered, calculation of required radiative properties of soot particles will be straightforward. Since the size of an individual soot sphere is much smaller than the wavelength of radiation, the Rayleigh limit (for small $x = \pi D/\lambda$) to the Lorenz-Mie theory can be used. Then, the soot absorption and scattering efficiency factors are given as

$$Q_{\text{abs, Rayleigh}} = 12x \frac{N_1}{M_1} = x \left\{ \frac{24n_\lambda k_\lambda}{(n_\lambda^2 - k_\lambda^2 + 2)^2 + 4n_\lambda^2 k_\lambda^2} \right\} \quad (7.183)$$

$$Q_{\text{sca, Rayleigh}} = \frac{8}{3} x^4 \left(1 - 3 \frac{M_2}{M_1} \right) \quad (7.184)$$

where

$$M_1 = |2 + m^2|^2 = N_1^2 + (2 + N_2)^2 \quad M_2 = 1 + 2N_2$$

$$N_1 = 2nk \equiv -I(m^2) \quad N_2 = n^2 - k^2 \equiv R(m^2) \quad (7.185)$$

Selamet and Arpaci [186, 187] have investigated the accuracy of the Rayleigh approximation for soot particles and proposed a simple extension based on the Penndorf approximation. According to their study, for larger particles, the extinction efficiency should be modified to:

$$Q_{\text{ext}} = Q_{\text{abs, Rayleigh}} + 2x^3 \left[N_1 \left(\frac{1}{15} + \frac{5}{3} \frac{1}{M_4} + \frac{6}{5} \frac{M_5}{M_1^2} \right) + \frac{4}{3} \frac{M_6}{M_1^2} x \right] \quad (7.186)$$

where

$$\begin{aligned} M_4 &= 4N_1^2 + (3 + 2N_2)^2 & M_5 &= 4(N_2 - 5) + 7N_3 \\ M_6 &= (N_2 + N_3 - 2)^2 - 9N_1^2 & N_3 &= (n^2 + k^2)^2 = N_1^2 + N_2^2 \end{aligned} \quad (7.187)$$

These equations can be used up to size parameter of $x = 0.8$ for soot index of refraction range of $1.5 \leq n \leq 4.0$ and $0.5 \leq k \leq 3.0$ with acceptable accuracy [187].

The soot absorption coefficient is calculated from Eq. 7.182, which can be simplified further for a monodisperse particle cloud as:

$$\kappa_\lambda = Q_{\text{abs}} N A_c = \frac{3Q_{\text{abs}} f_v}{2D} \quad (7.188)$$

where A_c is the particle cross sectional area and f_v is the volume fraction of soot particles in the medium.

For modeling soot radiation, a very simple engineering equation was suggested by Hottel and Sarofim [35] in the form of:

$$\kappa_\lambda = K f_v / \lambda \quad (7.189)$$

where K is a constant, which depends on the complex index of refraction. Hottel and Sarofim used a value of 7 for K in their calculations. Later, Siegel [188] suggested different values for different fuels: 6.3 for oil flames, 4.9 and 4.0 for propane and acetylene flames, and a range between 3.7 to 7.5 for coal flames. Modak [140] has incorporated this expression into a computer code to calculate the radiant emission from a mixture of soot and H_2O and CO_2 gases. Note that this approximation implies that the soot particles are small compared to the wavelength of radiation, and scattering is not important.

The size parameter $x = \pi D / \lambda$ is in the order of 10^{-1} if λ is about 1 or 2 μm . Therefore, Q_{sca} , which is proportional to x^4 , is small. Because of this, scattering of radiation by *individual* soot particles is safely neglected for radiation heat transfer calculations. This conclusion, however, is only applicable to small soot spheres; if these small particles agglomerate, the importance of scattering increases. If the agglomerates are treated in calculations as if they are small spheres, then the radiative energy gain and loss cannot be predicted accurately. This, in turn, affects the predictions of temperature and species distribution, devolatilization, chemical kinetics, and soot formation.

There have been several attempts in the literature to model soot agglomerates as homogeneous solid particles. These approaches yield acceptable results for calculation of soot absorption coefficients, even though they are not exact. This is because the soot volume fraction is required along with absorption cross section to calculate the absorption coefficient (see Eq. 7.183), and the uncertainty in the value of local soot volume fraction is usually larger than that for the cross sections. For example, soot agglomerates were simulated as prolate and oblate spheroids and as infinite-length cylinders [189–192].

For a cloud of randomly oriented small spheroids, the spectral absorption (= extinction) coefficient is given as (Lee and Tien [189]):

$$\kappa_\lambda = \frac{4\pi n_\lambda k_\lambda}{3\lambda} f_v \sum_{j=1,2} \frac{j}{[1 + (n_\lambda^2 - k_\lambda^2 - 1)P_j]^2 + (2n_\lambda k_\lambda P_j)^2} \quad (7.190)$$

where P_1 and P_2 are the depolarization factors, and $P_1 = 1 - 2P_2$. For prolate spheroids:

$$P_1 = \frac{1 - e^2}{e^2} \left[\frac{1}{2e} \ln \left(\frac{1 + e}{1 - e} \right) - 1 \right] \quad (7.191)$$

and for oblate spheroids:

$$P_1 = \frac{1}{e^2} \left[1 - \left(\frac{1 - e^2}{e^2} \right)^{1/2} \sin^{-1} e \right] \quad (7.192)$$

where e is the eccentricity factor, defined as $D_{\text{minor}}/D_{\text{major}}$.

For cylinders, it is difficult to obtain a similar expression analytically. However, an approximate expression for the absorption efficiency factor was given as [189]:

$$Q_{\text{abs}} = x\gamma \frac{\pi}{4} n_\lambda k_\lambda \left\{ 1 + \frac{4}{(n_\lambda^2 - k_\lambda^2 + 1)^2 + 4n_\lambda^2 k_\lambda^2} \right\} \quad (7.193)$$

where γ is a constant. Lee and Tien [189] recommended $\gamma = 1.1$ for infrared wavelengths. Charalampopoulos and Hahn [192] suggested a functional form for γ , as

$$\gamma = a + by + cy^2 \quad (7.194)$$

where $y = x/|m|$, and $|m|$ is the modulus of the complex index of refraction. They recommended the following values for the coefficients: $a = 1.005563$, $b = 5.313441$, $c = -8.011187$. This expression yields very good agreement with the exact results over the wavelength spectrum of 0.4–15 μm and temperature range of 600–2000 K.

For cylindrical-shaped soot agglomerates, Mackowski et al. [190] presented more detailed expressions for both absorption and scattering efficiency factors, and showed that the expressions were reliable from the visible wavelength range up to 5 μm . They also applied a hybrid sphere/cylinder-shaped soot agglomerate model to interpret the experimental results obtained for the hydrocarbon flames, and showed that a larger fraction of soot agglomerates behave like cylinders [190, 191].

Determining the scattering characteristics of an agglomerate is more complicated than that for a homogeneous but irregularly shaped particle. For the latter, a solution is obtained by matching the amplitude and phase of the electromagnetic waves inside and outside of the particle, which is mathematically difficult but straightforward. For agglomerates, however, the interaction between individual spheres is to be considered. This can be done by superposing the electric field components of scattered electromagnetic waves from each individual sphere.

Coherent scattering of radiation by soot agglomerates has been studied by various researchers. The first model developed to examine irregularly shaped particles and agglomerates in a comprehensive way, including the retardation effects, is the discrete-dipole approximation (DDA) of Purcell and Pennypacker [172], who used it to study interstellar dust. The DDA is a general and flexible method for computing the approximate extinction and scattering cross sections of particles of arbitrary shape. The particle is modeled by an array of N polarizable elements (called dipoles) in vacuum. In their original study, Purcell and Pennypacker presented solutions for particles with $N < 256$. The reader is referred to Ref. 174 for a recent review of agglomerate approaches. The following is a brief survey to highlight some of the milestones.

Draine [173] presented a comprehensive treatment of the problem and discussed the validity of different approximations. A detailed review of DDA for scattering calculations and its relation to the other methods was presented by Draine and Flatau [193]. Vaglieco et al. [194] applied this approach to investigate the spectral characteristics of diesel soot. Ivezic and Mengüç [195] used the DDA to study dependent/independent scattering by agglomerates. A different approach to predict scattering and absorption coefficients of multiple-sphere clusters was presented by Mackowski [196] and Fuller [197], who considered superposition of radiative interactions among spheres. Analytical expressions were derived for orientation-averaged scattering and absorption coefficients.

For agglomerates of small spheres, a solution technique developed by Jones [198, 199] has received considerable attention [191, 200–205]. In this approach, the primary soot particles are assumed to be in the Rayleigh limit. The accuracy of the model decreases significantly as the individual soot spheres become larger compared to the wavelength of radiation, i.e., when

they cannot be considered as Rayleigh spheres. Note that, even for primary soot particles as small as 50 nm in diameter, the Rayleigh theory yields errors at visible wavelengths. In another model proposed by Iskander et al. [206], an irregularly shaped particle was divided into a number of cubical cells, and, inside each cell, the electromagnetic field was assumed to be uniform. Then a control volume approach was employed to reduce the governing equations to a set of linear algebraic equations.

Ku and Shim [204] used these formulations [172, 198, 199, 206] to model soot agglomerates with different shapes. They compared the extinction coefficient, single scattering albedo, and the phase function of agglomerates determined from these three approaches. They concluded that, among all available techniques, the approach given by Iskander et al. [206] is the most reliable. Their results show that the scattering coefficient and phase function of soot agglomerates are strongly dependent on the overall size parameter and the number of individual spheres that make the agglomerate.

Recent studies have shown that the morphology of soot agglomerates can be represented as fractals (see Refs. 174, 185, 207–214). The fractal-like structure of the agglomerates obeys the relation $N = k_f [R_g/d_p]^{D_f}$. Here, N is the number of primary spheres in the agglomerate, R_g is the radius of gyration of the agglomerate, d_p is the diameter of the primary sphere, k_f is the prefactor to be determined, and D_f is the fractal dimension of the agglomerate. For most flame soot, D_f is around 1.75, and $k_f = 8.0$ [213, 214]. A major consensus of the available studies is that the fractal geometry is better suited for understanding of soot morphology and for accurately interpreting the data obtained from optical diagnostic techniques.

Complex Index of Refraction of Soot. Soot refractive index has been measured by several researchers. The experimental techniques used can be broadly categorized as in situ and ex situ techniques. In the former, the measurements are performed nonintrusively in a flame environment. The necessary information is retrieved either from spectral transmission data or both the transmission and scattering information, as in Refs. 215–224. The ex situ measurements involve the reflection/transmission of incident spectral radiation on planar pellets of soot, and the optical properties are determined using the Fresnel relations [225]. An alternative ex situ technique was used by Janzen [226], who dispersed the soot particles in a KBr matrix and used transmission measurements to extract the required optical properties.

The Fresnel equations give a relation between transmission and reflection of radiation incident on a plane-parallel homogeneous layer and the real and imaginary parts of the complex refractive index, $m_\lambda = n_\lambda - ik_\lambda$. Therefore, if a homogeneous thin waffle of soot particles can be prepared and experiments are performed at several different wavelengths, corresponding complex index of refraction data can be obtained. There are, however, two main drawbacks of this technique. First of all, it is difficult to claim that the optical properties of the compressed waffles would be identical to those of individual particles. The waffle samples prepared for the experiments are usually not homogeneous, and the physical and molecular structure of particles are altered during the sample preparation, which requires compression and sometimes heating. It is almost impossible to prepare smooth surfaces for the samples, even after careful polishing. For application of the Fresnel equations, it is very important to have surface roughness below a fraction of the wavelength of incident radiation. Otherwise, surface scattering becomes dominant over reflection, which yields physically incorrect refractive index data.

In spite of these problems, the Fresnel reflection-transmission technique is relatively easy to use, and, because of that, it has been employed by various researchers to determine the coal refractive index (see Refs. 227 and 228 for reviews).

In Fig. 7.25, the spectral variations of the real and the imaginary part of the complex index of refraction of soot as reported by a number of different researchers are depicted (based on dispersion relations reported in Ref. 228).

One of the most important parameters required to account for the soot contribution to radiative energy balance is the soot volume fraction. This information is to be obtained from rigorous soot formation models or should be measured experimentally. Unless this information is available, the error induced due to the uncertainty in soot agglomerate size, shape, and

FIGURE 7.25 Spectral refractive index data for soot particles as determined by different researchers: (a) Refractive index, n_λ ; (b) absorption index (k_λ).

complex index of refraction will always be secondary in calculating radiative heat transfer in furnaces. Unfortunately, prediction of soot volume fraction distribution in combustion systems (or even in small flames) is complicated, as it requires the equations for fluid flow, energy transfer, turbulence, chemical kinetics, and radiative transfer to be solved simultaneously. A number of approaches have recently appeared for modeling soot formation, which were reviewed by Fletcher et al. [228].

Coal and Char Particles. Coal and char particles affect the absorption/scattering characteristics of particle-laden flames. It is important to have the absorption and scattering coefficients of these inhomogeneous, irregularly shaped particles to predict the temperature

distribution in furnaces, even though their contribution is mostly restricted to the flame zone. If coal particles are considered as homogeneous spheres, then the Lorenz-Mie theory can be used to determine the required parameters, provided that the spectral complex index of refraction data are available. Note that, even if there were agreement on the complex index of refraction data of coals, this would not necessarily mean that radiative properties can be determined exactly from the theory. This is because pulverized-coal and char particles have irregular shapes that change during the combustion process. In a combustion environment, it is very difficult to classify the particles into a single, unique shape. The simple shape assumptions are usually made to reduce the computational effort.

The real part n_λ of the refractive index for all coals, as reported by all researchers, is between 1.5 and 2.1 within the spectral range of 1 to 20 μm . The imaginary part k_λ , however, shows a larger variation (and higher uncertainty), as the reported values are between 0.01 and 1.2. For anthracite coal, for example, Blokh [230] reported k_λ values close to 0.9 at near infrared wavelengths; within the visible spectrum, however, the values are closer to 0.1. For bituminous coals, k_λ is constant at about 0.3 up to 6 μm and then increases linearly with the wavelength. These n_λ and k_λ values are plotted in Fig. 7.26.

Brewster and Kunitomo [231] attempted to obtain coal refractive indices with a different approach. Following an earlier work by Janzen [226], they suspended coal particles in a KBr matrix and measured spectral transmission from the samples. Assuming particles are spherical and knowing the size distribution and volume fraction of coal in the sample, they predicted the extinction efficiency factor Q_{ext} . Using a dispersion equation curve fitting for Q_{ext} , they determined the complex index of refraction of different coal samples. They reported values for the absorption index k_λ that was an order of magnitude smaller than earlier studies.

Although there is no doubt that the particle extinction method is superior to classical reflection/transmission techniques for determining the effective complex index of refraction of coal, it is more suitable for spherical particles rather than irregularly shaped particles. For coal and char particles, it is very likely that material and shape nonhomogeneity will affect the results obtained in experiments. Therefore, the particle extinction technique can be used to obtain *average* index of refraction data for coal particles.

FIGURE 7.26 Complex index of refraction of coal/char particles [237]: (a) Anthracite; (b) bituminous (BLV).

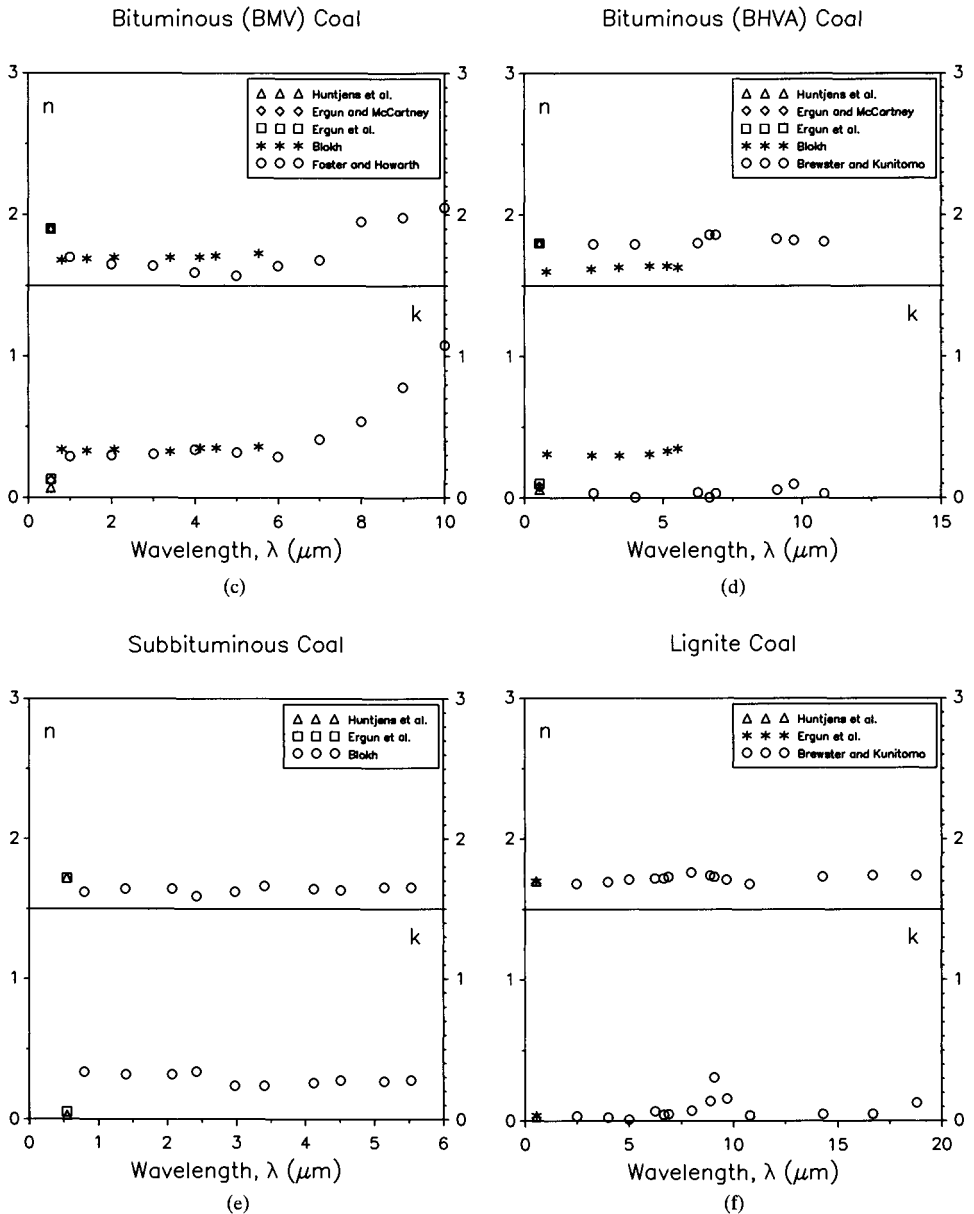

FIGURE 7.26 (Continued) Complex index of refracton of coal/char particles [237]: (c) bituminous (BMV); (d) bituminous (BHVA); (e) subbituminous; (f) lignite.

The effective emissivity and transmissivity of coal flames were measured in situ, although the scattering effects were not accounted for in detail [232–236]. These data are best suited for use in zonal method calculations and cannot be employed readily in differential models of the radiative transfer equation. Therefore, they cannot be considered very useful for the present or next-generation modeling attempts. However, it is possible to use this information to vali-

date the trends in different types of experiments performed with similar coals. For example, the data reported by Solomon et al. [236] seem to support the findings of Brewster and Kunitomo [231] in that the imaginary part of the complex index of refraction is much smaller than those previously reported in the literature.

Manickavasagam and Mengüç [229] performed experiments to determine the effective index of refraction of coal/char particles. The particles were suspended in a KBr matrix and measured wide-angle transmission of radiation within the wavelength interval of 2 to 22 μm . The experimental data included transmitted as well as part of the scattered light in a forward cone. These data were used in an inverse analysis to arrive at the best-match spectral index of refraction values, which includes the effects of inhomogeneities and particle irregularities. To validate this approach, additional scattering experiments were performed at a wavelength of 10.6 μm [237, 238, 239], and the corresponding index of refraction was evaluated using a different type of inverse analysis.

Figure 7.27 depicts the results from the experiments of Brewster and Kunitomo [231] and Manickavasagam and Mengüç [229]. It is important to note the similarity in the spectral variation of the extinction index k . Here, the Manickavasagam and Mengüç data need a careful interpretation: *if* the real part of the coal refractive index is assumed 1.8 *and* the imaginary part has the spectral profile depicted in the figure, then the coal radiative properties calculated using the Lorenz-Mie theory yield the experimental results. Even though these refractive index values are not true physical values for coal, the radiative properties calculated with the spherical-particle assumption would be accurate.

FIGURE 7.27 Absorption index (k_λ) of coal/char particles determined by including the scattering effects.

Fly Ash Particles. When coal particles burn in a combustion system, the ash present in coal coalesces into small micron- and submicron-sized particles and are carried throughout the system [240]. It has been shown that the shape of the fly ash particles in combustion chambers is primarily spherical. This suggests that, if the complex index of refraction of fly ash particles is known, the Lorenz-Mie theory can be used to determine the required radiative properties.

Fly ash particles are comprised of varying amounts of oxides of silicon (SiO_2), iron (Fe_2O_3), calcium (CaO), and aluminum (Al_2O_3). It may be postulated, then, that the corresponding complex index of refraction is a function of the relative amount of each of these constituents. Depending on the coal rank, type, and flame characteristics, the refractive index of fly ash particles formed may vary, even within the same flame. For example, Wall et al. [241] reported a range of values for fly ash particles, varying from $m = n - ik = 1.43 - 0.307i$ to $m = 1.50 - 0.005i$.

Blokh [230] reported similar values for the imaginary part of the refractive index, though the real part reported showed some differences.

Several other researchers reported the refractive indices of fly ash particles determined from different techniques. Lowe et al. [242] and Gupta and Wall [243, 244] reported refractive index values obtained from in situ measurements of fly ash emissivities at the flue gas exit of a pulverized coal burner. Lowe et al. [242] found values of k ranging from 0.01 to 0.02 for the imaginary part; Gupta and Wall's results were smaller by a factor of two. In obtaining these values, the effect of residual carbon within the experimental control volume was not considered, and, in data reduction, the effect of scattering was neglected.

Fly ash optical properties were measured by Wyatt [245] using single, levitated particles, and values of k between 0 and 0.008 were reported. However, a later study indicated that this technique was less reliable for measuring the imaginary part if it was very small, as in the case of fly ash [246].

Extensive studies of the refractive index of fly ash were performed first by Goodwin [247] and later by Ghosal [248] and Ebert [249] at Stanford University. Goodwin used polished wafer layers of several different natural and synthetic coal slags in the experiments and measured transmittance and near-normal reflectance of radiation within the 1–12 μm wavelength range. He deduced the fly ash complex index of refraction using Fresnel reflection theory, as a function of wavelength, temperature, and composition (see Fig. 7.28). Although this is an ex-situ technique, the data obtained can be considered quite reliable because it was possible to prepare uniform samples with polished surfaces, and the structure of fly ash is unlikely to be affected by the wafer preparation.

FIGURE 7.28 Typical spectral refractive index data for fly ash [247].

On the other hand, any uncertainty in the composition and complex refractive index of fly ash particles is likely to be less than the uncertainty in the volume fraction distribution of fly ash particles. It was shown that, using detailed spectral data for fly ash particles, one may obtain significantly different results for radiative flux from the flame to the walls of large scale pulverized-coal furnace compared to the results predicted using wavelength-independent properties; however, the difference is lost if the accurate number densities of fly ash and soot present near the walls are not available [52, 250].

The temperature has an insignificant effect on the radiative properties of fly ash particles [247]. Yet, if the medium temperature varies, the spectral variation of fly ash particles be-

comes more important because of the shift in the peak wavelength of blackbody emission. This shift was shown to affect the divergence of the radiative flux term significantly [250].

Recently, Ebert extended Goodwin's approach and measured the optical properties of molten slags at 1600°C. Figure 7.29 depicts the spectral variation of n_λ and k_λ for three different samples over a spectral wavelength range of 1 to 13 μm . Ebert suggested that the model (which is shown by the lines in the figure) is reliable if three conditions are met: (1) SiO_2 weight percentage is less than 95 percent, (2) the sum of weight percentages of SiO_2 , Al_2O_3 , CaO , Fe_2O_3 , MgO , and TiO_2 is 80 percent or higher, and (3) the weight percentage of Fe_2O_3 is less than 30 percent. It is important to note that the spread shown in the k_λ values in Fig. 7.29 within the spectral range of 3 to 8 μm is roughly the same spread reported by Goodwin for a temperature range of 295 to 1295 K.

FIGURE 7.29 Spectral refractive index data for three different molten slags at 1600°C [249].

Radiative Properties of Porous Materials

Most porous materials have very small mean free paths for radiation and can be treated as opaque substances. In that case, radiation can be treated as a boundary effect, as for any opaque solid. However, there are at least two important exceptions.

The first is composite materials, which have long fibers imbedded in a matrix of transparent material such as epoxy resin. The properties of these materials are important because of

the need for modeling of the radiative transfer in the infrared-assisted curing process for thermosets and the high-temperature molding process for some thermoplastics. The second exception is the class of materials known as reticulated porous ceramics, which have an open pore structure and porosities greater than 80 percent. These materials are used in various high-temperature applications, and radiative transfer through the pore structure is important.

Properties of Composite Fiber/Matrix Systems. The volume fraction of fibers in most filament-wound structures and in laid-up composite layers can exceed 60 percent. For carbon fibers at this volume fraction, the composite has such a high absorption coefficient that it can be treated as opaque [251]; however, for glass-epoxy composites, the absorption coefficient is small enough, particularly in some spectral windows, that radiation must be treated as a volumetric effect. The situation is complicated by the high fiber volume fraction, which causes the fiber absorption and scattering to be in the dependent regime; however, some data are presented in Ref. 251.

Properties of Reticulated Ceramics. Reticulated ceramics are used as flame holders for the combustion of gaseous and liquid fuels and in high-temperature solar collectors. Because of their open structure and high porosity (above 80 percent), these materials have a small effective extinction coefficient relative to most porous materials.

Calculation of radiative properties through modeling of radiation absorption and reflection from the ceramic structure has not yet been attempted. Instead, the porous medium is treated as a homogeneous absorbing and scattering medium. For such a treatment, it is necessary to know the effective absorption and scattering coefficients of the medium as well as the scattering phase function.

Hsu et al. [88], during measurement of the thermal conductivity of porous partially stabilized zirconia, used a two-flux radiation model to infer the effective radiative extinction coefficient as a function of pore size. They present a correlation of the data of the form

$$\beta = 1340 - 1540d + 527d^2 \quad (7.195)$$

where β is the mean (spectrally averaged for long wavelength radiation) extinction coefficient in m^{-1} and d is the actual pore diameter in mm. This correlation was for pore sizes in the range $0.3 \text{ mm} \leq d \leq 1.5 \text{ mm}$. The data were collected for temperatures in the range $290 \leq T \leq 890 \text{ K}$; no temperature dependence was observed. Additionally, Hsu and Howell present a geometric optics prediction of the extinction coefficient versus pore diameter that fits the data very well:

$$\beta = (3/d)(1 - p) \quad (7.196)$$

which applies for $d \geq 0.6 \text{ mm}$. Here, p is the porosity of the sample, which varied from 0.87 at large pore diameters to 0.84 at the smallest diameters. The method used to obtain these correlations required the assumption of isotropic scattering, and it was not possible to determine independent values of albedo or scattering or absorption coefficients.

Hale and Bohn [252] measured the scattered radiation from a finite sample of reticulated alumina from an incident laser beam at 488 nm. They then matched Monte Carlo predictions of the scattered radiation calculated from various values of extinction coefficient and scattering albedo and chose the values that best matched the experimental data for reticulated alumina samples of 10, 20, 30, and 65 ppi. A scattering albedo of 0.999 and an assumed isotropic scattering phase function reproduced the measured data for all pore sizes. The large reported albedo value indicates that alumina is very highly scattering and that radiative absorption is extremely small for this material.

Hendricks and Howell [253] measured the spectral normal transmittance and normal hemispherical reflectance of three sample thicknesses each of reticulated partially stabilized zirconia and silicon carbide at pore sizes of 10, 20, and 65 ppi. The measurements covered a spectral range of 400–500 nm. They used an inverse discrete ordinates method to find the spectrally dependent absorption and scattering coefficients as well as the constants appropri-

ate for use in the Henyey-Greenstein approximate phase function. Both materials showed best agreement with experimental data when this anisotropic scattering phase function was used. The data for absorption and scattering coefficient for silicon carbide were fairly independent of wavelength, which is the same as the spectral behavior of pure silicon carbide in solid form (see App. A and Refs. 11, 12, 16, and 254). For partially stabilized zirconia, the properties showed a significant change across the range 2500 to 3000 nm but were wavelength-independent on each side of this value. The spectral characteristics of pure and stabilized zirconia do not show this behavior [12]. The phase function in particular shows a radical change in behavior for the reticulated ceramics across this spectral range for PSZ. Scattering albedos varied with wavelength in the range of 0.81–0.999 for zirconia, with some variation with pore diameter, and 0.55–0.81 for silicon carbide.

Integration of the spectral results of Hendricks and Howell [253] provides mean extinction coefficient data that can be compared with that of Hsu et al. [88]. The Hale and Bohn [252] data are only for the wavelength of 488 nm. Hendricks and Howell [253] found that a modified geometrical optics relation also fit the data for the spectrally integrated extinction coefficient of both zirconia and silicon carbide. They recommend the relation

$$\beta = (4.4/d)(1 - p) \quad (7.197)$$

where again β is in m^{-1} and d is the actual pore diameter in mm.

The data presented in Fig. 7.30 obviously have similar characteristics, regardless of the material. The Hale and Bohn data are plotted based on the pore diameter calculated as the inverse of the ppi values reported; however, measured pore sizes are generally smaller than nominal sizes computed in this way [255]. It may be possible to collapse all of the data for extinction coefficient onto a single curve if the Hale and Bohn data are adjusted to actual pore size rather than a pore size calculated from nominal ppi values. This was not attempted, because actual pore size data were not reported in Ref. 252. Even if the data can be collapsed in this way, it will be necessary to have additional data for the scattering albedo of the material so that the individual scattering and absorption coefficients can be recovered from the extinction coefficient data.

Mital et al. [256] have measured the radiative extinction coefficient and scattering albedo for five different porous ceramics in the temperature range from 1200–1400 K, assuming a gray isotropically scattering medium. Doermann and Sacadura [257] have proposed a method for predicting the radiative absorption and scattering coefficients and the phase function of open-celled materials based on the structure of the solid. Recently these authors have presented a comprehensive review of the subject [258].

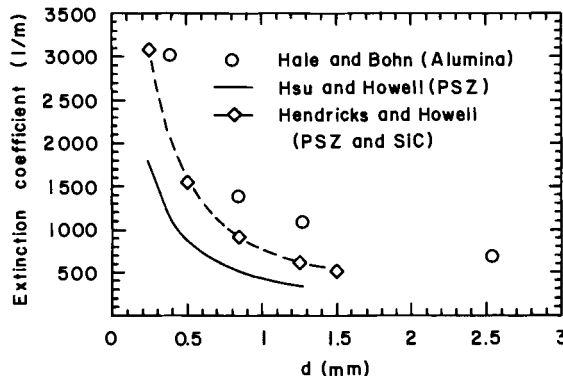

FIGURE 7.30 Extinction coefficient versus pore diameter for alumina, partially stabilized zirconia, and silicon carbide.

Radiative Properties of Semitransparent Materials

Often, layers of materials with differing radiative properties are adjacent to one another, and the transmission of energy through the layers is needed. If the layers have a thickness that is large compared with the wavelength of the radiation, as is the case with sheets of window glass, then a net radiation approach (geometric optics) can be used. If the layer thickness is small compared with the wavelength, then the effects of wave interference (coherence) must be considered, and, for very thin layers, a microscopic approach that considers material structure to the molecular scale may be necessary. For layers intermediate between the geometric optics and coherent optics regime, an analysis using partial coherence effects must be used.

Geometric Optics Results for Cold Plates. For parallel plates of thickness L with surface reflectivity ρ and transmittance $\tau = \exp(-aL)$, multiple internal reflections occur at both plate-air interfaces within the parallel plate, causing portions of the radiation to have quite long paths within the plates and thus increased absorption and reflection from the primary surface. For a single plate that is cold enough that emission of radiation can be ignored and with $L \gg \lambda$, the fractions of incident energy on one face that are absorbed A , reflected R , and transmitted T , are

$$A = (1 - \rho)(1 - \tau)/(1 - \rho\tau) \quad (7.198)$$

$$R = \rho(1 + \tau T) \quad (7.199)$$

$$T = \tau(1 - \rho)^2/(1 - \rho^2\tau^2) \quad (7.200)$$

Siegel and Howell [1] treat the transmittance, absorptance, and reflectance of multiple parallel plates, each with the same or differing ρ and τ . The normal reflectance for smooth dielectric materials can be estimated from Eq. 7.40.

In Eqs. 198–200, the reflectance can be found for any angle of incidence θ by using the Fresnel relations [Eq. 7.41] for reflectance $\rho(\theta)$ and correcting the transmittance τ with the angle of refraction χ to give $\tau = \exp(-aL/\cos \chi) = \exp(-aL/n \cos \theta)$. This requires knowledge of the refractive index of the plate material.

Geometric Optics Results with Emission. When the temperature of a semitransparent layer is large, emission of radiation becomes significant, and the problem of radiative transfer becomes more complex. The change in refractive index at each interface causes total internal reflection of radiation in the medium with higher refractive index at the boundary. This effect must be treated in the RTE at the boundary of the medium, and diffuse boundary conditions are no longer correct for the exact solution of this type of problem. Various approaches have been attempted.

Spuckler and Siegel [259, 260] have treated single and multiple semitransparent layers, and they have presented two-flux solutions to steady problems with internal radiation and conduction in the semitransparent layer with convective and radiative loss or gain at the surface [261] and transient problems with similar conditions [262].

Thin Films. When geometric optics cannot be applied, coherence effects require that electromagnetic wave theory be applied until extremely thin films are treated. For example, the normal reflectance R of a thin nonabsorbing film of refractive index n_1 on a substrate with refractive index n_2 is found to be

$$R = (r_1^2 + r_2^2 + 2r_1r_2 \cos \gamma_1)/(1 + r_1^2r_2^2 + 2r_1r_2 \cos \gamma_1) \quad (7.201)$$

where $\gamma_1 = 4\pi n_1 L/\lambda_o$ and r_1 and r_2 are the normal reflectances of the air-coating and coating-substrate interfaces, respectively, and are given by $r_1 = (n_1 - n_2)/(n_1 + n_2)$ and $r_2 = (n_2 - n_1)/(n_2 + n_1)$. For the special case of a layer thickness that is $1/4$ wavelength (in the medium) in thickness so that $\gamma_1 = 4\pi n_1 L/\lambda_o = \pi$, Eq. 7.201 reduces to

$$R = [(n_1 n_2 - n_1^2)/(n_1 n_2 + n_1^2)]^2 \quad (7.202)$$

If the refractive index of the coating is made equal to $(n_1 n_2)^{1/2}$, then Eq. 7.202 reduces to $R = 0$. Such a film thus produces an antireflective coating. This result will apply only for normal incidence and at a particular wavelength.

Films that are greater than a few wavelengths in thickness but not yet in the geometric optics region are treated by Chen and Tien [263], and a recent review of thin film and partial coherence effects as well as very thin film effects is in Chen [264].

COMBINED MODES WITH RADIATION

Almost all real engineering problems involving radiative transfer have present other energy transfer modes (conduction, convection, advection) and/or sources or sinks of energy (nuclear reactions and chemical reactions such as combustion). These all affect the temperature of a medium through the energy equation, and thus radiation is nearly always coupled to these other energy forms. Radiative transfer depends on the fourth power of the absolute temperature, while other energy transfer modes depend on local temperature gradients (conduction) or temperature differences (convection). Therefore, we expect a general energy equation to be nonlinear and contain often both integrals of fourth-power temperature for radiative terms and second partial derivatives of temperature for conduction. Such nonlinear integro-partial differential equations do not have the wealth of analytical and numerical solution methods that have been developed for simpler forms. Here, we present a brief review of contemporary methods for solution of combined-mode problems.

The General Energy Equation

A general energy conservation equation is of the form

$$\rho c_p \frac{DT}{D\tau} = \beta T \frac{DP}{D\tau} + \vec{\nabla} \cdot (k \vec{\nabla} T - \vec{q}_{\text{rad}}) + S + \Phi_d \quad (7.203)$$

where $D/D\tau$ is the substantial derivative, β is the temperature coefficient of volume expansion, S is the volumetric source term, and Φ_d is the viscous dissipation. To solve for the temperature distribution in a participating medium, the radiative flux divergence $\vec{\nabla} \cdot \vec{q}_{\text{rad}}$ must be known.* Any of the methods discussed in previous sections (zonal method, multiframe approximations, differential or moment methods, Monte Carlo, discrete ordinate, finite element, finite volume, and so on) can be used along with Eq. 7.105 to evaluate the radiative flux divergence. However, $\vec{\nabla} \cdot \vec{q}_{\text{rad}}$ is itself temperature-dependent, so solution of the energy equation and the radiative flux divergence are coupled.

General CFD solvers are available for the energy equation, but most have at best approximate forms for the radiative flux divergence. The method of choice in commercial codes is often the first-order spherical harmonics (P_1) approximation, because it is in straightforward differential equation form and is easily included in existing numerical codes. However, as noted in the discussion of this method, it is prone to serious errors in many geometries and over wide ranges of parameters so that solutions using this method are suspect. However, it is difficult to couple more general radiative transfer solutions to the energy equation for a number of reasons. One is that the gridding for accurate solution of the RTE may be greatly different from that needed, for example, for resolving a boundary layer flow. If the boundary-

* Here, subscript rad is used to separate radiative flux from conductive, convective, or total heat flux.

layer-generated grid is used for the RTE solution, the time required for solution of the RTE may be prohibitive; yet such gridding is necessary to resolve convective effects.

Recently, Burns and Howell [110] and Farmer and Howell [101] have developed solutions for $\vec{\nabla} \cdot \vec{q}_{\text{rad}}$ on an externally generated finite element grid so that existing energy equation solvers could be directly accessed; the former used a direct finite-element solution to the RTE, while the latter used Monte Carlo. Both include spectral properties and anisotropic scattering.

Interaction with Conduction and Convection

For problems where convection and/or conduction within a medium are coupled with radiative transfer, a number of methods and solutions are available in the literature. Most such solutions are for simple geometries (e.g., free convection in the annulus between two concentric horizontal cylinders at different temperatures).

Simplified but useful solutions can be obtained for some cases. For example, if the medium is optically thick at all important wavelengths, then the local radiative flux can be related to the gradient in the local medium emissive power, or

$$q_{\text{rad},x} = -\left(\frac{4}{3\kappa_R}\right) \frac{\partial E}{\partial x} = -\left(\frac{4\sigma}{3\kappa_R}\right) \frac{\partial T^4}{\partial x} = -\left(\frac{16\sigma T^3}{3\kappa_R}\right) \frac{\partial T}{\partial x} = -k_r \frac{\partial T}{\partial x} \quad (7.204)$$

where $k_r = 16\sigma T^3/3\kappa_R$ is a radiative conductivity, and κ_R is the Rosseland mean absorption coefficient defined by Eq. 7.178.

If portions of the spectrum are transparent, then this method will fail unless the problem is segmented into transparent and optically thick regions, and the results for the entire spectrum are added.

Equation 7.204 has the same form as the Fourier law for conduction heat transfer. However, the equivalent conductivity is highly temperature dependent. For a medium such as a high-temperature solid where convective effects and sources are absent, the general energy equation (Eq. 7.203) reduces to

$$\vec{\nabla} \cdot (k\vec{\nabla}T - \vec{q}_{\text{rad}}) = \vec{\nabla} \cdot (k\vec{\nabla}T + k_r\vec{\nabla}T) = \vec{\nabla} \cdot [(k + k_r)\vec{\nabla}T] = 0 \quad (7.205)$$

Solution of the combined conduction/radiation problem in this case reduces to solution of a conduction problem with temperature-dependent thermal conductivity.

For most problems such as determining the heat transfer characteristics of an industrial furnace or power plant steam generator, simplifying assumptions are simply not justified, as radiation, advection, and conduction are all important, and the effects of spectral properties and anisotropic scattering must also be included. These effects plus compact real geometries make such problems tax even the largest computers.

Efficient treatment of complete combined mode problems is an area of contemporary research, and the texts by Siegel and Howell [1], Modest [3], and Özişik [6] give a good introduction.

Interaction with Combustion and Turbulence

In combustion chambers, radiation transfer from hot combustion products to cooler walls and/or gases/particles depends strongly on the concentration of particles and combustion gases as well as their temperatures. In a typical practical system, these properties fluctuate because of the presence of the turbulent flow field. Radiation transfer affects the fate of particles/droplets at different locations in the flame, which, in turn, influences their concen-

tration distributions. The effect of radiation transfer also depends on the thermophysical properties of the medium, which vary with the degree of interactions. The variations in thermophysical properties, concentrations, and temperatures result in local radiation intensity distributions as well as divergence of radiative flux (i.e., radiative sources and sinks) that oscillate as a function of time. These oscillations, in turn, affect the chemical reactions as well as soot formation/oxidation mechanisms. This cycle is the main impetus for radiation turbulence and radiation combustion interactions.

The first attempt to include the effect of radiation on flow and temperature fields in a turbulent environment was made by Townsend [265]. More recent studies include those of Faeth, Gore, Sivathanu, and their coworkers [266–273], Grosshandler and Joulain [274], Song and Viskanta [275], Yuen et al. [276], and Adams and Smith [277].

Recently, McDonough et al. [278] and Mengüç et al. [279] have approached the problem from a different direction and modeled the fluctuations of the species important for radiation-turbulence interactions using chaotic maps, which appears to be a promising technique.

Although several significant advances have been made in understanding the turbulence-radiation interactions in gaseous flames (especially by Faeth and his coworkers), we still need more fundamental approaches that allow the study of these interactions starting from first principles. There is also a need to employ more sophisticated turbulence simulation techniques along with accurate and reliable radiation and chemical kinetics models to develop a thorough understanding of these complex phenomena and their interactions.

CLOSING REMARKS

In this chapter, we presented a general overview of radiative heat transfer. A number of practical models were included for the solution of the radiative transfer equation and to calculate the required radiative properties of particles, combustion gases, and surfaces. Even though the material presented can allow the reader to tackle a radiative transfer problem, it is not possible to claim that our coverage of the subject was comprehensive. We tried to list most significant references, and the reader is encouraged to consult the literature for more detailed and the most up-to-date analyses and data.

Within the constraints of this chapter, we were forced not to include a number of important topics, including the discussions on dependent-independent scattering, laser-material interactions, and the effect of radiation on manufacturing processes, among others. These are very important subjects; however, it will be difficult to include them in a short chapter like this. Again, the reader is referred to the literature for more detailed discussions of these problems (see Refs. 1, 2, and 3, and the references therein).

APPENDIX A: RADIATIVE PROPERTY TABLES

TABLE A.7.1 Selected Surface Properties

Surface	Temperature, °C (°F)	ϵ_L	Surface	Temperature, °C (°F)	ϵ_L
Metals					
Aluminum:			Heat resistant oxidized	200 (392)	0.639
Bright rolled	170 (338)	0.039	Cast iron, bright	93 (200)	0.21

APPENDIX B: RADIATION CONFIGURATION FACTORS**Element-Element Factors**

1. Elemental area of any length z to infinitely long parallel strip of differential width; plane containing element does not intersect strip

Reference: Siegel and Howell [1]

$$\text{Governing equation: } dF_{dA_1-dA_2} = \frac{\cos \beta d\beta}{2}$$

2. Parallel differential strip elements in intersecting planes

Reference: Siegel and Howell [1]

Definition: $Y = y/x$

Governing equation:

$$dF_{d1-d2} = \frac{Y \sin^2 \phi dY}{2(1 + Y^2 - 2Y \cos \phi)^{3/2}}$$

3. Two elemental areas lying on parallel lines

Reference: Sparrow and Eckert [302]

Definition: $X = x/r$

Governing equation:

$$dF_{d1-d2} = \frac{\sin \delta [(1 + X) \cos \delta - 1]}{2[X^2 + 2(X + 1)(1 - \cos \delta)]^{3/2}} dX$$

4. Strip of finite length and of differential width, to differential strip of same length on parallel generating line

Reference: Jakob [293]

Definition: $B = b/S$

Governing equation: $dF_{d1-d2} = \frac{\cos \phi d\phi}{\pi} \tan^{-1} B$

5. Differential ring element to opposed ring element on coaxial disk

Reference: Sparrow and Gregg [303]

Definitions: $R = r_2/r_1$; $H = h/r_1$; $Y = H^2 + R^2 + 1$

Governing equation: $dF_{d1-d2} = \frac{2RH^2Y}{[Y^2 - 4R^2]^{3/2}} dR$

6. Differential ring element on circular disk to opposed coaxial ring element on coaxial disk separated by coaxial cylinder

Reference: Masuda [298]

Definitions: $R_1 = r_1/r$; $R_2 = r_2/r$;
 $H = h/r$; $X = R_1^2 + R_2^2 + H^2$;
 $\Phi = \cos^{-1}(1/R_1) + \cos^{-1}(1/R_2)$

Governing equation:

$$dF_{d1-a2} = \frac{4H^2 R_2 dR_2}{\pi(X^2 - 4R_1^2 R_2^2)} \left\{ \frac{R_1 R_2 \sin \Phi}{(X - 2R_1 R_2 \cos \Phi)} + \frac{X}{(X^2 - 4R_1^2 R_2^2)^{1/2}} \tan^{-1} \left[\left(\frac{X + 2R_1 R_2}{X - 2R_1 R_2} \right)^{1/2} \tan \frac{\Phi}{2} \right] \right\}$$

7. Circumferential ring element on interior of right circular cylinder to coaxial ring element on base

Reference: Sparrow et al. [301]

Definitions: $X = x/r_1$; $R = r_2/r_1$

Governing equation:

$$dF_{d1-a2} = \frac{2XR(1 + X^2 - R^2)}{[(1 + X^2 + R^2)^2 - 4R^2]^{3/2}} dR$$

8. Ring element on exterior of tube to ring element on coaxial annular element on circular fin

Reference: Masuda [298]

Definitions: $H = h/r_1$; $R = r_2/r_1$; $Z = 1 + R^2 + L^2$

Governing equation:

$$dF_{d1-a2} = \frac{2HRdR}{\pi(Z^2 - 4R^2)} \left\{ (R^2 - 1)^{1/2} + \frac{2(R^2 - H^2 - 1)}{(Z^2 - 4R^2)^{1/2}} \tan^{-1} \left[\left(\frac{Z + 2R}{Z - 2R} \frac{R - 1}{R + 1} \right)^{1/2} \right] \right\}$$

9. Two ring elements on the interior of a right circular cylinder

References: Hottel and Keller [291]; Sydnor [305]

Definition: $X = x/2r$

Governing equation: $dF_{d1-a2} = \left[1 - \frac{2X^3 + 3X}{2(X^2 + 1)^{3/2}} \right] dX_2$

Element-Area Factors

1. Differential element of any length to semiinfinite plane.
Plane containing element and receiving semiinfinite plane intersect at angle ϕ at edge of semiinfinite plane

Reference: Hamilton and Morgan [289]

Governing equation: $F_{d1-2} = \frac{1}{2} (1 + \cos \phi)$

2. Differential tilted planar element dA_1 to disk A_2 . Element lies on normal to disk passing through disk center.

References: Naraghi and Chung [300]; Naraghi [299]

Definitions: $H = h/r$; $X = (1 - H^2 \cot^2 \theta)^{1/2}$

Governing equations:

$$F_{d1-2} = \frac{1}{1 + H^2} \cos \theta; \theta \leq \cot^{-1} \left(\frac{1}{H} \right)$$

$$F_{d1-2} = \frac{-HX \sin \theta}{\pi(1 + H^2)} + \frac{1}{\pi} \tan^{-1} \left(\frac{X \sin \theta}{H} \right) + \frac{\cos \theta}{\pi(1 + H^2)} [\pi - \cos^{-1} (H \cot \theta)]; \theta \geq \cot^{-1} \left(\frac{1}{H} \right)$$

3. Plane element to interior of coaxial right circular cylinder

Reference: Chung and Sumitra [284]

Definitions: $H = h/x$; $R = r/x$

Governing equations:

$$\text{for } H < 1: F_{d1-2} = \frac{1}{1 + R^2} - \frac{(1 - H)^2}{(1 - H)^2 + R^2}$$

$$\text{for } H \geq 1: F_{d1-2} = \frac{1}{1 + R^2}$$

4. Element on plane to exterior of right circular cylinder of finite length. Plane does not intersect cylinder

Reference: Leuenberger and Person [297]

Definitions: $S = s/r$; $X = x/r$; $Y = y/r$; $H = h/r$;
 $A = X^2 + Y^2 + S^2$; $B = S^2 + X^2$

Governing equation:

$$F_{d1-2} = \frac{S}{B} \left(1 - \frac{1}{2\pi} \left\{ \cos^{-1} \left(\frac{Y^2 - B + 1}{A - 1} \right) + \cos^{-1} \left[\frac{(H - Y)^2 - B + 1}{(H - Y)^2 + B - 1} \right] \right\} \right. \\ \left. - Y \left[\frac{A + 1}{((A - 1)^2 + 4Y^2)^{1/2}} \right] \cos^{-1} \left[\frac{Y^2 - B + 1}{(A - 1)B^{1/2}} \right] \right. \\ \left. - (H - Y) \left[\frac{(H - Y)^2 + B + 1}{[[(H - Y)^2 + B - 1]^2 + 4(H - Y)^2]^{1/2}} \right] \cos^{-1} \left[\frac{(H - Y)^2 - B + 1}{[(H - Y)^2 + B - 1]B^{1/2}} \right] + H \cos^{-1} \frac{1}{B^{1/2}} \right)$$

5. Differential element of any length to surface generated by a line of infinite length parallel to the plane of the element, and moved parallel to itself. Plane of element does not intersect surface

References: Hottel [290]; Hamilton and Morgan [289]

Governing equation: $F_{d1-2} = \frac{1}{2}(\sin \phi_2 - \sin \phi_1)$

6. Infinitely long strip element to infinitely long parallel cylinder; $r < y$

Reference: Feingold and Gupta [286]

Definitions: $X = x/r$; $Y = y/r$

Governing equation: $F_{d1-2} = \frac{Y}{X^2 + Y^2}$

7. Spherical point source to sphere

Reference: Chung and Sumitra [284]

Definition: $R = r/h$

Governing equation: $F_{d1-2} = \frac{1}{2}[1 - (1 - R^2)^{1/2}]$

Area-Area Factors

1. Two infinitely long parallel plates of different widths; centerlines of plates are connected by perpendicular between plates

Reference: Wong [306]

Definitions: $B = b/a$; $C = c/a$

Governing equation:

$$F_{1-2} = \frac{1}{2B} \{ [(B + C)^2 + 4]^{1/2} - [(C - B)^2 + 4]^{1/2} \}$$

2. Infinitely long enclosure formed by three planar or convex surfaces

Reference: Siegel and Howell [1]

Governing equation: $F_{1-2} = \frac{L_1 + L_2 - L_3}{2L_1}$

3. Infinite plane to row of parallel cylinders, or n rows of inline cylinders

References: Hottel [290]; Kuroda and Munakata [296]

Definition: $D = d/b$

Governing equations:

$$\text{For } n = 1: F_{1-2} = 1 - (1 - D^2)^{1/2} + D \tan^{-1} \left(\frac{1 - D^2}{D^2} \right)^{1/2}$$

$$\text{For } n > 1: F_{1-n \text{ rows}} = 1 - (1 - F_{1-2})^n$$

4. Top surface of finite rectangle tilted relative to an infinite plane

Reference: Siegel and Howell [1]

$$\text{Governing equation: } F_{1-2} = \frac{1 - \cos \eta}{2}$$

5. Coaxial parallel squares of different edge length

Reference: Crawford [285]

Definitions: $A = a/c$; $B = b/a$;

$X = A(1 + B)$; $Y = A(1 - B)$

Governing equations:

$$F_{1-2} = \frac{1}{\pi A^2} \left\{ \ln \frac{[A^2(1 + B^2) + 2]^2}{(Y^2 + 2)(X^2 + 2)} + (Y^2 + 4)^{1/2} \left[Y \tan^{-1} \frac{Y}{(Y^2 + 4)^{1/2}} - X \tan^{-1} \frac{X}{(Y^2 + 4)^{1/2}} \right] \right. \\ \left. + (X^2 + 4)^{1/2} \left[X \tan^{-1} \frac{X}{(X^2 + 4)^{1/2}} - Y \tan^{-1} \frac{Y}{(X^2 + 4)^{1/2}} \right] \right\}$$

$$\text{If } A < 0.2, \text{ then } F_{1-2} = \frac{(AB)^2}{\pi}$$

6. Rectangle to rectangle in a parallel plane;
all boundaries are parallel or perpendicular
to x and ξ boundaries

References: Gross et al. [288]; also see Boeke
and Wall [280]; Chekhovskii et al. [283];
Hsu [292]

Definitions: $X = x/z$; $N = \eta/z$; $Y = y/z$;
 $S = \xi/z$; $\alpha_{ii} = S_i - X_i$; $\beta_{kj} = N_k - Y_j$

Governing equation:

$$F_{1-2} = \frac{1}{(X_2 - X_1)(Y_2 - Y_1)} \sum_{i=1}^2 \sum_{k=1}^2 \sum_{j=1}^2 \sum_{l=1}^2 \left[(-1)^{(i+j+k+l)} G(\alpha_{ii}, \beta_{jk}) \right]$$

where $G(\alpha_{ii}, \beta_{jk}) = \frac{1}{2\pi} \left\{ \alpha_{ii}(1 + \beta_{kj}^2)^{1/2} \tan^{-1} \left[\frac{\alpha_{ii}}{(1 + \beta_{kj}^2)^{1/2}} \right] - \beta_{kj} \tan^{-1} \beta_{kj} \right.$
 $\left. + \beta_{jk}(1 + \alpha_{ii}^2)^{1/2} \tan^{-1} \left[\frac{\beta_{jk}}{(1 + \alpha_{ii}^2)^{1/2}} \right] - \frac{1}{2} \alpha_{ii}^2 \ln \alpha_{ii}^2 + \frac{1}{2} \ln(1 + \beta_{kj}^2) - \frac{1}{2} \ln(1 + \alpha_{ii}^2 + \beta_{kj}^2) \right\}$

7. Rectangle to rectangle in a perpendicular plane;
all boundaries are parallel or perpendicular
to x and ξ boundaries

References: Gross et al. [288]; also see Boeke
and Wall [280]; Chekhovskii et al. [283]

Definitions: $\alpha_{ii} = (\xi_i^2 + x_i^2)^{1/2}$; $\beta_{jk} = y_j - \eta_k$

Governing equation:

$$F_{1-2} = \frac{1}{(x_2 - x_1)(y_2 - y_1)} \sum_{i=1}^2 \sum_{k=1}^2 \sum_{j=1}^2 \sum_{l=1}^2 \left[(-1)^{(i+j+k+l)} G(\alpha_{ii}, \beta_{jk}) \right]$$

where $G(\alpha_{ii}, \beta_{jk}) = \frac{1}{2\pi} \left\{ \alpha_{ii} \beta_{jk} \tan^{-1} \left[\frac{\beta_{jk}}{\alpha_{ii}} \right] - \frac{1}{2} (\alpha_{ii}^2 - \beta_{jk}^2) \ln(\alpha_{ii}^2 + \beta_{jk}^2)^{1/2} + \frac{1}{4} \beta_{jk}^2 (1 - 2 \ln \beta_{jk}^2) + \frac{1}{2} \alpha_{ii}^2 \ln \alpha_{ii} \right\}$

8. Disk to parallel disk of unequal radius

References: Keene [295]; Hottel [290]; Hamilton
and Morgan [289]; Leuenberger and Person [297]

Definitions: $R_1 = r_1/a$; $R_2 = r_2/a$; $X = 1 + \frac{1 + R_2^2}{R_1^2}$

Governing equation: $F_{1-2} = \frac{1}{2} \left\{ X - \left[X^2 - 4 \left(\frac{R_2}{R_1} \right)^2 \right]^{1/2} \right\}$

9. Exterior of infinitely long cylinder to unsymmetrically placed infinitely long parallel plate; $r < a$

References: Feingold and Gupta [286];
Hamilton and Morgan [289]

Definitions: $B_1 = b_1/a$; $B_2 = b_2/a$

Governing equation: $F_{1-2} = \frac{1}{2\pi} (\tan^{-1} B_1 - \tan^{-1} B_2)$

10. Concentric cylinders of infinite length

Reference: Hottel [290]

Definition: $D = D_1/D_2$

Governing equations: $F_{1-2} = 1$; $F_{2-2} = 1 - D$; $F_{2-1} = D$

11. Infinite parallel cylinders of different radius

References: Felske [287]; Juul [294]

Definitions: $R = r_2/r_1$; $S = s/r_1$; $C = 1 + R + S$

Governing equations:

Approximate (within 3.9 percent),

Felske: $F_{1-2} = \frac{C}{\pi} \sin^{-1} \left(\frac{1}{C} \right) \times \sin^{-1} \left(\frac{R}{C} \right)$

Exact solution, Juul:

$$F_{1-2} = \frac{1}{2\pi} \left\{ \pi + [C^2 - (R+1)^2]^{1/2} - [C^2 - (R-1)^2]^{1/2} + (R-1) \cos^{-1} \left[\left(\frac{R}{C} \right) - \left(\frac{1}{C} \right) \right] \right. \\ \left. - (R+1) \cos^{-1} \left[\left(\frac{R}{C} \right) + \left(\frac{1}{C} \right) \right] \right\}$$

12. Outer surface of cylinder to disk at end of cylinder

References: Sparrow et al. [304];
Naraghi and Chung [300]; Masuda [298]

Definitions: $R = r_1/r_2$; $H = h/r_2$;

$A = H^2 + R^2 - 1$; $B = H^2 - R^2 + 1$

Governing equation:

$$F_{1-2} = \frac{B}{8RH} + \frac{1}{2\pi} \left\{ \cos^{-1} \left(\frac{A}{B} \right) - \frac{1}{2H} \left[\frac{(A+2)^2}{R^2} - 4 \right]^{1/2} \cos^{-1} \left(\frac{AR}{B} \right) - \frac{A}{2RH} \sin^{-1} R \right\}$$

13. Inner surface of right circular cylinder to itself

Reference: Buschman and Pittman [282]

Definition: $H = h/2r$

Governing equation: $F_{1-1} = 1 + H - (1 + H^2)^{1/2}$

14. Base of right circular cylinder to inside surface of cylinder

References: Leuenberger and Person [297];
Buschman and Pittman [282]; Buraczewski [281]

Definition: $H = h/2r$

Governing equation: $F_{1-2} = 2H[(1 + H^2)^{1/2} - H]$

15. Sphere to coaxial disk

References: Feingold and Gupta [286];
Naraghi and Chung [300]

Definitions: $R = r/h$

Governing equation: $F_{1-2} = \frac{1}{2} \left[1 - \frac{1}{(1 + R^2)^{1/2}} \right]$

NOMENCLATURE

Symbol, Definition, Unit

A	Area (m ²); fraction absorbed by slab
a_i	Coefficients of the Legendre polynomial expansion of scattering phase function, Eq. 7.100
b_i	Coefficients of the polynomial expansion of the WSGG models, Eq. 7.176
C	Cross sections for particle absorption, extinction, scattering (m ²)
C_1, C_2	Radiation constants, Eq. 7.4
C_3	Constant in Wien's law, Eq. 7.10
c	Speed of light (m/s)
c_p	Specific heat (kJ/kg - K)
D	Particle diameter (μm)
d	Differential; pore diameter (mm)
e	Eccentricity factor for ellipsoidal particles ($= D_{\text{minor}}/D_{\text{major}}$), Eqs. 7.191, 7.192
e_b	Planck's blackbody emissive power (W/m ²)

$F_{0-n\lambda T}$	Fractional blackbody function of first kind
F	Configuration factor
f_v	Volume fraction of particles (m^3/m^3)
f, g	Constants in phase function, Eqs. 7.102, 7.103
G	Incident radiation, Eq. 7.109
h	Planck's constant ($\text{J} - \text{s}$)
I	Radiation intensity ($\text{W}/\text{m}^2 - \text{sr}$)
K	Constant
k	Imaginary part of the complex index of refraction; Boltzmann constant (J/K); conductivity ($\text{W}/\text{m} - \text{K}$)
L_e	Effective path length, (m)
l	Path
M	Radiation intensity in upper/lower hemispheres, Eqs. 7.112, 7.113
m	Complex index of refraction, $m = n - ik$
N	Particle number density ($\#/\text{m}^3$); number of surfaces in enclosure; number of Monte Carlo samples
n	Real part of the complex index of refraction
\hat{n}	Surface normal
P	Total pressure (atm)
p	Partial pressure (atm)
Q	Efficiency factors for particle absorption, extinction, scattering (m^2), Eq. 7.180
q	Radiative flux (W/m^2)
R	Random number; fraction reflected from slab
r	Radius (m)
r_e	Electrical resistivity (ohm - cm)
S	Event counter in Monte Carlo analysis; volumetric source term (kW/m^3)
T	Temperature (K); fraction transmitted through slab
V_p	Volume of the computational cell (m^3)
w	Weights in discrete ordinates approximation; energy per sample in Monte Carlo analysis
x	Size parameter ($= \pi D/\lambda$)
x, y, z	Cartesian coordinates (m)

Greek Letters

α	Absorptivity; band strength parameter
β	Extinction coefficient (m^{-1}); coefficient of volume expansion, Eq. 7.197
γ	Constant, Eqs. 7.193 and 7.194
δ_{kj}	Kronecker delta function
ϵ	Emissivity
η	Direction cosine, Eq. 7.111; wave number ($= 1/\lambda$) [cm^{-1}]
Θ	Scattering angle
θ	Zenith angle
κ	Absorption coefficient (m^{-1})

λ	Wavelength (μm ; nm)
μ	Direction cosine, Eq. 7.111
ν	Frequency (sec^{-1})
ξ	Direction cosine, Eq. 7.111; $C_2/n\lambda T$, Eq. 7.14
ρ	Reflectivity; density (kg/m^3)
σ	Stefan-Boltzmann constant, Eq. 7.13; scattering coefficient (m^{-1})
τ	Optical thickness; transmissivity
Φ	Scattering phase function, Eq. 7.99; function given by Eq. 7.157
ϕ	Azimuthal angle
Ψ	Function given by Eq. 7.156
χ	Angle of refraction
Ω	Solid angle (sr)
ω	Single scattering albedo; bandwidth parameter (cm^{-1})

Subscripts

abs	Absorption
<i>b</i>	Blackbody
ext	Extinction
<i>g</i>	Gas
<i>i</i>	Incident; incoming
<i>m</i>	Gaussian quadrature index, Eqs. 7.132, 7.133
<i>o</i>	Outgoing
<i>P</i>	Planck mean value
<i>R</i>	Rosseland mean value
<i>r</i>	Radial component; reflected
rad	Radiative
<i>s</i>	Source; substrate
sca	Scattering
<i>z</i>	Axial component
λ	Spectral (wavelength-dependent)
η	Spectral (wave-number-dependent)
ν	Spectral (frequency-dependent)
0	In vacuum

Superscripts

<i>d</i>	Diffuse
<i>s</i>	Specular
2	Function of two independent parameters, Eq. 7.53
3	Function of three independent parameters, Eqs. 7.49–7.52
–	Normalized or averaged coefficients
→	Vector
'	Directional dependent properties
+, –	Upper, lower hemispheres in DP_1 approximation, Eqs. 7.112, 7.113

Others

RTE	Radiative transfer equation
∇	Divergence operator

CHAPTER 8

MICROSCALE TRANSPORT PHENOMENA

A. Majumdar

University of California at Berkeley

INTRODUCTION

Heat transfer involves the transport of energy from one place to another by energy carriers. In gas phase, gas molecules carry energy either by random molecular motion (diffusion) or by an overall drift of the molecules in a certain direction (advection). In liquids, too, energy can be transported by diffusion and advection of molecules. In solids, however, energy is transported by phonons, electrons, or photons. A *phonon* is a quantum of crystal vibrational energy and dominates heat conduction in insulators and semiconductors. Electrons dominate energy transport in metals. *Photons* are quanta of electromagnetic energy and can transport energy in solids as well as interact with photons and phonons to render radiative properties of solids. The only mode of energy transport in vacuum is by photons.

The study of heat transfer at macroscales by all these energy carriers is well established and is based on continuum theories. For example, energy diffusion in gases, liquids, and solids is usually studied by the Fourier law of heat conduction. Although the physics of all the energy carriers are vastly different, what seems remarkable is the applicability of the Fourier law of heat conduction for any energy carrier—molecules, phonons, electrons, and even photons under the optically thick limit. So, there must be some universality in the transport of all these energy carriers at the macroscopic or continuum scales. The question that one could ask is the following. Does this universality break down at some length scale or is it universal over all length scales? This chapter will attempt to answer this question.

The second fact that is implicit in macroscopic or continuum laws is the idea of local thermodynamic equilibrium. For example, when we write the Fourier law of heat conduction, it is inherently assumed that one can define a temperature at any point in space. This is a rather severe assumption since temperature can be defined only under thermodynamic equilibrium. The question that we might ask is the following. If there is thermodynamic equilibrium in a system, then why should there be any net transport of energy? Thus, we implicitly resort to the concept of local thermodynamic equilibrium, where we assume that thermodynamic equilibrium can be defined over a volume which is much smaller than the overall size of the system. What happens when the size of the object becomes on the order of this volume? Obviously, the macroscopic or continuum theories break down and new laws based on nonequilibrium thermodynamics need to be formulated. This chapter focuses on developing more generalized theories of transport which can be used for nonequilibrium conditions. This involves going to the root of the macroscopic or continuum theories.

Nonequilibrium conditions can be created not only by size restrictions, but also by short time scales. For example, the response time for electrons in metals is much shorter than that of the crystal vibrations or phonons. Hence, if we heat a metal by a sufficiently short pulse of energy, only the electrons will be energized leaving the phonons relatively untouched. This can create nonequilibrium between the electrons and phonons in a metal which can also lead to nonequilibrium phenomena. This chapter addresses such nonequilibrium conditions.

TIME AND LENGTH SCALES

It is clear that continuum and noncontinuum effects must be demarcated by certain characteristic time and length scales of the energy carriers. The smallest length scale for each of the energy carriers in a solid—phonon, electron, or photon—is its wavelength λ . For electrons in a metal that are involved in energy transport, this is typically on the order of 1 to 10 Å. For phonons in semiconductors and insulators, energy is spread over a whole range of wavelengths. However, the wavelength range dominant in energy is typically on the order of 3 to 20 Å at room temperature, which can increase to the 1 μm range as the temperature is reduced. Photons in the visible spectrum fall in the range of 0.4 to 0.7 μm . The near to far infrared span 0.7 to about 50 μm . For gas molecules, the wavelength is too short for wave effects to be important.

Scattering of energy carriers poses resistance to energy transport. In its absence, energy transport will occur at infinite conductivity or conductance. Therefore, it is necessary to study the scattering process in more detail. Associated with scattering are several characteristic time and length scales. These are illustrated in Table 8.1. Consider the timescales first.

TABLE 8.1 Characteristic Time- and Length Scales and Corresponding Transport Phenomena of Energy Carriers

Time scales	Length scales			
	Wavelength λ	Mean free path ℓ	Relaxation length ℓ_r	Diffusion length ℓ_d
Collision time τ_c		Wave transport		
Mean free time τ	Wave transport	Microscopic particle transport theories		
Relaxation time τ_r				
Diffusion time τ_d				Macroscopic or continuum transport

The smallest timescale is the collision time or duration of collision τ_c . Collisions are normally considered instantaneous in classical physics. However, this is not entirely true and there is a finite collision time during wave scattering. This is on the order of the wavelength of the carrier divided by the propagation speed. For electrons in a metal, this is about 10^{-15} s (1 fs) whereas for phonons this is about 10^{-13} s (100 fs). The next timescale is the average time between collision τ or the mean free time. For timescales $t \leq \tau$, carriers travel ballistically and the evolution of the system depends strongly on the details of the initial state. Note that τ is not the relaxation time since it takes several collisions to reach equilibrium. Generally $\tau \gg \tau_c$, although this breaks down in certain cases. For electrons in a metal at room temperature, τ is on the order of 10^{-14} s whereas for phonons in solids it is on the order of 10^{-11} s. For gas molecules, the mean free time is given as ℓ/v where ℓ is the mean free path and v is the molecule velocity. The mean free path depends on the number density ρ and collision cross-sectional area σ and follows the relation $\ell \approx (\rho\sigma)^{-1}$ and is about 0.2 to 0.3 μm for molecules in air at atmospheric pressure. The root-mean-square velocity for gas molecules depends on the

temperature T and the molecule mass m and is given by the relation $v = \sqrt{3k_B T/m}$, where k_B is the Boltzmann constant. The velocity of oxygen and nitrogen molecules in air at room temperature is about 400 to 500 m/s making the mean free time about 10^{-10} to 10^{-9} s. In liquids, the mean free path is on the order of atomic dimensions or 10^{-10} m whereas the speeds of propagation are about 10^3 m/s. Hence, the mean free time is about 10^{-13} s. Collision-induced equilibrium gives rise to the relaxation time τ_r . Relaxation times are associated with local thermodynamic equilibrium. Since equilibrium is achieved in 5 to 20 collisions, $\tau_r > \tau$. Note that momentum and energy relaxation times of a system can be different. For example, an elastic collision of an electron can change its momentum but not its energy. Hence, energy relaxation times τ_{re} are typically longer than momentum relaxation times τ_{rm} . The last timescale is the diffusion time τ_d , which is on the order of $\tau_d \approx L^2/\alpha$ where L is the size of the object and α is the thermal diffusivity. This depends on particle speed v and mean free time as $\alpha \approx v^2\tau$. Clearly, $\tau_d \approx t_b^2/\tau$ where t_b is the time it takes for the particle to ballistically travel the distance L at speed v . For ballistic transport over a distance L , of course, $\tau \approx \tau_d$.

Note that the diffusion timescale τ_d contains a characteristic size of an object L . This ties in the length scale of the problem. Similarly, the mean free path ℓ can be associated with mean free time between collisions τ by the relation $\ell = v\tau$. Note that this is a statistical quantity since collision distances are not fixed. However, the probability p that a particle emerging from a collision travels a distance x without a collision is related to the mean free path as $p = \exp(-x/\ell)$. Associated with the relaxation time τ_r is a length scale ℓ_r , which is the characteristic size of a volume over which local thermodynamic equilibrium can be defined. Generally, the hierarchy of the length scales is $\lambda < \ell < \ell_r$.

Depending on time t and length L scales of interest, different transport laws can be used. Consider first the smallest length and timescales. For all objects that are comparable in size to the wavelength of the energy carrier, energy transport involves wave phenomena such as reflection, refraction, diffraction, tunneling, and so forth. When the timescale of interest t is of the order collision timescale τ_c , then, again, time-dependent wave mechanics must be used. For electrons and phonons, the Schrodinger equation must be solved to study such phenomena, whereas for photons, Maxwell's equations must be solved. We will not discuss wave transport in this chapter. Instead we will study the intermediate regime of length scales larger than the wavelength of the energy carrier and smaller than the macroscopic scales where continuum theories are valid. This intermediate length scale deals with scattering of energy carriers.

Now consider the next larger length and timescales ℓ or ℓ_r and τ or τ_r . When $L \approx \ell$, ℓ_r and $t \gg \tau$, τ_r , transport is ballistic in nature and local thermodynamic equilibrium cannot be defined. This transport is nonlocal in space. One has to resort to time-averaged statistical particle transport equations. On the other hand, if $L \gg \ell$, ℓ_r and $t \approx \tau$, τ_r , then approximations of local thermodynamic equilibrium can be assumed over space although time-dependent terms cannot be averaged. The nonlocality is in time but not in space. When both $L \approx \ell$, ℓ_r and $t \approx \tau$, τ_r , statistical transport equations in full form should be used and no spatial or temporal averages can be made. Finally, when both $L \gg \ell$, ℓ_r and $t \gg \tau$, τ_r , local thermodynamic equilibrium can be applied over space and time leading to macroscopic transport laws such as the Fourier law of heat conduction.

Let us consider the last case first since that is the easiest one and it also ties the microscopic transport characteristics to the macroscopic world.

KINETIC THEORY

Formulation

The kinetic theory of transport phenomena is the most elementary and perhaps the first step toward understanding more complex transport theories [1]. Consider a plane z , across which particles travel carrying mass and kinetic energy. Consider two fictitious planes at $z + \ell_z$ and

FIGURE 8.1 Schematic diagram showing energy flux across a z plane used in kinetic theory.

$z - \ell_z$ on either side of the z plane as shown in Fig. 8.1. Here, ℓ_z is the z component of the mean free path ℓ which makes an angle θ from the direction perpendicular to z . On average, the particles moving down from $z + \ell_z$ contain an energy density u that is characteristic of the location $u(z + \ell_z)$, whereas those moving up from $z - \ell_z$ have characteristic energy density $u(z - \ell_z)$. If the particles move with a characteristic velocity v then the net flux of energy in the positive z direction is

$$q_z = \frac{1}{2} v_z [u(z - \ell_z) - u(z + \ell_z)] \quad (8.1)$$

where v_z is the z component of the velocity and the factor $\frac{1}{2}$ is used since only half of the total number of particles at each location move up from $z - \ell_z$ or down from $z + \ell_z$. Using Taylor expansion and keeping only the first order terms, one gets

$$q_z = -v_z \ell_z \frac{du}{dz} = -(\cos^2 \theta) v \ell \frac{du}{dz} \quad (8.2)$$

where it is assumed that $\ell_z = \ell \cos \theta$ and $v_z = v \cos \theta$. Averaging over the whole hemisphere of solid angle 2π , one gets

$$q_z = -v \ell \frac{du}{dz} \left[\frac{1}{2\pi} \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} \cos^2 \theta \sin \theta \, d\theta \, d\phi \right] = -\frac{1}{3} v \ell \frac{du}{dz} \quad (8.3)$$

where ϕ is the azimuthal angle and θ is the polar angle and $\sin \theta \, d\theta \, d\phi$ is the elemental solid angle. Assuming local thermodynamic equilibrium such that u is a function of temperature, one can write the flux as

$$q_z = -\frac{1}{3} v \ell \frac{du}{dT} \frac{dT}{dz} = -\frac{1}{3} C v \ell \frac{dT}{dz} \quad (8.4)$$

This is the Fourier law of heat conduction with the thermal conductivity being $k = C v \ell / 3$. Note that we have not made any assumption of the type of energy carrier and, hence, this is a universal law for all energy carriers. The only assumption made is that of local thermodynamic equilibrium such that the energy density u at any location is a function of the local temperature.

The characteristics of the energy carrier are included in the heat capacity C , velocity v , and the mean free path ℓ . Neglecting photons for now, the thermal conductivity can be written as

$$k = \frac{1}{2}[(Cv\ell)_l + (Cv\ell)_e] \quad (8.5)$$

where the first term is the lattice contribution and the second term comes from electrons. In the case of electrons in a metal, the electron contribution is dominant, whereas for semiconductors and insulators, the phonon contribution is dominant.

For gas molecules, the heat capacity is a constant equal to $C = (n/2)\rho k_B$ where n is the number of degrees of freedom for molecule motion, ρ is the number density, and k_B is the Boltzmann constant. The rms speed of molecules is given as $v = \sqrt{3k_B T/m}$, whereas the mean free path depends on collision cross section and number density as $\ell \approx (\rho\sigma)^{-1}$. When they are put together, one finds that the thermal conductivity of a gas is independent of ρ and therefore independent of the gas pressure. This is a classic result of kinetic theory. Note that this is valid only under the assumption that the mean free path is limited by intermolecular collision.

Thermal Conductivity of Crystalline and Amorphous Solids

Since the thermal conductivity depends on C , v , and ℓ , let us investigate the characteristics of these quantities. The electron heat capacity in a metal varies linearly with temperature $C = (\pi^2 \rho k_B^2 / 2E_F) T$ where E_F is the Fermi energy of a metal and ρ is the electron number density. This is a consequence of the free electron theory of metals in which only electrons within an energy range $k_B T$ around the Fermi energy E_F are responsible for transport phenomena [2]. Here, k_B is the Boltzmann constant (1.38×10^{-23} J/K) and T is the absolute temperature. The Fermi energy of most metals falls in the range of 3 to 10 eV whereas the thermal energy $k_B T$ is 0.026 eV at room temperature. Hence, only a small fraction of all the electrons in a metal contribute to energy transport in metals.

The velocity relevant for transport is the Fermi velocity of electrons. This is typically on the order of 10^6 m/s for most metals and is independent of temperature [2]. The mean free path ℓ can be calculated from $\ell = v_F \tau$ where τ is the mean free time between collisions. At low temperature, the electron mean free path is determined mainly by scattering due to crystal imperfections such as defects, dislocations, grain boundaries, and surfaces. Electron-phonon scattering is frozen out at low temperatures. Since the defect concentration is largely temperature independent, the mean free path is a constant in this range. Therefore, the only temperature dependence in the thermal conductivity at low temperature arises from the heat capacity which varies as $C \propto T$. Under these conditions, the thermal conductivity varies linearly with temperature as shown in Fig. 8.2. The value of k , though, is sample-specific since the mean free path depends on the defect density. Figure 8.2 plots the thermal conductivities of two metals. The data are the best recommended values based on a combination of experimental and theoretical studies [3].

As the temperature is increased, electron-phonon scattering becomes dominant. The mean free path for such scattering varies as $\ell \propto T^{-n}$ with n larger than unity. The mean free path of electrons at room temperature is typically on the order of 100 Å. The mean free path depends on the material but is independent of the sample, since electron-phonon scattering is an intrinsic process. As a result of electron-phonon scattering, thermal conductivity of metals decreases at higher temperatures.

Although the lattice heat capacity in a metal is much larger than its electronic contribution, the Fermi velocity of electrons (typically 10^6 m/s) is much larger than the speed of sound (about 10^3 m/s). Due to the higher energy carrier speed, the electronic contribution to the thermal conductivity turns out to be more dominant than the lattice contribution. For a semiconductor, however, the velocity is not the Fermi velocity but equal to the thermal velocity of the electrons or holes in the conduction or valence bands, respectively. This can be approximated as $v \approx \sqrt{3k_B T/m^*}$, where m^* is the effective electron mass in the conduction band or hole mass in the valence band. This is on the order of 10^5 m/s at room temperature. In addition, the number density of conduction band electrons in a semiconductor is much less than

FIGURE 8.2 Thermal conductivity of aluminum and copper as a function of temperature [3]. Note that at low temperature, the thermal conductivity increases linearly with temperature. In this regime, defect scattering dominates and the mean free path is independent of temperature. The thermal conductivity in this regime depends on the purity of the sample. The linear behavior arises from the linear relation between the electronic heat capacity and temperature. As the temperature is increased, phonon scattering starts to dominate and the mean free path reduces with increasing temperature. To a large extent, the thermal conductivity of a metal is independent of the purity of the sample.

the electron density in metals. Hence, the electronic heat capacity is also lower than that of metals. This leads to the fact that electrons play an insignificant role in heat conduction in semiconductors. Therefore, as far as heat conduction is concerned, semiconductors and insulators fall in the same class of materials.

Phonons are quanta of crystal vibration [2,4]. The physics of phonons is quite similar to that of photons in that they follow Bose-Einstein statistics. However, there are some key differences, namely: (1) phonons have a lower cut-off in wavelength and upper cut-off in frequency whereas photon wavelength and frequency are not limited; (2) phonons can have longitudinal polarization whereas photons are transverse waves; (3) phonon-phonon interaction can emit or annihilate phonons and thereby restore thermodynamic equilibrium. Despite these differences, heat conduction by phonons can be studied as a radiative transfer problem.

Figure 8.3 shows the thermal conductivity of crystalline diamond samples with different defect concentrations [5]. At low temperatures, the thermal conductivities of all the samples are nearly equal and follow the T^3 behavior [2,4,6]. This arises from the Planck distribution of phonons at low temperatures. The dominant phonon wavelength at low temperatures can be very large as suggested by the relation $\lambda_{\text{dom}} = hv_s/3k_B T$. This is essentially the Wien's displacement law applied to phonons. Hence, the dominant wavelength at low temperatures can be much larger than crystal imperfections such as point defects, dislocations, and grain boundaries. Therefore, mean free path is not limited by the defect scattering but by the size of the crystal. Hence, the mean free path at very low temperatures is temperature-independent.

Phonon velocity is constant and is the speed of sound for acoustic phonons. The only temperature dependence comes from the heat capacity. Since at low temperature, photons and phonons behave very similarly, the energy density of phonons follows the Stefan-Boltzmann relation $\sigma T^4/v_s$, where σ is the Stefan-Boltzmann constant for phonons. Hence, the heat capacity follows as $C \propto T^3$ since it is the temperature derivative of the energy density. However, this T^3 behavior prevails only below the Debye temperature which is defined as $\theta_D = \hbar\omega_D/k_B$. The Debye temperature is a fictitious temperature which is characteristic of the material since it involves the upper cutoff frequency ω_D which is related to the chemical bond strength and the mass of the atoms. The temperature range below the Debye temperature can be thought as the quantum requirement for phonons, whereas above the Debye temperature the heat capacity follows the classical Dulong-Petit law, $C = 3\eta k_B$ [2,4] where η is the number density of atoms. The thermal conductivity well below the Debye temperature shows the T^3 behavior and is often called the *Casimir limit*.

FIGURE 8.3 Thermal conductivity of diamond as a function of temperature [5]. The solid line represents the T^3 behavior.

As the temperature is increased, λ_{dom} becomes comparable to the defect sizes and, hence, the defect concentration in the crystal determines the thermal conductivity. This is the regime near the peak of the thermal conductivity which occurs when the temperature is on the order of $T \approx \theta_D/10$. Although defect scattering is temperature-independent, phonon-phonon interactions are highly temperature-dependent. There are two types of phonon-phonon interactions, namely, normal and Umklapp. *Normal* or *N-scattering* conserves energy and momentum during collision of two or more phonons, whereas *Umklapp* or *U-scattering* conserves energy but does not conserve momentum. Although normal scattering does not directly pose any resistance, it distributes the phonon energy to higher frequencies.

As the temperature is increased beyond $\theta_D/10$, C becomes a constant ($=3\eta k_B$). Also, the phonon density at high frequency and large wave vectors becomes sufficiently high that phonon-phonon Umklapp scattering dominates and determines the phonon mean free path.

Hence, the mean free path decreases drastically with temperature which results in a sharp drop in thermal conductivity with increasing temperature.

Figure 8.4 shows the thermal conductivity for quartz (crystalline SiO_2) and amorphous silica (a-SiO_2) [7]. The quartz data follows the T^3 behavior at low temperature, peaks at about 10 K, and then drops with increasing temperature. As discussed before, this is the expected trend for a crystalline solid. However, amorphous silica behaves very differently. The value of the thermal conductivity is much lower than that of the crystalline sample for all values of temperature. In addition, the temperature dependence of the conductivity is also vastly different. Hence, the model proposed for crystalline solids cannot be applied for such a case. Note that the relation $k = C v \ell / 3$ is still valid although the heat capacity and the mean free path cannot be determined by relations used for crystalline solids.

In 1911, Einstein proposed a model for heat conduction in amorphous solids. In this model, he assumed that all the atoms vibrate as harmonic oscillators at the same frequency ω_E . In addition, he also assumed that a particular oscillator (or atom) is coupled to only first, second, and third nearest neighbors. Hence, the vibrational energy of the oscillator can only be transferred to these atoms. A further assumption was that the phases of these oscillators were uncorrelated and were completely random. Using these assumptions, he derived the thermal conductivity to be

$$k_E = \frac{k_B^2}{\hbar} \frac{\eta^{1/3}}{\pi} \theta_E \frac{x^2 e^x}{(e^x - 1)^2} \quad (8.6)$$

where η is the number density of oscillators, θ_E is the Einstein temperature, and $x = \theta_E/T$. The Einstein temperature is defined as $\theta_E = \hbar \omega_E / k_B$. Unfortunately, the predictions of this theory

FIGURE 8.4 Thermal conductivity of quartz and glassy silica as a function of temperature [7]. The quartz thermal conductivity exhibits a T^3 behavior at low temperature, a peak at about 10 K, then reduction at higher temperatures. This is typical of a crystalline solid. For amorphous glass the thermal conductivity increases as T^2 plateaus between 1 to 10 K and then increases monotonically with temperature. Also plotted are the predictions of the Cahill-Pohl and Einstein models. The Cahill-Pohl model provides accurate predictions for temperatures higher than 50 K but cannot predict the low temperature behavior. The Einstein model predictions are much lower than the measured values.

were far below those of the measured data as can be observed in Fig. 8.4. The major flaw in this theory was in the assumption that the phases of the neighboring oscillators were uncorrelated. The success of the Debye theory was based on the fact that it considered the coherence of a crystal wave for a distance on the order of a mean free path.

Cahill and Pohl [8,9] recently developed a hybrid model which has the essence of both the localized oscillators of the Einstein model and coherence of the Debye model. In the Cahill-Pohl model, it was assumed that a solid can be divided into localized regions of size $\lambda/2$. These localized regions were assumed to vibrate at frequencies equal to $\omega = 2\pi v_s/\lambda$ where v_s is the speed of sound. Such an assumption is characteristic of the Debye model. The mean free time of each oscillator was assumed to be one-half the period of vibration or $\tau = \pi/\omega$. This implies that the mean free path is equal to the size of the region or $\lambda/2$. Using these assumptions, they derived the thermal conductivity to be

$$k_{CP} = \left(\frac{\pi}{6}\right)^{1/3} k_B \eta^{2/3} \sum_i v_{si} \left(\frac{T}{\theta_i}\right)^2 \int_0^{\theta_i/T} \frac{x^3 e^x}{(e^x - 1)^2} dx \quad (8.7)$$

where $x = \theta_i/T$ and $\theta_i = v_{si}(\hbar/k_B)(6\pi\eta)^{1/3}$ is a characteristic temperature equivalent to the Debye and Einstein temperatures. The summation is over the two transverse and one longitudinal polarizations for which the speeds of sound can be different. Note that the agreement between the Cahill-Pohl model and the measured thermal conductivity above 50 K is excellent. The validity of the model is further verified by comparing the measured and predicted thermal conductivities of several amorphous solids at 300 K. Below 50 K, there exists a plateau in the thermal conductivity and a sharp drop at temperatures below 10 K. In the limit $T \ll \theta_i$, the integral in Eq. 8.7 becomes a constant, and the thermal conductivity is expected to vary as $k_{CP} \propto T^2$. Although the trend seems to be correct, the measured values are higher than the predictions by an order of magnitude. This is due to the fact that the Cahill-Pohl model assumes the mean free path to be on the order of the phonon wavelength. At low temperatures ($T < 1$ K), however, the mean free path of the dominant phonons can be larger than the wavelength by a factor of 100.

Although the kinetic theory has been successfully applied to predict the thermal conductivity, it cannot be used under nonequilibrium conditions. For such cases, the Boltzmann transport theory is required.

BOLTZMANN TRANSPORT THEORY

General Formulation

Local thermodynamic equilibrium in space and time is inherently assumed in the kinetic theory formulation. The length scale that is characteristic of this volume is ℓ , whereas the timescale is τ . When either $L \approx \ell$, ℓ , or $t \approx \tau$, τ , or both, the kinetic theory breaks down because local thermodynamic equilibrium cannot be defined within the system. A more fundamental theory is required. The Boltzmann transport equation is a result of such a theory. Its generality is impressive since macroscopic transport behavior such as the Fourier law, Ohm's law, Fick's law, and the hyperbolic heat equation can be derived from this in the macroscale limit. In addition, transport equations such as equation of radiative transfer as well as the set of conservation equations of mass, momentum, and energy can all be derived from the Boltzmann transport equation (BTE). Some of the derivations are shown here.

In a general form, the BTE can be written as the following [4]:

$$\frac{\partial f}{\partial t} + \mathbf{v} \cdot \nabla f + \mathbf{F} \cdot \frac{\partial f}{\partial \mathbf{p}} = \left(\frac{\partial f}{\partial t}\right)_{\text{scat}} \quad (8.8)$$

where $f(\mathbf{r}, \mathbf{p}, t)$ is the statistical distribution function of an ensemble of particles, which varies with time t , particle position vector \mathbf{r} , and momentum vector \mathbf{p} . \mathbf{F} is the force applied to the

particles. The terms on the left side are called *drift terms*, whereas that on the right is the *scattering term*. The BTE applies to all ensembles of particles—electrons, ions, phonons, photons, gas molecules, and so forth—that follow a certain statistical distribution. Of all these, only charged particles such as electrons and ions can usually encounter an appreciable force \mathbf{F} due to electric and magnetic fields. In the case of electrons under an electric field, for example, the third term on the left side can be written as

$$-\frac{e\mathbf{E}}{\hbar} \cdot \frac{\partial f}{\partial \mathbf{k}} \quad (8.9)$$

where \mathbf{E} is the electric field vector, e is the electron charge, and \mathbf{k} is the electron wave vector.

The right-hand side of Eq. 8.8 is the rate of change of the distribution due to collisions or scattering. This is the term which restores equilibrium. In its most rigorous form, this is very complicated since collisions transfer particles from one set of $(\mathbf{r}, \mathbf{p}')$ coordinates to another set of (\mathbf{r}, \mathbf{p}) coordinates. This can be written as

$$\left(\frac{\partial f}{\partial t}\right)_{\text{scat}} = \sum_{\mathbf{p}'} [W(\mathbf{p}, \mathbf{p}')f(\mathbf{p}') - W(\mathbf{p}', \mathbf{p})f(\mathbf{p})] \quad (8.10)$$

where $W(\mathbf{p}, \mathbf{p}')$ is the scattering rate from state \mathbf{p}' to \mathbf{p} . The first term in the summation is from scattering from \mathbf{p}' state to \mathbf{p} and the second term is vice versa. The scattering rates W are often nonlinear functions of \mathbf{p} which make it quite difficult to solve the BTE. However, a simplification is often made through the relaxation-time approximation which assumes that

$$\left(\frac{\partial f}{\partial t}\right)_{\text{scat}} = \frac{f_0 - f}{\tau(\mathbf{r}, \mathbf{p})} \quad (8.11)$$

where f_0 is the equilibrium distribution and $\tau(\mathbf{r}, \mathbf{p})$ is the relaxation time as a function of position and momentum. This approximation linearizes the BTE and implies that if a system is thrown out of equilibrium such that $f - f_0$ is nonzero, then collisions restore equilibrium with the dynamics following an exponential decay $f - f_0 \approx \exp(-t/\tau)$. Thus, the BTE under the relaxation-time approximation becomes

$$\frac{\partial f}{\partial t} + \mathbf{v} \cdot \nabla f + \mathbf{F} \cdot \frac{\partial f}{\partial \mathbf{p}} = \frac{f_0 - f}{\tau(\mathbf{r}, \mathbf{p})} \quad (8.12)$$

The equilibrium distribution could be of any type—Maxwell-Boltzmann for gas molecules, Fermi-Dirac for electrons, and Bose-Einstein for photons and phonons.

To study energy transport by particles, it is necessary to solve the BTE to determine the distribution function $f(\mathbf{r}, \mathbf{p}, t)$. Once found, the rate of energy flow per unit area or the energy flux can then be written as

$$\mathbf{q}(\mathbf{r}, t) = \sum_{\mathbf{p}} \mathbf{v}(\mathbf{r}, t) f(\mathbf{r}, \mathbf{p}, t) \epsilon(\mathbf{p}) \quad (8.13)$$

where $\mathbf{q}(\mathbf{r}, t)$ is the energy flux vector, $\mathbf{v}(\mathbf{r}, t)$ is the velocity vector, and $\epsilon(\mathbf{p})$ is the particle energy as a function of particle momentum. Note that the units of $f(\mathbf{r}, \mathbf{p}, t)$ is number per unit volume per unit momentum. The summation over momentum space can be changed into an integral over momentum

$$\mathbf{q}(\mathbf{r}, t) = \int \mathbf{v}(\mathbf{r}, t) f(\mathbf{r}, \mathbf{p}, t) \epsilon(\mathbf{p}) d^3\mathbf{p} \quad (8.14)$$

The integral can be changed to that over energy with the introduction of a density of states $D(\epsilon)$. The energy flux vector can then be written as

$$\mathbf{q}(\mathbf{r}, t) = \int \mathbf{v}(\mathbf{r}, t) f(\mathbf{r}, \epsilon, t) \epsilon D(\epsilon) d\epsilon \quad (8.15)$$

Fourier and Ohm's Laws

Although the solution of the BTE is not trivial, several simplifications can be made. If $t \gg \tau$, τ is assumed, then the most common simplification is to drop the time-varying term in Eq. 8.12. In addition, if $L \gg \ell$, ℓ is assumed, then the gradient term can be approximated as $\nabla f \approx \nabla f_0$ such that in the one-dimensional case, the BTE can be solved to yield

$$f = f_0 - \tau v_x \frac{\partial f_0}{\partial x} \quad (8.16)$$

where v_x is the x component of velocity. This can be called the *quasi-equilibrium* approximation. The only term that contains lack of equilibrium is the scattering term. Local thermodynamic equilibrium is inherently implied by the approximation $df/dx \approx df_0/dx$. However, since the local equilibrium f_0 can be defined only over a length scale ℓ , the approximation finally boils down to $df/dx \approx \Delta f_0/\ell$. This and the timescale approximations are also made in the kinetic theory, and, hence, one should expect the same results. Since the equilibrium distribution is a function of temperature, one can express

$$\frac{\partial f_0}{\partial x} = \frac{df_0}{dT} \frac{\partial T}{\partial x} \quad (8.17)$$

This leads to the energy flux

$$q_x(x) = - \frac{\partial T}{\partial x} \int v_x^2 \tau \frac{df_0}{dT} \varepsilon D(\varepsilon) d\varepsilon \quad (8.18)$$

The first term containing f_0 drops out since the integral over all the directions becomes zero. Equation 8.18 is the Fourier law of heat conduction with the integral being the thermal conductivity k . If one assumes that the relaxation time and velocity are independent of particle energy, then the integral becomes

$$k = \int v_x^2 \tau \frac{df_0}{dT} \varepsilon D(\varepsilon) d\varepsilon = v_x^2 \tau \int \frac{df_0}{dT} \varepsilon D(\varepsilon) d\varepsilon = \frac{1}{3} C v^2 \tau \quad (8.19)$$

This is exactly the kinetic theory result $k = C v \ell / 3$. Similar derivations and conclusions can be made for Fick's law.

Ohm's law is characterized by the relation $\mathbf{J} = \sigma \mathbf{E}$ where \mathbf{J} is the current density vector at any point in space, \mathbf{E} is the electric field vector, and σ is the electrical conductivity. The Fourier law is the energy analog of Ohm's law due to the following reasons. The electric field vector \mathbf{E} can be written as the negative gradient of the electric potential $\mathbf{E} = -\nabla \Phi$ and hence is analogous to the negative gradient of temperature. The energy flux vector \mathbf{q} in the Fourier law is analogous to the current density vector \mathbf{J} in Ohm's law. Using kinetic theory, it can be shown that the electrical conductivity follows the relation

$$\sigma = \frac{\eta_e e^2 \tau_m}{m} \quad (8.20)$$

where η_e is the density of electrons, e is the electron charge, τ_m is the momentum relaxation time, and m is the electron mass. The ratio of the thermal and electrical conductivity can be expressed by the Weidemann-Franz law [2] which is given as follows, where the right side contains only physical constants and is known as the Lorenz number [2].

$$\frac{k}{\sigma T} = \frac{\pi^2}{3} \left(\frac{k_B}{e} \right)^2 = 2.44 \times 10^{-8} \frac{W}{\Omega - K^2} \quad (8.21)$$

Note, however, that electrical conductivity is related to the momentum relaxation time, whereas the thermal conductivity is related to the energy relaxation time. They are usually close at room temperature or at very low temperatures.

Hyperbolic Heat Equation

If the Boltzmann transport equation is multiplied by the factor $v_x \varepsilon D(\varepsilon) d\varepsilon$ on both sides and integrated over energy, then the equation transforms into

$$\frac{\partial q_x}{\partial t} + \int v_x^2 \frac{\partial f}{\partial x} \varepsilon D(\varepsilon) d\varepsilon = - \int \frac{f v_x \varepsilon D(\varepsilon) d\varepsilon}{\tau(x, \varepsilon)} \quad (8.22)$$

The acceleration term is dropped in this equation. Consider the situation that $L \gg \ell$, ℓ_r and $t \approx \tau$, τ_r . Now make the following assumptions: (1) the relaxation time is independent of particle energy and is a constant; and (2) the quasi-equilibrium assumption is made for the term $\partial f / \partial x = (df_0/dT)(\partial T/\partial x)$. Then Eq. 8.22 becomes

$$\frac{\partial q_x}{\partial t} + \frac{q_x}{\tau} = - \frac{k}{\tau} \frac{\partial T}{\partial x} \quad (8.23)$$

This is the Cattaneo equation [10], which, in combination with the following energy conservation equation,

$$C \frac{\partial T}{\partial t} + \frac{\partial q_x}{\partial x} = 0 \quad (8.24)$$

leads to the hyperbolic heat equation of the form [10]

$$\tau \frac{\partial^2 T}{\partial t^2} + \frac{\partial T}{\partial t} = \frac{k}{C} \frac{\partial^2 T}{\partial x^2} \quad (8.25)$$

The solution of Eq. 8.25 is wavelike, suggesting that the temperature field propagates as a wave. The speed of propagation of this wave is equal to $\sqrt{k/C\tau}$ which also happens to be the speed of the energy carrier, for example, the speed of sound for phonons. So, this model is nonlocal in time but local in space since the temperature represents a spatially localized thermodynamic equilibrium.

Mass, Momentum, and Energy Conservation—Hydrodynamic Equations

The conservation equations that are encountered in fluid mechanics, heat transfer, and electron transport can be derived as different moments of the BTE [11]. Consider a function $\phi(\mathbf{p})$, which is a power of the particle momentum $\phi(\mathbf{p}) = \mathbf{p}^n$ where n is an integer ($n = 0, 1, 2, \dots$). Its average can be described as

$$\langle \phi(\mathbf{p}) \rangle = \frac{1}{\rho} \int \phi(\mathbf{p}) f(\mathbf{p}) d^3 \mathbf{p} \quad (8.26)$$

where ρ is the number density of particles. The BTE is now multiplied by $\phi(\mathbf{p})$ and integrated over momentum. In general form, this gives the *moment equation*

$$\frac{\partial(\rho\langle\phi\rangle)}{\partial t} + \frac{1}{m} \nabla \cdot (\rho\langle\mathbf{p}\phi\rangle) - \rho \mathbf{F} \cdot \left\langle \frac{\partial \phi}{\partial \mathbf{p}} \right\rangle = \rho \sum_{\mathbf{p}'} [\langle W(\mathbf{p}, \mathbf{p}') \phi(\mathbf{p}') \rangle - \langle W(\mathbf{p}', \mathbf{p}) \phi(\mathbf{p}) \rangle] \quad (8.27)$$

Note that the momentum of each particle can be divided into two components as follows

$$\mathbf{p} = \mathbf{p}_d + \mathbf{p}_r \quad (8.28)$$

where \mathbf{p}_d is the average or drift momentum corresponding to a collective motion of particles in response to an external potential gradient, and \mathbf{p}_r is the random component of the momentum which arises due to thermal motion and is responsible for diffusion. Note that $\langle \mathbf{p} \rangle = \mathbf{p}_d$ since the average of the random component over all the momentum space is zero.

The zeroth moment is when $n = 0$ and $\phi(\mathbf{p})$ is a constant. Using this, one gets the continuity or number conservation equation which is

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}_d) = S_0 - S_i \quad (8.29)$$

where \mathbf{v}_d is the drift velocity, S_0 is the source or rate of generation rate of particles and S_i is the sink or removal rate of particles. In the case of fluids, there are no sources or sinks and hence the right side is zero. However, when electrons and holes are considered, the zeroth moment equation can be written for each valley of the electronic structure of a semiconductor or a metal. Intervalley scattering due to electron-electron, electron-hole, electron-photon, or electron-phonon interactions may be responsible for particle exchange between the different valleys and bands. This creates a source or sink in each valley in which case the right side of Eq. 8.29 may be nonzero. However, if all the valleys and bands are considered together, the right side would be zero since charge or mass must be conserved.

The momentum conservation equation is obtained by taking the first moment, $\phi(\mathbf{p}) = \mathbf{p} = m\mathbf{v}$. This yields the following equation

$$\frac{\partial(\rho \mathbf{p}_d)}{\partial t} + \frac{1}{m} \nabla \cdot (\rho \langle \mathbf{p} \mathbf{p} \rangle) - \rho \mathbf{F} = \left(\frac{\partial(\rho \mathbf{p})}{\partial t} \right)_{\text{scat}} \quad (8.30)$$

The second term is the average of a tensorial quantity. However, since the average of odd powers of \mathbf{p} , is zero, we get $\langle \mathbf{p} \mathbf{p} \rangle = \mathbf{p}_d \mathbf{p}_d + p^2 \delta_{ij}$ where δ_{ij} is the unit tensor. The third term of the left side is what is referred to as a *body force term* in fluid mechanics. It is perhaps more appropriate to refer to it as a *potential gradient term* since a thermodynamic force can be written as a gradient of any potential $\mathbf{F} = -\nabla U$. The potential U is a sum of the gravitational potential G , electrochemical potential Φ , and so forth. For electrons in a metal or semiconductor, the force can be due to electric or magnetic fields which can also be expressed as a gradient of a potential. The right side of Eq. 8.30 is the scattering term. Under the relaxation time approximation, the right side can be assumed to follow

$$\left(\frac{\partial(\rho \mathbf{p})}{\partial t} \right)_{\text{scat}} = -\frac{\rho \mathbf{p}}{\tau_m} \quad (8.31)$$

where τ_m is the momentum relaxation time. Therefore, the momentum conservation equation becomes

$$\frac{\partial(\rho \mathbf{p}_d)}{\partial t} + \frac{1}{m} \nabla \cdot (\rho \mathbf{p}_d \mathbf{p}_d) + \frac{1}{m} \nabla(\rho p^2) = -\rho \nabla(G + \Phi + \dots) - \frac{\rho \mathbf{p}_d}{\tau_m} \quad (8.32)$$

The third term on the left side has the form of the kinetic energy of the random particle motion and is representative of the pressure of the particles. Therefore, Eq. 8.32 can be rewritten in the following form:

$$\frac{\partial(\rho m \mathbf{v}_d)}{\partial t} + \nabla \cdot (\rho m \mathbf{v}_d \mathbf{v}_d) = -\rho \nabla \left(\frac{P}{\rho} + G + \Phi + \dots \right) - \frac{\rho m \mathbf{v}_d}{\tau_m} \quad (8.33)$$

The second term on the left side is often referred to as the *advection term*. When this is negligible, Eq. 8.33 under zero acceleration reduces to the form

$$\mathbf{v}_d = -\frac{\tau_m}{m} \nabla \left(\frac{P}{\rho} + G + \Phi + \dots \right) \quad (8.34)$$

In the case of electron transport where $\Phi = eV + k_B T \ln(\rho)$ is the electrochemical potential, one can derive the familiar drift-diffusion equation [11]:

$$\mathbf{J} = \frac{\rho e^2 \tau_m}{m} \mathbf{E} + \frac{\rho e \tau_m}{m} \nabla(k_B T \ln \rho) \quad (8.35)$$

Here, the first term is the drift term representing Ohm's law with the electrical conductivity being $\sigma = \rho e^2 \tau_m / m$. The second term is the diffusion term which gives rise to thermoelectric effects and current flow due to electron concentration gradients. In the case of fluid transport, neglecting the left side of Eq. 8.34 gives

$$\mathbf{v} = -\frac{\tau_m}{m} \nabla \left(\frac{P}{\rho} \right) \quad (8.36)$$

which is equivalent to the Darcy equation for flows in porous media. It is evident that Eq. 8.33 has the familiar form of the Navier-Stokes equation except for the last term involving collisions. The Navier-Stokes equation can be derived from the BTE using the Chapman-Enskog approximation where the right side of Eq. 8.33 leads to the diffusion term [1].

The energy conservation equation is obtained from Eq. 8.27 if the second moment is taken $\phi(\mathbf{p}) = p^2$ since energy $\varepsilon = p^2/2m$. This yields the following equation:

$$\frac{\partial \xi}{\partial t} + \nabla \cdot \mathbf{J}_\xi = -\rho \mathbf{F} \cdot \mathbf{v}_d + \rho \sum_{\mathbf{p}'} \left[\left\langle W(\mathbf{p}, \mathbf{p}') \frac{p'^2}{2m} \right\rangle - \left\langle W(\mathbf{p}', \mathbf{p}) \frac{p^2}{2m} \right\rangle \right] \quad (8.37)$$

where $\xi = \rho \varepsilon$ is the energy density in J/m^3 and \mathbf{J}_ξ is energy flux vector in W/m^2 which can be expressed in general form as

$$\mathbf{J}_\xi = \mathbf{v}_d \xi + \mathbf{q} \quad (8.38)$$

The term $\mathbf{v}_d \xi$ is the advection of energy which comes from the drift contribution, and \mathbf{q} is the heat flux vector due to diffusion which arises from the random motion of the particles. This reduces the energy equation to

$$\frac{\partial \xi}{\partial t} + \nabla \cdot (\mathbf{v}_d \xi) = \rho \mathbf{v}_d \cdot \nabla U - \nabla \cdot \mathbf{q} + \left(\frac{\partial \xi}{\partial t} \right)_{so} - \left(\frac{\partial \xi}{\partial t} \right)_{si} \quad (8.39)$$

where U is the sum of all the potentials discussed earlier. Here, the scattering term from Eq. 8.37 is divided into an energy source and an energy sink term which are discussed shortly. The first term on the right side is the work done by a force on the particles and, therefore, must appear in the energy conservation equation. To obtain a relation for \mathbf{q} , the next higher moment of the BTE needs to be taken. However, closure is often obtained by assuming the Fourier law $\mathbf{q} = -k \nabla T$. But, recalling the fact that the Fourier law is derived under the assumption of quasi-equilibrium in both space and time, this may not always be a valid assumption. A higher-order relation which takes into account nonlocality in time but quasi-equilibrium in space is the Cattaneo equation for heat flux described in Eq. 8.23.

The energy density ξ of a particle system has contribution from entropic motion as well as from the drift and can be written as

$$\xi = \frac{3}{2} \rho k_B T + \frac{1}{2} \rho m v_d^2 \quad (8.40)$$

Note that the factor $3/2$ is valid for particles such as monoatomic gas molecules and electrons, with only three degrees of freedom of motion, each degree possessing an energy of $k_B T/2$. By multiplying the momentum conservation equation (Eq. 8.33) by \mathbf{v}_d and subtracting it out of the energy conservation equation (Eq. 8.39), the thermal energy conservation equation can be derived as

$$\frac{\partial T}{\partial t} + \mathbf{v}_d \cdot \nabla T + \frac{2}{3} T \nabla \cdot \mathbf{v}_d = \frac{2}{3 \rho k_B} \nabla \cdot \mathbf{q} + \left(\frac{\partial T}{\partial t} \right)_{so} - \left(\frac{\partial T}{\partial t} \right)_{si} \quad (8.41)$$

Note that the work term $\rho \mathbf{v}_d \cdot \nabla U$ drops out since work increases mechanical energy but does not increase entropy or temperature of a system. Only when this work is dissipated by scattering, the entropy of the system is raised and the temperature increases. The scattering term in Eq. 8.41 can be written as follows [12]:

$$\left(\frac{\partial T}{\partial t}\right)_{s_0} - \left(\frac{\partial T}{\partial t}\right)_{s_i} = -\left(\frac{T - T_0}{\tau_e(T, v)}\right) + \frac{mv_a^2}{3k_B} \left(\frac{2}{\tau_m} - \frac{1}{\tau_e}\right) \quad (8.42)$$

where T_0 is a reservoir temperature and τ_e is the energy relaxation time. The first term on the right side is simply the energy relaxation term with respect to an equilibrium temperature T_0 . The second term comes from the difference between the momentum and energy relaxation processes. The energy relaxation time is different from the momentum relaxation time since a collision may change the particle momentum but not its energy. Even if both these times were the same, the term would be nonzero. This is the contribution of the kinetic energy of the particle to the temperature rise. Hence, this is the fraction of the work done which is dissipated resulting in entropy generation and temperature rise. If we consider electrons that are energized by the work done by an external electric field, the electron-phonon interactions eventually dissipate this work and result in energy loss to the phonons. Hence, the reservoir temperature is that of the phonons. Note that although the work term $\rho \mathbf{v} \cdot \mathbf{F}$ is not present, the term $(2mv_a^2/3k_B\tau_m)$ in Eq. 8.42 represents the dissipated work which adds thermal energy to the system. The ratio (τ_e/τ_m) can be called the Prandtl number Pr of the fluid since the fluid diffusivities are inversely proportional to their respective relaxation times.

Equation of Radiative Transfer for Photons and Phonons

Photons and phonons do not follow number conservation as do electrons and molecules. However, they do follow energy conservation. An intensity of photons or phonons can be defined as follows

$$I_k(\mathbf{r}, \mathbf{k}, s, t) = \mathbf{v}(\mathbf{k}, s) f(\mathbf{r}, \mathbf{k}, s, t) \hbar \omega(\mathbf{k}, s) \quad (8.43)$$

where I_k is the intensity with wave vector \mathbf{k} , \mathbf{v} is the velocity at wave vector \mathbf{k} , s is the polarization, and $\hbar \omega$ is the energy. The intensity can also be defined in terms of frequency ω and angle (θ, ϕ) in polar coordinates corresponding to the direction of vector \mathbf{k} as follows:

$$I_\omega(\mathbf{r}, \omega, \theta, \phi, s, t) = \mathbf{v}(\omega, \theta, \phi, s) f(\mathbf{r}, \omega, \theta, \phi, t) \hbar \omega D(\omega, s) \quad (8.44)$$

where $D(\omega, s)$ is the density of \mathbf{k} states in the frequency range ω and $\omega + d\omega$. If the BTE of Eq. 8.8 is multiplied by the factor $\mathbf{v}(\omega, \theta, \phi, s) \hbar \omega D(\omega, s)$, the following equation is obtained:

$$\frac{\partial I_\omega(\mathbf{r}, \omega, \theta, \phi, s, t)}{\partial t} + \mathbf{v} \cdot \nabla I_\omega(\mathbf{r}, \omega, \theta, \phi, s, t) = \left(\frac{\partial I_\omega}{\partial t}\right)_{\text{scat}} \quad (8.45)$$

$$\begin{aligned} \text{where } \left(\frac{\partial I_\omega}{\partial t}\right)_{\text{scat}} = & \sum_{(\omega', \theta', \phi', s')} \left[W(\omega', \theta', \phi', s' \rightarrow \omega, \theta, \phi, s) I_\omega(\mathbf{r}, \omega', \theta', \phi', s', t) \right. \\ & \left. - W(\omega, \theta, \phi, s \rightarrow \omega', \theta', \phi', s') I_\omega(\mathbf{r}, \omega, \theta, \phi, s, t) \right] \\ & + \sum_{(j, \Omega)} [W(j, \Omega \rightarrow \omega, \theta, \phi, s) \epsilon(\mathbf{r}, j, \Omega, t) - W(\omega, \theta, \phi, s \rightarrow j, \Omega) I_\omega(\mathbf{r}, \omega, \theta, \phi, s, t)] \quad (8.46) \end{aligned}$$

Here, each W is a scattering rate. It is evident that the scattering term is quite complicated and needs explanation.

Equation 8.45 is the conservation of energy based on the intensity at frequency ω , polarization s , and direction (θ, ϕ) . Consider now the first summation in Eq. 8.46. This increases the intensity $I_\omega(\mathbf{r}, \omega, \theta, \phi, s, t)$ due to scattering in frequency $\omega' \rightarrow \omega$, polarization $s' \rightarrow s$, and direction $\theta', \phi' \rightarrow \theta, \phi$. The second term is the loss of intensity $I_\omega(\mathbf{r}, \omega, \theta, \phi, s, t)$ due to scattering to other frequencies, polarizations, and directions. Note, however, that if photons are considered, then this term represents photon-photon scattering and not scattering between photons and other particles. So, this term accounts for scattering among the particle type, either photon-photon or phonon-phonon, respectively. This is often known as the *in-scattering term* in photon radiative transfer, although scattering is usually considered only in direction $\theta', \phi' \rightarrow \theta, \phi$

and not in frequency and polarization. This is because, inelastic photon scattering is normally ignored in engineering calculations unless processes such as Raman scattering are involved. For phonon radiative transfer, however, inelastic scattering such as normal and Umklapp processes are very common and must be accounted for in this term. In addition, such phonon-phonon scattering is often between different phonon polarizations as allowed by phonon energy and momentum conservation during the collision.

The second summation term in Eq. 8.46 is for increase or decrease in intensity $I_\omega(\mathbf{r}, \omega, \theta, \phi, s, t)$ due to interactions with other particles. The particle type is given a tag j , and the phase space defined by momentum and direction is given a tag Ω . For example, an energetic electron in a metal or in the conduction band of a semiconductor can drop in energy by emitting a phonon of a certain polarization (e.g., LO-phonon) due to electron-phonon interactions. Here, the electron is given a tag j and the phonon is given a tag Ω . The frequency, direction, and polarization of this phonon is decided by energy and momentum conservation of the scattering process. In photon radiative transfer, this term is often referred to as the *blackbody source term*. This is true for the particular case of blackbody radiation. However, in a device such as a semiconductor laser or a light-emitting diode, photons are not emitted in a blackbody spectrum but within a certain spectral band that is decided by the semiconductor electronic band structure. Hence, this term is kept as a general emission term in Eq. 8.46. Similarly, there is a loss term when a phonon or a photon is absorbed by another particle and removed from the system.

It is clear that in the most general form as described in Eq. 8.45, the scattering terms pose difficulty for solving. Therefore, the relaxation-time approximation is usually made for convenience, in which case the equation of radiative transfer reduces to

$$\frac{\partial I_\omega}{\partial t} + \mathbf{v} \cdot \nabla I_\omega = -\frac{I_\omega}{\tau_s} - \frac{I_\omega}{\tau_a} + \frac{\epsilon(j, \Omega)}{\tau_e} + \iint_{\omega', \Theta'} \frac{I_{\omega'}(\mathbf{r}, \omega', \Theta', t)}{\tau_s} d\omega' \frac{d\Theta'}{4\pi} \quad (8.47)$$

The first term on the right side is the out-scattering term with τ_s being the scattering relaxation time, the second term is the photon/phonon absorption (or transfer of energy to other particles such as electrons, or photons to phonons or phonons to photons, etc.) where τ_a is the absorption time, the third term is the emission term with $1/\tau_e$ being the emission rate. Here, energy from other particles is converted and contributed to the intensity I_ω . The last term is the in-scattering term from other frequencies and solid angles Θ' . In an even simpler form, the equation of radiative transfer can be written as

$$\frac{\partial I_\omega}{\partial t} + \mathbf{v} \cdot \nabla I_\omega = \frac{I_\omega^0 - I_\omega}{\tau_s} - \frac{I_\omega}{\tau_a} + \frac{\epsilon(j, \Omega)}{\tau_e} \quad (8.48)$$

where the in-scattering term is totally ignored but it is assumed that $\omega' \rightarrow \omega$ scattering restores equilibrium that is represented by I_ω^0 . This is often the assumption made in phonon radiative transfer where interfrequency scattering restores phonon equilibrium.

The equation of radiative transfer will not be solved here since solutions to some approximations of the equation are well known. In photon radiation, it has served as the framework for photon radiative transfer. It is well known that in the optically thin or ballistic photon limit, one gets the heat flux as $q = \sigma(T_1^4 - T_2^4)$ from this equation for radiation between two black surfaces [13]. For the case of phonons, this is known as the Casimir limit. In the optically thick or diffusive limit, the equation reduces to $q = -k_p \nabla T$ where k_p is the photon thermal conductivity. The same results can be derived for phonon radiative transfer [14,15].

NONEQUILIBRIUM ENERGY TRANSFER

The discussion in the previous sections concentrated on transport by a single carrier, that is, heat conduction by electrons or phonons, charge transport by electrons, and energy transport

by photons. Relatively little attention was paid to energy transfer processes between the energy carriers. For example, Joule heating occurs due to electron-phonon interactions whereas radiative heating involves photon-electron and electron-phonon interactions. These are examples of what are commonly called *heat generation mechanisms*.

Traditionally, it is assumed that electrons and phonons within a solid are locally under equilibrium such that a heat generation term can be added to the energy conservation equation. For example, Joule heating during electron transport is usually modeled as I^2R where I is the current and R is the electrical resistance. Such a term is added to the energy conservation equation for the whole solid. Such an equation uses a single temperature T to describe the solid at a point \mathbf{r} and time t . It inherently assumes that there is equilibrium between the electrons and the phonons. However, this is not quite the picture in many cases. The equilibrium between electrons and phonons can be disrupted by several processes. For example, in the presence of a sufficiently high electric field, electrons can be energized and thrown far out of equilibrium from the phonons. Such nonequilibrium conditions can now be achieved in contemporary technology where electronic devices with submicrometer feature sizes undergo high-field transport. In the case of radiative heating in a metal, for example, the electrons are again thrown out of equilibrium from the lattice due to excitations by ultra-short laser pulses that are on the order of 100 fs. Such lasers are now available and are widely used in physics, chemistry, and materials processing. Therefore, it is clear that when modern engineering systems involving transport phenomena become small and fast, the energy dissipation process required by the second law of thermodynamics can take a highly nonequilibrium path. In this section, a close look is taken at microscopic mechanisms of heat generation and dissipation and models are presented to analyze such problems.

Joule Heating in High-Field Electronic Devices

One of the major goals of the electronics industry is to increase the density of devices on a single chip by reducing the minimum size of features. This has two purposes: (1) to miniaturize and increase the functionality of a single chip; and (2) to increase the speed of logic operations. By the year 2001, the minimum feature size will reduce to 0.18 μm and the speed and power density will increase significantly. A single chip in the future is likely to contain both power and logic devices. This will lead to high temperature and temperature gradients within a chip. New materials choices based on electrical characteristics also influence the thermal problem. For example, the close proximity of transistors on a high-density silicon (Si) chip requires the use of dielectric material such as silicon dioxide (SiO_2) for electrical insulation between devices. Since the thermal conductivity of SiO_2 is about 100 times lower than Si, it leads to high temperatures and temperature gradients [16–18].

Simple Transistors. Figure 8.5 shows schematic diagrams of a metal-oxide-semiconductor field-effect transistor (MOSFET) and metal-semiconductor field-effect transistor (MESFET) [19]. The MOSFET is usually made of silicon (Si) and is the workhorse of all logic devices and microprocessors. MESFETs are usually made of III-V materials such as GaAs and are usually used in high-speed communication devices such as microwave receivers and transmitters. GaAs is preferable for such devices since the electron mobility is higher than in Si. The current-voltage (I-V) characteristics of these devices are also shown. The voltage bias on the gate opens and closes the gate and in effect controls the resistance between the source and the drain. So, the drain current is a strong function of the gate voltage. Other high-electron mobility transistors also operate in a similar fashion except that the electron channel under the gate has different configurations due to clever control and manipulation of material interfaces and properties.

Most of the potential drop between the drain and the source occurs across the gate. So, the characteristic electric field in a device is on the order of V_{ds}/L_g where V_{ds} is the drain-source voltage and L_g is the gate length. When a voltage bias of about 2 V is applied across a

FIGURE 8.5 Schematic diagram and current-voltage (I-V) characteristics of (a) metal-semiconductor field-effect transistor (MESFET) and (b) metal-oxide semiconductor field-effect transistor (MOSFET).

device with a minimum feature size of $0.2 \mu\text{m}$, extremely high electric fields (about 10^7 V/m) are generated. The dynamics of an electron can be expressed as $m^* \dot{v} = -eE$ where m^* is the effective electron mass, \dot{v} is the acceleration vector, and E is the electric field vector. The electron velocity gained between two collisions is equal to $eE\tau/m^*$ where τ is the average time between collisions. When the electric field is very high, the velocity and the electron energy also becomes very high. Such hot electrons are thrown far out of equilibrium with the lattice vibrations. However, the hot electrons collide with the lattice and at some of these collisions, the electron energy is transferred to the lattice to produce a phonon. The hot electrons do not always follow Ohm's law and, hence, their transport must be studied by the Boltzmann transport equation.

Energy Transfer Processes. Heat generation occurs by transfer of energy from electrons to phonons. Since Si has two atoms per unit cell, two vibrational modes are present—optical mode and acoustic mode. Similar is the case for GaAs and other III-V materials. Optical phonon energies are higher than that of acoustic phonons. Although electrons interact with both types of phonons, the interactions with optical phonons are restricted to conditions when the electron energy gained from the electric field is higher than the optical phonon energy. So, there exists a critical field beyond which electron-optical phonon interactions can occur. In GaAs for instance, the atomic bond is slightly polar and LO-mode of vibration results in an oscillating dipole which strongly scatters electrons. Hence, electron-LO phonon interaction determines the critical field.

In both Si and GaAs, the critical electric field is on the order of 10^6 V/m . It is clear that in state-of-the-art submicrometer devices with fields on the order of 10^7 V/m , optical phonons will be generated. Although optical phonons interact with hot electrons, their group velocity is very small and hence they do not conduct any heat. So, they eventually decay into acoustic

phonons which conduct heat through the device and throughout the package. Therefore, although LO-phonons gain energy from electrons, they must transfer it to acoustic phonons for heat conduction in the solid. Such an energy transfer occurs during scattering of LO-phonons and acoustic phonons which has a characteristic timescale of $\tau_{LO-A} \approx 6-10$ ps in GaAs [11,20] and about 10 ps in Si [11]. Thus, the electron-LO phonon timescale $\tau_{e-LO} \approx 0.1$ ps is two orders of magnitude faster than τ_{LO-A} . The timescale of electron-phonon and phonon-phonon interactions can be quite different giving rise to interesting dynamics. Figure 8.6 shows a schematic diagram of the nonequilibrium Joule heating process.

The effect of device temperature on the electrical behavior of the device occurs due to the lattice temperature dependence of the electron scattering rate. When the LO phonon and acoustic phonon temperatures rise, the electron scattering rate increases, thus increasing the electrical resistance or decreasing the carrier mobility. The coupling of electrical and thermal characteristics suggest that these must be analyzed concurrently.

FIGURE 8.6 A flowchart showing the energy transfer mechanisms during Joule heating in high-electric field electronic devices. Note that optical phonons will be emitted only when the electric field is higher than the critical field. Otherwise, hot electrons will directly emit acoustic phonons. The number of phonons (or the phonon temperature) influences the electron scattering rate which in turn changes the device's electrical characteristics. The electron scattering rate depends on both electron and phonon temperatures and follows the qualitative trend shown. The flowchart also shows the typical timescales involved in each process and the energies of phonons.

Governing Equations. If the problem is to be solved rigorously, the BTE must be solved for electrons in each valley, optical phonons, and acoustic phonons. The distribution function of each of these depends on six variables—three space and three momentum (or energy). The solution to BTE for this complexity becomes very computer intensive, especially due to the fact that the timescales of electron-phonon and phonon-phonon interactions vary by two orders of magnitude. Monte Carlo simulations are sometimes used although this, too, is very time-consuming. Therefore, researchers have resorted mainly to hydrodynamic equations for modeling electron and phonon transport for practical device simulation.

Based on the mechanism of nonequilibrium Joule heating, the governing equations for charge and energy transport are

$$\nabla^2 V = -\frac{e}{\epsilon_s} (N_D - \rho); \quad \mathbf{E} = -\nabla V \quad (8.49)$$

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0 \quad (8.50)$$

$$\rho m^* \left(\frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} \right) = -e \rho \mathbf{E} - \nabla \cdot (\rho k_B T_e) - \frac{\rho m^* \mathbf{v}}{\tau_m} \quad (8.51)$$

$$\begin{aligned} \frac{\partial T_e}{\partial t} + \nabla \cdot (\mathbf{v} T_e) &= \frac{1}{3} T_e \nabla \cdot \mathbf{v} \\ &+ \frac{2}{3 n k_B} \nabla \cdot (k_e \nabla T_e) - \frac{T_e - T_{LO}}{\tau_{e-LO}} - \frac{T_e - T_A}{\tau_{e-A}} + \frac{m^* v^2}{3 k_B} \left(\frac{3}{\tau_m} - \frac{1}{\tau_{e-LO}} - \frac{1}{\tau_{e-A}} \right) \end{aligned} \quad (8.52)$$

$$C_{LO} \frac{\partial T_{LO}}{\partial t} = \frac{3 \rho k_B}{2} \left(\frac{T_e - T_{LO}}{\tau_{e-LO}} \right) + \frac{\rho m^* v^2}{2 \tau_{e-LO}} - C_{LO} \left(\frac{T_{LO} - T_A}{\tau_{LO-A}} \right) \quad (8.53)$$

$$C_A \frac{\partial T_A}{\partial t} = \nabla \cdot (k_A \nabla T_A) + C_{LO} \left(\frac{T_{LO} - T_A}{\tau_{LO-A}} \right) + \frac{3 \rho k_B}{2} \left(\frac{T_e - T_A}{\tau_{e-A}} \right) \quad (8.54)$$

The derivation of these equations is described in detail in Refs. 12 and 21. Equation 8.49 is the Poisson equation which satisfies Gauss's law of charge and field. Here V is the potential, ϵ_s is the dielectric constant of the medium, N_D is the doping concentration, ρ is the electron concentration, and \mathbf{E} is the electric field vector. Equations 8.50 and 8.51 are the electron continuity and energy momentum equations which follow the development in the section entitled "Boltzmann Transport Theory." The momentum equation is quite similar to the Navier-Stokes equation of fluid mechanics. By nondimensionalizing this equation, Lai and Majumdar [22] derived an equivalent electron Reynolds number in terms of device parameters given as $Re = e V_{ds} \tau_m^2 / (m^* L_g^2)$. For most operating conditions of V_{ds} and L_g and values of m^* and τ_m , $Re \ll 1$ and so the nonlinear convective term can be neglected. In the electron energy conservation equation (Eq. 8.52), the Fourier law of heat conduction has been assumed for the heat flux where k_e is the electron thermal conductivity, T_O is the optical phonon temperature, and τ_{e-o} is the electron energy relaxation time for electron-optical phonon scattering. The right side of Eq. 8.52 contains loss of electron energy to optical phonons, to acoustic phonons, as well as a heat generation term that comes from dissipation of the kinetic energy gained by the electrons. Equation 8.53 represents energy conservation for optical phonons where C_O is the optical phonon heat capacity. The terms on the right side represent energy gain from electrons and loss to acoustic phonons. Note that there is no heat diffusion term due to negligible group velocity of optical phonons. Equation 8.54 represents energy conservation of acoustic phonons where C_A is the acoustic phonon heat capacity, T_A is the acoustic phonon temperature, and the right side contains the heat diffusion term (first term on the right side), the term

representing energy gain from the optical phonons, as well as that representing energy gain directly from electrons. Note that all the relaxation times used in the energy equations must be the energy relaxation times which involve inelastic scattering such that energy is transferred during scattering.

The numerical solution of these equations for the case of microelectronic devices have been developed and can be found elsewhere [21,22]. It was found that under steady-state conditions that are realistic for modern devices, the electron temperature is an order of magnitude higher than those of the phonons. This shows the nonequilibrium nature of the Joule heating process. However, the difference between the optical and acoustic phonon temperature is comparatively much smaller. Hence, under steady-state conditions, it is sufficient to group the optical and acoustic phonon temperatures into one equation called the *lattice energy conservation equation*. However, it is important to note that in high-speed devices this is not valid. The phonon-phonon scattering time is about 10 ps in most semiconductors at room temperature. This corresponds to a frequency of 100 GHz which is in the microwave region of the electromagnetic spectrum and is used in wireless communications. Devices that are operated in this regime undergo unsteady heating with a period comparable to the phonon-phonon scattering time. Since electron-optical phonon scattering time is on the order of 100 fs, the electron energy can be efficiently transferred to the optical phonons. However, optical phonons cannot transfer their energy fast enough to the acoustic phonons. Hence, a *phonon bottleneck* is encountered where the optical phonon temperature becomes much higher than the acoustic phonon temperature. This changes the electron scattering rate and thereby changes the electrical performance of the device.

Radiative Heating by Ultrashort Laser Pulses

Pulsed lasers with pulse widths less than 100 fs and as low as 10 fs are now commercially available. It is important to compare the timescale with some characteristic timescales involved in microscale energy transfer processes. As we have noted earlier, the electron-phonon scattering timescale is on the order of 100 fs in most metals and semiconductors at room temperature. This is also the shortest time it takes for the ions in the solid to undergo one vibrational period. In other words, the highest phonon frequency is about 10^{13} Hz which corresponds to 100 fs in time period. Such laser pulse widths are much shorter than the phonon-phonon scattering time at room temperature which is on the order of 10 ps.

If we calculate the period of oscillation of an electron wave function, that is, $t = \lambda/v$, then using λ of 10 \AA and v of 10^6 m/s for a Fermi electron, we get the period to be 1 fs. The period of oscillation for a photon in the visible spectrum is also about 1 fs. Therefore, we see that laser pulses of 10 fs contain at least 10 electromagnetic waves and are longer than the time period for wave function of Fermi electrons. Hence, such laser pulses can excite electrons within the duration of a pulse if there are no phonons involved, that is, if the excitation is a direct process. Such pulsed lasers are now widely used to study the electron dynamics in chemical bond formation and dissociation, to investigate carrier relaxation processes in metals and semiconductors, as well as for materials processing with extremely high depth resolution. It is instructive to go through the microscopic energy transfer processes before the governing equations are derived.

Energy Transfer Processes. The photon energies of such pulsed lasers range from 1 to 5 eV. Using $k_B T$ as the thermal energy of the electrons, we can see that this corresponds to a temperature level of about 10^4 K. Hence, the electrons which absorb these photons and undergo a direct transition in the Brillouin zone are extremely hot for a very short period of time. Note that the electron-electron scattering rate is typically on the order of 10 to 50 fs in metals. In semiconductors, this rate depends on the electron concentration in the conduction band but is also typically in this range. Hence, the distribution of electrons is initially highly nonequilibrium with a large number of electrons at the excited state of 1 to 5 eV due to photon

absorption. However, the energy gets quickly redistributed between the electrons such that by about 100 fs the electrons reach the equilibrium Fermi-Dirac distribution. Note, however, that since the electrons do not lose energy to the phonons within this time period, they remain quite energetic. But since equilibrium is established between the electrons, one can define an electron temperature T_e . During this time, the phonons remain at the original ambient temperature T_o . So, as far as the phonons are concerned, they encounter a hot electron reservoir at T_e . Typically, this is about 10^3 to 10^4 K. The temperature difference $T_e - T_o$ drives energy flow from the electron to the phonons.

The most efficient way for the electrons to lose energy is through emission of optical phonons since their wave vectors span the entire Brillouin zone at the same energy. The electron energy, however, must be larger than the optical phonon energy which is typically in the range of 10 to 50 meV. In addition, since optical phonon energies are higher than those of acoustic phonons, optical phonon emission is a faster and more efficient way of energy transfer. When polar interactions are involved, such as in polar bonds in GaAs or other III-V or II-VI materials, the coupling to electrons is even stronger. In such cases, LO-phonons are most efficiently emitted by hot electrons. Optical phonons eventually scatter and emit acoustic phonons which are responsible for lattice heat conduction.

Governing Equations. To study the dynamics and interactions of photons, electrons, and phonons rigorously from a particle transport viewpoint, the Boltzmann transport equation for all these individual systems must be solved simultaneously. This is a very challenging task and has not been adopted by most investigators. What people have used are the averaged moments of the Boltzmann equation which produce the conservation equations [23–25]. It must be noted, however, that the moments always contain less information than the Boltzmann transport equation and, invariably, an assumption needs to be made at some stage. Otherwise, we have to take higher and higher moments. This is normally called the *closure problem*. However, several assumptions can be made and they seem to work reasonably well for the cases studied in the past.

The energy conservation equations are as follows:

$$\frac{\partial u_c}{\partial t} = \nabla \cdot (k_c \nabla T_c) - \frac{3\rho k_B}{2} \left(\frac{T_c - T_o}{\tau_{c-o}} \right) - \frac{3\rho k_B}{2} \left(\frac{T_c - T_A}{\tau_{c-A}} \right) + S \quad (8.55)$$

$$\frac{\partial U_o}{\partial t} = \frac{3\rho k_B}{2} \left(\frac{T_c - T_o}{\tau_{c-o}} \right) - C_o \left(\frac{T_o - T_A}{\tau_{o-A}} \right) \quad (8.56)$$

$$\frac{\partial u_A}{\partial t} = \nabla \cdot (k_A \nabla T_A) + \frac{3\rho k_B}{2} \left(\frac{T_c - T_A}{\tau_{c-A}} \right) + C_o \left(\frac{T_o - T_A}{\tau_{o-A}} \right) \quad (8.57)$$

Equation 8.55 is the carrier energy conservation equation which involves heat conduction by carriers, energy loss to optical phonons that occur at a timescale of τ_{c-o} , energy loss to acoustic phonons at timescale τ_{c-A} , and a source term containing energy increase due to photon absorption. Note that the assumption of Fourier law is not really valid for short timescale studies but this is an approximation that invokes closure in these hydrodynamic equations. The second equation conserves energy for the optical phonons where the two terms on the right side represent energy gain from electrons and energy loss to acoustic phonons. The third equation is that for acoustic phonons where, again, the Fourier law is used for heat flux. It should be noted that in most of the previous work [23–25], the lattice has been assumed to be a single thermodynamic system. This implicitly assumes equilibrium between optical and acoustic phonons. However, since the timescales for electron–optical phonon (100 fs) and phonon–phonon (10 ps) interactions are different by two orders of magnitude, it is perhaps not a reasonable assumption. Hence, they have been considered as separate systems in this presentation.

The energy densities in the three systems are

$$u_c = \rho E_g + C_c T_c; \quad u_o = C_o T_o; \quad u_A = C_A T_A \quad (8.58)$$

where ρE_g is the energy density the electrons gain for excitation across the band gap E_g ; ρ is the density of the electrons. The source term can be written as

$$S = \frac{\alpha(T_c, \rho) 2J\sqrt{\ln 2}}{t_p \sqrt{\pi}} [1 - R(T_c, \rho_s)] \exp\left(-\int_0^y \alpha dz\right) \exp\left[-4 \ln 2 \left(\frac{t}{t_p}\right)^2\right] \quad (8.59)$$

where $\alpha(T_c, \rho)$ is the absorption coefficient which is a function of local carrier temperature and density, J is the laser fluence (J/m^2), t_p is the laser pulse width, and R is the surface reflectivity which is a function of the surface carrier temperature and density. The carrier density follows the continuity equation

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = \frac{S_1}{\hbar \omega} - \gamma \rho^3 \quad (8.60)$$

where S_1 is the absorption source term that corresponds to direct interband transition that excites an electron to the conduction band and creates an electron-hole pair. Here, $\hbar \omega$ is the photon energy, \mathbf{v} is the carrier velocity, and the last term represents the Auger recombination term. The carrier momentum equation can be written as

$$\rho m^* \left(\frac{\partial \mathbf{v}}{\partial t} \right) = -\nabla(\rho k_B T_e) - \frac{\rho m^* \mathbf{v}}{\tau_m} \quad (8.61)$$

where the last term contains the momentum relaxation time τ_m .

It is quite evident that the set of conservation equations is nonlinear and highly coupled. They are usually solved numerically which will not be covered here but can be found in the literature.

SUMMARY

This chapter provides an introduction to microscopic transport phenomena with special emphasis on energy transport in solids. The first step in this process is to identify the time- and length scales that are characteristic of the transport process. Based on these scales, the regimes where continuum or macroscopic theories break down are identified. Having done so, the regimes where microscopic transport phenomena occur in both the wave and particle regimes are also indicated. The chapter does not address wave transport issues such as diffraction, refraction, interference, or tunneling, which occur when the size of an object is on the order of the wavelength of an energy carrier or if the phase information of an energy carrier becomes significant during scattering. Hence, this monograph concentrates only on microscopic particle transport theories.

Kinetic theory is introduced and developed as the initial step toward understanding microscopic transport phenomena. It is used to develop relations for the thermal conductivity which are compared to experimental measurements for a variety of solids. Next, it is shown that if the time- or length scale of the phenomena are on the order of those for scattering, kinetic theory cannot be used but instead Boltzmann transport theory should be used. It was shown that the Boltzmann transport equation (BTE) is fundamental since it forms the basis for a vast variety of transport laws such as the Fourier law of heat conduction, Ohm's law of electrical conduction, and hyperbolic heat conduction equation. In addition, for an ensemble of particles for which the particle number is conserved, such as in molecules, electrons, holes, and so forth, the BTE forms the basis for mass, momentum, and energy conservation equa-

tions. In cases where particle numbers are not conserved, such as in photons and phonons, the BTE forms the basis for the equation of transfer which span the ballistic to the diffusive transport regimes.

After showing how the BTE forms the fundamental basis for particle transport theories, the monograph describes two case studies: (1) nonequilibrium Joule heating in submicrometer transistors; and (2) nonequilibrium radiative heating by ultrashort laser pulses. Through these case studies, mechanisms and theories of nonequilibrium energy transfer are introduced.

NOMENCLATURE

Symbol, Definition, Units

C	specific heat per unit volume ($\text{J}/\text{m}^3\text{-K}$)
D	density of states
e	electron charge, 1.6×10^{-19} (C)
\mathbf{E}	electric field vector (V/m)
E_F	Fermi energy of electrons (eV or J)
f	distribution function of an ensemble of particles
\mathbf{F}	force vector (N)
G	gravitational potential (m^2/s^2)
h	Planck's constant, 6.63×10^{-34} (J-s)
\hbar	Planck's constant divided by 2π
I	intensity
j	particle tag
\mathbf{J}	flux vector
k	thermal conductivity ($\text{W}/\text{m-K}$)
\mathbf{k}	wave vector (m^{-1})
k_B	Boltzmann constant, 1.38×10^{-23} (J/K)
ℓ	characteristic length scale for scattering (m)
L_g	gate width (m)
m	mass (kg)
N_D	doping concentration (m^{-3})
p	momentum (kg-m/s)
P	pressure (N/m^2)
q	heat flux (W/m^2)
R	reflectivity
Re	electron Reynolds number
s	polarization
S	source function
t	time (s)
T	temperature (K)
u	energy density (J/m^3)
U	thermodynamic potential per unit mass (m^2/s^2)

v	velocity (m/s)
V	voltage (V)
W	scattering rate (1/s)

Greek Letters

α	absorption coefficient (m^{-1})
ε	energy (J)
λ	wavelength of energy carrier (m)
η	number density of particles (m^{-3})
ω	angular frequency (rad/s)
ρ	number density of particles (m^{-3})
σ	scattering cross-sectional area (m^2) electrical conductivity [$(\Omega\text{m})^{-1}$]
θ	polar angle or characteristic temperature (K)
ϕ	azimuthal angle
Φ	electrochemical potential (m^2/s^2)
τ	characteristic time scale for scattering (s)
ξ	energy density (J/m^3)

Subscripts

a	absorption
A	acoustic phonon
c	collision
d	diffusion, drift
dom	dominant
ds	drain-to-source
D	Debye, doping
e	electron, energy, emission
E	Einstein
F	Fermi
l	lattice
LO	longitudinal-optical phonon
m	momentum
o	equilibrium
r	relaxation, random
s	sound, scattering
ω	frequency

CHAPTER 9

HEAT TRANSFER IN POROUS MEDIA

Massoud Kaviany
University of Michigan

INTRODUCTION

Examination of heat transfer in natural and engineered porous media relies on the knowledge we have gained in studying heat transfer in plain media. The presence of a permeable solid (which we assume to be rigid and stationary) influences these phenomena significantly. Due to practical limitations, as a general approach we choose to describe these phenomena at a small length scale which is yet larger than the linear dimension of the pore or the linear dimension of the solid particle (for a particle-based porous medium). This requires the use of the local volume-averaging theories. Also, depending on the validity, local mechanical, thermal, and chemical equilibrium or nonequilibrium may be imposed between the fluid (liquid and/or gas) and solid phases.

Figure 9.1 gives a classification of the transport phenomena in porous media based on the single- or two-phase flow through the pores. Figure 9.2 renders these phenomena at the pore level. Description of transport of species, momentum and energy, chemical reaction (endothermic or exothermic), and phase change (solid/liquid, solid/gas, and liquid/gas) at the differential, local phase-volume level and the application of the volume-averaging theories lead to a relatively accurate and yet solvable local description.

The analysis of heat transfer in porous media is required in a large range of applications. The porous media can be *naturally formed* (e.g., rocks, sand beds, sponges, woods) or *fabricated* (e.g., catalytic pellets, wicks, insulations). A review of engineered porous materials is given in Schaefer [1] and the physics and chemistry of porous media is reviewed by Banavar et al. [2]. The applications are in the areas of chemical, environmental, mechanical, and petroleum engineering and in geology. As expected, the range of pore sizes or particle sizes (when considering the solid matrix to be made of consolidated or nonconsolidated particles) is vast and can be of the order of molecular size (ultramicropores with $3 < d < 7 \text{ \AA}$, where d is the average pore size), the order of centimeters (e.g., pebbles, food stuff, debris), or larger. Figure 9.3 gives a classification of the particle size based on measurement technique, application, and statistics. A review of the particle characteristics for particles with diameters smaller than 1 cm is given by Porter et al. [3].

Also shown in Fig. 9.3 is the capillary pressure in a water-air system with the mean radius of curvature equal to the particle radius. It is clear that as the particle size spans over many orders of magnitude, the handling of the radiative heat transfer and the significance of forces such as capillarity and gravity also vary greatly.

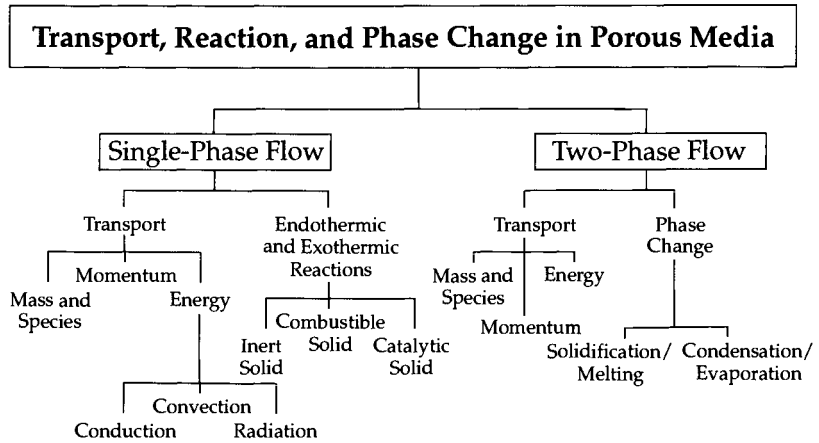

FIGURE 9.1 Aspects of treatment of transport, reaction, and phase change in porous media.

FIGURE 9.2 A rendering of the pore-level transport, reaction, and phase change in porous media.

Other than the particle dimension d , the porous medium has a system dimension L , which is generally much larger than d . There are cases where L is of the order d such as thin porous layers coated on the heat transfer surfaces. These systems with $L/d \approx O(1)$ are treated by the examination of the fluid flow and heat transfer through a small number of particles, a treatment we call *direct simulation* of the transport. In these treatments, no assumption is made about the existence of the local thermal equilibrium between the finite volumes of the phases. On the other hand, when $L/d \gg 1$ and when the variation of temperature (or concentration) across d is negligible compared to that across L for both the solid and fluid phases, then we can assume that within a distance d both phases are in thermal equilibrium (*local thermal equilibrium*). When the solid matrix structure cannot be fully described by the prescription of solid-phase distribution over a distance d , then a representative elementary volume with a linear dimension larger than d is needed. We also have to extend the requirement of a negligible temperature (or concentration) variation to that over the linear dimension of the representa-

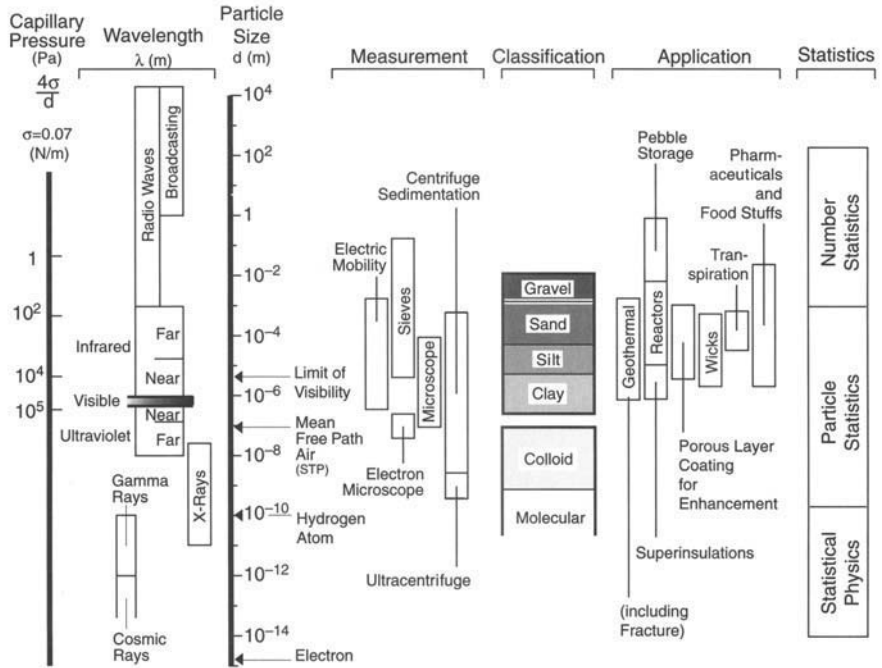

FIGURE 9.3 Particle sizes and their classifications, measurements, and applications.

tive elementary volume ℓ . For some fabricated solid matrices we have $\ell/d \approx O(1)$, and for natural solid matrices we have $\ell/d \approx O(10 \text{ or larger})$. In addition to d , ℓ , and L , a length scale equal to the square root of the permeability is also used. This length scale (called the *Brinkman screening distance*) $K^{1/2}$ is smaller than d and is generally $O(10^{-2}d)$, where K is the permeability. The four length scales, with a loose requirement for the presence of local thermal equilibrium (based on the length scale only), are written as

$$K^{1/2} \ll d < \ell \ll L$$

The solutions to the conservation equations, marked by the boundary-layer analyses of Cheng and Minkowycz [4] and Vafai and Tien [5] and as reviewed by Nield and Bejan [6] and as part of the general treatment of convective heat transfer by Kaviany [7] are not addressed here. Yet, by undertaking the discussion of principles of the fluid flow, conduction, convection, and radiation for both the single- and two-phase flows in porous media, such treatments must lack the depth that these topics deserve. The permeability, the effective thermal conductivity, and the dispersion tensors are discussed. The governing conservation equations are reached by the method of local volume averaging with these tensors appearing as the effective properties. The materials presented here are excerpts from a monograph on the topic.*

For radiation heat transfer in porous media, the same unit-cell approach is used and the particles in each cell are treated as scatterers. The scattering also becomes dependent when the porosity is not close to unity. The radiation properties are related to the optical properties and the porosity.

* *Principles in Heat Transfer in Porous Media*, by M. Kaviany, 2d ed., Springer-Verlag, New York, 1995.

The two-phase flow in porous media (a three-phase system) is approached from the pore-level fluid mechanics. The pertinent forces and their expected contributions are examined, and when available, empirical results are used. After arriving at a set of volume-averaged governing conservation and constitutive equations, some liquid-vapor phase change problems are examined.

Except in the section entitled "Two-Medium Treatment," the local thermal equilibrium is assumed between the phases. A glossary of common words used in transport in porous media is given in the glossary included with this chapter.

SINGLE-PHASE FLOW

Conduction Heat Transfer

Heat conduction through fully-saturated matrices (i.e., a single-phase fluid occupying the pores), as with heat conduction through any heterogeneous media, depends on the structure of the matrix and the thermal conductivity of each phase. One of the most difficult aspects of the analysis of heat conduction through a porous medium is the structural modeling. This is because the representative elementary volumes are three-dimensional and have complicated structures that vary greatly among different porous media. Since the thermal conductivity of the solid phase is generally different than that of the fluid, the manner in which the solid is interconnected influences the conduction significantly. Even when dealing with the nonconsolidated particles, the contact between the particles plays a significant role.

For the analysis of the macroscopic heat flow through heterogeneous media, the local volume-averaged (or *effective*) properties such as the *effective thermal conductivity* $\langle k \rangle = k_e$ are used. These local effective properties such as the *heat capacity* $\langle \rho c_p \rangle$, thermal conductivity $\langle k \rangle$, and radiation absorption and scattering coefficients $\langle \sigma_a \rangle$ and $\langle \sigma_s \rangle$ need to be arrived at from the application of the first principles to the volume over which these local properties are averaged, that is, the representative elementary volume.

As shown later, the local average $\langle \rho c_p \rangle$ is obtained by a simple volume averaging. However, we reiterate that the effective thermal conductivity is expected to depend on the following:

The *thermal conductivity* of each phase; that is, the relative magnitude of k_s/k_f is important.

The *structure* of the solid matrix; that is, the extent of the continuity of the solid phase is very important.

The *contact resistance* between the nonconsolidated particles; that is, the solid surface oxidation and other coatings are all important.

For gases, when the ratio of the *mean free path* and the *average linear pore dimension* (i.e., the *Knudsen number*) becomes large, the bulk gas conductivity cannot be used for the fluid phase.

In the following, after reviewing the requirements for the validity of the assumption of the local thermal equilibrium, the attempt at predicting the effective thermal conductivity is reviewed along with some correlations and comparisons with experimental results.

Local Thermal Equilibrium. In principle, determination of the thermal conductivity of saturated porous media involves application of the point conduction (energy) equation to a point in the representative elementary volume of the matrix and the integration over this volume. In doing so, we realize that at the pore level there will be a difference ΔT_d between the temperature at a point in the solid and in the fluid. Similarly, across the representative elementary volume, we have a maximum temperature difference ΔT_e . However, we assume that

these temperature differences are much smaller than those occurring over the system dimension ΔT_L . Thus, we impose the assumption of local thermal equilibrium by requiring that

$$\Delta T_d < \Delta T_\ell \ll \Delta T_L \quad (9.1)$$

With this assumed negligible local temperature difference between the phases, we assume that within the local representative elementary volume $V = V_f + V_s$, the solid and fluid phases are in *local thermal equilibrium*. This is stated using the *phase* (or *intrinsic*) and *both-phases* volume averaged temperatures as

$$\langle T \rangle' \equiv \frac{1}{V_f} \int_{V_f} T_f dV = \langle T \rangle^s \equiv \frac{1}{V_s} \int_{V_s} T_s dV = \langle T \rangle \equiv \langle T \rangle \frac{1}{V} \int_V T dV \quad (9.2)$$

Note that, although ΔT_d and ΔT_ℓ are small, their gradients in their respective length scales are not small.

For very fast transients and when heat generation exists in the solid or fluid phase, inequality (Eq. 9.1) may not be satisfied and a *two-temperature treatment* should be made. This is further discussed in the section entitled “Two-Medium Treatment” in connection with the local thermal *nonequilibrium* among phases.

Note that in the analysis of the unit cells, we use ΔT_d and ΔT_ℓ , and in dealing with the macroscopic heat transfer of the saturated matrix, we deal with ΔT_L .

Local Volume Averaging. The *porosity* ε is defined as

$$\varepsilon = \frac{V_f}{V_f + V_s} \quad (9.3)$$

Then the fluid (or solid) temperature within V is decomposed using

$$T_f = \langle T \rangle' + T_f' \quad (9.4)$$

where T_f' is the *spatial deviation* component.

Nozad et al. [8] discuss a set of *closure constitutive equations* (or *transformations*) given by

$$T_f' = \mathbf{b}_f \cdot \nabla \langle T \rangle \quad (9.5)$$

$$T_s' = \mathbf{b}_s \cdot \nabla \langle T \rangle \quad (9.6)$$

The required choice of a transformation vector \mathbf{b} instead of a scalar also satisfies the tensorial character of the effective thermal conductivity (similar to permeability). Note that $\mathbf{b} = \mathbf{b}(\mathbf{x})$, where \mathbf{x} is within the representative elementary volume, transforms the gradient of local volume-averaged temperature (changing over the length scale L) into deviations changing over length scale ℓ . The *effective thermal conductivity tensor* \mathbf{K}_e is defined, and by using (Eq. 9.5) in the thermal energy equation, we have

$$[\varepsilon(\rho c_p)_f + (1 - \varepsilon)(\rho c_p)_s] \frac{\partial \langle T \rangle}{\partial t} = \nabla \cdot (\mathbf{K}_e \cdot \nabla \langle T \rangle) \quad (9.7)$$

where \mathbf{K}_e is given by

$$\mathbf{K}_e = [\varepsilon k_f + (1 - \varepsilon)k_s] \mathbf{I} + \frac{k_f - k_s}{V} \int_{A_{fs}} \mathbf{n}_{fs} \mathbf{b}_f dA = [\varepsilon k_f + (1 - \varepsilon)k_s] \mathbf{I} + (k_f - k_s) \varepsilon \frac{1}{V_f} \int_{A_{fs}} \mathbf{n}_{fs} \mathbf{b}_f dA \quad (9.8)$$

A product (of two vectors) such as $\mathbf{n}_{fs} \mathbf{b}_f$ is called a *dyad product* and is a special form of the second-order tensors.

Also, the unit tensor used in (Eq. 9.8) is

$$\mathbf{I} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (9.9)$$

Determination of \mathbf{b} for periodic structures is reviewed by Kaviany [9].

Correlations for Effective Conductivity. For packed beds of particles and for the entire range of values of k_s/k_f (larger and smaller than unity) some *empirical* correlations are available for the *isotropic* effective thermal conductivity $\langle k \rangle = k_e$. Three of these are constructed by Krupiczka [10], Kunii and Smith [11], and Zehnder and Schlünder [12]. An extensive review of the literature on the effective thermal conductivity prior to 1960 is given by Krupiczka [10]. The prediction of Krupiczka gives (for $0.2 \leq \varepsilon \leq 0.6$)

$$\frac{k_e}{k_f} = \left(\frac{k_s}{k_f} \right)^{+0.280 - 0.757 \log \varepsilon - 0.057 \log (k_s/k_f)} \quad (9.10)$$

The prediction of Kunii and Smith [11] (for $0.260 \leq \varepsilon \leq 0.476$) gives

$$\frac{k_e}{k_f} = \varepsilon + \frac{(1 - \varepsilon)}{\phi_2 + 4.63(\varepsilon - 0.26)(\phi_1 - \phi_2) + \frac{2}{3}(k_f/k_s)} \quad (9.11)$$

where $\phi_1 = \phi_1(k_f/k_s)$ and $\phi_2 = \phi_2(k_f/k_s)$ and they are monotonically decreasing functions of k_s/k_f . The prediction of Zehnder and Schlünder [12] is

$$\frac{k_e}{k_f} = 1 - (1 - \varepsilon)^{1/2} + \frac{2(1 - \varepsilon)^{1/2}}{1 - (k_f/k_s)B} \left\{ \frac{[1 - (k_f/k_s)]B}{[1 + (k_f/k_s)B]^2} \ln \frac{1}{(k_f/k_s)B} - \frac{B + 1}{2} - \frac{B - 1}{1 - (k_f/k_s)B} \right\} \quad (9.12)$$

where

$$B = 1.25 \left(\frac{1 - \varepsilon}{\varepsilon} \right)^{10/9} \quad (9.13)$$

A modification to the Zehnder-Schlünder correlation is given by Hsu et al. [13].

Hadley [14] combines the Maxwell upper bound with an expression obtained by the introduction of an adjustable function $f_0(\varepsilon)$. In combining these, he uses a weighting function $\alpha_0(\varepsilon)$ which, along with $f_0(\varepsilon)$, is found from the experimental results. While $f_0(\varepsilon)$ changes slightly with ε , α_0 is very sensitive to changes in ε . Hadley's correlation is (for $0 \leq \varepsilon \leq 0.580$)

$$\frac{k_e}{k_f} = (1 - \alpha_0) \frac{\varepsilon f_0 + (k_s/k_f)(1 - \varepsilon f_0)}{1 - \varepsilon(1 - f_0) + (k_s/k_f)\varepsilon(1 - f_0)} + \alpha_0 \frac{2(k_s/k_f)^2(1 - \varepsilon) + (1 + 2\varepsilon)(k_s/k_f)}{(2 + \varepsilon)(k_s/k_f) + 1 - \varepsilon} \quad (9.14)$$

$$f_0 = 0.8, \quad (9.15)$$

where

$$\begin{aligned} \log \alpha_0 &= -4.898\varepsilon & 0 \leq \varepsilon \leq 0.0827 \\ \log \alpha_0 &= -0.405 - 3.154(\varepsilon - 0.0827) & 0.0827 \leq \varepsilon \leq 0.298 \\ \log \alpha_0 &= -1.084 - 6.778(\varepsilon - 0.298) & 0.298 \leq \varepsilon \leq 0.580 \end{aligned} \quad (9.16)$$

Prasad et al. [15] performed experiments for k_s/k_f larger and smaller than unity (but for only one order magnitude to either side of unity) and examined the accuracy of the preceding three predictions. In Fig. 9.4, the experimental results of Prasad et al. [15], Nozad [16], and other experimental results reported by her are plotted against these correlations. While for moderate values of k_s/k_f the four predictions are in agreement, for high values, *only* the Hadley correlation can predict the effective thermal conductivity correctly. Another correlation that uses k_s/k_f and ε as parameters is that of Nimick and Leith [17] with accuracies similar to that of Hadley. A correlation for the effective conductivity of rocks based on a geometric model of nonintersecting, oblate spherical pores has been developed by Zimmer-

FIGURE 9.4 Comparison of several correlations for the effective thermal conductivity with experimental results from several sources.

man [18]. Correlations for fibrous insulations are given by Stark and Frickle [19]. For two-dimensional structures, some correlations for the bulk effective thermal conductivity are given by Sahraoui and Kaviany [20] and Ochoa-Tapia et al. [21] and by Hsu et al. [22] for two- and three-dimensional periodic structures.

The pore-level structure of the solid and fluid phases significantly influences the effective conductivity, and in general the specifications of ϵ and k_s/k_f do not suffice. When gases are involved, rarefaction (for small pore size, for low pressure, or near constrictions) should be attended. The thermal conduction of each phase is temperature-dependent (and for gases, also pressure-dependent), and that should also be considered.

Convection Heat Transfer

As we consider simultaneous fluid flow and heat transfer in porous media, the role of the macroscopic (Darcean) and microscopic (pore-level) velocity fields on the temperature field needs to be examined. Experiments have shown that the mere inclusion of $\mathbf{u}_D \cdot \nabla \langle T \rangle$ in the energy equation does not accurately account for all the hydrodynamic effects. The pore-level hydrodynamics also influence the temperature field. Inclusion of the effect of the pore-level velocity nonuniformity on the temperature distribution (called the *dispersion effect* and generally included as a diffusion transport) is the main focus in this section.

This is similar to the Taylor dispersion in tubes, which is the result of area-averaging across the tube. Here a general volume-averaged treatment is presented. The available treatments and closure conditions for periodic structures and the predicted dispersion tensor are examined and comparisons with the experimental results are made. We then look at the correlations available for the dispersion coefficients.

Darcy Equation. The bulk resistance to flow of an incompressible fluid through a solid matrix, as compared to the resistance at and near the surfaces confining this solid matrix, was first measured by Darcy [23]. Since in his experiment the internal surface area (*interstitial area*) was many orders of magnitude larger than the area of the confining surfaces, the *bulk shear stress resistance* was dominant.

His experiment used nearly uniform size particles that were randomly and loosely packed, that is, a *nonconsolidated, uniform, rigid, and isotropic* solid matrix. The macroscopic flow

FIGURE 9.5 Determination of filter (or Darcy) velocity.

was steady, one-dimensional, and driven by gravity. A schematic of the flow is given in Fig. 9.5. The mass flow rate of the liquid \dot{m} was measured and the filtration or filter velocity u_D was determined by dividing \dot{m} by the product of the fluid density (assumed incompressible) and the cross-sectional area A of the channel (which was filled with the particles and then the liquid was flown through it). In applying a volumetric force balance to this flow, he discovered that the bulk resistance can be characterized by the viscosity of the Newtonian fluid (fluid parameter) μ and the *permeability* of the solid matrix (solid matrix parameter) K , such that

$$-\frac{dp}{dx} = \frac{\mu}{K} u_D \quad (9.17)$$

where the dimension of K is in square of length, such as m^2 . Interpretation of Eq. 9.17 has evolved and one unit still used is *darcy*.^{*} One unit of darcy equals $9.87 \times 10^{-13} m^2$. The permeability accounts for the interstitial surface area, the fluid particle path as it flows through the matrix, and other related hydrodynamic characteristics of the matrix. The Darcy model has been examined rather extensively and is not closely followed for liquid flows at high velocities and for gas flows at very low pressures and very high velocities.

At low gas pressures and for small pore size, the mean free path of the gas molecules may be on the order of the pore size and therefore velocity slip occurs (Knudsen effect), resulting in higher permeabilities. However, an increase in the permeability due to an increase in gas pressure has been found in some experiments. Scheidegger [24] discusses the effect of the Knudsen slip, the internal surface roughness, surface absorption, capillary condensation, and molecular diffusion on the measured permeability. By examining these effects at the pore level, it becomes clear that the measured gas and liquid permeabilities can be noticeably different.

For *isotropic media* where the pressure gradient ∇p and the velocity vector \mathbf{u}_D are parallel, Eq. 9.17 is generalized to

$$-\nabla p = \frac{\mu}{K} \mathbf{u}_D \quad (9.18)$$

^{*} One *darcy* is the permeability of a matrix when a cubic sample with each side having a width of 1 cm is used and a fluid with viscosity of 1 centipoise is flown (one-dimensional) through it, resulting in a pressure drop of 1 atmosphere (1.013×10^5 Pa).

For *anisotropic media*, in general, these two vectors are not parallel and a linear transformation can be made using the permeability tensor \mathbf{K} .

$$-\nabla p = \frac{\mu}{\mathbf{K}} \mathbf{u}_D \quad (9.19)$$

A Semiheuristic Momentum Equation. As much as it is desirable to have one set of governing equations that can describe both the momentum transport through the porous media (K being small) as well as that in the plain media (K being very large), such equations, if they become available, will be too complicated to be of practical use. However, as initiated by Brinkman [25] with his inclusion of a viscous shear stress term (other than the bulk viscous shear stress), which can take into account the shear stresses initiated at the surfaces bounding the porous media (macroscopic shear), attempts are being made to arrive at an equivalent of the Navier-Stokes equation for the description of flow through porous media.

In an effort to extend the Darcy law, the following momentum equation has been suggested by Brinkman and extended to the high-velocity regime for isotropic media and is

$$\frac{\rho_0}{\varepsilon} \left(\frac{\partial \mathbf{u}_D}{\partial t} + \mathbf{u}_D \cdot \nabla \mathbf{u}_D \right) = -\frac{\delta \langle p \rangle^f}{\delta x_i} + \frac{\mu'}{\varepsilon} \nabla^2 \mathbf{u}_D - \frac{\mu}{K} \mathbf{u}_D - \frac{F\varepsilon}{K^{1/2}} \rho |\mathbf{u}_D| \mathbf{u}_D \quad (9.20)$$

Note that the viscosity used in both the microscopic and macroscopic viscous terms is the fluid viscosity. Lundgren [26], in giving justification to the Brinkman equation, shows that for spherical particles $\mu' = \mu g(\varepsilon)$, where $0 < g(\varepsilon)$ and $g(1) = 1$ but others have used $\mu' > \mu$.

For the matrices obeying the modified Ergun relation we have

$$\frac{F\varepsilon}{K^{1/2}} = \frac{1.8(1-\varepsilon)}{\varepsilon^3} \frac{1}{d}, \quad \text{where } K = \frac{1}{180} \frac{\varepsilon^3}{(1-\varepsilon)^2} d^2 \quad (9.21)$$

Some other semiheuristic momentum equations have been recommended, among these is

$$\begin{aligned} \frac{\rho_0}{\varepsilon} \left(\frac{\partial \mathbf{u}_D}{\partial t} + \mathbf{u}_D \cdot \nabla \mathbf{u}_D \right) &= -\nabla p + \rho \mathbf{f} \\ &\quad \begin{array}{ccc} \text{(macroscopic inertial} & \text{(pore} & \text{(body} \\ \text{force or macroflow-} & \text{pressure} & \text{force)} \\ \text{development term)} & \text{gradient)} & \end{array} \\ &+ \frac{\mu}{\varepsilon} \nabla^2 \mathbf{u}_D - \frac{\mu}{K} \mathbf{u}_D - \frac{C_E}{K^{1/2}} \rho |\mathbf{u}_D| \mathbf{u}_D \quad (9.22) \\ &\quad \begin{array}{ccc} \text{(macroscopic or bulk} & \text{(microscopic} & \text{(microscopic} \\ \text{viscous shear stress} & \text{viscous shear} & \text{inertial force,} \\ \text{diffusion, also called} & \text{stress, Darcy} & \text{also called Ergun} \\ \text{Brinkman viscous term} & \text{term)} & \text{inertial term} \\ \text{or bounding surface} & & \text{or microflow-} \\ \text{effect)} & & \text{development term)} \end{array} \end{aligned}$$

where we have used the empirical in place of $F\varepsilon$ Ergun constant C_E .

This is a *semiheuristic volume-averaged* treatment of the flow field. The experimental observations of Dybbs and Edwards [27] show that the macroscopic viscous shear stress diffusion and the flow development (convection) are significant only over a length scale of ℓ from the vorticity generating boundary and the entrance boundary, respectively. However, Eq. 9.22 predicts these effects to be confined to distances of the order of $K^{1/2}$ and Ku_D/ν , respectively. We note that $K^{1/2}$ is smaller than d . Then Eq. 9.22 predicts a macroscopic boundary-layer thickness, which is not only smaller than the representative elementary volume ℓ when $\ell \gg d$, but even smaller than the particle size. However, Eq. 9.22 allows estimation of these macroscopic length scales and shows that for most practical cases, the Darcy law (or the Ergun extension) is sufficient.

Local Volume Averaging. The principle of volume averaging and the requirement of existence of the local thermal equilibrium between the fluid and solid phases was discussed in the section entitled “Conduction Heat Transfer.” In addition to the diffusion time and length scale requirements for the existence of the local thermal equilibrium, the residence timescales (the time it takes for a fluid particle to cover the length scales d , ℓ , and L) must be included in the length and timescale requirements.

Under the assumption of the local thermal equilibrium and by adding the solid- and fluid-phase averaged energy equations, we have

$$[\varepsilon(\rho c_p)_f + (1 - \varepsilon)(\rho c_p)_s] \frac{\partial \langle T \rangle}{\partial t} + (\rho c_p)_f \mathbf{u}_D \cdot \nabla \langle T \rangle = (\rho c_p)_f \nabla \cdot (\mathbf{D} \cdot \nabla \langle T \rangle) \quad (9.23)$$

where $\langle T \rangle^s = \langle T \rangle^f = \langle T \rangle$, and the total diffusivity tensor is

$$\mathbf{D} = \frac{\mathbf{K}_e}{(\rho c_p)_f} + \varepsilon \mathbf{D}^d \quad (9.24)$$

Here \mathbf{D}^d is the *dispersion tensor*.

As before, a knowledge of \mathbf{b} , the transformation vector, leads to the determination of \mathbf{K}_e and \mathbf{D}^d . The vector \mathbf{b} , which is a function of position only, has a magnitude of the order of the representative elementary volume ℓ and is determined from the differential equation and boundary conditions for T' and its determination is discussed by Kaviany [9].

Correlation for Dispersion Tensor. Given here are some of the properties of the dispersion tensor.

- \mathbf{D} is a *second-rank* tensor.
- \mathbf{D} is *positive-definite*.
- \mathbf{D} is *symmetrical* for random structures, that is, $D_{ij}^d = D_{ji}^d$.
- The *off-diagonal* elements of \mathbf{D} are zero for isotropic media, that is, $D_{ij}^d = 0$ for $i \neq j$.
- \mathbf{D} is *invariant* to the origin of the coordinate system.
- For *isotropic* media, the *longitudinal* dispersion is given as $D_{\parallel}^d = (\mathbf{u}_D/u_D) \cdot \mathbf{D}^d \cdot (\mathbf{u}_D/u_D)$.
- For *isotropic* media, there is a transverse isotropy in \mathbf{D}^d , such that the *transverse* dispersion for \mathbf{n} perpendicular to \mathbf{u}_D is $D_{\perp} = \mathbf{n} \cdot \mathbf{D}^d \cdot \mathbf{n}$.
- The last two can be combined to give $\mathbf{D}^d = \mathbf{nn}D_{\parallel}^d + (\mathbf{I} - \mathbf{nn})D_{\perp}^d$.
- For *periodic* structures, D_{\parallel}^d is small (but its magnitude depends on the direction of flow with respect to the symmetry axis of the unit cell).
- It is expected that

$$\mathbf{D}^d = \mathbf{D}^d \left(\text{structure}, \varepsilon, \frac{(\rho c_p)_s}{(\rho c_p)_f}, \frac{k_s}{k_f}, \text{Pr}, \text{Re}_d \right) \quad (9.25)$$

The high Pe prediction of Koch and Brady [28] is chosen to apply at $\text{Pe} \geq 1$. The values for \mathbf{D}^d (which is *isotropic*) are those given in Table 9.1 and compared with the experimental result in Fig. 9.6. The hydrodynamic treatment of Koch and Brady involves the leading order analysis of the Stokes (creeping) flow. Therefore, no Reynolds number effects are included. With this in mind, we should interpret their large Pe predictions as being for large Pr (or Sc), not for large Re. This low Re and high Pe restriction is not satisfied in all the experimental data given by Fried and Combarnous [29].

The agreement between the predictions and the experiments is good except for $\text{Pe} \leq 20$. The prediction of Jeffrey [30] for \mathbf{D}^d does not agree with the experimental results. Note that the improvement over the Maxwell prediction, that is, the Jeffrey results for $\mathbf{K}_e/(\rho c_p)_f = \varepsilon \alpha_f \mathbf{I} + \mathbf{D}^d$, is for *dilute* concentration, that is, is valid only for $\varepsilon \rightarrow 1$.

TABLE 9.1 Leading Order Behavior of the Dispersion Coefficient for Various Peclet Number Regimes [28]

$D_{ }^d/\alpha_f$	D_{\perp}^d/α_f
(a) $\frac{3(k_s/k_f - 1)}{k_s/k_f + 2} (1 - \epsilon) + \frac{2^{1/2}}{15} \frac{Pe^2}{(1 - \epsilon)^{1/2}}$	(a) $\frac{3(k_s/k_f - 1)}{k_s/k_f} (1 - \epsilon) + \frac{2^{1/2}}{60} \frac{Pe^2}{(1 - \epsilon)^{1/2}}$
(b) $\left[\frac{3}{4} \frac{Pe K^{1/2}}{R^{1/2}} - 2 - \frac{3}{2} \frac{R^{1/2}}{Pe K^{1/2}} + \frac{3R}{Pe^2 K} \right. \\ \left. + \left(\frac{3R^{1/2}}{Pe K^{1/2}} - \frac{3R^{3/2}}{Pe^3 K^{3/2}} \right) \times \ln \left(\frac{Pe K^{1/2}}{R^{1/2}} + 1 \right) \right] \left(\frac{R}{K} \right)^{1/2}$	(b) $\left[\frac{1}{4} + \frac{3}{4} \frac{R^{1/2}}{Pe K^{1/2}} - \frac{3}{4} \frac{R}{Pe^2 K} \right. \\ \left. + \left(\frac{3}{2} \frac{R^{3/2}}{Pe^3 K^{3/2}} - \frac{3}{4} \frac{R^{1/2}}{Pe K^{1/2}} \right) \times \ln \left(\frac{Pe K^{1/2}}{R^{1/2}} + 1 \right) \right] \left(\frac{R}{K} \right)^{1/2}$
(c) $\frac{3}{4} Pe$	(c) $\frac{3(2)^{1/2}}{8} (1 - \epsilon)^{1/2}$
(d) $\frac{3}{4} Pe + \frac{1}{6} \pi^2 (1 - \epsilon) Pe \ln Pe + \frac{C}{15} (1 + \gamma)^2 \frac{\alpha_f (1 - \epsilon) Pe^2}{\alpha_s}$	(d) $\frac{63(2)^{1/2}}{320} (1 - \epsilon)^{1/2} Pe$

Note: $Pe = u_D R/\alpha_f$, C , and γ are defined in text.

(a) For $Pe \ll (1 - \epsilon)^{1/2} \ll 1$, $Pe K^{1/2}/R^{1/2} \ll 1$; (b) For $(1 - \epsilon)^{3/4} \ll Pe \ll 1$; (c) For $(1 - \epsilon)^{1/2} \ll Pe \ll 1$, $Pe K^{1/2}/R^{1/2} \gg 1$; (d) For $Pe \gg 1$, the last term in $D_{||}^d/\alpha_f$ is for mass transfer only.

Also note that up to $Pe = 1$, the effective molecular diffusion dominates. Therefore, the very low Pe results given in Table 9.1 do not make any significant contribution to the total diffusivity. With this in mind, and for Pr characteristics of gases (< 1), the significant dispersion contribution will be associated with $Re > 1$. This, in principle, requires inclusion of the inertial term in the momentum equation. However, as is shown later, the experimental results indicate that even for the inertial regime, Pe remains the only parameter on which D^d depends.

Tables 9.2 and 9.3 list some of the closed-form solutions and correlations for the longitudinal and transverse dispersion coefficients for ordered and disordered media.

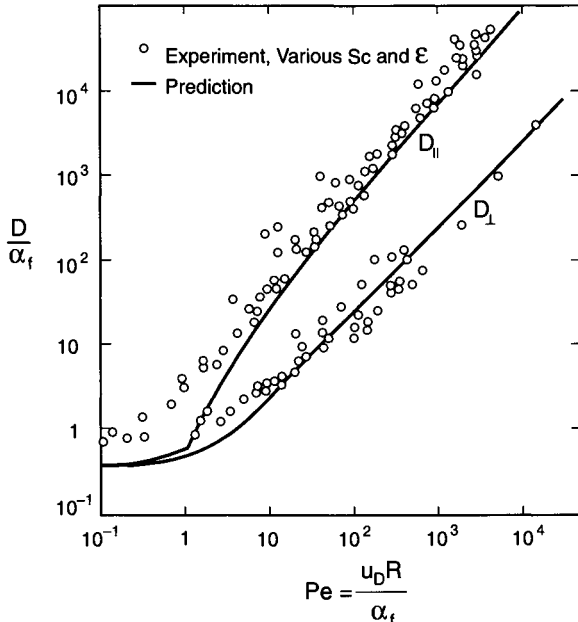

FIGURE 9.6 The prediction of Koch and Brady (for random arrangement of spheres) [28] for longitudinal and transverse total effective thermal diffusivity, compared with the experimental results of many investigators as presented in Fried and Combarous [29].

The nonuniformities in the phase distributions at and near the bounding surface and their effects on the fluid flow and heat transfer are most significant if the primary heat transfer is through these surfaces. In analyzing the variation of the dispersion coefficient at and near these surfaces, the following should be considered.

- Both D_{\perp}^d and $D_{||}^d$ are expected to vanish at the bounding solid surface.
- Near the bounding surface (fluid or solid), the porosity distribution is nonuniform.
- For packed beds of spheres, the porosity is generally larger near the bounding solid surface, resulting in an increase in the local velocity (component parallel to the surface) and the local Reynolds number.
- Since the Darcian velocity is taken to be uniform, it does not allow for the local variations in $D_{||}(Pe)$ and therefore does not lead to vanishing $D_{||}$ and D_{\perp} on the solid surface. Inclusion of the porosity variation near the surface results in an increase in $D_{\perp}(Pe)$ and $D_{||}(Pe)$. Inclusion of the macroscopic shear stress (Brinkman) term $\mu' \nabla^2 \mathbf{u}$ insures that $D_{||} = D_{\perp} = 0$ at the surface. But since the Brinkman screening length is much smaller than the pore size, this inclusion does not account for the actual effect of the pore-level hydrodynamics on the local variation of $D_{||}$ and D_{\perp} .
- Inclusion of the pore-level (or particle-based) hydrodynamics along with the appropriate volume averaging allows for the inclusion of the local variation of D_{\perp} and $D_{||}$ into the energy equations. In principle, these variations can only be included if the change from the bulk value to zero at the surface takes place over several representative elementary volumes. Otherwise it will not be in accord with the volume averaging.
- This leaves the rigorous continuum treatment of the near-surface hydrodynamics heat transfer to be rather impossible. The alternative has been the use of various area averages introduced into the volume-averaged equations. These area-averaging-continuum descrip-

TABLE 9.3 Various Correlations for Total Diffusivity Coefficient D

tions do not describe the flow and heat transfer accurately, but contain a few adjustable constants, which enable them to match specific experimental data.

- An alternative is the direct simulation of the flow and heat transfer at and near the bounding surfaces. Because of the computational limitations, only simple periodic structures can be analyzed.

Radiation Heat Transfer

We first discuss the equation of radiative transfer and the effective radiative properties. The spectral radiative behavior of a single isolated particle (i.e., independent scattering) is considered. Then the limits, based on large and small particle sizes, are discussed and various predictions are compared. Next the ranges of validity of the independent and dependent scattering are discussed, along with variative properties. Two simplified methods, the geometric layered and the effective radiant conductivity, are also discussed.

- In the presence of a solid matrix, the absorption/emission/scattering from gases is generally masked by the absorption/emission/scattering from the matrix [42]. If the gas contribution

is significant, it will be included as if independent of the matrix contributions, that is, the spectral or band contributions will be superimposed,

$$\text{such as} \quad \langle \sigma_{\lambda a} \rangle = \langle (\sigma_{\lambda a})_s \rangle + \langle (\sigma_{\lambda a})_g \rangle \quad (9.26)$$

This relation is strictly true only if the assumption of independent scattering holds.

- For liquids, the temperature difference existing in the system is generally small and the liquids are highly absorbing in the infrared wavelength range. Therefore, in general, no radiation heat transfer is considered in dealing with fully or partially liquid-saturated matrices. However, when it is necessary to include radiation heat transfer with liquids, the relative index of refraction n used for the properties is n_s/n_f (i.e., for gases $n_f = 1$, but *not* for liquids).
- Because the source of thermal radiation energy is generally nonpolarized (gas or solid surface) and because the waves undergo substantial reflections in the interstices of the matrix, the thermal radiation is conceived as being nonpolarized.

Equation of Radiative Transfer and Effective Radiative Properties. The fundamentals of radiation heat transfer in absorbing/emitting/scattering media have been given by Chandrasekhar [43], Ozisik [44], Siegel and Howell [45, 46], Brewster [47], and Modest [48]. Some of the principles are briefly given herein. Their approach treats the solid-fluid phases as a single continuum. Therefore, the following applies to *heterogeneous* (solid and fluid phases are present simultaneously) differential elements. A schematic showing the coordinate system for a *plane-parallel* geometry (which is the geometry used through most of this chapter) is given in Fig. 9.7. The unit vector in the beam direction is given by s and the length of the position vector is given by S . The incident beam is shown with subscript i and the incident solid angle is shown by $d\Omega_i$.

FIGURE 9.7 A schematic of the coordinate system.

- It is assumed that the particle size is much smaller than the linear size of the system. Then, the radiative properties are averaged over a representative elementary volume with a linear dimension ℓ , such that $d \ll \ell \ll L$.
- The matrix-fluid system is treated as a continuum by assuming that the local thermal equilibrium (as discussed in the section on continuum treatment) exists in accord with the treatment of conduction and convection.
- Azimuthal symmetry is assumed so that $I_\lambda(\theta, \phi) = I_\lambda(\theta)$.
- The spectral (indicated by subscript λ) radiation intensity I_λ is the radiation energy in the direction θ per unit time, per unit projected area, per unit solid angle, and per interval $d\lambda$ around λ . Then I_λ is given in $W/(m^2\text{-sr-}\mu\text{m})$.
- The solid angle differential is $d\Omega = \sin \theta \, d\phi \, d\theta$, when θ is the polar angle and ϕ is the azimuthal angle. Since an azimuthal symmetry is assumed in the following, the differential solid angle is taken as $d\Omega = 2\pi \sin \theta \, d\theta = -2\pi \, d \cos \theta$.
- The absorbed energy is $dI_\lambda = -\sigma_{\lambda a} I_\lambda \, dS$, where again S is the path length and $\sigma_{\lambda a}$ is the absorption coefficient (1/m). Figure 9.7 shows dS and $dI_\lambda = I_\lambda(S + dS, \theta) - I_\lambda(S, \theta)$.
- The equation of radiative transfer for radiation in a direction θ becomes

$$\frac{\partial I_\lambda(S)}{\partial S} = -\langle \sigma_{\lambda a} \rangle I_\lambda(S) + \langle \sigma_{\lambda a} \rangle I_{\lambda b}[T(S)] - \langle \sigma_{\lambda s} \rangle I_\lambda(S) + \frac{\langle \sigma_{\lambda s} \rangle}{2} \int_{-1}^1 I_\lambda(S, \theta_i) \langle \Phi_\lambda \rangle(\theta_i \rightarrow \theta) \, d \cos \theta_i \quad (9.27)$$

The arrow indicates from the incident to the scattered direction and θ_o is the angle between the incident (θ_i) and scattered (θ) beam. When rewritten, we have

$$\frac{\partial I_\lambda}{\partial S} = \langle \sigma_{\lambda a} \rangle I_{\lambda b} - (\langle \sigma_{\lambda a} \rangle + \langle \sigma_{\lambda s} \rangle) I_\lambda + \frac{\langle \sigma_{\lambda s} \rangle}{2} \int_{-1}^1 I_\lambda(\Phi_\lambda)(\mu_i \rightarrow \mu) d\mu_i \quad (9.28)$$

where we have used $\mu = \cos \theta$.

- The spectral radiative heat flux in the direction normal to the parallel slab faces is found from the directional spectral intensity $I_\lambda(\theta)$ by noting that I_λ is per unit projected area ($dA \cos \theta$) and is in the θ direction. Then the contribution from all directions to the normal heat flux is

$$q_{\lambda r} = 2\pi \int_{-1}^1 I_\lambda \cos \theta d \cos \theta \quad (9.29)$$

where $I_\lambda \cos \theta$ is the spectral directional emissive power. In vectorial form, we have

$$\mathbf{q}_{\lambda r} = 2\pi \int_{-1}^1 \mathbf{s} I_\lambda(S, \mathbf{s}) d\mu \quad (9.30)$$

- The divergence of the total radiative heat flux, which is used in the energy equation, is found from the radiative transfer equation by its integration over $\int_{4\pi} d\Omega$ and $\int_0^\infty d\lambda$. This gives

$$\int_0^\infty \int_{4\pi} \nabla \cdot \mathbf{s} I_\lambda d\Omega d\lambda = \nabla \cdot \mathbf{q}_r = 4\pi \int_0^\infty \langle \sigma_{\lambda a} \rangle I_{\lambda b} [T(S)] d\lambda - 2\pi \int_0^\infty \langle \sigma_{\lambda a} \rangle \int_{-1}^1 I_\lambda(S, \theta) d \cos \theta d\lambda \quad (9.31)$$

$$\text{or} \quad \nabla \cdot \mathbf{q}_r = 4\pi \int_0^\infty \langle \sigma_{\lambda a} \rangle I_{\lambda b}(S) d\lambda - 2\pi \int_0^\infty \langle \sigma_{\lambda a} \rangle \int_{-1}^1 I_\lambda(S, \theta) d\mu d\lambda \quad (9.32)$$

When no other mode of heat transfer is present and the emitted and absorbed energy are equal, then $\nabla \cdot \mathbf{q}_r = 0$, and the state of radiative equilibrium exists.

Radiative Properties of a Single Particle. In this section, we treat scattering from a single (i.e., single scatterers) particle. Then, we relate the radiation properties obtained for the individual particles to that for the collection of such elements in the representative elementary volume. Figure 9.8 gives a classification for single-particle scattering, where variation in optical properties, size, shape, and the incident radiation are considered. In terms of the theoretical treatments, the most important distinction, which also leads to significant variation in the rigor of treatment, is that based on size of the spherical particles. For large size parameter $\alpha_R = \pi d/\lambda$ geometric optics can be used. The applicability of various theories, i.e., the Rayleigh, Mie, and geometric optic theories, is discussed. In approaching the theoretical treatment of scattering from particles, we consider cases where the following simplifications can apply: (1) constant optical properties n_s and κ_s within the scatterers, where n_s and κ_s are the solid index of refraction and extinction, respectively, and, (2) smooth scattering surface. The optical properties for solids are strongly wavelength-dependent. We examine this spectral behavior before considering the incidence of electromagnetic waves upon an isolated solid particle.

Wavelength Dependence of Optical Properties. The relationship between the optical properties n and κ and the other molecular-crystalline properties of the solid are discussed by Siegel and Howell [45]. The theoretical treatments of the prediction of these properties are also discussed by them. Here, we examine some of the limited experimental data on $n(\lambda)$ and $\kappa(\lambda)$ for solids.

Figure 9.9 shows the measured wavelength-dependence of n_s for materials used in visible and infrared optics. We have included these as examples (and because their spectral behavior is studied most extensively) and not because of their common use in heat transfer in porous

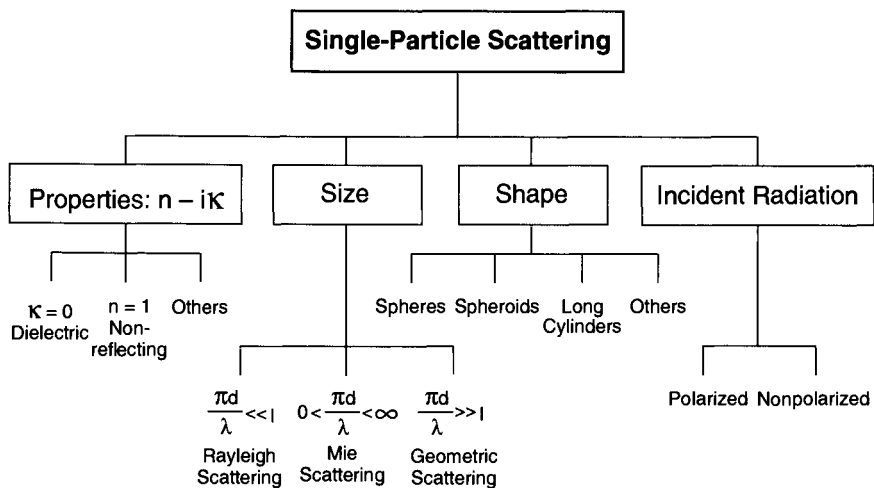

FIGURE 9.8 Parameters influencing scattering from a single particle.

FIGURE 9.9 Variation of index of refraction of some solids used in optics (visible and infrared), with respect to wavelength. This variation is generally negligible for these materials.

media. For these optical materials, the wavelength-dependence is not very strong (in as far as the radiative heat transfer is concerned), except for cadmium, telluride, and crystalline quartz. Because of their near-room-temperature applications, the measured values are for 300 K.

Figure 9.10a and b give $n_s(\lambda)$ and $\kappa_s(\lambda)$ for nonmetallic solids. Again most of the data is for near room temperature. For $n_s(\lambda)$, other than Ge and Si, the other materials shown exhibit strong wavelength-dependence (Fig. 9.10a). The variations in the region $\lambda > 10 \mu\text{m}$, corresponding to below-room-temperature applications, are in general as significant as they are for $\lambda < 10 \mu\text{m}$. The high-temperature applications require data for $\lambda \approx 1 \mu\text{m}$. Note the variations in $\kappa_s(\lambda)$ shown in Fig. 9.10b. For large particles, the values of κ_s as small as 10^{-5} can result in significant absorption because the attenuation is a function of the product $\kappa_s \alpha_R$. Therefore, reliable data for $\kappa_s(\lambda)$ are very important in determining the transmission through beds. The wavelength-dependence of κ_s is very strong and should be included in the radiative heat transfer analysis.

Figure 9.11a and b give $n_s(\lambda)$ and $\kappa_s(\lambda)$ for metallic solids. Note that n_s does not increase monotonically with λ (through the spectrum shown) for all the materials in Fig. 9.11a, even though Al, Cu, Ag, and Au do show monotonic increase of κ_s with λ . Therefore, for high-temperature applications where $\lambda = O(1 \mu\text{m})$, extreme care should be used in order to properly account for variation of n_s with λ . Figure 9.11b shows that except for titanium below

FIGURE 9.10 (a) Variation of index of refraction for some nonmetallic solids, with respect to the wavelength; (b) variation of index of extinction for some nonmetallic solids, with respect to the wavelength.

FIGURE 9.11 (a) Variation of index of refraction for some metallic solids, with respect to the wavelength; (b) variation of index of extinction for some metallic solids, with respect to the wavelength.

$\lambda = 5 \mu\text{m}$, κ_s increases monotonically with λ for metals. Extensive documentation of the optical properties of metals can be found in Weaver [49].

As was mentioned, when the fluid phase is a liquid, we do not expect the radiation heat transfer to be significant, although there are exceptions for some high-temperature applications. However, in Table 9.5, the index of refraction of some liquids is given for the sake of completeness. In treatment of scattering from particles, the *relative index of refraction*, that is, n_s/n_f , is the significant parameter, and as expected when dealing with liquids, this ratio can be substantially different from n_s .

Comparison of Predictions. We expect the Mie theory to be applicable for all values of n , κ , and size parameter α_R . The Rayleigh theory is applicable for small α_R and small values of $|m\alpha_R|$, $m = n - i\kappa$, and the geometric treatment is expected to be valid for $\alpha_R \gg 1$. Here, we consider spherical particles only. The optical properties are expected to be wavelength-dependent. Van de Hulst [50] gives the classifications for the case of $\kappa_s = 0$. His results are plotted in a diagram named after him and this diagram is shown in Fig. 9.12. He gives the asymptotic relations for the *extinction efficiency* η_{ex} so that the necessity of carrying out the full Mie solution can be avoided. The extinction efficiency η_{ex} is the sum of scattering and absorption efficiencies.

Some of these asymptotes are shown in the van de Hulst diagram. However, because of faster computers and improved subroutines, carrying out a full Mie solution is no longer as prohibitive a task as it once was. The problem lies more in making practical use of it, because no

FIGURE 9.12 The α_R - n plane (van de Hulst diagram) showing the various asymptotes for prediction of the extinction efficiency based on the Mie theory. The results are for $\kappa_s = 0$.

method of solution can handle the sharp forward peak produced for large particles. Thus, this peak has to be truncated for geometric size particles and the phase function renormalized to ensure energy conservation. The computation involved increases with increasing α_R . However, for very large values of α_R , the theory of geometric scattering provides a convenient alternative.

For small particles, the Rayleigh theory can be used. Although this does not result in a substantial savings in computation over the Mie theory, it provides a closed-form solution. Here, we compute the *scattering efficiency* $\eta_{\lambda_s}(\lambda)$, the *absorption efficiency* $\eta_{\lambda_a}(\lambda)$, the *asymmetry parameter* $g_{\lambda}(\lambda)$, and the *phase function* $\Phi_{\lambda}(\lambda)$ for a 0.2-mm sphere using the available experimental results for $n_s(\lambda)$ and $\kappa_s(\lambda)$ for glass. The results are shown in Fig. 9.13. The computations are based on the Rayleigh, Mie, and geometric treatments (see Fig. 9.13). Then comparisons among the results of these three theories show the limit of applicability of the Rayleigh and geometric treatments.

Effective Radiative Properties: Dependent and Independent. The properties of an isolated single particle were discussed in the previous section. However, the equation of radiative transfer (Eq. 9.28) requires knowledge of the radiative properties of the medium, that is, $\langle \sigma_a \rangle$, $\langle \sigma_s \rangle$, and $\langle \Phi_{\lambda} \rangle$. The scattering and absorption are called *dependent* if the scattering and absorbing characteristics of a particle in a medium are influenced by neighboring particles and are called *independent* if the presence of neighboring particles has no effect on absorption and scattering by a single particle. The assumption of independent scattering greatly simplifies the task of obtaining the radiative properties of the medium. Also, many important applications lie in the independent regime; therefore, the independent theory and its limits will be examined in detail in this section.

In obtaining the properties of a packed bed, the independent theory assumes the following.

- *No interference* occurs between the scattered waves (far-field effects). This leads to a limit on the minimum value of C/λ , where C is the average interparticle clearance. However, most packed beds are made of large particles and can therefore be assumed to be above any such limit.

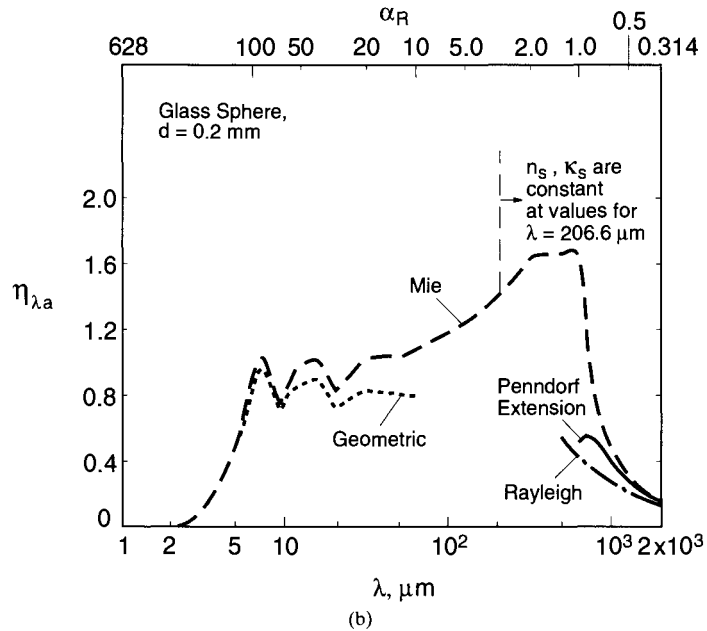

FIGURE 9.13 (a) Variation of the spectral scattering efficiency with respect to wavelength for a glass spherical particle of diameter 0.2 mm. When appropriate, the Rayleigh, Mie, and geometrical treatments are shown. Also shown is the Penndorf extension; (b) same as (a), except for the variation of the spectral absorption efficiency.

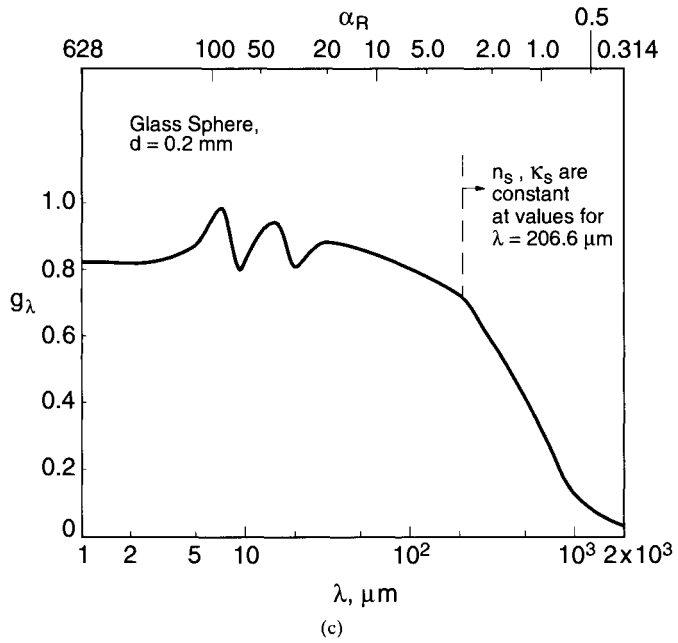

FIGURE 9.13 (Continued) (c) same as (a), except for the variation of the spectral asymmetry factor; (d) same as (a), except for the distribution of the phase function.

- *Point scattering* occurs, that is, the distance between the particles is large compared to their size. Thus, a representative elementary volume containing many particles can be found in which there is no multiple scattering and each particle scatters as if it were alone. Then this small volume can be treated as a single scattering volume. This leads to a limit on the porosity.
- The *variation of intensity* across this elemental volume is not large.

Then the radiative properties of the particles can be averaged across this small volume by adding their scattering (absorbing) cross sections. The total scattering (absorbing) cross sections divided by this volume gives the scattering (absorbing) coefficient. The phase function of the single scattering volume is the same as that for a single particle.

Using the number of the scatterers per unit volume N_s (particles/m³) and assuming independent scattering from each scatterer, the spectral scattering coefficient for uniformly distributed monosize scatterers is defined as

$$\langle \sigma_{\lambda s} \rangle = N_s A_{\lambda s} \quad (9.33)$$

Similarly, $\langle \sigma_{\lambda a} \rangle = N_s A_{\lambda a}$ and $\langle \sigma_{\lambda ex} \rangle = \langle \sigma_{\lambda s} \rangle + \langle \sigma_{\lambda a} \rangle$. For spherical particles, the volume of each particle is $4\pi R^3/3$, and in terms of porosity ϵ , we have

$$4/3\pi N_s R^3 = 1 - \epsilon \quad \text{or} \quad N_s = \frac{3}{4\pi} \frac{1 - \epsilon}{R^3} \quad (9.34)$$

Then we have
$$\langle \sigma_{\lambda s} \rangle = \frac{3}{4\pi} \frac{(1 - \epsilon)}{R^3} A_{\lambda s} \quad (9.35)$$

or
$$\langle \sigma_{\lambda s} \rangle = \frac{3}{4} \frac{(1 - \epsilon)}{R} \eta_{\lambda s} \quad (9.36)$$

When the particle diameter is not uniform, we can describe the distribution $N_s(R) dR$, that is, the number of particles with a radius between $R + dR$ per unit volume (number density). Note that $N_s(R) dR$ has a dimension of particles/m³. Then, assuming independent scattering, we can define the average spectral scattering coefficient as

$$\langle \sigma_{\lambda s} \rangle = \int_0^{\infty} \eta_{\lambda s}(R) \pi R^2 N_s(R) dR \quad (9.37)$$

A similar treatment is given to the absorption and scattering coefficients. The volumetric size distribution function satisfies

$$N_s = \int_0^{\infty} N_s(R) dR \quad (9.38)$$

where N_s is the average number of scatterers per unit volume.

Whenever the particles are placed close to each other, it is expected that they interact. One of these interactions is the *radiation* interaction, in particular, the extent to which the scattering and absorption of radiation by a particle is influenced by the presence of the neighboring particles. This influence is classified by two mechanisms: the coherent addition, which accounts for the phase difference of the superimposed far-field-scattered radiations and the disturbance of the internal field of the individual particle due to the presence of other particles [51]. These interactions among particles can in principle be determined from the Maxwell equations along with the particle arrangement and interfacial conditions. However, the complete solution is very difficult, and, therefore, approximate treatments, that is, modeling of the interactions, have been performed. This analysis leads to the prediction of the extent of interactions, that is, dependency of the scattering and absorption of individual particles on the presence of the other particles. One possible approach is to solve the problem of scattering by

a collection of particles and attempt to obtain the radiative properties of the medium from it. However the collection cannot in general be assumed to be a single-scattering volume. For closely packed particles, even a small collection of particles is not a single-scattering volume. Thus, some sort of a regression method might be required to obtain the dependent properties of the medium. For Rayleigh scattering-absorption of dense concentration of small particles, the interaction has been analyzed by Ishimaru and Kuga [52], Cartigny et al. [53], and Drolen and Tien [54].

Hottel et al. [55] were among the first to examine the interparticle radiation interaction by measuring the bidirectional reflectance and transmittance of suspensions and comparing them with the predictions based on Mie theory, that is, by examining $(\eta_{\lambda_{\text{ex}}})_{\text{exp}}/(\eta_{\lambda_{\text{ex}}})_{\text{Mie}}$. They used visible radiation and a small concentration of small particles. An arbitrary criterion of 0.95 has been assigned. Therefore, if this ratio is less than 0.95, the scattering is considered dependent (because the interference of the surrounding particles is expected to redirect the scattered energy back to the forward direction).

Hottel et al. [55] identified the limits of independent scattering as $C/\lambda > 0.4$ and $C/d > 0.4$ (i.e., $\epsilon > 0.73$). Brewster and Tien [56] and Brewster [57] also considered larger particles (maximum value of $\alpha_R = 74$). Their results indicated that no dependent effects occur as long as $C/\lambda > 0.3$, even for a close pack arrangement ($\epsilon = 0.3$). It was suggested by Brewster [57] that the point-scattering assumption is only an artifice necessary in the derivation of the theory and is not crucial to its application or validity. Thereafter, the C/λ criteria for the applicability of the theory of independent scattering was verified by Yamada et al. [58] ($C/\lambda > 0.5$), and Drolen and Tien [54]. However, Ishimaru and Kuga [52] note dependent effects at much higher values of C/λ . In sum, these experiments seem to have developed confidence in application of the theory of independent scattering in packed beds consisting of large particles, where C/λ almost always has a value much larger than the mentioned limit of the theory of independent scattering. Thus, the approach of obtaining the radiative properties of the packed beds from the independent properties of an individual particle has been applied to packed beds without any regard to their porosity [54, 57]. However, as is shown later, all these experiments were similar in design and most of these experiments used suspensions of small transparent latex particles. Only in the Brewster experiment was a close packing of large semitransparent spheres considered.

Figure 9.14 shows a map of independent/dependent scattering for packed beds and suspensions of spherical particles [59]. The map is developed based on available experimental results. The experiments are from several investigators, and some of the experiments are reviewed later. The results show that for relatively high temperatures in most packed beds, the scattering of thermal radiation can be considered independent.

The rhombohedral lattice arrangement gives the maximum concentration for a given interparticle spacing. This is assumed in arriving at the relation between the average interparticle clearance C and the porosity. This relation is

$$\frac{C}{d} = \frac{0.905}{(1-\epsilon)^{1/3}} - 1 \quad \text{or} \quad \frac{C}{\lambda} = \frac{\alpha_R}{\pi} \left[\frac{0.905}{(1-\epsilon)^{1/3}} - 1 \right] \quad (9.39)$$

where $C/\lambda > 0.5$ (some suggest 0.3) has been recommended for independent scattering (based on the experimental results). The total interparticle clearance should include the average distance from a point on the surface of one particle to the nearest point on the surface of the adjacent particle in a close pack. This average close-pack separation should be added to the interparticle clearance C obtained when the actual packing is referred to a rhombohedral packing ($\epsilon = 0.26$). This separation can be represented by $a_1 d$ where a_1 is a constant ($a_1 = 0.1$). Therefore, we suggest that the condition for independent scattering be modified to

$$C + 0.1d > 0.5\lambda \quad (9.40)$$

where C is given earlier [60]. This is also plotted in Fig. 9.14. As expected for $\epsilon \rightarrow 1$, this correction is small, while for $\epsilon \rightarrow 0.26$, it becomes significant.

FIGURE 9.14 Experimental results for dependent versus independent scattering shown in the α_R - ϵ plane. Also shown are two empirical boundaries separating the two regimes.

In Fig. 9.13, the size parameters associated with a randomly packed bed of 0.2-mm-diameter spheres at very high (combustion), intermediate (room temperature), and very low (cryogenic) temperatures are also given. Note that based on Eq. 9.40 only the first temperature range falls into the dependent scattering regime (for $d = 0.2$ mm and $\epsilon = 0.4$). Table 9.4 gives the range of temperatures, wavelengths, and size parameters for the 0.2-mm sphere considered.

Singh and Kaviani [61] examine dependent scattering in beds consisting of large particles (geometric range) by carrying out Monte Carlo simulations. They argue that the C/λ criterion

TABLE 9.4 Size Parameter $\alpha_R = \pi d/\lambda$ for a 0.2-mm-diameter Particle

λT ($\mu\text{m}\cdot\text{K}$) ($F_{0-\lambda T}$)*	1,888 (0.05)	2,898 (0.25)	12,555 (0.95)
T (K) = 4	$\lambda = 472(\mu\text{m})/(\pi d/\lambda) = 1.33$		
300	6.29/10 ²	9.66/65	41.9/15
1500	1.26/2.00 $\times 10^2$	1.93/3.25 $\times 10^2$	8.37/75

$$* F_{0-\lambda T} = \frac{15}{\pi^4} \sum_{i=1}^4 \frac{e^{-ix}}{i} \left(x^3 + \frac{3x^2}{i} + \frac{6x}{i^2} + \frac{6}{i^3} \right) \quad \text{for } x = \frac{14,388(\mu\text{m}\cdot\text{K})}{\lambda T}$$

only accounts for the far-field effects and that the porosity of the system is of critical importance if near-field effects are to be considered. According to the regime map shown in Fig. 9.14, a packed bed of large particles should lie in the independent range. This is because a very large diameter ensures a large value of C/λ even for small porosities. However, Singh and Kaviani [61] show dependent scattering for very large particles in systems with low porosity. The transmittance through packed beds of different porosities and at different values of τ_{ind} was calculated by the method of discrete ordinates using a 24-point gaussian quadrature.

They show that the independent theory gives good predictions for the bulk behavior of highly porous systems ($\epsilon \geq 0.992$) for all cases considered. Two distinct dependent scattering effects were identified. The multiple scattering of the reflected rays increases the effective scattering and absorption cross sections of the particles. This results in a decrease in transmission through the bed. The transmission through a particle in a packed bed results in a decrease in the effective cross sections, resulting in an increase in the transmission through a bed. For opaque particles, only the multiple scattering effect is found, while for transparent and semitransparent particles, both of these effects are found and tend to oppose each other.

In conclusion, we note that both the C/λ criterion and the porosity criterion must be satisfied before the independent theory can be used with confidence.

Some Relations for Effective Radiative Properties from Independent Scattering. If the scatterers behave independently, a simple volume integration over the particle concentration distribution results. We now look back at the scattering property of spherical particles as predicted by Rayleigh, Mie, and geometric analyses. We assume independent scattering. Assuming that a continuum treatment of radiation in solid-fluid systems using independent scattering is possible, we use volume averaging over a representative elementary volume to average over the scatterers as in Eq. 9.37.

Tables 9.5 and 9.6 give some approximations for $\langle \sigma_{\lambda s} \rangle \langle \sigma_{\lambda a} \rangle$ and $\langle \Phi_{\lambda} \rangle (\theta_0)$ along with the applicable constraints. The wavelength λ is that for the wave traveling in the fluid, and if $n_f \neq 1$, then $\lambda = \lambda_0/n_f$, where λ_0 is for travel in vacuum. Table 9.6 shows the various approximations used to represent the phase function $\langle \Phi_{\lambda} \rangle (\theta_0)$ in terms of Legendre polynomials.

The scattering-absorption of incident beams by a long circular cylinder has also been studied by van de Hulst [50]. He also considers other particle shapes. Wang and Tien [62], Tong and Tien [63], and Tong et al. [64] consider fibers used in insulations. They use the efficiencies derived by van de Hulst [50] and examine the effects of κ_s and d on the overall performance of the insulations. The effect of fiber orientation on the scattering-phase function of the medium is discussed by Lee [65]. The effective radiative properties of a fiber-sphere composite is predicted by Lee et al. [66].

For small particles, a simplified approach to modeling the spectral scattering and absorption coefficient is given by Mengüç and Viskanta [71].

Approximate Geometric, Layered Model. Using geometric optics (radiation size parameter α_R , larger than about five) and the concept of view factor, the emission, transmission, and reflection of periodically arranged, diffuse, opaque particles has been modeled by Mazza et

al. [76]. For a one-dimensional radiative transfer through a porous medium, with fluxes q_j^+ and q_j^- arriving and leaving from layer j from the left side and fluxes q_{j+1}^+ and q_{j+1}^- leaving and arriving from the right side, the radiative heat flux (across an area A) is given by

$$q_j^- A = \langle T_r \rangle q_{j+1}^- A + \langle \rho_r \rangle q_j^+ A + \langle \epsilon_r \rangle \sigma T_j^4 A \quad (9.41)$$

$$q_{j+1}^+ A = \langle T_r \rangle q_j^+ A + \langle \rho_r \rangle q_{j+1}^- A + \langle \epsilon_r \rangle \sigma T_j^4 A \quad (9.42)$$

The effective radiative properties, that is, effective transmissivity $\langle T_r \rangle$, effective reflectivity $\langle \rho_r \rangle$, and effective emissivity (assumed equal to absorptivity) $\langle \epsilon_r \rangle$, are determined for various two-dimensional arrangements of spherical particles. Emerging correlations, relating these effective properties to the particle surface emissivity ϵ_s , and medium porosity ϵ , do not appear to depend significantly on the arrangement. These correlations obtained by Mazza et al. [76] are

$$\langle T_r \rangle = 1 - \langle \rho_r \rangle - \langle \epsilon_r \rangle \quad (9.43)$$

$$\langle \rho_r \rangle = \frac{\pi(1 - \epsilon_r) a_1 N_s d^2}{2} \quad (9.44)$$

$$\langle \epsilon_r \rangle = \frac{\pi \epsilon_r a_2 N_s d^2}{2} \quad (9.45)$$

$$a_1 = \frac{2}{3[1 + a_3(N_s d^2)^{1.41}]^{1/2}} \quad (9.46)$$

TABLE 9.6 Phase Function in Terms of Legendre Polynomials

Approximations for $\langle \Phi_\lambda \rangle(\theta_0)$	
(a) Spherical particles, independent scattering	$\langle \Phi_\lambda \rangle(\theta_0) = \sum_{i=0}^N (2i+1) A_i P_i(\cos \theta_0)$ <p>where $\cos \theta_0 = \cos \theta_i \cos \theta + \sin \theta_i \sin \theta \cos(\phi - \phi_i)$, $A_i = (1/2) \int_0^\pi \Phi_\lambda(\theta_0) P_i(\cos \theta_0) d \cos \theta_0$, P_i is the Legendre polynomial of degree i, and $\Phi_\lambda(\theta_0)$ is the exact phase function obtained through the Mie scattering analysis</p> <ul style="list-style-type: none"> • For isotropic scattering $A_0 = 1, A_i = 0$ • For Rayleigh scattering $A_0 = 1, A_2 = 1/10, A_i = 0$ • For linear-isotropic scattering $A_0 = 1, -1/3 \leq A_1 \leq 1/3, A_i = 0$ <p>Strong forward scattering</p> $\langle \Phi_\lambda \rangle(\theta_0) = 2f_\lambda \delta(1 - \cos \theta_0) + (1 - f_\lambda) \sum_{i=0}^M (2i+1) \hat{A}_i P_i(\cos \theta_0)$ <p>where $f_\lambda = A_{M+1}$, $\hat{A}_i = (A_i - f_\lambda)/(1 - f_\lambda)$, $i = 0, 1, \dots, M$ and δ are the Dirac delta, $(M+1)/2$ is the order of approximation for a spike in the forward direction ($\delta - M$) approximation</p>
(b) Strongly forward scattering	$\langle \Phi_\lambda \rangle(\theta_0) = 2f_\lambda \delta(1 - \cos \theta_0) + (1 - f_\lambda)(1 + 3\hat{A}_1 \cos \theta_0)$ <p>is the Delta-Eddington approximation</p> $f_\lambda = \begin{cases} A_2, & A_2 \geq (3A_1 - 1)/2 \\ (A_3 - 1)/2, & \text{else} \end{cases} \quad \text{with } \hat{A}_1 = \frac{A_1 - A_2}{1 - A_2}$
(c) Not very accurate [72]. For the two-flux model an approximation (linear isotropic) is forward scattered,	$f_\lambda = \frac{1}{2} \int_0^{\pi/2} \langle \Phi_\lambda \rangle(\theta_0) d \cos \theta_0 \approx \frac{1}{2} + \frac{1}{2} \sum_{i=0}^{\infty} \frac{(-1)^i A_{2i+1} (2i)!}{2^{2i+1} i! (i+1)!}$ <p>backward scattered,</p> $b_\lambda = \frac{1}{2} \int_{-\pi/2}^0 \langle \Phi_\lambda \rangle(\theta_0) d \cos \theta_0 = 1 - f_\lambda$
(d) Strongly forward scattering	$\langle \Phi_\lambda \rangle(\cos \theta_0) = 2f_\lambda \delta(1 - \cos \theta_0) + (1 - f_\lambda) \frac{1 - g_\lambda^2}{(1 + g_\lambda^2 - 2 \cos \theta_0)^{3/2}}$ <p>is the δ-Heney-Greenstein approximation,</p> $g_\lambda = \frac{A_1 - A_2}{1 - A_1} \quad \text{and} \quad f_\lambda = \frac{A_2 - A_1^2}{1 - 2A_1 + A_2}$

(a) Chu and Churchill [73]; (b) Wiscombe [74], McKellar and Box [75]; (c) Lee and Buckius [72]; (d) McKellar and Box [75].

$$a_2 = \frac{1}{[1 + a_4(N_s d^2)^{1.74}]^{1/2}} \quad (9.47)$$

$$a_3 = \frac{1.46\epsilon_r + 0.484}{1 + 0.16\epsilon_r} \quad (9.48)$$

$$a_4 = \frac{1.967\epsilon_r + 0.00330}{1 + 0.07\epsilon_r} \quad (9.49)$$

where N_s is the number of scatterers per unit area.

The correlation applies to $0.630 < N_s d^2 < 1.155$, where the upper limit corresponds to the closest two-dimensional packing of spheres.

The variational upper and lower bounds for the effective emissivity of randomly arranged particles has been obtained by Xia and Strieder [77, 78].

Approximate Radiant Conductivity Model. The radiative heat transfer for a one-dimensional, plane geometry with emitting particles under the steady-state condition is given by [79]:

$$q_r = \frac{F\sigma}{[(1 + \rho_w)/(1 - \rho_w)] + L/d} (T_1^4 - T_2^4) \quad (9.50)$$

where F is called the *radiative exchange factor* and the properties are assumed to be wavelength-independent. If $\rho_w = 0$ and the bed is several particles deep, then the first term of the denominator can be neglected. Then, for $T_1 - T_2 < 200$ K, a radiant conductivity is defined [59]:

$$\mathbf{q}_r = -k_r \nabla T, \quad k_r = 4Fd\sigma T_m^3 \quad (9.51)$$

The approach has many limitations, but the single most important limitation is that the value of F cannot be easily calculated. Of all the methods, the Monte Carlo method can be used for calculating F for semitransparent particles. The value of F also depends upon the value of the conductivity of the solid phase. In the Kasperek experiment [79] infinite conductivity is assumed, which is justified for metals. Similarly, the case of zero conductivity can be easily treated by considering the rays to be emitted from the same point at which they were absorbed. However, the intermediate case, that is, when the conductivity is comparable to the radiant conductivity, shows a strong dependence of radiant conductivity on the solid conductivity. The extent of this dependence may be seen by comparing the difference in the values of F in Table 9.7 corresponding to low and high emissivities. If the conductivity was small, all the F values would be close to those obtained for the $\epsilon_r = 0$ case. Thus, a simple tabulation of F as in Table 9.7 is of limited use. On the other hand, this approach is simple.

TABLE 9.7 Radiation Exchange Factor F ($\epsilon = 0.4$)

Model	Emissivity				
	0.2	0.35	0.60	0.85	1.0
Two-flux (diffuse)	0.88	0.91	1.02	1.06	1.11

Monte Carlo (specular)	0.34	0.47	0.69	0.95	1.10

Determination of F. Many different models are available for the prediction of F , and these are reviewed by Vortmeyer [79]. Here, the main emphasis is on examining the validity of the radiant conductivity approach by comparing the results of some of these models with the Monte Carlo simulations and with the available experimental results.

A solution to this problem based on the two-flux model is given by Tien and Drolen [59]:

$$F = \frac{2}{d(\bar{\sigma}_{\lambda a} + 2\bar{\sigma}_{\lambda s})} \quad (9.52)$$

which can be written as

$$F = \frac{2}{3(1 - \epsilon)(\eta_{\lambda a} + 2B\eta_{\lambda s})} \quad (9.53)$$

For isotropic scattering, $B = 0.5$ and Eq. 9.53 becomes independent of the particle emissivity (for large particles).

The low and high conductivity limits of this problem have been explored experimentally [79] and by the Monte Carlo method [61]. In the low-conductivity asymptote, the rays are considered to be emitted from the same point on the sphere at which they were absorbed. In the high-conductivity asymptote, an individual sphere is assumed to be isothermal and a ray absorbed by the sphere is given an equal probability of being emitted from anywhere on the sphere surface. This results in an increase in the radiant conductivity, because the rays absorbed on one side can be emitted from the other side thus bypassing the radiative resistance. In the general problem, the solid and the radiant conductivities can have arbitrary magnitudes. Then, the radiative heat flux q_r for this one-dimensional, plane geometry is given by Eq. 9.50. The radiant conductivity k_r is given by Eq. 9.51, where

$$F = F(k_s^*, \epsilon_r, \epsilon) \quad (9.54)$$

and T_m is the mean temperature. The dimensionless solid conductivity k_s^* is defined as

$$k_s^* = \frac{k_s}{4d\sigma T_m^3} \quad (9.55)$$

Within the bed, the radiation is treated by combining the ray tracing with the Monte Carlo method. The conduction through the spheres is allowed by solving for the temperature distribution in a representative sphere for each particle layer in the bed.

The results for $\epsilon = 0.476$ and various values of ϵ_r and k_s^* have been obtained for both diffuse and specular surfaces. The results are shown in Fig. 9.15a and b. The results for both surfaces are nearly the same. Both low and high k_s^* asymptotes are present. The low k_s^* asymptotes are reached for $k_s^* < 0.10$ and the high k_s^* asymptote is approached for $k_s^* > 10$. There is a monotonic increase with ϵ_r , that is, as absorption increases, the radiant conductivity increases for high k_s^* .

The results of Fig. 9.15a and b have been correlated using [9]

$$F = a_1\epsilon_r \tan^{-1} \left(a_2 \frac{k_s^{*a_3}}{\epsilon_r} \right) + a_4 \quad (9.56)$$

for given ϵ . The best-fit values of the constants are given in Table 9.8.

TABLE 9.8 Constants in the Exchange Factor Correlation ($\epsilon = 0.476$)

	Specular	Diffuse

FIGURE 9.15 Effect of dimensionless solid conductivity on the dimensionless radiant conductivity for (a) diffuse particle surface and (b) specular particle surface [9].

The computer-intensive nature of the problem prevented a thorough sweep of the porosity range as an independent variable. However, the effect of the porosity in the high-conductivity limit has been discussed by Singh and Kaviany [61]. For example, by decreasing the porosity from 0.6 to 0.5, the magnitude of F changes from 0.47 to 0.51 for $\epsilon_r = 0.35$ (specular surfaces) and from 0.94 to 0.97 for $\epsilon_r = 0.85$ (diffuse surfaces). In practical packed beds, the porosity ranges between 0.3 to 0.6 with a value of 0.4 for randomly arranged, loosely packed monosized spheres. Therefore, the sensitivity of the radiant conductivity with respect to the porosity (as compared to other parameters) is not expected to be very significant.

The variational upper bound on the radiant conductivity, including the conduction through the particle, has been predicted by Wolf et al. [80].

Summary. In conclusion, some suggestions are made on how to model the problem of radiative heat transfer in porous media. First, we must choose between a direct simulation and a continuum treatment. Wherever possible, continuum treatment should be used because of the lower cost of computation. However, the volume-averaged radiative properties may not be available in which case continuum treatment cannot be used. Except for the Monte Carlo techniques for large particles, direct simulation techniques have not been developed to solve but the simplest of problems. However, direct simulation techniques should be used in case the number of particles is too small to justify the use of a continuum treatment and as a tool to verify dependent scattering models.

If the continuum treatment is to be employed, we must first identify the elements that make up the system. The choice of elements might be obvious (as in the case of a packed bed of spheres) or some simplifying assumptions might have to be made. Common simplifying assumptions are assuming the system to be made up of cylinders of infinite length (for fibrous media) or assuming arbitrary convex-surfaced particles to be spheres of equivalent cross section or volume. Then the properties of an individual particle can be determined. If the system cannot be broken down into elements, then we have no choice but to determine its radiative properties experimentally.

On the other hand, if we can treat the system as being made up of elements, then we must identify the system as independent or dependent. In theory, all systems are dependent, but if the deviation from the independent theory is not large, the assumption of independent scattering should be made. The range of validity of this assumption can be approximately set at $C/\lambda > 0.5$ and $\epsilon > 0.95$. If the problem lies in the independent range, then the properties of the bed can be readily calculated, and the equation of transfer can be solved.

However, if the system is in the dependent range, some modeling of the extent of dependence is necessary to get the properties of the packed bed. Models for particles in the Rayleigh

range and the geometric range are available. However, no approach is yet available for particles of arbitrary size, and experimental determination of properties is again necessary.

An approximate, geometric, layered model can be used for large particles and the method is described here.

Finally, we note that the thermal conductivity of the solid phase influences the radiation properties. When using the radiant conductivity model, the results show that k_r can increase by fivefold for $k_s \rightarrow \infty$ as compared to that for $k_s \rightarrow 0$ (for $\epsilon_r = 1$ and typical porosities).

Two-Medium Treatment

In this section, we examine the single-phase flow through solid matrices where the assumption of the local thermal equilibrium between the phases is not valid, i.e., $\langle T \rangle / \langle T \rangle^s$. When there is a significant heat generation occurring in any one of the phases (solid or fluid), that is, when the primary heat transfer is by heat generation in a phase and the heat transfer through surfaces bounding the porous medium is less significant, then the local (finite and small) volumes of the solid and fluid phases will be far from the local thermal equilibrium. Also, when the temperature at the bounding surface changes significantly with respect to time, then in the presence of an interstitial flow and when solid and fluid phases have significantly different heat capacities and thermal conductivities, the local rate of change of temperature for the two phases will not be equal.

In the two-medium treatment of the single-phase flow and heat transfer through porous media, no local thermal equilibrium is assumed between the fluid and solid phases, but it is assumed that each phase is continuous and represented with an appropriate effective total thermal conductivity. Then the thermal coupling between the phases is approached either by the examination of the microstructure (for simple geometries) or by empiricism. When empiricism is applied, simple two-equation (or two-medium) models that contain a modeling parameter h_{sf} (called the *interfacial convective heat transfer coefficient*) are used. As is shown in the following sections, only those empirical treatments that contain not only h_{sf} but also the appropriate effective thermal conductivity tensors (for both phases) and the dispersion tensor (in the fluid-phase equation) are expected to give reasonably accurate predictions.

We begin with the phase volume averaging of the energy equations, which shows how the fluid phase dispersion as well as the other convective and conductive effects appear as the coupling coefficients in the energy equations. Then, these coefficients, including the interfacial heat convection coefficient, are evaluated for a simple porous medium, that is, capillary tubes. Then, we examine the existing heuristic two-medium treatments and show that most of them are inconsistent with the results of the local phase volume averaging. Also, in order to examine the cases where the assumptions made in the phase-averaged treatments do not hold, we examine pointwise solutions to a periodic flow. Finally, the chemical reaction in the fluid phase and departure from local thermal equilibrium is examined in an example of premixed combustion in a two-dimensional porous media. For this problem, the results of pointwise (i.e., direct simulation), single- and two-medium treatments is compared for the flame speed and flame structure.

Local Volume Averaging. The local volume-averaging treatment leading to the coupling between the energy equation for each phase is formulated by Carbonell and Whitaker [81] and is given in Zanotti and Carbonell [82], Levec and Carbonell [83], and Quintard et al. [84]. Their development for the transient heat transfer with a steady flow is reviewed here. Some of the features of their treatment are discussed first.

- For the transient behavior, it is assumed that the penetration depth (in the fluid and solid phases) is larger than the linear dimension of the representative elementary volume. This is required in order to volume-average over the representative elementary volume while sat-

isfying that ΔT_ℓ over this volume is much smaller than that over the system ΔT_L , that is, not all the temperature drop occurs within the representative elementary volume. If ΔT_ℓ is nearly equal to ΔT_L , then the direct simulation of the heat transfer over length ℓ has to be performed. Except for very fast transients, the time for the penetration over ℓ , that is, ℓ^2/α , is much smaller than the timescales associated with the system transients of interest.

- Each phase is treated as a continuum. The phase volume-averaged total thermal diffusivity tensor will be determined for each phase.
- Closure constitutive equations are developed similar to those used when the existence of the local thermal equilibrium was assumed. This requires relating the disturbances in the temperature fields to the gradients of the volume-averaged temperatures and to the difference between the phase volume-averaged temperatures.

After the formal derivations, the energy equation for each phase ($\langle T \rangle^f$ and $\langle T \rangle^s$) can be written in a more compact form by defining the following coefficients. Note that both the hydrodynamic dispersion, that is, the influence of the presence of the matrix on the flow (no-slip condition on the solid surface), as well as the interfacial heat transfer need to be included. The total thermal diffusivity tensors \mathbf{D}_{ff} , \mathbf{D}_{ss} , \mathbf{D}_f , and \mathbf{D}_s and the interfacial convective heat transfer coefficient h_{sf} are introduced. The total thermal diffusivity tensors include both the effective thermal diffusivity tensor (stagnant) as well as the hydrodynamic dispersion tensor. A total convective velocity \mathbf{v} is defined such that the two-medium energy equations become

$$\frac{\partial \langle T \rangle^f}{\partial t} + \mathbf{v}_{ff} \cdot \nabla \langle T \rangle^f + \mathbf{v}_f \cdot \nabla \langle T \rangle^s = \nabla \cdot \mathbf{D}_{ff} \cdot \nabla \langle T \rangle^f + \nabla \cdot \mathbf{D}_f \cdot \nabla \langle T \rangle^s + \frac{A_{fs}}{V_f(\rho c_p)_f} h_{sf} (\langle T \rangle^s - \langle T \rangle^f) \quad (9.57)$$

$$\frac{\partial \langle T \rangle^s}{\partial t} + \mathbf{v}_{sf} \cdot \nabla \langle T \rangle^f + \mathbf{v}_s \cdot \nabla \langle T \rangle^s = \nabla \cdot \mathbf{D}_s \cdot \nabla \langle T \rangle^f + \nabla \cdot \mathbf{D}_{ss} \cdot \nabla \langle T \rangle^s + \frac{A_{fs}}{V_s(\rho c_p)_s} h_{sf} (\langle T \rangle^f - \langle T \rangle^s) \quad (9.58)$$

As is discussed later, h_{sf} is also used as an overall convection heat transfer coefficient. When h_{sf} is determined experimentally, it is important to note whether the complete form of Eqs. 9.57 and 9.58 are used for its evaluation. The use of oversimplified versions of Eqs. 9.57 and 9.58 results in the inclusion of the neglected terms into h_{sf} . This simplification results in values for h_{sf} that are valid only for those particular experiments.

Interfacial Heat Transfer Coefficient h_{sf} . In the earlier treatments of transient heat transfer in packed beds, various heuristic models were used instead of the two equations given by Eqs. 9.57 and 9.58. Wakao and Kagueli [85] give the history of the development in this area. In the following, some of these models, which all use an interfacial convection heat transfer coefficient h_{sf} , are discussed. The distinction should be between h_{sf} found from the energy Eqs. 9.57 and 9.58, and that found from the simplified forms of energy equations. Since these different models are used in the determination of h_{sf} , the literature on the reported value of h_{sf} is rather incoherent. Wakao and Kagueli [85] have carefully examined these reported values and classified the modeling efforts.

It should be noted that h_{sf} for a heated single particle in an otherwise uniform temperature field is expected to be significantly different than that for particles in packed beds. Also, since, in general, the thermal conductivity of the solid is not large enough to lead to an isothermal surface temperature, the conductivity of the solid also influences the temperature field around it. Therefore, the interstitial convection heat transfer coefficient obtained from a given fluid-solid combination is not expected to hold valid for some other combinations.

The coefficients in Eqs. 9.57 and 9.58 have been computed for some geometry and range of parameters [84]. Simplified h_{sf} -based models can still be used, and we review some of these

heuristic models. However, their inadequacy to explain the process and their limitations cannot be overemphasized.

Models Based on h_{sf} . There are many h_{sf} -based models appearing in the literature. Three such models are given here [85]. These are generally for the one-dimensional Darcean flow and heat transfer and for packed beds of spherical particles.

1. *Schumann Model.* This is the simplest and the least accurate of all models. The two equations are given as

$$\frac{\partial \langle T \rangle^f}{\partial t} + \langle u \rangle^f \frac{\partial \langle T \rangle^f}{\partial x} = \frac{h_{sf} A_0}{\varepsilon (\rho c_p)_f} (\langle T \rangle^s - \langle T \rangle^f) \quad (9.59)$$

$$\frac{\partial \langle T \rangle^s}{\partial t} = - \frac{h_{sf} A_0}{(1 - \varepsilon)(\rho c_p)_s} (\langle T \rangle^s - \langle T \rangle^f) \quad (9.60)$$

where $A_0 = A_{fs}/V$ is the specific surface area and $u_p = \langle u \rangle^f$ is the average pore velocity. No account is made of the axial conduction and the dispersion in the solid energy equation. This model is for transient problems only.

2. *Continuous-Solid Model.* In this model, the axial conduction, in both phases, is included through the use of effective thermal conductivities k_{fe} and k_{se} . This gives

$$\frac{\partial \langle T \rangle^f}{\partial t} + \langle u \rangle^f \frac{\partial \langle T \rangle^f}{\partial x} = \frac{\langle k \rangle^f}{\varepsilon (\rho c_p)_f} \frac{\partial^2 \langle T \rangle^f}{\partial x^2} + \frac{h_{sf} A_0}{\varepsilon (\rho c_p)_f} (\langle T \rangle^s - \langle T \rangle^f) \quad (9.61)$$

$$\frac{\partial \langle T \rangle^s}{\partial t} = \frac{\langle k \rangle^s}{(1 - \varepsilon)(\rho c_p)_s} \frac{\partial^2 \langle T \rangle^s}{\partial x^2} - \frac{h_{sf} A_0}{(1 - \varepsilon)(\rho c_p)_s} (\langle T \rangle^s - \langle T \rangle^f) \quad (9.62)$$

No account is made of the dispersion and $\langle k \rangle^f$, $\langle k \rangle^s$, and h_{sf} are to be determined experimentally.

3. *Dispersion-Particle-Based Model.* This is an improvement over the continuous-solid model and allows for dispersion. The results are

$$\frac{\partial \langle T \rangle^f}{\partial t} + \langle u \rangle^f \frac{\partial \langle T \rangle^f}{\partial x} = \frac{1}{\varepsilon} \left(\frac{\langle k \rangle}{(\rho c_p)_f} + D_{xx}^d \right) \frac{\partial^2 \langle T \rangle^f}{\partial x^2} + \frac{h_{sf} A_0}{\varepsilon (\rho c_p)_f} (T_{sf} - \langle T \rangle^f) \quad (9.63)$$

$$\frac{\partial T_s}{\partial t} = \frac{\langle k \rangle^s}{(\rho c_p)_s} \frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial T_s}{\partial r} \right) \quad (9.64)$$

$$-k_s \frac{\partial T_s}{\partial r} = h_{sf} (T_{sf} - \langle T \rangle^f) \quad \text{on } A_{fs} \quad (9.65)$$

where $T_{sf} = T_s$ on A_{fs} . Wakao and Kaguei [85] suggest $D_{11}^d/\alpha_f = 0.5$ Pe with $\text{Pe} = \varepsilon u_p d/\alpha_f$. Note that the bed effective thermal conductivity k is included in the fluid-phase equation [85]. Also note that the suggested coefficient for Pe in the expression for the dispersion is smaller than that given in the section entitled "Convection Heat Transfer," where the presence of the local thermal equilibrium was assumed. This particle-based model is the most accurate among the three and is widely used. This model is for transient problems only.

Experimental Determination of h_{sf} . Wakao and Kaguei [85] have critically examined the experimental results on h_{sf} and have selected experiments (steady-state and transient) which they found to be reliable. They have used Eqs. 9.59 through 9.65 for the evaluation of h_{sf} . This is a rather indirect method of measuring h_{sf} , and, as was mentioned, the results depend on the

model used. They have found the following correlation for h_{sf} for spherical particles (or the dimensionless form of it, the Nusselt number)

$$\text{Nu}_d = \frac{h_{sf}d}{k_f} = 2 + 1.1\text{Re}^{0.6} \text{Pr}^{1/3} \quad (9.66)$$

for spherical particles where $\text{Re} = \epsilon u_p d/\nu = u_D d/\nu$. Equation 9.66 gives a $\text{Re} \rightarrow 0$ asymptote of $h_{sf}d/k_f = 2$, which is more reasonable than $h_{sf} \rightarrow 0$ found when models other than Eqs. 9.63 to 9.65 are used. It should be mentioned that the measurement of h_{sf} becomes more difficult and the experimental uncertainties become much higher as $\text{Re} \rightarrow 0$. Figure 9.16 shows the experimental results compiled by Wakao and Kaguei [85] and their proposed correlation. Note also that at low Re , the interfacial convection heat transfer is insignificant compared to the other terms in the energy equations, and, therefore, the suggested $\text{Re} \rightarrow 0$ asymptote cannot be experimentally verified.

FIGURE 9.16 Experimental results compiled from many sources by Wakao and Kaguei [85] (for steady-state and transient experiments). Also given is their proposed correlation.

The steady-state results are for the heated spheres (the analogous mass transfer is the sublimation of spherical particles).

For ceramic foams, with air as the fluid, Yunis and Viskanta [86] have indirectly measured Nu_d and obtained correlations with Re_d as the variable. They obtain a lower value for the power Re_d . The interfacial heat transfer is also discussed in detail by Kaviany [7].

TWO-PHASE FLOW

In this section, the hydrodynamics and heat transfer of the two-phase (liquid-gas) flow in porous media is addressed. First the volume-averaged momentum equation (for each phase) is considered. The elements of the hydrodynamics of three-phase systems (solid-liquid-gas) are discussed. Then the energy equation and the effective properties are reviewed.

Momentum Equations for Liquid-Gas Flow

The hydrodynamics of two-phase flow in porous media is in part controlled by the dynamics of the liquid-gas-solid contact line. This is in turn determined by the interfacial tensions, the static contact angle, the moving contact angle, and the van der Waals interfacial-layer forces. We need to examine the interfacial tension between a liquid and another fluid. For the case of a static equilibrium at this interface, we can examine the effect of the curvature for the simple problem of ring formation between spheres (and cylinders). For dynamic aspects, we need to examine the combined effect of capillarity and buoyancy by discussing the rise of a bubble in a capillary tube. Then, we should consider more realistic conditions and examine the effects of various factors on the phase distributions and the existing results for the phase distributions in flow through packed beds. The moving contact line and the effects of solid surface tension and the surface roughness and heterogeneities should also be discussed. For the perfectly wetting liquids at equilibrium, a thin extension of the liquid is present on the surface. After the phase-volume averaging of the momentum equation, we discuss the various coefficients that appear in the two momentum equations (one for the wetting phase and one for the nonwetting phase). The coefficients are generally determined empirically, because of the complexity of the phase distributions and their strong dependence on the local saturation. The capillary pressure, phase permeabilities, liquid-gas interfacial drag (due to the difference in the local phase velocities), and the surface tension gradient-induced shear at the liquid-gas interface are discussed in some detail. The special transient problem of immiscible displacement [9] is not examined here. In the following paragraphs, we review some of the definitions used in two-phase flow through porous media and identify the key variables influencing the hydrodynamics.

When compared to the single-phase flows, the two-phase flow in porous media has one significant peculiarity and that is the wetting of the surface of the matrix by one of the fluid phases. Although here the attention is basically on a liquid-phase wetting the surface and a gaseous phase being the nonwetting phase, in some applications the two phases can be two liquids where one preferentially wets the surface. The presence of a curvature at the liquid-gas interface results in a difference between the local gaseous and liquid-phase pressures (capillary pressure). This difference in pressure depends on the fraction of the average pore volume (or porosity of the representative elementary volume) occupied by the wetting phase. This fraction is called the *saturation* and is given as

$$\frac{\varepsilon_\ell}{\varepsilon} \equiv \text{saturation} = s = \frac{\text{fraction of the volume occupied by the wetting phase}}{\text{porosity}} \quad (9.67)$$

As with the single-phase flows, the fractions of the representative elementary volume occupied by the liquid and gas phases are

$$\varepsilon_\ell(\mathbf{x}) = \frac{V_\ell}{V} = \varepsilon s \quad (9.68)$$

$$\varepsilon_g(\mathbf{x}) = \frac{V_g}{V} = \varepsilon(1 - s) \quad (9.69)$$

$$\varepsilon_s + \varepsilon_\ell + \varepsilon_g = 1 \quad (9.70)$$

$$V_s + V_\ell + V_g = V \quad (9.71)$$

$$\varepsilon_s = 1 - \varepsilon \quad (9.72)$$

The subscript ℓ refers to the liquid or wetting phase and g refers to the gaseous or nonwetting phase.

As with the fluid dynamics of two-phase flows in plain media, when the two phases do not have the same interstitial velocity, there will be an interfacial drag whose determination requires a knowledge of the interfacial area $A_{g\ell}$ as well as the local flow field in each phase. This interfacial drag is expected to be important only at high flow rates.

In transient two-phase flows, one phase replaces the other and the dynamics of the wetting-dewetting of the surface, which is influenced by the fluid-fluid interfacial tension, solid-fluid interfacial tensions, and the solid-surface forces, must be closely examined. The research on the dynamics of the contact line (fluid-fluid-solid contact line) has been advanced in the last decade.

Based on this, we expect the following parameters (variables) to influence the dynamics of two-phase flow in porous media.

- *Surface tension.* Assuming that a membrane stretches over each interface, the magnitudes of the interfacial tension between each pair of phases are the fluid-fluid interfacial tension $\sigma_{g\ell}$, the wetting fluid-solid interfacial tension $\sigma_{\ell s}$, and the nonwetting fluid-solid interfacial tension σ_{gs} . When in static equilibrium, the vectorial force balance at the line of contact (the law of Neumann triangle, Ref. 87) gives

$$\sigma_{g\ell} + \sigma_{\ell s} + \sigma_{gs} = \mathbf{0} \quad (9.73)$$

at contact line. The static mechanical equilibrium of the g - ℓ surface is given by the Young-Laplace equation

$$p_c = p_g - p_\ell = \sigma_{g\ell} \left(\frac{1}{r_1} + \frac{1}{r_2} \right) \equiv \sigma \left(\frac{1}{r_1} + \frac{1}{r_2} \right) \equiv 2H\sigma \quad \text{on } A_{g\ell} \quad (9.74)$$

where p_c is the capillary pressure and r_1 and r_2 are the two principal radii of curvature of $A_{g\ell}$ and where for simplicity we have used $\sigma_{g\ell} \equiv \sigma$. The mean curvature of the interface H is defined as

$$H \equiv \frac{1}{2} \left(\frac{1}{r_1} + \frac{1}{r_2} \right) \quad (9.75)$$

- *Wettability.* The extent to which the wetting phase spreads over the solid surface. The angle, measured in the wetting phase, between the solid surface and the g - ℓ interface, is called the *contact angle* θ_c where $\theta_c = 0$ corresponds to complete wetting. Presence of surface roughness, adsorbed surface layers, or surfactants influence θ_c significantly.
- *Matrix structure.* The size, dimensionality, pore coordinate number, and topology of the matrix influence the phase distributions significantly.
- *Viscosity ratio.* μ_g/μ_ℓ influences the relative flow rates directly and indirectly through the interfacial shear stress. In fast transient flows (e.g., immiscible displacement), depending on whether the viscosity of the displacing fluid is larger than that of the displaced fluid, or vice versa, different displacement frontal behaviors are found.
- *Density ratio.* ρ_g/ρ_ℓ , in addition to the body force, signifies the relative importance of the inertial force for the two phases.
- *Saturation.* This is the extent to which the wetting phase occupies (averaged over the representative elementary volume) the pore space. At very low saturations the wetting phase becomes disconnected (or immobile). At very high saturations, the nonwetting phase becomes disconnected.

In addition, the presence of temperature and concentration gradients results in interfacial tension gradients and influences the phase distributions and flow rates. In dynamic systems, the history of the flows and the surface conditions also play a role and lead to the observed hysteresis in the phase distributions.

In order to arrive at a local volume-averaged momentum equation for each phase, the effect of the preceding parameters on the microscopic hydrodynamics must be examined. This is done to an extent through the particular forces that appear in the momentum equations.

Now, by including the microscopic inertial and macroscopic inertial terms and by introducing $K_{\ell g1}$, $K_{\ell g2}$, $K_{g\ell1}$, and $K_{g\ell2}$ as the coefficients in the liquid-gas interfacial drag forces, and by assuming that this drag is proportional to the difference in the phase velocities and that for cocurrent flows $|\langle u_j \rangle^g| > |\langle u_j \rangle^\ell|$, we have the following pair of momentum equations for two-phase flow in porous media.

Liquid phase

$$\frac{\rho_\ell}{\epsilon s} \left(\frac{\partial \langle \mathbf{u}_\ell \rangle}{\partial t} + \langle \mathbf{u}_\ell \rangle \cdot \nabla \langle \mathbf{u}_\ell \rangle \right) = -\nabla \langle p \rangle^\ell + \rho_\ell \mathbf{g} - \frac{\mu_\ell}{K_\ell} \langle \mathbf{u}_\ell \rangle - \frac{\rho_\ell}{K_{\ell i}} |\langle \mathbf{u}_\ell \rangle| \langle \mathbf{u}_\ell \rangle$$

(ℓ -phase macroscopic inertial force)
(ℓ -phase pore pressure gradient)
(ℓ -phase body force)
(microscopic interfacial ($A_{\ell i}$) shear stress)
(microscopic inertial force)

$$+ [K_{\ell g1} |\langle \mathbf{u} \rangle^g - \langle \mathbf{u} \rangle^\ell| + K_{\ell g2} (\langle \mathbf{u} \rangle^g - \langle \mathbf{u} \rangle^\ell)^2] \frac{\langle \mathbf{u} \rangle^\ell}{|\langle \mathbf{u} \rangle^\ell|} + \mu_\ell \frac{K_{\ell \Delta \sigma}}{K_\ell} \nabla \sigma \quad (9.76)$$

(microscopic interfacial ($A_{\ell g}$) shear stress)
(microscopic interfacial ($A_{\ell g}$) surface tension gradient force)

Gas phase

$$\frac{\rho_g}{\epsilon(1-s)} \left(\frac{\partial \langle \mathbf{u}_g \rangle}{\partial t} + \langle \mathbf{u}_g \rangle \cdot \nabla \langle \mathbf{u}_g \rangle \right) = -\nabla \langle p \rangle^g + \rho_g \mathbf{g} - \frac{\mu_g}{K_g} \langle \mathbf{u}_g \rangle - \frac{\rho_g}{K_{gi}} |\langle \mathbf{u}_g \rangle| \langle \mathbf{u}_g \rangle$$

$$+ [K_{g\ell1} |\langle \mathbf{u} \rangle^g - \langle \mathbf{u} \rangle^\ell| + K_{g\ell2} (\langle \mathbf{u} \rangle^g - \langle \mathbf{u} \rangle^\ell)^2] \frac{\langle \mathbf{u} \rangle^g}{|\langle \mathbf{u} \rangle^g|} + \mu_g \frac{K_{g\Delta \sigma}}{K_g} \nabla \sigma \quad (9.77)$$

where we have assumed that all the coefficients are isotropic. This assumption simplifies the preceding equations and is justified because presently only the simple isotropic coefficients are available.

Note that from the definition of the phase averaging, that is, $\langle \mathbf{u} \rangle^\ell = (1/V_\ell) \int_{V_\ell} \mathbf{u} dV$, etc., we have

$$\langle \mathbf{u} \rangle^\ell = \frac{\langle \mathbf{u}_\ell \rangle}{\epsilon s} \quad \text{and} \quad \langle \mathbf{u} \rangle^g = \frac{\langle \mathbf{u}_g \rangle}{\epsilon(1-s)} \quad (9.78)$$

These momentum equations are solved along with the continuity equations and the appropriate boundary conditions. These are discussed and given in Ref. 9.

Some of the correlations for the coefficients appearing in the momentum equations are given in Tables 9.9 through 9.12.

Local Volume Averaging of Energy Equation

The principles of the local volume averaging as applied to the conduction equation, the single-phase flow convection equation, and the two-phase flow momentum equation is now applied to the two-phase flow energy equation. The concept is that developed by Whitaker [101], where the extensive derivations are given. We expect to arrive at a local volume-averaged energy equation in which the *effective thermal conductivity* is the combined contribution of the three phases (s , ℓ , and g) to the molecular conduction, and the *thermal dispersion* is the combined dispersion in the ℓ and g phases. We consider the general case of transient temperature fields with a local heat generation \dot{s} and the ℓ - g phase change \dot{n} . The closure conditions lead to equations for the transformation vectors. For simplicity, we consider the simple case of

TABLE 9.9 Correlations for Capillary Pressure

Constraints	Correlation
(a) Water-air-sand	$\langle p_c \rangle = \frac{\sigma}{(K/\epsilon)^{1/2}} \left[0.364(1 - e^{-40(1-s)}) + 0.221(1-s) + \frac{0.005}{s-0.08} \right]$
(b) Water-air-soil and sandstones	$s = s_{ir} + \frac{1 - s_{ir} - s_{irg}}{\left[1 + \left(a_1 \frac{\langle p_c \rangle}{\rho_l g} \right)^n \right]^{1-1/n}}$ where $n > 1$, a_1 is a constant, n and a_1 depend on the matrix and the drainage or imbibition process
(c) Imbibition, nonconsolidated sand, from Leverett [88] data of water-air	$\langle p_c \rangle = \frac{\sigma}{(K/\epsilon)^{1/2}} [1.417(1-S) - 2.120(1-S)^2 + 1.263(1-S)^3]$ where $S = \frac{s - s_{ir}}{1 - s_{ir} - s_{irg}}$
(d) Drainage, oil-water in sandstone	$\langle p_c \rangle = \frac{\sigma}{(K/\epsilon)^{1/2}} [a_1 - a_2 \ln(s - s_{ir})]$ where $a_1 = 0.30$, $a_2 = 0.0633$, $s_{ir} = 0.15$

(a) Tutu et al. [98]; (b) Schulenberg and Müller [99]; (c) Tung and Dhir [100].

a unit cell in a periodic fluid-solid structure. The energy equation given in the last section contains terms that are similar to those that were previously labeled as the effective thermal conductivity and thermal dispersion.

The *total conductivity tensor* \mathbf{D} is defined as

$$\mathbf{D} = \frac{\mathbf{K}_e}{(\rho c_p)_t} + \mathbf{D}^d \quad (9.79)$$

By using these in the thermal energy equation we have

$$\begin{aligned} [(1-\varepsilon)(\rho c_p)_s + \varepsilon s(\rho c_p)_t + \varepsilon(1-s)(\rho)^s c_{p_g}] \frac{\partial \langle T \rangle}{\partial t} + [(\rho c_p)_t \langle \mathbf{u}_t \rangle + (\rho c_p)_g \langle \mathbf{u}_g \rangle] \cdot \nabla \langle T \rangle + \Delta i_{tg} \langle \dot{r} \rangle \\ = \nabla \cdot [\mathbf{K}_e + (\rho c_p)_t \mathbf{D}^d] \cdot \nabla \langle T \rangle + \langle \dot{s} \rangle \quad (9.80) \end{aligned}$$

Effective Thermal Conductivity

Then we expect a functional relationship for the effective thermal conductivity tensor, of the form

$$\mathbf{K}_e = \mathbf{K}_e[k_s, k_t, k_g, a_t(\mathbf{x}), a_g(\mathbf{x})] \quad (9.81)$$

However, \mathbf{K}_e can be given in terms of the more readily measurable quantities such as

$$\mathbf{K}_e = \mathbf{K}_e(k_s, k_t, k_g, \mathbf{u}_g, \mathbf{u}_t, \sigma, \frac{\mu_g}{\mu_t}, \frac{\rho_g}{\rho_t}, s, \theta_c, \varepsilon, \text{solid structure, history}) \quad (9.82)$$

This replacement of the variables is done noting that the phase distributions depend on the velocity field and so forth. We also expect two asymptotic behaviors for \mathbf{K}_e , which for isotropic phase distributions are given as the following:

$$\begin{aligned} \text{for } s \rightarrow 1 \quad \mathbf{K}_e &= k_{e(s-t)} \mathbf{I} = k_e(s=1) \mathbf{I} \\ \text{for } s \rightarrow 0 \quad \mathbf{K}_e &= k_{e(s-g)} \mathbf{I} = k_e(s=0) \mathbf{I} \\ k_e &= k_e(k_s, k_f, \varepsilon, \text{solid structure}) \quad (9.83) \end{aligned}$$

Since in two-phase flow and heat transfer in porous media for any direction, the bulk effective thermal conductivity is generally much smaller than the bulk thermal dispersion, the available studies on \mathbf{K}_e are limited. In the following, we briefly discuss the anisotropy of \mathbf{K}_e and then review the available treatments.

Presently no rigorous solutions for $k_{e\parallel}$ and $k_{e\perp}$ are available. Although not attempted, one of the readily solvable problems would be that of the periodically constricted tube introduced by Saez et al. [102]. For this simple unit-cell phase distribution (which is an approximation to the simple-cubic arrangement of monosize spheres), we expect

$$k_{e\parallel} \gg k_{e\perp} \quad (9.84)$$

because of the smaller thermal conductivity of the gas phase.

Most of the reported experimental results for $\mathbf{K}_e(s)$ are obtained for $\mathbf{u} \neq 0$, and, therefore, are the results of the simultaneous evaluation of $\mathbf{K}_e(s)$ and $\mathbf{D}^d(s)$. In these experiments, generally, $\mathbf{K}_e \ll (\rho c_p)_t \mathbf{D}^d$. An exception is the experiment of Somerton et al. [103], where only $\mathbf{K}_e = \mathbf{I} k_e(s)$ was determined but with no examination of the anisotropy. Another one is that of Matsuura et al. [104], where the velocity was reduced sufficiently to allow for the determination of $k_e(s)$ with some accuracy; again, no directional dependence was considered.

Table 9.13 summarizes some of the available empirical correlations for $k_{e\parallel}(s)$ and $k_{e\perp}(s)$ for packed beds of spherical particles. The experiments of Specchia and Baldi [105], Hashimoto

TABLE 9.13 Correlations for Two-Phase Effective Thermal Conductivity

(a) Alumina spheres-water-air	$\frac{k_{e\perp}}{k_t} = a_1$ where a_1 is determined experimentally
(b) Glass spheres-water-air ($\epsilon = 0.375$)	$\frac{k_{e\perp}}{k_t} = a_1, \quad 0.13 < s < 0.6$ where a_1 is determined experimentally
(c) Glass spheres-water-air ($\epsilon = 0.4$)	$\frac{k_{e\perp}}{k_t} = 1.5, \quad 0.08 < s < 0.21$
(d) Glass and ceramic spheres-water-air	$\frac{k_{e\perp}}{k_t} = \frac{k_e(s=0)}{k_t}$
(e) Nonconsolidated sands-brine-air (moist), no directional dependence investigated	$\frac{k_{e\parallel}}{k_t} = \frac{k_{e\perp}}{k_t} = \frac{k_e(s=0)}{k_t} + s^{1/2} \left[\frac{k_e(s=1) - k_e(s=0)}{k_t} \right]$
(f) Disordered porous media, not experimentally verified	$\frac{k_{e\parallel}}{k_t} = s \frac{k_e(s=1)}{k_t} + (1-s) \frac{k_e(s=0)}{k_t}$
(g) Disordered porous media, not experimentally verified	$\frac{k_{e\perp}}{k_t} = \left[\frac{k_e(s=1)}{k_t} \right]^s \left[\frac{k_e(s=0)}{k_t} \right]^{1-s}$

(a) Weekman and Myers [107]; (b) Hashimoto et al. [106]; (c) Matsuura et al. [104]; (d) Specchia and Baldi [105]; (e) Somerton et al. [103] and Udell and Fitch [109]; (f) parallel arrangement; (g) geometric mean.

et al. [106], and Weekman and Myers [107] are not of high enough accuracies at low velocities, and, therefore, their values for a_1 are not expected to be accurate [104]. Also, Matsuura et al. [108] could not resolve the saturation-dependence of k_e in their experiments. Somerton et al. [103] do find a saturation dependence as given in Table 9.13. Also shown in the table are the estimates based on the parallel arrangement and geometric mean.

Examination of Table 9.13 shows that further study of the parameters influencing \mathbf{K}_e is needed. This includes the effects of the wettability and the significance of the expected hysteresis in $\mathbf{K}_e(s)$.

Thermal Dispersion

Under steady-state conditions without a heat source, we can rewrite Eq. 9.80 as

$$\left[\langle \mathbf{u}_\ell \rangle + \frac{(\rho c_p)_g}{(\rho c_p)_\ell} \langle \mathbf{u}_g \rangle \right] \cdot \nabla T = \nabla \cdot \left[\frac{\mathbf{K}_e}{(\rho c_p)_\ell} + \mathbf{D}_\ell^d + \frac{(\rho c_p)_g}{(\rho c_p)_\ell} \mathbf{D}_g^d \right] \cdot \nabla T \quad (9.85)$$

\mathbf{D}_ℓ^d and \mathbf{D}_g^d depend on the pore-level velocity and phase distributions (in their respective phases). These phase velocity distributions are coupled at $A_{\ell g}$, and therefore, the motion of one phase influences the other. The general relations for \mathbf{D}_ℓ^d and \mathbf{D}_g^d are of the form

$$\mathbf{D}_\ell^d = \mathbf{D}_\ell^d[k_s, k_\ell, k_g, a_\ell(\mathbf{x}), a_g(\mathbf{x}), (\rho c_p)_\ell, (\rho c_p)_g, \mathbf{u}_\ell, \mathbf{u}_g, \mu_\ell, \mu_g, \sigma, \theta_c, \text{history}] \quad (9.86)$$

A similar relationship can be given for \mathbf{D}_g^d . Note that the various flow regimes (such as the trickle, pulsing, and bubble regimes in the cocurrent and countercurrent downflow in packed

beds of spheres are all represented by a_t and a_g . We expect to recover the two asymptotic behaviors, that is,

$$\begin{aligned} \text{for } s \rightarrow 1: \quad \mathbf{D}_\ell^d &= \mathbf{D}_\ell^d(s=1) = \varepsilon \mathbf{D}^d, & \mathbf{D}_g^d &= 0 \\ \text{for } s \rightarrow 0: \quad \mathbf{D}_\ell^d &= 0, & \mathbf{D}_g^d &= \mathbf{D}_g^d(s=0) = \varepsilon \mathbf{D}^d \end{aligned} \quad (9.87)$$

where $\mathbf{D}_\ell^d(s=1)$ and $\mathbf{D}_g^d(s=0)$ are the single-phase flow thermal dispersion tensor (multiplied by ε) given in the section on convection heat transfer. From the results of that previous section, we know that

$$\mathbf{D}^d(s=0 \text{ or } s=1) = \mathbf{D}^d\left(\text{Pe}, \frac{k_s}{k_f}, \varepsilon, \text{solid structure}\right) \quad (9.88)$$

with a weak dependence on Pr.

Table 9.14 lists existing correlations for the lateral dispersion coefficient for two-phase flow.

TABLE 9.14 Correlations for Two-Phase Flow Lateral Dispersion Coefficient

Constraints	Correlation
(a) Cocurrent, downward flow in packed bed of spheres, air-water-glass, wall heating	$\frac{D_\perp^d}{\alpha_t} = 0.00174 \text{ Pe}_t + 0.172 \text{ Pe}_g$ $\text{Pe}_t = \frac{\langle u_t \rangle d}{\alpha_t}, \quad \text{Pe}_g = \frac{\langle u_g \rangle d}{\alpha_g}$
(b) Glass and ceramic spheres and ceramic rings, with water-air, wall heating	$D_\perp^d = D_{g\perp}^d + D_{t\perp}^d$ $D_{g\perp}^d = D_{g\perp}^d(s=0), \quad D_{g\perp}^d \ll D_{t\perp}^d$ $\frac{\langle u_t \rangle d}{D_{t\perp}^d} = 338 \text{Re}_t^{0.67} H^{0.29} \left(\frac{dA_0}{\varepsilon}\right)^{-2.7}$ <p>where $H(\text{Re}_t, \text{etc.})$ is the liquid holdup, A_0 is the specific surface area, $\text{Re}_t = \langle u_t \rangle d / \nu_t$, and H is correlated by Saez and Carbonell [92] and Crine [110]</p>

PHASE CHANGE

In this section, we examine evaporation and condensation in porous media in detail and briefly review melting and solidification in porous media. The heat supply or removal causing these to occur is generally through the bounding surfaces and these surfaces can be impermeable or permeable. We begin by considering condensation and evaporation adjacent to vertical impermeable surfaces. These are the counterparts of the film condensation and evaporation in plain media. The presence of the solid matrix results in the occurrence of a two-phase flow region governed by gravity and capillarity. The study of this two-phase flow and its effect on the condensation or evaporation rate (i.e., the heat transfer rate) has begun recently. Evaporation from horizontal impermeable surfaces is considered next. Because the evaporation is mostly from thin-liquid films forming on the solid matrix (in the evaporation zone), the evaporation does not require a significant superheat. The onset of dryout, that is, the failure of the gravity and capillarity to keep the surface wet, occurs at a critical heat flux but only small superheat is required. We examine the predictions of the critical heat flux and the treatment of the vapor-film and the two-phase regions. We also examine the case of thin porous-layer coating of horizontal surfaces and review the limited data on the porous-layer thickness dependence of the heat flow rate versus the superheat curve. Then, we turn to permeable bounding surfaces and examine the moving condensation front occurring when a vapor is injected in a liquid-filled solid matrix. Finally, we examine the heating at a permeable bounding surface where the surface temperature is below the saturation temperature and the resulting surface and internal evaporations result in the gradual drying of the surface. The melting and solidification of single and multicomponent systems are discussed as part of phase change in condensed phase.

Condensation at Vertical Impermeable Bounding Surfaces

When a vertical impermeable surface bounding a semi-infinite vapor-phase domain is cooled below the saturation temperature and when nucleation sites are present, condensation begins, and if the condensed phase (liquid) wets the surface perfectly, the film-condensation flow occurs. For phase-density buoyant flows (i.e., flows caused by the density difference between phases and in presence of the gravity field), if the vapor is in the pores of a solid matrix bounded by this vertical surface, the liquid flows through the matrix both along the gravity vector (due to buoyancy) and perpendicular to it (due to capillarity). A single-phase region (liquid-film region) must be present adjacent to the wall where the liquid is subcooled up to the edge of this film (a distance δ_l from the surface). Beyond δ_l , the capillarity results in a two-phase region that is nearly isothermal. For the phase-density buoyant film condensation flow

FIGURE 9.17 Condensation at an impermeable vertical surface for cases with $\delta_l/d < 1$, $\delta_l/d = 1$, and $\delta_l/d > 1$.

in plain media, the film thickness is generally small. δ_l increases as $x^{1/4}$ with x taken along the gravity vector and measured from the leading edge of the film. This is characteristic of natural convection in plain media. For condensation in porous media, the local film thickness can be much larger than the pore (or particle) size, which will allow for a local volume-averaged treatment of this fluid-solid heterogeneous system. However, when the local film thickness is smaller or comparable in size to the pore size, the local volume-averaged treatments will no longer be applicable. Figure 9.17 depicts the local flow of liquid for cases where $\delta_l/d < 1$, $\delta_l/d = 1$, and $\delta_l/d > 1$. As was mentioned, for cases with a large δ_l/d , a two-phase region also exists extending from $y = \delta_l$ to $y = \delta_{lg}$.

The case of combined buoyant-forced (i.e., applied external-pressure gradient film condensation flow in porous media) has been examined by Renken et al. [112], and here we examine the case when there is no external pressure gradient.

In the following, we only examine in sufficient detail the fluid flow and heat transfer for thick liquid films, that is, $\delta_\ell/d > 1$.

In order to study two-phase flow and heat transfer for this phase change problem, we assume that the local volume-averaged conservation equations (including the assumption of local thermal equilibrium) are applicable. For this problem, we note the following.

- The liquid-film and two-phase regions each must contain many pores, that is, for gravity-capillarity-dominated ($Bo \approx 1$) and capillarity-dominated ($Bo < 1$) flows, we require

$$\frac{\delta_\ell}{d} \gg 1 \quad \text{and} \quad \frac{\delta_{\ell g}}{d} \gg 1 \quad \text{for } Bo = \frac{g(\rho_\ell - \rho_g)K/\varepsilon}{\sigma} \ll 1 \quad (9.89)$$

$$\frac{\delta_\ell}{d} \gg 1 \quad \text{for } Bo \lesssim 1 \quad (9.90)$$

For the gravity-dominated flows, the two-phase region is absent. This large Bond number asymptote is discussed later.

- The liquid viscosity varies with temperature $\mu_\ell = \mu_\ell(T)$ and can be included in the analysis. However, when μ_ℓ is evaluated at the average film temperature, this variation can be represented with sufficient accuracy.
- The solid structure and the hydrodynamic nonuniformities can cause large variations of ε , K , $k_{\ell\perp}$, and D_\perp^d near the bounding surface. Special attention should be given to these nonuniformities. For the continuum treatment, we require that

$$(\nabla\varepsilon)d \ll 1 \quad (9.91)$$

that is, a large porosity variation near the bounding surface requires a special treatment.

- The boundary-layer treatment is assumed to be justifiable, that is, $\delta_\ell/L \ll 1$.
- At and near the bounding surface, the lateral effective thermal conductivity $k_{\ell\perp}(y=0)$ depends on the thermal conductivity of the bounding surface (in addition to the other parameters affecting the bulk values of $k_{\ell\perp}$). Therefore, in using

$$\left(k_{\ell\perp} \frac{\partial T}{\partial y}\right)_{y=0} \approx \dot{m}_{g\ell} i_{\ell g} \quad (9.92)$$

a special attention should be given to evaluation of $k_{\ell\perp}(y=0)$, whenever the experimental results for $T(x, y)$ are used for the evaluation of $(\partial T/\partial y)_{y=0}$. Generally, the local condensation rate $\dot{m}_{g\ell}$ is measured instead of $T(x, y)$. This is because δ_ℓ is generally small, and, therefore, the accuracy of $T(x, 0 < y < \delta_\ell)$ is not high enough to result in acceptable gradients.

- The gaseous phase is assumed to be a simple single-component system. The presence of noncondensable gases, which results in a significant reduction in the condensation rate (because of their accumulation near $y = \delta_\ell$ and their resistance to the flow of vapor toward this interface), can be addressed by the inclusion of the species conservation equation (i.e., the mass diffusion equation). For the $y \geq \delta_\ell + \delta_{\ell g}$ domain, the single-phase mass diffusion can be used. For the two-phase region, a mass diffusion equation for the gaseous phase can be written by noting the anisotropy of the effective mass diffusion and the dispersion tensors. As is discussed later, the determination of the saturation distribution for this condensation problem is not yet satisfactorily resolved, and, therefore, the analysis of the effect of the noncondensables has not yet been carried out with any reasonable accuracy. Since the temperature gradient in the two-phase region is negligibly small, there is a discontinuity in the

FIGURE 9.18 Film condensation at a vertical impermeable surface with $\delta_\ell/d > 1$ and $\delta_{\ell g}/d > 1$. Distributions of saturation, temperature, and liquid phase velocity are also depicted.

gradient of the temperature at δ_ℓ (Fig. 9.18). Then, following the standard procedures, the analytical treatment is based on the separation of the domains. Here, there are three domains, namely, $0 \leq y \leq \delta_\ell(x)$, $\delta_\ell(x) \leq y \leq \delta_\ell + \delta_{\ell g}(x)$, and $\delta_\ell + \delta_{\ell g}(x) \leq y \leq \infty$. In the following, we treat the first two domains; the third domain is assumed to have uniform fields.

Liquid-Film Region. The single-phase flow and heat transfer in this region can be described by the continuity equation, the momentum equation in Eqs. 9.76 and 9.77, and the energy equation (Eq. 9.80). We deal only with the volume-averaged velocities, such as $\langle u_\ell \rangle = u_\ell$; therefore, we drop the averaging symbol from the superficial (or Darcian) velocities. For the two-dimensional steady-state boundary-layer flow and heat transfer, we have (the coordinates are those shown in Fig. 9.18) the following:

$$\frac{\partial u_\ell}{\partial y} + \frac{\partial v_\ell}{\partial x} = 0 \tag{9.93}$$

$$\frac{\rho_\ell}{\epsilon} \left(u_\ell \frac{\partial u_\ell}{\partial x} + v_\ell \frac{\partial u_\ell}{\partial y} \right) = \frac{\mu_\ell(x, y)}{\epsilon} \frac{\partial^2 u_\ell}{\partial y^2} - \frac{\mu_\ell(x, y)}{K} u_\ell + g(\rho_\ell - \rho_g) \tag{9.94}$$

$$u_\ell \frac{\partial T}{\partial x} + v_\ell \frac{\partial T}{\partial y} = \frac{\partial}{\partial y} \left[\frac{k_{\ell\perp}(y)}{(\rho c_p)_\ell} + \epsilon D_1^d(x, y) \right] \frac{\partial T}{\partial y} \tag{9.95}$$

The boundary conditions are

$$\begin{aligned} u_\ell = v_\ell = 0, \quad T = T_0 \quad \text{at } y = 0 \\ u_\ell = u_{\ell i}, \quad T = T_s \quad \text{at } y = \delta_\ell \end{aligned} \quad (9.96)$$

T_s is the saturation temperature.

Since the liquid velocity at δ_ℓ , $u_{\ell i}$ is not known, an extra boundary condition is needed. For single-phase flows using the Brinkman treatment, we have

$$(\mu'_\ell)_{\delta_\ell^-} \frac{\partial u_\ell}{\partial y} \Big|_{\delta_\ell^-} = (\mu'_\ell)_{\delta_\ell^+} \frac{\partial u_\ell}{\partial y} \Big|_{\delta_\ell^+} \quad \text{at } y = \delta_\ell \quad (9.97)$$

This allowed us to make the transition at $y = \delta_\ell$ due to the solid matrix structural change (e.g., discontinuity in permeability), where μ'_ℓ depends on the matrix structure. Presently, we do not have much knowledge about μ'_ℓ for two-phase flows (even though we have assumed that the vapor shear is not significant because at $y = \delta_\ell$ we have $s = 1$). The simplest, but not necessarily an accurate assumption, is that of $(\mu'_\ell)_{\delta_\ell^-} = (\mu'_\ell)_{\delta_\ell^+}$.

The maximum velocity possible in the liquid phase is found by neglecting the macroscopic inertial and viscous terms. The result is

$$u_{\ell m} = \frac{K}{\mu_\ell} g(\rho_\ell - \rho_g) \quad (9.98)$$

where, since this idealized flow is one-dimensional, as μ_ℓ decreases with increase in y , $u_{\ell m}$ increases with a maximum at $y = \delta_\ell$. However, in practice, u_ℓ does not reach $u_{\ell m}$ because of the lateral flow toward the two-phase region. Also, in most cases of practical interest, $\delta_\ell/d = O(1)$, and, therefore, the velocity no-slip condition at $y = 0$ causes a significant flow retardation throughout the liquid-film region. The velocity reaches its maximum value at $y = \delta_\ell$ if the shear stress $\mu_\ell \partial u_\ell / \partial y$ at δ_ℓ is zero; otherwise it peaks at $y < \delta_\ell$. This is also depicted in Fig. 9.18.

The convection heat transfer in the liquid-film region is generally negligible [113], therefore, Eq. 9.95 can be written as

$$D_\perp \frac{\partial T}{\partial y} \equiv \left[\frac{k_{\ell\perp}}{(\rho c_p)_\ell} + \varepsilon D_\perp^d \right] \frac{\partial T}{\partial y} = \text{constant} \quad (9.99)$$

For $k_\ell < k_s$, D_\perp is generally smallest near the bounding surface (A_f/A , is largest) resulting in an expected significant deviation from the linear temperature distribution found in the film condensation in plain media.

Two-Phase Region. The two-phase flow and heat transfer are given by the continuity equations for the ℓ and g phases, the momentum equations (Eqs. 9.76 and 9.77), and the energy equation (Eq. 9.80). The two-phase region is assumed to be isothermal by neglecting the effect of the curvature (i.e., saturation) on the thermodynamic equilibrium state. This is justifiable, except for the very small pores (large p_c). For the steady-state flow considered here, we have (for the assumed isotropic phase permeabilities)

$$\frac{\partial u_\ell}{\partial x} + \frac{\partial v_\ell}{\partial y} = 0 \quad (9.100)$$

$$\frac{\partial u_g}{\partial x} + \frac{\partial u_g}{\partial y} = 0 \quad (9.101)$$

$$\frac{\rho \ell}{\varepsilon s} \left(u_\ell \frac{\partial u_\ell}{\partial x} + v_\ell \frac{\partial u_\ell}{\partial y} \right) = - \frac{\partial p_\ell}{\partial x} + \rho_\ell g - \frac{\mu_\ell}{KK_{r\ell}} u_\ell \quad (9.102)$$

$$\frac{\rho_\ell}{\varepsilon s} \left(u_\ell \frac{\partial v_\ell}{\partial x} + v_\ell \frac{\partial v_\ell}{\partial y} \right) = -\frac{\partial p_\ell}{\partial y} - \frac{\mu_\ell}{KK_{r_\ell}} v_\ell \quad (9.103)$$

$$\frac{\rho_g}{\varepsilon(1-s)} \left(u_g \frac{\partial u_g}{\partial x} + v_g \frac{\partial u_g}{\partial y} \right) = -\frac{\partial p_g}{\partial x} + \rho_g g - \frac{\mu_g}{KK_{r_g}} u_g \quad (9.104)$$

$$\frac{\rho_g}{\varepsilon(1-s)} \left(u_g \frac{\partial v_g}{\partial x} + v_g \frac{\partial v_g}{\partial y} \right) = -\frac{\partial p_g}{\partial y} - \frac{\mu_g}{KK_{r_g}} v_g \quad (9.105)$$

along with

$$p_g - p_\ell = p_c(s, \text{etc.}) \quad (9.106)$$

When the Leverett idealization (Table 9.9) is used, Eq. 9.106 reduces to $p_c = p_c(s)$. The convective terms in Eqs. 9.102 to 9.105 can be significant when the effect of thickening of δ_ℓ and $\delta_{\ell g}$ and the effect of g and p_c tend to redistribute the phases along the x axis (flow development effects). If the capillarity is more significant than the gravity, that is, $\sigma/[g(\rho_\ell - \rho_g)K/\varepsilon]$ is larger than unity, then we expect larger $\delta_{\ell g}$, and vice versa. The overall energy balance yields

$$\int_0^x \left(k_{\ell\perp} \frac{\partial T}{\partial y} \right)_{y=0} dx = \int_0^{\delta_\ell} \rho_\ell i_{\ell g} u_\ell dy + \int_{\delta_\ell}^{\delta_{\ell g}} \rho_g i_{\ell g} u_\ell dy + \int_0^{\delta_{\ell g}} (\rho c_p)_\ell u_\ell (T_s - T) dy \quad (9.107)$$

where T_s is the saturation temperature. The last term on the right-hand side makes a negligible contribution to the overall heat transfer.

Large Bond Number Asymptote. Although for the cases where d is small enough to result in $\delta_\ell/d \gg 1$ the capillarity will also become important, we begin by considering the simple case of negligible capillarity. As is shown later, the capillary pressure causes lateral flow of the liquid, thus tending to decrease δ_ℓ . However, the presence of the lateral flow also tends to decrease the longitudinal velocity in the liquid-film region, and this tends to increase δ_ℓ . The sum of these two effects makes for a δ_ℓ , which may deviate significantly from the large Bond number asymptotic behavior. Therefore, the limitation of the large Bond number asymptote, especially its overprediction of u_ℓ , should be kept in mind.

Assuming that $\text{Bo} \rightarrow \infty$, we replace the boundary condition on u_ℓ at location δ_ℓ with a zero shear stress condition (i.e., $\delta_{\ell g} = 0$ and only two regions are present). In addition, we have the initial conditions

$$u_\ell = v_\ell = 0, \quad T = T_s, \quad \text{at } x = 0 \quad (9.108)$$

Next, we examine variations in $\mu_\ell(T)$, $\varepsilon(y)$, and $D_\perp(\text{Pe}_\ell, y)$, where $\text{Pe}_\ell = \bar{u}_\ell d/\alpha_\ell$. The variation in μ_ℓ can be nearly accounted for by using $\mu_\ell[(T_s + T_0)/2]$ in Eq. 9.94. For the packed beds of spheres, the variation of ε is significant only for $0 < y < 2d$. White and Tien [114] have included the effect of the variable porosity by using the variation in A_f/A_s . Here, we assume that $\delta_\ell/d \gg 1$, and, therefore, we do not expect the channeling to be significant. For the case of $\delta_\ell/d \approx O(1)$, this porosity variation must be considered. We note that Pe_ℓ can be larger than unity and that the average liquid velocity \bar{u}_ℓ increases with x , and, in general, the variation of D_\perp with respect to y should be included.

A similarity solution is available for Eqs. 9.93 to 9.95 subject to negligible macroscopic inertial and viscous forces, that is, small permeabilities and constant D_\perp [115, 116]. The inertial and viscous forces are included by Kaviany [117] through the regular perturbation of the similarity solution for plain media, that is, the Nusselt solution [113]. The perturbation parameter used is

$$\xi_x = 2 \left[\frac{\varepsilon g (\rho_\ell - \rho_g)}{\rho_\ell v_\ell^2} \right]^{-1/2} \frac{\varepsilon x^{1/2}}{K} \quad (9.109)$$

and for large ξ_x , the Darcian flow exists. The other dimensionless parameters are the sub-cooling parameter $c_{p\ell}(T_s - T_0)/i_{\ell g}$ and Prandtl number $\text{Pr}_\ell = \alpha_\ell/v_\ell$. The results show that, as is

the case with the plain media, the film thickness is small. For example, for water with $\text{Pr}_\ell = 10$ and $c_{p\ell}(T_s - T_0)/i_{\ell g} = 0.004$ to 0.2 (corresponding to 2 to 100°C subcooling), the film thickness δ_ℓ is between 1 and 8 mm for $K = 10^{-10}$ m² and between 0.1 and 0.8 mm for $K = 10^{-8}$ m². By using the Carman-Kozeny relation and $\varepsilon = 0.4$, we find that the latter permeability results in $\delta_\ell/d = 0.03 - 0.25$, which violates the local volume-averaging requirement.

The results of Parmentier [115] and Cheng [116] are (for $\delta_\ell/d \gg 1$) as follows:

$$\frac{2^{1/2}\text{Nu}_x}{\text{Gr}_x^{1/4}} = \frac{2}{\pi^{1/2}} \left[\frac{\text{Pr}_\ell}{\xi_x \text{erf}(\Delta \text{Pr}_\ell^{1/2}/\xi_x^{1/2})} \right]^{1/2} \quad \text{for } \text{Bo} > 1 \quad (9.110)$$

$$\frac{i_{\ell g}}{2c_{p\ell}(T_s - T_0)} + \frac{1}{\pi} = \frac{1}{\pi[\text{erf}(\Delta \text{Pr}_\ell^{1/2}/\xi_x^{1/2})]^2} \quad \text{for } \text{Bo} > 1 \quad (9.111)$$

where for a given $i_{\ell g}/[c_{p\ell}(T_s - T_0)]$, Pr_ℓ , and ξ_x , Δ , and Nu_x are found, and where

$$\text{Nu} = \frac{qx}{(T_s - T_0)k_{e\perp}}, \quad \Delta = \frac{\delta_\ell}{x} \left(\frac{\text{Gr}_x}{4} \right)^{1/4}, \quad \text{Gr}_x = \frac{\varepsilon g(\rho_\ell - \rho_g)x^3}{\rho_\ell \nu_\ell^2} \quad (9.112)$$

Note that for small K , the Bond number $[g(\rho_\ell - \rho_g)K/\varepsilon]/\sigma$ is also small; therefore, the capillarity (i.e., the two-phase region) must be included. This is attended to next.

Small Bond Number Approximation. Presently no rigorous solution to the combined liquid-film and two-phase regions is available. However, some approximate solutions are available [118, 119, 120]. The available experimental results [120, 121] are not conclusive as they are either for $\delta_\ell/d \approx O(1)$ or when they contain a significant scatter.

By considering capillary-affected flows, we expect that $v_g \gg u_g$, since $\partial s/\partial y \gg \partial s/\partial x$. Also, because the inertial force is negligible for the vapor flow, we reduce Eqs. 9.104 and 9.105 to

$$0 = -\frac{\partial p_g}{\partial y} - \frac{\mu_g}{KK_{rg}} v_g \quad \text{or} \quad v_g = -\frac{1}{\mu_g} KK_{rg} \frac{\partial p_g}{\partial y} = -\frac{\dot{m}_g \ell}{\rho_g} \quad (9.113)$$

Note that from Eq. 9.101, we find that v_g is constant along y . For the liquid phase, both u_ℓ and v_ℓ are significant, and v_ℓ changes from a relatively large value at δ_ℓ to zero at $\delta_\ell + \delta_{\ell g}$; therefore, $v_\ell \partial v_\ell/\partial y$ will not be negligibly small. Also, $v_g \partial u_\ell/\partial y$ may not be negligible. Then we have

$$\frac{\rho_\ell}{\varepsilon s} v_\ell \frac{\partial u_\ell}{\partial y} = -\frac{\partial p_\ell}{\partial x} + \rho_\ell g + \frac{\mu_\ell}{KK_{r\ell}} u_\ell \quad (9.114)$$

$$\frac{\rho_\ell}{\varepsilon s} v_\ell \frac{\partial v_\ell}{\partial y} = -\frac{\partial p_\ell}{\partial y} - \frac{\mu_\ell}{KK_{r\ell}} v_\ell \quad (9.115)$$

Here, we assume that the gaseous phase hydrostatic pressure is negligible. We note that the approximations made in the evaluations of $K_{r\ell}$ and p_c cause more errors in the determination of u_ℓ and v_ℓ than the exclusion of the inertial terms. Furthermore, we expect $\partial p_\ell/\partial x$ to be small. Then, we can write Eqs. 9.114 and 9.115 as

$$0 = \rho_\ell g - \frac{\mu_\ell}{KK_{r\ell}} u_\ell \quad \text{or} \quad u_\ell = \frac{g}{\nu_\ell} KK_{r\ell} \quad (9.116)$$

$$0 = -\frac{\partial p_\ell}{\partial y} - \frac{\mu_\ell}{KK_{r\ell}} v_\ell \quad \text{or} \quad v_\ell = \frac{1}{\mu_\ell} KK_{r\ell} \frac{\partial p_\ell}{\partial y} \quad (9.117)$$

The velocity distribution given by Eq. 9.116 is that of a monotonic decrease from the value of $u_{\ell i}$ at δ_ℓ to zero at $\delta_\ell + \delta_{\ell g}$. The specific distribution depends on the prescribed $K_{r\ell}(s)$, etc.). The distribution of v_ℓ given by Eq. 9.117 is more complex, because $-\partial p_\ell/\partial y$ increases as s decreases (as $y \rightarrow \delta_\ell + \delta_{\ell g}$). Although $\partial p_g/\partial y$ is needed to derive the vapor to δ_ℓ , we note that

$$\frac{\partial p_\ell}{\partial y} = -\frac{\partial p_c}{\partial y} + \frac{\partial p_g}{\partial y} \approx \frac{\partial p_c}{\partial y} \tag{9.118}$$

From the experimental results on $p_c(s)$, we can conclude that in the two-phase region v_ℓ also decreases monotonically with y . By using Eq. 9.118, we write Eq. 9.117 as

$$v_\ell = \frac{1}{\mu_\ell} K K_{r\ell} \frac{\partial p_c}{\partial y} \tag{9.119}$$

The momentum equations (Eqs. 9.116 and 9.119) can be inserted in Eq. 9.100, and when p_c and $K_{r\ell}$ are given in terms of s , the following saturation equation is obtained:

$$\frac{\partial u_\ell}{\partial x} + \frac{\partial v_\ell}{\partial y} = \frac{gK}{v_\ell} \frac{\partial K_{r\ell}}{\partial x} + \frac{K}{\mu_\ell} \frac{\partial}{\partial y} \left(K_{r\ell} \frac{\partial p_c}{\partial y} \right) \tag{9.120}$$

with $s = 1$ at $y = \delta_\ell$
 $s = 0$ at $y = \delta_\ell + \delta_{\ell g}$
 $s = 0$ at $x = 0$ (9.121)

The evaluation of $u_{\ell i}$, δ_ℓ , and $\delta_{\ell g}$ requires the analysis of the liquid-film region. For a negligible inertial force and with the use of the viscosity evaluated at the average film temperature $\bar{\mu}$ and the definition of $u_{\ell m}$, that is, Eq. 9.98, we can integrate Eqs. 9.94 and 9.96 to arrive at [120]

$$u_\ell = \frac{u_{\ell i} - u_{\ell m} + u_{\ell m} \cosh [\delta_\ell / (K/\varepsilon)^{1/2}]}{\sinh [\delta_\ell / (K/\varepsilon)^{1/2}]} \sinh \frac{y}{(K/\varepsilon)^{1/2}} + u_{\ell m} \left[1 - \cosh \frac{y}{(K/\varepsilon)^{1/2}} \right] \tag{9.122}$$

Now, using $(\mu'_\ell)_{\delta_\ell^-} = (\mu'_\ell)_{\delta_\ell^+}$ in Eq. 9.97 and the overall mass balance given by

$$\int_0^x \dot{m}_{g\ell} dx = \int_0^{\delta_\ell(x)} \rho_\ell u_\ell dy + \int_{\delta_\ell(x)}^{\delta_{\ell g}(x)} \rho_\ell u_\ell dy \tag{9.123}$$

Chung et al. [120] solve for the previously mentioned three unknowns. Their experimental and predicted results for $d = 0.35$ mm are shown in Fig. 9.19, where $Ra_x = Gr_x Pr_\ell$. We note that in their experiment (a closed system) the condensate collects, that is, the liquid film thickens, at the bottom of the cooled plate. When the plate length is very large, this nonideal lower por-

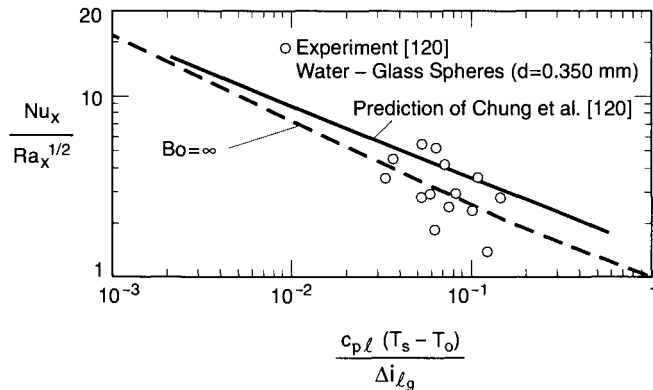

FIGURE 9.19 Prediction and experimental results of Chung et al. [120] for condensation (in a packed bed of spheres) at a bounding vertical impermeable surface. The large Bo results of Cheng [116] are also shown.

tion behavior may be neglected. However, in their experiment with the relatively short plate, this can significantly influence the phase distributions and velocities. The Bond number is 4×10^{-5} . For this size particle and for $c_{pe}(T_s - T_0)/i_{\ell g} = 0.1$, they find $u_{\ell i}/u_{\ell m} \approx 0.06$, that is, the velocity at δ_ℓ is much less than the maximum Darcean velocity given by Eq. 9.98. Note that although the velocity in the liquid phase is so small, the thickness of the liquid-film region is not substantially different than that found for the single-layer ($Bo > 1$) model of Cheng [116] (as evident from the heat transfer rate). The analysis of Chung et al. [120] shows that $\delta_\ell/d \approx 3.3$. They also use $(A_f/A_t)(y)$ in their computation. Note that for this analysis to be meaningful, δ_ℓ/d has to be larger than, say, 10, so that the variation of u_ℓ in $0 \leq y \leq \delta_\ell$ can be predicted with sufficient accuracy. Therefore, the applicability of the analysis to their experimental condition is questionable.

Evaporation at Vertical Impermeable Bounding Surfaces

For plain media, the film evaporation adjacent to a heated vertical surface is similar to the film condensation. In porous media, we also expect some similarity between these two processes. For the reasons given in the last section, we do not discuss the cases where $\delta_g/d \approx 1$, where δ_g is the vapor-film region thickness. When $\delta_g/d \gg 1$ and because the liquid flows (due to capillarity) toward the surface located at $y = \delta_g$, we also expect a large two-phase region, that is, $\delta_{g\ell}/d \gg 1$. Then a local volume-averaged treatment can be applied.

The asymptotic solution for $Bo > 1$, where $\delta_{g\ell} = 0$ (as was $\delta_{\ell g}$) and the similarity solution given there holds. Parmentier [115] has discussed this asymptotic solution. When given in terms of Ra_x , this solution is (given the superheating parameter and Ra_x , then Nu_x and Δ_g are solved simultaneously)

$$\frac{Nu_x}{Ra_x^{1/2}} = \frac{1}{\pi^{1/2} \operatorname{erf}(\Delta_g/2)} \quad \text{for } Bo \rightarrow \infty \quad (9.124)$$

$$\frac{c_{pg}(T_0 - T_s)}{\Delta i_{\ell g}} = \frac{\pi^{1/2} \Delta_g}{2} \exp(\Delta^2/2) \operatorname{erf}(\Delta_g/2) \quad \text{for } Bo \rightarrow \infty \quad (9.125)$$

$$\text{with} \quad Ra_x = \frac{(\rho_\ell - \rho_g)gKx}{\rho_g \nu_g \alpha_\ell}, \quad \Delta_g = \frac{\delta_g}{x} Ra_x^{1/2} \quad (9.126)$$

Note that Eqs. 9.110 and 9.111 are given in terms of the perturbation parameter ξ_x , but otherwise are identical to Eqs. 9.124 and 9.125. As we discussed, for small Bond numbers, which is the case whenever $\delta_g/d \gg 1$, a nearly isothermal two-phase region exists. The vapor will be rising due to buoyancy, similar to the falling of the liquid given by Eq. 9.116, except here we include the hydrostatic pressure of the liquid phase. This gives (defining x to be along $-g$)

$$0 = (\rho_\ell - \rho_g)g - \frac{\mu_g}{KK_{rg}} u_g \quad \text{or} \quad u_g = \frac{(\rho_\ell - \rho_g)g}{\mu_g} KK_{rg} \quad (9.127)$$

The lateral motion of the vapor is due to the capillarity, and in a manner similar to Eq. 9.117, we can write

$$0 = -\frac{\partial p_g}{\partial y} - \frac{\mu_g}{KK_{rg}} v_g \quad \text{or} \quad v_g = -\frac{1}{\mu_g} KK_{rg} \frac{\partial p_g}{\partial y} \quad (9.128)$$

The axial motion of the liquid phase is negligible and the lateral flow is similar to that given by Eq. 9.113 and is described as

$$0 = -\frac{\partial p_\ell}{\partial y} - \frac{\mu_\ell}{KK_{r\ell}} v_\ell \quad \text{or} \quad v_\ell = \frac{\dot{m}_{\ell g}}{\rho_\ell} = -\frac{1}{\mu_\ell} KK_{r\ell} \frac{\partial p_\ell}{\partial y} \approx \frac{1}{\mu_\ell} KK_{r\ell} \frac{\partial p_c}{\partial y} \quad (9.129)$$

The saturation will increase monotonically with y with $s = 0$ at $y = \delta_g$, and $s = 1$ at $y = \delta_{ge}$. In principle, we then expect the results of Chung et al. [120] for the condensation to apply to the evaporation. However, since the available experimental results for p_c (drainage versus imbibition) show a hysteresis, and also due to the lack of symmetry in $K_{rc}(s)/K_{rg}$, we do not expect a complete analogy.

Evaporation at Horizontal Impermeable Bounding Surfaces

We now consider heat addition to a horizontal surface bounding a liquid-filled porous media from below. When the temperature of the bounding surface is at or above the saturation temperature of the liquid occupying the porous media, evaporation occurs. We limit our discussion to matrices that remain unchanged. When nonconsolidated particles make up a bed, the evaporation can cause void channels through which the vapor escapes [122, 123, 124]. Here, we begin by mentioning a phenomenon observed in some experiments [125] where no significant superheat is required for the evaporation to start, that is, evaporation is through surface evaporation of thin liquid films covering the solid surface (in the evaporation zone). By choosing the surface heating (or external heating), we do not address the volumetrically heated beds (e.g., Ref. 126). For small Bond numbers, for small heat flux, that is, when $(T_0 - T_s) \approx 0$, the vapor generated at the bottom surface moves upward, the liquid flows downward to replenish the surface, and the surface remains wetted. When a critical heat flux q_{cr} is exceeded, a vapor film will be formed adjacent to the heated surface, and a two-phase region will be present above this vapor-film region. The two-phase region will have an evaporation zone where the temperature is not uniform and a nearly isothermal region where no evaporation occurs. As Bo increases, the role of capillarity diminishes. For $Bo > 1$, the behavior is nearly the same as when no rigid matrix is present, that is, the conventional pool boiling curve will be nearly observed.

In the following, we examine the experimental results [127], that support these two asymptotic behaviors, that is, $Bo > 1$, the high-permeability asymptote, and $Bo \ll 1$, the low-permeability asymptote. Then, we discuss the low-permeability asymptote using a one-dimensional model [109, 125, 128]. The one-dimensional model is also capable of predicting q_{cr} , that is, the onset of dryout. We note that the hysteresis observed in isothermal two-phase flow in porous media is also found in evaporation-condensation and that the q versus $T_0 - T_s$ curve shows a decreasing q (or $T_0 - T_s$) and an increasing q (or $T_0 - T_s$) branch.

Effect of Bond Number. In the experiments of Fukusako et al. [127], packed beds of spheres (glass, steel, and aluminum) occupied by fluorocarbon refrigerants were heated from below to temperatures above saturation. Their results for the glass (Freon-11) system with a bed height of 80 mm and for four different particle sizes (Bond numbers) are given in Fig. 9.20. Also shown are their results for pool boiling (no particles). They have not reported the heat flux corresponding to $(T_0 - T_s) < 8^\circ\text{C}$ for this solid-fluid system, because all of their results are for $q \geq 10^4 \text{ W/m}^2$. For $Bo \rightarrow \infty$, that is, with no solid matrix present, the conventional pool boiling curve is obtained, that is, as $(T_0 - T_s)$ increases, after the required superheat for nucleation is exceeded, the nucleate (with a maximum), the transient (with a minimum), and the film boiling regimes are observed. For large particles, this behavior is not significantly altered. However, as the particle size reduces, this maximum and minimum become less pronounced, and for very small particles, they disappear. For the solid-fluid system used in their experiment, this transition appears to occur at $Bo \leq 0.0028$. Note that we have only been concerned with the heating from planar horizontal surfaces. For example, the experimental results of Fand et al. [130] for heating of a 2-mm-diameter tube in a packed bed of glass spheres-water ($d = 3 \text{ mm}$, $Bo = 0.003$) shows that unlike the results of Fukusako et al. [127], no monotonic increase in q is found for $(T_0 - T_s) > 100^\circ\text{C}$. Tsung et al. [131] use a heated sphere in a bed of spheres ($d \geq 2.9 \text{ mm}$). Their results also show that as d decreases, the left-hand portion of the

FIGURE 9.20 Experimental results of Fukusako et al. [127] for the bounding surface heating of the liquid-filled beds of spheres to temperatures above saturation. The case of pool boiling ($Bo \rightarrow \infty$) is also shown along with the dryout heat flux predicted by Udell [90] and given in the measurement of Jones et al. [129].

q versus ΔT curve moves upward, that is, the required superheat for a given q is smaller in porous media (compared to plain media).

The results given in Fig. 9.20 show that for very small values of Bo ($Bo \leq 0.01$), the surface temperature also increases monotonically with the heat flux. This supports the theory of a heat removal mechanism that does not change, unlike that observed in the pool boiling in plain media. For the system shown in Fig. 9.20 and for $d = 1.1$ mm, the transition from the surface-wetted condition to the formation of a vapor film occurs at the critical heat flux

$$q_{cr} = \frac{K\Delta i_{\ell g}(\rho_{\ell} - \rho_g)g}{v_g} \left[1 + \left(\frac{v_g}{v_{\ell}} \right)^{1/4} \right]^{-4} = 4.4 \times 10^4 \text{ W/m}^2 \quad (9.130)$$

Jones et al. [129] measure q_{cr} using various fluids. They obtain a range of q_{cr} with the lowest value very close to that predicted by Eq. 9.130. These values of q_{cr} are also shown in Fig. 9.20. Based on the theory of evaporation in porous media given earlier, no vapor film is present until q exceeds q_{cr} (for small Bo). Then, for $q > q_{cr}$, the surface temperature begins to rise, that is, $T_0 - T_s > 0$. Now, by further examination of Fig. 9.20, we note that this low Bond number asymptote—that is, the liquid wetting of the surface for $(T_0 - T_s) = 0$ followed by the simultaneous presence of the vapor film and the two-phase regions in series for $(T_0 - T_s) > 0$ —is not distinctly found from the experimental results of Fukusako et al. [127]. Although as $Bo \rightarrow 0$, the trend in their results supports this theory; the Bo encountered in their experiment can yet be too large for the realization of this asymptotic behavior.

In Fig. 9.21, q versus ΔT curves are drawn based on the $Bo \rightarrow \infty$ and the $Bo \rightarrow 0$ asymptotes and the intermediate Bo results of Fukusako et al. [127]. The experimental results of

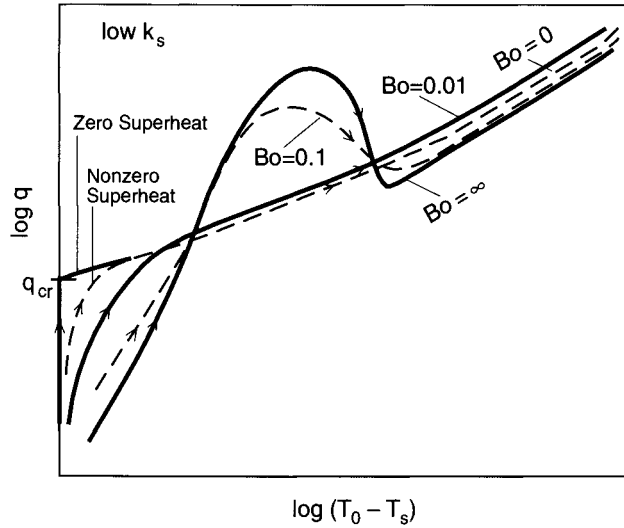

FIGURE 9.21 Effect of the Bond number on the q versus $T_0 - T_s$ curve is depicted based on the $Bo \rightarrow 0$ and ∞ asymptotes and the experimental results of Fukusako et al. [127]. The solid phase thermal conductivity is low.

Udell [90] for $Bo \rightarrow 0$ do not allow for the verification of the $Bo \rightarrow 0$ curve in this figure, that is, the verification of q versus ΔT for $Bo \rightarrow 0$ is not yet available. Also, the effect of the particle size (Bond number) on the heat flux for $(T_0 - T_s) > 100^\circ\text{C}$ is not rigorously tested, and the trends shown are based on the limited results of Fukusako et al. [127] for this temperature range. In examining the q versus ΔT behavior for porous media, we note the following.

- The thermal conductivity of the solid matrix greatly influences the q versus ΔT curve, and the results of Fukusako et al. [127] are for a nonmetallic solid matrix. Later, we examine some of the results for metallic matrices and show that as k_s increases, q increases (for a given $T_0 - T_s$).
- In the experiments discussed earlier, no mention of any hysteresis has been made in the q versus $(T_0 - T_s)$ curve. However, as is shown later, at least for thin porous layer coatings, hysteresis has been found, and in the q decreasing branch, the corresponding $(T_0 - T_s)$ for a given q is much larger than that for an increasing q branch.
- In the behavior depicted in Fig. 9.21, it is assumed that only the particle size is changing, that is, particle shape, porosity, fluid properties, heated surface, and so forth, all remain the same.
- The theoretical zero superheat at the onset of evaporation is not realized, and experiments do show a finite $\partial q / \partial T_0$ as $(T_0 - T_s) \rightarrow 0$.

The analysis for large particle sizes is expected to be difficult. For example, when $(T_0 - T_s) > 0$ and a thin vapor film is found on the heated surface, the thickness of this film will be less than the particle size; therefore, $(T_0 - T_s)$ occurs over a distance less than d . Since $k_s \neq k_f$, this violates the assumption of the local thermal equilibrium. Also, as the particle size increases, boiling occurs with a large range of bubble sizes, that is, the bubbles may be smaller and larger (elongated) than the particle size.

In the following section, we examine the $Bo \rightarrow 0$ asymptotic behavior by using the volume-averaged governing equations. This one-dimensional analysis allows for an estimation of q_{cr} and the length of the isothermal two-phase region for $q > q_{cr}$.

A One-Dimensional Analysis for $Bo \ll 1$. Figure 9.22 depicts the one-dimensional model for evaporation in porous media with heat addition q from the impermeable lower bounding surface maintained at $T_0 > T_s$, where T_s is the saturation temperature. The vapor-film region has a thickness δ_g , and the two-phase region has a length $\delta_{g\ell}$.

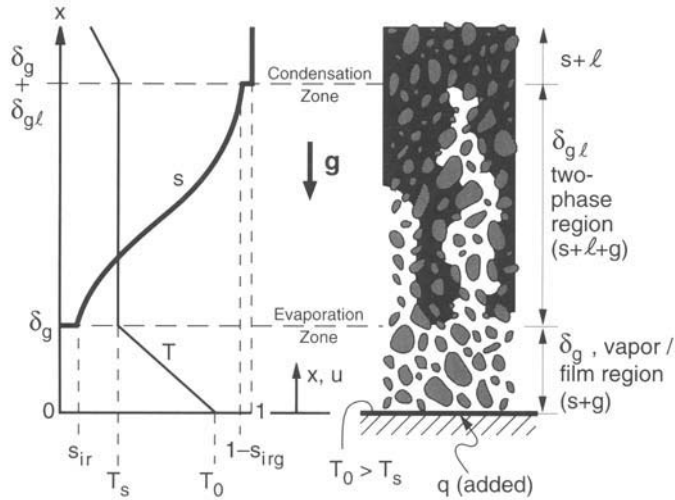

FIGURE 9.22 Evaporation due to the heat addition from below at temperatures above the saturation. The vapor-film region, the two-phase region, and the liquid region, as well as the evaporation and condensation zones are shown. Also shown are the distributions of temperature and saturation within these regions.

For $\delta_g \leq x \leq \delta_g + \delta_{g\ell}$, the saturation is expected to increase monotonically with x . The vapor generated at the evaporation zone (the thickness of this zone is in practice finite but here taken as zero) at $x = \delta_g$, moves upward (buoyancy-driven), condenses (condensation occurs in the condensation zone which is taken to have zero thickness) at $x = \delta_g + \delta_{g\ell}$, and returns as liquid (buoyancy- and capillary-driven). By allowing for irreducible saturations s_{ir} and s_{irg} , that is, assuring continuous phase distributions for the two-phase flow, we have to assume an evaporation zone just below $x = \delta_g$ in which s undergoes a step change and evaporation occurs. A similar zone is assumed to exist above $x = \delta_g + \delta_{g\ell}$ over which s undergoes another step change and condensation occurs (condensation zone). Next, we consider cases with $\delta_g > d$ and $\delta_{g\ell} \gg d$, where we can apply the volume-averaged governing equations based on bulk properties. For $s < 1$, the liquid will be in a superheated state depending on the local radius of curvature of the meniscus. Therefore, the two-phase region is only approximately isothermal. For steady-state conditions, the heat supplied q is removed from the upper single-phase (liquid) region. Since the heat supplied to the liquid region causes an unstable stratification, natural convection can occur that can influence the two-phase region [125, 132]. In the following one-dimensional analysis, this phenomenon is not considered.

Vapor-Film Region. The one-dimensional heat conduction for the stagnant vapor-film region is given by

$$q = -k_e(x) \frac{dT}{dx} \quad (9.131)$$

Since $k_g/k_s < 1$, we expect that for the packed beds near the bounding surface the magnitude of k_e will be smaller than the bulk value. Therefore, a nonlinear temperature distribution is

expected near this surface. However, if we assume k_c to be constant within δ_g , then we will have

$$q = k_t \frac{T_0 - T_s}{\delta_g} \quad (9.132)$$

where, for a given q , we have $T_0 - T_s$ and δ_g as the unknowns. Generally, $T_0 - T_s$ is also measured, which leads to the determination of δ_g . We note again that between the vapor film and the two-phase region an evaporation zone exists in which the saturation and temperature are expected to change continuously. If a jump in s was allowed across it, it would be inherently unstable and would invade the two adjacent regions intermittently. The condensation zone at $x = \delta_g + \delta_{g\ell}$ is expected to have a similar behavior. The present one-dimensional model does not address the examination of these zones.

Two-Phase Region. The analysis of the two-phase region is given by Sondergeld and Turcotte [125], Bau and Torrance [128], and more completely by Udell [90] and Jennings and Udell [133]. The vapor that is generated at $x = \delta_g$ and is given by

$$(\rho_g u_g)_{\delta_g} = \frac{q}{\Delta i_{tg}} \quad (9.133)$$

flows upward primarily due to buoyancy. By allowing for the variation in p_g , the momentum equation for the gas phase will be Eq. 9.77, except that the inertial, drag, and surface-tension gradient terms are negligible because of the small Bond number assumption. This gives

$$0 = -\frac{dp_g}{dx} + \rho_g g - \frac{\mu_g}{KK_{rg}} u_g \quad (9.134)$$

where we have used $u_g = \langle u_g \rangle$, $p_g = \langle p \rangle^g$, and $K_g = KK_{rg}$. Since the net flow at any cross section is zero, we have

$$\rho_g u_g + \rho_\ell u_\ell = 0 \quad (9.135)$$

as the continuity equation. The momentum equation for the liquid phase (Eq. 9.76) becomes

$$0 = -\frac{dp_\ell}{dx} + \rho_\ell g - \frac{\mu_\ell}{KK_{r\ell}} u_\ell \quad (9.136)$$

where the local pressure p_g and p_ℓ are related through the capillary pressure (Eq. 9.106).

By using Eqs. 9.134 through 9.136 and Eq. 9.106, we have

$$\frac{dp_c}{dx} = -\frac{q}{Ki_{tg}} \left(\frac{v_g}{K_{rg}} + \frac{v_\ell}{K_{r\ell}} \right) + (\rho_\ell - \rho_g)g \quad (9.137)$$

Next, by assuming that the Leverett J function is applicable and that $K_{r\ell}$ and K_{rg} can be given as functions of s only, Eq. 9.137 can be written in terms of the saturation only. Udell [90] uses the p_c correlation given in Table 9.9 and the relative permeabilities suggested by Wyllie [93] as given in Table 9.10. By using these, Eq. 9.137 becomes

$$\frac{\sigma}{(K/\epsilon)^{1/2}} \frac{dJ}{dx} = -\frac{q}{Ki_{tg}} \left[\frac{v_g}{(1-S)^3} + \frac{v_\ell}{S^3} \right] + (\rho_\ell - \rho_g)g = \frac{\sigma}{(K/\epsilon)^{1/2}} \frac{dJ}{ds} \frac{ds}{dx} \quad (9.138)$$

where, as before,

$$S = \frac{s - s_{ir}}{1 - s_{ir} - s_{irg}} \quad (9.139)$$

Next, we can translate the origin of x to δ_g , and then by integrating over the two-phase zone, we will have

$$\delta_{g\ell} = \int_0^1 \frac{[\sigma/(K/\varepsilon)^{1/2}](dJ/dS)}{-[q/Ki_{\ell g}]\{[v_g/(1-S)^3] + (v_\ell/S^3)\} + (\rho_g - \rho_\ell)g} dS \quad (9.140)$$

Whenever q , the liquid and vapor properties, and K are known, $\delta_{g\ell}$ can be determined from Eq. 9.140 and the saturation distribution can be found from Eqs. 9.138 and 9.139.

Note that when in Eq. 9.137 the viscous and gravity forces exactly balance, the capillary pressure gradient and, therefore, the saturation gradient become zero. For this condition, we have the magnitude $\delta_{g\ell}$ tending to infinity. This is evident in Eq. 9.140. The heat flux corresponding to this condition is called the *critical heat flux* q_{cr} . For $q > q_{cr}$, the thickness of the two-phase region decreases monotonically with q . Figure 9.23 shows the prediction of Udell [90] as given by Eq. 9.140, along with his experimental results for the normalized $\delta_{g\ell}$ as a function of the normalized q . For large q , an asymptotic behavior is observed. The critical heat flux q_{cr} (normalized) is also shown for the specific cases of $v_\ell/v_g = 0.0146$ and $Bo = 5.5 \times 10^{-7}$.

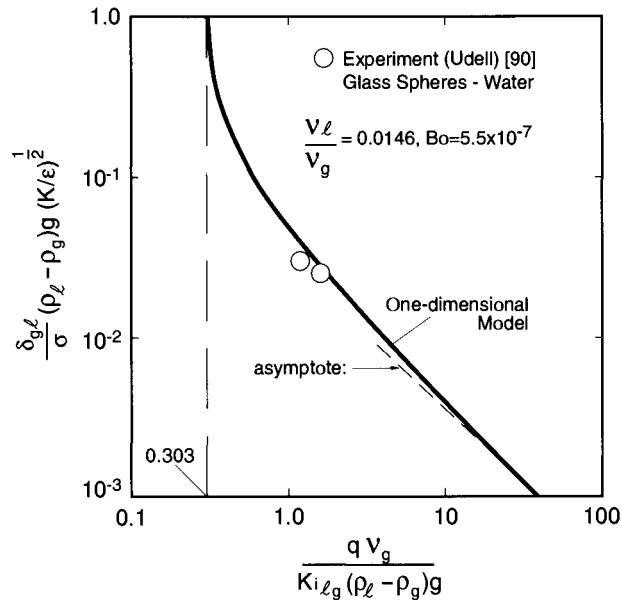

FIGURE 9.23 Variation of the normalized thickness of the two-phase region as a function of the normalized heat flux for evaporation from the heated horizontal surface.

Onset of Film Evaporation. The saturation at which the saturation gradient is zero (and $\delta_{g\ell} \rightarrow \infty$) is found by setting the denominator of Eq. 9.140 to zero, that is,

$$\frac{q_{cr}}{K \Delta i_{\ell g}} \left[\frac{v_g}{(1 - S_{cr})^3} + \frac{v_\ell}{S_{cr}^3} \right] = (\rho_\ell - \rho_g)g \quad (9.141)$$

For this critical reduced saturation S_{cr} , the critical heat flux is given by Eq. 9.130.

Bau and Torrance [128] use a different relative permeability-saturation relation and arrive at a slightly different relation. Jones et al. [129] use a similar treatment and find a relationship for q_{cr} that gives values lower than those predicted by Eq. 9.130 by a factor of approximately 2. It should be noted that these predictions of q_{cr} are estimations and that the effects of wettability, solid matrix structure (all of these studies consider spherical particles only), and surface tension (all of which influence the phase distributions) are included only through the

relative permeabilities. These permeabilities, in turn, are given as simple functions of the saturation only. Therefore, the use of realistic and accurate relative permeability relations is critical in the prediction of q_{cr} .

Evaporation at Thin Porous-Layer-Coated Surfaces

Evaporation within and over thin porous layers is of interest in wicked heat pipes and in surface modifications for the purpose of heat transfer enhancement. The case of very thin layers, that is, $\delta/d = 1$ where δ is the porous-layer thickness, has been addressed by Konev et al. [134], Styrikovich et al. [135], and Kovalev et al. [136]. Due to the lack of the local thermal equilibrium in the two-phase region inside the thin porous layer, we do not pursue the analysis for the case of $\delta/d = 1$.

When $\delta/d \gg 1$ but $\delta/(\delta_g + \delta_{ge}) < 1$, the two-phase region extends to the plain medium surrounding the porous layer. Presently, no detailed experimental results exist for horizontal surfaces coated with porous layers with $\delta \neq \delta_g + \delta_{ge}$. The experimental results of Afgan et al. [137] are for heated horizontal tubes (diameter D) and as is shown in their experiments $\delta < \delta_g + \delta_{ge}$. Their porous layers are made by the sintering of metallic particles. The particles are spherical (average diameter $d = 81 \mu\text{m}$) and are fused onto the tube in the process of sintering. From the various porous-layer coatings they use, we have selected the following three cases in order to demonstrate the general trends in their results.

- A layer of thickness $\delta/d \approx 27$ with $K = 1.4 \times 10^{-10} \text{ m}^2$, $\epsilon = 0.70$, $Bo = 2.6 \times 10^{-5}$, made of stainless steel particles ($k_s = 14 \text{ W/m-K}$), and coated over a 16-mm-diameter stainless steel tube ($D/\delta = 7.3$).
- A layer of thickness $\delta/d = 6.7$ with $K = 3 \times 10^{-11} \text{ m}^2$, $\epsilon = 0.50$, $Bo = 7.2 \times 10^{-6}$, made of titanium particles ($k_s = 21 \text{ W/m-K}$), and coated over an 18-mm-diameter stainless steel tube ($D/\delta = 33$).
- A layer of thickness $\delta/d \approx 5.5$ with $K = 2.0 \times 10^{-12} \text{ m}^2$, $\epsilon = 0.30$, $Bo = 8.9 \times 10^{-7}$, made of stainless steel particles, and coated over a 3-mm-diameter stainless steel tube ($D/\delta = 6.7$).

We have used the mean particle size d of $81 \mu\text{m}$ and the Carman-Kozeny equation for the calculation of the permeability. The fluid used is water. Their experimental results for these three cases are given in Fig. 9.24. In their experimental results, q is larger in the desaturation

FIGURE 9.24 Experimental results of Afgan et al. [137] for evaporation from tubes coated with porous layers and submerged in a pool of water.

branch, while in the experimental results of Bergles and Chyu [138], q is larger in the saturation branch. In order to examine whether the porous-layer thicknesses used in these experiments are larger than $\delta_g + \delta_{g\ell}$, we apply the prediction of Udell [90] for the thickness of the two-phase region. His results are shown in Fig. 9.23. The asymptote for heat fluxes much larger than the critical heat flux is given by

$$\frac{\delta_{g\ell}(\rho_g - \rho_\ell)g(K/\varepsilon)^{1/2}}{\sigma} \frac{qv_g}{K\Delta i_{\ell g}(\rho_\ell - \rho_g)g} = 0.0368 \quad q \gg q_{cr} \quad (9.142)$$

$$\text{or} \quad \delta_{g\ell} = 0.0368 \frac{\sigma\Delta i_{\ell g}(K\varepsilon)^{1/2}}{qv_g} \quad q \gg q_{cr} \quad (9.143)$$

For $\delta_{g\ell} = \delta$, we have

$$q(\delta_{g\ell} = \delta) = \frac{0.0368\sigma\Delta i_{\ell g}(K\varepsilon)^{1/2}}{\delta v_g} \quad (9.144)$$

For those cases presented in Fig. 9.24, we have calculated the required q for $\delta_{g\ell} = \delta$. The values are

$$\begin{aligned} q\left(\delta_{g\ell} = \delta, \frac{\delta}{d} = 27, \varepsilon = 0.7 \text{ sample}\right) &= 1.10 \times 10^6 \text{ W/m}^2 \\ q\left(\delta_{g\ell} = \delta, \frac{\delta}{d} = 6.7, \varepsilon = 0.5 \text{ sample}\right) &= 1.73 \times 10^6 \text{ W/m}^2 \\ q\left(\delta_{g\ell} = \delta, \frac{\delta}{d} = 5.5, \varepsilon = 0.3 \text{ sample}\right) &= 4.23 \times 10^5 \text{ W/m}^2 \end{aligned} \quad (9.145)$$

We note that these heat fluxes are lower bounds, because δ is actually occupied by the vapor-film region, evaporation zone, as well as the two-phase region. For the porous layer to contain both of the layers, we need heat fluxes much larger than those given by Eq. 9.145, that is,

$$\delta \geq \delta_g + \delta_{g\ell} \quad \text{or} \quad q > q(\delta = \delta_{g\ell}) \quad (9.146)$$

Upon examining the experimental results given in Fig. 9.24, we note that except for the $\delta/d = 5.5$ layer, we have $q < q(\delta = \delta_{g\ell})$, that is, the two-phase region extends beyond the porous layer and into the plain medium.

No rigorous analysis for the case of $\delta < \delta_g + \delta_{g\ell}$ is available. Assuming that the theory of isothermal two-phase is applicable, we postulate that the portion of the two-phase region that is inside the porous layer will be unstable. This instability will be in the form of intermittent drying of this portion, that is, the entire porous layer becoming intermittently invaded by the vapor phase only. When the porous media is dry, there will be a nucleate boiling at the interface of the porous plain medium. Figure 9.25 depicts such an intermittent drying. When the two-phase region extends into the porous layer, the two-phase region will be at the saturation temperature (assuming negligible liquid superheat due to the capillarity). The evaporation takes place in the evaporation zone, just below the two-phase zone. The saturation at $x = \delta$ will be smaller than $1 - s_{ir,g}$. This saturation is designated by s_m , which is similar to that for thick porous layers discussed in the previous sections. When the porous layer dries out, the evaporation will be at $x = \delta$. The frequency of this transition (i.e., intermittent drying of the porous layer) decreases as the porous-layer thickness increases and should become zero for $\delta > \delta_g + \delta_{g\ell}$. It should be mentioned that, in principle, the theory of evaporation-isothermal two-phase region cannot be extended to thin porous-layer coatings. The previously given arguments are only speculative. The theory of thin porous layers has not yet been constructed.

We now return to Fig. 9.24. For the $\delta/d = 27$ case, we estimate the bulk value of k_e for the vapor-film region ($k_s/k_g = 500$, $\varepsilon = 0.7$) by using Eq. 9.10, and we find k_e to be 0.132 W/m-K.

FIGURE 9.25 Evaporation from a horizontal impermeable surface coated with a porous layer with $\delta < \delta_g + \delta_{g\ell}$. The speculated intermittent drying of the layer and the associated temperature and saturation distributions are shown.

We note that the photomicrographs of Afgan et al. [137] show that the particle distribution near the bounding surface is significantly different than that in the bulk. Therefore, this k_c is only an estimate. From Eq. 9.132, we have

$$\delta_g = \frac{k_t(T_0 - T_s)}{q} \tag{9.147}$$

For $q = 4 \times 10^4 \text{ W/m}^2$ and $T_0 - T_s = 100^\circ\text{C}$, we have $\delta_g/d = 0.41$, that is, the vapor-film region is less than one particle thick. Then, for $\delta/d = 27$, only part of the two-phase region is in the porous layer.

For the $\delta/d = 5.5$ and 6.7 cases, the vapor-film region thickness is also small and nearly a particle in diameter thick. However, the remaining space occupied by the two-phase region is also very small. Therefore, both the vapor-film and two-phase regions do not lend themselves to the analyses based on the existence of the local thermal equilibrium and the local volume averaging. The two thin porous layers, $\delta/d = 5.5$ and 6.7 , result in different heat transfer rates (for a given $T_0 - T_s$), and this difference is also due to the structure of the solid matrix and the value of D/d . For the case of $\delta/d = 5.5$, the one-dimensional analysis predicts that the two-phase region is entirely placed in the porous layer (although the validity of this analysis for such small $\delta_{g\ell}/d$ is seriously questionable). This indicates that the liquid supply to the heated surface is enhanced when the capillary action can transport the liquid through the entire two-phase region. The optimum porous-layer thickness, which results in a small resistance to vapor and liquid flows, a large effective thermal conductivity for the vapor-film region, and possibly some two- and three-dimensional motions, has not yet been rigorously analyzed.

Melting and Solidification

In single-component systems (or pure substances), the chemical composition in all phases is the same. In multicomponent systems, the chemical composition of a given phase changes in response to pressure and temperature changes and these compositions are not the same in all phases. For single-component systems, first-order phase transitions occur with a discontinuity in the first derivative of the Gibbs free energy. In the transitions, T and p remain constant.

FIGURE 9.26 The thermodynamic equilibrium phase diagram for a binary solid-liquid system. The eutectic temperature and species *A* mass fraction and a dendritic temperature and liquidus and solidus species *A* mass fractions are also shown.

In Fig. 9.26, the thermodynamic equilibrium, solid-liquid phase diagram of a binary (species *A* and *B*) system is shown for a nonideal solid solution (i.e., miscible liquid but immiscible solid phase). The melting temperatures of pure substances are shown with $T_{m,A}$ and $T_{m,B}$. At the eutectic-point mole fraction, designated by the subscript *e*, both solid and liquid can coexist at equilibrium. In this diagram the liquidus and solidus lines are approximated as straight lines. A dendritic temperature T and the dendritic mass fractions of species $\langle \rho \rangle^s / \langle \rho \rangle^l$ and $\langle \rho \rangle^l / \langle \rho \rangle^s$ are also shown. The equilibrium partition ratio k_p is used to relate the solid- and liquid-phase mass fractions of species $\langle \rho \rangle^s / \langle \rho \rangle^l$ and $\langle \rho \rangle^l / \langle \rho \rangle^s$ on the liquidus and solidus lines at a given temperature and pressure, that is,

$$k_p = \left. \frac{\langle \rho_A \rangle^s / \langle \rho \rangle^s}{\langle \rho_A \rangle^l / \langle \rho \rangle^l} \right|_{T,p} \quad (9.148)$$

A finite, two-phase region (called the *mushy region*) can exist for $k_p < 1$ and corresponds to the case where species *A* has a limited solubility in the solid phase. For $k_p = 1$, a discrete phase change occurs with no mushy region. This mushy region is a solid-liquid mixture where it is generally assumed that the solid phase is continuous and therefore treated as a permeable solid, that is, a porous medium with the liquid being capable of motion through the porous media.

Figure 9.27 gives a classification of the solid-liquid phase change in porous media. For single-component systems at a given pressure, melting or solidification as a distinct phase change is assumed at a saturation temperature corresponding to the pressure, that is, $T_{m,A}$ for species *A*. Although at the interface between the solid and liquid this saturation condition holds, the local, bulk phases (i.e., away from the interface) may not be at this temperature, and, therefore, a subcooled liquid (during solidification) or a superheated solid (during melting) may be assumed. For multicomponent systems, in addition to the distinct liquid and solid phases, a mushy (two-phase) region also exists. We note that the solid phase may not only contain the phase-change substance but can contain an inert (not changing phase) solid substance, for example, during solidification of a multicomponent liquid (i.e., molten) when the pore space of a solid matrix is filled with a much higher melting temperature. During this process, the solid fraction increases due to the formation of both a solid phase and a mushy region from the liquid phase (e.g., Ref. 139).

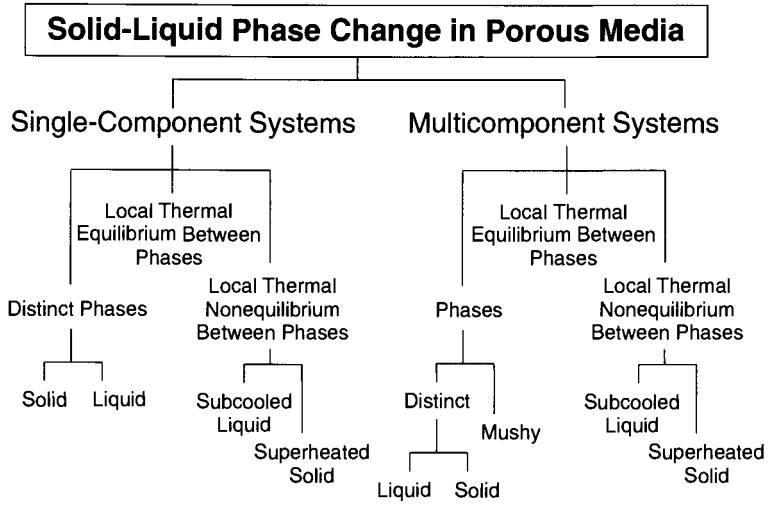

FIGURE 9.27 A classification of solid-liquid phase change in porous media.

A review of melting and solidification of single-component systems follows, as well as a discussion of the multicomponent systems. A more extensive treatment is given by Kaviany [7].

Single-Component Systems. As an example of solid-liquid phase change in porous media, we consider melting of the solid matrix by flow of a superheated liquid through it. The analysis, based on local thermal nonequilibrium between solid and liquid phases, has been performed by Plumb [140] and is reviewed here.

Because of the phase change, the solid-liquid interfacial location changes and this interfacial mass transfer $\langle \dot{n} \rangle$ must be included. The lack of local thermal equilibrium and introduction of local solid and liquid temperature $\langle T \rangle^s$ and $\langle T \rangle^\ell$ can be addressed similar to the two-medium thermal treatment (without phase change). Plumb suggests simplified, semi-heuristic phasic energy equations. These are based on the assumption that the solid is locally at the melting temperature T_m which makes the solid-phase energy equation trivial, and for a one-dimensional transport gives

$$\frac{\partial \varepsilon \langle T \rangle^\ell}{\partial t} - \frac{\langle \dot{n}_\ell \rangle T_m}{\rho_\ell} + \frac{\partial}{\partial x} \varepsilon \langle T \rangle^\ell \langle u_\ell \rangle = \frac{\partial}{\partial x} \left[\frac{\langle k \rangle}{(\rho c_p)_\ell} + \varepsilon D_{xx}^d \right] \frac{\partial \langle T \rangle^\ell}{\partial x} - \frac{h_{s\ell}}{(\rho c_p)_\ell} \frac{A_{\ell s}}{V} (\langle T \rangle^\ell - T_m) \quad (9.149)$$

$$\langle T \rangle^s = T_m \quad (9.150)$$

$$\langle \dot{n}_\ell \rangle \Delta i_{\ell s} = h_{sf} \frac{A_{\ell s}}{V} (\langle T \rangle^\ell - T_m) \quad (9.151)$$

When Eqs. 9.149 and 9.151 are combined, we have

$$\frac{\partial \langle T \rangle^\ell}{\partial t} + \langle u_\ell \rangle \frac{\partial \langle T \rangle^\ell}{\partial x} = \frac{\partial}{\partial x} \left[\frac{\langle k \rangle}{(\rho c_p)_\ell} + \varepsilon D_{xx}^d \right] \frac{\partial \langle T \rangle^\ell}{\partial x} - \left[\frac{h_{s\ell}}{(\rho c_p)_\ell \varepsilon} \frac{A_{\ell s}}{V} + \langle \dot{n}_\ell \rangle c_{p\ell} \varepsilon \right] (\langle T \rangle^\ell - T_m) \quad (9.152)$$

In Eq. 9.152, $\langle k \rangle$ is the effective conductivity D_{xx}^d is the axial dispersion coefficient, and $h_{s\ell}$ is the interfacial heat transfer coefficient.

Using the preceding conservation equations and for an adiabatic system (i.e., no heat losses), subject to a prescribed inlet liquid velocity and liquid superheat $\langle T \rangle_0^l - T_m$ flowing into a wettable solid matrix with porosity ε_0 , Plumb [140] determines the porosity distribution in the melting front. The approximate melt-front speed is determined from the overall energy balance and by neglecting the axial conduction and is

$$u_F = \frac{\rho_\ell c_{p,\ell} (\langle T \rangle_0^l - T_m) \langle u_\ell \rangle_0}{\rho_s \Delta i_{\ell s} \{ (1 - \varepsilon)_0 + (\rho_\ell / \rho_s) [c_{p,\ell} (\langle T \rangle_0^l - T_m) / \Delta i_{\ell s}] \}} \quad (9.153)$$

The numerical results show that the thickness of the melting front is proportional to the liquid velocity to a power of 0.4. At low velocities, the melt-front thickness can become nearly the same as the pore (or particle) size, and at very low velocities, diffusion dominates the axial heat transfer.

Multicomponent Systems. Melting and solidification in multicomponent systems is of interest in geological and engineering applications. In solidification, dendritic growth of crystals has been analyzed under the assumption of thermal and chemical equilibrium (as a columnar dendritic growth) and also under the assumption of nonequilibrium, that is, liquid subcooling (as a dispersed equiaxial dendritic growth). The process of solidification of multicomponent liquids is discussed by Kurz and Fisher [141] and a review with the geological applications is given by Huppert [142] and with engineering applications by Beckermann and Viskanta [143]. A more extensive review is given by Kaviani [7] and excerpts of this review are given here. The melting of multicomponent solids is reviewed by Woods [144]. Here, brief reviews of the equilibrium and nonequilibrium treatments are given.

Equilibrium Treatment of Solidification. As an example of liquid-solid phase change in solid-fluid flow systems with the assumption of local thermal equilibrium imposed, consider the formulation of solid-fluid phase change (solidification/melting or sublimation/frosting) of a binary mixture. For this problem, the equilibrium condition extends to the local thermodynamic equilibrium where the local phasic temperature (thermal equilibrium), pressure (mechanical equilibrium), and chemical potential (chemical equilibrium) are assumed to be equal between the solid and the fluid phases. This is stated as

$$\langle T \rangle^s = \langle T \rangle^f \quad (9.154)$$

$$\langle p \rangle^s = \langle p \rangle^f \quad (9.155)$$

$$\langle \mu_A \rangle^s = \langle \mu_A \rangle^f \quad (9.156)$$

The local volume averaging of the energy equations, with allowance for a phase change in a binary system, has been discussed by Bennon and Incropera [145], Rappaz and Voller [146], Poirier et al. [147], and Hills et al. [148]. In their single-medium treatment, that is, a local volume-averaged description with the assumption of local thermodynamic equilibrium, a distinct interface between the region of solid phase and the region of fluid phase has not been assumed; instead, the fluid-phase volume fraction (i.e., the porosity) is allowed to change continuously. This continuous-medium treatment is in contrast to the multiple-medium treatment which allows for separate solid, fluid, and mushy (i.e., solid-fluid) media (e.g., Refs. 149, 150, 151). Since the explicit tracking of the various distinct interfaces, as defined in the multiple-medium treatment, is not needed in the continuous single-medium treatment, it is easier to implement. Also, for binary systems, the equilibrium temperature depends on the local species concentrations, and due to the variation of the concentration within the medium, the phase transition occurs over a range of temperatures; therefore, the single-medium treatment is even more suitable. In the following, the single-medium treatment of Bennon and Incropera [145] is reviewed. Many simplifications made in the development of this treatment are discussed by Hills et al. [148]. Alternative derivations and assumptions are discussed by Rappaz and Voller [146] and Poirier et al. [147], among others.

Nonequilibrium Treatment of Solidification. In the following, as examples of nonequilibrium treatments of solidification in a binary system, a kinetic-diffusion controlled dendritic crystal growth and a buoyancy-influenced dendritic crystal growth are examined.

A dispersed-element model for kinetic-diffusion controlled growth. Assuming that a total number n_s of spherical crystals are nucleated per unit volume at a supercooling of $\Delta T_{sc} = T_m - T_e$, then these crystals can grow to final grain radius of R_c

$$R_c = \left(\frac{3}{4\pi n_s} \right)^{1/3} \quad (9.157)$$

The initially spherical crystal will have a dendritic growth and, between the nucleation at time $t = 0$ and the complete growth (end of the solidification) at $t = t_f$, the grain envelope radius R will grow from a radius R_0 (i.e., the initial radius of the nuclei) to R_c . The grain envelope is initially around the crystal, and during the dendritic growth, the envelope contains solid and liquid phases, and finally at the end of the solidification, it will again contain only solid. The content of the grain envelope is treated as a dispersed element and the liquid fraction (or porosity) ϵ_s of this dispersed element is initially zero and then increases rapidly followed by an eventual decrease, finally becoming zero again. This dispersed element and its surrounding liquid makes a unit-cell model and has been introduced and analyzed by Rappaz and Thévoz [152]. A schematic of this unit-cell model is shown in Fig. 9.28a. The growth of the dispersed element subject to the cooling rate of the unit cell given by the heat transfer rate $q_c 4\pi R_c^2$ with no liquid motion has been analyzed.

The elemental-liquid fraction ϵ_e and the cell porosity ϵ_c are defined as

$$\epsilon_e = 1 - \frac{V_s}{V_e} \quad \epsilon_c = 1 - \frac{V_e}{V_c} = 1 - \frac{R^3}{R_c^3} \quad (9.158)$$

The solid volume is

$$V_s = (1 - \epsilon_e)V_e = (1 - \epsilon_e)^{4/3}\pi R^3 \quad (9.159)$$

The quantities ϵ_e and ϵ_c are determined from the heat and mass transfer analyses. An apparent solid radius can be defined as

$$R_s^3 = \frac{V_s}{4/3\pi} = (1 - \epsilon_e)R^3 \quad \text{or} \quad R_s = (1 - \epsilon_e)^{1/3}R \quad (9.160)$$

For convenience, the volume fraction of the solid in the unit cell f_s and the volume fraction of the dispersed element in the unit cell f_c , which are related to ϵ_e and ϵ_c , are used in the analysis. These are

$$f_s = \frac{V_s}{V_c} = \frac{R_s^3}{R_c^3} = (1 - \epsilon_e)(1 - \epsilon_c) \quad f_c = \frac{V_e}{V_c} = \frac{R^3}{R_c^3} \quad (9.161)$$

Assuming an equilibrium phase diagram, such as that shown in Fig. 9.28b, the definition of the equilibrium partition ratio k_p was given by Eq. 9.148 and is repeated here.

$$k_p = [(\rho_A/\rho)]_{\ell_s}/[(\rho_A/\rho)]_{s\ell}]_{T,p} \quad (9.162)$$

where the solid-liquid interfacial concentrations are $(\rho_A/\rho)_{s\ell}$ and $(\rho_A/\rho)_{\ell_s}$ from the solidus and liquidus lines, respectively. The liquidus line mass fraction is related to the temperature using

$$T_{\ell_s} - T_{s\ell} = -\gamma \left(\frac{\rho_A}{\rho} \Big|_{\ell_s} - \frac{\rho_A}{\rho} \Big|_{s\ell} \right) \quad \text{or} \quad T_e - T_{m,B} = \gamma \frac{\rho_A}{\rho} \Big|_e \quad (9.163)$$

where

$$\gamma = \frac{dT_{\ell_s}}{d(\rho_A/\rho)_{\ell_s}} \Big|_p = \frac{T_e - T_{m,B}}{(\rho_A/\rho)_e} \quad (9.164)$$

FIGURE 9.28 (a) Unit-cell model of the equiaxed dendritic growth of a crystal. The liquid within the grain envelope and within the element are shown as well as the mass fraction distribution of the species A ; (b) the idealized phase diagram; (c) the mass fraction distribution of the species A for two different elapsed times. (From Rappaz and Thévoz, Ref. 152, reproduced by permission ©1987 Pergamon.)

The mass fraction difference can also be written as

$$(\rho_A/\rho)_{\ell s} - (\rho_A/\rho)_{s\ell} = (\rho_A/\rho)_{s\ell} \frac{1 - k_p}{k_p} \quad (9.165)$$

As the crystal grows, the concentration of species A in the solid increases slightly. This corresponds to a negligible mass diffusion in the solid ($D_s \rightarrow 0$). Other assumptions about the magnitude of D_s (i.e., $D_s \rightarrow \infty$ or a finite D_s) do not change the predicted growth rate [152]. The rejected species A (i.e., solute) will result in the increase of the concentration of species A in the liquid contained in the envelope and in the remainder of liquid in the unit cell. This is depicted in Fig. 28c where the concentration distributions in the solid ($0 \leq r \leq R_s$), in the interelemental liquid ($R_s \leq r \leq R$), and in the cell liquid ($R < r \leq R_c$) are shown for two elapsed times. In the model, the liquid concentration within the element is assumed to be uniform and its magnitude $(\rho_A/\rho)_{\ell s}$ is given by the phase diagram and as a function of T_e . Then, in this model, the dendritic tip concentration and the temperature are $(\rho_A/\rho)_{\ell s}$ and T_e , respectively, and their interrelation is given by Eq. 9.163.

The mass fraction distribution in the liquid region is determined for the species conservation equation which for constant ρ_ℓ and D_ℓ gives

$$\frac{\partial}{\partial t} \frac{\rho_{A,\ell}}{\rho_\ell} = D_\ell \left(\frac{\partial}{\partial r^2} + \frac{2}{r} \frac{\partial}{\partial r} \right) \frac{\rho_{A,\ell}}{\rho_\ell} \quad R_s \leq r \leq R_c \quad (9.166)$$

the initial and boundary conditions are

$$\frac{\rho_{A,\ell}}{\rho_\ell}(r, 0) = \frac{\rho_{A,\ell}}{\rho_\ell}(t=0) \quad R_s \leq r \leq R_c \quad (9.167)$$

$$\frac{\partial}{\partial r} \frac{\rho_{A,\ell}}{\rho_\ell} = 0 \quad r = R_c \quad (9.168)$$

The concentration at $r = R$ is found from the species balance made over $0 \leq r \leq R_c$. This is done by the integration of the distributions shown in Fig. 9.28c, that is,

$$\int_0^{R_s} k_p \frac{\rho_A}{\rho} \Big|_{\ell_s} 4\pi r dr + \frac{\rho_A}{\rho} \Big|_{\ell_s} \frac{4}{3}\pi(R^3 - R_s^3) + \int_R^{R_c} \frac{\rho_{A,\ell}}{\rho_\ell} 4\pi r dr = \frac{\rho_{A,\ell}}{\rho}(t=0) \frac{4}{3}\pi R_c^3 \quad (9.169)$$

By differentiating this with respect to time and using Eq. 9.166, we have

$$-4\pi D_\ell R^2 \frac{\partial}{\partial r} \frac{\rho_A}{\rho_\ell} \Big|_R = -\frac{4}{3} \pi \frac{d}{dt} \frac{\rho_A}{\rho} \Big|_{\ell_s} (R^3 - R_s^3) + 4\pi R^2 \frac{dR}{dt} (1 - k_p) \frac{\rho_A}{\rho} \Big|_{\ell_s} \quad (9.170)$$

This states that the outward solute flow rate through $r = R$ is determined by the solute ejected due to the solidification and the temperature-caused change in the mass fraction of the interdendritic liquid.

For large solid and liquid conductivities, within the cell the solid, the interdendritic liquid, and the cell liquid can all be in a near-thermal equilibrium. For a temperature change occurring on the boundaries of the cell, the assumption of a uniform temperature within the cell requires that the cell Biot number, that is,

$$\text{Bi} = \frac{\text{Nu}_{d_c}^{\text{ext}} k_\infty}{6 \langle k \rangle_{V_c}} \quad \text{Nu}_{d_c}^{\text{ext}} = \frac{q_c 2R_c}{(T_c - T_\infty) k_\infty} \quad (9.171)$$

be less than 0.1. This condition is assumed to hold (for metals) and a single temperature T_c is used for the unit cell.

The thermal energy balance on the unit cell gives

$$q_c 4\pi R_c^2 = \left[\rho_\ell \Delta i_{\ell_s} \frac{df_s}{dt} + \langle \rho c_p \rangle_{V_c} \frac{dT_c}{dt} \right] + \frac{4}{3}\pi R_c^3 \quad (9.172)$$

where Δi_{ℓ_s} is the heat of solidification and

$$\langle \rho c_p \rangle_{V_c} = (1 - \varepsilon_s)(1 - \varepsilon_c)(\rho c_p)_s + [\varepsilon_s(1 - \varepsilon_c) + \varepsilon_c](\rho c_p)_\ell \quad (9.173)$$

The variation of temperature can be replaced by that of the concentration by assuming that the cell temperature is the equilibrium temperature at the liquidus line. Then using Eq. 9.163, Eq. 9.172 becomes

$$\frac{3q_c}{R_c} = \Delta i_{\ell_s} \frac{df_s}{dt} + \langle \rho c_p \rangle_{V_c} \gamma \frac{d}{dt} \frac{\rho_A}{\rho} \Big|_{\ell_s} \quad (9.174)$$

The growth rate of the dendritic tip is modeled using the available results for low Péclet number growth in unbounded liquid. The model used by Rappaz and Thévoz [152] is

$$\frac{dR}{dt} = \frac{\gamma D_\ell}{\pi^2 (k_p - 1) (\sigma_{\ell_s} / \Delta s_{\ell_s}) (\rho_{A,\ell} / \rho_\ell) (t=0)} \left(\frac{\rho_A}{\rho} \Big|_{\ell_s} - \frac{\rho_{A,\ell}}{\rho_\ell} \Big|_R \right)^2 \quad (9.175)$$

This kinetic condition is discussed by Hills and Roberts [153]. The distribution of $\rho_{A,\ell}/\rho_\ell$ in $R \leq r \leq R_c$ as well as the variations of f_s , f_c , $(\rho_A/\rho)_{\ell s}$, and $(\rho_{A,\ell}/\rho_\ell)_R$ with respect to time are determined by solving Eqs. 9.160, 9.169, 9.170, 9.174, and 9.175, simultaneously. This is done numerically and some of their results are reviewed in the following.

The results are for the solidification of Al-Si with an initial silicon concentration $(\rho_{A,\ell}/\rho_\ell)(t=0) = 0.05$, a eutectic concentration of 0.108, $D_\ell = 3 \times 10^{-9} \text{ m}^2/\text{s}$, $k_p = 0.117$, $\gamma = -7.0$, $\rho_\ell \Delta i_{\ell s} = 9.5 \times 10^8 \text{ J/m}^3$, $T_{m,B}$ (aluminum) = 660°C , $T_e = 577^\circ\text{C}$, $\sigma_{\ell s}/\Delta s_{\ell} = 9 \times 10^{-8} \text{ m}\cdot\text{K}$, and $\langle \rho_{cp} \rangle_{v_c} = 2.35 \times 10^6 \text{ J/m}^3\cdot\text{K}$. Figure 9.29a shows the results for $\Delta T_{sc} = 0^\circ\text{C}$, $R_c = 100 \mu\text{m}$, $R_{s_0} = 1 \mu\text{m}$, and a cooling rate that results in the total solidification of the cell in 10 s.

The variation of temperature T_c and solid and element volume fractions f_s and f_c , respectively, with respect to time, up to the time of the complete solidification, are shown. Since the mass fraction $(\rho_A/\rho)_{\ell s}$ has to increase in order for the growth of the dendrite to begin, as stated by Eq. 9.175, then no change in dT/dt occurs until the point of undershoot is reached, and growth begins with a large and sudden increase in f_c . Since the growth rate of the dendritic tip is larger than the rate of the solidification allowed by the heat removal, the volume fraction of the interdendritic liquid ε_c increases substantially. Therefore, f_s increases much slower than f_c . This increase in f_s decreases $(\rho_A/\rho)_{\ell s}$ and increases T_c , as stated by Eqs. 9.172 and 9.174. The increase in T_c is called *recalescence*. The concentration distributions in the interdendritic liquid and in the cell liquid are shown in Fig. 9.29b for several elapsed times. The elapsed times

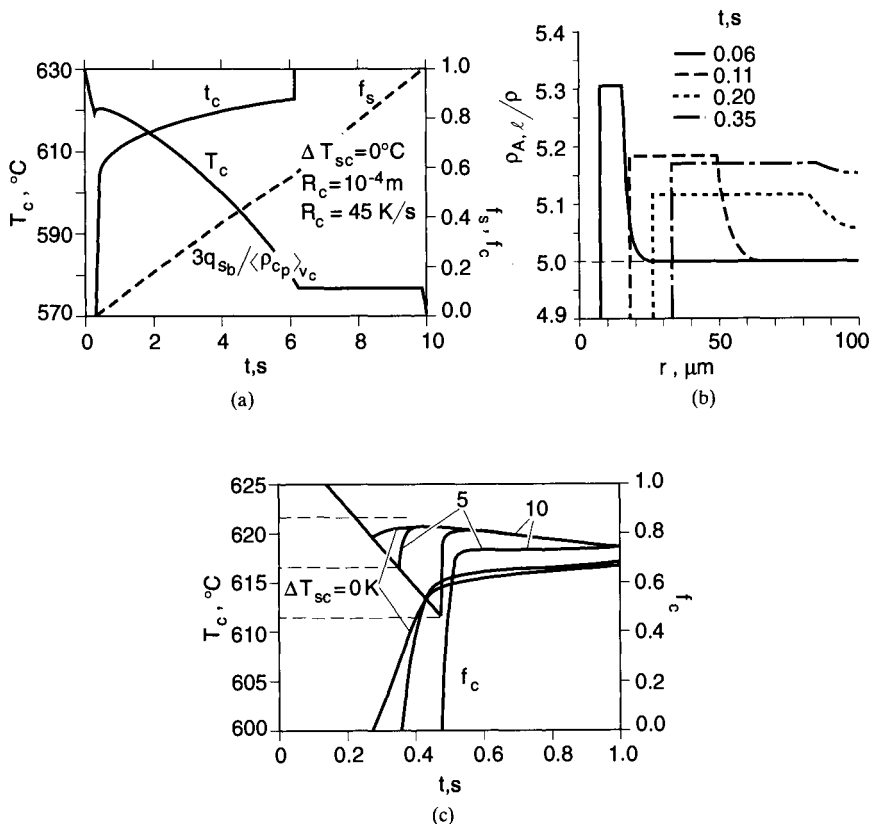

FIGURE 9.29 (a) Computed time variation of temperatures and solid and element volume fractions; (b) radial distribution of the species A in the liquid for four different elapsed times; (c) same as a but for three different supercooling conditions.

correspond to the time of undershoot, shortly after the rise in T_c begins, when T_c reaches a maximum, and shortly after the decrease in T_c begins. For $t > 0.20$ s, the temperature decreases while $(\rho_A/\rho)_\varepsilon$ increases. For an elapsed time slightly larger than 6 s, the element grows to the maximum radius R_c and only the solidification of the interdendritic liquid occurs. This ends when all this liquid is solidified. The undershoot temperature predicted for no supercooling, shown in Fig. 9.29a, will correspond to the supercooling ΔT_{sc} when substantial liquid supercooling exists. Figure 9.29c shows the results for the same conditions as in Fig. 9.29a and b, except 5 and 10°C supercooling are allowed. The results show that the larger the supercooling, the faster the temperature rises after the initial growth (i.e., accelerated recalescence).

Inclusion of buoyant liquid and crystal motions. The unit-cell-based, diffusion-controlled dendritic growth previously discussed has been extended to thermo- and diffusobuoyant convection by using local phase-volume-averaged conservation equations and local thermal and chemical nonequilibrium among the liquid phase, the solid-particles (equiaxed dendritics) phase, and the confining surfaces of the mold. As before, the crystals are assumed to be formed by the bulk nucleation in a supercooled liquid. The liquid temperature $\langle T \rangle^\ell$, the liquid volume fraction ε and its solid particle counterparts $\langle T \rangle^s$ and $1 - \varepsilon$, the velocities $\langle \mathbf{u} \rangle^\ell$ and $\langle \mathbf{u} \rangle^s$, the volumetric solidification rate $\langle \dot{n} \rangle^s$, and the concentration of species A in each phase $\langle \rho_A \rangle^\ell / \rho_\ell$, $\langle \rho_A \rangle^s / \rho_s$ are all determined from the solution of the local phase-volume-averaged conservation equations. The thermodynamic conditions are applied similar to those in the preceding diffusion treatment, but the growth rate of the dendritic tip is not prescribed. Instead, the interfacial heat and mass transfer is modeled using interfacial Nusselt and Sherwood numbers for the particulate flow and heat transfer. Also, interfacial heat and mass transfer is prescribed as functions of the Reynolds number and is based on the relative velocity and solid particle diameter d .

The local, phase-volume-averaged treatment of flow and heat and mass transfer has been addressed by Voller et al. [154], Prakash [155], Beckermann and Ni [156], Prescott et al. [157], and Wang and Beckermann [158], and a review is given by Beckermann and Viskanta [143]. Here we will not review the conservation equations and thermodynamic reactions. They can be found, along with the models for the growth of bubble-nucleated crystals, in Ref. 158.

Laminar flow is assumed and the modeling of $\langle \mathbf{S} \rangle^\ell$, $\langle \mathbf{S} \rangle^s$, and τ_d are pursued similar to the hydrodynamics of the particulate flow. Since the solid particles are not spherical, the dendritic arms and other geometric parameters should be included in the models. Ahuja et al. [159] develop a drag coefficient for equiaxed dendrites.

The effective media properties \mathbf{D}_m^ℓ , \mathbf{D}^ℓ , \mathbf{D}_m^s , and \mathbf{D}^s , which include both the molecular (i.e., conductive) and the hydrodynamic dispersion components, are also modeled. Due to the lack of any predictive correlations for the nonequilibrium transport, local thermal equilibrium conditions are used. For the interfacial convective transport, the local Nusselt and Sherwood numbers are prescribed. The effect of the solid particles geometry must also be addressed [160].

NOMENCLATURE

Uppercase bold letters indicate that the quantity is a second-order tensor, and lowercase bold letters indicate that the quantity is a vector (or spatial tensor). Some symbols, which are introduced briefly through derivations and, otherwise, are not referred to in the text are locally defined in the appropriate locations and are not listed here. The mks units are used throughout.

a	phase distribution function
a_j	$j = 1, 2, \dots$, constants
A	area, cross section (m^2)

A_0	volumetric (or specific) surface area (1/m)
A_{sf}	interfacial area between solid and fluid phases (m ²)
Bo	Bond or Eötvös number $\rho_\ell g R^2 / \sigma$ where ℓ stands for the wetting phase, also $\rho_\ell g K / \varepsilon / \sigma$
C	average interparticle clearance (m)
C_E	coefficient in Ergun modification of Darcy law
c_p	specific heat capacity (J/kg-°C)
Ca	capillary number where ℓ stands for the wetting phase $\mu_\ell u_{D\ell} / \sigma$
d	pore-level linear length scale (m) or diameter (m)
d	displacement tensor (m)
D^d	dispersion tensor (m ² /s)
D^d	dispersion coefficient (m ² /s)
D	total diffusion tensor (m ² /s)
D	total dispersion coefficient (m ² /s)
D_K	Knudsen mass diffusivity (m ² /s)
e	electric field intensity vector (V/m)
E	strain tensor
f	force (N)
f_δ	van der Waals force (N/m ²)
f	force vector (m/s ²)
F	radiant exchanger factor
g	gravitational constant (m/s ²) or asymmetry parameter
g	gravitational acceleration vector (m/s ²)
h	gap size (m) or height (m)
h_{sf}	solid-fluid interfacial heat transfer coefficient (W/m ² -K)
H	mean curvature of the meniscus $(1/2)(1/r_1 + 1/r_2)$ (m) where r_1 and r_2 are the two principal radii of curvature
I	radiation intensity (W/m ²)
I	second-order identity tensor
J	Leverett function
k	conductivity (W/m-K)
k_e	effective conductivity (W/m-K)
k_B	Boltzmann constant 1.381×10^{-23} (J/K)
k_K	Kozeny constant
k_p	equilibrium partition ratio
K	permeability (m ²)
K_{rg}	nonwetting phase relative permeability
$K_{r\ell}$	wetting phase relative permeability
Kn	Knudsen number, λ (mean free path)/ C (average interparticle clearance)
K	permeability tensor (m ²)
K_e	effective conductivity tensor (W/m-K)
ℓ	linear length scale for representative elementary volume or unit-cell length (m)

ℓ	length of a period vector (m)
L, L_1, L_2	system dimension, linear length scale (m)
\dot{m}	mass flux ($\text{kg}/\text{m}^2\text{-s}$)
$\dot{\mathbf{m}}$	mass flux vector ($\text{kg}/\text{m}^2\text{-s}$)
M	molecular weight ($\text{kg}/\text{kg}\cdot\text{mole}$)
Ma	Marangoni number $(\partial\sigma/\partial T)(\Delta T)R/(\alpha\mu)$
n	number of molecules per unit volume (molecules/ m^3)
\dot{n}_i	volumetric rate of production of component i ($\text{kg}/\text{m}^3\text{-s}$)
n_r	number of components in the gas mixture
\mathbf{n}	normal unit vector
N_A	Avogadro number 6.0225×10^{23} (molecules/mole)
Nu	Nusselt number
p	pressure (Pa)
p_c	capillary pressure (Pa)
P	probability density function
P_i	Legendre polynomial
Pe	Peclet number
Pr	Prandtl number
q	heat flux (W/m^2)
r	radial coordinate axis (m), separation distance (m)
\mathbf{r}	radial position vector (m)
R	radius (m)
R_g	universal gas constant 8.3144 ($\text{kJ}/\text{kg}\cdot\text{mole}\cdot\text{K}$) = $k_B N_A$
Re_x	Reynolds number ux/v
s	saturation
s_1	surface saturation
s_{ir}	immobile (or irreducible) wetting phase saturation
s_{irg}	immobile (or irreducible) nonwetting saturation
s_g	nonwetting phase saturation ϵ_g/ϵ
\mathbf{s}	unit vector
S	reduced (or effective) saturation $(s - s_{ir})/(1 - s_{ir} - s_{irg})$ or path length (m)
\mathbf{S}	shear component of stress tensor (Pa)
t	time (s)
\mathbf{t}	tangential unit vector
T	temperature (K)
\mathbf{T}	stress tensor (Pa)
u, v, w	components of velocity vector in $x, y,$ and z directions (m/s)
\mathbf{u}	velocity vector (m/s)
\mathbf{u}_D	Darcean (or superficial) velocity vector (m/s)
\mathbf{u}_F	Front velocity (m/s)
\mathbf{u}_p	pore (interstitial or fluid intrinsic) velocity vector (m/s)
V	volume (m^3)

x, y, z	coordinate axes (m)
\mathbf{x}	position vector (m)
We	Weber number where ℓ stands for the wetting phase $\rho_\ell u_{D\ell}^2 d / \sigma$

Greek

α	thermal diffusivity (m^2/s)
α_R	size parameter
δ	boundary layer thickness (m) or liquid film thickness (m)
δ_j	$j = 1, 2, \dots$, linear dimension of microstructure (m)
Δ	surface roughness (m)
ε	porosity
ε_r	emissivity
$\eta_{\lambda s}$	scattering efficiency
θ	polar angle (rad)
θ_c	contact angle (rad) measured through the wetting fluid
λ	mean free path (m)
μ	dynamic viscosity (kg/m-s)
ν	kinematic viscosity μ/ρ (m^2/s)
ρ	density (kg/m^3) or electrical resistivity (ohm/m) or reflectivity
σ	Stefan-Boltzmann constant 5.6696×10^{-8} ($\text{W}/\text{m}^2 \cdot \text{K}^4$)
τ	shear stress (Pa) or tangential or tortuosity
Φ_λ	phase function
φ	scalar

Superscripts

$\hat{}$	Fourier Laplace or other transformation
$\bar{}$	average value
\dagger	transpose
*	dimensionless quantity
'	deviation from volume-averaged value or directional quantity
ℓ	liquid
f	fluid
fs	fluid-solid
g	gas
s	solid
sf	solid-fluid

Subscripts

b	boundary
cr	critical
d	particle
D	Darcy
e	effective
f	fluid-phase

f_s	solid-fluid interface
g	gas-phase
$g\ell$	gas (or nonwetting phase) liquid interface
$g\ell^1, g\ell^2$	gas-liquid drag
$g\Delta\sigma$	gas-phase surface tension gradient
g_i	gas-phase inertia
h	hydraulic
H	curvature
i	interfacial
ℓ	liquid (or wetting phase), representative elementary volume
ℓ_f	liquid film
ℓ_g	liquid-gas
ℓ_g^1, ℓ_g^2	liquid-gas drag
ℓ_i	liquid-phase inertia
$\ell\Delta\sigma$	liquid-phase surface tension gradient
L	system
m	mean
n	normal
o	reference
p	pore
pa	porous-ambient
r	relative
s	solid or saturation
s_b	bounding solid surface
$s\ell$	solid-liquid interface
sf	solid-fluid
sg	solid-gas interface
x, y	x, y component
Others	
[]	matrix
$\langle \rangle$	volume average
$O()$	order of magnitude

GLOSSARY

absorption coefficient Inverse of the mean free path that a photon travels before undergoing absorption. The spectral absorption coefficient a_λ is found from $I_\lambda(x) = I_\lambda(0) \times \exp[-\int_0^x \sigma_{\lambda a}(x) dx]$, where the beam is traveling along x .

adsorption Enrichment of one or more components in an interfacial layer.

adsorption isotherm Variation of the extent of enrichment of one component (amount adsorbed) in the solid-gas interfacial layer with respect to the gas pressure and at a constant

temperature. For porous media, the amount adsorbed can be expressed in terms of the gram of gas adsorbed per gram of solid.

Brinkman screening length A distance o ($K^{1/2}$) over which the velocity disturbances, caused by a source, decay; the same as the boundary-layer thickness.

bulk properties Quantities measured or assigned to the matrix/fluid system without consideration of the existence of boundaries (due to finiteness of the system). Some properties take on different values than their bulk values at or adjacent to these boundaries.

capillary pressure Local pressure difference between the nonwetting phase and wetting phase (or the pressure difference between the concave and convex sides of the meniscus).

channeling In packed beds made of nearly spherical particles, the packing near the boundaries is not uniform and the local porosity (if a meaningful representative elementary volume could be defined) is larger than the bulk porosity. When the packed bed is confined by a solid surface and a fluid flows through the bed, this increase in the local porosity (a decrease in the local flow resistance) causes an increase in the local velocity. This increase in the velocity adjacent to the solid boundary is called channeling.

coordination number The number of contact points between a sphere (or particle of any regular geometry) and adjacent spheres (or particles of the same geometry).

Darcean flow A flow that obeys $\mathbf{u}_D = -(\mathbf{K}/\mu) \cdot \nabla p$.

dispersion In the context of heat transfer in porous media and in the presence of a net Darcean motion and a temperature gradient, dispersion is the spreading of heat accounted for separately from the Darcean convection and the effective (collective) molecular conduction. It is a result of the simultaneous existence of temperature and velocity gradients within the pores. Due to the volume averaging over the pore space, this contribution is not included in the Darcean convection, and because of its dependence on $\nabla \langle T \rangle$, it is included in the total effective thermal diffusivity tensor.

drainage Displacement of a wetting phase by a nonwetting phase. Also called desaturation or dewetting. A more restrictive definition requires that the only force present during draining must be the capillary force.

Dupuit-Forchheimer velocity Same as pore or interstitial velocity, defined as u_D/ϵ where u_D is the filter (or superficial or Darcy) velocity and ϵ is porosity.

effective porosity The interconnected void volume divided by the total (solid plus total void) volume. The effective porosity is smaller than or equal to porosity.

effective thermal conductivity Local volume-averaged thermal conductivity used for the fluid-filled matrices along with the assumption of local thermal equilibrium between the solid and fluid phases. The effective thermal conductivity is not only a function of porosity and the thermal conductivity of each phase, but is very sensitive to the microstructure.

extinction coefficient Sum of the scattering and absorption coefficients $\sigma_s + \sigma_a = \sigma_{ex}$.

extinction of radiation intensity Sum of the absorbed and scattered radiation energy, as the incident beam travels through a particle or a collection of particles.

formation factor Ratio of electrical resistivity of fully saturated matrix (with an electrolyte fluid) to the electrical resistivity of the fluid.

funicular state Or funicular flow regime. The flow regime in two-phase flow through porous media, where the wetting phase is continuous. The name *funicular* is based on the concept of a continuous wetting phase flowing on the outside of the nonwetting phase and over the solid phase (this two-phase flow arrangement is not realized in practice; instead each phase flows through its individual network of interconnected channels, see Ref. 161).

hydrodynamic dispersion In the presence of both a net and nonuniform fluid motion and a gradient in temperature, that portion of diffusion or spreading of heat caused by the nonuniformity of velocity within each pore. Also called *Taylor-Aris dispersion*.

hysteresis Any difference in behavior associated with the past state of the phase distributions. Examples are the hysteresis loop in the capillary pressure-saturation, relative permeability-saturation, or adsorption isotherm-saturation curves. In these curves, depending on whether a given saturation is reached through drainage (reduction in the wetting phase saturation) or by imbibition (increase in the wetting phase saturation), a different value for the dependent variable is found.

imbibition Displacement of a nonwetting phase with a wetting phase. Also called *saturation, free, or spontaneous imbibition*. A more restrictive definition requires that the only force present during imbibition be the capillary force.

immiscible displacement Displacement of one phase (wetting or nonwetting) by another phase (nonwetting or wetting) without any mass transfer at the interface between the phases (diffusion or phase change). In some cases, a displacement or front develops and right downstream of it the saturation of the phase being displaced is the largest, and behind the front, the saturation of the displacing phase is the largest.

immobile or irreducible saturations s_{ir} The reduced volume of the wetting phase retained at the highest capillary pressure. For very smooth surfaces, the wetting phase saturation does not reduce any further as the capillary pressure increases. However, for rough and etched surfaces, the irreducible saturation can be zero. The nonwetting phase immobile saturation s_{irg} is found when the capillary pressure is nearly zero and yet some of the nonwetting phase is trapped.

infiltration Displacement of a wetting (or nonwetting) phase by a nonwetting (or wetting) phase.

intrinsic phase average For any quantity ψ , the intrinsic phase average over any phase ℓ is defined as

$$\langle \psi_\ell \rangle^\ell = \frac{1}{V_\ell} \int_{V_\ell} \psi_\ell dV$$
