Consider a narrow tube in space, whose walls are generated by steady flow lines (streamlines), which are tangent to the steady velocity field \mathbf{v} (Fig. 13.11). Denote the tube's interior by \mathcal{V} and its boundary by $\partial\mathcal{V}$. Because the flow is steady, the law of mass conservation, $(\rho_o u^\alpha)_{;\alpha} = 0$, reduces to the vanishing spatial divergence: $(\rho_o u^j)_{;j} = (\rho_o \gamma v^j)_{;j} = 0$. Integrate this equation over the tube's interior, and apply Gauss's law to obtain $\int_{\partial\mathcal{V}} \rho_o \gamma v^j d\Sigma_j = 0$. Because the walls of the tube are parallel to v^j , they make no contribution. The contribution from the ends is $(\rho_o \gamma v)_2 A_2 - (\rho_o \gamma v)_1 A_1 = 0$. In other words, *the product $\rho_o \gamma v A$ —the discharge—is constant along the stream tube.*

Similarly, for our steady flow the law of energy conservation, $T^{0\alpha}_{;\alpha} = 0$, reduces to the vanishing spatial divergence, $T^{0j}_{;j} = [(\rho + P)\gamma^2 v^j]_{;j} = 0$, which, when integrated over the tube's interior and converted to a surface integral using Gauss's

theorem, implies that *the product $(\rho + P)\gamma^2 v A$ —the power—is constant along the stream tube.*

The ratio of these two constants, $(\rho + P)\gamma/\rho_o = B$, *must also be constant along the stream tube*; equivalently (since it is independent of the area of the narrow tube), *B must be constant along a streamline*, which is Bernoulli's theorem.

relativistic jets

Important venues for relativistic fluid mechanics are the early universe (Secs. 28.4 and 28.5), and also the narrow relativistic jets that emerge from some galactic nuclei and gamma ray bursts. The flow velocities in some of these jets are measured to be so close to the speed of light that $\gamma \sim 1,000$. For the moment, ignore dissipation and electromagnetic contributions to the stress-energy tensor (which are quite important in practice), and assume that the gas pressure P and mass-energy density ρ are dominated by relativistic particles, so the equation of state is $P = \rho/3 = K\rho_o^{4/3}$ [Eq. (13.87)]. Then we can use the above, italicized conservation laws for the discharge, power, and Bernoulli function to learn how ρ , P , and γ evolve along such a jet.

From the relativistic Bernoulli theorem (the ratio B of the two constants, discharge and power) and the equation of state, we deduce that $\gamma \propto B\rho_o/(\rho + P) \propto \rho_o/\rho_o^{4/3} \propto \rho_o^{-1/3} \propto \rho^{-1/4}$. This describes a conversion of the jet's internal mass-energy ($\sim\rho$) into bulk flow energy ($\sim\gamma$): as the internal energy (energy of random thermal motions of the jet's particles) goes down, the bulk flow energy (energy of organized flow) goes up.

This energy exchange is actually driven by changes in the jet's cross sectional area, which (in some jets) is controlled by competition between the inward pressure of surrounding, slowly moving gas and outward pressure from the jet itself. Since $\rho_o\gamma v A \simeq \rho_o\gamma A$ is constant along the jet, we have $A \propto 1/(\rho_o\gamma) \propto \gamma^2 \propto \rho^{-1/2}$. Therefore, as the jet's cross sectional area A increases, internal energy ($\rho \propto 1/A^2$) goes down, and the energy of bulk flow ($\gamma \propto A^{1/2}$) goes up. Another way to think about this is in terms of the relativistic distribution function of the constituent particles. As the volume of configuration space $d\mathcal{V}_x$ that they occupy increases, their volume of momentum space $d\mathcal{V}_p$ decreases (Secs. 3.2.2 and 3.6).

We explore the origin of relativistic jets in Sec. 26.5.

EXERCISES

Exercise 13.20 *Derivation: Relativistic Bernoulli Theorem* T2

By manipulating the differential forms of the law of rest-mass conservation and the law of energy conservation, derive the constancy of $B = (\rho + P)\gamma/\rho_o$ along steady flow lines, Eq. (13.88).

Exercise 13.21 *Example: Relativistic Momentum Conservation* T2

Give an expression for the change in the *thrust*—the momentum crossing a surface perpendicular to the tube per unit time—along a slender stream tube when the discharge and power are conserved. Explain why the momentum has to change.

13.8.3 Nonrelativistic Limit of the Stress-Energy Tensor T2

13.8.3

T2

It is instructive to evaluate the nonrelativistic limit of the perfect-fluid stress-energy tensor, $T^{\alpha\beta} = (\rho + P)u^\alpha u^\beta + P g^{\alpha\beta}$, and verify that it has the form we deduced in our study of nonrelativistic fluid mechanics (see Table 13.1) with vanishing gravitational potential $\Phi = 0$.

In the nonrelativistic limit, the fluid is nearly at rest in the chosen Lorentz reference frame. It moves with ordinary velocity $\mathbf{v} = d\mathbf{x}/dt$ that is small compared to the speed of light, so the temporal part of its 4-velocity $u^0 = 1/\sqrt{1-v^2}$ and the spatial part $\mathbf{u} = u^0 \mathbf{v}$ can be approximated as

$$u^0 \simeq 1 + \frac{1}{2}v^2, \quad \mathbf{u} \simeq \left(1 + \frac{1}{2}v^2\right) \mathbf{v}. \quad (13.89a)$$

nonrelativistic limit of 4-velocity

We write $\rho = \rho_o(1 + u)$ [Eq. (13.84)], where u is the specific internal energy (not to be confused with the fluid 4-velocity \vec{u} or its spatial part \mathbf{u}). In our chosen Lorentz frame the volume of each fluid element is Lorentz contracted by the factor $\sqrt{1-v^2}$, and therefore the rest mass density is increased from ρ_o to $\rho_o/\sqrt{1-v^2} = \rho_o u^0$. Correspondingly the rest-mass flux is increased from $\rho_o \mathbf{v}$ to $\rho_o u^0 \mathbf{v} = \rho_o \mathbf{u}$ [Eq. (2.62)], and the law of rest-mass conservation becomes $\partial(\rho_o u^0)/\partial t + \partial(\rho_o u^j)/\partial x^j = 0$. When taking the Newtonian limit, we should identify the Newtonian mass ρ_N with the low-velocity limit of this Lorentz-contracted rest-mass density:

$$\rho_N = \rho_o u^0 \simeq \rho_o \left(1 + \frac{1}{2}v^2\right). \quad (13.89b)$$

nonrelativistic limit of Lorentz-contracted mass density

In the nonrelativistic limit the specific internal energy u , the kinetic energy per unit mass $\frac{1}{2}v^2$, and the ratio of pressure to rest-mass density P/ρ_o are of the same order of smallness:

$$u \sim \frac{1}{2}v^2 \sim \frac{P}{\rho_o} \ll 1, \quad (13.90)$$

and the momentum density T^{j0} is accurate to first order in $v \equiv |\mathbf{v}|$, the momentum flux (stress) T^{jk} and the energy density T^{00} are both accurate to second order in v , and the energy flux T^{0j} is accurate to third order in v . To these accuracies, the perfect-fluid stress-energy tensor (13.85), when combined with Eqs. (13.84) and (13.89), takes the following form:

nonrelativistic limit of stress-energy tensor for ideal (perfect) fluid

$$\begin{aligned} T^{j0} &= \rho_N v^j, & T^{jk} &= P g^{jk} + \rho_N v^j v^k, \\ T^{00} &= \rho_N + \frac{1}{2}\rho_N v^2 + \rho_N u, & T^{0j} &= \rho_N v^j + \left(\frac{1}{2}v^2 + u + \frac{P}{\rho_N}\right) \rho_N v^j; \end{aligned} \quad (13.91)$$

see Ex. 13.22. These are precisely the same as the nonrelativistic momentum density, momentum flux, energy density, and energy flux in Table 13.1, aside from (i) the

T2

notational change $\rho \rightarrow \rho_N$ from there to here, (ii) including the rest mass-energy, $\rho_N = \rho_N c^2$, in T_{00} here but not there, and (iii) including the rest-mass-energy flux $\rho_N v^j$ in T^{0j} here but not there.

EXERCISES

Exercise 13.22 *Derivation: Nonrelativistic Limit of Perfect-Fluid Stress-Energy Tensor* T2

- (a) Show that in the nonrelativistic limit, the components of the perfect-fluid stress-energy tensor (13.85) take on the forms (13.91), and verify that these agree with the densities and fluxes of energy and momentum that are used in nonrelativistic fluid mechanics (Table 13.1).
- (b) Show that the contribution of the pressure P to the relativistic density of inertial mass causes the term $(P/\rho_N)\rho_N \mathbf{v} = P\mathbf{v}$ to appear in the nonrelativistic energy flux.

BOX 13.5. TERMINOLOGY USED IN CHAPTER 13

This chapter introduces a large amount of terminology. We list much of it here.

adiabatic A process in which each fluid element conserves its entropy.

adiabatic index The parameter Γ that relates pressure and density changes, $\delta P/P = \Gamma \delta \rho/\rho$, in an adiabatic process. For an ideal gas, it is the ratio of specific heats: $\Gamma = \gamma \equiv C_P/C_V$.

advective time derivative The time derivative moving with the fluid: $d/dt = \partial/\partial t + \mathbf{v} \cdot \nabla$. Also called the convective time derivative.

barotropic A process or equation in which pressure can be regarded as a function solely of density: $P = P(\rho)$.

Bernoulli function, also sometimes called Bernoulli constant:

$$B = \rho(\frac{1}{2}v^2 + h + \Phi).$$

bulk viscosity, coefficient of The proportionality constant ζ relating rate of expansion to viscous stress: $\mathbf{T}_{\text{vis}} = -\zeta \theta \mathbf{g}$.

convective time derivative See advective time derivative.

dissipation A process that increases the entropy. Viscosity and diffusive heat flow (heat conduction) are forms of dissipation.

dynamic viscosity The coefficient of shear viscosity, η .

(continued)

BOX 13.5. (continued)

equation of state In this chapter, where chemical and nuclear reactions do not occur: relations of the form $u(\rho, s)$, $P(\rho, s)$ or $u(\rho, T)$, $P(\rho, T)$.

Euler equation Newton's second law for an ideal fluid: $\rho d\mathbf{v}/dt = -\nabla P + \rho\mathbf{g}$.

Eulerian changes Changes in a quantity measured at fixed locations in space; cf. Lagrangian changes.

expansion, rate of Fractional rate of increase of a fluid element's volume: $\theta = \nabla \cdot \mathbf{v}$.

gas A fluid in which the separations between molecules are large compared to the molecular sizes, and no long-range forces act among molecules except gravity; cf. liquid.

ideal flow A flow in which there is no dissipation.

ideal fluid A fluid in which there are no dissipative processes (also called "perfect fluid").

ideal gas A gas in which the sizes of the molecules and (nongravitational) forces among them are neglected, so the pressure is due solely to the molecules' kinetic motions: $P = nk_B T = [\rho/(\mu m_p)]k_B T$.

incompressible A process or fluid in which the fractional changes of density are small, $\delta\rho/\rho \ll 1$, so the velocity can be approximated as divergence free: $\nabla \cdot \mathbf{v} = 0$.

inviscid Having negligible viscosity.

irrotational A flow or fluid with vanishing vorticity.

isentropic A process or fluid in which the entropy per unit rest mass s is the same everywhere.

isobar A surface of constant pressure.

isothermal A process or fluid in which the temperature is the same everywhere.

kinematic viscosity The ratio of the coefficient of shear viscosity to the density: $\nu \equiv \eta/\rho$.

Lagrangian changes Changes measured moving with the fluid; cf. Eulerian changes.

laminar flow A nonturbulent flow.

(continued)

BOX 13.5. (continued)

liquid A fluid in which the molecules are packed side by side (e.g., water); contrast this with a gas.

mean molecular weight The average mass of a molecule in a fluid, divided by the mass of a proton: μ .

Navier-Stokes equation Newton's second law for a viscous, incompressible fluid: $d\mathbf{v}/dt = -(1/\rho)\nabla P + \nu\nabla^2\mathbf{v} + \mathbf{g}$.

Newtonian fluid A (i) nonrelativistic fluid, or (ii) a fluid in which the shear-stress tensor is proportional to the rate of shear σ and is time-independent when σ is constant.

perfect fluid See ideal fluid.

perfect gas An ideal gas (with $P = [\rho/(\mu m_p)]k_B T$) that has negligible excitation of internal molecular degrees of freedom.

polytropic A barotropic pressure-density relation of the form $P \propto \rho^{1+1/n}$ for some constant n called the *polytropic index*. The proportionality constant is usually a function of entropy.

Reynolds number The ratio $Re = LV/\nu$, where L is the characteristic lengthscale of a flow, V is the characteristic velocity, and ν is the kinematic viscosity. In order of magnitude it is the ratio of inertial acceleration $(\mathbf{v} \cdot \nabla)\mathbf{v}$ to viscous acceleration $\nu\nabla^2\mathbf{v}$ in the Navier-Stokes equation.

rotation, rate of Antisymmetric part of the gradient of velocity; vorticity converted into an antisymmetric tensor using the Levi-Civita tensor.

shear, rate of Symmetric, trace-free part of the gradient of velocity: σ .

shear viscosity, coefficient of The proportionality constant η relating rate of shear to viscous stress: $\mathbf{T}_{\text{vis}} = -\eta\sigma$.

steady flow Flow that is independent of time in some chosen reference frame.

turbulent flow Flow characterized by chaotic fluid motions.

vorticity The curl of the velocity field: $\boldsymbol{\omega} = \nabla \times \mathbf{v}$.

Bibliographic Note

There are many good texts on fluid mechanics. Among those with a physicist's perspective, we particularly like Acheson (1990) and Lautrup (2005) at an elementary level, and Lighthill (1986) and Batchelor (2000) at a more advanced level. Landau

and Lifshitz (1959), as always, is terse but good for physicists who already have some knowledge of the subject. Tritton (1987) takes an especially physical approach to the subject with lots of useful diagrams and photographs of fluid flows. Faber (1995) gives a more deductive yet still physical approach, including a broader range of flows. A general graduate text covering many topics that we discuss (including blood flow) is Kundu, Cohen, and Dowling (2012). For relativistic fluid mechanics we recommend Rezzolla and Zanotti (2013).

Given the importance of fluids to modern engineering and technology, it should not be surprising that there are many more texts with an engineering perspective than with a physics one. Those we particularly like include Potter, Wiggert, and Ramadan (2012), which has large numbers of useful examples, illustrations, and exercises; also recommended are Munson, Young, and Okiishi (2006) and White (2008).

Physical intuition is very important in fluid mechanics and is best developed with the aid of visualizations—both movies and photographs. In recent years many visualizations have been made available on the web. Movies that we have found especially useful are those produced by the National Committee for Fluid Mechanics Films (Shapiro 1961a) and those produced by Hunter Rouse (1963a–f).

The numerical solution of the equations of fluid dynamics on computers (computational fluid dynamics, or CFD) is a mature field of science in its own right. CFD simulations are widely used in engineering, geophysics, astrophysics, and the movie industry. We do not treat CFD in this book. For an elementary introduction, see Lautrup (2005, Chap. 21) and Kundu, Cohen, and Dowling (2012, Chap. 11). For more thorough pedagogical treatments see, for example, Fletcher (1991) and Toro (2010); in the relativistic domain, see Rezzolla and Zanotti (2013).

Vorticity

The flow of wet water

RICHARD FEYNMAN (1964, VOLUME 2, CHAP. 41)

14.1 Overview

14.1

In the last chapter, we introduced an important quantity called *vorticity*, which is the principal subject of the present chapter. Although the most mathematically simple flows are potential, with velocity $\mathbf{v} = \nabla\psi$ for some ψ so the vorticity $\boldsymbol{\omega} = \nabla \times \mathbf{v}$ vanishes, most naturally occurring flows are *vortical*, with $\boldsymbol{\omega} \neq 0$. By studying vorticity, we shall develop an intuitive understanding of how flows evolve. We shall also see that computing the vorticity can be a powerful step along the path to determining a flow's full velocity field.

We all think we can recognize a vortex. The most hackneyed example is water disappearing down a drainhole in a bathtub or shower. The angular velocity around the drain increases inward, because the angular momentum per unit mass is conserved when the water moves radially slowly, in addition to rotating. Remarkably, angular momentum conservation means that the product of the circular velocity v_ϕ and the radius ϖ is independent of radius, which in turn implies that $\nabla \times \mathbf{v} = 0$. So this is a vortex without vorticity! (Except, as we shall see, a delta-function spike of vorticity right at the drainhole's center; see Sec. 14.2 and Ex. 14.24.) Vorticity is a precise physical quantity defined by $\boldsymbol{\omega} = \nabla \times \mathbf{v}$, not just any vaguely circulatory motion.

In Sec. 14.2, we introduce two tools for analyzing and using vorticity: vortex lines and circulation. Vorticity is a vector field and therefore has integral curves obtained by solving $d\mathbf{x}/d\lambda = \boldsymbol{\omega}$ for some parameter λ . These integral curves are the *vortex lines*; they are analogous to magnetic field lines. The flux of vorticity $\int_S \boldsymbol{\omega} \cdot d\boldsymbol{\Sigma}$ across a surface S is equal to the integral of the velocity field, $\Gamma \equiv \int_{\partial S} \mathbf{v} \cdot d\mathbf{x}$, around the surface's boundary ∂S (by Stokes' theorem). We call this Γ the *circulation* around ∂S ; it is analogous to magnetic-field flux. In fact, the analogy with magnetic fields turns out to be extremely useful. Vorticity, like a magnetic field, automatically has vanishing divergence, which means that the vortex lines are continuous, just like magnetic field lines. Vorticity, again like a magnetic field, is an axial vector and thus can be written

BOX 14.1. READERS' GUIDE

- This chapter relies heavily on Chap. 13.
- Chapters 15–19 (fluid mechanics and magnetohydrodynamics) are extensions of this chapter; to understand them, this chapter must be mastered.
- Portions of Part VI, Plasma Physics (especially Chap. 21 on the two-fluid formalism), rely on this chapter.

as the curl of a polar vector potential, the velocity \mathbf{v} .¹ Vorticity has the interesting property that it evolves in a perfect fluid (ideal fluid) in such a manner that the flow carries the vortex lines along with it; we say that the vortex lines are “frozen into the fluid.” When viscous stresses make the fluid imperfect, then the vortex lines diffuse through the moving fluid with a diffusion coefficient that is equal to the kinematic viscosity ν .

In Sec. 14.3, we study a classical problem that illustrates both the action and the propagation of vorticity: the *creeping* flow of a low-Reynolds-number fluid around a sphere. (Low-Reynolds-number flow arises when the magnitude of the viscous-acceleration term in the equation of motion is much larger than the magnitude of the inertial acceleration.) The solution to this problem finds contemporary application in the sedimentation rates of soot particles in the atmosphere.

In Sec. 14.4, we turn to high-Reynolds-number flows, in which the viscous stress is quantitatively weak over most of the fluid. Here, the action of vorticity can be concentrated in relatively thin *boundary layers* in which the vorticity, created at a wall, diffuses away into the main body of the flow. Boundary layers arise because in real fluids, intermolecular attraction requires that the component of the fluid velocity parallel to the boundary (not just the normal component) vanish. The vanishing of both components of velocity distinguishes real fluid flow at high Reynolds number (i.e., low viscosity) from the solutions obtained assuming no vorticity. Nevertheless, it is often (but sometimes not) a good approximation to seek a solution to the equations of fluid dynamics in which vortex-free fluid slips freely past the solid and then match it to a boundary-layer solution near the solid.

Stirred water in a tea cup and Earth's oceans and atmosphere rotate nearly rigidly, so they are most nicely analyzed in a co-rotating reference frame. In Sec. 14.5, we use

1. Pursuing the electromagnetic analogy further, we can ask the question, “Given a specified vorticity field $\boldsymbol{\omega}(\mathbf{x}, t)$, can I solve uniquely for the velocity $\mathbf{v}(\mathbf{x}, t)$?” The answer, of course, is “No.” There is gauge freedom, so many solutions exist. Interestingly, if we specify that the flow be incompressible $\nabla \cdot \mathbf{v} = 0$ (i.e., be the analog of the Coulomb gauge), then $\mathbf{v}(\mathbf{x}, t)$ is unique up to an additive constant.

BOX 14.2. MOVIES RELEVANT TO THIS CHAPTER

In the 1960s, Asher Shapiro and the National Committee for Fluid Mechanics Films and Hunter Rouse at the University of Iowa produced movies that are pedagogically powerful and still fully relevant a half-century later. Those most germane to this chapter are:

- Shapiro (1961b), relevant to the entire chapter;
- Taylor (1964), relevant to Sec. 14.3;
- Abernathy (1968), the portion dealing with (nonturbulent) laminar boundary layers, relevant to Sec. 14.4;
- Rouse (1963e), relevant to Sec. 14.4;
- Fultz (1969), relevant to Sec. 14.5; and
- Taylor (1968), relevant to Sec. 14.5.4.

Also relevant are many segments of the movies produced at the University of Iowa, such as Rouse (1963a–f).

such an analysis to discover novel phenomena produced by Coriolis forces—including winds around pressure depressions; Taylor columns of fluid that hang together like a rigid body; Ekman boundary layers with spiral-shaped velocity fields; gyres (humps of water, e.g., the Sargasso Sea), around which ocean currents (e.g., the Gulf Stream) circulate; and tea leaves that accumulate at the bottom center of a tea cup.

When a flow has a large amount of shear, Nature often finds ways to tap the relative kinetic energy of neighboring stream tubes. In Sec. 14.6 we explore the resulting instabilities, focusing primarily on horizontally stratified fluids with relative horizontal velocities, which have vorticity concentrated in regions where the velocity changes sharply. The instabilities we encounter show up, in Nature, as (among other things) billow clouds and clear-air turbulence in the stratosphere. These phenomena provide motivation for the principal topic of the next chapter: turbulence.

Physical insight into the phenomena of this chapter is greatly aided by movies of fluid flows. The reader is urged to view relevant movies in parallel with reading this chapter; see Box 14.2.

14.2 Vorticity, Circulation, and Their Evolution

14.2

In Sec. 13.5.4, we defined the vorticity as the curl of the velocity field, $\boldsymbol{\omega} = \nabla \times \mathbf{v}$, analogous to defining the magnetic field as the curl of a vector potential. To get insight into vorticity, consider the three simple 2-dimensional flows shown in Fig. 14.1.

FIGURE 14.1 Vorticity in three 2-dimensional flows. The vorticity vector points in the z direction (orthogonal to the plane of the flow) and so can be thought of as a scalar ($\omega = \omega_z$). (a) Constant angular velocity Ω . If we measure radius ϖ from the center \mathcal{P} , the circular velocity satisfies $v = \Omega\varpi$. This flow has vorticity $\omega = 2\Omega$ everywhere. (b) Constant angular momentum per unit mass j , with $v = j/\varpi$. This flow has zero vorticity except at its center, $\omega = 2\pi j\delta(\mathbf{x})$. (c) Shearing flow in a laminar boundary layer, $v_x = -\omega y$ with $\omega < 0$. The vorticity is $\omega = -v_x/y$, and the rate of shear is $\sigma_{xy} = \sigma_{yx} = -\frac{1}{2}\omega$.

Figure 14.1a shows *uniform (rigid) rotation*, with constant angular velocity $\mathbf{\Omega} = \Omega\mathbf{e}_z$. The velocity field is $\mathbf{v} = \mathbf{\Omega} \times \mathbf{x}$, where \mathbf{x} is measured from the rotation axis. Taking its curl, we discover that $\boldsymbol{\omega} = 2\mathbf{\Omega}$ everywhere.

Figure 14.1b shows a flow in which the angular momentum per unit mass $\mathbf{j} = j\mathbf{e}_z$ is constant, because it was approximately conserved as the fluid gradually drifted inward to create this flow. In this case the rotation is *differential* (radially changing angular velocity), with $\mathbf{v} = \mathbf{j} \times \mathbf{x}/\varpi^2$ (where $\varpi = |\mathbf{x}|$ and $\mathbf{j} = \text{const}$). This is the kind of flow that occurs around a bathtub vortex and around a tornado—but outside the vortex’s or tornado’s core. The vorticity is $\boldsymbol{\omega} = 2\pi j\delta(\mathbf{x})$ (where $\delta(\mathbf{x})$ is the 2-dimensional Dirac delta function in the plane of the flow), so it vanishes everywhere except at the center, $\mathbf{x} = 0$ (or, more precisely, except in the vortex’s or tornado’s core). Anywhere in the flow, two neighboring fluid elements, separated tangentially, rotate about each other with an angular velocity $+\mathbf{j}/\varpi^2$, but when the two elements are separated radially, their relative angular velocity is $-\mathbf{j}/\varpi^2$; see Ex. 14.1. The average of these two angular velocities vanishes, which seems reasonable, since the vorticity vanishes.

The vanishing vorticity in this case is an illustration of a simple geometrical description of vorticity in any 2-dimensional flow (Ex. 13.15): If we orient the \mathbf{e}_z axis of a Cartesian coordinate system along the vorticity, then

$$\omega = \left(\frac{\partial v_y}{\partial x} - \frac{\partial v_x}{\partial y} \right) \mathbf{e}_z. \quad (14.1)$$

This expression implies that the vorticity at a point is the sum of the angular velocities of a pair of mutually perpendicular, infinitesimal lines passing through that point (one along the x direction, the other along the y direction) and moving with the fluid; for example, these lines could be thin straws suspended in the fluid. If we float a little

vorticity without vorticity
except at its center

vorticity measured by a
vane with orthogonal fins

vane with orthogonal fins in the flow, with the vane parallel to $\boldsymbol{\omega}$, then the vane will rotate with an angular velocity that is the average of the flow's angular velocities at its fins, which is half the vorticity. Equivalently, the vorticity is twice the rotation rate of the vane. In the case of constant-angular-momentum flow in Fig. 14.1b, the average of the two angular velocities is zero, the vane doesn't rotate, and the vorticity vanishes.

Figure 14.1c shows the flow in a plane-parallel shear layer. In this case, a line in the flow along the x direction does not rotate, while a line along the y direction rotates with angular velocity ω . The sum of these two angular velocities, $0 + \omega = \omega$, is the vorticity. Evidently, curved streamlines are not a necessary condition for vorticity.

EXERCISES

Exercise 14.1 *Practice: Constant-Angular-Momentum Flow—Relative Motion of Fluid Elements*

Verify that for the constant-angular-momentum flow of Fig. 14.1b, with $\mathbf{v} = \mathbf{j} \times \mathbf{x}/\varpi^2$, two neighboring fluid elements move around each other with angular velocity $+j/\varpi^2$ when separated tangentially and $-j/\varpi^2$ when separated radially. [Hint: If the fluid elements' separation vector is $\boldsymbol{\xi}$, then their relative velocity is $\nabla_{\boldsymbol{\xi}}\mathbf{v} = \boldsymbol{\xi} \cdot \nabla\mathbf{v}$. Why?]

Exercise 14.2 *Practice: Vorticity and Incompressibility*

Sketch the streamlines for the following stationary 2-dimensional flows, determine whether the flow is compressible, and evaluate its vorticity. The coordinates are Cartesian in parts (a) and (b), and are circular polar with orthonormal bases $\{\mathbf{e}_{\varpi}, \mathbf{e}_{\phi}\}$ in (c) and (d).

- (a) $v_x = 2xy, \quad v_y = x^2,$
- (b) $v_x = x^2, \quad v_y = -2xy,$
- (c) $v_{\varpi} = 0, \quad v_{\phi} = \varpi,$
- (d) $v_{\varpi} = 0, \quad v_{\phi} = \varpi^{-1}.$

Exercise 14.3 ***Example: Rotating Superfluids*

At low temperatures certain fluids undergo a phase transition to a superfluid state. A good example is ${}^4\text{He}$, for which the transition temperature is 2.2 K. As a superfluid has no viscosity, it cannot develop vorticity. How then can it rotate? The answer (e.g., Feynman 1972, Chap. 11) is that not all the fluid is in a superfluid state; some of it is normal and can have vorticity. When the fluid rotates, all the vorticity is concentrated in microscopic vortex cores of normal fluid that are parallel to the rotation axis and have quantized circulations $\Gamma = h/m$, where m is the mass of the atoms and h is Planck's constant. The fluid external to these vortex cores is irrotational (has vanishing vorticity). These normal fluid vortices may be pinned at the walls of the container.

- (a) Explain, using a diagram, how the vorticity of the macroscopic velocity field, averaged over many vortex cores, is twice the mean angular velocity of the fluid.

- (b) Make an order-of-magnitude estimate of the spacing between these vortex cores in a beaker of superfluid helium on a turntable rotating at 10 rpm.
- (c) Repeat this estimate for a neutron star, which mostly comprises superfluid neutron pairs at the density of nuclear matter and spins with a period of order a millisecond. (The mass of the star is roughly 3×10^{30} kg.)

14.2.1

14.2.1 Vorticity Evolution

vortex lines

By analogy with magnetic field lines, we define a flow's *vortex lines* to be parallel to the vorticity vector $\boldsymbol{\omega}$ and to have a line density proportional to $\boldsymbol{\omega} = |\boldsymbol{\omega}|$. These vortex lines are always continuous throughout the fluid, because the vorticity field, like the magnetic field, is a curl and therefore is necessarily solenoidal ($\nabla \cdot \boldsymbol{\omega} = 0$). However, vortex lines can begin and end on solid surfaces, as the equations of fluid dynamics no longer apply there. Figure 14.2 shows an example: vortex lines that emerge from the wingtip of a flying airplane.

Vorticity and its vortex lines depend on the velocity field at a particular instant and evolve with time as the velocity field evolves. We can determine how by manipulating the Navier-Stokes equation.

In this chapter and the next one, we restrict ourselves to flows that are incompressible in the sense that $\nabla \cdot \mathbf{v} = 0$. As we saw in Sec. 13.6, this is the case when the flow is substantially subsonic and gravitational potential differences are not too extreme. We also require (as is almost always the case) that the shear viscosity vary spatially far

FIGURE 14.2 (a) Sketch of the wing of a flying airplane and the vortex lines that emerge from the wing tip and sweep backward behind the plane. The lines are concentrated in a region with small cross section, a vortex of whirling air. The closed red curves encircle the wing and the vortex; the integral of the velocity field around these curves, $\Gamma = \int \mathbf{v} \cdot d\mathbf{x}$, is the circulation contained in the wing and its boundary layers, and in the vortex; see Sec. 14.2.4 and especially Ex. 14.8. (b) Photograph of the two vortices emerging from the wingtips of an Airbus, made visible by light scattering off water droplets in the vortex cores (Ex. 14.6). Photo © Daniel Umaña. (c) Sketch of vortex lines (dashed) in the wingtip vortices of a flying bird and the flow lines (solid) of air around them. Sketch from Vogel, 1994, Fig. 12.7c, reprinted by permission.

more slowly than the shear itself. These restrictions allow us to write the Navier-Stokes equation in its simplest form:

$$\boxed{\frac{d\mathbf{v}}{dt} \equiv \frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \nabla)\mathbf{v} = -\frac{\nabla P}{\rho} - \nabla\Phi + \nu\nabla^2\mathbf{v}} \quad (14.2)$$

[Eq. (13.70) with $\mathbf{g} = -\nabla\Phi$].

To derive the desired evolution equation for vorticity, we take the curl of Eq. (14.2) and use the vector identity $(\mathbf{v} \cdot \nabla)\mathbf{v} = \nabla(v^2)/2 - \mathbf{v} \times \boldsymbol{\omega}$ (easily derivable using the Levi-Civita tensor and index notation) to obtain

$$\frac{\partial \boldsymbol{\omega}}{\partial t} = \nabla \times (\mathbf{v} \times \boldsymbol{\omega}) - \frac{\nabla P \times \nabla \rho}{\rho^2} + \nu \nabla^2 \boldsymbol{\omega}. \quad (14.3)$$

Although the flow is assumed incompressible, $\nabla \cdot \mathbf{v} = 0$, the density can vary spatially due to a varying chemical composition (e.g., some regions might be oil and others water) or varying temperature and associated thermal expansion. Therefore, we must not omit the $\nabla P \times \nabla \rho$ term.

It is convenient to rewrite the vorticity evolution equation (14.3) with the aid of the relation (again derivable using the Levi-Civita tensor)

$$\nabla \times (\mathbf{v} \times \boldsymbol{\omega}) = (\boldsymbol{\omega} \cdot \nabla)\mathbf{v} + \mathbf{v}(\nabla \cdot \boldsymbol{\omega}) - \boldsymbol{\omega}(\nabla \cdot \mathbf{v}) - (\mathbf{v} \cdot \nabla)\boldsymbol{\omega}. \quad (14.4)$$

Inserting this into Eq. (14.3), using $\nabla \cdot \boldsymbol{\omega} = 0$ and $\nabla \cdot \mathbf{v} = 0$, and introducing a new type of time derivative²

$$\boxed{\frac{D\boldsymbol{\omega}}{Dt} \equiv \frac{\partial \boldsymbol{\omega}}{\partial t} + (\mathbf{v} \cdot \nabla)\boldsymbol{\omega} - (\boldsymbol{\omega} \cdot \nabla)\mathbf{v} = \frac{d\boldsymbol{\omega}}{dt} - (\boldsymbol{\omega} \cdot \nabla)\mathbf{v}}, \quad (14.5)$$

we bring Eq. (14.3) into the following form:

$$\boxed{\frac{D\boldsymbol{\omega}}{Dt} = -\frac{\nabla P \times \nabla \rho}{\rho^2} + \nu \nabla^2 \boldsymbol{\omega}. \quad (14.6)$$

vorticity evolution equation for incompressible flow

This is our favorite form for the vorticity evolution equation for an incompressible flow, $\nabla \cdot \mathbf{v} = 0$. If there are additional accelerations acting on the fluid, then their curls must be added to the right-hand side. The most important examples are the Coriolis acceleration $-2\boldsymbol{\Omega} \times \mathbf{v}$ in a reference frame that rotates rigidly with angular velocity $\boldsymbol{\Omega}$ (Sec. 14.5.1), and the Lorentz-force acceleration $\mathbf{j} \times \mathbf{B}/\rho$ when the fluid has an internal electric current density \mathbf{j} and an immersed magnetic field \mathbf{B} (Sec. 19.2.1); then Eq. (14.6) becomes

$$\frac{D\boldsymbol{\omega}}{Dt} = -\frac{\nabla P \times \nabla \rho}{\rho^2} + \nu \nabla^2 \boldsymbol{\omega} - 2\nabla \times (\boldsymbol{\Omega} \times \mathbf{v}) + \nabla \times (\mathbf{j} \times \mathbf{B}/\rho). \quad (14.7)$$

influence of Coriolis and Lorentz forces on vorticity

2. The combination of spatial derivatives appearing here is called the *Lie derivative* and is denoted $\mathcal{L}_{\mathbf{v}}\boldsymbol{\omega} \equiv (\mathbf{v} \cdot \nabla)\boldsymbol{\omega} - (\boldsymbol{\omega} \cdot \nabla)\mathbf{v}$; it is also the *commutator* of \mathbf{v} and $\boldsymbol{\omega}$ and is denoted $[\mathbf{v}, \boldsymbol{\omega}]$. It is often encountered in differential geometry.

FIGURE 14.3 Equation of motion for an infinitesimal vector $\Delta \mathbf{x}$ connecting two fluid elements. As the fluid elements at \mathcal{P} and \mathcal{Q} move to \mathcal{P}' and \mathcal{Q}' in a time interval dt , the vector changes by $(\Delta \mathbf{x} \cdot \nabla) \mathbf{v} dt$.

In the remainder of Sec. 14.2, we explore the predictions of our favorite form [Eq. (14.6)] of the vorticity evolution equation.

The operator D/Dt [defined by Eq. (14.5) when acting on a vector and by $D/Dt = d/dt$ when acting on a scalar] is called the *fluid derivative*. (Warning: The notation D/Dt is used in some older texts for the convective derivative d/dt .) The geometrical meaning of the fluid derivative can be understood from Fig. 14.3. Denote by $\Delta \mathbf{x}(t)$ the vector connecting two points \mathcal{P} and \mathcal{Q} that are moving with the fluid. Then the figure shows that the convective derivative $d\Delta \mathbf{x}/dt$ is the relative velocity of these two points, namely $(\Delta \mathbf{x} \cdot \nabla) \mathbf{v}$. Therefore, by the second equality in Eq. (14.5), the fluid derivative of $\Delta \mathbf{x}$ vanishes:

$$\frac{D\Delta \mathbf{x}}{Dt} = 0. \quad (14.8)$$

meaning of the fluid derivative D/Dt

Correspondingly, *the fluid derivative of any vector is its rate of change relative to a vector, such as $\Delta \mathbf{x}$, whose tail and head move with the fluid.*

14.2.2

14.2.2 Barotropic, Inviscid, Compressible Flows: Vortex Lines Frozen into Fluid

To understand the vorticity evolution law (14.6) physically, we explore various special cases in this and the next few subsections.

Here we specialize to a barotropic [$P = P(\rho)$], inviscid ($\nu = 0$) fluid flow. (This kind of flow often occurs in Earth's atmosphere and oceans, well away from solid boundaries.) Then the right-hand side of Eq. (14.6) vanishes, leaving $D\boldsymbol{\omega}/Dt = 0$.

For generality, we temporarily (this subsection only) abandon our restriction to incompressible flow, $\nabla \cdot \mathbf{v} = 0$, but keep the flow barotropic and inviscid. Then it is straightforward to deduce, from the curl of the Euler equation (13.44), that

$$\frac{D\boldsymbol{\omega}}{Dt} = -\boldsymbol{\omega} \nabla \cdot \mathbf{v} \quad (14.9)$$

(Ex. 14.4). This equation shows that the vorticity has a fluid derivative parallel to itself: the fluid slides along its vortex lines, or equivalently, the vortex lines are frozen into

FIGURE 14.4 Simple demonstration of the kinematics of vorticity propagation in a compressible, barotropic, inviscid flow. A short, thick cylindrical fluid element with generators parallel to the local vorticity is deformed, by the flow, into a long, slender cylinder. By virtue of Eq. (14.10), we can think of the vortex lines as being convected with the fluid, with no creation of new lines or destruction of old ones, so that the number of vortex lines passing through the cylinder (through its end surface $\Delta\Sigma$) remains constant.

(i.e., are carried by) the moving fluid. The wingtip vortex lines of Fig. 14.2 are an example. They are carried backward by the air that flowed over the wingtips, and they endow that air with vorticity that emerges from a wingtip.

We can actually make the fluid derivative vanish by substituting $\nabla \cdot \mathbf{v} = -\rho^{-1}d\rho/dt$ (the equation of mass conservation) into Eq. (14.9); the result is

$$\boxed{\frac{D}{Dt} \left(\frac{\boldsymbol{\omega}}{\rho} \right) = 0 \quad \text{for barotropic, inviscid flow.}} \quad (14.10)$$

Therefore, the quantity $\boldsymbol{\omega}/\rho$ evolves according to the same equation as the separation $\Delta\mathbf{x}$ of two points in the fluid. To see what this implies, consider a small cylindrical fluid element whose symmetry axis is parallel to $\boldsymbol{\omega}$ (Fig. 14.4). Denote its vectorial length by $\Delta\mathbf{x}$, its vectorial cross sectional area by $\Delta\Sigma$, and its conserved mass by $\Delta M = \rho \Delta\mathbf{x} \cdot \Delta\Sigma$. Then, since $\boldsymbol{\omega}/\rho$ points along $\Delta\mathbf{x}$ and both are frozen into the fluid, it must be that $\boldsymbol{\omega}/\rho = \text{const} \times \Delta\mathbf{x}$. Therefore, the fluid element's conserved mass is $\Delta M = \rho \Delta\mathbf{x} \cdot \Delta\Sigma = \text{const} \times \boldsymbol{\omega} \cdot \Delta\Sigma$, so $\boldsymbol{\omega} \cdot \Delta\Sigma$ is conserved as the cylindrical fluid element moves and deforms. We thereby conclude that the fluid's vortex lines, with number per unit area proportional to $|\boldsymbol{\omega}|$, are convected by our barotropic, inviscid fluid, without being created or destroyed.

for barotropic, inviscid flow: vortex lines are convected (frozen into the fluid)

Now return to an incompressible flow, $\nabla \cdot \mathbf{v} = 0$ (which includes, of course, Earth's oceans and atmosphere), so the vorticity evolution equation becomes $D\boldsymbol{\omega}/Dt = 0$. Suppose that the flow is 2 dimensional (as it commonly is to moderate accuracy when averaged over transverse scales large compared to the thickness of the atmosphere and oceans), so \mathbf{v} is in the x and y directions and is independent of z . Then $\boldsymbol{\omega} = \omega \mathbf{e}_z$, and we can regard the vorticity as the scalar ω . Then Eq. (14.5) with $(\boldsymbol{\omega} \cdot \nabla)\mathbf{v} = 0$ implies that the vorticity obeys the simple propagation law

$$\frac{d\omega}{dt} = 0. \quad (14.11)$$

Thus, in a 2-dimensional, incompressible, barotropic, inviscid flow, the scalar vorticity is conserved when convected, just like entropy per unit mass in an adiabatic fluid.

EXERCISES

Exercise 14.4 *Derivation: Vorticity Evolution in a Compressible, Barotropic, Inviscid Flow*

By taking the curl of the Euler equation (13.44), derive the vorticity evolution equation (14.9) for a compressible, barotropic, inviscid flow.

14.2.3

14.2.3 Tornadoes

A particularly graphic illustration of the behavior of vorticity is provided by a tornado. Tornadoes in North America are most commonly formed at a front where cold, dry air from the north meets warm, moist air from the south, and huge, cumulonimbus thunderclouds form. A strong updraft of the warm, moist air creates rotational motion about a horizontal axis, and updraft of the central part of the rotation axis itself makes it somewhat vertical. A low-pressure vortical core is created at the center of this spinning fluid (recall Crocco's theorem, Ex. 13.9), and the spinning region lengthens under the action of up- and downdrafts. Now, consider this process in the context of vorticity propagation. As the flow (to first approximation) is incompressible, a lengthening of the spinning region's vortex lines corresponds to a reduction in the cross section and a strengthening of the vorticity. This in turn corresponds to an increase in the tornado's circulatory speeds. (Speeds in excess of 450 km/hr have been reported.) If and when the tornado touches down to the ground and its very-low-pressure core passes over the walls and roof of a building, the far larger, normal atmospheric pressure inside the building can cause the building to explode. Further details are explored in Exs. 13.9 and 14.5.

EXERCISES

Exercise 14.5 *Problem: Tornado*

- Figure 14.5 shows photographs of two particularly destructive tornadoes and one waterspout (a tornado sucking water from the ocean). For the tornadoes the wind speeds near the ground are particularly high: about 450 km/hr. Estimate the wind speeds at the top, where the tornadoes merge with the clouds. For the water spout, the wind speed near the water is about 150 km/hr. Estimate the wind speed at the top.
- Estimate the air pressure in atmospheres in the cores of these tornadoes and water spout. (Hint: Use Crocco's theorem, Ex. 13.9.)

FIGURE 14.5 (a,b) Two destructive tornados and (c) a waterspout. (a) Eric Nguyen / Science Source; (b) Justin James Hobson, licensed under Creative Commons-ShareAlike 3.0 Unported (CC BY-SA 3.0); (c) NOAA; <http://www.spc.noaa.gov/faq/tornado/wtrspout.htm>.

Exercise 14.6 *Problem: Visualizing a Wingtip Vortex*

Explain why the pressure and temperature of the core of a wingtip vortex are significantly lower than the pressure and temperature of the ambient air. Under what circumstances will this lead to condensation of tiny water droplets in the vortex core, off which light can scatter, as in Fig. 14.2b?

14.2.4 Circulation and Kelvin's Theorem

Intimately related to vorticity is a quantity called *circulation* Γ ; it is defined as the line integral of the velocity around a closed curve ∂S lying in the fluid:

$$\Gamma \equiv \int_{\partial S} \mathbf{v} \cdot d\mathbf{x}; \quad (14.12a)$$

it can be regarded as a property of the closed curve ∂S . We can invoke Stokes' theorem to convert this circulation into a surface integral of the vorticity passing through a surface S bounded by ∂S :

$$\Gamma = \int_S \boldsymbol{\omega} \cdot d\boldsymbol{\Sigma}. \quad (14.12b)$$

[Note, though, that Eq. (14.12b) is only valid if the area bounded by the contour is simply connected. If the area enclosed contains a solid body, this equation may fail.] Equation (14.12b) states that the circulation Γ around ∂S is the flux of vorticity through S , or equivalently, it is proportional to the number of vortex lines passing through S . Circulation is thus the fluid counterpart of magnetic flux.

14.2.4

circulation

circulation as the flux of vorticity

Kelvin's theorem tells us the rate of change of the circulation associated with a particular contour $\partial\mathcal{S}$ that is attached to the moving fluid. Let us evaluate this rate directly using the convective derivative of Γ . We do this by differentiating the two vector quantities inside the integral (14.12a):

$$\begin{aligned}\frac{d\Gamma}{dt} &= \int_{\partial\mathcal{S}} \frac{d\mathbf{v}}{dt} \cdot d\mathbf{x} + \int_{\partial\mathcal{S}} \mathbf{v} \cdot d\left(\frac{d\mathbf{x}}{dt}\right) \\ &= - \int_{\partial\mathcal{S}} \frac{\nabla P}{\rho} \cdot d\mathbf{x} - \int_{\partial\mathcal{S}} \nabla\Phi \cdot d\mathbf{x} + \nu \int_{\partial\mathcal{S}} (\nabla^2 \mathbf{v}) \cdot d\mathbf{x} + \int_{\partial\mathcal{S}} d\frac{1}{2}v^2, \quad (14.13)\end{aligned}$$

where we have used the Navier-Stokes equation (14.2) with $\nu = \text{constant}$. The second and fourth terms on the right-hand side of Eq. (14.13) vanish around a closed curve, and the first can be rewritten in different notation to give

Kelvin's theorem for evolution of circulation

$$\boxed{\frac{d\Gamma}{dt} = - \int_{\partial\mathcal{S}} \frac{dP}{\rho} + \nu \int_{\partial\mathcal{S}} (\nabla^2 \mathbf{v}) \cdot d\mathbf{x}.} \quad (14.14)$$

This is Kelvin's theorem for the evolution of circulation. It is an integral version of our evolution equation (14.6) for vorticity. In a rotating reference frame it must be augmented by the integral of the Coriolis acceleration $-2\boldsymbol{\Omega} \times \mathbf{v}$ around the closed curve $\partial\mathcal{S}$, and if the fluid is electrically conducting with current density \mathbf{j} and possesses a magnetic field \mathbf{B} , it must be augmented by the integral of the Lorentz force per unit mass $(\mathbf{j} \times \mathbf{B})/\rho$ around $\partial\mathcal{S}$:

$$\frac{d\Gamma}{dt} = - \int_{\partial\mathcal{S}} \frac{dP}{\rho} + \nu \int_{\partial\mathcal{S}} (\nabla^2 \mathbf{v}) \cdot d\mathbf{x} - 2 \int_{\partial\mathcal{S}} \boldsymbol{\Omega} \times \mathbf{v} \cdot d\mathbf{x} + \int_{\partial\mathcal{S}} \frac{\mathbf{j} \times \mathbf{B}}{\rho} \cdot d\mathbf{x}. \quad (14.15)$$

This is the integral form of Eq. (14.7).

If the fluid is barotropic, $P = P(\rho)$, and the effects of viscosity are negligible (and the coordinates are inertial and there is no magnetic field and no electric current), then the right-hand sides of Eqs. (14.14) and (14.15) vanish, and Kelvin's theorem takes the simple form

conservation of circulation in a barotropic inviscid flow

$$\boxed{\frac{d\Gamma}{dt} = 0 \quad \text{for barotropic, inviscid flow.}} \quad (14.16)$$

Eq. (14.16) is the global version of our result that the circulation $\boldsymbol{\omega} \cdot \Delta\boldsymbol{\Sigma}$ of an infinitesimal fluid element is conserved.

The qualitative content of Kelvin's theorem is that vorticity in a fluid is long lived. A fluid's vorticity and circulation (or lack thereof) will persist, unchanged, unless and until viscosity or a $(\nabla P \times \nabla\rho)/\rho^2$ term (or a Coriolis or Lorentz force term) comes into play in the vorticity evolution equation (14.3). We now explore these sources and modifications of vorticity and circulation.

14.2.5 Diffusion of Vortex Lines

14.2.5

First consider the action of viscous stresses on an existing vorticity distribution. For an incompressible, barotropic fluid with nonnegligible viscosity, the vorticity evolution law (14.6) becomes

$$\boxed{\frac{D\boldsymbol{\omega}}{Dt} = \nu \nabla^2 \boldsymbol{\omega} \quad \text{for an incompressible, barotropic fluid.}} \quad (14.17)$$

diffusion equation for vorticity

This is a *convective vectorial diffusion equation*: the viscous term $\nu \nabla^2 \boldsymbol{\omega}$ causes the vortex lines to diffuse through the moving fluid, and the kinematic viscosity ν is the diffusion coefficient for the vorticity. When viscosity is negligible, the vortex lines are frozen into the flow. When viscosity is significant and no boundaries impede the vorticity's diffusion and the vorticity initially is concentrated in a thin vortex, then as time t passes the vorticity diffuses outward into a cross sectional area $\sim \nu t$ in the moving fluid (Ex. 14.7; i.e., the vortex expands). Thus the kinematic viscosity not only has the dimensions of a diffusion coefficient, it also actually controls the diffusion of vortex lines relative to the moving fluid.

diffusion of vortex lines

As a simple example of the spreading of vortex lines, consider an infinite plate moving parallel to itself relative to a fluid at rest. Transform to the rest frame of the plate (Fig. 14.6a) so the fluid moves past it. Suppose that at time $t = 0$ the velocity has

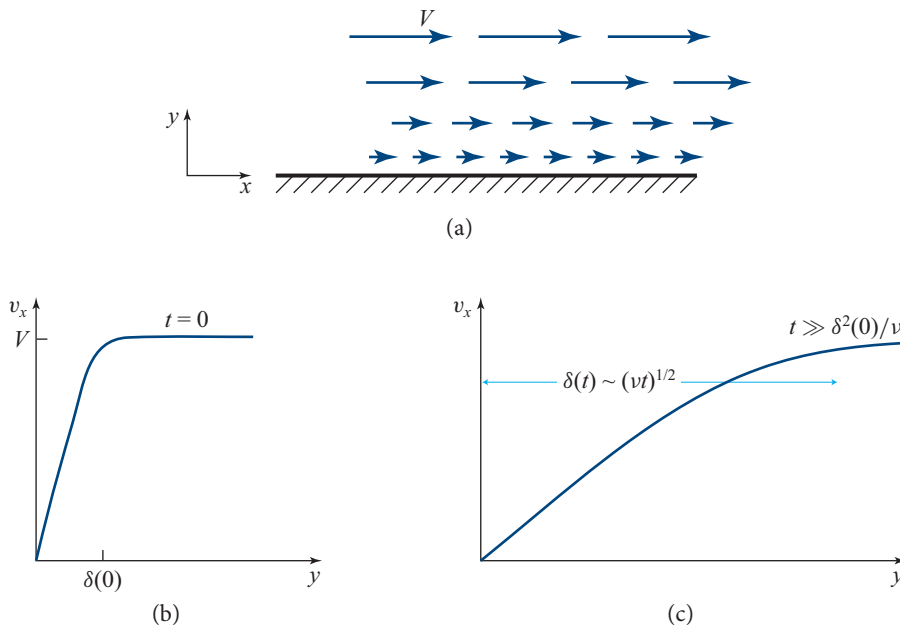

FIGURE 14.6 A simple shear layer that is translation invariant along the flow direction x . Vorticity diffuses away from the static plate at $y = 0$, under the action of viscous torques, in much the same way that heat diffuses away from a heated surface.

only a component v_x parallel to the plate, which depends solely on the distance y from the plate, so the flow is translation invariant in the x direction; then it will continue always to be translation invariant. Suppose further that, at $t = 0$, v_x is constant, $v_x = V$, except in a thin boundary layer near the plate, where it drops rapidly to 0 at $y = 0$ (as it must, because of the plate's no-slip boundary condition; Fig. 14.6b). As the flow is a function only of y (and t), and \mathbf{v} and $\boldsymbol{\omega}$ point in directions orthogonal to \mathbf{e}_y , in this flow the fluid derivative D/Dt [Eq. (14.5)] reduces to $\partial/\partial t$, and the convective diffusion equation (14.17) becomes an ordinary scalar diffusion equation for the only nonzero component of the vorticity: $\partial\omega_z/\partial t = \nu\nabla^2\omega_z$. Let the initial thickness of the boundary layer at time $t = 0$ be $\delta(0)$. Then our experience with the diffusion equation (e.g., Exs. 3.17 and 6.3) tells us that the viscosity will diffuse through the fluid under the action of viscous stress, and as a result, the boundary-layer thickness will increase with time as

$$\delta(t) \sim (\nu t)^{\frac{1}{2}} \quad \text{for } t \gtrsim \delta(0)^2/\nu; \quad (14.18)$$

see Fig. 14.6c. We compute the evolving structure $v_x(y, t)$ of the expanding boundary layer in Sec. 14.4.

EXERCISES

Exercise 14.7 ***Example: Diffusive Expansion of a Vortex*

At time $t = 0$, a 2-dimensional barotropic flow has a velocity field, in circular polar coordinates, $\mathbf{v} = (j/\varpi)\mathbf{e}_\phi$ (Fig. 14.1b); correspondingly, its vorticity is $\boldsymbol{\omega} = 2\pi j\delta(x)\delta(y)\mathbf{e}_z$: it is a delta-function vortex. In this exercise you will solve for the full details of the subsequent evolution of the flow.

- Solve the vorticity evolution equation (14.6) to determine the vorticity as a function of time. From your solution, show that the area in which the vorticity is concentrated (the cross sectional area of the vortex) at time t is $A \sim \nu t$, and show that the vorticity is becoming smoothed out—it is evolving toward a state of uniform vorticity, where the viscosity will no longer have any influence.
- From your computed vorticity in part (a), plus circular symmetry, compute the velocity field as a function of time.
- From the Navier-Stokes equation (or equally well, from Crocco's theorem), compute the evolution of the pressure distribution $P(\varpi, t)$.

Remark: This exercise illustrates a frequent phenomenon in fluid mechanics: The pressure adjusts itself to whatever it needs to be to accommodate the flow. One can often solve for the pressure distribution in the end, after having worked out other details. This happens here because, when one takes the curl of the Navier-Stokes equation for a barotropic fluid (which we did to get the evolution equation for vorticity), the pressure drops out—it decouples from the evolution equation for vorticity and hence velocity.

FIGURE 14.7 (a) Air flow around an airfoil viewed in cross section. The solid green lines are flow lines with velocity \mathbf{v} ; the incoming velocity is \mathbf{V} . (b) Air flow around a sail. The shaded body represents the hull of a boat seen from above.

Exercise 14.8 ***Example: The Lift on an Airplane Wing, Wingtip Vortices, Sailing Upwind, and Fish Locomotion*

When an appropriately curved airfoil (e.g., an airplane wing) is introduced into a steady flow of air, the air has to flow faster along the upper surface than along the lower surface, which can create a lifting force (Fig. 14.7a). In this situation, compressibility and gravity are usually unimportant for the flow.

- (a) Show that the pressure difference across the airfoil is given approximately by $\Delta P = \frac{1}{2}\rho\Delta(v^2) = \rho v\Delta v$. Hence show that the lift exerted by the air on an airfoil of length L is given approximately by

$$F_L = L \int \Delta P dx = \rho V L \Gamma, \quad (14.19)$$

where Γ is the circulation around the airfoil, and V is the air's incoming speed in the airfoil's rest frame. This is known as *Kutta-Joukowski's theorem*. Interpret this result in terms of the conservation of linear momentum, and sketch the overall flow pattern.

- (b) Explain why the circulation around an airplane wing (left orange curve in Fig. 14.2a) is the same as that around the wingtip's vortex (right orange curve in

FIGURE 14.8 (a) Smoke rings blown by a man travel away from his mouth. Photo ©Andrew Vargas. (b) A ring-shaped wingtip vortex is produced by each half beat of the wings of a hovering hummingbird; the vortices travel downward. Sketch from Vogel, 1994, Fig. 12.7a, reprinted by permission.

- Fig. 14.2a), and correspondingly explain why wingtip vortices are essential features of an airplane's flight. Without them, an airplane could not take off.
- (c) How might birds' wingtip vortices (Fig. 14.2c) be related to the V-shaped configuration of birds in a flying flock? (For discussion, see Vogel, 1994, p. 288.)
 - (d) Explain how the same kind of lift as occurs on an airplane wing propels a sailboat forward when sailing upwind, as in Fig. 14.7b.
 - (e) Snakes, eels, and most fish undulate their bodies and/or fins as they swim. Draw pictures that explain how the same principle that propels a sailboat pushes these animals forward as well.

Exercise 14.9 *Problem: Vortex Rings*

Smoke rings (ring-shaped vortices) blown by a person (Fig. 14.8a) propagate away from him. Similarly, a hovering hummingbird produces ring-shaped vortices that propagate downward (Fig. 14.8b). Sketch the velocity field of such a vortex and explain how it propels itself through the ambient air. For the hovering hummingbird, discuss the role of the vortices in momentum conservation.

14.2.6

14.2.6 Sources of Vorticity

Having discussed how vorticity is conserved in simple inviscid flows and how it diffuses away under the action of viscosity, we now consider its sources. The most important source is a solid surface. When fluid suddenly encounters a solid surface, such as the leading edge of an airplane wing or a spoon stirring coffee, intermolecular forces act to decelerate the fluid rapidly in a thin boundary layer along the surface. This deceleration introduces circulation and consequently vorticity into the flow, where

FIGURE 14.9 Mechanical explanation for the creation of vorticity in a nonbarotropic fluid. The net pressure gradient force \mathbf{F} , acting at the geometric center of a small fluid element, is normal to the isobars (solid lines) and does not pass through the center of mass of the element; thereby a torque is produced.

none existed before; that vorticity then diffuses into the bulk flow, thickening the boundary layer (Sec. 14.4).

If the fluid is nonbarotropic (usually due to spatially variable chemical composition or spatially variable temperature), then pressure gradients can also create vorticity, as described by the first term on the right-hand side of the vorticity evolution law (14.6): $(-\nabla P \times \nabla \rho) / \rho^2$. Physically, when the surfaces of constant pressure (*isobars*) do not coincide with the surfaces of constant density (*isochors*), then the net pressure force on a small fluid element does not pass through its center of mass. The pressure therefore exerts a torque on the fluid element, introducing some rotational motion and vorticity (Fig. 14.9). Nonbarotropic pressure gradients can therefore create vorticity within the body of the fluid. Note that because the vortex lines must be continuous, any fresh ones that are created in the fluid must be created as loops that expand from a point or a line.

There are three other common sources of vorticity in fluid dynamics:

1. Coriolis forces, when one's reference frame is rotating rigidly;
2. Lorentz forces, when the fluid is magnetized and electrically conducting [last two terms in Eqs. (14.7) and (14.15)]; and
3. curving shock fronts (when the fluid speed is supersonic).

We discuss these sources in Sec. 14.5 and Chaps. 19 and 17, respectively.

vorticity generated by nonbarotropic pressure gradients

vorticity generated by Coriolis forces, Lorentz forces, and curving shock fronts

Exercise 14.10 *Problem: Vortices Generated by a Spatula*

Fill a bathtub with water and sprinkle baby powder liberally over the water's surface to aid in viewing the motion of the surface water. Then take a spatula, insert it gently into the water, move it slowly and briefly perpendicular to its flat face, then extract it

EXERCISES

gently from the water. Twin vortices will have been generated. Observe the vortices' motions. Explain (i) the generation of the vortices, and (ii) the sense in which the velocity field of each vortex convects the other vortex through the ambient water. Use your bathtub or a swimming pool to perform other experiments on the generation and propagation of vortices.

Exercise 14.11 *Example: Vorticity Generated by Heating*

Rooms are sometimes heated by radiators (hot surfaces) that have no associated blowers or fans. Suppose that, in a room whose air is perfectly still, a radiator is turned on to high temperature. The air will begin to circulate (convect), and that air motion contains vorticity. Explain how the vorticity is generated in terms of the $-\int dP/\rho$ term of Kelvin's theorem (14.14) and the $(-\nabla P \times \nabla \rho)/\rho^2$ term of the vorticity evolution equation (14.6).

14.3

14.3 Low-Reynolds-Number Flow—Stokes Flow and Sedimentation

Reynolds number as ratio of inertial acceleration to viscous acceleration

low-Re flow: pressure gradient balances viscous stress

low-Re flow is nearly reversible

regimes of low-Re flow

In the previous chapter, we defined the Reynolds number Re to be the product of the characteristic speed V and lengthscale a of a flow divided by its kinematic viscosity $\nu = \eta/\rho$: $Re \equiv Va/\nu$. The significance of the Reynolds number follows from the fact that, in the Navier-Stokes equation (14.2), the ratio of the magnitude of the inertial acceleration $|(\mathbf{v} \cdot \nabla)\mathbf{v}|$ to the viscous acceleration $|\nu \nabla^2 \mathbf{v}|$ is approximately equal to Re . Therefore, when $Re \ll 1$, the inertial acceleration can often be ignored, and the velocity field is determined by balancing the pressure gradient against the viscous stress. The velocity then scales linearly with the magnitude of the pressure gradient and vanishes when the pressure gradient vanishes.

This has the amusing consequence that a low-Reynolds-number flow driven by a solid object moving through a fluid at rest is effectively reversible. An example, depicted in the movie by Taylor (1964), is a rotating sphere. If it is rotated slowly in a viscous fluid for N revolutions in one direction, then rotated in reverse for N revolutions, the fluid elements will return almost to their original positions. This phenomenon is easily understood by examining the Navier-Stokes equation (14.2) with the inertial acceleration $d\mathbf{v}/dt$ neglected and gravity omitted: $\nabla P = \eta \nabla^2 \mathbf{v}$; pressure gradient balances viscous force density. No time derivatives appear here, and the equation is linear. When the direction of the sphere's rotation is reversed, the pressure gradients reverse and the velocity field reverses, bringing the fluid back to its original state.

From the magnitudes of viscosities of real fluids (Table 13.2), it follows that the low-Reynolds-number limit is appropriate either for small-scale flows (e.g., the motion of microorganisms in water; see Box 14.3) or for very viscous large scale fluids (e.g., Earth's mantle; Ex. 14.13).

BOX 14.3. SWIMMING AT LOW AND HIGH REYNOLDS NUMBER: FISH VERSUS BACTERIA

Swimming provides insight into the differences between flows with low and high Reynolds numbers. In water, the flow around a swimming fish has $Re \sim 10^6$, while that around a bacterium has $Re \sim 10^{-5}$. In the simplest variant of fish locomotion, the fish wags its tail fin back and forth nearly rigidly, pushing water backward and itself forward with each stroke [schematic drawing (a) below]. And a simple variant of bacterial propulsion is that of the *E. coli* bacterium: it has a rigid corkscrew-shaped tail (made from several flagella), which rotates, pushing water backward via friction (viscosity) and itself forward [schematic drawing (b), adapted from Nelson (2008)].

A fish's tail-wagging propulsion would fail at low Reynolds number, because the flow would be reversible: after each back-forth wagging cycle, the fluid would return to its original state—a consequence of the linear, no-time-derivatives balance of pressure and viscous forces: $\nabla P = \eta \nabla^2 \mathbf{v}$ (see second paragraph of Sec. 14.3). However, for the fish with high Reynolds number, aside from a very thin boundary layer near the fin's surface, viscosity is negligible, and so the flow is governed by Euler's equation: $d\mathbf{v}/dt = (\partial/\partial t + \mathbf{v} \cdot \nabla)\mathbf{v} = -\nabla P/\rho$ (and of course mass conservation). The time derivatives and nonlinearity make the fluid's motion nonreversible in this case. With each back-forth cycle of wag, the tail feeds substantial net backward momentum into the water, and the fish acquires net forward momentum (which will be counteracted by friction in boundary layers along the fish's body if the fish is moving fast enough).

(continued)

BOX 14.3. (continued)

E. coli's corkscrew propulsion would fail at high Reynolds number, because its tail's flagella are so thin ($d \sim 20$ nm) that they could not push any noticeable amount of water inertially. However, at *E. coli*'s low Reynolds number, the amount of water entrained by the tail's viscous friction is almost independent of the tail's thickness. To understand the resulting frictional propulsion, consider a segment of the tail shown white in drawing (b). It moves laterally with velocity \mathbf{V} . If the segment's length ℓ is huge compared to its thickness d , then the water produces a drag force \mathbf{F} on it of magnitude $F \sim 2\pi\eta V\ell / \ln(v/Vd)$ (Ex. 14.12) that points *not* opposite to \mathbf{V} but rather somewhat forward of that direction, as shown in the drawing. The reason is that this segment of a thin rod has a drag that is larger (by about a factor two) when pulled perpendicular to its long axis than when pulled along its long axis. Hence the drag is a tensorial function of \mathbf{V} , $F_i = H_{ij}V_j$, and is not parallel to \mathbf{V} . In drawing (b) the transverse component of the drag cancels out when one integrates it along the winding tail, but the forward component adds coherently along the tail, giving the bacterium a net forward force.

For further discussion of fish as well as bacteria, see, for example, Vogel (1994) and Nelson (2008).

14.3.1 14.3.1 Motivation: Climate Change

An important example of a small-scale flow arises when we ask whether cooling of Earth due to volcanic explosions can mitigate global warming.

The context is concern about anthropogenic (human-made) climate change. Earth's atmosphere is a subtle and fragile protector of the environment that allows life to flourish. Especially worrisome is the increase in atmospheric carbon dioxide—by nearly 25% over the past 50 years to a mass of 3×10^{15} kg. As an important greenhouse gas, carbon dioxide traps solar radiation. Increases in its concentration are contributing to the observed increase in mean surface temperature, the rise of sea levels, and the release of oceanic carbon dioxide with potential runaway consequences.

These effects are partially mitigated by volcanos like Krakatoa, which exploded in 1883,³ releasing roughly 250 megatons or $\sim 10^{18}$ J of energy and nearly 10^{14} kg of small particles (aerosols, ash, soot, etc.), of which $\sim 10^{12}$ kg was raised into the stratosphere,

3. A more recent example was the Pinatubo volcano in 1991, which released roughly a tenth the mass of Krakatoa. Studying the consequences of this explosion provided important calibration for models of greater catastrophes.

FIGURE 14.10 Flow lines for Stokes flow around a sphere.

where much of it remained for several years. These micron-sized particles absorb light with roughly their geometrical cross section. The area of Earth's surface is roughly $5 \times 10^{14} \text{ m}^2$, and the density of the particles is roughly 2000 kg m^{-3} , so that 10^{12} kg of aerosols is sufficient to blot out the Sun. More specifically, the micron-sized particles absorb solar optical and ultraviolet radiation while remaining reasonably transparent to infrared radiation escaping from Earth's surface. The result is a noticeable global cooling of Earth for as long as the particles remain suspended in the atmosphere.⁴

A key issue in assessing how our environment is likely to change over the next century is how long particles of size $1\text{--}10 \mu\text{m}$ will remain in the atmosphere after volcanic explosions (i.e., their rate of sedimentation). This problem is one of low-Reynolds-number flow.

We model the sedimentation by computing the speed at which a spherical soot particle falls through quiescent air when the Reynolds number is small. The speed is governed by a balance between the downward force of gravity and the speed-dependent upward drag force of the air. We compute this sedimentation speed by first evaluating the force of the air on the moving particle ignoring gravity, and then, at the end of the calculation, inserting the influence of gravity.

14.3.2 Stokes Flow

We model the soot particle as a sphere with radius a . The low-Reynolds-number flow of a viscous fluid past such a sphere is known as *Stokes flow*. We calculate the flow's velocity field, and then from it, the force of the fluid on the sphere. (This calculation also finds application in the famous Millikan oil-drop experiment and is a prototype for many more complex calculations of low-Reynolds-number flow.)

SOLUTION FOR VELOCITY FIELD AND PRESSURE

It is easiest to tackle this problem in the frame of the sphere, where the flow is stationary (time-independent; Fig. 14.10). We seek a solution to the Navier-Stokes equation in which the flow velocity $\mathbf{v}(\mathbf{x})$ tends to a constant value \mathbf{V} (the velocity of the sphere

14.3.2

Stokes flow

4. Similar effects could follow the explosion of nuclear weapons in a major nuclear war according to Turco et al. (1986), a phenomenon they called *nuclear winter*.

insignificance of inertial acceleration

through the fluid) at large distances from the sphere's center. We presume the asymptotic flow velocity \mathbf{V} to be highly subsonic, so the flow is effectively incompressible: $\nabla \cdot \mathbf{v} = 0$.

We define the Reynolds number for this flow by $\text{Re} = \rho Va/\eta = Va/\nu$. As this is assumed to be small, in the Navier-Stokes equation (14.2) we can ignore the inertial term, which is $O(V \Delta v/a)$, in comparison with the viscous term, which is $O(\nu \Delta v/a^2)$; here $\Delta v \sim V$ is the total velocity variation. The time-independent Navier-Stokes equation (14.2) can thus be well approximated by $\nabla P = \rho \mathbf{g} + \eta \nabla^2 \mathbf{v}$. The uniform gravitational force density $\rho \mathbf{g}$ is obviously balanced by a uniform pressure gradient (hydrostatic equilibrium). Removing these uniform terms from both sides of the equation, we get

$$\nabla P = \eta \nabla^2 \mathbf{v}, \tag{14.20}$$

where ∇P is now just the nonuniform part of the pressure gradient required to balance the viscous force density. The full details of the flow are governed by this force-balance equation, the flow's incompressibility

$$\nabla \cdot \mathbf{v} = 0, \tag{14.21}$$

and the boundary conditions $\mathbf{v} = 0$ at $r = a$ and $\mathbf{v} \rightarrow \mathbf{V}$ at $r \rightarrow \infty$.

From force balance (14.20) we infer that in order of magnitude the difference between the fluid's pressure on the front of the sphere and that on the back is $\Delta P \sim \eta V/a$. We also expect a viscous drag stress along the sphere's sides of magnitude $T_{r\theta} \sim \eta V/a$, where V/a is the magnitude of the shear. These two stresses, acting on the sphere's surface area $\sim a^2$, will produce a net drag force $F \sim \eta Va$. Our goal is to verify this order-of-magnitude estimate, compute the force more accurately, then balance this force against gravity (adjusted for the much smaller Archimedes buoyancy force produced by the uniform part of the pressure gradient), and thereby infer the speed of fall V of a soot particle.

For a highly accurate analysis of the flow, we could write the full solution as a perturbation expansion in powers of the Reynolds number Re . We compute only the leading term in this expansion; the next term, which corrects for inertial effects, will be smaller than our solution by a factor $O(\text{Re})$.

some general solution ideas

Our solution to this classic problem is based on some general ideas that ought to be familiar from other areas of physics. First, we observe that the quantities in which we are interested are the pressure P , the velocity \mathbf{v} , and the vorticity $\boldsymbol{\omega}$ —a scalar, a polar vector, and an axial vector, respectively—and to first order in the Reynolds number they should be linear in \mathbf{V} . The only scalar we can form that is linear in \mathbf{V} is $\mathbf{V} \cdot \mathbf{x}$, so we expect the variable part of the pressure to be proportional to this combination. For the polar-vector velocity we have two choices, a part $\propto \mathbf{V}$ and a part $\propto (\mathbf{V} \cdot \mathbf{x})\mathbf{x}$; both terms are present. Finally, for the axial-vector vorticity, our only option is a term $\propto \mathbf{V} \times \mathbf{x}$. We use these combinations below.

Now take the divergence of Eq. (14.20), and conclude that the pressure must satisfy Laplace's equation: $\nabla^2 P = 0$. The solution should be axisymmetric about \mathbf{V} , and we know that axisymmetric solutions to Laplace's equation that decay as $r \rightarrow \infty$ can be expanded as a sum over Legendre polynomials, $\sum_{\ell=0}^{\infty} P_{\ell}(\mu)/r^{\ell+1}$, where μ is the cosine of the angle θ between \mathbf{V} and \mathbf{x} , and r is $|\mathbf{x}|$. Since the variable part of P is proportional to $\mathbf{V} \cdot \mathbf{x}$, the dipolar ($\ell = 1$) term [for which $P_1(\mu) = \mu = \mathbf{V} \cdot \mathbf{x}/(Vr)$] is all we need; the higher-order polynomials will be higher-order in \mathbf{V} and thus must arise at higher orders of the Reynolds-number expansion. We therefore write

$$P = P_{\infty} + \frac{k\eta(\mathbf{V} \cdot \mathbf{x})a}{r^3}. \quad (14.22)$$

Here k is a numerical constant that must be determined, we have introduced a factor η to make k dimensionless, and P_{∞} is the pressure far from the sphere.

Next consider the vorticity. Since it is proportional to $\mathbf{V} \times \mathbf{x}$ and cannot depend in any other way on \mathbf{V} , it must be expressible as

$$\boldsymbol{\omega} = \frac{\mathbf{V} \times \mathbf{x}}{a^2} f(r/a). \quad (14.23)$$

The factor a appears in the denominator to make the unknown function f dimensionless. We determine this unknown function by rewriting Eq. (14.20) in the form

$$\nabla P = -\eta \nabla \times \boldsymbol{\omega} \quad (14.24)$$

[which we can do because $\nabla \times \boldsymbol{\omega} = -\nabla^2 \mathbf{v} + \nabla(\nabla \cdot \mathbf{v})$, and $\nabla \cdot \mathbf{v} = 0$], and then inserting Eqs. (14.22) and (14.23) into (14.24) to obtain $f(\xi) = k\xi^{-3}$; hence we have

$$\boldsymbol{\omega} = \frac{k(\mathbf{V} \times \mathbf{x})a}{r^3}. \quad (14.25)$$

Equation (14.25) for the vorticity looks familiar. It has the form of the Biot-Savart law for the magnetic field from a current element. We can therefore write down immediately a formula for its associated "vector potential," which in this case is the velocity:

$$\mathbf{v}(\mathbf{x}) = \frac{ka\mathbf{V}}{r} + \nabla\psi. \quad (14.26)$$

The addition of the $\nabla\psi$ term corresponds to the familiar gauge freedom in defining the vector potential. However, in the case of fluid dynamics, where the velocity is a directly observable quantity, the choice of the scalar ψ is fixed by the boundary conditions instead of being free. As ψ is a scalar linear in \mathbf{V} , it must be expressible in terms of a second dimensionless function $g(\xi)$ as

$$\psi = g(r/a)\mathbf{V} \cdot \mathbf{x}. \quad (14.27)$$

electromagnetic analogy

Next we recall that the flow is incompressible: $\nabla \cdot \mathbf{v} = 0$. Substituting Eq. (14.27) into Eq. (14.26) and setting the divergence expressed in spherical polar coordinates to zero, we obtain an ordinary differential equation for g :

$$\frac{d^2 g}{d\xi^2} + \frac{4}{\xi} \frac{dg}{d\xi} - \frac{k}{\xi^3} = 0. \quad (14.28)$$

This has the solution

$$g(\xi) = A - \frac{k}{2\xi} + \frac{B}{\xi^3}, \quad (14.29)$$

where A and B are integration constants. As $\mathbf{v} \rightarrow \mathbf{V}$ far from the sphere, the constant $A = 1$. The constants B and k can be found by imposing the boundary condition $\mathbf{v} = \mathbf{0}$ for $r = a$. We thereby obtain $B = -1/4$ and $k = -3/2$. After substituting these values into Eq. (14.26), we obtain for the velocity field:

$$\mathbf{v} = \left[1 - \frac{3}{4} \left(\frac{a}{r} \right) - \frac{1}{4} \left(\frac{a}{r} \right)^3 \right] \mathbf{V} - \frac{3}{4} \left(\frac{a}{r} \right)^3 \left[1 - \left(\frac{a}{r} \right)^2 \right] \frac{(\mathbf{V} \cdot \mathbf{x})\mathbf{x}}{a^2}. \quad (14.30)$$

velocity, pressure, and vorticity in Stokes flow

The associated pressure and vorticity, from Eqs. (14.22) and (14.25), are given by

$$\begin{aligned} P &= P_\infty - \frac{3\eta a(\mathbf{V} \cdot \mathbf{x})}{2r^3}, \\ \boldsymbol{\omega} &= \frac{3a(\mathbf{x} \times \mathbf{V})}{2r^3}. \end{aligned} \quad (14.31)$$

The pressure is seen to be largest on the upstream hemisphere, as expected. However, the vorticity, which points in the direction of \mathbf{e}_ϕ , is seen to be symmetric between the front and the back of the sphere. This is because our low-Reynolds-number approximation neglects the advection of vorticity by the velocity field and only retains the diffusive term. Vorticity is generated on the front surface of the sphere and diffuses into the surrounding flow; then, after the flow passes the sphere's equator, the vorticity diffuses back inward and is absorbed onto the sphere's back face.

An analysis that includes higher orders in the Reynolds number would show that not all of the vorticity is reabsorbed; a small portion is left in the fluid downstream from the sphere.

We have been able to obtain a simple solution for low-Reynolds-number flow past a sphere. Although closed-form solutions like this are not common, the methods used to derive it are of widespread applicability. Let us recall them. First, we approximated the equation of motion by omitting the subdominant inertial term and invoked a symmetry argument. We used our knowledge of elementary electrostatics to write the pressure in the form of Eq. (14.22). We then invoked a second symmetry argument to solve for the vorticity and drew on another analogy with electromagnetic theory to derive a differential equation for the velocity field, which was solved subject to the no-slip boundary condition on the surface of the sphere.

Having obtained a solution for the velocity field and pressure, it is instructive to reexamine our approximations. The first point to notice is that the velocity perturbation, given by Eq. (14.30), dies off slowly—it is inversely proportional to distance r from the sphere. Thus for our solution to be valid, the region through which the sphere is moving must be much larger than the sphere; otherwise, the boundary conditions at $r \rightarrow \infty$ have to be modified. This is not a concern for a soot particle in the atmosphere. A second, related point is that, if we compare the sizes of the inertial term (which we neglected) and the pressure gradient (which we kept) in the full Navier-Stokes equation, we find that

$$|(\mathbf{v} \cdot \nabla)\mathbf{v}| \sim \frac{V^2 a}{r^2}, \quad \left| \frac{\nabla P}{\rho} \right| \sim \frac{\eta a V}{\rho r^3}. \quad (14.32)$$

At $r = a$ their ratio is $V a \rho / \eta = V a / \nu$, which is the (small) Reynolds number. However, at a distance $r \sim \eta / \rho V = a / \text{Re}$ from the sphere's center, the inertial term becomes comparable to the pressure term. Correspondingly, to improve on our zero-order solution, we must perform a second expansion at large r including inertial effects and then match it asymptotically to our near-zone expansion (see, e.g., Panton, 2005, Sec. 21.9). This technique of *matched asymptotic expansions* (Panton, 2005, Chap. 15) is a very powerful and general way of finding approximate solutions valid over a wide range of lengthscales, where the dominant physics changes from one scale to the next. We present an explicit example of such a matched asymptotic expansion in Sec. 16.5.3.

matched asymptotic expansions

DRAG FORCE

Let us return to the problem that motivated this calculation: computing the drag force on the sphere. It can be computed by integrating the stress tensor $\mathbf{T} = P\mathbf{g} - 2\eta\boldsymbol{\sigma}$ over the sphere's surface. If we introduce a local orthonormal basis $\{\mathbf{e}_r, \mathbf{e}_\theta, \mathbf{e}_\phi\}$ with polar axis ($\theta = 0$) along the flow direction \mathbf{V} , then we readily see that the only nonzero viscous contribution to the surface stress tensor is $T_{r\theta} = T_{\theta r} = \eta \partial v_\theta / \partial r$. The net resistive force along the direction of the velocity (drag force) is then given by

$$\begin{aligned} F &= \int_{r=a} \frac{d\Sigma \cdot \mathbf{T} \cdot \mathbf{V}}{V} \\ &= \int_0^{2\pi} 2\pi a^2 \sin \theta d\theta \left[-P_\infty \cos \theta + \frac{3\eta V \cos^2 \theta}{2a} + \frac{3\eta V \sin^2 \theta}{2a} \right], \end{aligned} \quad (14.33)$$

where the first two terms are from the fluid's pressure on the sphere and the third is from its viscous stress. The integrals are easy and give $F = 6\pi\eta a V$ for the force, in the direction of the flow. In the rest frame of the fluid, the sphere moves with velocity $\mathbf{V}_{\text{sphere}} = -\mathbf{V}$, so the drag force that the sphere experiences is

$$\boxed{\mathbf{F} = -6\pi\eta a \mathbf{V}_{\text{sphere}}} \quad (14.34)$$

Stokes' law for drag force in low-Re flow

Eq. (14.34) is Stokes' law for the drag force in low-Reynolds-number flow. Two-thirds of the force comes from the viscous stress and one third from the pressure. When the

influence of inertial forces at $r \gtrsim a/\text{Re}$ is taken into account via matched asymptotic expansions, one obtains a correction to the drag force:

correction to drag force

$$\mathbf{F} = -6\pi\eta a \mathbf{V}_{\text{sphere}} \left(1 + \frac{3aV}{8\nu} \right) = -6\pi\eta a \mathbf{V}_{\text{sphere}} \left(1 + \frac{3\text{Re}_d}{16} \right), \quad (14.35)$$

where (as is common) the Reynolds number Re_d is based on the sphere's diameter $d = 2a$ rather than its radius.

EXERCISES

Exercise 14.12 *Problem: Stokes Flow around a Cylinder: Stokes' Paradox*

Consider low-Reynolds-number flow past an infinite cylinder whose axis coincides with the z -axis. Try to repeat the analysis we used for a sphere to obtain an order-of-magnitude estimate for the drag force per unit length. [Hint: You might find it useful to write $\mathbf{v} = \nabla \times (\zeta \mathbf{e}_z)$, which guarantees $\nabla \cdot \mathbf{v} = 0$ (cf. Box 14.4); then show that the scalar *stream function* $\zeta(\varpi, \phi)$ satisfies the biharmonic equation $\nabla^2 \nabla^2 \zeta = 0$.] You will encounter difficulty in finding a solution for \mathbf{v} that satisfies the necessary boundary conditions at the cylinder's surface $\varpi = a$ and at large radii $\varpi \gg a$. This difficulty is called *Stokes' paradox*, and the resolution to it by including inertial forces at large radii was given by Carl Wilhelm Oseen (see, e.g., Panton, 2005, Sec. 21.10). The result for the drag force per unit length is $\mathbf{F} = -2\pi\eta\mathbf{V}(\alpha^{-1} - 0.87\alpha^{-3} + \dots)$, where $\alpha = \ln(3.703/\text{Re}_d)$, and $\text{Re}_d = 2aV/\nu$ is the Reynolds number computed from the cylinder's diameter $d = 2a$. The logarithmic dependence on the Reynolds number and thence on the cylinder's diameter is a warning of the subtle mixture of near-cylinder viscous flow and far-distance inertial flow that influences the drag.

14.3.3

14.3.3 Sedimentation Rate

Now we return to the problem that motivated our study of Stokes flow: the rate of sedimentation of soot particles (the rate at which they sink to the ground) after a gigantic volcanic eruption. To analyze this, we must restore gravity to our analysis. We can do so by restoring to the Navier-Stokes equation the uniform pressure gradient and balancing gravitational term that we removed just before Eq. (14.20). Gravity and the buoyancy (Archimedes) force from the uniform pressure gradient exert a net downward force $(4\pi a^3/3)(\rho_s - \rho)g$ on the soot particle, which must balance the upward resistive force (14.34). Here $\rho_s \sim 2,000 \text{ kg m}^{-3}$ is the density of soot and $\rho \sim 1 \text{ kg m}^{-3}$ is the far smaller (and here negligible) density of air. Equating these forces, we obtain

sedimentation speed

$$V = \frac{2\rho_s a^2 g}{9\eta}. \quad (14.36)$$

The kinematic viscosity of air at sea level is, according to Table 13.2, $\nu \sim 10^{-5} \text{ m}^2 \text{ s}^{-1}$, and the density is $\rho_a \sim 1 \text{ kg m}^{-3}$, so the coefficient of viscosity is $\eta = \rho_a \nu \sim 10^{-5} \text{ kg m}^{-1} \text{ s}^{-1}$. This viscosity is proportional to the square root of temperature and is independent of the density [cf. Eq. (13.72)]; however, the temperature does not

vary by more than about 25% up to the stratosphere (Fig. 13.2), so for an approximate calculation, we can use its value at sea level. Substituting the above values into Eq. (14.36), we obtain an equilibrium sedimentation speed

$$V \sim 0.5(a/1 \mu\text{m})^2 \text{ mm s}^{-1}. \quad (14.37)$$

For self-consistency we should also estimate the Reynolds number:

$$\text{Re} \sim \frac{2\rho_a V a}{\eta} \sim 10^{-4} \left(\frac{a}{1 \mu\text{m}} \right)^3. \quad (14.38)$$

Our analysis is therefore only likely to be adequate for particles of radius $a \lesssim 10 \mu\text{m}$.

There is also a lower bound to the size of the particle for validity of this analysis: the mean free path of the nitrogen and oxygen molecules must be smaller than the particle. The mean free path is $\sim 0.3 \mu\text{m}$, so the resistive force is reduced when $a \lesssim 1 \mu\text{m}$.⁵

The sedimentation speed (14.37) is much smaller than wind speeds in the upper atmosphere: $v_{\text{wind}} \sim 30 \text{ m s}^{-1}$. However, as the stratosphere is reasonably stratified, the net vertical motion due to the winds is quite small,⁶ and so we can estimate the settling time by dividing the stratosphere's height $\sim 30 \text{ km}$ by the speed [Eq. (14.37)] to obtain

$$t_{\text{settle}} \sim 6 \times 10^7 \left(\frac{a}{1 \mu\text{m}} \right)^{-2} \text{ s} \sim 2 \left(\frac{a}{1 \mu\text{m}} \right)^{-2} \text{ years}. \quad (14.39)$$

This calculation is a simple model for more serious and complex analyses of sedimentation after volcanic eruptions, and the resulting mitigation of global warming. Of course, huge volcanic eruptions are rare, so no matter the result of reliable future analyses, we cannot count on volcanos to save humanity from runaway global warming. And the consequences of “geo-engineering” fixes in which particles are deliberately introduced into the atmosphere are correspondingly uncertain.

limitations on validity of analysis

Exercise 14.13 Problem: Viscosity of Earth's Mantle

Episodic glaciation subjects Earth's crust to loading and unloading by ice. The last major ice age was 10,000 years ago, and the subsequent unloading produces a nontidal contribution to the acceleration of Earth's rotation rate of order $|\dot{\Omega}|/|\dot{\Omega}| \simeq 6 \times 10^{11} \text{ yr}$, detectable from observing the positions of distant stars. Corresponding changes in Earth's oblateness produce a decrease in the rate of nodal line regression of the geodetic satellites LAGEOS.

(a) Estimate the speed with which the polar regions (treated as spherical caps of radius $\sim 1,000 \text{ km}$) are rebounding now. Do you think the speed was much greater in the past?

5. A dimensionless number—the ratio of the mean free path to the lengthscale of the flow (in this case the radius of the particle), called the *Knudsen number* or Kn —has been defined to describe this situation. Corrections to Stokes' law for the drag force are needed when $\text{Kn} \gtrsim 1$.
6. Brownian motion also affects the sedimentation rate for very small particles.

EXERCISES

- (b) Geological evidence suggests that a particular glaciated region of radius about 1,000 km sank in $\sim 3,000$ yr during the last ice age. By treating this as a low-Reynolds-number viscous flow, make an estimate of the coefficient of viscosity for the mantle.

Exercise 14.14 *Example: Undulatory Locomotion in Microorganisms*

Many microorganisms propel themselves, at low Reynolds number, using undulatory motion. Examples include the helical motion of *E. coli*'s corkscrew tail (Box 14.3), and undulatory waves in a forest of cilia attached to an organism's surface, or near a bare surface itself. As a 2-dimensional model for locomotion via surface waves, we idealize the organism's undisturbed surface as the plane $y = 0$, and we assume the surface undulates in and out with displacement $\delta y = (-u/kC) \sin[k(x - Ct)]$ and hence velocity $V_y = u \cos[k(x - Ct)]$. Here u is the amplitude, k the wave number, and C the surface speed in the organism's rest frame. Derive the velocity field \mathbf{v} for the fluid at $y > 0$ produced by this wall motion, and from it deduce the velocity of the organism through the fluid. You could proceed as follows.

- (a) The velocity field must satisfy the incompressible, low-Reynolds-number equations $\nabla P = \eta \nabla^2 \mathbf{v}$ and $\nabla \cdot \mathbf{v} = 0$ [Eqs. (14.20) and (14.21)]. Explain why \mathbf{v} (which must point in the x and y directions) can be expressed as the curl of a vector potential that points in the z direction: $\mathbf{v} = \nabla \times (\zeta \mathbf{e}_z)$; and show that $\zeta(t, x, y)$ (the *stream function*; see Box 14.4 in Sec. 14.4.1) satisfies the biharmonic equation: $\nabla^2 \nabla^2 \zeta = 0$.
- (b) Show that the following ζ satisfies the biharmonic equation and satisfies the required boundary conditions at the organism's surface, $v_x[x, \delta y(x, t), t] = 0$ and $v_y[x, \delta y(x, t), t] = V_y(x, t)$, and the appropriate boundary conditions at $y \rightarrow \infty$:

$$\zeta = -\frac{u}{k}(1 + ky) \exp(-ky) \sin[k(x - Ct)] + \frac{u^2}{2C} y \{1 - \exp(-2ky) \cos[2k(x - Ct)]\} + O(u^3). \quad (14.40)$$

Explain how $\nabla P = \eta \nabla^2 \mathbf{v}$ is then easily satisfied.

- (c) Show that the streamlines (tangent to \mathbf{v}) are surfaces of constant ζ . Plot these streamlines at $t = 0$ and discuss how they change as t passes. Explain why they are physically reasonable.
- (d) Show that at large y the fluid moves with velocity $\mathbf{v} = [u^2/(2C)]\mathbf{e}_x$, and that therefore, in the asymptotic rest frame of the fluid, the organism moves with velocity $-[u^2/(2C)]\mathbf{e}_x$, opposite to \mathbf{k} . Is this physically reasonable? Why does the organism's inertia (and hence its mass) not influence this velocity? That the organism's velocity is second order in the velocity of its surface waves illustrates the difficulty of locomotion at low Reynolds number.

- (e) Now consider what happens if the undulation is longitudinal with motion lying in the plane of the undulating surface. Sketch the flow pattern, and show that the organism will now move in the direction of \mathbf{k} .

14.4 High-Reynolds-Number Flow—Laminar Boundary Layers

14.4

As we have described, flow near a solid surface creates vorticity, and consequently, the velocity field near the surface cannot be derived from a scalar potential, $\mathbf{v} = \nabla\psi$. However, if the Reynolds number is high, then the vorticity may be localized in a thin boundary layer adjacent to the surface, as in Fig. 14.6. Then the flow may be very nearly of potential form $\mathbf{v} = \nabla\psi$ outside that boundary layer. In this section, we use the equations of hydrodynamics to model the flow in the simplest example of such a boundary layer: that formed when a long, thin plate is placed in a steady, uniform flow $\mathbf{v} = V\mathbf{e}_x$ with its surface parallel to the flow (Fig. 14.11).

boundary layers in high-Re flow

If the plate is not too long, then the flow will be *laminar*, that is, steady and 2-dimensional—a function only of the distances x along the plate's length and y perpendicular to the plate (both being measured from an origin at the plate's front). We assume the flow to be highly subsonic, so it can be regarded as incompressible. As the viscous stress decelerates the fluid close to the plate, it must therefore be deflected away from the plate to avoid accumulating, thereby producing a small y component of velocity along with the larger x component. As the velocity is uniform well away from the plate, the pressure is constant outside the boundary layer. We use this condition to motivate the approximation that P is also constant in the boundary layer. After solving for the flow, we will check the self-consistency of this ansatz (guess). With

laminar flow

FIGURE 14.11 Laminar boundary layer formed by a long, thin plate in a flow with asymptotic speed V . The length ℓ of the plate must give a Reynolds number $\text{Re}_\ell \equiv V\ell/\nu$ in the range $10 \lesssim \text{Re}_\ell \lesssim 10^6$. If Re_ℓ is much less than 10, the plate will be in or near the regime of low-Reynolds-number flow (Sec. 14.3), and the boundary layer will be so thick everywhere that our analysis will fail. If Re_ℓ is much larger than 10^6 , then at sufficiently great distances x down the plate ($\text{Re}_x = Vx/\nu \gtrsim 10^6$), a portion of the boundary layer will become turbulently unstable and its simple laminar structure will be destroyed (see Chap. 15).

$P = \text{constant}$ and the flow stationary, only the inertial and viscous terms remain in the Navier-Stokes equation (14.2):

$$(\mathbf{v} \cdot \nabla)\mathbf{v} \simeq \nu \nabla^2 \mathbf{v}. \quad (14.41)$$

This equation must be solved in conjunction with $\nabla \cdot \mathbf{v} = 0$ and the boundary conditions $\mathbf{v} \rightarrow V \mathbf{e}_x$ as $y \rightarrow \infty$ and $\mathbf{v} \rightarrow 0$ as $y \rightarrow 0$.

The fluid first encounters the no-slip boundary condition at the front of the plate, $x = y = 0$. The flow there abruptly decelerates to vanishing velocity, creating a steep velocity gradient that contains a sharp spike of vorticity. This is the birth of the boundary layer.

vorticity created at beginning of plate; circulation conserved thereafter

Farther downstream, the total flux of vorticity inside the rectangle C of Fig. 14.12, $\int \boldsymbol{\omega} \cdot d\boldsymbol{\Sigma}$, is equal to the circulation $\Gamma_C = \int_C \mathbf{v} \cdot d\mathbf{x}$ around C . The flow velocity is zero on the bottom leg of C , and it is (very nearly) orthogonal to C on the vertical legs, so the only nonzero contribution is from the top leg, which gives $\Gamma_C = V \Delta x$. Therefore, the circulation per unit length (flux of vorticity per unit length $\Gamma_C/\Delta x$) is V everywhere along the plate. This means that there is no new vorticity acquired, and none is lost after the initial spike at the front of the plate.

As the fluid flows down the plate, from $x = 0$ to larger x , the spike of vorticity, created at the plate's leading edge, gradually diffuses outward from the wall into the flow, thickening the boundary layer.

Let us compute the order of magnitude of the boundary layer's thickness $\delta(x)$ as a function of distance x down the plate. Incompressibility, $\nabla \cdot \mathbf{v} = 0$, implies that $v_y \sim v_x \delta/x$. Using this to estimate the relative magnitudes of the various terms in the x component of the force-balance equation (14.41), we see that the dominant inertial term (left-hand side) is $\sim V^2/x$ and the dominant viscous term (right-hand side) is $\sim \nu V/\delta^2$. We therefore obtain the estimate $\delta \sim \sqrt{\nu x/V}$. This motivates us to define the function

boundary layer thickens due to viscous diffusion of vorticity

$$\delta(x) \equiv \sqrt{\frac{\nu x}{V}} \quad (14.42)$$

for use in our quantitative analysis. Our analysis will reveal that the actual thickness of the boundary layer is several times larger than this $\delta(x)$.

Equation (14.42) shows that the boundary layer has a parabolic shape: $y \sim \delta(x) = \sqrt{\nu x/V}$. To keep the analysis manageable, we confine ourselves to the region, not too close to the front of the plate, where the layer is thin, $\delta \ll x$, and the velocity is nearly parallel to the plate, $v_y \sim (\delta/x)v_x \ll v_x$.

14.4.1

14.4.1 Blasius Velocity Profile Near a Flat Plate:

Stream Function and Similarity Solution

To proceed further, we use a technique of widespread applicability in fluid mechanics: we make a *similarity ansatz*, whose validity we elucidate near the end of the calculation.

similarity ansatz

FIGURE 14.12 A rectangle C used in showing that a boundary layer's circulation per unit length $\Gamma_C/\Delta x$ is equal to the flow speed V just above the boundary layer.

We suppose that, once the boundary layer has become thin ($\delta \ll x$), the cross sectional shape of the flow is independent of distance x down the plate (it is “similar” at all x , also called “self-similar”). Stated more precisely, we assume that $v_x(x, y)$ (which has magnitude $\sim V$) and $(x/\delta)v_y$ (which also has magnitude $\sim V$) are functions only of the single transverse, dimensionless variable:

$$\xi = \frac{y}{\delta(x)} = y \sqrt{\frac{V}{\nu x}}. \quad (14.43)$$

Then our task is to compute $\mathbf{v}(\xi)$ subject to the boundary conditions $\mathbf{v} = 0$ at $\xi = 0$, and $\mathbf{v} = V\mathbf{e}_x$ at $\xi \gg 1$. We do so with the aid of a second, very useful calculational device. Recall that any vector field $[\mathbf{v}(\mathbf{x})$ in our case] can be expressed as the sum of the gradient of a scalar potential and the curl of a vector potential: $\mathbf{v} = \nabla\psi + \nabla \times \mathbf{A}$. If our flow were irrotational ($\boldsymbol{\omega} = 0$), we would need only $\nabla\psi$, but it is not; the vorticity in the boundary layer is large. On the other hand, to high accuracy the flow is incompressible, $\theta = \nabla \cdot \mathbf{v} = 0$, which means we need only the vector potential: $\mathbf{v} = \nabla \times \mathbf{A}$. And because the flow is 2-dimensional (depends only on x and y and has \mathbf{v} pointing only in the x and y directions), the vector potential need only have a z component: $\mathbf{A} = A_z\mathbf{e}_z$. We denote its nonvanishing component by $A_z \equiv \zeta(x, y)$ and give it the name *stream function*, since it governs how the laminar flow streams. In terms of the stream function, the relation $\mathbf{v} = \nabla \times \mathbf{A}$ takes the simple form

$$v_x = \frac{\partial \zeta}{\partial y}, \quad v_y = -\frac{\partial \zeta}{\partial x}. \quad (14.44)$$

Equation (14.44) automatically satisfies $\nabla \cdot \mathbf{v} = 0$. Notice that $\mathbf{v} \cdot \nabla \zeta = v_x \partial \zeta / \partial x + v_y \partial \zeta / \partial y = -v_x v_y + v_y v_x = 0$. Thus *the stream function is constant along streamlines*. (As an aside that often will be useful, e.g., in Exs. 14.12 and 14.20, we generalize this stream function in Box 14.4.)

stream function

BOX 14.4. STREAM FUNCTION FOR A GENERAL, TWO-DIMENSIONAL, INCOMPRESSIBLE FLOW T2

Consider any orthogonal coordinate system in flat 3-dimensional space, for which the metric coefficients are independent of one of the coordinates, say, x_3 :

$$ds^2 = g_{11}(x_1, x_2) dx_1^2 + g_{22}(x_1, x_2) dx_2^2 + g_{33}(x_1, x_2) dx_3^2. \quad (1)$$

The most common examples are Cartesian coordinates $\{x, y, z\}$ with $g_{11} = g_{22} = g_{33} = 1$; cylindrical coordinates $\{\varpi, z, \phi\}$ with $g_{11} = g_{22} = 1$ and $g_{33} = \varpi^2$; and spherical coordinates $\{r, \theta, \phi\}$ with $g_{11} = 1$, $g_{22} = r^2$, and $g_{33} = r^2 \sin^2 \theta$. Suppose the velocity field is also independent of x_3 , so it is effectively 2-dimensional (translation invariant for Cartesian coordinates; axisymmetric for cylindrical or spherical coordinates).

Because the flow is incompressible, $\nabla \cdot \mathbf{v} = 0$, we can write the velocity as the curl of a vector potential: $\mathbf{v} = \nabla \times \mathbf{A}(t, x_1, x_2)$. By imposing the Lorenz gauge on the vector potential (i.e., making it divergence free, as is commonly done in electromagnetism), we can ensure that its only nonvanishing component is $A_3 = \mathbf{A} \cdot \mathbf{e}_3$, where \mathbf{e}_3 is the unit vector pointing in the x_3 direction. Now, a special role is played by the vector that generates local translations along the x_3 direction (i.e., that generates the flow's symmetry). If we write a location \mathcal{P} in space as a function of the coordinates $\mathcal{P}(x_1, x_2, x_3)$, then this generator is $\partial\mathcal{P}/\partial x_3 = \sqrt{g_{33}} \mathbf{e}_3$. We define the flow's stream function by

$$\zeta(t, x_1, x_2) \equiv \mathbf{A} \cdot \partial\mathcal{P}/\partial x_3, \quad (2)$$

which implies that the only nonzero component of the vector potential is $A_3 = \zeta/\sqrt{g_{33}}$.

Then it is straightforward to show (Ex. 14.19) the following. (i) The orthonormal components of the velocity field $\mathbf{v} = \nabla \times \mathbf{A}$ are

$$v_1 = \frac{1}{\sqrt{g_{22}g_{33}}} \frac{\partial\zeta}{\partial x_2}, \quad v_2 = \frac{-1}{\sqrt{g_{11}g_{33}}} \frac{\partial\zeta}{\partial x_1}. \quad (3)$$

These expressions enable one to reduce an analysis of the flow to solving for three scalar functions of (t, x_1, x_2) : the stream function ζ , the pressure P , and the density ρ . (ii) The stream function is a constant along flow lines: $\mathbf{v} \cdot \nabla\zeta = 0$. (iii) The stream function is proportional to the flow rate (the amount of fluid volume crossing a surface per unit time). More specifically,

(continued)

BOX 14.4. (continued)

consider a segment of some curve reaching from point \mathcal{A} to point \mathcal{B} in a surface of constant x_3 , and expand this curve into a segment of a 2-dimensional surface by translating it through some Δx_3 along the symmetry generator $\partial\mathcal{P}/\partial x_3$. Then the flow rate across this surface is

$$\begin{aligned}\mathcal{F} &= \int_{\mathcal{A}}^{\mathcal{B}} \mathbf{v} \cdot \left(\Delta x_3 \frac{\partial \mathcal{P}}{\partial x_3} \times d\mathbf{x} \right) \\ &= \int_{\mathcal{A}}^{\mathcal{B}} \mathbf{v} \cdot (\sqrt{g_{33}} \Delta x_3 \mathbf{e}_3 \times d\mathbf{x}) = [\zeta(\mathcal{B}) - \zeta(\mathcal{A})] \Delta x_3.\end{aligned}\quad (4)$$

Since the stream function varies on the lengthscale δ , to produce a velocity field with magnitude $\sim V$, it must have magnitude $\sim V\delta$. This motivates us to guess that it has the functional form

$$\zeta = V\delta(x)f(\xi), \quad (14.45)$$

where $f(\xi)$ is some dimensionless function of order unity. This guess will be good if, when inserted into Eq. (14.44), it produces a self-similar flow [i.e., one with v_x and $(x/\delta)v_y$ depending only on ξ]. Indeed, inserting Eq. (14.45) into Eq. (14.44), we obtain

$$v_x = Vf', \quad v_y = \frac{\delta(x)}{2x} V(\xi f' - f), \quad (14.46a)$$

where the prime denotes $d/d\xi$. These equations have the desired self-similar form.

By inserting these self-similar v_x and v_y into the x component of the force-balance equation $\mathbf{v} \cdot \nabla \mathbf{v} = \nu \nabla^2 \mathbf{v}$ [Eq. (14.41)] and neglecting $\partial^2 v_x / \partial x^2$ compared to $\partial^2 v_x / \partial y^2$, we obtain a nonlinear third-order differential equation for $f(\xi)$:

$$\frac{d^3 f}{d\xi^3} + \frac{f}{2} \frac{d^2 f}{d\xi^2} = 0. \quad (14.46b)$$

That this equation involves x and y only in the combination $\xi = y\sqrt{V/\nu x}$ confirms that our self-similar ansatz was a good one. Equation (14.46b) must be solved subject to the boundary condition that the velocity vanish at the surface and approach V as $y \rightarrow \infty$ ($\xi \rightarrow \infty$) [cf. Eqs. (14.46a)]:

$$f(0) = f'(0) = 0, \quad f'(\infty) = 1. \quad (14.46c)$$

Not surprisingly, Eq. (14.46b) does not admit an analytic solution. However, it is simple to compute a numerical solution with the boundary conditions (14.46c).

mathematical form of
self-similar boundary layer

FIGURE 14.13 Laminar boundary layer near a flat plate: the Blasius velocity profile $v_x/V = f'(\xi)$ (blue curve) and vorticity profile $(\delta/V)\omega = -f'''(\xi)$ (red curve) as functions of scaled perpendicular distance $\xi = y/\delta$. Note that the flow speed is 90% of V at a distance of 3δ from the surface, so δ is a good measure of the thickness of the boundary layer.

Blasius profile for self-similar boundary layer

The result for $v_x/V = f'(\xi)$ is shown in Fig. 14.13. This solution, the *Blasius profile*, qualitatively has the form we expected: the velocity v_x rises from 0 to V in a smooth manner as one moves outward from the plate, achieving a sizable fraction of V at a distance several times larger than $\delta(x)$.

This Blasius profile is not only our first example (aside from Ex. 14.12) of the use of a stream function ($v_x = \partial\zeta/\partial y$, $v_y = -\partial\zeta/\partial x$); it is also our first example of another common procedure in fluid dynamics: *taking account of a natural scaling in the problem to make a self-similar ansatz and thereby transform the partial differential fluid equations into ordinary differential equations*. Solutions of this type are known as *similarity solutions* and also as *self-similar solutions*.

self-similar solutions

The motivation for using similarity solutions is obvious. The nonlinear partial differential equations of fluid dynamics are much harder to solve, even numerically, than are ordinary differential equations. Elementary similarity solutions are especially appropriate for problems where there is no intrinsic characteristic lengthscale or timescale associated with the relevant physical quantities except those explicitly involving the spatial and temporal coordinates. High-Reynolds-number flow past a large plate has a useful similarity solution, whereas flow with $\text{Re}_\ell \sim 1$, where the size of the plate is clearly a significant scale in the problem, does not. We shall encounter more examples of similarity solutions in the following chapters.

Now that we have a solution for the flow, we must examine a key approximation that underlies it: constancy of the pressure P . To do this, we begin with the y component of the force-balance equation (14.41) (a component that we never used explicitly in our analysis). The inertial and viscous terms are both $O(V^2\delta/x^2)$, so if we reinstate a term $-\nabla P/\rho \sim -\Delta P/\rho\delta$, it can be no larger than $\sim V^2\delta/x^2$. From this we estimate

that the pressure difference across the boundary layer is $\Delta P \lesssim \rho V^2 \delta^2/x^2$. Using this estimate in the x component of force balance (14.41) (the component on which our analysis was based), we verify that the pressure gradient term is smaller than those we kept by a factor $\lesssim \delta^2/x^2 \ll 1$. For this reason, *when the boundary layer is thin, we can indeed neglect pressure gradients across it when computing its structure from longitudinal force balance.*

14.4.2 Blasius Vorticity Profile

14.4.2

It is illuminating to consider the structure of the Blasius boundary layer in terms of its vorticity. Since the flow is 2-dimensional with velocity $\mathbf{v} = \nabla \times (\zeta \mathbf{e}_z)$, its vorticity is $\boldsymbol{\omega} = \nabla \times \nabla \times (\zeta \mathbf{e}_z) = -\nabla^2(\zeta \mathbf{e}_z)$, which has as its only nonzero component

$$\omega \equiv \omega_z = -\nabla^2 \zeta = -\frac{V}{\delta} f''(\xi), \quad (14.47)$$

aside from fractional corrections of order δ^2/x^2 . This vorticity is exhibited in Fig. 14.13.

From Eq. (14.46b), we observe that the gradient of vorticity vanishes at the plate. This means that the vorticity is not diffusing out from the plate's surface. Neither is it being convected away from the plate's surface, as the perpendicular velocity vanishes there. This confirms what we already learned from Fig. 14.12: the flux of vorticity per unit length is conserved along the plate, once it has been created as a spike at the plate's leading edge.

If we transform to a frame moving with an intermediate speed $\sim V/2$, and measure time t since passing the leading edge, the vorticity will diffuse a distance $\sim (vt)^{1/2} \sim (vx/V)^{1/2} = \delta(x)$ away from the surface after time t ; see the discussion of vorticity diffusion in Sec. 14.2.5. This behavior exhibits the connection between that diffusion discussion and the similarity solution for the boundary layer in this section.

vorticity diffusion in boundary layer

14.4.3 Viscous Drag Force on a Flat Plate

14.4.3

It is of interest to compute the total drag force exerted on the plate. Let ℓ be the plate's length and $w \gg \ell$ be its width. Noting that the plate has two sides, the drag force produced by the viscous stress acting on the plate's surface is

$$F = 2 \int T_{xy}^{\text{vis}} dx dz = 2 \int (-2\eta\sigma_{xy}) dx dz = 2w \int_0^\ell \rho\nu \left(\frac{\partial v_x}{\partial y} \right)_{y=0} dx. \quad (14.48)$$

Inserting $\partial v_x/\partial y = (V/\delta)f''(0) = V\sqrt{V/(vx)}f''(0)$ from Eqs. (14.46a) and performing the integral, we obtain

$$F = \frac{1}{2} \rho V^2 \times (2\ell w) \times C_D, \quad (14.49)$$

where

$$C_D = 4f''(0)\text{Re}_\ell^{-1/2}. \quad (14.50)$$

drag coefficient

Here we have introduced an often-used notation for expressing the drag force of a fluid on a solid body. We have written it as half the incoming fluid's kinetic stress ρV^2 times the surface area of the body $2\ell w$ on which the drag force acts, times a dimensionless drag coefficient C_D . We have expressed the drag coefficient in terms of the Reynolds number

$$\text{Re}_\ell = \frac{V\ell}{\nu} \tag{14.51}$$

formed from the body's relevant dimension, ℓ , and the speed and viscosity of the incoming fluid.

From Fig. 14.13, we estimate that $f''(0) \simeq 0.3$ (an accurate numerical value is 0.332), and so $C_D \simeq 1.328\text{Re}_\ell^{-1/2}$. Note that the drag coefficient decreases as the viscosity decreases and the Reynolds number increases. However, as we discuss in Sec. 15.5, this model breaks down for very large Reynolds numbers $\text{Re}_\ell \gtrsim 10^6$, because a portion of the boundary layer becomes turbulent (cf. caption of Fig. 14.11).

14.4.4 14.4.4 Boundary Layer Near a Curved Surface: Separation

Next consider flow past a nonplanar surface (e.g., the aircraft wings of Fig. 14.2a,b). In this case, in general a longitudinal pressure gradient exists along the boundary layer, which cannot be ignored, in contrast to the transverse pressure gradient across the boundary layer. If the pressure decreases along the flow, the flow will accelerate, and so more vorticity will be created at the surface and will diffuse away from the surface. However, if there is an "adverse" pressure gradient causing the flow to decelerate, then negative vorticity must be created at the wall. For a sufficiently adverse gradient, the negative vorticity gets so strong that it cannot diffuse fast enough into and through the boundary layer to maintain a simple boundary-layer-type flow. Instead, the boundary layer *separates* from the surface, as shown in Fig. 14.14, and a backward flow is generated beyond the separation point by the negative vorticity. This phenomenon can occur on an aircraft when the wings' angle of attack (i.e., the inclination of the wings to the horizontal) is too great. An adverse pressure gradient develops on the

adverse pressure gradient

boundary-layer separation

FIGURE 14.14 Separation of a boundary layer in the presence of an adverse pressure gradient.

upper wing surfaces, the flow separates, and the plane stalls. The designers of wings make great efforts to prevent this, as we discuss briefly in Sec. 15.5.2.

EXERCISES

Exercise 14.15 *Problem: Reynolds Numbers*

Estimate the Reynolds numbers for the following flows. Make sketches of the flow fields, pointing out any salient features.

- (a) A hang glider in flight.
- (b) Plankton in the ocean.
- (c) A physicist waving her hands.

Exercise 14.16 ***Problem: Fluid Dynamical Scaling*

An auto manufacturer wishes to reduce the drag force on a new model by changing its design. She does this by building a one-sixth scale model and putting it into a wind tunnel. How fast must the air travel in the wind tunnel to simulate the flow at 40 mph on the road?

[Remark: This is our first example of “scaling” relations in fluid dynamics, a powerful concept that we develop and explore in later chapters.]

Exercise 14.17 *Example: Potential Flow around a Cylinder (D’Alembert’s Paradox)*

Consider stationary incompressible flow around a cylinder of radius a with sufficiently large Reynolds number that viscosity may be ignored except in a thin boundary layer, which is assumed to extend all the way around the cylinder. The velocity is assumed to have the uniform value \mathbf{V} at large distances from the cylinder.

- (a) Show that the velocity field outside the boundary layer can be derived from a scalar *velocity potential* (introduced in Sec. 13.5.4), $\mathbf{v} = \nabla\psi$, that satisfies Laplace’s equation: $\nabla^2\psi = 0$.
- (b) Write down suitable boundary conditions for ψ .
- (c) Write the velocity potential in the form

$$\psi = \mathbf{V} \cdot \mathbf{x} + f(\mathbf{x}),$$

and solve for f . Sketch the streamlines and equipotentials.

- (d) Use Bernoulli’s theorem to compute the pressure distribution over the surface and the net drag force given by this solution. Does your drag force seem reasonable? It did not seem reasonable to d’Alembert in 1752, and it came to be called *d’Alembert’s paradox*.
- (e) Finally, consider the effect of the pressure distribution on the boundary layer. How do you think this will make the real flow different from the potential solution? How will the drag change?

Exercise 14.18 *Example: Stationary Laminar Flow down a Long Pipe*

Fluid flows down a long cylindrical pipe of length b much larger than radius a , from a reservoir maintained at pressure P_0 (which connects to the pipe at $x = 0$) to a free end at large x , where the pressure is negligible. In this problem, we try to understand the velocity field $v_x(\varpi, x)$ as a function of radius ϖ and distance x down the pipe, for a given discharge (i.e., mass flow per unit time) \dot{M} . Assume that the Reynolds number is small enough for the flow to be treated as laminar all the way down the pipe.

- Close to the entrance of the pipe (small x), the boundary layer will be thin, and the velocity will be nearly independent of radius. What is the fluid velocity outside the boundary layer in terms of its density and \dot{M} ?
- How far must the fluid travel along the pipe before the vorticity diffuses into the center of the flow and the boundary layer becomes as thick as the radius? An order-of-magnitude calculation is adequate, and you may assume that the pipe is much longer than your estimate.
- At a sufficiently great distance down the pipe, the profile will cease evolving with x and settle down into the Poiseuille form derived in Sec. 13.7.6, with the discharge \dot{M} given by the Poiseuille formula. Sketch how the velocity profile changes along the pipe, from the entrance to this final Poiseuille region.
- Outline a procedure for computing the discharge in a long pipe of arbitrary cross section.

Exercise 14.19 *Derivation: Stream Function in General* T2

Derive results (i), (ii), and (iii) in the last paragraph of Box 14.4. [Hint: The derivation is simplest if one works in a coordinate basis (Sec. 24.3) rather than in the orthonormal bases that we use throughout Parts I–VI of this book.]

Exercise 14.20 *Problem: Stream Function for Stokes Flow around a Sphere* T2

Consider low-Reynolds-number flow around a sphere. Derive the velocity field (14.30) using the stream function of Box 14.4. This method is more straightforward but less intuitive than that used in Sec. 14.3.2.

14.5

14.5 Nearly Rigidly Rotating Flows—Earth's Atmosphere and Oceans

In Nature one often encounters fluids that rotate nearly rigidly (i.e., fluids with a nearly uniform distribution of vorticity). Earth's oceans and atmosphere are important examples, where the rotation is forced by the underlying rotation of Earth. Such rotating fluids are best analyzed in a rotating reference frame, in which the unperturbed fluid is at rest and the perturbations are influenced by Coriolis forces, resulting in surprising phenomena. We explore some of these phenomena in this section.

14.5.1 Equations of Fluid Dynamics in a Rotating Reference Frame

14.5.1

As a foundation for this exploration, we transform the Navier-Stokes equation from the inertial frame in which it was derived to a uniformly rotating frame: the mean rest frame of the flows we study.

We begin by observing that the Navier-Stokes equation has the same form as Newton's second law for particle motion:

$$\frac{d\mathbf{v}}{dt} = \mathbf{f}, \quad (14.52)$$

where the force per unit mass is $\mathbf{f} = -\nabla P/\rho - \nabla\Phi + \nu\nabla^2\mathbf{v}$. We transform to a frame rotating with uniform angular velocity $\boldsymbol{\Omega}$ by adding “fictitious” Coriolis and centrifugal accelerations, given by $-2\boldsymbol{\Omega} \times \mathbf{v}$ and $-\boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{x})$, respectively, and expressing the force \mathbf{f} in rotating coordinates. The fluid velocity transforms as

$$\mathbf{v} \rightarrow \mathbf{v} + \boldsymbol{\Omega} \times \mathbf{x}. \quad (14.53)$$

It is straightforward to verify that this transformation leaves the expression for the viscous acceleration, $\nu\nabla^2\mathbf{v}$, unchanged. Therefore the expression for the force \mathbf{f} is unchanged, and the Navier-Stokes equation in rotating coordinates becomes

$$\frac{d\mathbf{v}}{dt} = -\frac{\nabla P}{\rho} - \nabla\Phi + \nu\nabla^2\mathbf{v} - 2\boldsymbol{\Omega} \times \mathbf{v} - \boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{x}). \quad (14.54)$$

The centrifugal acceleration $-\boldsymbol{\Omega} \times (\boldsymbol{\Omega} \times \mathbf{x})$ can be expressed as the gradient of a centrifugal potential, $\nabla[\frac{1}{2}(\boldsymbol{\Omega} \times \mathbf{x})^2] = \nabla[\frac{1}{2}(\Omega\varpi)^2]$, where ϖ is distance from the rotation axis. (The location of the rotation axis is actually arbitrary, aside from the requirement that it be parallel to $\boldsymbol{\Omega}$; see Box 14.5.) For simplicity we confine ourselves to an incompressible fluid, so that ρ is constant. This allows us to define an *effective pressure*

$$P' = P + \rho \left[\Phi - \frac{1}{2}(\boldsymbol{\Omega} \times \mathbf{x})^2 \right] \quad (14.55)$$

that includes the combined effects of the real pressure, gravity, and the centrifugal force. In terms of P' the Navier-Stokes equation in the rotating frame becomes

$$\frac{d\mathbf{v}}{dt} = -\frac{\nabla P'}{\rho} + \nu\nabla^2\mathbf{v} - 2\boldsymbol{\Omega} \times \mathbf{v}. \quad (14.56a)$$

The quantity P' will be constant if the fluid is at rest in the rotating frame, $\mathbf{v} = 0$, in contrast to the true pressure P , which does have a gradient. Equation (14.56a) is the most useful form for the Navier-Stokes equation in a rotating frame. In keeping with our assumptions that ρ is constant and the flow speeds are very low in comparison with the speed of sound, we augment Eq. (14.56a) by the incompressibility condition

Coriolis and centrifugal accelerations in rigidly rotating reference frame

Navier-Stokes equation in rotating reference frame

effective pressure for incompressible fluid in rotating reference frame

Navier-Stokes equation for incompressible fluid in rotating reference frame

$\nabla \cdot \mathbf{v} = 0$, which is left unchanged by the transformation (14.53) to a rotating reference frame:

$$\nabla \cdot \mathbf{v} = 0. \quad (14.56b)$$

It should be evident from Eq. (14.56a) that two dimensionless numbers characterize rotating fluids. The first is the *Rossby number*,

Rossby number

$$\text{Ro} = \frac{V}{\Omega L}, \quad (14.57)$$

where V is a characteristic velocity of the flow relative to the rotating frame, and L is a characteristic length. Ro measures the relative strength of the inertial acceleration and the Coriolis acceleration:

$$\text{Ro} \sim \frac{|(\mathbf{v} \cdot \nabla)\mathbf{v}|}{|2\boldsymbol{\Omega} \times \mathbf{v}|} \sim \frac{\text{inertial force}}{\text{Coriolis force}}. \quad (14.58)$$

The second dimensionless number is the *Ekman number*,

Ekman number

$$\text{Ek} = \frac{\nu}{\Omega L^2}, \quad (14.59)$$

which analogously measures the relative strengths of the viscous and Coriolis accelerations:

$$\text{Ek} \sim \frac{|\nu \nabla^2 \mathbf{v}|}{|2\boldsymbol{\Omega} \times \mathbf{v}|} \sim \frac{\text{viscous force}}{\text{Coriolis force}}. \quad (14.60)$$

Notice that $\text{Ro}/\text{Ek} = \text{Re}$ is the Reynolds number.

storms, ocean currents,
and tea cups

The three traditional examples of rotating flows are large-scale storms and other weather patterns on rotating Earth, deep currents in Earth's oceans, and water in a stirred tea cup.

For a typical storm, the wind speed might be $V \sim 25$ mph ($\sim 10 \text{ m s}^{-1}$), and a characteristic lengthscale might be $L \sim 1,000$ km. The effective angular velocity at a temperate latitude is (see Box 14.5) $\Omega_* = \Omega_{\oplus} \sin 45^\circ \sim 10^{-4} \text{ rad s}^{-1}$, where Ω_{\oplus} is Earth's rotational angular velocity. As the air's kinematic viscosity is $\nu \sim 10^{-5} \text{ m}^2 \text{ s}^{-1}$, we find that $\text{Ro} \sim 0.1$ and $\text{Ek} \sim 10^{-13}$. This tells us immediately that Coriolis forces are important but not totally dominant, compared to inertial forces, in controlling the weather, and that viscous forces are unimportant except in thin boundary layers.

For deep ocean currents, such as the Gulf Stream, V ranges from ~ 0.01 to $\sim 1 \text{ m s}^{-1}$, so we use $V \sim 0.1 \text{ m s}^{-1}$, lengthscales are $L \sim 1,000$ km, and for water $\nu \sim 10^{-6} \text{ m}^2 \text{ s}^{-1}$, so $\text{Ro} \sim 10^{-3}$ and $\text{Ek} \sim 10^{-14}$. Thus, Coriolis accelerations are far more important than inertial forces, and viscous forces are important only in thin boundary layers.

BOX 14.5. ARBITRARINESS OF ROTATION AXIS; Ω FOR ATMOSPHERIC AND OCEANIC FLOWS

ARBITRARINESS OF ROTATION AXIS

Imagine yourself on the rotation axis $\mathbf{x} = 0$ of a rigidly rotating flow. All fluid elements circulate around you with angular velocity Ω . Now move perpendicular to the rotation axis to a new location $\mathbf{x} = \mathbf{a}$, and ride with the flow there. All other fluid elements will still rotate around you with angular velocity Ω ! The only way you can tell you have moved (if all fluid elements look identical) is that you will now experience a centrifugal force $\Omega \times (\Omega \times \mathbf{a})$.

This shows up mathematically in the rotating-frame Navier-Stokes equation (14.54). When we set $\mathbf{x} = \mathbf{x}_{\text{new}} - \mathbf{a}$, the only term that changes is the centrifugal force; it becomes $-\Omega \times (\Omega \times \mathbf{x}_{\text{new}}) + \Omega \times (\Omega \times \mathbf{a})$. If we absorb the new, constant, centrifugal term $\Omega \times (\Omega \times \mathbf{a})$ into the gravitational acceleration $\mathbf{g} = -\nabla\Phi$, then the Navier-Stokes equation is completely unchanged. In this sense, the choice of rotation axis is arbitrary.

ANGULAR VELOCITY Ω FOR LARGE-SCALE FLOWS IN EARTH'S ATMOSPHERE AND OCEANS

For large-scale flows in Earth's atmosphere and oceans (e.g., storms), the rotation of the unperturbed fluid is that due to the rotation of Earth. One might think that this means we should take as the angular velocity Ω in the Coriolis term of the Navier-Stokes equation (14.56a) Earth's angular velocity Ω_{\oplus} . Not so. The atmosphere and ocean are so thin vertically that vertical motions cannot achieve small Rossby numbers: Coriolis forces are unimportant for vertical motions. Correspondingly, the only component of Earth's angular velocity Ω_{\oplus} that is important for Coriolis forces is that which couples horizontal flows to horizontal flows: the vertical component $\Omega_* = \Omega_{\oplus} \sin(\text{latitude})$. (A similar situation occurs for a Foucault pendulum.) Thus, in the Coriolis term of the Navier-Stokes equation, we must set $\Omega = \Omega_* \mathbf{e}_z = \Omega_{\oplus} \sin(\text{latitude}) \mathbf{e}_z$, where \mathbf{e}_z is the vertical unit vector. By contrast, in the centrifugal potential $\frac{1}{2}(\Omega \times \mathbf{x})^2$, Ω remains the full angular velocity of Earth, Ω_{\oplus} —unless (as is commonly done) we absorb a portion of it into the gravitational potential as when we change rotation axes, in which case we can use $\Omega = \Omega_* \mathbf{e}_z$ in the centrifugal potential.

For water stirred in a tea cup (with parameters typical of many flows in the laboratory), $L \sim 10$ cm, $\Omega \sim V/L \sim 10$ rad s^{-1} , and $\nu \sim 10^{-6}$ m² s⁻¹ giving $Ro \sim 1$ and $Ek \sim 10^{-5}$. Coriolis and inertial forces are comparable in this case, and viscous forces again are confined to boundary layers, but the layers are much thicker relative to the bulk flow than in the atmospheric and oceanic cases.

Notice that for all these flows—atmospheric, oceanic, and tea cup—the (effective) rotation axis is vertical: Ω is vertically directed (cf. Box 14.5). This will be the case for all nearly rigidly rotating flows considered in this chapter.

14.5.2

14.5.2 Geostrophic Flows

geostrophic flow

Stationary flows $\partial \mathbf{v} / \partial t = 0$ in which both the Rossby and Ekman numbers are small (i.e., with Coriolis forces big compared to inertial and viscous forces) are called *geostrophic*, even in the laboratory. Geostrophic flow is confined to the bulk of the fluid, well away from all boundary layers, since viscosity will become important in those layers. For such geostrophic flows, the Navier-Stokes equation (14.56a) reduces to

Navier-Stokes equation for geostrophic flow

$$2\Omega \times \mathbf{v} = -\frac{\nabla P'}{\rho}. \quad (14.61)$$

This equation states that the velocity \mathbf{v} (measured in the rotating frame) is orthogonal to the body force $\nabla P'$, which drives it. Correspondingly, the streamlines are perpendicular to the gradient of the generalized pressure (i.e., they lie on surfaces of constant P').

An example of geostrophic flow is the motion of atmospheric winds around a low pressure region or *depression*. [Since $P' = P + \rho(\Phi - \frac{1}{2}\Omega^2 \varpi^2)$, when the actual pressure P goes up or down at some fixed location, P' goes up or down by the same amount, so a depression of P' is a depression of P .] The geostrophic equation (14.61) tells us that such winds must be counterclockwise in the northern hemisphere as seen from a satellite, and clockwise in the southern hemisphere. For a flow with speed $v \sim 10$ m s⁻¹ around a $\sim 1,000$ -km depression, the drop in effective pressure at the depression's center is $\Delta P' = \Delta P \sim 1$ kPa ~ 10 mbar ~ 0.01 atmosphere ~ 0.3 inches of mercury ~ 4 inches of water. Around a high-pressure region, winds circulate in the opposite direction.

It is here that we can see the power of introducing the effective pressure P' . In the case of atmospheric and oceanic flows, the true pressure P changes significantly vertically, and the pressure scale height is generally much shorter than the horizontal lengthscale. However, the effective pressure will be almost constant vertically, any small variation being responsible for minor updrafts and downdrafts, which we generally ignore when describing the wind or current flow pattern. It is the horizontal pressure gradients that are responsible for driving the flow. When pressures are quoted, they must therefore be referred to some reference equipotential surface: $\Phi - \frac{1}{2}(\Omega \times \mathbf{x})^2 = \text{const}$. The convenient one to use is the equipotential associated

FIGURE 14.15 Taylor column. A solid cylinder (white) is placed in a large container of water, which is then spun up on a turntable to a high enough angular velocity Ω that the Ekman number is small: $Ek = \nu/(\Omega L^2) \ll 1$. A slow, steady flow relative to the cylinder is then induced. [The flow's velocity \mathbf{v} in the rotating frame must be small enough to keep the Rossby number $Ro = v/(\Omega L) \ll 1$.] The water in the bottom half of the container flows around the cylinder. The water in the top half does the same as if there were an invisible cylinder present. This is an illustration of the Taylor–Proudman theorem, which states that there can be no vertical gradients in the velocity field. The effect can also be demonstrated with vertical velocity: If the cylinder is slowly made to rise, then the fluid immediately above it will also be pushed upward rather than flow past the cylinder—except at the water's surface, where the geostrophic flow breaks down. The fluid above the cylinder, which behaves as though it were rigidly attached to the cylinder, is called a *Taylor column*.

with the surface of the ocean, usually called “mean sea level.” This is the pressure that appears on a meteorological map.

14.5.3 Taylor-Proudman Theorem

14.5.3

There is a simple theorem due to Taylor and Proudman that simplifies the description of 3-dimensional, geostrophic flows. Take the curl of Eq. (14.61) and use $\nabla \cdot \mathbf{v} = 0$; the result is

$$(\boldsymbol{\Omega} \cdot \nabla) \mathbf{v} = 0. \quad (14.62)$$

Taylor-Proudman theorem for geostrophic flow

Thus, there can be no vertical gradient (gradient along $\boldsymbol{\Omega}$) of the velocity under geostrophic conditions. This result provides a good illustration of the stiffness of vortex lines: the vortex lines associated with the rigid rotation $\boldsymbol{\Omega}$ are frozen in the fluid under geostrophic conditions (where other contributions to the vorticity are small), and they refuse to be bent. The simplest demonstration of this is the Taylor column of Fig. 14.15.

It is easy to see that any vertically constant, divergence-free velocity field $\mathbf{v}(x, y)$ can be a solution to the geostrophic equation (14.61). The generalized pressure P' can be adjusted to make it a solution (see the discussion of pressure adjusting itself to whatever the flow requires, in Ex. 14.7). However, one must keep in mind that to guarantee it is also a true (approximate) solution of the full Navier-Stokes equation (14.56a), its Rossby and Ekman numbers must be $\ll 1$.

As we have seen, Ekman numbers are typically small in the bulk of a rotating fluid. However, as was true in the absence of rotation, the no-slip condition at a solid surface generates a boundary layer that can significantly influence the global velocity field, albeit indirectly.

When the Rossby number is less than one, the structure of a laminar boundary layer is dictated by a balance between viscous and Coriolis forces rather than between viscous and inertial forces. Balancing the relevant terms in Eq. (14.56a), we obtain an estimate of the boundary-layer thickness:

Ekman boundary layer and its thickness

$$\text{thickness} \sim \delta_E \equiv \sqrt{\frac{\nu}{\Omega}}. \quad (14.63)$$

In other words, the thickness of the boundary layer is that which makes the layer's Ekman number unity: $\text{Ek}(\delta_E) = \nu/(\Omega\delta_E^2) = 1$.

Consider such an “Ekman boundary layer” at the bottom or top of a layer of geostrophically flowing fluid. For the same reasons as for ordinary laminar boundary layers (Sec. 14.4), the generalized pressure P' will be nearly independent of height z through the Ekman layer, that is, it will have the value dictated by the flow just outside the layer: $\nabla P' = -2\rho\boldsymbol{\Omega} \times \mathbf{V} = \text{const}$. Here \mathbf{V} is the velocity just outside the layer (the velocity of the bulk flow), which we assume to be constant on scales $\sim\delta_E$. Since $\boldsymbol{\Omega}$ is vertical, $\nabla P'$, like \mathbf{V} , will be horizontal (i.e., they both will lie in the x - y plane). To simplify the analysis, we introduce the fluid velocity relative to the bulk flow,

$$\mathbf{w} \equiv \mathbf{v} - \mathbf{V}, \quad (14.64)$$

which goes to zero outside the boundary layer. When rewritten in terms of \mathbf{w} , the Navier-Stokes equation (14.56a) [with $\nabla P'/\rho = -2\boldsymbol{\Omega} \times \mathbf{V}$ and with $d\mathbf{v}/dt = \partial\mathbf{v}/\partial t + (\mathbf{v} \cdot \nabla)\mathbf{v} = 0$, because the flow in the thin boundary layer is steady and \mathbf{v} is horizontal and varies only vertically] takes the simple form $d^2\mathbf{w}/dz^2 = (2/\nu)\boldsymbol{\Omega} \times \mathbf{w}$. Choosing Cartesian coordinates with an upward vertical z direction, assuming $\boldsymbol{\Omega} = +\Omega\mathbf{e}_z$ (as is the case for the oceans and atmosphere in the northern hemisphere), and introducing the complex quantity

complex velocity field

$$w = w_x + iw_y \quad (14.65)$$

to describe the horizontal velocity field, we can rewrite $d^2\mathbf{w}/dz^2 = (2/\nu)\boldsymbol{\Omega} \times \mathbf{w}$ as

$$\frac{d^2w}{dz^2} = \frac{2i}{\delta_E^2} w = \left(\frac{1+i}{\delta_E}\right)^2 w. \quad (14.66)$$

Equation (14.66) must be solved subject to $w \rightarrow 0$ far from the water's boundary and some appropriate condition at the boundary.

For a first illustration of an Ekman layer, consider the effects of a wind blowing in the \mathbf{e}_x direction above a still ocean, $\mathbf{V} = 0$, and set $z = 0$ at the ocean's surface. The

FIGURE 14.16 Ekman spiral (water velocity as a function of depth) at the ocean surface, where the wind exerts a stress.

wind will exert, through a turbulent boundary layer of air, a stress $-T_{xz} > 0$ on the ocean's surface. This stress must be balanced by an equal, viscous stress $\nu\rho dw_x/dz$ at the top of the water's boundary layer, $z = 0$. Thus there must be a velocity gradient, $dw_x/dz = -T_{xz}/\nu\rho = |T_{xz}|/\nu\rho$, in the water at $z = 0$. (This replaces the no-slip boundary condition that we have when the boundary is a solid surface.) Imposing this boundary condition along with $w \rightarrow 0$ as $z \rightarrow -\infty$ (down into the ocean), we find from Eqs. (14.66) and (14.65):

$$v_x = w_x = \left(\frac{|T_{xz}|\delta_E}{\sqrt{2}\nu\rho} \right) e^{z/\delta_E} \cos(z/\delta_E - \pi/4),$$

$$v_y = w_y = \left(\frac{|T_{xz}|\delta_E}{\sqrt{2}\nu\rho} \right) e^{z/\delta_E} \sin(z/\delta_E - \pi/4), \quad (14.67)$$

for $z \leq 0$ (Fig. 14.16). As a function of depth, this velocity field has the form of a spiral—the so-called *Ekman spiral*. When Ω points toward us (as in Fig. 14.16), the spiral is clockwise and tightens as we move away from the boundary ($z = 0$ in the figure) into the bulk flow.

By integrating the mass flux $\rho\mathbf{w}$ over z , we find for the total mass flowing per unit time per unit length of the ocean's surface

$$\mathbf{F} = \rho \int_{-\infty}^0 \mathbf{w} dz = -\frac{\delta_E^2}{2\nu} |T_{xz}| \mathbf{e}_y; \quad (14.68)$$

see Fig. 14.16. Thus the wind, blowing in the \mathbf{e}_x direction, causes a net mass flow in the direction of $\mathbf{e}_x \times \Omega/\Omega = -\mathbf{e}_y$. This response (called “Ekman pumping”) may seem less paradoxical if one recalls how a gyroscope responds to applied forces.

This mechanism is responsible for the creation of *gyres* in the oceans (Ex. 14.21 and Fig. 14.18 below).

As a second illustration of an Ekman boundary layer, we consider a geostrophic flow with nonzero velocity $\mathbf{V} = V\mathbf{e}_x$ in the bulk of the fluid, and examine this flow's

wind-driven Ekman boundary layer at top of a geostrophic flow

structure of the boundary layer: Ekman spiral

Ekman pumping

gyres

FIGURE 14.17 Ekman spiral (water velocity as a function of height) in the bottom boundary layer, when the bulk flow above it moves geostrophically with speed $V\mathbf{e}_x$.

interaction with a static, solid surface at its bottom. We set $z = 0$ at the bottom, with z increasing upward, in the Ω direction. The structure of the boundary layer on the bottom is governed by the same differential equation (14.66) as at the wind-blown surface, but with altered boundary conditions. The solution is

$$\begin{aligned} v_x - V = w_x &= -V \exp(-z/\delta_E) \cos(z/\delta_E), \\ v_y = w_y &= +V \exp(-z/\delta_E) \sin(z/\delta_E). \end{aligned} \quad (14.69)$$

This solution is shown in Fig. 14.17.

Recall that we have assumed Ω points in the upward $+z$ direction, which is appropriate for the ocean and atmosphere in the northern hemisphere. If, instead, Ω points downward (as in the southern hemisphere), then the handedness of the Ekman spiral is reversed.

Ekman boundary layers are important, because they can circulate rotating fluids faster than viscous diffusion can. Suppose we have a nonrotating container (e.g., a tea cup) of radius L containing a fluid that rotates with angular velocity Ω (e.g., due to stirring; cf. Ex. 14.22). As you will see in your analysis of Ex. 14.22, the Ekman layer at the container's bottom experiences a pressure difference between the wall and the container's center given by $\Delta P \sim \rho L^2 \Omega^2$. This drives a fluid circulation in the Ekman layer, from the wall toward the center, with radial speed $V \sim \Omega L$. The circulating fluid must upwell at the bottom's center from the Ekman layer into the bulk fluid. This produces a poloidal mixing of the fluid on a timescale given by

$$t_E \sim \frac{L^3}{L\delta_E V} \sim \frac{L\delta_E}{\nu}. \quad (14.70)$$

This timescale is shorter than that for simple diffusion of vorticity, $t_v \sim L^2/\nu$, by a factor $t_E/t_v \sim \sqrt{\text{Ek}}$, which (as we have seen) can be very small. This circulation and mixing are key to the piling up of tea leaves at the bottom center of a stirred tea cup, and to the mixing of the tea or milk into the cup's hot water (Ex. 14.22).

Ekman boundary layer at bottom of a geostrophic flow

Ekman boundary layers drive circulation in rotating fluids

The circulation driven by an Ekman layer is an example of a *secondary flow*—a weakly perturbative bulk flow that is produced by interaction with a boundary. For other examples of secondary flows, see Taylor (1968).

EXERCISES

Exercise 14.21 **Example: Winds and Ocean Currents in the North Atlantic

The north Atlantic Ocean exhibits the pattern of winds and ocean currents shown in Fig. 14.18. Westerly winds blow from west to east at 40° latitude. Trade winds blow from east to west at 20° latitude. In between, around 30° latitude, is the Sargasso Sea: a 1.5-m-high gyre (raised hump of water). The gyre is created by ocean surface currents, extending down to a depth of only about 30 m, that flow northward from the trade-wind region and southward from the westerly wind region (upper inset in Fig. 14.18). A deep ocean current, extending from the surface down to near the bottom, circulates around the Sargasso Sea gyre in a clockwise manner. This current goes under different names in different regions of the ocean: Gulf Stream, West Wind Drift, Canaries Current, and North Equatorial Current. Explain both qualitatively and semiquantitatively (in terms of order of magnitude) how the winds are ultimately responsible for all these features of the ocean. More specifically, do the following.

- (a) Explain the surface currents in terms of an Ekman layer at the top of the ocean, with thickness δ_E about 30 m. From this measured δ_E compute the kinematic viscosity ν in the boundary layer. Your result, $\nu \sim 0.03 \text{ m}^2 \text{ s}^{-1}$, is far larger than

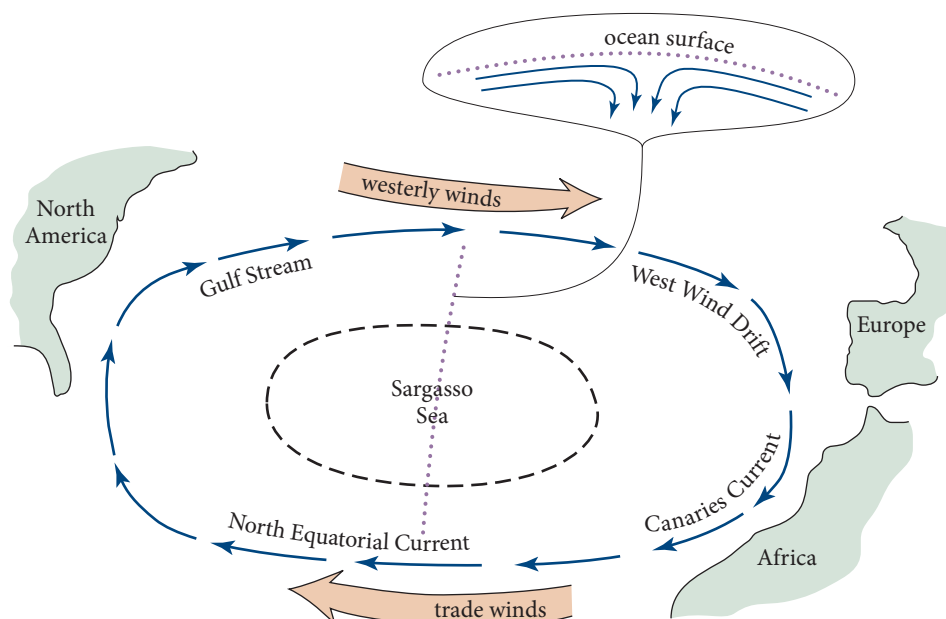

FIGURE 14.18 Winds and ocean currents in the north Atlantic. The upper inset shows the surface currents, along the dotted north-south line, that produce the Sargasso Sea gyre.

the molecular viscosity of water, $\sim 10^{-6} \text{ m}^2 \text{ s}^{-1}$ (Table 13.2). The reason is that the boundary layer is turbulent, and its eddies produce this large viscosity (see Sec. 15.4.2).

- (b) Explain why the height of the gyre that the surface currents produce in the Sargasso Sea is about 1.5 m.
- (c) Explain the deep ocean current (Gulf Stream, etc.) in terms of a geostrophic flow, and estimate the speed of this current. This current, like circulation in a tea cup, is an example of a “secondary flow.”
- (d) If there were no continents on Earth, but only an ocean of uniform depth, what would be the flow pattern of this deep current—its directions of motion at various locations around Earth, and its speeds? The continents (North America, Europe, and Africa) must be responsible for the deviation of the actual current (Gulf Stream, etc.) from this continent-free flow pattern. How do you think the continents give rise to the altered flow pattern?

Exercise 14.22 ***Example: Circulation in a Tea Cup*

Place tea leaves and water in a tea cup, glass, or other larger container. Stir the water until it is rotating uniformly, and then stand back and watch the motion of the water and leaves. Notice that the tea leaves tend to pile up at the cup’s center. An Ekman boundary layer on the bottom of the cup is responsible for this phenomenon. In this exercise you explore the origin and consequences of this Ekman layer.

- (a) Evaluate the pressure distribution $P(\varpi, z)$ in the bulk flow (outside all boundary layers), assuming that it rotates rigidly. (Here z is height and ϖ is distance from the water’s rotation axis.) Perform your evaluation in the water’s rotating reference frame. From this $P(\varpi, z)$ deduce the shape of the top surface of the water. Compare your deduced shape with the actual shape in your experiment.
- (b) Estimate the thickness of the Ekman layer at the bottom of your container. It is very thin. Show, using the Ekman spiral diagram (Fig. 14.17), that the water in this Ekman layer flows inward toward the container’s center, causing the tea leaves to pile up at the center. Estimate the radial speed of this Ekman-layer flow and the mass flux that it carries.
- (c) To get a simple physical understanding of this inward flow, examine the radial gradient $\partial P / \partial \varpi$ of the pressure P in the bulk flow just above the Ekman layer. Explain why $\partial P / \partial \varpi$ in the Ekman layer will be the same as in the rigidly rotating flow above it. Then apply force balance in an inertial frame to deduce that the water in the Ekman layer will be accelerated inward toward the center.
- (d) Using geostrophic-flow arguments, deduce the fate of the boundary-layer water after it reaches the center of the container’s bottom. Where does it go? What is the large-scale circulation pattern that results from the “driving force” of the Ekman layer’s mass flux? What is the Rossby number for this large-scale circulation

pattern? How and where does water from the bulk, nearly rigidly rotating flow, enter the bottom boundary layer so as to be swept inward toward the center?

- (e) Explain how this large-scale circulation pattern can mix much of the water through the boundary layer in the time t_E of Eq. (14.70). What is the value of this t_E for the water in your container? Explain why this, then, must also be the time for the angular velocity of the bulk flow to slow substantially. Compare your computed value of t_E with the observed slow-down time for the water in your container.

Exercise 14.23 ***Problem: Water down a Drain in Northern and Southern Hemispheres*

One often hears the claim that water in a bathtub or basin swirls down a drain clockwise in the northern hemisphere and counterclockwise in the southern hemisphere. In fact, on YouTube you are likely to find video demonstrations of this (e.g., by searching on “water down drain at equator”). Show that for Earth-rotation centrifugal forces to produce this effect, it is necessary that the water in the basin initially be moving with a speed smaller than

$$v_{\max} \sim a\Omega_* \sim a\Omega_{\oplus} \frac{\ell}{R_{\oplus}} \sim \frac{30 \text{ cm}}{\text{yr}} \left(\frac{a}{1 \text{ m}} \right) \left(\frac{\ell}{1 \text{ km}} \right). \quad (14.71)$$

Here Ω_{\oplus} is Earth’s rotational angular velocity, Ω_* is its vertical component (Box 14.5), R_{\oplus} is Earth’s radius, a is the radius of the basin, and ℓ is the distance of the basin from the equator. Even for a basin in Europe or North America, this maximum speed is $\sim 3 \text{ mm min}^{-1}$ for a 1-m-diameter basin—exceedingly difficult to achieve. Therefore, the residual initial motion of the water in any such basin will control the direction in which the water swirls down the drain. There is effectively no difference between northern and southern hemispheres.

Exercise 14.24 ***Example: Water down Drain: Experiment*

- (a) In a shower or bathtub with the drain somewhere near the center, not the wall, set water rotating so a whirlpool forms over the drain. Perform an experiment to see where the water going down the drain comes from: the surface of the water, its bulk, or its bottom. For example, you could sprinkle baby powder on top of the water, near the whirlpool, and measure how fast the powder is pulled inward and down the drain; put something neutrally buoyant in the bulk and watch its motion; and put sand on the bottom of the shower near the whirlpool and measure how fast the sand is pulled inward and down the drain.
- (b) Explain the result of your experiment in part (a). How is it related to the tea cup problem, Ex. 14.22?
- (c) Compute the shape of the surface of the water near and in the whirlpool.

14.6 Instabilities of Shear Flows—Billow Clouds and Turbulence in the Stratosphere T2

Kelvin-Helmholtz instability

Here we explore the stability of a variety of shear flows. We begin with the simplest case of two incompressible fluids, one above the other, that move with different uniform speeds, when gravity is negligible. Such a flow has a delta-function spike of vorticity at the interface between the fluids, and, as we shall see, the interface is always unstable against growth of so-called *internal waves*. This is the *Kelvin-Helmholtz instability*. We then explore the ability of gravity to suppress this instability. If the densities of the two fluids are nearly the same, there is no suppression, which is why the Kelvin-Helmholtz instability is seen in a variety of places in Earth's atmosphere and oceans. If the densities are substantially different, then gravity easily suppresses the instability, unless the two flow speeds are very different. Finally, we allow the density and horizontal velocity to change continuously in the vertical direction (e.g., in Earth's stratosphere), and for such a flow we deduce the *Richardson criterion for instability*, which is often satisfied in the stratosphere and leads to turbulence. Along the way we briefly visit several other instabilities that occur in stratified fluids.

14.6.1

14.6.1 Discontinuous Flow: Kelvin-Helmholtz Instability T2

A particularly interesting and simple type of vorticity distribution is one where the vorticity is confined to a thin, plane interface between two immiscible fluids. In other words, one fluid is in uniform motion relative to the other. This type of flow arises quite frequently; for example, when the wind blows over the ocean or when smoke from a smokestack discharges into the atmosphere (a flow that is locally but not globally planar).

We analyze the stability of such flows, initially without gravity (this subsection), then with gravity present (next subsection). Our analysis provides another illustration of the behavior of vorticity and an introduction to techniques that are commonly used to analyze fluid instabilities.

We restrict attention to the simplest version of this flow: an equilibrium with a fluid of density ρ_+ moving horizontally with speed V above a second fluid, which is at rest, with density ρ_- . Let x be a Cartesian coordinate measured along the planar interface in the direction of the flow, and let y be measured perpendicular to it. The equilibrium contains a sheet of vorticity lying in the plane $y = 0$, across which the velocity changes discontinuously. Now, this discontinuity ought to be treated as a boundary layer, with a thickness determined by the viscosity. However, in this problem we analyze disturbances with lengthscales much greater than the thickness of the boundary layer, and so we can ignore it. As a corollary, we can also ignore viscous stresses in the body of the flow. In addition, we specialize to very subsonic speeds, for which the flow can be treated as incompressible; we also ignore the effects of surface tension as well as gravity.

A full description of this flow requires solving the full equations of fluid dynamics, which are quite nonlinear and, as it turns out, for this problem can only be solved numerically. However, we can make progress analytically on an important subproblem. This is the issue of whether this equilibrium flow is stable to small perturbations, and if unstable, the nature of the growing modes. To answer this question, we linearize the fluid equations in the amplitude of the perturbations.

We consider a small vertical perturbation $\delta y = \zeta(x, t)$ in the location of the interface (see Fig. 14.19a below). We denote the associated perturbations to the pressure and velocity by δP and $\delta \mathbf{v}$. That is, we write

$$P(\mathbf{x}, t) = P_0 + \delta P(\mathbf{x}, t), \quad \mathbf{v} = V H(y) \mathbf{e}_x + \delta \mathbf{v}(\mathbf{x}, t), \quad (14.72)$$

where P_0 is the constant pressure in the equilibrium flow about which we are perturbing, V is the constant speed of the flow above the interface, and $H(y)$ is the Heaviside step function (1 for $y > 0$ and 0 for $y < 0$). We substitute these $P(\mathbf{x}, t)$ and $\mathbf{v}(\mathbf{x}, t)$ into the governing equations: the incompressibility relation,

$$\nabla \cdot \mathbf{v} = 0, \quad (14.73)$$

and the viscosity-free Navier-Stokes equation (i.e., the Euler equation),

$$\frac{d\mathbf{v}}{dt} = \frac{-\nabla P}{\rho}. \quad (14.74)$$

We then subtract off the equations satisfied by the equilibrium quantities to obtain, for the perturbed variables,

$$\nabla \cdot \delta \mathbf{v} = 0, \quad (14.75)$$

$$\frac{d\delta \mathbf{v}}{dt} = -\frac{\nabla \delta P}{\rho}. \quad (14.76)$$

Combining these two equations, we find, as for Stokes flow (Sec. 14.3.2), that the pressure satisfies Laplace's equation:

$$\nabla^2 \delta P = 0. \quad (14.77)$$

We now follow the procedure used in Sec. 12.4.2 when treating Rayleigh waves on the surface of an elastic medium: we seek an internal wave mode, in which the perturbed quantities vary $\propto \exp[i(kx - \omega t)]f(y)$, with $f(y)$ dying out away from the interface. From Laplace's equation (14.77), we infer an exponential falloff with $|y|$:

$$\delta P = \delta P_0 e^{-k|y| + i(kx - \omega t)}, \quad (14.78)$$

where δP_0 is a constant.

Our next step is to substitute this δP into the perturbed Euler equation (14.76) to obtain

$$\delta v_y = \frac{ik\delta P}{(\omega - kV)\rho_+} \quad \text{for } y > 0, \quad \delta v_y = \frac{-ik\delta P}{\omega\rho_-} \quad \text{for } y < 0. \quad (14.79)$$

We must impose two boundary conditions at the interface between the fluids: continuity of the vertical displacement ξ of the interface (the tangential displacement need not be continuous, since we are examining scales large compared to the boundary layer), and continuity of the pressure P across the interface. [See Eq. (12.44) and associated discussion for the analogous boundary conditions at a discontinuity in an elastic medium.] The vertical interface displacement ξ is related to the velocity perturbation by $d\xi/dt = \delta v_y(y=0)$, which implies that

$$\begin{aligned}\xi &= \frac{i\delta v_y}{(\omega - kV)} \quad \text{at } y = 0_+ \quad (\text{immediately above the interface}), \\ \xi &= \frac{i\delta v_y}{\omega} \quad \text{at } y = 0_- \quad (\text{immediately below the interface}).\end{aligned}\quad (14.80)$$

Then, by virtue of Eqs. (14.78), (14.80), and (14.79), the continuity of pressure and vertical displacement at $y = 0$ imply that

$$\rho_+(\omega - kV)^2 + \rho_-\omega^2 = 0, \quad (14.81)$$

where ρ_+ and ρ_- are the densities of the fluid above and below the interface, respectively. Solving for frequency ω as a function of horizontal wave number k , we obtain the following dispersion relation for internal wave modes localized at the interface, which are also called *linear Kelvin-Helmholtz modes*:

dispersion relation for linear Kelvin-Helmholtz modes at an interface

$$\omega = kV \left(\frac{\rho_+ \pm i(\rho_+\rho_-)^{1/2}}{\rho_+ + \rho_-} \right). \quad (14.82)$$

This dispersion relation can be used to describe both a sinusoidal perturbation whose amplitude grows in time, and a time-independent perturbation that grows spatially:

TEMPORAL GROWTH

Suppose that we create some small, localized disturbance at time $t = 0$. We can Fourier analyze the disturbance in space, and—as we have linearized the problem—can consider the temporal evolution of each Fourier component separately. What we ought to do is solve the initial value problem carefully, taking account of the initial conditions. However, when there are growing modes, we can usually infer the long-term behavior by ignoring the transients and just considering the growing solutions. In our case, we infer from Eqs. (14.78)–(14.80) and the dispersion relation (14.82) that a mode with spatial frequency k must grow as

temporal growth of mode with wavelength $2\pi/k$

$$\delta P, \xi \propto \exp \left[\left(\frac{kV(\rho_+\rho_-)^{1/2}}{(\rho_+ + \rho_-)} \right) t + ik \left(x - V \frac{\rho_+}{\rho_+ + \rho_-} t \right) \right]. \quad (14.83)$$

Thus, this mode grows exponentially with time (Fig. 14.19a). Note that the mode is nondispersive, and if the two densities are equal, it e -folds in $1/(2\pi)$ times a period. This means that the fastest modes to grow are those with the shortest periods and hence the shortest wavelengths. (However, the wavelength must not approach the

FIGURE 14.19 Kelvin-Helmholtz instability. (a) Temporally growing mode. (b) Spatially growing mode.

thickness of the boundary layer and thereby compromise our assumption that the effects of viscosity are negligible.)

We can understand this growing mode somewhat better by transforming to the center-of-momentum frame, which moves with speed $\rho_+ V / (\rho_+ + \rho_-)$ relative to the frame in which the lower fluid is at rest. In this (primed) frame, the velocity of the upper fluid is $V' = \rho_- V / (\rho_+ + \rho_-)$, and so the perturbations evolve as

$$\delta P, \zeta \propto \exp[kV'(\rho_+/\rho_-)^{1/2}t] \cos(kx'). \quad (14.84)$$

In this frame the wave is purely growing, whereas in our original frame it oscillated with time as it grew.

SPATIAL GROWTH

An alternative type of mode is one in which a small perturbation is excited temporally at some point where the shear layer begins (Fig. 14.19b). In this case we regard the frequency ω as real and look for the mode with negative imaginary k corresponding to spatial growth. Using Eq. (14.82), we obtain

$$k = \frac{\omega}{V} \left[1 - i \left(\frac{\rho_-}{\rho_+} \right)^{1/2} \right]. \quad (14.85)$$

The mode therefore grows exponentially with distance from the point of excitation.

PHYSICAL INTERPRETATION OF THE INSTABILITY

We have performed a normal mode analysis of a particular flow and discovered that there are unstable internal wave modes. However much we calculate the form of the growing modes, though, we cannot be said to understand the instability until we can explain it physically. In the case of this Kelvin-Helmholtz instability, this task is simple.

The flow pattern is shown schematically in Fig. 14.20. The upper fluid will have to move faster when passing over a crest in the water wave, because the cross sectional

spatial growth of mode with angular frequency ω

physical origin of Kelvin-Helmholtz instability

FIGURE 14.20 Physical explanation for the Kelvin-Helmholtz instability.

area of a flow tube diminishes and the flux of fluid must be conserved. By Bernoulli's theorem, the upper pressure will be lower than ambient at this point, and so the crest will rise even higher. Conversely, in the trough of the wave the upper fluid will travel slower, and its pressure will increase. The pressure differential will push the trough downward, making it grow.

Equivalently, we can regard the boundary layer as a plane containing parallel vortex lines that interact with one another, much like magnetic field lines exert pressure on one another. When the vortex lines all lie strictly in a plane, they are in equilibrium, because the repulsive force exerted by one on its neighbor is balanced by an opposite force exerted by the opposite neighbor. However, when this equilibrium is disturbed, the forces become unbalanced and the vortex sheet effectively buckles.

More generally, when there is a large amount of relative kinetic energy available in a high-Reynolds-number flow, there exists the possibility of unstable modes that can tap this energy and convert it into a spectrum of growing modes. These modes can then interact nonlinearly to create fluid turbulence, which ultimately is dissipated as heat. However, the availability of free kinetic energy does not necessarily imply that the flow is unstable; sometimes it is stable. Instability must be demonstrated—often a very difficult task.

14.6.2 Discontinuous Flow with Gravity T2

What happens to this Kelvin-Helmholtz instability if we turn on gravity? To learn the answer, we insert a downward gravitational acceleration \mathbf{g} into the above analysis. The result (Ex. 14.25) is the following modification of the dispersion relation (14.82):

$$\frac{\omega}{k} = \frac{\rho_+ V}{\rho_+ + \rho_-} \pm \left[\frac{g}{k} \left(\frac{\rho_- - \rho_+}{\rho_+ + \rho_-} \right) - \frac{\rho_+ \rho_-}{(\rho_+ + \rho_-)^2} V^2 \right]^{1/2}. \quad (14.86)$$

gravity suppresses Kelvin-Helmholtz instability

If the lower fluid is sufficiently more dense than the upper fluid (ρ_- sufficiently bigger than ρ_+), then gravity g will change the sign of the quantity inside the square root, making ω/k real, which means the Kelvin-Helmholtz instability is suppressed. In other words, *for the flow to be Kelvin-Helmholtz unstable in the presence of gravity, the two fluids must have nearly the same density:*

FIGURE 14.21 Billow clouds above San Francisco. The cloud structure is generated by the Kelvin-Helmholtz instability. These types of billow clouds may have inspired the swirls in Vincent van Gogh's famous painting "Starry Night." Courtesy of Science Source.

$$\frac{\rho_- - \rho_+}{\rho_+ + \rho_-} < \frac{\rho_+ \rho_-}{(\rho_+ + \rho_-)^2} \frac{kV^2}{g}. \quad (14.87)$$

This is the case for many interfaces in Nature, which is why the Kelvin-Helmholtz instability is often seen. An example is the interface between a water-vapor-laden layer of air under a fast-moving, drier layer. The result is the so-called "billow clouds" shown in Fig. 14.21. Other examples are flow interfaces in the ocean and the edges of dark smoke pouring out of a smoke stack.

As another application of the dispersion relation (14.86), consider the excitation of ocean waves by a laminar-flowing wind. In this case, the "+" fluid is air, and the "-" fluid is water, so the densities are very different: $\rho_+/\rho_- \simeq 0.001$. The instability criterion (14.87) tells us the minimum wind velocity V required to make the waves grow:

$$V_{\min} \simeq \left(\frac{g \rho_-}{k \rho_+} \right)^{1/2} \simeq 450 \text{ km h}^{-1} \sqrt{\lambda/10 \text{ m}}, \quad (14.88)$$

where $\lambda = 2\pi/k$ is the waves' wavelength.

Obviously, this answer is physically wrong. Water waves are easily driven by winds that are far slower than this. Evidently, some other mechanism of interaction between wind and water must drive the waves much more strongly. Observations of wind over water reveal the answer: The winds near the sea's surface are typically quite turbulent (Chap. 15), not laminar. The randomly fluctuating pressures in a turbulent wind are far more effective than the smoothly varying pressure of a laminar wind in driving ocean waves. For two complementary models of this, see Phillips (1957) and Miles (1993).

As another, very simple application of the dispersion relation (14.86), set the speed V of the upper fluid to zero. In this case, the interface is unstable if and only if the upper

Rayleigh-Taylor instability

T2

fluid has higher density than the lower fluid: $\rho_+ > \rho_-$. This is called the *Rayleigh-Taylor instability* for incompressible fluids.

EXERCISES

Exercise 14.25 *Problem: Discontinuous Flow with Gravity* T2

Insert gravity into the analysis of the Kelvin-Helmholtz instability (with the uniform gravitational acceleration \mathbf{g} pointing perpendicularly to the fluid interface, from the upper “+” fluid to the lower “-” fluid). Thereby derive the dispersion relation (14.86).

14.6.3

14.6.3 Smoothly Stratified Flows: Rayleigh and Richardson Criteria for Instability T2

Sometimes one can diagnose a fluid instability using simple physical arguments rather than detailed mathematical analysis. We conclude this chapter with two examples.

First, we consider *rotating Couette flow*: the azimuthal flow of an incompressible, effectively inviscid fluid, rotating axially between two coaxial cylinders (Fig. 14.22).

We explore the stability of this flow to purely axisymmetric perturbations by using a thought experiment in which we interchange two fluid rings. As there are no azimuthal forces (no forces in the ϕ direction), the interchange will occur at constant angular momentum per unit mass. Suppose that the ring that moves outward in radius ϖ has lower specific angular momentum j than the surroundings into which it has moved; then it will have less centrifugal force per unit mass j^2/ϖ^3 than its surroundings and will thus experience a restoring force that drives it back to its original position. Conversely, if the surroundings’ angular momentum per unit mass decreases outward, then the displaced ring will continue to expand. We conclude on this basis that *Couette and similar flows are unstable when the angular momentum per unit mass decreases outward*. This is known as the *Rayleigh criterion*. We return to Couette flow in Sec. 15.6.1.

Compact stellar objects (black holes, neutron stars, and white dwarfs) are sometimes surrounded by orbiting *accretion disks* of gas (Exs. 26.17 and 26.18). The gas in these disks orbits with its angular velocity approximately dictated by Kepler’s laws. Therefore, the specific angular momentum of the gas increases radially outward, approximately proportional to the square root of the orbital radius. Consequently, accretion disks are stable to this type of instability.

For our second example of a simple physical diagnosis of instability, consider the situation analyzed in Ex. 14.25 (Kelvin-Helmholtz instability with gravity present) but with the density and velocity changing continuously instead of discontinuously, as one moves upward. More specifically, focus on Earth’s stratosphere, which extends from ~ 10 km height to ~ 40 km. The density in the stratosphere decreases upward faster than if the stratosphere were isentropic. This means that, when a fluid element moves upward adiabatically, its pressure-induced density reduction is smaller than the density decrease in its surroundings. Since it is now more dense than its surroundings, the downward pull of gravity on the fluid element will exceed the upward buoyant

rotating Couette flow

Rayleigh criterion for instability of rotating flows

stability of a superadiabatic density gradient

FIGURE 14.22 Rotating Couette flow.

force, so the fluid element will be pulled back down. Therefore, the stratosphere is stably stratified. (We shall return to this phenomenon, in the context of stars, in Sec. 18.5.)

However, it may be possible for the stratosphere to tap the relative kinetic energy in its horizontal winds, so as to mix the air vertically. Consider the pedagogical example of two thin stream tubes of horizontally flowing air in the stratosphere, separated vertically by a distance $\delta\ell$ large compared to their thicknesses. The speed of the upper stream will exceed that of the lower stream by $\delta V = V'\delta\ell$, where $V' = dV/dz$ is the velocity gradient. In the center of velocity frame, the streams each have speed $\delta V/2$, and they differ in density by $\delta\rho = |\rho'\delta\ell|$. To interchange these streams requires doing work per unit mass⁷ $\delta W = g[\delta\rho/(2\rho)]\delta\ell$ against gravity (where the factor 2 comes from the fact that there are two unit masses involved in the interchange, one going up and the other coming down). This work can be supplied by the streams' kinetic energy, if the available kinetic energy per unit mass, $\delta E_k = (\delta V/2)^2/2$, exceeds the required work. A *necessary condition for instability* is then that

$$\delta E_k = (\delta V)^2/8 > \delta W = g|\rho'/(2\rho)|\delta\ell^2, \quad (14.89)$$

or

$$\text{Ri} = \frac{|\rho'|g}{\rho V'^2} < \frac{1}{4}, \quad (14.90)$$

Richardson criterion for instability of a stratified shear flow

7. Here, for simplicity we idealize the streams' densities as not changing when they move vertically—an idealization that makes gravity be more effective at resisting the instability. In the stratosphere, where the temperature is constant (Fig. 13.2) so the density drops vertically much faster than if it were isentropic, this idealization is pretty good.

where $V' = dV/dz$ is the velocity gradient. This is known as the *Richardson criterion for instability*, and Ri is the *Richardson number*. Under a wide variety of circumstances this criterion turns out to be sufficient for instability.

The density scale height in the stratosphere is $\rho/|\rho'| \sim 10$ km. Therefore the maximum velocity gradient allowed by the Richardson criterion is

$$V' \lesssim 60 \frac{\text{m s}^{-1}}{\text{km}}. \quad (14.91)$$

Larger velocity gradients are rapidly disrupted by instabilities. This instability is responsible for much of the clear air turbulence encountered by airplanes, and it is to a discussion of turbulence that we turn in the next chapter.

Bibliographic Note

Vorticity is so fundamental to fluid mechanics that it and its applications are treated in detail in all fluid-dynamics textbooks. Among those with a physicist's perspective, we particularly like Acheson (1990) and Lautrup (2005) at an elementary level, and Landau and Lifshitz (1959), Lighthill (1986), and Batchelor (2000) at a more advanced level. Tritton (1987) is especially good for physical insight. Panton (2005) is almost encyclopedic and nicely bridges the viewpoints of physicists and engineers. For an engineering emphasis, we like Munson, Young, and Okiishi (2006) and Potter, Wiggert, and Ramadan (2012); see also the more advanced text on viscous flow, White (2006). For the viewpoint of an applied mathematician, see Majda and Bertozzi (2002).

To build up physical intuition, we recommend Tritton (1987) and the movies listed in Box 14.2. For a textbook treatment of rotating flows and weak perturbations of them, we recommend Greenspan (1973). For geophysical applications at an elementary level, we like Cushman-Roisin and Beckers (2011), and for a more mathematical treatment Pedlosky (1987). A more encyclopedic treatment at an elementary level (including some discussion of simulations) can be found in Gill (1982) and Vallis (2006).

Turbulence

Big whirls have little whirls, which feed on their velocity.

Little whirls have lesser whirls, and so on to viscosity.

LEWIS RICHARDSON (1922)

15.1 Overview

15.1

In Sec. 13.7.6, we derived the Poiseuille formula for the flow of a viscous fluid down a pipe by assuming that the flow is laminar (i.e., that it has a velocity parallel to the pipe wall). We showed how balancing the stress across a cylindrical surface led to a parabolic velocity profile and a rate of flow proportional to the fourth power of the pipe diameter d . We also defined the Reynolds number; for pipe flow it is $Re_d \equiv \bar{v}d/\nu$, where \bar{v} is the mean speed in the pipe, and ν is the kinematic viscosity. Now, it turns out experimentally that the pipe flow only remains laminar up to a critical Reynolds number that has a value in the range $\sim 10^3$ – 10^5 , depending on the smoothness of the pipe's entrance and roughness of its walls. If the pressure gradient is increased further (and thence the mean speed \bar{v} and Reynolds number Re_d are increased), then the velocity field in the pipe becomes irregular both temporally and spatially, a condition known as *turbulence*.

Turbulence is common in high-Reynolds-number flows. Much of our experience with fluids involves air or water, for which the kinematic viscosities are $\sim 10^{-5}$ and $10^{-6} \text{ m}^2 \text{ s}^{-1}$, respectively. For a typical everyday flow with a characteristic speed of $v \sim 10 \text{ m s}^{-1}$ and a characteristic length of $d \sim 1 \text{ m}$, the Reynolds number is huge: $Re = vd/\nu \sim 10^6 - 10^7$. It is therefore not surprising that we see turbulent flows all around us. Smoke in a smokestack, a cumulus cloud, and the wake of a ship are examples.

In Sec. 15.2 we illustrate the phenomenology of the transition to turbulence as the Reynolds number increases using a particularly simple example: the flow of a fluid past a circular cylinder oriented perpendicular to the flow's incoming velocity. We shall see how the flow pattern is dictated by the Reynolds number, and how the velocity changes from steady creeping flow at low Re to fully developed turbulence at high Re .

BOX 15.1. READERS' GUIDE

- This chapter relies heavily on Chaps. 13 and 14.
- The remaining chapters on fluid mechanics and magnetohydrodynamics (Chaps. 16–19) do not rely significantly on this chapter, nor do any of the remaining chapters in this book.

What is turbulence? Fluid dynamicists can recognize it, but they have a hard time defining it precisely¹ and an even harder time describing it quantitatively.² So typically for a definition they rely on empirical, qualitative descriptions of its physical properties (Sec. 15.3). Closely related to this description is the crucial role of vorticity in driving turbulent energy from large scales to small (Sec. 15.3.1).

At first glance, a quantitative description of turbulence appears straightforward. Decompose the velocity field into Fourier components just as is done for the electromagnetic field when analyzing electromagnetic radiation. Then recognize that the equations of fluid dynamics are nonlinear, so there will be coupling between different modes (akin to wave-wave coupling between optical modes in a nonlinear crystal, discussed in Chap. 10). Analyze that coupling perturbatively. The resulting *weak-turbulence formalism* is sketched in Secs. 15.4.1 and 15.4.2 and in Ex. 15.5.³

However, most turbulent flows come under the heading of *fully developed* or *strong turbulence* and cannot be well described by weak-turbulence models. Part of the problem is that the $(\mathbf{v} \cdot \nabla)\mathbf{v}$ term in the Navier-Stokes equation is a strong nonlinearity, not a weak coupling between linear modes. As a consequence, eddies of size ℓ persist for typically no more than one turnover timescale $\sim \ell/v$ before they are broken up, and so they do not behave like weakly coupled normal modes.

In the absence of a decent quantitative theory of strong turbulence, fluid dynamicists sometimes simply push the weak-turbulence formalism into the strong-turbulence regime and use it there to gain qualitative or semiquantitative insights (e.g., Fig. 15.7 below and associated discussion in the text). A simple alternative (which we explore in Sec. 15.4.3 in the context of wakes and jets and in Sec. 15.5 for turbulent boundary layers) is intuitive, qualitative, and semiquantitative approaches to the *physical* description of turbulence. We emphasize the adjective “physical,” because our goal is to start to comprehend the underlying physical character of turbulence, going beyond empirical descriptions of its consequences on the one hand and uninstruc-

1. The analogy to Justice Potter Stewart’s definition of pornography should be resisted.
2. Werner Heisenberg’s dissertation was “On the Stability and Turbulence of Fluid Flow.” He was disappointed with his progress and was glad to change to a more tractable problem.
3. Another weak-turbulence formalism that is developed along similar lines is the *quasilinear* theory of nonlinear plasma interactions, which we discuss in Chap. 23.

tive mathematical expansions on the other. Much modern physics has this character. An important feature that we meet in Sec. 15.4.3, when we discuss wakes and jets, is *entrainment*. This leads to irregular boundaries of turbulent flows caused by giant eddies and to dramatic time dependence, including *intermittency*.

One triumph of this approach (Sec. 15.4.4) is the Kolmogorov analysis of the shape of the time-averaged turbulent energy spectrum (the turbulent energy per unit wave number as a function of wave number) in a stationary turbulent flow. This spectrum has been verified experimentally under many different conditions. The arguments used to justify it are characteristic of many semiempirical derivations of scaling relations that find confident practical application in the world of engineering.

In the context of turbulent boundary layers, our physical approach will reveal semiquantitatively the structures of such boundary layers (Sec. 15.5.1), and it will explain why turbulent boundary layers generally exert more shear stress on a surface than do laminar boundary layers, but nevertheless usually produce less total drag on airplane wings, baseballs, etc. (Sec. 15.5.2).

Whether or not a flow becomes turbulent can have a major influence on how fast chemical reactions occur in liquids and gases. In Sec. 15.5.3, we briefly discuss how turbulence can arise through instability of a laminar boundary layer.

One can gain additional insight into turbulence by a technique that is often useful when struggling to understand complex physical phenomena: Replace the system being studied by a highly idealized model system that is much simpler than the original one, both conceptually and mathematically, but that retains at least one central feature of the original system. Then analyze the model system completely, with the hope that the quantitative insight so gained will be useful in understanding the original problem. Since the 1970s, new insights into turbulence have come from studying idealized dynamical systems that have very few degrees of freedom but have the same kinds of nonlinearities as produce turbulence in fluids (e.g., Ott, 1982; Ott, 1993). We examine several such low-dimensional dynamical systems and the insights they give in Sec. 15.6.

The most useful of those insights deal with the onset of weak turbulence and the observation that it seems to have much in common with the onset of chaos (irregular and unpredictable dynamical behavior) in a wide variety of other dynamical systems. A great discovery of modern classical physics/mathematics has been that there exist organizational principles that govern the behavior of these seemingly quite different chaotic physical systems.

In parallel with studying this chapter, to build up physical intuition the reader is urged to watch movies and study photographs that deal with turbulence; see Box 15.2.

15.2 The Transition to Turbulence—Flow Past a Cylinder

15.2

We illustrate qualitatively how a flow (and especially its transition to turbulence) depends on its Reynolds number by considering a specific problem: the flow of a

BOX 15.2. MOVIES AND PHOTOGRAPHS ON TURBULENCE

The most relevant movies for this chapter are:

- Stewart (1968)—demonstrates key features of turbulent flows.
- Rouse (1963d)—exhibits the transition from laminar to turbulent flow.

Also useful are photographs of turbulence (e.g., in Van Dyke, 1982).

uniformly moving fluid past a cylinder oriented transversely to the flow's incoming velocity (Fig. 15.1). We assume that the flow velocity is small compared with the speed of sound, so the effects of compressibility can be ignored. Let the cylinder diameter be d , and choose this as the characteristic length in the problem. Similarly, let the velocity far upstream be V and choose this as the characteristic velocity, so the Reynolds number is⁴

$$\text{Re}_d = \frac{Vd}{\nu}. \quad (15.1)$$

Initially, we assume that the flow is stationary (no turbulence) as well as incompressible, and the effects of gravity are negligible. Then the equations governing the flow are incompressibility,

$$\nabla \cdot \mathbf{v} = 0, \quad (15.2a)$$

and the time-independent Navier-Stokes equation (13.69) with $\partial \mathbf{v} / \partial t = 0$:

$$(\mathbf{v} \cdot \nabla) \mathbf{v} = -\frac{\nabla P}{\rho} + \nu \nabla^2 \mathbf{v}. \quad (15.2b)$$

These four equations (one for incompressibility, three for the components of Navier-Stokes) can be solved for the pressure and the three components of velocity subject to the velocity vanishing on the surface of the cylinder and becoming uniform far upstream.

From the parameters of the flow (the cylinder's diameter d ; the fluid's incoming velocity V , its density ρ , and its kinematic viscosity ν) we can construct only one dimensionless number, the Reynolds number $\text{Re}_d = Vd/\nu$. (If the flow speed were high enough that incompressibility fails, then the sound speed c_s would also be a relevant parameter, and a second dimensionless number could be formed: the Mach number, $M = V/c_s$; Chap. 17.) With Re_d the only dimensionless number, we are

4. The subscript d is just a reminder that in this instance we have chosen the diameter as the characteristic lengthscale; for other applications, the length of the cylinder might be more relevant.

Reynolds number

equations governing stationary, unperturbed flows

FIGURE 15.1 Schematic depiction of flow past a cylinder for steadily increasing values of the Reynolds number $Re_d = Vd/\nu$ as labeled. There are many photographs, drawings, and simulations of this flow on the web, perhaps best found by doing a search on “Kármán vortex street.”

guaranteed on dimensional grounds that the solution to the flow equations can be expressed as

$$\mathbf{v}/V = \mathbf{U}(\mathbf{x}/d, Re_d). \quad (15.3)$$

dimensional analysis gives functional form of flow

Here \mathbf{U} is a dimensionless function of the dimensionless \mathbf{x}/d , and it can take wildly different forms, depending on the value of the Reynolds number Re_d (cf. Fig. 15.1, which we discuss below).

The functional form of \mathbf{v} [Eq. (15.3)] has important implications. If we compute the flow for specific values of the upstream velocity V , the cylinder’s diameter d , and the kinematic viscosity ν and then double V and d and quadruple ν so that Re_d is unchanged, then the new solution will be *similar* to the original one. It can be produced from the original by rescaling the flow velocity to the new upstream velocity and the distance to the new cylinder diameter. [For this reason, Eq. (15.3) is sometimes called a *scaling relation*.] By contrast, if we had only doubled the kinematic

scaling relation

viscosity, the Reynolds number would have also doubled, and we could be dealing with a qualitatively different flow.

When discussing flow past the cylinder, a useful concept is the *stagnation pressure* in the upstream flow. This is the pressure the fluid would have, according to the Bernoulli principle ($v^2/2 + \int dP/\rho = \text{const}$), if it were brought to rest at the leading edge of the cylinder without significant action of viscosity. Ignoring the effects of compressibility (so ρ is constant), this stagnation pressure is

stagnation pressure

$$P_{\text{stag}} = P_0 + \frac{1}{2} \rho V^2, \quad (15.4)$$

where P_0 is the upstream pressure. Suppose that this stagnation pressure were to act over the whole front face of the cylinder, while the pressure P_0 acted on the downstream face. The net force on the cylinder per unit length, F_D , would then be $\frac{1}{2}\rho V^2 d$. This is a first rough estimate for the drag force. It is conventional to define a *drag coefficient* as the ratio of the actual drag force per unit length to this rough estimate:

drag coefficient

$$C_D \equiv \frac{F_D}{\frac{1}{2}\rho V^2 d}. \quad (15.5)$$

drag coefficient is function of Reynolds number

This drag coefficient, being a dimensionless feature of the flow (15.3), can depend only on the dimensionless Reynolds number Re_d : $C_D = C_D(Re_d)$; see Fig. 15.2. Similarly for flow past a 3-dimensional body with cross sectional area A perpendicular to the flow and with any other shape, the drag coefficient

$$C_D \equiv \frac{F_D}{\frac{1}{2}\rho V^2 A} \quad (15.6)$$

FIGURE 15.2 Drag coefficient C_D for flow past a cylinder as a function of Reynolds number $Re_d = Vd/\nu$. This graph, adapted from Tritton (1987, Fig. 3.15), is based on experimental measurements.

will be a function only of Re . However, the specific functional form of $C_D(Re)$ will depend on the body's shape and orientation.

Now, turn to the details of the flow around a cylinder as described in Figs. 15.1 and 15.2. At low Reynolds number, $Re_d \ll 1$, there is creeping flow (Fig. 15.1a) just like that analyzed in detail for a spherical obstacle in Sec. 14.3.2. As you might have surmised by tackling Ex. 14.12, the details of low-Reynolds-number flow past a long object, such as a cylinder, are subtly different from those of flow past a short one, such as a sphere. This is because, for a cylinder, inertial forces become comparable with viscous and pressure forces at distances $\sim d/Re_d$, where the flow is still significantly perturbed from uniform motion, while for short objects inertial forces become significant only at much larger radii, where the flow is little perturbed by the object's presence. Despite this, the flow streamlines around a cylinder at $Re_d \ll 1$ (Fig. 15.1a) are similar to those for a sphere (Fig. 14.10) and are approximately symmetric between upstream and downstream. The fluid is decelerated by viscous stresses as it moves past the cylinder along these streamlines, and the pressure is higher on the cylinder's front face than on its back. Both effects contribute to the net drag force acting on the cylinder. The momentum removed from the flow is added to the cylinder. At cylindrical radius $\varpi \ll d/Re_d$ the viscous stress dominates over the fluid's inertial stress, and the fluid momentum therefore is being transferred largely to the cylinder at a rate per unit area $\sim \rho V^2$. In contrast, for $\varpi \gtrsim d/Re_d$ the viscous and inertial stresses are comparable and balance each other, and the flow's momentum is not being transferred substantially to the cylinder. This implies that the effective cross sectional width over which the cylinder extracts the fluid's momentum is $\sim d/Re_d$, and correspondingly, the net drag force per unit length is $F \sim \rho V^2 d/Re_d$, which implies [cf. Eq. (15.5)] a drag coefficient $\sim 1/Re_d$ at low Reynolds numbers ($Re_d \ll 1$). A more careful analysis gives $C_D \sim 6/Re_d$, as shown experimentally in Fig. 15.2.

As the Reynolds number is increased to ~ 1 (Fig. 15.1b), the effective cross section gets reduced to roughly the cylinder's diameter d ; correspondingly, the drag coefficient decreases to $C_D \sim 1$. At this Reynolds number, $Re_d \sim 1$, the velocity field begins to appear asymmetric from front to back.

With a further increase in Re_d , a laminar boundary layer of thickness $\delta \sim d/\sqrt{Re_d}$ starts to form. The viscous force per unit length due to this boundary layer is $F \sim \rho V^2 d/\sqrt{Re_d}$ [cf. Eqs. (14.49)–(14.51) divided by the transverse length w , and with $\ell \sim d$ and $v_o = V$]. It might therefore be thought that the drag would continue to decrease as $C_D \sim 1/\sqrt{Re_d}$, when Re_d increases substantially above unity, making the boundary layer thin and the external flow start to resemble potential flow. However, this does *not* happen. Instead, at $Re_d \sim 5$, the flow begins to separate from the back side of the cylinder and is there replaced by two retrograde eddies (Fig. 15.1c). As described in Sec. 14.4.4, this separation occurs because an adverse pressure gradient $(\mathbf{v} \cdot \nabla)P > 0$ develops outside the boundary layer, near the cylinder's downstream face, and causes the separated boundary layer to be replaced by these two counter-rotating eddies. The pressure in these eddies, and thus also on the cylinder's back face,

at $Re_d \ll 1$: creeping flow
and $C_D \sim 6/Re_d$

at $Re_d \sim 1$: $C_D \sim 1$ and
laminar boundary layer
starts to form

at $Re_d \sim 5$: separation
begins

is of order the flow's incoming pressure P_0 and is significantly less than the stagnation pressure $P_{\text{stag}} = P_0 + \frac{1}{2}\rho V^2$ at the cylinder's front face, so the drag coefficient stabilizes at $C_D \sim 1$.

at $Re_d \sim 100$: eddies shed dynamically; form Kármán vortex street

As the Reynolds number increases above $Re_d \sim 5$, the size of the two eddies increases until, at $Re_d \sim 100$, the eddies are shed dynamically, and the flow becomes nonstationary. The eddies tend to be shed alternately in time, first one and then the other, producing a beautiful pattern of alternating vortices downstream known as a *Kármán vortex street* (Fig. 15.1d).

at $Re_d \sim 1,000$: turbulent wake

When $Re_d \sim 1,000$, the downstream vortices are no longer visible, and the wake behind the cylinder contains a velocity field irregular on all macroscopic scales (Fig. 15.1e). This downstream flow has become turbulent. Finally, at $Re_d \sim 3 \times 10^5$, the boundary layer itself, which has been laminar up to this point, becomes turbulent (Fig. 15.1f), reducing noticeably the drag coefficient (Fig. 15.2). We explore the cause of this reduction in Sec. 15.5. [The physically relevant Reynolds number for onset of turbulence in the boundary layer is that computed not from the cylinder diameter d , $Re_d = Vd/\nu$, but rather from the boundary layer thickness $\delta \sim d/Re_d^{1/2}$:

at $Re_d \sim 3 \times 10^5$: turbulent boundary layer

$$\boxed{Re_\delta = \frac{V\delta}{\nu} \sim \frac{VdRe_d^{-1/2}}{\nu} = \sqrt{Re_d}.} \quad (15.7)$$

The onset of boundary-layer turbulence is at $Re_\delta \sim \sqrt{3 \times 10^5} \sim 500$, about the same as the $Re_d \sim 1,000$ for the onset of turbulence in the wake.]

turbulence is 3-dimensional

An important feature of this changing flow pattern is that at $Re_d \ll 1,000$ (Figs. 15.1a–d), before any turbulence sets in, the flow (whether steady or dynamical) is translation symmetric—it is independent of distance z down the cylinder (i.e., it is 2-dimensional). This is true even of the Kármán vortex street. By contrast, the turbulent velocity field at $Re_d \gtrsim 1,000$ is fully 3-dimensional. At these high Reynolds numbers, small, nontranslation-symmetric perturbations of the translation-symmetric flow grow into vigorous, 3-dimensional turbulence. This is a manifestation of the inability of 2-dimensional flows to exhibit all the chaotic motion associated with 3-dimensional turbulence (Sec. 15.4.4).

critical Reynolds number for onset of turbulence

The most important feature of this family of flows—one that is characteristic of most such families—is that there is a critical Reynolds number for the onset of turbulence. That critical number can range from ~ 30 to $\sim 10^5$, depending on the geometry of the flow and on precisely what length and speed are used to define the Reynolds number.

EXERCISES

Exercise 15.1 ***Example: The 2-Dimensional Laminar Wake behind a Cylinder*

In Sec. 15.4.3, we explore the structure of the wake behind the cylinder when the Reynolds number is high enough that the flow is turbulent. For comparison, here we

FIGURE 15.3 The 2-dimensional laminar wake behind an infinitely long cylinder. (This figure also describes a turbulent wake, at high Reynolds numbers, if v_x is replaced by the time-averaged \bar{v}_x ; Sec. 15.4.3.)

compute the wake's structure at lower Reynolds numbers, when the wake is laminar. This computation is instructive: using order-of-magnitude estimates first, followed by detailed calculations, it illustrates the power of momentum conservation. It is our first encounter with the velocity field in a wake.

- Begin with an order-of-magnitude estimate. Characterize the wake by its width $w(x)$ at distance x downstream from the cylinder and by the reduction in the flow velocity (the "velocity deficit"), $u_o(x) \equiv V - v_x(x)$, at the center of the wake; see Fig. 15.3. From the diffusion of vorticity show that $w \simeq 2\sqrt{\nu x/V}$.
- Explain why momentum conservation requires that the force per unit length on the cylinder, $F_D = C_D \frac{1}{2} \rho V^2 d$ [Eq. (15.5)], equals the transverse integral $\int T_{xx} dy$ of the fluid's kinetic stress ($T_{xx} = \rho v_x v_x$) before the fluid reaches the sphere, minus that integral at distance x after the sphere. Use this requirement to show that the fractional velocity deficit at the center of the wake is $u_o/V \simeq \frac{1}{4} C_D d/w \simeq C_D \sqrt{d \text{Re}_d / (64x)}$.
- For a more accurate description of the flow, solve the Navier-Stokes equation to obtain the profile of the velocity deficit, $u(x, y) \equiv V - v_x(x, y)$. [Hint: Ignoring the pressure gradient, which is negligible (Why?), the Navier-Stokes equation should reduce to the 1-dimensional diffusion equation, which we have met several times previously in this book.] Your answer should be

$$u = u_o e^{-(2y/w)^2}, \quad w = 4 \left(\frac{\nu x}{V} \right)^{1/2}, \quad u_o = V C_D \left(\frac{d \text{Re}_d}{16\pi x} \right)^{1/2}, \quad (15.8)$$

where w and u_o are more accurate values of the wake's width and its central velocity deficit.

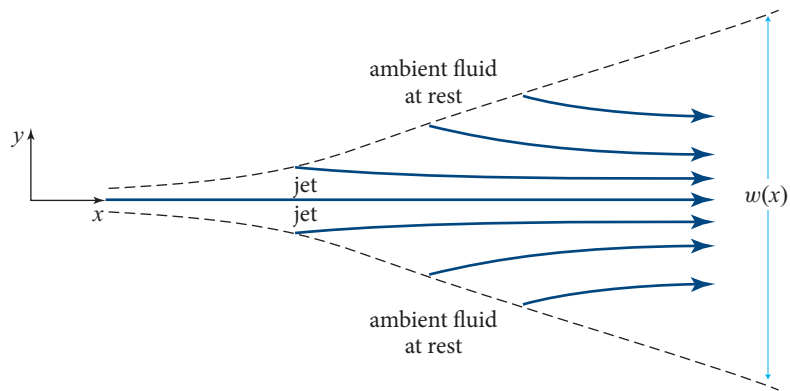

FIGURE 15.4 2-dimensional laminar jet. As the jet widens, it entrains ambient fluid.

Exercise 15.2 *Problem: The 3-Dimensional Laminar Wake behind a Sphere*

Repeat Ex. 15.1 for the 3-dimensional laminar wake behind a sphere.

Exercise 15.3 *Example: Structure of a 2-Dimensional Laminar Jet; Entrainment*

Consider a narrow, 2-dimensional, incompressible (i.e., subsonic) jet emerging from a 2-dimensional nozzle into ambient fluid at rest with the same composition and pressure. (By 2-dimensional we mean that the nozzle and jet are translation symmetric in the third dimension.) Let the Reynolds number be low enough for the flow to be laminar; we study the turbulent regime in Ex. 15.7. We want to understand how rapidly this laminar jet spreads.

- (a) Show that the pressure forces far downstream from the nozzle are likely to be much smaller than the viscous forces and can therefore be ignored.
- (b) Let the jet's thrust per unit length (i.e., the momentum per unit time per unit length flowing through the nozzle) be \mathcal{F} . Introduce Cartesian coordinates x , y , with x parallel to and y perpendicular to the jet (cf. Fig. 15.4). As in Ex. 15.1, use vorticity diffusion (or the Navier-Stokes equation) and momentum conservation to estimate the speed v_x of the jet and its width w as functions of distance x downstream.
- (c) Use the scalings from part (b) to modify the self-similarity analysis of the Navier-Stokes equation that we used for the laminar boundary layer in Sec. 14.4, and thereby obtain the following approximate solution for the jet's velocity profile:

$$v_x = \left(\frac{3\mathcal{F}^2}{32\rho^2\nu x} \right)^{1/3} \operatorname{sech}^2 \left[\left(\frac{\mathcal{F}}{48\rho\nu^2 x^2} \right)^{1/3} y \right]. \quad (15.9)$$

- (d) Equation (15.9) shows that the jet width w increases downstream as $x^{2/3}$. As the jet widens, it scoops up (entrains) ambient fluid, as depicted in Fig. 15.4. This

entrainment actually involves pulling fluid inward in a manner described by the y component of velocity, v_y . Solve the incompressibility equation $\nabla \cdot \mathbf{v} = 0$ to obtain the following expression for v_y :

$$v_y = -\frac{1}{3x} \left(\frac{3\mathcal{F}^2}{32\rho^2\nu x} \right)^{1/3} \quad (15.10)$$

$$\times \left\{ \left(\frac{48\rho\nu^2x^2}{\mathcal{F}} \right)^{1/3} \tanh \left[\left(\frac{\mathcal{F}}{48\rho\nu^2x^2} \right)^{1/3} y \right] - 2y \operatorname{sech}^2 \left[\left(\frac{\mathcal{F}}{48\rho\nu^2x^2} \right)^{1/3} y \right] \right\}$$

$$\simeq -\left(\frac{1}{6} \frac{\mathcal{F}\nu}{\rho x^2} \right)^{1/3} \operatorname{sign}(y) \quad \text{for } |y| \gg \frac{1}{2}w(x) = \left(\frac{48\rho\nu^2x^2}{\mathcal{F}} \right)^{1/3}.$$

Thus ambient fluid is pulled inward from both sides to satisfy the jet's entrainment appetite.

Exercise 15.4 Example: Marine Animals

One does not have to be a biologist to appreciate the strong evolutionary advantage that natural selection confers on animals that can reduce their drag coefficients. It should be no surprise that the shapes and skins of many animals are highly streamlined. This is particularly true for aquatic animals. Of course, an animal minimizes drag while developing efficient propulsion and lift, which change the flow pattern. Comparisons of the properties of flows past different stationary (e.g., dead or towed) animals are, therefore, of limited value. The species must also organize its internal organs in 3 dimensions, which is an important constraint. The optimization varies from species to species and is suited to the environment. There are some impressive performers in the animal world.

- (a) First, idealize our animal as a thin rectangle with thickness t , length ℓ , and width w such that $t \ll \ell \ll w$.⁵ Let the animal be aligned with the flow parallel to the ℓ direction. Assuming an area of $A = 2\ell w$, the drag coefficient is $C_D = 1.33\operatorname{Re}_\ell^{-0.5}$ [Eq. (14.50)]. This assumes that the flow is laminar. The corresponding result for a turbulent flow is $C_D \simeq 0.072\operatorname{Re}_\ell^{-0.2}$. Show that the drag can be considerably reduced if the transition to turbulence takes place at high Re_ℓ . Estimate the effective Reynolds number for an approximately flat fish like a flounder of size ~ 0.3 m that can move with a speed ~ 0.3 m s⁻¹, and then compute the drag force. Express your answer as a stopping length.
- (b) One impressive performer is the mackerel (a highly streamlined fish), for which the reported drag coefficient is 0.0043 at $\operatorname{Re} \sim 10^5$. Compare this with a thin plate and a sphere. (The drag coefficient for a sphere is $C_D \sim 0.5$, assuming a reference area equal to the total area of the sphere. The drag decreases abruptly when there is a transition to turbulence, just as we found with the cylinder.)

5. The aquatic counterpart to the famous Spherical Cow!

- (c) Another fine swimmer is the California sea lion, which has a drag coefficient of $C_D = 0.0041$ at $Re \sim 2 \times 10^6$. How does this compare with a plate and a sphere? Further details can be found in Vogel (1994) and references therein.
-

15.3

15.3 Empirical Description of Turbulence

Empirical studies of turbulent flows have revealed some universal properties that are best comprehended through movies (Box 15.2). Here we simply list the most important of them and comment on them briefly. We revisit most of them in more detail in the remainder of the chapter. Throughout, we restrict ourselves to turbulence with velocities that are very subsonic, and thus the fluid is incompressible.

characteristics of
turbulence

Turbulence is characterized by:

- *Disorder, irreproducible in detail but with rich, nonrandom structure.* This disorder is intrinsic to the flow. It appears to arise from a variety of instabilities. No forcing by external agents is required to produce it. If we try to resolve the flow into modes, however, we find that the phases of the modes are not fully random, either spatially or temporally: there are strong correlations.⁶ Correspondingly, if we look at a snapshot of a turbulent flow, we frequently observe large, well-defined coherent structures like eddies and jets, which suggests that the flow is more organized than a purely random superposition of modes, just as the light reflected from the surface of a painting differs from that emitted by a blackbody. If we monitor the time variation of some fluid variable, such as one component of the velocity at a given point in the flow, we observe *intermittency*—the irregular starting and ceasing of strong turbulence. Again, this effect is so pronounced that more than a random-mode superposition is at work, reminiscent of the distinction between noise and music (at least some music). [A major consequence that we shall have to face is that strong turbulence is *not* well treated by perturbation theory. As an alternative, semiquantitative techniques of analysis must be devised.]
- *A wide range of interacting scales.* When the fluid velocity and pressure are Fourier analyzed, one finds them varying strongly over many decades of wave number and frequency. We can think of these variations as due to *eddies* with a huge range of sizes. These eddies interact strongly. Typically, large eddies appear to feed their energy to smaller eddies, which in turn feed energy to still smaller eddies, and so forth. Occasionally, amazingly, the flow of energy appears to reverse: small-scale turbulent structures give rise

6. As we discuss in Chap. 28, many cosmologists suspected that the primordial fluctuations, out of which galaxies and stars eventually grew, would share this characteristic with turbulence. Insofar as we can measure, this is not the case, and the fluctuations appear to be quite random and uncorrelated.

FIGURE 15.5 Schematic illustration of the propagation of turbulence by the stretching of vortex lines. The tube of vortex lines in (a) is stretched and thereby forced into a reduced cross section by the turbulent evolution from (a) to (b) to (c). The reduced cross section means an enhanced vorticity on smaller scales.

to large-scale structures,⁷ resulting in intermittency. A region of the flow that appears to have calmed down may suddenly and unexpectedly become excited again.

- *Vorticity, irregularly distributed in three dimensions.* This vorticity varies in magnitude and direction over the same wide range of scales as for the fluid velocity. It appears to play a central role in coupling large scales to small; see Sec. 15.3.1.
- *Large dissipation.* Typically, turbulent energy is fed from large scales to small in just one turnover time of a large eddy. This is extremely fast. The energy cascades down to smaller and smaller lengthscales in shorter and shorter timescales until it reaches eddies so small that their shear, coupled to molecular viscosity, converts the turbulent energy into heat.
- *Efficient mixing and transport.* Most everything that can be transported is efficiently mixed and moved: momentum, heat, salt, chemicals, and so forth.

15.3.1 The Role of Vorticity in Turbulence

15.3.1

Turbulent flows contain tangled vorticity. As we discussed in Sec. 14.2.2, when viscosity is unimportant, vortex lines are frozen into the fluid and can be stretched by the action of neighboring vortex lines. As a bundle of vortex lines is stretched and twisted (Fig. 15.5), the incompressibility of the fluid causes the bundle's cross section to decrease and correspondingly causes the magnitude of its vorticity to increase and the lengthscale on which the vorticity changes to decrease (cf. Sec. 14.2). The continuous lengthening and twisting of fluid elements therefore creates vorticity on progressively smaller lengthscales.

evolution of vorticity in turbulence: toward progressively smaller scales

7. The creation of larger structures from smaller ones—sometimes called an *inverse cascade*—is a strong feature of 2-dimensional fluid turbulence.

Note that, when the flow is 2-dimensional (i.e., has translation symmetry), the vortex lines point in the translational direction, so they do not get stretched, and there is thus no inexorable driving of the turbulent energy to smaller and smaller lengthscales. This is one reason why true turbulence does not occur in 2 dimensions, only in 3.

However, something akin to turbulence but with much less richness and small-scale structure, *does* occur in 2 dimensions (e.g., in 2-dimensional simulations of the Kelvin-Helmholtz instability; Box 15.3). But in the real world, once the Kelvin-Helmholtz instability is fully developed, 3-dimensional instabilities grow strong, vortex-line stretching increases, and the flow develops full 3-dimensional turbulence. The same happens in other ostensibly 2-dimensional flows (e.g., the “2-dimensional” wake behind a long circular cylinder and “2-dimensional” jets and boundary layers; Secs. 15.4.3 and 15.5).

15.4 15.4 Semiquantitative Analysis of Turbulence

weak turbulence versus strong turbulence

In this section, we develop a semiquantitative mathematical analysis of turbulence and explore a few applications. This analysis is fairly good for weak turbulence. However, for the much more common strong turbulence, it is at best semiquantitative—but nonetheless widely used for lack of anything simple that is much better.

15.4.1 15.4.1 Weak-Turbulence Formalism

weak turbulence

The meaning of weak turbulence can be explained in terms of interacting eddies (a concept we exploit in Sec. 15.4.4 when studying the flow of turbulent energy from large scales to small). One can regard turbulence as weak if the timescale τ_* for a large eddy to feed most of its energy to smaller eddies is long compared to the large eddy’s turnover time τ (i.e., its rotation period). The weak-turbulence formalism (model) that we sketch here can be thought of as an expansion in τ/τ_* .

Unfortunately, for most turbulence seen in fluids, the large eddies’ energy-loss time is of order its turnover time, $\tau/\tau_* \sim 1$, which means the eddy loses its identity in roughly one turnover time and the turbulence is strong. In this case, the weak-turbulence formalism that we sketch here is only semiquantitatively accurate.

Our formalism for weak turbulence (with gravity negligible and the flow highly subsonic, so it can be regarded as incompressible) is based on the standard incompressibility equation and the time-dependent Navier-Stokes equation, which we write as

$$\nabla \cdot \mathbf{v} = 0, \quad (15.11a)$$

$$\rho \frac{\partial \mathbf{v}}{\partial t} + \nabla \cdot (\rho \mathbf{v} \otimes \mathbf{v}) = -\nabla P + \rho \nu \nabla^2 \mathbf{v}, \quad (15.11b)$$

assuming for simplicity that ρ is constant. [Equation (15.11b) is equivalent to (15.2b) with $\partial \mathbf{v}/\partial t$ added to account for time dependence and with the inertial force term rewritten using $\nabla \cdot (\rho \mathbf{v} \otimes \mathbf{v}) = \rho (\mathbf{v} \cdot \nabla) \mathbf{v}$, or equivalently in index notation, $(\rho v_i v_j)_{;i} = \rho_{,i} v_i v_j + \rho (v_{i;i} v_j + v_i v_{j;i}) = \rho v_i v_{j;i}$.] Equations (15.11) are four scalar

BOX 15.3. CONSEQUENCES OF THE KELVIN-HELMHOLTZ INSTABILITY

The Kelvin-Helmholtz instability arises when two fluids with nearly the same density are in uniform motion past each other (Sec. 14.6.1). Their interface (a vortex sheet) develops corrugations that grow (Figs. 14.19 and 14.20). That growth bends the corrugations more and more sharply. Along the corrugated interface the fluids on each side are still sliding past each other, so the instability arises again on this smaller scale—and again and again, somewhat like the cascade of turbulent energy from large scales to small.

In the real world, 3-dimensional instabilities also arise, and the flow becomes fully turbulent. However, much insight is gained into the difference between 2- and 3-dimensional flow by artificially constraining the Kelvin-Helmholtz flow to remain 2-dimensional. This is easily done in numerical simulations. Movies of such simulations abound on the web (e.g., on the Wikipedia web page for the Kelvin-Helmholtz instability; the following picture is a still from that movie).

By Bdubb12 (Own work) [Public domain], via Wikimedia Commons.
<https://commons.wikimedia.org/wiki/File%3AKHI.gif>

Although the structures in this simulation are complex, they are much less rich than those that appear in fully 3-dimensional turbulence—perhaps largely due to the absence of stretching and twisting of vortex lines when the flow is confined to 2 dimensions. (Not surprisingly, the structures in this simulation resemble some in Jupiter’s atmosphere, which also arise from a Kelvin-Helmholtz instability.)

equations for four unknowns, $P(\mathbf{x}, t)$ and the three components of $\mathbf{v}(\mathbf{x}, t)$; ρ and ν can be regarded as constants.

To obtain the weak-turbulence versions of these equations, we split the velocity field $\mathbf{v}(\mathbf{x}, t)$ and pressure $P(\mathbf{x}, t)$ into steady parts $\bar{\mathbf{v}}$, \bar{P} , plus fluctuating parts, $\delta\mathbf{v}$, δP :

$$\mathbf{v} = \bar{\mathbf{v}} + \delta\mathbf{v}, \quad P = \bar{P} + \delta P. \quad (15.12)$$

foundations for weak-turbulence theory

We can think of (or, in fact, define) $\bar{\mathbf{v}}$ and \bar{P} as the time averages of \mathbf{v} and P , and define $\delta\mathbf{v}$ and δP as the difference between the exact quantities and the time-averaged quantities.

The time-averaged variables $\bar{\mathbf{v}}$ and \bar{P} are governed by the time-averaged incompressibility and Navier-Stokes equations (15.11). Because the incompressibility equation is linear, its time average,

$$\nabla \cdot \bar{\mathbf{v}} = 0, \quad (15.13a)$$

entails no coupling of the steady variables to the fluctuating ones. By contrast, the nonlinear inertial term $\nabla \cdot (\rho\mathbf{v} \otimes \mathbf{v})$ in the Navier-Stokes equation gives rise to such a coupling in the (time-independent) time-averaged equation:

$$\rho(\bar{\mathbf{v}} \cdot \nabla)\bar{\mathbf{v}} = -\nabla\bar{P} + \rho\nu\nabla^2\bar{\mathbf{v}} - \nabla \cdot \mathbf{T}_R. \quad (15.13b)$$

time-averaged Navier-Stokes equation: couples turbulence (via Reynolds stress tensor) to time-averaged flow

Here

$$\mathbf{T}_R \equiv \overline{\rho\delta\mathbf{v} \otimes \delta\mathbf{v}} \quad (15.13c)$$

is known as the *Reynolds stress tensor*. It serves as a driving term in the time-averaged Navier-Stokes equation (15.13b)—a term by which the fluctuating part of the flow acts back on and so influences the time-averaged flow.

This Reynolds stress \mathbf{T}_R can be regarded as an additional part of the total stress tensor, analogous to the gas pressure computed in kinetic theory,⁸ $P = \frac{1}{3}\rho\overline{v^2}$, where v is the molecular speed. \mathbf{T}_R will be dominated by the largest eddies present, and it can be anisotropic, especially when the largest-scale turbulent velocity fluctuations are distorted by interaction with an averaged shear flow [i.e., when $\bar{\sigma}_{ij} = \frac{1}{2}(\bar{v}_{i;j} + \bar{v}_{j;i})$ is large].

Reynolds stress for stationary, homogeneous turbulence

If the turbulence is both stationary and homogeneous (a case we specialize to below when studying the Kolmogorov spectrum), then the Reynolds stress tensor can be written in the form $\mathbf{T}_R = P_R\mathbf{g}$, where P_R is the Reynolds pressure, which is independent of position, and \mathbf{g} is the metric, so $g_{ij} = \delta_{ij}$. In this case, the turbulence exerts no force density on the mean flow, so $\nabla \cdot \mathbf{T}_R = \nabla P_R$ will vanish in the time-averaged Navier-Stokes equation (15.13b). By contrast, near the edge of a turbulent region (e.g., near the edge of a turbulent wake, jet, or boundary layer), the turbulence is inhomogeneous, and thereby (as we shall see in Sec. 15.4.2) exerts an important influence on the time-independent, averaged flow.

correlation functions in turbulence

Notice that the Reynolds stress tensor is the tensorial *correlation function* (also called “autocorrelation function”) of the velocity fluctuation field at zero time delay (multiplied by density ρ ; cf. Secs. 6.4.1 and 6.5.1). Notice also that it involves the

8. Deducible from Eq. (3.37c) or from Eqs. (3.39b) and (3.39c) with mean energy per particle $\bar{E} = \frac{1}{2}m\overline{v^2}$.

temporal cross-correlation function of components of the velocity fluctuation [e.g., $\overline{\delta v_x(\mathbf{x}, t)\delta v_y(\mathbf{x}, t)}$; Sec. 6.5.1]. It is possible to extend this weak-turbulence formalism so it probes the statistical properties of turbulence more deeply, with the aid of correlation functions with finite time delays and correlation functions of velocity components (or other relevant physical quantities) at two different points in space simultaneously; see, for example, Sec. 28.5.3. (It is relatively straightforward experimentally to measure these correlation functions.) As we discuss in greater detail in Sec. 15.4.4 (and also saw for 1- and 2-dimensional random processes in Secs. 6.4.4 and 6.5.2, and for multidimensional, complex random processes in Ex. 9.8), the Fourier transforms of these correlation functions give the spatial and temporal spectral densities of the fluctuating quantities.

Just as the structure of the time-averaged flow is governed by the time-averaged incompressibility and Navier-Stokes equations (15.13) (with the fluctuating variables acting on the time-averaged flow through the Reynolds stress), so also the fluctuating part of the flow is governed by the fluctuating (difference between instantaneous and time-averaged) incompressibility and Navier-Stokes equations. For details, see Ex. 15.5. This exercise is important; it exhibits the weak-turbulence formalism in action and underpins the application to spatial energy flow in a 2-dimensional, turbulent wake in Fig. 15.7 below.

EXERCISES

Exercise 15.5 ***Example: Reynolds Stress; Fluctuating Part of Navier-Stokes Equation in Weak Turbulence*

- Derive the time-averaged Navier-Stokes equation (15.13b) from the time-dependent form [Eq. (15.11b)], and thereby infer the definition (15.13c) for the Reynolds stress. Equation (15.13b) shows how the Reynolds stress affects the evolution of the mean velocity. However, it does not tell us how the Reynolds stress evolves.
- Explain why an equation for the evolution of the Reynolds stress must involve averages of triple products of the velocity fluctuation. Similarly, the time evolution of the averaged triple products will involve averaged quartic products, and so on (cf. the BBGKY hierarchy of equations in plasma physics, Sec. 22.6.1). How do you think you might “close” this sequence of equations (i.e., terminate it at some low order) and get a fully determined system of equations? [Answer: The simplest way is to use the concept of turbulent viscosity discussed in Sec. 15.4.2.]
- Show that the fluctuating part of the Navier-Stokes equation (the difference between the exact Navier-Stokes equation and its time average) takes the following form:

$$\boxed{\begin{aligned} \frac{\partial \delta \mathbf{v}}{\partial t} + (\bar{\mathbf{v}} \cdot \nabla) \delta \mathbf{v} + (\delta \mathbf{v} \cdot \nabla) \bar{\mathbf{v}} + [(\delta \mathbf{v} \cdot \nabla) \delta \mathbf{v} - \overline{(\delta \mathbf{v} \cdot \nabla) \delta \mathbf{v}}] = \\ - \frac{1}{\rho} \nabla \delta P + \nu \nabla^2 (\delta \mathbf{v}) \end{aligned}} \quad (15.14a)$$

This equation and the fluctuating part of the incompressibility equation

$$\nabla \cdot \delta \mathbf{v} = 0 \quad (15.14b)$$

govern the evolution of the fluctuating variables $\delta \mathbf{v}$ and δP . [The challenge, of course, is to devise ways to solve these equations despite the nonlinearities and the coupling to the mean flow $\bar{\mathbf{v}}$ that show up strongly in Eq. (15.14a).]

- (d) By dotting $\delta \mathbf{v}$ into Eq. (15.14a) and then taking its time average, derive the following law for the spatial evolution of the turbulent energy density $\frac{1}{2} \rho \overline{\delta v^2}$:

spatial evolution equation for turbulent energy density

$$\bar{\mathbf{v}} \cdot \nabla \left(\frac{1}{2} \rho \overline{\delta v^2} \right) + \nabla \cdot \left(\frac{1}{2} \rho \overline{\delta v^2 \delta \mathbf{v}} + \delta P \delta \mathbf{v} \right) = -T_R^{ij} \bar{v}_{i;j} + \nu \rho \overline{\delta \mathbf{v} \cdot (\nabla^2 \delta \mathbf{v})}. \quad (15.15)$$

Here $T_R^{ij} = \rho \overline{\delta v_i \delta v_j}$ is the Reynolds stress [Eq. (15.13c)]. Interpret each term in this equation. [The four interpretations will be discussed below, for a 2-dimensional turbulent wake, in Sec. 15.4.3.]

- (e) Now derive a similar law for the spatial evolution of the energy density of ordered motion, $\frac{1}{2} \rho \bar{\mathbf{v}}^2$. Show that the energy lost by the ordered motion is compensated for by the energy gained by the turbulent motion.

15.4.2

15.4.2 Turbulent Viscosity

Additional tools that are often introduced in the theory of weak turbulence come from taking the analogy with the kinetic theory of gases one stage further and defining *turbulent transport coefficients*, most importantly a turbulent viscosity that governs the turbulent transport of momentum. These turbulent transport coefficients are derived by simple analogy with the kinetic-theory transport coefficients (Sec. 3.7).

Momentum, heat, and so forth are transported most efficiently by the largest turbulent eddies in the flow; therefore, when estimating the transport coefficients, we replace the particle mean free path by the size ℓ of the largest eddies and the mean particle speed by the magnitude v_ℓ of the fluctuations of velocity in the largest eddies. The result, for momentum transport, is a model turbulent viscosity:

turbulent viscosity determined by largest eddies

$$v_t \simeq \frac{1}{3} v_\ell \ell \quad (15.16)$$

[cf. Eq. (13.72) for molecular viscosity, with $\nu = \eta/\rho$]. The Reynolds stress is then approximated as a turbulent shear stress of the standard form:

$$\mathbf{T}_R \simeq -2\rho v_t \bar{\boldsymbol{\sigma}}. \quad (15.17)$$

Here $\bar{\boldsymbol{\sigma}}$ is the rate of shear tensor (13.67b) evaluated using the mean velocity field $\bar{\mathbf{v}}$. Note that the turbulent kinematic viscosity defined in this manner, ν_t , is a property of

the turbulent flow and not an intrinsic property of the fluid; it differs from molecular viscosity in this important respect.

We have previously encountered turbulent viscosity in our study of the physical origin of the Sargasso Sea gyre in the north Atlantic Ocean and the gyre's role in generating the Gulf Stream (Ex. 14.21). The gyre is produced by water flowing in a wind-driven Ekman boundary layer at the ocean's surface. From the measured thickness of that boundary layer, $\delta_E \sim 30$ m, we deduced that the boundary layer's viscosity is $\nu \sim 0.03 \text{ m}^2 \text{ s}^{-1}$, which is 30,000 times larger than water's molecular viscosity; it is the turbulent viscosity of Eq. (15.16).

By considerations similar to those above for turbulent viscosity, one can define and estimate a turbulent thermal conductivity for the spatial transport of time-averaged heat (cf. Sec. 3.7.2) and a turbulent diffusion coefficient for the spatial transport of one component of a time-averaged fluid through another, for example, an odor crossing a room (cf. Ex. 3.20).

The turbulent viscosity ν_t and the other turbulent transport coefficients can be far larger than their kinetic-theory counterparts. Besides the Sargasso Sea gyre, another example is air in a room subjected to typical uneven heating and cooling. The air may circulate with an average largest eddy velocity of $v_\ell \sim 1 \text{ cm s}^{-1}$ and an associated eddy size of $\ell \sim 3$ m. (The values can be estimated by observing the motion of illuminated dust particles.) The turbulent viscosity ν_t and the turbulent diffusion coefficient D_t (Ex. 3.20) associated with these motions are $\nu_t \sim D_t \sim 10^{-2} \text{ m}^2 \text{ s}^{-1}$, some three orders of magnitude larger than the molecular values.

turbulent thermal conductivity and turbulent diffusion coefficient

15.4.3 Turbulent Wakes and Jets; Entrainment; the Coanda Effect

15.4.3

As instructive applications of turbulent viscosity and related issues, we now explore in an order-of-magnitude way the structures of turbulent wakes and jets. The more complicated extension to a turbulent boundary layer will be explored in Sec. 15.5. In the text of this section we focus on the 2-dimensional wake behind a cylinder. In Exs. 15.6, 15.7, and 15.8, we study the 3-dimensional wake behind a sphere and 2- and 3-dimensional jets.

TWO-DIMENSIONAL TURBULENT WAKE: ORDER-OF-MAGNITUDE COMPUTATION OF WIDTH AND VELOCITY DEFICIT; ENTRAINMENT

For the turbulent wake behind a cylinder at high Reynolds number (see Fig. 15.3), we begin by deducing the turbulent viscosity $\nu_t \sim \frac{1}{3} v_\ell \ell$. It is reasonable to expect (and observations confirm) that the largest eddies in a turbulent wake, at distance x past the cylinder, extend transversely across nearly the entire width $w(x)$ of the wake, so their size is $\ell \sim w(x)$. What is the largest eddies' circulation speed v_ℓ ? Because these eddies' energies are fed into smaller eddies in (roughly) one eddy turnover time, these eddies must be continually regenerated by interaction between the wake and the uniform flow at its transverse boundaries. This means that the wake's circulation speed v_ℓ cannot be sensitive to the velocity difference V between the incoming flow and the

wake's eddy circulation speed and turbulent viscosity

cylinder far upstream; the wake has long since lost memory of that difference. The only characteristic speed that influences the wake is the difference between its own mean downstream speed \bar{v}_x and the speed V of the uniform flow at its boundaries. It seems physically reasonable that the interaction between these two flows will drive the eddy to circulate with that difference speed, the deficit u_o depicted in Fig. 15.3, which observations show to be true. Thus we have $v_\ell \sim u_o$. This means that the turbulent viscosity is $\nu_t \sim \frac{1}{3}v_\ell \ell \sim \frac{1}{3}u_o(x)w(x)$.

Knowing the viscosity, we can compute our two unknowns, the wake's velocity deficit $u_o(x)$ and its width $w(x)$, from vorticity diffusion and momentum conservation, as we did for a laminar wake in Ex. 15.1a,b.

First, consider momentum conservation. Here, as in Ex. 15.1b, the drag force per unit length on the cylinder, $F_D = C_D \frac{1}{2} \rho V^2 d$, must be equal to the difference between the momentum per unit length ($\int \rho V^2 dy$) in the water impinging on the cylinder and that ($\int \rho v_x^2 dy$) at any chosen distance x behind the cylinder. That difference is easily seen, from Fig. 15.3, to be $\sim \rho V u_o w$. Equating this to F_D , we obtain the product $u_o w$ and thence $\nu_t \sim \frac{1}{3}u_o w \sim \frac{1}{6}C_D V d$.

Thus, remarkably, the turbulent viscosity is independent of distance x downstream from the cylinder. This means that the wake's vorticity (which is contained primarily in its large eddies) will diffuse transversely in just the manner we have encountered several times before [Sec. 14.2.5, Eq. (14.42), and Ex. 15.1a], causing its width to grow as $w \sim \sqrt{\nu_t x / V}$. Inserting $\nu_t \sim \frac{1}{6}C_D V d \sim \frac{1}{3}u_o w$, we obtain

average structure of turbulent wake

$$w \sim \left(\frac{C_D d}{6} x \right)^{1/2}, \quad u_o \sim V \left(\frac{3C_D d}{2x} \right)^{1/2} \quad (15.18)$$

for the width and velocity deficit in the turbulent wake.

entrainment and its role in a turbulent wake

In this analysis, our appeal to vorticity diffusion obscures the physical mechanism by which the turbulent wake widens downstream. That mechanism is entrainment—the capture of fluid from outside the wake into the wake (a phenomenon we met for a laminar jet in Ex. 15.3d). The inertia of the largest eddies enables them to sweep outward into the surrounding flow with a transverse speed that is a sizable fraction of their turnover speed, say, $\frac{1}{6}v_\ell$ (the $1/6$ ensures agreement with the diffusion argument). This means that, moving with the flow at speed V , the eddy widens by entrainment at a rate $dw/dt = V dw/dx \sim \frac{1}{6}v_\ell \sim \frac{1}{6}u_o$. Inserting $u_o \sim \frac{1}{2}V C_D d/w$ from momentum conservation and solving the resulting differential equation, we obtain the same wake width $w \sim \sqrt{C_D d x / 6}$ as we got from our diffusion argument.

DISTRIBUTION OF VORTICITY IN THE WAKE; IRREGULARITY OF THE WAKE'S EDGE

The wake's fluid can be cleanly distinguished from the exterior, ambient fluid by vorticity: the ambient flow velocity $\mathbf{v}(\mathbf{x}, t)$ is vorticity free; the wake has nonzero vorticity. If we look at the actual flow velocity and refrain from averaging, the only way a fluid element in the wake can acquire vorticity is by molecular diffusion. Molecular diffusion is so slow that the boundary between a region with vorticity and one without

FIGURE 15.6 Contours of constant magnitude of vorticity $|\omega|$ in the 2-dimensional turbulent wake between and behind a pair of cylinders. The outer edge of the blue region is the edge of the wake. From a numerical simulation by the research group of Sanjiva K. Lele at Stanford University, <http://flowgallery.stanford.edu/research.html>.

(the boundary between the wake fluid and the ambient fluid) is very sharp. Sharp, yes, but straight, no! The wake's eddies, little as well as big, drive the boundary into a very convoluted shape (Fig. 15.6). Correspondingly, the order-of-magnitude wake width $w \sim \sqrt{C_D d x/6}$ that we have derived is only the width of a thoroughly averaged flow and is not at all the instantaneous, local width of the wake.

Intermittency is one consequence of the wake's highly irregular edge. A fixed location behind the cylinder that is not too close to the wake's center will sometimes be outside the wake and sometimes inside it. This will show up in one's measurement of any flow variable [e.g., $v_y(t)$, $\omega_x(t)$, or pressure P] at the fixed location. When outside the wake, the measured quantities will be fairly constant; when inside, they will change rapidly and stochastically. The quiet epochs combined with interspersed stochastic epochs are a form of intermittency.

intermittency

AVERAGED ENERGY FLOW IN THE WAKE

The weak-turbulence formalism of Sec. 15.4.1 and Ex. 15.5 can be used to explore the generation and flow of turbulent energy in the 2-dimensional wake behind a cylinder. This formalism, even when extended, is not good enough to make definitive predictions, but it *can* be used to deduce the energy flow from measurements of the mean (time-averaged) flow velocity $\bar{\mathbf{v}}$, the turbulent velocity $\delta\mathbf{v}$, and the turbulent pressure δP . A classic example of this was carried out long ago by Townsend (1949) and is summarized in Fig. 15.7.

FIGURE 15.7 The four terms in the rate of change of the time-averaged turbulent energy density [Eq. (15.15)] for the 2-dimensional turbulent wake behind a cylinder. The horizontal axis measures the distance y across the wake in units of the wake's mean width $w(x)$. The vertical axis shows the numerical value of each term. For a discussion of the four terms, see the four bulleted points in the text. Energy conservation and stationarity of the averaged flow guarantee that the sum of the four terms vanishes at each y [Eq. (15.15)]. Adapted from Tritton (1987, Fig. 21.8), which is based on measurements and analysis by Townsend (1949) at $Re_d = 1,360$ and $x/d > 500$.

averaged energy flow
in a wake: production,
advection, and dissipation

The time-averaged turbulent energy density changes due to four processes that are graphed in that figure as a function of distance y across the wake:

- *Production.* Energy in the organized bulk flow (mean flow) $\bar{\mathbf{v}}$ is converted into turbulent energy by the interaction of the mean flow's shear with the turbulence's Reynolds stress, at a rate per unit volume of $T_R^{ij} \bar{v}_{i,j}$. This production vanishes at the wake's center ($y = 0$), because the shear of the mean flow vanishes there; it also vanishes at the edge of the wake, because both the mean-flow shear and the Reynolds stress go to zero there.
- *Advection by mean flow.* Once produced, the turbulent energy is advected across the wake by the mean flow. This causes an increase in turbulent energy density in the center of the wake and a decrease in the wake's outer parts at the rate $\nabla \cdot (\frac{1}{2} \rho \delta v^2 \bar{\mathbf{v}}) = (\bar{\mathbf{v}} \cdot \nabla) (\frac{1}{2} \rho \delta v^2)$.

FIGURE 15.8 The Coanda effect. A turbulent jet emerging from an orifice in the left wall is attracted to the solid bottom wall.

- *Advection by turbulent flow.* The turbulent energy also is advected by the turbulent part of the flow, causing a decrease of turbulent energy density in the central regions of the wake and an increase in the outer regions at the rate $\nabla \cdot (\frac{1}{2}\rho\delta v^2\delta\mathbf{v} + \delta P\delta\mathbf{v})$.
- *Dissipation.* The turbulent energy is converted to heat by molecular viscosity at a rate per unit volume given by $-\nu\rho\delta\mathbf{v} \cdot (\nabla^2\delta\mathbf{v})$. This dissipation is largest at the wake's center and falls off gradually toward the wake's averaged edge.

Energy conservation plus stationarity of the averaged flow guarantees that the sum of these four terms vanishes at all locations in the wake (all y of Fig. 15.7). This is the physical content of Eq. (15.15) and is confirmed in Fig. 15.7 by the experimental data.

ENTRAINMENT AND COANDA EFFECT

Notice how much wider the (averaged) turbulent wake is than the corresponding laminar wake of Ex. 15.1. The ratio of their widths [Eqs. (15.18) and (15.8)] is $w_t/w_l \sim \sqrt{C_D V d/\nu}$. For $C_D \sim 1$ in the turbulent wake, $V \sim 1 \text{ m s}^{-1}$, $d \sim 1 \text{ m}$, and water's kinematic viscosity $\nu \sim 10^{-6} \text{ m}^2 \text{ s}^{-1}$, the ratio is $w_t/w_l \sim 10^3$, independent of distance x downstream. In this sense, entrainment in the turbulent wake is a thousand times stronger than entrainment in the laminar wake. Turbulent wakes and jets have voracious appetites for ambient fluid!

Entrainment is central to the *Coanda effect*, depicted in Fig. 15.8. Consider a turbulent flow (e.g., the jet of Fig. 15.8) that is widening by entrainment of surrounding fluid. The jet normally widens downstream by pulling surrounding fluid into itself, and the inflow toward the jet extends far beyond the jet's boundaries (see, e.g., Ex. 15.3d). However, when a solid wall is nearby, so there is no source for inflowing ambient fluid, the jet's entrainment causes a drop in the pressure of the ambient fluid near the wall. The resulting pressure gradient pushes the jet toward the wall as depicted in Fig. 15.8.

strong entrainment in
turbulent jets and wakes

Similarly, if a turbulent flow is already close to a wall and the wall begins to curve away from the flow, the flow develops a pressure gradient that tends to keep the turbulent region attached to the wall. In other words, turbulent flows are attracted to solid surfaces and tend to stick to them. This is the Coanda effect.

The Coanda effect also occurs for laminar flows, but because entrainment is typically orders of magnitude weaker in laminar flows than in turbulent ones, the effect is also orders of magnitude weaker.

The Coanda effect is important in aeronautics; for example, it is exploited to prevent the separation of the boundary layer from the upper surface of a wing, thereby improving the wing's lift and reducing its drag, as we discuss in Sec. 15.5.2.

EXERCISES

Exercise 15.6 *Problem: Turbulent Wake behind a Sphere*

Compute the width $w(x)$ and velocity deficit $u_o(x)$ for the 3-dimensional turbulent wake behind a sphere.

Exercise 15.7 *Problem: Turbulent Jets in 2 and 3 Dimensions*

Consider a 2-dimensional turbulent jet emerging into an ambient fluid at rest, and contrast it to the laminar jet analyzed in Ex. 15.3.

- Find how the mean jet velocity and the jet width scale with distance downstream from the nozzle.
- Repeat the exercise for a 3-dimensional jet.

Exercise 15.8 *Problem: Entrainment and Coanda Effect in a 3-Dimensional Jet*

- Evaluate the scaling of the rate of mass flow (discharge) $\dot{M}(x)$ along the 3-dimensional turbulent jet of the previous exercise. Show that \dot{M} increases with distance from the nozzle, so that mass must be entrained in the flow and become turbulent.
- Compare the entrainment rate for a turbulent jet with that for a laminar jet (Ex. 15.3). Do you expect the Coanda effect to be stronger for a turbulent or a laminar jet?

15.4.4

15.4.4 Kolmogorov Spectrum for Fully Developed, Homogeneous, Isotropic Turbulence

When a fluid exhibits turbulence over a large volume that is well removed from any solid bodies, there will be no preferred directions and no substantial gradients in the statistically averaged properties of the turbulent velocity field. This suggests that the statistical properties of the turbulence will be stationary and isotropic. We derive a semiquantitative description of some of these statistical properties, proceeding in two steps: first we analyze the turbulence's velocity field and then the turbulent distribution of quantities that are transported by the fluid.

TURBULENT VELOCITY FIELD

Our analysis will be based on the following simple physical model. We idealize the turbulent velocity field as made of a set of large eddies, each of which contains a set of smaller eddies, and so on. We suppose that each eddy splits into eddies roughly half its size after a few turnover times. This process can be described mathematically as nonlinear or triple velocity correlation terms [terms like the second one in Eq. (15.15)] producing, in the law of energy conservation, an energy transfer (a “cascade” of energy) from larger eddies to smaller ones. Now, for large enough eddies, we can ignore the effects of molecular viscosity in the flow. However, for sufficiently small eddies, viscous dissipation will convert the eddy bulk kinetic energy into heat. This simple model enables us to derive a remarkably successful formula (the *Kolmogorov spectrum*) for the distribution of turbulent energy over eddy size.

We must first introduce and define the turbulent energy per unit wave number and per unit mass, $u_k(k)$. For this purpose, we focus on a volume \mathcal{V} much larger than the largest eddies. At some moment of time t , we compute the spatial Fourier transform of the fluctuating part of the velocity field $\delta\mathbf{v}(\mathbf{x})$, confined to this volume [with $\delta\mathbf{v}(\mathbf{x})$ set to zero outside \mathcal{V}], and also write down the inverse Fourier transform:

$$\delta\tilde{\mathbf{v}}(\mathbf{k}) = \int_{\mathcal{V}} d^3x \delta\mathbf{v}(\mathbf{x}) e^{-i\mathbf{k}\cdot\mathbf{x}}, \quad \delta\mathbf{v} = \int \frac{d^3k}{(2\pi)^3} \delta\tilde{\mathbf{v}} e^{i\mathbf{k}\cdot\mathbf{x}} \quad \text{inside } \mathcal{V}. \quad (15.19)$$

The total energy per unit mass u in the turbulence, averaged over the box \mathcal{V} , is then

$$u = \int \frac{d^3x}{\mathcal{V}} \frac{1}{2} |\delta\mathbf{v}|^2 = \int \frac{d^3k}{(2\pi)^3} \frac{|\overline{\delta\tilde{\mathbf{v}}}|^2}{2\mathcal{V}} \equiv \int_0^\infty dk u_k(k), \quad (15.20)$$

where we have used Parseval’s theorem in the second equality, we have used $d^3k = 4\pi k^2 dk$, and we have defined

$$u_k(k) \equiv \frac{|\overline{\delta\tilde{\mathbf{v}}}|^2 k^2}{4\pi^2 \mathcal{V}}. \quad (15.21)$$

Here the bars denote a time average, k is the magnitude of the wave vector: $k \equiv |\mathbf{k}|$ (i.e., it is the wave number or equivalently 2π divided by the wavelength), and $u_k(k)$ is called the *spectral energy per unit mass* of the turbulent velocity field $\delta\mathbf{v}$. In the third equality in Eq. (15.20), we have assumed that the turbulence is isotropic, so the integrand depends only on wave number k and not on the direction of \mathbf{k} . Correspondingly, we have defined $u_k(k)$ as the energy per unit wave number rather than an energy per unit volume of \mathbf{k} -space. This means that $u_k(k)dk$ is the average kinetic energy per unit mass associated with modes that have k lying in the interval dk ; we treat k as positive.

In Chap. 6, we introduced the concepts of a random process and its spectral density. The Cartesian components of the fluctuating velocity δv_x , δv_y , and δv_z obviously are random processes that depend on vectorial location in space \mathbf{x} rather than on time

physical model underlying Kolmogorov spectrum for turbulence: cascading eddies

spectral energy per unit mass in turbulence

as in Chap. 6. It is straightforward to show that their *double-sided* spectral densities are related to $u_k(k)$ by

spectral densities of velocity field

$$S_{v_x}(\mathbf{k}) = S_{v_y}(\mathbf{k}) = S_{v_z}(\mathbf{k}) = \frac{(2\pi)^2}{3k^2} \times u_k(k). \quad (15.22)$$

If we fold negative k_x into positive, and similarly for k_y and k_z , so as to get the kind of single-sided spectral density (Sec. 6.4.2) that we used in Chap. 6, then these spectral densities should be multiplied by $2^3 = 8$.

We now use our physical model of turbulence to derive an expression for $u_k(k)$. Denote by $k_{\min} = 2\pi/\ell$ the wave number of the largest eddies, and by k_{\max} that of the smallest ones (those in which viscosity dissipates the cascading, turbulent energy). Our derivation will be valid (and the result valid) only when $k_{\max}/k_{\min} \gg 1$: only when there is a long sequence of eddies from the largest to half the largest to a quarter the largest and so forth down to the smallest.

eddy turnover speed and time

As a tool in computing $u_k(k)$, we introduce the root-mean-square turbulent turnover speed of the eddies with wave number k : $v(k) \equiv v$. Ignoring factors of order unity, we treat the size of these eddies as k^{-1} . Then their turnover time is $\tau(k) \sim k^{-1}/v(k) = 1/[kv(k)]$. Our model presumes that in this same time τ (to within a factor of order unity), each eddy of size k^{-1} splits into eddies of half this size (i.e., the turbulent energy cascades from k to $2k$). In other words, our model presumes the turbulence is strong. Since the energy cascade is presumed stationary (i.e., no energy is accumulating at any wave number), the energy per unit mass that cascades in a unit time from k to $2k$ must be independent of k . Denote by q that k -independent, cascading energy per unit mass per unit time. Since the energy per unit mass in the eddies of size k^{-1} is v^2 (aside from a factor 2, which we neglect), and the cascade time is $\tau \sim 1/(kv)$, then $q \sim v^2/\tau \sim v^3k$. This tells us that the rms turbulent velocity is

$$v(k) \sim (q/k)^{1/3}. \quad (15.23)$$

Our model lumps together all eddies with wave numbers in a range $\Delta k \sim k$ around k and treats them all as having wave number k . The total energy per unit mass in these eddies is $u_k(k)\Delta k \sim ku_k(k)$ when expressed in terms of the sophisticated quantity $u_k(k)$; it is $\sim v(k)^2$ when expressed in terms of our simple model. Thus our model predicts that $u_k(k) \sim v(k)^2/k$, which by Eqs. (15.23) and (15.22) implies

Kolmogorov spectrum for stationary, isotropic, incompressible turbulence

$$u_k(k) \sim q^{2/3}k^{-5/3}, \quad S_{v_j}(\mathbf{k}) \sim q^{2/3}k^{-11/3} \quad \text{for } k_{\min} \ll k \ll k_{\max}; \quad (15.24)$$

see Fig. 15.9. This is the *Kolmogorov spectrum* for the spectral energy density of stationary, isotropic, incompressible turbulence. It is valid only in the range $k_{\min} \ll k \ll k_{\max}$, because only in this range are the turbulent eddies continuously receiving energy from larger lengthscales and passing it on to smaller scales. At the ends of the range, the spectrum has to be modified in the manner illustrated qualitatively in Fig. 15.9.

FIGURE 15.9 The Kolmogorov spectral energy per unit mass for stationary, homogeneous turbulence.

At the smallest lengthscales present, k_{\max}^{-1} , the molecular viscous forces become competitive with inertial forces in the Navier-Stokes equation; these viscous forces convert the cascading energy into heat. Since the ratio of inertial forces to viscous forces is the Reynolds number, the smallest eddies have a Reynolds number of order unity: $\text{Re}_{k_{\max}} = v(k_{\max})k_{\max}^{-1}/\nu \sim 1$. Inserting Eq. (15.23) for $v(k)$, we obtain

$$k_{\max} \sim q^{1/4} \nu^{-3/4}. \quad (15.25)$$

The largest eddies have sizes $\ell \sim k_{\min}^{-1}$ and turnover speeds $v_\ell = v(k_{\min}) \sim (q/k_{\min})^{1/3}$. By combining these relations with Eq. (15.25), we see that the ratio of the largest wave numbers present in the turbulence to the smallest is

$$\boxed{\frac{k_{\max}}{k_{\min}} \sim \left(\frac{v_\ell \ell}{\nu}\right)^{3/4} = \text{Re}_\ell^{3/4}}. \quad (15.26)$$

range of wave numbers in turbulence

Here Re_ℓ is the Reynolds number for the flow's largest eddies.

Let us now take stock of our results. If we know the scale ℓ of the largest eddies and their rms turnover speeds v_ℓ (and, of course, the viscosity of the fluid), then we can compute their Reynolds number Re_ℓ ; from that, Eq. (15.26), and $k_{\min} \sim \ell^{-1}$, we can compute the flow's maximum and minimum wave numbers; and from $q \sim v_\ell^3/\ell$ and Eq. (15.24), we can compute the spectral energy per unit mass in the turbulence.

We can also compute the total time required for energy to cascade from the largest eddies to the smallest. Since $\tau(k) \sim 1/(kv) \sim 1/(q^{1/3}k^{2/3})$, each successive set of eddies feeds its energy downward in a time $2^{-2/3}$ shorter than the preceding set did. As a result, it takes roughly the same amount of time for energy to pass from the second-largest eddies (size $\ell/2$) to the very smallest (size k_{\max}^{-1}) as it takes for the second-largest to extract the energy from the very largest. The total cascade occurs in a time of several ℓ/v_ℓ (during which time, of course, the mean flow has fed new energy into the largest eddies and they are sending it downward).

These results are accurate only to within factors of order unity—with one major exception. The $-5/3$ power law in the Kolmogorov spectrum is very accurate. That this ought to be so one can verify in two equivalent ways: (i) Repeat the above derivation inserting arbitrary factors of order unity at every step. These factors will influence the final multiplicative factor in the Kolmogorov spectrum but will not influence the $-5/3$ power. (ii) Use dimensional analysis. Specifically, notice that the only dimensional entities that can influence the spectrum in the region $k_{\min} \ll k \ll k_{\max}$ are the energy cascade rate q and the wave number k . Then notice that the only quantity with the dimensions of $u_k(k)$ (energy per unit mass per unit wave number) that can be constructed from q and k is $q^{2/3}k^{-5/3}$. Thus, aside from a multiplicative factor of order unity, this must be the form of $u_k(k)$.

phenomena missed by
Kolmogorov spectrum
intermittency

Let us now review and critique the assumptions that went into our derivation of the Kolmogorov spectrum. First, we assumed that the turbulence is stationary and homogeneous. Real turbulence is neither of these, since it exhibits intermittency (Sec. 15.3), and smaller eddies tend to occupy less volume overall than do larger eddies and so cannot be uniformly distributed in space. Second, we assumed that the energy source is large-lengthscale motion and that the energy transport is local in k -space from the large lengthscales to steadily smaller ones. In the language of a Fourier decomposition into normal modes, we assumed that nonlinear coupling between modes with wave number k causes modes with wave number of order $2k$ to grow but does not significantly enhance modes with wave number $100k$ or $0.01k$. Again this behavior is not completely in accord with observations, which reveal the development of *coherent structures*—large-scale regions with correlated vorticity in the flow. These structures are evidence for a reversed flow of energy in k -space from small scales to large ones, and they play a major role in another feature of real turbulence, entrainment—the spreading of an organized motion (e.g., a jet) into the surrounding fluid (Sec. 15.4.3).

coherent structures, flow
of energy from small scales
to large, and entrainment

Despite these issues with its derivation, the Kolmogorov law is surprisingly accurate and useful. It has been verified in many laboratory flows, and it describes many naturally occurring instances of turbulence. For example, the twinkling of starlight is caused by refractive index fluctuations in Earth's atmosphere, whose power spectrum we can determine optically. The underlying turbulence spectrum turns out to be of Kolmogorov form; see Box 9.2.

KOLMOGOROV SPECTRUM FOR QUANTITIES TRANSPORTED BY THE FLUID

In applications of the Kolmogorov spectrum, including twinkling starlight, one often must deal with such quantities as the index of refraction n that, in the turbulent cascade, are transported passively with the fluid, so that $dn/dt = 0$.⁹ As the cascade

9. In Earth's atmospheric turbulence, n is primarily a function of the concentration of water molecules and the air density, which is controlled by temperature via thermal expansion and contraction. Both water concentration and temperature are carried along by the fluid in the turbulent cascade, whence so is n .

strings out and distorts fluid elements, it will also stretch and distort any inhomogeneities of n , driving them toward smaller lengthscales (larger k).

What is the k -dependence of the resulting spectral density $S_n(k)$? The quickest route to an answer is dimensional analysis. This S_n can be influenced only by the quantities that characterize the velocity field (its wave number k and its turbulent-energy cascade rate q) plus a third quantity: the rate $q_n = d\sigma_n^2/dt$ at which the variance $\sigma_n^2 = \int S_n d^3k/(2\pi)^3$ of n would die out if the forces driving the turbulence were turned off. (This q_n is the analog, for n , of q for velocity.) The only combination of k , q , and q_n that has the same dimensions as S_n is (Ex. 15.9)

$$S_n \sim q_n q^{-1/3} k^{-11/3}. \quad (15.27)$$

Kolmogorov spectrum for quantities transported with the fluid in its turbulent cascade

This is the same $-11/3$ power law as for S_{v_j} [Eq. (15.24)], and it will hold true also for any other quantity Θ that is transported with the fluid ($d\Theta/dt = 0$) in the turbulent cascade.

As for the velocity's inhomogeneities, so also for the inhomogeneities of n , there is some small lengthscale, $1/k_{n \max}$, at which diffusion wipes them out, terminating the cascade. Because n is a function of temperature and water concentration, the relevant diffusion is a combination of thermal diffusion and water-molecule diffusion, which will proceed at a (perhaps modestly) different rate from the viscous diffusion for velocity inhomogeneities. Therefore, the maximum k in the cascade may be different for the index of refraction (and for any other quantity transported by the fluid) than for the velocity.

In applications, one often needs a spatial description of the turbulent spectrum rather than a wave-number description. This is normally given by the Fourier transform of the spectral density, which is the correlation function $C_n(\xi) = \langle \delta n(x) \delta n(\mathbf{x} + \xi) \rangle$ (where δn is the perturbation away from the mean and $\langle \cdot \rangle$ is the ensemble average or average over space); see Sec. 6.4. For turbulence, the correlation function has the unfortunate property that $C_n(0) = \langle \delta n^2 \rangle \equiv \sigma_n^2$ is the variance, which is dominated by the largest lengthscales, where the Kolmogorov power-law spectrum breaks down. To avoid this problem it is convenient, when working with turbulence, to use in place of the correlation function the so-called *structure function*:

$$D_n(\xi) = \langle [\delta n(\mathbf{x} + \xi) - \delta n(\mathbf{x})]^2 \rangle = 2[\sigma_n^2 - C_n(\xi)]. \quad (15.28)$$

structure function for spatial structure of turbulence

By Fourier transforming the spectral density (15.27), or more quickly by dimensional analysis, one can infer the Kolmogorov spectrum for this structure function:

$$D_n(\xi) \sim (q_n/q^{1/3}) \xi^{2/3} \quad \text{for} \quad k_{\max}^{-1} \lesssim \xi \lesssim k_{\min}^{-1}. \quad (15.29)$$

In Box 9.2, we use this version of the spectrum to analyze the twinkling of starlight due to atmospheric turbulence.

Exercise 15.9 *Derivation and Practice: Kolmogorov Spectrum for Quantities Transported by the Fluid*

- (a) Fill in the details of the dimensional-analysis derivation of the Kolmogorov spectrum (15.27) for a quantity such as n that is transported by the fluid and thus satisfies $dn/dt = 0$. In particular, convince yourself (or refute!) that the only quantities S_n can depend on are k , q , and q_n , identify their dimensions and the dimension of S_n , and use those dimensions to deduce Eq. (15.27).
- (b) Derive the spatial version (15.29) of the Kolmogorov spectrum for a transported quantity by two methods: (i) Fourier transforming the wave-number version (15.27), and (ii) dimensional analysis.

Exercise 15.10 *Example: Excitation of Earth's Normal Modes by Atmospheric Turbulence*¹⁰

Earth has normal modes of oscillation, many of which are in the milli-Hertz frequency range. Large earthquakes occasionally excite these modes strongly, but the quakes are usually widely spaced in time compared to the ringdown time of a particular mode (typically a few days). There is evidence of a background level of continuous excitation of these modes, with an rms ground acceleration per mode of $\sim 10^{-10} \text{ cm s}^{-2}$ at seismically “quiet” times. The excitation mechanism is suspected to be stochastic forcing by the pressure fluctuations associated with atmospheric turbulence. This exercise deals with some aspects of this hypothesis.

- (a) Estimate the rms pressure fluctuations $P(f)$ at frequency f , in a bandwidth equal to frequency $\Delta f = f$, produced on Earth's surface by atmospheric turbulence, assuming a Kolmogorov spectrum for the turbulent velocities and energy. Make your estimate using two methods: (i) using dimensional analysis (what quantity can you construct from the energy cascade rate q , atmospheric density ρ , and frequency f that has dimensions of pressure?) and (ii) using the kinds of arguments about eddy sizes and speeds developed in Sec. 15.4.4.
- (b) Your answer using method (i) in part (a) should scale with frequency as $P(f) \propto 1/f$. In actuality, the measured pressure spectra have a scaling law more nearly like $P(f) \propto 1/f^{2/3}$, not $P(f) \propto 1/f$ (e.g., Tanimoto and Um, 1999, Fig. 2a). Explain this discrepancy [i.e., what is wrong with the argument in method (i) and how can you correct it to give $P(f) \propto 1/f^{2/3}$?].
- (c) The low-frequency cutoff for the $P(f) \propto 1/f^{2/3}$ pressure spectrum is about 0.5 mHz, and at 1 mHz, $P(f)$ has the value $P(f = 1 \text{ mHz}) \sim 0.3 \text{ Pa}$, which is

10. Problem devised by David Stevenson, based in part on Tanimoto and Um (1999), who, however, used the pressure spectrum deduced in method (i) of part (a) rather than the more nearly correct spectrum of part (b). The difference in spectra does not much affect their conclusions.

about 3×10^{-6} of atmospheric pressure. Assuming that 0.5 mHz corresponds to the largest eddies, which have a lengthscale of a few kilometers (a little less than the scale height of the atmosphere), derive an estimate for the eddies' turbulent viscosity ν_t in the lower atmosphere. By how many orders of magnitude does this exceed the molecular viscosity? What fraction of the Sun's energy input to Earth ($\sim 10^6 \text{ erg cm}^{-2} \text{ s}^{-1}$) goes into maintaining this turbulence (assumed to be distributed over the lowermost 10 km of the atmosphere)?

- (d) At $f = 1 \text{ mHz}$, what is the characteristic spatial scale (wavelength) of the relevant normal modes of Earth? [Hint: The relevant modes have few or no nodes in the radial direction. All you need to answer this question is a typical wave speed for seismic shear waves, which you can take to be 5 km s^{-1} .] What is the characteristic spatial scale (eddy size) of the atmospheric pressure fluctuations at this same frequency, assuming isotropic turbulence? Suggest a plausible estimate for the rms amplitude of the pressure fluctuation averaged over a surface area equal to one square wavelength of Earth's normal modes. (You must keep in mind the random spatially and temporally fluctuating character of the turbulence.)
- (e) Challenge: Using your answer from part (d) and a characteristic shear and bulk modulus for Earth's deformations of $K \sim \mu \sim 10^{12} \text{ dyne cm}^{-2}$, comment on how the observed rms normal-mode acceleration ($10^{-10} \text{ cm s}^{-2}$) compares with that expected from stochastic forcing due to atmospheric turbulence. You may need to review Chaps. 11 and 12, and think about the relationship between surface force and surface deformation. [Note: Several issues emerge when doing this assessment accurately that have not been dealt with in this exercise (e.g., number of modes in a given frequency range), so don't expect to be able to get an answer more accurate than an order of magnitude.]

15.5 Turbulent Boundary Layers

15.5

Great interest surrounds the projection of spheres of cork, rubber, leather, and string by various parts of the human anatomy, with and without the mechanical advantage of levers of willow, ceramic, and the finest Kentucky ash. As is well known, changing the surface texture, orientation, and spin of a sphere in various sports can influence its trajectory markedly. Much study has been made of ways to do this both legally and illegally. Some procedures used by professional athletes are pure superstition, but many others find physical explanations that are good examples of the behavior of boundary layers. Many sports involve the motion of balls at Reynolds numbers where the boundary layers can transition between laminar and turbulent, which allows opportunities for controlling the flow. With the goal of studying this transition, let us now consider the structure of a turbulent boundary layer—first along a straight wall and later along a ball's surface.

In Sec. 14.4.1, we derived the Blasius profile for a laminar boundary layer and showed that its thickness a distance x downstream from the start of the boundary layer was roughly $3\delta = 3(\nu x/V)^{1/2}$, where V is the free-stream speed (cf. Fig. 14.13). As we have described, when the Reynolds number is large enough— $Re_d = Vd/\nu \sim 3 \times 10^5$ or $Re_\delta \sim \sqrt{Re_d} \sim 500$ in the case of flow past a cylinder (Figs. 15.1 and 15.2)—the boundary layer becomes turbulent.

turbulent boundary layer's
laminar sublayer and
turbulent zone

A turbulent boundary layer consists of a thin laminar sublayer of thickness δ_{ls} close to the wall and a much thicker turbulent zone of thickness δ_t (Fig. 15.10).

In the following paragraphs we use the turbulence concepts developed in the previous sections to compute the order of magnitude of the structures of the laminar sublayer and the turbulent zone, and the manner in which those structures evolve along the boundary. We let the wall have any shape, so long as its radius of curvature is large compared to the boundary layer's thickness, so it looks locally planar. We also use locally Cartesian coordinates with distance y measured perpendicular to the boundary and distance x along it, in the direction of the near-wall flow.

One key to the structure of the boundary layer is that, in the x component of the time-averaged Navier-Stokes equation, the stress-divergence term $T_{xy,y}$ has the *potential* to be so large (because of the boundary layer's small thickness) that no other term can compensate for it. This is true in the turbulent zone, where T_{xy} is the huge Reynolds stress; it is also true in the laminar sublayer, where T_{xy} is the huge viscous stress produced by a large shear that results from the thinness of the layer. (One can check at the end of the following analysis that, for the computed boundary-layer structure, other terms in the x component of the Navier-Stokes equation are indeed so small that they could not compensate a significantly nonzero $T_{xy,y}$.) This potential dominance by $T_{xy,y}$ implies that the flow must adjust itself to make $T_{xy,y}$ nearly zero, so T_{xy} must be (very nearly) independent of distance y from the boundary.

FIGURE 15.10 (a) Physical structure of a turbulent boundary layer. (b) Mean flow speed \bar{v}_x as a function of distance from the wall for the turbulent boundary layer [solid curve, Eqs. (15.30)] and for a laminar boundary layer [dashed curve; the Blasius profile, Eqs. (14.46)].

In the turbulent zone, T_{xy} is the Reynolds stress, ρv_ℓ^2 , where v_ℓ is the turbulent velocity of the largest eddies at a distance y from the wall; therefore, constancy of T_{xy} implies constancy of v_ℓ . The largest eddies at y have a size ℓ of order the distance y from the wall; correspondingly, the turbulent viscosity is $\nu_t \sim v_\ell y/3$. Equating the expression ρv_ℓ^2 for the Reynolds stress to the alternative expression $2\rho\nu_t \frac{1}{2}\bar{v}_{,y}$ (where \bar{v} is the mean-flow speed at y , and $\frac{1}{2}\bar{v}_{,y}$ is the shear), and using $\nu_t \sim v_\ell y/3$ for the turbulent viscosity, we discover that in the turbulent zone the mean flow speed varies logarithmically with distance from the wall: $\bar{v} \sim v_\ell \ln y + \text{constant}$. Since the turbulence is created at the inner edge of the turbulent zone, $y \sim \delta_{ls}$ (Fig. 15.10) by interaction of the mean flow with the laminar sublayer, the largest turbulent eddies there must have their turnover speeds v_ℓ equal to the mean-flow speed there: $\bar{v} \sim v_\ell$ at $y \sim \delta_{ls}$. This tells us the normalization of the logarithmically varying mean-flow speed:

$$\bar{v} \sim v_\ell [1 + \ln(y/\delta_{ls})] \quad \text{at } y \gtrsim \delta_{ls}. \quad (15.30a)$$

profile of mean flow speed
in turbulent zone

Turn next to the structure of the laminar sublayer. There the constant shear stress is viscous, $T_{xy} = \rho\nu\bar{v}_{,y}$. Stress balance at the interface between the laminar sublayer and the turbulent zone requires that this viscous stress be equal to the turbulent zone's ρv_ℓ^2 . This equality implies a linear profile for the mean-flow speed in the laminar sublayer, $\bar{v} = (v_\ell^2/\nu)y$. The thickness of the sublayer is then fixed by continuity of \bar{v} at its outer edge: $(v_\ell^2/\nu)\delta_{ls} = v_\ell$. Combining these last two relations, we obtain the following profile and laminar-sublayer thickness:

$$\bar{v} \sim v_\ell \left(\frac{y}{\delta_{ls}} \right) \quad \text{at } y \lesssim \delta_{ls} \sim \nu/v_\ell. \quad (15.30b)$$

mean flow velocity in
laminar sublayer

Having deduced the internal structure of the boundary layer, we turn to the issue of what determines the y -independent turbulent velocity v_ℓ of the largest eddies. This v_ℓ is fixed by matching the turbulent zone to the free-streaming region outside it. The free-stream velocity V (which may vary slowly with x due to curvature of the wall) must be equal to the mean flow velocity \bar{v} [Eq. (15.30a)] at the outer edge of the turbulent zone. The logarithmic term dominates, so $V = v_\ell \ln(\delta_t/\delta_{ls})$. Introducing an overall Reynolds number for the boundary layer,

$$\text{Re}_\delta \equiv V\delta_t/\nu, \quad (15.31)$$

and noting that turbulence requires a huge value ($\gtrsim 1,000$) of this Re_δ , we can reexpress V as $V \sim v_\ell \ln \text{Re}_\delta$. This should actually be regarded as an equation for the turbulent velocity of the largest-scale eddies in terms of the free-stream velocity:

$$v_\ell \sim \frac{V}{\ln \text{Re}_\delta}. \quad (15.32)$$

turbulent velocity of
largest-scale eddies in
turbulent zone

If the free-stream velocity $V(x)$ and the thickness $\delta_t + \delta_{ls} \simeq \delta_t$ of the entire boundary layer are given, then Eq. (15.31) determines the boundary layer's Reynolds number, Eq. (15.32) then determines the turbulent velocity, and Eqs. (15.30) determine the layer's internal structure.

Finally, we turn to the issue of how the boundary layer thickness δ_t evolves with distance x down the wall (and, correspondingly, how the rest of the boundary layer's structure, which is fixed by δ_t , evolves). The key to the evolution of δ_t is entrainment, which we met in our discussion of turbulent wakes and jets (Sec. 15.4.3). At the turbulent zone's outer edge, the largest turbulent eddies move with speed $\sim v_\ell$ into the free-streaming fluid, entraining that fluid into themselves. Correspondingly, the thickness grows at a rate

thickness of turbulent boundary layer

$$\frac{d\delta_t}{dx} \sim \frac{v_\ell}{V} \sim \frac{1}{\ln \text{Re}_\delta}. \quad (15.33)$$

Since $\ln \text{Re}_\delta$ depends only extremely weakly on δ_t , the turbulent boundary layer expands essentially linearly with distance x , by contrast with a laminar boundary layer's $\delta \propto x^{1/2}$.

15.5.2

15.5.2 Coanda Effect and Separation in a Turbulent Boundary Layer

One can easily verify that not only does the turbulent boundary layer expand more rapidly than the corresponding laminar boundary layer would (if it were stable) but also that the turbulent layer is thicker at all locations down the wall. Physically, this distinction can be traced, in part, to the fact that the turbulent boundary layer involves a 3-dimensional velocity field, whereas the corresponding laminar layer would involve only a 2-dimensional field. The enhanced thickness and expansion contribute to the Coanda effect for a turbulent boundary layer—the layer's ability to stick to the wall under adverse conditions (Sec. 15.4.3).

However, there is a price to be paid for this benefit. Since the velocity gradient is increased near the surface, the actual surface shear stress exerted by the turbulent layer, through its laminar sublayer, is significantly larger than in the corresponding laminar boundary layer. As a result, if the entire boundary layer were to remain laminar, the portion that would adhere to the surface would produce less viscous drag than the near-wall laminar sublayer of the turbulent boundary layer. Correspondingly, in a long, straight pipe, the drag on the pipe wall goes up when the boundary layer becomes turbulent.

influence of turbulence on separation of boundary layer and thence on drag

However, for flow around a cylinder or other confined body, the drag goes down! (Cf. Fig. 15.2.) The reason is that in the separated, laminar boundary layer the dominant source of drag is not viscosity but rather a pressure differential between the front face of the cylinder (where the layer adheres) and the back face (where the reverse eddies circulate). The pressure is much lower in the back-face eddies than in the front-face boundary layer, and that pressure differential gives rise to a significant drag, which is reduced when the boundary layer goes turbulent and adheres to the back

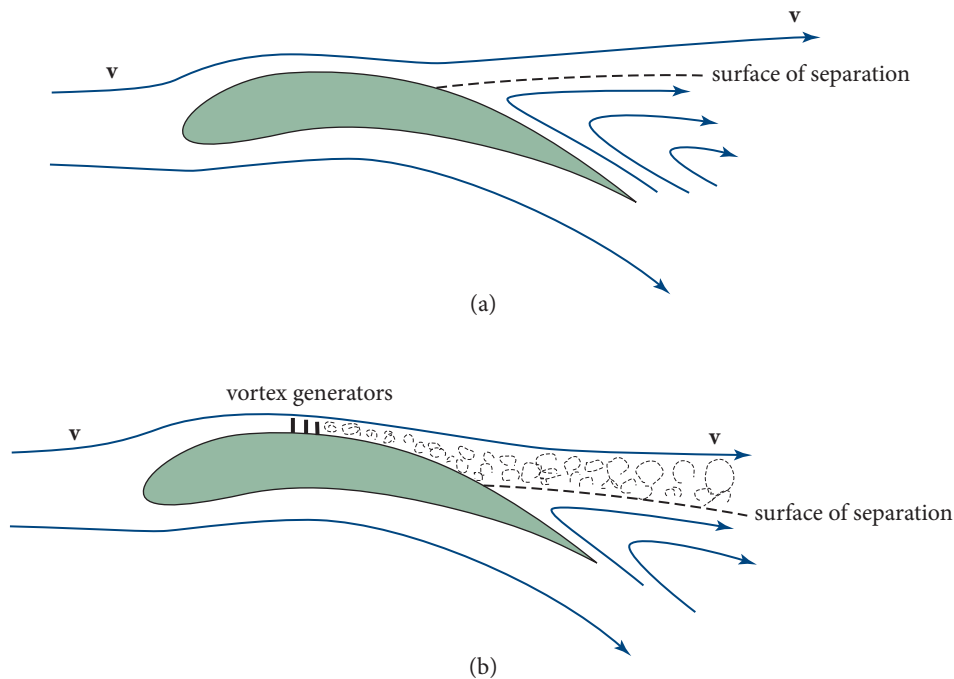

FIGURE 15.11 (a) A laminar boundary layer separating from an airplane wing due to an adverse pressure gradient in the wing's back side. (b) Vortex generators attached to the wing's top face generate turbulence. The turbulent boundary layer sticks to the wing more effectively than does the laminar boundary layer (the Coanda effect). Separation from the wing is delayed, and the wing's lift is increased and drag is decreased.

face. Therefore, if one's goal is to reduce the overall drag and the laminar flow is prone to separation, a nonseparating (or delayed-separation) turbulent layer is preferred to the laminar layer. Similarly (and for essentially the same reason), for an airplane wing, if one's goal is to maintain a large lift, then a nonseparating (or delayed-separation) turbulent layer is superior to a separating, laminar one.¹¹

For this reason, steps are often taken in engineering flows to ensure that boundary layers become and remain turbulent. A crude but effective example is provided by the vortex generators that are installed on the upper surfaces of some airplane wings (Fig. 15.11). These structures are small obstacles on the wing that penetrate through a laminar boundary layer into the free flow. By changing the pressure distribution, they force air into the boundary layer and initiate 3-dimensional vortical motion in the boundary layer, forcing it to become partially turbulent. This turbulence improves the

vortex generators on airplane wings

11. Another example of separation occurs in "lee waves," which can form when wind blows over a mountain range. These consist of standing-wave eddies in the separated boundary layer, somewhat analogous to the Kármán vortex street of Fig. 15.1d. Lee waves are sometimes used by glider pilots to regain altitude.

wing's lift, it allows the airplane to climb more steeply without stalling from boundary-layer separation, and it helps reduce aerodynamical drag.

15.5.3 Instability of a Laminar Boundary Layer

Much work has been done on the linear stability of laminar boundary layers. The principles of such stability analyses should now be familiar, although the technical details are formidable. In the simplest case, an equilibrium flow is identified (e.g., the Blasius profile), and the equations governing the time evolution of small perturbations are written down. The individual Fourier components are assumed to vary in space and time as $\exp i(\mathbf{k} \cdot \mathbf{x} - \omega t)$, and we seek modes that have zero velocity perturbation on the solid surface past which the fluid flows and that decay to zero in the free stream. We ask whether there are unstable modes (i.e., modes with real \mathbf{k} for which the imaginary part of ω is positive, so they grow exponentially in time). Such exponential growth drives the perturbation to become nonlinear, which then typically triggers turbulence.

The results can generally be expressed in the form of a diagram like that in Fig. 15.12. As shown in that figure, there is generally a critical Reynolds number $Re_{crit} \sim 500$ at which one mode becomes linearly unstable. At higher values of the Reynolds number, modes with a range of \mathbf{k} -vectors are linearly unstable. One interesting result of these calculations is that in the absence of viscous forces (i.e., in the limit $Re_\delta \rightarrow \infty$), the boundary layer is unstable if and only if there is a point of inflection in the velocity profile (a point where d^2v_x/dy^2 changes sign; cf. Fig. 15.12 and Ex. 15.11).

dynamically stable and unstable modes in laminar boundary layer

FIGURE 15.12 Values of wave number k for stable and unstable wave modes in a laminar boundary layer with thickness δ , as a function of the boundary layer's Reynolds number $Re_\delta = V\delta/\nu$. If the unperturbed velocity distribution $v_x(y)$ has no inflection point (i.e., if $d^2v_x/dy^2 < 0$ everywhere, as is the case for the Blasius profile; Fig. 14.13), then the unstable modes are confined to the shaded region. If there is an inflection point (so d^2v_x/dy^2 is positive near the wall but becomes negative farther from the wall, as is the case near a surface of separation; Fig. 14.14), then the unstable region is larger (dashed boundary) and does not asymptote to $k = 0$ as $Re_\delta \rightarrow \infty$.

Although, in the absence of an inflection, an inviscid flow $v_x(y)$ is stable, for some such profiles even the slightest viscosity can trigger instability. Physically, this is because viscosity can tap the relative kinetic energies of adjacent flow lines. Viscous-triggered instabilities of this sort are sometimes called *secular instabilities* by contrast with the *dynamical instabilities* that arise in the absence of viscosity. Secular instabilities are quite common in fluid mechanics.

secular instabilities
contrasted with dynamical
instabilities

Exercise 15.11 *Problem: Tollmien-Schlichting Waves*

Consider an inviscid ($\nu = 0$), incompressible flow near a plane wall where a laminar boundary layer is established. Introduce coordinates x parallel to the wall and y perpendicular to it. Let the components of the equilibrium velocity be $v_x(y)$.

- (a) Show that a weak propagating-wave perturbation in the velocity, $\delta v_y \propto \exp ik(x - Ct)$, with k real and frequency Ck possibly complex, satisfies the differential equation

$$\frac{\partial^2 \delta v_y}{\partial y^2} = \left[\frac{1}{(v_x - C)} \frac{d^2 v_x}{dy^2} + k^2 \right] \delta v_y. \quad (15.34)$$

These are called *Tollmien-Schlichting waves*.

- (b) Hence argue that a sufficient condition for unstable wave modes [$\text{Im}(C) > 0$] is that the velocity field possess a point of inflection (i.e., a point where $d^2 v_x / dy^2$ changes sign; cf. Fig. 15.12). The boundary layer can also be unstable in the absence of a point of inflection, but viscosity must then trigger the instability.

EXERCISES

15.5.4 Flight of a Ball

Having developed some insights into boundary layers and their stability, we now apply those insights to the balls used in various sports.

The simplest application is to the dimples on a golf ball (Fig. 15.13a). The dimples provide finite-amplitude disturbances in the flow that can trigger growing wave modes and then turbulence in the boundary layer. The adherence of the boundary layer to the ball is improved, and separation occurs farther behind the ball, leading to a lower drag coefficient and a greater range of flight; see Figs. 15.2 and 15.13a.

A variant on this mechanism is found in the game of cricket, which is played with a ball whose surface is polished leather with a single equatorial seam of rough stitching. When the ball is “bowled” in a nonspinning way with the seam inclined to the direction of motion, a laminar boundary layer exists on the smooth side and a turbulent one on the side with the rough seam (Fig. 15.13b). These two boundary layers separate at different points behind the flow, leading to a net deflection of the air. The ball therefore swerves toward the side with the leading seam. (The effect is strongest when the ball is new and still shiny and on days when the humidity is high, so the thread in the seam swells and is more efficient at making turbulence.)

layers, turbulent and
laminar, produce
deflection

FIGURE 15.13 Boundary layers around (a) golf ball, (b) cricket ball, and (c) baseball as they move leftward relative to the air (i.e., as the air flows rightward as seen in their rest frames).

This mechanism is different from that used to throw a slider or curveball in baseball, in which the pitcher causes the ball to spin about an axis roughly perpendicular to the direction of motion. In the slider the axis is vertical; for a curveball it is inclined at about 45° to the vertical. The spin of the ball creates circulation (in a nonrotating, inertial frame) like that around an airfoil. The pressure forces associated with this circulation produce a net sideways force in the direction of the baseball's rotational velocity on its leading hemisphere (i.e., as seen by the hitter; Fig. 15.13c). The physical origin of this effect is actually quite complex and is only properly described with reference to experimental data. The major effect is that separation is delayed on the side of the ball where the rotational velocity is in the same direction as the airflow and happens sooner on the opposite side (Fig. 15.13c), leading to a pressure differential. The reader may be curious as to how this circulation can be established in view of Kelvin's theorem, Eq. (14.16), which states that if we use a closed curve ∂S , Eq. (14.12a), that is so far from the ball and its wake that viscous forces cannot cause the vorticity to diffuse to it, then the circulation must be zero. What actually happens is similar to an airplane wing (Fig. 14.2b). When the flow is initiated, starting vortices are shed by the baseball and are then convected downstream, leaving behind the net circulation Γ that passes through the ball (Fig. 15.14). This effect is very much larger in 2 dimensions with a rotating cylinder than in 3 dimensions, because the magnitude of the shed vorticity is much larger. It goes by the name of *Magnus effect* in 2 dimensions and *Robins effect* in 3, and it underlies Kutta-Joukowski's theorem for the lift on an airplane wing (Ex. 14.8).

In table tennis, a drive is often hit with *topspin*, so that the ball rotates about a horizontal axis perpendicular to the direction of motion. In this case, the net force is downward, and the ball falls faster toward the table, the effect being largest after it has somewhat decelerated. This allows a ball to be hit hard over the net and bounce before passing the end of the table, increasing the margin for errors in the direction of the hit.

circulation produces
deflection

Magnus and Robins effects

FIGURE 15.14 Vortex lines passing through a spinning ball. The starting vortex is created and shed when the ball is thrown and is carried downstream by the flow as seen in the ball's frame of reference. The vortex lines connecting this starting vortex to the ball lengthen as the flow continues.

Those wishing to improve their curveballs or cure a bad slice are referred to the monographs by Adair (1990), Armenti (1992), and Lighthill (1986).

EXERCISES

Exercise 15.12 *Problem: Effect of Drag*

A well-hit golf ball travels about 300 yards. A fast bowler or fastball pitcher throws a cricket ball or baseball at more than 90 mph (miles per hour). A table-tennis player can hit a forehand return at about 30 mph. The masses and diameters of each of these four types of balls are $m_g \sim 46$ g, $d_g \sim 43$ mm; $m_c \sim 160$ g, $d_c \sim 70$ mm; $m_b \sim 140$ g, $d_b \sim 75$ mm; and $m_{tt} \sim 2.5$ g, $d_{tt} \sim 38$ mm.

- For golf, cricket (or baseball), and table tennis, estimate the Reynolds number of the flow and infer the drag coefficient C_D . (The variation of C_D with Re_d can be assumed to be similar to that in flow past a cylinder; Fig. 15.2.)
- Hence estimate the importance of aerodynamic drag in determining the range of a ball in each of these three cases.

15.6 The Route to Turbulence—Onset of Chaos

15.6

15.6.1 Rotating Couette Flow

15.6.1

Let us examine qualitatively how a viscous flow becomes turbulent. A good example is rotating Couette flow between two long, concentric, differentially rotating cylinders, as introduced in Sec. 14.6.3 and depicted in Fig. 15.15a. This flow was studied in a classic set of experiments by Gollub, Swinney, and collaborators (Fenstermacher, Swinney, and Gollub, 1979; Gorman and Swinney, 1982, and references therein). In these experiments, the inner cylinder rotates and the outer one does not, and the fluid is a liquid whose viscosity is gradually decreased by heating it, so the Reynolds number gradually increases. At low Reynolds numbers, the equilibrium flow is stable,

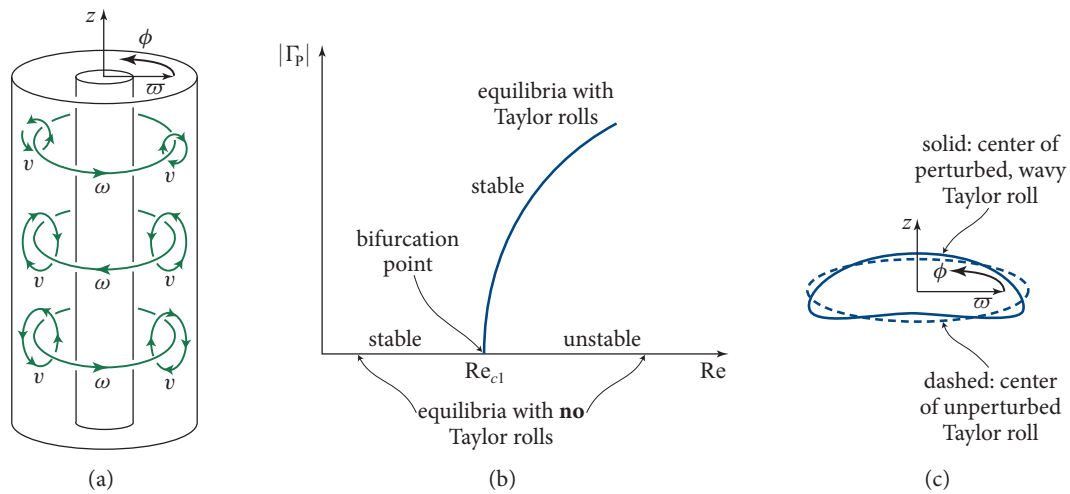

FIGURE 15.15 Bifurcation of equilibria in rotating Couette flow. (a) Equilibrium flow with Taylor rolls. (b) Bifurcation diagram in which the amplitude of the poloidal circulation $|\Gamma_p|$ in a Taylor roll is plotted against the Reynolds number. At low Reynolds numbers ($Re < Re_{c1}$), the only equilibrium flow configuration is smooth, azimuthal flow. At larger Reynolds numbers ($Re_{c1} < Re < Re_{c2}$), there are two equilibria, one with Taylor rolls and stable; the other with smooth, azimuthal flow, which is unstable. (c) Shape of a Taylor roll at $Re_{c1} < Re < Re_{c2}$ (dashed ellipse) and at higher values, $Re_{c2} < Re < Re_{c3}$ (solid, wavy curve).

stationary, and azimuthal (strictly in the ϕ direction; Fig. 15.15a). At very high Reynolds numbers, the flow is unstable, according to the Rayleigh criterion (angular momentum per unit mass decreases outward; Sec. 14.6.3). Therefore, as the Reynolds number is gradually increased, at some critical value Re_{c1} , the flow becomes unstable to the growth of small perturbations. These perturbations drive a transition to a new stationary equilibrium whose form is what one might expect from the Rayleigh-criterion thought experiment (Sec. 14.6.3): it involves poloidal circulation (quasi-circular motions in the r and z directions, called *Taylor rolls*; see Fig. 15.15a).

Thus an equilibrium with a high degree of symmetry has become unstable, and a new, lower-symmetry, stable equilibrium has been established; see Fig. 15.15b. Translational invariance along the cylinder axis has been lost from the flow, even though the boundary conditions remain translationally symmetric. This transition is another example of the bifurcation of equilibria that we discussed when treating the buckling of beams and playing cards (Secs. 11.6 and 12.3.5).

As the Reynolds number is increased further, this process repeats. At a second critical Reynolds number Re_{c2} , a second bifurcation of equilibria occurs in which the azimuthally smooth Taylor rolls become unstable and are replaced by new, azimuthally wavy Taylor rolls; see Fig. 15.15c. Again, an equilibrium with higher symmetry (rotation invariance) has been replaced at a bifurcation point by one of lower symmetry (no rotation invariance). A fundamental frequency f_1 shows up in the fluid's velocity $\mathbf{v}(\mathbf{x}, t)$ as the wavy Taylor rolls circulate around the central cylinder.

Taylor rolls

bifurcation to a lower symmetry state

FIGURE 15.16 The energy spectrum of velocity fluctuations in rotating Couette flow (schematic). (a) Spectrum for a moderate Reynolds number, $Re_{c2} < Re < Re_{c3}$, at which the stable equilibrium flow is that with the wavy Taylor rolls of Fig. 15.15c. (b) Spectrum for a higher Reynolds number, $Re_{c3} < Re < Re_{c4}$, at which the stable flow has wavy Taylor rolls with two incommensurate fundamental frequencies present. (c) Spectrum for a still higher Reynolds number, $Re > Re_{c4}$, at which turbulence has set in.

Since the waves are nonlinearly large, harmonics of this fundamental are also seen when the velocity field is Fourier decomposed (cf. Fig. 15.16a). When the Reynolds number is increased still further to some third critical value Re_{c3} , there is yet another bifurcation. The Taylor rolls now develop a second set of waves, superimposed on the first, with a corresponding new fundamental frequency f_2 that is incommensurate with f_1 . In the energy spectrum one now sees various harmonics of f_1 and of f_2 , as well as sums and differences of these two fundamentals (Fig. 15.16b).

wavy Taylor rolls: two frequencies

It is exceedingly difficult to construct an experimental apparatus that is clean enough—and sufficiently free from the effects of finite lengths of the cylinders—to reveal what happens next as the Reynolds number increases. However, despite the absence of clean experiments, it seemed obvious before the 1970s what would happen. The sequence of bifurcations would continue, with ever-decreasing intervals of Reynolds number ΔRe between them, eventually producing such a complex maze of frequencies, harmonics, sums, and differences, as to be interpreted as turbulence. Indeed, one finds the onset of turbulence described in just this manner in the classic fluid mechanics textbook of Landau and Lifshitz (1959), based on earlier research by Landau (1944).

The 1970s and 1980s brought a major breakthrough in our understanding of the onset of turbulence. This breakthrough came from studies of model dynamical systems with only a few degrees of freedom, in which nonlinear effects play similar roles to the nonlinearities of the Navier-Stokes equation. These studies revealed only a handful of routes to irregular or unpredictable behavior known as chaos, and none were of the Landau type. However, one of these routes starts out in the same manner as does rotating Couette flow: As a control parameter (the Reynolds number in the case of Couette flow) is gradually increased, first oscillations with one fundamental frequency f_1 and its harmonics turn on; then a second frequency f_2 (incommensurate with the first) and its harmonics turn on, along with sums and differences of f_1

route to turbulence in rotating Couette flow: one frequency, two frequencies, then turbulence (chaos)

and f_2 ; and then, suddenly, chaos sets in. Moreover, the chaos is clearly not being produced by a complicated superposition of new frequencies; it is fundamentally different from that.

Remarkably, the experiments of Gollub, Swinney, and colleagues gave convincing evidence that the onset of turbulence in rotating Couette flow takes precisely this route (Fig. 15.16c).

15.6.2 Feigenbaum Sequence, Poincaré Maps, and the Period-Doubling Route to Turbulence in Convection

The simplest of systems in which one can study the several possible routes to chaos are 1-dimensional mathematical maps. A lovely example is the *Feigenbaum sequence*, explored by Mitchell Feigenbaum (1978).

The Feigenbaum sequence is a sequence $\{x_1, x_2, x_3, \dots\}$ of values of a real variable x , given by the rule (sometimes called the *logistic equation*)¹²

$$x_{n+1} = 4ax_n(1 - x_n). \quad (15.35)$$

Here a is a fixed control parameter. It is easy to compute Feigenbaum sequences $\{x_1, x_2, x_3, \dots\}$ for different values of a on a personal computer (Ex. 15.13). What is found is that there are critical parameters a_1, a_2, \dots at which the character of the sequence changes sharply. For $a < a_1$, the sequence asymptotes to a stable fixed point. For $a_1 < a < a_2$, the sequence asymptotes to stable, periodic oscillations between two fixed points. If we increase the parameter further, so that $a_2 < a < a_3$, the sequence becomes a periodic oscillation between four fixed points. The period of the oscillation has doubled. This *period doubling* (not to be confused with frequency doubling) happens again: When $a_3 < a < a_4$, x asymptotes to regular motion between eight fixed points. Period doubling increases with shorter and shorter intervals of a until at some value a_∞ , the period becomes infinite, and the sequence does not repeat. Chaos has set in.

This period doubling is a second route to chaos, very different in character from the one-frequency, two-frequencies, chaos route that appears to occur in rotating Couette flow. Remarkably, fluid dynamical turbulence can set in by this second route as well as by the first. It does so in certain very clean experiments on convection. We return to this phenomenon at the end of this section and then again in Sec. 18.4.

How can so starkly simple and discrete a model as a 1-dimensional map bear any relationship to the continuous solutions of the fluid dynamical differential equations? The answer is quite remarkable.

12. This equation first appeared in discussions of population biology (Verhulst, 1838). If we consider x_n as being proportional to the number of animals in a species (traditionally rabbits), the number in the next season should be proportional to the number of animals already present and to the availability of resources, which will decrease as x_n approaches some maximum value, in this case unity. Hence the terms x_n and $1 - x_n$ in Eq. (15.35).

logistic equation and its Feigenbaum sequence

period doubling route to chaos for Feigenbaum sequence

FIGURE 15.17 (a) Representation of a single periodic oscillation as motion in phase space. (b) Motion in phase space after period doubling. The behavior of the system may also be described by using the coordinate x of the Poincaré map.

Consider a steady flow in which one parameter a (e.g., the Reynolds number) can be adjusted. Now, as we change a and approach turbulence, the flow may develop a periodic oscillation with a single frequency f_1 . We could measure this by inserting some probe at a fixed point in the flow to measure a fluid variable y (e.g., one component of the velocity). We can detect the periodicity either by inspecting the readout $y(t)$ or its Fourier transform \tilde{y} . However, there is another way, which may be familiar from classical mechanics. This is to regard $\{y, \dot{y}\}$ as the two coordinates of a 2-dimensional phase space. (Of course, instead one could measure many variables and their time derivatives, resulting in an arbitrarily large phase space, but let us keep matters as simple as possible.) For a single periodic oscillation, the system will follow a closed path in this phase space (Fig. 15.17a). As we increase a further, a period doubling may occur, and the trajectory in phase space may look like Fig. 15.17b. As we are primarily interested in the development of the oscillations, we need only keep one number for every fundamental period $P_1 = 1/f_1$. Let us do this by taking a section through phase space and introducing a coordinate x on this section, as shown in Fig. 15.17. The n th time the trajectory crosses this section, its crossing point is x_n , and the mapping from x_n to x_{n+1} can be taken as a representative characterization of the flow. When only the frequency f_1 is present, the map reads $x_{n+2} = x_n$ (Fig. 15.17a). When f_1 and $f_2 = \frac{1}{2}f_1$ are present, the map reads $x_{n+4} = x_n$ (Fig. 15.17b). (These specific maps are overly simple compared to what one may encounter in a real flow, but they illustrate the idea.)

To reiterate, instead of describing the flow by the full solution $\mathbf{v}(\mathbf{x}, t)$ to the Navier-Stokes equation and the flow's boundary conditions, we can construct the simple map $x_n \rightarrow x_{n+1}$ to characterize the flow. This procedure is known as a *Poincaré map*. The mountains have labored and brought forth a mouse! However, this mouse turns out to be all that we need. For some convection experiments, the same period-

phase-space
representation of
dynamics

reducing the dynamics of a
fluid's route to turbulence
to a 1-dimensional map:
the Poincaré map

doubling behavior and approach to chaos are present in these maps as in the 2-dimensional phase-space diagram and in the full solution to the fluid dynamical equations. Furthermore, when observed in the Poincaré maps, the transition looks qualitatively the same as in the Feigenbaum sequence. It is remarkable that for a system with so many degrees of freedom, chaotic behavior can be observed by suppressing almost all of them.

If, in the period-doubling route to chaos, we compute the limiting ratio of successive critical parameters,

$$\mathcal{F} = \lim_{j \rightarrow \infty} \frac{a_j - a_{j-1}}{a_{j+1} - a_j}, \quad (15.36)$$

we find that it has the value 4.66920160910 This *Feigenbaum number* seems to be a universal constant characteristic of most period-doubling routes to chaos, independent of the particular map that was used. For example, if we had used

$$x_{n+1} = a \sin \pi x_n \quad (15.37)$$

we would have gotten the same constant.

The most famous illustration of the period-doubling route to chaos is a set of experiments by Libchaber and colleagues on convection in liquid helium, water, and mercury, culminating with the mercury experiment by Libchaber, Laroche, and Fauve (1982). In each experiment (depicted in Fig. 18.1), the temperature at a point was monitored with time as the temperature difference ΔT between the fluid's bottom and top surfaces was slowly increased. In each experiment, at some critical temperature difference ΔT_1 the temperature began to oscillate with a single period; then at some ΔT_2 that oscillation was joined by another at twice the period; at some ΔT_3 another period doubling occurred; at ΔT_4 another; and at ΔT_5 yet another. The frequency doubling could not be followed beyond this because the signal was too weak, but shortly thereafter the convection became turbulent. In each experiment it was possible to estimate the Feigenbaum ratio (15.36), with a_j being the j th critical ΔT . For the highest-accuracy (mercury) experiment, the experimental result agreed with the Feigenbaum number 4.669 . . . to within the experimental accuracy (about 6%); the helium and water experiments also agreed with Feigenbaum to within their experimental accuracies. This result was remarkable. *There truly is a deep universality in the route to chaos, a universality that extends even to fluid-dynamical convection!* This work won Libchaber and Feigenbaum together the prestigious 1986 Wolf Prize.

Feigenbaum number for period doubling route to chaos, and its universality

period doubling route to turbulence in Libchaber convection experiments

universality in the route to chaos

EXERCISES

Exercise 15.13 *Problem: Feigenbaum Number for the Logistic Equation*

Use a computer to calculate the first five critical parameters a_j for the sequence of numbers generated by the logistic equation (15.35). Hence verify that the ratio of successive differences tends toward the Feigenbaum number \mathcal{F} quoted in Eq. (15.36). (Hint: To find suitable starting values x_1 and starting parameter a , you might find it

helpful to construct a graph.) For insights into the universality of the Feigenbaum number, based in part on the renormalization group (Sec. 5.8.3), see Sethna (2006, Ex. 12.9).

15.6.3 Other Routes to Turbulent Convection

15.6.3

Some other routes to turbulence have been seen in convection experiments, in addition to the Feigenbaum/Libchaber period-doubling route. Particularly impressive were convection experiments by Gollub and Benson (1980), which showed—depending on the experimental parameters and the nature of the initial convective flow—four different routes:

four different routes to turbulence in convection experiments

1. The period-doubling route.
2. A variant of the one-frequency, two-frequencies, chaos route. In this variant, a bit after (at higher ΔT) the second frequency appears, incommensurate with the first, the two frequencies become commensurate and their modes become phase locked (one entrains the other); and then a bit later (higher ΔT) the phase lock is broken and simultaneously turbulence sets in.
3. A one-frequency, two-frequencies, three-frequencies, chaos route.
4. An intermittency route, in which, as ΔT is increased, the fluid oscillates between a state with two or three incommensurate modes and a state with turbulence.

These four routes to chaos are all seen in simple mathematical maps or low-dimensional dynamical systems; for example, the intermittency route is seen in the Lorenz equations of Ex. 15.16.

Note that the convective turbulence that is triggered by each of these routes is *weak*; the control parameter ΔT must be increased further to drive the fluid into a fully developed, strong-turbulence state.

weakness and confinement of the turbulence that follows these routes

Also important is the fact that these experimental successes, which compare the onset of turbulence with the behaviors of simple mathematical maps or low-dimensional dynamical systems, all entail fluids that are confined by boundaries and have a modest aspect ratio (ratio of the largest to the smallest dimension), 20:1 for rotating Couette flow and 5:1 for convection. For confined fluids with much larger aspect ratios, and for unconfined fluids, there has been no such success. It may be that the successes are related to the small number of relevant modes in a system with modest aspect ratio.

These successes occurred in the 1970s and 1980s. Much subsequent research focuses on the mechanism by which the final transition to turbulence occurs [e.g., the role of the Navier-Stokes nonlinear term $(\mathbf{v} \cdot \nabla)\mathbf{v}$]. This research involves a mixture of analytical work and numerical simulations, plus some experiment (see, e.g., Grossman, 2000).

The evolution of a dynamical system becomes essentially incalculable after the onset of chaos. This is because, as can be shown mathematically, the state of the system (as measured by the value of a map, or in a fluid by the values of a set of fluid variables) at some future time becomes highly sensitive to the assumed initial state. Paths (in the map or in phase space) that start arbitrarily close together diverge from each other exponentially rapidly with time.

It is important to distinguish this unpredictability of classical chaos from unpredictability in the evolution of a quantum mechanical system. A classical system evolves under precisely deterministic differential equations. Given a full characterization of the system at any time t , the system is fully specified at a later time $t + \Delta t$, for any Δt . However, what characterizes chaos is that the evolution of two identical systems in neighboring initial states will eventually evolve so that they follow totally different histories. The time it takes for this to happen is called the *Lyapunov time*. The practical significance of this essentially mathematical feature is that if, as will always be the case, we can only specify the initial state up to a given accuracy (due to practical considerations, not issues of principle), then the true initial state could be any one of those lying in some region, so we have no way of predicting what the state will be after a few Lyapunov times have elapsed.

Lyapunov time: characterizes sensitivity of a classical system to initial conditions

quantum indeterminacy

Quantum mechanical indeterminacy is different. If we can prepare a system in a given state described by a wave function, then the wave function's evolution will be governed fully deterministically by the time-dependent Schrödinger equation. However, if we choose to make a measurement of an observable, many quite distinct outcomes are immediately possible, and (for a high-precision measurement) the system will be left in an eigenstate corresponding to the actual measured outcome. The quantum mechanical description of classical chaos is the subject of *quantum chaos* (e.g., Gutzwiller, 1990).

The realization that many classical systems have an intrinsic unpredictability despite being deterministic from instant to instant has been widely publicized in popularizations of research on chaos. However, the concept is not particularly new. It was well understood, for example, by Poincaré around 1900, and watching the weather report on the nightly news bears witness to its dissemination into popular culture! What *is* new and intriguing is the manner in which a system transitions from a deterministic to an unpredictable evolution.

examples of chaotic behavior

Chaotic behavior is well documented in a variety of physical dynamical systems: electrical circuits, nonlinear pendula, dripping faucets, planetary dynamics, and so on. The extent to which the principles that have been devised to describe chaos in these systems can also be applied to general fluid turbulence remains a matter for debate. There is no question that similarities exist, and (as we have seen) quantitative success has been achieved by applying chaos results to particular forms of turbulent convection. However, most forms of turbulence are not so easily described, and

there is still a huge gap between the intriguing mathematics of chaotic dynamics and practical applications to natural and technological flows.

EXERCISES

Exercise 15.14 Example: Lyapunov Exponent

Consider the logistic equation (15.35) for the special case $a = 1$, which is large enough to ensure that chaos has set in.

- Make the substitution $x_n = \sin^2 \pi \theta_n$, and show that the logistic equation can be expressed in the form $\theta_{n+1} = 2\theta_n \pmod{1}$; that is, θ_{n+1} equals the fractional part of $2\theta_n$.
- Write θ_n as a “binimal” (binary decimal). For example, $11/16 = 1/2 + 0/4 + 1/8 + 1/16$ has the binary decimal form 0.1011. Explain what happens to this number in each successive iteration.
- Now suppose that an error is made in the i th digit of the starting binimal. When will it cause a major error in the predicted value of x_n ?
- If the error after n iterations is written ϵ_n , show that the Lyapunov exponent p defined by

$$p = \lim_{n \rightarrow \infty} \frac{1}{n} \ln \left| \frac{\epsilon_n}{\epsilon_0} \right| \quad (15.38)$$

is $\ln 2$ (so $\epsilon_n \simeq 2^n \epsilon_0$ for large enough n). Lyapunov exponents play an important role in the theory of dynamical systems.

Exercise 15.15 Example: Strange Attractors

Another interesting 1-dimensional map is provided by the recursion relation

$$x_{n+1} = a \left(1 - 2 \left| x_n - \frac{1}{2} \right| \right). \quad (15.39)$$

- Consider the asymptotic behavior of the variable x_n for different values of the parameter a , with both x_n and a being confined to the interval $[0, 1]$. In particular, find that for $0 < a < a_{\text{crit}}$ (for some a_{crit}), the sequence x_n converges to a stable fixed point, but for $a_{\text{crit}} < a < 1$, the sequence wanders chaotically through some interval $[x_{\text{min}}, x_{\text{max}}]$.
- Using a computer, calculate the value of a_{crit} and the interval $[x_{\text{min}}, x_{\text{max}}]$ for $a = 0.8$.
- The interval $[x_{\text{min}}, x_{\text{max}}]$ is an example of a *strange attractor*. It has the property that if we consider sequences with arbitrarily close starting values, their values of x_n in this range will eventually diverge. Show that the attractor is strange by computing the sequences with $a = 0.8$ and starting values $x_1 = 0.5, 0.51, 0.501$, and 0.5001 . Determine the number of iterations n_ϵ required to produce significant divergence as a function of $\epsilon = x_1 - 0.5$. It is claimed that $n_\epsilon \sim -\ln_2(\epsilon)$. Can you

verify this? Note that the onset of chaos at $a = a_{\text{crit}}$ is quite sudden in this case, unlike the behavior exhibited by the Feigenbaum sequence. See Ruelle (1989) for more on strange attractors.

Exercise 15.16 *Problem: Lorenz Equations*

One of the first discoveries of chaos in a mathematical model was by Lorenz (1963), who made a simple model of atmospheric convection. In this model, the temperature and velocity field are characterized by three variables, x , y , and z , which satisfy the coupled, nonlinear differential equations

$$\begin{aligned}dx/dt &= 10(y - x), \\dy/dt &= -xz + 28x - y, \\dz/dt &= xy - 8z/3.\end{aligned}\tag{15.40}$$

(The precise definitions of x , y , and z need not concern us here.) Integrate these equations numerically to show that x , y , and z follow nonrepeating orbits in the 3-dimensional phase space that they span, and quickly asymptote to a 2-dimensional strange attractor. (It may be helpful to plot out the trajectories of pairs of the dependent variables.)

These Lorenz equations are often studied with the numbers 10, 28, 8/3 replaced by parameters σ , ρ , and β . As these parameters are varied, the behavior of the system changes.

Bibliographic Note

For physical insight into turbulence, we strongly recommend the movies cited in Box 15.2 and the photographs in Van Dyke (1982) and Tritton (1987).

Many fluid mechanics textbooks have good treatments of turbulence. We particularly like White (2008), and also recommend Lautrup (2005) and Panton (2005). Some treatises on turbulence go into the subject much more deeply (though the deeper treatments often have somewhat limited applicability); among these, we particularly like Tennekes and Lumley (1972) and also recommend the more up-to-date Davidson (2005) and Pope (2000). Standard fluid mechanics textbooks for engineers focus particularly on turbulence in pipe flow and in boundary layers (see, e.g., Munson, Young, and Okiishi, 2006; White, 2006; Potter, Wiggert, and Ramadan, 2012).

For the influence of boundary layers and turbulence on the flight of balls of various sorts, see Lighthill (1986), Adair (1990), and Armenti (1992).

For the onset of turbulence in unstable laminar flows, we particularly like Sagdeev, Usikov, and Zaslowsky (1988, Chap. 11) and Acheson (1990, Chap. 9). For the route to chaos in low-dimensional dynamical systems with explicit connections to the onset of turbulence, see Ruelle (1989); for chaos theory with little or no discussion of turbulence, Baker and Gollub (1990), Alligood, Sauer, and Yorke (1996), and Strogatz (2008).

Waves

An ocean traveller has even more vividly the impression
that the ocean is made of waves than that it is made of water.

ARTHUR EDDINGTON (1927)

16.1 Overview

16.1

In the preceding chapters, we have derived the basic equations of fluid dynamics and developed a variety of techniques to describe stationary flows. We have also demonstrated how, even if there exists a rigorous, stationary solution of these equations for a time-steady flow, instabilities may develop, in which the amplitude of an oscillatory disturbance grows with time. These unstable modes of an unstable flow can usually be thought of as waves that interact strongly with the flow and extract energy from it. Of course, wave modes can also be stable and can be studied as independent, individual modes.

Fluid dynamical waves come in a wide variety of forms. They can be driven by a combination of gravitational, pressure, rotational, and surface-tension stresses and also by mechanical disturbances, such as water rushing past a boat or air passing through a larynx. In this chapter, we describe a few examples of wave modes in fluids, chosen to illustrate general wave properties.

The most familiar types of wave are probably *gravity waves* on the surface of a large body of water (Sec. 16.2), such as ocean waves and waves on lakes and rivers. We consider them in the linear approximation and find that they are dispersive in general, though they become nondispersive in the long-wavelength (shallow-water) limit (i.e., when they are influenced by the water's bottom). We also examine the effects of surface tension on gravity waves, which converts them into *capillary waves*, and in this connection we develop a mathematical description of surface tension (see Box 16.4). Boundary conditions can give rise to a discrete spectrum of normal modes, which we illustrate by *helioseismology*: the study of coherent-wave modes excited in the Sun by convective overturning motions.

By contrast with the elastodynamic waves of Chap. 12, waves in fluids often develop amplitudes large enough that nonlinear effects become important (Sec. 16.3). The nonlinearities can cause the front of a wave to steepen and then break—a phenomenon we have all seen at the sea shore. It turns out that, at least under some

BOX 16.1. READERS' GUIDE

- This chapter relies heavily on Chaps. 13 and 14, and less heavily on geometric-optics concepts introduced in Secs. 7.2 and 7.3.
- Chap. 17 relies to some extent on Secs. 16.2, 16.3, and 16.5 of this chapter.
- Sec. 16.3 on solitons on water is a foundation for Sec. 23.6 on solitons in plasmas.
- The remaining chapters of this book do not rely significantly on this chapter.

restrictive conditions, nonlinear waves have very surprising properties. There exist *soliton* or *solitary-wave* modes, in which the front-steepening due to nonlinearity is stably held in check by dispersion, so particular wave profiles are quite robust and propagate for long intervals of time without breaking or dispersing. We demonstrate this behavior by studying flow in a shallow channel. We also explore the remarkable behaviors of such solitons when they pass through each other.

In a nearly rigidly rotating fluid, there are remarkable waves in which the restoring force is the Coriolis effect; they have the unusual property that their group and phase velocities are oppositely directed. These so-called *Rossby waves*, studied in Sec. 16.4, are important in both the oceans and the atmosphere.

The simplest fluid waves of all are small-amplitude *sound waves*—a paradigm for scalar waves. They are nondispersive, just like electromagnetic waves, and are therefore sometimes useful for human communication. We shall study sound waves in Sec. 16.5 and use them to explore (i) the radiation reaction force that acts back on a wave-emitting object (a fundamental physics issue) and (ii) matched asymptotic expansions (a mathematical physics technique). We also describe how sound waves can be produced by fluid flows. This process will be illustrated with the problem of sound generation by high-speed turbulent flows—a problem that provides a good starting point for the topic of the following chapter, compressible flows.

Other examples of fluid waves are treated elsewhere in Part V: Kelvin-Helmholtz waves at the interface between two fluids that move relative to each other (Sec. 14.6.1); Tollmien-Schlichting waves in a laminar boundary layer (Ex. 15.11); lee waves in a separated boundary layer (footnote in Sec. 15.5.2); wavy Taylor rolls in rotating Couette flow (Sec. 15.6.1); shock waves (Sec. 17.5); Sedov-Taylor blast waves (Sec. 17.6); hydraulic jumps (Ex. 17.10); internal waves, which propagate when fluid is stratified in a gravitational field (Ex. 18.8); and various types of magnetohydrodynamic waves (Chap. 19).

BOX 16.2. MOVIES RELEVANT TO THIS CHAPTER

We strongly recommend that the reader view the following movies dealing with waves:

- Bryson (1964)—waves in fluids.
- Fultz (1969)—relevant to Rossby waves, Sec. 16.4.
- Rouse (1963c)—relevant to gravity waves on the surface of water, Sec. 16.2.

As in Chaps. 14 and 15, readers are urged to watch movies in parallel with reading this chapter; see Box 16.2.

16.2 Gravity Waves on and beneath the Surface of a Fluid

*Gravity waves*¹ are waves on and beneath the surface of a fluid, for which the restoring force is the downward pull of gravity. Familiar examples are ocean waves and the waves produced on the surface of a pond when a pebble is thrown in. Less familiar examples are “g modes” of vibration inside the Sun, discussed at the end of this section.

Consider a small-amplitude wave propagating along the surface of a flat-bottomed lake with depth h_0 , as shown in Fig. 16.1. As the water’s displacement is small, we can describe the wave as a linear perturbation about equilibrium. The equilibrium water is at rest (i.e., it has velocity $\mathbf{v} = 0$). The water’s perturbed motion is essentially inviscid and incompressible, so $\nabla \cdot \mathbf{v} = 0$. A simple application of the equation of vorticity transport, Eq. (14.6), assures us that, since the water is static and thus irrotational before and after the wave passes, it must also be irrotational in the wave. Therefore, we can describe the wave inside the water by a velocity potential ψ whose gradient is the velocity field:

$$\mathbf{v} = \nabla \psi. \quad (16.1)$$

Incompressibility, $\nabla \cdot \mathbf{v} = 0$, applied to this equation, implies that ψ satisfies Laplace’s equation:

$$\nabla^2 \psi = 0. \quad (16.2)$$

We introduce horizontal coordinates x, y and a vertical coordinate z measured upward from the lake’s equilibrium surface (Fig. 16.1). For simplicity we confine

1. Not to be confused with gravitational waves, which are waves in the relativistic gravitational field (spacetime curvature) that propagate at the speed of light, and which we meet in Chap. 27.

16.2

gravity waves

velocity potential

Laplace’s equation
for irrotational,
incompressible flow

FIGURE 16.1 Gravity waves propagating horizontally across a lake with constant depth h_o .

attention to a sinusoidal wave propagating in the x direction with angular frequency ω and wave number k . Then ψ and all other perturbed quantities have the form $f(z) \exp[i(kx - \omega t)]$ for some function $f(z)$. More general disturbances can be expressed as a superposition of many of these elementary wave modes propagating in various horizontal directions (and in the limit, as a Fourier integral over modes). All the properties of such superpositions follow straightforwardly from those of our elementary plane-wave mode (see Secs. 7.2.2 and 7.3), so we continue to focus on it.

We can use Laplace's equation (16.2) to solve for the vertical variation $f(z)$ of the velocity potential. As the horizontal variation at a particular time is $\propto \exp(ikx)$, direct substitution into Eq. (16.2) gives two possible vertical variations: $\psi \propto \exp(\pm kz)$. The precise linear combination of these two forms is dictated by the boundary conditions. The boundary condition we need is that the vertical component of velocity $v_z = \partial\psi/\partial z$ vanish at the bottom of the lake ($z = -h_o$). The only combination that can vanish is a sinh function. Its integral, the velocity potential, therefore involves a cosh function:

$$\psi = \psi_0 \cosh[k(z + h_o)] \exp[i(kx - \omega t)]. \quad (16.3)$$

An alert reader might note at this point that, for this ψ , the horizontal component of velocity $v_x = \psi_{,x} = ik\psi$ does not vanish at the lake bottom, in violation of the no-slip boundary condition. In fact, as we discussed in Sec. 14.4, a thin, viscous boundary layer along the bottom of the lake will join our potential-flow solution (16.3) to nonslip fluid at the bottom. We ignore the boundary layer under the (justifiable) assumption that for our oscillating waves, it is too thin to affect much of the flow.

Returning to the potential flow, we must also impose a boundary condition at the surface. This can be obtained from Bernoulli's law. The version of Bernoulli's law that we need is that for an irrotational, isentropic, time-varying flow:

$$\mathbf{v}^2/2 + h + \Phi + \partial\psi/\partial t = \text{const everywhere in the flow} \quad (16.4)$$

boundary condition at bottom of lake

velocity potential for gravity waves

[Eqs. (13.51), (13.54)]. We apply this law at the surface of the perturbed water. Let us examine each term:

1. The term $\mathbf{v}^2/2$ is quadratic in a perturbed quantity and therefore can be dropped.
2. The enthalpy $h = u + P/\rho$ (cf. Box 13.2) is a constant, since u and ρ are constants throughout the fluid and P is constant on the surface (equal to the atmospheric pressure).²
3. The gravitational potential at the fluid surface is $\Phi = g\zeta$, where $\zeta(x, t)$ is the surface's vertical displacement from equilibrium, and we ignore an additive constant.
4. The constant on the right-hand side, which could depend on time [$C(t)$], can be absorbed in the velocity potential term $\partial\psi/\partial t$ without changing the physical observable $\mathbf{v} = \nabla\psi$.

Bernoulli's law applied at the surface therefore simplifies to give

$$g\zeta + \frac{\partial\psi}{\partial t} = 0. \quad (16.5)$$

The vertical component of the surface velocity in the linear approximation is just $v_z(z=0, t) = \partial\zeta/\partial t$. Expressing v_z in terms of the velocity potential, we then obtain

$$\frac{\partial\zeta}{\partial t} = v_z = \frac{\partial\psi}{\partial z}. \quad (16.6)$$

Combining this expression with the time derivative of Eq. (16.5), we obtain an equation for the vertical gradient of ψ in terms of its time derivative:

$$g \frac{\partial\psi}{\partial z} = - \frac{\partial^2\psi}{\partial t^2}. \quad (16.7)$$

Finally, substituting Eq. (16.3) into Eq. (16.7) and setting $z = 0$ [because we derived Eq. (16.7) only at the water's surface], we obtain the dispersion relation³ for linearized gravity waves:

$$\omega^2 = gk \tanh(kh_o). \quad (16.8)$$

How do the individual elements of fluid move in a gravity wave? We can answer this question (Ex. 16.1) by computing the vertical and horizontal components of the velocity $v_x = \psi_{,x}$, and $v_z = \psi_{,z}$, with ψ given by Eq. (16.3). We find that the fluid elements undergo forward-rotating elliptical motion, as depicted in Fig. 16.1, similar

2. Actually, a slight variation of the surface pressure is caused by the varying weight of the air above the surface, but as the density of air is typically $\sim 10^{-3}$ that of water, this correction is very small.
3. For a discussion of the dispersion relation, phase velocity, and group velocity for waves, see Sec. 7.2.

to that for Rayleigh waves on the surface of a solid (Sec. 12.4.2). However, in gravity waves, the sense of rotation is the same (forward) at all depths, in contrast to reversals with depth found in Rayleigh waves [cf. the discussion following Eq. (12.62)].

We now consider two limiting cases: deep water and shallow water.

16.2.1 Deep-Water Waves and Their Excitation and Damping

When the water is deep compared to the wavelength of the waves, $kh_o \gg 1$, the dispersion relation (16.8) becomes

$$\omega = \sqrt{gk}. \quad (16.9)$$

Thus deep-water waves are dispersive (see Sec. 7.2); their group velocity $V_g \equiv d\omega/dk = \frac{1}{2}\sqrt{g/k}$ is half their phase velocity, $V_{ph} \equiv \omega/k = \sqrt{g/k}$. [Note that we could have deduced the deep-water dispersion relation (16.9), up to a dimensionless multiplicative constant, by dimensional arguments: The only frequency that can be constructed from the relevant variables g , k , and ρ is \sqrt{gk} .]

The quintessential example of deep-water waves is waves on an ocean or a lake before they near the shore, so the water's depth is much greater than their wavelength. Such waves, of course, are excited by wind. We have discussed this excitation in Sec. 14.6.2. There we found that the Kelvin-Helmholtz instability (where air flowing in a laminar fashion over water would raise waves) is strongly suppressed by gravity, so this mechanism does not work. Instead, the excitation is by a turbulent wind's randomly fluctuating pressures pounding on the water's surface. Once the waves have been generated, they can propagate great distances before viscous dissipation damps them; see Ex. 16.2.

16.2.2 Shallow-Water Waves

For shallow-water waves ($kh_o \ll 1$), the dispersion relation (16.8) becomes

$$\omega = \sqrt{gh_o} k. \quad (16.10)$$

Thus these waves are nondispersive; their phase and group velocities are equal: $V_{ph} = V_g = \sqrt{gh_o}$.

Later, when studying solitons, we shall need two special properties of shallow-water waves. First, when the depth of the water is small compared with the wavelength, but not very small, the waves will be slightly dispersive. We can obtain a correction to Eq. (16.10) by expanding the tanh function of Eq. (16.8) as $\tanh x = x - x^3/3 + \dots$. The dispersion relation then becomes

$$\omega = \sqrt{gh_o} \left(1 - \frac{1}{6}k^2h_o^2 \right) k. \quad (16.11)$$

Second, by computing $\mathbf{v} = \nabla\psi$ from Eq. (16.3), we find that in the shallow-water limit the water's horizontal motions are much larger than its vertical motions and are

dispersion relation for gravity waves in deep water

dispersion relation from dimensional argument

dispersion relation for gravity waves in shallow water

essentially independent of depth. The reason, physically, is that the fluid acceleration is produced almost entirely by a horizontal pressure gradient (caused by spatially variable water depth) that is independent of height; see Ex. 16.1.

Often shallow-water waves have heights ξ that are comparable to the water's undisturbed depth h_o , and h_o changes substantially from one region of the flow to another. A familiar example is an ocean wave nearing a beach. In such cases, the wave equation is modified by nonlinear and height-dependent effects. In Box 16.3 we derive the equations that govern such waves, and in Ex. 16.3 and Sec. 16.3 we explore properties of these waves.

BOX 16.3. NONLINEAR SHALLOW-WATER WAVES WITH VARIABLE DEPTH

Consider a nonlinear shallow-water wave propagating on a body of water with variable depth. Let $h_o(x, y)$ be the depth of the undisturbed water at location (x, y) , and let $\xi(x, y, t)$ be the height of the wave, so the depth of the water in the presence of the wave is $h = h_o + \xi$. As in the linear-wave case, the transverse fluid velocity (v_x, v_y) inside the water is nearly independent of height z , so the wave is characterized by three functions $\xi(x, y, t)$, $v_x(x, y, t)$, and $v_y(x, y, t)$. These functions are governed by the law of mass conservation and the inviscid Navier-Stokes equation (i.e., the Euler equation).

The mass per unit area is $\rho h = \rho(h_o + \xi)$, and the corresponding mass flux (mass crossing a unit length per unit time) is $\rho h \mathbf{v} = \rho(h_o + \xi) \mathbf{v}$, where \mathbf{v} is the 2-dimensional, horizontal vectorial velocity $\mathbf{v} = v_x \mathbf{e}_x + v_y \mathbf{e}_y$. Mass conservation, then, requires that $\partial[\rho(h_o + \xi)]/\partial t + {}^{(2)}\nabla \cdot [\rho(h_o + \xi) \mathbf{v}] = 0$, where ${}^{(2)}\nabla$ is the 2-dimensional gradient operator that acts solely in the horizontal $(x-y)$ plane. Since ρ is constant, and h_o is time independent, this expression becomes

$$\partial \xi / \partial t + {}^{(2)}\nabla \cdot [(h_o + \xi) \mathbf{v}] = 0. \quad (1a)$$

The Euler equation for \mathbf{v} at an arbitrary height z in the water is $\partial \mathbf{v} / \partial t + (\mathbf{v} \cdot {}^{(2)}\nabla) \mathbf{v} = -(1/\rho) {}^{(2)}\nabla P$, and hydrostatic equilibrium gives the pressure as the weight per unit area of the overlying water: $P = g(\xi - z)\rho$ (where height z is measured from the water's undisturbed surface). Combining these equations, we obtain

$$\partial \mathbf{v} / \partial t + (\mathbf{v} \cdot {}^{(2)}\nabla) \mathbf{v} + g {}^{(2)}\nabla \xi = 0. \quad (1b)$$

Equations (1) are used, for example, in theoretical analyses of tsunamis (Ex. 16.3).

Exercise 16.1 *Example: Fluid Motions in Gravity Waves*

- (a) Show that in a gravity wave in water of arbitrary depth (deep, shallow, or in between), each fluid element undergoes forward-rolling elliptical motion as shown in Fig. 16.1. (Assume that the amplitude of the water's displacement is small compared to a wavelength.)
- (b) Calculate the longitudinal diameter of the motion's ellipse, and the ratio of vertical to longitudinal diameters, as functions of depth.
- (c) Show that for a deep-water wave, $kh_o \gg 1$, the ellipses are all circles with diameters that die out exponentially with depth.
- (d) We normally think of a circular motion of fluid as entailing vorticity, but a gravity wave in water has vanishing vorticity. How can this vanishing vorticity be compatible with the circular motion of fluid elements?
- (e) Show that for a shallow-water wave, $kh_o \ll 1$, the motion is (nearly) horizontal and is independent of height z .
- (f) Compute the fluid's pressure perturbation $\delta P(x, z, t)$ inside the fluid for arbitrary depth. Show that, for a shallow-water wave, the pressure is determined by the need to balance the weight of the overlying fluid, but for greater depth, vertical fluid accelerations alter this condition of weight balance.

Exercise 16.2 *Problem: Viscous Damping of Deep-Water Waves*

- (a) Show that viscosity damps a monochromatic deep-water wave with an amplitude e -folding time $\tau_* = (2\nu k^2)^{-1}$, where k is the wave number, and ν is the kinematic viscosity. [Hint: Compute the energy E in the wave and the rate of loss of energy to viscous heating \dot{E} , and argue that $\tau_* = -2E/\dot{E}$. Recall the discussions of energy in Sec. 13.5.5 and viscous heating in Sec. 13.7.4.]
- (b) As an example, consider the ocean waves that one sees at an ocean beach when the surf is "up" (large-amplitude waves). These are usually generated by turbulent winds in storms in the distant ocean, 1,000 km or farther from shore. The shortest wavelengths present should be those for which the damping length $C\tau_*$ is about 1,000 km; shorter wavelengths than that will have been dissipated before reaching shore. Using the turbulent viscosity $\nu \sim 0.03 \text{ m}^2 \text{ s}^{-1}$ that we deduced from the observed thicknesses of wind-driven Ekman layers in the ocean (Ex. 14.21), compute this shortest wavelength for the large-amplitude waves, and compare with the wavelengths you have observed at an ocean beach. You should get pretty good agreement, thanks to a weak sensitivity of the wavelength to the rather uncertain turbulent viscosity.
- (c) Make similar comparisons of theory and observation for (i) the choppy, short-wavelength ocean waves that one sees when (and only when) a local wind is blowing, and (ii) waves on a small lake.

Exercise 16.3 Example: Shallow-Water Waves with Variable Depth; Tsunamis⁴

Consider small-amplitude (linear) shallow-water waves in which the height of the bottom boundary varies, so the unperturbed water's depth is variable: $h_o = h_o(x, y)$.

- (a) Using the theory of nonlinear shallow-water waves with variable depth (Box 16.3), show that the wave equation for the perturbation $\xi(x, y, t)$ of the water's height takes the form

$$\frac{\partial^2 \xi}{\partial t^2} - {}^{(2)}\nabla \cdot (gh_o {}^{(2)}\nabla \xi) = 0. \quad (16.12)$$

Here ${}^{(2)}\nabla$ is the 2-dimensional gradient operator that acts in the horizontal (i.e., x - y) plane. Note that gh_o is the square of the wave's propagation speed C^2 (phase speed and group speed), so this equation takes the same form as Eq. (7.17) from the geometric-optics approximation in Sec. 7.3.1, with $W = 1$.

- (b) Describe what happens to the direction of propagation of a wave as the depth h_o of the water varies (either as a set of discrete jumps in h_o or as a slowly varying h_o). As a specific example, how must the propagation direction change as waves approach a beach (but when they are sufficiently far out from the beach that nonlinearities have not yet caused them to begin to break)? Compare with your own observations at a beach.
- (c) Tsunamis are gravity waves with enormous wavelengths (~ 100 km or so) that propagate on the deep ocean. Since the ocean depth is typically $h_o \sim 4$ km, tsunamis are governed by the shallow-water wave equation (16.12). What would you have to do to the ocean floor to create a lens that would focus a tsunami, generated by an earthquake near Japan, so that it destroys Los Angeles? (For simulations of tsunami propagation, see, e.g., <http://bullard.esc.cam.ac.uk/~taylor/Tsunami.html>.)
- (d) The height of a tsunami, when it is in the ocean with depth $h_o \sim 4$ km, is only ~ 1 m or less. Use the geometric-optics approximation (Sec. 7.3) to show that the tsunami's wavelength decreases as $\lambda \propto \sqrt{h_o}$ and its amplitude increases as $\max(\xi) \propto 1/h_o^{1/4}$ as the tsunami nears land and the water's depth h_o decreases.

How high [$\max(\xi)$] does the tsunami get when nonlinearities become strongly important? (Assume a height of 1 m in the deep ocean.) How does this compare with the heights of historically disastrous tsunamis when they hit land? From your answer you should conclude that the nonlinearities must play a major role in raising the height. Equations (16.11) in Box 16.3 are used by geophysicists to analyze this nonlinear growth of the tsunami height. If the wave breaks, then these equations fail, and ideas developed (in rudimentary form) in Ex. 17.10 must be used.

4. Exercise courtesy of David Stevenson.

When the wavelength is short (so k is large), we must include the effects of *surface tension* on the surface boundary condition. Surface tension can be treated as an isotropic force per unit length, γ , that lies in the surface and is unaffected by changes in the shape or size of the surface; see Box 16.4. In the case of a gravity wave traveling in the x direction, this tension produces on the fluid's surface a net downward force per unit area $-\gamma d^2\xi/dx^2 = \gamma k^2\xi$, where k is the horizontal wave number. [This downward force is like that on a violin string; cf. Eq. (12.29) and associated discussion.] This additional force must be included as an augmentation of $\rho g\xi$. Correspondingly, the effect of surface tension on a mode with wave number k is simply to change the true acceleration of gravity to an effective acceleration of gravity:

$$g \rightarrow g + \frac{\gamma k^2}{\rho}. \quad (16.13)$$

The remainder of the derivation of the dispersion relation for deep-water gravity waves carries over unchanged, and the dispersion relation becomes

BOX 16.4. SURFACE TENSION

In a water molecule, the two hydrogen atoms stick out from the larger oxygen atom somewhat like Mickey Mouse's ears, with an H-O-H angle of 105° . This asymmetry of the molecule gives rise to a large electric dipole moment. In the interior of a body of water the dipole moments are oriented rather randomly, but near the water's surface they tend to be parallel to the surface and bond with one another to create surface tension—a macroscopically isotropic, 2-dimensional tension force (force per unit length) γ that is confined to the water's surface.

More specifically, consider a line L of unit length in the water's surface [drawing (a)]. The surface water on one side of L exerts a tension (pulling) force on the surface water on the other side. The magnitude of this force is γ , and it is orthogonal to the line L regardless of L 's orientation. This behavior is analogous to an isotropic pressure P in 3 dimensions, which acts orthogonally across any unit area.

(continued)

BOX 16.4. (continued)

Choose a point \mathcal{P} in the water's surface, and introduce local Cartesian coordinates there with x and y lying in the surface and z orthogonal to it [drawing (b)]. In this coordinate system, the 2-dimensional stress tensor associated with surface tension has components ${}^{(2)}T_{xx} = {}^{(2)}T_{yy} = -\gamma$, analogous to the 3-dimensional stress tensor for an isotropic pressure: $T_{xx} = T_{yy} = T_{zz} = P$. We can also use a 3-dimensional stress tensor to describe the surface tension: $T_{xx} = T_{yy} = -\gamma\delta(z)$; all other $T_{jk} = 0$. If we integrate this 3-dimensional stress tensor through the water's surface, we obtain the 2-dimensional stress tensor: $\int T_{jk}dz = {}^{(2)}T_{jk}$ (i.e., $\int T_{xx}dz = \int T_{yy}dz = -\gamma$). The 2-dimensional metric of the surface is ${}^{(2)}\mathbf{g} = \mathbf{g} - \mathbf{e}_z \otimes \mathbf{e}_z$; in terms of this 2-dimensional metric, the surface tension's 3-dimensional stress tensor is $\mathbf{T} = -\gamma\delta(z){}^{(2)}\mathbf{g}$.

Water is not the only fluid that exhibits surface tension; all fluids do so, at the interfaces between themselves and other substances. For a thin film (e.g., a soap bubble), there are two interfaces (the top and bottom faces of the film), so if we ignore the film's thickness, its stress tensor is twice as large as for a single surface, $\mathbf{T} = -2\gamma\delta(z){}^{(2)}\mathbf{g}$.

The hotter the fluid, the more randomly its surface molecules will be oriented (and hence the smaller the fluid's surface tension γ will be). For water, γ varies from 75.6 dyne/cm at $T = 0^\circ\text{C}$, to 72.0 dyne/cm at $T = 25^\circ\text{C}$, to 58.9 dyne/cm at $T = 100^\circ\text{C}$.

In Exs. 16.4–16.6, we explore some applications of surface tension. In Sec. 16.2.3 and Exs. 16.7 and 16.8, we consider the influence of surface tension on water waves. In Ex. 5.14, we study the statistical thermodynamics of surface tension and its role in the nucleation of water droplets in clouds and fog.

$$\omega^2 = gk + \frac{\gamma k^3}{\rho} \quad (16.14)$$

[cf. Eqs. (16.9) and (16.13)]. When the second term dominates, the waves are sometimes called *capillary waves*. In Exs. 16.7 and 16.8 we explore some aspects of capillary waves. In Exs. 16.4–16.6 we explore some other aspects of surface tension.

dispersion relation for gravity waves in deep water with surface tension

capillary waves

Exercise 16.4 *Problem: Maximum Size of a Water Droplet*

What is the maximum size of water droplets that can form by water very slowly dripping out of a syringe? Out of a water faucet (whose opening is far larger than that of a syringe)?

EXERCISES

Exercise 16.5 *Problem: Force Balance for an Interface between Two Fluids*

Consider a point \mathcal{P} in the curved interface between two fluids. Introduce Cartesian coordinates at \mathcal{P} with x and y parallel to the interface and z orthogonal [as in diagram (b) in Box 16.4], and orient the x - and y -axes along the directions of the interface's principal curvatures, so the local equation for the interface is

$$z = \frac{x^2}{2R_1} + \frac{y^2}{2R_2}. \quad (16.15)$$

Here R_1 and R_2 are the surface's principal radii of curvature at \mathcal{P} ; note that each of them can be positive or negative, depending on whether the surface bends up or down along their directions. Show that, in equilibrium, stress balance, $\nabla \cdot \mathbf{T} = 0$, for the surface implies that the pressure difference across the surface is

$$\Delta P = \gamma \left(\frac{1}{R_1} + \frac{1}{R_2} \right), \quad (16.16)$$

where γ is the surface tension.

Exercise 16.6 *Challenge: Minimum Area of a Soap Film*

For a soap film that is attached to a bent wire (e.g., to the circular wire that a child uses to blow a bubble), the air pressure on the film's two sides is the same. Therefore, Eq. (16.16) (with γ replaced by 2γ , since the film has two faces) tells us that at every point in the film, its two principal radii of curvature must be equal and opposite: $R_1 = -R_2$. It is an interesting exercise in differential geometry to show that this requirement means that the soap film's surface area is an extremum with respect to variations of the film's shape, holding its boundary on the wire fixed. If you know enough differential geometry, prove this extremal-area property of soap films, and then show that for the film's shape to be stable, its extremal area must actually be a minimum.

Exercise 16.7 *Problem: Capillary Waves*

Consider deep-water gravity waves of short enough wavelength that surface tension must be included, so the dispersion relation is Eq. (16.14). Show that there is a minimum value of the group velocity, and find its value together with the wavelength of the associated wave. Evaluate these for water ($\gamma \sim 0.07 \text{ N m}^{-1} = 70 \text{ dyne/cm}$). Try performing a crude experiment to verify this phenomenon.

Exercise 16.8 *Example: Boat Waves*

A toy boat moves with uniform velocity \mathbf{u} across a deep pond (Fig. 16.2). Consider the wave pattern (time-independent in the boat's frame) produced on the water's surface at distances large compared to the boat's size. Both gravity waves and surface-tension (*capillary*) waves are excited. Show that capillary waves are found both ahead of and behind the boat, whereas gravity waves occur solely inside a trailing wedge. More specifically, do the following.

FIGURE 16.2 Capillary and gravity waves excited by a small boat (Ex. 16.8).

- (a) In the rest frame of the water, the waves' dispersion relation is Eq. (16.14). Change notation so that ω is the waves' angular velocity as seen in the boat's frame, and ω_o in the water's frame, so the dispersion relation becomes $\omega_o^2 = gk + (\gamma/\rho)k^3$. Use the Doppler shift (i.e., the transformation between frames) to derive the boat-frame dispersion relation $\omega(k)$.
- (b) The boat radiates a spectrum of waves in all directions. However, only those with vanishing frequency in the boat's frame, $\omega = 0$, contribute to the time-independent (stationary) pattern. As seen in the water's frame and analyzed in the geometric-optics approximation of Chap. 7, these waves are generated by the boat (at points along its horizontal dash-dot trajectory in Fig. 16.2) and travel outward with the group velocity \mathbf{V}_{go} . Regard Fig. 16.2 as a snapshot of the boat and water at a particular moment of time. Consider a wave that was generated at an earlier time, when the boat was at location \mathcal{P} , and that traveled outward from there with speed V_{go} at an angle ϕ to the boat's direction of motion. (You may restrict yourself to $0 \leq \phi \leq \pi/2$.) Identify the point \mathcal{Q} that this wave has reached, at the time of the snapshot, by the angle θ shown in the figure. Show that θ is given by

$$\tan \theta = \frac{V_{go}(k) \sin \phi}{u - V_{go}(k) \cos \phi}, \quad (16.17a)$$

where k is determined by the dispersion relation $\omega_o(k)$ together with the vanishing ω condition:

$$\omega_o(k, \phi) = uk \cos \phi. \quad (16.17b)$$

- (c) Specialize to capillary waves [$k \gg \sqrt{g\rho/\gamma}$]. Show that

$$\tan \theta = \frac{3 \tan \phi}{2 \tan^2 \phi - 1}. \quad (16.18)$$

Demonstrate that the capillary-wave pattern is present for all values of θ (including in front of the boat, $\pi/2 < \theta < \pi$, and behind it, $0 \leq \theta \leq \pi/2$).

(d) Next, specialize to gravity waves, and show that

$$\tan \theta = \frac{\tan \phi}{2 \tan^2 \phi + 1}. \quad (16.19)$$

Demonstrate that the gravity-wave pattern is confined to a trailing wedge with angles $\theta < \theta_{\text{gw}} = \sin^{-1}(1/3) = 19.47^\circ$ (cf. Fig. 16.2). You might try to reproduce these results experimentally.

16.2.4

16.2.4 Helioseismology

The Sun provides an excellent example of the excitation of small-amplitude waves in a fluid body. In the 1960s, Robert Leighton and colleagues at Caltech discovered that the surface of the Sun oscillates vertically with a period of roughly 5 min and a speed of $\sim 1 \text{ km s}^{-1}$. This motion was thought to be an incoherent surface phenomenon until it was shown that the observed variation was, in fact, the superposition of thousands of highly coherent wave modes excited in the Sun's interior—normal modes of the Sun. Present-day techniques allow surface velocity amplitudes as small as 2 mm s^{-1} to be measured, and phase coherence for intervals as long as a year has been observed. Studying the frequency spectrum and its variation provides a unique probe of the Sun's interior structure, just as the measurement of conventional seismic waves (Sec. 12.4) probes Earth's interior.

The description of the Sun's normal modes requires some modification of our treatment of gravity waves. We eschew the details and just outline the principles—which are rather similar to those for normal modes of a homogeneous elastic sphere (Sec. 12.4.4 and Ex. 12.12). First, the Sun is (very nearly) spherical. We therefore work in spherical polar coordinates rather than Cartesian coordinates. Second, the Sun is made of hot gas, and it is no longer a good approximation to assume that the fluid is incompressible. We must therefore replace the equation $\nabla \cdot \mathbf{v} = 0$ with the full equation of continuity (mass conservation) together with the equation of energy conservation, which governs the relationship between the perturbations of density and pressure. Third, the Sun is not uniform. The pressure and density in the unperturbed gas vary with radius in a known manner and must be included. Fourth, the Sun has a finite surface area. Instead of assuming a continuous spectrum of waves, we must now anticipate that the boundary conditions will lead to a discrete spectrum of normal modes. Allowing for these complications, it is possible to derive a differential equation for the perturbations to replace Eq. (16.7). It turns out that a convenient dependent variable (replacing the velocity potential ψ) is the pressure perturbation. The boundary conditions are that the displacement vanish at the center of the Sun and the pressure perturbation vanish at the surface.

At this point the problem is reminiscent of the famous solution for the eigenfunctions of the Schrödinger equation for a hydrogen atom in terms of associated Laguerre

properties of the Sun that influence its helioseismic modes

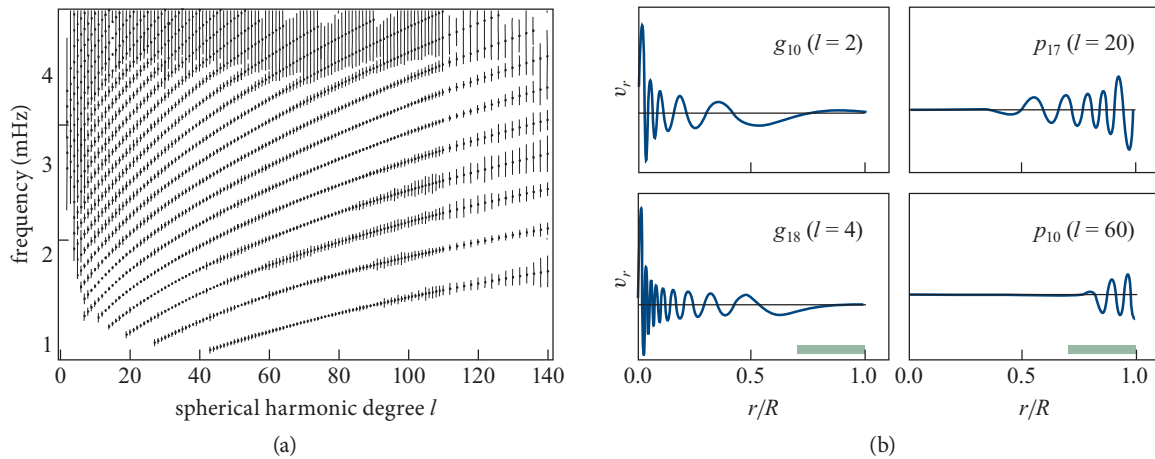

FIGURE 16.3 (a) Measured frequency spectrum for solar p modes with different values of the quantum numbers n and l . The error bars are magnified by a factor of 1,000. The lowest ridge is $n = 0$, the next is $n = 1, \dots$ (b) Sample eigenfunctions for g and p modes labeled by n (subscripts) and l (in parentheses). The ordinate is the radial velocity, and the abscissa is fractional radial distance from the Sun's center to its surface. The solar convection zone is the shaded region at the bottom. Adapted from Libbrecht and Woodard (1991).

polynomials. The wave frequencies of the Sun's normal modes are given by the eigenvalues of the differential equation. The corresponding eigenfunctions can be classified using three quantum numbers, n, l, m , where n counts the number of radial nodes in the eigenfunction, and the angular variation of the pressure perturbation is proportional to the spherical harmonic $Y_l^m(\theta, \phi)$. If the Sun were precisely spherical, the modes with the same n and l but different m would be degenerate, just as is the case for an atom when there is no preferred direction in space. However, the Sun rotates with a latitude-dependent period in the range $\sim 25\text{--}30$ days, which breaks the degeneracy, just as an applied magnetic field in an atom breaks the degeneracy of the atom's states (the Zeeman effect). From the observed splitting of the solar-mode spectrum, it is possible to learn about the distribution of rotational angular momentum inside the Sun.

When this problem is solved in detail, it turns out that there are two general classes of modes. One class is similar to gravity waves, in the sense that the forces that drive the gas's motions are produced primarily by gravity (either directly, or indirectly via the weight of overlying material producing pressure that pushes on the gas). These are called g modes. In the second class (known as p modes),⁵ the pressure forces arise mainly from the compression of the fluid just like in sound waves (which we study in Sec. 16.5). It turns out that the g modes have large amplitudes in the middle of the Sun, whereas the p modes are dominant in the outer layers (Fig. 16.3b). The reasons for this are relatively easy to understand and introduce ideas to which we shall return.

g modes of the Sun or other gravitating fluid spheres

p modes of the Sun or other gravitating fluid spheres

5. There are also formally distinguishable f -modes, which for our purposes are just a subset of the p -modes.

properties of p modes

properties of g modes

The Sun is a hot body, much hotter at its center ($T \sim 1.5 \times 10^7$ K) than on its surface ($T \sim 6,000$ K). The sound speed C is therefore much greater in its interior, and so p modes of a given frequency ω can carry their energy flux $\sim \rho \xi^2 \omega^2 C$ (Sec. 16.5) with much smaller amplitudes ξ than near the surface. Therefore the p -mode amplitudes are much smaller in the center of the Sun than near its surface.

The g modes are controlled by different physics and thus behave differently. The outer $\sim 30\%$ (by radius) of the Sun is *convective* (Chap. 18), because the diffusion of heat is inadequate to carry the huge amount of nuclear power being generated in the solar core. The convection produces an equilibrium variation of pressure and density with radius that are just such as to keep the Sun almost neutrally stable, so that regions that are slightly hotter (cooler) than their surroundings will rise (sink) in the solar gravitational field. Therefore there cannot be much of a mechanical restoring force that would cause these regions to oscillate about their average positions, and so the g modes (which are influenced almost solely by gravity) have little restoring force and thus are evanescent in the convection zone; hence their amplitudes decay quickly with increasing radius there.

We should therefore expect only p modes to be seen in the surface motions, which is indeed the case. Furthermore, we should not expect the properties of these modes to be very sensitive to the physical conditions in the core. A more detailed analysis bears this out.

16.3 16.3 Nonlinear Shallow-Water Waves and Solitons

In recent decades, *solitons* or solitary waves have been studied intensively in many different areas of physics. However, fluid dynamicists became familiar with them in the nineteenth century. In an oft-quoted passage, John Scott-Russell (1844) described how he was riding along a narrow canal and watched a boat stop abruptly. This deceleration launched a single smooth pulse of water which he followed on horseback for 1 or 2 miles, observing it “rolling on a rate of some eight or nine miles an hour, preserving its original figure some thirty feet long and a foot to a foot and a half in height.” This was a soliton—a 1-dimensional, nonlinear wave with fixed profile traveling with constant speed. Solitons can be observed fairly readily when gravity waves are produced in shallow, narrow channels. We use the particular example of a shallow, nonlinear gravity wave to illustrate solitons in general.

16.3.1 16.3.1 Korteweg–de Vries (KdV) Equation

The key to a soliton’s behavior is a robust balance between the effects of dispersion and those of nonlinearity. When one grafts these two effects onto the wave equation for shallow-water waves, then to leading order in the strengths of the dispersion and nonlinearity one gets the *Korteweg–de Vries* (KdV) equation for solitons. Since a completely rigorous derivation of the KdV equation is quite lengthy, we content ourselves with a somewhat heuristic derivation that is based on this grafting process and is designed to emphasize the equation’s physical content.

We choose as the dependent variable in our wave equation the height ζ of the water's surface above its quiescent position, and we confine ourselves to a plane wave that propagates in the horizontal x direction, so $\zeta = \zeta(x, t)$.

In the limit of very weak waves, $\zeta(x, t)$ is governed by the shallow-water dispersion relation, $\omega = \sqrt{gh_o} k$, where h_o is the depth of the quiescent water. This dispersion relation implies that $\zeta(x, t)$ must satisfy the following elementary wave equation [cf. Eq. (16.12)]:

$$0 = \frac{\partial^2 \zeta}{\partial t^2} - gh_o \frac{\partial^2 \zeta}{\partial x^2} = \left(\frac{\partial}{\partial t} - \sqrt{gh_o} \frac{\partial}{\partial x} \right) \left(\frac{\partial}{\partial t} + \sqrt{gh_o} \frac{\partial}{\partial x} \right) \zeta. \quad (16.20)$$

In the second expression, we have factored the wave operator into two pieces, one that governs waves propagating rightward, and the other for those moving leftward. To simplify our derivation and the final wave equation, we confine ourselves to rightward-propagating waves; correspondingly, we can simply remove the left-propagation operator, obtaining

$$\frac{\partial \zeta}{\partial t} + \sqrt{gh_o} \frac{\partial \zeta}{\partial x} = 0. \quad (16.21)$$

(Leftward-propagating waves are described by this same equation with a change of sign on one of the terms.)

We now graft the effects of dispersion onto this rightward-wave equation. The dispersion relation, including the effects of dispersion to leading order, is $\omega = \sqrt{gh_o} k (1 - \frac{1}{6} k^2 h_o^2)$ [Eq. (16.11)]. Now, this dispersion relation ought to be derivable by assuming a variation $\zeta \propto \exp[i(kx - \omega t)]$ and substituting into a generalization of Eq. (16.21) with corrections that take account of the finite depth of the channel. We take a short cut and reverse this process to obtain the generalization of Eq. (16.21) from the dispersion relation. The result is

$$\frac{\partial \zeta}{\partial t} + \sqrt{gh_o} \frac{\partial \zeta}{\partial x} = -\frac{1}{6} \sqrt{gh_o} h_o^2 \frac{\partial^3 \zeta}{\partial x^3}, \quad (16.22)$$

as a simple calculation confirms. This is the linearized KdV equation. It incorporates weak dispersion associated with the finite depth of the channel but is still a linear equation, only useful for small-amplitude waves.

Now let us set aside the dispersive correction and tackle the nonlinearity using the equations derived in Box 16.3. Denoting the depth of the disturbed water by $h = h_o + \zeta$, the nonlinear law of mass conservation [Eq. (1a) of Box 16.3] becomes

$$\frac{\partial h}{\partial t} + \frac{\partial(hv)}{\partial x} = 0, \quad (16.23a)$$

and the Euler equation [Eq. (1b) of Box 16.3] becomes

$$\frac{\partial v}{\partial t} + v \frac{\partial v}{\partial x} + g \frac{\partial h}{\partial x} = 0. \quad (16.23b)$$

Here we have specialized the equations in Box 16.3 to a 1-dimensional wave in the channel and to a constant depth h_o of the channel's undisturbed water. Equations (16.23a) and (16.23b) can be combined to obtain

$$\frac{\partial (v - 2\sqrt{gh})}{\partial t} + (v - \sqrt{gh}) \frac{\partial (v - 2\sqrt{gh})}{\partial x} = 0. \quad (16.23c)$$

This equation shows that the quantity $v - 2\sqrt{gh}$ is constant along characteristics that propagate with speed $v - \sqrt{gh}$. (This constant quantity is a special case of a *Riemann invariant*, a concept that we study in Sec. 17.4.1.) When (as we require below) the nonlinearities are modest, so h does not differ greatly from h_o and the water speed v is small, these characteristics propagate leftward, which implies that for rightward-propagating waves they begin at early times in undisturbed fluid, where $v = 0$ and $h = h_o$. Therefore, the constant value of $v - 2\sqrt{gh}$ is $-2\sqrt{gh_o}$, and correspondingly in regions of disturbed fluid we have

$$v = 2 \left(\sqrt{gh} - \sqrt{gh_o} \right). \quad (16.24)$$

Substituting this into Eq. (16.23a), we obtain

$$\frac{\partial h}{\partial t} + \left(3\sqrt{gh} - 2\sqrt{gh_o} \right) \frac{\partial h}{\partial x} = 0. \quad (16.25)$$

We next substitute $\xi = h - h_o$ and expand to second order in ξ to obtain the final form of our wave equation with nonlinearities but no dispersion:

$$\frac{\partial \xi}{\partial t} + \sqrt{gh_o} \frac{\partial \xi}{\partial x} = -\frac{3\xi}{2} \sqrt{\frac{g}{h_o}} \frac{\partial \xi}{\partial x}, \quad (16.26)$$

where the term on the right-hand side is the nonlinear correction.

We now have separate dispersive corrections (16.22) and nonlinear corrections (16.26) to the rightward-wave equation (16.21). Combining the two corrections into a single equation, we obtain

$$\frac{\partial \xi}{\partial t} + \sqrt{gh_o} \left[\left(1 + \frac{3\xi}{2h_o} \right) \frac{\partial \xi}{\partial x} + \frac{h_o^2}{6} \frac{\partial^3 \xi}{\partial x^3} \right] = 0. \quad (16.27)$$

Finally, we substitute

$$\chi \equiv x - \sqrt{gh_o} t \quad (16.28)$$

to transform to a frame moving rightward with the speed of small-amplitude gravity waves. The result is the full *Korteweg-de Vries* or KdV equation:

$$\frac{\partial \xi}{\partial t} + \frac{3}{2} \sqrt{\frac{g}{h_o}} \left(\xi \frac{\partial \xi}{\partial \chi} + \frac{1}{9} h_o^3 \frac{\partial^3 \xi}{\partial \chi^3} \right) = 0. \quad (16.29)$$

rightward moving spatial coordinate

Korteweg-de Vries (KdV) equation

FIGURE 16.4 Steepening of a Gaussian wave profile by the nonlinear term in the KdV equation. The increase of wave speed with amplitude causes the leading part of the profile to steepen with time (going left to right) and the trailing part to flatten. In the full KdV equation (16.29), this effect can be balanced by the effect of dispersion, which causes the high-frequency Fourier components in the wave to travel slightly slower than the low-frequency ones. This allows stable solitons to form.

16.3.2 Physical Effects in the KdV Equation

16.3.2

Before exploring solutions to the KdV equation (16.29), let us consider the physical effects of its nonlinear and dispersive terms. The second (nonlinear) term $\frac{3}{2}\sqrt{g/h_o} \xi \partial \xi / \partial \chi$ derives from the nonlinearity in the $(\mathbf{v} \cdot \nabla) \mathbf{v}$ term of the Euler equation. The effect of this nonlinearity is to steepen the leading edge of a wave profile and flatten the trailing edge (Fig. 16.4). Another way to understand the effect of this term is to regard it as a nonlinear coupling of linear waves. Since it is nonlinear in the wave amplitude, it can couple waves with different wave numbers k . For example, if we have a purely sinusoidal wave $\propto \exp(ikx)$, then this nonlinearity leads to the growth of a first harmonic $\propto \exp(2ikx)$. Similarly, when two linear waves with spatial frequencies k and k' are superposed, this term describes the production of new waves at the sum and difference of spatial frequencies. We have already met such wave-wave coupling in our study of nonlinear optics (Chap. 10), and in the route to turbulence for rotating Couette flow (Fig. 15.16). We meet it again in nonlinear plasma physics (Chap. 23).

The third term in Eq. (16.29), $\frac{1}{6}\sqrt{g/h_o} h_o^3 \partial^3 \xi / \partial \chi^3$, is linear and is responsible for a weak dispersion of the wave. The higher-frequency Fourier components travel with slower phase velocities than do the lower-frequency components. This has two effects. One is an overall spreading of a wave in a manner qualitatively familiar from elementary quantum mechanics (cf. Ex. 7.2). For example, in a Gaussian wave packet with width Δx , the range of wave numbers k contributing significantly to the profile is $\Delta k \sim 1/\Delta x$. The spread in the group velocity is then $\Delta v_g \sim \Delta k \partial^2 \omega / \partial k^2 \sim (gh_o)^{1/2} h_o^2 k \Delta k$ [cf. Eq. (16.11)]. The wave packet will then double in size in a time

$$t_{\text{spread}} \sim \frac{\Delta x}{\Delta v_g} \sim \left(\frac{\Delta x}{h_o} \right)^2 \frac{1}{k \sqrt{gh_o}}. \quad (16.30)$$

FIGURE 16.5 Production of stable solitons out of an irregular initial wave profile.

The second effect is that since the high-frequency components travel somewhat slower than the low-frequency ones, the profile tends to become asymmetric, with the leading edge less steep than the trailing edge.

Given the opposite effects of these two corrections (nonlinearity makes the wave's leading edge steeper; dispersion reduces its steepness), it should not be too surprising in hindsight that it is possible to find solutions to the KdV equation in which nonlinearity balances dispersion, so there is no change of shape as the wave propagates and no spreading. What is quite surprising, though, is that these solutions, called *solitons*, are very robust and arise naturally out of random initial data. That is to say, if we solve an initial value problem numerically starting with several peaks of random shape and size, then although much of the wave will spread and disappear due to dispersion, we will typically be left with several smooth soliton solutions, as in Fig. 16.5.

solitons in which nonlinearity balances dispersion

16.3.3 Single-Soliton Solution

We can discard some unnecessary algebraic luggage in the KdV equation (16.29) by transforming both independent variables using the substitutions

$$\zeta = \frac{\xi}{h_0}, \quad \eta = \frac{3\chi}{h_0} = \frac{3(x - \sqrt{gh_0}t)}{h_0}, \quad \tau = \frac{9}{2} \sqrt{\frac{g}{h_0}} t. \quad (16.31)$$

The KdV equation then becomes

$$\frac{\partial \zeta}{\partial \tau} + \zeta \frac{\partial \zeta}{\partial \eta} + \frac{\partial^3 \zeta}{\partial \eta^3} = 0. \quad (16.32)$$

There are well-understood mathematical techniques (see, e.g., Whitham, 1974) for solving equations like the KdV equation. However, here we just quote solutions and explore their properties. The simplest solution to the dimensionless KdV equation (16.32) is

$$\zeta = \zeta_0 \operatorname{sech}^2 \left[\left(\frac{\zeta_0}{12} \right)^{1/2} \left(\eta - \frac{1}{3} \zeta_0 \tau \right) \right]. \quad (16.33)$$

simplified form of KdV equation

single-soliton solution of KdV equation

FIGURE 16.6 Profile of the single-soliton solution [Eqs. (16.33) and (16.31)] of the KdV equation. The half-width $\chi_{1/2}$ is inversely proportional to the square root of the peak height ξ_0 .

This solution, depicted in Fig. 16.6, describes a one-parameter family of stable solitons. For each such soliton (each ζ_0), the soliton maintains its shape while propagating at speed $d\eta/d\tau = \zeta_0/3$ relative to a weak wave. By transforming to the rest frame of the unperturbed water using Eqs. (16.28) and (16.31), we find for the soliton's speed there:

$$\frac{dx}{dt} = \sqrt{gh_o} \left(1 + \frac{\xi_0}{2h_o} \right). \quad (16.34)$$

speed of soliton

The first term is the propagation speed of a weak (linear) wave. The second term is the nonlinear correction, proportional to the wave amplitude $\xi_0 = h_o\zeta_0$. A "half-width" of the wave may be defined by setting the argument of the hyperbolic secant to unity. It is $\eta_{1/2} = (12/\zeta_0)^{1/2}$, corresponding to

$$x_{1/2} = \chi_{1/2} = \left(\frac{4h_o^3}{3\xi_0} \right)^{1/2}. \quad (16.35)$$

half-width of soliton

The larger the wave amplitude, the narrower its width will be, and the faster it will propagate (cf. Fig. 16.6).

Let us return to Scott-Russell's soliton (start of Sec. 16.3). Converting to SI units, the observed speed was about 4 m s^{-1} , giving an estimate of the depth of the canal of $h_o \sim 1.6 \text{ m}$. Using the observed half-width $x_{1/2} \sim 5 \text{ m}$, we obtain a peak height $\xi_0 \sim 0.22 \text{ m}$, somewhat smaller than quoted but within the errors allowing for the uncertainty in the definition of the width.

16.3.4 Two-Soliton Solution

16.3.4

One of the most fascinating properties of solitons is the way that two or more waves interact. The expectation, derived from physics experience with weakly coupled normal modes, might be that, if we have two well-separated solitons propagating in the

FIGURE 16.7 Two-soliton solution to the dimensionless KdV equation (16.32). This solution describes two waves well separated at $\tau \rightarrow -\infty$ that coalesce and then separate, producing the original two waves in reverse order at $\tau \rightarrow +\infty$. The notation is that of Eq. (16.36); the values of the parameters in that equation are $\eta_1 = \eta_2 = 0$ (so the solitons will merge at position $\eta = 0$), $\alpha_1 = 1$, and $\alpha_2 = 1.4$.

same direction with the larger wave chasing the smaller one, then the larger will eventually catch up with the smaller, and nonlinear interactions between the two waves will essentially destroy both, leaving behind a single, irregular pulse that will spread and decay after the interaction. However, this is not what happens. Instead, the two waves pass through each other unscathed and unchanged, except that they emerge from the interaction a bit sooner than they would have had they moved with their original speeds during the interaction. See Fig. 16.7. We shall not pause to explain why the two waves survive unscathed, except to remark that there are topological invariants in the solution that must be preserved. However, we can exhibit one such two-soliton solution analytically:

two-soliton solution of KdV equation

$$\zeta = \frac{\partial^2}{\partial \eta^2} [12 \ln F(\eta, \tau)],$$

$$\text{where } F = 1 + f_1 + f_2 + \left(\frac{\alpha_2 - \alpha_1}{\alpha_2 + \alpha_1} \right)^2 f_1 f_2,$$

$$\text{and } f_i = \exp[-\alpha_i(\eta - \eta_i) + \alpha_i^3 \tau], \quad i = 1, 2; \quad (16.36)$$

here α_i and η_i are constants. This solution is depicted in Fig. 16.7.

16.3.5 Solitons in Contemporary Physics

Solitons were rediscovered in the 1960s when they were found in numerical simulations of plasma waves. Their topological properties were soon understood, and general methods to generate solutions were derived. Solitons have been isolated in such different subjects as the propagation of magnetic flux in a Josephson junction, elastic waves in anharmonic crystals, quantum field theory (as *instantons*), and classical general relativity (as solitary, nonlinear gravitational waves). Most classical solitons are solutions to one of a relatively small number of nonlinear partial differential equations, including the KdV equation, the *nonlinear Schrödinger equation* (which governs

some equations with soliton solutions

solitons in optical fibers; Sec. 10.8.3), *Burgers equation*, and the *sine-Gordon equation*. Unfortunately, it has proved difficult to generalize these equations and their soliton solutions to 2 and 3 spatial dimensions.

Just like research into chaos (Sec. 15.6), studies of solitons have taught physicists that nonlinearity need not lead to maximal disorder in physical systems, but instead can create surprisingly stable, ordered structures.

EXERCISES

Exercise 16.9 Example: Breaking of a Dam

Consider the flow of water along a horizontal channel of constant width after a dam breaks. Sometime after the initial transients have died away⁶ the flow may be described by the nonlinear, unidirectional, shallow-water wave equations (16.23a) and (16.23b):

$$\frac{\partial h}{\partial t} + \frac{\partial(hv)}{\partial x} = 0, \quad \frac{\partial v}{\partial t} + v \frac{\partial v}{\partial x} + g \frac{\partial h}{\partial x} = 0. \quad (16.37)$$

Here h is the height of the flow, v is the horizontal speed of the flow, and x is distance along the channel measured from the location of the dam. Solve for the flow, assuming that initially (at $t = 0$) $h = h_o$ for $x < 0$ and $h = 0$ for $x > 0$ (no water). Your solution should have the form shown in Fig. 16.8. What is the speed of the front of the water? [Hint: From the parameters of the problem we can construct only one velocity, $\sqrt{gh_o}$, and no length except h_o . It therefore is a reasonable guess that the solution has the self-similar form $h = h_o \tilde{h}(\xi)$, $v = \sqrt{gh_o} \tilde{v}(\xi)$, where \tilde{h} and \tilde{v} are dimensionless functions of the similarity variable

$$\xi = \frac{x/t}{\sqrt{gh_o}}. \quad (16.38)$$

FIGURE 16.8 The water's height $h(x, t)$ after a dam breaks.

6. In the idealized case that the dam is removed instantaneously, there are no transients, and Eqs. (16.37) describe the flow from the outset.

Using this ansatz, convert the partial differential equations (16.37) into a pair of ordinary differential equations that can be solved so as to satisfy the initial conditions.]

Exercise 16.10 *Derivation: Single-Soliton Solution*

Verify that expression (16.33) does indeed satisfy the dimensionless KdV equation (16.32).

Exercise 16.11 *Derivation: Two-Soliton Solution*

- (a) Verify, using symbolic-manipulation computer software (e.g., Maple, Matlab, or Mathematica) that the two-soliton expression (16.36) satisfies the dimensionless KdV equation. (Warning: Considerable algebraic travail is required to verify this by hand directly.)
- (b) Verify analytically that the two-soliton solution (16.36) has the properties claimed in the text. First consider the solution at early times in the spatial region where $f_1 \sim 1$, $f_2 \ll 1$. Show that the solution is approximately that of the single soliton described by Eq. (16.33). Demonstrate that the amplitude is $\zeta_{01} = 3\alpha_1^2$, and find the location of its peak. Repeat the exercise for the second wave and for late times.
- (c) Use a computer to follow numerically the evolution of this two-soliton solution as time η passes (thereby filling in timesteps between those shown in Fig. 16.7).

16.4

16.4 Rossby Waves in a Rotating Fluid

Coriolis force as restoring force for Rossby waves

In a nearly rigidly rotating fluid with the rotational angular velocity $\mathbf{\Omega}$ parallel or antiparallel to the acceleration of gravity $\mathbf{g} = -g\mathbf{e}_z$, the Coriolis effect observed in the co-rotating reference frame (Sec. 14.5) provides the restoring force for an unusual type of wave motion called *Rossby waves*. These waves are seen in Earth's oceans and atmosphere [with $\mathbf{\Omega} = (\text{Earth's rotational angular velocity}) \sin(\text{latitude})\mathbf{e}_z$; see Box 14.5].

For a simple example, we consider the sea above a sloping seabed; Fig. 16.9. We assume the unperturbed fluid has vanishing velocity $\mathbf{v} = 0$ in Earth's rotating frame, and we study weak waves in the sea with oscillating velocity \mathbf{v} . (Since the fluid is at rest in the equilibrium state about which we are perturbing, we write the perturbed velocity as \mathbf{v} rather than $\delta\mathbf{v}$.) We assume that the wavelengths are long enough that viscosity and surface tension are negligible. In this case we also restrict attention to small-amplitude waves, so that nonlinear terms can be dropped from the dynamical equations. The perturbed Navier-Stokes equation (14.56a) then becomes (after linearization)

$$\frac{\partial \mathbf{v}}{\partial t} + 2\mathbf{\Omega} \times \mathbf{v} = \frac{-\nabla \delta P'}{\rho}. \tag{16.39}$$

FIGURE 16.9 Geometry of the sea for Rossby waves.

Here, as in Sec. 14.5, $\delta P'$ is the perturbation in the effective pressure [which includes gravitational and centrifugal effects: $P' = P + \rho\Phi - \frac{1}{2}\rho(\boldsymbol{\Omega} \times \mathbf{x})^2$]. Taking the curl of Eq. (16.39), we obtain for the time derivative of the waves' vorticity:

$$\frac{\partial \boldsymbol{\omega}}{\partial t} = 2(\boldsymbol{\Omega} \cdot \nabla) \mathbf{v}. \quad (16.40)$$

We seek a wave mode with angular frequency ω (not to be confused with vorticity $\boldsymbol{\omega}$) and wave number k , in which the horizontal fluid velocity oscillates in the x direction and (in accord with the Taylor-Proudman theorem; Sec. 14.5.3) is independent of z , so

$$v_x \text{ and } v_y \propto \exp[i(kx - \omega t)], \quad \frac{\partial v_x}{\partial z} = \frac{\partial v_y}{\partial z} = 0. \quad (16.41)$$

The only allowed vertical variation is in the vertical velocity v_z ; differentiating $\nabla \cdot \mathbf{v} = 0$ with respect to z , we obtain

$$\frac{\partial^2 v_z}{\partial z^2} = 0. \quad (16.42)$$

The vertical velocity therefore varies linearly between the surface and the sea floor (Fig. 16.9). One boundary condition is that the vertical velocity must vanish at the sea's surface. The other is that at the sea floor $z = -h$, we must have $v_z(-h) = -\alpha v_y$, where α is the tangent of the angle of inclination of the sea floor. The solution to Eq. (16.42) satisfying these boundary conditions is

$$v_z = \frac{\alpha z}{h} v_y. \quad (16.43)$$

Taking the vertical component of Eq. (16.40) and evaluating $\omega_z = v_{y,x} - v_{x,y} = ikv_y$, we obtain

$$\omega k v_y = 2\Omega \frac{\partial v_z}{\partial z} = \frac{2\Omega \alpha v_y}{h}. \quad (16.44)$$

The dispersion relation therefore has the quite unusual form $\omega \propto 1/k$:

$$\boxed{\omega k = \frac{2\Omega \alpha}{h}}. \quad (16.45)$$

dispersion relation for Rossby waves

Rossby waves have interesting properties. They can only propagate in one direction—parallel to the intersection of the sea floor with the horizontal (our \mathbf{e}_x direction). Their phase velocity \mathbf{V}_{ph} and group velocity \mathbf{V}_{g} are equal in magnitude but opposite in direction:

$$\mathbf{V}_{\text{ph}} = -\mathbf{V}_{\text{g}} = \frac{2\Omega\alpha}{k^2h} \mathbf{e}_x. \quad (16.46)$$

Using $\nabla \cdot \mathbf{v} = 0$, we discover that the two components of horizontal velocity are in quadrature: $v_x = i\alpha v_y / (kh)$. This means that the fluid circulates in the opposite sense to the angular velocity Ω .

Rossby waves play an important role in the circulation of Earth's oceans (see, e.g., Chelton and Schlax, 1996). A variant of these Rossby waves in air can be seen as undulations in the atmosphere's jet stream, produced when the stream goes over a sloping terrain, such as that of the Rocky Mountains. Another variant found in neutron stars, called "r modes," generates gravitational waves (ripples of spacetime curvature) that are a promising source for ground-based gravitational-wave detectors, such as LIGO.

EXERCISES

Exercise 16.12 *Example: Rossby Waves in a Cylindrical Tank with a Sloping Bottom*

In the film *Fultz* (1969), about 20 min 40 s into the film, an experiment is described in which Rossby waves are excited in a rotating cylindrical tank with inner and outer vertical walls and a sloping bottom. Figure 16.10a is a photograph of the tank from the side, showing its bottom, which slopes upward toward the center, and a hump on the bottom that generates the Rossby waves. The tank is filled with water, then set into rotation with an angular velocity Ω . The water is given time to settle down into rigid rotation with the cylinder. Then the cylinder's angular velocity is reduced by a small amount, so the water is rotating at angular velocity $\Delta\Omega \ll \Omega$ relative to the cylinder. As the water passes over the hump on the tank bottom, the hump generates Rossby waves. Those waves are made visible by injecting dye at a fixed radius through a syringe attached to the tank. Figure 16.10b is a photograph of the dye trace as seen looking down on the tank from above. If there were no Rossby waves present, the trace would be circular. The Rossby waves make it pentagonal. In this exercise you will work out the details of the Rossby waves, explore their physics, and explain the shape of the trace.

Because the slope of the bottom is cylindrical rather than planar, this is somewhat different from the situation discussed in the text (see Fig. 16.9). However, we can deduce the details of the waves in this cylindrical case from those for the planar case by using geometric-optics considerations (Sec. 7.3), making modest errors because the wavelength of the waves is not all that small compared to the circumference of the tank.

- (a) Using geometric optics, show that the rays along which the waves propagate are circles centered on the tank's symmetry axis.

(a)

(b)

FIGURE 16.10 Rossby waves in a rotating cylinder with sloping bottom. (a) Side view. (b) Top view, showing dye trace. Images from *NCFMF Book of Film Notes*, 1972; The MIT Press with Education Development Center, Inc. © 2014 Education Development Center, Inc. Reprinted with permission with all other rights reserved.

- (b) Focus on the ray that is halfway between the inner and outer walls of the tank. Let its radius be a , the depth of the water there be h , and the slope angle of the tank floor be α . Introduce quasi-Cartesian coordinates $x = a\phi$ and $y = -\varpi$, where $\{\varpi, \phi, z\}$ are cylindrical coordinates. By translating the Cartesian-coordinate waves of the text into quasi-Cartesian coordinates and noting from Fig. 16.10b that five wavelengths must fit into the circumference around the cylinder, show that the velocity field has the form $v_{\varpi}, v_{\phi}, v_z \propto e^{i(5\phi + \omega t)}$, and deduce the ratios of the three components of velocity to one another. The solution has nonzero radial velocity at the walls—a warning that edge effects will modify the waves somewhat. This analysis ignores those edge effects.
- (c) Because the waves are generated by the ridge on the bottom of the tank, the wave pattern must remain at rest relative to that ridge, which means it must rotate relative to the fluid's frame with the angular velocity $d\phi/dt = -\Delta\Omega$. From the waves' dispersion relation, deduce $\Delta\Omega/\Omega$ (the fractional slowdown of the tank that had to be imposed to generate the observed pentagonal wave).
- (d) Compute the displacement field $\delta\mathbf{x}(\varpi, \phi, z, t)$ of a fluid element whose undisplaced location (in the rigidly rotating cylindrical coordinates) is (ϖ, ϕ, z) . Explain the pentagonal shape of the movie's dye lines in terms of this displacement field.
- (e) Compute the wave's vertical vorticity field ω_z (relative to the rigidly rotating flow), and show that as a fluid element moves and the vertical vortex line through it shortens or lengthens due to the changing water depth, ω_z changes proportionally to the vortex line's length.

16.5 16.5 Sound Waves

So far our discussion of fluid dynamics has mostly been concerned with flows sufficiently slow that the density can be treated as constant. We now introduce the effects of compressibility in the context of sound waves (in a nonrotating reference frame). Sound waves are prototypical scalar waves and therefore are simpler in many respects than vector electromagnetic waves and tensor gravitational waves.

Consider a small-amplitude sound wave propagating through a homogeneous, time-independent fluid. The wave's oscillations are generally quick compared to the time for heat to diffuse across a wavelength, so the pressure and density perturbations are adiabatically related:

$$\delta P = C^2 \delta \rho, \quad (16.47)$$

where

$$C \equiv \left[\left(\frac{\partial P}{\partial \rho} \right)_s \right]^{1/2}, \quad (16.48)$$

adiabatic sound speed

which will turn out to be the wave's propagation speed—the speed of sound. The perturbation of the fluid velocity (which we denote \mathbf{v} , since the unperturbed fluid is static) is related to the pressure perturbation by the linearized Euler equation:

$$\frac{\partial \mathbf{v}}{\partial t} = -\frac{\nabla \delta P}{\rho}. \quad (16.49a)$$

A second relation between \mathbf{v} and δP can be obtained by combining the linearized law of mass conservation, $\partial \rho / \partial t = -\rho \nabla \cdot \mathbf{v}$, with the adiabatic pressure-density relation (16.47):

$$\nabla \cdot \mathbf{v} = -\frac{1}{\rho C^2} \frac{\partial \delta P}{\partial t}. \quad (16.49b)$$

By equating the divergence of Eq. (16.49a) to the time derivative of Eq. (16.49b), we obtain a simple, dispersion-free wave equation for the pressure perturbation:

$$\left(\frac{\partial^2}{\partial t^2} - C^2 \nabla^2 \right) \delta P = 0. \quad (16.50)$$

wave equation for sound waves

Thus, as claimed, C is the wave's propagation speed.

For a perfect gas, this adiabatic sound speed is $C = (\gamma P / \rho)^{1/2}$, where γ is the ratio of specific heats (see Ex. 5.4). The sound speed in air at 20 °C is 343 m s⁻¹. In water under atmospheric conditions, it is about 1.5 km s⁻¹ (not much different from sound speeds in solids).

Because the vorticity of the unperturbed fluid vanishes and the wave contains no vorticity-producing forces, the wave's vorticity vanishes: $\nabla \times \mathbf{v} = 0$. This permits us to express the wave's velocity perturbation as the gradient of a velocity potential: $\mathbf{v} = \nabla \psi$.

Inserting this expression into the perturbed Euler equation (16.49a), we express the pressure perturbation in terms of ψ :

$$\delta P = -\rho \frac{\partial \psi}{\partial t}, \quad \text{where } \mathbf{v} = \nabla \psi. \quad (16.51)$$

velocity potential for sound waves

The first of these relations guarantees that ψ satisfies the same wave equation as δP :

$$\left(\frac{\partial^2}{\partial t^2} - C^2 \nabla^2 \right) \psi = 0. \quad (16.52)$$

It is sometimes useful to describe the wave by its oscillating pressure δP and sometimes by its oscillating potential ψ .

The general solution of the wave equation (16.52) for plane sound waves propagating in the $\pm x$ directions is

$$\psi = f_1(x - Ct) + f_2(x + Ct), \quad (16.53)$$

where f_1 and f_2 are arbitrary functions.

Exercise 16.13 *Problem: Sound Wave in an Inhomogeneous Fluid*

EXERCISES

Consider a sound wave propagating through a static, inhomogeneous fluid with no gravity. Explain why the unperturbed fluid has velocity $\mathbf{v} = 0$ and pressure $P_o = \text{constant}$, but can have variable density and sound speed, $\rho_o(\mathbf{x})$ and $C(\mathbf{x}, t)$. By repeating the analysis in Eqs. (16.47)–(16.50), show that the wave equation is $\partial^2 \delta P / \partial t^2 = C^2 \rho_o \nabla \cdot (\rho_o^{-1} \nabla \delta P)$, which can be rewritten as

$$W \frac{\partial^2 \delta P}{\partial t^2} - \nabla \cdot (WC^2 \nabla \delta P) = 0, \quad (16.54)$$

where $W = (C^2 \rho_o)^{-1}$. [Hint: It may be helpful to employ the concept of Lagrangian versus Eulerian perturbations, as described by Eq. (19.44).] Equation (16.54) is an example of the prototypical wave equation (7.17) that we used in Sec. 7.3.1 to illustrate the geometric-optics formalism. The functional form of W and the placement of W and C^2 (inside versus outside the derivatives) have no influence on the wave's dispersion relation or its rays or phase in the geometric-optics limit, but they do influence the propagation of the wave's amplitude. See Sec. 7.3.1.

16.5.1 Wave Energy

16.5.1

In Sec. 7.3.1 and Ex. 7.4, we used formal mathematical techniques to derive the energy density U and energy flux \mathbf{F} [Eqs. (7.18)] associated with waves satisfying the prototypical wave equation (16.54). In this section, we rederive U and \mathbf{F} for sound

waves using a physical, fluid dynamical analysis. We get precisely the same expressions up to a constant multiplicative factor ρ^2 . Because of the formal nature of the arguments leading to Eqs. (7.18), we only had a right to expect the same answer up to some multiplicative constant.

The fluid's energy density is $U = (\frac{1}{2}v^2 + u)\rho$ (Table 13.1 with $\Phi = 0$). The first term is the fluid's kinetic energy density; the second is its internal energy density. The internal energy density can be evaluated by a Taylor expansion in the wave's density perturbation:

$$u\rho = [u\rho] + \left[\left(\frac{\partial(u\rho)}{\partial\rho} \right)_s \right] \delta\rho + \frac{1}{2} \left[\left(\frac{\partial^2(u\rho)}{\partial\rho^2} \right)_s \right] \delta\rho^2, \quad (16.55)$$

where the three coefficients in square brackets are evaluated at the equilibrium density. The first term in Eq. (16.55) is the energy of the background fluid, so we drop it. The second term averages to zero over a wave period, so we also drop it. The third term can be simplified using the first law of thermodynamics in the form $du = Tds - Pd(1/\rho)$ (which implies $[\partial(u\rho)/\partial\rho]_s = u + P/\rho$). We then apply the definition $h = u + P/\rho$ of enthalpy density, followed by the first law in the form $dh = Tds + dP/\rho$, and then followed by expression (16.48) for the speed of sound. The result is

$$\left(\frac{\partial^2(u\rho)}{\partial\rho^2} \right)_s = \left(\frac{\partial h}{\partial\rho} \right)_s = \frac{C^2}{\rho}. \quad (16.56)$$

Inserting this relation into the third term of Eq. (16.55) and averaging over a wave period and wavelength, we obtain for the wave energy per unit volume $U = \frac{1}{2}\rho\overline{v^2} + [C^2/(2\rho)]\overline{\delta\rho^2}$. Using $\mathbf{v} = \nabla\psi$ [the second of Eqs. (16.51)] and $\delta\rho = (\rho/C^2)\partial\psi/\partial t$ [from $\delta\rho = (\partial\rho/\partial P)_s\delta P = \delta P/C^2$ and the first of Eqs. (16.51)], we bring the equation for U into the form

$$U = \frac{1}{2}\rho \left[\overline{(\nabla\psi)^2} + \frac{1}{C^2} \overline{\left(\frac{\partial\psi}{\partial t} \right)^2} \right] = \rho \overline{(\nabla\psi)^2}. \quad (16.57)$$

energy density for sound waves

The second equality can be deduced by multiplying the wave equation (16.52) by ψ and averaging. Thus, energy is equipartitioned between the kinetic and internal energy terms.

The energy flux is $\mathbf{F} = (\frac{1}{2}v^2 + h)\rho\mathbf{v}$ (Table 13.1 with $\Phi = 0$). The kinetic energy flux (first term) is third order in the velocity perturbation and therefore vanishes on average. For a sound wave, the internal energy flux (second term) can be brought into a more useful form by expanding the enthalpy per unit mass:

$$h = [h] + \left[\left(\frac{\partial h}{\partial P} \right)_s \right] \delta P = [h] + \frac{\delta P}{\rho}. \quad (16.58)$$

Here we have used the first law of thermodynamics $dh = Tds + (1/\rho)dP$ and adiabaticity of the perturbation ($s = \text{const}$); the terms in square brackets are unperturbed quantities. Inserting Eq. (16.58) into $\mathbf{F} = h\rho\mathbf{v}$, expressing δP and \mathbf{v} in terms of the

velocity potential [Eqs. (16.51)], and averaging over a wave period and wavelength, we obtain for the energy flux $\mathbf{F} = \overline{\rho h \mathbf{v}} = \overline{\delta P \mathbf{v}}$, which becomes

$$\mathbf{F} = -\rho \overline{\left(\frac{\partial \psi}{\partial t}\right)} \nabla \psi. \quad (16.59)$$

energy flux for soundwaves

Aside from a multiplicative constant factor ρ^2 , this equation and Eq. (16.57) agree with Eqs. (7.18) [with ψ there being this chapter's velocity potential ψ , and with $W = (C^2 \rho)^{-1}$; Eq. (16.54)], which we derived by formal techniques in Sec. 7.3.1 and Ex. 7.4.

For a locally plane wave with $\psi = \psi_o \cos(\mathbf{k} \cdot \mathbf{x} - \omega t + \varphi)$ (where φ is an arbitrary phase), the energy density (16.57) is $U = \frac{1}{2} \rho \psi_o^2 k^2$, and the energy flux (16.59) is $\mathbf{F} = \frac{1}{2} \rho \psi_o^2 \omega \mathbf{k}$. Since for this dispersion-free wave, the phase and group velocities are both $\mathbf{V} = (\omega/k) \hat{\mathbf{k}} = C \hat{\mathbf{k}}$ (where $\hat{\mathbf{k}} = \mathbf{k}/k$ is the unit vector pointing in the wave-propagation direction), the energy density and flux are related by

$$\mathbf{F} = U \mathbf{V} = U C \hat{\mathbf{k}}. \quad (16.60)$$

The energy flux is therefore the product of the energy density and the wave velocity, as it must be [Eq. (7.31), where we see that, if the waves were to have dispersion, it would be the group velocity that appears in this expression].

The energy flux carried by sound is conventionally measured in dB (decibels). The flux in decibels, F_{dB} , is related to the flux F in $W \text{ m}^{-2}$ by

$$F_{\text{dB}} = 120 + 10 \log_{10}(F). \quad (16.61)$$

Sound that is barely audible is about 1 dB. Normal conversation is about 50–60 dB. Jet aircraft, rock concerts, and volcanic eruptions can cause exposure to more than 120 dB, with consequent damage to the ear.

16.5.2 Sound Generation

16.5.2

So far in this book we have been concerned with describing how different types of waves propagate. It is also important to understand how they are generated. We now outline some aspects of the theory of sound generation.

The reader should be familiar with the theory of electromagnetic wave emission (e.g., Jackson, 1999, Chap. 9). For electromagnetic waves one considers a localized region containing moving charges and varying currents. The source can be described as a sum over electric and magnetic multipoles, and each multipole produces a characteristic angular variation of the distant radiation field. The radiation-field amplitude decays inversely with distance from the source, and so the Poynting flux varies with the inverse square of the distance. Integrating over a large sphere gives the total power radiated by the source, broken down into the power radiated by each multipolar component. The ratio of the power in successive multipole pairs [e.g., (magnetic dipole power)/(electric dipole power) \sim (electric quadrupole power)/(electric dipole power)] is typically $\sim (b/\lambda)^2$, where b is the size of the source, and $\lambda = 1/k$ is the

waves' reduced wavelength. When λ is large compared to b (a situation referred to as *slow motion*, since the source's charges then generally move at speeds $\sim(b/\lambda)c$ small compared to the speed of light c), the most powerful radiating multipole is the electric dipole $\mathbf{d}(t)$, unless it happens to be suppressed. The dipole's average emitted power is given by the Larmor formula:

$$\mathcal{P} = \frac{\overline{\dot{\mathbf{d}}^2}}{6\pi\epsilon_0 c^3}, \quad (16.62)$$

where $\ddot{\mathbf{d}}$ is the second time derivative of \mathbf{d} , the bar denotes a time average, ϵ_0 is the permittivity of free space, and c is the speed of light.

This same procedure can be followed when describing sound generation. However, as we are dealing with a scalar wave, sound can have a monopolar source. As a pedagogical example, let us set a small, spherical, elastic ball, surrounded by fluid, into radial oscillation (not necessarily sinusoidal) with oscillation frequencies of order ω , so the emitted waves have reduced wavelengths of order $\lambda = C/\omega$. Let the surface of the ball have radius $a + \xi(t)$, and impose the slow-motion and small-amplitude conditions that

$$\lambda \gg a \gg |\xi|. \quad (16.63)$$

As the waves will be spherical, the relevant outgoing-wave solution of the wave equation (16.52) is

$$\psi = \frac{f(t - r/C)}{r}, \quad (16.64)$$

where f is a function to be determined. Since the fluid's velocity at the ball's surface must match that of the ball, we have (to first order in \mathbf{v} and ψ):

$$\dot{\xi} \mathbf{e}_r = \mathbf{v}(a, t) = \nabla \psi \simeq -\frac{f(t - a/C)}{a^2} \mathbf{e}_r \simeq -\frac{f(t)}{a^2} \mathbf{e}_r, \quad (16.65)$$

where in the third equality we have used the slow-motion condition $\lambda \gg a$. Solving for $f(t)$ and inserting into Eq. (16.64), we see that

$$\psi(r, t) = -\frac{a^2 \dot{\xi}(t - r/C)}{r}. \quad (16.66)$$

It is customary to express the radial velocity perturbation v in terms of an oscillating fluid *monopole moment*

$$q = 4\pi\rho a^2 \dot{\xi}. \quad (16.67)$$

Physically, this is the total radial discharge of air mass (i.e., mass per unit time) crossing an imaginary fixed spherical surface of radius slightly larger than that of the oscillating ball. In terms of q , we have $\dot{\xi}(t) = q(t)/[4\pi\rho a^2]$. Using this expression and Eq. (16.66), we compute for the power radiated as sound waves [Eq. (16.59) integrated over a sphere centered on the ball]:

monopole moment for spherical sound waves from an oscillating ball

$$\mathcal{P} = \frac{\overline{\dot{q}^2}}{4\pi\rho C}. \quad (16.68)$$

power emitted into spherical sound waves

Note that the power is inversely proportional to the signal speed, which is characteristic of monopolar emission and is in contrast to the inverse-cube variation for dipolar emission [Eq. (16.62)].

The emission of monopolar waves requires that the volume of the emitting solid body oscillate. When the solid simply oscillates without changing its volume (e.g., the reed in a musical instrument), dipolar emission usually dominates. We can think of this as two monopoles of size a in antiphase separated by some displacement $b \sim a$. The velocity potential in the far field is then the sum of two monopolar contributions, which almost cancel. Making a Taylor expansion, we obtain

$$\frac{\psi_{\text{dipole}}}{\psi_{\text{monopole}}} \sim \frac{b}{\lambda} \sim \frac{\omega b}{C}, \quad (16.69)$$

typical multipolar sound-wave strengths

where ω and λ are the characteristic magnitudes of the angular frequency and reduced wavelength of the waves (which we have not assumed to be precisely sinusoidal).

This reduction of ψ by the slow-motion factor b/λ implies that the dipolar power emission is weaker than the monopolar power by a factor $\sim (b/\lambda)^2$ for similar frequencies and amplitudes of motion—the same factor as for electromagnetic waves (see the start of this subsection). However, to emit dipole radiation, momentum must be given to and removed from the fluid. In other words, the fluid must be forced by a solid body. In the absence of such a solid body, the lowest multipole that can be radiated effectively is quadrupolar radiation, which is weaker by yet one more factor of $(b/\lambda)^2$.

lowest order sound wave emitted in absence of solid-body forcing: quadrupolar

These considerations are important for understanding how noise is produced by the intense turbulence created by jet engines, especially close to airports. We expect that the sound emitted by the free turbulence in the wake just behind the engine will be quadrupolar and will be dominated by emission from the largest (and hence fastest) turbulent eddies. (See the discussion of turbulent eddies in Sec. 15.4.4.) Denote by ℓ and v_ℓ the size and turnover speed of these largest eddies. Then the characteristic size of the sound's source is $a \sim b \sim \ell$, the mass discharge is $q \sim \rho \ell^2 v_\ell$, the characteristic frequency is $\omega \sim v_\ell/\ell$, the reduced wavelength of the sound waves is $\lambda = C/\omega \sim \ell C/v_\ell$, and the slow-motion parameter is $b/\lambda \sim \omega b/C \sim v_\ell/C$. The quadrupolar power radiated per unit volume [Eq. (16.68) divided by the volume ℓ^3 of an eddy and reduced by $\sim (b/\lambda)^4$] is therefore

sound-wave power from free turbulence

$$\frac{d\mathcal{P}}{d^3x} \sim \rho \frac{v_\ell^3}{\ell} \left(\frac{v_\ell}{C} \right)^5, \quad (16.70)$$

and this power is concentrated around frequency $\omega \sim v_\ell/\ell$. For air of fixed sound speed and lengthscale ℓ of the largest eddies, and for which the largest eddy speed v_ℓ is proportional to some characteristic speed V (e.g., the average speed of the air leaving

the engine), Eq. (16.70) says the sound generation increases proportional to the eighth power of the Mach number $M = V/C$. This is known as Lighthill's law (Lighthill 1952, 1954). The implications for the design of jet engines should be obvious.

EXERCISES

Exercise 16.14 *Problem: Attenuation of Sound Waves*

Viscosity and thermal conduction will attenuate sound waves. For the moment just consider a monatomic gas where the bulk viscosity can be neglected.

- Consider the entropy equation (13.75), and evaluate the influence of the heat flux on the relationship between the pressure and the density perturbations. [Hint: Assume that all quantities vary as $e^{i(kx-\omega t)}$, where k is real and ω complex.]
- Consider the momentum equation (13.69), and include the viscous term as a perturbation.
- Combine these two relations in parts (a) and (b), together with the equation of mass conservation, to solve for the imaginary part of ω in the linear regime.
- Substitute kinetic-theory expressions for the coefficient of shear viscosity and the coefficient of thermal conductivity (Secs. 13.7.3 and 3.7) to obtain a simple expression for the attenuation length involving the wave's wavelength and the atoms' collisional mean free path.
- How do you think the wave attenuation will be affected if the fluid is air or is turbulent, or both?

See Faber (1995) for more details.

Exercise 16.15 *Example: Plucked Violin String*

Consider the G string (196 Hz) of a violin. It is ~ 30 cm from bridge to nut (the fixed endpoints), and the tension in the string is ~ 40 N.

- Infer the mass per unit length in the string and estimate its diameter. Hence estimate the strain in the string before being plucked. Estimate the strain's increase if its midpoint is displaced through 3 mm.
- Now suppose that the string is released. Estimate the speed with which it moves as it oscillates back and forth.
- Estimate the dipolar sound power emitted and the distance out to which the note can be heard (when its intensity is a few decibels). Do your answers seem reasonable? What factors, omitted from this calculation, might change your answers?

Exercise 16.16 *Example: Trumpet*

Idealize the trumpet as a bent pipe of length 1.2 m from the mouthpiece (a node of the air's displacement) to the bell (an antinode). The lowest note is a first overtone and should correspond to B flat (233 Hz). Does it?

Exercise 16.17 *Problem: Aerodynamic Sound Generation*

Consider the emission of quadrupolar sound waves by a Kolmogorov spectrum of free turbulence (Sec. 15.4.4). Show that the power radiated per unit frequency interval has a spectrum

$$\mathcal{P}_\omega \propto \omega^{-7/2}.$$

Also show that the total power radiated is roughly a fraction M^5 of the power dissipated in the turbulence, where M is the Mach number.

16.5.3 Radiation Reaction, Runaway Solutions, and Matched Asymptotic Expansions T2

Let us return to our idealized example of sound waves produced by a radially oscillating, spherical ball. We use this example to illustrate several deep issues in theoretical physics: the *radiation-reaction force* that acts back on a source due to its emission of radiation, a spurious *runaway solution* to the source's equation of motion caused by the radiation-reaction force, and *matched asymptotic expansions*, a mathematical technique for solving field equations when there are two different regions of space in which the equations have rather different behaviors.⁷ These issues also arise, in a rather more complicated way, in analyses of the electromagnetic radiation reaction force on an accelerated electron (the "Abraham-Lorentz force"), and the radiation-reaction force caused by emission of gravitational waves; see the derivation, by Burke (1971), of gravitational results quoted in Sec. 27.5.3.

For our oscillating ball, the two different regions of space that we match to each other are the *near zone*, $r \ll \lambda$, and the *wave zone*, $r \gtrsim \lambda$.

We consider, first, the near zone, and we redo, from a new point of view, the analysis of the matching of the near-zone fluid velocity to the ball's surface velocity and the computation of the pressure perturbation. Because the region near the ball is small compared to λ and the fluid speeds are small compared to C , the flow is very nearly incompressible, $\nabla \cdot \mathbf{v} = \nabla^2 \psi = 0$; see the discussion of conditions for incompressibility in Sec. 13.6. (The near-zone equation $\nabla^2 \psi = 0$ is analogous to $\nabla^2 \Phi = 0$ for the Newtonian gravitational potential in the weak-gravity near zone of a gravitational-wave source; Sec. 27.5.)

The general monopolar (spherical) solution to $\nabla^2 \psi = 0$ is

$$\psi = \frac{A(t)}{r} + B(t). \quad (16.71)$$

Matching the fluid's radial velocity $v = \partial \psi / \partial r = -A/r^2$ at $r = a$ to the ball's radial velocity $\dot{\xi}$, we obtain

$$A(t) = -a^2 \dot{\xi}(t). \quad (16.72)$$

7. Our treatment is based on Burke (1970).

16.5.3

sound waves from radially oscillating ball

near zone and wave zone

From the point of view of near-zone physics, no mechanism exists for generating a nonzero spatially constant term $B(t)$ in ψ [Eq. (16.71)], so if one were unaware of the emitted sound waves and their action back on the source, one would be inclined to set $B(t)$ to zero. [This line of reasoning is analogous to that of a Newtonian physicist, who would be inclined to write the quadrupolar contribution to an axisymmetric source's external gravitational field in the form $\Phi = P_2(\cos \theta)[A(t)r^{-3} + B(t)r^2]$ and then, being unaware of gravitational waves and their action back on the source, would set $B(t)$ to zero.] Taking this near-zone viewpoint, with $B = 0$, we infer that the fluid's pressure perturbation acting on the ball's surface is

$$\delta P = -\rho \frac{\partial \psi(a, t)}{\partial t} = -\rho \frac{\dot{A}}{a} = \rho a \ddot{\xi} \quad (16.73)$$

[Eqs. (16.51) and (16.72)].

The motion $\xi(t)$ of the ball's surface is controlled by the elastic restoring forces in its interior and the fluid pressure perturbation δP on its surface. In the absence of δP the surface would oscillate sinusoidally with some angular frequency ω_o , so $\ddot{\xi} + \omega_o^2 \xi = 0$. The pressure will modify this expression to

$$m(\ddot{\xi} + \omega_o^2 \xi) = -4\pi a^2 \delta P, \quad (16.74)$$

where m is an effective mass, roughly equal to the ball's true mass, and the right-hand side is the integral of the radial component of the pressure perturbation force over the sphere's surface. Inserting the near-zone viewpoint's pressure perturbation (16.73), we obtain

$$(m + 4\pi a^3 \rho) \ddot{\xi} + m \omega_o^2 \xi = 0. \quad (16.75)$$

Evidently, the fluid increases the ball's effective inertial mass (it *loads* additional mass on the ball) and thereby reduces its frequency of oscillation to

$$\omega = \frac{\omega_o}{\sqrt{1 + \kappa}}, \quad \text{where } \kappa = \frac{4\pi a^3 \rho}{m} \quad (16.76)$$

is a measure of the coupling strength between the ball and the fluid. In terms of this loaded frequency, the equation of motion becomes

$$\ddot{\xi} + \omega^2 \xi = 0. \quad (16.77)$$

This near-zone viewpoint is not quite correct, just as the standard Newtonian viewpoint is not quite correct for the near-zone gravity of a gravitational-wave source (Sec. 27.5.3). To improve on this viewpoint, we temporarily move out into the wave zone and identify the general, outgoing-wave solution to the sound wave equation:

$$\psi = \frac{f(t - \epsilon r/C)}{r} \quad (16.78)$$

[Eq. (16.64)]. Here f is a function to be determined by matching to the near zone, and ϵ is a parameter that has been inserted to trace the influence of the outgoing-wave

boundary condition. For outgoing waves (the real, physical, situation), $\epsilon = +1$; if the waves were ingoing, we would have $\epsilon = -1$.

This wave-zone solution remains valid into the near zone. In the near zone we can perform a slow-motion expansion to bring it into the same form as the near-zone velocity potential (16.71):

$$\psi = \frac{f(t)}{r} - \epsilon \frac{\dot{f}(t)}{C} + \dots \quad (16.79)$$

The second term is sensitive to whether the waves are outgoing or incoming and thus must ultimately be responsible for the radiation-reaction force that acts back on the oscillating ball; for this reason we call it the *radiation-reaction potential*.

Equating the first term of this ψ to the first term of Eq. (16.71) and using the value in Eq. (16.72) of $A(t)$, which was obtained by matching the fluid velocity to the ball velocity, we obtain

$$f(t) = A(t) = -a^2 \dot{\xi}(t). \quad (16.80)$$

This equation tells us that the wave field $f(t - r/C)/r$ generated by the ball's surface displacement $\xi(t)$ is given by $\psi = -a^2 \dot{\xi}(t - r/C)/r$ [Eq. (16.66)]—the result we derived more quickly in the previous section. We can regard Eq. (16.80) as matching the near-zone solution outward onto the wave-zone solution to determine the wave field as a function of the source's motion.

Equating the second term of Eq. (16.79) to the second term of the near-zone velocity potential (16.71), we obtain

$$B(t) = -\epsilon \frac{\dot{f}(t)}{C} = \epsilon \frac{a^2}{C} \ddot{\xi}(t). \quad (16.81)$$

This is the term in the near-zone velocity potential $\psi = A/r + B$ that is responsible for radiation reaction. *We can regard this radiation-reaction potential $\psi^{\text{RR}} = B(t)$ as having been generated by matching the wave zone's outgoing ($\epsilon = +1$) or ingoing ($\epsilon = -1$) wave field back into the near zone.* [A similar matching analysis by Burke (1971) led him to the gravitational radiation-reaction potential (27.64).]

This pair of matchings, outward then inward (Fig. 16.11), is a special, almost trivial example of the technique of matched asymptotic expansions—a technique developed by applied mathematicians to deal with much more complicated matching problems than this one (see, e.g., Cole, 1974).

The radiation-reaction potential $\psi^{\text{RR}} = B(t) = \epsilon(a^2/C)\ddot{\xi}(t)$ gives rise to a radiation-reaction contribution to the pressure on the ball's surface: $\delta P^{\text{RR}} = -\rho \dot{\psi}^{\text{RR}} = -\epsilon(\rho a^2/C)\dot{\ddot{\xi}}$. Inserting this into the equation of motion (16.74) along with the loading pressure (16.73) and performing the same algebra as before, we get the following radiation-reaction-modified form of Eq. (16.77):

$$\boxed{\ddot{\xi} + \omega^2 \xi = \epsilon \tau \ddot{\xi}}, \quad \text{where} \quad \tau = \frac{\kappa}{1 + \kappa} \frac{a}{C} \quad (16.82)$$

radiation-reaction potential

how radiation-reaction potential is generated

matched asymptotic expansions

radiation-reaction pressure on ball's surface

ball's equation of motion with radiation reaction

FIGURE 16.11 Matched asymptotic expansions for an oscillating ball emitting sound waves. The near-zone expansion feeds the radiation field $\psi = \frac{1}{r}A(t-r/C) = -\frac{1}{r}a^2\dot{\xi}(t-r/C)$ into the wave zone. The wave-zone expansion then feeds the radiation-reaction field $\psi^{RR} = B = \epsilon(a^2/C)\ddot{\xi}$ back into the near zone, where it produces the radiation-reaction pressure $\delta P^{RR} = -\rho\dot{\psi}^{RR}$ on the ball's surface.

is less than the fluid's sound travel time to cross the ball's radius, a/C . The term $\epsilon\tau\ddot{\xi}$ in the equation of motion is the ball's *radiation-reaction acceleration*, as we see from the fact that it would change sign if we switched from outgoing waves ($\epsilon = +1$) to incoming waves ($\epsilon = -1$).

radiation-reaction induced damping

In the absence of radiation reaction, the ball's surface oscillates sinusoidally in time: $\xi = e^{\pm i\omega t}$. The radiation-reaction term produces a weak damping of these oscillations:

$$\xi \propto e^{\pm i\omega t} e^{-\sigma t}, \quad \sigma = \frac{1}{2}\epsilon(\omega\tau)\omega, \quad (16.83)$$

where σ is the radiation-reaction-induced damping rate (with $\epsilon = +1$). Note that in order of magnitude the ratio of the damping rate to the oscillation frequency is $\sigma/\omega \sim \omega\tau \lesssim \omega a/C = a/\lambda$, which is small compared to unity by virtue of the slow-motion assumption. If the waves were incoming rather than outgoing, $\epsilon = -1$, the fluid's oscillations would grow. In either case, outgoing waves or ingoing waves, the radiation-reaction force removes energy from the ball or adds it at the same rate as the sound waves carry energy off or bring it in. The total energy, wave plus ball, is conserved.

Expression (16.83) is two linearly independent solutions to the equation of motion (16.82), one with the plus sign and the other with the minus sign. Since this equation of motion has been made third order by the radiation-reaction term, there must be a third independent solution. It is easy to see that, up to a tiny fractional correction, that third solution is

$$\xi \propto e^{\epsilon t/\tau}. \quad (16.84)$$

runaway solution to ball's equation of motion

For outgoing waves, $\epsilon = +1$, this solution grows exponentially in time on an extremely rapid timescale, $\tau \lesssim a/C$; it is called a *runaway solution*.

Such runaway solutions are ubiquitous in equations of motion with radiation reaction. For example, a computation of the electromagnetic radiation reaction on a small, classical, electrically charged, spherical particle gives the Abraham-Lorentz equation of motion:

$$m(\ddot{\mathbf{x}} - \tau \dddot{\mathbf{x}}) = \mathbf{F}_{\text{ext}} \quad (16.85)$$

(Rohrlich, 1965; Jackson, 1999, Sec. 16.2). Here $\mathbf{x}(t)$ is the particle's world line, \mathbf{F}_{ext} is the external force that causes the particle to accelerate, and the particle's inertial mass m includes an electrostatic contribution analogous to $4\pi a^3 \rho$ in our fluid problem. The timescale τ , like that in our fluid problem, is very short, and when the external force is absent, there is a runaway solution $\mathbf{x} \propto e^{t/\tau}$.

Much human heat and confusion were generated, in the early and mid-twentieth century, over these runaway solutions (see, e.g., Rohrlich, 1965). For our simple model problem, there need be little heat or confusion. One can easily verify that the runaway solution (16.84) violates the slow-motion assumption $a/\lambda \ll 1$ that underlies our derivation of the radiation-reaction acceleration. It therefore is a spurious solution.

Our model problem is sufficiently simple that one can dig deeper into it and learn that the runaway solution arises from the slow-motion approximation failing to reproduce a genuine, rapidly damped solution and getting the sign of the damping wrong (Ex. 16.19 and Burke, 1970).

runaway solutions for an electrically charged particle

origin of runaway solution

Exercise 16.18 *Problem: Energy Conservation for Radially Oscillating Ball Plus Sound Waves*

For the radially oscillating ball as analyzed in Sec. 16.5.3, verify that the radiation-reaction acceleration removes energy from the ball, plus the fluid loaded onto it, at the same rate as the sound waves carry energy away. See Ex. 27.12 for the analogous gravitational-wave result.

Exercise 16.19 *Problem: Radiation Reaction without the Slow-Motion Approximation*

Redo the computation of radiation reaction for a radially oscillating ball immersed in a fluid without imposing the slow-motion assumption and approximation. Thereby obtain the following coupled equations for the radial displacement $\xi(t)$ of the ball's surface and the function $\Phi(t) \equiv a^{-2} f(t - \epsilon a/C)$, where $\psi = r^{-1} f(t - \epsilon r/C)$ is the sound-wave field:

$$\ddot{\xi} + \omega_0^2 \xi = \kappa \dot{\Phi}, \quad \dot{\xi} = -\Phi - \epsilon(a/C) \dot{\Phi}. \quad (16.86)$$

Show that in the slow-motion regime, this equation of motion has two weakly damped solutions of the same form as we derived using the slow-motion approximation [Eq. (16.83)], and one rapidly damped solution: $\xi \propto \exp(-\epsilon \kappa t/\tau)$. Burke (1970) shows that the runaway solution (16.84) obtained using the slow-motion approximation is caused by that approximation's futile attempt to reproduce this genuine, rapidly damped solution.

EXERCISES

Exercise 16.20 *Problem: Sound Waves from a Ball Undergoing Quadrupolar Oscillations*

Repeat the analysis of sound-wave emission, radiation reaction, and energy conservation—as given in Sec. 16.5.3 and Ex. 16.18—for axisymmetric, quadrupolar oscillations of an elastic ball: $r_{\text{ball}} = a + \zeta(t)P_2(\cos \theta)$.

Comment: Since the lowest multipolar order for gravitational waves is quadrupolar, this exercise is closer to the analogous problem of gravitational wave emission (Secs. 27.5.2 and 27.5.3) than is the monopolar analysis in the text.

[Hint: If ω is the frequency of the ball's oscillations, then the sound waves have the form

$$\psi = K \Re \left[e^{-i\omega t} \left(\frac{n_2(\omega r/C) - i\epsilon j_2(\omega r/C)}{r} \right) \right] P_2(\cos \theta), \quad (16.87)$$

where K is a constant; $\Re(X)$ is the real part of X ; ϵ is $+1$ for outgoing waves and -1 for ingoing waves; j_2 and n_2 are the spherical Bessel and spherical Neuman functions of order 2, and P_2 is the Legendre polynomial of order 2. In the distant wave zone, $x \equiv \omega r/C \gg 1$, we have

$$n_2(x) - i\epsilon j_2(x) = \frac{e^{i\epsilon x}}{x}; \quad (16.88)$$

in the near zone $x = \omega r/C \ll 1$, we have

$$n_2(x) = -\frac{3}{x^3} (1 \& x^2 \& x^4 \& \dots), \quad j_2(x) = \frac{x^2}{15} (1 \& x^2 \& x^4 \& \dots). \quad (16.89)$$

Here “ $\& x^n$ ” means “ $+$ (some constant) x^n ”.]

Bibliographic Note

For physical insight into waves in fluids, we recommend the movies discussed in Box 16.2. Among fluid-dynamics textbooks, those that we most like for their treatment of waves are Acheson (1990), Lautrup (2005), and Kundu, Cohen, and Dowling (2012). For greater depth and detail, we recommend two books solely devoted to waves: Lighthill (2001) and Whitham (1974).

For Rossby waves (which are omitted from most fluid-dynamics texts), we recommend the very physical descriptions and analyses in Tritton (1987). For solitons, we like Whitham (1974, Chap. 17); also Drazin and Johnson (1989), which focuses on the mathematics of the Korteweg–de Vries equation; Ablowitz (2011), which treats the mathematics of solitons plus applications to fluids and nonlinear optics; and Dauxois and Peyrard (2010), which treats the mathematics and applications to plasmas and condensed-matter physics.

The mathematics of matched asymptotic expansions is nicely developed by Cole (1974) and Lagerstrom (1988). Radiation reaction in wave emission is not treated pedagogically in any textbook that we know of except ours; for pedagogical original literature, we like Burke (1970).

Compressible and Supersonic Flow

Rocket science is tough, and rockets have a way of failing.

PHYSICIST, ASTRONAUT, AND EDUCATOR SALLY RIDE (2012)

17.1 Overview

17.1

So far we have mainly been concerned with flows that are slow enough that they may be treated as incompressible. We now consider flows in which the velocity approaches or even exceeds the speed of sound and in which changes of density along streamlines cannot be ignored. Such flows are common in aeronautics and astrophysics. For example, the motion of a rocket through the atmosphere is faster than the speed of sound in air. In other words, it is *supersonic*. Therefore, if we transform into the frame of the rocket, the flow of air past the rocket is also supersonic.

When the flow speed exceeds the speed of sound in some reference frame, it is not possible for a pressure pulse to travel upstream in that frame and change the direction of the flow. However, if there is a solid body in the way (e.g., a rocket or aircraft), the flow direction must change (Fig. 17.1). In a supersonic flow, this change happens nearly discontinuously, through the formation of *shock fronts*, at which the flow suddenly decelerates from supersonic to subsonic. Shock fronts are an inevitable feature of supersonic flows.

In another example of supersonic flow, a rocket itself is propelled by the thrust created by its nozzle's escaping hot gases. These hot gases move through the rocket nozzle at supersonic speeds, expanding and cooling as they accelerate. In this manner, the random thermal motion of the gas molecules is converted into an organized bulk motion that carries negative momentum away from the rocket and pushes it forward.

The solar wind furnishes yet another example of a supersonic flow. This high-speed flow of ionized gas is accelerated in the solar corona and removes a fraction of $\sim 10^{-14}$ of the Sun's mass every year. Its own pressure accelerates it to supersonic speeds of $\sim 400 \text{ km s}^{-1}$. When the outflowing solar wind encounters a planet, it is rapidly decelerated to subsonic speed by passing through a strong discontinuity, known as a *bow shock*, that surrounds the planet (Fig. 17.2). The bulk kinetic energy in the solar wind, built up during acceleration, is rapidly and irreversibly transformed into heat as it passes through this shock front.

BOX 17.1. READERS' GUIDE

- This chapter relies heavily on Chap. 13 and on Secs. 16.2, 16.3, and 16.5.
- No subsequent chapters rely substantially on this one.

FIGURE 17.1 Complex pattern of shock fronts formed around a model aircraft in a wind tunnel with air moving 10% faster than the speed of sound (i.e., with Mach number $M = 1.1$). Image from NASA/Ames Imaging Library System.

FIGURE 17.2 The supersonic solar wind forms a type of shock front known as a bow shock when it passes by a planet. Earth is ~ 200 solar radii from the Sun.

BOX 17.2. MOVIES RELEVANT TO THIS CHAPTER

We strongly recommend that the reader view the following movies dealing with compressible and supersonic flows:

- Rouse (1963f)—covers most of this chapter except Riemann invariants.
- Coles (1965)—focuses on shock fronts and quasi-1-dimensional flow through throats.
- Bryson (1964)—includes segments on shock fronts and hydraulic jumps.

In this chapter, we study some properties of supersonic flows. After restating the basic equations of compressible fluid dynamics (Sec. 17.2), we analyze three important, simple cases: stationary, quasi-1-dimensional flow (Sec. 17.3); time-dependent, 1-dimensional flow (Sec. 17.4); and normal adiabatic shock fronts (Sec. 17.5). In these sections, we apply the results of our analyses to some contemporary examples, including the Space Shuttle (Box 17.4); rocket engines; shock tubes; and the Mach cone, N-wave, and sonic booms produced by supersonic projectiles and aircraft. In Sec. 17.6, we develop similarity-solution techniques for supersonic flows and apply them to supernovae, underwater depth charges, and nuclear-bomb explosions in Earth's atmosphere.

As in our previous fluid-dynamics chapters, we strongly encourage readers to view relevant movies in parallel with reading this chapter. See Box 17.2.

17.2 Equations of Compressible Flow

In Chap. 13, we derived the equations of fluid dynamics, allowing for compressibility. We expressed them as laws of mass conservation [Eq. (13.29)], momentum conservation [$\partial(\rho\mathbf{v})/\partial t + \nabla \cdot \mathbf{T} = 0$, with \mathbf{T} as given in Table 13.3], energy conservation [$\partial U/\partial t + \nabla \cdot \mathbf{F} = 0$, with U and \mathbf{F} as given in Table 13.3], and also an evolution law for entropy [Eq. (13.76)]. When, as in this chapter, heat conduction is negligible ($\kappa \rightarrow 0$) and the gravitational field is a time-independent, external one (not generated by the flowing fluid), these equations become

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \quad (17.1a)$$

$$\frac{\partial(\rho \mathbf{v})}{\partial t} + \nabla \cdot (P \mathbf{g} + \rho \mathbf{v} \otimes \mathbf{v} - 2\eta \boldsymbol{\sigma} - \zeta \theta \mathbf{g}) = \rho \mathbf{g}, \quad (17.1b)$$

17.2

equations of compressible flow

mass conservation

momentum conservation

energy conservation

$$\frac{\partial}{\partial t} \left[\left(\frac{1}{2} v^2 + u + \Phi \right) \rho \right] + \nabla \cdot \left[\left(\frac{1}{2} v^2 + h + \Phi \right) \rho \mathbf{v} - 2\eta \boldsymbol{\sigma} \cdot \mathbf{v} - \zeta \theta \mathbf{v} \right] = 0, \quad (17.1c)$$

entropy evolution

$$\frac{\partial(\rho s)}{\partial t} + \nabla \cdot (\rho s \mathbf{v}) = \frac{1}{T} (2\eta \boldsymbol{\sigma} : \boldsymbol{\sigma} + \zeta \theta^2). \quad (17.1d)$$

Here $\boldsymbol{\sigma} : \boldsymbol{\sigma}$ is index-free notation for $\sigma_{ij}\sigma_{ij}$.

Some comments are in order. Equation (17.1a) is the complete mass-conservation equation (continuity equation), assuming that matter is neither added to nor removed from the flow, for example, no electron-positron pair creation. Equation (17.1b) expresses the conservation of momentum allowing for one external force, gravity. Other external forces (e.g., electromagnetic) can be added. Equation (17.1c), expressing energy conservation, includes a viscous contribution to the energy flux. If there are sources or sinks of fluid energy, then these must be included on the right-hand side of this equation. Possible sources of energy include chemical or nuclear reactions; possible energy sinks include cooling by emission of radiation. Equation (17.1d) expresses the evolution of entropy and will also need modification if there are additional contributions to the energy equation. The right-hand side of this equation is the rate of increase of entropy due to viscous heating. This equation is not independent of the preceding equations and the laws of thermodynamics, but it is often convenient to use. In particular, one often uses it (together with the first law of thermodynamics) in place of energy conservation (17.1c).

equation of state

These equations must be supplemented with an equation of state in the form $P(\rho, T)$ or $P(\rho, s)$. For simplicity, we often focus on an ideal gas (one with $P \propto \rho k_B T$) that undergoes adiabatic evolution with constant specific-heat ratio (adiabatic index γ ; Ex. 5.4), so the equation of state has the simple polytropic form (Box 13.2)

adiabatic index

$$P = K(s) \rho^\gamma. \quad (17.2a)$$

polytropic equation of state

Here $K(s)$ is a function of the entropy per unit mass s and is thus constant during adiabatic evolution, but it will change across shocks, because the entropy increases in a shock (Sec. 17.5). The value of γ depends on the number of thermalized internal degrees of freedom of the gas's constituent particles (Ex. 17.1). For a gas of free particles (e.g., fully ionized hydrogen), the value is $\gamma = 5/3$; for Earth's atmosphere at temperatures between about 10 K and 400 K, it is $\gamma = 7/5 = 1.4$ (Ex. 17.1).

polytropic relations

For a polytropic gas with $P = K(s) \rho^\gamma$, we can integrate the first law of thermodynamics (Box 13.2) to obtain a formula for the internal energy per unit mass:

$$u = \frac{P}{(\gamma - 1)\rho}, \quad (17.2b)$$

where we have assumed that the internal energy vanishes as the temperature $T \rightarrow 0$ and thence $P \rightarrow 0$. It will prove convenient to express the density ρ , the internal

energy per unit mass u , and the enthalpy per unit mass h in terms of the sound speed:

$$C = \sqrt{\left(\frac{\partial P}{\partial \rho}\right)_s} = \sqrt{\frac{\gamma P}{\rho}} \quad (17.2c)$$

[Eq. (16.48)]. A little algebra gives

$$\rho = \left(\frac{C^2}{\gamma K}\right)^{1/(\gamma-1)}, \quad u = \frac{C^2}{\gamma(\gamma-1)}, \quad h = u + \frac{P}{\rho} = \frac{C^2}{\gamma-1} = \frac{\gamma P}{(\gamma-1)\rho}. \quad (17.2d)$$

EXERCISES

Exercise 17.1 ***Example: Values of γ*

Consider an ideal gas consisting of several different particle species (e.g., diatomic oxygen molecules and nitrogen molecules in the case of Earth's atmosphere). Consider a sample of this gas with volume V , containing N_A particles of various species A , all in thermodynamic equilibrium at a temperature T sufficiently low that we can ignore the effects of special relativity. Let species A have ν_A internal degrees of freedom with the hamiltonian quadratic in their generalized coordinates (e.g., rotation and vibration), and assume that those degrees of freedom are sufficiently thermally excited to have reached energy equipartition. Then the equipartition theorem (Sec. 4.4.4) dictates that each such particle has $\frac{3}{2}k_B T$ of translational energy plus $\frac{1}{2}\nu_A k_B T$ of internal energy, and because the gas is ideal, each particle contributes $k_B T/V$ to the pressure. Correspondingly, the sample's total energy E and pressure P are

$$E = \sum_A \left(\frac{3}{2} + \frac{\nu_A}{2}\right) N_A k_B T, \quad P = \frac{1}{V} \sum_A N_A k_B T. \quad (17.3a)$$

- (a) Use the laws of thermodynamics to show that the specific heats at fixed volume and pressure are

$$C_V \equiv \left(T \frac{\partial S}{\partial T}\right)_{V, N_A} = \frac{E}{T} = \sum_A \left(\frac{3}{2} + \frac{\nu_A}{2}\right) N_A k_B, \\ C_P = \left(T \frac{\partial S}{\partial T}\right)_{P, N_A} = C_V + \frac{PV}{T}, \quad (17.3b)$$

so the ratio of specific heats is

$$\gamma = \frac{C_P}{C_V} = 1 + \frac{\sum_A N_A}{\sum_A N_A \left(\frac{3}{2} + \frac{\nu_A}{2}\right)} \quad (17.3c)$$

(cf. Ex. 5.4).

- (b) If there are no thermalized internal degrees of freedom, $\nu_A = 0$ (e.g., for a fully ionized, nonrelativistic gas), then $\gamma = 5/3$. For Earth's atmosphere, at temperatures between about 10 K and 400 K, the rotational degrees of freedom of the O_2 and N_2 molecules are thermally excited, but the temperature is too low to excite their vibrational degrees of freedom. Explain why this means that $\nu_{O_2} = \nu_{N_2} = 2$,

FIGURE 17.3 The ratio of specific heats γ for air as a function of temperature.

which implies $\gamma = 7/5 = 1.4$. [Hint: There are just two orthogonal axes around which the diatomic molecule can rotate.]

- (c) Between about 1,300 K and roughly 10,000 K the vibrational degrees of freedom are thermalized, but the molecules have not dissociated substantially into individual atoms, nor have they become substantially ionized. Explain why this means that $\nu_{O_2} = \nu_{N_2} = 4$ in this temperature range, which implies $\gamma = 9/7 \simeq 1.29$. [Hint: An oscillator has kinetic energy and potential energy.]
- (d) At roughly 10,000 K the two oxygen atoms in O_2 dissociate, the two nitrogen atoms in N_2 dissociate, and electrons begin to ionize. Explain why this drives γ up toward $5/3 \simeq 1.67$.

The actual value of γ as a function of temperature for the range 200 K to 1,300 K is shown in Fig. 17.3. Evidently, as stated, $\gamma = 1.4$ is a good approximation only up to about 400 K, and the transition toward $\gamma = 1.29$ occurs gradually between about 400 K and 1,400 K as the vibrational degrees of freedom gradually become thermalized and begin to obey the equipartition theorem (Sec. 4.4.4).

17.3

17.3 Stationary, Irrotational, Quasi-1-Dimensional Flow

17.3.1

17.3.1 Basic Equations; Transition from Subsonic to Supersonic Flow

In their full generality, the fluid dynamic equations (17.1) are quite unwieldy. To demonstrate some of the novel features of supersonic flow, we proceed as in earlier chapters: we specialize to a simple type of flow in which the physical effects of interest are strong, and extraneous effects are negligible.

In particular, in this section, we seek insight into smooth transitions between subsonic and supersonic flow by restricting ourselves to a stationary ($\partial/\partial t = 0$),

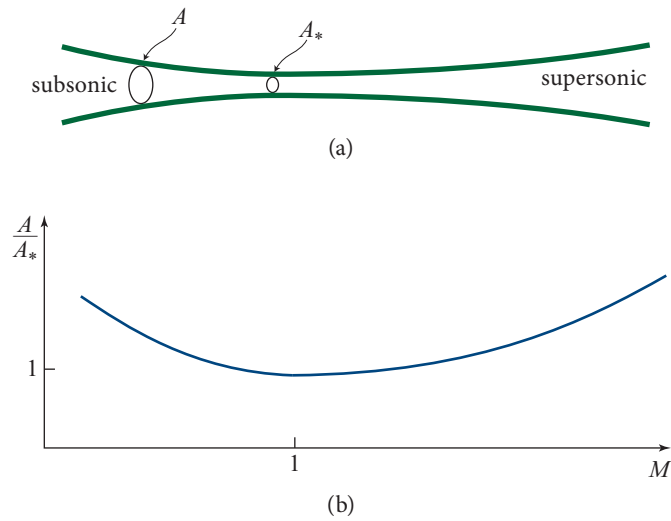

FIGURE 17.4 Stationary, transonic flow in a converging and then diverging streamtube. (a) The streamtube. (b) The flow's Mach number $M = v/C$ (horizontal axis) as a function of the streamtube's area A (vertical axis). The flow is subsonic to the left of the streamtube's throat $A = A_*$, sonic at the throat, and supersonic to the right.

irrotational ($\nabla \times \mathbf{v} = 0$) flow in which gravity and viscosity are negligible ($\Phi = \mathbf{g} = \eta = \zeta = 0$), as are various effects not included in our general equations: chemical reactions, thermal conductivity, and radiative losses. (We explore some effects of gravity in Ex. 17.5.) The vanishing viscosity implies [from the entropy evolution equation (17.1d)] that the entropy per baryon s is constant along each flow line. We assume that s is the same on all flow lines, so the flow is fully isentropic (s is constant everywhere), and the pressure $P = P(\rho, s)$ can thus be regarded as a function only of the density: $P = P(\rho)$. When we need a specific form for $P(\rho)$, we will use the polytropic form $P = K(s)\rho^\gamma$ for an ideal gas with constant specific-heat ratio γ [Eqs. (17.2); Ex. 17.1], but much of our analysis is done for a general isentropic $P(\rho)$. We make one further approximation: the flow is almost 1-dimensional. In other words, the velocity vectors all make small angles with one another in the region of interest.

These drastic simplifications are actually appropriate for many cases of practical interest. Granted these simplifications, we can consider a narrow bundle of streamlines—which we call a *streamtube*—and introduce as a tool for analysis its cross sectional area A normal to the flow (Fig. 17.4a).

As the flow is stationary, the equation of mass conservation (17.1a) states that the rate \dot{m} at which mass passes through the streamtube's cross section must be independent of position along the tube:

$$\rho v A = \dot{m} = \text{const}; \quad (17.4a)$$

stationary, irrotational, isentropic flow without gravity or viscosity

streamtube

here v is the speed of the fluid in the streamtube. Rewriting this in differential form, we obtain

$$\frac{dA}{A} + \frac{d\rho}{\rho} + \frac{dv}{v} = 0. \quad (17.4b)$$

Because the flow is stationary and inviscid, the law of energy conservation (17.1c) reduces to Bernoulli's theorem [Eqs. (13.51), (13.50)]:

$$h + \frac{1}{2}v^2 = h_1 = \text{const} \quad (17.4c)$$

along each streamline and thus along our narrow streamtube. Here h_1 is the specific enthalpy at a location where the flow velocity v vanishes (e.g., in chamber 1 of Fig. 17.5a below). Since the flow is adiabatic, we can use the first law of thermodynamics (Box 13.2) $dh = dP/\rho + Tds = dP/\rho = C^2 d\rho/\rho$ [where C is the speed of sound; Eq. (17.2c)] to write Eq. (17.4c) in the differential form

$$\frac{d\rho}{\rho} + \frac{v dv}{C^2} = 0. \quad (17.4d)$$

Finally and most importantly, we combine Eqs. (17.4b) and (17.4d) to obtain

$$\boxed{\frac{dv}{v} = \frac{dA/A}{M^2 - 1}, \quad \frac{d\rho}{\rho} = \frac{dA/A}{M^{-2} - 1}}, \quad (17.5)$$

where

$$\boxed{M \equiv v/C} \quad (17.6)$$

is the *Mach number*. This Mach number is an important dimensionless number that is used to characterize compressible flows. When the Mach number is less than 1, the flow is *subsonic*; when $M > 1$, it is *supersonic*. By contrast with the Reynolds, Rossby, and Ekman numbers, which are usually defined using a single set of (characteristic) values of the flow parameters (V , v , Ω , and L) and thus have a single value for any given flow, the Mach number by convention is defined at each point in the flow and thus is a flow variable, $M(\mathbf{x})$, similar to $v(\mathbf{x})$ and $\rho(\mathbf{x})$.

Equations (17.5) make remarkable predictions, which we illustrate in Fig. 17.4 for a particular flow called “transonic”:

1. The only locations along a streamtube at which M can be unity ($v = C$) are those where A is an extremum—for example, for the streamtube in Fig. 17.4, the minimum $A = A_*$ (the tube's throat).
2. At points along a streamtube where the flow is subsonic, $M < 1$ (left side of the streamtube in Fig. 17.4), v increases when A decreases, in accord with everyday experience.

- At points where the flow is supersonic, $M > 1$ (right side of Fig. 17.4), v increases when A increases—just the opposite of everyday experience.

These conclusions are useful when analyzing stationary, high-speed flows.

17.3.2 Setting up a Stationary, Transonic Flow

17.3.2

At this point the reader may wonder whether it is easy to set up a transonic flow in which the speed of the fluid changes continuously from subsonic to supersonic, as in Fig. 17.4. The answer is quite illuminating. We can illustrate the answer using two chambers maintained at different pressures, P_1 and P_2 , and connected through a narrow channel, along which the cross sectional area passes smoothly through a minimum $A = A_*$, the channel's throat (Fig. 17.5a). When $P_2 = P_1$, no flow occurs between the two chambers. When we decrease P_2 slightly below P_1 , a slow subsonic flow moves through the channel (curves 1 in Fig. 17.5b,c). As we decrease P_2 further, there comes a point ($P = P_2^{\text{crit}}$) at which the flow becomes transonic at the channel's throat $A = A_*$ (curves 2). For all pressures $P_2 < P_2^{\text{crit}}$, the flow is also transonic at the throat and has a universal form to the left of and near the throat, independent of the value of P_2 (curves 2)—including a universal value \dot{m}_{crit} for the rate of mass flow through the throat! This universal flow is supersonic to the right of the throat (curves 2b), but it must be brought to rest in chamber 2, since there is a hard wall at the chamber's end. How is it brought to rest? Through a shock front, where it is driven subsonic almost discontinuously (curves 3 and 4; see Sec. 17.5).

inducing transonic flow by increasing pressure difference

How, physically, is it possible for the transonic flow to have a universal form to the left of the shock? The key is that, in any supersonic region of the flow, disturbances are unable to propagate upstream, so the upstream fluid has no way of knowing what the pressure P_2 is in chamber 2. Although the flow to the left of the shock is universal, the location of the shock and the nature of the subsonic, post-shock flow are affected by P_2 , since information can propagate upstream through that subsonic flow, from chamber 2 to the shock.

The reader might now begin to suspect that the throat, in the transonic case, is a special location. It is, and that location is known as a *critical point* of the stationary flow. From a mathematical point of view, critical points are singular points of the equations (17.4) and (17.5) of stationary flow. This singularity shows up in the solutions to the equations, as depicted in Fig. 17.5c. The universal solution that passes transonically through the critical point (solution 2) joins onto two different solutions to the right of the throat: solution 2a, which is supersonic, and solution 2b, which is subsonic. Which solution occurs in practice depends on conditions downstream. Other solutions that are arbitrarily near this universal solution (dashed curves in Fig. 17.5c) are either double valued and consequently unphysical, or are everywhere subsonic or everywhere supersonic (in the absence of shocks); see Box 17.3 and Ex. 17.2.

critical point of a stationary flow

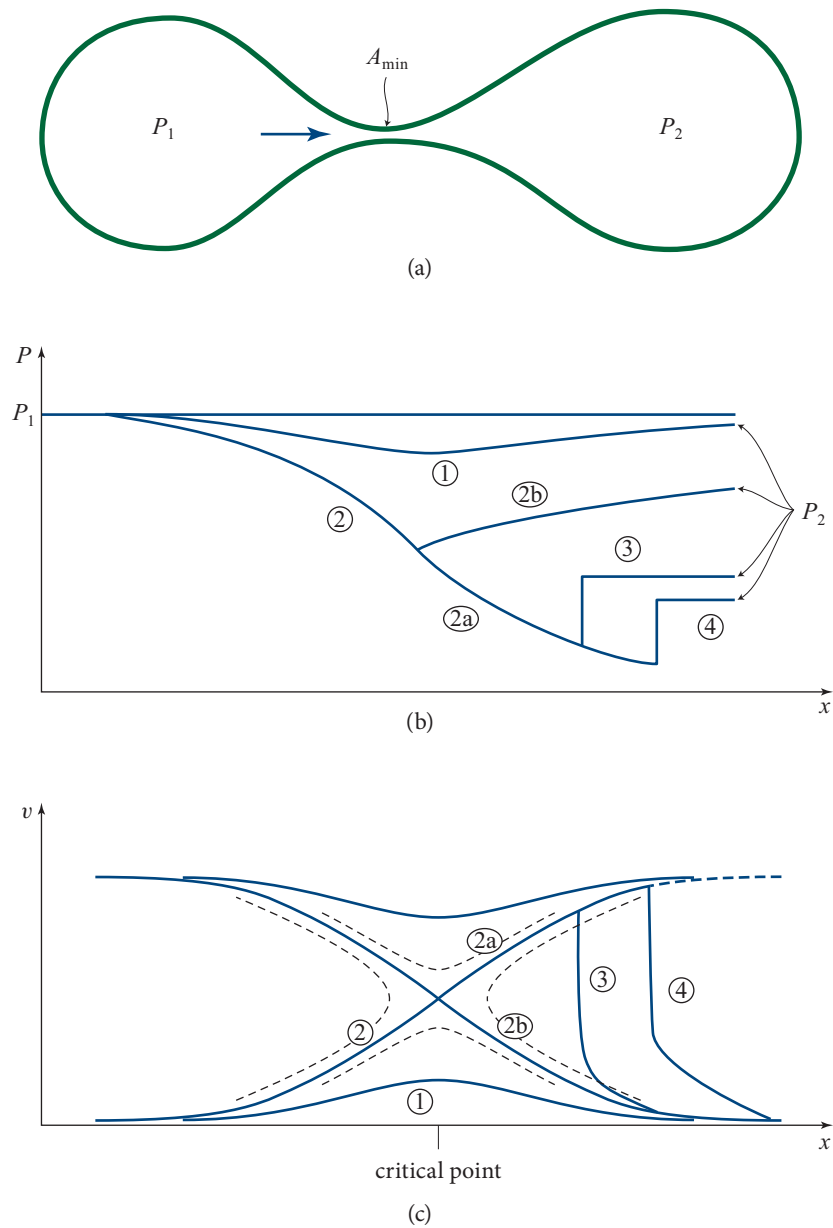

FIGURE 17.5 Stationary flow through a channel between two chambers maintained at different pressures P_1 and P_2 . (a) Setup of the chambers. When the pressure difference $P_1 - P_2$ is large enough [see curves in panel (b)], the flow is subsonic to the left of the channel's throat and supersonic to the right [see curves in panel (c)]. As it nears or enters the second chamber, the supersonic flow must encounter a strong shock, where it decelerates abruptly to subsonic speed [panels (b) and (c)]. The forms of the various velocity profiles $v(x)$ in panel (c) are explained in Box 17.3.

BOX 17.3. VELOCITY PROFILES FOR 1-DIMENSIONAL FLOW BETWEEN CHAMBERS

Consider the adiabatic, stationary flow of an isentropic, polytropic fluid $P = K\rho^\gamma$ between the two chambers shown in Fig. 17.5. Describe the channel between chambers by its cross sectional area $A(x)$ as a function of distance x , and describe the flow by the fluid's velocity $v(x)$ and its sound speed $C(x)$. There are two coupled algebraic equations for $v(x)$ and $C(x)$: mass conservation $\rho v A = \dot{m}$ [Eq. (17.4a)] and the Bernoulli theorem $h + \frac{1}{2}v^2 = h_1$ [Eq. (17.4c)], which, for our polytropic fluid, become [see Eqs. (17.2d)]:

$$C^{2/(\gamma-1)}v = (\gamma K)^{1/(\gamma-1)}\dot{m}/A, \quad \frac{C^2}{\gamma-1} + \frac{v^2}{2} = \frac{C_1^2}{\gamma-1}. \quad (1)$$

These equations are graphed in diagrams below for three different mass flow rates \dot{m} . Mass conservation [the first of Eqs. (1)] is a set of generalized hyperbolas, one for each value of the channel's area $A_* < A_a < A_b < A_c$. The Bernoulli theorem [the second of Eqs. (1)] is a single ellipse. On a chosen diagram (for a chosen \dot{m}), the dot at the intersection of the ellipse with a hyperbola tells us the flow velocity v and speed of sound C at each of the two points in the channel where the area A has the hyperbola's value.

There is a critical mass-flow rate \dot{m}_{crit} (central diagram above), such that the hyperbola $A = A_*$ (the channel's throat) is tangent to the ellipse at the point $v = C$, so the flow is Mach 1 ($v = C$). For this \dot{m} , the sequence of dots along the ellipse, moving from lower right to upper left, represents the transonic flow, which begins as subsonic and becomes supersonic (upward swooping solid curve in the drawing below); and the same sequence of dots, moving in the opposite direction from upper left to lower right, represents a flow that begins as supersonic and smoothly transitions to subsonic (downward swooping solid curve, below). When $\dot{m} < \dot{m}_{\text{crit}}$ (left diagram above; top and bottom quadrants below), the sequence of dots beginning at lower

(continued)

BOX 17.3. (continued)

right reaches the throat $A = A_*$ at a subsonic velocity, so the solution climbs up along the ellipse to that point and then descends back down, mapping out a fully subsonic solution $v(x)$ below—and similarly for the dots on the upper branch of the ellipse, which map out a fully supersonic solution below. When $\dot{m} > \dot{M}_{\text{crit}}$ (right diagram above), the dots map out curves in the left and right quadrants below that never reach the sonic point and are double valued for $v(x)$ —and are thus unphysical. Therefore, the mass flow rate \dot{m} can never exceed \dot{m}_{crit} .

The existence of critical points is a price we must pay, mathematically, for not allowing our equations to be time dependent. If we were to solve the time-dependent equations (which would then be partial differential equations), we would find that they change from elliptic to hyperbolic as the flow passes through a critical point.

properties of critical points

From a physical point of view, critical points are the places where a sound wave propagating upstream remains at rest in the flow. They are therefore the one type of place from which time-dependent transients, associated with setting up the flow in the first place, cannot decay away (if the equations are dissipation-free, i.e., inviscid). Thus, even the time-dependent equations can display peculiar behaviors at a critical point. However, when dissipation, for example due to viscosity, is introduced, these peculiarities get smeared out.

dissipation smears out critical points

EXERCISES

Exercise 17.2 *Problem: Explicit Solution for Flow between Chambers When $\gamma = 3$*
 For $\gamma = 3$ and for a channel with $A = A_*(1 + x^2)$, solve the flow equations (1) of Box 17.3 analytically and explicitly for $v(x)$, and verify that the solutions have the qualitative forms depicted in the last figure of Box 17.3.

FIGURE 17.6 Schematic illustration of a rocket engine. Note the skirt, which increases the thrust produced by the escaping exhaust gases.

17.3.3 Rocket Engines

17.3.3

We have shown that, to push a quasi-1-dimensional flow from subsonic to supersonic, one must send it through a throat. This result is exploited in the design of rocket engines and jet engines.

In a rocket engine, hot gas is produced by controlled burning of fuel in a large chamber, and the gas then escapes through a *converging-diverging* (also known as a *De Laval*¹) nozzle, as shown in Fig. 17.6. The nozzle is designed with a skirt so the flow becomes supersonic smoothly when it passes through the nozzle's throat.

De Laval nozzle

To analyze this flow in some detail, let us approximate it as precisely steady, isentropic, and quasi-1-dimensional, and the gas as ideal and inviscid with a constant ratio of specific heats γ . In this case, the enthalpy is $h = C^2/(\gamma - 1)$ [Eqs. (17.2d)], so Bernoulli's theorem (17.4c) reduces to

$$\frac{C^2}{(\gamma - 1)} + \frac{1}{2}v^2 = \frac{C_1^2}{(\gamma - 1)}. \quad (17.7)$$

Here C is the sound speed in the flow and C_1 is the *stagnation* sound speed (i.e., the sound speed evaluated in the rocket chamber where $v = 0$). Dividing this Bernoulli theorem by C^2 and manipulating, we learn how the sound speed varies with Mach number $M = v/C$:

$$C = C_1 \left[1 + \frac{\gamma - 1}{2} M^2 \right]^{-1/2}. \quad (17.8)$$

how sound speed varies with Mach number

From mass conservation [Eq. (17.4a)], we know that the cross sectional area A varies as $A \propto \rho^{-1}v^{-1} \propto \rho^{-1}M^{-1}C^{-1} \propto M^{-1}C^{(\gamma+1)/(1-\gamma)}$, where we have used $\rho \propto C^{2/(\gamma-1)}$ [Eqs. (17.2d)]. Combining with Eq. (17.8), and noting that $M = 1$ where $A = A_*$ (i.e.,

1. First used in a steam turbine in 1882 by the Swedish engineer Gustaf de Laval. De Laval is most famous for developing a device to separate cream from milk, centrifugally!

the flow is sonic at the throat), we find that

how Mach number varies with area

$$\frac{A}{A_*} = \frac{1}{M} \left[\frac{2}{\gamma + 1} + \left(\frac{\gamma - 1}{\gamma + 1} \right) M^2 \right]^{\frac{\gamma + 1}{2(\gamma - 1)}}. \quad (17.9)$$

The pressure P_* at the throat can be deduced from $P \propto \rho^\gamma \propto C^{2\gamma/(\gamma-1)}$ [Eqs. (17.2a) and (17.2d)] together with Eq. (17.8) with $M = 0$ and $P = P_1$ (stagnation pressure) in the chamber and $M = 1$ at the throat:

$$P_* = P_1 \left(\frac{2}{\gamma + 1} \right)^{\frac{\gamma}{\gamma - 1}}. \quad (17.10)$$

We use these formulas in Box 17.4 and Ex. 17.3 to evaluate, numerically, some features of the Space Shuttle and its rocket engines.

momentum flow inside nozzle

Bernoulli's theorem is a statement that the fluid's energy is conserved along a streamtube. (For conceptual simplicity we regard the entire interior of the nozzle as a single streamtube.) By contrast with energy, the fluid's momentum is not conserved, since it pushes against the nozzle wall as it flows. As the subsonic flow accelerates down the nozzle's converging region, the area of its streamtube diminishes, and the momentum flowing per second in the streamtube, $(P + \rho v^2)A$, decreases; momentum is being transferred to the nozzle wall. If the rocket did not have a skirt but instead opened up completely to the outside world at its throat, the rocket thrust would be

$$T_* = (\rho_* v_*^2 + P_*)A_* = (\gamma + 1)P_*A_*. \quad (17.11)$$

This is much less than if momentum had been conserved along the subsonic, accelerating streamtubes.

role of a rocket engine's skirt

Much of the "lost" momentum is regained, and the thrust is made significantly larger than T_* , by the force of the skirt on the stream tube in the diverging part of the nozzle (Fig. 17.6). The nozzle's skirt keeps the flow quasi-1-dimensional well beyond the throat, driving it to be more and more strongly supersonic. In this accelerating, supersonic flow the tube's rate of momentum flow $(\rho v^2 + P)A$ increases downstream, with a compensating increase of the rocket's forward thrust. This skirt-induced force accounts for a significant fraction of the thrust of a well-designed rocket engine.

matching exit pressure to external pressure

Rockets work most efficiently when the exit pressure of the gas, as it leaves the base of the skirt, matches the external pressure in the surrounding air. When the pressure in the exhaust is larger than the external pressure, the flow is termed *underexpanded* and a pulse of low pressure, known as a *rarefaction*, will be driven into the escaping gases, causing them to expand and increasing their speed. However, the exhaust will now be pushing on the surrounding air, rather than on the rocket. More thrust could have been exerted on the rocket if the flow had not been underexpanded. By contrast, when the exhaust has a smaller pressure than the surrounding air (i.e., is *overexpanded*), shock fronts will form near the exit of the nozzle, affecting the fluid flow and sometimes causing separation of the flow from the nozzle's walls. It is important that the nozzle's skirt be shaped so that the exit flow is neither seriously over- nor underexpanded.

BOX 17.4. SPACE SHUTTLE

NASA's (now retired) Space Shuttle provides many nice examples of the behavior of supersonic flows. At launch, the shuttle and fuel had a mass $\sim 2 \times 10^6$ kg. The maximum thrust, $T \sim 3 \times 10^7$ N, occurred at lift-off and gave the rocket an initial acceleration relative to the ground of $\sim 0.5g$. This increased to $\sim 3g$ as the fuel was burned and the total mass diminished. Most of the thrust was produced by two solid-fuel boosters that burned fuel at a combined rate of $\dot{m} \sim 10,000$ kg s^{-1} over a 2-min period. Their combined thrust was $T \sim 2 \times 10^7$ N averaged over the 2 minutes, from which we can estimate the speed of the escaping gases as they left the nozzles' skirts. Assuming this speed was quite supersonic (so $P_e \ll \rho_e v_e^2$), we estimate that $v_e \sim T/\dot{m} \sim 2$ km s^{-1} . The combined exit areas of the two skirts was $A_e \sim 20$ m², roughly four times the combined throat area, A_* . Using Eq. (17.9) with $\gamma \sim 1.29$, we deduce that the exit Mach number was $M_e \sim 3$.

From $T \sim \rho_e v_e^2 A_e$ and $P_e = C_e^2 \rho_e / \gamma$, we deduce the exit pressure, $P_e \sim T/(\gamma M_e^2 A_e) \sim 8 \times 10^4$ N m^{-2} , about atmospheric. The stagnation pressure in the combustion region was [combine Eqs. (17.2a), (17.2d), and (17.8)]

$$P_1 \sim P_e \left[1 + \frac{(\gamma - 1)M_e^2}{2} \right]^{\frac{\gamma}{\gamma-1}} \sim 35 \text{ atmospheres.} \quad (1)$$

Of course, the actual operation was far more complex than this. For example, to optimize the final altitude, one must allow for the decreasing mass and atmospheric pressure as well as the 2-dimensional gas flow through the nozzle.

The Space Shuttle can also be used to illustrate the properties of shock waves (Sec. 17.5). When the shuttle reentered the atmosphere, it was highly supersonic, and therefore was preceded by a strong shock front that heated the onrushing air and consequently heated the shuttle. The shuttle continued moving supersonically down to an altitude of 15 km, and until this time it created a shock-front pattern that could be heard on the ground as a sonic boom. The maximum heating rate occurred at 70 km. Here, the shuttle moved at $V \sim 7$ km s^{-1} , and the sound speed is about 280 m s^{-1} , giving a Mach number of 25. For the specific-heat ratio $\gamma \sim 1.5$ and mean molecular weight $\mu \sim 10$ appropriate to dissociated air, the strong-shock Rankine-Hugoniot relations (17.37) (see Sec. 17.5.2), together with $P = [\rho/(\mu m_p)] k_B T$ and $C^2 = \gamma P/\rho$, predict a post-shock temperature of

$$T \sim \frac{2(\gamma - 1)\mu m_p V^2}{(\gamma + 1)^2 k_B} \sim 9,000 \text{ K.} \quad (2)$$

Exposure to gas at this high temperature heated the shuttle's nose to $\sim 1,800$ K.

(continued)

BOX 17.4. (continued)

There is a second, well-known consequence of this high temperature: it is sufficient to ionize the air partially as well as dissociate it. As a result, during reentry the shuttle was surrounded by a sheath of plasma, which, as we shall discover in Chap. 19, prevented radio communication. The blackout lasted for about 12 minutes.

EXERCISES**Exercise 17.3** *Problem: Space Shuttle's Solid-Fuel Boosters*

Use the rough figures in Box 17.4 to estimate the energy released per unit mass in burning the fuel. Does your answer seem reasonable?

Exercise 17.4 *Problem: Relativistic 1-Dimensional Flow* **T2**

Use the development of relativistic gas dynamics in Sec. 13.8.2 to show that the cross sectional area of a relativistic 1-dimensional flow tube is also minimized when the flow is transonic. Assume that the equation of state is $P = \frac{1}{3}\rho c^2$. For details see Blandford and Rees (1974).

Exercise 17.5 ***Example: Adiabatic, Spherical Accretion of Gas onto a Black Hole or Neutron Star*

Consider a black hole or neutron star with mass \mathcal{M} at rest in interstellar gas that has constant ratio of specific heats γ . In this exercise you will derive some features of the adiabatic, spherical accretion of the gas onto the hole or star, a problem first solved by Bondi (1952b). This exercise shows how gravity can play a role analogous to a De Laval nozzle: it can trigger a transition of the flow from subsonic to supersonic. Although, near the black hole or neutron star, spacetime is significantly curved and the flow becomes relativistic, we shall confine ourselves to a Newtonian treatment.

- Let ρ_∞ and C_∞ be the density and sound speed in the gas far from the hole (at radius $r = \infty$). Use dimensional analysis to estimate the rate of accretion of mass $\dot{\mathcal{M}}$ onto the star or hole in terms of the parameters of the system: \mathcal{M} , γ , ρ_∞ , C_∞ , and Newton's gravitation constant G . [Hint: Dimensional considerations alone cannot give the answer. Why? Augment your dimensional considerations by a knowledge of how the answer should scale with one of the parameters (e.g., the density ρ_∞).]
- Give a simple physical argument, devoid of dimensional considerations, that produces the same answer for $\dot{\mathcal{M}}$, to within a multiplicative factor of order unity, as you deduced in part (a).
- Because the neutron star and black hole are both very compact with intense gravity near their surfaces, the inflowing gas is guaranteed to accelerate to su-

sonic speeds as it falls in. Explain why the speed will remain supersonic in the case of the hole, but must transition through a shock to subsonic flow near the surface of the neutron star. If the star has the same mass \mathcal{M} as the hole, will the details of its accretion flow $[\rho(r), C(r), v(r)]$ be the same as or different from those for the hole, outside the star's shock? Will the mass accretion rates $\dot{\mathcal{M}}$ be the same or different? Justify your answers physically.

- (d) By combining the Euler equation for $v(r)$ with the equation of mass conservation, $\dot{\mathcal{M}} = 4\pi r^2 \rho v$, and with the sound-speed equation $C^2 = (\partial P / \partial \rho)_s$, show that

$$(v^2 - C^2) \frac{1}{\rho} \frac{d\rho}{dr} = \frac{G\mathcal{M}}{r^2} - \frac{2v^2}{r}, \quad (17.12)$$

and the flow speed v_s , sound speed C_s , and radius r_s at the *sonic point* (the transition from subsonic to supersonic; the flow's critical point) are related by

$$v_s^2 = C_s^2 = \frac{G\mathcal{M}}{2r_s}. \quad (17.13)$$

- (e) By combining with the Bernoulli equation (with the effects of gravity included), deduce that the sound speed at the sonic point is related to that at infinity by

$$C_s^2 = \frac{2C_\infty^2}{5 - 3\gamma} \quad (17.14)$$

and that the radius of the sonic point is

$$r_s = \frac{(5 - 3\gamma)}{4} \frac{G\mathcal{M}}{C_\infty^2}. \quad (17.15)$$

Thence also deduce a precise value for the mass accretion rate $\dot{\mathcal{M}}$ in terms of the parameters of the problem. Compare with your estimate of $\dot{\mathcal{M}}$ in parts (a) and (b). [Comment: For $\gamma = 5/3$, which is the value for hot, ionized gas, this analysis places the sonic point at an arbitrarily small radius. In this limiting case, (i) general relativistic effects strengthen the gravitational field (Sec. 26.2), thereby moving the sonic point well outside the star or hole, and (ii) the answer for $\dot{\mathcal{M}}$ has a finite value close to the general relativistic prediction.]

- (f) Much of the interstellar medium is hot and ionized, with a density of about 1 proton per cubic centimeter and temperature of about 10^4 K. In such a medium, what is the mass accretion rate onto a 10-solar-mass hole, and approximately how long does it take for the hole's mass to double?

17.4 1-Dimensional, Time-Dependent Flow

17.4

17.4.1 Riemann Invariants

17.4.1

Let us turn now to time-dependent flows. Again we confine our attention to the simplest situation that illustrates the physics—in this case, truly 1-dimensional motion of an isentropic fluid in the absence of viscosity, thermal conductivity, and gravity, so

1-dimensional flow of an isentropic fluid without viscosity, thermal conductivity, or gravity

the flow is adiabatic as well as isentropic (entropy constant in time as well as space). The motion of the gas in such a flow is described by the equation of continuity (17.1a) and the Euler equation (17.1b) specialized to 1 dimension:

$$\frac{d\rho}{dt} = -\rho \frac{\partial v}{\partial x}, \quad \frac{dv}{dt} = -\frac{1}{\rho} \frac{\partial P}{\partial x}, \quad (17.16)$$

where

$$\frac{d}{dt} = \frac{\partial}{\partial t} + v \frac{\partial}{\partial x} \quad (17.17)$$

is the convective (advective) time derivative—the time derivative moving with the fluid.

Given an isentropic equation of state $P = P(\rho)$ that relates the pressure to the density, these two nonlinear equations can be combined into a single second-order differential equation in the velocity. However, it is more illuminating to work with the first-order set. As the gas is isentropic, the density ρ and sound speed $C = (dP/d\rho)^{1/2}$ can both be regarded as functions of a single thermodynamic variable, which we choose to be the pressure.

Taking linear combinations of Eqs. (17.16), we obtain two partial differential equations:

$$\frac{\partial v}{\partial t} \pm \frac{1}{\rho C} \frac{\partial P}{\partial t} + (v \pm C) \left(\frac{\partial v}{\partial x} \pm \frac{1}{\rho C} \frac{\partial P}{\partial x} \right) = 0, \quad (17.18)$$

which together are equivalent to Eqs. (17.16). We can rewrite these equations in terms of *Riemann invariants*

Riemann invariants

$$J_{\pm} \equiv v \pm \int \frac{dP}{\rho C} \quad (17.19)$$

and *characteristic speeds*

characteristic speeds

$$V_{\pm} \equiv v \pm C \quad (17.20)$$

in the following way:

flow equations

$$\left(\frac{\partial}{\partial t} + V_{\pm} \frac{\partial}{\partial x} \right) J_{\pm} = 0. \quad (17.21)$$

Riemann invariant conserved along its characteristic

Equation (17.21) tells us that the convective derivative of each Riemann invariant J_{\pm} vanishes for an observer who moves, not with the fluid speed, but, instead, with the speed V_{\pm} . We say that each Riemann invariant is conserved along its characteristic (denoted by \mathcal{C}_{\pm}), which is a path through spacetime satisfying

$$\mathcal{C}_{\pm}: \quad \frac{dx}{dt} = v \pm C. \quad (17.22)$$

Note that in these equations, both v and C are functions of x and t .

FIGURE 17.7 Spacetime diagram showing the characteristics (thin solid and dashed lines) for a 1-dimensional adiabatic flow of an isentropic gas. The paths of the fluid elements are shown as thick solid lines. Initial data are presumed to be specified over some interval ∂S of x at time $t = 0$. The Riemann invariant J_+ is constant along each characteristic C_+ (thin dashed line) and thus at point \mathcal{P} it has the same value, unchanged, as at point A in the initial data. Similarly J_- is invariant along each characteristic C_- (thin solid line) and thus at \mathcal{P} it has the same value as at B . The shaded area of spacetime is the domain of dependence S of ∂S .

The characteristics have a natural interpretation. They describe the motion of small disturbances traveling backward and forward relative to the fluid at the local sound speed. As seen in the fluid's local rest frame $v = 0$, two neighboring events in the flow, separated by a small time interval Δt and a space interval $\Delta x = +C \Delta t$ —so that they lie on the same C_+ characteristic—will have small velocity and pressure differences satisfying $\Delta v = -\Delta P / (\rho C)$ [as one can deduce from Eqs. (17.16) with $v = 0$, $d/dt = \partial/\partial t$, and $C^2 = dP/d\rho$]. Now, for a linear sound wave propagating along the positive x direction, Δv and ΔP will separately vanish. However, in a nonlinear wave, only the combination $\Delta J_+ = \Delta v + \Delta P / (\rho C)$ will vanish along C_+ . Integrating over a finite interval of time, we recover the constancy of J_+ along the characteristic C_+ [Eq. (17.21)].

The Riemann invariants provide a general method for deriving the details of the flow from initial conditions. Suppose that the fluid velocity and the thermodynamic variables are specified over an interval of x , designated ∂S , at an initial time $t = 0$ (Fig. 17.7). This means that J_{\pm} are also specified over this interval. We can then determine J_{\pm} at any point \mathcal{P} in the *domain of dependence* S of ∂S (i.e., at any point linked to ∂S by two characteristics C_{\pm}) by simply propagating each of J_{\pm} unchanged along its characteristic. From these values of J_{\pm} at \mathcal{P} , we can solve algebraically for all the other flow variables (v , P , ρ , etc.) at \mathcal{P} . To learn the evolution outside the domain of dependence S , we must specify the initial conditions outside ∂S .

physical interpretation of characteristics

using characteristics and Riemann invariants to solve for details of flow in domain of dependence

FIGURE 17.8 Evolution of a nonlinear sound wave. (a) The fluid at the crest of the wave moves faster than the fluid in the trough. (b) Mathematically, the flow eventually becomes triple-valued (dashed curve). Physically, a shock wave develops (vertical solid line).

In practice, we do not actually know the characteristics \mathcal{C}_{\pm} until we have solved for the flow variables, so we must solve for the characteristics as part of the solution process. This means, in practice, that the solution involves algebraic manipulations of (i) the equation of state and the relations $J_{\pm} = v \pm \int dP/(\rho C)$, which give J_{\pm} in terms of v and C ; and (ii) the conservation laws that J_{\pm} are constant along \mathcal{C}_{\pm} (i.e., along curves $dx/dt = v \pm C$). These algebraic manipulations have the goal of deducing $C(x, t)$ and $v(x, t)$ from the initial conditions on ∂S . We exhibit a specific example in Sec. 17.4.2.

how a nonlinear sound wave evolves to form a shock wave

We can use Riemann invariants to understand qualitatively how a nonlinear sound wave evolves with time. If the wave propagates in the positive x direction into previously undisturbed fluid (fluid with $v = 0$), then the J_- invariant, propagating backward along \mathcal{C}_- , is constant everywhere, so $v = \int dP/(\rho C) + \text{const}$. Let us use $q \equiv \int dP/(\rho C)$ as our wave variable. For an ideal gas with a constant ratio of specific heats γ , we have $q = 2C/(\gamma - 1)$, so our oscillating wave variable is essentially the oscillating sound speed. Constancy of J_- then says that $v = q - q_0$, where q_0 is the stagnation value of q (i.e., the value of q in the undisturbed fluid in front of the wave).

Now, $J_+ = v + q$ is conserved on each rightward characteristic \mathcal{C}_+ , and so both v and q are separately conserved on each \mathcal{C}_+ . If we sketch a profile of the wave pulse as in Fig. 17.8 and measure its amplitude using the quantity q , then the relation $v = q - q_0$ requires that the fluid at the crest of the wave moves faster than the fluid in a trough. This causes the leading edge of the wave to steepen, a process we have already encountered in our discussion of shallow-water solitons (Fig. 16.4). Now, sound waves, by contrast with shallow-water waves (where dispersion counteracts the steepening), are nondispersive so the steepening will continue until $|dv/dx| \rightarrow \infty$ (Fig. 17.8). When the velocity gradient becomes sufficiently large, viscosity and dissipation become strong, producing an increase of entropy and a breakdown of our isentropic flow. This breakdown and entropy increase will occur in an extremely thin region—a shock wave, which we study in Sec. 17.5.

FIGURE 17.9 Shock tube. (a) At $t \leq 0$ gas is held at rest at high pressure P_0 in the left half of the tube. (b) At $t > 0$ the high-pressure gas moves rightward down the tube at high speed, and a rarefaction wave propagates leftward at the sound speed. (c) Space-time diagram showing the flow's characteristics (C_+ : thin dashed lines; C_- : thin solid lines) and fluid paths (thick solid lines). To the left of the rarefaction wave, $x < -C_0t$, the fluid is undisturbed. To the right of the gas front, $x > [2/(\gamma - 1)]C_0t$, resides undisturbed (near) vacuum.

17.4.2 Shock Tube

17.4.2

We have shown how 1-dimensional isentropic flows can be completely analyzed by propagating the Riemann invariants along characteristics. Let us illustrate this in more detail by analyzing a shock tube, a laboratory device for creating supersonic flows and studying the behavior of shock waves. In a shock tube, high-pressure gas is retained at rest in the left half of a long tube by a thin membrane (Fig. 17.9a). At time $t = 0$, the membrane is ruptured by a laser beam, and the gas rushes into the tube's right half, which has usually been evacuated. Diagnostic photographs and velocity and pressure measurements are synchronized with the onset of the flow.

Let us idealize the operation of a shock tube by assuming, once more, that the gas is ideal with constant γ , so that $P \propto \rho^\gamma$. For times $t \leq 0$, we suppose that the gas has uniform density ρ_0 and pressure P_0 (and consequently, uniform sound speed C_0) at $x \leq 0$, and that $\rho = P = 0$ at $x \geq 0$. At time $t = 0$, the barrier is ruptured, and the gas flows toward positive x . The first Riemann invariant J_+ is conserved on C_+ , which originates in the static gas, so it has the value

$$J_+ = v + \frac{2C}{\gamma - 1} = \frac{2C_0}{\gamma - 1}. \quad (17.23)$$

Note that in this case, the invariant is the same on all rightward characteristics (i.e., throughout the flow), so that

$$v = \frac{2(C_0 - C)}{\gamma - 1} \quad \text{everywhere.} \quad (17.24)$$

The second invariant is

$$J_- = v - \frac{2C}{\gamma - 1}. \quad (17.25)$$

Its constant values are not so easy to identify, because those characteristics \mathcal{C}_- that travel through the perturbed flow all emerge from the origin, where v and C are indeterminate (cf. Fig. 17.9c). However, by combining Eq. (17.24) with Eq. (17.25), we deduce that v and C are separately constant on each characteristic \mathcal{C}_- . This enables us, trivially, to solve the differential equation $dx/dt = v - C$ for the leftward characteristics \mathcal{C}_- , obtaining

$$\mathcal{C}_-: \quad x = (v - C)t. \quad (17.26)$$

Here we have set the constant of integration equal to zero to obtain all the characteristics that propagate through the perturbed fluid. (For those in the unperturbed fluid, $v = 0$ and $C = C_0$, so $x = x_0 - C_0t$, with $x_0 < 0$ the characteristic's initial location.)

Now Eq. (17.26) is true on each characteristic in the perturbed fluid. Therefore, it is true throughout the perturbed fluid. We can then combine Eqs. (17.24) and (17.26) to solve for $v(x, t)$ and $C(x, t)$ throughout the perturbed fluid. That solution, together with the obvious solution (same as initial data) to the left and right of the perturbed fluid, is:

$$\begin{aligned} v = 0, \quad C = C_0 \quad \text{at } x < -C_0t, \\ v = \frac{2}{\gamma + 1} \left(C_0 + \frac{x}{t} \right), \quad C = \frac{2C_0}{\gamma + 1} - \left(\frac{\gamma - 1}{\gamma + 1} \right) \frac{x}{t} \quad \text{at } -C_0t < x < \frac{2C_0}{\gamma - 1}t, \\ \text{vacuum prevails at } x > \frac{2C_0}{\gamma - 1}t. \end{aligned} \quad (17.27)$$

In this solution, notice that the gas at $x < 0$ remains at rest until a *rarefaction wave* from the origin reaches it. Thereafter, it is accelerated rightward by the local pressure gradient, and as it accelerates it expands and cools, so its sound speed C goes down; asymptotically it reaches zero temperature, as exhibited by $C = 0$ and an asymptotic speed $v = 2C_0/(\gamma - 1)$ [cf. Eq. (17.23)]; see Fig. 17.9b,c. In the expansion, the internal random velocity of the gas molecules is transformed into an ordered velocity, just as in a rocket's exhaust. However, the total energy per unit mass in the stationary gas is $u = C_0^2/[\gamma(\gamma - 1)]$ [Eq. (17.2d)], which is less than the asymptotic kinetic energy per unit mass of $2C_0^2/(\gamma - 1)^2$. The additional energy has come from the gas in the rarefaction wave, which is pushing the asymptotic gas rightward.

In the more realistic case, where there initially is some low-density gas in the evacuated half of the tube, the expanding driver gas creates a strong shock as it plows into the low-density gas; hence the name "shock tube." In the next section we explore the structure of this and other shock fronts.

flow in a shock tube

rarefaction wave as flow initiator

Exercise 17.6 *Problem: Fluid Paths in Free Expansion*

We have computed the velocity field for a freely expanding gas in 1 dimension, Eqs. (17.27). Use this result to show that the path of an individual fluid element, which begins at $x = x_0 < 0$, is

$$x = \frac{2C_0 t}{\gamma - 1} + \left(\frac{\gamma + 1}{\gamma - 1}\right) x_0 \left(\frac{-C_0 t}{x_0}\right)^{\frac{2}{\gamma+1}} \quad \text{at } 0 < -\frac{x_0}{C_0} < t.$$

Exercise 17.7 *Problem: Riemann Invariants for Shallow-Water Flow; Breaking of a Dam*

Consider the 1-dimensional flow of shallow water in a straight, narrow channel, neglecting dispersion and boundary layers. The equations governing the flow, as derived and discussed in Box 16.3 and Eqs. (16.23), are

$$\frac{\partial h}{\partial t} + \frac{\partial(hv)}{\partial x} = 0, \quad \frac{\partial v}{\partial t} + v \frac{\partial v}{\partial x} + g \frac{\partial h}{\partial x} = 0. \quad (17.28)$$

Here $h(x, t)$ is the height of the water, and $v(x, t)$ is its depth-independent velocity.

- (a) Find two Riemann invariants J_{\pm} for these equations, and find two conservation laws for these J_{\pm} that are equivalent to the shallow-water equations (17.28).
- (b) Use these Riemann invariants to demonstrate that shallow-water waves steepen in the manner depicted in Fig. 16.4, a manner analogous to the peaking of the nonlinear sound wave in Fig. 17.8.
- (c) Use these Riemann invariants to solve for the flow of water $h(x, t)$ and $v(x, t)$ after a dam breaks (the problem posed in Ex. 16.9, and there solved via similarity methods). The initial conditions (at $t = 0$) are $v = 0$ everywhere, and $h = h_0$ at $x < 0$, $h = 0$ (no water) at $x > 0$.

17.5 Shock Fronts

We have just demonstrated that in an ideal gas with constant adiabatic index γ , large perturbations to fluid dynamical variables inevitably evolve to form a divergently large velocity gradient—a “shock front,” or a “shock wave,” or simply a “shock.” When the velocity gradient becomes large, we can no longer ignore the viscous stress, because the viscous terms in the Navier-Stokes equation involve second derivatives of \mathbf{v} in space, whereas the inertial term involves only first derivatives. As in turbulence and in boundary layers, so also in a shock front, the viscous stresses convert the fluid’s ordered, bulk kinetic energy into microscopic kinetic energy (i.e., thermal energy). The ordered fluid velocity \mathbf{v} thereby is rapidly—almost discontinuously—reduced from supersonic to subsonic, and the fluid is heated.

17.5

inevitability of shock fronts

terminology for shocks

The cooler, supersonic region of incoming fluid is said to be *ahead of* or *upstream from* the shock, and it hits the shock's *front side*; the hotter, subsonic region of outgoing fluid is said to be *behind* or *downstream from* the shock, and it emerges from the shock's *back side*; see Fig. 17.10 below.

17.5.1

17.5.1 Junction Conditions across a Shock; Rankine-Hugoniot Relations

role of viscosity in a shock

Viscosity is crucial to the internal structure of the shock, but it is just as negligible in the downstream flow behind the shock as in the upstream flow ahead of the shock, since there velocity gradients are modest again. Remarkably, if (as is usually the case) the shock front is very thin compared to the length scales in the upstream and downstream flows, and the time for the fluid to pass through the shock is short compared to the upstream and downstream timescales, then we can deduce the net influence of the shock on the flow without any reference to the viscous processes that operate in the shock and without reference to the shock's detailed internal structure. We do so by treating the shock as a discontinuity across which certain junction conditions must be satisfied. This is similar to electromagnetic theory, where the junction conditions for the electric and magnetic fields across a material interface are independent of the detailed structure of the interface.

The keys to the shock's junction conditions are the conservation laws for mass, momentum, and energy: The fluxes of mass, momentum, and energy must usually be the same in the downstream flow, emerging from the shock, as in the upstream flow, entering it. To understand this, we first note that, because the time to pass through the shock is so short, mass, momentum, and energy cannot accumulate in the shock, so the flow can be regarded as stationary. In a stationary flow, the mass flux is always constant, as there is no way to create new mass or destroy old mass. Its continuity across the shock can be written as

mass conservation across shock

$$[\rho \mathbf{v} \cdot \mathbf{n}] = 0, \tag{17.29a}$$

where \mathbf{n} is the unit normal to the shock front, and the square bracket means the difference in the values on the downstream and upstream sides of the shock. Similarly, the total momentum flux $\mathbf{T} \cdot \mathbf{n}$ must be conserved in the absence of external forces. Now \mathbf{T} has both a mechanical component, $P\mathbf{g} + \rho\mathbf{v} \otimes \mathbf{v}$, and a viscous component, $-\zeta\theta\mathbf{g} - 2\eta\sigma$. However, the viscous component is negligible in the upstream and downstream flows, which are being matched to each other, so the mechanical component by itself must be conserved across the shock front:

momentum conservation

$$[(P\mathbf{g} + \rho\mathbf{v} \otimes \mathbf{v}) \cdot \mathbf{n}] = 0. \tag{17.29b}$$

Similar remarks apply to the energy flux, though here we must be slightly more restrictive. There are three ways that a change in the energy flux could occur. First, energy may be added to the flow by chemical or nuclear reactions that occur in the shock front. Second, the gas may be heated to such a high temperature that it will lose energy in the shock front through the emission of radiation. Third, energy may

be conducted far upstream by suprathermal particles so as to preheat the incoming gas. Any of these processes will thicken the shock front and may make it so thick that it can no longer sensibly be approximated as a discontinuity. If any of these processes occurs, we must check to see whether it is strong enough to significantly influence energy conservation across the shock. What such a check often reveals is that preheating is negligible, and the lengthscales over which the chemical and nuclear reactions and radiation emission operate are much greater than the length over which viscosity acts. In this case we can conserve energy flux across the viscous shock and then follow the evolutionary effects of reactions and radiation (if significant) in the downstream flow.

A shock with negligible preheating—and with negligible radiation emission and chemical and nuclear reactions inside the shock—will have the same energy flux in the departing, downstream flow as in the entering, upstream flow, so it will satisfy

$$\boxed{\left[\left(\frac{1}{2}v^2 + h \right) \rho \mathbf{v} \cdot \mathbf{n} \right] = 0.} \quad (17.29c)$$

energy conservation

Shocks that satisfy the conservation laws of mass, momentum, and energy, Eqs. (17.29), are said to be *adiabatic*.

By contrast to mass, momentum, and energy, the entropy will not be conserved across a shock front, since viscosity and other dissipative processes increase the entropy as the fluid flows through the shock. So far, the only type of dissipation that we have discussed is viscosity, and this is sufficient by itself to produce a shock front and keep it thin. However, heat conduction (Sec. 18.2) and electrical resistivity, which is important in magnetic shocks (Chap. 19), can also contribute to the dissipation and can influence the detailed structure of the shock front.

For an adiabatic shock, the three requirements of mass, momentum, and energy conservation [Eqs. (17.29)], known collectively as the *Rankine-Hugoniot relations*, enable us to relate the downstream flow and its thermodynamic variables to their upstream counterparts.²

Let us work in a reference frame where the incoming flow is normal to the shock front and the shock is at rest, so the flow is stationary in the shock's vicinity. Then the conservation of tangential momentum—the tangential component of Eq. (17.29b)—tells us that the outgoing flow is also normal to the shock in our chosen reference frame. We say that the shock is *normal*, not *oblique*.

We use the subscripts 1, 2 to denote quantities measured ahead of and behind the shock, respectively (i.e., 1 denotes the incoming flow, and 2 denotes the outgoing flow;

2. The existence of shocks was actually understood quite early on, more or less in this way, by Stokes. However, he was persuaded by his former student Rayleigh and others that such discontinuities were impossible, because they would violate energy conservation. With a deference that professors traditionally show their students, Stokes believed Rayleigh. They were both making an error in their analysis of energy conservation, due to an inadequate understanding of thermodynamics in that era.

FIGURE 17.10 Terminology and notation for a shock front and the flow into and out of it.

Fig. 17.10). The Rankine-Hugoniot relations (17.29) then take the forms:

$$\rho_2 v_2 = \rho_1 v_1 = j, \quad (17.30a)$$

$$P_2 + \rho_2 v_2^2 = P_1 + \rho_1 v_1^2, \quad (17.30b)$$

$$h_2 + \frac{1}{2} v_2^2 = h_1 + \frac{1}{2} v_1^2, \quad (17.30c)$$

where j is the mass flux, which is determined by the upstream flow.

These equations can be brought into a more useful form by replacing the density ρ with the specific volume $V \equiv 1/\rho$, replacing the specific enthalpy h by its value in terms of P and V , $h = u + P/\rho = u + PV$, and performing some algebra. The result is

Rankine-Hugoniot jump conditions across a shock

$$u_2 - u_1 = \frac{1}{2}(P_1 + P_2)(V_1 - V_2), \quad (17.31a)$$

$$j^2 = \frac{P_2 - P_1}{V_1 - V_2}, \quad (17.31b)$$

$$v_1 - v_2 = [(P_2 - P_1)(V_1 - V_2)]^{1/2}. \quad (17.31c)$$

This is the most widely used form of the Rankine-Hugoniot relations. It must be augmented by an equation of state in the form

equation of state

$$u = u(P, V). \quad (17.32)$$

shock adiabat

Some of the physical content of these Rankine-Hugoniot relations is depicted in Fig. 17.11. The thermodynamic state of the upstream (incoming) fluid is the point (V_1, P_1) in this volume-pressure diagram. The thick solid curve, called the *shock adiabat*, is the set of all possible downstream (outgoing) fluid states. This shock adiabat can be computed by combining Eq. (17.31a) with the equation of state (17.32). Those

FIGURE 17.11 Shock adiabat. The pressure and specific volume $V = 1/\rho$ in the upstream flow are P_1 and V_1 , and in the downstream flow they are P_2 and V_2 . The dashed curves are ordinary adiabats (curves of constant entropy per unit mass s). The thick curve is the shock adiabat, the curve of allowed downstream states (V_2, P_2) for a given upstream state (V_1, P_1) . The actual location of the downstream state on this adiabat is determined by the mass flux j flowing through the shock: the slope of the dotted line connecting the upstream and downstream states is $-j^2$.

equations will actually give a curve that extends away from (V_1, P_1) in both directions, up-leftward and down-rightward. Only the up-leftward portion is compatible with an increase of entropy across the shock; the down-rightward portion requires an entropy decrease, which is forbidden by the second law of thermodynamics and therefore is not drawn in Fig. 17.11. The actual location (V_2, P_2) of the downstream state along the shock adiabat is determined by Eq. (17.31b) in a simple way: the slope of the dotted line connecting the upstream and downstream states is $-j^2$, where j is the mass flux passing through the shock. When one thereby has learned (V_2, P_2) , one can compute the downstream speed v_2 from Eq. (17.31c).

It can be shown that the pressure and density always increase across a shock (as is the case in Fig. 17.11), and the fluid always decelerates:

$$P_2 > P_1, \quad V_2 < V_1, \quad v_2 < v_1; \quad (17.33)$$

see Ex. 17.8. It also can be demonstrated in general—and will be verified in a particular case below, that the Rankine-Hugoniot relations require the flow to be supersonic with respect to the shock front upstream $v_1 > C_1$ and subsonic downstream, $v_2 < C_2$. Physically, this requirement is sensible (as we have seen): When the fluid approaches the shock supersonically, it is not possible to communicate a pressure pulse upstream from the shock (via a Riemann invariant moving at the speed of sound relative to the

pressure and density increase, and velocity decrease across shock

flow) and thereby cause the flow to decelerate; therefore, to slow the flow, a shock must develop.³ By contrast, the shock front can and does respond to changes in the downstream conditions, since it is in causal contact with the downstream flow; sound waves and a Riemann invariant can propagate upstream, through the downstream flow, to the shock.

To summarize, shocks are machines that decelerate a normally incident upstream flow to a subsonic speed, so it can be in causal contact with conditions downstream. In the process, bulk momentum flux ρv^2 is converted into pressure, bulk kinetic energy is converted into internal energy, and entropy is manufactured by the dissipative processes at work in the shock front. For given upstream conditions, the downstream conditions are fixed by the conservation laws of mass, momentum, and energy and are independent of the detailed dissipation mechanisms.

EXERCISES

Exercise 17.8 *Derivation and Challenge: Signs of Change across a Shock*

- (a) Almost all equations of state satisfy the condition $(\partial^2 V / \partial P^2)_s > 0$. Show that, when this condition is satisfied, the Rankine-Hugoniot relations and the law of entropy increase imply that the pressure and density must increase across a shock and the fluid must decelerate: $P_2 > P_1$, $V_2 < V_1$, and $v_2 < v_1$.
- (b) Show that in a fluid that violates $(\partial^2 V / \partial P^2)_s > 0$, the pressure and density must still increase and the fluid decelerate across a shock, as otherwise the shock would be unstable.

For a solution to this exercise, see Landau and Lifshitz (1959, Sec. 84).

Exercise 17.9 *Problem: Relativistic Shock* T2

In astrophysics (e.g., in supernova explosions and in jets emerging from the vicinities of black holes), one sometimes encounters shock fronts for which the flow speeds relative to the shock approach the speed of light, and the internal energy density is comparable to the fluid's rest-mass density.

- (a) Show that the relativistic Rankine-Hugoniot equations for such a shock take the following form:

$$\eta_2^2 - \eta_1^2 = (P_2 - P_1)(\eta_1 V_1 + \eta_2 V_2), \quad (17.34a)$$

$$j^2 = \frac{P_2 - P_1}{\eta_1 V_1 - \eta_2 V_2}, \quad (17.34b)$$

$$v_2 \gamma_2 = j V_2, \quad v_1 \gamma_1 = j V_1. \quad (17.34c)$$

3. Of course, if there is some faster means of communication, for example, photons or, in an astrophysical context, cosmic rays or neutrinos, then there may be a causal contact between the shock and the inflowing gas, which can either prevent shock formation or lead to a more complex shock structure.

Here,

- (i) We use units in which the speed of light is 1 (as in Chap. 2).
 - (ii) The volume per unit rest mass is $V \equiv 1/\rho_o$, and ρ_o is the rest-mass density (equal to some standard rest mass per baryon times the number density of baryons; cf. Sec. 2.12.3).
 - (iii) We denote the total density of mass-energy including rest mass by ρ_R (it was denoted ρ in Chap. 2) and the internal energy per unit rest mass by u , so $\rho_R = \rho_o(1 + u)$. In terms of these the quantity $\eta \equiv (\rho_R + P)/\rho_o = 1 + u + P/\rho_o = 1 + h$ is the relativistic enthalpy per unit rest mass (i.e., the enthalpy per unit rest mass, including the rest-mass contribution to the energy) as measured in the fluid rest frame.
 - (iv) The pressure as measured in the fluid rest frame is P .
 - (v) The flow velocity in the shock's rest frame is v , and $\gamma \equiv 1/\sqrt{1 - v^2}$ (not the adiabatic index!), so $v\gamma$ is the spatial part of the flow 4-velocity.
 - (vi) The rest-mass flux is j (rest mass per unit area per unit time) entering and leaving the shock.
- (b) Use a pressure-volume diagram to discuss these relativistic Rankine-Hugoniot equations in a manner analogous to Fig. 17.11.
- (c) Show that in the nonrelativistic limit, the relativistic Rankine-Hugoniot equations (17.34) reduce to the nonrelativistic ones (17.31).
- (d) It can be shown (Thorne, 1973) that relativistically, just as for nonrelativistic shocks, in general $P_2 > P_1$, $V_2 < V_1$, and $v_2 < v_1$. Consider, as an example, a relativistic shock propagating through a fluid in which the mass density due to radiation greatly exceeds that due to matter (a *radiation-dominated fluid*), so $P = \rho_R/3$ (Sec. 3.5.5). Show that $v_1 v_2 = 1/3$, which implies $v_1 > 1/\sqrt{3}$ and $v_2 < 1/\sqrt{3}$. Show further that $P_2/P_1 = (9v_1^2 - 1)/[3(1 - v_1^2)]$.

Exercise 17.10 ***Problem: Hydraulic Jumps and Breaking Ocean Waves*

Run water at a high flow rate from a kitchen faucet onto a dinner plate (Fig. 17.12). What you see is called a hydraulic jump. It is the kitchen analog of a breaking ocean wave, and the shallow-water-wave analog of a shock front in a compressible gas. In this exercise you will develop the theory of hydraulic jumps (and breaking ocean waves) using the same tools as those used for shock fronts.

- (a) Recall that for shallow-water waves, the water motion, below the water's surface, is nearly horizontal, with speed independent of depth z (Ex. 16.1). The same is true of the water in front of and behind a hydraulic jump. Apply the conservation of mass and momentum to a hydraulic jump, in the jump's rest frame, to obtain equations for the height of the water h_2 and water speed v_2 behind the jump (emerging from it) in terms of those in front of the jump, h_1 and v_1 . These are the analog of the Rankine-Hugoniot relations for a shock front. [Hint: For

FIGURE 17.12 Hydraulic jump on a dinner plate under a kitchen tap.

momentum conservation you will need to use the pressure P as a function of height in front of and behind the jump.]

- (b) You did not use energy conservation across the jump in your derivation, but it was needed in the analysis of a shock front. Why?
- (c) Show that the upstream speed v_1 is greater than the speed $\sqrt{gh_1}$ of small-amplitude, upstream gravity waves [shallow-water waves; Eq. (16.10) and associated discussion]; thus the upstream flow is supersonic. Similarly, show that the downstream flow speed v_2 is slower than the speed $\sqrt{gh_2}$ of small-amplitude, downstream gravity waves (i.e., the downstream flow is subsonic).
- (d) We normally view a breaking ocean wave in the rest frame of the quiescent upstream water. Use your hydraulic-jump equations to show that the speed of the breaking wave as seen in this frame is related to the depths h_1 and h_2 in front of and behind the breaking wave by

$$v_{\text{break}} = \left[\frac{g(h_1 + h_2)h_2}{2h_1} \right]^{1/2};$$

see Fig. 17.13.

17.5.2

shock Mach number

17.5.2 Junction Conditions for Ideal Gas with Constant γ

To make the shock junction conditions more explicit, let us again specialize to an ideal gas with constant specific-heat ratio γ (a polytropic gas), so the equation of state is

FIGURE 17.13 An ocean wave breaking on a gradually sloping beach. The depth of water ahead of the wave is h_1 , and the depth behind the wave is h_2 .

$u = PV/(\gamma - 1)$, and the sound speed is $C = \sqrt{\gamma P/\rho} = \sqrt{\gamma PV}$ [Eqs. (17.2)]. We measure the strength of the shock using the *shock Mach number* M , which is defined to be the Mach number in the upstream flow relative to the shock:

$$M \equiv M_1 = v_1/C_1 = \sqrt{v_1^2/(\gamma P_1 V_1)}. \quad (17.35)$$

With the aid of this equation of state and Mach number, we can bring the Rankine-Hugoniot relations (17.31) into the form:

$$\frac{\rho_1}{\rho_2} = \frac{V_2}{V_1} = \frac{v_2}{v_1} = \frac{\gamma - 1}{\gamma + 1} + \frac{2}{(\gamma + 1)M^2}, \quad (17.36a)$$

Rankine-Hugoniot relations for polytropic equation of state

$$\frac{P_2}{P_1} = \frac{2\gamma M^2}{\gamma + 1} - \frac{\gamma - 1}{\gamma + 1}, \quad (17.36b)$$

$$M_2^2 = \frac{2 + (\gamma - 1)M^2}{2\gamma M^2 - (\gamma - 1)}. \quad (17.36c)$$

Here $M_2 \equiv v_2/c_2$ is the downstream Mach number.

The results for this equation of state illustrate a number of general features of shocks. The density and pressure increase across the shock, the flow speed decreases, and the downstream flow is subsonic—all discussed previously—and one important new feature: a shock weakens as its Mach number M decreases. In the limit that $M \rightarrow 1$, the jumps in pressure, density, and speed vanish, and the shock disappears.

In the *strong-shock limit*, $M \gg 1$, the jumps are

$$\frac{\rho_1}{\rho_2} = \frac{V_2}{V_1} = \frac{v_2}{v_1} \simeq \frac{\gamma - 1}{\gamma + 1}, \quad (17.37a)$$

Rankine-Hugoniot relations for strong polytropic shock

$$\frac{P_2}{P_1} \simeq \frac{2\gamma M^2}{\gamma + 1}. \quad (17.37b)$$

Thus the density jump is always of order unity, but the pressure jump grows ever larger as M increases. Air has $\gamma \simeq 1.4$ (Ex. 17.1), so the density compression ratio for a strong shock in air is $\rho_2/\rho_1 = 6$, and the pressure ratio is $P_2/P_1 = 1.2M^2$. The Space Shuttle's reentry provides a nice example of these strong-shock Rankine-Hugoniot relations; see the bottom half of Box 17.4.

EXERCISES

Exercise 17.11 *Problem: Shock Tube*

Consider a shock tube as discussed in Sec. 17.4.2 and Fig. 17.9. High density “driver” gas with sound speed C_0 and specific heat ratio γ is held in place by a membrane that separates it from target gas with very low density, sound speed C_1 , and the same specific-heat ratio γ . When the membrane is ruptured, a strong shock propagates into the target gas. Show that the Mach number of this shock is given approximately by

$$M = \left(\frac{\gamma + 1}{\gamma - 1} \right) \left(\frac{C_0}{C_1} \right). \quad (17.38)$$

[Hint: Think carefully about which side of the shock is supersonic and which side subsonic.]

17.5.3

17.5.3 Internal Structure of a Shock

molecular collisions as dissipation mechanism in some shocks

Although they are often regarded as discontinuities, shocks, like boundary layers, do have structure. The simplest case is that of a gas in which the shear-viscosity coefficient is molecular in origin and is given by $\eta = \rho v \sim \rho \lambda v_{\text{th}}/3$, where λ is the molecular mean free path, and $v_{\text{th}} \sim C$ is the mean thermal speed of the molecules (Ex. 3.19). In this case for 1-dimensional flow $v = v_x(x)$, the viscous stress $T_{xx} = -\zeta\theta - 2\eta\sigma_{xx}$ is $-(\zeta + 4\eta/3)dv/dx$, where ζ is the coefficient of bulk viscosity, which can be of the same order as the coefficient of shear viscosity. In the shock, this viscous stress must roughly balance the total kinetic momentum flux $\sim \rho v^2$. If we estimate the velocity gradient dv/dx by v_1/δ_S , where δ_S is a measure of the shock thickness, and we estimate the sound speed in the shock front by $C \sim v_1$, then we deduce that the shock thickness δ_S is roughly equal to λ , the collision mean free path in the gas. For air at standard temperature and pressure, the mean free path is $\lambda \sim (\sqrt{2}n\pi\sigma^2)^{-1} \sim 70$ nm, where n is the molecular density, and σ is the molecular diameter. This is very small! Microscopically, it makes sense that $\delta_S \sim \lambda$, as an individual molecule only needs a few collisions to randomize its ordered motion perpendicular to the shock front. However, this estimate raises a problem, as it brings into question our use of the continuum approximation (cf. Sec. 13.2). It turns out that, when a more careful calculation of the shock structure is carried out incorporating heat conduction, the shock thickness is several mean free paths, fluid dynamics is acceptable for an approximate theory, and the results are in rough accord with measurements of the velocity profiles of shocks with modest Mach numbers. Despite this, for an accurate description of the shock structure, a kinetic treatment is usually necessary.

shock thickness: several mean free paths

FIGURE 17.14 Construction for the Mach cone formed by a supersonic projectile. The cone angle is $\alpha = \sin^{-1}(1/M)$, where $M = v_p/C_0$ is the Mach number of the projectile.

So far we have assumed that the shocked fluid is made of uncharged molecules. A more complicated type of shock can arise in an ionized gas (i.e., a plasma; Part VI). Shocks in the solar wind are examples. In this case the collision mean free paths are enormous; in fact, they are comparable to the transverse size of the shock, and therefore one might expect the shocks to be so thick that the Rankine-Hugoniot relations fail. However, spacecraft measurements reveal solar-wind shocks that are relatively thin—far thinner than the collisional mean free paths of the plasma’s electrons and ions. In this case, it turns out that collisionless, collective electromagnetic and charged-particle interactions in the plasma are responsible for the viscosity and dissipation. (The particles create plasma waves, which in turn deflect the particles.) These processes are so efficient that thin shock fronts can occur without individual particles having to hit one another. Since the shocks are thin, they must satisfy the Rankine-Hugoniot relations. We discuss these collisionless shocks further in Sec. 23.6.

dissipation mechanisms for shocks in collisionless plasmas

17.5.4 Mach Cone

17.5.4

The shock waves formed by a supersonically moving body are quite complex close to the body and depend on its detailed shape, Reynolds’ number, and so forth (see, e.g., Fig. 17.1). However, far from the body, the leading shock has the form of the *Mach cone* shown in Fig. 17.14. We can understand this cone by the construction shown in the figure. The shock is the boundary between the fluid that is in sound-based causal contact with the projectile and the fluid that is not. This boundary is mapped out by (conceptual) sound waves that propagate into the fluid from the projectile at the ambient sound speed C_0 . When the projectile is at the indicated position, the envelope of the circles is the shock front and has the shape of the Mach cone, with opening angle (the *Mach angle*)

Mach cone

$$\alpha = \sin^{-1}(1/M). \quad (17.39)$$

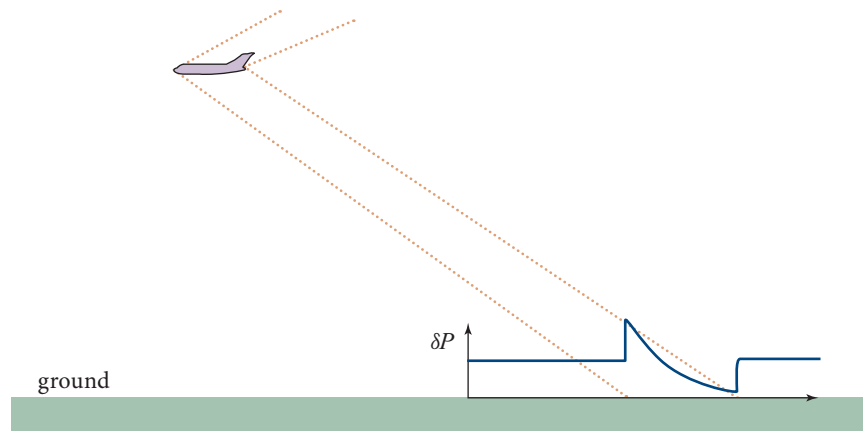

FIGURE 17.15 Double shock created by a supersonic body and its associated N-wave pressure distribution on the ground.

Usually, there are two such shock cones, one attached to the projectile's bow shock and the other formed out of the complex shock structure in its tail region. The pressure must jump twice, once across each of these shocks, and therefore forms an *N wave*, which propagates cylindrically away from the projectile, as shown in Fig. 17.15. Behind the first shock, the density and pressure drop off gradually by more than the first shock's compression. As a result, the fluid flowing into the second shock has a lower pressure, density, and sound speed than that flowing into the first (Fig. 17.15). This causes the Mach number of the second shock to be higher than that of the first, and its Mach angle thus to be smaller. As a result, the separation between the shocks increases as they travel as $\varpi^{1/2}$, it turns out. The pressure jumps across the shocks decrease as $\varpi^{-3/4}$. Here ϖ is the perpendicular distance of the point of observation from the projectile's trajectory. Often a double boom can be heard on the ground. For a detailed analysis, see Whitham (1974, Sec. 9.3).

EXERCISES

Exercise 17.12 *Problem: Sonic Boom from the Space Shuttle*

Use the quoted scaling of N-wave amplitude with cylindrical radius ϖ to make an order-of-magnitude estimate of the flux of acoustic energy produced by the Space Shuttle flying at Mach 2 at an altitude of 20 km. Give your answer in decibels [Eq. (16.61)].

17.6

17.6 Self-Similar Solutions—Sedov-Taylor Blast Wave

Strong explosions can generate shock waves. Examples include atmospheric nuclear explosions, supernova explosions, and depth charges. The debris from a strong explosion is at much higher pressure than the surrounding gas and therefore drives a strong spherical shock into its surroundings. Initially, this shock wave travels at roughly the

radial speed of the expanding debris. However, the mass of fluid swept up by the shock eventually exceeds that of the explosion debris. The shock then decelerates and the energy of the explosion is transferred to the swept-up fluid. It is of obvious importance to be able to calculate how fast and how far the shock front will travel.

17.6.1 The Sedov-Taylor Solution

17.6.1

We first make an order-of-magnitude estimate. Let the total energy of the explosion be E and the density of the surrounding fluid (assumed uniform) be ρ_0 . Then after time t , when the shock radius is $R(t)$, the mass of swept-up fluid will be $m \sim \rho_0 R^3$. The fluid velocity behind the shock will be roughly the radial velocity of the shock front, $v \sim \dot{R} \sim R/t$, and so the kinetic energy of the swept-up gas will be $\sim m v^2 \sim \rho_0 R^5/t^2$. There will also be internal energy in the post-shock flow, with energy density roughly equal to the post-shock pressure: $\rho u \sim P \sim \rho_0 \dot{R}^2$ [cf. the strong-shock jump condition (17.37b) with $P_1 \sim \rho_0 C_0^2$, so $P_1 M^2 \sim \rho_0 v^2 \sim \rho_0 \dot{R}^2$]. The total internal energy behind the expanding shock will then be $\sim \rho \dot{R}^2 R^3 \sim \rho_0 R^5/t^2$, equal in order of magnitude to the kinetic energy. Equating this to the total energy E of the explosion, we obtain the estimate

$$E = \kappa \rho_0 R^5 t^{-2}, \quad (17.40)$$

where κ is a numerical constant of order unity. This expression implies that at time t the shock front has reached the radius

$$R = \left(\frac{E}{\kappa \rho_0} \right)^{1/5} t^{2/5}. \quad (17.41)$$

radius of a strong, spherical shock as a function of time

This scaling should hold roughly from the time that the mass of the swept-up gas is of order that of the exploding debris, to the time that the shock weakens to a Mach number of order unity so we can no longer use the strong-shock value $\sim \rho_0 \dot{R}^2$ for the post-shock pressure.

Note that we could have obtained Eq. (17.41) by a purely dimensional argument: E and ρ_0 are the only significant controlling parameters in the problem, and $E^{1/5} \rho_0^{-1/5} t^{2/5}$ is the only quantity with dimensions of length that can be constructed from E , ρ_0 , and t . However, it is usually possible and always desirable to justify any such dimensional argument on the basis of the governing equations.

If, as we shall assume, the motion remains radial and the gas is ideal with constant specific-heat ratio γ , then we can solve for the details of the flow behind the shock front by integrating the radial flow equations:

$$\frac{\partial \rho}{\partial t} + \frac{1}{r^2} \frac{\partial}{\partial r} (r^2 \rho v) = 0, \quad (17.42a)$$

$$\frac{\partial v}{\partial t} + v \frac{\partial v}{\partial r} + \frac{1}{\rho} \frac{\partial P}{\partial r} = 0, \quad (17.42b)$$

$$\frac{\partial}{\partial t} \left(\frac{P}{\rho^\gamma} \right) + v \frac{\partial}{\partial r} \left(\frac{P}{\rho^\gamma} \right) = 0. \quad (17.42c)$$

The first two equations are the familiar continuity equation and Euler equation written for a spherical flow. The third equation is energy conservation expressed as the adiabatic-expansion relation, $P/\rho^\gamma = \text{const}$ moving with a fluid element. Although P/ρ^γ is time independent for each fluid element, its value will change from element to element. Gas that has passed through the shock more recently will be given a smaller entropy than gas that was swept up when the shock was stronger, and thus it will have a smaller value of P/ρ^γ .

Given suitable initial conditions, the partial differential equations (17.42) can be integrated numerically. However, there is a practical problem: it is not easy to determine the initial conditions in an explosion! Fortunately, at late times, when the initial debris mass is far less than the swept-up mass, the fluid evolution is independent of the details of the initial expansion and in fact can be understood analytically as a *similarity solution*. By this term we mean that the shape of the radial profiles of pressure, density, and velocity are independent of time.

We have already met three examples of similarity solutions: the Blasius structure of a laminar boundary layer (Sec. 14.4.1), the structure of a turbulent jet (Ex. 15.3), and the flow of water following the sudden rupture of a dam (Ex. 16.9). The one we explored in greatest detail was the Blasius boundary layer (Sec. 14.4.1). There we argued on the basis of mass and momentum conservation (or, equally well, by dimensional analysis) that the thickness of the boundary layer as a function of distance x downstream would be $\sim \delta = (\nu x / V)^{1/2}$, where V is the speed of the flow above the boundary layer. This motivated us to introduce the dimensionless variable $\xi = y/\delta$ and argue that the boundary layer's speed $v_x(x, y)$ would be equal to the free-stream velocity V times some universal function $f'(\xi)$. This ansatz converted the fluid's partial differential equations into an ordinary differential equation for $f(\xi)$, which we solved numerically.

Our explosion problem is somewhat similar. The characteristic scaling length in the explosion is the radius $R(t) = [E/(\kappa\rho_0)]^{1/5}t^{2/5}$ of the shock [Eq. (17.41)], with κ an as-yet-unknown constant, so the fluid and thermodynamic variables should be expressible as some characteristic values multiplying universal functions of

$$\xi \equiv r/R(t). \quad (17.43)$$

Our thermodynamic variables are P , ρ , and u , and natural choices for their characteristic values are the values P_2 , ρ_2 , and v_2 immediately behind the shock. If we assume the shock is strong, then we can use the strong-shock jump conditions (17.37) to determine those values, and then write

$$P = \frac{2}{\gamma + 1} \rho_0 \dot{R}^2 \tilde{P}(\xi), \quad (17.44a)$$

$$\rho = \frac{\gamma + 1}{\gamma - 1} \rho_0 \tilde{\rho}(\xi), \quad (17.44b)$$

$$v = \frac{2}{\gamma + 1} \dot{R} \tilde{v}(\xi), \quad (17.44c)$$

examples of similarity solutions

similarity solution behind strong, spherical shock

with $\tilde{P}(1) = \tilde{\rho}(1) = \tilde{v}(1) = 1$, since $\xi = 1$ is the shock's location. Note that the velocity v is scaled to the post-shock velocity v_2 measured in the inertial frame in which the upstream fluid is at rest, rather than in the noninertial frame in which the decelerating shock is at rest. The self-similarity ansatz (17.44) and resulting similarity solution for the flow are called the *Sedov-Taylor blast-wave solution*, since L. I. Sedov and G. I. Taylor independently developed it (Sedov, 1946, 1993; Taylor, 1950).

The partial differential equations (17.42) can now be transformed into ordinary differential equations by inserting the ansatz (17.44) together with expression (17.41) for $R(t)$, changing the independent variables from r and t to R and ξ and using

$$\left(\frac{\partial}{\partial t}\right)_r = -\left(\frac{\xi \dot{R}}{R}\right)\left(\frac{\partial}{\partial \xi}\right)_R + \dot{R}\left(\frac{\partial}{\partial R}\right)_\xi = -\left(\frac{2\xi}{5t}\right)\left(\frac{\partial}{\partial \xi}\right)_R + \frac{2R}{5t}\left(\frac{\partial}{\partial R}\right)_\xi, \quad (17.45)$$

$$\left(\frac{\partial}{\partial r}\right)_t = \left(\frac{1}{R}\right)\left(\frac{\partial}{\partial \xi}\right)_R. \quad (17.46)$$

Mass conservation, the Euler equation, and the equation of adiabatic expansion become, in that order:

$$0 = 2\tilde{\rho}\tilde{v}' - (\gamma + 1)\xi\tilde{\rho}' + \tilde{v}\left(2\tilde{\rho}' + \frac{4}{\xi}\tilde{\rho}\right), \quad (17.47a)$$

$$0 = \tilde{\rho}\tilde{v}[3(\gamma + 1) - 4\tilde{v}'] + 2(\gamma + 1)\xi\tilde{\rho}\tilde{v}' - 2(\gamma - 1)\tilde{P}', \quad (17.47b)$$

$$3 = \left(\frac{2\tilde{v}}{\gamma + 1} - \xi\right)\left(\frac{\tilde{P}'}{\tilde{P}} - \gamma\frac{\tilde{\rho}'}{\tilde{\rho}}\right). \quad (17.47c)$$

These self-similarity equations can be solved numerically, subject to the boundary conditions that \tilde{v} , $\tilde{\rho}$, and \tilde{P} are all zero at $\xi = 0$ and 1 at $\xi = 1$. Remarkably, Sedov and Taylor independently found an analytic solution (also given in Landau and Lifshitz, 1959, Sec. 99). The solutions for an explosion in air ($\gamma = 1.4$) are exhibited in Fig. 17.16.

Armed with the solution for $\tilde{v}(\xi)$, $\tilde{\rho}(\xi)$, and $\tilde{P}(\xi)$ (numerical or analytic), we can evaluate the flow's energy E , which is equal to the explosion's total energy during the time interval when this similarity solution is accurate. The energy E is given by the integral

$$\begin{aligned} E &= \int_0^R 4\pi r^2 dr \rho \left(\frac{1}{2}v^2 + u\right) \\ &= \frac{4\pi\rho_0 R^3 \dot{R}^2 (\gamma + 1)}{(\gamma - 1)} \int_0^1 d\xi \xi^2 \tilde{\rho} \left(\frac{2\tilde{v}^2}{(\gamma + 1)^2} + \frac{2\tilde{P}}{(\gamma + 1)^2 \tilde{\rho}}\right). \end{aligned} \quad (17.48)$$

Here we have used Eqs. (17.44) and substituted $u = P/[\rho(\gamma - 1)]$ for the internal energy [Eq. (17.2b)]. The energy E appears not only on the left-hand side of this equation but also on the right, in the terms $\rho_0 R^3 \dot{R}^2 = (4/25)E/\kappa$. Thus, E cancels

differential equations for similarity solution

explosion's total energy

FIGURE 17.16 Scaled pressure, density, and velocity as a function of scaled radius behind a Sedov-Taylor blast wave in air with $\gamma = 1.4$.

out, and Eq. (17.48) becomes an equation for the unknown constant κ . Evaluating that equation numerically, we find that κ varies from $\kappa = 0.85$ for $\gamma = 1.4$ (air) to $\kappa = 0.49$ for $\gamma = 1.67$ (monatomic gas or fully ionized plasma).

It is enlightening to see how the fluid behaves in this blast-wave solution. The fluid that passes through the shock is compressed, so that it mostly occupies a fairly thin spherical shell immediately behind the shock [see the spike in $\tilde{\rho}(\xi)$ in Fig. 17.16]. The fluid in this shell moves somewhat more slowly than the shock [$v = 2\dot{R}/(\gamma + 1)$; Eq. (17.44c) and Fig. 17.16]; it flows from the shock front through the high-density shell (fairly slowly relative to the shell, which remains attached to the shock), and on into the lower density post-shock region. Since the post-shock flow is subsonic, the pressure in the blast wave is fairly uniform [see the curve $\tilde{P}(\xi)$ in Fig. 17.16]; in fact the central pressure is typically about half the maximum pressure immediately behind the shock. This pressure pushes on the spherical shell, thereby accelerating the freshly swept-up fluid.

17.6.2

17.6.2 Atomic Bomb

The first atomic bomb was exploded in New Mexico in 1945, and photographs released in 1947 (Fig. 17.17) showed the radius of the blast wave as a function of time. The pictures were well fit by $R \sim 37(t/1 \text{ ms})^{0.4}$ m up to about $t = 100$ ms, when the shock Mach number fell to about unity (Fig. 17.17). Combining this information with the similarity solution (Sec. 17.6.1), that they had earlier derived independently, the Russian physicist L. I. Sedov and the British physicist G. I. Taylor were both able to infer the total energy released, which was an official American secret at the time. Their analyses of the data were published later (Taylor, 1950; Sedov, 1957, 1993).

Adopting the specific-heat ratio $\gamma = 1.4$ of air, the corresponding value $\kappa = 0.85$, and the measured $R \sim 37(t/1 \text{ ms})^{0.4}$ m, we obtain from Eq. (17.48) the estimate

FIGURE 17.17 Photographs of the fireball (very hot post-shock gas) from the first atomic bomb explosion, at Alamogordo, New Mexico, on July 16, 1945. Courtesy of the Los Alamos National Laboratory Archives.

$E \sim 7.2 \times 10^{13}$ J, which is about the same energy release as 17 kilotons of TNT. This estimate is close to the Los Alamos scientists' estimate of 18–20 kilotons. (Hydrogen bombs have been manufactured that are more than a thousand times more energetic than this—as much as 57 megatons—but such awesome weapons have not been deemed militarily useful, so today's arsenals contain bombs that are typically *only* ~ 1 megaton!)

We can use the Sedov-Taylor solution to infer some further features of the explosion. The post-shock gas is at density $\sim (\gamma + 1)/(\gamma - 1) \sim 5$ times the ambient density $\rho_0 \sim 1 \text{ kg m}^{-3}$. Similarly, using the ideal gas law $P = [\rho/(m_p \mu)] k_B T$ with

a mean molecular weight $\mu \sim 10$ and the strong-shock jump conditions (17.37), the post-shock temperature can be computed:

$$T_2 = \frac{m_p \mu}{\rho_2 k_B} P_2 \sim 4 \times 10^4 \left(\frac{t}{1 \text{ ms}} \right)^{-1.2} \text{ K.} \quad (17.49)$$

At early times, this temperature is high enough to ionize the gas.

17.6.3 17.6.3 Supernovae

The evolution of most massive stars ends in a supernova explosion (like the one observed in 1987 in the Large Magellanic Cloud), in which a neutron star of mass $m \sim 3 \times 10^{30}$ kg is usually formed. This neutron star has a gravitational binding energy of about $0.1mc^2 \sim 3 \times 10^{46}$ J. Most of this binding energy is released in the form of neutrinos in the collapse that forms the neutron star, but an energy $E \sim 10^{44}$ J drives off the outer envelope of the pre-supernova star, a mass $M_0 \sim 10^{31}$ kg. This stellar material escapes with an rms speed $V_0 \sim (2E/M_0)^{1/2} \sim 5,000$ km s⁻¹. The expanding debris drives a blast wave into the surrounding interstellar medium, which has density $\rho_0 \sim 10^{-21}$ kg m⁻³. The expansion of the blast wave can be modeled using the Sedov-Taylor solution after the mass of the swept-up interstellar gas has become large enough to dominate the blast debris, so the star-dominated initial conditions are no longer important—after a time $\sim (3M_0/4\pi\rho_0)^{1/3}/V_0 \sim 1,000$ yr. The blast wave then decelerates as for a Sedov-Taylor similarity solution until the shock speed nears the sound speed in the surrounding gas; this takes about 100,000 yr. *Supernova remnants* of this sort are efficient emitters of radio waves and X-rays, and several hundred have been observed in our Milky Way galaxy.

In some of the younger examples, like Tycho's remnant (Fig. 17.18), it is possible to determine the expansion speed, and the effects of deceleration can be measured. The observations from remnants like this are close to the prediction of the Sedov-Taylor solution; namely, the radius variation satisfies $d \ln R/d \ln t = 0.4$. (For Tycho's remnant, a value of 0.54 ± 0.05 is found, and using the estimated density of the interstellar medium plus the kinematics, an explosion energy of $E \sim 5 \times 10^{43}$ J is inferred.)

EXERCISES

Exercise 17.13 *Problem: Underwater Explosions*

A simple analytical solution to the Sedov-Taylor similarity equations can be found for the particular case $\gamma = 7$. This is a fair approximation to the behavior of water under explosive conditions, as it will be almost incompressible.

- (a) Make the ansatz (whose self-consistency we will check later) that the velocity in the post-shock flow varies linearly with radius from the origin to the shock: $\tilde{v}(\xi) = \xi$. Use Eq. (17.45) to transform the equation of continuity into an ordinary differential equation and hence solve for the density function $\tilde{\rho}(\xi)$.

FIGURE 17.18 This remnant of the supernova explosion observed by the astronomer Tycho Brahe in 1572 is roughly 7,000 light-years from us. (Recent observations of a *light echo* have demonstrated that the supernova was of the same type used to discover the acceleration of the universe, which is discussed in Ex. 28.6.) This image was made by the Chandra X-ray Observatory and shows the emission from the hot (in red) ($\sim 1 - 10 \times 10^7$ K) gas heated by the outer and inner shock fronts as well as the even more energetic (in blue) X-rays that delineate the position of the outer shock front. Shock fronts like this are believed to be the sites for acceleration of galactic cosmic rays (cf. Sec. 19.7, Ex. 23.8). NASA/CXC/Rutgers/J. Warren and J. Hughes, et al.

- (b) Next use the equation of motion to discover that $\tilde{P}(\xi) = \xi^3$.
- (c) Verify that your solutions for the functions \tilde{P} , $\tilde{\rho}$, and \tilde{v} satisfy the remaining entropy equation, thereby vindicating the original ansatz.
- (d) Substitute your results from parts (a) and (b) into Eq. (17.48) to show that

$$E = \frac{2\pi R^5 \rho_0}{225t^2}.$$

- (e) An explosive charge weighing 100 kg with an energy release of 10^8 J kg⁻¹ is detonated underwater. For what range of shock radii do you expect the Sedov-Taylor similarity solution to be valid?

Exercise 17.14 *Problem: Stellar Winds*

Many stars possess powerful stellar winds that drive strong spherical shock waves into the surrounding interstellar medium. If the strength of the wind remains constant, the

kinetic and internal energy of the swept-up interstellar medium will increase linearly with time.

- (a) Modify the text's analysis of a point explosion to show that in this case the speed of the shock wave at time t is $\frac{3}{5}R(t)/t$, where R is the associated shock radius. What is the speed of the post-shock gas?
- (b) Now suppose that the star explodes as a supernova, and the blast wave expands into the relatively slowly moving stellar wind. Suppose that before the explosion the rate at which mass left the star and the speed of the wind were constant for a long time. How do you expect the density of gas in the wind to vary with radius? Modify the Sedov-Taylor analysis again to show that the expected speed of the shock wave at time t is now $\frac{2}{3}R(t)/t$.

Exercise 17.15 *Problem: Similarity Solution for a Shock Tube*

Use a similarity analysis to derive the solution (17.27) for the shock-tube flow depicted in Fig. 17.9.

Bibliographic Note

For physical insight into compressible flows and shock waves, we recommend the movies cited in Box 17.2. For textbook treatments, we recommend the relevant sections of Landau and Lifshitz (1959); Thompson (1984); Liepmann and Roshko (2002); Anderson (2003); and, at a more elementary and sometimes cursory level, Lautrup (2005). Whitham (1974) is superb on all aspects, from an applied mathematician's viewpoint.

Engineering-oriented textbooks on fluid mechanics generally contain detailed treatments of quasi-1-dimensional flows, shocks, hydraulic jumps, and their real-world applications. We like Munson, Young, and Okiishi (2006), White (2006), and Potter, Wiggert, and Ramadan (2012).

The two-volume treatise Zel'dovich and Raizer (2002) is a compendium of insights into shock waves and high-temperature hydrodynamics by an author (Yakov Borisovich Zel'dovich) who had a huge influence on the design of atomic and thermonuclear weapons in the Soviet Union and later on astrophysics and cosmology. Stanyukovich (1960) is a classic treatise on nonstationary flows, shocks and detonation waves. Sedov (1993)—the tenth edition of a book whose first was in 1943—is a classic and insightful treatise on similarity methods in physics.

Convection

Approximation methods derived from physical intuition are frequently more reliable than rigorous mathematical methods, because in the case of the latter it is easier for errors to creep into the fundamental assumptions.

WERNER HEISENBERG (1969)

18.1 Overview

18.1

In Chaps. 13 and 14, we demonstrated that viscosity can exert a major influence on subsonic fluid flows. When the viscosity ν is large and the Reynolds number ($Re = LV/\nu$) is low, viscous stresses transport momentum directly, and the fluid's behavior can be characterized by the diffusion of the vorticity ($\boldsymbol{\omega} = \nabla \times \mathbf{v}$) through the fluid [cf. Eq. (14.3)]. As the Reynolds number increases, the advection of the vorticity becomes more important. In the limit of large Reynolds number, we think of the vortex lines as being frozen into the flow. However, as we learned in Chap. 15, this insight is only qualitatively helpful, because high-Reynolds-number flows are invariably turbulent. Large, irregular, turbulent eddies transport shear stress very efficiently. This is particularly in evidence in turbulent boundary layers.

When viewed microscopically, heat conduction is a similar transport process to viscosity, and it is responsible for analogous physical effects. If a viscous fluid has high viscosity, then vorticity diffuses through it rapidly; similarly, if a fluid has high thermal conductivity, then heat diffuses through it rapidly. In the other extreme, when viscosity is low (i.e., when the Reynolds number is high), instabilities produce turbulence, which transports vorticity far more rapidly than diffusion could possibly do. Analogously, in heated fluids with low conductivity, the local accumulation of heat drives the fluid into convective motion, and the heat is transported much more efficiently by this motion than by thermal diffusion. As the convective heat transport increases, the fluid motion becomes more vigorous, and if the viscosity is sufficiently low, the thermally driven flow can also become turbulent. These effects are very much in evidence near solid boundaries, where thermal boundary layers can be formed, analogous to viscous boundary layers.

In addition to thermal effects that resemble the effects of viscosity, there are also unique thermal effects—particularly the novel and subtle combined effects of gravity and heat. Heat, unlike vorticity, causes a fluid to expand and thus, in the presence

BOX 18.1. READERS' GUIDE

- This chapter relies heavily on Chap. 13.
- No subsequent chapters rely substantially on this one.

of gravity, to become buoyant; this buoyancy can drive thermal circulation or *free convection* in an otherwise stationary fluid. (Free convection should be distinguished from *forced convection*, in which heat is carried passively in a flow driven by externally imposed pressure gradients, e.g., when you blow on hot food to cool it, or stir soup on a hot stove.)

The transport of heat is a fundamental characteristic of many flows. It dictates the form of global weather patterns and ocean currents. It is also of great technological importance and is studied in detail, for example, in the cooling of nuclear reactors and the design of automobile engines. From a more fundamental perspective, as we have already discussed, the analysis and experimental studies of convection have led to major insights into the route to chaos (Sec. 15.6).

In this chapter, we describe some flows where thermal effects are predominant. We begin in Sec. 18.2 by writing down and then simplifying the equations of fluid mechanics with heat conduction. Then in Sec. 18.3, we discuss the *Boussinesq approximation*, which is appropriate for modest-scale flows where buoyancy is important. This allows us in Sec. 18.4 to derive the conditions under which convection is initiated. Unfortunately, this Boussinesq approximation sometimes breaks down. In particular, as we discuss in Sec. 18.5, it is inappropriate for convection in stars and planets, where circulation takes place over several gravitational scale heights. For such cases we have to use alternative, more heuristic arguments to derive the relevant criterion for convective instability, known as the *Schwarzschild criterion*, and to quantify the associated heat flux. We shall apply this theory to the solar convection zone.

Finally, in Sec. 18.6 we return to simple buoyancy-driven convection in a stratified fluid to consider *double diffusion*, a quite general type of instability that can arise when the diffusion of two physical quantities (in our case heat and the concentration of salt) render a fluid unstable even though the fluid would be stably stratified if there were only concentration gradients of one of these quantities.

18.2 **18.2 Diffusive Heat Conduction—Cooling a Nuclear Reactor; Thermal Boundary Layers**

So long as the mean free path of heat-carrying particles is small compared to the fluid's inhomogeneity lengthscales (as is almost always the case), and the fractional temperature change in one mean free path is small (as is also almost always true), the

energy flux of heat flow takes the thermal-diffusion form

$$\mathbf{F}_{\text{cond}} = -\kappa \nabla T; \quad (18.1)$$

see Secs. 3.7 and 13.7.4. Here κ is the thermal conductivity.

For a viscous, heat-conducting fluid flowing in an external gravitational field, the most general governing equations are the fundamental thermodynamic potential $u(\rho, s)$; the first law of thermodynamics, Eq. (2) or (3) of Box 13.2; the law of mass conservation [Eq. (13.29) or (13.31)]; the Navier-Stokes equation (13.69); and the law of dissipative entropy production (13.75):

$$u = u(\rho, s), \quad (18.2a)$$

$$\frac{du}{dt} = T \frac{ds}{dt} - P \frac{d(1/\rho)}{dt}, \quad (18.2b)$$

$$\frac{d\rho}{dt} = -\rho \nabla \cdot \mathbf{v}, \quad (18.2c)$$

$$\rho \frac{d\mathbf{v}}{dt} = -\nabla P + \rho \mathbf{g} + \nabla(\zeta \theta) + 2\nabla \cdot (\eta \boldsymbol{\sigma}), \quad (18.2d)$$

$$T \left[\rho \left(\frac{ds}{dt} \right) + \nabla \cdot \left(\frac{-\kappa \nabla T}{T} \right) \right] = \zeta \theta^2 + 2\eta \boldsymbol{\sigma} : \boldsymbol{\sigma} + \frac{\kappa}{T} (\nabla T)^2. \quad (18.2e)$$

These are four scalar equations and one vector equation for four scalar and one vector variables: the density ρ , internal energy per unit mass u , entropy per unit mass s , pressure P , and velocity \mathbf{v} . The thermal conductivity κ and coefficients of shear viscosity ζ and bulk viscosity $\eta = \rho\nu$ are presumed to be functions of ρ and s (or equally well, ρ and T).

This set of equations is far too complicated to solve, except via massive numerical simulations, unless some strong simplifications are imposed. We therefore introduce approximations. Our first approximation (already implicit in the above equations) is that the thermal conductivity κ is constant, as are the coefficients of viscosity. For most real applications this approximation is close to true, and no significant physical effects are missed by assuming it. Our second approximation, which does limit somewhat the type of problem we can address, is that the fluid motions are very slow—slow enough that, not only can the flow be regarded as incompressible ($\theta = \nabla \cdot \mathbf{v} = 0$), but also the squares of the shear $\boldsymbol{\sigma}$ and expansion θ (which are quadratic in the fluid speed) are negligibly small, and we thus can ignore viscous dissipation. These approximations bring the last three of the fluid evolution equations (18.2) into the simplified form

$$\nabla \cdot \mathbf{v} \simeq 0, \quad d\rho/dt \simeq 0, \quad (18.3a)$$

$$\frac{d\mathbf{v}}{dt} = -\frac{\nabla P}{\rho} + \mathbf{g} + \nu \nabla^2 \mathbf{v}, \quad (18.3b)$$

$$\rho T \frac{ds}{dt} = \kappa \nabla^2 T. \quad (18.3c)$$

evolution equations for a viscous, heat-conducting fluid in an external gravitational field

approximations

[Our reasons for using “ \simeq ” in Eqs. (18.3a) become clear in Sec. 18.3, in connection with buoyancy.] Note that Eq. (18.3b) is the standard form of the Navier-Stokes equation for incompressible flows, which we have used extensively in the past several chapters. Equation (18.3c) is an elementary law of energy conservation: the temperature times the rate of increase of entropy density moving with the fluid is equal to minus the divergence of the conductive energy flux, $\mathbf{F}_{\text{heat}} = -\kappa \nabla T$.

We can convert the entropy evolution equation (18.3c) into an evolution equation for temperature by expressing the changes ds/dt of entropy per unit mass in terms of changes dT/dt of temperature. The usual way to do this is to note that $T ds$ (the amount of heat deposited in a unit mass of fluid) is given by cdT , where c is the fluid’s specific heat per unit mass. However, the specific heat depends on what one holds fixed during the energy deposition: the fluid element’s volume or its pressure. As we have assumed that the fluid motions are slow, the fractional pressure fluctuations will be correspondingly small. (This assumption does not preclude significant temperature perturbations, provided they are compensated by density fluctuations of opposite sign.) Therefore, the relevant specific heat for a slowly moving fluid is the one at constant pressure, c_p , and we must write $T ds = c_p dT$.¹ Equation (18.3c) then becomes a linear partial differential equation for the temperature:

temperature diffusion equation

$$\frac{dT}{dt} \equiv \frac{\partial T}{\partial t} + \mathbf{v} \cdot \nabla T = \chi \nabla^2 T, \quad (18.4)$$

where

thermal diffusivity

$$\chi = \kappa / (\rho c_p) \quad (18.5)$$

is known as the *thermal diffusivity*, and we have again taken the easiest route in treating c_p and ρ as constant. When the fluid moves so slowly that the advective term $\mathbf{v} \cdot \nabla T$ is negligible, then Eq. (18.4) shows that the heat simply diffuses through the fluid, with the thermal diffusivity χ being the diffusion coefficient for temperature.

Prandtl number: vorticity diffusion over heat diffusion

The diffusive transport of heat by thermal conduction is similar to the diffusive transport of vorticity by viscous stress [Eq. (14.3)], and the thermal diffusivity χ is the direct analog of the kinematic viscosity ν . This observation motivates us to introduce a new dimensionless number known as the *Prandtl number*, which measures the relative importance of viscosity and heat conduction (in the sense of their relative abilities to diffuse vorticity and heat):

$$\text{Pr} = \frac{\nu}{\chi}. \quad (18.6)$$

1. See, e.g., Turner (1973) for a more formal justification of the use of the specific heat at constant pressure rather than at constant volume.

TABLE 18.1: Order-of-magnitude estimates for kinematic viscosity ν , thermal diffusivity χ , and Prandtl number $Pr = \nu/\chi$ for earth, fire, air, and water

Fluid	ν ($\text{m}^2 \text{s}^{-1}$)	χ ($\text{m}^2 \text{s}^{-1}$)	Pr
Earth's mantle	10^{17}	10^{-6}	10^{23}
Solar interior	10^{-2}	10^2	10^{-4}
Atmosphere	10^{-5}	10^{-5}	1
Ocean	10^{-6}	10^{-7}	10

For gases, both ν and χ are given to order of magnitude by the product of the mean molecular speed and the mean free path, and so Prandtl numbers are typically of order unity. (For air, $Pr \sim 0.7$.) By contrast, in liquid metals the free electrons carry heat very efficiently compared with the transport of momentum (and vorticity) by diffusing ions, and so their Prandtl numbers are small. This is why liquid sodium is used as a coolant in nuclear power reactors. At the other end of the spectrum, water is a relatively poor thermal conductor with $Pr \sim 6$, and Prandtl numbers for oils, which are quite viscous and are poor conductors, measure in the thousands. Other Prandtl numbers are given in Table 18.1.

One might think that, when the Prandtl number is small (so κ is large compared to ν), one should necessarily include heat flow in the fluid equations and pay attention to thermally induced buoyancy (Sec. 18.3). Not so. In some low-Prandtl-number flows the heat conduction is so effective that the fluid becomes essentially isothermal, and buoyancy effects are minimized. Conversely, in some large-Prandtl-number flows the large viscous stress reduces the velocity gradient so that slow, thermally driven circulation takes place, and thermal effects are very important. In general the kinematic viscosity is of direct importance in controlling the transport of momentum, and hence in establishing the velocity field, whereas heat conduction affects the velocity field only indirectly (Sec. 18.3). We must therefore examine each flow on its individual merits.

Another dimensionless number is commonly introduced when discussing thermal effects: the *Péclet number*. It is defined, by analogy with the Reynolds number, as

$$Pe = \frac{LV}{\chi}, \quad (18.7)$$

where L is a characteristic length scale of the flow, and V is a characteristic speed. The Péclet number measures the relative importance of advection and heat conduction.

typical Prandtl numbers

Péclet number: heat advection over heat conduction

Exercise 18.1 *Problem: Fukushima-Daiichi Power Plant*

After the earthquake that triggered the catastrophic failure of the Fukushima-Daiichi nuclear power plant on March 11, 2011, reactor operation was immediately stopped. However, the subsequent tsunami disabled the cooling system needed to remove the decay heat, which was still being generated. This system failure led to a meltdown of three reactors and escape of radioactive material.

The *boiling water reactors* that were in use each generated ~ 500 MW of heat, under normal operation, and the decay-heat production amounted to ~ 30 MW. Suppose that this decay heat was being carried off equally by a large number of cylindrical pipes of length $L \sim 10$ m and inner radius $R \sim 10$ mm, taking it from the reactor core, where the water temperature was $T_0 \sim 550$ K and the pressure was $P_0 \sim 10^7$ N m $^{-2}$, to a heat exchanger. Suppose, initially, that the flow was laminar, so that the fluid velocity had the parabolic Poiseuille profile:

$$v = 2\bar{v} \left(1 - \frac{\varpi^2}{R^2} \right) \quad (18.8)$$

[Eq. (13.80) and associated discussion]. Here, ϖ is the cylindrical radial coordinate measured from the axis of the pipe, and \bar{v} is the mean speed along the pipe. As the goal was to carry the heat away efficiently during normal operation, the pipe was thermally well insulated, so its inner wall was at nearly the same temperature as the core of the fluid (at $\varpi = 0$). The total temperature drop ΔT down the length L was then $\Delta T \ll T_0$, and the longitudinal temperature gradient was constant, so the temperature distribution in the pipe had the form:

$$T = T_0 - \Delta T \frac{z}{L} + f(\varpi). \quad (18.9)$$

(a) Use Eq. (18.4) to show that

$$f = \frac{\bar{v} R^2 \Delta T}{2\chi L} \left[\frac{3}{4} - \frac{\varpi^2}{R^2} + \frac{1}{4} \frac{\varpi^4}{R^4} \right]. \quad (18.10)$$

(b) Derive an expression for the conductive heat flux through the walls of the pipe and show that the ratio of the heat escaping through the walls to that advected by the fluid was $\Delta T/T$. (Ignore the influence of the temperature gradient on the velocity field, and treat the thermal diffusivity and specific heat as constant throughout the flow.)

(c) The flow would only remain laminar so long as the Reynolds number was $\text{Re} \lesssim \text{Re}_{\text{crit}} \sim 2,000$, the critical value for transition to turbulence. Show that the maximum power that could be carried by a laminar flow was:

$$\dot{Q}_{\text{max}} \sim \frac{\pi}{2} \rho R v \text{Re}_{\text{crit}} c_p T_0 \sim \frac{\pi}{4} \left(\frac{\rho P_0 R^5 \text{Re}_{\text{crit}}}{L} \right)^{1/2} c_p T_0. \quad (18.11)$$

Estimate the mean velocity \bar{v} , the temperature drop ΔT , and the number of cooling pipes needed in normal operation, when the flow was about to transition to turbulence. Assume that $\chi = 10^{-7} \text{ m}^2 \text{ s}^{-1}$, $c_p = 6 \text{ kJ kg}^{-1} \text{ K}^{-1}$, and $\rho\nu = \eta = 1 \times 10^{-4} \text{ Pa s}^{-1}$.

- (d) Describe qualitatively what would happen if the flow became turbulent (as it did under normal operation).

Exercise 18.2 *Problem: Thermal Boundary Layers*

In Sec. 14.4, we introduced the notion of a laminar boundary layer by analyzing flow past a thin plate. Now suppose that this same plate is maintained at a different temperature from the free flow. A thermal boundary layer will form, in addition to the viscous boundary layer, which we presume to be laminar. These two boundary layers both extend outward from the wall but (usually) have different thicknesses.

- (a) Explain why their relative thicknesses depend on the Prandtl number.
 (b) Using Eq. (18.4), show that in order of magnitude the thickness δ_T of the thermal boundary layer is given by

$$v(\delta_T)\delta_T^2 = \ell\chi,$$

where $v(\delta_T)$ is the fluid velocity parallel to the plate at the outer edge of the thermal boundary layer, and ℓ is the distance downstream from the leading edge.

- (c) Let V be the free-stream fluid velocity and ΔT be the temperature difference between the plate and the body of the flow. Estimate δ_T in the limits of large and small Prandtl numbers.
 (d) What will be the boundary layer's temperature profile when the Prandtl number is exactly unity? [Hint: Seek a self-similar solution to the relevant equations. For the solution, see Lautrup (2005, Sec. 31.1).]

18.3 Boussinesq Approximation

18.3

When heat fluxes are sufficiently small, we can use Eq. (18.4) to solve for the temperature distribution in a given velocity field, ignoring the feedback of thermal effects on the velocity. However, if we imagine increasing the flow's temperature differences, so the heat fluxes also increase, at some point thermal feedback effects begin to influence the velocity significantly. Typically, the first feedback effect to occur is *buoyancy*, the tendency of the hotter (and hence lower-density) fluid to rise in a gravitational field and the colder (and hence denser) fluid to descend.² In this section, we describe the

2. This effect is put to good use in a domestic "gravity-fed" warm-air circulation system. The furnace generally resides in the basement, not the attic!

effects of buoyancy as simply as possible. The minimal approach, which is adequate surprisingly often, is called the *Boussinesq approximation*. Leading to Eqs. (18.12), (18.18), and (18.19), it can be used to describe many heat-driven laboratory flows and atmospheric flows, and some geophysical flows.

The types of flows for which the Boussinesq approximation is appropriate are those in which the fractional density changes are small ($|\Delta\rho| \ll \rho$). By contrast, the velocity can undergo large changes, though it remains constrained by the incompressibility relation (18.3a):

$$\nabla \cdot \mathbf{v} = 0 \quad \text{Boussinesq (1).} \quad (18.12)$$

One might think that this constraint implies constant density moving with a fluid element, since mass conservation requires $d\rho/dt = -\rho \nabla \cdot \mathbf{v}$. However, thermal expansion causes small density changes, with tiny corresponding violations of Eq. (18.12); this explains the “ \simeq ” that we used in Eqs. (18.3a). The key point is that, for these types of flows, the density is controlled to high accuracy by thermal expansion, and the velocity field is divergence free to high accuracy.

When discussing thermal expansion, it is convenient to introduce a *reference density* ρ_0 and *reference temperature* T_0 , equal to some mean of the density and temperature in the region of fluid that one is studying. We shall denote by

$$\tau \equiv T - T_0 \quad (18.13)$$

the perturbation of the temperature away from its reference value. The thermally perturbed density can then be written as

$$\rho = \rho_0(1 - \alpha\tau), \quad (18.14)$$

where α is the thermal expansion coefficient for volume³ [evaluated at constant pressure for the same reason as the specific heat was chosen as at constant pressure in the paragraph following Eq. (18.3c)]:

$$\alpha = - \left(\frac{\partial \ln \rho}{\partial T} \right)_P. \quad (18.15)$$

Equation (18.14) enables us to eliminate density perturbations as an explicit variable and replace them by temperature perturbations.

Now turn to the Navier-Stokes equation (18.3b) in a uniform external gravitational field. We expand the pressure-gradient term as

$$-\frac{\nabla P}{\rho} \simeq -\frac{\nabla P}{\rho_0}(1 + \alpha\tau) = \frac{\nabla P}{\rho_0} - \alpha\tau \mathbf{g}, \quad (18.16)$$

3. Note that α is three times larger than the thermal expansion coefficient for the linear dimensions of the fluid.

where we have used hydrostatic equilibrium for the unperturbed flow. As in our analysis of rotating flows [Eq. (14.55)], we introduce an *effective pressure* designed to compensate for the first-order effects of the uniform gravitational field:

$$P' = P + \rho_0 \Phi = P - \rho_0 \mathbf{g} \cdot \mathbf{x}. \quad (18.17)$$

(Notice that P' measures the amount the pressure differs from the value it would have in supporting a hydrostatic atmosphere of the fluid at the reference density.) The Navier-Stokes equation (18.3b) then becomes

$$\frac{d\mathbf{v}}{dt} = -\frac{\nabla P'}{\rho_0} - \alpha \tau \mathbf{g} + \nu \nabla^2 \mathbf{v} \quad \text{Boussinesq (2)}, \quad (18.18)$$

dropping the small term $O(\alpha P')$. In words, a fluid element accelerates in response to a buoyancy force [the sum of the first and second terms on the right-hand side of Eq. (18.18)] and a viscous force.

To solve this equation, we must be able to solve for the temperature perturbation τ . This evolves according to the standard equation of heat diffusion [Eq. (18.4)]:

$$\frac{d\tau}{dt} = \chi \nabla^2 \tau \quad \text{Boussinesq (3)}. \quad (18.19)$$

Equations (18.12), (18.18), and (18.19) are the equations of fluid flow in the Boussinesq approximation; they control the coupled evolution of the velocity \mathbf{v} and the temperature perturbation τ . We now use them to discuss free convection in a laboratory apparatus.

18.4 Rayleigh-Bénard Convection

In a relatively simple laboratory experiment to demonstrate convection, a fluid is confined between two rigid plates a distance d apart, each maintained at a fixed temperature, with the upper plate cooler than the lower by ΔT . When ΔT is small, viscous stresses, together with the no-slip boundary conditions at the plates, inhibit circulation; so, despite the upward buoyancy force on the hotter, less-dense fluid near the bottom plate, the fluid remains stably at rest with heat being conducted diffusively upward. If the plates' temperature difference ΔT is gradually increased, the buoyancy becomes gradually stronger. At some critical ΔT it will overcome the restraining viscous forces, and the fluid starts to circulate (convect) between the two plates. Our goal is to determine the critical temperature difference ΔT_{crit} for the onset of this *Rayleigh-Bénard* convection.

We now make some physical arguments to simplify the calculation of ΔT_{crit} . From our experience with earlier instability calculations, especially those involving elastic bifurcations (Secs. 11.6.1 and 12.3.5), we anticipate that for $\Delta T < \Delta T_{\text{crit}}$ the response of the equilibrium to small perturbations will be oscillatory (i.e., will have positive squared eigenfrequency ω^2), while for $\Delta T > \Delta T_{\text{crit}}$, perturbations will grow

Boussinesq equations

18.4

Rayleigh-Bénard convection

FIGURE 18.1 Rayleigh-Bénard convection. A fluid is confined between two horizontal surfaces separated by a vertical distance d . When the temperature difference between the two plates ΔT is increased sufficiently, the fluid starts to convect heat vertically. The reference effective pressure P'_0 and reference temperature T_0 are the values of P' and T measured at the midplane $z = 0$.

exponentially (i.e., will have negative ω^2). Correspondingly, at $\Delta T = \Delta T_{\text{crit}}$, ω^2 for some mode will be zero. This zero-frequency mode marks the bifurcation of equilibria from one with no fluid motions to one with slow, convective motions. We search for ΔT_{crit} by searching for a solution to the Boussinesq equations (18.12), (18.18), and (18.19) that represents this zero-frequency mode. In those equations, we choose for the reference temperature T_0 , density ρ_0 , and effective pressure P_0 the values at the midplane between the plates, $z = 0$ (cf. Fig. 18.1).

The unperturbed equilibrium, when $\Delta T = \Delta T_{\text{crit}}$, is a solution of the Boussinesq equations (18.12), (18.18), and (18.19) with vanishing velocity, a time-independent vertical temperature gradient $dT/dz = -\Delta T/d$, and a compensating, time-independent, vertical pressure gradient:

$$\mathbf{v} = 0, \quad \tau = T - T_0 = -\frac{\Delta T}{d}z, \quad P' = P'_0 + g\rho_0\alpha \frac{\Delta T}{d} \frac{z^2}{2}. \quad (18.20)$$

When the zero-frequency mode is present, the velocity \mathbf{v} is nonzero, and the temperature and effective pressure have additional perturbations $\delta\tau$ and $\delta P'$:

$$\mathbf{v} \neq 0, \quad \tau = T - T_0 = -\frac{\Delta T}{d}z + \delta\tau, \quad P' = P'_0 + g\rho_0\alpha \frac{\Delta T}{d} \frac{z^2}{2} + \delta P'. \quad (18.21)$$

The perturbations \mathbf{v} , $\delta\tau$, and $\delta P'$ are governed by the Boussinesq equations and the boundary conditions at the plates ($z = \pm d/2$): $\mathbf{v} = 0$ (no-slip) and $\delta\tau = 0$. We manipulate these equations and boundary conditions in such a way as to get a partial differential equation for the scalar temperature perturbation $\delta\tau$ by itself, decoupled from the velocity and the pressure perturbation.

First consider the result of inserting expressions (18.21) into the Boussinesq-approximated Navier-Stokes equation (18.18). Because the perturbation mode has

zero frequency, $\partial \mathbf{v} / \partial t$ vanishes; and because \mathbf{v} is extremely small, we can neglect the quadratic advective term $\mathbf{v} \cdot \nabla \mathbf{v}$, thereby bringing Eq. (18.18) into the form:

$$\frac{\nabla \delta P'}{\rho_0} = \nu \nabla^2 \mathbf{v} - \mathbf{g} \alpha \delta \tau. \quad (18.22)$$

We want to eliminate $\delta P'$ from this equation. The other Boussinesq equations are of no help for this, since $\delta P'$ is absent from them. One might be tempted to eliminate δP using the equation of state $P = P(\rho, T)$; but in the present analysis our Boussinesq approximation insists that the only significant changes of density are those due to thermal expansion (i.e., it neglects the influence of pressure on density), so the equation of state cannot help us. Lacking any other way to eliminate $\delta P'$, we employ a common trick: we take the curl of Eq. (18.22). As the curl of a gradient vanishes, $\delta P'$ drops out. We then take the curl one more time and use $\nabla \cdot \mathbf{v} = 0$ to obtain

$$\nu \nabla^2 (\nabla^2 \mathbf{v}) = \alpha \mathbf{g} \nabla^2 \delta \tau - \alpha (\mathbf{g} \cdot \nabla) \nabla \delta \tau. \quad (18.23)$$

Next turn to the Boussinesq version of the equation of heat transport [Eq. (18.19)]. Inserting into it Eqs. (18.21) for τ and \mathbf{v} , setting $\partial \delta \tau / \partial t$ to zero (because our perturbation has zero frequency), linearizing in the perturbation, and using $\mathbf{g} = -g \mathbf{e}_z$, we obtain

$$\frac{v_z \Delta T}{d} = -\chi \nabla^2 \delta \tau. \quad (18.24)$$

This is an equation for the vertical velocity v_z in terms of the temperature perturbation $\delta \tau$. By inserting this v_z into the z component of Eq. (18.23), we achieve our goal of a scalar equation for $\delta \tau$ alone:

$$\boxed{\nu \chi \nabla^2 \nabla^2 \nabla^2 \delta \tau = \frac{\alpha g \Delta T}{d} \left(\frac{\partial^2 \delta \tau}{\partial x^2} + \frac{\partial^2 \delta \tau}{\partial y^2} \right)}. \quad (18.25)$$

linearized perturbation equation for Rayleigh-Bénard convection

This is a sixth-order differential equation, even more formidable than the fourth-order equations that arise in the elasticity calculations of Chaps. 11 and 12. We now see how prudent it was to make simplifying assumptions at the outset!

The differential equation (18.25) is, however, linear, so we can seek solutions using separation of variables. As the equilibrium is unbounded horizontally, we look for a single horizontal Fourier component with some wave number k ; that is, we seek a solution of the form

$$\delta \tau \propto \exp(ikx) f(z), \quad (18.26)$$

where $f(z)$ is some unknown function. Such a $\delta \tau$ will be accompanied by motions \mathbf{v} in the x and z directions (i.e., $v_y = 0$) that also have the form $v_j \propto \exp(ikx) f_j(z)$ for some other functions $f_j(z)$.

The ansatz (18.26) converts the partial differential equation (18.25) into the single ordinary differential equation

$$\left(\frac{d^2}{dz^2} - k^2\right)^3 f + \frac{\text{Ra} k^2 f}{d^4} = 0, \quad (18.27)$$

where we have introduced yet another dimensionless number

$$\text{Ra} = \frac{\alpha g \Delta T d^3}{\nu \chi} \quad (18.28)$$

Rayleigh number:
buoyancy force over
viscous force

called the *Rayleigh number*. By virtue of relation (18.24) between v_z and $\delta\tau$, the Rayleigh number is a measure of the ratio of the strength of the buoyancy term $-\alpha\delta\tau\mathbf{g}$ to the viscous term $\nu\nabla^2\mathbf{v}$ in the Boussinesq version [Eq. (18.18)] of the Navier-Stokes equation:

$$\text{Ra} \sim \frac{\text{buoyancy force}}{\text{viscous force}}. \quad (18.29)$$

The general solution of Eq. (18.27) is an arbitrary, linear combination of three sine functions and three cosine functions:

$$f = \sum_{n=1}^3 A_n \cos(\mu_n kz) + B_n \sin(\mu_n kz), \quad (18.30)$$

where the dimensionless numbers μ_n are given by

$$\mu_n = \left[\left(\frac{\text{Ra}}{k^4 d^4} \right)^{1/3} e^{2\pi ni/3} - 1 \right]^{1/2}; \quad n = 1, 2, 3, \quad (18.31)$$

which involves the three cube roots of unity, $e^{2\pi ni/3}$. The values of five of the coefficients A_n , B_n are fixed in terms of the sixth (an overall arbitrary amplitude) by five boundary conditions at the bounding plates. A sixth boundary condition then determines the critical temperature difference ΔT_{crit} (or equivalently, the critical Rayleigh number Ra_{crit}) at which convection sets in.

boundary conditions
for Rayleigh-Bénard
convection

The six boundary conditions are paired as follows:

1. The requirement that the fluid temperature be the same as the plate temperature at each plate, so $\delta\tau = 0$ at $z = \pm d/2$.
2. The no-slip boundary condition $v_z = 0$ at each plate, which by virtue of Eq. (18.24) and $\delta\tau = 0$ at the plates, translates to $\delta\tau_{,zz} = 0$ at $z = \pm d/2$ (where the indices after the comma are partial derivatives).
3. The no-slip boundary condition $v_x = 0$, which by virtue of incompressibility $\nabla \cdot \mathbf{v} = 0$ implies $v_{z,z} = 0$ at the plates, which in turn by Eq. (18.24) implies $\delta\tau_{,zzz} + \delta\tau_{,xxz} = 0$ at $z = \pm d/2$.

It is straightforward but computationally complex to impose these six boundary conditions and from them deduce the critical Rayleigh number for onset of convection (Pellew and Southwell, 1940). Rather than present the nasty details, we switch to a toy problem in which the boundary conditions are adjusted to give a simpler solution but one with the same qualitative features as for the real problem. Specifically, we replace the no-slip condition (3) ($v_x = 0$ at the plates) by a condition of no shear:

$$3'. v_{x,z} = 0 \text{ at the plates. By virtue of incompressibility } \nabla \cdot \mathbf{v} = 0, \text{ the } x \text{ derivative of this condition translates to } v_{z,zz} = 0, \text{ which by Eq. (18.24) becomes } \delta\tau_{,zzxx} + \delta\tau_{,zzzz} = 0.$$

To recapitulate, we seek a solution of the form (18.30) and (18.31) that satisfies the boundary conditions (1), (2), and (3').

The terms in Eq. (18.30) with $n = 1, 2$ always have complex arguments and thus always have z dependences that are products of hyperbolic and trigonometric functions with real arguments. For $n = 3$ and a large enough Rayleigh number, μ_3 is positive, and the solutions are pure sines and cosines. Let us just consider the $n = 3$ terms alone, in this regime, and impose boundary condition (1): $\delta\tau = 0$ at the plates. The cosine term by itself,

$$\delta\tau = \text{const} \times \cos(\mu_3 kz) e^{ikx}, \quad (18.32)$$

satisfies this boundary condition, if we set

$$\frac{\mu_3 kd}{2} \equiv \left[\left(\frac{\text{Ra}}{k^4 d^4} \right)^{1/3} - 1 \right]^{1/2} \frac{kd}{2} = \left(m + \frac{1}{2} \right) \pi, \quad (18.33)$$

where m is an integer. It is straightforward to show, remarkably, that Eqs. (18.32) and (18.33) also satisfy boundary conditions (2) and (3'), so they solve the toy version of our problem.

As ΔT is gradually increased from zero, the Rayleigh number gradually grows, passing through the sequence of values given by Eq. (18.33) with $m = 0, 1, 2, \dots$ (for any chosen k). At each of these values there is a zero-frequency, circulatory mode of fluid motion with horizontal wave number k , which is passing from stability to instability. The first of these, $m = 0$, represents the onset of circulation for the chosen k , and the Rayleigh number at this onset [Eq. (18.33) with $m = 0$] is

$$\text{Ra} = \frac{(k^2 d^2 + \pi^2)^3}{k^2 d^2}. \quad (18.34)$$

This $\text{Ra}(k)$ relation is plotted as a thick curve in Fig. 18.2.

Notice in Fig. 18.2 that there is a critical Rayleigh number Ra_{crit} below which all modes are stable, independent of their wave numbers, and above which modes in some range $k_{\text{min}} < k < k_{\text{max}}$ are unstable. From Eq. (18.34) we deduce that for our toy problem, $\text{Ra}_{\text{crit}} = 27\pi^4/4 \simeq 658$.

FIGURE 18.2 Horizontal wave number k of the first mode to go unstable, as a function of Rayleigh number. Along the solid curve the mode has zero frequency; to the left of the curve it is stable, to the right it is unstable. Ra_{crit} is the minimum Rayleigh number for convective instability.

When one imposes the correct boundary conditions (1), (2), and (3) [instead of our toy choice (1), (2), and (3')] and works through the nasty details of the computation, one obtains a relation for $Ra(k)$ that looks qualitatively the same as Fig. 18.2. One deduces that convection should set in at $Ra_{\text{crit}} = 1,708$, which agrees reasonably well with experiment. One can carry out the same computation with the fluid's upper surface free to move (e.g., due to placing air rather than a solid plate at $z = d/2$). Such a computation predicts that convection begins at $Ra_{\text{crit}} \simeq 1,100$, though in practice surface tension is usually important, and its effect must be included.

One feature of these critical Rayleigh numbers is very striking. Because the Rayleigh number is an estimate of the ratio of buoyancy forces to viscous forces [Eq. (18.29)], an order-of-magnitude analysis suggests that convection should set in at $Ra \sim 1$ —which is wrong by three orders of magnitude! This provides a vivid reminder that order-of-magnitude estimates can be quite inaccurate. In this case, the main reason for the discrepancy is that the convective onset is governed by a sixth-order differential equation (18.25) and thus is highly sensitive to the lengthscale d used in the order-of-magnitude analysis. If we choose d/π rather than d as the length scale, then an order-of-magnitude estimate could give $Ra \sim \pi^6 \sim 1,000$, a much more satisfactory value.

Once convection has set in, the unstable modes grow until viscosity and nonlinearities stabilize them, at which point they carry far more heat upward between the plates than does conduction. The convection's velocity pattern depends in practice on the manner in which the heat is applied, the temperature dependence of the viscosity, and the fluid's boundaries. For a limited range of Rayleigh numbers near Ra_{crit} , it is possible to excite a hexagonal pattern of *convection cells* as is largely but not entirely the case in Fig. 18.3; however other patterns can also be excited.

critical Rayleigh number for onset of Rayleigh-Bénard convection

how order-of-magnitude analyses can fail

patterns of convection cells in Rayleigh-Bénard convection

FIGURE 18.3 Convection cells in Rayleigh-Bénard convection. The fluid, which is visualized using aluminum powder, rises at the center of each cell and falls around its edges. From Maroto, Perez-Munuzuri, and Romero-Cano (2007).

Drazin and Reid (2004) suggest a kitchen experiment for observing convection cells. Place a 2-mm layer of corn or canola oil on the bottom of a skillet, and sprinkle cocoa or Ovaltine or other powder over it. Heat the skillet bottom gently and uniformly. The motion of the powder particles will reveal the convection cells, with upwelling at the cell centers and surface powder collecting and falling at the edges.

kitchen experiment

In Rayleigh-Bénard convection experiments, as the Rayleigh number is increased beyond the onset of convection, one or another sequences of equilibrium bifurcations leads to weak turbulence (see Secs. 15.6.2 and 15.6.3). When the Rayleigh number becomes very large, the convection becomes strongly turbulent.

bifurcation of Rayleigh-Bénard equilibria leading to convective turbulence

Free convection, like that in these laboratory experiments, also occurs in meteorological and geophysical flows. For example, for air in a room, the relevant parameter values are $\alpha = 1/T \sim 0.003 \text{ K}^{-1}$ (Charles' Law), and $\nu \sim \chi \sim 10^{-5} \text{ m}^2 \text{ s}^{-1}$, so the Rayleigh number is $\text{Ra} \sim 3 \times 10^8 (\Delta T/1 \text{ K})(d/1 \text{ m})^3$. Convection in a room thus occurs extremely readily, even for small temperature differences. In fact, so many modes of convective motion can be excited that heat-driven air flow is invariably turbulent. It is therefore common in everyday situations to describe heat transport using a phenomenological turbulent thermal conductivity (Sec. 15.4.2; White, 2008, Sec. 6.10.1).

A second example, convection in Earth's mantle, is described in Box 18.2.

BOX 18.2. MANTLE CONVECTION AND CONTINENTAL DRIFT

As is now well known, the continents drift over the surface of the globe on a timescale of roughly 100 million years. Despite the clear geographical evidence that the continents fit together, some geophysicists were, for a long while, skeptical that this occurred, because they were unable to identify the forces responsible for overcoming the visco-elastic resilience of the crust. It is now known that these motions are in fact slow convective circulation of the mantle driven by internally generated heat from the radioactive decay of unstable isotopes, principally uranium, thorium, and potassium.

When the heat is generated in the convective layer (which has radial thickness d), rather than passively transported from below, we must modify our definition of the Rayleigh number. Let the heat generated per unit mass per unit time be Q . In the analog of our laboratory analysis, where the fluid is assumed marginally unstable to convective motions, this Q will generate a heat flux $\sim \rho Q d$, which must be carried diffusively. Equating this flux to $\kappa \Delta T / d$, we can solve for the temperature difference ΔT between the lower and upper edges of the convective mantle: $\Delta T \sim \rho Q d^2 / \kappa$. Inserting this ΔT into Eq. (18.28), we obtain a modified expression for the Rayleigh number

$$\text{Ra}' = \frac{\alpha \rho g Q d^5}{\kappa \chi \nu}. \quad (1)$$

Let us now estimate the value of Ra' for Earth's mantle. The mantle's kinematic viscosity can be measured by post-glacial rebound studies (cf. Ex. 14.13) to be $\nu \sim 10^{17} \text{ m}^2 \text{ s}^{-1}$. We can use the rate of attenuation of diurnal and annual temperature variation with depth in surface rock to estimate a thermal diffusivity $\chi \sim 10^{-6} \text{ m}^2 \text{ s}^{-1}$. Direct experiment furnishes an expansion coefficient, $\alpha \sim 3 \times 10^{-5} \text{ K}^{-1}$ and thermal conductivity $\kappa \sim 4 \text{ W m}^{-1} \text{ K}^{-1}$. The thickness of the upper mantle is $d \sim 700 \text{ km}$, and the rock density is $\rho \sim 4,000 \text{ kg m}^{-3}$. The rate of heat generation can be estimated both by chemical analysis and direct measurement at Earth's surface and turns out to be $Q \sim 10^{-11} \text{ W kg}^{-1}$. Combining these quantities, we obtain an estimated Rayleigh number $\text{Ra}' \sim 10^7$, well in excess of the critical value for convection under free slip conditions, which evaluates to $\text{Ra}'_{\text{crit}} = 868$ (Turcotte and Schubert, 1982). For this reason, it is now believed that continental drift is driven primarily by mantle convection.

Exercise 18.3 *Problem: Critical Rayleigh Number*

Use the Rayleigh criterion to estimate the temperature difference that would have to be maintained for 2 mm of corn/canola oil, or water, or mercury in a skillet to start convecting. Look up the relevant physical properties and comment on your answers. Do not perform this experiment with mercury.

Exercise 18.4 *Problem: Width of a Thermal Plume*

Consider a knife on its back, so its sharp edge points in the upward, z direction. The edge (idealized as extending infinitely far in the y direction) is hot, and by heating adjacent fluid, it creates a rising thermal plume. Introduce a temperature deficit $\Delta T(z)$ that measures the typical difference in temperature between the plume and the surrounding, ambient fluid at height z above the knife edge, and let $\delta_p(z)$ be the width of the plume at height z .

- (a) Show that energy conservation implies the constancy of $\delta_p \Delta T \bar{v}_z$, where $\bar{v}_z(z)$ is the plume's mean vertical speed at height z .
- (b) Make an estimate of the buoyancy acceleration, and use it to estimate \bar{v}_z .
- (c) Use Eq. (18.19) to relate the width of the plume to the speed. Hence, show that the width of the plume scales as $\delta_p \propto z^{2/5}$ and the temperature deficit as $\Delta T \propto z^{-3/5}$.
- (d) Repeat this exercise for a 3-dimensional plume above a hot spot.

18.5 Convection in Stars

18.5

The Sun and other stars generate heat in their interiors by nuclear reactions. In most stars the internal energy is predominantly in the form of hot hydrogen and helium ions and their electrons, while the thermal conductivity is due primarily to diffusing photons (Sec. 3.7.1), which have much longer mean free paths than the ions and electrons. When the photon mean free path becomes small due to high opacity (as happens in the outer 30% of the Sun; Fig. 18.4), the thermal conductivity goes down, so to transport the heat from nuclear burning, the star develops an increasingly steep

FIGURE 18.4 A convection zone occupies the outer 30% of a solar-type star.

temperature gradient. The star may then become convectively unstable and transport its energy far more efficiently by circulating its hot gas than it could have done by photon diffusion. Describing this convection is a key step in understanding the interiors of the Sun and other stars.

A heuristic argument provides the basis for a surprisingly simple description of this convection. As a foundation for our argument, let us identify the relevant physics:

1. The pressure in stars varies through many orders of magnitude (a factor $\sim 10^{12}$ for the Sun). Therefore, we cannot use the Boussinesq approximation; instead, as a fluid element rises or descends, we must allow for its density to change in response to large changes of the surrounding pressure.
2. The convection involves circulatory motions on such large scales that the attendant shears are small, and viscosity is thus unimportant.
3. Because the convection is driven by the ineffectiveness of conduction, we can idealize each fluid element as retaining its heat as it moves, so the flow is adiabatic.
4. The convection is usually well below sonic, as subsonic motions are easily sufficient to transport the nuclear-generated heat, except very close to the solar surface.

heuristic analysis of the onset of convection in stars

Our heuristic argument, then, focuses on convecting fluid blobs that move through the star's interior very subsonically, adiabatically, and without viscosity. As the motion is subsonic, each blob remains in pressure equilibrium with its surroundings. Now, suppose we make a virtual interchange between two blobs at different heights (Fig. 18.5). The blob that rises (blob B in the figure) experiences a decreased pressure and thus expands, so its density diminishes. If its density after rising is lower than that of its surroundings, then it is buoyant and continues to rise. Conversely, if the raised blob is denser than its surroundings, then it will sink back to its original location. Therefore, a criterion for convective instability is that the raised blob has lower density than its surroundings. Since the blob and its surroundings have the same pressure, and since the larger is the entropy s per unit mass of gas, the lower is its density (there being more phase space available to its particles), the fluid is convectively unstable if the raised blob has a higher entropy than its surroundings. Now, the blob's motion was adiabatic, so its entropy per unit mass s is the same after it rises as before. Therefore, the fluid is convectively unstable if the entropy per unit mass s at the location where the blob began (lower in the star) is greater than that at the location to which it rose (higher in the star); that is, *the star is convectively unstable if its entropy per unit mass decreases outward: $ds/dr < 0$* . For small blobs, this instability will be counteracted by both viscosity and heat conduction. But for large blobs, viscosity and conduction are ineffective, and the convection proceeds.

When building stellar models, astrophysicists find it convenient to determine whether a region of a model is convectively unstable by computing what its struc-

FIGURE 18.5 Convectively unstable interchange of two blobs in a star whose entropy per unit mass increases downward. Blob B rises to the former position of blob A and expands adiabatically to match the surrounding pressure. The entropy per unit mass of the blob is higher than that of the surrounding gas, and so the blob has a lower density. It will therefore be buoyant and continue to rise. Similarly, blob A will continue to sink.

ture would be without convection (i.e., with all its heat carried radiatively). That computation gives some temperature gradient dT/dr . If this computed dT/dr is *superadiabatic*, that is, if

$$-\frac{d \ln T}{d \ln r} > \left(\frac{\partial \ln T}{\partial \ln P} \right)_s \left(-\frac{d \ln P}{d \ln r} \right) \equiv - \left(\frac{d \ln T}{d \ln r} \right)_s, \quad (18.35)$$

then the entropy s decreases outward, and the star is convectively unstable. This is known as the *Schwarzschild criterion for convection*, since it was formulated by the same Karl Schwarzschild who discovered the Schwarzschild solution to Einstein's equations (which describes a nonrotating black hole; Chap. 26).

In practice, if the star is convective, then the convection is usually so efficient at transporting heat that the actual temperature gradient is only slightly superadiabatic, that is, the entropy s is nearly independent of radius—it decreases outward only very slightly. (Of course, the entropy can increase significantly outward in a convectively stable zone, where radiative diffusion is adequate to transport heat.)

We can demonstrate the efficiency of convection by estimating the convective heat flux when the temperature gradient is slightly superadiabatic, that is, when $\Delta|\nabla T| \equiv |(dT/dr)| - |(dT/dr)_s|$ is slightly positive. As a tool in our estimate, we introduce the concept of the *mixing length*, denoted by l —the typical distance a blob travels before breaking up. As the blob is in pressure equilibrium, we can estimate its fractional density difference from its surroundings by $\Delta\rho/\rho \sim \Delta T/T \sim \Delta|\nabla T|l/T$. Invoking Archimedes' law, we estimate the blob's acceleration to be $\sim g\Delta\rho/\rho \sim g\Delta|\nabla T|l/T$ (where g is the local acceleration of gravity); hence the average speed with which a

Schwarzschild criterion for convection in stars

actual temperature gradient in convective region of a star

mixing length

blob rises or sinks is $\bar{v} \sim (g\Delta|\nabla T|/T)^{1/2}l$. The convective heat flux is then given by

estimate of convective heat flux

$$\begin{aligned} F_{\text{conv}} &\sim c_p \rho \bar{v} l \Delta|\nabla T| \\ &\sim c_p \rho (g/T)^{1/2} (\Delta|\nabla T|)^{3/2} l^2. \end{aligned} \quad (18.36)$$

estimate of amount by which temperature gradient exceeds adiabatic in convective region

We can bring this expression into a more useful form, accurate to within factors of order unity, by (i) setting the mixing length equal to the pressure scale height $l \sim H = |dr/d \ln P|$ (as is usually the case in the outer parts of a star); (ii) setting $c_p \sim h/T$, where h is the enthalpy per unit mass [cf. the first law of thermodynamics, Eq. (3) of Box 13.2]; (iii) setting $g = -(P/\rho)d \ln P/dr \sim C^2|d \ln P/dr|$ [cf. the equation of hydrostatic equilibrium (13.13) and Eq. (16.48) for the speed of sound C]; and (iv) setting $|\nabla T| \equiv |dT/dr| \sim T|d \ln P/dr|$. The resulting expression for F_{conv} can then be inverted to give

$$\frac{|\Delta \nabla T|}{|\nabla T|} \sim \left(\frac{F_{\text{conv}}}{h\rho C} \right)^{2/3} \sim \left(\frac{F_{\text{conv}}}{\frac{5}{2}P\sqrt{k_B T/m_p}} \right)^{2/3}. \quad (18.37)$$

Here the last expression is obtained from the fact that the gas is fully ionized, so its enthalpy is $h = \frac{5}{2}P/\rho$, and its speed of sound is about the thermal speed of its protons (the most numerous massive particle), $C \sim \sqrt{k_B T/m_p}$ (with k_B Boltzmann's constant and m_p the proton rest mass).

solar convection zone

It is informative to apply this estimate to the convection zone of the Sun (the outer $\sim 30\%$ of its radius; Fig. 18.4). The luminosity of the Sun is $\sim 4 \times 10^{26}$ W, and its radius is 7×10^5 km, so its convective energy flux is $F_{\text{conv}} \sim 10^8$ W m $^{-2}$. First consider the convection zone's base. The pressure there is $P \sim 1$ TPa, and the temperature is $T \sim 10^6$ K, so Eq. (18.37) predicts $|\Delta \nabla T|/|\nabla T| \sim 3 \times 10^{-7}$, so the temperature gradient at the base of the convection zone need only be superadiabatic by a few parts in 10 million to carry the solar energy flux.

By contrast, at the top of the convection zone (which is nearly at the solar surface), the gas pressure is only ~ 10 kPa, and the sound speed is ~ 10 km s $^{-1}$, so $h\rho C \sim 10^8$ W m $^{-2}$, and $|\Delta \nabla T|/|\nabla T| \sim 1$; that is, the temperature gradient must depart significantly from the adiabatic gradient to carry the heat. Moreover, the convective elements, in their struggle to carry the heat, move with a significant fraction of the sound speed, so it is no longer true that they are in pressure equilibrium with their surroundings. A more sophisticated theory of convection is therefore necessary near the solar surface.

Convection is important in some other types of stars. It is the primary means of heat transport in the cores of stars with high mass and high luminosity, and throughout very young stars before they start to burn their hydrogen in nuclear reactions.

Exercise 18.5 *Problem: Radiative Transport*

The density and temperature in the deep interior of the Sun are roughly 0.1 kg m^{-3} and $1.5 \times 10^7 \text{ K}$.

- Estimate the central gas pressure and radiation pressure and their ratio.
- The mean free path of the radiation is determined almost equally by Thomson scattering, bound-free absorption, and free-free absorption. Estimate numerically the photon mean free path and hence estimate the photon escape time and the luminosity. How well do your estimates compare with the known values for the Sun?

Exercise 18.6 *Problem: Bubbles*

Consider a small bubble of air rising slowly in a large expanse of water. If the bubble is large enough for surface tension to be ignored, then it will form an irregular cap of radius r . Show that the speed with which the bubble rises is roughly $(gr)^{1/2}$. (A more refined estimate gives a numerical coefficient of $2/3$.)

18.6 Double Diffusion—Salt Fingers T2**18.6**

As we have described it so far, convection is driven by the presence of an unbalanced buoyancy force in an equilibrium distribution of fluid. However, it can also arise as a higher-order effect, even if the fluid initially is stably stratified (i.e., if the density gradient is in the same direction as gravity). An example is *salt fingering*, a rapid mixing that can occur when warm, salty water lies at rest above colder fresh water. The higher temperature of the upper fluid outbalances the weight of its salt, making it more buoyant than the fresh water below. However, in a small, localized, downward perturbation of the warm, salty water, heat diffuses laterally into the colder surrounding water faster than salt diffuses, increasing the perturbation's density, so it will continue to sink.

salt fingering and the mechanism behind it

It is possible to describe this instability using a local perturbation analysis. The setup is somewhat similar to the one we used in Sec. 18.4 to analyze Rayleigh-Bénard convection. We consider a stratified fluid in an equilibrium state, in which there is a vertical gradient of the temperature, and as before, we measure its departure from a reference temperature T_0 at a midplane ($z = 0$) by $\tau \equiv T - T_0$. We presume that in the equilibrium state τ varies linearly with z , so $\nabla\tau = (d\tau/dz)\mathbf{e}_z$ is constant. Similarly, we characterize the salt concentration by $\mathcal{C} \equiv (\text{concentration}) - (\text{equilibrium concentration at the midplane})$; and we assume that in the equilibrium state, \mathcal{C} , like τ , varies linearly with height, so $\nabla\mathcal{C} = (d\mathcal{C}/dz)\mathbf{e}_z$ is constant. The density ρ is equal to the equilibrium density at the midplane plus corrections due to thermal expansion and salt concentration:

$$\rho = \rho_0 - \alpha\rho_0\tau + \beta\rho_0\mathcal{C} \quad (18.38)$$

[cf. Eq. (18.14)]. Here β is a constant for concentration analogous to the thermal expansion coefficient α for temperature. In this problem, by contrast with Rayleigh-Bénard convection, it is easier to work directly with the pressure than with the modified pressure. In equilibrium, hydrostatic equilibrium dictates that its gradient be $\nabla P = -\rho\mathbf{g}$.

Now, let us perturb about this equilibrium state and write down the linearized equations for the evolution of the perturbations. We denote the perturbation of temperature (relative to the reference temperature) by $\delta\tau$, of salt concentration by $\delta\mathcal{C}$, of density by $\delta\rho$, of pressure by δP , and of velocity by simply \mathbf{v} (since the unperturbed state has $\mathbf{v} = 0$). We do not ask about the onset of instability, but rather (because we expect our situation to be generically unstable) we seek a dispersion relation $\omega(\mathbf{k})$ for the perturbations. Correspondingly, in all our perturbation equations we replace $\partial/\partial t$ with $-i\omega$ and ∇ with $i\mathbf{k}$, except for the equilibrium $\nabla\mathcal{C}$ and $\nabla\tau$, which are constants.

The first of our perturbation equations is the linearized Navier-Stokes equation (18.3b):

$$-i\omega\rho_0\mathbf{v} = -i\mathbf{k}\delta P + \mathbf{g}\delta\rho - \nu k^2\rho_0\mathbf{v}, \quad (18.39a)$$

where we have kept the viscous term, because we expect the Prandtl number to be of order unity (for water, $\text{Pr} \sim 6$). Low velocity implies incompressibility $\nabla \cdot \mathbf{v} = 0$, which becomes

$$\mathbf{k} \cdot \mathbf{v} = 0. \quad (18.39b)$$

The density perturbation follows from the perturbed form of Eq. (18.38):

$$\delta\rho = -\alpha\rho_0\delta\tau + \beta\rho_0\delta\mathcal{C}. \quad (18.39c)$$

The temperature perturbation is governed by Eq. (18.19), which linearizes to

$$-i\omega\delta\tau + (\mathbf{v} \cdot \nabla)\tau = -\chi k^2\delta\tau. \quad (18.39d)$$

Assuming that the timescale for the salt to diffuse is much longer than that for the temperature to diffuse, we can ignore salt diffusion altogether, so that $d\delta\mathcal{C}/dt = 0$:

$$-i\omega\delta\mathcal{C} + (\mathbf{v} \cdot \nabla)\mathcal{C} = 0. \quad (18.39e)$$

Equations (18.39) are five equations for the five unknowns δP , $\delta\rho$, $\delta\mathcal{C}$, $\delta\tau$, and \mathbf{v} , one of which is a three-component vector! Unless we are careful, we will end up with a seventh-order algebraic equation. Fortunately, there is a way to keep the algebra manageable. First, we eliminate the pressure perturbation by taking the curl of Eq. (18.39a) [or equivalently, by crossing \mathbf{k} into Eq. (18.39a)]:

$$(-i\omega + \nu k^2)\rho_0\mathbf{k} \times \mathbf{v} = \mathbf{k} \times \mathbf{g}\delta\rho. \quad (18.40a)$$

Taking the curl of this equation again allows us to incorporate incompressibility (18.39b). Then dotting into \mathbf{g} , we obtain

$$(i\omega - \nu k^2)\rho_0 k^2 \mathbf{g} \cdot \mathbf{v} = [(\mathbf{k} \cdot \mathbf{g})^2 - k^2 g^2]\delta\rho. \quad (18.40b)$$

Since \mathbf{g} points vertically, Eq. (18.40b) is one equation for the density perturbation in terms of the vertical velocity perturbation v_z . We can obtain a second equation of this sort by inserting Eq. (18.39d) for $\delta\tau$ and Eq. (18.39e) for $\delta\mathcal{C}$ into Eq. (18.39c); the result is

$$\delta\rho = - \left(\frac{\alpha\rho_0}{i\omega - \chi k^2} \right) (\mathbf{v} \cdot \nabla)\tau + \frac{\beta\rho_0}{i\omega} (\mathbf{v} \cdot \nabla)\mathcal{C}. \quad (18.40c)$$

Since the unperturbed gradients of temperature and salt concentration are both vertical, Eq. (18.40c), like Eq. (18.40b), involves only v_z and not v_x or v_y . Solving both Eqs. (18.40b) and (18.40c) for the ratio $\delta\rho/v_z$ and equating these two expressions, we obtain the following dispersion relation for our perturbations:

$$\omega(\omega + i\nu k^2)(\omega + i\chi k^2) + \left[1 - \frac{(\mathbf{k} \cdot \mathbf{g})^2}{k^2 g^2} \right] [\omega\alpha(\mathbf{g} \cdot \nabla)\tau - (\omega + i\chi k^2)\beta(\mathbf{g} \cdot \nabla)\mathcal{C}] = 0. \quad (18.41)$$

dispersion relation for salt-fingering perturbations

When \mathbf{k} is real, as we shall assume, we can write this dispersion relation as a cubic equation for $p = -i\omega$ with real coefficients. The roots for p are either all real or one real and two complex conjugates, and growing modes have the real part of p positive. When the constant term in the cubic is negative, that is, when

$$(\mathbf{g} \cdot \nabla)\mathcal{C} < 0, \quad (18.42)$$

we are guaranteed that there is at least one positive, real root p and this root corresponds to an unstable, growing mode. Therefore, *a sufficient condition for instability is that the concentration of salt increase with height!*

sufficient condition for salt-fingering instability

By inspecting the dispersion relation, we conclude that the growth rate will be maximal when $\mathbf{k} \cdot \mathbf{g} = 0$ (i.e., when the wave vector is horizontal). What is the direction of the velocity \mathbf{v} for these fastest-growing modes? The incompressibility equation (18.39b) shows that \mathbf{v} is orthogonal to the horizontal \mathbf{k} ; Eq. (18.40a) states that $\mathbf{k} \times \mathbf{v}$ points in the same direction as $\mathbf{k} \times \mathbf{g}$, which is horizontal, since \mathbf{g} is vertical. These two conditions imply that \mathbf{v} points vertically. Therefore, these fastest modes represent *fingers* of salty water descending past rising fingers of fresh water (Fig. 18.6). For large k (narrow fingers), the dispersion relation (18.41) predicts a growth rate given approximately by

$$p = -i\omega \sim \frac{\beta(-\mathbf{g} \cdot \nabla)\mathcal{C}}{\nu k^2}. \quad (18.43)$$

fastest salt-fingering modes

Thus the growth of narrow fingers is driven by the concentration gradient and retarded by viscosity. For larger fingers, the temperature gradient participates in the retardation, since the heat must diffuse to break the buoyant stability.

Now let us turn to the nonlinear development of this instability. Although we have just considered a single Fourier mode, the fingers that grow are roughly cylindrical rather than sheet-like. They lengthen at a rate that is slow enough for the heat to diffuse horizontally, though not so slow that the salt can diffuse. Let the diffusion coefficient for the salt be $\chi_{\mathcal{C}}$ by analogy with χ for temperature. If the length of the fingers is L

FIGURE 18.6 Salt fingers in a fluid in which warm, salty water lies on top of cold, fresh water.

and their width is δ_f , then to facilitate heat diffusion and prevent salt diffusion, the vertical speed v must satisfy

$$\frac{\chi_c L}{\delta_f^2} \ll v \ll \frac{\chi L}{\delta_f^2}. \quad (18.44)$$

Balancing the viscous acceleration $\nu v/\delta_f^2$ by the buoyancy acceleration $g\beta\delta C$, we obtain

$$v \sim \frac{g\beta\delta C\delta_f^2}{\nu}. \quad (18.45)$$

We can therefore rewrite Eq. (18.44) as

$$\left(\frac{\chi_c \nu L}{g\beta\delta C}\right)^{1/4} \ll \delta_f \ll \left(\frac{\chi \nu L}{g\beta\delta C}\right)^{1/4}. \quad (18.46)$$

Typically, $\chi_c \sim 0.01\chi$, so Eq. (18.46) implies that the widths of the fingers lie in a narrow range, as is verified by laboratory experiments.

Salt fingering can occur naturally, for example, in an estuary where cold river water flows beneath sea water warmed by the Sun. However, the development of salt fingers is quite slow, and in practice it only leads to mixing when the equilibrium velocity field is very small.

This instability is one example of a quite general type of instability known as *double diffusion*, which can arise when two physical quantities can diffuse through a fluid at different rates. Other examples include the diffusion of two different solutes and the diffusion of vorticity and heat in a rotating flow.

EXERCISES

Exercise 18.7 *Problem: Laboratory Experiment with Salt Fingers* T2

Make an order-of-magnitude estimate of the size of the fingers and the time it takes for them to grow in a small transparent jar. You might like to try an experiment.

Exercise 18.8 *Problem: Internal Waves* T2

Consider a stably stratified fluid at rest with a small (negative) vertical density gradient $d\rho/dz$.

- (a) By modifying the analysis in this section, ignoring the effects of viscosity, heat conduction, and concentration gradients, show that small-amplitude linear waves, which propagate in a direction making an angle θ to the vertical, have an angular frequency given by $\omega = N|\sin \theta|$, where $N \equiv [(\mathbf{g} \cdot \nabla) \ln \rho]^{1/2}$ is known as the *Brunt-Väisälä frequency*. These waves are called *internal waves*. They can also be found at abrupt discontinuities as well as in the presence of a slow variation in the background medium. They are analogous to the Love and Rayleigh waves we have already met in our discussion of seismology (Sec. 12.4.2). Another type of internal wave is the Kelvin-Helmholtz wave (Sec. 14.6.1).
- (b) Show that the group velocity of these waves is orthogonal to the phase velocity, and interpret this result physically.

Bibliographic Note

For pedagogical treatments of almost all the topics in this chapter plus much more related material, we particularly like Tritton (1987), whose phenomenological approach is lucid and appealing; and also Turner (1973), which is a thorough treatise on the influence of buoyancy (thermally induced and otherwise) on fluid motions.

Lautrup (2005) treats very nicely all this chapter's topics except convection in stars, salt fingers, and double diffusion. Landau and Lifshitz (1959, Chaps. 5 and 6) give a fairly succinct treatment of diffusive heat flow in fluids, the onset of convection in several different physical situations, and the concepts underlying double diffusion. Chandrasekhar (1961, Chaps. 2–6) gives a thorough and rich treatment of the influence of a wide variety of phenomena on the onset of convection, and on the types of fluid motions that can occur near the onset of convection. For a few pages on strongly turbulent convective heat transfer, see White (2006, Sec. 6-10).

Engineering-oriented textbooks typically say little about convection. For an engineer's viewpoint and engineering issues in convection, we recommend more specialized texts, such as Bejan (2013). For an applied mathematician's viewpoint, we suggest the treatise Pop and Ingham (2001).

Magnetohydrodynamics

... it is only the plasma itself which does not 'understand' how beautiful the theories are and absolutely refuses to obey them.

HANNES ALFVÉN (1970)

19.1 Overview

19.1

In preceding chapters we have described the consequences of incorporating viscosity and thermal conductivity into the description of a fluid. We now turn to our final embellishment of fluid mechanics, in which the fluid is electrically conducting and moves in a magnetic field. The study of flows of this type is known as *magnetohydrodynamics*, or MHD for short. In our discussion, we eschew full generality and with one exception just use the basic Euler equation (no viscosity, no heat diffusion, etc.) augmented by magnetic terms. This approach suffices to highlight peculiarly magnetic effects and is adequate for many applications.

The simplest example of an electrically conducting fluid is a liquid metal, for example, mercury or liquid sodium. However, the major application of MHD is in plasma physics—discussed in Part VI. (A plasma is a hot, ionized gas containing free electrons and ions.) It is by no means obvious that plasmas can be regarded as fluids, since the mean free paths for Coulomb-force collisions between a plasma's electrons and ions are macroscopically long. However, as we shall learn in Sec. 20.5, collective interactions between large numbers of plasma particles can isotropize the particles' velocity distributions in some local mean reference frame, thereby making it sensible to describe the plasma macroscopically by a mean density, velocity, and pressure. These mean quantities can then be shown to obey the same conservation laws of mass, momentum, and energy as we derived for fluids in Chap. 13. As a result, a fluid description of a plasma is often reasonably accurate. We defer to Part VI further discussion of this point, asking the reader to take it on trust for the moment. In MHD, we also implicitly assume that the average velocity of the ions is nearly the same as the average velocity of the electrons. This is usually a good approximation; if it were not so, then the plasma would carry an unreasonably large current density.

Two serious technological applications of MHD may become very important in the future. In the first, strong magnetic fields are used to confine rings or columns of hot plasma that (it is hoped) will be held in place long enough for thermonuclear fusion to occur and for net power to be generated. In the second, which is directed toward a

BOX 19.1. READERS' GUIDE

- This chapter relies heavily on Chap. 13 and somewhat on the treatment of vorticity transport in Sec. 14.2.
- Part VI, Plasma Physics (Chaps. 20–23), relies heavily on this chapter.

similar goal, liquid metals or plasmas are driven through a magnetic field to generate electricity. The study of magnetohydrodynamics is also motivated by its widespread application to the description of space (in the solar system) and astrophysical plasmas (beyond the solar system). We illustrate the principles of MHD using examples drawn from all these areas.

After deriving the basic equations of MHD (Sec. 19.2), we elucidate magnetostatic (also called “hydromagnetic”) equilibria by describing a *tokamak* (Sec. 19.3). This is currently the most popular scheme for the magnetic confinement of hot plasma. In our second application (Sec. 19.4) we describe the flow of conducting liquid metals or plasma along magnetized ducts and outline its potential as a practical means of electrical power generation and spacecraft propulsion. We then return to the question of magnetostatic confinement of hot plasma and focus on the stability of equilibria (Sec. 19.5). This issue of stability has occupied a central place in our development of fluid mechanics, and it will not come as a surprise to learn that it has dominated research on thermonuclear fusion in plasmas. When a magnetic field plays a role in the equilibrium (e.g., for magnetic confinement of a plasma), the field also makes possible new modes of oscillation, and some of these MHD modes can be unstable to exponential growth. Many magnetic-confinement geometries exhibit such instabilities. We demonstrate this qualitatively by considering the physical action of the magnetic field, and also formally by using variational methods.

In Sec. 19.6, we turn to a geophysical problem, the origin of Earth’s magnetic field. It is generally believed that complex fluid motions in Earth’s liquid core are responsible for regenerating the field through dynamo action. We use a simple model to illustrate this process.

When magnetic forces are added to fluid mechanics, a new class of waves, called magnetosonic waves, can propagate. We conclude our discussion of MHD in Sec. 19.7 by deriving the properties of these wave modes in a homogeneous plasma and discussing how they control the propagation of cosmic rays in the interplanetary and interstellar media.

As in previous chapters, we encourage our readers to view films; on magnetohydrodynamics, for example, Shercliff (1965).

19.2 19.2 Basic Equations of MHD

The equations of MHD describe the motion of a conducting fluid in a magnetic field. This fluid is usually either a liquid metal or a plasma. In both cases, the conductivity,

strictly speaking, should be regarded as a tensor (Sec. 20.6.3) if the electrons' cyclotron frequency (Sec. 20.6.1) exceeds their collision frequency (the inverse of the mean time between collisions; Sec. 20.4.1). (If there are several collisions per cyclotron orbit, then the influence of the magnetic field on the transport coefficients will be minimal.) However, to keep the mathematics simple, we treat the conductivity as a constant scalar, κ_e . In fact, it turns out that for many of our applications, it is adequate to take the conductivity as infinite, and it does not matter whether that infinity is a scalar or a tensor!

Two key physical effects occur in MHD, and understanding them well is key to developing physical intuition. The first effect arises when a good conductor moves into a magnetic field (Fig. 19.1a). Electric current is induced in the conductor, which, by Lenz's law, creates its own magnetic field. This induced magnetic field tends to cancel the original, externally supported field, thereby in effect excluding the magnetic field lines from the conductor. Conversely, when the magnetic field penetrates the conductor and the conductor is moved out of the field, the induced field reinforces the applied field. The net result is that the lines of force appear to be dragged along with the conductor—they “go with the flow.” Naturally, if the conductor is a fluid with complex motions, the ensuing magnetic field distribution can become quite complex, and the current builds up until its growth is balanced by Ohmic dissipation.

The second key effect is dynamical. When currents are induced by a motion of a conducting fluid through a magnetic field, a Lorentz (or $\mathbf{j} \times \mathbf{B}$) force acts on the fluid and modifies its motion (Fig. 19.1b). In MHD, the motion modifies the field, and the field, in turn, reacts back and modifies the motion. This behavior makes the theory highly nonlinear.

Before deriving the governing equations of MHD, we should consider the choice of primary variables. In electromagnetic theory, we specify the spatial and temporal variation of either the electromagnetic field or its source, the electric charge density and current density. One choice is computable (at least in principle) from the other

FIGURE 19.1 The two key physical effects that occur in MHD. (a) A moving conductor modifies the magnetic field by dragging the field lines with it. When the conductivity is infinite, the field lines are frozen in the moving conductor. (b) When electric current, flowing in the conductor, crosses magnetic field lines, a Lorentz force is generated that accelerates the fluid.

two key physical effects in MHD

in MHD the magnetic field is the primary variable

Maxwell's equations

using Maxwell's equations, augmented by suitable boundary conditions. So it is with MHD, and the choice depends on convenience. It turns out that for the majority of applications, it is most instructive to deal with the magnetic field as primary, and to use Maxwell's equations

$$\nabla \cdot \mathbf{E} = \frac{\rho_e}{\epsilon_0}, \quad (19.1a)$$

$$\nabla \cdot \mathbf{B} = 0, \quad (19.1b)$$

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}, \quad (19.1c)$$

$$\nabla \times \mathbf{B} = \mu_0 \mathbf{j} + \mu_0 \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} \quad (19.1d)$$

to express the electric field \mathbf{E} , the current density \mathbf{j} , and the charge density ρ_e in terms of the magnetic field (next subsection).

19.2.1 Maxwell's Equations in the MHD Approximation

As normally formulated, Ohm's law is valid only in the rest frame of the conductor. In particular, for a conducting fluid, Ohm's law relates the current density \mathbf{j}' measured in the fluid's local rest frame to the electric field \mathbf{E}' measured there:

$$\mathbf{j}' = \kappa_e \mathbf{E}', \quad (19.2)$$

where κ_e is the scalar electric conductivity. Because the fluid is generally accelerated, $d\mathbf{v}/dt \neq 0$, its local rest frame is generally not inertial. Since it would produce a terrible headache to have to transform time and again from some inertial frame to the continually changing local rest frame when applying Ohm's law, it is preferable to reformulate Ohm's law in terms of the fields \mathbf{E} , \mathbf{B} , and \mathbf{j} measured in an inertial frame. To facilitate this (and for completeness), we explore the frame dependence of all our electromagnetic quantities \mathbf{E} , \mathbf{B} , \mathbf{j} , and ρ_e .

Throughout our development of magnetohydrodynamics, we assume that the fluid moves with a nonrelativistic speed $v \ll c$ relative to our chosen reference frame. We can then express the rest-frame electric field in terms of the inertial-frame electric and magnetic fields as

$$\mathbf{E}' = \mathbf{E} + \mathbf{v} \times \mathbf{B}; \quad E' = |\mathbf{E}'| \ll E, \quad \text{so } \mathbf{E} \simeq -\mathbf{v} \times \mathbf{B}. \quad (19.3a)$$

In the first equation we have set the Lorentz factor $\gamma \equiv 1/\sqrt{1 - v^2/c^2}$ to unity, consistent with our nonrelativistic approximation. The second equation follows from the high conductivity of the fluid, which guarantees that current will quickly flow in whatever manner it must to annihilate any electric field \mathbf{E}' that might be formed in the fluid's local rest frame. By contrast with the extreme frame dependence (19.3a) of the electric

field, the magnetic field is essentially the same in the fluid's local rest frame as in the laboratory. More specifically, the analog of Eq. (19.3a) is $\mathbf{B}' = \mathbf{B} - (\mathbf{v}/c^2) \times \mathbf{E}$; and since $E \sim vB$, the second term is of magnitude $(v/c)^2 B$, which is negligible, giving

$$\mathbf{B}' \simeq \mathbf{B}. \quad (19.3b)$$

Because \mathbf{E} is highly frame dependent, so is its divergence, the electric charge density ρ_e . In the laboratory frame, where $E \sim vB$, Gauss's and Ampère's laws [Eqs. (19.1a,d)] imply that $\rho_e \sim \epsilon_0 v B/L \sim (v/c^2) j$, where L is the lengthscale on which \mathbf{E} and \mathbf{B} vary; and the relation $E' \ll E$ with Gauss's law implies $|\rho'_e| \ll |\rho_e|$:

$$\rho_e \sim j v/c^2, \quad |\rho'_e| \ll |\rho_e|. \quad (19.3c)$$

By transforming the current density between frames and approximating $\gamma \simeq 1$, we obtain $\mathbf{j}' = \mathbf{j} + \rho_e \mathbf{v} = \mathbf{j} + O(v/c)^2 j$; so in the nonrelativistic limit (first order in v/c) we can ignore the charge density and write

$$\mathbf{j}' = \mathbf{j}. \quad (19.3d)$$

To recapitulate, in nonrelativistic magnetohydrodynamic flows, the magnetic field and current density are frame independent up to fractional corrections of order $(v/c)^2$, while the electric field and charge density are highly frame dependent and are generally small in the sense that $E/c \sim (v/c)B \ll B$ and $\rho_e \sim (v/c^2)j \ll j/c$ [in Gaussian cgs units we have $E \sim (v/c)B \ll B$ and $\rho_e c \sim (v/c)j \ll j$].

Combining Eqs. (19.2), (19.3a), and (19.3d), we obtain the nonrelativistic form of Ohm's law in terms of quantities measured in our chosen inertial, laboratory frame:

$$\mathbf{j} = \kappa_e (\mathbf{E} + \mathbf{v} \times \mathbf{B}). \quad (19.4)$$

We are now ready to derive explicit equations for the (inertial-frame) electric field and current density in terms of the (inertial-frame) magnetic field. In our derivation, we denote by L the lengthscale on which the magnetic field changes.

We begin with Ampère's law written as $\nabla \times \mathbf{B} - \mu_0 \mathbf{j} = \mu_0 \epsilon_0 \partial \mathbf{E} / \partial t = (1/c^2) \partial \mathbf{E} / \partial t$, and we notice that the time derivative of \mathbf{E} is of order $E v/L \sim B v^2/L$ (since $E \sim vB$). Therefore, the right-hand side is $O[B v^2/(c^2 L)]$ and thus can be neglected compared to the $O(B/L)$ term on the left, yielding:

$$\mathbf{j} = \frac{1}{\mu_0} \nabla \times \mathbf{B}. \quad (19.5a)$$

We next insert this expression for \mathbf{j} into the inertial-frame Ohm's law (19.4), thereby obtaining

$$\mathbf{E} = -\mathbf{v} \times \mathbf{B} + \frac{1}{\kappa_e \mu_0} \nabla \times \mathbf{B}. \quad (19.5b)$$

in MHD, magnetic field and current density are approximately frame independent; electric field and charge density are small and frame dependent

Ohm's law

current density in terms of magnetic field

electric field in terms of magnetic field

If we happen to be interested in the charge density (which is rare in MHD), we can compute it by taking the divergence of this electric field:

charge density in terms of magnetic field

$$\rho_e = -\epsilon_0 \nabla \cdot (\mathbf{v} \times \mathbf{B}). \quad (19.5c)$$

Equations (19.5) express all the secondary electromagnetic variables in terms of our primary one, \mathbf{B} . This has been possible because of the high electric conductivity κ_e and our choice to confine ourselves to nonrelativistic (low-velocity) situations; it would not be possible otherwise.

We next derive an evolution law for the magnetic field by taking the curl of Eq. (19.5b), using Maxwell's equation $\nabla \times \mathbf{E} = -\partial \mathbf{B} / \partial t$ and the vector identity $\nabla \times (\nabla \times \mathbf{B}) = \nabla(\nabla \cdot \mathbf{B}) - \nabla^2 \mathbf{B}$, and using $\nabla \cdot \mathbf{B} = 0$. The result is

evolution law for magnetic field

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times (\mathbf{v} \times \mathbf{B}) + \left(\frac{1}{\mu_0 \kappa_e} \right) \nabla^2 \mathbf{B}, \quad (19.6)$$

which, using Eqs. (14.4) and (14.5) with $\boldsymbol{\omega}$ replaced by \mathbf{B} , can also be written as

$$\frac{D\mathbf{B}}{Dt} = -\mathbf{B} \nabla \cdot \mathbf{v} + \left(\frac{1}{\mu_0 \kappa_e} \right) \nabla^2 \mathbf{B}, \quad (19.7)$$

where D/Dt is the fluid derivative defined in Eq. (14.5). When the flow is incompressible (as it often will be), the $\nabla \cdot \mathbf{v}$ term vanishes.

Equation (19.6)—or equivalently, Eq. (19.7)—is called the *induction equation* and describes the temporal evolution of the magnetic field. It is the same in form as the propagation law for vorticity $\boldsymbol{\omega}$ in a flow with $\nabla P \times \nabla \rho = 0$ [Eq. (14.3), or (14.6) with $\boldsymbol{\omega} \nabla \cdot \mathbf{v}$ added in the compressible case]. The $\nabla \times (\mathbf{v} \times \mathbf{B})$ term in Eq. (19.6) dominates when the conductivity is large and can be regarded as describing the freezing of magnetic field lines in the fluid in the same way as the $\nabla \times (\mathbf{v} \times \boldsymbol{\omega})$ term describes the freezing of vortex lines in a fluid with small viscosity ν (Fig. 19.2). By analogy with Eq. (14.10), when flux-freezing dominates, the fluid derivative of \mathbf{B}/ρ can be written as

for large conductivity: freezing of magnetic field into the fluid

$$\frac{D}{Dt} \left(\frac{\mathbf{B}}{\rho} \right) \equiv \frac{d}{dt} \left(\frac{\mathbf{B}}{\rho} \right) - \left(\frac{\mathbf{B}}{\rho} \cdot \nabla \right) \mathbf{v} = 0, \quad (19.8)$$

where ρ is mass density (not to be confused with charge density ρ_e). Equation (19.8) states that \mathbf{B}/ρ evolves in the same manner as the separation $\Delta \mathbf{x}$ between two points in the fluid (cf. Fig. 14.4 and associated discussion).

The term $[1/(\mu_0 \kappa_e)] \nabla^2 \mathbf{B}$ in the B-field evolution equation (19.6) or (19.7) is analogous to the vorticity diffusion term $\nu \nabla^2 \boldsymbol{\omega}$ in the vorticity evolution equation (14.3) or (14.6). Therefore, when κ_e is not too large, magnetic field lines will diffuse through the fluid. The effective diffusion coefficient (analogous to ν) is

magnetic diffusion coefficient

$$D_M = 1/(\mu_0 \kappa_e). \quad (19.9a)$$

FIGURE 19.2 Pictorial representation of the evolution of the magnetic field in a fluid endowed with infinite electrical conductivity. (a) A uniform magnetic field at time $t = 0$ in a vortex. (b) At a later time, when the fluid has rotated through $\sim 30^\circ$, the circulation has stretched and distorted the magnetic field.

Earth's magnetic field provides an example of field diffusion. That field is believed to be supported by electric currents flowing in Earth's iron core. Now, we can estimate the electric conductivity of iron under these conditions and from it deduce a value for the diffusivity, $D_M \sim 1 \text{ m}^2 \text{ s}^{-1}$. The size of Earth's core is $L \sim 10^4 \text{ km}$, so if there were no fluid motions, then we would expect the magnetic field to diffuse out of the core and escape from Earth in a time

$$\tau_M \sim \frac{L^2}{D_M} \quad (19.9b)$$

magnetic decay time

~ 3 million years, which is much shorter than the age of Earth, ~ 5 billion years. The reason for this discrepancy, as we discuss in Sec. 19.6, is that there are internal circulatory motions in the liquid core that are capable of regenerating the magnetic field through dynamo action.

Although Eq. (19.6) describes a genuine diffusion of the magnetic field, to compute with confidence the resulting magnetic decay time, one must solve the complete boundary value problem. To give a simple illustration, suppose that a poor conductor (e.g., a weakly ionized column of plasma) is surrounded by an excellent conductor (e.g., the metal walls of the container in which the plasma is contained), and that magnetic field lines supported by wall currents thread the plasma. The magnetic field will only diminish after the wall currents undergo Ohmic dissipation, which can take much longer than the diffusion time for the plasma column alone.

It is customary to introduce a dimensionless number called the *magnetic Reynolds number*, R_M , directly analogous to the fluid Reynolds number Re , to describe the relative importance of flux freezing and diffusion. The fluid Reynolds number can be regarded as the ratio of the magnitude of the vorticity-freezing term, $\nabla \times (\mathbf{v} \times \boldsymbol{\omega}) \sim (V/L)\boldsymbol{\omega}$, in the vorticity evolution equation, $\partial\boldsymbol{\omega}/\partial t = \nabla \times (\mathbf{v} \times \boldsymbol{\omega}) + \nu\nabla^2\boldsymbol{\omega}$, to the magnitude of the diffusion term, $\nu\nabla^2\boldsymbol{\omega} \sim (\nu/L^2)\boldsymbol{\omega}$: $Re = (V/L)(\nu/L^2)^{-1} = VL/\nu$. Here V is a characteristic speed, and L a characteristic lengthscale of the flow. Similarly, the magnetic Reynolds number is the ratio of the magnitude of the

TABLE 19.1: Characteristic magnetic diffusivities D_M , decay times τ_M , and magnetic Reynolds numbers R_M for some common MHD flows with characteristic length scales L and velocities V

Substance	L (m)	V (m s ⁻¹)	D_M (m ² s ⁻¹)	τ_M (s)	R_M
Mercury	0.1	0.1	1	0.01	0.01
Liquid sodium	0.1	0.1	0.1	0.1	0.1
Laboratory plasma	1	100	10	0.1	10
Earth's core	10 ⁷	0.1	1	10 ¹⁴	10 ⁶
Interstellar gas	10 ¹⁷	10 ³	10 ³	10 ³¹	10 ¹⁷

magnetic-flux-freezing term, $\nabla \times (\mathbf{v} \times \mathbf{B}) \sim (V/L)B$, to the magnitude of the magnetic-flux-diffusion term, $D_M \nabla^2 \mathbf{B} = [1/(\mu_0 \kappa_e)] \nabla^2 \mathbf{B} \sim B/(\mu_0 \kappa_e L^2)$, in the induction equation (19.6):

$$R_M = \frac{V/L}{D_M/L^2} = \frac{VL}{D_M} = \mu_0 \kappa_e VL. \quad (19.9c)$$

When $R_M \gg 1$, the field lines are effectively frozen in the fluid; when $R_M \ll 1$, Ohmic dissipation is dominant, and the field lines easily diffuse through the fluid.

Magnetic Reynolds numbers and diffusion times for some typical MHD flows are given in Table 19.1. For most laboratory conditions, R_M is modest, which means that electric resistivity $1/\kappa_e$ is significant, and the magnetic diffusivity D_M is rarely negligible. By contrast, in space physics and astrophysics, R_M is usually very large, $R_M \gg 1$, so the resistivity can be ignored almost always and everywhere. This limiting case, when the electric conductivity is treated as infinite, is often called *perfect MHD*.

The phrase “almost always and everywhere” needs clarification. Just as for large-Reynolds-number fluid flows, so also here, boundary layers and discontinuities can be formed, in which the gradients of physical quantities are automatically large enough to make $R_M \sim 1$ locally. An important example discussed in Sec. 19.6.3 is *magnetic reconnection*. This occurs when regions magnetized along different directions are juxtaposed, for example, when the solar wind encounters Earth's magnetosphere. In such discontinuities and boundary layers, the current density is high, and magnetic diffusion and Ohmic dissipation are important. As in ordinary fluid mechanics, these dissipative layers and discontinuities can control the character of the overall flow despite occupying a negligible fraction of the total volume.

19.2.2

19.2.2 Momentum and Energy Conservation

The fluid dynamical aspects of MHD are handled by adding an electromagnetic force term to the Euler or Navier-Stokes equation. The magnetic force density $\mathbf{j} \times \mathbf{B}$ is the sum of the Lorentz forces acting on all the fluid's charged particles in a unit volume.

magnetic Reynolds number and magnetic field freezing

perfect MHD: infinite conductivity and magnetic field freezing

magnetic reconnection and its influence

There is also an electric force density $\rho_e \mathbf{E}$, but this is smaller than $\mathbf{j} \times \mathbf{B}$ by a factor $O(v^2/c^2)$ by virtue of Eqs. (19.5), so we ignore it. When $\mathbf{j} \times \mathbf{B}$ is added to the Euler equation (13.44) (or equivalently, to the Navier-Stokes equation with the viscosity neglected as unimportant in the situations we shall study), it takes the following form:

$$\rho \frac{d\mathbf{v}}{dt} = \rho \mathbf{g} - \nabla P + \mathbf{j} \times \mathbf{B} = \rho \mathbf{g} - \nabla P + \frac{(\nabla \times \mathbf{B}) \times \mathbf{B}}{\mu_0}. \quad (19.10)$$

MHD equation of motion for fluid

Here we have used expression (19.5a) for the current density in terms of the magnetic field. This is our basic MHD force equation. In Sec. 20.6.2 we will generalize it to situations where, due to electron cyclotron motion, the pressure P is anisotropic.

Like all other force densities in this equation, the magnetic one $\mathbf{j} \times \mathbf{B}$ can be expressed as minus the divergence of a stress tensor, the magnetic portion of the Maxwell stress tensor:

$$\mathbf{T}_M = \frac{B^2 \mathbf{g}}{2\mu_0} - \frac{\mathbf{B} \otimes \mathbf{B}}{\mu_0}; \quad (19.11)$$

magnetic stress tensor

see Ex. 19.1. By virtue of $\mathbf{j} \times \mathbf{B} = -\nabla \cdot \mathbf{T}_M$ and other relations explored in Sec. 13.5 and Box 13.4, we can convert the force-balance equation (19.10) into the conservation law for momentum [generalization of Eq. (13.42)]:

momentum conservation

$$\frac{\partial(\rho \mathbf{v})}{\partial t} + \nabla \cdot (P \mathbf{g} + \rho \mathbf{v} \otimes \mathbf{v} + \mathbf{T}_g + \mathbf{T}_M) = 0. \quad (19.12)$$

Here \mathbf{T}_g is the gravitational stress tensor [Eq. (1) of Box 13.4], which resembles the magnetic one:

$$\mathbf{T}_g = -\frac{g^2 \mathbf{g}}{8\pi G} + \frac{\mathbf{g} \otimes \mathbf{g}}{4\pi G}; \quad (19.13)$$

it is generally unimportant in laboratory plasmas but can be quite important in and near stars and black holes.

The two terms in the magnetic Maxwell stress tensor [Eq. (19.11)] can be identified as the “push” of an isotropic magnetic pressure of $B^2/(2\mu_0)$ that acts just like the gas pressure P , and the “pull” of a tension B^2/μ_0 that acts parallel to the magnetic field. The combination of the tension and the isotropic pressure give a net tension $B^2/(2\mu_0)$ along the field and a net pressure $B^2/(2\mu_0)$ perpendicular to the field lines (Ex. 1.14).

The magnetic force density

magnetic force density

$$\mathbf{f}_m = -\nabla \cdot \mathbf{T}_M = \mathbf{j} \times \mathbf{B} = \frac{(\nabla \times \mathbf{B}) \times \mathbf{B}}{\mu_0} \quad (19.14)$$

can be rewritten, using standard vector identities, as

$$\mathbf{f}_m = -\nabla \left(\frac{B^2}{2\mu_0} \right) + \frac{(\mathbf{B} \cdot \nabla) \mathbf{B}}{\mu_0} = - \left[\nabla \left(\frac{B^2}{2\mu_0} \right) \right]_{\perp} + \left[\frac{(\mathbf{B} \cdot \nabla) \mathbf{B}}{\mu_0} \right]_{\perp}. \quad (19.15)$$

FIGURE 19.3 Contributions to the electromagnetic force density acting on a conducting fluid in a nonuniform magnetic field. A magnetic-pressure force density $-\left[\nabla B^2/(2\mu_0)\right]_{\perp}$ acts perpendicularly to the field. And a magnetic-curvature force density $[(\mathbf{B} \cdot \nabla)\mathbf{B}/\mu_0]_{\perp}$, which is also perpendicular to the magnetic field and lies in the plane of the field's bend, points toward its center of curvature. The magnitude of this curvature force density is $B^2/(\mu_0 R)$, where R is the radius of curvature.

Here “ \perp ” means keep only the components perpendicular to the magnetic field; the fact that $\mathbf{f}_m = \mathbf{j} \times \mathbf{B}$ guarantees that the net force parallel to \mathbf{B} must vanish, so we can throw away the component along \mathbf{B} in each term. This transversality of \mathbf{f}_m means that the magnetic force neither inhibits nor promotes motion of the fluid along the magnetic field. Instead, fluid elements are free to slide along the field like beads that slide without friction along a magnetic “wire.”

The “ \perp ” expressions in Eq. (19.15) indicate that the magnetic force density has two parts: first, the negative of the 2-dimensional gradient of the magnetic pressure $B^2/(2\mu_0)$ orthogonal to \mathbf{B} (Fig. 19.3a), and second, an orthogonal *curvature force* $(\mathbf{B} \cdot \nabla)\mathbf{B}/\mu_0$, which has magnitude $B^2/(\mu_0 R)$, where R is the radius of curvature of a field line. This curvature force acts toward the field line's center of curvature (Fig. 19.3b) and is the magnetic-field-line analog of the force that acts on a curved wire or curved string under tension.

Just as the magnetic force density dominates and the electric force is negligible $[O(v^2/c^2)]$ in our nonrelativistic situation, so also the electromagnetic contribution to the energy density is predominantly due to the magnetic term $U_M = B^2/(2\mu_0)$ with negligible electric contribution. The electromagnetic energy flux is just the Poynting flux $\mathbf{F}_M = \mathbf{E} \times \mathbf{B}/\mu_0$, with \mathbf{E} given by Eq. (19.5b). Inserting these expressions into the law of energy conservation (13.58) (and continuing to neglect viscosity), we obtain

energy conservation

$$\frac{\partial}{\partial t} \left[\left(\frac{1}{2}v^2 + u + \Phi \right) \rho + \frac{B^2}{2\mu_0} \right] + \nabla \cdot \left[\left(\frac{1}{2}v^2 + h + \Phi \right) \rho \mathbf{v} + \frac{\mathbf{E} \times \mathbf{B}}{\mu_0} \right] = 0. \quad (19.16)$$

When the fluid's self-gravity is important, we must augment this equation with the gravitational energy density and flux, as discussed in Box 13.4.

As in Sec. 13.7.4, we can combine this energy conservation law with mass conservation and the first law of thermodynamics to obtain an equation for the evolution of entropy: Eqs. (13.75) and (13.76) are modified to read

$$\boxed{\frac{\partial(\rho s)}{\partial t} + \nabla \cdot (\rho s \mathbf{v}) = \rho \frac{ds}{dt} = \frac{j^2}{\kappa_e T}} \quad (19.17)$$

entropy evolution; Ohmic dissipation

Thus, just as viscosity increases entropy through viscous dissipation, and thermal conductivity increases entropy through diffusive heat flow [Eqs. (13.75) and (13.76)], so also electrical resistivity (formally, κ_e^{-1}) increases entropy through Ohmic dissipation. From Eq. (19.17) we see that our fourth transport coefficient κ_e , like our previous three (the two coefficients of viscosity $\eta \equiv \rho \nu$ and ζ and the thermal conductivity κ), is constrained to be positive by the second law of thermodynamics.

Exercise 19.1 Derivation: Basic Equations of MHD

EXERCISES

- Verify that $-\nabla \cdot \mathbf{T}_M = \mathbf{j} \times \mathbf{B}$, where \mathbf{T}_M is the magnetic stress tensor (19.11).
- Take the scalar product of the fluid velocity \mathbf{v} with the equation of motion (19.10) and combine with mass conservation to obtain the energy conservation equation (19.16).
- Combine energy conservation (19.16) with the first law of thermodynamics and mass conservation to obtain Eq. (19.17) for the evolution of the entropy.

19.2.3 Boundary Conditions

19.2.3

The equations of MHD must be supplemented by boundary conditions at two different types of interfaces. The first is a *contact discontinuity* (i.e., the interface between two distinct media that do not mix; e.g., the surface of a liquid metal or a rigid wall of a plasma containment device). The second is a shock front that is being crossed by the fluid. Here the boundary is between shocked and unshocked fluid.

types of interfaces: contact discontinuity and shock front

We can derive the boundary conditions by transforming into a primed frame in which the interface is instantaneously at rest (not to be confused with the fluid's local rest frame) and then transforming back into our original unprimed inertial frame. In the primed frame, we resolve the velocity and magnetic and electric vectors into components normal and tangential to the surface. If \mathbf{n} is a unit vector normal to the surface, then the normal and tangential components of velocity in either frame are

$$v_n = \mathbf{n} \cdot \mathbf{v}, \quad \mathbf{v}_t = \mathbf{v} - (\mathbf{n} \cdot \mathbf{v})\mathbf{n}, \quad (19.18)$$

FIGURE 19.4 Elementary pill box \mathcal{V} and elementary circuit \mathcal{C} used in deriving the MHD junction conditions at a surface \mathcal{S} .

and similarly for the \mathbf{E} and \mathbf{B} . At a contact discontinuity, we have

$$v'_n = v_n - v_{sn} = 0 \quad (19.19a)$$

on both sides of the interface surface; here v_{sn} is the normal velocity of the surface. At a shock front, mass flux across the surface is conserved [cf. Eq. (17.29a)]:

$$[\rho v'_n] = [\rho(v_n - v_{sn})] = 0. \quad (19.19b)$$

Here, as in Sec. 17.5, we use the notation $[X]$ to signify the difference in some quantity X across the interface, that is, the *junction condition* for X .

When we consider the magnetic field, it does not matter which frame we use, since \mathbf{B} is unchanged to the Galilean order at which we are working. Let us construct a thin “pill box” \mathcal{V} (Fig. 19.4) and integrate the equation $\nabla \cdot \mathbf{B} = 0$ over its volume, invoke the divergence theorem, and let the box thickness diminish to zero; thereby we see that

$$[B_n] = 0. \quad (19.19c)$$

By contrast, the tangential component of the magnetic field can be discontinuous across an interface because of surface currents: by integrating $\nabla \times \mathbf{B} = \mu_0 \mathbf{j}$ across the shock front, we can deduce that

$$[\mathbf{B}_t] = -\mu_0 \mathbf{n} \times \mathbf{J}, \quad (19.19d)$$

where \mathbf{J} is the surface current density.

We deduce the junction condition on the electric field by integrating Maxwell’s equation $\nabla \times \mathbf{E} = -\partial \mathbf{B} / \partial t$ over the area bounded by the circuit \mathcal{C} in Fig. 19.4 and using Stokes’ theorem, letting the two short legs of the circuit vanish. We thereby obtain

$$[\mathbf{E}'_t] = [\mathbf{E}_t] + [(\mathbf{v}_s \times \mathbf{B})_t] = 0, \quad (19.19e)$$

boundary conditions at interfaces: Eqs. (19.19)

junction condition for mass flux

electromagnetic junction conditions

where \mathbf{v}_s is the velocity of a frame that moves with the surface. Note that only the normal component of the velocity contributes to this expression, so we can replace \mathbf{v}_s by $v_{sn}\mathbf{n}$. The normal component of the electric field, like the tangential component of the magnetic field, can be discontinuous, as there may be surface charge at the interface.

There are also dynamical junction conditions that can be deduced by integrating the laws of momentum conservation (19.12) and energy conservation (19.16) over the pill box and using Gauss's theorem to convert the volume integral of a divergence to a surface integral. The results, naturally, are the requirements that the normal fluxes of momentum $\mathbf{T} \cdot \mathbf{n}$ and energy $\mathbf{F} \cdot \mathbf{n}$ be continuous across the surface. Here \mathbf{T} is the total stress [i.e., the quantity inside the divergence in Eq. (19.12)], and \mathbf{F} is the total energy flux [i.e., the quantity inside the divergence in Eq. (19.16)]; see Eqs. (17.29)–(17.31) and associated discussion. The normal and tangential components of $[\mathbf{T} \cdot \mathbf{n}] = 0$ read

$$\left[P + \rho(v_n - v_{sn})^2 + \frac{B_t^2}{2\mu_0} \right] = 0, \quad (19.19f)$$

dynamical junction conditions

$$\left[\rho(v_n - v_{sn})(\mathbf{v}_t - \mathbf{v}_{st}) - \frac{B_n \mathbf{B}_t}{\mu_0} \right] = 0, \quad (19.19g)$$

where we have omitted the gravitational stress, since it will always be continuous in situations studied in this chapter (no surface layers of mass). Similarly, continuity of the energy flux $[\mathbf{F} \cdot \mathbf{n}] = 0$ reads

$$\left[\left(\frac{1}{2}v^2 + h \right) \rho(v_n - v_{sn}) + \frac{\mathbf{n} \cdot [(\mathbf{E} + \mathbf{v}_s \times \mathbf{B}) \times \mathbf{B}]}{\mu_0} \right] = 0. \quad (19.19h)$$

When the interface has plasma on one side and a vacuum magnetic field on the other, as in devices for magnetic confinement of plasmas (Sec. 19.3), the vacuum electromagnetic field, like that in the plasma, has small time derivatives: $\partial/\partial t \sim v\partial/\partial x^j$. As a result, the vacuum displacement current $\epsilon_0\partial\mathbf{E}/\partial t$ is very small, and the vacuum Maxwell equations reduce to the same form as those in the MHD plasma but with ρ_e and \mathbf{j} zero. As a result, the boundary conditions at the vacuum-plasma interface (Ex. 19.2) are those discussed above [Eqs. (19.19)], but with ρ and P vanishing on the vacuum side.

Exercise 19.2 Example and Derivation: Perfect MHD Boundary Conditions at a Fluid-Vacuum Interface

When analyzing the stability of configurations for magnetic confinement of a plasma (Sec. 19.5), one needs boundary conditions at the plasma-vacuum interface for the special case of perfect MHD (electrical conductivity idealized as arbitrarily large).

EXERCISES

Denote by a tilde ($\tilde{\mathbf{B}}$ and $\tilde{\mathbf{E}}$) the magnetic and electric fields in the vacuum, and reserve non-tilde symbols for quantities on the plasma side of the interface.

- (a) Show that the normal-force boundary condition (19.19f) reduces to an equation for the vacuum region's tangential magnetic field:

$$\frac{\tilde{B}_t^2}{2\mu_0} = P + \frac{B_t^2}{2\mu_0}. \quad (19.20a)$$

- (b) By combining Eqs. (19.19c) and (19.19g) and noting that $v_n - v_{sn}$ must vanish (why?), and assuming that the magnetic confinement entails surface currents on the interface, show that the normal component of the magnetic field must vanish on both sides of the interface:

$$\tilde{B}_n = B_n = 0. \quad (19.20b)$$

- (c) When analyzing energy flow across the interface, it is necessary to know the tangential electric field. On the plasma side $\tilde{\mathbf{E}}_t$ is a secondary quantity fixed by projecting tangentially the relation $\mathbf{E} + \mathbf{v} \times \mathbf{B} = 0$. On the vacuum side it is fixed by the boundary condition (19.19e). By combining these two relations, show that

$$\tilde{\mathbf{E}}_t + \mathbf{v}_{sn} \times \tilde{\mathbf{B}}_t = 0. \quad (19.20c)$$

Exercise 19.3 *Problem: Diffusion of Magnetic Field*

Consider an infinitely long cylinder of plasma with constant electric conductivity, surrounded by vacuum. Assume that the cylinder initially is magnetized uniformly parallel to its length, and assume that the field decays quickly enough that the plasma's inertia keeps it from moving much during the decay (so $\mathbf{v} \simeq 0$).

- (a) Show that the reduction of magnetic energy as the field decays is compensated by the Ohmic heating of the plasma plus energy lost to outgoing electromagnetic waves (which will be negligible if the decay is slow).
- (b) Compute the approximate magnetic profile after the field has decayed to a small fraction of its original value. Your answer should be expressible in terms of a Bessel function.

Exercise 19.4 *Example: Shock with Transverse Magnetic Field*

Consider a normal shock wave (\mathbf{v} perpendicular to the shock front), in which the magnetic field is parallel to the shock front, analyzed in the shock front's rest frame.

- (a) Show that the junction conditions across the shock are the vanishing of all the following quantities:

$$[\rho v] = [P + \rho v^2 + B^2/(2\mu_0)] = [h + v^2/2 + B^2/(\mu_0\rho)] = [vB] = 0. \quad (19.21)$$

- (b) Specialize to a fluid with equation of state $P \propto \rho^\gamma$. Show that these junction conditions predict no compression, $[\rho] = 0$, if the upstream velocity is $v_1 = C_f \equiv \sqrt{(B_1^2/\mu_0 + \gamma P_1)/\rho_1}$. For v_1 greater than this C_f , the fluid gets compressed.

- (c) Explain why the result in part (b) means that the speed of sound perpendicular to the magnetic field must be C_f . As we shall see in Sec. 19.7.2, this indeed is the case: C_f is the speed [Eq. (19.77)] of a *fast magnetosonic wave*, the only kind of sound wave that can propagate perpendicular to \mathbf{B} .

Exercise 19.5 *Problem: Earth's Bow Shock*

The solar wind is a supersonic, hydromagnetic flow of plasma originating in the solar corona. At the radius of Earth's orbit, the wind's density is $\rho \sim 6 \times 10^{-21} \text{ kg m}^{-3}$, its velocity is $v \sim 400 \text{ km s}^{-1}$, its temperature is $T \sim 10^5 \text{ K}$, and its magnetic field strength is $B \sim 1 \text{ nT}$.

- (a) By balancing the wind's momentum flux with the magnetic pressure exerted by Earth's dipole magnetic field, estimate the radius above Earth at which the solar wind passes through a bow shock (Fig. 17.2).
- (b) Consider a strong perpendicular shock at which the magnetic field is parallel to the shock front. Show that the magnetic field strength will increase by the same ratio as the density, when crossing the shock front. Do you expect the compression to increase or decrease as the strength of the field is increased, keeping all of the other flow variables constant?

19.2.4 Magnetic Field and Vorticity

19.2.4

We have already remarked on how the magnetic field and the vorticity are both axial vectors that can be written as the curl of a polar vector and that they satisfy similar transport equations. It is not surprising that they are physically intimately related. To explore this relationship in full detail would take us beyond the scope of this book. However, we can illustrate their interaction by showing how they can create each other. In brief: vorticity can twist a magnetic field, amplifying it; and an already twisted field, trying to untwist itself, can create vorticity.

vorticity-magnetic-field interactions

First, consider a simple vortex through which passes a uniform magnetic field (Fig. 19.2a). If the magnetic Reynolds number is large enough, then the magnetic field is carried with the flow and is wound up like spaghetti on the end of a fork (Fig. 19.2b, continued for a longer time). This process increases the magnetic energy in the vortex, though not the mean flux of the magnetic field. This amplification continues until either the field gradient is large enough that the field decays through Ohmic dissipation, or the field strength is large enough to react back on the flow and stop it from spinning.

Second, consider an irrotational flow containing a twisted magnetic field (Fig. 19.5a). Provided that the magnetic Reynolds number is sufficiently large, the magnetic stress, attempting to untwist the field, will act on the flow and induce vorticity (Fig. 19.5b). We can describe this formally by taking the curl of the equation

FIGURE 19.5 (a) A twisted magnetic field is frozen in an irrotational flow. (b) The field tries to untwist and in the process creates vorticity.

of motion (19.10). Assuming, for simplicity, that the density ρ is constant and the electric conductivity is infinite, we obtain

$$\frac{\partial \boldsymbol{\omega}}{\partial t} - \nabla \times (\mathbf{v} \times \boldsymbol{\omega}) = \frac{\nabla \times [(\nabla \times \mathbf{B}) \times \mathbf{B}]}{\mu_0 \rho}. \quad (19.22)$$

The term on the right-hand side of this equation changes the number of vortex lines threading the fluid, just like the $-\nabla P \times \nabla \rho / \rho^2$ term on the right-hand side of Eq. (14.3). However, because the divergence of the vorticity is zero, any fresh vortex lines that are made must be created as continuous curves that grow out of points or lines where the vorticity vanishes.

19.3 Magnetostatic Equilibria

19.3.1

19.3.1 Controlled Thermonuclear Fusion

GLOBAL POWER DEMAND

We start this section with an oversimplified discussion of the underlying problem. Earth's population has quadrupled over the past century to its present (2016) value of 7.4 billion and is still rising. We consume ~ 16 TW of power more or less equally for manufacture, transportation, and domestic use. The power is derived from oil (~ 5 TW), coal (~ 4 TW), gas (~ 4 TW), nuclear (fission) reactors (~ 1 TW), hydroelectric turbines (~ 1 TW), and alternative sources, such as solar, wind, wave, and biomass (~ 1 TW). The average power consumption is ~ 2 kW per person, with Canada and the United States in the lead, consuming ~ 10 kW per person. Despite conservation efforts, the demand for energy still appears to be rising.

Meanwhile, the burning of coal, oil, and gas produces carbon dioxide at a rate of $\sim 1 \text{ Gg s}^{-1}$, about 10% of the total transfer rate in Earth's biomass-atmosphere-ocean *carbon cycle*. This disturbance of the carbon-cycle equilibrium has led to an increase in the atmospheric concentration of carbon dioxide by about a third over the past century and it is currently growing at an average rate of about a half percent per year. There is strong evidence to link this increase in carbon dioxide and other greenhouse gases to climate change, as exemplified by an increase in the globally averaged mean temperature of ~ 1 K over the past century. Given the long time constants associated with the three components of the carbon cycle, future projections of climate change

motivation for controlled fusion program

are alarming. These considerations strongly motivate the rapid deployment of low-carbon sources of power—renewables and nuclear—and conservation.

THERMONUCLEAR FUSION

For more than 60 years, plasma physicists have striven to address this problem by releasing nuclear energy in a controlled, peaceful manner through confining plasma at a temperature in excess of 100 million degrees using strong magnetic fields. In the most widely studied scheme, deuterium and tritium combine according to the reaction

d, t fusion reaction

The energy release is equivalent to $\sim 400 \text{ TJ kg}^{-1}$. The fast neutrons can be absorbed in a surrounding blanket of lithium, and the heat can then be used to drive a generator.

PLASMA CONFINEMENT

At first this task seemed quite simple. However, it eventually became clear that it is very difficult to confine hot plasma with a magnetic field, because most confinement geometries are unstable. In this book we restrict our attention to a few simple confinement devices, emphasizing the one that is the basis of most modern efforts, the *tokamak*.¹ In this section, we treat equilibrium configurations; in Sec. 19.5, we consider their stability.

In our discussions of both equilibrium and stability, we treat the plasma as a magnetized fluid in the MHD approximation. At first sight, treating the plasma as a fluid might seem rather unrealistic, because we are dealing with a dilute gas of ions and electrons that undergo infrequent Coulomb collisions. However, as we discuss in Sec. 20.5.2 and justify in Chaps. 22 and 23, collective effects produce a sufficiently high effective collision frequency to make the plasma behave like a fluid, so MHD is usually a good approximation for describing these equilibria and their rather slow temporal evolution.

Let us examine some numbers that characterize the regime in which a successful controlled-fusion device must operate.

PLASMA PRESSURE

The ratio of plasma pressure to magnetic pressure

$$\beta \equiv \frac{P}{B^2/(2\mu_0)} \quad (19.24)$$

pressure ratio β for controlled fusion

plays a key role. For the magnetic field to have any chance of confining the plasma, its pressure must exceed that of the plasma (i.e., β must be less than one). The most successful designs achieve $\beta \sim 0.2$. The largest field strengths that can be safely

1. Originally proposed in the Soviet Union by Andrei Sakharov and Igor Tamm in 1950. The word is a Russian abbreviation for “toroidal magnetic field.”

maximum gas pressure for magnetic confinement

sustained in the laboratory are $B \sim 10 \text{ T} = 100 \text{ kG}$, so $\beta \lesssim 0.2$ limits the gas pressure to $P \lesssim 10^7 \text{ Pa} \sim 100 \text{ atmospheres}$.

LAWSON CRITERION

Plasma fusion can only be economically feasible if more power is released by nuclear reactions than is lost to radiative cooling. Both heating and cooling are proportional to the square of the number density of hydrogen ions, n^2 . However, while the radiative cooling rate increases comparatively slowly with temperature, the nuclear reaction rate increases very rapidly. (This is because, as the mean energy of the ions increases, the number of ions in the Maxwellian tail of the distribution function that are energetic enough to penetrate the Coulomb barrier increases exponentially.) Thus for the rate of heat production to greatly exceed the rate of cooling, the temperature need only be modestly higher than that required for the rates to be equal—which is a minimum temperature essentially fixed by atomic and nuclear physics. In the case of a d-t plasma, this is $T_{\min} \sim 10^8 \text{ K}$. The maximum hydrogen density that can be confined is therefore $n_{\max} = P/(2k_B T_{\min}) \sim 3 \times 10^{21} \text{ m}^{-3}$. (The factor 2 comes from the electrons, which produce the same pressure as the ions.)

minimum temperature for fusion and maximum density for confinement

Now, if a volume V of plasma is confined at a given number density n and temperature T_{\min} for a time τ , then the amount of nuclear energy generated will be proportional to $n^2 V \tau$, while the energy to heat the plasma up to T_{\min} is $\propto nV$. Therefore, there is a minimum value of the product $n\tau$ that must be attained before net energy is produced. This condition is known as the *Lawson criterion*. Numerically, the plasma must be confined for

Lawson criterion for net energy production in controlled fusion

$$\tau \sim (n/10^{20} \text{ m}^{-3})^{-1} \text{ s}, \tag{19.25}$$

typically $\sim 30 \text{ ms}$. The sound speed at these temperatures is $\sim 1 \times 10^6 \text{ m s}^{-1}$, and so an unconfined plasma would hit the few-meter-sized walls of the vessel in which it is held in a few μs . Therefore, the magnetic confinement must be effective for typically 10^4 – 10^5 dynamical timescales (sound-crossing times). It is necessary that the plasma be confined and confined well if we want to build a viable fusion reactor.

19.3.2

19.3.2 Z-Pinch

Z-pinch configuration for plasma confinement

Before discussing plasma confinement by tokamaks, we describe a simpler confinement geometry known as the *Z-pinch* and often called the Bennett pinch (Fig. 19.6a). In a Z-pinch, electric current is induced to flow along a cylinder of plasma. This current creates a toroidal magnetic field whose tension prevents the plasma from expanding radially, much like hoops on a barrel prevent it from exploding. Let us assume that the cylinder has a radius R and is surrounded by vacuum.

Now, in static equilibrium we must balance the plasma pressure gradient by a Lorentz force:

$$\nabla P = \mathbf{j} \times \mathbf{B}. \tag{19.26}$$

FIGURE 19.6 (a) The Z-pinch. (b) The Θ -pinch. (c) The tokamak.

(Gravitational forces can safely be ignored.) Equation (19.26) implies immediately that $\mathbf{B} \cdot \nabla P = \mathbf{j} \cdot \nabla P = 0$, so both the magnetic field and the current density lie on constant pressure (or *isobaric*) surfaces. An equivalent version of the force-balance equation (19.26), obtained using Eq. (19.15) and Fig. 19.3, is

$$\frac{d}{d\varpi} \left(P + \frac{B^2}{2\mu_0} \right) = -\frac{B^2}{\mu_0\varpi}, \quad (19.27)$$

where ϖ is the radial cylindrical coordinate. Equation (19.27) exhibits the balance between the gradient of plasma and magnetic pressure on the left, and the magnetic tension (the “hoop force”) on the right. Treating it as a differential equation for B^2 and integrating it, assuming that P falls to zero at the surface of the column, we obtain for the surface magnetic field

$$B^2(R) = \frac{4\mu_0}{R^2} \int_0^R P\varpi d\varpi. \quad (19.28)$$

We can reexpress the surface toroidal field in terms of the total current flowing along the plasma as $B(R) = \mu_0 I / (2\pi R)$ (Ampère’s law); and assuming that the plasma is primarily hydrogen (so its ion density n and electron density are equal), we can write the pressure as $P = 2nk_B T$. Inserting these expressions into Eq. (19.28), integrating, and solving for the current, we obtain

$$I = \left(\frac{16\pi N k_B T}{\mu_0} \right)^{1/2}, \quad (19.29)$$

where N is the number of ions per unit length. For a column of plasma with diameter $2R \sim 1$ m, hydrogen density $n \sim 10^{20} \text{ m}^{-3}$, and temperature $T \sim 10^8$ K, Eq. (19.29) indicates that currents ~ 1 MA are required for confinement.

The most promising Z-pinch experiments to date have been carried out at Sandia National Laboratories in Albuquerque, New Mexico. The experimenters have impulsively compressed a column of gas into a surprisingly stable cylinder of diameter ~ 1 mm for a time ~ 100 ns, using a current of ~ 30 MA from giant capacitor banks. A transient field of ~ 1 kT was created.

19.3.3

19.3.3 \ominus -Pinch

\ominus -pinch configuration for plasma confinement

There is a complementary equilibrium for a cylindrical plasma, in which the magnetic field lies parallel to the axis and the current density encircles the cylinder (Fig. 19.6b). This configuration is called the \ominus -pinch. It is usually established by making a cylindrical metal tube with a small gap, so that current can flow around it as shown in the figure. The tube is filled with cold plasma, and then the current is turned on quickly, producing a quickly growing longitudinal field in the tube (as in a solenoid). Since the plasma is highly conducting, the field lines cannot penetrate the plasma column but instead exert a pressure on its surface, causing it to shrink radially and rapidly. The plasma heats up due to both the radial work done on it and Ohmic heating. Equilibrium is established when the plasma’s pressure P balances the magnetic pressure $B^2/(2\mu_0)$ at the plasma’s surface.

Despite early promise, interest in Θ -pinches has waned, and mirror machines (Sec. 19.5.3) have become more popular.

19.3.4 Tokamak

One of the problems with the Θ - and Z-pinches (and we shall find other problems below!) is that they have ends through which plasma can escape. This is readily addressed by replacing the cylinder with a torus. The most stable geometry, called the *tokamak*, combines features of both Z- and Θ -pinches; see Fig. 19.6c. If we introduce spherical coordinates (r, θ, ϕ) , then magnetic field lines and currents that lie in an r - θ plane (orthogonal to \mathbf{e}_ϕ) are called *poloidal*, whereas their ϕ components are called *toroidal*. In a tokamak, the toroidal magnetic field is created by external poloidal current windings. However, the poloidal field is mostly created as a consequence of toroidal current induced to flow in the plasma torus. The resulting net field lines wrap around the plasma torus in a helical manner, defining a magnetic surface on which the pressure is constant. The number of poloidal transits around the torus during one toroidal transit is denoted $\iota/(2\pi)$; ι is called the *rotational transform* and is a property of the magnetic surface on which the field line resides. If $\iota/(2\pi)$ is a rational number, then the field line will close after a finite number of circuits. However, in general, $\iota/(2\pi)$ will not be rational, so a single field line will cover the whole magnetic surface ergodically. This allows the plasma to spread over the whole surface rapidly. The rotational transform is a measure of the toroidal current flowing inside the magnetic surface and of course increases as we move out from the innermost magnetic surface, while the pressure decreases.

The best performers to date (2016) include the MIT Alcator C-Mod ($n \sim 2 \times 10^{20} \text{ m}^{-3}$, $T \sim 35 \text{ MK}$, $B \sim 6 \text{ T}$, $\tau \sim 2 \text{ s}$), and the larger Joint European Torus or JET (Keilhacker and the JET team, 1998). JET generated 16 MW of nuclear power with $\tau \sim 1 \text{ s}$ by burning d-t fuel, but its input power was $\sim 25 \text{ MW}$ and so, despite being a major step forward, JET fell short of achieving “break even.”

The largest device, currently under construction, is the International Thermonuclear Experimental Reactor (ITER) (whose acronym means “journey” in Latin). ITER is a tokamak-based experimental fusion reactor being constructed in France by a large international consortium (see <http://www.iter.org/>). The outer diameter of the device is $\sim 20 \text{ m}$, and the maximum magnetic field produced by its superconducting magnets will be $\sim 14 \text{ T}$. Its goal is to use d-t fuel to convert an input power of $\sim 50 \text{ MW}$ into an output power of $\sim 500 \text{ MW}$, sustained for $\sim 3,000 \text{ s}$.² However, many engineering, managerial, financial, and political challenges remain to be addressed before mass production of economically viable, durable, and safe fusion reactors can begin.

2. Note that it would require of order 10,000 facilities with ITER's projected peak power operating continuously to supply, say, one-third of the current global power demand.

tokamak configuration for plasma confinement

JET

ITER

Exercise 19.6 *Problem: Strength of Magnetic Field in a Magnetic Confinement Device*

The currents that are sources for strong magnetic fields have to be held in place by solid conductors. Estimate the limiting field that can be sustained using normal construction materials.

Exercise 19.7 *Problem: Force-Free Equilibria*

In an equilibrium state of a very low- β plasma, the plasma's pressure force density $-\nabla P$ is ignorably small, and so the Lorentz force density $\mathbf{j} \times \mathbf{B}$ must vanish [Eq. (19.10)]. Such a plasma is said to be "force-free." As a result, the current density is parallel to the magnetic field, so $\nabla \times \mathbf{B} = \alpha \mathbf{B}$. Show that α must be constant along a field line, and that if the field lines eventually travel everywhere, then α must be constant everywhere.

Exercise 19.8 *Example and Challenge: Spheromak*

Another magnetic confinement device which brings out some important principles is the *spheromak*. Spheromaks can be made in the laboratory (Bellan, 2000) and have also been proposed as the basis of a fusion reactor.³ It is simplest to consider a spheromak in the limit when the plasma pressure is ignorable (low β) and the magnetic field distribution is force-free (Ex. 19.7). We just describe the simplest example of this regime.

- (a) As in the previous exercise, assume that α is constant everywhere and, without loss of generality, set it equal to unity. Show that the magnetic field—and also the current density and vector potential, adopting the Coulomb gauge—satisfy the vector Helmholtz equation: $\nabla^2 \mathbf{B} + \alpha^2 \mathbf{B} = 0$.
- (b) Introduce a scalar χ such that $\mathbf{B} = \alpha \mathbf{r} \times \nabla \chi + \nabla \times (\mathbf{r} \times \nabla \chi)$, with \mathbf{r} the radial vector pointing out of the spheromak's center, and show that χ satisfies the scalar Helmholtz equation: $\nabla^2 \chi + \alpha^2 \chi = 0$.
- (c) The Helmholtz equation in part (b) separates in spherical coordinates (r, θ, ϕ) . Show that it has a nonsingular solution $\chi = j_l(\alpha r) Y_{lm}(\theta, \phi)$, where $j_l(\alpha r)$ is a spherical Bessel function, and $Y_{lm}(\theta, \phi)$ is a spherical harmonic. Evaluate this for the simplest example, the spheromak, with $l = 2$ and $m = 0$.
- (d) Calculate expressions for the associated magnetic field in part (c) and either sketch or plot it.
- (e) Show that the magnetic field's radial component vanishes on the surface of a sphere of radius equal to the first zero of j_l . Hence explain why a spheromak may be confined in a conducting sphere or, alternatively, by a current-free field that is uniform at large distance.

3. Spheromak configurations of magnetic fields have even been associated with ball lightning!

Exercise 19.9 *Problem: Magnetic Helicity*

- (a) A physical quantity that turns out to be useful in describing the evolution of magnetic fields in confinement devices is *magnetic helicity*. This is defined by $H = \int dV \mathbf{A} \cdot \mathbf{B}$, where \mathbf{A} is the vector potential, and the integral should be performed over all the space visited by the field lines to remove a dependence on the electromagnetic gauge. Compute the partial derivative of \mathbf{A} and \mathbf{B} with respect to time to show that H is conserved if $\mathbf{E} \cdot \mathbf{B} = 0$.
- (b) The helicity H primarily measures the topological linkage of the magnetic field lines. Therefore, it should not be a surprise that H turns out to be relatively well-preserved, even when the plasma is losing energy through resistivity and radiation. To discuss magnetic helicity properly would take us too far into the domain of classical electromagnetic theory, but some indication of its value follows from computing it for the case of two rings of magnetic field containing fluxes Φ_1 and Φ_2 . Start with the rings quite separate, and show that $H = 0$. Then allow the rings to be linked while not sharing any magnetic field lines. Show that now $H = 2\Phi_1\Phi_2$ and that $dH/dt = -2 \int dV \mathbf{E} \cdot \mathbf{B}$.⁴

19.4 Hydromagnetic Flows

We now introduce fluid motions into our applications of magnetohydrodynamics. Specifically, we explore a simple class of *stationary hydromagnetic flows*: the flow of an electrically conducting fluid along a duct of constant cross section perpendicular to a uniform magnetic field B_0 (see Fig. 19.7). This is sometimes known as *Hartmann flow*. The duct has two insulating walls (top and bottom, as shown in the figure), separated by a distance $2a$ that is much smaller than the separation of short side walls, which are electrically conducting.

To relate Hartmann flow to magnetic-free Poiseuille flow (viscous, laminar flow between plates; Ex. 13.18), we reinstate the viscous force in the equation of motion. For simplicity we assume that the time-independent flow ($\partial \mathbf{v} / \partial t = 0$) has traveled sufficiently far down the duct (x direction) to have reached a z -independent form, so $\mathbf{v} \cdot \nabla \mathbf{v} = 0$ and $\mathbf{v} = \mathbf{v}(y, z)$. We also assume that gravitational forces are unimportant. Then the flow's equation of motion takes the form

$$\nabla P = \mathbf{j} \times \mathbf{B} + \eta \nabla^2 \mathbf{v}, \quad (19.30)$$

where $\eta = \rho \nu$ is the coefficient of dynamical viscosity. The magnetic (Lorentz) force $\mathbf{j} \times \mathbf{B}$ alters the balance between the Poiseuille flow's viscous force $\eta \nabla^2 \mathbf{v}$ and the

4. For further discussion, see Bellan (2000).

19.4

Hartmann flow and its applications

FIGURE 19.7 Hartmann flow with average speed v along a duct of thickness $2a$, perpendicular to an applied magnetic field of strength B_0 . The short side walls are conducting and the two long horizontal walls are electrically insulating.

four versions of Hartmann flow

pressure gradient ∇P . The details of that altered balance and the resulting magnetic-influenced flow depend on how the walls are connected electrically. Let us consider four possibilities chosen to bring out the essential physics.

ELECTROMAGNETIC BRAKE

We short circuit the electrodes, so a current \mathbf{j} can flow (Fig. 19.8a). The magnetic field lines are partially dragged by the fluid, bending them (as embodied in $\nabla \times \mathbf{B} = \mu_0 \mathbf{j}$), so they can exert a decelerating tension force $\mathbf{j} \times \mathbf{B} = (\nabla \times \mathbf{B}) \times \mathbf{B} / \mu_0 = \mathbf{B} \cdot \nabla \mathbf{B} / \mu_0$ on the flow (Fig. 19.3b). This configuration is an electromagnetic brake. The pressure gradient, which is trying to accelerate the fluid, is balanced by the magnetic tension and viscosity. The work being done (per unit volume) by the pressure gradient, $\mathbf{v} \cdot (-\nabla P)$, is converted into heat through viscous and Ohmic dissipation.

MHD POWER GENERATOR

The MHD power generator is similar to the electromagnetic brake except that an external load is added to the circuit (Fig. 19.8b). Useful power can be extracted from the flow. Variants of this configuration were developed in the 1970s–1990s in many countries, but they are currently not seen to be economically competitive with other power-generation methods.

FLOW METER

When the electrodes in a flow meter are on an open circuit, the induced electric field produces a measurable potential difference across the duct (Fig. 19.8c). This voltage will increase monotonically with the rate of flow of fluid through the duct and therefore can provide a measurement of the flow.

ELECTROMAGNETIC PUMP

Finally, we can attach a battery to the electrodes and allow a current to flow (Figs. 19.7 and 19.8d). This produces a Lorentz force which either accelerates or decelerates the

FIGURE 19.8 Four variations on Hartmann flow: (a) Electromagnetic brake. (b) MHD power generator. (c) Flow meter. (d) Electromagnetic pump.

flow, depending on the direction of the magnetic field. This method can be used to pump liquid sodium coolant around a nuclear reactor. It has also been proposed as a means of spacecraft propulsion in interplanetary space.

We consider in more detail two limiting cases of the electromagnetic pump. When there is a constant pressure gradient $Q = -dP/dx$ but no magnetic field, a flow with modest Reynolds number will be approximately laminar with velocity profile (Ex. 13.18):

$$v_x(z) = \frac{Qa^2}{2\eta} \left[1 - \left(\frac{z}{a} \right)^2 \right], \quad (19.31)$$

where a is the half-width of the channel. This flow is the 1-dimensional version of the Poiseuille flow in a pipe, such as a blood artery, which we studied in Sec. 13.7.6 [cf. Eq. (13.82a)]. Now suppose that uniform electric and magnetic fields E_0 and B_0 are applied along the \mathbf{e}_y and \mathbf{e}_z directions, respectively (Fig. 19.7). The resulting magnetic force $\mathbf{j} \times \mathbf{B}$ can either reinforce or oppose the fluid's motion. When the applied magnetic field is small, $B_0 \ll E_0/v_x$, the effect of the magnetic force will be similar to that of the pressure gradient, and Eq. (19.31) must be modified by replacing $Q \equiv -dP/dx$ by $-dP/dx + j_y B_z = -dP/dx + \kappa_e E_0 B_0$. [Here $j_y = \kappa_e (E_y - v_x B_z) \simeq \kappa_e E_0$.]

If the strength of the magnetic field is increased sufficiently, then the magnetic force will dominate the viscous force, except in thin boundary layers near the walls. Outside the boundary layers, in the bulk of the flow, the velocity will adjust so that the electric field vanishes in the rest frame of the fluid (i.e., $v_x = E_0/B_0$). In the boundary layers v_x drops sharply from E_0/B_0 to zero at the walls, and correspondingly, a strong viscous force $\eta \nabla^2 \mathbf{v}$ develops. Since the pressure gradient ∇P must be essentially the same in the boundary layer as in the adjacent bulk flow and thus cannot balance this

FIGURE 19.9 Velocity profiles [Eq. (19.35)] for flow in an electromagnetic pump of width $2a$ with small and large Hartmann number scaled to the velocity at the center of the channel. The dashed curve shows the almost parabolic profile for $Ha = 0.1$ [Eq. (19.31)]. The solid curve shows the almost flat-topped profile for $Ha = 10$.

large viscous force, it must be balanced instead by the magnetic force: $\mathbf{j} \times \mathbf{B} + \eta \nabla^2 \mathbf{v} = 0$ [Eq. (19.30)], with $\mathbf{j} = \kappa_e(\mathbf{E} + \mathbf{v} \times \mathbf{B}) \sim \kappa_e v_x B_0 \mathbf{e}_y$. We thereby see that the thickness of the boundary layer is given by

$$\delta_H \sim \left(\frac{\eta}{\kappa_e B_0^2} \right)^{1/2}. \quad (19.32)$$

This suggests a new dimensionless number to characterize the flow,

$$\boxed{Ha = \frac{a}{\delta_H} = B_0 a \left(\frac{\kappa_e}{\eta} \right)^{1/2}}, \quad (19.33)$$

Hartmann number

called the *Hartmann number*. The square of the Hartmann number, Ha^2 , is essentially the ratio of the magnetic force, $|\mathbf{j} \times \mathbf{B}| \sim \kappa_e v_x B_0^2$, to the viscous force, $\sim \eta v_x / a^2$, assuming a lengthscale a rather than δ_H for variations of the velocity.

The detailed velocity profile $v_x(z)$ away from the vertical side walls is computed in Ex. 19.10 and is shown for low and high Hartmann numbers in Fig. 19.9. Notice that at low Hartmann numbers, the plotted profile is nearly parabolic as expected, and at high Hartmann numbers it consists of boundary layers at $z \sim -a$ and $z \sim a$, and a uniform flow in between.

In Exs. 19.11 and 19.12 we explore two important astrophysical examples of hydro-magnetic flow: the magnetosphere of a rotating, magnetized star or other body, and the solar wind.

EXERCISES

Exercise 19.10 Example: Hartmann Flow

Compute the velocity profile of a conducting fluid in a duct of thickness $2a$ perpendicular to externally generated, uniform electric and magnetic fields ($E_0 \mathbf{e}_y$,

and $B_0\mathbf{e}_z$) as shown in Fig. 19.7. Away from the vertical sides of the duct, the velocity v_x is just a function of y , and the pressure can be written in the form $P = -Qx + p(z)$, where Q is the longitudinal pressure gradient.

(a) Show that the velocity field satisfies the differential equation

$$\frac{d^2v_x}{dz^2} - \frac{\kappa_e B_0^2}{\eta} v_x = -\frac{(Q + \kappa_e B_0 E_0)}{\eta}. \quad (19.34)$$

(b) Impose suitable boundary conditions at the bottom and top walls of the channel, and solve this differential equation to obtain the following velocity field:

$$v_x = \frac{Q + \kappa_e B_0 E_0}{\kappa_e B_0^2} \left[1 - \frac{\cosh(\text{Ha } z/a)}{\cosh(\text{Ha})} \right], \quad (19.35)$$

where Ha is the Hartmann number (see Fig. 19.9).

Exercise 19.11 ***Example: Rotating Magnetospheres*

Many self-gravitating cosmic bodies are both spinning and magnetized. Examples are Earth, the Sun, black holes surrounded by highly conducting accretion disks (which hold a magnetic field on the hole), neutron stars (pulsars), and magnetic white dwarfs. As a consequence of the magnetic field's spin-induced motion, large electric fields are produced outside the rotating body. The divergence of these electric fields must be balanced by free electric charge, which implies that the region around the body cannot be a vacuum. It is usually filled with plasma and is called a *magnetosphere*. MHD provides a convenient formalism for describing the structure of this magnetosphere. Magnetospheres are found around most planets and stars. Magnetospheres surrounding neutron stars and black holes are believed to be responsible for the emissions from pulsars and quasars.

As a model of a rotating magnetosphere, consider a magnetized and infinitely conducting star, spinning with angular frequency Ω_* . Suppose that the magnetic field is stationary and axisymmetric with respect to the spin axis and that the magnetosphere, like the star, is perfectly conducting.

(a) Show that the azimuthal component E_ϕ of the magnetospheric electric field must vanish if the magnetic field is to be stationary. Hence show that there exists a function $\mathbf{\Omega}(\mathbf{r})$ that must be parallel to $\mathbf{\Omega}_*$ and must satisfy

$$\mathbf{E} = -(\mathbf{\Omega} \times \mathbf{r}) \times \mathbf{B}. \quad (19.36)$$

Show that if the motion of the magnetosphere's conducting fluid is simply a rotation, then its angular velocity must be $\mathbf{\Omega}$.

(b) Use the induction equation (magnetic-field transport law) to show that

$$(\mathbf{B} \cdot \nabla)\mathbf{\Omega} = 0. \quad (19.37)$$

- (c) Use the boundary condition at the surface of the star to show that the magnetosphere corotates with the star (i.e., $\boldsymbol{\Omega} = \boldsymbol{\Omega}_*$). This is known as *Ferraro's law of isorotation*.

Exercise 19.12 *Example: Solar Wind*

The solar wind is a magnetized outflow of plasma that emerges from the solar corona. We make a simple model of it by generalizing the results from the previous exercise that emphasize its hydromagnetic features while ignoring gravity and thermal pressure (which are also important in practice). We consider stationary, axisymmetric motion in the equatorial plane, and idealize the magnetic field as having the form $B_r(r)$, $B_\phi(r)$. (If this were true at all latitudes, the Sun would have to contain magnetic monopoles!)

- (a) Use the results from the previous exercise plus the perfect MHD relation, $\mathbf{E} = -\mathbf{v} \times \mathbf{B}$, to argue that the velocity field can be written in the form

$$\mathbf{v} = \frac{\kappa \mathbf{B}}{\rho} + (\boldsymbol{\Omega} \times \mathbf{r}), \quad (19.38)$$

where κ and $\boldsymbol{\Omega}$ are constant along a field line. Interpret this relation kinematically.

- (b) Resolve the velocity and the magnetic field into radial and azimuthal components, v_r , v_ϕ , and B_r , B_ϕ , and show that $\rho v_r r^2$ and $B_r r^2$ are constant.
- (c) Use the induction equation to show that

$$\frac{v_r}{v_\phi - \Omega r} = \frac{B_r}{B_\phi}. \quad (19.39)$$

- (d) Use the equation of motion to show that the specific angular momentum, including both the mechanical and the magnetic contributions,

$$\Lambda = r v_\phi - \frac{r B_r B_\phi}{\mu_0 \rho v_r}, \quad (19.40)$$

is constant.

- (e) Combine Eqs. (19.39) and (19.40) to argue that

$$v_\phi = \frac{\Omega r [M_A^2 \Lambda / (\Omega r^2) - 1]}{M_A^2 - 1}, \quad (19.41)$$

where

$$M_A = \frac{v_r (\mu_0 \rho)^{1/2}}{B_r} \quad (19.42)$$

is the Alfvén Mach number [cf. Eq. (19.73)]. Show that the solar wind must pass through a critical point (Sec. 17.3.2) where its radial speed equals the Alfvén speed.

- (f) Suppose that the critical point in part (e) is located at 20 solar radii and that $v_r = 100 \text{ km s}^{-1}$, $v_\phi = 20 \text{ km s}^{-1}$, and $B_r = 400 \text{ nT}$ there. Calculate values for Λ , B_ϕ , ρ and use these to estimate the fraction of the solar mass and the solar

angular momentum that could have been carried off by the solar wind over its ~ 5 Gyr lifetime. Comment on your answer.

- (g) Suppose that there is no poloidal current density so that $B_\phi \propto r^{-1}$, and deduce values for the velocity and the magnetic field in the neighborhood of Earth where $r \sim 200$ solar radii. Sketch the magnetic field and the path of the solar wind as it flows from r_c to Earth.

The solar mass, radius and rotation period are $\sim 2 \times 10^{30}$ kg, $\sim 7 \times 10^8$ m, and ~ 25 d.

19.5 Stability of Magnetostatic Equilibria

19.5

Having used the MHD equation of motion to analyze some simple flows, we return to the problem of magnetic confinement and demonstrate a procedure to analyze the stability of the confinement's magnetostatic equilibria. We first perform a straightforward linear perturbation analysis about equilibrium, obtaining an eigenequation for the perturbation's oscillation frequencies ω . For sufficiently simple equilibria, this eigenequation can be solved analytically, but most equilibria are too complex for this approach, so the eigenequation must be solved numerically or by other approximation techniques. This is rather similar to the task one faces in attempting to solve the Schrödinger equation for multi-electron atoms. It will not be a surprise to learn that variational methods are especially practical and useful, and we develop a suitable formalism for them.

We develop the perturbation theory, eigenequation, and variational formalism in some detail not only because of their importance for the stability of magnetostatic equilibria, but also because essentially the same techniques (with different equations) are used in studying the stability of other equilibria. One example is the oscillations and stability of stars, in which the magnetic field is unimportant, while self-gravity is crucial [see, e.g., Shapiro and Teukolsky (1983, Chap. 6), and Sec. 16.2.4 of this book, on helioseismology]. Another example is the oscillations and stability of elastostatic equilibria, in which \mathbf{B} is absent but shear stresses are important (Secs. 12.3 and 12.4).

19.5.1 Linear Perturbation Theory

19.5.1

Consider a perfectly conducting, isentropic fluid at rest in equilibrium, with pressure gradients that balance magnetic forces—for example, the Z-pinch, Θ -pinch, and tokamak configurations of Fig. 19.6. For simplicity, we ignore gravity. (This is usually justified in laboratory situations.) The equation of equilibrium then reduces to

$$\nabla P = \mathbf{j} \times \mathbf{B} \quad (19.43)$$

[Eq. (19.10)].

equation of magnetostatic equilibrium without gravity

We now perturb slightly about our chosen equilibrium and ignore the (usually negligible) effects of viscosity and magnetic-field diffusion, so $\eta = \rho\nu \simeq 0$ and $\kappa_e \simeq \infty$. It is useful and conventional to describe the perturbations in terms of two different types of quantities: (i) The change in a quantity (e.g., the fluid density) moving with the fluid, which is called a *Lagrangian* perturbation and is denoted by the symbol Δ (e.g., the lagrangian density perturbation $\Delta\rho$). (ii) The change at a fixed location in

Lagrangian and Eulerian perturbations and how they are related

space, which is called an *Eulerian* perturbation and is denoted by the symbol δ (e.g., the Eulerian density perturbation $\delta\rho$). The fundamental variable used in the theory is the fluid's *Lagrangian displacement* $\Delta\mathbf{x} \equiv \boldsymbol{\xi}(\mathbf{x}, t)$ (i.e., the change in a fluid element's location). A fluid element whose location is \mathbf{x} in the unperturbed equilibrium is moved to location $\mathbf{x} + \boldsymbol{\xi}(\mathbf{x}, t)$ by the perturbations. From their definitions, one can see that the Lagrangian and Eulerian perturbations are related by

$$\Delta = \delta + \boldsymbol{\xi} \cdot \nabla \quad (\text{e.g., } \Delta\rho = \delta\rho + \boldsymbol{\xi} \cdot \nabla\rho). \quad (19.44)$$

Now consider the transport law for the magnetic field in the limit of infinite electrical conductivity, $\partial\mathbf{B}/\partial t = \nabla \times (\mathbf{v} \times \mathbf{B})$ [Eq. (19.6)]. To linear order, the fluid velocity is $\mathbf{v} = \partial\boldsymbol{\xi}/\partial t$. Inserting this into the transport law and setting the full magnetic field at fixed \mathbf{x} and t equal to the equilibrium field plus its Eulerian perturbation $\mathbf{B} \rightarrow \mathbf{B} + \delta\mathbf{B}$, we obtain $\partial\delta\mathbf{B}/\partial t = \nabla \times [(\partial\boldsymbol{\xi}/\partial t) \times (\mathbf{B} + \delta\mathbf{B})]$. Linearizing in the perturbation, and integrating in time, we obtain for the Eulerian perturbation of the magnetic field:

$$\delta\mathbf{B} = \nabla \times (\boldsymbol{\xi} \times \mathbf{B}). \quad (19.45a)$$

Since the current and the field are related, in general, by the linear equation $\mathbf{j} = \nabla \times \mathbf{B}/\mu_0$, their Eulerian perturbations are related in the same way:

$$\delta\mathbf{j} = \nabla \times \delta\mathbf{B}/\mu_0. \quad (19.45b)$$

In the equation of mass conservation, $\partial\rho/\partial t + \nabla \cdot (\rho\mathbf{v}) = 0$, we replace the density by its equilibrium value plus its Eulerian perturbation, $\rho \rightarrow \rho + \delta\rho$, and replace \mathbf{v} by $\partial\boldsymbol{\xi}/\partial t$. We then linearize in the perturbation to obtain

$$\delta\rho + \rho\nabla \cdot \boldsymbol{\xi} + \boldsymbol{\xi} \cdot \nabla\rho = 0. \quad (19.45c)$$

The Lagrangian density perturbation, obtained from this via Eq. (19.44), is

$$\Delta\rho = -\rho\nabla \cdot \boldsymbol{\xi}. \quad (19.45d)$$

We assume that, as it moves, the fluid gets compressed or expanded adiabatically (no Ohmic or viscous heating, or radiative cooling). Then the Lagrangian change of pressure ΔP in each fluid element (moving with the fluid) is related to the Lagrangian change of density by

$$\Delta P = \left(\frac{\partial P}{\partial \rho} \right)_s \Delta\rho = \frac{\gamma P}{\rho} \Delta\rho = -\gamma P \nabla \cdot \boldsymbol{\xi}, \quad (19.45e)$$

where γ is the fluid's adiabatic index (ratio of specific heats), which might or might not be independent of position in the equilibrium configuration. Correspondingly, the Eulerian perturbation of the pressure (perturbation at fixed location) is

$$\delta P = \Delta P - (\boldsymbol{\xi} \cdot \nabla)P = -\gamma P(\nabla \cdot \boldsymbol{\xi}) - (\boldsymbol{\xi} \cdot \nabla)P. \quad (19.45f)$$

This is the pressure perturbation that appears in the fluid's equation of motion.

By replacing $\mathbf{v} \rightarrow \partial \boldsymbol{\xi} / \partial t$, $P \rightarrow P + \delta P$, $\mathbf{B} \rightarrow \mathbf{B} + \delta \mathbf{B}$, and $\mathbf{j} \rightarrow \mathbf{j} + \delta \mathbf{j}$ in the fluid's equation of motion (19.10) and neglecting gravity, and by then linearizing in the perturbation, we obtain

$$\rho \frac{\partial^2 \boldsymbol{\xi}}{\partial t^2} = \mathbf{j} \times \delta \mathbf{B} + \delta \mathbf{j} \times \mathbf{B} - \nabla \delta P \equiv \hat{\mathbf{F}}[\boldsymbol{\xi}]. \quad (19.46)$$

dynamical equation for adiabatic perturbations of a magnetostatic equilibrium

Here $\hat{\mathbf{F}}$ is a real, linear differential operator, whose form one can deduce by substituting expressions (19.45a), (19.45b), and (19.45f) for $\delta \mathbf{B}$, $\delta \mathbf{j}$, and δP , and by substituting $\nabla \times \mathbf{B} / \mu_0$ for \mathbf{j} . Performing these substitutions and carefully rearranging the terms, we eventually convert the operator $\hat{\mathbf{F}}$ into the following form, expressed in slot-naming index notation:

$$\hat{F}_i[\boldsymbol{\xi}] = \left\{ \left[(\gamma - 1)P + \frac{B^2}{2\mu_0} \right] \zeta_{k;k} + \frac{B_j B_k}{\mu_0} \zeta_{j;k} \right\}_{;i} + \left[\left(P + \frac{B^2}{2\mu_0} \right) \zeta_{j;i} + \frac{B_j B_k}{\mu_0} \zeta_{i;k} + \frac{B_i B_j}{\mu_0} \zeta_{k;k} \right]_{;j}. \quad (19.47)$$

Honestly! Here the semicolons denote gradients (partial derivatives in Cartesian coordinates; connection coefficients (Sec. 11.8) are required in curvilinear coordinates).

We write the operator \hat{F}_i in the explicit form (19.47) because of its power for demonstrating that \hat{F}_i is self-adjoint (Hermitian, with real variables rather than complex): by introducing the Kronecker-delta components of the metric, $g_{ij} = \delta_{ij}$, we can easily rewrite Eq. (19.47) in the form

$$\hat{F}_i[\boldsymbol{\xi}] = (T_{ijkl} \zeta_{k;l})_{;j}, \quad (19.48)$$

where T_{ijkl} are the components of a fourth-rank tensor that is symmetric under interchange of its first and second pairs of indices: $T_{ijkl} = T_{klij}$.

Now, our magnetic-confinement equilibrium configuration (e.g., Fig. 19.6) typically consists of a plasma-filled interior region \mathcal{V} surrounded by a vacuum magnetic field (which in turn may be surrounded by a wall). Our MHD equations with force operator $\hat{\mathbf{F}}$ are valid only in the plasma region \mathcal{V} , and not in vacuum, where Maxwell's equations with small displacement current prevail. We use Eq. (19.48) to prove that $\hat{\mathbf{F}}$ is a self-adjoint operator when integrated over \mathcal{V} , with the appropriate boundary conditions at the vacuum interface.

Specifically, we contract a vector field $\boldsymbol{\zeta}$ into $\hat{\mathbf{F}}[\boldsymbol{\xi}]$, integrate over \mathcal{V} , and perform two integrations by parts to obtain

$$\begin{aligned} \int_{\mathcal{V}} \boldsymbol{\zeta} \cdot \mathbf{F}[\boldsymbol{\xi}] dV &= \int_{\mathcal{V}} \zeta_i (T_{ijkl} \zeta_{k;l})_{;j} dV = - \int_{\mathcal{V}} T_{ijkl} \zeta_{i;j} \zeta_{k;l} dV = \int_{\mathcal{V}} \zeta_i (T_{ijkl} \zeta_{k;l})_{;j} dV \\ &= \int_{\mathcal{V}} \boldsymbol{\xi} \cdot \mathbf{F}[\boldsymbol{\zeta}] dV. \end{aligned} \quad (19.49)$$

force operator $\hat{F}_i[\boldsymbol{\xi}]$ is self-adjoint

Here we have discarded the integrals of two divergences, which by Gauss's theorem can be expressed as surface integrals at the fluid-vacuum interface $\partial\mathcal{V}$. Those unwanted surface integrals vanish if ξ and ζ satisfy

$$T_{ijkl}\xi_{k;l}\zeta_in_j = 0, \quad \text{and} \quad T_{ijkl}\zeta_{k;l}\xi_in_j = 0, \quad (19.50)$$

with n_j the normal to the interface $\partial\mathcal{V}$.

boundary conditions for perturbations

Now, ξ and ζ are physical displacements of the MHD fluid, and as such, they must satisfy the appropriate boundary conditions at the boundary $\partial\mathcal{V}$ of the plasma region \mathcal{V} . In the simplest, idealized case, the conducting fluid would extend far beyond the region where the disturbances have appreciable amplitude, so $\xi = \zeta = 0$ at the distant boundary, and Eqs. (19.50) are satisfied. More reasonably, the fluid might butt up against rigid walls at $\partial\mathcal{V}$, where the normal components of ξ and ζ vanish, guaranteeing again that Eqs. (19.50) are satisfied. This configuration is fine for liquid mercury or sodium, but not for a hot plasma, which would quickly destroy the walls. For confinement by a surrounding vacuum magnetic field, no current flows outside \mathcal{V} , and the displacement current is negligible, so $\nabla \times \delta\mathbf{B} = 0$ there. By combining this with the rest of Maxwell's equations and paying careful attention to the motion of the interface and boundary conditions [Eqs. (19.20)] there, one can show, once again, that Eqs. (19.50) are satisfied (see, e.g., Goedbloed and Poedts, 2004, Sec. 6.6.2). Therefore, in all these cases Eq. (19.49) is also true, which demonstrates the self-adjointness (Hermiticity) of $\hat{\mathbf{F}}$.⁵ We use this property below.

Returning to our perturbed MHD system, we seek its normal modes by assuming a harmonic time dependence, $\xi \propto e^{-i\omega t}$. The first-order equation of motion (19.46) then becomes

Sturm-Liouville type eigenequation for perturbations

$$\hat{\mathbf{F}}[\xi] + \rho\omega^2\xi = 0. \quad (19.51)$$

This is an eigenequation for the fluid's Lagrangian displacement ξ , with eigenvalue ω^2 . It must be augmented by the boundary conditions (19.20) at the edge $\partial\mathcal{V}$ of the fluid.

properties of eigenfrequencies and eigenfunctions

By virtue of the elegant, self-adjoint mathematical form (19.48) of the differential operator $\hat{\mathbf{F}}$, our eigenequation (19.51) is of a very special and powerful type, called *Sturm-Liouville*; see any good text on mathematical physics (e.g., Mathews and Walker, 1970; Arfken, Weber, and Harris, 2013; Hassani, 2013). From the general (rather simple) theory of Sturm-Liouville equations, we can infer that all the eigenvalues ω^2 are real, so the normal modes are purely oscillatory ($\omega^2 > 0$, $\xi \propto e^{\pm i|\omega|t}$) or are purely exponentially growing or decaying ($\omega^2 < 0$, $\xi \propto e^{\pm|\omega|t}$). Exponentially growing modes represent instabilities. Sturm-Liouville theory also implies that all

5. Self-adjointness can also be deduced from energy conservation without getting entangled in detailed boundary conditions (see, e.g., Bellan, 2006, Sec. 10.4.2).

eigenfunctions [labeled by indices “(n)”] with different eigenfrequencies are orthogonal to one another, in the sense that $\int_V \rho \xi^{(n)} \cdot \xi^{(m)} dV = 0$.

EXERCISES

Exercise 19.13 *Derivation: Properties of Eigenmodes*

Derive the properties of the eigenvalues and eigenfunctions for perturbations of an MHD equilibrium that are asserted in the last paragraph of Sec. 19.5.1, namely, the following.

- For each normal mode the eigenfrequency ω_n is either real or imaginary.
- Eigenfunctions $\xi^{(m)}$ and $\xi^{(n)}$ that have different eigenvalues $\omega_m \neq \omega_n$ are orthogonal to each other: $\int \rho \xi^{(m)} \cdot \xi^{(n)} dV = 0$.

19.5.2 Z-Pinch: Sausage and Kink Instabilities

19.5.2

We illustrate MHD stability theory using a simple, analytically tractable example: a variant of the Z-pinch configuration of Fig. 19.6a. We consider a long, cylindrical column of a conducting, incompressible liquid (e.g., mercury) with column radius R and fluid density ρ . The column carries a current I longitudinally along its surface (rather than in its interior as in Fig. 19.6a), so $\mathbf{j} = [I/(2\pi R)]\delta(\varpi - R)\mathbf{e}_z$, and the liquid is confined by the resulting external toroidal magnetic field $B_\phi \equiv B$. The interior of the plasma is field free and at constant pressure P_0 . From $\nabla \times \mathbf{B} = \mu_0 \mathbf{j}$, we deduce that the exterior magnetic field is

$$B_\phi \equiv B = \frac{\mu_0 I}{2\pi \varpi} \quad \text{at } \varpi \geq R. \quad (19.52)$$

Here (ϖ, ϕ, z) are the usual cylindrical coordinates. This is a variant of the Z-pinch, because the z -directed current on the column's surface creates the external toroidal field B , which pinches the column until its internal pressure is balanced by the field's pressure:

$$P_0 = \left(\frac{B^2}{2\mu_0} \right)_{\varpi=R}. \quad (19.53)$$

It is quicker and more illuminating to analyze the stability of this Z-pinch equilibrium directly instead of by evaluating $\hat{\mathbf{F}}$, and the outcome is the same. (For a treatment based on $\hat{\mathbf{F}}$, see Ex. 19.16.) Treating only the most elementary case, we consider small, axisymmetric perturbations with an assumed variation $\xi \propto e^{i(kz - \omega t)} \mathbf{f}(\varpi)$ for some function \mathbf{f} . As the magnetic field interior to the column vanishes, the equation of motion $\rho d\mathbf{v}/dt = -\nabla(P + \delta P)$ becomes

$$-\omega^2 \rho \xi_{\varpi\varpi} = -\delta P', \quad -\omega^2 \rho \xi_z = -ik \delta P, \quad (19.54a)$$

where the prime denotes differentiation with respect to radius ϖ . Combining these two equations, we obtain

$$\xi_z' = ik \xi_{\varpi}. \quad (19.54b)$$

Because the fluid is incompressible, it satisfies $\nabla \cdot \xi = 0$:

$$\varpi^{-1}(\varpi \zeta_\varpi)' + ik\zeta_z = 0, \quad (19.54c)$$

which, with Eq. (19.54b), leads to

$$\zeta_z'' + \frac{\zeta_z'}{\varpi} - k^2\zeta_z = 0. \quad (19.54d)$$

The solution of this equation that is regular at $\varpi = 0$ is

$$\zeta_z = AI_0(k\varpi) \quad \text{at } \varpi \leq R, \quad (19.54e)$$

where A is a constant, and $I_n(x)$ is the modified Bessel function: $I_n(x) = i^{-n}J_n(ix)$. From Eq. (19.54b) and $dI_0(x)/dx = I_1(x)$, we obtain

$$\zeta_\varpi = -iAI_1(k\varpi). \quad (19.54f)$$

Next we consider the region exterior to the fluid column. As this is vacuum, it must be current free; and as we are dealing with a purely axisymmetric perturbation, the ϖ component of Maxwell's equation $\nabla \times \delta\mathbf{B} = 0$ (with negligible displacement current) reads

$$\frac{\partial \delta B_\phi}{\partial z} = ik\delta B_\phi = 0. \quad (19.54g)$$

The ϕ component of the magnetic perturbation therefore vanishes outside the column.

The interior and exterior solutions must be connected by the law of force balance, that is, by the boundary condition (19.19f) [or equivalently, Eq. (19.20a) with the tildes removed] at the plasma's surface. Allowing for the displacement of the surface and retaining only linear terms, this becomes

$$P_0 + \Delta P = P_0 + (\xi \cdot \nabla)P_0 + \delta P = \frac{(B + \Delta B_\phi)^2}{2\mu_0} = \frac{B^2}{2\mu_0} + \frac{B}{\mu_0}(\xi \cdot \nabla)B + \frac{B\delta B_\phi}{\mu_0}, \quad (19.54h)$$

where all quantities are evaluated at $\varpi = R$. The equilibrium force-balance condition gives us $P_0 = B^2/(2\mu_0)$ [Eq. (19.53)] and $\nabla P_0 = 0$. In addition, we have shown that $\delta B_\phi = 0$. Therefore, Eq. (19.54h) becomes simply

$$\delta P = \frac{BB'}{\mu_0}\zeta_\varpi. \quad (19.54i)$$

FIGURE 19.10 Physical interpretation of (a) sausage and (b) kink instabilities.

Substituting δP from Eqs. (19.54a) and (19.54e), B from Eq. (19.52), and ξ_{ϖ} from Eq. (19.54f), we obtain the dispersion relation

$$\begin{aligned}\omega^2 &= \frac{-\mu_0 I^2}{4\pi^2 R^4 \rho} \frac{k R I_1(kR)}{I_0(kR)} \\ &\simeq \frac{-\mu_0 I^2}{8\pi^2 R^2 \rho} k^2; \quad \text{for } k \ll R^{-1} \\ &\simeq \frac{-\mu_0 I^2}{4\pi^2 R^3 \rho} k; \quad \text{for } k \gg R^{-1},\end{aligned}\quad (19.55)$$

where we have used $I_0(x) \sim 1$, $I_1(x) \sim x/2$ as $x \rightarrow 0$ and $I_1(x)/I_0(x) \rightarrow 1$ as $x \rightarrow \infty$.

Because I_0 and I_1 are positive for all $kR > 0$, for every wave number k this dispersion relation shows that ω^2 is negative. Therefore, ω is imaginary, the perturbation grows exponentially with time, and so *the Z-pinch configuration is dynamically unstable*. If we define a characteristic Alfvén speed by $a = B(R)/(\mu_0 \rho)^{1/2}$ [see Eq. (19.73)], then we see that the growth time for modes with wavelengths comparable to the column diameter is roughly an Alfvén crossing time $2R/a$. This is fast!

This instability is sometimes called a *sausage instability*, because its eigenfunction $\xi_{\varpi} \propto e^{ikz}$ consists of oscillatory pinches of the column's radius that resemble the pinches between sausages in a link. This sausage instability has a simple physical interpretation (Fig. 19.10a), one that illustrates the power of the concepts of flux freezing and magnetic tension for developing intuition. If we imagine an inward radial motion of the fluid, then the toroidal loops of magnetic field will be carried inward, too, and will therefore shrink. As the external field is unperturbed, $\delta B_{\phi} = 0$, we have $B_{\phi} \propto 1/\varpi$, whence the surface field at the inward perturbation increases, leading to a larger “hoop” stress or, equivalently, a larger $\mathbf{j} \times \mathbf{B}$ Lorentz force, which accelerates the inward perturbation (see Fig. 19.10a).

So far, we have only considered axisymmetric perturbations. We can generalize our analysis by allowing the perturbations to vary as $\xi \propto \exp(im\phi)$. (Our sausage instability corresponds to $m = 0$.) Modes with $m \geq 1$, like $m = 0$, are also generically unstable. The $m = 1$ modes are known as *kink modes*. In this case the column bends,

sausage instability of Z-pinch

kink instability of Z-pinch

FIGURE 19.11 (a) Stabilizing magnetic fields for Θ -pinch configuration. (b) Flute instability for Θ -pinch configuration made into a torus.

and the field strength is intensified along the inner face of the bend and reduced on the outer face, thereby amplifying the instability (Fig. 19.10b). The incorporation of compressibility, as is appropriate for plasma instead of mercury, introduces only algebraic complexity; the conclusions are unchanged. The column is still highly unstable. It remains so if we distribute the longitudinal current throughout the column's interior, thereby adding a magnetic field to the interior, as in Fig. 19.6a.

MHD instabilities such as these have bedeviled attempts to confine plasma long enough to bring about nuclear fusion. Indeed, considerations of MHD stability were one of the primary motivations for the tokamak, the most consistently successful of experimental fusion devices.

19.5.3

19.5.3 The Θ -Pinch and Its Toroidal Analog; Flute Instability; Motivation for Tokamak

full stability of Θ -pinch

By contrast with the extreme instability of the Z-pinch configuration, the Θ -pinch configuration (Sec. 19.3.3 and Fig. 19.6b) is fully stable against MHD perturbations! (See Ex. 19.14.) This is easily understood physically (Fig. 19.11a). When the plasma cylinder is pinched or bent, at outward displaced regions of the cylinder, the external longitudinal magnetic field lines are pushed closer together, thereby strengthening the magnetic field and its pressure and thence creating an inward restoring force. Similarly, at inward displaced regions, the field lines are pulled apart, weakening their pressure and creating an outward restoring force.

Unfortunately, the Θ -pinch configuration cannot confine plasma without closing its ends. The ends can be partially closed by a pair of magnetic mirrors, but there remain losses out the ends that cause problems. The ends can be fully closed by bending the column into a closed torus, but, sadly, the resulting toroidal Θ -pinch configuration exhibits a new MHD “flute” instability (Fig. 19.11b).

toroidal Θ -pinch: flute instability

This flute instability arises on and near the outermost edge of the torus. That edge is curved around the torus's symmetry axis in just the same way as the face of the Z-pinch configuration is curved around its symmetry axis—with the magnetic field in both cases forming closed loops around the axis. As a result, this outer edge is subject to a sausage-type instability, similar to that of the Z-pinch. The resulting corrugations are translated along the torus, so they resemble the flutes on a Greek column that supports an architectural arch or roof (hence the name “flute instability”). This fluting can also be understood as a flux-tube interchange instability (Ex. 19.15).

The flute instability can be counteracted by endowing the torus with an internal magnetic field that twists (shears) as one goes radially inward (the tokamak configuration of Fig. 19.6c). Adjacent magnetic surfaces (isobars), with their different field directions, counteract each other's MHD instabilities. The component of the magnetic field along the plasma torus provides a pressure that stabilizes against sausage instabilities and a tension that stabilizes against kink-type instabilities; the component around the torus's guiding circle acts to stabilize its flute modes. In addition, the formation of image currents in the conducting walls of a tokamak vessel can also have a stabilizing influence.

how tokamak configuration counteracts instabilities

Exercise 19.14 *Problem and Challenge: Stability of Θ -Pinch*

Derive the dispersion relation $\omega^2(k)$ for axisymmetric perturbations of the Θ -pinch configuration when the magnetic field is confined to the cylinder's exterior, and conclude from it that the Θ -pinch is stable against axisymmetric perturbations. [Hint: The analysis of the interior of the cylinder is the same as for the Z-pinch analyzed in the text.] Repeat your analysis for a general, variable-separated perturbation of the form $\xi \propto e^{i(m\theta + kz - \omega t)}$, and thereby conclude that the Θ -pinch is fully MHD stable.

Exercise 19.15 *Example: Flute Instability Understood by Flux-Tube Interchange*

Carry out an analysis of the flute instability patterned after that for rotating Couette flow (first long paragraph of Sec. 14.6.3) and that for convection in stars (Fig. 18.5): Imagine exchanging two plasma-filled magnetic flux tubes that reside near the outermost edge of the torus. Argue that the one displaced outward experiences an unbalanced outward force, and the one displaced inward experiences an unbalanced inward force. [Hint: (i) To simplify the analysis, let the equilibrium magnetic field rise from zero continuously in the outer layers of the torus rather than arising discontinuously at its surface, and consider flux tubes in that outer, continuous region. (ii) Argue that the unbalanced force per unit length on a displaced flux tube is $[-\nabla(P + B^2/(2\mu_0)) - (B_{\text{tube}}^2/\varpi)\mathbf{e}_\varpi]A$. Here A is the tube's cross sectional area, ϖ is distance from the torus's symmetry axis, \mathbf{e}_ϖ is the unit vector pointing away from the symmetry axis, B_{tube} is the field strength inside the displaced tube, and $\nabla(P + B^2/(2\mu_0))$ is the net surrounding pressure gradient at the tube's

EXERCISES

displaced location.] Argue further that the innermost edge of the torus is stable against flux-tube interchange, so the flute instability is confined to the torus's outer face.

19.5.4 19.5.4 Energy Principle and Virial Theorems T2

For the perturbation eigenequation (19.46) and its boundary conditions, analytical or even numerical solutions are only readily obtained in the most simple of geometries and for the simplest fluids. However, as the eigenequation is self-adjoint, it is possible to write down a variational principle and use it to derive approximate stability criteria. This variational principle has been a powerful tool for analyzing the stability of tokamak and other magnetostatic configurations.

To derive the variational principle, we begin by multiplying the fluid velocity $\dot{\xi} = \partial\xi/\partial t$ into the eigenequation (equation of motion) $\rho\partial^2\xi/\partial t^2 = \hat{F}[\xi]$. We then integrate over the plasma-filled region \mathcal{V} , and use the self-adjointness of \hat{F} to write $\int_{\mathcal{V}} dV \dot{\xi} \cdot \hat{F}[\xi] = \frac{1}{2} \int_{\mathcal{V}} dV (\dot{\xi} \cdot \hat{F}[\xi] + \xi \cdot \hat{F}[\dot{\xi}])$. We thereby obtain

$$\frac{dE}{dt} = 0, \quad \text{where } E = T + W, \quad (19.56a)$$

$$T = \int_{\mathcal{V}} dV \frac{1}{2} \rho \dot{\xi}^2, \quad \text{and} \quad W = W[\xi] \equiv -\frac{1}{2} \int_{\mathcal{V}} dV \xi \cdot \hat{F}[\xi]. \quad (19.56b)$$

The integrals T and W are the perturbation's kinetic and potential energy, and $E = T + W$ is the conserved total energy.

Any solution of the equation of motion $\partial^2\xi/\partial t^2 = \hat{F}[\xi]$ can be expanded in terms of a complete set of normal modes $\xi^{(n)}(\mathbf{x})$ with eigenfrequencies ω_n : $\xi = \sum_n A_n \xi^{(n)} e^{-i\omega_n t}$. Because \hat{F} is a real, self-adjoint operator, these normal modes can all be chosen to be real and orthogonal, even when some of their frequencies are degenerate. As the perturbation evolves, its energy sloshes back and forth between kinetic T and potential W , so time averages of T and W are equal: $\overline{T} = \overline{W}$. This implies, for each normal mode,

$$\omega_n^2 = \frac{W[\xi^{(n)}]}{\int_{\mathcal{V}} dV \frac{1}{2} \rho \xi^{(n)2}}. \quad (19.57)$$

As the denominator is positive definite, we conclude that *a magnetostatic equilibrium is stable against small perturbations if and only if the potential energy $W[\xi]$ is a positive-definite functional of the perturbation ξ* . This is sometimes called the *Rayleigh principle* for a general Sturm-Liouville problem. In the MHD context, it is known as the *energy principle*.

It is straightforward to verify, by virtue of the self-adjointness of $\hat{F}[\xi]$, that expression (19.57) serves as an action principle for the eigenfrequencies: If one inserts into Eq. (19.57) a trial function ξ_{trial} in place of $\xi^{(n)}$, then the resulting value of the equation will be stationary under small variations of ξ_{trial} if and only if ξ_{trial} is equal to

conserved energy for adiabatic perturbations of magnetostatic configurations

energy principle (Rayleigh principle) for stability

action principle for eigenfrequencies

some eigenfunction $\xi^{(n)}$; and the stationary value of Eq. (19.57) is that eigenfunction's squared eigenfrequency ω_n^2 . This action principle is most useful for estimating the lowest few squared frequencies ω_n^2 . Because first-order differences between ξ_{trial} and $\xi^{(n)}$ produce second-order errors in ω_n^2 , relatively crude trial eigenfunctions can furnish surprisingly accurate eigenvalues.

Whatever may be our chosen trial function ξ_{trial} , the computed value of the action (19.57) will always be larger than ω_0^2 , the squared eigenfrequency of the most unstable mode. Therefore, if we compute a negative value of Eq. (19.57) using some trial eigenfunction, we know that the equilibrium must be even more unstable.

The MHD energy principle and action principle are special cases of the general conservation law and action principle for Sturm-Liouville differential equations (see, e.g., Mathews and Walker, 1970; Arfken, Weber, and Harris, 2013; Hassani, 2013). For further insights into the energy and action principles, see the original MHD paper by Bernstein et al. (1958), in which these ideas were developed; also see Mikhailovskii (1998), Goedbloed and Poedts (2004, Chap. 6), and Bellan (2006, Chap. 10).

EXERCISES

Exercise 19.16 *Example: Reformulation of the Energy Principle;*

Application to Z-Pinch T2

The form of the potential energy functional derived in the text [Eq. (19.47)] is optimal for demonstrating that the operator $\hat{\mathbf{F}}$ is self-adjoint. However, there are several simpler, equivalent forms that are more convenient for practical use.

(a) Use Eq. (19.46) to show that

$$\begin{aligned} \xi \cdot \hat{\mathbf{F}}[\xi] = & \mathbf{j} \times \mathbf{b} \cdot \xi - \mathbf{b}^2/\mu_0 - \gamma P(\nabla \cdot \xi)^2 - (\nabla \cdot \xi)(\xi \cdot \nabla)P \\ & + \nabla \cdot [(\xi \times \mathbf{B}) \times \mathbf{b}/\mu_0 + \gamma P \xi(\nabla \cdot \xi) + \xi(\xi \cdot \nabla)P], \end{aligned} \quad (19.58)$$

where $\mathbf{b} \equiv \delta \mathbf{B}$ is the Eulerian perturbation of the magnetic field.

(b) Insert Eq. (19.58) into expression (19.56b) for the potential energy $W[\xi]$ and convert the volume integral of the divergence into a surface integral. Then impose the boundary condition of a vanishing normal component of the magnetic field at $\partial \mathcal{V}$ [Eq. (19.20b)] to show that

$$\begin{aligned} W[\xi] = & \frac{1}{2} \int_{\mathcal{V}} dV \left[-\mathbf{j} \times \mathbf{b} \cdot \xi + \mathbf{b}^2/\mu_0 + \gamma P(\nabla \cdot \xi)^2 + (\nabla \cdot \xi)(\xi \cdot \nabla)P \right] \\ & - \frac{1}{2} \int_{\partial \mathcal{V}} d\Sigma \cdot \xi \left[\gamma P(\nabla \cdot \xi) + \xi \cdot \nabla P - \mathbf{B} \cdot \mathbf{b}/\mu_0 \right]. \end{aligned} \quad (19.59)$$

(c) Consider axisymmetric perturbations of the cylindrical Z-pinch of an incompressible fluid, as discussed in Sec. 19.5.2, and argue that the surface integral vanishes.

(d) Adopt a simple trial eigenfunction, and obtain a variational estimate of the growth rate of the sausage instability's fastest growing mode.

Exercise 19.17 *Problem: Potential Energy in Its Most Physically Interpretable Form* T2

- (a) Show that the potential energy (19.59) can be transformed into the following form:

$$W[\boldsymbol{\xi}] = \frac{1}{2} \int_{\mathcal{V}} dV \left[-\mathbf{j} \times \mathbf{b} \cdot \boldsymbol{\xi} + \frac{\mathbf{b}^2}{\mu_0} + \delta P \frac{\Delta \rho}{\rho} \right] \\ + \frac{1}{2} \int_{\partial V} d\boldsymbol{\Sigma} \cdot \nabla \left(\frac{\tilde{B}^2}{2\mu_0} - P - \frac{B^2}{2\mu_0} \right) \xi_n^2 + \frac{1}{2} \int_{\text{vacuum}} dV \frac{\tilde{\mathbf{b}}^2}{\mu_0}. \quad (19.60)$$

Here symbols without tildes represent quantities in the plasma region, and those with tildes are in the vacuum region; ξ_n is the component of the fluid displacement orthogonal to the vacuum-plasma interface.

- (b) Explain the physical interpretation of each term in the expression for the potential energy in part (a). Notice that, although our original expression for the potential energy, $W = -\frac{1}{2} \int_{\mathcal{V}} \boldsymbol{\xi} \cdot \mathbf{F}[\boldsymbol{\xi}] dV$, entails an integral only over the plasma region, it actually includes the vacuum region's magnetic energy.

Exercise 19.18 *Example: Virial Theorems* T2

Additional mathematical tools that are useful in analyzing MHD equilibria and their stability—and are also useful in astrophysics—are the *virial theorems*. In this exercise and the next, you will deduce time-dependent and time-averaged virial theorems for any system for which the law of momentum conservation can be written in the form

$$\frac{\partial(\rho v_j)}{\partial t} + T_{jk;k} = 0. \quad (19.61)$$

Here ρ is mass density, v_j is the material's velocity, ρv_j is momentum density, and T_{jk} is the stress tensor. We have met this formulation of momentum conservation in elastodynamics [Eq. (12.2b)], in fluid mechanics with self-gravity [Eq. (2) of Box 13.4], and in magnetohydrodynamics with self-gravity [Eq. (19.12)].

The virial theorems involve integrals over any region \mathcal{V} for which there is no mass flux or momentum flux across its boundary: $\rho v_j n_j = T_{jk} n_k = 0$ everywhere on $\partial \mathcal{V}$, where n_j is the normal to the boundary.⁶ For simplicity we use Cartesian coordinates, so there are no connection coefficients to worry about, and momentum conservation becomes $\partial(\rho v_j) + \partial T_{jk} / \partial x_k = 0$.

- (a) Show that mass conservation, $\partial \rho / \partial t + \nabla \cdot (\rho \mathbf{v}) = 0$, implies that for any field f (scalar, vector, or tensor), we have

$$\frac{d}{dt} \int_{\mathcal{V}} \rho f dV = \int_{\mathcal{V}} \rho \frac{df}{dt} dV. \quad (19.62)$$

6. If self-gravity is included, then the boundary will have to be at spatial infinity (i.e., no boundary), as $T_{jk}^{\text{grav}} n_k$ cannot vanish everywhere on a finite enclosing wall.

(b) Use Eq. (19.62) to show that

$$\boxed{\frac{d^2 I_{jk}}{dt^2} = 2 \int_{\mathcal{V}} \tau_{jk} dV,} \quad (19.63a)$$

where I_{jk} is the second moment of the mass distribution:

$$I_{jk} = \int_{\mathcal{V}} \rho x_j x_k dV \quad (19.63b)$$

with x_j the distance from a chosen origin. This is the *time-dependent tensor virial theorem*. (Note that the system's mass quadrupole moment is the trace-free part of I_{jk} , $\mathcal{I}_{jk} = I_{jk} - \frac{1}{3} I g_{jk}$, and the system's moment of inertia tensor is $\mathfrak{J}_{jk} = I_{jk} - I g_{jk}$, where $I = I_{jj}$ is the trace of I_{jk} .)

(c) If the time integral of $d^2 I_{jk}/dt^2$ vanishes, then the time-averaged stress tensor satisfies

$$\boxed{\int_{\mathcal{V}} \bar{\tau}_{jk} dV = 0.} \quad (19.64)$$

This is the *time-averaged tensor virial theorem*. Under what circumstances is this theorem true?

Exercise 19.19 Example: Scalar Virial Theorems T2

(a) By taking the trace of the time-dependent tensorial virial theorem and specializing to an MHD plasma with (or without) self-gravity, show that

$$\boxed{\frac{1}{2} \frac{d^2 I}{dt^2} = 2E_{\text{kin}} + E_{\text{mag}} + E_{\text{grav}} + 3E_P,} \quad (19.65a)$$

where I is the trace of I_{jk} , E_{kin} is the system's kinetic energy, E_{mag} is its magnetic energy, E_P is the volume integral of its pressure, and E_{grav} is its gravitational self-energy:

$$I = \int_{\mathcal{V}} \rho \mathbf{x}^2 dV, \quad E_{\text{kin}} = \int_{\mathcal{V}} \frac{1}{2} \rho \mathbf{v}^2 dV, \quad E_{\text{mag}} = \int \frac{\mathbf{B}^2}{2\mu_0}, \quad E_P = \int_{\mathcal{V}} P dV,$$

$$E_{\text{grav}} = \frac{1}{2} \int_{\mathcal{V}} \rho \Phi = - \int_{\mathcal{V}} \frac{1}{8\pi G} (\nabla \Phi)^2 = - \frac{1}{2} \int_{\mathcal{V}} \int_{\mathcal{V}} G \frac{\rho(\mathbf{x})\rho(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|} dV' dV, \quad (19.65b)$$

with Φ the gravitational potential energy [cf. Eq. (13.62)].

(b) When the time integral of $d^2 I/dt^2$ vanishes, then the time average of the right-hand side of Eq. (19.65a) vanishes:

$$\boxed{2\bar{E}_{\text{kin}} + \bar{E}_{\text{mag}} + \bar{E}_{\text{grav}} + 3\bar{E}_P = 0.} \quad (19.66)$$

This is the *time-averaged scalar virial theorem*. Give examples of circumstances in which it holds.

T2

- (c) Equation (19.66) is a continuum analog of the better-known scalar virial theorem, $2\bar{E}_{\text{kin}} + \bar{E}_{\text{grav}} = 0$, for a system consisting of particles that interact via their self-gravity—for example, the solar system (see, e.g., Goldstein, Poole, and Safko, 2002, Sec. 3.4).
- (d) As a simple but important application of the time-averaged scalar virial theorem, show—neglecting self-gravity—that it is impossible for internal currents in a plasma to produce a magnetic field that confines the plasma to a finite volume: external currents (e.g., in solenoids) are necessary.
- (e) For applications to the oscillation and stability of self-gravitating systems, see Chandrasekhar (1961, Sec. 118).

19.6

19.6 Dynamos and Reconnection of Magnetic Field Lines T2

dynamo

As we have already remarked, the timescale for Earth's magnetic field to decay is estimated to be roughly 1 million years. Since Earth is far older than that, some process inside Earth must be regenerating the magnetic field. This process is known as a *dynamo*. Generally speaking, in a dynamo the motion of the fluid stretches the magnetic field lines, thereby increasing their magnetic energy density, which compensates for the decrease in magnetic energy associated with Ohmic decay. The details of how this happens inside Earth are not well understood. However, some general principles of dynamo action have been formulated, and their application to the Sun is somewhat better understood (Exs. 19.20 and 19.21).

19.6.1

19.6.1 Cowling's Theorem T2

It is simple to demonstrate the impossibility of dynamo action in any time-independent, axisymmetric flow. Suppose that there were such a dynamo configuration, and the time-independent, poloidal (meridional) field had—for concreteness—the form sketched in Fig. 19.12. Then there must be at least one neutral point marked \mathcal{P} (actually a circle about the symmetry axis), where the poloidal field vanishes. However, the curl of the magnetic field does not vanish at \mathcal{P} , so a toroidal current j_ϕ must exist there. Now, in the presence of finite resistivity, there must also be a toroidal electric field at \mathcal{P} , since

$$j_\phi = \kappa_e [E_\phi + (\mathbf{v}_P \times \mathbf{B}_P)_\phi] = \kappa_e E_\phi. \quad (19.67)$$

Here \mathbf{v}_P and \mathbf{B}_P are the poloidal components of \mathbf{v} and \mathbf{B} . The nonzero E_ϕ in turn implies, via $\nabla \times \mathbf{E} = -\partial \mathbf{B} / \partial t$, that the amount of poloidal magnetic flux threading the circle at \mathcal{P} must change with time, violating our original supposition that the magnetic field distribution is stationary.

Cowling's theorem for dynamos

We therefore conclude that any time-independent, self-perpetuating dynamo must be more complicated than a purely axisymmetric magnetic field. This result is known as *Cowling's theorem*.

FIGURE 19.12 Impossibility of an axisymmetric dynamo.

19.6.2 Kinematic Dynamos T2

19.6.2

The simplest types of dynamo to consider are those in which we specify a particular velocity field and allow the magnetic field to evolve according to the transport law (19.6). Under certain circumstances, this can produce dynamo action. Note that we do not consider in our discussion the dynamical effect of the magnetic field on the velocity field.

The simplest type of motion is one in which a *dynamo cycle* occurs. In this cycle, there is one mechanism for creating a toroidal magnetic field from a poloidal field and a separate mechanism for regenerating the poloidal field. The first mechanism is usually differential rotation. The second is plausibly magnetic buoyancy, in which a toroidal magnetized loop is lighter than its surroundings and therefore rises in the gravitational field. As the loop rises, Coriolis forces twist the flow, causing a poloidal magnetic field to appear, which completes the dynamo cycle.

dynamo cycle

Small-scale, turbulent velocity fields may also be responsible for dynamo action. In this case, it can be shown on general symmetry grounds that the velocity field must contain *hydrodynamic helicity*—a nonzero mean value of $\mathbf{v} \cdot \boldsymbol{\omega}$ [which is an obvious analog of magnetic helicity (Ex. 19.9), the volume integral or mean value of $\mathbf{A} \cdot \mathbf{B} = \mathbf{A} \cdot (\nabla \times \mathbf{A})$].

dynamo action in turbulence

hydrodynamic helicity

If the magnetic field strength grows, then its dynamical effect will eventually react back on the flow and modify the velocity field. A full description of a dynamo must include this back reaction. Dynamos are a prime target for numerical simulations of MHD, and in recent years, significant progress has been made using these simulations to understand the terrestrial dynamo and other specialized problems.

Exercise 19.20 Problem: Differential Rotation in the Solar Dynamo T2

EXERCISES

This problem shows how differential rotation leads to the production of a toroidal magnetic field from a poloidal field.

- (a) Verify that for a fluid undergoing differential rotation around a symmetry axis with angular velocity $\Omega(r, \theta)$, the ϕ component of the induction equation reads

$$\frac{\partial B_\phi}{\partial t} = \sin \theta \left(B_\theta \frac{\partial \Omega}{\partial \theta} + B_r r \frac{\partial \Omega}{\partial r} \right), \quad (19.68)$$

where θ is the co-latitude. (The resistive term can be ignored.)

- (b) It is observed that the angular velocity on the solar surface is largest at the equator and decreases monotonically toward the poles. Analysis of solar oscillations (Sec. 16.2.4) has shown that this variation $\Omega(\theta)$ continues inward through the convection zone (cf. Sec. 18.5). Suppose that the field of the Sun is roughly poloidal. Sketch the appearance of the toroidal field generated by the poloidal field.

Exercise 19.21 *Problem: Buoyancy in the Solar Dynamo* T2

Consider a slender flux tube with width much less than its length which, in turn, is much less than the external pressure scale height H . Also assume that the magnetic field is directed along the tube so there is negligible current along the tube.

- (a) Show that the requirement of magnetostatic equilibrium implies that inside the flux tube

$$\nabla \left(P + \frac{B^2}{2\mu_0} \right) \simeq 0. \quad (19.69)$$

- (b) Consider a segment of this flux tube that is horizontal and has length ℓ . Holding both ends fixed, bend it vertically upward so that the radius of curvature of its center line is $R \gg \ell$. Assume that the fluid is isentropic with adiabatic index γ . By balancing magnetic tension against buoyancy, show that magnetostatic equilibrium is possible if $R \simeq 2\gamma H$. Do you think this equilibrium could be stable?
- (c) In the solar convection zone (cf. Sec. 18.5), small entropy differences are important in driving the convective circulation. Following Ex. 19.20(b), suppose that a length of toroidal field is carried upward by a convecting “blob.” Consider the action of the Coriolis force due to the Sun’s rotation (cf. Sec. 14.2.1) on a single blob, and argue that it will rotate. What will this do to the magnetic field? Sketch the generation of a large-scale poloidal field from a toroidal field through the combined effects of many blobs. What do you expect to observe when a flux tube breaks through the solar surface (known as the photosphere)?

The combined effect of differential rotation, magnetic stress, and buoyancy, as outlined in Exs. 19.20 and 19.21, is thought to play an important role in sustaining the solar dynamo cycle. See Goedbloed and Poedts (2004, Secs. 8.2, 8.3) for further insights.

19.6.3 Magnetic Reconnection T2

So far, our discussion of the evolution of the magnetic field has centered on the induction equation (19.6) (the magnetic transport law). We have characterized the

FIGURE 19.13 Magnetic reconnection. In the shaded reconnection region, Ohmic diffusion is important and allows magnetic field lines to “exchange partners,” changing the overall field topology. Magnetic field components perpendicular to the plane of the illustration do not develop large gradients and so do not inhibit the reconnection process.

magnetized fluid by a magnetic Reynolds number using some characteristic length L associated with the flow, and have found that, when $R_M \gg 1$, Ohmic dissipation and field-line diffusion in the transport law are unimportant. This is reminiscent of the procedure we followed when discussing vorticity. However, for vorticity we discovered a very important exception to an uncritical neglect of viscosity, dissipation, and vortex-line diffusion at large Reynolds numbers, namely, boundary layers (Sec. 14.4). In particular, we found that large-Reynolds-number flows near solid surfaces develop large velocity gradients on account of the no-slip boundary condition, and that the local Reynolds number can thereby decrease to near unity, allowing viscous stress to change the character of the flow completely. Something similar, called *magnetic reconnection*, can happen in hydromagnetic flows with large R_M , even without the presence of solid surfaces.

Consider two oppositely magnetized regions of conducting fluid moving toward each other (the upper and lower regions in Fig. 19.13). Mutual magnetic attraction of the two regions occurs, as magnetic energy would be reduced if the two sets of field lines were superposed. However, strict flux freezing prevents superposition. Something has to give! What happens is a compromise. The attraction causes large magnetic gradients to develop, accompanied by a buildup of large current densities, until Ohmic diffusion ultimately allows the magnetic field lines to slip sideways through the fluid and to *reconnect* with the field in the other region (the sharply curved field lines in Fig. 19.13).

This reconnection mechanism can be clearly observed at work in tokamaks and in Earth’s magnetopause, where the solar wind’s magnetic field meets Earth’s magnetosphere. However, the details of the reconnection mechanism are quite complex, involving plasma instabilities, anisotropic electrical conductivity, and shock fronts.

how magnetic reconnection occurs at high R_M

Large, inductive electric fields can also develop when the magnetic geometry undergoes rapid change. This can happen in the reversing magnetic field in Earth's *magnetotail*,⁷ leading to the acceleration of charged particles that impact Earth during a *magnetic substorm*. Like dynamo action, reconnection has a major role in determining how magnetic fields actually behave in both laboratory and space plasmas.

For further detail on the physics and observations of reconnection, see, for example, Birn and Priest (2007) and Forbes and Priest (2007).

19.7 Magnetosonic Waves and the Scattering of Cosmic Rays

magnetosonic waves

In Sec. 19.5, we discussed global perturbations of a nonuniform magnetostatic plasma and described how they may be unstable. We now consider a different, particularly simple example of dynamical perturbations: planar, monochromatic, propagating waves in a uniform, magnetized, conducting medium. These are called *magnetosonic waves*. They can be thought of as sound waves that are driven not just by gas pressure but also by magnetic pressure and tension.

Although magnetosonic waves have been studied experimentally under laboratory conditions, there the magnetic Reynolds numbers are generally quite small, so the waves damp quickly by Ohmic dissipation. No such problem arises in space plasmas, where magnetosonic waves are routinely studied by the many spacecraft that monitor the solar wind and its interaction with planetary magnetospheres. It appears that these modes perform an important function in space plasmas: they control the transport of cosmic rays. Let us describe some properties of cosmic rays before giving a formal derivation of the magnetosonic-wave dispersion relation.

19.7.1 Cosmic Rays

cosmic-ray spectrum

Cosmic rays are the high-energy particles, primarily protons, that bombard Earth's magnetosphere from outer space. They range in energy from ~ 1 MeV to $\sim 3 \times 10^{11}$ GeV = 0.3 ZeV ~ 50 J. (The highest cosmic-ray energy ever measured was ~ 50 J. Thus, naturally occurring particle accelerators are far more impressive than their terrestrial counterparts, which can only reach ~ 10 TeV = 10^4 GeV!) Most subrelativistic particles originate in the solar system. Their relativistic counterparts, up to energies ~ 100 TeV, are believed to come mostly from interstellar space, where they are accelerated by expanding shock waves created by supernova explosions (cf. Sec. 17.6.3). The origin of the highest energy particles, greater than ~ 100 TeV, is an intriguing mystery.

isotropy

The distribution of cosmic-ray arrival directions at Earth is inferred to be quite isotropic (to better than 1 part in 10^4 at an energy of 10 GeV). This is somewhat surprising, because their sources, both in and beyond the solar system, are believed to be distributed anisotropically, so the isotropy needs to be explained. Part of the reason for the isotropy is that the interplanetary and interstellar media are magnetized, and

7. The magnetotail is the region containing trailing field lines on the night side of Earth.

the particles gyrate around the magnetic field with the gyro (relativistic cyclotron) frequency $\omega_G = eBc^2/\mathcal{E}$, where \mathcal{E} is the (relativistic) particle energy including rest mass, and B is the magnetic field strength. The gyro (Larmor) radii of the non-relativistic particle orbits are typically small compared to the size of the solar system, and those of the relativistic particles are typically small compared to characteristic lengthscales in the interstellar medium. Therefore, this gyrational motion can effectively erase any azimuthal asymmetry around the field direction. However, this does not stop the particles from streaming away from their sources along the magnetic field, thereby producing anisotropy at Earth. So something else must be impeding this along-line flow, by scattering the particles and causing them to effectively diffuse along and across the field through interplanetary and interstellar space.

As we verify in Sec. 20.4, Coulomb collisions are quite ineffective (even if they were effective, they would cause huge cosmic-ray energy losses, in violation of observations). We therefore seek some means of changing a cosmic ray's momentum without altering its energy significantly. This is reminiscent of the scattering of electrons in metals, where it is phonons (elastic waves in the crystal lattice) that are responsible for much of the scattering. It turns out that in the interstellar medium, magnetosonic waves can play a role analogous to phonons and can scatter the cosmic rays. As an aid to understanding this phenomenon, we now derive the waves' dispersion relation.

19.7.2 Magnetosonic Dispersion Relation

19.7.2

Our procedure for deriving the dispersion relation (last paragraph of Sec. 7.2.1) should be familiar by now. We consider a uniform, isentropic, magnetized fluid at rest; we perform a linear perturbation and seek monochromatic plane-wave solutions varying as $e^{i(\mathbf{k}\cdot\mathbf{x}-\omega t)}$. We ignore gravity and dissipative processes (specifically, viscosity, thermal conductivity, and electrical resistivity), as well as gradients in the equilibrium, which can all be important in some circumstances.

It is convenient to use the velocity perturbation $\delta\mathbf{v}$ as the independent variable. The perturbed and linearized equation of motion (19.10) then takes the form

$$-i\rho\omega\delta\mathbf{v} = -iC^2\mathbf{k}\delta\rho + \frac{(i\mathbf{k} \times \delta\mathbf{B}) \times \mathbf{B}}{\mu_0}. \quad (19.70)$$

Here C is the sound speed [$C^2 = (\partial P/\partial\rho)_s = \gamma P/\rho$, not to be confused with the speed of light c], and $\delta P = C^2\delta\rho$ is the Eulerian pressure perturbation for our homogeneous equilibrium.⁸ (Note that $\nabla P = \nabla\rho = 0$, so Eulerian and Lagrangian perturbations are the same.) The perturbed equation of mass conservation, $\partial\rho/\partial t + \nabla \cdot (\rho\mathbf{v}) = 0$, becomes

$$\omega\delta\rho = \rho\mathbf{k} \cdot \delta\mathbf{v}, \quad (19.71)$$

8. Note that we are assuming that (i) the equilibrium pressure tensor is isotropic and (ii) the perturbations to the pressure are also isotropic. This is unlikely to be the case for a collisionless plasma, so our treatment there must be modified. See Sec. 20.6.2 and Ex. 21.1.

and the MHD law of magnetic-field transport with dissipation ignored, $\partial \mathbf{B} / \partial t = \nabla \times (\mathbf{v} \times \mathbf{B})$, becomes

$$\omega \delta \mathbf{B} = -\mathbf{k} \times (\delta \mathbf{v} \times \mathbf{B}). \quad (19.72)$$

Alfvén velocity

We introduce the Alfvén velocity

$$\mathbf{a} \equiv \frac{\mathbf{B}}{(\mu_0 \rho)^{1/2}}, \quad (19.73)$$

and insert $\delta \rho$ [Eq. (19.71)] and $\delta \mathbf{B}$ [Eq. (19.72)] into Eq. (19.70) to obtain

eigenequation for magnetosonic waves

$$\{\mathbf{k} \times [\mathbf{k} \times (\delta \mathbf{v} \times \mathbf{a})]\} \times \mathbf{a} + C^2(\mathbf{k} \cdot \delta \mathbf{v})\mathbf{k} = \omega^2 \delta \mathbf{v}. \quad (19.74)$$

Equation (19.74) is an eigenequation for the wave's squared frequency ω^2 and eigendirection $\delta \mathbf{v}$. The straightforward way to solve it is to rewrite it in the standard matrix form $M_{ij} \delta v_j = \omega^2 \delta v_i$ and then use standard matrix (determinant) methods. It is quicker, however, to seek the three eigendirections $\delta \mathbf{v}$ and eigenfrequencies ω one by one, by projection along preferred directions.

Alfvén mode and its dispersion relation

We first seek a solution to Eq. (19.74) for which $\delta \mathbf{v}$ is orthogonal to the plane formed by the unperturbed magnetic field and the wave vector, $\delta \mathbf{v} = \mathbf{a} \times \mathbf{k}$ up to a multiplicative constant. Inserting this $\delta \mathbf{v}$ into Eq. (19.74), we obtain the dispersion relation

$$\omega = \pm \mathbf{a} \cdot \mathbf{k}; \quad \frac{\omega}{k} = \pm a \cos \theta, \quad (19.75)$$

where θ is the angle between \mathbf{k} and the unperturbed field, and $a \equiv |\mathbf{a}| = B/(\mu_0 \rho)^{1/2}$ is the Alfvén speed. This type of wave is known as the *intermediate magnetosonic mode* and also as the *Alfvén mode*. Its phase speed $\omega/k = a \cos \theta$ is plotted as the larger figure-8 curve in Fig. 19.14. The velocity and magnetic perturbations $\delta \mathbf{v}$ and $\delta \mathbf{B}$ are both along the direction $\mathbf{a} \times \mathbf{k}$, so the Alfvén wave is fully transverse. There is no compression ($\delta \rho = 0$), which accounts for the absence of the sound speed C in the dispersion relation. This Alfvén mode has a simple physical interpretation in the limiting case when \mathbf{k} is parallel to \mathbf{B} . We can think of the magnetic field lines as strings with tension B^2/μ_0 and inertia ρ , which are plucked transversely. Their transverse oscillations then propagate with speed $\sqrt{\text{tension}/\text{inertia}} = B/\sqrt{\mu_0 \rho} = a$. For details and delicacies, see Ex. 21.8.

Alfvén-mode properties

The dispersion relations for the other two modes can be deduced by projecting the eigenequation (19.74) successively along \mathbf{k} and along \mathbf{a} to obtain two scalar equations:

$$\begin{aligned} k^2(\mathbf{k} \cdot \mathbf{a})(\mathbf{a} \cdot \delta \mathbf{v}) &= [(a^2 + C^2)k^2 - \omega^2](\mathbf{k} \cdot \delta \mathbf{v}), \\ C^2(\mathbf{k} \cdot \mathbf{a})(\mathbf{k} \cdot \delta \mathbf{v}) &= \omega^2(\mathbf{a} \cdot \delta \mathbf{v}). \end{aligned} \quad (19.76)$$

FIGURE 19.14 Phase-velocity surfaces for the three types of magnetosonic modes: fast (f), intermediate (i), and slow (s). The three curves are polar plots of the wave phase velocity ω/k in units of the Alfvén speed $a = B/\sqrt{\mu_0\rho}$. In the particular example shown, the sound speed C is half the Alfvén speed.

Combining these equations, we obtain the dispersion relation

$$\left(\frac{\omega}{k}\right)^2 = \frac{1}{2}(a^2 + C^2) \left[1 \pm \left(1 - \frac{4C^2 a^2 \cos^2 \theta}{(a^2 + C^2)^2} \right)^{1/2} \right]. \quad (19.77)$$

dispersion relation for fast (+) and slow (–) magnetosonic modes

(By inserting this dispersion relation, with the upper or lower sign, back into Eqs. (19.76), we can deduce the mode's eigendirection $\delta\mathbf{v}$.) This dispersion relation tells us that ω^2 is positive, so no unstable modes exist, which seems reasonable, as there is no source of free energy. (The same is true, of course, for the Alfvén mode.)

These waves are compressive, with the gas being moved by a combination of gas pressure and magnetic pressure and tension. The modes can be seen to be non-dispersive, which is also to be expected, as we have introduced neither a characteristic timescale nor a characteristic length into the problem.

The mode with the plus signs in Eq. (19.77) is called the *fast magnetosonic mode*; its phase speed is depicted by the outer, quasi-circular curve in Fig. 19.14. A good approximation to its phase speed when $a \gg C$ or $a \ll C$ is $\omega/k \simeq \pm(a^2 + C^2)^{1/2}$. When propagating perpendicularly to \mathbf{B} , the fast mode can be regarded as simply a longitudinal sound wave in which the gas pressure is augmented by the magnetic pressure $B^2/(2\mu_0)$ (adopting a specific-heat ratio γ for the magnetic field of 2, as $B \propto \rho$ and so $P_{\text{mag}} \propto \rho^2$ under perpendicular compression).

fast magnetosonic-mode properties

The mode with the minus signs in Eq. (19.77) is called the *slow magnetosonic mode*. Its phase speed (depicted by the inner figure-8 curve in Fig. 19.14) can be approximated by $\omega/k = \pm aC \cos \theta / (a^2 + C^2)^{1/2}$ when $a \gg C$ or $a \ll C$. Note that

slow magnetosonic-mode properties

slow mode—like the intermediate mode but unlike the fast mode—is incapable of propagating perpendicularly to the unperturbed magnetic field; see Fig. 19.14. In the limit of vanishing Alfvén speed or vanishing sound speed, the slow mode ceases to exist for all directions of propagation.

In Chap. 21, we will discover that MHD is a good approximation to the behavior of plasmas only at frequencies below the “ion cyclotron frequency,” which is a rather low frequency. For this reason, magnetosonic modes are usually regarded as low-frequency modes.

19.7.3

19.7.3 Scattering of Cosmic Rays by Alfvén Waves

mechanism for Alfvén waves to scatter cosmic-ray particles

Now let us return to the issue of cosmic-ray propagation, which motivated our investigation of magnetosonic modes. Let us consider 100-GeV particles in the interstellar medium. The electron (and ion, mostly proton) density and magnetic field strength are typically $n \sim 3 \times 10^4 \text{ m}^{-3}$ and $B \sim 300 \text{ pT}$. The Alfvén speed is then $a \sim 30 \text{ km s}^{-1}$, much slower than the speeds of the cosmic rays. When analyzing cosmic-ray propagation, a magnetosonic wave can therefore be treated as essentially a magnetostatic perturbation. A relativistic cosmic ray of energy \mathcal{E} has a gyro (relativistic Larmor) radius of $r_G = \mathcal{E}/eBc$, in this case $\sim 3 \times 10^{12} \text{ m}$. Cosmic rays will be unaffected by waves with wavelength either much greater than or much less than r_G . However, magnetosonic waves (especially Alfvén waves, which are responsible for most of the scattering), with wavelength matched to the gyro radius, will be able to change the particle’s *pitch angle* α (the angle its momentum makes with the mean magnetic field direction). See Sec. 23.4.1 for some details. If the Alfvén waves in this wavelength range have rms dimensionless amplitude $\delta B/B \ll 1$, then the particle’s pitch angle will change by an amount $\delta\alpha \sim \delta B/B$ for every wavelength. Now, if the wave spectrum is broadband, individual waves can be treated as uncorrelated, so the particle pitch angle changes stochastically. In other words, the particle diffuses in pitch angle. The effective diffusion coefficient is

$$D_\alpha \sim \left(\frac{\delta B}{B} \right)^2 \omega_G, \quad (19.78)$$

where $\omega_G = c/r_G$ is the gyro frequency (relativistic analog of cyclotron frequency ω_c). The particle is therefore scattered by roughly a radian in pitch angle every time it traverses a distance $\ell \sim (B/\delta B)^2 r_G$. This is effectively the particle’s collisional mean free path. Associated with this mean free path is a spatial diffusion coefficient

$$D_x \sim \frac{\ell c}{3}. \quad (19.79)$$

It is thought that $\delta B/B \sim 10^{-1}$ in the relevant wavelength range in the interstellar medium. An estimate of the collision mean free path is then $\ell(100 \text{ GeV}) \sim 10^{14} \text{ m}$. Now, the thickness of our galaxy’s interstellar disk of gas is roughly $L \sim 3 \times 10^{18} \text{ m} \sim 10^4 \ell$. Therefore, an estimate of the cosmic-ray anisotropy is

estimated and measured cosmic-ray anisotropy

$\sim \ell/L \sim 3 \times 10^{-5}$, roughly compatible with the measurements. Although this discussion is an oversimplification, it does demonstrate that the cosmic rays in the interplanetary, interstellar, and intergalactic media can be scattered efficiently by magnetosonic waves. This allows the particle transport to be impeded without much loss of energy, so that the theory of cosmic-ray acceleration (Ex. 23.12) and scattering (this section) together can account for the particle fluxes observed as a function of energy and direction at Earth.

A good question to ask at this point is “Where do the Alfvén waves come from?” The answer turns out to be that they are maintained as part of a turbulence spectrum and created by the cosmic rays themselves through the growth of plasma instabilities. To proceed further and give a more quantitative description of this interaction, we must go beyond a purely fluid description and explore the motions of individual particles. This is where we shall turn in the next few chapters, culminating with a return to the interaction of cosmic rays with Alfvén waves in Sec. 23.4.1.

Bibliographic Note

For intuitive insight into magnetohydrodynamics, we recommend Shercliff (1965).

For textbook introductions to magnetohydrodynamics, we recommend the relevant chapters of Landau, Pitaevskii, and Lifshitz (1979), Schmidt (1979), Boyd and Sanderson (2003), and Bellan (2006). For far greater detail, we recommend a textbook that deals solely with magnetohydrodynamics: Goedbloed and Poedts (2004) and its advanced supplement Goedbloed, Keppens, and Poedts (2010). For a very readable treatment from the viewpoint of an engineer, with applications to engineering and metallurgy, see Davidson (2001).

For the theory of MHD instabilities and applications to magnetic confinement, see the above references, and also Bateman (1978) and the collection of early papers edited by Jeffrey and Taniuti (1966). For applications to astrophysics and space physics, see Parker (1979), Parks (2004), and Kulsrud (2005).

PLASMA PHYSICS

A *plasma* is a gas that is significantly ionized (through heating or photoionization) and thus is composed of electrons and ions, and that has a low enough density to behave classically (i.e., to obey Maxwell-Boltzmann statistics rather than Fermi-Dirac or Bose-Einstein). Plasma physics originated in the nineteenth century, with the study of gas discharges (Crookes, 1879). In 1902, Heaviside and Kennelly realized that plasma is also the key to understanding the propagation of radio waves across the Atlantic. The subject received a further boost in the early 1950s, with the start of the controlled (and the uncontrolled) thermonuclear fusion program. The various confinement devices described in the preceding chapter are intended to hold plasma at temperatures as high as $\sim 10^8$ K, high enough for fusion to begin; the difficulty of this task has turned out to be an issue of plasma physics as much as of MHD. The next new venue for plasma research was extraterrestrial. Although it was already understood that Earth was immersed in a tenuous outflow of ionized hydrogen known as the solar wind, the dawn of the space age in 1957 also initiated experimental *space plasma physics*. More recently, the interstellar and intergalactic media beyond the solar system as well as exotic astronomical objects like quasars and pulsars have allowed us to observe plasmas under quite extreme conditions, irreproducible in any laboratory experiment.

The dynamical behavior of a plasma is more complex than the dynamics of the gases and fluids we have met so far. This dynamical complexity has two main origins:

1. The dominant form of interparticle interaction in a plasma, Coulomb scattering, is so weak that the mean free paths of the electrons and ions are often larger than the plasma's macroscopic lengthscales. This allows the particles' momentum distribution functions to deviate seriously from their equilibrium Maxwellian forms and, in particular, to be highly anisotropic.
2. The electromagnetic fields in a plasma are of long range. This allows charged particles to couple to one another electromagnetically and act in concert as modes of excitation (plasma waves) that behave like single dynamical entities

(plasmons). Much of plasma physics consists of the study of the properties and interactions of these modes.

The dynamical behavior of a plasma depends markedly on frequency. At the lowest frequencies, the ions and electrons are locked together by electrostatic forces and behave like an electrically conducting fluid; this is the regime of MHD (Chap. 19). At somewhat higher frequencies, the electrons and the ions can move relative to each other, behaving like two separate, interpenetrating fluids; we study this two-fluid regime in Chap. 21. At still higher frequencies, complex dynamics are supported by momentum space anisotropies and can be analyzed using a variant of the kinetic-theory collisionless Boltzmann equation that we introduced in Chap. 3. We study such dynamics in Chap. 22. In the two-fluid and collisionless-Boltzmann analyses of Chaps. 21 and 22, we focus on phenomena that can be treated as linear perturbations of an equilibrium state. However, the complexities and long mean free paths of plasmas also produce rich nonlinear phenomena; we study some of these in Chap. 23. But first, as a foundation for the dynamical studies in Chaps. 21, 22, and 23, we develop in Chap. 20 detailed insights into the microscopic structure of a plasma.

The Particle Kinetics of Plasma

The study of individual particles frequently gives insight
into the behavior of an ionized gas.

LYMAN SPITZER (1962)

20.1 Overview

20.1

The preceding chapter, Chap. 19, can be regarded as a transition from fluid mechanics to plasma physics. In the context of a magnetized plasma, it describes equilibrium and low-frequency dynamical phenomena using fluid-mechanics techniques. In this chapter, we prepare for more sophisticated descriptions of a plasma by introducing a number of elementary foundational concepts peculiar to plasmas and by exploring a plasma's structure on the scale of individual particles using elementary techniques from kinetic theory.

Specifically, in Sec. 20.2, we identify the region of densities and temperatures in which matter, in statistical equilibrium, takes the form of a plasma, and we meet specific examples of plasmas that occur in Nature and in the laboratory. Then in Sec. 20.3, we study two phenomena that are important for plasmas: the collective manner in which large numbers of electrons and ions shield out the electric field of a charge in a plasma (Debye shielding), and the oscillations of a plasma's electrons relative to its ions (plasma oscillations).

In Sec. 20.4, we study the Coulomb scattering by which a plasma's electrons and ions deflect an individual charged particle from straight-line motion and exchange energy with it. We then examine the statistical properties of large numbers of such Coulomb scatterings—most importantly, the rates (inverse timescales) for the velocities of a plasma's electrons and ions to isotropize, and the rates for them to thermalize. Our calculations reveal that Coulomb scattering is so weak that, in most plasmas encountered in Nature, it is unlikely to produce isotropized or thermalized velocity distributions. In Sec. 20.5, we give a brief preview of the fact that in real plasmas the scattering of electrons and ions off collective plasma excitations (*plasmions*) often isotropizes and thermalizes their velocities far faster than would Coulomb scattering. Thus many real plasmas are far more isotropic and thermalized than our Coulomb-scattering analyses suggest. (We explore this “anomalous” behavior in Chaps. 22 and 23.) In Sec. 20.5, we also use the statistical properties

BOX 20.1. READERS' GUIDE

- This chapter relies significantly on portions of nonrelativistic kinetic theory as developed in Chap. 3.
- It also relies a bit (but not greatly) on portions of MHD as developed in Chap. 19.
- Chapters 21–23 of Part VI rely heavily on this chapter.

of Coulomb scatterings to derive a plasma's transport coefficients—specifically, its electrical and thermal conductivities—for situations where Coulomb scattering dominates over particle-plasmon scattering.

Most plasmas are significantly magnetized. This introduces important new features into their dynamics, which we describe in Sec. 20.6: cyclotron motion (the spiraling of particles around magnetic field lines), a resulting anisotropy of the plasma's pressure (different pressures along and orthogonal to the field lines), and the split of a plasma's adiabatic index into four different adiabatic indices for four different types of compression. Finally, in Sec. 20.7, we examine the motion of an individual charged particle in a slightly inhomogeneous and slowly time-varying magnetic field, and we describe *adiabatic invariants*, which control that motion in easily understood ways.

20.2 20.2 Examples of Plasmas and Their Density-Temperature Regimes

The density-temperature regime in which matter behaves as a nonrelativistic plasma is shown in Fig. 20.1. In this figure, and in most of Part VI, we confine our attention to pure hydrogen plasma comprising protons and electrons. Many plasmas contain large fractions of other ions, which can have larger charges and do have greater masses than protons. This generalization introduces few new issues of principle so, for simplicity, we eschew it and focus on a hydrogen plasma.

The boundaries of the plasma regime in Fig. 20.1 are dictated by the following considerations.

20.2.1 20.2.1 Ionization Boundary

We are mostly concerned with fully ionized plasmas, even though partially ionized plasmas, such as the ionosphere, are often encountered in physics, astronomy, and engineering, and more complex plasmas (such as dusty plasmas) can also be important. The plasma regime's ionization boundary is the bottom curve in Fig. 20.1, at a temperature of a few thousand Kelvins. This boundary is dictated by chemical equilibrium for the reaction

ionization boundary

FIGURE 20.1 The density-temperature regime in which matter, made largely of hydrogen, behaves as a nonrelativistic plasma. The densities and temperatures of specific examples of plasmas are indicated by dashed lines. The number density n of electrons (and also of protons) is shown horizontally at the bottom, and the corresponding mass density ρ is shown at the top. The temperature T is shown at the left in Kelvins, and at the right $k_B T$ is shown in keV, thousands of electron volts. The bottom-most scale is the plasma frequency, discussed in Sec. 20.3.3. This figure is a more detailed version of Fig. 3.7.

as described by the Saha equation (Ex. 5.10):

$$\frac{n_e n_p}{n_H} = \frac{(2\pi m_e k_B T)^{3/2}}{h^3} e^{-I_p/(k_B T)}. \quad (20.2)$$

Here n_e , n_p , and n_H are the number densities of electrons, protons, and neutral hydrogen atoms (at the relevant temperatures hydrogen molecules have dissociated into individual atoms), respectively; T is temperature; m_e is the electron rest mass; h is Planck's constant; k_B is Boltzmann's constant; and $I_p = 13.6$ eV is the ionization

energy of hydrogen (i.e., the binding energy of its ground state). Notice that the prefactor in Eq. (20.2) is $\lambda_{T\text{dB}}^{-3}$ with $\lambda_{T\text{dB}} \equiv h/\sqrt{2\pi m_e k_B T}$, the electrons' thermal de Broglie wavelength. The bottom boundary in Fig. 20.1 is that of 50% ionization [i.e., $n_e = n_p = n_H = \rho/(2m_H)$, with m_H the mass of a hydrogen atom]; but because of the exponential factor in Eq. (20.2), the line of 90% ionization is virtually indistinguishable from that of 50% ionization on the scale of the figure. Using the rough equivalence $1 \text{ eV} \cong 10^4 \text{ K}$, we might have expected that the ionization boundary would correspond to a temperature $T \sim I_p/k_B \sim 10^5 \text{ K}$. However, this is true only near the degeneracy boundary (see below). When the plasma is strongly nondegenerate, ionization occurs at a significantly lower temperature due to the vastly greater number of states available to an electron when free than when bound in a hydrogen atom. Equivalently, at low densities, once a hydrogen atom has been broken up into an electron plus a proton, the electron (or proton) must travel a large distance before encountering another proton (or electron) with which to recombine, making a new hydrogen atom; as a result, equilibrium occurs at a lowered temperature, where the ionization rate is thereby lowered to match the smaller recombination rate.

20.2.2

20.2.2 Degeneracy Boundary

degeneracy boundary

The electrons, with their small rest masses, become degenerate more easily than the protons or hydrogen atoms. The slanting line on the right side of Fig. 20.1 is the plasma's boundary of electron degeneracy. This boundary is determined by the demand that the mean occupation number of the electrons' single-particle quantum states not be $\ll 1$. In other words, the volume of phase space per electron—the product of the volumes of real space $\sim n_e^{-1}$ and of momentum space $\sim (m_e k_B T)^{3/2}$ occupied by each electron—should be comparable with the elementary quantum mechanical phase-space volume given by the uncertainty principle, h^3 . Inserting the appropriate factors of order unity [cf. Eq. (3.41)], this relation becomes the boundary equation:

$$n_e \simeq 2 \frac{(2\pi m_e k_B T)^{3/2}}{h^3}. \quad (20.3)$$

When the electrons become degenerate (rightward of the degeneracy line in Fig. 20.1), as they do in a metal or a white dwarf, the electron de Broglie wavelength becomes large compared with the mean interparticle spacing, and quantum mechanical considerations are of paramount importance.

20.2.3

20.2.3 Relativistic Boundary

relativistic boundary

Another important limit arises when the electron thermal speeds become relativistic. This occurs when

$$T \sim m_e c^2/k_B \sim 6 \times 10^9 \text{ K} \quad (20.4)$$

(top horizontal line in Fig. 20.1). Although we shall not consider them much further, the properties of relativistic plasmas (above this line) are mostly analogous to those of nonrelativistic plasmas (below it).

20.2.4 Pair-Production Boundary

20.2.4

Finally, for plasmas in statistical equilibrium, electron-positron pairs are created in profusion at high enough temperatures. In Ex. 5.9 we showed that, for $k_B T \ll m_e c^2$ but T high enough that pairs begin to form, the density of positrons divided by that of protons is

$$\frac{n_+}{n_p} = \frac{1}{2y[y + (1 + y^2)^{1/2}]}, \quad \text{where } y \equiv \frac{1}{4} n_e \left(\frac{h}{\sqrt{2\pi m_e k_B T}} \right)^3 e^{m_e c^2 / (k_B T)}. \quad (20.5)$$

Setting this expression to unity gives the pair-production boundary. This boundary curve, labeled “pairs” in Fig. 20.1, is similar in shape to the ionization boundary but shifted in temperature by $\sim 2 \times 10^4 \sim \alpha_F^{-2}$, where α_F is the fine structure constant. This is because we are now effectively “ionizing the vacuum” rather than a hydrogen atom, and the “ionization potential of the vacuum” is $\sim 2m_e c^2 = 4I_p / \alpha_F^2$.

We shall encounter a plasma above the pair-production boundary, and thus with a profusion of electron-positron pairs, in our discussion of the early universe in Secs. 28.4.1 and 28.4.2.

pair-production boundary

20.2.5 Examples of Natural and Human-Made Plasmas

20.2.5

Figure 20.1 and Table 20.1 show the temperature-density regions for the following plasmas:

- *Laboratory gas discharge.* The plasmas created in the laboratory by electric currents flowing through hot gas (e.g., in vacuum tubes, spark gaps, welding arcs, and neon and fluorescent lights).
- *Controlled thermonuclear fusion experiments.* The plasmas in which experiments for controlled thermonuclear fusion are carried out (e.g., in tokamaks).
- *Ionosphere.* The part of Earth’s upper atmosphere (at heights of ~ 50 – 300 km) that is partially photoionized by solar ultraviolet radiation.
- *Magnetosphere.* The plasma of high-speed electrons and ions that are locked on Earth’s dipolar magnetic field and slide around on its field lines at several Earth radii.
- *Sun’s core.* The plasma at the center of the Sun, where fusion of hydrogen to form helium generates the Sun’s heat.
- *Solar wind.* The wind of plasma that blows off the Sun and outward through the region between the planets.
- *Interstellar medium.* The plasma, in our galaxy, that fills the region between the stars. This plasma exhibits a fairly wide range of density and temperature as a result of such processes as heating by photons from stars, heating and compression by shock waves from supernovae, and cooling by thermal emission of radiation.

TABLE 20.1: Representative electron number densities n , temperatures T , and magnetic field strengths B , together with derived plasma parameters in a variety of environments

Plasma	n (m^{-3})	T (K)	B (T)	λ_D (m)	N_D	ω_p (s^{-1})	ν_{ee} (s^{-1})	ω_c (s^{-1})	r_L (m)
Gas discharge	10^{16}	10^4	—	10^{-4}	10^4	10^{10}	10^5	—	—
Fusion experiments	10^{20}	10^8	10	10^{-4}	10^8	10^{12}	10^4	10^{12}	10^{-5}
Ionosphere	10^{12}	10^3	10^{-5}	10^{-3}	10^5	10^8	10^3	10^6	10^{-1}
Magnetosphere	10^7	10^7	10^{-8}	10^2	10^{10}	10^5	10^{-8}	10^3	10^4
Sun's core	10^{32}	10^7	—	10^{-11}	1	10^{18}	10^{16}	—	—
Solar wind	10^6	10^5	10^{-9}	10	10^{11}	10^5	10^{-6}	10^2	10^4
Interstellar medium	10^5	10^4	10^{-10}	10	10^{10}	10^4	10^{-5}	10	10^4
Intergalactic medium	10^{-1}	10^6	—	10^5	10^{15}	10^2	10^{-12}	—	—

Notes: The derived parameters, discussed later in this chapter, are: λ_D , Debye length; N_D , Debye number; ω_p , plasma frequency; ν_{ee} , equilibration rate for electron energy; ω_c , electron cyclotron frequency; and r_L , electron Larmor radius. Values are given to order of magnitude, as all of these environments are quite inhomogeneous. — indicates this quantity is irrelevant.

- *Intergalactic medium.* The plasma that fills the space outside galaxies and clusters of galaxies (the locale of almost all the universe's plasma). We shall meet the properties and evolution of this intergalactic plasma in our study of cosmology, Sec. 28.3.1.

Characteristic plasma properties in these various environments are collected in Table 20.1. In the next three chapters we study applications from all these environments.

EXERCISES

Exercise 20.1 Derivation: Boundary of Degeneracy

Show that the condition $n_e \ll (2\pi m_e k_B T)^{3/2} / h^3$ [cf. Eq. (20.3)] that electrons be nondegenerate is equivalent to the following statements.

- The mean separation between electrons, $l \equiv n_e^{-1/3}$, is large compared to the electrons' thermal de Broglie wavelength, $\lambda_{T \text{ dB}} = h / \sqrt{2\pi m_e k_B T}$.
- The uncertainty in the location of an electron drawn at random from the thermal distribution is small compared to the average inter-electron spacing.
- The quantum mechanical zero-point energy associated with squeezing each electron into a region of size $l = n_e^{-1/3}$ is small compared to the electron's mean thermal energy $k_B T$.

20.3 Collective Effects in Plasmas—Debye Shielding and Plasma Oscillations

20.3

In this section, we introduce two key ideas that are associated with most of the collective effects in plasma dynamics: Debye shielding (also called Debye screening) and plasma oscillations.

20.3.1 Debye Shielding

20.3.1

Any charged particle inside a plasma attracts other particles with opposite charge and repels those with the same charge, thereby creating a net cloud of opposite charges around itself. This cloud shields the particle's own charge from external view (i.e., it causes the particle's Coulomb field to fall off exponentially at large radii, rather than falling off as $1/r^2$).¹

mechanism of Debye shielding

This Debye shielding (or screening) of a particle's charge can be demonstrated and quantified as follows. Consider a single fixed test charge Q surrounded by a plasma of protons and electrons. Denote the average densities of protons and electrons—considered as smooth functions of radius r from the test charge—by $n_p(r)$ and $n_e(r)$, and let the mean densities of electrons and protons (averaged over a large volume) be \bar{n} . (The mean electron and proton densities must be equal because of overall charge neutrality, which is enforced by the electrostatic restoring force that we explore in Sec. 20.3.3.) Then the electrostatic potential $\Phi(r)$ outside the particle satisfies Poisson's equation, which we write in SI units:²

$$\nabla^2 \Phi = -\frac{(n_p - n_e)e}{\epsilon_0} - \frac{Q}{\epsilon_0} \delta(\mathbf{r}). \quad (20.6)$$

Poisson's equation

(We denote the positive charge of a proton by $+e$ and the negative charge of an electron by $-e$.)

A proton at radius r from the particle has an electrostatic potential energy $e\Phi(r)$. Correspondingly, the number density of protons at radius r is altered from \bar{n} by the Boltzmann factor $\exp[-e\Phi/(k_B T)]$; and, similarly, the density of electrons is altered by $\exp[+e\Phi/(k_B T)]$:

$$\begin{aligned} n_p &= \bar{n} \exp[-e\Phi/(k_B T)] \simeq \bar{n} [1 - e\Phi/(k_B T)], \\ n_e &= \bar{n} \exp[+e\Phi/(k_B T)] \simeq \bar{n} [1 + e\Phi/(k_B T)], \end{aligned} \quad (20.7)$$

where we have made a Taylor expansion of the Boltzmann factor valid for $|e\Phi| \ll k_B T$. By inserting the linearized versions of Eqs. (20.7) into Eq. (20.6), we obtain

$$\nabla^2 \Phi = \frac{2e^2 \bar{n}}{\epsilon_0 k_B T} \Phi - \frac{Q}{\epsilon_0} \delta(\mathbf{r}). \quad (20.8)$$

1. Analogous effects are encountered in condensed-matter physics and quantum electrodynamics.
2. For those who prefer Gaussian units, the translation is most easily effected by the transformations $4\pi\epsilon_0 \rightarrow 1$ and $\mu_0/(4\pi) \rightarrow 1$, and inserting factors of c by inspection using dimensional analysis. It is also useful to recall that $1 \text{ T} \equiv 10^4 \text{ Gauss}$ and that the charge on an electron is $-1.602 \times 10^{-19} \text{ C} \equiv -4.803 \times 10^{-10} \text{ esu}$.

The spherically symmetric solution to this equation,

$$\Phi = \frac{Q}{4\pi\epsilon_0 r} e^{-\sqrt{2}r/\lambda_D}, \quad (20.9)$$

has the form of a Coulomb field with an exponential cutoff. The characteristic length-scale of the exponential cutoff,

Debye length

$$\lambda_D \equiv \left(\frac{\epsilon_0 k_B T}{\bar{n} e^2} \right)^{1/2} = 69 \left(\frac{T/1 \text{ K}}{\bar{n}/1 \text{ m}^{-3}} \right)^{1/2} \text{ m}, \quad (20.10)$$

is called the *Debye length*. It is a rough measure of the size of the Debye shielding cloud that the charged particle carries with itself.

The charged particle could be some foreign charged object (not a plasma electron or proton), or equally well, it could be one of the plasma's own electrons or protons. Thus, we can think of each electron in the plasma as carrying with itself a positively charged Debye shielding cloud of size λ_D , and each proton as carrying a negatively charged cloud. Each electron and proton not only carries its own cloud; it also plays a role as one of the contributors to the clouds around other electrons and protons.

20.3.2

20.3.2 Collective Behavior

A charged particle's Debye cloud is almost always made of a huge number of electrons and very nearly the same number of protons. It is only a tiny, time-averaged excess of electrons over protons (or protons over electrons) that produces the cloud's net charge and the resulting exponential decay of the electrostatic potential. Ignoring this tiny excess, the mean number of electrons in the cloud and the mean number of protons are roughly

Debye number

$$N_D \equiv \bar{n} \frac{4\pi}{3} \lambda_D^3 = 1.4 \times 10^6 \frac{(T/1 \text{ K})^{3/2}}{(\bar{n}/1 \text{ m}^{-3})^{1/2}}. \quad (20.11)$$

This *Debye number* is large compared to unity throughout the density-temperature regime of plasmas, except for the tiny lower right-hand corner of Fig. 20.1. The boundary of that region (labeled "collective behavior"/"independent particles") is given by $N_D = 1$. The upper left-hand side of that boundary has $N_D \gg 1$ and is called the regime of collective behavior, because a huge number of particles are collectively responsible for the Debye cloud; this leads to a variety of collective dynamical phenomena in the plasma. The lower right-hand side has $N_D < 1$ and is called the regime of independent particles, because in it collective phenomena are of small importance. (In this regime Φ on the right-hand side of Eq. (20.8) is replaced by $(kT/e) \sinh[e\Phi/(k_B T)]$.) In this book we restrict ourselves to the extensive regime of collective behavior and ignore the tiny regime of independent particles.

Characteristic values for the Debye length and Debye number in a variety of environments are listed in Table 20.1.

20.3.3 Plasma Oscillations and Plasma Frequency

20.3.3

Of all the dynamical phenomena that can occur in a plasma, perhaps the most important is a relative oscillation of the plasma's electrons and protons. A simple, idealized version of this *plasma oscillation* is depicted in Fig. 20.2. Suppose for the moment that the protons are all fixed, and displace the electrons rightward (in the x direction) with respect to the protons by an amount ξ , thereby producing a net negative charge per unit area $-e\bar{n}\xi$ at the right end of the plasma, a net positive charge per unit area $+e\bar{n}\xi$ at the left end, and a corresponding electric field $E = e\bar{n}\xi/\epsilon_0$ in the x direction throughout the plasma. The electric field pulls on the plasma's electrons and protons, giving the electrons an acceleration $d^2\xi/dt^2 = -eE/m_e$ and the protons an acceleration smaller by $m_e/m_p = 1/1,836$, which we neglect. The result is an equation of motion for the electrons' collective displacement:

$$\frac{d^2\xi}{dt^2} = -\frac{e}{m_e}E = -\frac{e^2\bar{n}}{\epsilon_0 m_e}\xi. \quad (20.12)$$

Since Eq. (20.12) is a harmonic-oscillator equation, the electrons oscillate sinusoidally, $\xi = \xi_o \cos(\omega_p t)$, at the *plasma (angular) frequency*

$$\omega_p \equiv \left(\frac{\bar{n}e^2}{\epsilon_0 m_e}\right)^{1/2} = 56.3 \left(\frac{\bar{n}}{1 \text{ m}^{-3}}\right)^{1/2} \text{ s}^{-1}. \quad (20.13)$$

plasma frequency, for plasma oscillations

Notice that this frequency of plasma oscillations depends only on the plasma density \bar{n} and not on its temperature. Note that, if we define the electron thermal speed to be $v_e \equiv (k_B T_e/m_e)^{1/2}$, then $\omega_p \equiv v_e/\lambda_D$. In other words, a thermal electron travels roughly a Debye length in a plasma oscillation period. We can think of the Debye length as the electrostatic correlation length, and the plasma period as the electrostatic correlation time.

FIGURE 20.2 Idealized depiction of the displacement of electrons relative to protons, which occurs during plasma oscillations.

Characteristic values for the plasma frequency in a variety of environments are listed in Table 20.1 and depicted on the bottom-most scale of Fig. 20.1.

20.4 20.4 Coulomb Collisions

In this section and the next, we study transport coefficients (electrical and thermal conductivities) and the establishment of local thermodynamic equilibrium in a plasma under the hypothesis that Coulomb collisions are the dominant source of scattering for both electrons and protons. In fact, as we shall see later, Coulomb scattering is usually a less-effective scattering mechanism than *collisionless* processes mediated by fluctuating electromagnetic fields (plasmons).

20.4.1 20.4.1 Collision Frequency

Consider first, as we did in our discussion of Debye shielding, a single test particle—let it be an electron—interacting with background field particles—let these be protons for the moment. The test electron moves with speed v_e . The field protons will move much more slowly if the electron and protons are near thermodynamic equilibrium (as the proton masses are much greater than that of the electron), so the protons can be treated, for the moment, as at rest. When the electron flies by a single proton, we can characterize the encounter using an *impact parameter* b , which is what the distance of closest approach would have been if the electron were not deflected; see Fig. 20.3. The electron will be scattered by the Coulomb field of the proton, a process sometimes called *Rutherford scattering*. If the deflection angle is small, $\theta_D \ll 1$, we can approximate its value by computing the perpendicular impulse exerted by the proton's Coulomb field, integrating along the electron's unperturbed straight-line trajectory:

Rutherford scattering

$$m_e v_e \theta_D = \int_{-\infty}^{+\infty} \frac{e^2 b}{4\pi \epsilon_0 (b^2 + v_e^2 t^2)^{3/2}} dt = \frac{e^2}{2\pi \epsilon_0 v_e b}, \quad (20.14a)$$

which implies that

$$\theta_D = b_o/b \text{ for } b \gg b_o, \quad (20.14b)$$

where

$$b_o \equiv \frac{e^2}{2\pi \epsilon_0 m_e v_e^2}. \quad (20.14c)$$

When $b \lesssim b_o$, this approximation breaks down, and the deflection angle is of order 1 radian.³

Below we shall need to know how much energy the electron loses, for the large-impact-parameter case. That energy loss, $-\Delta E$, is equal to the energy gained by the

3. A more careful calculation gives $2 \tan(\theta_D/2) = b_o/b$; see, e.g., Bellan (2006, Assignment 1 in Sec. 1.13).

FIGURE 20.3 The geometry of a Coulomb collision.

proton. Since the proton is initially at rest, and since momentum conservation implies it gains a momentum $\Delta p = m_e v_e \theta_D$, ΔE must be

$$\Delta E = -\frac{(\Delta p)^2}{2m_p} = -\frac{m_e}{m_p} \left(\frac{b_o}{b}\right)^2 E, \quad \text{for } b \gg b_o. \quad (20.15)$$

Here $E = \frac{1}{2}m_e v_e^2$ is the electron's initial energy.

We turn from an individual Coulomb collision to the net, statistically averaged effect of many collisions. The first thing we compute is the mean time t_D required for the orbit of the test electron to be deflected by an angle of order 1 radian from its initial direction, and the inverse of t_D , which we call the “deflection rate” or “deflection frequency” and denote $\nu_D = 1/t_D$. If the dominant source of this deflection were a single large-angle scattering event, then the relevant cross section would be $\sigma = \pi b_o^2$ (since all impact parameters $\lesssim b_o$ produce large-angle scatterings), and the mean deflection time and frequency would be

$$\nu_D \equiv \frac{1}{t_D} = n\sigma v_e = n\pi b_o^2 v_e. \quad (20.16)$$

Here n is the proton number density, which is the same as the electron number density in our hydrogen plasma.

The cumulative, random-walk effects of many small-angle scatterings off field protons actually produce a net deflection of order 1 radian in a time shorter than this. As the directions of the individual scatterings are random, the mean deflection angle after many scatterings vanishes. However, the mean-square deflection angle, $\langle \Theta^2 \rangle = \sum_{\text{all encounters}} \theta_D^2$, will not vanish. That mean-square deflection angle, during a time t , accumulates to

$$\langle \Theta^2 \rangle = \int_{b_{\min}}^{b_{\max}} \left(\frac{b_o}{b}\right)^2 n v_e t 2\pi b db = n 2\pi b_o^2 v_e t \ln \left(\frac{b_{\max}}{b_{\min}}\right). \quad (20.17)$$

Here the factor $(b_o/b)^2$ in the integrand is the squared deflection angle θ_D^2 for impact parameter b , and the remaining factor $n v_e t 2\pi b db$ is the number of encounters that occur with impact parameters between b and $b + db$ during time t . The integral diverges logarithmically at both its lower limit b_{\min} and its upper limit b_{\max} . In Sec. 20.4.2 we discuss the physical origins of and values of the cutoffs b_{\min} and b_{\max} . The value of t that makes the mean-square deflection angle $\langle \Theta^2 \rangle$ equal to unity is, to

time and frequency for a single large-angle deflection of an electron by a proton

mean-square deflection from small-angle scatterings

within factors of order unity, the deflection time t_D (and inverse deflection frequency ν_D^{-1}):

time and frequency for large net deflection of an electron by protons

$$\nu_D^{ep} = \frac{1}{t_D^{ep}} = n2\pi b_0^2 v_e \ln \Lambda = \frac{ne^4 \ln \Lambda}{2\pi \epsilon_0^2 m_e^2 v_e^3}, \quad \text{where } \Lambda = b_{\max}/b_{\min}. \quad (20.18a)$$

Here the superscript ep indicates that the test particle is an electron and the field particles are protons. Notice that this deflection frequency is larger, by a factor $2 \ln \Lambda$, than the frequency (20.16) for a single large-angle scattering.

We must also consider the repulsive collisions of our test electron with field electrons. Although we are no longer justified in treating the field electrons as being at rest, the impact parameter for a large angle deflection is still $\sim b_0$, so Eq. (20.18a) is also appropriate to this case, in order of magnitude:

time and frequency for large net deflection of an electron by electrons

$$\nu_D^{ee} = \frac{1}{t_D^{ee}} \sim \nu_D^{ep} = n2\pi b_0^2 v_e \ln \Lambda = \frac{ne^4 \ln \Lambda}{2\pi \epsilon_0^2 m_e^2 v_e^3}. \quad (20.18b)$$

Finally, and in the same spirit, we can compute the collision frequency for the protons. Because electrons are so much lighter than protons, proton-proton collisions will be more effective in deflecting protons than are proton-electron collisions. Therefore, the proton collision frequency is given by Eq. (20.18b) with the electron subscripts replaced by proton subscripts:

time and frequency for large net deflection of a proton by protons

$$\nu_D^{pp} = \frac{1}{t_D^{pp}} \sim \frac{ne^4 \ln \Lambda}{2\pi \epsilon_0^2 m_p^2 v_p^3}. \quad (20.18c)$$

20.4.2

20.4.2 The Coulomb Logarithm

The maximum impact parameter b_{\max} , which appears in $\Lambda \equiv b_{\max}/b_{\min}$, is the Debye length λ_D , since for impact parameters $b \gg \lambda_D$ the Debye shielding screens out a field particle's Coulomb field, while for $b \ll \lambda_D$ Debye shielding is unimportant.

The minimum impact parameter b_{\min} has different values, depending on whether quantum mechanical wave-packet spreading is important for the test particle during the collision. Because of wave-packet spreading, the nearest the test particle can come to a field particle is the test particle's de Broglie wavelength: $b_{\min} = \hbar/mv$. However, if the de Broglie wavelength is smaller than b_0 , then the effective value of b_{\min} will be simply b_0 . Therefore, in $\ln \Lambda = \ln(b_{\max}/b_{\min})$ (the *Coulomb logarithm*), we have

Coulomb logarithm

$$b_{\min} = \max[b_0 = e^2/(2\pi \epsilon_0 m_e v_e^2), \hbar/(m_e v_e)], \quad \text{and} \quad b_{\max} = \lambda_D \quad \text{for test electrons;} \\ b_{\min} = \max[b_0 = e^2/(2\pi \epsilon_0 m_p v_p^2), \hbar/(m_p v_p)], \quad \text{and} \quad b_{\max} = \lambda_D \quad \text{for test protons.} \quad (20.19)$$

Over most of the accessible range of density and temperature for a plasma, we have $3 \lesssim \ln \Lambda \lesssim 30$. Therefore, if we set

$$\ln \Lambda \simeq 10,$$

(20.20)

our estimate is good to a factor ~ 3 . For numerical values of $\ln \Lambda$ in a thermalized plasma, see Spitzer (1962, Table 5.1).

Logarithmic terms, closely related to the Coulomb logarithm, arise in a variety of other situations where one is dealing with a field whose potential varies as $1/r$ and force as $1/r^2$ —and for the same reason: one encounters integrals of the form $\int (1/r) dr$ that diverge logarithmically. Specific examples are (i) the *Gaunt factors*, which arise in the theory of bremsstrahlung radiation (electromagnetic waves from Coulomb scattering of charged particles), (ii) *Coulomb wave functions* (solutions to the Schrödinger equation for the quantum mechanical theory of Coulomb scattering), and (iii) the Shapiro time delay for electromagnetic waves that travel past a general relativistic gravitating body, such as the Sun (Sec. 27.2.4).

EXERCISES

Exercise 20.2 *Problem: The Coulomb Logarithm*

- Express the Coulomb logarithm in terms of the Debye number, N_D , in the classical regime, where $b_{\min} \sim b_0$.
- What range of electron temperatures corresponds to the classical regime, and what range to the quantum regime?
- Use the representative parameters from Table 20.1 to evaluate Coulomb logarithms for the Sun's core, a tokamak, and the interstellar medium, and verify that they lie in the range $3 \lesssim \ln \Lambda \lesssim 30$.

Exercise 20.3 *Example: Parameters for Various Plasmas*

Estimate the Debye length λ_D , the Debye number N_D , the plasma frequency $f_p \equiv \omega_p/2\pi$, and the electron deflection timescale $t_D^{ee} \sim t_D^{ep}$, for the following plasmas.

- An atomic bomb explosion in Earth's atmosphere 1 ms after the explosion. (Use the Sedov-Taylor similarity solution for conditions behind the bomb's shock wave; Sec. 17.6.)
- The ionized gas that enveloped the Space Shuttle (Box 17.4) as it reentered Earth's atmosphere.
- The expanding universe during its early evolution, just before it became cool enough for electrons and protons to combine to form neutral hydrogen (i.e., just before ionization “turned off”). (As we shall discuss in Chap. 28, the universe today is filled with blackbody radiation, produced in the big bang, that has a temperature $T = 2.7$ K, and the universe today has a mean density of hydrogen $\rho \sim 4 \times 10^{-28}$ kg m $^{-3}$. Extrapolate backward in time to infer the density and temperature at the epoch just before ionization turned off.)

Suppose that a hydrogen plasma is heated in some violent way (e.g., by a shock wave). Such heating will typically give the plasma's electrons and protons a non-Maxwellian velocity distribution. Coulomb collisions then, as time passes (and in the absence of more violent disruptions), will force the particles to exchange energy in random ways, gradually driving them into thermal equilibrium. As we shall see, thermal equilibration is achieved at different rates for the electrons and the protons. Correspondingly, the following three timescales are all different:

$$\begin{aligned}
 t_{ee}^{\text{eq}} &\equiv \left(\begin{array}{l} \text{time required for electrons to equilibrate with one another,} \\ \text{achieving a near-Maxwellian velocity distribution} \end{array} \right), \\
 t_{pp}^{\text{eq}} &\equiv (\text{time for protons to equilibrate with one another}), \\
 t_{ep}^{\text{eq}} &\equiv (\text{time for electrons to equilibrate with protons}).
 \end{aligned}
 \tag{20.21}$$

In this section we compute these three equilibration times.

ELECTRON-ELECTRON EQUILIBRATION

To evaluate t_{ee}^{eq} , we assume that the electrons begin with typical individual energies of order $k_B T_e$, where T_e is the temperature to which they are going to equilibrate, but their initial velocity distribution is rather non-Maxwellian. Then we can choose a typical electron as the “test particle.” We have argued that Coulomb interactions with electrons and protons are comparably effective in deflecting test electrons. However, they are not comparably effective in transferring energy. When the electron collides with a stationary proton, the energy transfer is

$$\frac{\Delta E}{E} \simeq -\frac{m_e}{m_p} \theta_D^2
 \tag{20.22}$$

[Eq. (20.15)]. This is smaller than the typical energy transfer in an electron-electron collision by the ratio m_e/m_p . Therefore, the collisions between electrons are responsible for establishing an electron Maxwellian distribution function.

The alert reader may spot a problem at this point. According to Eq. (20.22), electrons always lose energy to protons and never gain it. This would cause the electron temperature to continue to fall below the proton temperature, in clear violation of the second law of thermodynamics. Actually what happens in practice is that, if we allow for nonzero proton velocities, then the electrons can gain energy from some electron-proton collisions. This is also the case for the electron-electron collisions of immediate concern.

The most accurate formalism for dealing with this situation is the Fokker-Planck formalism, discussed in Sec. 6.9 and made explicit for Coulomb scattering in Ex. 20.8. Fokker-Planck is appropriate because, as we have shown, many weak scatterings dominate the few strong scatterings. If we use the Fokker-Planck approach to compute an energy equilibration time for a nearly Maxwellian distribution of electrons with tem-

perature T_e , then it turns out that a simple estimate, based on combining the deflection time (20.16) with the typical energy transfer (20.22) (with $m_p \rightarrow m_e$), and on assuming a typical electron velocity $v_e = (3k_B T_e/m_e)^{1/2}$, gives an answer good to a factor of 2. It is actually convenient to express this electron energy equilibration timescale using its reciprocal, the *electron-electron equilibration rate*, ν_{ee} . This facilitates comparison with the other frequencies characterizing the plasma. The true Fokker-Planck result for electrons near equilibrium is then

$$\begin{aligned} \nu_{ee} = \frac{1}{t_{ee}} &= \frac{n\sigma_T c \ln \Lambda}{2\pi^{1/2}} \left(\frac{k_B T_e}{m_e c^2} \right)^{-3/2} \\ &= 2.6 \times 10^{-5} \left(\frac{n}{1 \text{ m}^{-3}} \right) \left(\frac{T_e}{1 \text{ K}} \right)^{-3/2} \left(\frac{\ln \Lambda}{10} \right) \text{ s}^{-1} \end{aligned} \quad (20.23a)$$

electron-electron
equilibration rate

where we have used the Thomson cross section

$$\sigma_T = \frac{8\pi}{3} \left(\frac{e^2}{4\pi\epsilon_0 m_e c^2} \right)^2 = 6.65 \times 10^{-29} \text{ m}^2. \quad (20.23b)$$

PROTON-PROTON EQUILIBRATION

As for proton deflections [Eq. (20.18c)], so also for proton energy equilibration: the light electrons are far less effective at influencing the protons than are other protons. Therefore, the protons achieve a thermal distribution by equilibrating with one another, and their *proton-proton equilibration rate* can be written down immediately from Eq. (20.23a) by replacing the electron masses and temperatures with the proton values:

$$\begin{aligned} \nu_{pp} = \frac{1}{t_{pp}} &= \frac{n\sigma_T c \ln \Lambda}{2\pi^{1/2}} \left(\frac{m_e}{m_p} \right)^{1/2} \left(\frac{k_B T_p}{m_e c^2} \right)^{-3/2} \\ &= 6.0 \times 10^{-7} \left(\frac{n}{1 \text{ m}^{-3}} \right) \left(\frac{T_p}{1 \text{ K}} \right)^{-3/2} \left(\frac{\ln \Lambda}{10} \right) \text{ s}^{-1} \end{aligned} \quad (20.23c)$$

proton-proton
equilibration rate

ELECTRON-PROTON EQUILIBRATION

Finally, if the electrons and protons have different temperatures, we should compute the timescale for the two species to equilibrate with each other. This again is easy to estimate using the energy-transfer equation (20.22): $t_{ep} \simeq (m_p/m_e)t_{ee}$. The more accurate Fokker-Planck result for the *electron-proton equilibration rate* is again close to this value and is given by

$$\begin{aligned} \nu_{ep} = \frac{1}{t_{ep}} &= \frac{2n\sigma_T c \ln \Lambda}{\pi^{1/2}} \left(\frac{m_e}{m_p} \right) \left(\frac{k_B T_e}{m_e c^2} \right)^{-3/2} \\ &= 5.6 \times 10^{-8} \left(\frac{n}{1 \text{ m}^{-3}} \right) \left(\frac{T_e}{1 \text{ K}} \right)^{-3/2} \left(\frac{\ln \Lambda}{10} \right) \text{ s}^{-1} \end{aligned} \quad (20.23d)$$

electron-proton
equilibration rate

Thus, at the same density and temperature, protons require $\sim(m_p/m_e)^{1/2} = 43$ times longer to reach thermal equilibrium among themselves than do the electrons, and

proton-electron equilibration takes a time $\sim(m_p/m_e) = 1,836$ longer than electron-electron equilibration.

20.4.4 20.4.4 Discussion

Table 20.1 lists the electron-electron equilibration rates for a variety of plasma environments. Generally, they are very small compared with the plasma frequencies. For example, if we take parameters appropriate to fusion experiments (e.g., a tokamak), we find that $\nu_{ee} \sim 10^{-8}\omega_p$ and $\nu_{ep} \sim 10^{-11}\omega_p$. In fact, the equilibration time is comparable, to order of magnitude, with the total plasma confinement time ~ 0.1 s (cf. Sec. 19.3). The disparity between ν_{ee} and ω_p is even greater in the interstellar medium. For this reason most plasmas are well described as collisionless, and we must anticipate that the particle distribution functions will depart significantly from Maxwellian.

EXERCISES

Exercise 20.4 *Derivation: Electron-Electron Equilibration Rate*

Using the non-Fokker-Planck arguments outlined in the text, compute an estimate of the electron-electron equilibration rate, and show that it agrees with the Fokker-Planck result, Eq. (20.23a), to within a factor of 2.

Exercise 20.5 *Problem: Dependence of Thermal Equilibration on Charge and Mass*

Compute the ion equilibration rate for a pure He^3 plasma with electron density 10^{20} m^{-3} and temperature 10^8 K .

Exercise 20.6 *Example: Stopping of α -Particles*

A 100-MeV α -particle is incident on a plastic object. Estimate the distance that it will travel before coming to rest. This is known as the particle's *range*. [Hints: (i) Debye shielding does not occur in a plastic. (Why?) (ii) The α -particle loses far more energy to Coulomb scattering off electrons than off atomic nuclei. (Why?) Estimate the electron density as $n_e = 2 \times 10^{29} \text{ m}^{-3}$. (iii) Ignore relativistic corrections and refinements, such as the so-called *density effect*. (iv) Consider the appropriate values of b_{max} and b_{min} .]

Exercise 20.7 *Problem: Equilibration Time for a Globular Star Cluster*

Collections of stars have many similarities to a plasma of electrons and ions. These similarities arise from the fact that in both cases the interaction between the individual particles (stars, or ions and electrons) is a radial, $1/r^2$ force. The principal difference is that the force between stars is always attractive, so there is no analog of Debye shielding. One consequence of this difference is that a plasma can be spatially homogeneous and static, when one averages over lengthscales large compared to the interparticle separation; but a collection of stars cannot be—the stars congregate into clusters that are held together by the stars' mutual gravity.

A globular star cluster is an example. A typical globular cluster is a nearly spherical swarm of stars with the following parameters: cluster radius $\equiv R = 10$ light-years;

total number of stars in the cluster $\equiv N = 10^6$; and mass of a typical star $\equiv m = 0.4$ solar masses $= 8 \times 10^{32}$ g. Each star moves on an orbit of the average, “smeared out” gravitational field of the entire cluster. Since that smeared-out gravitational field is independent of time, each star conserves its total energy (kinetic plus gravitational) as it moves. Actually, the total energy is only approximately conserved. Just as in a plasma, gravitational “Coulomb collisions” of the star with other stars produce changes in the star’s energy.

- (a) What is the mean time t_E for a typical star in a globular cluster to change its energy substantially? Express your answer, accurate to within a factor of ~ 3 , in terms of N , R , and m . Evaluate it numerically and compare it with the age of the universe.
- (b) The cluster evolves substantially on the timescale t_E . What type of evolution would you expect to occur? What type of stellar energy distribution would you expect to result from this evolution?⁴

Exercise 20.8 ***Example and Challenge: Fokker-Planck Formalism for Coulomb Collisions* T2

Consider two families of particles that interact via Coulomb collisions (e.g., electrons and protons, or electrons and electrons). Regard one family as test particles, with masses m and charges q and a kinetic-theory distribution function $f(\mathbf{v}) = dN/d\mathcal{V}_x d\mathcal{V}_v$ that is homogeneous in space and thus only a function of the test particles’ velocities \mathbf{v} . (For discussion of this distribution function, see Sec. 3.2.3, and in greater detail, Sec. 22.2.1.) Regard the other family as field particles, with masses m' and charges q' and a spatially homogeneous distribution function $f_F(\mathbf{v}')$.

The Fokker-Planck equation (Sec. 6.9.3) can be used to give a rather accurate description of how the field particles’ distribution function $f(\mathbf{v}, t)$ evolves due to Coulomb collisions with the test particles. In this exercise, you will work out explicit versions of this Fokker-Planck equation. These explicit versions are concrete foundations for deducing Eqs. (20.23) for the electron and proton equilibration rates, Eqs. (20.26) for the thermal and electrical conductivities of a plasma, and other evolutionary effects of Coulomb collisions.

- (a) Explain why, for a spatially homogeneous plasma with the only electromagnetic fields present being the Coulomb fields of the plasma particles, the collisionless Boltzmann transport equation (3.65) (with \mathcal{N} replaced by f and p_j by v_j) becomes simply $\partial f/\partial t = 0$. Then go on to explain why the collision terms in the collisional Boltzmann transport equation (3.66) are of Fokker-Planck form, Eq. (6.106a):

$$\frac{\partial f}{\partial t} = -\frac{\partial}{\partial v_j} [A_j(\mathbf{v})f(\mathbf{v}, t)] + \frac{1}{2} \frac{\partial^2}{\partial v_j \partial v_k} [B_{jk}(\mathbf{v})f(\mathbf{v}, t)], \quad (20.24a)$$

4. For a detailed discussion, see, e.g., Binney and Tremaine (2003).

where A_j and B_{jk} are, respectively, the slowdown rate and velocity diffusion rate of the test particles due to Coulomb scatterings off the field particles:

$$A_j = \lim_{\Delta t \rightarrow 0} \left(\frac{\overline{\Delta v_j}}{\Delta t} \right), \quad B_{jk} = \lim_{\Delta t \rightarrow 0} \left(\frac{\overline{\Delta v_j \Delta v_k}}{\Delta t} \right)$$

[Eqs. (6.106b) and (6.106c)].

- (b) Analyze, in the center-of-mass reference frame, the small-angle Coulomb scattering of a test particle off a field particle (with some chosen impact parameter b and relative velocity $\mathbf{v}_{\text{rel}} = \mathbf{v} - \mathbf{v}' =$ difference between lab-frame velocities), and then transform to the laboratory frame where the field particles on average are at rest. Then add up the scattering influences of all field particles on the chosen test particle (i.e., integrate over b and over \mathbf{v}') to show that the test particle's rate of change of velocity is

$$A_j = \Gamma \frac{\partial}{\partial v_j} h(\mathbf{v}). \quad (20.24b)$$

Here the constant Γ and the *first Rosenbluth potential* h are

$$\Gamma = \frac{q^2 q'^2 \ln \Lambda}{4\pi \epsilon_0^2 m^2}, \quad h(\mathbf{v}) = \frac{m}{\mu} \int \frac{f_F(\mathbf{v}')}{|\mathbf{v} - \mathbf{v}'|} d\mathcal{V}_{v'}. \quad (20.24c)$$

In addition, $\mu = mm'/(m + m')$ is the reduced mass, which appears in the center-of-mass-frame analysis of the Coulomb collision; $\Lambda = b_{\text{max}}/b_{\text{min}}$ is the ratio of the maximum to the minimum possible impact parameters as in Sec. 20.4.2; and $d\mathcal{V}_{v'} = dv'_x dv'_y dv'_z$ is the volume element in velocity space. Although b_{min} depends on the particles' velocities, without significant loss of accuracy we can evaluate it for some relevant mean velocity and pull it out from under the integral, as we have done. This is because $\Lambda = b_{\text{max}}/b_{\text{min}}$ appears only in the logarithm.

- (c) By the same method as in part (b), show that the velocity diffusion rate is

$$B_{jk}(\mathbf{v}) = \Gamma \frac{\partial^2}{\partial v_j \partial v_k} g(\mathbf{v}), \quad (20.24d)$$

where the *second Rosenbluth potential* is

$$g(\mathbf{v}) = \int |\mathbf{v} - \mathbf{v}'| f_F(\mathbf{v}') d\mathcal{V}_{v'}. \quad (20.24e)$$

- (d) Show that, with A_j and B_{jk} expressed in terms of the Rosenbluth potentials [Eqs. (20.24b) and (20.24d)], the Fokker-Planck equation (20.24a) can be brought into the following alternative form:

$$\frac{\partial f}{\partial t} = \frac{\Gamma m}{2} \frac{\partial}{\partial v_j} \int \frac{\partial^2 |\mathbf{v} - \mathbf{v}'|}{\partial v_j \partial v_k} \left[\frac{f_F(\mathbf{v}')}{m} \frac{\partial f(\mathbf{v})}{\partial v_k} - \frac{f(\mathbf{v})}{m'} \frac{\partial f_F(\mathbf{v}')}{\partial v'_k} \right] d\mathcal{V}_{v'}. \quad (20.25)$$

[Hint: Manipulate the partial derivatives in a wise way and perform integrations by parts.]

- (e) Using Eq. (20.25), show that, if the two species—test and field—are thermalized at the same temperature, then the test-particle distribution function will remain unchanged: $\partial f/\partial t = 0$.

For details of the solution to this exercise see, for example, the original paper by Rosenbluth, MacDonald, and Judd (1957), or the pedagogical treatments in standard plasma physics textbooks (e.g., Boyd and Sanderson, 2003, Sec. 8.4; Bellan, 2006, Sec. 13.2).

The explicit form (20.24) of the Fokker-Planck equation has been solved approximately for idealized situations. It has also been integrated numerically for more realistic situations, so as to evolve the distribution functions of interacting particle species and, for example, watch them thermalize. (See, e.g., Bellan, 2006, Sec. 13.2; Boyd and Sanderson, 2003, Secs. 8.5, 8.6; and Shkarofsky, Johnston, and Bachynski, 1966, Secs. 7.5–7.11.) An extension to a plasma with an applied electric field and/or temperature gradient (using techniques developed in Sec. 3.7.3) has been used to deduce the electrical and thermal conductivities discussed in the next section (see, e.g., Shkarofsky, Johnston, and Bachynski, 1966, Chap. 8).

20.5 Transport Coefficients

20.5

Because electrons have far lower masses than ions, they have far higher typical speeds at fixed temperature and are much more easily accelerated (i.e., they are much more mobile). As a result, it is the motion of the electrons, not the ions, that is responsible for the transport of heat and charge through a plasma. In the spirit of the discussion above, we can compute transport properties, such as the electric conductivity and thermal conductivity, on the presumption that it is Coulomb collisions that determine the electron mean free paths and that magnetic fields are unimportant. (Later we will see that collisionless effects—scattering off plasmons—usually provide a more serious impediment to charge and heat flow than Coulomb collisions and thus dominate the conductivities.)

20.5.1 Coulomb Collisions

20.5.1

First consider an electron exposed to a constant, accelerating electric field E . The electron's typical field-induced velocity is along the direction of the electric field and has magnitude $-eE/(m_e\nu_D)$, where ν_D is the deflection frequency (rate) evaluated in Eqs. (20.18a) and (20.18b). We call this a *drift velocity*, because it is superposed on the electrons' collision-induced isotropic velocity distribution. The associated current density is $j \sim ne^2E/(m_e\nu_D)$, and the electrical conductivity therefore is $\kappa_e \sim ne^2/(m_e\nu_D)$. (Note that electron-electron collisions conserve momentum and thus

do not impede the flow of current, so electron-proton collisions, which happen about as frequently, produce all the electrical resistance and are thus responsible for this κ_e .)

The thermal conductivity can likewise be estimated by noting that a typical electron travels a mean distance $\ell \sim v_e/v_D$ between large net deflections, from an initial location where the average temperature is different from the final location's temperature by an amount $\Delta T \sim \ell|\nabla T|$. The heat flux transported by the electrons is therefore $\sim n v_e k_B \Delta T$, which should be equated to $-\kappa \nabla T$. We thereby obtain the electron contribution to the thermal conductivity as $\kappa \sim n k_B^2 T / (m_e v_D)$.

Computations based on the Fokker-Planck approach (Spitzer and Harm, 1953; see also Ex. 20.8) produce equations for the electrical and thermal conductivities that agree with the above estimates within factors of order ten:

$$\kappa_e = 4.9 \left(\frac{e^2}{\sigma_T c \ln \Lambda m_e} \right) \left(\frac{k_B T_e}{m_e c^2} \right)^{3/2} = 1.5 \times 10^{-3} \left(\frac{T_e}{1 \text{ K}} \right)^{3/2} \left(\frac{\ln \Lambda}{10} \right)^{-1} \Omega^{-1} \text{ m}^{-1}, \quad (20.26a)$$

$$\kappa = 19.1 \left(\frac{k_B c}{\sigma_T \ln \Lambda} \right) \left(\frac{k_B T_e}{m_e c^2} \right)^{5/2} = 4.4 \times 10^{-11} \left(\frac{T_e}{1 \text{ K}} \right)^{5/2} \left(\frac{\ln \Lambda}{10} \right)^{-1} \text{ W m}^{-1} \text{ K}^{-1}. \quad (20.26b)$$

Here σ_T is the Thomson cross section, Eq. (20.23b). Note that neither transport coefficient depends explicitly on the density; increasing the number of charge or heat carriers is compensated by the reduction in their mean free paths.

20.5.2

20.5.2 Anomalous Resistivity and Anomalous Equilibration

We have demonstrated that the theoretical Coulomb interaction between charged particles gives very long mean free paths. Correspondingly, the electrical and thermal conductivities (20.26) are very large in practical, geophysical, and astrophysical applications. Is this the way that real plasmas behave? The answer is almost always “no.”

As we shall show in the next three chapters, a plasma can support a variety of modes of collective excitation (plasmons), in which large numbers of electrons and/or ions move in collective, correlated fashions that are mediated by electromagnetic fields that they create. When the modes of a plasma are sufficiently excited (which is common), the electromagnetic fields carried by the excitations can be much more effective than Coulomb scattering at deflecting the orbits of individual electrons and ions and at feeding energy into or removing it from the electrons and ions. Correspondingly, the electrical and thermal conductivities will be reduced. The reduced transport coefficients are termed *anomalous*, as is the scattering by plasmons that controls them. Providing quantitative calculations of the anomalous scattering and these anomalous transport coefficients is one of the principal tasks of nonlinear plasma physics—as we start to discuss in Chap. 22.

electrical and thermal conductivities when Coulomb collisions are responsible for the resistivity

mechanism for anomalous resistivity and equilibration

Exercise 20.9 *Example: Bremsstrahlung*

Bremsstrahlung (or *free-free* radiation) arises when electrons are accelerated by ions and the changing electric dipole moment that they create leads to the emission of photons. This process can only be fully described using quantum mechanics, though the low-frequency spectrum can be calculated accurately using classical electromagnetism. Here we make a “back of the envelope” estimate of the absorption coefficient and convert it into an emission coefficient.

- Consider an electron with average speed v oscillating in an electromagnetic wave of electric field amplitude E and (slow) angular frequency ω . Show that its energy of oscillation is $E_{\text{osc}} \sim e^2 E^2 m^{-1} \omega^{-2}$.
- Let the electron encounter an ion and undergo a rapid deflection. Explain why the electron will, on average, gain energy of $\sim E_{\text{osc}}$ as a result of the encounter. Hence estimate the average rate of electron heating. (You may ignore the cumulative effects of distant encounters.)
- Recognizing that classical absorption at low frequency is the difference between quantum absorption and stimulated emission (e.g., Sec. 10.2.1), convert the result from part (b) into a spontaneous emission rate, assuming that the electron velocity is typical for a gas in thermal equilibrium at temperature T .
- Hence show that the free-free cooling rate (power radiated per unit volume) of an electron-proton plasma with electron density n_e and temperature T is $\sim n_e^2 \alpha_F \sigma_T c^2 (k_B T m_e)^{1/2}$, where $\alpha_F = e^2 / (4\pi \epsilon_0 \hbar c) = 7.3 \times 10^{-3}$ is the fine structure constant, and $\sigma_T = 6.65 \times 10^{-29} \text{ m}^2$ is the Thomson cross section. In a more detailed analysis, the long-range ($1/r^2$) character of the electric force gives rise to a multiplicative logarithmic factor, called the Gaunt factor, analogous to the Coulomb logarithm of Sec. 20.4.2.

This approach is useful when the plasma is so dense that the emission rate is significantly different from the rate in a vacuum (Boyd and Sanderson, 2003, Chap. 9).

Exercise 20.10 *Challenge and Example: Thermoelectric Transport Coefficients*

- Consider a plasma in which the magnetic field is so weak that it presents little impediment to the flow of heat and electric current. Suppose that the plasma has a gradient ∇T_e of its electron temperature and also has an electric field \mathbf{E} . It is a familiar fact that the temperature gradient will cause heat to flow and the electric field will create an electric current. Not so familiar, but somewhat obvious if one stops to think about it, is that the temperature gradient also creates an electric current and the electric field also causes heat flow. Explain in physical terms why this is so.
- So long as the mean free path of an electron between substantial deflections by electrons and protons, $\ell_{D,e} = (3k_B T_e / m_e)^{1/2} t_{D,e}$, is short compared to the lengthscale for substantial temperature change, $T_e / |\nabla T_e|$, and short compared to

the lengthscale for the electrons to be accelerated to near the speed of light by the electric field, $m_e c^2 / (eE)$, the fluxes of heat \mathbf{q} and of electric charge \mathbf{j} will be governed by nonrelativistic electron diffusion and will be linear in ∇T and \mathbf{E} :

$$\mathbf{q} = -\kappa \nabla T - \beta \mathbf{E}, \quad \mathbf{j} = \kappa_e \mathbf{E} + \alpha \nabla T. \quad (20.27)$$

The coefficients κ (heat conductivity), κ_e (electrical conductivity), β , and α are called *thermoelectric transport coefficients*. Use kinetic theory (Chap. 3), in a situation where $\nabla T = 0$, to derive the conductivity equations $\mathbf{j} = \kappa_e \mathbf{E}$ and $\mathbf{q} = -\beta \mathbf{E}$, and the following approximate formulas for the transport coefficients:

$$\kappa_e \sim \frac{ne^2 t_{D,e}}{m_e}, \quad \beta \sim \frac{k_B T}{e} \kappa_e. \quad (20.28a)$$

Show that, aside from a coefficient of order unity, this κ_e , when expressed in terms of the plasma's temperature and density, reduces to the Fokker-Planck result Eq. (20.26a).

- (c) Use kinetic theory, in a situation where $\mathbf{E} = 0$ and the plasma is near thermal equilibrium at temperature T , to derive the conductivity equations $\mathbf{q} = -\kappa \nabla T$ and $\mathbf{j} = \alpha \nabla T$, and the approximate formulas

$$\kappa \sim k_B n \frac{k_B T}{m_e} t_{D,e}, \quad \alpha \sim \frac{e}{k_B T} \kappa. \quad (20.28b)$$

Show that, aside from a coefficient of order unity, this κ reduces to the Fokker-Planck result Eq. (20.26b).

- (d) It can be shown (Spitzer and Harm, 1953) that for a hydrogen plasma

$$\frac{\alpha \beta}{\kappa_e \kappa} = 0.581. \quad (20.28c)$$

By studying the entropy-governed probability distributions for fluctuations away from statistical equilibrium, one can derive another relation among the thermoelectric transport coefficients, the *Onsager relation* (Kittel, 2004, Secs. 33, 34; Reif, 2008, Sec. 15.8):

$$\beta = \alpha T + \frac{5 k_B T_e}{2 e} \kappa_e; \quad (20.28d)$$

Eqs. (20.28c) and (20.28d) determine α and β in terms of κ_e and κ . Show that your approximate values of the transport coefficients, Eqs. (20.28a) and (20.28b), are in rough accord with Eqs. (20.28c) and (20.28d).

- (e) If a temperature gradient persists for sufficiently long, it will give rise to sufficient charge separation in the plasma to build up an electric field (called a "secondary field") that prevents further charge flow. Show that this cessation of charge flow suppresses the heat flow. The total heat flux is then $\mathbf{q} = -\kappa_{T \text{ effective}} \nabla T$, where

$$\kappa_{T \text{ effective}} = \left(1 - \frac{\alpha \beta}{\kappa_e \kappa} \right) \kappa = 0.419 \kappa. \quad (20.29)$$

20.6 Magnetic Field

20.6

20.6.1 Cyclotron Frequency and Larmor Radius

20.6.1

Many of the plasmas that we will encounter are endowed with a strong magnetic field. This causes the charged particles to travel along helical orbits about the field direction rather than move rectilinearly between collisions.

If we denote the magnetic field by \mathbf{B} , then the equation of motion for a nonrelativistic electron becomes

$$m_e \frac{d\mathbf{v}}{dt} = -e \mathbf{v} \times \mathbf{B}, \quad (20.30)$$

which gives rise to a constant speed v_{\parallel} parallel to the magnetic field and a circular motion perpendicular to the field with angular velocity sometimes denoted ω_{ce} and sometimes ω_c :

$$\omega_{ce} = \omega_c = \frac{eB}{m_e} = 1.76 \times 10^{11} \left(\frac{B}{1 \text{ T}} \right) \text{ s}^{-1}. \quad (20.31)$$

(electron) cyclotron frequency

This angular velocity is called the *electron cyclotron frequency*, or simply the *cyclotron frequency*; and it is sometimes called the *gyro frequency*. Notice that this cyclotron frequency depends only on the magnetic field strength B and not on the plasma's density n or the electron velocity (i.e., the plasma temperature T). Nor does it depend on the angle between \mathbf{v} and \mathbf{B} (the *pitch angle*, α).

The radius of the electron's gyrating (spiraling) orbit, projected perpendicular to the direction of the magnetic field, is called the *Larmor radius* and is given by

$$r_L = \frac{v_{\perp}}{\omega_{ce}} = \frac{v \sin \alpha}{\omega_{ce}} = 5.7 \times 10^{-9} \left(\frac{v_{\perp}}{1 \text{ km s}^{-1}} \right) \left(\frac{B}{1 \text{ T}} \right)^{-1} \text{ m}, \quad (20.32)$$

Larmor radius

where v_{\perp} is the electron's velocity projected perpendicular to the field. Protons (and other ions) in a plasma also undergo cyclotron motion. Because the proton mass is larger by $m_p/m_e = 1,836$ than the electron mass, its angular velocity

$$\omega_{cp} = \frac{eB}{m_p} = 0.96 \times 10^8 \text{ s}^{-1} \left(\frac{B}{1 \text{ T}} \right) \quad (20.33)$$

proton cyclotron frequency

is 1,836 times lower. The quantity ω_{cp} is called the *proton cyclotron frequency* or *ion cyclotron frequency*. The sense of gyration is, of course, opposite to that of the electrons. If the protons have similar temperatures to the electrons, their speeds are typically $\sim \sqrt{m_p/m_e} = 43$ times smaller than those of the electrons, and their typical Larmor radii are ~ 43 times larger than those of the electrons.

We demonstrated in Sec. 20.3.3 that all the electrons in a plasma can oscillate in phase at the plasma frequency. The electrons' cyclotron motions can also be coherent. Such coherent motions are called *cyclotron resonances* or *cyclotron oscillations*, and we shall study them in Chap. 21. Ion cyclotron resonances can also occur. Characteristic electron cyclotron frequencies and Larmor radii are tabulated in Table 20.1. As shown

cyclotron resonances (oscillations)

there, the cyclotron frequency, like the plasma frequency, is typically far larger than the rates for Coulomb-mediated energy equilibration.

20.6.2 20.6.2 Validity of the Fluid Approximation

MAGNETOHYDRODYNAMICS

conditions for validity of
MHD approximation

In Chap. 19, we developed the magnetohydrodynamic (MHD) description of a magnetized plasma. We described the plasma by its density and temperature (or equivalently, its pressure). Under what circumstances, for a plasma, is this description accurate? The answer to this question turns out to be quite complex, and a full discussion would go well beyond the scope of this book. Some aspects, however, are easy to describe. A fluid description ought to be acceptable when (i) the timescales τ that characterize the macroscopic flow are long compared with the time required to establish Maxwellian equilibrium (i.e., $\tau \gg \nu_{ep}^{-1}$), and (ii) the excitation level of collective wave modes is so small that the modes do not interfere seriously with the influence of Coulomb collisions. Unfortunately, these conditions rarely apply. (One type of plasma where they might be a quite good approximation is that in the interior of the Sun.)

Magnetohydrodynamics can still provide a moderately accurate description of a plasma, even if the electrons and ions are not fully equilibrated, when the electrical conductivity can be treated as very large and the thermal conductivity as very small. Then we can treat the magnetic Reynolds number [Eq. (19.9c)] as effectively infinite and the plasma as an adiabatic perfect fluid (as we assumed in much of Chap. 19). It is not so essential that the actual particle distribution functions be Maxwellian, merely that they have second moments that can be associated with a (roughly defined) common temperature.

Quite often in plasma physics almost all of the dissipation is localized—for example, to the vicinity of a shock front or a site of magnetic-field-line reconnection—and the remainder of the flow can be treated using MHD. The MHD description then provides a boundary condition for a fuller plasma physical analysis of the dissipative region. This approach simplifies the analysis of such situations.

GENERALIZATIONS OF MHD

The great advantage of fluid descriptions, and the reason physicists abandon them with such reluctance, is that they are much simpler than other descriptions of a plasma. One only has to cope with the fluid pressure, density, and velocity and does not have to deal with an elaborate statistical description of the positions and velocities of all the particles. Generalizations of the simple fluid approximation have therefore been devised that can extend the domain of validity of simple MHD ideas.

two-fluid approximation

One extension, which we develop in the following chapter, is to treat the protons and the electrons as two separate fluids and derive dynamical equations that describe their (coupled) evolution. Another extension, which we describe now, is to acknowledge that, in most plasmas:

1. the cyclotron period is very short compared with the Coulomb collision time (and with the anomalous scattering time), and
2. the timescale on which energy is transferred back and forth among the electrons, the protons, and the electromagnetic field is intermediate between ω_c^{-1} and ν_{ee}^{-1} .

Intuitively, these assumptions allow the electron and proton velocity distributions to become axisymmetric with respect to the magnetic field direction, though not fully isotropic. In other words, we can characterize the plasma using a density and two separate components of pressure, one associated with motion along the direction of the magnetic field, and the other with gyration around the field lines.

anisotropic fluid in presence of magnetic field

For simplicity, let us just consider the electrons and their stress tensor, which we can write as

$$T_e^{jk} = \int \mathcal{N}_e p^j p^k \frac{d\mathcal{V}_p}{m} \quad (20.34)$$

[Eq. (3.32d)], where \mathcal{N}_e is the electron number density in phase space and $d\mathcal{V}_p = dp_x dp_y dp_z$ is the volume element in phase space. If we orient Cartesian axes so that the direction of \mathbf{e}_z is parallel to the local magnetic field, then

$$||T_e^{jk}|| = \begin{bmatrix} P_{e\perp} & 0 & 0 \\ 0 & P_{e\perp} & 0 \\ 0 & 0 & P_{e\parallel} \end{bmatrix}, \quad (20.35)$$

anisotropic pressure

where $P_{e\perp}$ is the electron pressure perpendicular to \mathbf{B} , and $P_{e\parallel}$ is the electron pressure parallel to \mathbf{B} . Now suppose that there is a compression or expansion on a timescale that is long compared with the cyclotron period but short compared with the Coulomb collision and anomalous scattering timescales. Then we should not expect $P_{e\perp}$ to be equal to $P_{e\parallel}$, and we anticipate that they will evolve with density according to different laws.

The adiabatic indices governing P_{\perp} and P_{\parallel} in such a situation are easily derived from kinetic-theory arguments (Ex. 20.11). For compression perpendicular to \mathbf{B} and no change of length along \mathbf{B} , we have

$$\gamma_{\perp} \equiv \left(\frac{\partial \ln P_{\perp}}{\partial \ln \rho} \right)_s = 2, \quad \gamma_{\parallel} \equiv \left(\frac{\partial \ln P_{\parallel}}{\partial \ln \rho} \right)_s = 1; \quad (20.36a)$$

collisionless, anisotropic adiabatic indices

for compression parallel to \mathbf{B} and no change of transverse area, we have

$$\gamma_{\perp} \equiv \left(\frac{\partial \ln P_{\perp}}{\partial \ln \rho} \right)_s = 1, \quad \gamma_{\parallel} \equiv \left(\frac{\partial \ln P_{\parallel}}{\partial \ln \rho} \right)_s = 3. \quad (20.36b)$$

By contrast, if the expansion is sufficiently slow that Coulomb collisions are effective (though not so slow that heat conduction can operate), then we expect the velocity distribution to maintain isotropy and both components of pressure to evolve according to the law appropriate to a monatomic gas:

collisional, isotropic
adiabatic index

$$\gamma = \left(\frac{\partial \ln P_{\perp}}{\partial \ln \rho} \right)_s = \left(\frac{\partial \ln P_{\parallel}}{\partial \ln \rho} \right)_s = \frac{5}{3}. \quad (20.37)$$

20.6.3

20.6.3 Conductivity Tensor

As is evident from the foregoing remarks, if we are in a regime where Coulomb scattering really does determine the particle mean free path, then an extremely small magnetic field strength suffices to ensure that individual particles complete gyrotational orbits before they collide. Specifically, for electrons, the deflection time t_D , given by Eq. (20.18a,b), exceeds ω_c^{-1} if

$$B \gtrsim 10^{-16} \left(\frac{n}{1 \text{ m}^{-3}} \right) \left(\frac{T_e}{1 \text{ K}} \right)^{-3/2} \text{ T}. \quad (20.38)$$

This is almost always the case. It is also almost always true for the ions.

When inequality (20.38) is satisfied and also anomalous scattering is negligible on the timescale ω_c^{-1} , the transport coefficients must be generalized to form tensors. Let us compute the electrical conductivity tensor for a plasma in which a steady electric field \mathbf{E} is applied. Once again orienting our coordinate system so that the magnetic field is parallel to \mathbf{e}_z , we can write down an equation of motion for the electrons by balancing the electromagnetic acceleration with the average rate of loss of momentum due to collisions or anomalous scattering:

electron equation of
motion

$$-e(\mathbf{E} + \mathbf{v} \times \mathbf{B}) - m_e \nu_D \mathbf{v} = 0. \quad (20.39)$$

Solving for the velocity, we obtain

$$\begin{pmatrix} v_x \\ v_y \\ v_z \end{pmatrix} = -\frac{e}{m_e \nu_D (1 + \omega_c^2 / \nu_D^2)} \begin{pmatrix} 1 & \omega_c / \nu_D & 0 \\ -\omega_c / \nu_D & 1 & 0 \\ 0 & 0 & 1 + \omega_c^2 / \nu_D^2 \end{pmatrix} \begin{pmatrix} E_x \\ E_y \\ E_z \end{pmatrix}. \quad (20.40)$$

As the current density is $\mathbf{j}_e = -nev = \kappa_e \mathbf{E}$, the electrical conductivity tensor is given by

anisotropic electric
conductivity

$$\kappa_e = \frac{ne^2}{m_e \nu_D (1 + \omega_c^2 / \nu_D^2)} \begin{pmatrix} 1 & \omega_c / \nu_D & 0 \\ -\omega_c / \nu_D & 1 & 0 \\ 0 & 0 & 1 + \omega_c^2 / \nu_D^2 \end{pmatrix}. \quad (20.41)$$

It is apparent from the form of this conductivity tensor that, when $\omega_c \gg \nu_D$ (as is almost always the case), the conductivity perpendicular to the magnetic field is

greatly inhibited, whereas that along the magnetic field is unaffected. Similar remarks apply to the flow of heat. It is therefore often assumed that only transport parallel to the field is effective. However, as is made clear in the next section, if the plasma is inhomogeneous, then cross-field transport can be quite rapid in practice.

EXERCISES

Exercise 20.11 *Example and Derivation: Adiabatic Indices for Compression of a Magnetized Plasma*

Consider a plasma in which, in the local mean rest frame of the electrons, the electron stress tensor has the form (20.35) with \mathbf{e}_z the direction of the magnetic field. The following analysis for the electrons can be carried out independently for the ions, resulting in the same formulas.

(a) Show that

$$P_{e\parallel} = nm_e \langle v_{\parallel}^2 \rangle, \quad P_{e\perp} = \frac{1}{2} nm_e \langle |\mathbf{v}_{\perp}|^2 \rangle, \quad (20.42)$$

where $\langle v_{\parallel}^2 \rangle$ is the mean-square electron velocity parallel to \mathbf{B} , and $\langle |\mathbf{v}_{\perp}|^2 \rangle$ is the mean-square velocity orthogonal to \mathbf{B} . (The velocity distributions are not assumed to be Maxwellian.)

(b) Consider a fluid element with length l along the magnetic field and cross sectional area A orthogonal to the field. Let $\bar{\mathbf{v}}$ be the mean velocity of the electrons ($\bar{\mathbf{v}} = 0$ in the mean electron rest frame), and let θ and σ_{jk} be the expansion and shear of the mean electron motion as computed from $\bar{\mathbf{v}}$ (Sec. 13.7.1). Show that

$$\frac{dl/dt}{l} = \frac{1}{3}\theta + \sigma^{jk} b_j b_k, \quad \frac{dA/dt}{A} = \frac{2}{3}\theta - \sigma^{jk} b_j b_k, \quad (20.43)$$

where $\mathbf{b} = \mathbf{B}/|\mathbf{B}| = \mathbf{e}_z$ is a unit vector in the direction of the magnetic field.

(c) Assume that the timescales for compression and shearing are short compared with those for Coulomb scattering and anomalous scattering: $\tau \ll t_{D,e}$. Show, using the laws of energy and particle conservation, that

$$\begin{aligned} \frac{1}{\langle v_{\parallel}^2 \rangle} \frac{d\langle v_{\parallel}^2 \rangle}{dt} &= -\frac{2}{l} \frac{dl}{dt}, \\ \frac{1}{\langle v_{\perp}^2 \rangle} \frac{d\langle v_{\perp}^2 \rangle}{dt} &= -\frac{1}{A} \frac{dA}{dt}, \\ \frac{1}{n} \frac{dn}{dt} &= -\frac{1}{l} \frac{dl}{dt} - \frac{1}{A} \frac{dA}{dt}. \end{aligned} \quad (20.44)$$

(d) Show that

$$\begin{aligned} \frac{1}{P_{e\parallel}} \frac{dP_{e\parallel}}{dt} &= -3 \frac{dl/dt}{l} - \frac{dA/dt}{A} = -\frac{5}{3}\theta - 2\sigma^{jk} b_j b_k, \\ \frac{1}{P_{e\perp}} \frac{dP_{e\perp}}{dt} &= -\frac{dl/dt}{l} - 2 \frac{dA/dt}{A} = -\frac{5}{3}\theta + \sigma^{jk} b_j b_k. \end{aligned} \quad (20.45)$$

- (e) Show that, when the fluid is expanding or compressing entirely perpendicular to \mathbf{B} , with no expansion or compression along \mathbf{B} , the pressures change in accord with the adiabatic indices of Eq. (20.36a). Show, similarly, that when the fluid expands or compresses along \mathbf{B} , with no expansion or compression in the perpendicular direction, the pressures change in accord with the adiabatic indices of Eq. (20.36b).
- (f) Hence derive the so-called *double adiabatic* or *CGL* (Chew, Goldberger, and Low, 1956) equations of state:

$$P_{\parallel} \propto n^3/B^2, \quad P_{\perp} \propto nB, \quad (20.46)$$

valid for changes on timescales long compared with the cyclotron period but short compared with all Coulomb collision and anomalous scattering times.

Exercise 20.12 *Problem: Relativistic Electron Motion*

Use the relativistic equation of motion to show that the relativistic electron cyclotron frequency is $\omega_c = eB/(\gamma m_e)$, where $\gamma = 1/\sqrt{1 - (v/c)^2}$ is the electron Lorentz factor. What is the relativistic electron Larmor radius? What is the relativistic proton cyclotron frequency and Larmor radius?

Exercise 20.13 *Example: Ultra-High-Energy Cosmic Rays*

The most energetic (ultra-high-energy) cosmic rays are probably created with energies up to $\sim 1 \text{ ZeV} = 10^{21} \text{ eV}$ in sources roughly 100 million light-years away.

- (a) Show that they start with the “energy of a well-hit baseball and the momentum of a snail.” By the time they arrive at Earth, their energies are likely to have been reduced by a factor of ~ 3 .
- (b) Assuming that the intergalactic magnetic field is $\sim 10^{-13} \text{ T} \sim 10^{-9} \text{ G}$, compute the cosmic rays’ Larmor radii, assuming that they are protons and iron nuclei.
- (c) Do you expect their arrival directions to point back to their sources?
- (d) Suppose that an ultra-high-energy cosmic ray collides with a stationary nitrogen nucleus in our atmosphere. How much energy becomes available in the center-of-mass frame? Compare this with the energy at the Large Hadron Collider, where protons, each with energy $\sim 7 \text{ TeV}$, collide head on.

20.7

20.7 Particle Motion and Adiabatic Invariants

In the next three chapters we shall meet a variety of plasma phenomena that can be understood in terms of the orbital motions of individual electrons and ions. These phenomena typically entail motions in an electromagnetic field that is nearly but not quite spatially homogeneous on the scale of the Larmor radius r_L and nearly but not quite constant during a cyclotron period $2\pi/\omega_c$. In this section, in preparation

for the next three chapters, we review charged-particle motion in such nearly homogeneous, nearly time-independent fields.

Since the motions of electrons are usually of greater interest than those of ions, we presume throughout this section that the charged particle is an electron. We denote its charge by $-e$ and its mass by m_e .

20.7.1 Homogeneous, Time-Independent Magnetic Field and No Electric Field

20.7.1

From the nonrelativistic version of the Lorentz force equation, $d\mathbf{v}/dt = -(e/m_e)\mathbf{v} \times \mathbf{B}$, one readily deduces that an electron in a homogeneous, time-independent magnetic field \mathbf{B} moves with uniform velocity \mathbf{v}_{\parallel} parallel to the field, and it moves perpendicular to the field in a circular orbit with the cyclotron frequency $\omega_c = eB/m_e$ and Larmor radius $r_L = m_e v_{\perp}/(eB)$. Here v_{\perp} is the electron's time-independent transverse speed (speed perpendicular to \mathbf{B}).

20.7.2 Homogeneous, Time-Independent Electric and Magnetic Fields

20.7.2

Suppose that the homogeneous magnetic field \mathbf{B} is augmented by a homogeneous electric field \mathbf{E} , and assume initially that $|\mathbf{E} \times \mathbf{B}| < B^2 c$. Then examine the electric and magnetic fields in a new reference frame, one that moves with the velocity

$$\mathbf{v}_D = \frac{\mathbf{E} \times \mathbf{B}}{B^2}, \quad (20.47)$$

relative to the original frame. Note that the moving frame's velocity \mathbf{v}_D is perpendicular to both the magnetic field and the electric field. From the Lorentz transformation law for the electric field, $\mathbf{E}' = \gamma(\mathbf{E} + \mathbf{v}_D \times \mathbf{B})$, we infer that in the moving frame the electric field and the magnetic field are parallel to each other. As a result, in the moving frame the electron's motion perpendicular to the magnetic field is purely circular; and, correspondingly, in the original frame its perpendicular motion consists of a *drift* with velocity \mathbf{v}_D , and superposed on that drift, a circular motion (Fig. 20.4). In other words, the electron moves in a circle whose center (the electron's *guiding center*) drifts with velocity \mathbf{v}_D . Notice that the drift velocity (20.47) is independent of the electron's charge and mass, and thus is the same for ions as for electrons. This drift is called the " $\mathbf{E} \times \mathbf{B}$ drift."

guiding-center approximation; $\mathbf{E} \times \mathbf{B}$ drift

When the component of the electric field orthogonal to \mathbf{B} is so large that the drift velocity computed from Eq. (20.47) exceeds the speed of light, the electron's guiding center, of course, cannot move with that velocity. Instead, the electric field drives the electron up to higher and higher velocities as time passes, but in a sinusoidally modulated manner. Ultimately, the electron velocity becomes arbitrarily close to the speed of light.

breakdown of guiding-center approximation when \mathbf{B} is large

When a uniform, time-independent gravitational field \mathbf{g} accompanies a uniform, time-independent magnetic field \mathbf{B} , its effect on an electron will be the same as that

guiding-center approximation in gravitational field

FIGURE 20.4 The proton motion (upper trajectory) and electron motion (lower trajectory) orthogonal to the magnetic field, when there are constant electric and magnetic fields with $|\mathbf{E} \times \mathbf{B}| < B^2 c$. Each electron and proton moves in a circle with a superposed drift velocity \mathbf{v}_D given by Eq. (20.47).

of an electric field $\mathbf{E}_{\text{equivalent}} = -(m_e/e)\mathbf{g}$: The electron's guiding center will acquire a drift velocity

$$\mathbf{v}_D = -\frac{m_e \mathbf{g} \times \mathbf{B}}{e B^2}, \quad (20.48)$$

and similarly for a proton. This *gravitational drift* velocity is typically very small.

20.7.3

20.7.3 Inhomogeneous, Time-Independent Magnetic Field

When the electric field vanishes, but the magnetic field is spatially inhomogeneous and time-independent, and the inhomogeneity scale is large compared to the Larmor radius r_L of the electron's orbit, the electron motion again is nicely described in terms of a guiding center.

First consider the effects of a curvature of the field lines (Fig. 20.5a). Suppose that the speed of the electron along the field lines is v_{\parallel} . We can think of this as a longitudinal guiding-center motion. As the field lines bend in, say, the direction of the unit vector \mathbf{n} with radius of curvature R , this longitudinal guiding-center motion experiences the acceleration $\mathbf{a} = v_{\parallel}^2 \mathbf{n}/R$. That acceleration is equivalent to the effect of an electric field $\mathbf{E}_{\text{effective}} = (-m_e/e)v_{\parallel}^2 \mathbf{n}/R$, and it therefore produces a transverse drift of the guiding center with $\mathbf{v}_D = (\mathbf{E}_{\text{effective}} \times \mathbf{B})/B^2$. Since the curvature R of the field line and the direction \mathbf{n} of its bend are given by $B^{-2}(\mathbf{B} \cdot \nabla)\mathbf{B} = \mathbf{n}/R$, this *curvature drift* velocity is

$$\mathbf{v}_D = -\frac{m_e v_{\parallel}^2}{e} \mathbf{B} \times \frac{(\mathbf{B} \cdot \nabla)\mathbf{B}}{B^4}. \quad (20.49)$$

Notice that the magnitude of this drift is

$$v_D = \frac{r_L}{R} \frac{v_{\parallel}}{v_{\perp}} v_{\parallel}. \quad (20.50)$$

This particle drift and others discussed below also show up as fluid drifts in a magnetized plasma; see Ex. 21.1.

curvature drift

FIGURE 20.5 An electron's motion in a time-independent, inhomogeneous magnetic field. (a) The drift induced by the curvature of the field lines. (b) The drift induced by a transverse gradient of the magnitude of the magnetic field. (c) The change in electron pitch angle induced by a longitudinal gradient of the magnitude of the magnetic field.

A second kind of inhomogeneity is a transverse spatial gradient ∇B of the magnitude of \mathbf{B} . As is shown in Fig. 20.5b, such a gradient causes the electron's circular motion to be tighter (smaller radius of curvature of the circle) in the region of larger B than in the region of smaller B ; this difference in radii of curvature clearly induces a drift. It is straightforward to show that the resulting *gradient drift* velocity is

$$\mathbf{v}_D = \frac{-m_e v_{\perp}^2}{2e} \frac{\mathbf{B} \times \nabla B}{B^3}. \quad (20.51)$$

The third and final kind of inhomogeneity is a longitudinal gradient of the magnitude of \mathbf{B} (Fig. 20.5c). Such a gradient results from the magnetic field lines converging toward (or diverging away from) one another. The effect of this convergence (or divergence) is most easily inferred in a frame that moves longitudinally with the electron. In such a frame the magnetic field changes with time, $\partial \mathbf{B}' / \partial t \neq 0$, and correspondingly, the resultant electric field satisfies $\nabla \times \mathbf{E}' = -\partial \mathbf{B}' / \partial t$. The kinetic energy of the electron as measured in this longitudinally moving frame is the same as the transverse energy $\frac{1}{2} m_e v_{\perp}^2$ in the original frame. This kinetic energy is forced to change by the electric field \mathbf{E}' . The change in energy during one circuit around the magnetic field is

$$\Delta \left(\frac{1}{2} m_e v_{\perp}^2 \right) = -e \oint \mathbf{E}' \cdot d\mathbf{l} = e \int \frac{\partial \mathbf{B}'}{\partial t} \cdot d\mathbf{A} = e \left(\frac{\omega_c}{2\pi} \Delta B \right) \pi r_L^2 = \frac{m_e v_{\perp}^2}{2} \frac{\Delta B}{B}. \quad (20.52)$$

Here the second expression in the equation involves a line integral once around the electron's circular orbit. The third expression involves a surface integral over the interior of the orbit and has $\partial \mathbf{B}' / \partial t$ parallel to $d\mathbf{A}$. In the fourth the time derivative of the magnetic field has been expressed as $(\omega_c / (2\pi)) \Delta B$, where ΔB is the change in magnetic field strength along the electron's guiding center during one circular orbit.

Equation (20.52) can be rewritten as a conservation law along the world line of the electron's guiding center:

$$\frac{m_e v_{\perp}^2}{2B} = \text{const.} \quad (20.53)$$

gradient drift

effects of longitudinal gradient of B

conservation of enclosed flux (i.e., of magnetic moment)

Notice that the conserved quantity $m_e v_{\perp}^2 / (2B)$ is proportional to the total magnetic flux threading the electron's circular orbit, $\pi r_L^2 B$. Thus the electron moves along the field lines in such a manner as to keep constant the magnetic flux enclosed in its orbit; see Fig. 20.5c. A second interpretation of Eq. (20.53) is in terms of the magnetic moment created by the electron's circulatory motion. That moment is $\mu = -m_e v_{\perp}^2 / (2B^2) \mathbf{B}$, and its magnitude is the conserved quantity

$$\mu = \frac{m_e v_{\perp}^2}{2B} = \text{const.} \quad (20.54)$$

An important consequence of the conservation law (20.54) is a gradual change in the electron's pitch angle,

pitch angle of electron orbit

$$\alpha \equiv \tan^{-1}(v_{\parallel} / v_{\perp}), \quad (20.55)$$

as it spirals along the converging field lines. Because there is no electric field in the original frame, the electron's total kinetic energy is conserved in that frame:

$$E_{\text{kin}} = \frac{1}{2} m_e (v_{\parallel}^2 + v_{\perp}^2) = \text{const.} \quad (20.56)$$

This expression, together with the constancy of $\mu = m_e v_{\perp}^2 / (2B)$ and the definition of the electron pitch angle [Eq. (20.55)], implies that the pitch angle varies with magnetic field strength as

variation of pitch angle along guiding center

$$\tan^2 \alpha = \frac{E_{\text{kin}}}{\mu B} - 1. \quad (20.57)$$

Notice that as the field lines converge, B increases in magnitude, and α decreases. Ultimately, when B reaches a critical value $B_{\text{crit}} = E_{\text{kin}} / \mu$, the pitch angle α goes to zero. The electron then "reflects" off the strong-field region and starts moving back toward weak fields, with increasing pitch angle. The location at which the electron reflects is called the electron's *mirror point*.

mirror point

Figure 20.6 shows two examples of this mirroring. The first example is a "magnetic bottle" (Ex. 20.14). Electrons whose pitch angles at the center of the bottle are sufficiently small have mirror points in the bottle and thus cannot leak out. The second example is the van Allen belts of Earth. Electrons (and also ions) travel up and down the magnetic field lines of the van Allen belts, reflecting at mirror points.

magnetic bottle

It is not hard to show that the gradient of \mathbf{B} can be split up into the three pieces we have studied: a curvature with no change of $B = |\mathbf{B}|$ (Fig. 20.5a), a change of B orthogonal to the magnetic field (Fig. 20.5b), and a change of B along the magnetic field (Fig. 20.5c). When (as we have assumed) the lengthscales of these changes are far greater than the electron's Larmor radius, their effects on the electron's motion superpose linearly.

FIGURE 20.6 Two examples of the mirroring of particles in an inhomogeneous magnetic field. (a) A magnetic bottle. (b) Earth's van Allen belts.

20.7.4 A Slowly Time-Varying Magnetic Field

20.7.4

When the magnetic field changes on timescales long compared to the cyclotron period $2\pi/\omega_c$, its changes induce alterations of the electron's orbit that can be deduced with the aid of *adiabatic invariants*—quantities that are nearly constant when the field changes adiabatically, in other words, slowly (see, e.g., Lifshitz and Pitaevskii, 1981; Northrop, 1963). The conserved magnetic moment $\mu = m_e v_\perp^2 / (2B)$ associated with an electron's transverse, circular motion is an example of an adiabatic invariant. We proved its invariance in Eqs. (20.52) and (20.53) (in Sec. 20.7.3, where we were working in a reference frame in which the magnetic field changed slowly, and associated with that change was a weak electric field). This adiabatic invariant can be shown to be, aside from a constant multiplicative factor $2\pi m_e / e$, the action associated with the electron's circular motion: $J_\phi = \oint p_\phi d\phi$. Here ϕ is the angle around the circular orbit, and $p_\phi = (m_e v_\perp - eA_\phi)r_L$ is the ϕ component of the electron's canonical momentum. The action J_ϕ is a well-known adiabatic invariant.

adiabatic invariants

magnetic moment as circular-motion action

When a slightly inhomogeneous magnetic field varies slowly in time, not only is $\mu = m_e v_\perp^2 / (2B)$ adiabatically invariant (conserved), so also are two other actions. One is the action associated with motion from one mirror point of the magnetic field to another and back:

$$J_{||} = \oint \mathbf{p}_{||} \cdot d\mathbf{l}. \quad (20.58)$$

longitudinal, mirror-point action

Here $\mathbf{p}_{||} = m_e \mathbf{v}_{||} - e\mathbf{A}_{||} = m_e \mathbf{v}_{||}$ is the generalized (canonical) momentum along the field line, and $d\mathbf{l}$ is distance along the field line. Thus the adiabatic invariant is the spatial average $\langle v_{||} \rangle$ of the longitudinal speed of the electron, multiplied by m_e and twice the distance Δl between mirror points: $J_{||} = 2m_e \langle v_{||} \rangle \Delta l$.

guiding-center-drift action

The other (third) adiabatic invariant is the action associated with the drift of the guiding center: an electron mirroring back and forth along the field lines drifts sideways, and by its drift it traces out a 2-dimensional surface to which the magnetic

field is tangent (e.g., the surface of the center of the magnetic bottle in Fig. 20.6a, rotated around the horizontal axis). The action of the electron's drift around this magnetic surface turns out to be proportional to the total magnetic flux enclosed by the surface. Thus, if the field geometry changes slowly, the magnetic flux enclosed by the magnetic surface on which the electron's guiding center moves is adiabatically conserved.

accuracy of adiabatic invariants

How nearly constant are the adiabatic invariants? The general theory of adiabatic invariants shows that, so long as the temporal changes of the magnetic field structure are smooth enough to be described by analytic functions of time, the fractional failures of the adiabatic invariants to be conserved are of order $e^{-\tau/P}$. Here τ is the timescale on which the field changes, and P is the period of the motion associated with the adiabatic invariant. (This period P is $2\pi/\omega_c$ for the invariant μ ; it is the mirroring period for the longitudinal action, and it is the drift period for the magnetic flux enclosed in the electron's magnetic surface.) Because the exponential $e^{-\tau/P}$ dies out so quickly with increasing timescale τ , the adiabatic invariants are conserved to very high accuracy when $\tau \gg P$.

20.7.5

20.7.5 Failure of Adiabatic Invariants; Chaotic Orbits

When the magnetic field changes as fast as or more rapidly than a cyclotron orbit (in space or in time), then the adiabatic invariants fail, and the charged-particle orbits may even be chaotic in some cases.

failure of adiabatic invariants and chaotic motion near a magnetic neutral line

An example is charged-particle motion near a neutral line (also called an X-line) of a magnetic field. Near an X-line, the field has the hyperbolic shape $\mathbf{B} = B_0(y \mathbf{e}_x + \gamma x \mathbf{e}_y)$ with constants B_0 and γ ; see Fig. 19.13 for an example that occurs in magnetic-field-line reconnection. The X-line is the z -axis, $(x, y) = (0, 0)$, on which the field vanishes. Near there the Larmor radius becomes arbitrarily large, far larger than the scale on which the field changes. Correspondingly, no adiabatic invariants exist near the X-line, and it turns out that some charged-particle orbits near there are chaotic in the sense of extreme sensitivity to initial conditions (Sec. 15.6.4). An electric field in the \mathbf{e}_z direction (orthogonal to \mathbf{B} and parallel to the X-line) enhances the chaos (for details, see, e.g., Martin, 1986).

EXERCISES

Exercise 20.14 *Example: Mirror Machine*

One method for confining hot plasma is to arrange electric coils so as to make a mirror machine in which the magnetic field has the geometry sketched in Fig. 20.6a. Suppose that the magnetic field in the center is 1 T and the field strength at the two necks is 10 T, and that plasma is introduced with an isotropic velocity distribution near the center of the bottle.

- What fraction of the plasma particles will escape?
- Sketch the pitch-angle distribution function for the particles that remain.

FIGURE 20.7 Penning trap for localizing individual charged particles. The magnetic field is uniform and parallel to the vertical axis of symmetry \mathbf{e}_z . The electric field is maintained between a pair of hyperboloidal caps and a hyperboloidal ring.

- (c) Suppose that Coulomb collisions cause particles to diffuse in pitch angle α with a diffusion coefficient

$$D_{\alpha\alpha} \equiv \left\langle \frac{\Delta\alpha^2}{\Delta t} \right\rangle = t_D^{-1}. \quad (20.59)$$

Estimate how long it will take most of the plasma to escape the mirror machine.

- (d) What do you suspect will happen in practice?

Exercise 20.15 *Challenge: Penning Trap*

A clever technique for studying the behavior of individual electrons or ions is to entrap them using a combination of electric and magnetic fields. One of the simplest and most useful devices is the *Penning trap* (see, e.g., Brown and Gabrielse, 1986). Basically this comprises a uniform magnetic field B combined with a hyperboloidal electrostatic field that is maintained between hyperboloidal electrodes as shown in Fig. 20.7. The electrostatic potential has the form $\Phi(\mathbf{x}) = \Phi_0(z^2 - x^2/2 - y^2/2)/(2d^2)$, where Φ_0 is the potential difference maintained across the electrodes, and d is the minimum axial distance from the origin to the hyperboloidal cap (as well as being $1/\sqrt{2}$ times the minimum radius of the ring electrode).

- (a) Show that the potential satisfies Laplace's equation, as it must.
- (b) Now consider an individual charged particle in the trap. Show that three separate oscillations can be excited:
- (i) cyclotron orbits in the magnetic field with angular frequency ω_c ,
 - (ii) "magnetron" orbits produced by $\mathbf{E} \times \mathbf{B}$ drift around the axis of symmetry with angular frequency ω_m (which you should compute), and

(iii) axial oscillations parallel to the magnetic field with angular frequency ω_z (which you should also compute).

Assume that $\omega_m \ll \omega_z \ll \omega_c$, and show that $\omega_z^2 \simeq 2\omega_m\omega_c$.

- (c) Typically, the potential difference across the electrodes is ~ 10 V, the magnetic field strength is $B \sim 6$ T, and the radius of the ring and the height of the caps above the center of the traps are ~ 3 mm. Estimate the three independent angular frequencies for electrons and ions, verifying the ordering $\omega_m \ll \omega_z \ll \omega_c$. Also estimate the maximum velocities associated with each of these oscillations if the particle is to be retained in the trap.
- (d) Solve the classical equation of motion exactly, and demonstrate that the magnetron motion is formally unstable.

Penning traps have been used to perform measurements of the electron-proton mass ratio and the magnetic moment of the electron with unprecedented precision.

Bibliographic Note

For a thorough treatment of the particle kinetics of plasmas, see Shkarofsky, Johnston, and Bachynski (1966). For less detailed treatments, we recommend the relevant portions of Spitzer (1962), Bittencourt (2004), and Bellan (2006).

For applications of the Fokker-Planck equation to Coulomb scattering in plasmas, we like Shkarofsky, Johnston, and Bachynski (1966, Chaps. 7 and 8), Boyd and Sanderson (2003, Chap. 8), Kulsrud (2005, Chap. 8), and Bellan (2006, Chap. 13).

For charged-particle motion in inhomogeneous and time-varying magnetic fields, we recommend Northrop (1963); Jackson (1999, Chap. 12), which is formulated using special relativity; Bittencourt (2004, Chaps. 2–4); and Bellan (2006, Chap. 3).

Waves in Cold Plasmas: Two-Fluid Formalism

Waves from moving sources: Adagio. Andante. Allegro moderato.

OLIVER HEAVISIDE (1912)

21.1 Overview

21.1

The growth of plasma physics came about, in the early twentieth century, through studies of oscillations in electric discharges and the contemporaneous development of means to broadcast radio waves over great distances by reflecting them off Earth's ionosphere. It is therefore not surprising that most early plasma-physics research was devoted to describing the various modes of wave propagation. Even in the simplest, linear approximation for a plasma sufficiently cold that thermal effects are unimportant, we will see that the variety of possible modes is immense.

In the previous chapter, we introduced several length- and timescales, most importantly the Larmor (gyro) radius, the Debye length, the plasma period, the cyclotron (gyro) period, the collision time (inverse collision frequency), and the equilibration times (inverse collision rates). To these we must now add the wavelength and period of the wave under study. The wave's characteristics are controlled by the relative sizes of these parameters, and in view of the large number of parameters, there is a bewildering number of possibilities. If we further recognize that plasmas are collisionless, so there is no guarantee that the particle distribution functions can be characterized by a single temperature, then the possibilities multiply further.

Fortunately, the techniques needed to describe the propagation of linear wave perturbations in a particular equilibrium configuration of a plasma are straightforward and can be amply illustrated by studying a few simple cases. In this chapter, we follow this course by restricting our attention to one class of modes, those where we can either ignore completely the thermal motions of the ions and electrons that compose the plasma (i.e., treat these species as *cold*) or include them using just a velocity dispersion or temperature. We can then apply our knowledge of fluid dynamics by treating the ions and electrons separately as fluids acted on by electromagnetic forces. This is called the *two-fluid formalism* for plasmas. In the next chapter, we explore when and how waves are sensitive to the actual distribution of particle speeds by developing

BOX 21.1. READERS' GUIDE

- This chapter relies significantly on:
 - Chap. 20 on the particle kinetics of plasmas;
 - the basic concepts of fluid dynamics, Secs. 13.4 and 13.5;
 - magnetosonic waves, Sec. 19.7; and
 - the basic concepts of geometric optics, Secs. 7.2 and 7.3.
- The remaining Chaps. 22 and 23 of Part VI rely heavily on this chapter.

the more sophisticated *kinetic-theory formalism* and using it to study waves in *warm plasmas*.

We begin our two-fluid study of plasma waves in Sec. 21.2 by deriving a very general wave equation, which governs weak waves in a homogeneous plasma that may or may not have a magnetic field and also governs electromagnetic waves in any other dielectric medium. That wave equation and the associated dispersion relation for the wave modes depend on a dielectric tensor, which must be derived from an examination of the motions of the electrons and protons (or other charge carriers) inside the wave. Those motions are described, in our two-fluid (electron-fluid and proton-fluid) model by equations that we write down in Sec. 21.3.

In Sec. 21.4, we use those two-fluid equations to derive the dielectric tensor, and then we combine with our general wave equation from Sec. 21.2 to obtain the dispersion relation for wave modes in a uniform, unmagnetized plasma. The modes fall into two classes: (i) *Transverse or electromagnetic waves*, with the electric field \mathbf{E} perpendicular to the wave's propagation direction. These are modified versions of electromagnetic waves in vacuum. As we shall see, they can propagate only at frequencies above the plasma frequency; at lower frequencies they become evanescent. (ii) *Longitudinal waves*, with \mathbf{E} parallel to the propagation direction, which come in two species: *Langmuir waves* and *ion-acoustic waves*. Longitudinal waves are a melded combination of sound waves in a fluid and electrostatic plasma oscillations; their restoring force is a mixture of thermal pressure and electrostatic forces.

In Sec. 21.5, we explore how a uniform magnetic field changes the character of these waves. The \mathbf{B} field makes the plasma anisotropic but axially symmetric. As a result, the dielectric tensor, dispersion relation, and wave modes have much in common with those in an anisotropic but axially symmetric dielectric crystal, which we studied in the context of nonlinear optics in Chap. 10. A plasma, however, has a much richer set of characteristic frequencies than does a crystal (electron plasma frequency, electron cyclotron frequency, ion cyclotron frequency, etc.). As a result,

even in the regime of weak linear waves and a cold plasma (no thermal pressure), the plasma has a far greater richness of modes than does a crystal.

In Sec. 21.5.1, we derive the general dispersion relation that encompasses all these cold-magnetized-plasma modes, and in Secs. 21.5.2 and 21.5.3, we explore the special cases of modes that propagate parallel to and perpendicular to the magnetic field. Then in Sec. 21.5.4, we examine a practical example: the propagation of radio waves in Earth's ionosphere, where it is a good approximation to ignore the ion motion and work with a one-fluid (i.e., electron-fluid) theory. Having gained insight into simple cases (parallel modes, perpendicular modes, and one-fluid modes), we return in Sec. 21.5.5 to the full class of linear modes in a cold, magnetized, two-fluid plasma and briefly describe some tools by which one can make sense of them all.

Finally, in Sec. 21.6, we turn to the question of plasma stability. In Sec. 14.6.1 and Chap. 15, we saw that fluid flows that have sufficient shear are unstable; perturbations can feed off the relative kinetic energy of adjacent regions of the fluid and use that energy to power an exponential growth. In plasmas, with their long mean free paths, there can similarly exist kinetic energies of relative, ordered motion in velocity space; and perturbations, feeding off those energies, can grow exponentially. To study this phenomenon in full requires the kinetic-theory description of a plasma, which we develop in Chap. 22; but in Sec. 21.6 we gain insight into a prominent example of such a velocity-space instability by analyzing two cold plasma streams moving through each other. We illustrate the resulting *two-stream instability* by a short discussion of particle beams that are created in disturbances on the surface of the Sun and propagate out through the solar wind.

21.2 Dielectric Tensor, Wave Equation, and General Dispersion Relation

21.2

We begin our study of waves in plasmas by deriving a general wave equation that applies equally well to electromagnetic waves in unmagnetized plasmas; in magnetized plasmas; and in any other kind of dielectric medium, such as an anisotropic crystal. This wave equation is the same one we used in our study of nonlinear optics in Chap. 10 [Eqs. (10.50) and (10.51a)], and the derivation is essentially a linearized variant of the one we gave in Chap. 10 [Eqs. (10.16a)–(10.22b)].

When a wave propagates through a plasma (or other dielectric), it entails a relative motion of electrons and protons (or other charge carriers). Assuming the wave has small enough amplitude to be linear, those charge motions can be embodied in an oscillating polarization (electric dipole moment per unit volume) $\mathbf{P}(\mathbf{x}, t)$, which is related to the plasma's (or dielectric's) varying charge density ρ_e and current density \mathbf{j} in the usual way:

polarization vector

$$\rho_e = -\nabla \cdot \mathbf{P}, \quad \mathbf{j} = \frac{\partial \mathbf{P}}{\partial t}. \quad (21.1)$$

(These relations enforce charge conservation, $\partial\rho_e/\partial t + \nabla \cdot \mathbf{j} = 0$.) When these ρ_e and \mathbf{j} are inserted into the standard Maxwell equations for \mathbf{E} and \mathbf{B} , one obtains

Maxwell equations

$$\nabla \cdot \mathbf{E} = -\frac{\nabla \cdot \mathbf{P}}{\epsilon_0}, \quad \nabla \cdot \mathbf{B} = 0, \quad \nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}, \quad \nabla \times \mathbf{B} = \mu_0 \frac{\partial \mathbf{P}}{\partial t} + \frac{1}{c^2} \frac{\partial \mathbf{E}}{\partial t}.$$

(21.2)

If the plasma is endowed with a uniform magnetic field \mathbf{B}_0 , that field can be left out of these equations, as its divergence and curl are guaranteed to vanish. Thus we can regard \mathbf{E} , \mathbf{B} , and \mathbf{P} in these Maxwell equations as the perturbed quantities associated with the waves.

From a detailed analysis of the response of the charge carriers to the oscillating \mathbf{E} and \mathbf{B} fields, one can deduce a linear (frequency-dependent and wave-vector-dependent) relationship between the waves' electric field \mathbf{E} and the polarization \mathbf{P} :

$$P_j = \epsilon_0 \chi_{jk} E_k. \quad (21.3)$$

tensorial electric susceptibility

Here ϵ_0 is the vacuum permittivity, and χ_{jk} is a dimensionless, tensorial electric susceptibility [cf. Eq. (10.21)]. A different, but equivalent, viewpoint on the relationship between \mathbf{P} and \mathbf{E} can be deduced by taking the time derivative of Eq. (21.3); setting $\partial\mathbf{P}/\partial t = \mathbf{j}$; assuming a sinusoidal time variation $e^{-i\omega t}$ so that $\partial\mathbf{E}/\partial t = -i\omega\mathbf{E}$; and then reinterpreting the result as Ohm's law with a tensorial electric conductivity κ_{ejk} :

tensorial electric conductivity

$$\mathbf{j}_j = \kappa_{ejk} E_k, \quad \kappa_{ejk} = -i\omega\epsilon_0\chi_{jk}. \quad (21.4)$$

Evidently, for sinusoidal waves the electric susceptibility χ_{jk} and the electric conductivity κ_{ejk} embody the same information about the wave-particle interactions.

dielectric tensor

That information is also embodied in a third object: the dimensionless dielectric tensor ϵ_{jk} , which relates the electric displacement \mathbf{D} to the electric field \mathbf{E} :

$$D_j \equiv \epsilon_0 E_j + P_j = \epsilon_0 \epsilon_{jk} E_k, \quad \epsilon_{jk} = \delta_{jk} + \chi_{jk} = \delta_{jk} + \frac{i}{\epsilon_0 \omega} \kappa_{ejk}. \quad (21.5)$$

In the next section, we derive the value of the dielectric tensor ϵ_{jk} for waves in an unmagnetized plasma, and in Sec. 21.4.1, we derive it for a magnetized plasma.

Using the definition $\mathbf{D} = \epsilon_0\mathbf{E} + \mathbf{P}$, we can eliminate \mathbf{P} from Eqs. (21.2), thereby obtaining the familiar form of Maxwell's equations for dielectric media with no nonpolarization-based charges or currents:

$$\nabla \cdot \mathbf{D} = 0, \quad \nabla \cdot \mathbf{B} = 0, \quad \nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}, \quad \nabla \times \mathbf{B} = \mu_0 \frac{\partial \mathbf{D}}{\partial t}. \quad (21.6)$$

general wave equation in a dielectric

By taking the curl of the third of these equations and combining with the fourth and with $D_j = \epsilon_0 \epsilon_{jk} E_k$, we obtain the wave equation that governs the perturbations:

$$\nabla^2 \mathbf{E} - \nabla(\nabla \cdot \mathbf{E}) - \epsilon \cdot \frac{1}{c^2} \frac{\partial^2 \mathbf{E}}{\partial t^2} = 0, \quad (21.7)$$

where ϵ is our index-free notation for ϵ_{jk} . [This is the same as the linearized approximation Eq. (10.50) to our nonlinear-optics wave equation (10.22a).] Specializing to a plane-wave mode with wave vector \mathbf{k} and angular frequency ω , so $\mathbf{E} \propto e^{i\mathbf{k}\mathbf{x}} e^{-i\omega t}$, we convert this wave equation into a homogeneous, algebraic equation for the Cartesian components of the electric vector E_j (cf. Box 12.2):

$$L_{ij} E_j = 0, \quad (21.8)$$

algebratized wave equation

where

$$L_{ij} = k_i k_j - k^2 \delta_{ij} + \frac{\omega^2}{c^2} \epsilon_{ij}. \quad (21.9)$$

algebratized wave operator

We call Eq. (21.8) the *algebratized wave equation*, and L_{ij} the *algebratized wave operator*.

The algebratized wave equation (21.8) can have a solution only if the determinant of the 3-dimensional matrix L_{ij} vanishes:

$$\det ||L_{ij}|| \equiv \det \left\| \left\| k_i k_j - k^2 \delta_{ij} + \frac{\omega^2}{c^2} \epsilon_{ij} \right\| \right\|. \quad (21.10)$$

general dispersion relation for electromagnetic waves in a dielectric medium

This is a polynomial equation for the angular frequency as a function of the wave vector (with ω and \mathbf{k} appearing not only explicitly in L_{ij} but also implicitly in the functional form of ϵ_{jk}). Each solution $\omega(\mathbf{k})$ of this equation is the dispersion relation for a particular wave mode. Therefore, we can regard Eq. (21.10) as the general dispersion relation for plasma waves—and for linear electromagnetic waves in any other kind of dielectric medium.

To obtain an explicit form of the dispersion relation (21.10), we must give a prescription for calculating the dielectric tensor $\epsilon_{ij}(\omega, \mathbf{k})$, or equivalently [cf. Eq. (21.5)] the conductivity tensor κ_{eij} or the susceptibility tensor χ_{ij} . The simplest prescription involves treating the electrons and ions as independent fluids; so we digress, briefly, from our discussion of waves to present the two-fluid formalism for plasmas.

21.3 Two-Fluid Formalism

21.3

A plasma necessarily contains rapidly moving electrons and ions, and their individual responses to an applied electromagnetic field depend on their velocities. In the simplest model of these responses, we average over all the particles in a species (electrons or protons in this case) and treat them collectively as a fluid. Now, the fact that all the electrons are treated as one fluid does not mean that they have to collide with one

two-fluid formalism

another. In fact, as we have already emphasized in Chap. 20, electron-electron collisions are quite rare, and we can usually ignore them. Nevertheless, we can still define a mean fluid velocity for both the electrons and the protons by averaging over their total velocity distribution functions just as we would for a gas:

mean fluid velocity

$$\mathbf{u}_s = \langle \mathbf{v} \rangle_s; \quad s = p, e, \quad (21.11)$$

where the subscripts p and e refer to protons and electrons. Similarly, for each fluid we define a pressure tensor using the fluid's dispersion of particle velocities:

pressure tensor

$$\mathbf{P}_s = n_s m_s \langle (\mathbf{v} - \mathbf{u}_s) \otimes (\mathbf{v} - \mathbf{u}_s) \rangle \quad (21.12)$$

[cf. Eqs. (20.34) and (20.35)].

The density n_s and mean velocity \mathbf{u}_s of each species s must satisfy the equation of continuity (particle conservation):

particle conservation

$$\frac{\partial n_s}{\partial t} + \nabla \cdot (n_s \mathbf{u}_s) = 0. \quad (21.13a)$$

They must also satisfy an equation of motion: the law of momentum conservation (i.e., the Euler equation with the Lorentz force added to the right-hand side):

momentum conservation

$$n_s m_s \left(\frac{\partial \mathbf{u}_s}{\partial t} + (\mathbf{u}_s \cdot \nabla) \mathbf{u}_s \right) = -\nabla \cdot \mathbf{P}_s + n_s q_s (\mathbf{E} + \mathbf{u}_s \times \mathbf{B}). \quad (21.13b)$$

Here we have neglected the tiny influence of collisions between the two species. In these equations and below, $q_s = \pm e$ is the particles' charge (positive for protons and negative for electrons). Note that, as collisions are ineffectual, we cannot assume that the pressure tensors are isotropic.

Although the particle- and momentum-conservation equations (21.13) for each species (electron or proton) are formally decoupled from the equations for the other species, there is actually a strong physical coupling induced by the electromagnetic field. The two species together produce \mathbf{E} and \mathbf{B} through their joint charge density and current density:

charge and current density

$$\rho_e = \sum_s q_s n_s, \quad \mathbf{j} = \sum_s q_s n_s \mathbf{u}_s, \quad (21.14)$$

and those \mathbf{E} and \mathbf{B} fields strongly influence the electron and proton fluids' dynamics via their equations of motion (21.13b).

EXERCISES

Exercise 21.1 *Problem: Fluid Drifts in a Magnetized Plasma*

We developed a one-fluid (MHD) description of plasma in Chap. 19, and in Chap. 20 we showed how to describe the orbits of individual charged particles in a magnetic field that varies slowly compared with the particles' orbital periods and radii. In this

chapter, we describe the plasma as two or more cold fluids. We relate these three approaches in this exercise.

(a) Generalize Eq. (21.13b) to a single fluid as:

$$\rho \mathbf{a} = \rho \mathbf{g} - \nabla \cdot \mathbf{P} + \rho_e \mathbf{E} + \mathbf{j} \times \mathbf{B}, \quad (21.15)$$

where \mathbf{a} is the fluid acceleration, and \mathbf{g} is the acceleration of gravity, and write the pressure tensor as $\mathbf{P} = P_{\perp} \mathbf{g} + (P_{\parallel} - P_{\perp}) \mathbf{B} \otimes \mathbf{B} / B^2$, where we suppress the subscript s .¹ Show that the component of current density perpendicular to the local magnetic field is

$$\mathbf{j}_{\perp} = \frac{\mathbf{B} \times \nabla \cdot \mathbf{P}}{B^2} + \rho_e \frac{\mathbf{E} \times \mathbf{B}}{B^2} + \rho \frac{(\mathbf{g} - \mathbf{a}) \times \mathbf{B}}{B^2}. \quad (21.16a)$$

(b) Use vector identities to rewrite Eq. (21.16a) in the form:

$$\mathbf{j}_{\perp} = P_{\parallel} \frac{\mathbf{B} \times (\mathbf{B} \cdot \nabla) \mathbf{B}}{B^4} + P_{\perp} \frac{\mathbf{B} \times \nabla B}{B^3} - (\nabla \times \mathbf{M})_{\perp} + \rho_e \frac{\mathbf{E} \times \mathbf{B}}{B^2} + \rho \frac{(\mathbf{g} - \mathbf{a}) \times \mathbf{B}}{B^2}, \quad (21.16b)$$

where

$$\mathbf{M} = P_{\perp} \frac{\mathbf{B}}{B^3} \quad (21.16c)$$

is the *magnetization*.

- (c) Identify the first term of Eq. (21.16b) with the curvature drift (20.49) and the second term with the gradient drift (20.51).
- (d) Using a diagram, explain how the magnetization (20.54)—the magnetic moment per unit volume—can contribute to the current density. In particular, consider what might happen at the walls of a cavity containing plasma.² Argue that there should also be a local magnetization current parallel to the magnetic field, even when there is no net drift of the particles.
- (e) Associate the final two terms of Eq. (21.16b) with the “ $\mathbf{E} \times \mathbf{B}$ ” drift (20.47) and the gravitational drift (20.48). Explain the presence of the acceleration in the gravitational drift.
- (f) Discuss how to combine these contributions to rederive the standard formulation of MHD, and specify some circumstances under which MHD might be a poor approximation.

1. Note that when writing the pressure tensor this way, we are implicitly assuming that it has only two components, along and perpendicular to the local magnetic field. Physically, this is reasonable if the particles that make up the fluid are *magnetized*, i.e., the particles’ orbital periods and radii are short compared to the scales on which the magnetic field changes.
2. This is an illustration of a general theorem in statistical mechanics due to Niels Bohr in 1911, which essentially shows that magnetization cannot arise in classical physics. This theorem may have had a role in the early development of quantum mechanics.

Note that this single-fluid formalism does not describe the component of the current parallel to the magnetic field, \mathbf{j}_{\parallel} . For this, we need to introduce an effective collision frequency for the electrons and ions either with waves (Chap. 23) or with other particles (Chap. 20). If we assume that the electrical conductivity is perfect, then $\mathbf{E} \cdot \mathbf{B} = 0$, and \mathbf{j}_{\parallel} is essentially fixed by the boundary conditions.

21.4 Wave Modes in an Unmagnetized Plasma

We now specialize to waves in a homogeneous, unmagnetized electron-proton plasma.

unperturbed plasma

First consider an unperturbed plasma in the absence of a wave, and work in a frame in which the proton fluid velocity \mathbf{u}_p vanishes. By assumption, the equilibrium is spatially uniform. If there were an electric field, then charges would quickly flow to neutralize it; so there can be no electric field, and hence (since $\nabla \cdot \mathbf{E} = \rho_e/\epsilon_0$) no net charge density. Therefore, the electron density must equal the proton density. Furthermore, there can be no net current, as this would lead to a magnetic field; so since the proton current $e n_p \mathbf{u}_p$ vanishes, the electron current $= -e n_e \mathbf{u}_e$ must also vanish. Hence the electron fluid velocity \mathbf{u}_e must vanish in our chosen frame. Thus in an equilibrated homogeneous, unmagnetized plasma, \mathbf{u}_e , \mathbf{u}_p , \mathbf{E} , and \mathbf{B} all vanish in the protons' mean rest frame.

Now apply an electromagnetic perturbation. This will induce a small, oscillating fluid velocity \mathbf{u}_s in both the proton and electron fluids. It should not worry us that the fluid velocity is small compared with the random speeds of the constituent particles; the same is true in any subsonic gas dynamical flow, but the fluid description remains good there and also here.

21.4.1 Dielectric Tensor and Dispersion Relation for a Cold, Unmagnetized Plasma

Continuing to keep the plasma unmagnetized, let us further simplify matters (until Sec. 21.4.3) by restricting ourselves to a cold plasma, so the tensorial pressures vanish: $\mathbf{P}_s = 0$. As we are only interested in linear wave modes, we rewrite the two-fluid equations (21.13), just retaining terms that are first order in perturbed quantities [i.e., dropping the $(\mathbf{u}_s \cdot \nabla)\mathbf{u}_s$ and $\mathbf{u}_s \times \mathbf{B}$ terms]. Then, focusing on a plane-wave mode, $\propto \exp[i(\mathbf{k} \cdot \mathbf{x} - \omega t)]$, we bring the equation of motion (21.13b) into the form

linearized perturbative equation of motion

$$-i\omega n_s m_s \mathbf{u}_s = q_s n_s \mathbf{E} \quad (21.17)$$

for each species, $s = p, e$. From this, we can immediately deduce the linearized current density:

$$\mathbf{j} = \sum_s n_s q_s \mathbf{u}_s = \sum_s \frac{i n_s q_s^2}{m_s \omega} \mathbf{E}, \quad (21.18)$$

from which we infer that the conductivity tensor κ_e has Cartesian components

$$\kappa_{eij} = \sum_s \frac{in_s q_s^2}{m_s \omega} \delta_{ij}, \quad (21.19)$$

where δ_{ij} is the Kronecker delta. Note that the conductivity is purely imaginary, which means that the current oscillates out of phase with the applied electric field, which in turn implies that there is no time-averaged ohmic energy dissipation: $\langle \mathbf{j} \cdot \mathbf{E} \rangle = 0$. Inserting the conductivity tensor (21.19) into the general equation (21.5) for the dielectric tensor, we obtain

$$\epsilon_{ij} = \delta_{ij} + \frac{i}{\epsilon_0 \omega} \kappa_{eij} = \left(1 - \frac{\omega_p^2}{\omega^2} \right) \delta_{ij}. \quad (21.20)$$

Here and throughout this chapter, the plasma frequency ω_p is slightly different from that used in Chap. 20: it includes a tiny (1/1,836) correction due to the motion of the protons, which we neglected in our analysis of plasma oscillations in Sec. 20.3.3:

$$\omega_p^2 = \sum_s \frac{n_s q_s^2}{m_s \epsilon_0} = \frac{ne^2}{m_e \epsilon_0} \left(1 + \frac{m_e}{m_p} \right) = \frac{ne^2}{\mu \epsilon_0}, \quad (21.21)$$

plasma frequency

where μ is the reduced mass $\mu = m_e m_p / (m_e + m_p)$. Note that because there is no physical source of a preferred direction in the plasma, the dielectric tensor (21.20) is isotropic.

Now, without loss of generality, let the waves propagate in the z direction, so $\mathbf{k} = k\mathbf{e}_z$. Then the algebraized wave operator (21.9), with ϵ given by Eq. (21.20), takes the following form:

$$L_{ij} = \frac{\omega^2}{c^2} \begin{pmatrix} 1 - \frac{c^2 k^2}{\omega^2} - \frac{\omega_p^2}{\omega^2} & 0 & 0 \\ 0 & 1 - \frac{c^2 k^2}{\omega^2} - \frac{\omega_p^2}{\omega^2} & 0 \\ 0 & 0 & 1 - \frac{\omega_p^2}{\omega^2} \end{pmatrix}. \quad (21.22)$$

algebraized wave operator and general dispersion relation for waves in a cold, unmagnetized plasma

The corresponding dispersion relation $\det||L_{jk}|| = 0$ [Eq. (21.10)] becomes

$$\left(1 - \frac{c^2 k^2}{\omega^2} - \frac{\omega_p^2}{\omega^2} \right)^2 \left(1 - \frac{\omega_p^2}{\omega^2} \right) = 0. \quad (21.23)$$

This is a polynomial equation of order 6 for ω as a function of k , so formally there are six solutions corresponding to three pairs of modes propagating in opposite directions.

Two of the pairs of modes are degenerate with frequency

$$\omega = \sqrt{\omega_p^2 + c^2 k^2}. \quad (21.24)$$

plasma electromagnetic modes

These are called *plasma electromagnetic modes*, and we study them in the next subsection. The remaining pair of modes exist at a single frequency:

$$\omega = \omega_p. \tag{21.25}$$

electrostatic plasma oscillations

These must be the electrostatic plasma oscillations that we studied in Sec. 20.3.3 (though now with an arbitrary wave number k , while in Sec. 20.3.3 the wave number was assumed to be zero). In Sec. 21.4.3, we show that this is so and explore how these plasma oscillations are modified by finite-temperature effects.

21.4.2

21.4.2 Plasma Electromagnetic Modes

properties of plasma electromagnetic modes

To learn the physical nature of the modes with dispersion relation $\omega = \sqrt{\omega_p^2 + c^2k^2}$ [Eq. (21.24)], we must examine the details of their electric-field oscillations, magnetic-field oscillations, and electron and proton motions. A key to this is the algebraized wave equation $L_{ij}E_j = 0$, with L_{ij} specialized to the dispersion relation (21.24): $||L_{ij}|| = \text{diag}[0, 0, (\omega^2 - \omega_p^2)/c^2]$. In this case, the general solution to $L_{ij}E_j = 0$ is an electric field that lies in the x - y plane (transverse plane) and that therefore is orthogonal to the waves' propagation vector $\mathbf{k} = k\mathbf{e}_z$. The third of the Maxwell equations (21.2) implies that the magnetic field is

transverse electric and magnetic fields

$$\mathbf{B} = (\mathbf{k}/\omega) \times \mathbf{E}, \tag{21.26}$$

which also lies in the transverse plane and is orthogonal to \mathbf{E} . Evidently, these modes are close analogs of electromagnetic waves in vacuum; correspondingly, they are known as the plasma's *electromagnetic modes*. The electron and proton motions in these modes, as given by Eq. (21.17), are oscillatory displacements in the direction of \mathbf{E} but are out of phase with \mathbf{E} . The amplitudes of the fluid motions, at fixed electric-field amplitude, vary as $1/\omega$; when ω decreases, the fluid amplitudes grow.

The dispersion relation for these modes, Eq. (21.24), implies that they can only propagate (i.e., have real angular frequency when the wave vector is real) if ω exceeds the plasma frequency. As ω is decreased toward ω_p , k approaches zero, so these modes become electrostatic plasma oscillations with arbitrarily long wavelength orthogonal to the oscillation direction (i.e., they become a spatially homogeneous variant of the plasma oscillations studied in Sec. 20.3.3). At $\omega < \omega_p$ these modes become evanescent.

In their regime of propagation, $\omega > \omega_p$, these cold-plasma electromagnetic waves have a phase velocity given by

phase velocity

$$\mathbf{V}_{\text{ph}} = \frac{\omega}{k} \hat{\mathbf{k}} = c \left(1 - \frac{\omega_p^2}{\omega^2} \right)^{-1/2} \hat{\mathbf{k}}, \tag{21.27a}$$

where $\hat{\mathbf{k}} \equiv \mathbf{k}/k$ is a unit vector in the propagation direction. Although this phase velocity exceeds the speed of light, causality is not violated, because information (and energy) propagate at the group velocity, not the phase velocity. The group velocity is readily shown to be

$$\mathbf{V}_g = \nabla_{\mathbf{k}} \omega = \frac{c^2 \mathbf{k}}{\omega} = c \left(1 - \frac{\omega_p^2}{\omega^2} \right)^{1/2} \hat{\mathbf{k}}, \quad (21.27b)$$

group velocity

which is less than c as it must be.

These cold-plasma electromagnetic modes transport energy and momentum just like wave modes in a fluid. There are three contributions to the waves' mean (time-averaged) energy density: the electric, the magnetic, and the kinetic-energy densities. (If we had retained the pressure, then an additional contribution would come from the internal energy.) To compute these mean energy densities, we must form the time average of products of physical quantities. Now, we have used the complex representation to denote each of our oscillating quantities (e.g., E_x), so we must be careful to remember that $A = a e^{i(\mathbf{k} \cdot \mathbf{x} - \omega t)}$ is an abbreviation for the real part of this quantity—which is the physical A . It is easy to show (Ex. 21.3) that the time-averaged value of the physical A times the physical B (which we shall denote by $\langle AB \rangle$) is given in terms of their complex amplitudes by

$$\langle AB \rangle = \frac{AB^* + A^*B}{4}, \quad (21.28)$$

time-averaged product
in terms of complex
amplitudes

where $*$ denotes a complex conjugate.

Using Eqs. (21.26) and (21.27a), we can write the magnetic energy density in the form $\langle B^2 \rangle / (2\mu_0) = (1 - \omega_p^2/\omega^2) \epsilon_0 \langle E^2 \rangle / 2$. Using Eq. (21.17), the particle kinetic energy is $\sum_s n_s m_s \langle u_s^2 \rangle / 2 = (\omega_{pe}^2/\omega^2) \epsilon_0 \langle E^2 \rangle / 2$. Summing these contributions and using Eq. (21.28), we obtain

$$\begin{aligned} U &= \frac{\epsilon_0 E E^*}{4} + \frac{B B^*}{4\mu_0} + \sum_s \frac{n_s m_s u_s u_s^*}{4} \\ &= \frac{\epsilon_0 E E^*}{2}. \end{aligned} \quad (21.29a)$$

energy density

The mean energy flux in the wave is carried (to quadratic order) by the electromagnetic field and is given by the Poynting flux. (The kinetic energy flux vanishes to this order.) A straightforward calculation gives

$$\begin{aligned} \mathbf{F}_{EM} &= \langle \mathbf{E} \times \mathbf{B} \rangle = \frac{\mathbf{E} \times \mathbf{B}^* + \mathbf{E}^* \times \mathbf{B}}{4} = \frac{E E^* \mathbf{k}}{2\mu_0 \omega} \\ &= U \mathbf{V}_g, \end{aligned} \quad (21.29b)$$

energy flux

where we have used $\mu_0 = c^{-2} \epsilon_0^{-1}$. We therefore find that the energy flux is the product of the energy density and the group velocity, as is true quite generally (cf. Sec. 6.3). (If it were not true, then a localized wave packet, which propagates at the group velocity, would move along a different trajectory from its energy, and we would wind up with energy in regions with vanishing amplitude!)

EXERCISES

Exercise 21.2 Derivation: Phase and Group Velocities for Electromagnetic Modes

Derive Eqs. (21.27) for the phase and group velocities of electromagnetic modes in a plasma.

Exercise 21.3 Derivation: Time-Averaging Formula

Verify Eq. (21.28).

Exercise 21.4 Problem: Collisional Damping in an Electromagnetic Wave Mode

Consider a transverse electromagnetic wave mode propagating in an unmagnetized, partially ionized gas in which the electron-neutral collision frequency is ν_e . Include the effects of collisions in the electron equation of motion (21.17), by introducing a term $-n_e m_e \nu_e \mathbf{u}_e$ on the right-hand side. Ignore ion motion and electron-ion and electron-electron collisions.

Derive the dispersion relation when $\omega \gg \nu_e$, and show by explicit calculation that the rate of loss of energy per unit volume ($-\nabla \cdot \mathbf{F}_{EM}$, where \mathbf{F}_{EM} is the Poynting flux) is balanced by the Ohmic heating of the plasma. [Hint: It may be easiest to regard ω as real and \mathbf{k} as complex.]

21.4.3

21.4.3 Langmuir Waves and Ion-Acoustic Waves in Warm Plasmas

For our case of a cold, unmagnetized plasma, the third pair of modes embodied in the dispersion relation (21.23) only exists at a single frequency, the plasma frequency: $\omega = \omega_p$. These modes' wave equation $L_{ij} E_j = 0$ with $||L_{ij}|| = \text{diag}(-k^2, -k^2, 0)$ [Eq. (21.22) with $\omega^2 = \omega_p^2$] implies that \mathbf{E} points in the z direction (i.e., along \mathbf{k} , which is to say the longitudinal direction). Maxwell's equations then imply $\mathbf{B} = 0$, and the equation of motion (21.17) implies that the fluid displacements are also in the direction of \mathbf{E} —the longitudinal direction. Clearly, these modes, like electromagnetic modes in the limit $k = 0$ and $\omega = \omega_p$, are electrostatic plasma oscillations. However, in this case, where the spatial variations of \mathbf{E} and \mathbf{u}_e are along the direction of oscillation instead of perpendicular to it, k is not constrained to vanish; instead, all wave numbers are allowed. This means that the plasma can undergo plane-parallel oscillations at $\omega = \omega_p$ with displacements in some Cartesian z direction and with any arbitrary z -dependent amplitude that one might wish. But these oscillations cannot transport energy: because ω is independent of \mathbf{k} , their group velocity, $\mathbf{V}_g = \nabla_{\mathbf{k}} \omega$, vanishes. Their phase velocity, $\mathbf{V}_{ph} = (\omega_p/k)\hat{\mathbf{k}}$, by contrast, is finite.

So far, we have confined ourselves to wave modes in cold plasmas. When thermal motions are turned on, the resulting thermal pressure gradients convert longitudinal plasma oscillations, at finite wave number k , into propagating, energy-transporting, longitudinal modes called *Langmuir waves*.³ As we have already intimated, because

longitudinal electrostatic plasma oscillations

finite temperature converts longitudinal plasma oscillations into Langmuir waves

3. The chemist Irving Langmuir observed these waves and introduced the name “plasma” for ionized gas in 1927.

the plasma is collisionless, we must turn to kinetic theory (Chap. 22) to understand the thermal effects fully. However, using the present chapter's two-fluid formalism and with the guidance of physical arguments, we can deduce the leading-order effects of finite temperature.

In our physical arguments, we assume that the electrons are thermalized with one another at a temperature T_e , the protons are thermalized at temperature T_p , and T_e and T_p may differ (because the timescale for electrons and protons to exchange energy is so much longer than the timescales for electrons to exchange energy among themselves and for protons to exchange energy among themselves; see Sec. 20.4.3).

Physically, the key to the Langmuir waves' propagation is the warm electrons' thermal pressure. (The proton pressure is unimportant here, because the protons oscillate electrostatically with an amplitude that is tiny compared to the electron amplitude; nevertheless, as we shall see below, the proton pressure is important in other ways.)

In an adiabatic sound wave *in a fluid* (where the particle mean free paths are small compared to the wavelength), we relate the pressure perturbation to the density perturbation by assuming that the entropy is held constant in each fluid element. In other words, we write $\nabla P = C^2 m \nabla n$, where $C = [\gamma P / (nm)]^{1/2}$ is the adiabatic sound speed, n is the particle density, m is the particle mass, and γ is the adiabatic index [which is equal to the specific heat ratio $\gamma = c_p / c_v$ (Ex. 5.4)], whose value is 5/3 for a monatomic gas.

However, the electron gas *in the plasma we are considering* is collisionless on the short timescale of a perturbation period, and we are only interested in the tensorial pressure gradient parallel to \mathbf{k} (which we take to point in the z direction), $\delta P_{e\,zz,z}$. We can therefore ignore all electron motion perpendicular to the wave vector, as it is not coupled to the parallel motion. The electron motion is then effectively 1-dimensional, since there is only one (translational) degree of freedom. The relevant specific heat at constant volume is therefore just $k_B/2$ per electron, while that at constant pressure is $3k_B/2$, giving $\gamma = 3$.⁴ The effective sound speed for the electron gas is then $C = (3k_B T_e / m_e)^{1/2}$, and correspondingly, the perturbations of longitudinal electron pressure and electron density are related by

$$\frac{\delta P_{e\,zz}}{m_e \delta n_e} = C^2 = \frac{3k_B T_e}{m_e}. \quad (21.30a)$$

This is one of the equations governing Langmuir waves. The others are the linearized equation of continuity (21.13a), which relates the electrons' density perturbation to the longitudinal component of their fluid velocity perturbation:

$$\delta n_e = n_e \frac{k}{\omega} u_{e\,z}, \quad (21.30b)$$

4. We derived this longitudinal adiabatic index $\gamma = 3$ by a different method in Ex. 20.11e [Eq. (20.36b)] in the context of a plasma with a magnetic field along the longitudinal (or z) direction. It is valid also in our unmagnetized case, because the magnetic field has no influence on longitudinal electron motions.

properties of Langmuir waves:

perturbations of pressure, electron density, electron fluid velocity, and electric field

the linearized equation of motion (21.13b), which relates u_{ez} and δP_{ezz} to the longitudinal component of the oscillating electric field:

$$-i\omega n_e m_e u_{ez} = -ik\delta P_{ezz} - n_e e E_z, \quad (21.30c)$$

and the linearized form of Poisson's equation $\nabla \cdot \mathbf{E} = \rho_e/\epsilon_0$, which relates E_z to δn_e :

$$ikE_z = -\frac{\delta n_e e}{\epsilon_0}. \quad (21.30d)$$

Equations (21.30) are four equations for three ratios of the perturbed quantities. By combining these equations, we obtain a condition that must be satisfied for them to have a solution:

Bohm-Gross dispersion relation

$$\omega^2 = \omega_{pe}^2 + \frac{3k_B T_e}{m_e} k^2 = \omega_{pe}^2 (1 + 3k^2 \lambda_D^2). \quad (21.31)$$

Here $\lambda_D = \sqrt{\epsilon_0 k_B T_e / (n_e e^2)}$ is the Debye length [Eq. (20.10)]. Equation (21.31) is the *Bohm-Gross* dispersion relation for Langmuir waves.

From this dispersion relation, we deduce the phase speed of a Langmuir wave:

phase speed

$$V_{\text{ph}} = \frac{\omega}{k} = \left(\frac{k_B T_e}{m_e} \right)^{1/2} \left(3 + \frac{1}{k^2 \lambda_D^2} \right)^{1/2}. \quad (21.32)$$

Evidently, when the reduced wavelength $\lambda/(2\pi) = 1/k$ is less than or of order the Debye length ($k\lambda_D \gtrsim 1$), the phase speed becomes comparable with the electron thermal speed. It is then possible for individual electrons to transfer energy between adjacent compressions and rarefactions in the wave. As we shall see in Sec. 22.3, when we recover Eq. (21.31) from a kinetic treatment, the resulting energy transfers damp the wave; this is called *Landau damping*. Therefore, the Bohm-Gross dispersion relation is only valid for reduced wavelengths much longer than the Debye length (i.e., $k\lambda_D \ll 1$; Fig. 21.1).

Landau damping

properties of ion-acoustic waves:

low frequencies; electrons locked to protons

In our analysis of Langmuir waves we have ignored the proton motion. This is justified as long as the proton thermal speeds are small compared to the electron thermal speeds (i.e., $T_p \ll m_p T_e / m_e$), which will almost always be the case. Proton motion is, however, not ignorable in a second type of plasma wave that owes its existence to finite temperature: *ion-acoustic waves* (also called ion-sound waves). These are waves that propagate with frequencies far below the electron plasma frequency—frequencies so low that the electrons remain locked electrostatically to the protons, keeping the plasma charge neutral and preventing electromagnetic fields from participating in the oscillations. As for Langmuir waves, we can derive the ion-acoustic dispersion relation using fluid theory combined with physical arguments.

Using kinetic theory in the next chapter, we shall see that ion-acoustic waves can propagate only when the proton temperature is small compared with the electron temperature: $T_p \ll T_e$; otherwise they are damped. (Such a temperature disparity

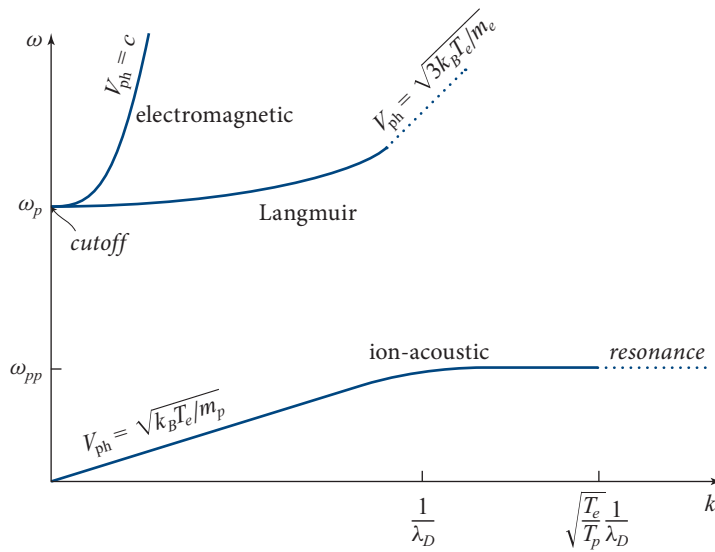

FIGURE 21.1 Dispersion relations for electromagnetic waves, Langmuir waves, and ion-acoustic waves in an unmagnetized plasma, whose electrons are thermalized with one another at temperature T_e , and whose protons are thermalized at a temperature T_p that might not be equal to T_e . In the dotted regions the waves are strongly damped, according to kinetic-theory analyses (Chap. 22). Ion-acoustic waves are wiped out by that damping at all k unless $T_p \ll T_e$ (as is assumed on the horizontal axis), in which case they survive on the non-dotted part of their curve.

can be produced, e.g., when a plasma passes through a shock wave, and it can be maintained for a long time because Coulomb collisions are so ineffective at restoring $T_p \sim T_e$; cf. Sec. 20.4.3.) Because $T_p \ll T_e$, the proton pressure can be ignored, and the waves' restoring force is provided by electron pressure. Now, in an ion-acoustic wave—by contrast with a Langmuir wave—the individual thermal electrons can travel over many wavelengths during a single wave period, so the electrons remain isothermal as their mean motion oscillates in lock-step with the protons' mean motion. Correspondingly, the electrons' effective (1-dimensional) specific-heat ratio is $\gamma_{\text{eff}} = 1$.

Although the electrons provide the ion-acoustic waves' restoring force, the inertia of the electrostatically locked electrons and protons is almost entirely that of the heavy protons. Correspondingly, the waves' phase velocity is

$$\mathbf{v}_{ia} = \left(\frac{\gamma_{\text{eff}} P_e}{n_p m_p} \right)^{1/2} \hat{\mathbf{k}} = \left(\frac{k_B T_e}{m_p} \right)^{1/2} \hat{\mathbf{k}} \quad (21.33)$$

(cf. Ex. 21.5), and the dispersion relation is $\omega = V_{\text{ph}} k = (k_B T_e / m_p)^{1/2} k$.

From this phase velocity and our physical description of these ion-acoustic waves, it should be evident that they are the magnetosonic waves of MHD theory (Sec. 19.7.2), in the limit that the plasma's magnetic field is turned off.

require low proton temperature; restoring force is electron pressure and inertia is proton mass

phase velocity

In Ex. 21.5, we show that the character of these waves is modified when their wavelength becomes of order the Debye length (i.e., when $k\lambda_D \sim 1$). The dispersion relation then becomes

$$\omega = \left(\frac{k_B T_e / m_p}{1 + \lambda_D^2 k^2} \right)^{1/2} k, \quad (21.34)$$

dispersion relation

proton plasma frequency

which means that for $k\lambda_D \gg 1$, the waves' frequency approaches the *proton plasma frequency* $\omega_{pp} \equiv \sqrt{ne^2/(\epsilon_0 m_p)} \simeq \sqrt{m_e/m_p} \omega_p$. A kinetic-theory treatment reveals that these waves are strongly damped when $k\lambda_D \gtrsim \sqrt{T_e/T_p}$. These features of the ion-acoustic dispersion relation are shown in Fig. 21.1.

MHD regime

The regime in which ion-acoustic (magnetosonic) waves can propagate, $\omega < \omega_{pp}$, is quite generally the regime in which the electrons and ions are locked to each other, making magnetohydrodynamics a good approximation to the plasma's dynamics.

EXERCISES

Exercise 21.5 *Derivation: Ion-Acoustic Waves*

Ion-acoustic waves can propagate in an unmagnetized plasma when the electron temperature T_e greatly exceeds the ion temperature T_p . In this limit, the electron density n_e can be approximated by $n_e = n_0 \exp[e\Phi/(k_B T_e)]$, where n_0 is the mean electron density, and Φ is the electrostatic potential.

- (a) Show that for ion-acoustic waves that propagate in the z direction, the nonlinear equations of continuity, the motion for the ion (proton) fluid, and Poisson's equation for the potential take the form

$$\begin{aligned} \frac{\partial n}{\partial t} + \frac{\partial(nu)}{\partial z} &= 0, \\ \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial z} &= -\frac{e}{m_p} \frac{\partial \Phi}{\partial z}, \\ \frac{\partial^2 \Phi}{\partial z^2} &= -\frac{e}{\epsilon_0} \left(n - n_0 e^{e\Phi/(k_B T_e)} \right). \end{aligned} \quad (21.35)$$

Here n is the proton density, and u is the proton fluid velocity (which points in the z direction).

- (b) Linearize Eqs. (21.35), and show that the dispersion relation for small-amplitude ion-acoustic modes is

$$\omega = \omega_{pp} \left(1 + \frac{1}{\lambda_D^2 k^2} \right)^{-1/2} = \left(\frac{k_B T_e / m_p}{1 + \lambda_D^2 k^2} \right)^{1/2} k, \quad (21.36)$$

where λ_D is the Debye length.

Exercise 21.6 *Challenge: Ion-Acoustic Solitons*

In this exercise we explore nonlinear effects in ion-acoustic waves (Ex. 21.5), and show that they give rise to solitons that obey the same KdV equation as governs

solitonic water waves (Sec. 16.3). This version of the solitons is only mildly nonlinear. In Sec. 23.6 we will generalize to strong nonlinearity.

- (a) Introduce a bookkeeping expansion parameter ε whose numerical value is unity,⁵ and expand the ion density, ion velocity, and potential in the forms

$$\begin{aligned} n &= n_0(1 + \varepsilon n_1 + \varepsilon^2 n_2 + \dots), \\ u &= (k_B T_e / m_p)^{1/2} (\varepsilon u_1 + \varepsilon^2 u_2 + \dots), \\ \Phi &= (k_B T_e / e) (\varepsilon \Phi_1 + \varepsilon^2 \Phi_2 + \dots). \end{aligned} \quad (21.37)$$

Here n_1 , u_1 , and Φ_1 are small compared to unity, and the factors of ε tell us that, as the wave amplitude is decreased, these quantities scale proportionally to one another, while n_2 , u_2 , and Φ_2 scale proportionally to the squares of n_1 , u_1 , and Φ_1 , respectively. Change independent variables from (t, z) to (τ, η) , where

$$\begin{aligned} \eta &= \sqrt{2} \varepsilon^{1/2} \lambda_D^{-1} [z - (k_B T_e / m_p)^{1/2} t], \\ \tau &= \sqrt{2} \varepsilon^{3/2} \omega_{pp} t. \end{aligned} \quad (21.38)$$

Explain, now or at the end, the chosen powers $\varepsilon^{1/2}$ and $\varepsilon^{3/2}$. By substituting Eqs. (21.37) and (21.38) into the nonlinear equations (21.35), equating terms of the same order in ε , and then setting $\varepsilon = 1$ (bookkeeping parameter!), show that n_1 , u_1 , and Φ_1 each satisfy the KdV equation (16.32):

$$\frac{\partial \zeta}{\partial \tau} + \zeta \frac{\partial \zeta}{\partial \eta} + \frac{\partial^3 \zeta}{\partial \eta^3} = 0. \quad (21.39)$$

- (b) In Sec. 16.3 we discussed the exact, single-soliton solution (16.33) to this KdV equation. Show that for an ion-acoustic soliton, this solution propagates with the physical speed $(1 + n_{1o})(k_B T_e / m_p)^{1/2}$ (where n_{1o} is the value of n_1 at the peak of the soliton), which is greater the larger is the wave's amplitude.

21.4.4 Cutoffs and Resonances

21.4.4

Electromagnetic waves, Langmuir waves, and ion-acoustic waves in an unmagnetized plasma provide examples of *cutoffs* and *resonances*.

A *cutoff* is a frequency at which a wave mode ceases to propagate because its wave number k there becomes zero. Langmuir and electromagnetic waves at $\omega \rightarrow \omega_p$ are examples; see their dispersion relations in Fig. 21.1. For concreteness, consider a monochromatic radio-frequency electromagnetic wave propagating upward into Earth's ionosphere at some nonzero angle to the vertical (left side of Fig. 21.2), and neglect the effects of Earth's magnetic field. As the wave moves deeper (higher) into the ionosphere, it encounters a rising electron density n and correspondingly, a rising plasma frequency ω_p . The wave's wavelength will typically be small compared to the

cutoff, where k goes to zero

5. See Box 7.2 for a discussion of such bookkeeping parameters in a different context.

FIGURE 21.2 Cutoff and resonance illustrated by wave propagation in Earth's ionosphere. The thick, arrowed curves are rays, and the thin, dashed lines are phase fronts. The electron density is proportional to the darkness of the shading.

inhomogeneity scale for ω_p , so the wave propagation can be analyzed using geometric optics (Sec. 7.3). Across a phase front, the portion of the wave that is higher in the ionosphere will have a smaller k and thus a larger wavelength and phase speed; it thus has a greater distance between phase fronts (dashed lines). Therefore, the rays, which are orthogonal to the phase fronts, will bend away from the vertical (left side of Fig. 21.2); that is, the wave will be reflected away from the cutoff, at which $\omega_p \rightarrow \omega$ and $k \rightarrow 0$. Clearly, this behavior is quite general. Wave modes are generally reflected from regions in which slowly changing plasma conditions give rise to cutoffs.

A *resonance* is a frequency at which a wave mode ceases to propagate because its wave number k there becomes infinite (i.e., its wavelength goes to zero). Ion-acoustic waves provide an example; see their dispersion relation in Fig. 21.1. For concreteness, consider an ion-acoustic wave deep in the ionosphere, where ω_{pp} is larger than the wave's frequency ω (right side of Fig. 21.2). As the wave propagates toward the upper edge of the ionosphere, at some nonzero angle to the vertical, the portion of a phase front that is higher sees a smaller electron density and thus a smaller ω_{pp} ; thence it has a larger k and shorter wavelength and thus a shorter distance between phase fronts (dashed lines). This causes the rays to bend toward the vertical (right side of Fig. 21.2). The wave is "attracted" to the region of the resonance, $\omega \rightarrow \omega_{pp}$, $k \rightarrow \infty$, where it is "Landau damped" (Chap. 22) and dies. This behavior is quite general. Wave modes are generally attracted to regions in which slowly changing plasma conditions give rise to resonances, and on reaching a resonance, they die.

We study wave propagation in the ionosphere in greater detail in Sec. 21.5.4.

21.5 Wave Modes in a Cold, Magnetized Plasma

21.5.1 Dielectric Tensor and Dispersion Relation

We now complicate matters somewhat by introducing a uniform magnetic field \mathbf{B}_0 into the unperturbed plasma. To avoid additional complications, we make the plasma

waves are reflected by cutoff regions

resonance, where k becomes infinite

waves are attracted to resonance regions, and damped

cold (i.e., we omit thermal effects). The linearized equation of motion (21.13b) for each species s then becomes

$$-i\omega\mathbf{u}_s = \frac{q_s\mathbf{E}}{m_s} + \frac{q_s}{m_s}\mathbf{u}_s \times \mathbf{B}_0. \quad (21.40)$$

It is convenient to multiply this equation of motion by $n_s q_s / \epsilon_0$ and introduce for each species a scalar plasma frequency and scalar and vectorial cyclotron frequencies:

$$\omega_{ps} = \left(\frac{n_s q_s^2}{\epsilon_0 m_s} \right)^{1/2}, \quad \omega_{cs} = \frac{q_s B_0}{m_s}, \quad \boldsymbol{\omega}_{cs} = \omega_{cs} \hat{\mathbf{B}}_0 = \frac{q_s \mathbf{B}_0}{m_s} \quad (21.41)$$

electron and proton plasma frequencies, and cyclotron frequencies

[so $\omega_{pp} = \sqrt{(m_e/m_p)} \omega_{pe} \simeq \omega_{pe}/43$, $\omega_p = \sqrt{\omega_{pe}^2 + \omega_{pp}^2}$, $\omega_{ce} < 0$, $\omega_{cp} > 0$, and $\omega_{cp} = (m_e/m_p)|\omega_{ce}| \simeq |\omega_{ce}|/1,836$]. Thereby we bring the equation of motion (21.40) into the form

$$-i\omega \left(\frac{n_s q_s}{\epsilon_0} \mathbf{u}_s \right) + \boldsymbol{\omega}_{cs} \times \left(\frac{n_s q_s}{\epsilon_0} \mathbf{u}_s \right) = \omega_{ps}^2 \mathbf{E}. \quad (21.42)$$

By combining this equation with $\boldsymbol{\omega}_{cs} \times$ (this equation) and $\boldsymbol{\omega}_{cs} \cdot$ (this equation), we can solve for the fluid velocity of species s as a linear function of the electric field \mathbf{E} :

properties of wave modes in a cold, magnetized plasma:

$$\frac{n_s q_s}{\epsilon_0} \mathbf{u}_s = -i \left(\frac{\omega \omega_{ps}^2}{\omega_{cs}^2 - \omega^2} \right) \mathbf{E} - \frac{\omega_{ps}^2}{(\omega_{cs}^2 - \omega^2)} \boldsymbol{\omega}_{cs} \times \mathbf{E} + \boldsymbol{\omega}_{cs} \frac{i \omega_{ps}^2}{(\omega_{cs}^2 - \omega^2) \omega} \boldsymbol{\omega}_{cs} \cdot \mathbf{E}. \quad (21.43)$$

fluid velocities

(This relation is useful for deducing the physical properties of wave modes.) From this fluid velocity we can read off the current $\mathbf{j} = \sum_s n_s q_s \mathbf{u}_s$ as a linear function of \mathbf{E} ; by comparing with Ohm's law, $\mathbf{j} = \boldsymbol{\kappa}_e \cdot \mathbf{E}$, we then obtain the tensorial conductivity $\boldsymbol{\kappa}_e$, which we insert into Eq. (21.20) to get the following expression for the dielectric tensor (in which \mathbf{B}_0 and hence $\boldsymbol{\omega}_{cs}$ are taken to be along the z -axis):

$$\boldsymbol{\epsilon} = \begin{pmatrix} \epsilon_1 & -i\epsilon_2 & 0 \\ i\epsilon_2 & \epsilon_1 & 0 \\ 0 & 0 & \epsilon_3 \end{pmatrix}, \quad (21.44)$$

dielectric tensor

where

$$\epsilon_1 = 1 - \sum_s \frac{\omega_{ps}^2}{\omega^2 - \omega_{cs}^2}, \quad \epsilon_2 = \sum_s \frac{\omega_{ps}^2 \omega_{cs}}{\omega(\omega^2 - \omega_{cs}^2)}, \quad \epsilon_3 = 1 - \sum_s \frac{\omega_{ps}^2}{\omega^2}. \quad (21.45)$$

Let the wave propagate in the x - z plane at an angle θ to the z -axis (i.e., to the magnetic field). Then the algebraized wave operator (21.9) takes the form

$$\|L_{ij}\| = \frac{\omega^2}{c^2} \begin{pmatrix} \epsilon_1 - n^2 \cos^2 \theta & -i\epsilon_2 & n^2 \sin \theta \cos \theta \\ i\epsilon_2 & \epsilon_1 - n^2 & 0 \\ n^2 \sin \theta \cos \theta & 0 & \epsilon_3 - n^2 \sin^2 \theta \end{pmatrix}, \quad (21.46)$$

where

$$\boxed{n = \frac{ck}{\omega}} \quad (21.47)$$

is the wave's index of refraction (i.e., the wave's phase velocity is $V_{\text{ph}} = \omega/k = c/n$). (Note: n must not be confused with the number density of particles n .) The algebraized wave operator (21.46) will be needed when we explore the physical nature of modes, in particular, the directions of their electric fields, which satisfy $L_{ij}E_j = 0$.

From the wave operator (21.46), we deduce the waves' dispersion relation $\det\|L_{ij}\| = 0$. Some algebra brings this into the form

$$\boxed{\tan^2 \theta = \frac{-\epsilon_3(n^2 - \epsilon_R)(n^2 - \epsilon_L)}{\epsilon_1(n^2 - \epsilon_3)(n^2 - \epsilon_R \epsilon_L / \epsilon_1)}}, \quad (21.48)$$

where

$$\boxed{\epsilon_L = \epsilon_1 - \epsilon_2 = 1 - \sum_s \frac{\omega_{ps}^2}{\omega(\omega - \omega_{cs})}, \quad \epsilon_R = \epsilon_1 + \epsilon_2 = 1 - \sum_s \frac{\omega_{ps}^2}{\omega(\omega + \omega_{cs})}.} \quad (21.49)$$

21.5.2

21.5.2 Parallel Propagation

waves propagating parallel to the magnetic field

As a first step in making sense out of the general dispersion relation (21.48) for waves in a cold, magnetized plasma, let us consider wave propagation along the magnetic field, so $\theta = 0$. The dispersion relation (21.48) then factorizes to give three solutions:

dispersion relations for three modes: left, right, and plasma oscillations; Fig. 21.3

$$n^2 \equiv \frac{c^2 k^2}{\omega^2} = \epsilon_L, \quad n^2 \equiv \frac{c^2 k^2}{\omega^2} = \epsilon_R, \quad \epsilon_3 = 0. \quad (21.50)$$

LEFT AND RIGHT MODES; PLASMA OSCILLATIONS

Consider the first solution in Eq. (21.50): $n^2 = \epsilon_L$. The algebraized wave equation $L_{ij}E_j = 0$ [with L_{ij} given by Eq. (21.46)] in this case with the wave propagating along the \mathbf{B} (\mathbf{e}_z) direction, requires that the electric field direction be $\mathbf{E} \propto (\mathbf{e}_x - i\mathbf{e}_y)e^{-i\omega t}$, which we define to be a left-hand circular polarized mode. The second solution in (21.50), $n^2 = \epsilon_R$, is the corresponding right-hand circular polarized mode. From Eqs. (21.49) we see that these two modes propagate with different phase velocities (but only slightly different, if ω is far from the electron cyclotron frequency and far

FIGURE 21.3 Square of wave refractive index for circularly polarized waves propagating along the static magnetic field in a proton-electron plasma with $\omega_{pe} > \omega_{ce}$. The horizontal, angular-frequency scale is logarithmic. *L* means left-hand circularly polarized (“left mode”), and *R*, right-hand circularly polarized (“right mode”).

from the proton cyclotron frequency). The third solution in Eq. (21.50), $\epsilon_3 = 0$, is just the electrostatic plasma oscillation in which the electrons and protons oscillate parallel to and are unaffected by the static magnetic field.

As an aid to exploring the frequency dependence of the left and right modes, Fig. 21.3 shows the refractive index $n = ck/\omega$ squared as a function of ω .

HIGH-FREQUENCIES: FARADAY ROTATION

In the high-frequency limit, the refractive index for both modes is slightly less than unity and approaches the index for an unmagnetized plasma, $n = ck/\omega \simeq 1 - \frac{1}{2}\omega_p^2/\omega^2$ [cf. Eq. (21.27a)], but with a small difference between the modes given, to leading order, by

$$n_L - n_R \simeq -\frac{\omega_{pe}^2 \omega_{ce}}{\omega^3}. \quad (21.51)$$

This difference is responsible for an important effect known as *Faraday rotation*.

Suppose that a linearly polarized wave is incident on a magnetized plasma and propagates parallel to the magnetic field. We can deduce the behavior of the polarization by expanding the mode as a linear superposition of the two circularly polarized eigenmodes, left and right. These two modes propagate with slightly different phase

Faraday rotation at high frequency: difference between left and right modes

velocities, so after propagating some distance through the plasma, they acquire a relative phase shift $\Delta\phi$. When one then reconstitutes the linear polarized mode from the circular eigenmodes, this phase shift is manifest in a rotation of the plane of polarization through an angle $\Delta\phi/2$ (for small $\Delta\phi$). This—together with the difference in refractive indices [Eq. (21.51)], which determines $\Delta\phi$ —implies a Faraday rotation rate for the plane of polarization given by (Ex. 21.7)

rate of rotation

$$\frac{d\chi}{dz} = -\frac{\omega_{pe}^2 \omega_{ce}}{2\omega^2 c}. \quad (21.52)$$

INTERMEDIATE FREQUENCIES: CUTOFFS

As the wave frequency is reduced, the refractive index decreases to zero, first for the right circular wave, then for the left one (Fig. 21.3). Vanishing of n at a finite frequency corresponds to vanishing of k and infinite wavelength, that is, it signals a cutoff (Fig. 21.2 and associated discussion). When the frequency is lowered further, the squared refractive index becomes negative, and the wave mode becomes evanescent. Correspondingly, when a circularly polarized electromagnetic wave with constant real frequency propagates into an inhomogeneous plasma parallel to its density gradient and parallel to a magnetic field, then beyond the spatial location of the wave's cutoff, its wave number k becomes purely imaginary, and the wave dies out with distance (gradually at first, then more rapidly).

The cutoff frequencies are different for the two modes and are given by

cutoff frequencies

$$\begin{aligned} \omega_{coR,L} &= \frac{1}{2} \left[\left\{ (\omega_{ce} + \omega_{cp})^2 + 4(\omega_{pe}^2 + \omega_{pp}^2) \right\}^{1/2} \pm (|\omega_{ce}| - \omega_{cp}) \right] \\ &\simeq \omega_{pe} \pm \frac{1}{2} |\omega_{ce}| \quad \text{if } \omega_{pe} \gg |\omega_{ce}|, \quad \text{as is often the case.} \end{aligned} \quad (21.53)$$

LOW FREQUENCIES: RESONANCES; WHISTLER MODES

As we lower the frequency further (Fig. 21.3), first the right mode and then the left regain the ability to propagate. When the wave frequency lies between the proton and electron gyro frequencies, $\omega_{cp} < \omega < |\omega_{ce}|$, only the right mode propagates. This mode is sometimes called a *whistler*. As the mode's frequency increases toward the electron gyro frequency $|\omega_{ce}|$ (where it first recovered the ability to propagate), its refractive index and wave vector become infinite—a signal that $\omega = |\omega_{ce}|$ is a resonance for the whistler (Fig. 21.2 and associated discussion). The physical origin of this resonance is that the wave frequency becomes resonant with the gyrational frequency of the electrons that are orbiting the magnetic field in the same sense as the wave's electric vector rotates. To quantify the strong wave absorption that occurs at this resonance, one must carry out a kinetic-theory analysis that takes account of the electrons' thermal motions (Chap. 22).

whistler mode at intermediate frequencies

resonance with electron gyrations

large dispersion near resonance

Another feature of the whistler is that it is highly dispersive close to resonance; its dispersion relation there is given approximately by

$$\omega \simeq \frac{|\omega_{ce}|}{1 + \omega_{pe}^2 / (c^2 k^2)}. \quad (21.54)$$

The group velocity, obtained by differentiating Eq. (21.54), is given approximately by

$$\mathbf{V}_g = \nabla_{\mathbf{k}} \omega \simeq \frac{2\omega_{ce}c}{\omega_{pe}} \left(1 - \frac{\omega}{|\omega_{ce}|}\right)^{3/2} \hat{\mathbf{B}}_0. \quad (21.55)$$

This velocity varies extremely rapidly close to resonance, so waves of slightly different frequency propagate at very different speeds.

This is the physical origin of the phenomenon by which whistlers were discovered. They were encountered in World War One by radio operators who heard, in their earphones, strange tones with rapidly changing pitch. These turned out to be whistler modes excited by lightning in the southern hemisphere; they propagated along Earth's magnetic field through the magnetosphere to the northern hemisphere. Only modes below the lowest electron gyro frequency on the waves' path (their geometric-optics ray) could propagate, and these were highly dispersed, with the lower frequencies arriving first.

There is also a resonance associated with the left circularly polarized wave, which propagates below the proton cyclotron frequency; see Fig. 21.3.

VERY LOW FREQUENCIES: ALFVÉN MODES

Finally, let us examine the very low-frequency limit of these waves (Fig. 21.3). We find that both dispersion relations $n^2 = \epsilon_L$ and $n^2 = \epsilon_R$ asymptote, at arbitrarily low frequencies, to

$$\omega = ak \left(1 + \frac{a^2}{c^2}\right)^{-1/2}. \quad (21.56)$$

Here $a = B_0[\mu_0 n_e(m_p + m_e)]^{-1/2}$ is the Alfvén speed that arose in our discussion of magnetohydrodynamics [Eq. (19.75)]. In fact at very low frequencies, both modes, left and right, have become the Alfvén waves that we studied using MHD in Sec. 19.7.2. However, our two-fluid formalism reports a phase speed $\omega/k = a/\sqrt{1 + a^2/c^2}$ for these Alfvén waves that is slightly lower than the speed $\omega/k = a$ predicted by our MHD formalism. The $1/\sqrt{1 + a^2/c^2}$ correction could not be deduced using non-relativistic MHD, because that formalism neglects the displacement current. (Relativistic MHD includes the displacement current and predicts precisely this correction factor.)

We can understand the physical origin of this correction by examining the particles' motions in a very-low-frequency Alfvén wave; see Fig. 21.4. Because the wave frequency is far below both the electron and the proton cyclotron frequencies, both types of particle orbit the field \mathbf{B}_0 many times in a wave period. When the wave's slowly changing electric field is applied, the guiding centers of both types of orbits acquire the same slowly changing drift velocity $\mathbf{v} = \mathbf{E} \times \mathbf{B}_0/B_0^2$, so the two fluid velocities also drift at this rate, and the currents associated with the proton and electron drifts cancel. However, when we consider corrections to the guiding-center response that are of higher order in ω/ω_{cp} and ω/ω_{ce} , we find that the ions drift slightly faster than the electrons, which produces a net current that modifies the magnetic field and gives rise to the $1/\sqrt{1 + a^2/c^2}$ correction to the Alfvén wave's phase speed.

Alfvén modes at very low frequencies

relativistic correction to phase speed

interpretation as drift motion

FIGURE 21.4 Gyration of electrons and ions in a very-low-frequency Alfvén wave. Although the electrons and ions gyrate with opposite senses about the magnetic field, their $\mathbf{E} \times \mathbf{B}$ drifts are similar. It is only in the next highest order of approximation that a net ion current is produced parallel to the applied electric field. Note that, if the electrons and ions have the same temperature, then the ratio of radii of the orbits is $\sim (m_e/m_i)^{1/2}$, or ~ 0.02 for protons.

interpretation as magnetic contribution to inertia

A second way to understand this correction is by the contribution of the magnetic field to the plasma’s inertial mass per unit volume (Ex. 21.8).

EXERCISES

Exercise 21.7 *Derivation: Faraday Rotation*

Derive Eq. (21.52) for Faraday rotation.

Exercise 21.8 *Example: Alfvén Waves as Plasma-Laden, Plucked Magnetic Field Lines*

A narrow bundle of magnetic field lines with cross sectional area A , together with the plasma attached to them, can be thought of as like a stretched string. When such a string is plucked, waves travel down it with phase speed $\sqrt{T/\Lambda}$, where T is the string’s tension, and Λ is its mass per unit length (Sec. 12.3.3). The plasma analog is Alfvén waves propagating parallel to the plasma-laden magnetic field.

- (a) Analyzed nonrelativistically, the tension for our bundle of field lines is $T = [B^2/(2\mu_0)]A$ and the mass per unit length is $\Lambda = \rho A$, so we expect a phase velocity $\sqrt{T/\Lambda} = \sqrt{B^2/(2\mu_0\rho)}$, which is $1/\sqrt{2}$ of the correct result. Where is the error? [Hint: In addition to the restoring force on bent field lines, due to tension along the field, there is also the curvature force $(\mathbf{B} \cdot \nabla)\mathbf{B}/\mu_0$; Eq. (19.15).]
- (b) In special relativity, the plasma-laden magnetic field has a tensorial inertial mass per unit volume that is discussed in Ex. 2.27. Explain why, when the field lines (which point in the z direction) are plucked so they vibrate in the x direction, the inertial mass per unit length that resists this motion is $\Lambda = (T^{00} + T^{xx})A = [\rho + B^2/(\mu_0 c^2)]A$. (In the first expression for Λ , T^{00} is the mass-energy density of plasma and magnetic field, T^{xx} is the magnetic pressure along the x direction, and the speed of light is set to unity as in Chap. 2; in the second expression, the

speed of light has been restored to the equation using dimensional arguments.) Show that the magnetic contribution to this inertial mass gives the relativistic correction $1/\sqrt{1+a^2/c^2}$ to the Alfvén waves' phase speed, Eq. (21.56).

21.5.3 Perpendicular Propagation

Turn next to waves that propagate perpendicular to the static magnetic field: $\mathbf{k} = k\mathbf{e}_x$; $\mathbf{B}_0 = B_0\mathbf{e}_z$; $\theta = \pi/2$. In this case our general dispersion relation (21.48) again has three solutions corresponding to three modes:

$$n^2 \equiv \frac{c^2 k^2}{\omega^2} = \epsilon_3, \quad n^2 \equiv \frac{c^2 k^2}{\omega^2} = \frac{\epsilon_R \epsilon_L}{\epsilon_1}, \quad \epsilon_1 = 0. \quad (21.57)$$

The first solution

$$n^2 = \epsilon_3 = 1 - \frac{\omega_p^2}{\omega^2} \quad (21.58)$$

has the same index of refraction as for an electromagnetic wave in an unmagnetized plasma [cf. Eq. (21.24)], so this is called the *ordinary mode*. In this mode the electric vector and velocity perturbation are parallel to the static magnetic field, so the field has no influence on the wave. The wave is identical to an electromagnetic wave in an unmagnetized plasma.

The second solution in Eq. (21.57),

$$n^2 = \epsilon_R \epsilon_L / \epsilon_1 = \frac{\epsilon_1^2 - \epsilon_2^2}{\epsilon_1}, \quad (21.59)$$

is known as the *extraordinary mode* and has an electric field that is orthogonal to \mathbf{B}_0 but not to \mathbf{k} . (Note that the names “ordinary” and “extraordinary” are used differently here than for waves in a nonlinear crystal in Sec. 10.6.)

The refractive indices for the ordinary and extraordinary modes are plotted as functions of frequency in Fig. 21.5. The ordinary-mode curve is dull; it is just like that in an unmagnetized plasma. The extraordinary-mode curve is more interesting. It has two cutoffs, with frequencies (ignoring the ion motions)

$$\omega_{co1,2} \simeq \left(\omega_{pe}^2 + \frac{1}{4} \omega_{ce}^2 \right)^{1/2} \pm \frac{1}{2} \omega_{ce}, \quad (21.60)$$

and two resonances with strong absorption, at frequencies known as the *upper hybrid* (UH) and *lower hybrid* (LH) frequencies. These frequencies are given approximately by

$$\omega_{UH} \simeq (\omega_{pe}^2 + \omega_{ce}^2)^{1/2},$$

$$\omega_{LH} \simeq \left[\frac{(\omega_{pe}^2 + |\omega_{ce}| \omega_{cp}) |\omega_{ce}| \omega_{cp}}{\omega_{pe}^2 + \omega_{ce}^2} \right]^{1/2}. \quad (21.61)$$

very low frequencies: fast magnetosonic mode and Alfvén mode

In the limit of very low frequency, the extraordinary, perpendicularly propagating mode has the same dispersion relation $\omega = ak/\sqrt{1 + a^2/c^2}$ as the parallel propagating modes [Eq. (21.56)]. In this regime the mode has become the fast magnetosonic wave, propagating perpendicularly to the static magnetic field (Sec. 19.7.2), while the parallel waves have become the Alfvén modes.

The third solution in Eq. (21.57), $\epsilon_1 = 0$, has vanishing eigenvector \mathbf{E} (i.e., $L_{ij}E_j = 0$ for $\epsilon_1 = 0$ implies $E_j = 0$), so it does not represent a physical oscillation of any sort.

21.5.4

21.5.4 Propagation of Radio Waves in the Ionosphere; Magnetoionic Theory

The discovery that radio waves could be reflected off the ionosphere, and thereby could be transmitted over long distances,⁶ revolutionized communications and stimulated intensive research on radio-wave propagation in a magnetized plasma. In this section, we discuss radio-wave propagation in the ionosphere for waves whose prop-

magnetoionic theory for radio waves in ionosphere

6. This effect was predicted independently by Heaviside and Kennelly in 1902. Appleton demonstrated its existence in 1924, for which he received the Nobel prize. It was claimed by some physicists that the presence of a wave speed $> c$ violated special relativity until it was appreciated that it is the group velocity that is relevant.

agation vectors make arbitrary angles θ to the magnetic field. The approximate formalism we develop is sometimes called *magneto-ionic theory*.

The ionosphere is a dense layer of partially ionized gas between 50 and 300 km above the surface of Earth. The ionization is due to incident solar ultraviolet radiation. Although the ionization fraction increases with height, the actual density of free electrons passes through a maximum whose height rises and falls with the position of the Sun.

The electron gyro frequency varies from ~ 0.5 to ~ 1 MHz in the ionosphere, and the plasma frequency increases from effectively zero to a maximum that can be as high as 100 MHz; so typically, but not everywhere, $\omega_{pe} \gg |\omega_{ce}|$. We are interested in wave propagation at frequencies above the electron plasma frequency, which in turn is well in excess of the ion plasma frequency and the ion gyro frequency. It is therefore a good approximation to ignore ion motions altogether. In addition, at the altitudes of greatest interest for radio-wave propagation, the temperature is low, $T_e \sim 200\text{--}600$ K, so the cold plasma approximation is well justified. A complication that one must sometimes face in the ionosphere is the influence of collisions (see Ex. 21.4), but in this section we ignore it.

It is conventional in magneto-ionic theory to introduce two dimensionless parameters:

$$X = \frac{\omega_{pe}^2}{\omega^2}, \quad Y = \frac{|\omega_{ce}|}{\omega}, \quad (21.62)$$

in terms of which (ignoring ion motions) the components (21.45) of the dielectric tensor (21.44) are

$$\epsilon_1 = 1 + \frac{X}{Y^2 - 1}, \quad \epsilon_2 = \frac{XY}{Y^2 - 1}, \quad \epsilon_3 = 1 - X. \quad (21.63)$$

In this case it is convenient to rewrite the dispersion relation $\det||L_{ij}|| = 0$ in a form different from Eq. (21.48)—a form derivable, for example, by computing explicitly the determinant of the matrix (21.46), setting

$$x = \frac{X - 1 + n^2}{1 - n^2}, \quad (21.64)$$

solving the resulting quadratic in x , and then solving for n^2 . The result is the *Appleton-Hartree* dispersion relation:

$$n^2 = 1 - \frac{X}{1 - \frac{Y^2 \sin^2 \theta}{2(1-X)} \pm \left[\frac{Y^4 \sin^4 \theta}{4(1-X)^2} + Y^2 \cos^2 \theta \right]^{1/2}}. \quad (21.65)$$

There are two commonly used approximations to this dispersion relation. The first is the *quasi-longitudinal* approximation, which is used when \mathbf{k} is approximately parallel to the static magnetic field (i.e., when θ is small). In this case, just retaining

properties of ionosphere

Appleton-Hartree dispersion relation

quasi-longitudinal approximation

the dominant terms in the dispersion relation, we obtain

$$n^2 \simeq 1 - \frac{X}{1 \pm Y \cos \theta}. \quad (21.66)$$

This is just the dispersion relation (21.50) for the left and right modes in strictly parallel propagation, with the substitution $B_0 \rightarrow B_0 \cos \theta$. By comparing the magnitude of the terms that we dropped from the full dispersion relation in deriving Eq. (21.66) with those that we retained, one can show that the quasi-longitudinal approximation is valid when

$$Y \sin^2 \theta \ll 2(1 - X) \cos \theta. \quad (21.67)$$

quasi-transverse approximation

The second approximation is the *quasi-transverse* approximation; it is appropriate when inequality (21.67) is reversed. In this case the two modes are generalizations of the precisely perpendicular ordinary and extraordinary modes, and their approximate dispersion relations are

$$\begin{aligned} n_O^2 &\simeq 1 - X, \\ n_X^2 &\simeq 1 - \frac{X(1 - X)}{1 - X - Y^2 \sin^2 \theta}. \end{aligned} \quad (21.68)$$

The ordinary-mode dispersion relation (subscript O) is unchanged from the strictly perpendicular one, Eq. (21.58); the extraordinary dispersion relation (subscript X) is obtained from the strictly perpendicular one [Eq. (21.59)] by the substitution $B_0 \rightarrow B_0 \sin \theta$.

The quasi-longitudinal and quasi-transverse approximations simplify the problem of tracing rays through the ionosphere.

ionospheric reflection of AM and SW radio waves

Commercial radio stations operate in the AM (amplitude-modulated) band (0.5–1.6 MHz), the SW (short-wave) band (2.3–18 MHz), and the FM (frequency-modulated) band (88–108 MHz). Waves in the first two bands are reflected by the ionosphere and can therefore be transmitted over large surface areas (Ex. 21.12). FM waves, with their higher frequencies, are not reflected and must therefore be received as “ground waves” (waves that propagate directly, near the ground). However, they have the advantage of a larger bandwidth and consequently a higher fidelity audio output. As the altitude of the reflecting layer rises at night, short-wave communication over long distances becomes easier.

EXERCISES

Exercise 21.9 Derivation: Appleton-Hartree Dispersion Relation

Derive Eq. (21.65).

Exercise 21.10 Example: Dispersion and Faraday Rotation of Pulsar Pulses

A radio pulsar emits regular pulses at 1-s intervals, which propagate to Earth through the ionized interstellar plasma with electron density $n_e \simeq 3 \times 10^4 \text{ m}^{-3}$. The pulses ob-

served at $f = 100$ MHz are believed to be emitted at the same time as those observed at much higher frequency, but they arrive with a delay of 100 ms.

- (a) Explain briefly why pulses travel at the group velocity instead of the phase velocity, and show that the expected time delay of the $f = 100$ -MHz pulses relative to the high-frequency pulses is given by

$$\Delta t = \frac{e^2}{8\pi^2 m_e \epsilon_0 f^2 c} \int n_e dx, \quad (21.69)$$

where the integral is along the waves' propagation path. Hence compute the distance to the pulsar.

- (b) Now suppose that the pulses are linearly polarized and that their propagation is accurately described by the quasi-longitudinal approximation. Show that the plane of polarization will be Faraday rotated through an angle

$$\Delta\chi = \frac{e\Delta t}{m_e} \langle B_{\parallel} \rangle, \quad (21.70)$$

where $\langle B_{\parallel} \rangle = \int n_e \mathbf{B} \cdot d\mathbf{x} / \int n_e dx$. The plane of polarization of the pulses emitted at 100 MHz is believed to be the same as the emission plane for higher frequencies, but when the pulses arrive at Earth, the 100-MHz polarization plane is observed to be rotated through 3 radians relative to that at high frequencies. Calculate the mean parallel component of the interstellar magnetic field.

Exercise 21.11 *Challenge: Faraday Rotation Paradox*

Consider a wave mode propagating through a plasma—for example, the ionosphere—in which the direction of the background magnetic field is slowly changing. We have just demonstrated that so long as \mathbf{B} is not almost perpendicular to \mathbf{k} , we can use the quasi-longitudinal approximation, the difference in phase velocity between the two eigenmodes is $\propto \mathbf{B} \cdot \mathbf{k}$, and the integral for the magnitude of the rotation of the plane of polarization is $\propto \int n_e \mathbf{B} \cdot d\mathbf{x}$.

Now, suppose that the parallel component of the magnetic field changes sign. It has been implicitly assumed that the faster eigenmode, which is circularly polarized in the quasi-longitudinal approximation, becomes the slower eigenmode (and vice versa) when the field is reversed, and the Faraday rotation is undone. However, if we track the modes using the full dispersion relation, we find that the faster quasi-longitudinal eigenmode remains the faster eigenmode in the quasi-perpendicular regime, and it becomes the faster eigenmode with opposite sense of circular polarization in the field-reversed quasi-longitudinal regime. Now, let there be a second field reversal where an analogous transition occurs. Following this logic, the net rotation should be $\propto \int n_e |\mathbf{B} \cdot d\mathbf{x}|$. What is going on?

Exercise 21.12 *Example: Reflection of Short Waves by the Ionosphere*

The free electron density in the night-time ionosphere increases exponentially from 10^9 m^{-3} to 10^{11} m^{-3} as the altitude increases from 100 to 200 km, and the density

diminishes above this height. Use Snell's law [Eq. (7.49)] to calculate the maximum range of 10-MHz waves transmitted from Earth's surface, assuming a single ionospheric reflection.

21.5.5

21.5.5 CMA Diagram for Wave Modes in a Cold, Magnetized Plasma

depicting phase speed as function of angle to magnetic field, two methods:

phase-velocity (wave-normal) surfaces, Fig. 21.6a

refractive-index surface, Fig. 21.6b

Magnetized plasmas are anisotropic, just like many nonlinear crystals (Chap. 10). This implies that the phase speed of a propagating wave mode depends on the angle between the direction of propagation and the magnetic field. Two convenient ways are used to exhibit this anisotropy diagrammatically. The first method, due originally to Fresnel, is to construct *phase-velocity surfaces* (also called *wave-normal surfaces*), which are polar plots of the wave phase velocity $V_{\text{ph}} = \omega/k$, at fixed frequency ω , as a function of the angle θ that the wave vector \mathbf{k} makes with the magnetic field; see Fig. 21.6a.

The second type of surface, used originally by Hamilton, is the *refractive-index surface*. This is a polar plot of the refractive index $n = ck/\omega$ for a given frequency, again as a function of the wave vector's angle θ to \mathbf{B} ; see Fig. 21.6b. This plot has the important property that the group velocity is perpendicular to the surface

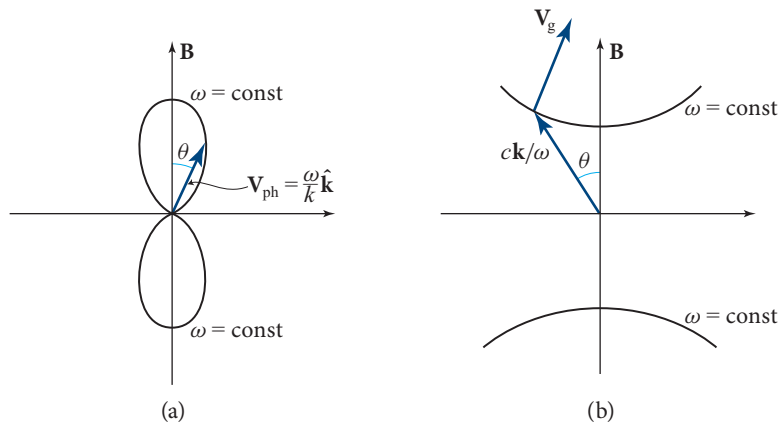

FIGURE 21.6 (a) *Wave-normal surface* (i.e., phase-velocity surface) for a whistler mode propagating at an angle θ with respect to the magnetic field direction. This diagram plots the phase velocity $\mathbf{V}_{\text{ph}} = (\omega/k)\hat{\mathbf{k}}$ as a vector from the origin, with the direction of the magnetic field chosen as upward. When we fix the frequency ω of the wave, the tip of the phase velocity vector sweeps out the figure-8 curve as its angle θ to the magnetic field changes. This curve should be thought of as rotated around the vertical (magnetic-field) direction to form the figure-8 wave-normal surface. Note that there are some directions where no mode can propagate. (b) *Refractive-index surface* for the same whistler mode. Here we plot ck/ω as a vector from the origin, and as its direction changes with fixed ω , this vector sweeps out the two hyperboloid-like surfaces. Since the length of the vector is $ck/\omega = n$, this figure can be thought of as a polar plot of the refractive index n as a function of wave-propagation direction θ for fixed ω ; hence the name “refractive-index surface.” The group velocity \mathbf{V}_{g} is orthogonal to the refractive-index surface (Ex. 21.13). Note that for this whistler mode, the energy flow (along \mathbf{V}_{g}) is focused toward the direction of the magnetic field.

(Ex. 21.13). As discussed above, the energy flow is along the direction of the group velocity and, in a magnetized plasma, this velocity can make a large angle with the wave vector.

A particularly useful application of these ideas is to a graphical representation of the various types of wave modes that can propagate in a cold, magnetized plasma (Fig. 21.7). This representation is known as the *Clemmow-Mullaly-Allis* or *CMA* diagram. The character of waves of a given frequency ω depends on the ratio of this frequency to the plasma frequency and the cyclotron frequency. This suggests defining two dimensionless numbers, $\omega_p^2/\omega^2 \equiv (\omega_{pe}^2 + \omega_{pp}^2)/\omega^2$ and $|\omega_{ce}|\omega_{cp}/\omega^2$, which are plotted on the horizontal and vertical axes of the CMA diagram. [Recall that $\omega_{pp} = \omega_{pe}\sqrt{m_e/m_p}$ and $\omega_{cp} = \omega_{ce}(m_e/m_p)$.] The CMA space defined by these two dimensionless parameters can be subdivided into sixteen regions, in each of which the propagating modes have a distinctive character. The mode properties are indicated by sketching the topological form of the *wave-normal surfaces* associated with each region.

The form of the wave-normal surface in each region can be deduced from the general dispersion relation (21.48). To deduce it, one must solve the dispersion relation for $1/n = \omega/kc = V_{ph}/c$ as a function of θ and ω , and then generate the polar plot of $V_{ph}(\theta)$.

On the CMA diagram's wave-normal curves, the characters of the parallel and perpendicular modes are indicated by labels: *R* and *L* for right and left parallel modes ($\theta = 0$), and *O* and *X* for ordinary and extraordinary perpendicular modes ($\theta = \pi/2$). As one moves across a boundary from one region to another, there is often a change of which parallel mode gets deformed continuously, with increasing θ , into which perpendicular mode. In some regions a wave-normal surface has a figure-8 shape, indicating that the waves can propagate only over a limited range of angles, $\theta < \theta_{max}$. In some regions there are two wave-normal surfaces, indicating that—at least in some directions θ —two modes can propagate; in other regions there is just one wave-normal surface, so only one mode can propagate; and in the bottom-right two regions there are no wave-normal surfaces, since no waves can propagate at these high densities and low magnetic-field strengths.

sixteen regions; topological form of wave-normal surfaces

Exercise 21.13 *Derivation: Refractive-Index Surface*

Verify that the group velocity of a wave mode is perpendicular to the refractive-index surface (Fig. 21.6b).

Exercise 21.14 *Problem: Exploration of Modes in the CMA Diagram*

For each of the following modes studied earlier in this chapter, identify in the CMA diagram the phase speed, as a function of frequency ω , and verify that the turning on and cutting off of the modes, and the relative speeds of the modes, are in accord with the CMA diagram's wave-normal curves.

EXERCISES

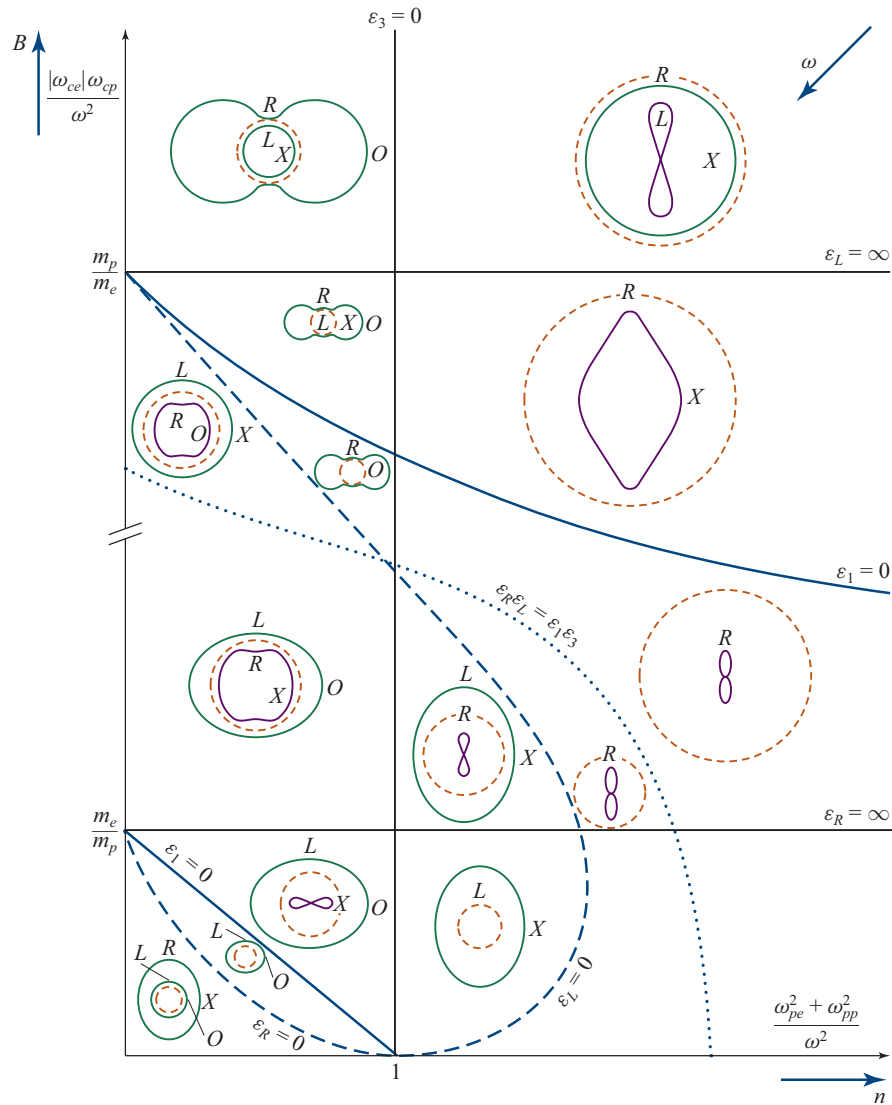

FIGURE 21.7 CMA diagram for wave modes with frequency ω propagating in a plasma with plasma frequencies ω_{pe} , ω_{pp} and gyro frequencies ω_{ce} , ω_{cp} . Plotted upward is the dimensionless quantity $|\omega_{ce}|\omega_{cp}/\omega^2$, which is proportional to B^2 , so magnetic field strength also increases upward. Plotted rightward is the dimensionless quantity $(\omega_{pe}^2 + \omega_{pp}^2)/\omega^2$, which is proportional to n , so the plasma number density also increases rightward. Since both the ordinate and the abscissa scale as $1/\omega^2$, ω increases in the left-down direction. This plane is split into sixteen regions by a set of curves on which various dielectric components have special values. In each of the sixteen regions are shown two, one, or no wave-normal surfaces (phase-velocity surfaces) at fixed ω (cf. Fig. 21.6a). These surfaces depict the types of wave modes that can propagate for that region's values of frequency ω , magnetic field strength B , and electron number density n . In each wave-normal diagram the dashed circle indicates the speed of light; a point outside that circle has phase velocity V_{ph} greater than c ; inside the circle, $V_{ph} < c$. The topologies of the wave-normal surfaces and speeds relative to c are constant throughout each of the sixteen regions; they change as one moves between regions. Adapted from Boyd and Sanderson (2003, Fig. 6.12), which in turn is adapted from Allis, Buchsbaum, and Bers (1963).

21.6 Two-Stream Instability

21.6

When considered on large enough scales, plasmas behave like fluids and are subject to a wide variety of fluid dynamical instabilities. However, as we are discovering, plasmas have internal degrees of freedom associated with their velocity distributions, which offers additional opportunities for unstable wave modes to grow and for free energy to be released. A full description of velocity-space instabilities is necessarily kinetic and must await the following chapter. However, it is instructive to consider a particularly simple example, the *two-stream instability*, using cold-plasma theory, as this brings out several features of the more general theory in a particularly simple manner.

We will apply our results in a slightly unusual way, to the propagation of fast electron beams through the slowly outflowing solar wind. These electron beams are created by coronal disturbances generated on the surface of the Sun (specifically, those associated with “Type III” radio bursts). The observation of these fast electron beams was initially a puzzle, because plasma physicists knew that they should be unstable to the exponential growth of electrostatic waves. What we do in this section is demonstrate the problem. What we will not do is explain what is thought to be its resolution, since that involves nonlinear plasma-physics considerations beyond the scope of this book (see, e.g., Melrose, 1980, or Sturrock, 1994).

Consider a simple, cold (i.e., with negligible thermal motions) electron-proton plasma at rest. Ignore the protons for the moment. We can write the dispersion relation for electron plasma oscillations in the form

$$\frac{\omega_{pe}^2}{\omega^2} = 1. \quad (21.71)$$

Now allow the ions also to oscillate about their mean positions. The dispersion relation is slightly modified to

$$\frac{\omega_p^2}{\omega^2} = \frac{\omega_{pe}^2}{\omega^2} + \frac{\omega_{pp}^2}{\omega^2} = 1 \quad (21.72)$$

[cf. Eq. (21.23)]. If we were to add other components (e.g., helium ions), that would simply add extra terms to Eq. (21.72).

Next, return to Eq. (21.71) and look at it in a reference frame in which the electrons are moving with speed u . The observed wave frequency is then Doppler shifted, and so the dispersion relation becomes

$$\frac{\omega_{pe}^2}{(\omega - ku)^2} = 1, \quad (21.73)$$

dispersion relation for electron plasma oscillations in a frame where electrons move with speed u

FIGURE 21.8 Left-hand side of the dispersion relation (21.74) for two cold plasma streams and two different choices of wave vector, k (small) and k' (large). For small enough k , there are only two real roots for ω .

where ω is now the angular frequency measured in this new frame. It should be evident from this how to generalize Eq. (21.72) to the case of several cold streams moving with different speeds u_i . We simply add the terms associated with each component using angular frequencies that have been appropriately Doppler shifted:

$$\frac{\omega_{p1}^2}{(\omega - ku_1)^2} + \frac{\omega_{p2}^2}{(\omega - ku_2)^2} + \dots = 1. \quad (21.74)$$

(This procedure will be justified via kinetic theory in the next chapter.)

The left-hand side of the dispersion relation (21.74) is plotted in Fig. 21.8 for the case of two cold plasma streams. Equation (21.74) in this case is a quartic in ω , and so it should have four roots. However, for small enough k only two of these roots will be real (solid curves in Fig. 21.8). The remaining two roots must be a complex-conjugate pair, and the root with the positive imaginary part corresponds to a growing mode. We have therefore shown that for small enough k the two-stream plasma will be unstable. Small electrostatic disturbances will grow exponentially to large amplitude and ultimately react back on the plasma. As we add more cold streams to the plasma, we add more modes, some of which will be unstable. This simple example demonstrates how easy it is for a plasma to tap the free energy residing in anisotropic particle-distribution functions.

Let us return to our solar-wind application and work in the rest frame of the wind ($u_1 = 0$), where the plasma frequency is $\omega_{p1} = \omega_p$. If the beam density is a small fraction α of the solar-wind density, so $\omega_{p2}^2 = \alpha\omega_p^2$, and the beam velocity (as seen in the wind's rest frame) is $u_2 = V$, then by differentiating Eq. (21.74), we find that the local minimum of the left-hand side occurs at $\omega = kV/(1 + \alpha^{1/3})$. The value of

dispersion relation for electron plasma oscillations in a plasma with counterstreaming beams

two-stream instability: tapping free energy of anisotropic particle-distribution functions

two-stream instability for electron beams in solar wind

the left-hand side at that minimum is $\omega_p^2(1 + \alpha^{1/3})/\omega^2$. This minimum exceeds unity (thereby making two roots of the dispersion relation complex) for

$$k < \frac{\omega_p}{V}(1 + \alpha^{1/3})^{3/2}. \quad (21.75)$$

This is therefore the condition for the existence of a growing mode. The maximum value for the growth rate can be found simply by varying k . It occurs at $k = \omega_p/V$ and is

$$\omega_i = \frac{3^{1/2}\alpha^{1/3}\omega_p}{2^{4/3}}. \quad (21.76)$$

For the solar wind near Earth, we have $\omega_p \sim 10^5 \text{ rad s}^{-1}$, $\alpha \sim 10^{-3}$, and $V \sim 10^4 \text{ km s}^{-1}$. We therefore find that the instability should grow, thereby damping the fast electron beam, in a length of 30 km, which is much less than the distance from the Sun ($1.5 \times 10^8 \text{ km}$)! This describes the problem that we will not resolve here.

EXERCISES

Exercise 21.15 Derivation: Two-Stream Instability

Verify Eq. (21.76).

Exercise 21.16 Problem: Relativistic Two-Stream Instability

In a very strong magnetic field, we can consider electrons as constrained to move in 1 dimension along the direction of the magnetic field. Consider a beam of relativistic protons propagating with density n_b and speed $u_b \sim c$ through a cold electron-proton plasma along \mathbf{B} . Generalize the dispersion relation (21.74) for modes with $\mathbf{k} \parallel \mathbf{B}$.

Exercise 21.17 Example: Drift Waves

Another type of wave mode that can be found from a fluid description of a plasma (but requires a kinetic treatment to understand completely) is a *drift wave*. Just as the two-stream instability provides a mechanism for plasmas to erase nonuniformity in velocity space, so drift waves can rapidly remove spatial irregularities.

The limiting case that we consider here is a modification of an ion-acoustic mode in a strongly magnetized plasma with a density gradient. Suppose that the magnetic field is uniform and points in the \mathbf{e}_z direction. Let there be a gradient in the equilibrium density of both the electrons and the protons: $n_0 = n_0(x)$. In the spirit of our description of ion-acoustic modes in an unmagnetized, homogeneous plasma [cf. Eq. (21.33)], treat the proton fluid as cold, but allow the electrons to be warm and isothermal with temperature T_e . We seek modes of frequency ω propagating perpendicular to the density gradient [i.e., with $\mathbf{k} = (0, k_y, k_z)$].

- (a) Consider the equilibrium of the warm electron fluid, and show that there must be a fluid drift velocity along the direction \mathbf{e}_y of magnitude

$$V_{de} = -\frac{V_{ia}^2}{\omega_{ci}} \frac{1}{n_0} \frac{dn_0}{dx}, \quad (21.77)$$

where $V_{ia} = (k_B T_e / m_p)^{1/2}$ is the ion-acoustic speed. Explain in physical terms the origin of this drift and why we can ignore the equilibrium drift motion for the ions (protons).

- (b) We limit our attention to low-frequency electrostatic modes that have phase velocities below the Alfvén speed. Under these circumstances, perturbations to the magnetic field can be ignored, and the electric field can be written as $\mathbf{E} = -\nabla\Phi$. Write down the three components of the linearized proton equation of motion in terms of the perturbation to the proton density n , the proton fluid velocity \mathbf{u} , and the electrostatic potential Φ .
- (c) Write down the linearized equation of proton continuity, including the gradient in n_0 , and combine with the equation of motion to obtain an equation for the fractional proton density perturbation at low frequencies:

$$\frac{\delta n}{n_0} = \left(\frac{(\omega_{cp}^2 k_z^2 - \omega^2 k^2) V_{ia}^2 + \omega_{cp}^2 \omega k_y V_{de}}{\omega^2 (\omega_{cp}^2 - \omega^2)} \right) \left(\frac{e\Phi}{k_B T_e} \right). \quad (21.78)$$

- (d) Argue that the fractional electron-density perturbation follows a linearized Boltzmann distribution, so that

$$\frac{\delta n_e}{n_0} = \frac{e\Phi}{k_B T_e}. \quad (21.79)$$

- (e) Use both the proton- and the electron-density perturbations in Poisson's equation to obtain the electrostatic drift wave dispersion relation in the low-frequency ($\omega \ll \omega_{cp}$), long-wavelength ($k\lambda_D \ll 1$) limit:

$$\omega = \frac{k_y V_{de}}{2} \pm \frac{1}{2} \left(k_y^2 V_{de}^2 + 4k_z^2 V_{ia}^2 \right)^{1/2}. \quad (21.80)$$

Describe the physical character of the mode in the additional limit $k_z \rightarrow 0$. A proper justification of this procedure requires a kinetic treatment, which also shows that, under some circumstances, drift waves can be unstable and grow exponentially.

Bibliographic Note

The definitive monograph on waves in plasmas is Stix (1992); also very good, and with a controlled-fusion orientation, is Swanson (2003).

For an elementary and lucid textbook treatment, which makes excellent contact with laboratory experiments, see Chap. 4 of Chen (1974) or Chen (2016). For more sophisticated and detailed textbook treatments, we especially like the relevant chapters of Clemmow and Dougherty (1969), Krall and Trivelpiece (1973), Lifshitz and Pitaevskii (1981), Sturrock (1994), Boyd and Sanderson (2003), Bittencourt (2004), and Bellan (2006). For treatments that focus on astrophysical plasmas, see Melrose (1980) and Parks (2004).

Kinetic Theory of Warm Plasmas

Any complete theory of the kinetics of a plasma cannot ignore the plasma oscillations.

IRVING LANGMUIR (1928)

22.1 Overview

22.1

At the end of Chap. 21, we showed how to generalize cold-plasma two-fluid theory to accommodate several distinct plasma beams, and thereby we discovered the two-stream instability. If the beams are not individually monoenergetic (i.e., cold), as we assumed there, but instead have broad velocity dispersions that overlap in velocity space (i.e., if the beams are *warm*), then the two-fluid approach of Chap. 21 cannot be used, and a more powerful, kinetic-theory description of the plasma is required.

Chapter 21's approach entailed specifying the positions and velocities of specific groups of particles (the “fluids”); this is an example of a *Lagrangian* description. It turns out that the most robust and powerful method for developing the kinetic theory of warm plasmas is an *Eulerian* one in which we specify how many particles are to be found in a fixed volume of one-particle phase space.

In this chapter, using this Eulerian approach, we develop the kinetic theory of plasmas. We begin in Sec. 22.2 by introducing kinetic theory's one-particle distribution function $f(\mathbf{v}, \mathbf{x}, t)$ and recovering its evolution equation (the collisionless Boltzmann equation, also called the Vlasov equation), which we have met previously in Chap. 3. We then use this *Vlasov equation* to derive the two-fluid formalism used in Chap. 21 and to deduce some physical approximations that underlie the two-fluid description of plasmas.

In Sec. 22.3, we explore the application of the Vlasov equation to Langmuir waves—the 1-dimensional electrostatic modes in an unmagnetized plasma that we studied in Chap. 21 using the two-fluid formalism. Using kinetic theory, we rederive Sec. 21.4.3's Bohm-Gross dispersion relation for Langmuir waves, and as a bonus we uncover a physical damping mechanism, called *Landau damping*, that did not and cannot emerge from the two-fluid analysis. This subtle process leads to the transfer of energy from a wave to those particles that can “surf” or “phase-ride” the wave (i.e., those whose velocity projected parallel to the wave vector is slightly less than the wave's phase speed). We show that Landau damping works because there are usually fewer

BOX 22.1. READERS' GUIDE

- This chapter relies significantly on:
 - Portions of Chap. 3 on kinetic theory: Secs. 3.2.1 and 3.2.3 on the distribution function, and Sec. 3.6 on Liouville's theorem and the collisionless Boltzmann equation.
 - Section 20.3 on Debye shielding, collective behavior of plasmas, and plasma oscillations.
 - Portions of Chap. 21: Sec. 21.2 on the wave equation and dispersion relation for dielectrics, Sec. 21.3 on the two-fluid formalism, Sec. 21.4 on Langmuir and ion-acoustic waves, and Sec. 21.6 on the two-stream instability.
- Chapter 23 on nonlinear dynamics of plasmas relies heavily on this chapter.

particles traveling faster than the wave and losing energy to it than those traveling slower and extracting energy from it. However, in a collisionless plasma, the particle distributions need not be Maxwellian. In particular, it is possible for a plasma to possess an “inverted” particle distribution with more fast than slow ones; then there is a net injection of particle energy into the waves, which creates an instability. In Sec. 22.4, we use kinetic theory to derive a necessary and sufficient criterion for this instability.

In Sec. 22.5, we examine in greater detail the physics of Landau damping and show that it is an intrinsically nonlinear phenomenon; and we give a semi-quantitative discussion of *nonlinear Landau damping*, preparatory to a more detailed treatment of some other nonlinear plasma effects in the following chapter.

Although the kinetic-theory, Vlasov description of a plasma that is developed and used in this chapter is a great improvement on the two-fluid description of Chap. 21, it is still an approximation, and some situations require more accurate descriptions. We conclude this chapter in Sec. 22.6 by introducing greater accuracy via *N-particle distribution functions*, and as applications we use them (i) to explore the approximations underlying the Vlasov description, and (ii) to explore two-particle correlations that are induced in a plasma by Coulomb interactions and the influence of those correlations on a plasma's equation of state.

22.2 Basic Concepts of Kinetic Theory and Its Relationship to Two-Fluid Theory

22.2.1 Distribution Function and Vlasov Equation

In Chap. 3, we introduced the number density of particles in phase space, the distribution function $\mathcal{N}(\mathbf{p}, \mathbf{x}, t)$. We showed that this quantity is Lorentz invariant, and that it satisfies the collisionless Boltzmann equation (3.64) and (3.65). We interpreted this

equation as \mathcal{N} being constant along the phase-space trajectory of any freely moving particle.

To comply with the conventions of the plasma-physics community, we use the name *Vlasov equation* in place of *collisionless Boltzmann equation*.¹ We change notation in a manner described in Sec. 3.2.3: we use a particle's velocity \mathbf{v} rather than its momentum \mathbf{p} as an independent variable, and we define the distribution function f to be the number density of particles in physical and velocity space:

$$f(\mathbf{v}, \mathbf{x}, t) = \frac{dN}{d\mathcal{V}_x d\mathcal{V}_v} = \frac{dN}{dx dy dz dv_x dv_y dv_z}. \quad (22.1)$$

Note that the integral of f over velocity space is the number density $n(\mathbf{x}, t)$ of particles in physical space:

$$\int f(\mathbf{v}, \mathbf{x}, t) d\mathcal{V}_v = n(\mathbf{x}, t), \quad (22.2)$$

where $d\mathcal{V}_v \equiv dv_x dv_y dv_z$ is the 3-dimensional volume element of velocity space. (For simplicity, we also restrict ourselves to nonrelativistic speeds; the generalization to relativistic plasma theory is straightforward.)

This one-particle distribution function $f(\mathbf{v}, \mathbf{x}, t)$ and its resulting kinetic theory give a good description of a plasma in the regime of large Debye number, $N_D \gg 1$ —which includes almost all plasmas that occur in the universe (cf. Sec. 20.3.2 and Fig. 20.1). The reason is that, when $N_D \gg 1$, we can define $f(\mathbf{v}, \mathbf{x}, t)$ by averaging over a physical-space volume that is large compared to the average interparticle spacing and that thus contains many particles, but is still small compared to the Debye length. By such an average—the starting point of kinetic theory—the electric fields of individual particles are made unimportant, as are the Coulomb-interaction-induced correlations between pairs of particles. We explore this issue in detail in Sec. 22.6.2, using a two-particle distribution function.

In Chap. 3, we showed that, in the absence of collisions (a good assumption for plasmas!), the distribution function evolves in accord with the Vlasov equation (3.64) and (3.65). We now rederive that Vlasov equation beginning with the law of conservation of particles for each species $s = e$ (electrons) and p (protons):

$$\frac{\partial f_s}{\partial t} + \nabla \cdot (f_s \mathbf{v}) + \nabla_v \cdot (f_s \mathbf{a}) \equiv \frac{\partial f_s}{\partial t} + \frac{\partial (f_s v_j)}{\partial x_j} + \frac{\partial (f_s a_j)}{\partial v_j} = 0. \quad (22.3)$$

1. This equation was introduced and explored in 1913 by James Jeans in the context of stellar dynamics, and then rediscovered and explored by Anatoly Alexandrovich Vlasov in 1938 in the context of plasma physics. Plasma physicists have honored Vlasov by naming the equation after him. For details of this history, see Hénon (1982).

conventions

particle conservation for
species s (electron or
proton)

Here

$$\mathbf{a} = \frac{d\mathbf{v}}{dt} = \frac{q_s}{m_s}(\mathbf{E} + \mathbf{v} \times \mathbf{B}) \quad (22.4)$$

is the electromagnetic acceleration of a particle of species s , which has mass m_s and charge q_s , and \mathbf{E} and \mathbf{B} are the electric and magnetic fields averaged over the same volume as is used in constructing f . Equation (22.3) has the standard form for a conservation law: the time derivative of a density (in this case density of particles in phase space, not just physical space), plus the divergence of a flux (in this case the spatial divergence of the particle flux, $f\mathbf{v} = f d\mathbf{x}/dt$, in the physical part of phase space, plus the velocity divergence of the particle flux, $f\mathbf{a} = f d\mathbf{v}/dt$, in velocity space) is equal to zero.

Now \mathbf{x} and \mathbf{v} are independent variables, so that $\partial x_i/\partial v_j = 0$ and $\partial v_i/\partial x_j = 0$. In addition, \mathbf{E} and \mathbf{B} are functions of \mathbf{x} and t but not of \mathbf{v} , and the term $\mathbf{v} \times \mathbf{B}$ is perpendicular to \mathbf{v} . Therefore, we have

$$\nabla_v \cdot (\mathbf{E} + \mathbf{v} \times \mathbf{B}) = 0. \quad (22.5)$$

These facts permit us to pull \mathbf{v} and \mathbf{a} out of the derivatives in Eq. (22.3), thereby obtaining

Vlasov equation for species s

$$\frac{\partial f_s}{\partial t} + (\mathbf{v} \cdot \nabla) f_s + (\mathbf{a} \cdot \nabla_v) f_s \equiv \frac{\partial f_s}{\partial t} + \frac{dx_j}{dt} \frac{\partial f_s}{\partial x_j} + \frac{dv_j}{dt} \frac{\partial f_s}{\partial v_j} = 0. \quad (22.6)$$

We recognize this as the statement that f_s is a constant along the trajectory of a particle in phase space:

$$\frac{df_s}{dt} = 0, \quad (22.7)$$

which is the *Vlasov equation* for species s .

Equation (22.7) tells us that, when the space density near a given particle increases, the velocity-space density must decrease, and vice versa. Of course, if we find that other forces or collisions are important in some situation, we can represent them by extra terms added to the right-hand side of the Vlasov equation (22.7) in the manner of the Boltzmann transport equation (3.66) (cf. Sec. 3.6).

So far, we have treated the electromagnetic field as being somehow externally imposed. However, it is actually produced by the net charge and current densities associated with the two particle species. These are expressed in terms of the distribution functions by

charge density and current density as integrals over distribution functions

$$\rho_e = \sum_s q_s \int f_s d\mathcal{V}_v, \quad \mathbf{j} = \sum_s q_s \int f_s \mathbf{v} d\mathcal{V}_v. \quad (22.8)$$

Equations (22.8), together with Maxwell's equations and the Vlasov equation (22.6), with $\mathbf{a} = d\mathbf{v}/dt$ given by the Lorentz force law (22.4), form a complete set of equations for the structure and dynamics of a plasma. They constitute the kinetic theory of plasmas.

22.2.2 Relation of Kinetic Theory to Two-Fluid Theory

22.2.2

Before developing techniques to solve the Vlasov equation, we first relate it to the two-fluid approach used in the previous chapter. We begin by constructing the moments of the distribution function f_s , defined by

$$\begin{aligned} n_s &= \int f_s d\mathcal{V}_v, \\ \mathbf{u}_s &= \frac{1}{n_s} \int f_s \mathbf{v} d\mathcal{V}_v, \\ \mathbf{P}_s &= m_s \int f_s (\mathbf{v} - \mathbf{u}_s) \otimes (\mathbf{v} - \mathbf{u}_s) \mathcal{V}_v. \end{aligned} \quad (22.9)$$

macroscopic, two-fluid quantities as integrals over distribution functions

These are respectively the density, the mean fluid velocity, and the pressure tensor for species s . (Of course, \mathbf{P}_s is just the 3-dimensional stress tensor \mathbf{T}_s [Eq. (3.32d)] evaluated in the rest frame of the fluid.)

By integrating the Vlasov equation (22.6) over velocity space and using

$$\begin{aligned} \int (\mathbf{v} \cdot \nabla) f_s d\mathcal{V}_v &= \int \nabla \cdot (f_s \mathbf{v}) d\mathcal{V}_v = \nabla \cdot \int f_s \mathbf{v} d\mathcal{V}_v, \\ \int (\mathbf{a} \cdot \nabla_v) f_s d\mathcal{V}_v &= - \int (\nabla_v \cdot \mathbf{a}) f_s d\mathcal{V}_v = 0, \end{aligned} \quad (22.10)$$

together with Eq. (22.9), we obtain the continuity equation,

$$\frac{\partial n_s}{\partial t} + \nabla \cdot (n_s \mathbf{u}_s) = 0, \quad (22.11)$$

continuity equation

for each particle species s . [It should not be surprising that the Vlasov equation implies the continuity equation, since the Vlasov equation is equivalent to the conservation of particles in phase space [Eq. (22.3)], while the continuity equation is just the conservation of particles in physical space.]

The continuity equation is the first of the two fundamental equations of two-fluid theory. The second is the equation of motion (i.e., the evolution equation for the fluid velocity \mathbf{u}_s). To derive this, we multiply the Vlasov equation (22.6) by the particle velocity \mathbf{v} and then integrate over velocity space (i.e., we compute the Vlasov equation's first moment). The details are a useful exercise for the reader (Ex. 22.1); the result is

$$n_s m_s \left(\frac{\partial \mathbf{u}_s}{\partial t} + (\mathbf{u}_s \cdot \nabla) \mathbf{u}_s \right) = -\nabla \cdot \mathbf{P}_s + n_s q_s (\mathbf{E} + \mathbf{u}_s \times \mathbf{B}), \quad (22.12)$$

equation of motion

which is identical with Eq. (21.13b).

constructing two-fluid equations from kinetic theory by method of moments

A difficulty now presents itself in the two-fluid approximation to kinetic theory. We can use Eqs. (22.8) to compute the charge and current densities from n_s and \mathbf{u}_s , which evolve via the fluid equations (22.11) and (22.12). However, we do not yet know how to compute the pressure tensor \mathbf{P}_s in the two-fluid approximation. We could derive a fluid equation for its evolution by taking the second moment of the Vlasov equation (i.e., multiplying it by $\mathbf{v} \otimes \mathbf{v}$ and integrating over velocity space), but that evolution equation would involve an unknown third moment of f_s on the right-hand side, $\mathbf{M}_3 = \int f_s \mathbf{v} \otimes \mathbf{v} \otimes \mathbf{v} d\mathcal{V}_v$, which is related to the heat-flux tensor. To determine the evolution of this \mathbf{M}_3 , we would have to construct the third moment of the Vlasov equation, which would involve the fourth moment of f_s as a driving term, and so on. Clearly, this procedure will never terminate unless we introduce some additional relationship between the moments. Such a relationship, called a *closure relation*, permits us to build a self-contained theory involving only a finite number of moments.

the need for a closure relation

For the two-fluid theory of Chap. 21, the closure relation that we implicitly used was the same idealization that one makes when regarding a fluid as perfect, namely, that the heat-flux tensor vanishes. This idealization is less well justified in a collisionless plasma, with its long mean free paths, than in a normal gas or liquid (which has short mean free paths).

An example of an alternative closure relation is one that is appropriate if radiative processes thermostat the plasma to a particular temperature, so $T_s = \text{const}$; then we can set $\mathbf{P}_s = n_s k_B T_s \mathbf{g} \propto n_s$, where \mathbf{g} is the metric tensor. Clearly, a fluid theory of plasmas can be no more accurate than its closure relation.

22.2.3

22.2.3 Jeans' Theorem

Let us now turn to the difficult task of finding solutions to the Vlasov equation. There is an elementary (and, after the fact, obvious) method to write down a class of solutions that is often useful. This is based on Jeans' theorem (named after the astronomer who first drew attention to it in the context of stellar dynamics; Jeans, 1929).

Suppose that we know the particle acceleration \mathbf{a} as a function of \mathbf{v} , \mathbf{x} , and t . (We assume this for pedagogical purposes; it is not necessary for our final conclusion.) Then for any particle with phase-space coordinates $(\mathbf{x}_0, \mathbf{v}_0)$ specified at time t_0 , we can (at least in principle) compute the particle's future motion: $\mathbf{x} = \mathbf{x}(\mathbf{x}_0, \mathbf{v}_0, t)$, $\mathbf{v} = \mathbf{v}(\mathbf{x}_0, \mathbf{v}_0, t)$. These particle trajectories are the *characteristics* of the Vlasov equation, analogous to the characteristics of the equations for 1-dimensional supersonic fluid flow that we studied in Sec. 17.4 (see Fig. 17.7). For many choices of the acceleration $\mathbf{a}(\mathbf{v}, \mathbf{x}, t)$, there are *constants of the motion*, also known as *integrals of the motion*, that are preserved along the particle trajectories. Simple examples, familiar from elementary mechanics, include the energy (for a time-independent plasma) and the angular momentum (for a spherically symmetric plasma). These integrals can be expressed in terms of the initial coordinates $(\mathbf{x}_0, \mathbf{v}_0)$. If we know n constants of

constants of motion for a particle

the motion, then only $6 - n$ additional variables need be chosen from $(\mathbf{x}_0, \mathbf{v}_0)$ to completely specify the motion of the particle.

The Vlasov equation tells us that f_s is constant along a trajectory in \mathbf{x} - \mathbf{v} space. Therefore, in general f_s must be expressible as a function of $(\mathbf{x}_0, \mathbf{v}_0)$. Equivalently, it can be rewritten as a function of the n constants of the motion and the remaining $6 - n$ initial phase-space coordinates. However, there is no requirement that it actually depend on all of these variables. In particular, any function of the integrals of motion alone that is independent of the remaining initial coordinates will satisfy the Vlasov equation (22.6). This is *Jeans' theorem*. In words, *functions of constants of the motion take constant values along actual dynamical trajectories in phase space and therefore satisfy the Vlasov equation*.

Jeans' theorem: solution of Vlasov equation based on constants of particle motion

Of course, a situation may be so complex that no integrals of the particles' equation of motion can be found, in which case Jeans' theorem won't help us find solutions of the Vlasov equation. Alternatively, there may be integrals but the initial conditions may be sufficiently complex that extra variables are required to determine f_s . However, it turns out that in a wide variety of applications, particularly those with symmetries (e.g., time independence $\partial f_s / \partial t = 0$), simple functions of simple constants of the motion suffice to describe a plasma's distribution functions.

We have already met and used a variant of Jeans' theorem in our analysis of statistical equilibrium in Sec. 4.4. There the statistical mechanics distribution function ρ was found to depend only on the integrals of the motion.

We have also, unknowingly, used Jeans' theorem in our discussion of Debye shielding in a plasma (Sec. 20.3.1). To understand this, let us suppose that we have a single isolated positive charge at rest in a stationary plasma ($\partial f_s / \partial t = 0$), and we want to know the electron distribution function in its vicinity. Let us further suppose that the electron distribution at large distances from the charge is known to be Maxwellian with temperature T : $f_e(\mathbf{v}, \mathbf{x}, t) \propto \exp[-\frac{1}{2}m_e v^2 / (k_B T)]$. Now, the electrons have an energy integral, $E = \frac{1}{2}m_e v^2 - e\Phi$, where Φ is the electrostatic potential. As Φ becomes constant at large distances from the charge, we can therefore write $f_e \propto \exp[-E / (k_B T)]$ at large distances. However, the particles near the charge must have traveled there from a large distance and so must have this same distribution function. Therefore, close to the charge, we have

$$f_e \propto e^{-E/k_B T} = e^{-(m_e v^2/2 - e\Phi)/(k_B T)}, \quad (22.13)$$

and the electron density is obtained by integration over velocity:

$$n_e = \int f_e d\mathcal{V}_v \propto e^{[e\Phi/(k_B T)]}. \quad (22.14)$$

This is just the Boltzmann distribution that we asserted to be appropriate in Sec. 20.3.1.

EXERCISES

Exercise 22.1 *Derivation: Two-Fluid Equation of Motion*

Derive the two-fluid equation of motion (22.12) by multiplying the Vlasov equation (22.6) by \mathbf{v} and integrating over velocity space.

Exercise 22.2 *Example: Positivity of Distribution Function*

The particle distribution function $f(\mathbf{v}, \mathbf{x}, t)$ ought not to become negative if it is to remain physical. Show that this is guaranteed if it initially is everywhere nonnegative and it evolves by the collisionless Vlasov equation.

Exercise 22.3 *Problem and Challenge: Jeans' Theorem in Stellar Dynamics*

Jeans' theorem is of great use in studying the motion of stars in a galaxy. The stars are also almost collisionless and can be described by a distribution function $f(\mathbf{v}, \mathbf{x}, t)$. However, there is only one sign of "charge" and no possibility of screening. In this problem, we make a model of a spherical galaxy composed of identical-mass stars.²

- (a) The simplest type of distribution function is a function of one integral of a star's motion, the energy per unit mass: $E = \frac{1}{2}v^2 + \Phi$, where Φ is the gravitational potential. A simple example is $f(E) \propto | -E|^{7/2}$ for negative energy and zero for positive energy. Verify that the associated mass density satisfies: $\rho \propto [1 + (r/s)^2]^{-5/2}$, where r is the radius, and s is a scale that you should identify.
- (b) This density profile does not agree with observations, so we need to find an algorithm for computing the distribution function that gives a specified density profile. Show that for a general $f(E)$ satisfying appropriate boundary conditions,

$$\frac{d\rho}{d\Phi} = -8^{1/2}\pi m \int_{\Phi}^0 dE \frac{f(E)}{(E - \Phi)^{1/2}}, \quad (22.15a)$$

where m is the mass of a star.

- (c) Equation (22.15a) is an Abel integral equation. Confirm that it can be inverted to give the desired algorithm:

$$f(E) = \frac{1}{8^{1/2}\pi^2 m} \frac{d}{dE} \int_E^0 d\Phi \frac{d\rho/d\Phi}{(\Phi - E)^{1/2}}. \quad (22.15b)$$

- (d) Compute the distribution function that is paired with the *Jaffe* profile, which looks more like a real galaxy:

$$\rho \propto \frac{1}{r^2(r + s)^2}. \quad (22.16)$$

2. We now know that the outer parts of galaxies are dominated by *dark matter* (Sec. 28.3.2), which may comprise weakly interacting elementary particles that should satisfy the Vlasov equation just as stars do.

- (e) We can construct *two-integral* spherical models using $f(E, L)$, where L is a star's total angular momentum per unit mass. What extra feature can we hope to capture using this broader class of distribution functions?

22.3 Electrostatic Waves in an Unmagnetized Plasma: Landau Damping

22.3

As our principal application of the kinetic theory of plasmas, we explore its predictions for the dispersion relations; stability; and damping of longitudinal, electrostatic waves in an unmagnetized plasma—Langmuir waves and ion-acoustic waves. When studying these waves in Sec. 21.4.3 using two-fluid theory, we alluded time and again to properties of the waves that could not be derived by fluid techniques. Our goal now is to elucidate those properties using kinetic theory. As we shall see, their origin lies in the plasma's velocity-space dynamics.

22.3.1 Formal Dispersion Relation

22.3.1

Consider an electrostatic wave propagating in the z direction. Such a wave is 1-dimensional in that the electric field points in the z direction, $\mathbf{E} = E\mathbf{e}_z$, and varies as $e^{i(kz-\omega t)}$, so it depends only on z and not on x or y ; the distribution function similarly varies as $e^{i(kz-\omega t)}$ and is independent of x , y ; and the Vlasov, Maxwell, and Lorentz force equations produce no coupling of particle velocities v_x and v_y to the z direction. These properties suggest the introduction of 1-dimensional distribution functions, obtained by integration over v_x and v_y :

$$F_s(v, z, t) \equiv \int f_s(v_x, v_y, v = v_z, z, t) dv_x dv_y. \quad (22.17)$$

1-dimensional distribution function for plasma interacting with a longitudinal electrostatic wave (Langmuir or ion-acoustic)

Here and throughout we suppress the subscript z on v_z .

Restricting ourselves to weak waves, so nonlinearities can be neglected, we linearize the 1-dimensional distribution functions:

$$F_s(v, z, t) \simeq F_{s0}(v) + F_{s1}(v, z, t). \quad (22.18)$$

Here $F_{s0}(v)$ is the distribution function of the unperturbed particles ($s = e$ for electrons and $s = p$ for protons) in the absence of the wave, and F_{s1} is the perturbation induced by and linearly proportional to the electric field E . The evolution of F_{s1} is governed by the linear approximation to the Vlasov equation (22.6):

$$\frac{\partial F_{s1}}{\partial t} + v \frac{\partial F_{s1}}{\partial z} + \frac{q_s E}{m_s} \frac{dF_{s0}}{dv} = 0. \quad (22.19)$$

Here E is a first-order quantity, so in its term we keep only the zero-order dF_{s0}/dv .

We seek a monochromatic plane-wave solution to this Vlasov equation, so $\partial/\partial t \rightarrow -i\omega$ and $\partial/\partial z \rightarrow ik$ in Eq. (22.19). Solving the resulting equation for F_{s1} , we obtain

solution of linearized Vlasov equation

$$F_{s1} = \frac{-iq_s}{m_s(\omega - kv)} \frac{dF_{s0}}{dv} E. \quad (22.20)$$

This equation implies that the charge density associated with the wave is related to the electric field by

$$\rho_e = \sum_s q_s \int_{-\infty}^{+\infty} F_{s1} dv = \left(\sum_s \frac{-iq_s^2}{m_s} \int_{-\infty}^{+\infty} \frac{F'_{s0} dv}{\omega - kv} \right) E, \quad (22.21)$$

where the prime denotes a derivative with respect to v : $F'_{s0} = dF_{s0}/dv$.

A quick route from here to the waves' dispersion relation is to insert this charge density into Poisson's equation, $\nabla \cdot \mathbf{E} = ikE = \rho_e/\epsilon_0$, and note that both sides are proportional to E , so a solution is possible only if

$$1 + \sum_s \frac{q_s^2}{m_s \epsilon_0 k} \int_{-\infty}^{+\infty} \frac{F'_{s0} dv}{\omega - kv} = 0. \quad (22.22)$$

An alternative route, which makes contact with the general analysis of waves in a dielectric medium (Sec. 21.2), is developed in Ex. 22.4. This route reveals that the dispersion relation is given by the vanishing of the zz component of the dielectric tensor, which we denoted ϵ_3 in Chap. 21 [Eq. (21.45)], and it shows that ϵ_3 is given by expression (22.22):

$$\epsilon_3(\omega, k) = 1 + \sum_s \frac{q_s^2}{m_s \epsilon_0 k} \int_{-\infty}^{+\infty} \frac{F'_{s0} dv}{\omega - kv} = 0. \quad (22.23)$$

Since $\epsilon_3 = \epsilon_{zz}$ is the only component of the dielectric tensor that we meet in this chapter, we simplify notation henceforth by omitting the subscript 3 (i.e., by denoting $\epsilon_{zz} = \epsilon$).

The form of the dispersion relation (22.23) suggests that we combine the unperturbed electron and proton distribution functions $F_{e0}(v)$ and $F_{p0}(v)$ to produce a single, unified distribution function:

unified distribution function

$$F(v) \equiv F_{e0}(v) + \frac{m_e}{m_p} F_{p0}(v), \quad (22.24)$$

in terms of which the dispersion relation takes the form

general dispersion relation for electrostatic waves—derived by Fourier techniques

$$\epsilon(\omega, k) = 1 + \frac{e^2}{m_e \epsilon_0 k} \int_{-\infty}^{+\infty} \frac{F' dv}{\omega - kv} = 0. \quad (22.25)$$

Note that each proton is weighted less heavily than each electron by a factor $m_e/m_p = 1/1,836$ in the unified distribution function (22.24) and the dispersion relation (22.25). This is due to the protons' greater inertia and corresponding weaker response to an applied electric field; it causes the protons to be of no importance in Langmuir waves (Sec. 22.3.5). However, in ion-acoustic waves (Sec. 22.3.6), the protons can play an important role, because large numbers of them may move with thermal speeds that are close to the waves' phase velocity, and thereby they can interact resonantly with the waves.

EXERCISES

Exercise 22.4 Example: Dielectric Tensor and Dispersion Relation for Longitudinal, Electrostatic Waves

Derive expression (22.23) for the zz component of the dielectric tensor in a plasma excited by a weak electrostatic wave, and show that the wave's dispersion relation is $\epsilon_3 = 0$. [Hint: Notice that the z component of the plasma's electric polarization P_z is related to the charge density by $\nabla \cdot \mathbf{P} = ikP_z = -\rho_e$ [Eq. (21.1)]. Combine this with Eq. (22.21) to get a linear relationship between P_z and $E_z = E$. Argue that the only nonzero component of the plasma's electric susceptibility is χ_{zz} , and deduce its value by comparing the above result with Eq. (21.3). Then construct the dielectric tensor ϵ_{ij} from Eq. (21.5) and the algebraized wave operator L_{ij} from Eq. (21.9), and deduce that the dispersion relation $\det||L_{ij}|| = 0$ takes the form $\epsilon_{zz} \equiv \epsilon_3 = 0$, where ϵ_3 is given by Eq. (22.23).]

22.3.2 Two-Stream Instability

22.3.2

As a first application of the general dispersion relation (22.25), we use it to rederive the dispersion relation (21.74) associated with the cold-plasma two-stream instability of Sec. 21.6.

We begin by performing an integration by parts on the general dispersion relation (22.25), obtaining:

$$\frac{e^2}{m_e \epsilon_0} \int_{-\infty}^{+\infty} \frac{F dv}{(\omega - kv)^2} = 1. \quad (22.26)$$

We then presume, as in Sec. 21.6, that the fluid consists of two or more streams of cold particles (protons or electrons) moving in the z direction with different fluid speeds u_1, u_2, \dots , so $F(v) = n_1 \delta(v - u_1) + n_2 \delta(v - u_2) + \dots$. Here n_j is the number density of particles in stream j if the particles are electrons, and m_e/m_p times the number density if they are protons. Inserting this $F(v)$ into Eq. (22.26) and noting

multi-stream approach to two-stream instability

that $n_j e^2 / (m_e \epsilon_0)$ is the squared plasma frequency ω_{pj}^2 of stream j , we obtain the dispersion relation

$$\frac{\omega_{p1}^2}{(\omega - ku_1)^2} + \frac{\omega_{p2}^2}{(\omega - ku_2)^2} + \dots = 1, \quad (22.27)$$

which is identical to the dispersion relation (21.74) used in our analysis of the two-stream instability.

It should be evident that the general dispersion relation (22.26) [or equally well, Eq. (22.25)] provides us with a tool for exploring how the two-stream instability is influenced by a warming of the plasma (i.e., by a spread of particle velocities around the mean, fluid velocity of each stream). We explore this in Sec. 22.4.

22.3.3

22.3.3 The Landau Contour

The general dispersion relation (22.25) has a troubling feature: for real ω and k its integrand becomes singular at $v = \omega/k =$ (the waves' phase velocity) unless dF/dv vanishes there, which is generically unlikely. This tells us that if k is real (as we shall assume), then ω cannot be real, except perhaps for a nongeneric mode whose phase velocity happens to coincide with a velocity for which $dF/dv = 0$.

ambiguity in general dispersion relation

With ω/k complex, we must face the possibility of some subtlety in how the integral over v in the dispersion relation (22.25) is performed—the possibility that we may have to make v complex in the integral and follow some special route in the complex velocity plane from $v = -\infty$ to $v = +\infty$. Indeed, there is such a subtlety, as Landau (1946) has shown. Our simple derivation of the dispersion relation in Sec. 22.3.1 cannot reveal this subtlety—and, indeed, is suspicious, since in going from Eq. (22.19) to Eq. (22.20), our derivation entailed dividing by $\omega - kv$, which vanishes when $v = \omega/k$, and dividing by zero is always a suspicious practice. Faced with this conundrum, Landau developed a more sophisticated derivation of the dispersion relation. It is based on posing generic initial data for electrostatic waves, then evolving those data forward in time and identifying the plasma's electrostatic modes by their late-time sinusoidal behaviors, and finally reading off the dispersion relation for the modes from the equations for the late-time evolution. In the remainder of this section, we present a variant of Landau's analysis.

derivation of general dispersion relation by Landau's method

This analysis is very important, including the portion (Ex. 22.5) assigned for the reader to work out. The reader is encouraged to read through this section slowly, with care, so as to understand clearly what is going on.

For simplicity, from the outset we restrict ourselves to plane waves propagating in the z direction with some fixed, real wave number k , so the linearized 1-dimensional distribution function and the electric field have the forms

$$F_s(v, z, t) = F_{s0}(v) + F_{s1}(v, t)e^{ikz}, \quad E(z, t) = E(t)e^{ikz}. \quad (22.28)$$

FIGURE 22.1 Contour of integration for evaluating $E(t)$ [Eq. (22.29)] as a sum over residues of the integrand's poles ω_n —the complex frequencies of the plasma's modes.

At $t = 0$ we pose initial data $F_{s1}(v, 0)$ for the electron and proton velocity distributions; these data determine the initial electric field $E(0)$ via Poisson's equation. We presume that these initial distributions [and also the unperturbed plasma's velocity distribution $F_{s0}(v)$] are analytic functions of velocity v , but aside from this constraint, the $F_{s1}(v, 0)$ are generic. (A Maxwellian distribution is analytic, and most any physically reasonable initial distribution can be well approximated by an analytic function.)

We then evolve these initial data forward in time. The ideal tool for such evolution is the Laplace transform, and *not* the Fourier transform. The power of the Laplace transform is much appreciated by engineers and is underappreciated by many physicists. Those readers who are not intimately familiar with evolution via Laplace transforms should work carefully through Ex. 22.5. That exercise uses Laplace transforms, followed by conversion of the final answer into Fourier language, to derive the following formula for the time-evolving electric field in terms of the initial velocity distributions $F_{s1}(v, 0)$:

$$E(t) = \int_{i\sigma - \infty}^{i\sigma + \infty} \frac{e^{-i\omega t}}{\epsilon(\omega, k)} \left[\sum_s \frac{q_s}{2\pi\epsilon_0 k} \int_{-\infty}^{+\infty} \frac{F_{s1}(v, 0)}{\omega - kv} dv \right] d\omega. \quad (22.29)$$

Here the integral in frequency space is along the solid horizontal line at the top of Fig. 22.1, with the imaginary part of ω held fixed at $\omega_i = \sigma$ and the real part ω_r varying from $-\infty$ to $+\infty$. The Laplace techniques used to derive this formula are carefully designed to avoid any divergences and any division by zero. This careful design leads to the requirement that the height σ of the integration line above the real frequency axis be greater than the e -folding rate $\Im(\omega)$ of the plasma's most rapidly growing mode (or, if none grow, still larger than zero and thus larger than $\Im(\omega)$ for the most slowly decaying mode):

$$\sigma > p_o \equiv \max_n \Im(\omega_n), \quad \text{and} \quad \sigma > 0. \quad (22.30)$$

key to the derivation—
evolve arbitrary initial data
using Laplace transform

FIGURE 22.2 Derivation of the Landau contour \mathcal{L} . (a) The dielectric function $\epsilon(\omega, k)$ is originally defined, in Eq. (22.31), solely for the pole (the point labeled ω/k) lying in the upper half plane; that is, for $\omega_i/k = \sigma/k > 0$. (b,c) Since $\epsilon(\omega, k)$ must be an analytic function of ω at fixed k and thus must vary continuously as ω is continuously changed, the dashed contour of integration in Eq. (22.31) must be kept always below the pole $v = \omega/k$.

Here $n = 1, 2, \dots$ labels the modes, ω_n is the complex frequency of mode n , and \Im means take the imaginary part of. We shall see that the ω_n are the zeros of the dielectric function $\epsilon(\omega, k)$ that appears in Eq. (22.29), that is, they are poles of the integrand of the frequency integral.

Equation (22.29) also entails a velocity integral. In the Laplace-based analysis (Ex. 22.5) that leads to this formula, there is never any question about the nature of the velocity v : it is always real, so the integral is over real v running from $-\infty$ to $+\infty$. However, because all the frequencies ω appearing in Eq. (22.29) have imaginary parts $\omega_i = \sigma > 0$, there is no possibility in the velocity integral of any divergence of the integrand.

In Eq. (22.29) for the evolving field, $\epsilon(\omega, k)$ is the same dielectric function (22.25) as we deduced in our previous analysis (Sec. 22.3.1):

$$\epsilon(\omega, k) = 1 + \frac{e^2}{m_e \epsilon_0 k} \int_{-\infty}^{+\infty} \frac{F' dv}{\omega - kv}, \quad \text{where } F(v) = F_{e0}(v) + \frac{m_e}{m_p} F_{p0}. \quad (22.31)$$

However, by contrast with Sec. 22.3.1, our derivation here dictates unequivocally how to handle the v integration—the same way as in Eq. (22.29): v is strictly real, and the only frequencies appearing in the evolution equations have $\omega_i = \sigma > 0$, so the v integral, running along the real velocity axis, passes under the integrand's pole at $v = \omega/k$, as shown in Fig. 22.2a.

To read off the modal frequencies from the evolving field $E(t)$ at times $t > 0$, we use techniques from complex-variable theory. It can be shown that, because (by hypothesis) $F_{s1}(v, 0)$ and $F_{s0}(v)$ are analytic functions of v , the integrand of the ω integral in Eq. (22.29) is meromorphic: when the integrand is analytically continued throughout the complex frequency plane, its only singularities are poles. This permits us to evaluate the frequency integral, at times $t > 0$, by closing the integration contour in the lower-half frequency plane, as shown by the dashed curve in Fig. 22.1. Because of the exponential factor $e^{-i\omega t}$, the contribution from the dashed part of the contour vanishes, which means that the integral around the contour is equal to $E(t)$ (the

contribution from the solid horizontal part). Complex-variable theory tells us that this integral is given by a sum over the residues R_n of the integrand at the poles (labeled $n = 1, 2, \dots$):

$$E(t) = 2\pi i \sum_n R_n = \sum_n A_n e^{-i\omega_n t}. \quad (22.32)$$

Here ω_n is the frequency at pole n , and A_n is $2\pi i R_n$ with its time dependence $e^{-i\omega_n t}$ factored out. It is evident, then, that each pole of the analytically continued integrand of Eq. (22.29) corresponds to a mode of the plasma, and the pole's complex frequency is the mode's frequency.

Now, for special choices of the initial data $F_{s1}(v, 0)$, there may be poles in the square-bracketed term in Eq. (22.29), but for generic initial data there will be none, and the only poles will be the zeros of $\epsilon(\omega, k)$. Therefore, generically, the modes' frequencies are the zeros of $\epsilon(\omega, k)$ —when that function (which was originally defined only for ω along the line $\omega_i = \sigma$) has been analytically extended throughout the complex frequency plane.

So how do we compute the analytically extended dielectric function $\epsilon(\omega, k)$? Imagine holding k fixed and real, and exploring the (complex) value of ϵ , thought of as a function of ω/k , by moving around the complex ω/k plane (same as the complex velocity plane). In particular, imagine computing ϵ from Eq. (22.31) at one point after another along the arrowed path shown in Fig. 22.2b,c. This path begins at an initial location ω/k , where $\omega_i/k = \sigma/k > 0$, and travels down to some other location below the real axis. At the starting point, the discussion in the paragraph following Eq. (22.30) tells us how to handle the velocity integral: just integrate v along the real axis. As ω/k is moved continuously (with k held fixed), $\epsilon(\omega, k)$ must vary continuously, because it is analytic. When ω/k crosses the real velocity axis, if the integration contour in Eq. (22.31) were to remain on the velocity axis, then the contour would jump over the integral's moving pole $v = \omega/k$, and the function $\epsilon(\omega, k)$ would jump discontinuously at the moment of crossing, which is not possible. To avoid such a discontinuous jump, it is necessary that the contour of integration be kept below the pole, $v = \omega/k$, as that pole moves into the lower half of the velocity plane (Fig. 22.2b,c).

The rule that the integration contour must always pass beneath the pole $v = \omega/k$ as shown in Fig. 22.2 is called the *Landau prescription*; the contour is called the *Landau contour* and is denoted \mathcal{L} . Our final formula for the dielectric function (and for its vanishing at the modal frequencies—the dispersion relation) is

$$\boxed{\epsilon(\omega, k) = 1 + \frac{e^2}{m_e \epsilon_0 k} \int_{\mathcal{L}} \frac{F' dv}{\omega - kv} = 0,} \quad \text{where} \quad \boxed{F(v) = F_e(v) + \frac{m_e}{m_p} F_p(v).} \quad (22.33)$$

For future use we have omitted the subscript 0 from the unperturbed distribution functions F_s , as there should be no confusion in future contexts. We refer

Landau contour and the unambiguous general dispersion relation for electrostatic waves in an unmagnetized plasma

to Eq. (22.33) as the general dispersion relation for electrostatic waves in an unmagnetized plasma.

EXERCISES

Exercise 22.5 ***Example: Electric Field for Electrostatic Wave Deduced*

Using Laplace Transforms

Use Laplace-transform techniques to derive Eqs. (22.29)–(22.31) for the time-evolving electric field of electrostatic waves with fixed wave number k and initial velocity perturbations $F_{s1}(v, 0)$. A sketch of the solution follows.

- (a) When the initial data are evolved forward in time, they produce $F_{s1}(v, t)$ and $E(t)$. Construct the Laplace transforms (see, e.g., Arfken, Weber, and Harris, 2013, Chap. 20, or Mathews and Walker, 1970, Sec. 4-3) of these evolving quantities:

$$\tilde{F}_{s1}(v, p) = \int_0^\infty dt e^{-pt} F_{s1}(v, t), \quad \tilde{E}(p) = \int_0^\infty dt e^{-pt} E(t). \quad (22.34)$$

To ensure that the time integral is convergent, insist that $\Re(p)$ be greater than $p_0 \equiv \max_n \Im(\omega_n) \equiv$ (the e -folding rate of the most strongly growing mode—or, if none grow, then the most weakly damped mode). Also, to simplify the subsequent analysis, insist that $\Re(p) > 0$. Below, in particular, we need the Laplace transforms for $\Re(p) =$ (some fixed value σ that satisfies $\sigma > p_0$ and $\sigma > 0$).

- (b) By constructing the Laplace transform of the 1-dimensional Vlasov equation (22.19) and integrating by parts the term involving $\partial F_{s1}/\partial t$, obtain an equation for a linear combination of $\tilde{F}_{s1}(v, p)$ and $\tilde{E}(p)$ in terms of the initial data $F_{s1}(v, t = 0)$. By then combining with the Laplace transform of Poisson's equation, show that

$$\tilde{E}(p) = \frac{1}{\epsilon(ip, k)} \sum_s \frac{q_s}{k \epsilon_0} \int_{-\infty}^{\infty} \frac{F_{s1}(v, 0)}{ip - kv} dv. \quad (22.35)$$

Here $\epsilon(ip, k)$ is the dielectric function (22.25) evaluated for frequency $\omega = ip$, with the integral running along the real v -axis, and [as we noted in part (a)] with $\Re(p)$ greater than p_0 , the largest ω_i of any mode, and greater than 0. This situation for the dielectric function is the one depicted in Fig. 22.2a.

- (c) Laplace-transform theory tells us that the time-evolving electric field (with wave number k) can be expressed in terms of its Laplace transform (22.35) by

$$E(t) = \int_{\sigma - i\infty}^{\sigma + i\infty} \tilde{E}(p) e^{pt} \frac{dp}{2\pi i}, \quad (22.36)$$

where σ [as introduced in part (a)] is any real number larger than p_0 and larger than 0. Combine this equation with expression (22.35) for $\tilde{E}(p)$, and set $p = -i\omega$. Thereby arrive at the desired result, Eq. (22.29).

In most practical situations, electrostatic waves are weakly damped or weakly unstable: $|\omega_i| \ll \omega_r$ (where ω_r and ω_i are the real and imaginary parts of the wave frequency ω), so the amplitude changes little in one wave period. In this case, the dielectric function (22.33) can be evaluated at $\omega = \omega_r + i\omega_i$ using the first term in a Taylor series expansion away from the real axis:

$$\begin{aligned}\epsilon(\omega_r + i\omega_i, k) &\simeq \epsilon(\omega_r, k) + \omega_i \left(\frac{\partial \epsilon_r}{\partial \omega_i} + i \frac{\partial \epsilon_i}{\partial \omega_i} \right)_{\omega_i=0} \\ &= \epsilon(\omega_r, k) + \omega_i \left(-\frac{\partial \epsilon_i}{\partial \omega_r} + i \frac{\partial \epsilon_r}{\partial \omega_r} \right)_{\omega_i=0} \\ &\simeq \epsilon(\omega_r, k) + i\omega_i \left(\frac{\partial \epsilon_r}{\partial \omega_r} \right)_{\omega_i=0}.\end{aligned}\quad (22.37)$$

Here ϵ_r and ϵ_i are the real and imaginary parts of ϵ . In going from the first line to the second we have assumed that $\epsilon(\omega, k)$ is an analytic function of ω near the real axis and hence have used the Cauchy-Riemann equations for the derivatives (see, e.g., Arfken, Weber, and Harris, 2013). In going from the second line to the third we have used the fact that $\epsilon_i \rightarrow 0$ when the velocity distribution is one that produces $\omega_i \rightarrow 0$ [cf. Eq. (22.39)], so the middle term on the second line is second order in ω_i and can be neglected.

Equation (22.37) expresses the dielectric function slightly away from the real axis in terms of its value and derivative on and along the real axis. The on-axis value can be computed from Eq. (22.33) by breaking the Landau contour depicted in Fig. 22.2b into three pieces—two lines from $\pm\infty$ to a small distance δ from the pole, plus a semicircle of radius δ under and around the pole—and by then taking the limit $\delta \rightarrow 0$. The first two terms (the two straight lines) together produce the Cauchy principal value of the integral (denoted \int_{P} below), and the third produces $2\pi i$ times half the residue of the pole at $v = \omega_r/k$, so Eq. (22.33) becomes:

$$\epsilon(\omega_r, k) = 1 - \frac{e^2}{m_e \epsilon_0 k^2} \left[\int_{\text{P}} \frac{F' dv}{v - \omega_r/k} dv + i\pi F'(v = \omega_r/k) \right]. \quad (22.38)$$

Inserting this equation and its derivative with respect to ω_r into Eq. (22.37), and setting the result to zero, we obtain

$$\begin{aligned}\epsilon(\omega_r + i\omega_i, k) &\simeq 1 - \frac{e^2}{m_e \epsilon_0 k^2} \left[\int_{\text{P}} \frac{F' dv}{v - \omega_r/k} + i\pi F'(\omega_r/k) \right. \\ &\quad \left. + i\omega_i \frac{\partial}{\partial \omega_r} \int_{\text{P}} \frac{F' dv}{v - \omega_r/k} \right] = 0.\end{aligned}\quad (22.39)$$

Notice that the vanishing of ϵ_r determines the real part ω_r of the frequency:

$$\boxed{1 - \frac{e^2}{m_e \epsilon_0 k^2} \int_{\text{P}} \frac{F'}{v - \omega_r/k} dv = 0,} \quad (22.40a)$$

and the vanishing of ϵ_i determines the imaginary part:

$$\omega_i = \frac{\pi F'(\omega_r/k)}{-\frac{\partial}{\partial \omega_r} \int_{\mathbb{P}} \frac{F'}{v-\omega_r/k} dv}. \quad (22.40b)$$

general dispersion relation for weakly damped elastostatic waves in an unmagnetized plasma

Equations (22.40) are the dispersion relation in the limit $|\omega_i| \ll \omega_r$. We refer to this as the small- $|\omega_i|$ dispersion relation for electrostatic waves in an unmagnetized plasma.

Notice that the sign of ω_i is influenced by the sign of $F' = dF/dv$ at $v = \omega_r/k = V_{\text{ph}}$ (the waves' phase velocity). As we shall see, this has a simple physical origin and important physical consequences. Usually, but not always, the denominator of Eq. (22.40b) is positive, so the sign of ω_i is the same as the sign of $F'(\omega_r/k)$.

22.3.5

22.3.5 Langmuir Waves and Their Landau Damping

We now apply the small- $|\omega_i|$ dispersion relation (22.40) to Langmuir waves in a thermalized plasma. Langmuir waves typically move so fast that the slow ions cannot interact with them, so their dispersion relation is influenced significantly only by the electrons. Therefore, we ignore the ions and include only the electrons in $F(v)$. We obtain $F(v)$ by integrating out v_y and v_z in the 3-dimensional Boltzmann distribution [Eq. (3.22d) with $E = \frac{1}{2}m_e(v_x^2 + v_y^2 + v_z^2)$]; the result, correctly normalized so that $\int F(v)dv = n$, is

$$F \simeq F_e = n \left(\frac{m_e}{2\pi k_B T} \right)^{1/2} e^{-[m_e v^2 / (2k_B T)]}, \quad (22.41)$$

where T is the electron temperature.

Now, as we saw in Eq. (22.40b), ω_i is proportional to $F'(v = \omega_r/k)$ with a proportionality constant that is usually positive. Physically, this proportionality arises from the manner in which electrons surf on the waves. Those electrons moving slightly faster than the waves' phase velocity $V_{\text{ph}} = \omega_r/k$ (usually) lose energy to the waves on average, while those moving slightly slower (usually) extract energy from the waves on average. Therefore,

energy conservation in Landau damping

1. if there are more slightly slower particles than slightly faster [$F'(v = \omega_r/k) < 0$], then the particles on average gain energy from the waves and the waves are damped [$\omega_i < 0$];
2. if there are more slightly faster particles than slightly slower [$F'(v = \omega_r/k) > 0$], then the particles on average lose energy to the waves and the waves are amplified [$\omega_i > 0$]; and
3. the bigger the disparity between the number of slightly faster electrons and the number of slightly slower electrons [i.e., the bigger $|F'(\omega_r/k)|$], the larger will be the damping or growth of wave energy (i.e., the larger will be $|\omega_i|$).

Quantitatively, it turns out that if the waves' phase velocity ω_r/k is anywhere near the steepest point on the side of the electron velocity distribution (i.e., if ω_r/k is of order the electron thermal velocity $\sqrt{k_B T/m_e}$), then the waves will be strongly damped: $\omega_i \sim -\omega_r$. Since our dispersion relation (22.41) is valid only when the waves are weakly damped, we must restrict ourselves to waves with $\omega_r/k \gg \sqrt{k_B T/m_e}$ (a physically allowed regime) or to $\omega_r/k \ll \sqrt{k_B T/m_e}$ (a regime that does not occur in Langmuir waves; cf. Fig. 21.1).

Requiring, then, that $\omega_r/k \gg \sqrt{k_B T/m_e}$ and noting that the integral in Eq. (22.39) gets its dominant contribution from velocities $v \lesssim \sqrt{k_B T/m_e}$, we can expand $1/(v - \omega_r/k)$ in the integrand as a power series in vk/ω_r , obtaining

$$\begin{aligned} \int_{\mathbb{P}} \frac{F' dv}{v - \omega_r/k} &= - \int_{-\infty}^{\infty} dv F' \left[\frac{k}{\omega_r} + \frac{k^2 v}{\omega_r^2} + \frac{k^3 v^2}{\omega_r^3} + \frac{k^4 v^3}{\omega_r^4} + \dots \right] \\ &= \frac{nk^2}{\omega_r^2} + \frac{3n\langle v^2 \rangle k^4}{\omega_r^4} + \dots \\ &= \frac{nk^2}{\omega_r^2} \left(1 + \frac{3k_B T k^2}{m_e \omega_r^2} + \dots \right) \\ &\simeq \frac{nk^2}{\omega_r^2} \left(1 + 3k^2 \lambda_D^2 \frac{\omega_p^2}{\omega_r^2} \right). \end{aligned} \quad (22.42)$$

Substituting Eqs. (22.41) and (22.42) into Eqs. (22.40a) and (22.40b), and noting that $\omega_r/k \gg \sqrt{k_B T/m_e} \equiv \omega_p \lambda_D$ implies $k\lambda_D \ll 1$ and $\omega_r \simeq \omega_p$, we obtain

$$\boxed{\omega_r = \omega_p (1 + 3k^2 \lambda_D^2)^{1/2}}, \quad (22.43a)$$

$$\boxed{\omega_i = - \left(\frac{\pi}{8} \right)^{1/2} \frac{\omega_p}{k^3 \lambda_D^3} \exp \left(- \frac{1}{2k^2 \lambda_D^2} - \frac{3}{2} \right)}. \quad (22.43b)$$

dispersion relation for Langmuir waves in an unmagnetized, thermalized plasma

The real part of this dispersion relation, $\omega_r = \omega_p \sqrt{1 + 3k^2 \lambda_D^2}$, reproduces the Bohm-Gross result (21.31) that we derived using the two-fluid theory in Sec. 21.4.3 and plotted in Fig. 21.1. The imaginary part reveals the damping of these Langmuir waves by surfing electrons—so-called *Landau damping*. The two-fluid theory could not predict this Landau damping, because the damping is a result of internal dynamics in the electrons' velocity space, of which that theory is oblivious.

Landau damping of Langmuir waves

Notice that, as the waves' wavelength is decreased (i.e., as k increases), the waves' phase velocity decreases toward the electron thermal velocity and the damping becomes stronger, as is expected from our discussion of the number of electrons that can surf on the waves. In the limit $k \rightarrow 1/\lambda_D$ (where our dispersion relation has broken down and so is only an order-of-magnitude guide), the dispersion relation predicts that $\omega_r/k \sim \sqrt{k_B T/m_e}$ and $\omega_i/\omega_r \sim 1/10$.

In the opposite regime of large wavelength $k\lambda_D \ll 1$ (where our dispersion relation should be quite accurate), the Landau damping is very weak—so weak that ω_i decreases to zero with increasing k faster than any power of k .

22.3.6

22.3.6 Ion-Acoustic Waves and Conditions for Their Landau Damping to Be Weak

As we saw in Sec. 21.4.3, ion-acoustic waves are the analog of ordinary sound waves in a fluid: they occur at low frequencies where the mean (fluid) electron velocity is very nearly locked to the mean (fluid) proton velocity, so the electric polarization is small; the restoring force is due to thermal pressure and not to the electrostatic field; and the inertia is provided by the heavy protons. It was asserted in Sec. 21.4.3 that to avoid these waves being strongly damped, the electron temperature must be much higher than the proton temperature: $T_e \gg T_p$. We can now understand this condition in terms of particle surfing and Landau damping.

requirement that $T_e \gg T_p$
for ion-acoustic waves

Suppose that the electrons and protons have Maxwellian velocity distributions but possibly with different temperatures. Because of their far greater inertia, the protons will have a far smaller mean thermal speed than the electrons, $\sqrt{k_B T_p/m_p} \ll \sqrt{k_B T_e/m_e}$, so the net 1-dimensional distribution function $F(v) = F_e(v) + (m_e/m_p)F_p(v)$ [Eq. (22.24)] that appears in the kinetic-theory dispersion relation has the form shown in Fig. 22.3. Now, if $T_e \sim T_p$, then the contributions of the electron pressure and proton pressure to the waves' restoring force will be comparable, and the waves' phase velocity will therefore be $\omega_r/k \sim \sqrt{k_B(T_e + T_p)/m_p} \sim \sqrt{k_B T_p/m_p} = v_{\text{th},p}$, which is the thermal proton velocity and also is the speed at which the proton contribution to $F(v)$ has its steepest slope (see the left tick mark on the horizontal axis in Fig. 22.3); so $|F'(v = \omega_r/k)|$ is large. This means large numbers of protons can surf on the waves and a disparity develops between the number moving slightly slower than the waves (which extract energy from the waves) and the number moving slightly faster (which give energy to the waves). The result will be strong Landau damping by the protons.

ion-acoustic waves'
strong Landau damping
if electrons and ions are
thermalized at same
temperature

This strong Landau damping is avoided if $T_e \gg T_p$. Then the waves' phase velocity will be $\omega_r/k \sim \sqrt{k_B T_e/m_p}$, which is large compared to the proton thermal velocity $v_{\text{th},p} = \sqrt{k_B T_p/m_p}$ and so is way out on the tail of the proton velocity distribution, where there are few protons that can surf and damp the waves; see the right tick mark on the horizontal axis in Fig. 22.3. Thus Landau damping by protons has been shut down by raising the electron temperature.

What about Landau damping by electrons? The phase velocity $\omega_r/k \sim \sqrt{k_B T_e/m_p}$ is small compared to the electron thermal velocity $v_{\text{th},e} = \sqrt{k_B T_e/m_e}$, so the waves reside near the peak of the electron velocity distribution, where $F_e(v)$ is large, so many electrons can surf with the waves. But $F_e'(v)$ is small, so there are nearly equal numbers of faster and slower electrons, and the surfing produces little net Landau damping. Thus $T_e/T_p \gg 1$ leads to successful propagation of ion acoustic waves.

A detailed computation, based on our small- ω_i kinetic-theory dispersion relation (22.40) makes this physical argument quantitative. The details are carried out in

FIGURE 22.3 Electron and ion contributions to the net distribution function $F(v)$ in a thermalized plasma. When $T_e \sim T_p$, the phase speed of ion acoustic waves is near the left tick mark on the horizontal axis—a speed at which surfing protons have maximum ability to Landau-damp the waves, and the waves are strongly damped. When $T_e \gg T_p$, the phase speed is near the right tick mark—far out on the tail of the proton velocity distribution—so few protons can surf and damp the waves. The phase speed is near the peak of the electron distribution, so the number of electrons moving slightly slower than the waves is nearly the same as the number moving slightly faster, and there is little net damping by the electrons. In this case the waves can propagate.

Ex. 22.6 under the assumptions that $T_e \gg T_p$ and $\sqrt{k_B T_p / m_p} \ll \omega_r / k \ll \sqrt{k_B T_e / m_e}$ (corresponding to the above discussion). The result is

$$\frac{\omega_r}{k} = \sqrt{\frac{k_B T_e / m_p}{1 + k^2 \lambda_D^2}}, \quad (22.44a)$$

$$\frac{\omega_i}{\omega_r} = -\frac{\sqrt{\pi/8}}{(1 + k^2 \lambda_D^2)^{3/2}} \left[\sqrt{\frac{m_e}{m_p}} + \left(\frac{T_e}{T_p}\right)^{3/2} \exp\left(\frac{-T_e/T_p}{2(1 + k^2 \lambda_D^2)} - \frac{3}{2}\right) \right]. \quad (22.44b)$$

dispersion relation for ion-acoustic waves in an unmagnetized plasma with electrons and ions thermalized at different temperatures, $T_e \gg T_p$

The real part of this dispersion relation was plotted in Fig. 21.1. As is shown there and in the above formulas, for $k\lambda_D \ll 1$ the waves' phase speed is $\sqrt{k_B T_e / m_p}$, and the waves are only weakly damped: they can propagate for roughly $\sqrt{m_p / m_e} \sim 43$ periods before damping has a strong effect. This damping is independent of the proton temperature, so it must be due to surfing electrons. When the wavelength is decreased (k is increased) into the regime $k\lambda_D \gtrsim 1$, the waves' frequency asymptotes toward $\omega_r = \omega_{pp}$, the proton plasma frequency. Then the phase velocity decreases, so more protons can surf the waves, and the Landau damping increases. Equations (22.44) show us that the damping becomes very strong when $k\lambda_D \sim \sqrt{T_e / T_p}$, and that this is also the point at which ω_r / k has decreased to the proton thermal velocity $\sqrt{k_B T_p / m_p}$ —which is in accord with our physical arguments about proton surfing.

When T_e/T_p is decreased from $\gg 1$ toward unity, the ion damping becomes strong regardless of how small may be k [cf. the second term of Eq. (22.44b)]. This is also in accord with our physical reasoning.

Ion-acoustic waves are readily excited at Earth's bow shock, where Earth's magnetosphere impacts the solar wind. It is observed that these waves are not able to propagate very far away from the shock, by contrast with Alfvén waves, which are much less rapidly damped.

EXERCISES

Exercise 22.6 *Derivation: Ion-Acoustic Dispersion Relation*

Consider a plasma in which the electrons have a Maxwellian velocity distribution with temperature T_e , the protons are Maxwellian with temperature T_p , and $T_p \ll T_e$. Consider an ion acoustic mode in this plasma for which $\sqrt{k_B T_p/m_p} \ll \omega_r/k \ll \sqrt{k_B T_e/m_e}$ (i.e., the wave's phase velocity is between the left and right tick marks in Fig. 22.3). As was argued in the text, for such a mode it is reasonable to expect weak damping: $|\omega_i| \ll \omega_r$. Making approximations based on these " \ll " inequalities, show that the small- $|\omega_i|$ dispersion relation (22.40) reduces to Eqs. (22.44).

Exercise 22.7 *Problem: Dispersion Relations for a Non-Maxwellian Distribution Function*

Consider a plasma with cold protons and hot electrons with a 1-dimensional distribution function proportional to $1/(v_0^2 + v^2)$, so the full 1-dimensional distribution function is

$$F(v) = \frac{nv_0}{\pi(v_0^2 + v^2)} + n \frac{m_e}{m_p} \delta(v). \quad (22.45)$$

- (a) Show that the dispersion relation for Langmuir waves, with phase speeds large compared to v_0 , is

$$\omega \simeq \omega_{pe} - ikv_0. \quad (22.46)$$

- (b) Compute the dispersion relation for ion-acoustic waves, assuming that their phase speeds are much less than v_0 but are large compared to the cold protons' thermal velocities (so the contribution from proton surfing can be ignored). Your result should be

$$\omega \simeq \frac{kv_0(m_e/m_p)^{1/2}}{[1 + (kv_0/\omega_{pe})^2]^{1/2}} - \frac{ikv_0(m_e/m_p)}{[1 + (kv_0/\omega_{pe})^2]^2}. \quad (22.47)$$

22.4

22.4 Stability of Electrostatic Waves in Unmagnetized Plasmas

Our small- ω_i dispersion relation (22.40) implies that the sign of F' at resonance dictates the sign of the imaginary part of ω . This raises the interesting possibility that

distribution functions that increase with velocity over some range of positive v might be unstable to the exponential growth of electrostatic waves. In fact, the criterion for instability turns out to be a little more complex than this [as one might suspect from the fact that the sign of the denominator of Eq. (22.40b) is not obvious], and deriving it is an elegant exercise in complex-variable theory.

We carry out our derivation in two steps. We first introduce a general method, due to Harry Nyquist, for diagnosing instabilities of dynamical systems. Then we apply Nyquist's method explicitly to electrostatic waves in an unmagnetized plasma and thereby deduce an instability criterion due to Oliver Penrose.

22.4.1 Nyquist's Method

22.4.1

Consider any dynamical system whose modes of oscillation have complex eigenfrequencies ω that are zeros of some function $\mathcal{D}(\omega)$. [In our case the dynamical system is electrostatic waves in an unmagnetized plasma with some chosen wave number k , and because the waves' dispersion relation is $\epsilon(\omega, k) = 0$, Eq. (22.33), the function \mathcal{D} can be chosen as $\mathcal{D}(\omega) = \epsilon(\omega, k)$.] Unstable modes are zeros of $\mathcal{D}(\omega)$ that lie in the upper half of the complex- ω plane.

Assume that $\mathcal{D}(\omega)$ is analytic in the upper half of the ω plane. Then a well-known theorem in complex-variable theory³ says that the number N_z of zeros of $\mathcal{D}(\omega)$ in the upper half-plane, minus the number N_p of poles, is equal to the number of times that $\mathcal{D}(\omega)$ encircles the origin counterclockwise, in the complex- \mathcal{D} plane, as ω travels counterclockwise along the closed path \mathcal{C} that encloses the upper half of the frequency plane; see Fig. 22.4.

If one knows the number of poles of $\mathcal{D}(\omega)$ in the upper half of the frequency plane, then one can infer, from the Nyquist diagram, the number of unstable modes of the dynamical system.

In Sec. 22.4.2, we use this Nyquist method to derive the Penrose criterion for instability of electrostatic modes of an unmagnetized plasma. As a second example, in Box 22.2, we show how it can be used to diagnose the stability of a feedback control system.

22.4.2 Penrose's Instability Criterion

22.4.2

The straightforward way to apply Nyquist's method to electrostatic waves would be to set $\mathcal{D}(\omega) = \epsilon(\omega, k)$. However, to reach our desired instability criterion more quickly, we set $\mathcal{D} = k^2\epsilon$; then the zeros of \mathcal{D} are still the electrostatic waves' modes. From Eq. (22.33) for ϵ , we see that

$$\mathcal{D}(\omega) = k^2 - Z(\omega/k), \quad (22.48a)$$

3. This is variously called "the principle of the argument" or "Cauchy's theorem," and it follows from the theorem of residues (e.g., Copson, 1935, Sec. 6.2; Arfken, Weber, and Harris, 2013, Chap. 11).

Nyquist diagram and method for deducing the number of unstable modes of a dynamical system

FIGURE 22.4 Nyquist diagram for stability of a dynamical system. (a) The curve \mathcal{C} in the complex- ω plane extends along the real frequency axis from $\omega_r = -\infty$ to $\omega_r = +\infty$, then closes up along the semicircle at $|\omega| = \infty$, so it encloses the upper half of the frequency plane. (b) As ω travels along \mathcal{C} , $\mathcal{D}(\omega)$ travels along the closed curve \mathcal{C}' in the complex- \mathcal{D} plane, which counterclockwise encircles the origin twice. Thus the number of zeros of the analytic function $\mathcal{D}(\omega)$ in the upper half of the frequency plane minus the number of poles is $N_z - N_p = 2$.

where

$$Z(\zeta) \equiv \frac{e^2}{m_e \epsilon_0} \int_{\mathcal{L}} \frac{F'}{v - \zeta} dv, \quad (22.48b)$$

with $\zeta = \omega/k$ the waves' phase velocity.

These equations have several important consequences.

1. For ζ in the upper half-plane—the region that concerns us—we can choose the Landau contour \mathcal{L} to travel along the real v -axis from $-\infty$ to $+\infty$, and the resulting $\mathcal{D}(\omega)$ is analytic in the upper half of the frequency plane, as required for Nyquist's method.
2. For all ζ in the upper half-plane, and for all distribution functions $F(v)$ that are nonnegative and normalizable and thus physically acceptable, the velocity integral is finite, so there are no poles of $\mathcal{D}(\omega)$ in the upper half-plane. Thus there is an unstable mode, for fixed k , if and only if $\mathcal{D}(\omega)$ encircles the origin at least once, as ω travels around the curve \mathcal{C} of Fig. 22.4. Note that the encircling is guaranteed to be counterclockwise, since there are no poles.
3. The wave frequency ω traveling along the curve \mathcal{C} in the complex-frequency plane is equivalent to ζ traveling along the same curve in the complex-phase-velocity plane; and \mathcal{D} encircling the origin of the complex- \mathcal{D} plane is equivalent to $Z(\zeta)$ encircling the point $Z = k^2$ on the positive real axis of the complex- Z plane.
4. For every point on the semicircular segment of the curve \mathcal{C} at $|\zeta| \rightarrow \infty$ (Fig. 22.4), $Z(\zeta)$ vanishes, so the curve \mathcal{C} can be regarded as going just along the real axis from $-\infty$ to $+\infty$, during which $Z(\zeta)$ emerges from the origin, travels around some curve, and returns to the origin.

**BOX 22.2. STABILITY OF A FEEDBACK-CONTROL SYSTEM:
ANALYSIS BY NYQUIST'S METHOD** T2

A control system can be described quite generally by the following block diagram.

An input signal $u_i(t)$ and the feedback signal $u_f(t)$ are added, then fed through a filter G to produce an output signal $u_o(t) = \int_{-\infty}^{+\infty} G(t-t')u(t')dt'$; or, in the Fourier domain, $\tilde{u}_o(\omega) = \tilde{G}(\omega)\tilde{u}(\omega)$. [See Sec. 6.7 for filtering of signals. Here, for consistency with this plasma-physics chapter, we adopt the opposite sign convention for Fourier transforms from that in Sec. 6.7.] Then the output signal is fed through a filter H to produce the feedback signal $u_f(t)$.

As an example, consider the following simple model for an automobile's cruise control. The automobile's speed v is to be locked to some chosen value V by measuring v and applying a suitable feedback acceleration. To simplify the analysis, we focus on the difference $u \equiv v - V$, which is to be locked to zero. The input to the control system is the speed $u_i(t)$ that the automobile would have in the absence of feedback, plus the speed change $u_f(t)$ due to the feedback acceleration. Their sum, $u = u_i + u_f$, is measured by averaging over a short time interval, with the average exponentially weighted toward the present (in our simple model), so the output of the measurement is $u_o(t) = (1/\tau) \int_{-\infty}^t e^{(t-t')/\tau} u(t')dt'$. By comparing with $u_o = \int_{-\infty}^{+\infty} G(t-t')u(t')dt'$ to infer the measurement filter's kernel $G(t)$, then Fourier transforming, we find that $\tilde{G}(\omega) \equiv \int_{-\infty}^{+\infty} G(t)e^{i\omega t} dt = 1/(1 - i\omega\tau)$. If $u_o(t)$ is positive, we apply to the automobile a negative feedback acceleration $a_f(t)$ proportional to it; if u_o is negative, we apply a positive feedback acceleration; so in either case, $a_f = -Ku_o$ for some positive constant K . The feedback speed u_f is the time integral of this acceleration: $u_f(t) = -K \int_{-\infty}^t u_o(t')dt'$. Setting this to $\int_{-\infty}^{\infty} H(t-t')u_o(t')dt'$, reading off the kernel H , and computing its Fourier transform, we find $\tilde{H}(\omega) = -K/(i\omega)$.

From the block diagram, we see, fully generally, that in the Fourier domain $\tilde{u}_o = \tilde{G}(\tilde{u}_i + \tilde{u}_f) = \tilde{G}(\tilde{u}_i + \tilde{H}\tilde{u}_o)$; so the output in terms of the input is

$$\tilde{u}_o = \frac{\tilde{G}}{1 + \tilde{G}\tilde{H}}\tilde{u}_i. \quad (1)$$

(continued)

BOX 22.2. (continued)

Evidently, the feedback system will undergo self-excited oscillations, with no input, at any complex frequency ω that is a zero of $\mathcal{D}(\omega) \equiv 1 + \tilde{G}(\omega)\tilde{H}(\omega)$. If that ω is in the lower half of the complex frequency plane, the oscillations will die out and so are not a problem; but if it is in the upper half-plane, they will grow exponentially with time. Thus the zeros of $\mathcal{D}(\omega)$ in the upper half of the ω plane represent unstable modes of self-excitation and must be avoided in the design of any feedback-control system.

For our cruise-control example, \mathcal{D} is $1 + \tilde{G}\tilde{H} = 1 - K[i\omega(1 - i\omega\tau)]^{-1}$, which can be brought into a more convenient form by introducing the dimensionless frequency $z = \omega\tau$ and dimensionless feedback strength $\kappa = K\tau$: $\mathcal{D} = 1 - \kappa[iz(1 - iz)]^{-1}$. The Nyquist diagram for this \mathcal{D} has the following form.

As $z = \omega\tau$ travels around the upper half of the frequency plane (curve \mathcal{C} in Fig. 22.4a), \mathcal{D} travels along the left curve (for feedback strength $\kappa = 0.2$), or the right curve (for $\kappa = 2$) in the above diagram. These curves do not encircle the origin at all—nor does the curve for any other $\kappa > 0$, so the number of zeros minus the number of poles in the upper half-plane is $N_z - N_p = 0$. Moreover, $\mathcal{D} = 1 - \kappa[iz(1 - iz)]^{-1}$ has no poles in the upper half-plane, so $N_p = 0$ and $N_z = 0$: our cruise-control feedback system is stable. For further details, see Ex. 22.10.

When designing control systems, it is important to have a significant margin of protection against instability. As an example, consider a control system for which $\tilde{G}\tilde{H} = -\kappa(1 + iz)[iz(1 - iz)]^{-1}$ (Ex. 22.11). The Nyquist diagrams take the common form shown here.

(continued)

There are no poles in the upper half-plane; and for $\kappa > 1$ (drawing a) the origin is encircled twice, while for $\kappa < 1$ it is not encircled at all (drawing b). Therefore, the control system is unstable for $\kappa > 1$ and stable for $\kappa < 1$. One often wants to push κ as high as possible to achieve one's stabilization goals but must maintain a margin of safety against instability. That margin is quantified by either or both of two quantities: (i) The *phase margin* (labeled PM in diagram c): the amount by which the phase of $\tilde{G}\tilde{H} = \mathcal{D} - 1$ exceeds 180° at the unity gain point, $|\tilde{G}\tilde{H}| = 1$ (red curve). (ii) The *gain margin* GM: the amount by which the gain $|\tilde{G}\tilde{H}|$ is less than 1 when the phase of $\tilde{G}\tilde{H}$ reaches 180° . As κ is increased toward the onset of instability, $\kappa = 1$, both PM and GM approach zero.

For the theory of control systems, see, for example, Franklin, Powell, and Emami-Naeini (2005); Dorf and Bishop (2012).

In view of these facts, Nyquist's method tells us the following: *there will be an unstable mode, for one or more values of k , if and only if, as ζ travels from $-\infty$ to $+\infty$, $Z(\zeta)$ encloses one or more points on the positive real Z -axis. In addition, the wave numbers for any resulting unstable modes are $k = \pm\sqrt{Z}$, for all Z on the positive real axis that are enclosed.*

In Fig. 22.5, we show three examples of $Z(\zeta)$ curves. For Fig. 22.5a, no points on the positive real axis are enclosed, so all electrostatic modes are stable for all wave numbers k . For Fig. 22.5b,c, a segment of the positive real axis is enclosed, so there are unstable modes; those unstable modes have $k = \pm\sqrt{Z}$ for all Z on the enclosed line segment.

Notice that in Fig. 22.5a,b, the rightmost crossing of the real axis is at positive Z , and the curve C' moves upward as it crosses. A little thought reveals that this must

Nyquist's method for diagnosing unstable electrostatic modes in an unmagnetized plasma

FIGURE 22.5 Nyquist diagrams for electrostatic waves. As a mode's real phase velocity ζ increases from $-\infty$ to $+\infty$, $Z(\zeta)$ travels, in the complex- Z plane, around the closed curve C' , which always begins and ends at the origin. (a) The curve C' encloses no points on the positive real axis, so there are no unstable electrostatic modes. (b,c) The curve does enclose a set of points on the positive real axis, so there are unstable modes.

always be the case: $Z(\zeta)$ will encircle, counterclockwise, points on the positive- Z axis if and only if it somewhere crosses the positive- Z axis traveling upward.

alternative Nyquist
criterion for instability

Therefore, *an unstable electrostatic mode exists in an unmagnetized plasma if and only if, as ζ travels along its real axis from $-\infty$ to $+\infty$, $Z(\zeta)$ crosses some point \mathcal{P} on its positive real axis, traveling upward*. This version of the Nyquist criterion enables us to focus on the small- ω_i domain (while still treating the general case)—for which $\epsilon(\zeta, k)$ is given by Eq. (22.39). From that expression and real ζ (our case), we infer that $Z(\zeta) = k^2[1 - \epsilon]$ is given by

$$Z(\zeta) = \frac{e^2}{m_e \epsilon_0} \left[\int_{\mathcal{P}} \frac{F' dv}{v - \zeta} + i\pi F'(\zeta) \right], \quad (22.49a)$$

where \mathcal{P} means the Cauchy principal value of the integral. This means that $Z(\zeta)$ crosses its real axis at any ζ where $F'(\zeta) = 0$, and it crosses moving upward if and only if $F''(\zeta) > 0$ at that crossing point. These two conditions together say that, at the crossing point \mathcal{P} , $\zeta = v_{\min}$, a particle speed at which $F(v)$ has a minimum. Moreover, Eq. (22.49a) says that $Z(\zeta)$ crosses its positive real axes (rather than negative) if and only if $\int_{\mathcal{P}} [F'/(v - v_{\min})] dv > 0$. We can evaluate this integral using an integration by parts:

$$\begin{aligned} \int_{\mathcal{P}} \frac{F'}{v - v_{\min}} dv &= \int_{\mathcal{P}} \frac{d[F(v) - F(v_{\min})]/dv}{v - v_{\min}} dv \\ &= \int_{\mathcal{P}} \frac{[F(v) - F(v_{\min})]}{(v - v_{\min})^2} dv + \lim_{\delta \rightarrow 0} \left[\frac{F(v_{\min} - \delta) - F(v_{\min})}{-\delta} \right. \\ &\quad \left. - \frac{F(v_{\min} + \delta) - F(v_{\min})}{\delta} \right]. \end{aligned} \quad (22.49b)$$

The $\lim_{\delta \rightarrow 0}$ terms inside the square bracket vanish since $F'(v_{\min}) = 0$, and in the first $\int_{\mathcal{P}}$ term we do not need the Cauchy principal value, because F is a minimum at v_{\min} . Therefore, our requirement is that

$$\int_{-\infty}^{+\infty} \frac{[F(v) - F(v_{\min})]}{(v - v_{\min})^2} dv > 0. \quad (22.50)$$

Thus, a necessary and sufficient condition for an unstable mode is that there exist some velocity v_{\min} at which the distribution function $F(v)$ has a minimum, and that in addition the minimum be deep enough that the integral (22.50) is positive. This is called the Penrose criterion for instability (Penrose, 1960).

For a more in-depth, pedagogical derivation and discussion of the Penrose criterion, see, for example, Krall and Trivelpiece (1973, Sec. 9.6).

Penrose's criterion for instability of an electrostatic wave in an unmagnetized plasma

Exercise 22.8 Example: Penrose Criterion

Consider an unmagnetized electron plasma with a 1-dimensional distribution function:

$$F(v) \propto [(v - v_0)^2 + u^2]^{-1} + [(v + v_0)^2 + u^2]^{-1}, \quad (22.51)$$

where v_0 and u are constants. Show that this distribution function possesses a minimum if $v_0 > 3^{-1/2}u$, but the minimum is not deep enough to cause instability unless $v_0 > u$.

Exercise 22.9 Problem: Range of Unstable Wave Numbers

Consider a plasma with a distribution function $F(v)$ that has precisely two peaks, at $v = v_1$ and $v = v_2$ [with $F(v_2) \geq F(v_1)$], and a minimum between them at $v = v_{\min}$, and assume that the minimum is deep enough to satisfy the Penrose criterion for instability [Eq. (22.50)]. Show that there will be at least one unstable mode for every wave number k in the range $k_{\min} < k < k_{\max}$, where

$$k_{\min}^2 = \frac{e^2}{\epsilon_0 m_e} \int_{-\infty}^{+\infty} \frac{F(v) - F(v_1)}{(v - v_1)^2} dv, \quad k_{\max}^2 = \frac{e^2}{\epsilon_0 m_e} \int_{-\infty}^{+\infty} \frac{F(v) - F(v_{\min})}{(v - v_{\min})^2} dv. \quad (22.52)$$

Show, further, that the marginally unstable mode at $k = k_{\max}$ has phase velocity $\omega/k = v_{\min}$, and the marginally unstable mode at $k = k_{\min}$ has $\omega/k = v_1$. [Hint: Use a Nyquist diagram like those in Fig. 22.5.]

Exercise 22.10 Example and Derivation: Cruise-Control System T2

- Show that the cruise-control feedback system described at the beginning of Box 22.2 has $\tilde{G}(z) = 1/(1 - iz)$ and $\tilde{H} = -\kappa/(iz)$, with $z = \omega\tau$ and $\kappa = K\tau$, as claimed.
- Show that the Nyquist diagram has the forms shown in the second figure in Box 22.2, and that this control system is stable for all feedback strengths $\kappa > 0$.
- Solve explicitly for the zeros of $\mathcal{D} = 1 + \tilde{G}(z)\tilde{H}(z)$, and verify that none are in the upper half of the frequency plane.

EXERCISES

- (d) To understand the stability from a different viewpoint, imagine that the automobile's speed v is oscillating with an amplitude δv and a real frequency ω around the desired speed V , $v = V + \delta v \sin(\omega t)$, and that the feedback is turned off. Show that the output of the control system is $u_o = [\delta v / \sqrt{1 + \omega^2 \tau^2}] \sin(\omega t - \Delta\varphi)$, with a phase delay $\Delta\varphi = \arctan(\omega\tau)$ relative to the oscillations of v . Now turn on the feedback, but at a low strength, so it only weakly changes the speed's oscillations in one period. Show that, because $\Delta\varphi < \pi/2$, $d(\delta v^2)/dt$ is negative, so the feedback damps the oscillations. Show that an instability would arise if the phase delay were in the range $\pi/2 < |\Delta\varphi| < 3\pi/2$. For high-frequency oscillations, $\omega\tau \gg 1$, $\Delta\varphi$ approaches $\pi/2$, so the cruise-control system is only marginally stable.

Exercise 22.11 *Derivation: Phase Margin and Gain Margin for a Feedback-Control System* T2

Consider the control system discussed in the last two long paragraphs of Box 22.2. It has $\tilde{G}\tilde{H} = -\kappa(1 + iz)[iz(1 - iz)]^{-1}$, with $z = \omega\tau$ a dimensionless frequency and τ some time constant.

- (a) Show that there are no poles of $\mathcal{D} = 1 + \tilde{G}\tilde{H}$ in the upper half of the complex frequency plane (z plane).
- (b) Construct the Nyquist diagram for various feedback strengths κ . Show that for $\kappa > 1$ the curve encircles the origin twice (diagram a in the third figure in Box 22.2), so the control system is unstable, while for $\kappa < 1$, it does not encircle the origin (diagram b in the same figure), so the control system is stable.
- (c) Show that the phase margin and gain margin, defined in diagram c in the third figure in Box 22.2, approach zero as κ increases toward the instability point, $\kappa = 1$.
- (d) Compute explicitly the zeros of $\mathcal{D} = 1 + \tilde{G}\tilde{H}$, and plot their trajectories in the complex frequency plane as κ increases from zero through one to ∞ . Verify that two zeros enter the upper half of the frequency plane as κ increases through one, and they remain in the upper half-plane for all $\kappa > 1$, as is guaranteed by the Nyquist diagrams.

22.5 Particle Trapping

We now return to the description of Landau damping. Our treatment so far has been essentially linear in the wave amplitude (or equivalently, in the perturbation to the distribution function). What happens when the wave amplitude is not infinitesimally small?

Consider a single Langmuir wave mode as observed in a frame moving with the mode's phase velocity and, for the moment, ignore its growth or damping. Then in this frame the electrostatic field oscillates spatially, $E = E_0 \sin kz$, but has no time

FIGURE 22.6 Phase-space orbits for trapped (dashed lines) and untrapped (solid lines) electrons.

dependence. Figure 22.6 shows some phase-space orbits of electrons in this oscillatory potential. The solid curves are orbits of particles that move fast enough to avoid being trapped in the potential wells at $kz = 0, 2\pi, 4\pi, \dots$. The dashed curves are orbits of trapped particles. As seen in another frame, these trapped particles are surfing on the wave, with their velocities performing low-amplitude oscillations around the wave's phase velocity ω/k .

The equation of motion for an electron trapped in the minimum $z = 0$ has the form

$$\begin{aligned} \ddot{z} &= \frac{-eE_0 \sin kz}{m_e} \\ &\simeq -\omega_b^2 z, \end{aligned} \quad (22.53)$$

where we have assumed small-amplitude oscillations and approximated $\sin kz \simeq kz$, and where

$$\omega_b = \left(\frac{eE_0 k}{m_e} \right)^{1/2} \quad (22.54)$$

is known as the *bounce frequency*. Since the potential well is actually anharmonic, the trapped particles will mix in phase quite rapidly.

The growth or damping of the wave is characterized by a growth or damping of E_0 , and correspondingly by a net acceleration or deceleration of untrapped particles, when averaged over a wave cycle. It is this net feeding of energy into and out of the untrapped particles that causes the wave's Landau damping or growth.

Now suppose that the amplitude E_0 of this particular wave mode is changing on a time scale τ due to interactions with the electrons, or possibly (as we shall see in Chap. 23) due to interactions with other waves propagating through the plasma. The potential well then changes on this same timescale, and we expect that τ is also a measure of the maximum length of time a particle can be trapped in the potential well. Evidently, nonlinear wave-trapping effects should only be important when the bounce period $\sim \omega_b^{-1}$ is short compared with τ , that is, when $E_0 \gg m_e/(ek\tau^2)$.

trapped and untrapped electrons in a Langmuir wave

Landau damping associated with accelerating or decelerating untrapped particles

radiation from bunched, trapped electrons: example of a nonlinear plasma effect

Electron trapping can cause particles to be bunched together at certain preferred phases of a growing wave. This can have important consequences for the radiative properties of the plasma. Suppose, for example, that the plasma is magnetized. Then the electrons gyrate around the magnetic field and emit cyclotron radiation. If their gyrational phases are random, then the total power that they radiate will be the sum of their individual particle powers. However, if N electrons are localized at the same gyrational phase due to being trapped in a potential well of a wave, then they will radiate like one giant electron with a charge $-Ne$. As the radiated power is proportional to the square of the charge carried by the radiating particle, the total power radiated by the bunched electrons will be N times the power radiated by the same number of unbunched electrons. Very large amplification factors are thereby possible both in the laboratory and in Nature, for example, in the Jovian magnetosphere.

This brief discussion suggests that there may be much more richness in plasma waves than is embodied in our dispersion relations with their simple linear growth and decay, even when the wave amplitude is small enough that the particle motion is only slightly perturbed by its interaction with the wave. This motivates us to discuss more systematically nonlinear plasma physics, which is the topic of our next chapter.

EXERCISES

Exercise 22.12 *Challenge: BGK Waves*

Consider a steady, 1-dimensional, large-amplitude electrostatic wave in an unmagnetized, proton-electron plasma. Write down the Vlasov equation for each particle species in a frame moving with the wave [i.e., a frame in which the electrostatic potential is a time-independent function of z , $\Phi = \Phi(z)$, not necessarily precisely sinusoidal].

- (a) Use Jeans' theorem to argue that proton and electron distribution functions that are just functions of the energy,

$$F_s = F_s(W_s), \quad W_s = \frac{m_s v_s^2}{2} + q_s \Phi(z), \quad (22.55a)$$

satisfy the Vlasov equation; here $s = p, e$, and as usual $q_p = e$, $q_e = -e$. Then show that Poisson's equation for the potential Φ can be rewritten in the form

$$\frac{1}{2} \left(\frac{d\Phi}{dz} \right)^2 + V(\Phi) = \text{const}, \quad (22.55b)$$

where the potential V is $-2/\epsilon_0$ times the kinetic-energy density of the particles:

$$V = \frac{-2}{\epsilon_0} \sum_s \int \frac{1}{2} m_s v_s^2 F_s dv_s, \quad (22.55c)$$

which depends on Φ . (Yes, it is weird to construct a potential V from kinetic energy, and a "kinetic energy" term from the electrical potential Φ , but it also is very clever.)

- (b) It is possible to find many electrostatic potential profiles $\Phi(z)$ and distribution functions $F_s[W_s(v, \Phi)]$ that satisfy Eqs. (22.55). These are called BGK waves after

FIGURE 22.7 BGK waves as analyzed in Ex. 22.12. Two quantities are plotted upward: $e\Phi$, where $\Phi(z)$ is the 1-dimensional electrostatic potential, and W_p , the proton total energy. Values $e\Phi_0$ and $-e\Phi_0$ of $e\Phi$, and W_+ of W_p are marked on the vertical axis. The electron total energy W_e is plotted downward, and its value W_- is marked on the axis. The shaded region shows the range of bound electron energies as a function of location z ; the solid line W_+ and dashed line W_- are the energies of the unbound protons and electrons.

Bernstein, Greene, and Kruskal (1957), who first analyzed them. Explain how, in principle, one can solve for (nonunique) BGK distribution functions F_s in a large-amplitude wave of given electrostatic potential profile $\Phi(z)$.

- (c) Carry out this procedure, assuming that the potential profile is of the form $\Phi(z) = \Phi_0 \cos kz$, with $\Phi_0 > 0$. Assume also that the protons are monoenergetic, with $W_p = W_+ > e\Phi_0$, and move along the positive z direction. In addition, assume that there are both monoenergetic (with $W_e = W_- > -e\Phi_0$), untrapped electrons (also moving along the positive z direction), and trapped electrons with distribution $F_e(W_e)$, $-e\Phi_0 \leq W_e < e\Phi_0$; see Fig. 22.7. Show that the density of trapped electrons must vanish at the wave troughs [at $z = (2n + 1)\pi/k$; $n = 0, 1, 2, 3, \dots$]. Let the proton density at the troughs be n_{p0} , and assume that there is no net current. Show that the total electron density can then be written as

$$n_e(z) = \left[\frac{m_e(W_+ + e\Phi_0)}{m_p(W_- + e\Phi)} \right]^{1/2} n_{p0} + \int_{-e\Phi}^{e\Phi_0} \frac{dW_e F_e(W_e)}{[2m_e(W_e + e\Phi)]^{1/2}}. \quad (22.56)$$

- (d) Use Poisson's equation to show that

$$\int_{-e\Phi}^{e\Phi_0} \frac{dW_e F_e(W_e)}{[2m_e(W_e + e\Phi)]^{1/2}} = -\frac{\epsilon_0 k^2 \Phi}{e} + n_{p0} \left[\left(\frac{W_+ + e\Phi_0}{W_+ - e\Phi} \right)^{1/2} - \left(\frac{m_e(W_+ + e\Phi_0)}{m_p(W_- + e\Phi)} \right)^{1/2} \right]. \quad (22.57)$$

- (e) Solve the integral equation in part (d) for $F_e(W_e)$. [Hint: It is of Abel type.]
(f) Exhibit some solutions of Eq. (22.57) graphically.

particle correlations are missed by the Vlasov formalism

Before turning to nonlinear phenomena in plasmas (the next chapter), let us digress briefly and explore ways to study correlations among particles, of which our Vlasov formalism is oblivious.

The Vlasov formalism treats each particle as independent, migrating through phase space in response to the local mean electromagnetic field and somehow unaffected by individual electrostatic interactions with neighboring particles. As we discussed in Chap. 20, this approximation is likely to be good in a collisionless plasma because of the influence of Debye screening—except in the tiny “independent-particle” region of Fig. 20.1. However, we would like to have some means of quantifying this and of deriving an improved formalism that takes into account the correlations among individual particles.

One environment where this formalism may be relevant is the interior of the Sun. Here, although the gas is fully ionized, the Debye number is not particularly large (i.e., one is near the independent-particle region of Fig. 20.1). As a result, Coulomb corrections to the perfect-gas equation of state may be responsible for measurable changes in the Sun’s internal structure, as deduced, for example, using helioseismological analysis (cf. Sec. 16.2.4). In this application our task is simpler than in the general case, because the gas will locally be in thermodynamic equilibrium at some temperature T . It turns out that the general case, where the plasma departs significantly from thermal equilibrium, is extremely hard to treat.

k-particle distribution functions

The one-particle distribution function that we use in the Vlasov formalism is the first member of a hierarchy of *k*-particle distribution functions: $f^{(k)}(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k, \mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k, t)$. For example, $f^{(2)}(\mathbf{x}_1, \mathbf{x}_2, \mathbf{v}_1, \mathbf{v}_2, t) d\mathbf{x}_1 d\mathbf{v}_1 d\mathbf{x}_2 d\mathbf{v}_2 \equiv$ [the probability of finding a particle (any particle) in a volume $d\mathbf{x}_1 d\mathbf{v}_1 \equiv dx_1 dy_1 dz_1 dv_{x_1} dv_{y_1} dv_{z_1}$ of phase space, and another particle (any particle) in volume $d\mathbf{x}_2 d\mathbf{v}_2$ of phase space].⁴ This definition and its obvious generalization dictate the normalization

$$\int f^{(k)} d\mathbf{x}_1 d\mathbf{v}_1 \cdots d\mathbf{x}_k d\mathbf{v}_k = N^k, \quad (22.58)$$

where $N \gg k \geq 1$ is the total number of particles.

N-particle distribution function f_{all} in *N*-particle plasma

It is useful to relate the distribution functions $f^{(k)}$ to the concepts of statistical mechanics, which we developed in Chap. 4. Suppose we have an ensemble of *N*-electron plasmas, and let the probability that a member of this ensemble is in a volume $d^N \mathbf{x} d^N \mathbf{v}$ of the $6N$ -dimensional phase space of all its particles be $f_{\text{all}} d^N \mathbf{x} d^N \mathbf{v}$ (N is

4. In this section—and only in this section—we adopt the volume notation commonly used in this multi-particle subject: we use $d\mathbf{x}_j \equiv dx_j dy_j dz_j$ and $d\mathbf{v}_j \equiv dv_{x_j} dv_{y_j} dv_{z_j}$ to denote the volume elements for particle j . Warning: Despite the boldface notation, $d\mathbf{x}_j$ and $d\mathbf{v}_j$ are not vectors! Also, in this section we do *not* study waves, so k represents the number of particles in a distribution function, rather than a wave number.

a very large number!). Of course, f_{all} satisfies the Liouville equation

T2

$$\frac{\partial f_{\text{all}}}{\partial t} + \sum_{i=1}^N [(\mathbf{v}_i \cdot \nabla_i) f_{\text{all}} + (\mathbf{a}_i \cdot \nabla_{\mathbf{v}_i}) f_{\text{all}}] = 0, \quad (22.59)$$

Liouville equation for f_{all}

where \mathbf{a}_i is the electromagnetic acceleration of the i th particle, and ∇_i and $\nabla_{\mathbf{v}_i}$ are gradients with respect to the position and velocity of particle i , respectively. We can construct the k -particle “reduced” distribution function from the statistical-mechanics distribution function f_{all} by integrating over all but k of the particles:

$$\begin{aligned} f^{(k)}(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k, \mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k, t) \\ = N^k \int d\mathbf{x}_{k+1} \dots d\mathbf{x}_N d\mathbf{v}_{k+1} \dots d\mathbf{v}_N f_{\text{all}}(\mathbf{x}_1, \dots, \mathbf{x}_N, \mathbf{v}_1, \dots, \mathbf{v}_N). \end{aligned} \quad (22.60)$$

k -particle distribution function constructed from f_{all}

(Note that k is typically a very small number, by contrast with N ; below we shall only be concerned with $k = 1, 2, 3$.) The reason for the prefactor N^k in Eq. (22.60) is that, whereas f_{all} refers to the probability of finding particle 1 in $d\mathbf{x}_1 d\mathbf{v}_1$, particle 2 in $d\mathbf{x}_2 d\mathbf{v}_2$, and so forth, the reduced distribution function $f^{(k)}$ describes the probability of finding *any* of the N identical (though distinguishable) particles in $d\mathbf{x}_1 d\mathbf{v}_1$ and so on. (As long as we are dealing with nondegenerate plasmas we can count the electrons classically.) As $N \gg k$, the number of possible ways we can choose k particles for k locations in phase space is approximately N^k .

For simplicity, suppose that the protons are immobile and form a uniform, neutralizing background of charge, so we need only consider the electron distribution and its correlations. Let us further suppose that the forces associated with the mean electromagnetic fields produced by external charges and currents can be ignored. We can then restrict our attention to direct electron-electron electrostatic interactions. The acceleration of an electron is then

$$\mathbf{a}_i = \frac{e}{m_e} \sum_j \nabla_i \Phi_{ij}, \quad (22.61)$$

where $\Phi_{ij}(x_{ij}) = -e/(4\pi\epsilon_0 x_{ij})$ is the electrostatic potential of electron i at the location of electron j , and $x_{ij} \equiv |\mathbf{x}_i - \mathbf{x}_j|$.

22.6.1 BBGKY Hierarchy T2

22.6.1

We can now derive the so-called BBGKY hierarchy of kinetic equations (Bogolyubov, 1962; Born and Green, 1949; Kirkwood, 1946; Yvon, 1935) which relate the k -particle distribution function to integrals over the $(k + 1)$ -particle distribution function. The first equation in this hierarchy is given by integrating the Liouville equation (22.59) over $d\mathbf{x}_2 \dots d\mathbf{x}_N d\mathbf{v}_2 \dots d\mathbf{v}_N$. If we assume that the distribution function decreases

to zero at large distances, then integrals of the type $\int d\mathbf{x}_i \nabla_i f_{\text{all}}$ vanish, and the one-particle distribution function evolves according to

$$\begin{aligned} \frac{\partial f^{(1)}}{\partial t} + (\mathbf{v}_1 \cdot \nabla_1) f^{(1)} &= \frac{-eN}{m_e} \int d\mathbf{x}_2 \dots d\mathbf{x}_N d\mathbf{v}_2 \dots d\mathbf{v}_N \sum_j \nabla_1 \Phi_{1j} \cdot \nabla_{\mathbf{v}_1} f_{\text{all}} \\ &= \frac{-eN^2}{m_e} \int d\mathbf{x}_2 \dots d\mathbf{x}_N d\mathbf{v}_2 \dots d\mathbf{v}_N \nabla_1 \Phi_{12} \cdot \nabla_{\mathbf{v}_1} f_{\text{all}} \\ &= \frac{-e}{m_e} \int d\mathbf{x}_2 d\mathbf{v}_2 \left(\nabla_{\mathbf{v}_1} f^{(2)} \cdot \nabla_1 \right) \Phi_{12}, \end{aligned} \quad (22.62)$$

where, in the second line, we have replaced the probability of having any particle at a location in phase space by N times the probability of having one specific particle there. The left-hand side of Eq. (22.62) describes the evolution of independent particles, and the right-hand side takes account of their pairwise mutual correlation.

The evolution equation for $f^{(2)}$ can similarly be derived by integrating the Liouville equation (22.59) over $d\mathbf{x}_3 \dots d\mathbf{x}_N d\mathbf{v}_3 \dots d\mathbf{v}_N$:

$$\begin{aligned} \frac{\partial f^{(2)}}{\partial t} + (\mathbf{v}_1 \cdot \nabla_1) f^{(2)} + (\mathbf{v}_2 \cdot \nabla_2) f^{(2)} + \frac{e}{m_e} \left[\left(\nabla_{\mathbf{v}_1} f^{(2)} \cdot \nabla_1 \right) \Phi_{12} + \left(\nabla_{\mathbf{v}_2} f^{(2)} \cdot \nabla_2 \right) \Phi_{12} \right] \\ = \frac{-e}{m_e} \int d\mathbf{x}_3 d\mathbf{v}_3 \left[\left(\nabla_{\mathbf{v}_1} f^{(3)} \cdot \nabla_1 \right) \Phi_{13} + \left(\nabla_{\mathbf{v}_2} f^{(3)} \cdot \nabla_2 \right) \Phi_{23} \right]. \end{aligned} \quad (22.63)$$

BBGKY hierarchy of evolution equations for k -particle distribution functions, derived by integrating the Liouville equation

Generalizing and allowing for the presence of a mean electromagnetic field (in addition to the inter-electron electrostatic field) causing an acceleration $\mathbf{a}^{\text{ext}} = -(e/m_e)(\mathbf{E} + \mathbf{v} \times \mathbf{B})$, we obtain the BBGKY hierarchy of kinetic equations:

$$\begin{aligned} \frac{\partial f^{(k)}}{\partial t} + \sum_{i=1}^k \left[(\mathbf{v}_i \cdot \nabla_i) f^{(k)} + (\mathbf{a}_i^{\text{ext}} \cdot \nabla_{\mathbf{v}_i}) f^{(k)} + \frac{e}{m_e} (\nabla_{\mathbf{v}_i} f^{(k)} \cdot \nabla_i) \sum_{j \neq i}^k \Phi_{ij} \right] \\ = \frac{-e}{m_e} \int d\mathbf{x}_{k+1} d\mathbf{v}_{k+1} \sum_{i=1}^k \left(\nabla_{\mathbf{v}_i} f^{(k+1)} \cdot \nabla_i \right) \Phi_{ik+1}. \end{aligned} \quad (22.64)$$

This k th equation in the hierarchy shows explicitly how we require knowledge of the $(k+1)$ -particle distribution function to determine the evolution of the k -particle distribution function.

22.6.2

22.6.2 Two-Point Correlation Function T2

It is convenient to define the *two-point correlation function*, $\xi_{12}(\mathbf{x}_1, \mathbf{v}_1, \mathbf{x}_2, \mathbf{v}_2, t)$ for particles 1 and 2, by

$$f^{(2)}(\mathbf{x}_1, \mathbf{v}_1, \mathbf{x}_2, \mathbf{v}_2, t) = f_1 f_2 (1 + \xi_{12}), \quad (22.65)$$

where we introduce the notation $f_1 = f^{(1)}(\mathbf{x}_1, \mathbf{v}_1, t)$, and $f_2 = f^{(1)}(\mathbf{x}_2, \mathbf{v}_2, t)$. For the analysis that follows to be accurate, we require $|\xi_{12}| \ll 1$. We restrict attention to a plasma in thermal equilibrium at temperature T . In this case, f_1 and f_2 are

two-point correlation function

Maxwellian distribution functions, independent of \mathbf{x} and t . Now, let us make an ansatz, namely, that ξ_{12} is just a function of the electrostatic interaction energy between the two electrons, and therefore it does not involve the electron velocities. (It is, actually, possible to justify this directly for an equilibrium distribution of particles interacting electrostatically, but we make do with showing that our final answer for ξ_{12} is just a function of $x_{12} = |\mathbf{x}_1 - \mathbf{x}_2|$, in accord with our ansatz.) As Debye screening should be effective at large distances, we anticipate that $\xi_{12} \rightarrow 0$ as $x_{12} \rightarrow \infty$.

Now turn to Eq. (22.62), and introduce the simplest imaginable closure relation: $\xi_{12} = 0$. In other words, completely ignore all correlations. We can then replace $f^{(2)}$ by $f_1 f_2$ and perform the integral over \mathbf{x}_2 and \mathbf{v}_2 to recover the collisionless Vlasov equation (22.6). Therefore, we see explicitly that particle-particle correlations are indeed ignored in the simple Vlasov approach.

For the three-particle distribution function, we expect that, when electron 1 is distant from both electrons 2 and 3, then $f^{(3)} \sim f_1 f_2 f_3 (1 + \xi_{23})$, and so forth. Summing over all three pairs, we write:

$$f^{(3)} = f_1 f_2 f_3 (1 + \xi_{23} + \xi_{31} + \xi_{12} + \chi_{123}), \quad (22.66)$$

where χ_{123} is the *three-point correlation function* that ought to be significant when all three particles are close together. The function χ_{123} is, of course, determined by the next equation in the BBGKY hierarchy.

We next make the closure relation $\chi_{123} = 0$, that is to say, we ignore the influence of third bodies on pair interactions. This is plausible because close, three-body encounters are even less frequent than close two-body encounters. We can now derive an equation for ξ_{12} by seeking a steady-state solution to Eq. (22.63), that is, a solution with $\partial f^{(2)}/\partial t = 0$. We substitute Eqs. (22.65) and (22.66) into Eq. (22.63) (with $\chi_{123} = 0$) to obtain

$$\begin{aligned} f_1 f_2 \left[(\mathbf{v}_1 \cdot \nabla_1) \xi_{12} + (\mathbf{v}_2 \cdot \nabla_2) \xi_{12} - \frac{e(1 + \xi_{12})}{k_B T} \{ (\mathbf{v}_1 \cdot \nabla_1) \Phi_{12} + (\mathbf{v}_2 \cdot \nabla_2) \Phi_{12} \} \right] \\ = \frac{e f_1 f_2}{k_B T} \int d\mathbf{x}_3 d\mathbf{v}_3 f_3 (1 + \xi_{23} + \xi_{31} + \xi_{12}) [(\mathbf{v}_1 \cdot \nabla_1) \Phi_{13} + (\mathbf{v}_2 \cdot \nabla_2) \Phi_{23}], \end{aligned} \quad (22.67)$$

where we have used the relation

$$\nabla_{\mathbf{v}_1} f_1 = -\frac{m_e \mathbf{v}_1 f_1}{k_B T}, \quad (22.68)$$

valid for an unperturbed Maxwellian distribution function. We can rewrite this equation using the relations

$$\nabla_1 \Phi_{12} = -\nabla_2 \Phi_{12}, \quad \nabla_1 \xi_{12} = -\nabla_2 \xi_{12}, \quad \xi_{12} \ll 1, \quad \int d\mathbf{v}_3 f_3 = n, \quad (22.69)$$

three-particle distribution function and three-point correlation function

closure relation for computing two-point correlation function

to obtain

$$\begin{aligned} & (\mathbf{v}_1 - \mathbf{v}_2) \cdot \nabla_1 \left(\xi_{12} - \frac{e\Phi_{12}}{k_B T} \right) \\ &= \frac{ne}{k_B T} \int d\mathbf{x}_3 (1 + \xi_{23} + \xi_{31} + \xi_{12}) [(\mathbf{v}_1 \cdot \nabla_1)\Phi_{13} + (\mathbf{v}_2 \cdot \nabla_2)\Phi_{23}]. \end{aligned} \quad (22.70)$$

Now, symmetry considerations tell us that

$$\int d\mathbf{x}_3 (1 + \xi_{31}) \nabla_1 \Phi_{13} = 0, \quad \int d\mathbf{x}_3 (1 + \xi_{23}) \nabla_2 \Phi_{23} = 0, \quad (22.71)$$

and, in addition,

$$\begin{aligned} \int d\mathbf{x}_3 \xi_{12} \nabla_1 \Phi_{13} &= -\xi_{12} \int d\mathbf{x}_3 \nabla_3 \Phi_{13} = 0, \\ \int d\mathbf{x}_3 \xi_{12} \nabla_2 \Phi_{23} &= -\xi_{12} \int d\mathbf{x}_3 \nabla_3 \Phi_{23} = 0. \end{aligned} \quad (22.72)$$

Therefore, we end up with

$$(\mathbf{v}_1 - \mathbf{v}_2) \cdot \nabla_1 \left(\xi_{12} - \frac{e\Phi_{12}}{k_B T} \right) = \frac{ne}{k_B T} \int d\mathbf{x}_3 [\xi_{23} (\mathbf{v}_1 \cdot \nabla_1)\Phi_{13} + \xi_{31} (\mathbf{v}_2 \cdot \nabla_2)\Phi_{23}]. \quad (22.73)$$

As this equation must be true for arbitrary velocities, we can set $\mathbf{v}_2 = 0$ and obtain

$$\nabla_1 (k_B T \xi_{12} - e\Phi_{12}) = ne \int d\mathbf{x}_3 \xi_{23} \nabla_1 \Phi_{13}. \quad (22.74)$$

We take the divergence of Eq. (22.74) and use Poisson's equation, $\nabla_1^2 \Phi_{12} = e\delta(\mathbf{x}_{12})/\epsilon_0$, to obtain

$$\nabla_1^2 \xi_{12} - \frac{\xi_{12}}{\lambda_D^2} = \frac{e^2}{\epsilon_0 k_B T} \delta(\mathbf{x}_{12}), \quad (22.75)$$

where $\lambda_D = [k_B T \epsilon_0 / (ne^2)]^{1/2}$ is the Debye length [Eq. (20.10)]. The solution of Eq. (22.75) is

$$\xi_{12} = \frac{-e^2}{4\pi\epsilon_0 k_B T} \frac{e^{-x_{12}/\lambda_D}}{x_{12}}. \quad (22.76)$$

Note that the sign is negative, because the electrons repel one another. Note also that, to order of magnitude, $\xi_{12}(x_{12} = \lambda_D) \sim -N_D^{-1}$, which is $\ll 1$ in magnitude if the Debye number N_D is much greater than unity. At the mean interparticle spacing, we have $\xi_{12}(x_{12} = n^{-1/3}) \sim -N_D^{-2/3}$. Only for distances $x_{12} \lesssim e^2/(\epsilon_0 k_B T)$ will the correlation effects become large and our expansion procedure and truncation ($\chi_{123} = 0$) become invalid. This analysis justifies the use of the Vlasov equation when $N_D \gg 1$; see the discussion at the end of Sec. 22.6.3.

two-point correlation function for electrons in an unmagnetized, thermalized plasma

Exercise 22.13 *Problem: Correlations in a Tokamak Plasma* T2

For a tokamak plasma, compute, to order of magnitude, the two-point correlation function for two electrons separated by

- (a) a Debye length, and
- (b) the mean interparticle spacing.

22.6.3 Coulomb Correction to Plasma Pressure T2

22.6.3

Let us now turn to the problem of computing the Coulomb correction to the pressure of a thermalized ionized gas. It is easiest to begin by computing the Coulomb correction to the internal energy density. Once again ignoring the protons, this is simply given by

$$U_c = \frac{-e}{2} \int d\mathbf{x}_1 n_1 n_2 \xi_{12} \Phi_{12}, \quad (22.77)$$

where the factor 1/2 compensates for double counting the interactions. Substituting Eq. (22.76) and performing the integral, we obtain

$$U_c = \frac{-ne^2}{8\pi\epsilon_0\lambda_D} = -\frac{(e^2n/\epsilon_0)^{3/2}}{8\pi(k_B T)^{1/2}}, \quad (22.78)$$

where n is the number density of electrons. The pressure can be obtained from this energy density using elementary thermodynamics. From the definition (5.32) of the physical free energy converted to a per-unit-volume basis and the first law of thermodynamics [Eq. (5.33)], the volume density of Coulomb free energy, \mathcal{F}_c , is given by integrating

$$U_c = -T^2 \left(\frac{\partial(\mathcal{F}_c/T)}{\partial T} \right)_n. \quad (22.79)$$

From this expression, we obtain $\mathcal{F}_c = \frac{2}{3}U_c$. The Coulomb contribution to the pressure is then given by $P = -\partial F/\partial V$ [Eq. (5.33)], rewritten as

$$P_c = n^2 \left(\frac{\partial(\mathcal{F}_c/n)}{\partial n} \right)_T = \frac{1}{3}U_c. \quad (22.80)$$

Therefore, including the Coulomb interaction decreases the pressure at a given density and temperature.

So far we have only allowed the electrons to move and have kept the protons fixed, and we found a Coulomb pressure and energy density independent of the mass of the electron. Therefore, if we had only allowed the protons to move, we would have gotten the same answer. If (as is the case in reality) we allow both protons and electrons to move, we must include the proton-electron attractions as well; but because U_c and P_c are proportional to e^2 , these contribute with identical magnitude and sign to the

T2

electron-electron repulsions. Therefore the electrons and protons play completely equivalent roles, and the full electron-proton U_c and P_c are simply obtained by replacing n by the total density of particles, $2n$. Inserting $\lambda_D = \sqrt{\epsilon_0 k_B T / (ne^2)}$, the end result for the Coulomb correction to the pressure is

Coulomb correction to pressure in a thermalized plasma

$$P_c = \frac{-n^{3/2} e^3}{2^{3/2} 3\pi \epsilon_0^{3/2} (k_B T)^{1/2}}, \quad (22.81)$$

where n is still the number density of electrons. Numerically, the gas pressure for a perfect electron-proton gas is

$$P = 1.6 \times 10^{13} (\rho / 1,000 \text{ kg m}^{-3}) (T / 10^6 \text{ K}) \text{ N m}^{-2}, \quad (22.82)$$

and the Coulomb correction to this pressure is

$$P_c = -7.3 \times 10^{11} (\rho / 1,000 \text{ kg m}^{-3})^{3/2} (T / 10^6 \text{ K})^{-1/2} \text{ N m}^{-2}. \quad (22.83)$$

In the interior of the Sun this is about 1% of the total pressure. In denser, cooler stars, it is significantly larger.

By contrast, for most of the plasmas that one encounters, our analysis implies that the order of magnitude of the two-point correlation function ξ_{12} is $\sim N_D^{-1}$ across a Debye sphere and only $\sim N_D^{-2/3}$ at the distance of the mean interparticle spacing (see end of Sec. 22.6.2). Only those particles that are undergoing large deflections, through angles ~ 1 radian, are close enough together for $\xi_{12} = O(1)$. This is the ultimate justification for treating plasmas as collisionless and for using mean electromagnetic fields in the Vlasov description.

EXERCISES

Exercise 22.14 *Derivation: Thermodynamic Identities* T2

Verify Eqs. (22.79) and (22.80).

Exercise 22.15 *Problem: Thermodynamics of a Coulomb Plasma* T2

Compute the entropy of a proton-electron plasma in thermal equilibrium at temperature T including the Coulomb correction.

Bibliographic Note

The kinetic theory of warm plasmas and its application to electrostatic waves and their stability are treated in nearly all texts on plasma physics. For maximum detail and good pedagogy, we particularly like Krall and Trivelpiece (1973, Chaps. 7, 8) (but beware of typographical errors). We also recommend, in Bellan (2006): the early parts of Chap. 2, and all of Chap. 5, and for the extension to magnetized plasmas, Chap. 8.

Also useful are Schmidt (1979, Chaps. 3, 7), Lifshitz and Pitaevskii (1981, Chap. 3), Stix (1992, Chaps. 8, 10), Boyd and Sanderson (2003, Chap. 8), and Swanson (2003, Chap. 4).

For brief discussions of the BBGKY hierarchy of N -particle distribution functions and their predicted correlations in a plasma, see Boyd and Sanderson (2003, Chap. 12) and Swanson (2003, Sec. 4.1.3). For detailed discussions, see the original literature cited in Sec. 22.6.1.

The theory of galaxy dynamics is very clearly developed in Binney and Tremaine (2003). The reader will find many parallels between warm plasmas and self-gravitating stellar distributions.

Nonlinear Dynamics of Plasmas

Plasma seems to have the kinds of properties one would like for life. It's somewhat like liquid water—unpredictable and thus able to behave in an enormously complex fashion. It could probably carry as much information as DNA does. It has at least the potential for organizing itself in interesting ways.

FREEMAN DYSON (1986)

23.1 Overview

23.1

In Sec. 21.6 we met our first example of a velocity-space instability: the two-stream instability, which illustrated the general principle that in a collisionless plasma, departures from Maxwellian equilibrium in velocity space can be unstable and lead to exponential growth of small-amplitude waves. This is similar to the Kelvin-Helmholtz instability in a fluid (Sec. 14.6.1), where a spatially varying fluid velocity produces an instability. In Chap. 22, we derived the dispersion relation for electrostatic waves in a warm, unmagnetized plasma. We discovered Landau damping of the waves when the phase-space density of the resonant particles diminishes with increasing speed, and we showed that in the opposite case of an increasing phase-space density, the waves can grow at the expense of the energies of near-resonant particles (a generalization of the two-stream instability). In this chapter, we explore the back-reaction of the waves on the near-resonant particles. This back-reaction is a (weakly) nonlinear process, so we have to extend our analysis of wave-particle interactions to include the leading nonlinearity.

This extension is called *quasilinear theory* or *the theory of weak plasma turbulence*, and it allows us to follow the time development of the waves and the near-resonant particles simultaneously. We develop this formalism in Sec. 23.2 and verify that it enforces the laws of particle conservation, energy conservation, and momentum conservation. Our initial development of the formalism is entirely in classical language and meshes nicely with the kinetic theory of electrostatic waves as presented in Chap. 22. In Sec. 23.3, we reformulate the theory in terms of the emission, absorption, and scattering of wave quanta, which are called *plasmons*. Although waves in plasmas almost always entail large quantum occupation numbers and thus are highly classical, this quantum formulation of the classical theory has great computational and heuristic power. And, as one might expect, despite the presence of Planck's reduced constant \hbar in the formalism, \hbar nowhere appears in the final answers to problems.

BOX 23.1. READERS' GUIDE

- This chapter relies significantly on:
 - portions of Chap. 3 on kinetic theory: Secs. 3.2.1 and 3.2.3 on the distribution function, Sec. 3.2.5 on the mean occupation number, and Sec. 3.6 on Liouville's theorem and the collisionless Boltzmann equation;
 - portions of Secs. 7.2 and 7.3 on geometric optics;
 - Sec. 20.3 on Debye shielding, collective behavior of plasmas and plasma oscillations; and
 - Secs. 22.1–22.5 on kinetic theory of warm plasmas.
- This chapter also relies to some extent but not greatly on:
 - the concept of spectral density as developed in Sec. 6.4, and
 - Sec. 6.9 on the Fokker-Planck equation.
- No subsequent material in this book relies significantly on this chapter.

Our initial derivation and development of the formalism is restricted to the interaction of electrons with electrostatic waves, but in Sec. 23.3 we also describe how the formalism can be generalized to describe a multitude of wave modes and particle species interacting with one another.

We also describe circumstances in which this formalism can fail because the resonant particles couple strongly, *not* to a broad-band distribution of incoherent waves (as the formalism presumes) but instead to one or a few individual, coherent modes. (In Sec. 23.6, we explore an example.)

In Sec. 23.4, we give two illustrative applications of quasilinear theory. For a warm electron beam that propagates through a stable plasma, generating Langmuir plasmons, we show how the plasmons act back on the beam's particle distribution function so as to shut down the plasmon production. For our second application, we describe how galactic cosmic rays (relativistic charged particles) generate Alfvén waves, which in turn scatter the cosmic rays, isotropizing their distribution functions and confining them to our galaxy's interior much longer than one might expect.

In the remainder of this chapter, we describe a few of the many other nonlinear phenomena that can be important in plasmas. In Sec. 23.5, we consider parametric instabilities in plasmas (analogous of the optical parametric amplification that we met in nonlinear crystals in Sec. 10.7). These instabilities are important for the absorption of laser light in experimental studies of the compression of small deuterium-tritium pellets—a possible forerunner of a commercial nuclear fusion reactor. In Sec. 23.6, we return to ion-acoustic solitons (which we studied, for small amplitudes, in Ex. 21.6)

and explore how they behave when their amplitudes are so large that nonlinearities are strong. We discover that dissipation can convert such a soliton into a collisionless shock, similar to the bow shock that forms where Earth's magnetic field meets the solar wind.

23.2 Quasilinear Theory in Classical Language

23.2

23.2.1 Classical Derivation of the Theory

23.2.1

In Chap. 22, we discovered that hot, thermalized electrons or ions can Landau damp a wave mode. We also showed that some nonthermal particle velocity distributions lead to exponential growth of the waves. Either way there is energy transfer between the waves and the particles. We now turn to the back-reaction of the waves on the near-resonant particles that damp or amplify them. For simplicity, we derive and explore the back-reaction equations (“quasilinear theory”) in the special case of electrons interacting with electrostatic Langmuir waves. Then we assert the (rather obvious) generalization to protons or other ions and (less obviously) to interactions with other types of wave modes.

TWO-LENGTHSCALE EXPANSION

We begin with the electrons' 1-dimensional distribution function $F_e(v, z, t)$ [Eq. (22.17)]. As in Sec. 22.3.1, we split F_e into two parts, but we must do so more carefully here than we did there. The foundation for our split is a two-lengthscale expansion of the same sort as we used in developing geometric optics (Sec. 7.3). We introduce two disparate lengthscales, the short one being the typical reduced wavelength of a Langmuir wave $\lambda \sim 1/k$, and the long one being a scale $L \gg \lambda$ over which we perform spatial averages. Later, when applying our formalism to an inhomogeneous plasma, L must be somewhat shorter than the spatial inhomogeneity scale but still $\gg \lambda$. In our present situation of a homogeneous background plasma, there can still be large-scale spatial inhomogeneities caused by the growth or damping of the wave modes via their interaction with the electrons. We must choose L somewhat smaller than the growth or damping length but still large compared to λ .

Our split of F_e is into the spatial average of F_e over the length L (denoted F_0) plus a rapidly varying part that averages to zero (denoted F_1):

$$F_0 \equiv \langle F_e \rangle, \quad F_1 \equiv F_e - F_0, \quad F_e = F_0 + F_1. \quad (23.1)$$

[For simplicity, we omit the subscript e from F_0 and F_1 . Therefore—by contrast with Chap. 22, where $F_0 = F_{e0} + (m_e/m_p)F_{p0}$ —we here include only F_{e0} in F_0 .]

The time evolution of F_e , and hence of F_0 and F_1 , is governed by the 1-dimensional Vlasov equation, in which we assume a uniform neutralizing ion (proton) background, no background magnetic field, and interaction with 1-dimensional (planar) electrostatic waves. We cannot use the linearized Vlasov equation (22.19), which formed the foundation for all of Chap. 22, because the processes we wish to study are nonlinear. Rather, we must use the fully nonlinear Vlasov equation [Eq. (22.6)

derivation of quasilinear theory

two-lengthscale expansion of electron distribution function

integrated over the irrelevant components v_x and v_y of velocity, as in Eq. (22.17)]:

$$\frac{\partial F_e}{\partial t} + v \frac{\partial F_e}{\partial z} - \frac{eE}{m_e} \frac{\partial F_e}{\partial v} = 0. \quad (23.2)$$

Here E is the rapidly varying electric field (pointing in the z direction) associated with the waves.

Inserting $F_e = F_0 + F_1$ into this Vlasov equation, and arranging the terms in an order that will make sense below, we obtain

$$\frac{\partial F_0}{\partial t} + v \frac{\partial F_0}{\partial z} - \frac{e}{m_e} \frac{\partial F_1}{\partial v} E + \frac{\partial F_1}{\partial t} + v \frac{\partial F_1}{\partial z} - \frac{e}{m_e} \frac{\partial F_0}{\partial v} E = 0. \quad (23.3)$$

We then split this equation into two parts: its average over the large lengthscale L and its remaining time-varying part.

The averaged part gets contributions only from the first three terms (since the last three are linear in F_1 and E , which have vanishing averages):

evolution of slowly
varying part F_0 of electron
distribution function

$$\frac{\partial F_0}{\partial t} + v \frac{\partial F_0}{\partial z} - \frac{e}{m_e} \left\langle \frac{\partial F_1}{\partial v} E \right\rangle = 0. \quad (23.4)$$

This is an evolution equation for the averaged distribution F_0 ; the third, nonlinear term drives the evolution. This driving term is the only nonlinearity that we keep in the quasilinear Vlasov equation.

RAPID EVOLUTION OF F_1

The rapidly varying part of the Vlasov equation (23.3) is just the last three terms of Eq. (23.3):

evolution of rapidly
varying part F_1 of electron
distribution function

$$\frac{\partial F_1}{\partial t} + v \frac{\partial F_1}{\partial z} - \frac{e}{m_e} \frac{\partial F_0}{\partial v} E = 0, \quad (23.5)$$

plus a nonlinear term

$$-\frac{e}{m_e} \left(\frac{\partial F_1}{\partial v} E - \left\langle \frac{\partial F_1}{\partial v} E \right\rangle \right), \quad (23.6)$$

three-wave mixing

which we discard as being far smaller than the linear ones. If we were to keep this term, we would find that it can produce a “three-wave mixing” (analogous to that for light in a nonlinear crystal, Sec. 10.6), in which two electrostatic waves with different wave numbers k_1 and k_2 interact weakly to try to generate a third electrostatic wave with wave number $k_3 = k_1 \pm k_2$. We discuss such three-wave mixing in Sec. 23.3.6; for the moment we ignore it and correspondingly discard the nonlinearity (23.6).

Equation (23.5) is the same linear evolution equation for F_1 as we developed and studied in Chap. 22. Here, as there, we bring its physics to the fore by decomposing into monochromatic modes; but here we are dealing with many modes and sums over the effects of many modes, so we must do the decomposition a little more carefully

than in Chap. 22. The foundation for the decomposition is a spatial Fourier transform inside our averaging “box” of length L :

$$\tilde{F}_1(v, k, t) = \int_0^L e^{-ikz} F_1(v, z, t) dz, \quad \tilde{E}(k, t) = \int_0^L e^{-ikz} E(z, t) dz. \quad (23.7)$$

Fourier analysis inside an averaging box

We take F_1 and E to represent the physical quantities and thus to be real; this implies that $\tilde{F}_1(-k) = \tilde{F}_1^*(k)$ and similarly for \tilde{E} , so the inverse Fourier transforms are

$$\begin{aligned} F_1(v, z, t) &= \int_{-\infty}^{\infty} e^{ikz} \tilde{F}_1(v, k, t) \frac{dk}{2\pi}, \\ E(z, t) &= \int_{-\infty}^{\infty} e^{ikz} \tilde{E}(v, k, t) \frac{dk}{2\pi}, \quad \text{for } 0 < z < L. \end{aligned} \quad (23.8)$$

(This choice of how to do the mathematics corresponds to idealizing F_1 and E as vanishing outside the box; alternatively, we could treat them as though they were periodic with period L and replace Eq. (23.8) by a sum over discrete values of k —multiples of $2\pi/L$.)

From our study of linearized waves in Chap. 21, we know that a mode with real wave number k will oscillate in time with some complex frequency $\omega(k)$:

conventions for linear modes

$$\tilde{F}_1 \propto e^{-i\omega(k)t}, \quad \tilde{E} \propto e^{-i\omega(k)t}. \quad (23.9)$$

For simplicity, we assume that the mode propagates in the $+z$ direction; when studying modes traveling in the opposite direction, we just turn our z -axis around. (In Sec. 23.2.4, we generalize to 3-dimensional situations and include all directions of propagation simultaneously.) For simplicity, we also assume that for each wave number k there is at most one mode type present (i.e., only a Langmuir wave or only an ion-acoustic wave). With these simplifications, $\omega(k)$ is a unique function with its real part positive ($\omega_r > 0$) when $k > 0$. Notice that the reality of $E(z, t)$ implies [from the second of Eqs. (23.7)] that $\tilde{E}(-k, t) = \tilde{E}^*(k, t)$ for all t ; in other words [cf. Eqs. (23.9)], $\tilde{E}(-k, 0)e^{-i\omega(-k)t} = \tilde{E}^*(k, 0)e^{+i\omega^*(k)t}$ for all t , which in turn implies

$$\omega(-k) = -\omega^*(k); \quad \text{or} \quad \omega_r(-k) = -\omega_r(k), \quad \omega_i(-k) = \omega_i(k). \quad (23.10)$$

These equations should be obvious physically: they say that, for our chosen conventions, both the negative k and positive k contributions to Eq. (23.8) propagate in the $+z$ direction, and both grow or are damped in time at the same rate. In general, $\omega(k)$ is determined by the Landau-contour dispersion relation (22.33). However, throughout Secs. 23.2–23.4, we specialize to weakly damped or growing Langmuir waves with phase velocities ω_r/k large compared to the rms electron speed:

$$v_{\text{ph}} = \frac{\omega_r}{k} \gg v_{\text{rms}} = \sqrt{\frac{1}{n} \int v^2 F_0(v) dv}. \quad (23.11)$$

dispersion relation for slowly evolving Langmuir waves

For such waves, from Eqs. (22.40a), (22.40b), and the first two lines of Eq. (22.42), we deduce the following explicit forms for the real and imaginary parts of ω :

$$\omega_r^2 = \omega_p^2 \left(1 + 3 \frac{v_{\text{rms}}^2}{(\omega_p/k)^2} \right), \quad \text{for } k > 0, \quad (23.12a)$$

$$\omega_i = \frac{\pi e^2}{2\epsilon_0 m_e} \frac{\omega_r}{k^2} F_0'(\omega_r/k), \quad \text{for } k > 0. \quad (23.12b)$$

The linearized Vlasov equation (23.5) implies that the modes' amplitudes $\tilde{F}_1(v, k, t)$ and $\tilde{E}(k, t)$ are related by

$$\tilde{F}_1 = \frac{ie}{m_e} \frac{\partial F_0 / \partial v}{\omega - kv} \tilde{E}. \quad (23.13)$$

This is just Eq. (22.20) with d/dv replaced by $\partial/\partial v$, because F_0 now varies slowly in space and time as well as varying with v .

SPECTRAL ENERGY DENSITY \mathcal{E}_K

Now leave the rapidly varying quantities F_1 and E and their Vlasov equation (23.5), dispersion relation (23.12a), and damping rate (23.12b), and turn to the spatially averaged distribution function F_0 and its spatially averaged Vlasov equation (23.4). We shall bring this Vlasov equation's nonlinear term into a more useful form. The key quantity in this nonlinear term is the average of the product of the rapidly varying quantities F_1 and E . Parseval's theorem permits us to rewrite this as

$$\langle EF_1 \rangle = \frac{1}{L} \int_0^L E F_1 dz = \frac{1}{L} \int_{-\infty}^{\infty} E F_1 dz = \int_{-\infty}^{\infty} \frac{dk}{2\pi} \frac{\tilde{E}^* \tilde{F}_1}{L}, \quad (23.14)$$

where in the second step we have used our mathematical idealization that F_1 and E vanish outside our averaging box, and the third equality is Parseval's theorem. Inserting Eq. (23.13), we bring Eq. (23.14) into the form

$$\langle EF_1 \rangle = \frac{e}{m_e} \int_{-\infty}^{\infty} \frac{dk}{2\pi} \frac{\tilde{E}^* \tilde{E}}{L} \frac{i}{\omega - kv} \frac{\partial F_0}{\partial v}. \quad (23.15)$$

The quantity $\tilde{E}^* \tilde{E}/L$ is a function of wave number k , time t , and also the location and size L of the averaging box. For Eq. (23.15) to be physically and computationally useful, it is essential that this quantity not fluctuate wildly as k , t , L , and the box location are varied. In most circumstances, if the box is chosen to be far larger than $\lambda = 1/k$, then $\tilde{E}^* \tilde{E}/L$ indeed will not fluctuate wildly. When one develops the quasilinear theory with greater care and rigor than we can do in so brief a treatment, one discovers that this nonfluctuation is a consequence of the *random-phase approximation* or RPA for short—an approximation that the phase of \tilde{E} varies randomly with k , t , L , and

random-phase approximation (RPA)

the box location on suitably short lengthscales.¹ Like ergodicity (Secs. 4.6 and 6.2.3), although the RPA is often valid, sometimes it can fail. Sometimes there is an organized bunching of the particles in phase space that induces nonrandom phases on the plasma waves. Quasilinear theory requires that RPA be valid, and for the moment we assume it is, but in Sec. 23.6 we meet an example for which it fails: strong ion-acoustic solitons.

The RPA implies that, as we increase the length L of our averaging box, $\tilde{E}^* \tilde{E} / L$ will approach a well-defined limit. This limit is half the spectral density $S_E(k)$ of the random process $E(z, t)$ at fixed time t [cf. Eq. (6.25)]. Correspondingly, it is natural to express quasilinear theory in the language of spectral densities. We shall do so, but with a normalization of the spectral density that is tied to the physical energy density and differs slightly from that used in Chap. 6: in place of $S_E(k)$, we use the *Langmuir-wave spectral energy density* \mathcal{E}_k . We follow plasma physicists' conventions by defining this quantity to include the oscillatory kinetic energy in the electrons, as well as the electrical energy to which it is, on average, equal. As in the theory of random processes (Chap. 6), we add the energy at $-k$ to that at $+k$, so that all the energy is regarded as residing at positive wave number, and $\int_0^\infty dk \mathcal{E}_k$ is the total wave energy per unit volume in the plasma, averaged over length L .

Invoking the RPA, we can use Parseval's theorem to compute the electrical energy density:

$$\frac{\epsilon_0 \langle E^2 \rangle}{2} = \int_{-\infty}^{\infty} \frac{dk}{2\pi} \epsilon_0 \left\langle \frac{\tilde{E} \tilde{E}^*}{2L} \right\rangle = \int_0^{\infty} \frac{dk}{2\pi} \epsilon_0 \left\langle \frac{\tilde{E} \tilde{E}^*}{L} \right\rangle, \quad (23.16)$$

where we have used $\tilde{E}(k) \tilde{E}^*(k) = \tilde{E}(-k) \tilde{E}^*(-k)$. We double this quantity to account for the wave energy in the oscillating electrons and then read off the spectral energy density as the integrand:

$$\boxed{\mathcal{E}_k = \frac{\epsilon_0 \langle \tilde{E} \tilde{E}^* \rangle}{\pi L}}. \quad (23.17)$$

spectral energy density of Langmuir waves

This wave energy density can be regarded as a function either of wave number k or wave phase velocity $v_{\text{ph}} = \omega_r / k$. It is useful to plot $\mathcal{E}_k(v_{\text{ph}})$ on the same graph as the averaged electron velocity distribution $F_0(v)$. Figure 23.1 is such a plot. It shows the physical situation we are considering: approximately thermalized electrons with (possibly) a weak beam (bump) of additional electrons at velocities $v \gg v_{\text{rms}}$, and a distribution of Langmuir waves with phase velocities $v_{\text{ph}} \gg v_{\text{rms}}$.

EVOLUTION OF WAVE SPECTRAL ENERGY DENSITY \mathcal{E}_k

There is an implicit time dependence associated with the growth or decay of the waves, so $\mathcal{E}_k \propto e^{2\omega_i t}$. Now, the waves' energy density \mathcal{E}_k travels through phase space (physical

1. For detailed discussions, see Davidson (1972) and Pines and Schrieffer (1962).

FIGURE 23.1 The spatially averaged electron velocity distribution $F_0(v)$ (solid curve) and wave spectral energy density $\mathcal{E}_k(v_{\text{ph}})$ (dashed curve) for the situation treated in Secs. 23.2–23.4.

space and wave-vector space) on the same trajectories as a wave packet (i.e., along the geometric-optics rays discussed in Sec. 7.3), which for our waves propagating in the z direction are given by

derivatives moving with Langmuir-wave rays (wave packets)

$$\left(\frac{dz}{dt}\right)_{\text{wp}} = \frac{\partial \omega_r}{\partial k_j}, \quad \left(\frac{dk}{dt}\right)_{\text{wp}} = -\frac{\partial \omega_r}{\partial z} \quad (23.18)$$

[Eqs. (7.25)]. Correspondingly, the waves' growth or decay actually occurs along these rays (with the averaging boxes also having to be carried along the rays). Thus the equation of motion for the waves' energy density is

evolution of Langmuir waves' spectral energy density along a ray

$$\frac{d\mathcal{E}_k}{dt} \equiv \frac{\partial \mathcal{E}_k}{\partial t} + \left(\frac{dz}{dt}\right)_{\text{wp}} \frac{\partial \mathcal{E}_k}{\partial z} + \left(\frac{dk}{dt}\right)_{\text{wp}} \frac{\partial \mathcal{E}_k}{\partial k} = 2\omega_i \mathcal{E}_k. \quad (23.19)$$

Here we have used the fact that the electrostatic waves are presumed to propagate in the z direction, so the only nonzero component of \mathbf{k} is $k_z \equiv k$, and the only nonzero component of the group velocity is $V_{gz} = (dz/dt)_{\text{wp}} = (\partial \omega_r / \partial k)_z$. For weakly damped, high-phase-speed Langmuir waves, $\omega_r(\mathbf{x}, k)$ is given by Eq. (23.12a), with the \mathbf{x} dependence arising from the slowly spatially varying electron density $n(\mathbf{x})$, which induces a slow spatial variation in the plasma frequency: $\omega_p = \sqrt{ne^2/(\epsilon_0 m_e)}$.

SLOW EVOLUTION OF F_0

evolution of slowly varying part F_0 of electron distribution function

The context in which the quantity $\tilde{E}(k)^* \tilde{E}(k) = (\pi L / \epsilon_0) \mathcal{E}_k$ arose was our evaluation of the nonlinear term in the Vlasov equation (23.4) for the electrons' averaged distribution function F_0 . By inserting Eqs. (23.15) and (23.17) into Eq. (23.4), we bring that nonlinear Vlasov equation into the form

$$\frac{\partial F_0}{\partial t} + v \frac{\partial F_0}{\partial z} = \frac{\partial}{\partial v} \left(D \frac{\partial F_0}{\partial v} \right), \quad (23.20)$$

where

$$\begin{aligned}
 D(v) &= \frac{e^2}{2\epsilon_0 m_e^2} \int_{-\infty}^{\infty} dk \mathcal{E}_k \frac{i}{\omega - kv} \\
 &= \frac{e^2}{\epsilon_0 m_e^2} \int_0^{\infty} dk \mathcal{E}_k \frac{\omega_i}{(\omega_r - kv)^2 + \omega_i^2}.
 \end{aligned} \tag{23.21}$$

diffusion coefficient for electrons

In the second equality we have used Eq. (23.10).

Equation (23.20) says that $F_0(v, z, t)$ is transported in physical space with the electron speed v and diffuses in velocity space with the *velocity diffusion coefficient* $D(v)$. Notice that $D(v)$ is manifestly real, and a major contribution to it comes from waves whose phase speeds ω_r/k nearly match the particle speed v (i.e., from resonant waves).

The two-lengthscale approximation that underlies quasilinear theory requires that the waves grow or damp on a lengthscale long compared to a wavelength, and equivalently, that $|\omega_i|$ be much smaller than ω_r . This allows us, for each v , to split the integral in Eq. (23.21) into a piece due to modes that can resonate with electrons of that speed because $\omega_r/k \simeq v$ plus a piece that cannot so resonate. We consider these two pieces in turn.

The resonant piece of the diffusion coefficient can be written, in the limit $|\omega_i| \ll \omega_r$, by approximating the resonance in Eq. (23.21) as a delta function:

$$D^{\text{res}} \simeq \frac{e^2 \pi}{\epsilon_0 m_e^2} \int_0^{\infty} dk \mathcal{E}_k \delta(\omega_r - kv). \tag{23.22a}$$

diffusion coefficient for electrons that are resonant with the waves

In the diffusion equation (23.20) this influences $F_0(v)$ only at those velocities v of resonating waves with substantial wave energy (i.e., on the tail of the electron velocity distribution, under the dashed \mathcal{E}_k curve of Fig. 23.1). We refer to electrons in this region as the *resonant electrons*. In Sec. 23.4, we explore the dynamical influence of this resonant diffusion coefficient on the velocity distribution $F_0(v)$ of the resonant electrons.

Nearly all the electrons reside at velocities $|v| \lesssim v_{\text{rms}}$, where there are no waves (because waves there get damped very quickly). For these *nonresonant electrons*, the denominator in Eq. (23.21) for the diffusion coefficient is approximately equal to $\omega_r^2 \simeq \omega_p^2 = e^2 n / (\epsilon_0 m_e)$, and correspondingly, the diffusion coefficient has the form

$$D^{\text{non-res}} \simeq \frac{1}{nm_e} \int_0^{\infty} \omega_i \mathcal{E}_k dk, \tag{23.22b}$$

diffusion coefficient for nonresonant electrons

which is independent of the electron velocity v .

The nonresonant electrons at $v \lesssim v_{\text{rms}}$ are the ones that participate in the wave motions and account for the waves' oscillating charge density (via F_1). The time-averaged kinetic energy of these nonresonant electrons (embodied in F_0) thus must

include a conserved part independent of the waves plus a part associated with the waves. The wave part must be equal to the waves' electrical energy and so to half the waves' total energy, $\frac{1}{2} \int_0^\infty dk \mathcal{E}_k$, and it thus must change at a rate $2\omega_i$ times that energy. Correspondingly, we expect the nonresonant piece of $D(v)$ to produce a rate change of the time-averaged electron energy (embodied in F_0) given by

nonresonant energy conservation

$$\frac{\partial U_e}{\partial t} + \frac{\partial \mathcal{F}_{ez}}{\partial z} = \frac{1}{2} \int_0^\infty dk 2\omega_i \mathcal{E}_k, \quad (23.23)$$

where \mathcal{F}_{ez} is the electron energy flux. Indeed, this is the case; see Ex. 23.1. Because we have already accounted for this electron contribution to the wave energy in our definition of \mathcal{E}_k , we ignore it henceforth in the evolution of $F_0(v)$, and correspondingly, for weakly damped or growing waves we focus solely on the resonant part of the diffusion coefficient, Eq. (23.22a).

EXERCISES

Exercise 23.1 *Problem: Nonresonant Particle Energy in Wave*

Show that the nonresonant part of the diffusion coefficient in velocity space, Eq. (23.22b), produces a rate of change of electron kinetic energy given by Eq. (23.23).

23.2.2

23.2.2 Summary of Quasilinear Theory

All the fundamental equations of quasilinear theory are now in hand. They are:

summary: fundamental equations of quasilinear theory for electrons interacting with Langmuir waves

1. The general dispersion relation (22.40) for the (real part of the) waves' frequency $\omega_r(k)$ and their growth rate $\omega_i(k)$ [which, for the high-speed Langmuir waves on which we are focusing, reduces to Eqs. (23.12)]; this dispersion relation depends on the electrons' slowly evolving, time-averaged velocity distribution $F_0(v, z, t)$.
2. The equation of motion (23.19) for the waves' slowly evolving spectral energy density $\mathcal{E}_k(k, z, t)$, in which appear $\omega_r(k)$ and $\omega_i(k)$.
3. Equations (23.21) or (23.22) for the diffusion coefficient $D(v)$ in terms of \mathcal{E}_k .
4. The diffusive evolution equation (23.20) for the slow evolution of $F_0(v, z, t)$.

The fundamental functions in this theory are $\mathcal{E}_k(k, z, t)$ for the waves and $F_0(v, z, t)$ for the electrons.

Quasilinear theory sweeps under the rug and ignores the details of the oscillating electric field $E(z, t)$ and the oscillating part of the distribution function $F_1(v, z, t)$. Those quantities were needed in deriving the quasilinear equations, but they are needed no longer—except, sometimes, as an aid to physical understanding.

It is instructive to verify that the quasilinear equations enforce the conservation of particles, momentum, and energy.

We begin with particles (electrons). The number density of electrons is $n = \int F_0 dv$, and the z component of particle flux is $S_z = \int n v dv$ (where F_1 contributes nothing because it is oscillatory, and here and below all velocity integrals go from $-\infty$ to $+\infty$). Therefore, by integrating the diffusive evolution equation (23.20) for F_0 over velocity, we obtain

$$\frac{\partial n}{\partial t} + \frac{\partial S_z}{\partial z} = \int \left(\frac{\partial}{\partial t} F_0 + v \frac{\partial}{\partial z} F_0 \right) dv = \int \frac{\partial}{\partial v} \left(D \frac{\partial F_0}{\partial v} \right) dv = 0, \quad (23.24)$$

particle conservation

which is the law of particle conservation for our 1-dimensional situation where nothing depends on x or y .

The z component of electron momentum density is $G_z^e \equiv \int m_e v F_0 dv$, and the zz component of electron momentum flux (stress) is $T_{zz}^e = \int m_e v^2 F_0 dv$; so evaluating the first moment of the evolution equation (23.20) for F_0 , we obtain

$$\begin{aligned} \frac{\partial G_z^e}{\partial t} + \frac{\partial T_{zz}^e}{\partial z} &= m_e \int v \left(\frac{\partial F_0}{\partial t} + v \frac{\partial F_0}{\partial z} \right) dv \\ &= m_e \int v \frac{\partial}{\partial v} \left(D \frac{\partial F_0}{\partial v} \right) dv = -m_e \int D \frac{\partial F_0}{\partial v} dv, \end{aligned} \quad (23.25)$$

where we have used integration by parts in the last step. The waves influence the momentum of the resonant electrons through the delta-function part of the diffusion coefficient D [Eq. (23.22a)], and the momentum of the nonresonant electrons through the nonresonant part of the diffusion coefficient (23.22b). Because we have included the evolving part of the nonresonant electrons' momentum and energy as part of the waves' momentum and energy, we must restrict attention in Eq. (23.25) to the resonant electrons (see last sentence in Sec. 23.2.1). We therefore insert the delta-function part of D [Eq. (23.22a)] into Eq. (23.25), thereby obtaining

$$\frac{\partial G_z^e}{\partial t} + \frac{\partial T_{zz}^e}{\partial z} = -\frac{\pi e^2}{\epsilon_0 m_e} \int dv \int dk \mathcal{E}_k \delta(\omega_r - kv) \frac{\partial F_0}{\partial v} = -\frac{\pi e^2}{\epsilon_0 m_e} \int \mathcal{E}_k F_0'(\omega_r/k) \frac{dk}{k}. \quad (23.26)$$

Here we have changed the order of integration, integrated out v , and set $F_0'(v) \equiv \partial F_0 / \partial v$. Assuming, for definiteness, high-speed Langmuir waves, we can rewrite the last expression in terms of ω_i with the aid of Eq. (23.12b):

$$\begin{aligned} \frac{\partial G_z^e}{\partial t} + \frac{\partial T_{zz}^e}{\partial z} &= -2 \int dk \omega_i \frac{\mathcal{E}_k k}{\omega_r} = -\frac{\partial}{\partial t} \int dk \frac{\mathcal{E}_k k}{\omega_r} - \frac{\partial}{\partial z} \int dk \frac{\mathcal{E}_k k}{\omega_r} \frac{\partial \omega_r}{\partial k} \\ &= -\frac{\partial G_z^w}{\partial t} - \frac{\partial T_{zz}^w}{\partial z}. \end{aligned} \quad (23.27)$$

conservation of total momentum in quasilinear theory

The second equality follows from Eq. (23.19) together with the fact that for high-speed Langmuir waves, $\omega_r \simeq \omega_p$ so $\partial\omega_r/\partial z \simeq \frac{1}{2}(\omega_p/n_e)\partial n_e/\partial z$ is independent of k . After the second equality in Eq. (23.19), $\int dk \mathcal{E}_k k/\omega_r = G_z^w$ is the waves' density of the z component of momentum [as one can see from the fact that each plasmon (wave quantum) carries a momentum $p_z = \hbar k$ and an energy $\hbar\omega_r$; cf. Secs. 7.3.2 and 23.3]. Similarly, since the waves' momentum and energy travel with the group velocity $d\omega_r/dk$, $\int dk \mathcal{E}_k(k/\omega_r)(\partial\omega_r/\partial k) = T_{zz}^w$ is the waves' flux of momentum. Obviously, Eq. (23.27) represents the conservation of total momentum, that of the resonant electrons plus that of the waves (which includes the evolving part of the nonresonant electron momentum).

conservation of total energy in quasilinear theory

Energy conservation can be handled in a similar fashion; see Ex. 23.2.

EXERCISES

Exercise 23.2 *Problem: Energy Conservation*

Show that the quasilinear evolution equations guarantee conservation of total energy—that of the resonant electrons plus that of the waves. Pattern your analysis after that for momentum, Eqs. (23.25)–(23.27).

23.2.4

quasilinear equations in 3 dimensions

waves' spectral energy density

23.2.4 Generalization to 3 Dimensions

So far, we have restricted our attention to Langmuir waves propagating in one direction, $+\mathbf{e}_z$. The generalization to 3 dimensions is straightforward. The waves' wave number k is replaced by the wave vector $\mathbf{k} = k\hat{\mathbf{k}}$, where $\hat{\mathbf{k}}$ is a unit vector in the direction of the phase velocity. The waves' spectral energy density becomes $\mathcal{E}_{\mathbf{k}}$, which depends on \mathbf{k} , varies slowly in space \mathbf{x} and time t , and is related to the waves' total energy density by

$$U_w = \int \mathcal{E}_{\mathbf{k}} d\mathcal{V}_{\mathbf{k}}, \quad (23.28)$$

where $d\mathcal{V}_{\mathbf{k}} \equiv dk_x dk_y dk_z$ is the volume integral in wave-vector space.

Because the plasma is isotropic, the dispersion relation $\omega(k) = \omega(|\mathbf{k}|)$ has the same form as in the 1-dimensional case, and the group and phase velocities point in the same direction $\hat{\mathbf{k}}$: $\mathbf{V}_{\text{ph}} = (\omega/k)\hat{\mathbf{k}}$, $\mathbf{V}_g = (d\omega_r/dk)\hat{\mathbf{k}}$. The evolution equation (23.19) for the waves' spectral energy density moving along a ray (a wave-packet trajectory) becomes

evolution of waves' spectral energy density

$$\frac{d\mathcal{E}_{\mathbf{k}}}{dt} \equiv \frac{\partial\mathcal{E}_{\mathbf{k}}}{\partial t} + \left(\frac{dx_j}{dt}\right)_{\text{wp}} \frac{\partial\mathcal{E}_{\mathbf{k}}}{\partial x_j} + \left(\frac{dk_j}{dt}\right)_{\text{wp}} \frac{\partial\mathcal{E}_{\mathbf{k}}}{\partial k_j} = 2\omega_i \mathcal{E}_{\mathbf{k}}, \quad (23.29a)$$

and the rays themselves are given by

rays

$$\left(\frac{dx_j}{dt}\right)_{\text{wp}} = \frac{\partial\omega_r}{\partial k_j} = V_{g j}, \quad \left(\frac{dk_j}{dt}\right)_{\text{wp}} = -\frac{\partial\omega_r}{\partial x_j}. \quad (23.29b)$$

We shall confine ourselves to the resonant part of the diffusion coefficient, as the nonresonant part is only involved in coupling a wave's electrostatic part to its oscillating, nonresonant-electron part, and we already understand that issue [Eqs. (23.22b), (23.23), and associated discussion] and shall not return to it.

The 3-dimensional velocity diffusion coefficient acts only along the direction of the waves; that is, its $\hat{\mathbf{k}} \otimes \hat{\mathbf{k}}$ component has the same resonant form [Eq. (23.22a)] as in the 1-dimensional case, and components orthogonal to $\hat{\mathbf{k}}$ vanish, so

$$\mathbf{D} = \frac{\pi e^2}{\epsilon_0 m_e^2} \int \mathcal{E}_{\mathbf{k}} \hat{\mathbf{k}} \otimes \hat{\mathbf{k}} \delta(\omega_r - \mathbf{k} \cdot \mathbf{v}) d\mathcal{V}_{\mathbf{k}}. \quad (23.29c)$$

tensorial diffusion coefficient for resonant electrons

Because the waves will generally propagate in a variety of directions, the net \mathbf{D} is not unidirectional. This diffusion coefficient enters into the obvious generalization of the Fokker-Planck-like evolution equation (23.20) for the averaged distribution function $f_0(\mathbf{v}, \mathbf{x}, t)$ —in which we suppress the subscript 0 for ease of notation:

$$\frac{\partial f}{\partial t} + \mathbf{v} \cdot \nabla f = \nabla_{\mathbf{v}} \cdot (\mathbf{D} \cdot \nabla_{\mathbf{v}} f), \quad \text{or} \quad \frac{\partial f}{\partial t} + v_j \frac{\partial f}{\partial x_j} = \frac{\partial}{\partial v_i} \left(D_{ij} \frac{\partial f}{\partial v_j} \right). \quad (23.29d)$$

evolution of electrons' averaged distribution function

Here $\nabla_{\mathbf{v}}$ (in index notation, $\partial/\partial v_j$) is the gradient in velocity space, not to be confused with the spatial derivative along a vector \mathbf{v} , $\nabla_{\mathbf{v}} \equiv \mathbf{v} \cdot \nabla = v_j \partial/\partial x_j$.

23.3 Quasilinear Theory in Quantum Mechanical Language

23.3

The attentive reader will have noticed a familiar structure to our quasilinear theory. It is reminiscent of the geometric-optics formalism that we introduced in Chap. 7. Here, as there, we can reinterpret the formalism in terms of quanta carried by the waves. At the most fundamental level, we could (second) quantize the field of plasma waves into quanta (usually called “plasmons”), and describe their creation and annihilation using quantum mechanical transition probabilities. However, there is no need to go through the rigors of the quantization procedure, since the basic concepts of creation, annihilation, and transition probabilities should already be familiar to most readers in the context of photons coupled to atomic systems. Those concepts can be carried over essentially unchanged to plasmons, and by doing so, we recover our quasilinear theory rewritten in quantum language.

plasmons: quantized plasma wave's particles

23.3.1 Plasmon Occupation Number η

23.3.1

A major role in the quantum theory is played by the *occupation number* for electrostatic wave modes, which are just the single-particle states of quantum theory. Our electrostatic waves have spin zero, since there is no polarization freedom (the direction of \mathbf{E} is unique: it must point along \mathbf{k}). In other words, there is only one polarization state for each \mathbf{k} , so the number of modes (i.e., of quantum states) in a volume

$d\mathcal{V}_x d\mathcal{V}_k = dx dy dz dk_x dk_y dk_z$ of phase space is $dN_{\text{states}} = d\mathcal{V}_x d\mathcal{V}_k / (2\pi)^3$, and correspondingly, the number density of states in phase space is

$$dN_{\text{states}}/d\mathcal{V}_x d\mathcal{V}_k = 1/(2\pi)^3 \quad (23.30)$$

(cf. Sec. 3.2.5 with $\mathbf{p} = \hbar\mathbf{k}$). The density of energy in phase space is $\mathcal{E}_{\mathbf{k}}$, and the energy of an individual plasmon is $\hbar\omega_r$, so the number density of plasmons in phase space is

$$dN_{\text{plasmons}}/d\mathcal{V}_x d\mathcal{V}_k = \mathcal{E}_{\mathbf{k}}/\hbar\omega_r. \quad (23.31)$$

Therefore, the states' occupation number is given by

Langmuir plasmons' mean occupation number

$$\eta(\mathbf{k}, \mathbf{x}, t) = \frac{dN_{\text{plasmons}}/d\mathcal{V}_x d\mathcal{V}_k}{dN_{\text{states}}/d\mathcal{V}_x d\mathcal{V}_k} = \frac{dN_{\text{plasmons}}}{d\mathcal{V}_x d\mathcal{V}_k / (2\pi)^3} = \frac{(2\pi)^3 \mathcal{E}_{\mathbf{k}}}{\hbar\omega_r}. \quad (23.32)$$

This is actually the mean occupation number; the occupation numbers of individual states will fluctuate statistically around this mean. In this chapter (as in most of our treatment of statistical physics in Part II of this book), we do not deal with the individual occupation numbers, since quasilinear theory is oblivious to them and deals only with the mean. Thus, without any danger of ambiguity, we simplify our terminology by suppressing the word "mean."

Equation (23.32) says that $\eta(\mathbf{k}, \mathbf{x}, t)$ and $\mathcal{E}_{\mathbf{k}}$ are the same quantity, aside from normalization. In the classical formulation of quasilinear theory we use $\mathcal{E}_{\mathbf{k}}$; in the equivalent quantum formulation we use η . We can think of η equally well as a function of the state's wave number \mathbf{k} or of the momentum $\mathbf{p} = \hbar\mathbf{k}$ of the individual plasmons that reside in the state.

The third expression in Eq. (23.32) allows us to think of η as the number density in \mathbf{x} - \mathbf{k} phase space, with the relevant phase-space volume renormalized from $d\mathcal{V}_k$ to $d\mathcal{V}_k / (2\pi)^3 = (dk_x/2\pi)(dk_y/2\pi)(dk_z/2\pi)$. The factors of 2π appearing here are the same ones as appear in the relationship between a spatial Fourier transform and its inverse [e.g., Eq. (23.8)]. We shall see the quantity $d\mathcal{V}_k / (2\pi)^3$ appearing over and over again in the quantum mechanical theory, and it can generally be traced to that Fourier transform relationship.

23.3.2 Evolution of η for Plasmons via Interaction with Electrons

CLASSICAL FORMULA FOR EVOLUTION OF η

The motion of individual plasmons is governed by Hamilton's equations with the hamiltonian determined by their dispersion relation:

$$H(\mathbf{p}, \mathbf{x}, t) = \hbar\omega_r(\mathbf{k} = \mathbf{p}/\hbar, \mathbf{x}, t); \quad (23.33)$$

see Sec. 7.3.2. The plasmon trajectories in phase space are, of course, identical to the wave-packet trajectories (the rays) of the classical wave theory, since

$$\frac{dx_j}{dt} = \frac{\partial H}{\partial p_j} = \frac{\partial \omega_r}{\partial k_j}, \quad \frac{dp_j}{dt} = \hbar \frac{\partial k_j}{\partial t} = -\frac{\partial H}{\partial x_j} = -\hbar \frac{\partial \omega_r}{\partial x_j}. \quad (23.34)$$

FIGURE 23.2 Feynman diagrams showing (a) creation and (b) annihilation of a plasmon (with momentum $\hbar\mathbf{k}$) by an electron (with momentum \mathbf{p}).

Interactions between the waves and resonant electrons cause $\mathcal{E}_{\mathbf{k}}$ to evolve as $d\mathcal{E}_{\mathbf{k}}/dt = 2\omega_i\mathcal{E}_{\mathbf{k}}$ [Eq. (23.29a)]. Therefore, the plasmon occupation number will also vary as

$$\boxed{\frac{d\eta}{dt} \equiv \frac{\partial\eta}{\partial t} + \frac{dx_j}{dt} \frac{\partial\eta}{\partial x_j} + \frac{dp_j}{dt} \frac{\partial\eta}{\partial p_j} = 2\omega_i\eta,} \quad (23.35)$$

evolution of plasmon (mean) occupation number

where dx_j/dt and dp_j/dt are given by Hamilton's equations (23.34).

QUANTUM FORMULA FOR EVOLUTION OF η

The fundamental process that we are dealing with in Eq. (23.35) is the creation (or annihilation) of a plasmon by an electron (Fig. 23.2). The kinematics of this process is simple: energy and momentum must be conserved in the interaction. In plasmon creation (Fig. 23.2a), the plasma gains one quantum of energy $\hbar\omega_r$, so the electron must lose this same energy: $\hbar\omega_r = -\Delta(m_e v^2/2) \simeq -\Delta\mathbf{p} \cdot \mathbf{v}$, where $\Delta\mathbf{p}$ is the electron's change of momentum, and \mathbf{v} is its velocity; by “ \simeq ” we assume that the electron's fractional change of energy is small (an assumption inherent in quasilinear theory). Since the plasmon momentum change, $\hbar\mathbf{k}$, is minus the electron momentum change, we conclude that

$$\hbar\omega_r = -\Delta(m_e v^2/2) \simeq -\Delta\mathbf{p} \cdot \mathbf{v} = \hbar\mathbf{k} \cdot \mathbf{v}. \quad (23.36)$$

conservation of energy and momentum in the creation of plasmons: electron resonance and surfing

This is just the resonance condition contained in the delta function $\delta(\omega_r - \mathbf{k} \cdot \mathbf{v})$ of Eq. (23.29c). Thus, energy and momentum conservation in the fundamental plasmon creation process imply that the electron producing the plasmon must resonate with the plasmon's mode (i.e., the component of the electron's velocity along \mathbf{k} must be the same as the mode's phase speed). In other words, the electron must “surf” with the wave mode in which it is creating the plasmon, always remaining in the same trough or crest of the mode.

A fundamental quantity in the quantum description is the probability per unit time for an electron with velocity \mathbf{v} to *spontaneously* emit a Langmuir plasmon into a volume $\Delta\mathcal{V}_{\mathbf{k}}$ in \mathbf{k} space (i.e., the number of \mathbf{k} plasmons emitted by a single velocity- \mathbf{v}

electron per unit time into the volume $\Delta\mathcal{V}_k$ centered on some wave vector \mathbf{k}). This probability is expressed in the following form:

spontaneous emission
of Langmuir plasmons:
fundamental probability W

$$\left(\frac{dN_{\text{plasmons}}}{dt} \right)_{\text{from one electron}} \equiv W(\mathbf{v}, \mathbf{k}) \frac{\Delta\mathcal{V}_k}{(2\pi)^3}. \quad (23.37)$$

In a volume $\Delta\mathcal{V}_x$ of physical space and $\Delta\mathcal{V}_v$ of electron-velocity space, there are $dN_e = f(\mathbf{v})\Delta\mathcal{V}_x\Delta\mathcal{V}_v$ electrons. Equation (23.37) tells us that these electrons increase the number of plasmons in $\Delta\mathcal{V}_x$, and with \mathbf{k} in $\Delta\mathcal{V}_k$, by

$$\left(\frac{dN_{\text{plasmons}}}{dt} \right)_{\text{from all electrons in } \Delta\mathcal{V}_x\Delta\mathcal{V}_v} \equiv W(\mathbf{v}, \mathbf{k}) \frac{\Delta\mathcal{V}_k}{(2\pi)^3} f(\mathbf{v})\Delta\mathcal{V}_x\Delta\mathcal{V}_v. \quad (23.38)$$

Dividing by $\Delta\mathcal{V}_x$ and by $\Delta\mathcal{V}_k/(2\pi)^3$, and using the second expression for η in Eq. (23.32), we obtain for the rate of change of the plasmon occupation number produced by electrons with velocity \mathbf{v} in $\Delta\mathcal{V}_v$:

$$\left(\frac{d\eta(\mathbf{k})}{dt} \right)_{\text{from all electrons in } \Delta\mathcal{V}_v} = W(\mathbf{v}, \mathbf{k}) f(\mathbf{v})\Delta\mathcal{V}_v. \quad (23.39)$$

Integrating over all of velocity space, we obtain a final expression for the influence of spontaneous plasmon emission, by electrons of all velocities, on the plasmon occupation number:

spontaneous plasmon
emission

$$\left(\frac{d\eta(\mathbf{k})}{dt} \right)_s = \int W(\mathbf{v}, \mathbf{k}) f(\mathbf{v}) d\mathcal{V}_v. \quad (23.40)$$

(Here and below the subscript s means “spontaneous.”) Our introduction of the factor $(2\pi)^3$ in the definition (23.37) of $W(\mathbf{v}, \mathbf{k})$ was designed to avoid a factor $(2\pi)^3$ in this equation for the evolution of the occupation number.

Below [Eq. (23.45)] we deduce the fundamental emission rate W for high-speed Langmuir plasmons by comparing with our classical formulation of quasilinear theory.

Because the plasmons have spin zero, they obey Bose-Einstein statistics, which means that the rate for *induced* emission of plasmons is larger than that for spontaneous emission by the occupation number η of the state that receives the plasmons. Furthermore, the principle of detailed balance (“unitarity” in quantum mechanical language) tells us that W is also the relevant transition probability for the inverse process of absorption of a plasmon in a transition between the same two electron momentum states (Fig. 23.2b). This permits us to write down a *master equation* for the evolution of the plasmon occupation number in a homogeneous plasma:

master equation for
evolution of plasmon
occupation number

$$\frac{d\eta}{dt} = \int W(\mathbf{v}, \mathbf{k}) \left\{ f(\mathbf{v})[1 + \eta(\mathbf{k})] - f(\mathbf{v} - \hbar\mathbf{k}/m_e)\eta(\mathbf{k}) \right\} d\mathcal{V}_v. \quad (23.41)$$

The $f(\mathbf{v})$ term in the integrand is the contribution from spontaneous emission, the $f(\mathbf{v})\eta(\mathbf{k})$ term is that from induced emission, and the $f(\mathbf{v} - \hbar\mathbf{k}/m_e)\eta(\mathbf{k})$ term is from absorption.

COMPARISON OF CLASSICAL AND QUANTUM FORMULAS FOR $d\eta/dt$;

THE FUNDAMENTAL QUANTUM EMISSION RATE W

The master equation (23.41) is actually the evolution law (23.35) for η in disguise, with the e -folding rate ω_i written in a fundamental quantum mechanical form. To make contact with Eq. (23.35), we first notice that in our classical development of quasilinear theory, for which $\eta \gg 1$, we neglected spontaneous emission, so we drop it from Eq. (23.41). In the absorption term, the momentum of the plasmon is so much smaller than the electron momentum that we can make a Taylor expansion:

$$f(\mathbf{v} - \hbar\mathbf{k}/m_e) \simeq f(\mathbf{v}) - (\hbar/m_e)(\mathbf{k} \cdot \nabla_v)f. \quad (23.42)$$

Inserting this into Eq. (23.41) and removing the spontaneous-emission term, we obtain

$$\frac{d\eta}{dt} \simeq \eta \int W \frac{\hbar}{m_e} (\mathbf{k} \cdot \nabla_v) f d\mathcal{V}_v. \quad (23.43)$$

For comparison, Eq. (23.35), with ω_i given by the classical high-speed Langmuir relation (23.12b) and converted to 3-dimensional notation, becomes

$$\frac{d\eta}{dt} = \eta \int \frac{\pi e^2 \omega_r}{\epsilon_0 k^2 m_e} \delta(\omega_r - \mathbf{k} \cdot \mathbf{v}) \mathbf{k} \cdot \nabla_v f d\mathcal{V}_v. \quad (23.44)$$

Comparing Eqs. (23.43) and (23.44), we infer that the fundamental quantum emission rate for plasmons must be

$$W = \frac{\pi e^2 \omega_r}{\epsilon_0 k^2 \hbar} \delta(\omega_r - \mathbf{k} \cdot \mathbf{v}). \quad (23.45)$$

fundamental plasmon
emission rate deduced
from classical limit

Note that this emission rate is inversely proportional to \hbar and is therefore a very large number under the classical conditions of our quasilinear theory.

This computation has shown that the classical absorption rate $-\omega_i$ is the difference between the quantum mechanical absorption rate and induced emission rate. Under normal conditions, when $\mathbf{k} \cdot \nabla_v f < 0$ ($\partial F_0/\partial v < 0$ in 1-dimensional language), the absorption dominates over emission, so the absorption rate $-\omega_i$ is positive, describing Landau damping. However (as we saw in Chap. 22), when this inequality is reversed, there can be wave growth [subject of course to there being a suitable mode into which the plasmons can be emitted, as guaranteed when the Penrose criterion (22.50) is fulfilled].

SPONTANEOUS EMISSION OF LANGMUIR PLASMONS AS CERENKOV RADIATION

Although spontaneous emission was absent from our classical development of quasilinear theory, it nevertheless can be a classical process and therefore must be added

FIGURE 23.3 Geometry for Cerenkov emission. An electron moving with velocity \mathbf{v} and speed $v = |\mathbf{v}|$ emits waves with phase speed $V_{\text{ph}} < v$ along a direction $\hat{\mathbf{k}}$ that makes an angle $\alpha = \cos^{-1}(V_{\text{ph}}/v)$ with the direction of the electron's motion. The slanted solid line is a phase front.

plasmon emission as Cerenkov radiation

to the quasilinear formalism. Classically or quantum mechanically, the spontaneous emission is a form of *Cerenkov radiation*, since (as for Cerenkov light emitted by electrons moving through a dielectric medium), the plasmons are produced when an electron moves through the plasma faster than the waves' phase velocity. More specifically, only when $v > V_{\text{ph}} = \omega_r/k$ can there be an angle α of \mathbf{k} relative to \mathbf{v} along which the resonance condition is satisfied: $\mathbf{v} \cdot \hat{\mathbf{k}} = v \cos \alpha = \omega_r/k$. The plasmons are emitted at this angle α to the electron's direction of motion (Fig. 23.3).

The spontaneous Cerenkov emission rate (23.40) takes the following form when we use the Langmuir expression (23.45) for W :

$$\left(\frac{d\eta}{dt}\right)_s = \frac{\pi e^2 \omega_r}{\epsilon_0 \hbar k^2} \int f(\mathbf{v}) \delta(\omega_r - \mathbf{k} \cdot \mathbf{v}) d\mathcal{V}_v. \quad (23.46)$$

Translated into classical language via Eq. (23.32), this Cerenkov emission rate is

$$\boxed{\left(\frac{d\mathcal{E}_{\mathbf{k}}}{dt}\right)_s = \frac{e^2 \omega_r^2}{8\pi^2 \epsilon_0 k^2} \int f(\mathbf{v}) \delta(\omega_r - \mathbf{k} \cdot \mathbf{v}) d\mathcal{V}_v.} \quad (23.47)$$

Note that Planck's constant is absent from the classical expression, but present in the quantum one.

In the above analysis, we computed the fundamental emission rate W by comparing the quantum induced emission rate minus absorption rate with the classical growth rate for plasma energy. An alternative route to Eq. (23.45) for W would have been to use classical plasma considerations to compute the classical Cerenkov emission rate (23.47), then convert to quantum language using $\eta = (2\pi)^3 \mathcal{E}_{\mathbf{k}} / \hbar \omega_r$, thereby obtaining Eq. (23.46), and then compare with the fundamental formula (23.40).

By comparing Eqs. (23.44) and (23.46) and assuming a thermal (Maxwellian) distribution for the electron velocities, we see that the spontaneous Cerenkov emission is ignorable in comparison with Landau damping when the electron temperature T_e is smaller than $\eta \hbar \omega_r / k_B$. Sometimes it is convenient to define a classical brightness

conditions for spontaneous Cerenkov emission to be ignorable

temperature $T_B(\mathbf{k})$ for the plasma waves given implicitly by

$$\eta(\mathbf{k}) \equiv [e^{\hbar\omega_r/[k_B T_B(\mathbf{k})]} - 1]^{-1} \quad (23.48)$$

$$\simeq \frac{k_B T_B(\mathbf{k})}{\hbar\omega_r} \quad \text{when } \eta(\mathbf{k}) \gg 1, \text{ as in the classical regime.}$$

In this language, spontaneous emission of plasmons with wave vector \mathbf{k} is generally ignorable when the wave brightness temperature exceeds the electron kinetic temperature—as one might expect on thermodynamic grounds. In a plasma in strict thermal equilibrium, Cerenkov emission is balanced by Landau damping, so as to maintain a thermal distribution of Langmuir waves with a temperature equal to that of the electrons: $T_B(\mathbf{k}) = T_e$ for all \mathbf{k} .

the balance of Cerenkov emission by Landau damping in thermal equilibrium

Exercise 23.3 Problem: Cerenkov Power in Electrostatic Waves

Show that the Langmuir wave power radiated by an electron moving with speed v in a plasma with plasma frequency ω_p is given by

$$P \simeq \frac{e^2 \omega_p^2}{4\pi \epsilon_0 v} \ln \left(\frac{k_{\max} v}{\omega_p} \right), \quad (23.49)$$

where k_{\max} is the largest wave number at which the waves can propagate. (For larger k the waves are strongly Landau damped.)

EXERCISES

23.3.3 Evolution of f for Electrons via Interaction with Plasmons

23.3.3

Now turn from the evolution of the plasmon distribution $\eta(\mathbf{k}, \mathbf{x}, t)$ to that of the particle distribution $f(\mathbf{v}, \mathbf{x}, t)$. Classically, f evolves via the velocity-space diffusion equation (23.29d). We shall write down a fundamental quantum mechanical evolution equation (the “kinetic equation”) that appears at first sight to differ remarkably from Eq. (23.29d), but then we will recover (23.29d) in the classical limit.

To derive the electron kinetic equation, we must consider three electron velocity states, \mathbf{v} and $\mathbf{v} \pm \hbar\mathbf{k}/m_e$ (Fig. 23.4). Momentum conservation says that an electron can move between these states by emission or absorption of a plasmon with wave vector \mathbf{k} . The fundamental probability for these transitions is the same one, W , as for plasmon

FIGURE 23.4 Three-level system for understanding the electron kinetic equation.

evolution of averaged electron distribution function due to plasmon emission and absorption—fundamental form of equation

emission, since these transitions are merely plasmon emissions and absorptions as seen from the electron's viewpoint. Therefore, the electron kinetic equation must take the form

$$\frac{df(\mathbf{v})}{dt} = \int \frac{d\mathcal{V}_k}{(2\pi)^3} \left\{ (1 + \eta) [W(\mathbf{v} + \hbar\mathbf{k}/m_e, \mathbf{k}) f(\mathbf{v} + \hbar\mathbf{k}/m_e) - W(\mathbf{v}, \mathbf{k}) f(\mathbf{v})] - \eta [W(\mathbf{v} + \hbar\mathbf{k}/m_e, \mathbf{k}) f(\mathbf{v}) - W(\mathbf{v}, \mathbf{k}) f(\mathbf{v} - \hbar\mathbf{k}/m_e)] \right\}. \quad (23.50)$$

The four terms can be understood by inspection of Fig. 23.4. The two downward transitions in that diagram entail plasmon emission and thus are weighted by $(1 + \eta)$, where the 1 is the spontaneous contribution and the η is the induced emission. In the first of these $(1 + \eta)$ terms in Eq. (23.50), the \mathbf{v} electron state gets augmented, so the sign is positive; in the second it gets depleted, so the sign is negative. The two upward transitions entail plasmon absorption and thus are weighted by η ; the sign in Eq. (23.50) is plus when the final electron state has velocity \mathbf{v} , and minus when the initial state is \mathbf{v} .

In the domain of classical quasilinear theory, the momentum of each emitted or absorbed plasmon must be small compared to that of the electron, so we can expand the terms in Eq. (23.50) in powers of $\hbar\mathbf{k}/m_e$. Carrying out that expansion to second order and retaining those terms that are independent of \hbar and therefore classical, we obtain (Ex. 23.4) the *quasilinear electron kinetic equation*:

evolution of averaged electron distribution in quasilinear domain—Fokker-Planck equation

$$\boxed{\frac{df}{dt} = \nabla_v \cdot [\mathbf{R}(\mathbf{v})f + \mathbf{D}(\mathbf{v}) \cdot \nabla_v f]}, \quad (23.51a)$$

where ∇_v is the gradient in velocity space (and not $\mathbf{v} \cdot \nabla$), and where

$$\mathbf{R}(\mathbf{v}) = \int \frac{d\mathcal{V}_k}{(2\pi)^3} \frac{W(\mathbf{v}, \mathbf{k}) \hbar\mathbf{k}}{m_e}, \quad (23.51b)$$

$$\mathbf{D}(\mathbf{v}) = \int \frac{d\mathcal{V}_k}{(2\pi)^3} \frac{\eta(\mathbf{k}) W(\mathbf{v}, \mathbf{k}) \hbar\mathbf{k} \otimes \hbar\mathbf{k}}{m_e^2}. \quad (23.51c)$$

Note that \mathbf{R} is a resistive coefficient associated with spontaneous emission, and \mathbf{D} is a diffusive coefficient associated with plasmon absorption and induced emission in the limit that electron recoil due to spontaneous emission can be ignored. Following Eq. (6.106c), we can rewrite Eq. (23.51c) for \mathbf{D} as

$$\mathbf{D} = \left\langle \frac{\Delta\mathbf{v} \otimes \Delta\mathbf{v}}{\Delta t} \right\rangle \quad (23.51d)$$

with $\Delta\mathbf{v} = -\hbar\mathbf{k}/m_e$.

Our electron kinetic equation (23.51a) has the standard Fokker-Planck form (6.94) derived in Sec. 6.9.1 (generalized to three dimensions), except that the resistive coefficient there is $A = -R + \partial D/\partial v$ and the diffusion coefficient there is $B = 2D$. Note that the diffusive term here has the form $(\partial/\partial v)(D \partial f/\partial v)$ discussed in Ex. 6.21 [Eq. (6.102)], as it should, because our formalism does not admit electron recoil (so

the probability of a change in \mathbf{v} due to plasmon absorption is the same as for the opposite change due to plasmon emission).

In our classical, quasilinear analysis, we ignored spontaneous emission and thus had no resistive term \mathbf{R} in the evolution equation (23.29d) for f . We can recover that evolution equation and its associated \mathbf{D} by dropping the resistive term from the quantum kinetic equation (23.51a) and inserting expression (23.45) for W into Eq. (23.51c) for the quantum \mathbf{D} . The results agree with the classical equations (23.29c) and (23.29d).

Exercise 23.4 *Derivation: Electron Fokker-Planck Equation*

Fill in the missing details in the derivation of the electron Fokker-Planck equation (23.51a). It may be helpful to use index notation.

23.3.4 Emission of Plasmons by Particles in the Presence of a Magnetic Field

23.3.4

Let us return briefly to Cerenkov emission by an electron or ion. In the presence of a background magnetic field \mathbf{B} , the resonance condition for Cerenkov emission must be modified. Only the momentum parallel to the magnetic field need be conserved, not the total vectorial momentum. The unbalanced components of momentum perpendicular to \mathbf{B} are compensated by a reaction force from \mathbf{B} itself and thence by the steady currents that produce \mathbf{B} ; correspondingly, the unbalanced perpendicular momentum ultimately does work on those currents. In this situation, one can show that the Cerenkov resonance condition $\omega_r - \mathbf{k} \cdot \mathbf{v} = 0$ is modified to

$$\omega_r - \mathbf{k}_{\parallel} \cdot \mathbf{v}_{\parallel} = 0, \quad (23.52)$$

where \parallel means the component parallel to \mathbf{B} . If we allow for the electron gyration motion as well, then some number N of gyration (cyclotron) quanta can be fed into each emitted plasmon, so Eq. (23.52) gets modified to read

$$\omega_r - \mathbf{k}_{\parallel} \cdot \mathbf{v}_{\parallel} = N\omega_{ce}, \quad (23.53)$$

where N is an integer. For nonrelativistic electrons, the strongest resonance is for $N = 1$. We use this modified Cerenkov resonance condition in Sec. 23.4.1.

Cerenkov resonance condition in presence of a magnetic field

23.3.5 Relationship between Classical and Quantum Mechanical Formalisms

23.3.5

We have demonstrated how the structure of the classical quasilinear equations is mandated by quantum mechanics. In developing the quantum equations, we had to rely on one classical calculation, Eq. (23.44), which gave us the emission rate W . However, even this was not strictly necessary, since with significant additional effort we could have calculated the relevant quantum mechanical matrix elements and then computed W directly from Fermi's golden rule.² This has to be the case, because

2. See, for example, Cohen-Tannoudji, Diu, and Laloë (1977), and, in the plasma physics context, Melrose (2008, 2012).

using quantum calculations in the classical domain

quantum mechanics is the fundamental physical theory and thus must be applicable to plasma excitations just as it is applicable to atoms. Of course, if we are only interested in classical processes, as is usually the case in plasma physics, then we end up taking the limit $\hbar \rightarrow 0$ in all observable quantities, and the classical rate is all we need.

This raises an important point of principle. Should we perform our calculations classically or quantum mechanically? The best answer is to be pragmatic. Many calculations in nonlinear plasma theory are so long and arduous that we need all the help we can get to complete them. We therefore combine both classical and quantum considerations (confident that both must be correct throughout their overlapping domain of applicability), in whatever proportion minimizes our computational effort.

23.3.6 Evolution of η via Three-Wave Mixing

We have discussed plasmon emission and absorption both classically and quantum mechanically. Our classical and quantum formalisms can be generalized straightforwardly to encompass other nonlinear processes.

Among the most important other processes are three-wave interactions (in which two waves coalesce to form a third wave or one wave splits up into two) and scattering processes (in which waves are scattered off particles without creating or destroying plasmons). In this section we focus on three-wave mixing. We present the main ideas in the text but leave most of the details to Exs. 23.5 and 23.6.

three-wave mixing in general

In three-wave mixing, where waves A and B combine to create wave C (Fig. 23.5a), the equation for the growth of the amplitude of wave C will contain nonlinear driving terms that combine the harmonic oscillations of waves A and B , that is, driving terms proportional to $\exp[i(\mathbf{k}_A \cdot \mathbf{x} - \omega_A t)] \exp[i(\mathbf{k}_B \cdot \mathbf{x} - \omega_B t)]$. For wave C to build up coherently over many oscillation periods, it is necessary that the spacetime dependence of these driving terms be the same as that of wave C , $\exp[i(\mathbf{k}_C \cdot \mathbf{x} - \omega_C t)]$; in other words, it is necessary that

$$\mathbf{k}_C = \mathbf{k}_A + \mathbf{k}_B, \quad \omega_C = \omega_A + \omega_B. \quad (23.54)$$

Quantum mechanically, these expressions can be recognized as momentum and energy conservation for the waves' plasmons. We have met three-wave mixing previously, for electromagnetic waves in a nonlinear dielectric crystal (Sec. 10.6). There, as here, the conservation laws (23.54) were necessary for the mixing to proceed; see Eqs. (10.29) and associated discussion.

When the three waves are all electrostatic, the three-wave mixing arises from the nonlinear term (23.6) in the rapidly varying part [wave part, Eq. (23.5)] of the Vlasov equation, which we discarded in our quasilinear analysis. Generalized to 3 dimensions with this term treated as a driver, that Vlasov equation takes the form

three-wave mixing for electrostatic waves: driving term from quasilinear analysis

$$\frac{\partial f_1}{\partial t} + \mathbf{v} \cdot \nabla f_1 - \frac{e}{m_e} \mathbf{E} \cdot \nabla_v f_0 = \frac{e}{m_e} (\mathbf{E} \cdot \nabla_v f_1 - (\mathbf{E} \cdot \nabla_v f_1)). \quad (23.55)$$

In the driving term (right-hand side of this equation), \mathbf{E} could be the electric field of wave A and f_1 could be the perturbed velocity distribution of wave B or vice versa,

FIGURE 23.5 (a) A three-wave process in which two plasmons A and B interact nonlinearly to create a third plasmon C . Conserving energy and linear momentum, we obtain $\omega_C = \omega_A + \omega_B$ and $\mathbf{k}_C = \mathbf{k}_A + \mathbf{k}_B$. For example, A and C might be transverse electromagnetic plasmons satisfying the dispersion relation (21.24), and B might be a longitudinal plasmon (Langmuir or ion acoustic); or A and C might be Langmuir plasmons, and B might be an ion-acoustic plasmon—the case treated in the text and in Exs. 23.5 and 23.6. (b) The time-reversed three-wave process in which plasmon C generates plasmon B by an analog of Cerenkov emission, and while doing so recoils into plasmon state A .

and the \mathbf{E} and f_1 terms on the left side could be those of wave C . If the wave vectors and frequencies are related by Eq. (23.54), then via this equation waves A and B will coherently generate wave C .

The dispersion relations for Langmuir and ion-acoustic waves permit the conservation law (23.54) to be satisfied if A is Langmuir (so $\omega_A \sim \omega_{pe}$), B is ion acoustic (so $\omega_B \lesssim \omega_{pp} \ll \omega_A$), and C is Langmuir. By working out the detailed consequences of the driving term (23.55) in the quasilinear formalism and comparing with the quantum equations for three-wave mixing (Ex. 23.5), one can deduce the fundamental rate for the process $A + B \rightarrow C$ [Fig. 23.5a; Eqs. (23.56)]. Detailed balance (unitarity) guarantees that the time-reversed process $C \rightarrow A + B$ (Fig. 23.5b) will have identically the same fundamental rate. This time-reversed process has a physical interpretation analogous to the emission of a Cerenkov plasmon by a high-speed, resonant electron: C is a “high-energy” Langmuir plasmon ($\omega_C \sim \omega_{pe}$) that can be thought of as Cerenkov-emitting a “low-energy” ion-acoustic plasmon ($\omega_B \lesssim \omega_{pp} \ll \omega_C$) and in the process recoiling slightly into Langmuir state A .

The fundamental rate that one obtains for this wave-wave Cerenkov process $A + B \rightarrow C$ and its time reversal $C \rightarrow A + B$, when the plasma’s electrons are thermalized at temperature T_e , is (Ex. 23.5)³

$$W_{AB \leftrightarrow C} = R_{AB \leftrightarrow C}(\mathbf{k}_A, \mathbf{k}_B, \mathbf{k}_C) \delta(\mathbf{k}_A + \mathbf{k}_B - \mathbf{k}_C) \delta(\omega_A + \omega_B - \omega_C), \quad (23.56a)$$

3. See also Tsytovich (1970, Eq. A.3.12). The rates for many other wave-wave mixing processes are worked out in this book, but beware: it contains a large number of typographical errors.

electrostatic three-wave mixing—two Langmuir waves (A and C) and one ion-acoustic wave (B)

fundamental rate for Cerenkov emission of ion-acoustic plasmon by Langmuir plasmon

where

$$R_{AB\leftrightarrow C}(\mathbf{k}_A, \mathbf{k}_B, \mathbf{k}_C) = \frac{8\pi^5 \hbar e^2 (m_p/m_e) \omega_B^3}{(k_B T_e)^2 k_{ia}^2} (\hat{\mathbf{k}}_A \cdot \hat{\mathbf{k}}_C)^2. \quad (23.56b)$$

[Here we have written the ion-acoustic plasmon's wave number as k_{ia} instead of k_B , to avoid confusion with Boltzmann's constant; i.e., $k_{ia} \equiv |\mathbf{k}_B|$.]

This is the analog of the rate (23.45) for Cerenkov emission by an electron. The ion-acoustic occupation number will evolve via an evolution law analogous to Eq. (23.41) with this rate replacing W on the right-hand side, η replaced by the ion-acoustic occupation number η_B , and the electron distribution replaced by the A -mode or C -mode Langmuir occupation number; see Ex. 23.5. Moreover, there will be a similar evolution law for the Langmuir occupation number, involving the same fundamental rate (23.56); Ex. 23.6.

EXERCISES

Exercise 23.5 Example and Challenge: Three-Wave

Mixing—Ion-Acoustic Evolution

Consider the three-wave processes shown in Fig. 23.5, with A and C Langmuir plasmons and B an ion-acoustic plasmon. The fundamental rate is given by Eqs. (23.56a) and (23.56b).

- (a) By summing the rates of forward and backward reactions (Fig. 23.5a,b), show that the occupation number for the ion-acoustic plasmons satisfies the kinetic equation

$$\frac{d\eta_B}{dt} = \int W_{AB\leftrightarrow C} [(1 + \eta_A + \eta_B)\eta_C - \eta_A\eta_B] \frac{d\mathcal{V}_{k_A}}{(2\pi)^3} \frac{d\mathcal{V}_{k_C}}{(2\pi)^3}. \quad (23.57)$$

[Hint: (i) The rate for $A + B \rightarrow C$ (Fig. 23.5a) will be proportional to $(\eta_C + 1)\eta_A\eta_B$; why? (ii) When you sum the rates for the two diagrams, Fig. 23.5a and b, the terms involving $\eta_A\eta_B\eta_C$ should cancel.]

- (b) The ion-acoustic plasmons have far lower frequencies than the Langmuir plasmons, so $\omega_B \ll \omega_A \simeq \omega_C$. Assume that they also have far lower wave numbers, $|\mathbf{k}_B| \ll |\mathbf{k}_A| \simeq |\mathbf{k}_C|$. Assume further (as will typically be the case) that the ion-acoustic plasmons, because of their tiny individual energies, have far larger occupation numbers than the Langmuir plasmons, so $\eta_B \gg \eta_A \sim \eta_C$. Using these approximations, show that the evolution law (23.57) for the ion-acoustic waves reduces to the form

$$\begin{aligned} & \frac{d\eta_B(\mathbf{k})}{dt} \\ &= \eta_B(\mathbf{k}) \int R_{AB\leftrightarrow C}(\mathbf{k}' - \mathbf{k}, \mathbf{k}, \mathbf{k}') \delta[\omega_B(\mathbf{k}) - \mathbf{k} \cdot \mathbf{V}_{gL}(\mathbf{k}')] \mathbf{k} \cdot \nabla_{\mathbf{k}'} \eta_L(\mathbf{k}') \frac{d\mathcal{V}_{k'}}{(2\pi)^6}, \end{aligned} \quad (23.58)$$

where η_L is the Langmuir (waves A and C) occupation number, \mathbf{V}_{gL} is the Langmuir group velocity, and $R_{C\leftrightarrow BA}$ is the fundamental rate (23.56b).

- (c) Notice the strong similarities between the evolution equation (23.58) for the ion-acoustic plasmons that are Cerenkov emitted and absorbed by Langmuir plasmons, and the evolution equation (23.44) for Langmuir plasmons that are Cerenkov emitted and absorbed by fast electrons! Discuss the similarities and the physical reasons for them.
- (d) *Challenge:* Carry out an explicit classical calculation of the nonlinear interaction between Langmuir waves with wave vectors \mathbf{k}_A and \mathbf{k}_C to produce ion-acoustic waves with wave vector $\mathbf{k}_B = \mathbf{k}_C - \mathbf{k}_A$. Base your calculation on the nonlinear Vlasov equation (23.55) and [for use in relating \mathbf{E} and f_1 in the nonlinear term] the 3-dimensional analog of Eq. (23.13). Assume a spatially independent Maxwellian averaged electron velocity distribution f_0 with temperature T_e (so $\nabla f_0 = 0$). From your result compute, in the random-phase approximation, the evolution of the ion-acoustic energy density $\mathcal{E}_{\mathbf{k}}$ and thence the evolution of the occupation number $\eta(\mathbf{k})$. Bring that evolution equation into the functional form (23.58). By comparing quantitatively with Eq. (23.58), read off the fundamental rate $R_{C\leftrightarrow BA}$. Your result should be the rate in Eq. (23.56b).

Exercise 23.6 *Example and Challenge: Three-Wave Mixing—Langmuir Evolution*

This exercise continues the analysis of the preceding one.

- (a) Derive the kinetic equation for the Langmuir occupation number. [Hint: You will have to sum over four Feynman diagrams, corresponding to the mode of interest playing the role of A and then the role of C in each of the two diagrams in Fig. 23.5.]
- (b) Using the approximations outlined in part (b) of Ex. 23.5, show that the Langmuir occupation number evolves in accord with the diffusion equation

$$\frac{d\eta_L(\mathbf{k}')}{dt} = \nabla_{\mathbf{k}'} \cdot [\mathbf{D}(\mathbf{k}') \cdot \nabla_{\mathbf{k}'} \eta_L(\mathbf{k}')], \quad (23.59a)$$

where the diffusion coefficient is given by the following integral over the ion-acoustic-wave distribution:

$$\mathbf{D}(\mathbf{k}') = \int \eta_B(\mathbf{k}) \mathbf{k} \otimes \mathbf{k} R_{AB\leftrightarrow C}(\mathbf{k}' - \mathbf{k}, \mathbf{k}, \mathbf{k}') \delta[\omega_B(\mathbf{k}) - \mathbf{k} \cdot \mathbf{V}_{gL}(\mathbf{k}')] \frac{d\mathcal{V}_{k'}}{(2\pi)^6}. \quad (23.59b)$$

- (c) Discuss the strong similarity between the evolution law (23.59) for resonant Langmuir plasmons interacting with ion-acoustic waves, and the one for resonant electrons interacting with Langmuir waves [Eqs. (23.29c), (23.29d)]. Why are they so similar?

23.4 Quasilinear Evolution of Unstable Distribution Functions—A Bump in the Tail

In plasma physics, one often encounters a weak beam of electrons passing through a stable Maxwellian plasma, with electron density n_e , beam density n_b , and beam speed v_b much larger than the thermal width σ_e of the background plasma. When the velocity width of the beam σ_b is small compared with v_b , the distribution is known as a *bump-in-tail* distribution (see Fig. 23.6). In this section, we explore the stability and nonlinear evolution of such a distribution.

We focus on the simple case of a 1-dimensional electron distribution function $F_0(v)$ and approximate the beam by a Maxwellian distribution:

$$F_b(v) = \frac{n_b}{(2\pi)^{1/2}\sigma_b} e^{-(v-v_b)^2/(2\sigma_b^2)}, \quad (23.60)$$

where n_b is the beam electron density. For simplicity, we treat the protons as a uniform neutralizing background.

Now, let us suppose that at time $t = 0$, the beam is established, and the Langmuir wave energy density \mathcal{E}_k is very small. The waves will grow fastest when the waves' phase velocity $V_{\text{ph}} = \omega_r/k$ resides where the slope of the distribution function is most positive (i.e., when $V_{\text{ph}} = v_b - \sigma_b$). The associated maximum growth rate as computed from Eq. (23.12b) is

maximum growth rate for Langmuir waves

$$\omega_{i\text{max}} = \left(\frac{\pi}{8e}\right)^{1/2} \left(\frac{v_b}{\sigma_b}\right)^2 \left(\frac{n_b}{n_e}\right) \omega_p, \quad (23.61)$$

where $e = 2.718 \dots$ is not the electron charge. Modes will grow over a range of wave phase velocities $\Delta V_{\text{ph}} \sim \sigma_b$. By using the Bohm-Gross dispersion relation (21.31) rewritten in the form

$$\omega = \omega_p (1 - 3\sigma_e^2/V_{\text{ph}}^2)^{-1/2}, \quad (23.62)$$

we find that the bandwidth of the growing modes is given roughly by

$$\Delta\omega = K\omega_p \frac{\sigma_b}{v_b}, \quad (23.63)$$

where $K = 3(\sigma_e/v_b)^2[1 - 3(\sigma_e/v_b)^2]^{-3/2}$ is a constant typically $\gtrsim 0.1$. Combining Eqs. (23.61) and (23.63), we obtain

$$\frac{\omega_{i\text{max}}}{\Delta\omega} \sim \left(\frac{\pi}{8eK^2}\right)^{1/2} \left(\frac{v_b}{\sigma_b}\right)^3 \left(\frac{n_b}{n_e}\right). \quad (23.64)$$

Dropping constants of order unity, we conclude that the waves' growth time $\sim(\omega_{i\text{max}})^{-1}$ is long compared with their coherence time $\sim(\Delta\omega)^{-1}$, provided that

$$\sigma_b \gtrsim \left(\frac{n_b}{n_e}\right)^{1/3} v_b. \quad (23.65)$$

validity of quasilinear analysis

When inequality (23.65) is satisfied, the waves will take several coherence times to grow, and so we expect that no permanent phase relations will be established in

FIGURE 23.6 Evolution of the 1-dimensional electron distribution function from a bump-on-tail shape to a flat distribution function, due to the growth and scattering of electrostatic waves. The direction of evolution is indicated by the downward-pointing arrow at $v = v_b$.

the electric field and that quasilinear theory is an appropriate tool. However, when this inequality is reversed, the instability resembles more the two-stream instability of Chap. 21, and the growth is so rapid as to imprint special phase relations on the waves, so the random-phase approximation fails and quasilinear theory is invalid.

Restricting ourselves to slow growth, we use quasilinear theory to explore the evolution of the wave and particle distributions. We can associate the wave energy density \mathcal{E}_k not just with a given value of k but also with a corresponding value of $V_{\text{ph}} = \omega_r/k$, and thence with the velocities $v = V_{\text{ph}}$ of electrons that resonate with the waves. Using Eq. (23.22a) for the velocity diffusion coefficient and Eq. (23.12b) for the associated wave-growth rate, we can then write the temporal evolution equations for the electron distribution function $F_0(v, t)$ and the wave energy density $\mathcal{E}_k(v, t)$ as

$$\frac{\partial F_0}{\partial t} = \frac{\pi e^2}{m_e^2 \epsilon_0} \frac{\partial}{\partial v} \left(\frac{\mathcal{E}_k}{v} \frac{\partial F_0}{\partial v} \right), \quad \frac{\partial \mathcal{E}_k}{\partial t} = \frac{\pi e^2}{m_e \epsilon_0 \omega_p} v^2 \mathcal{E}_k \frac{\partial F_0}{\partial v}. \quad (23.66)$$

Here $v = \omega_r/k$ and, for simplicity, we have assumed a spatially homogeneous distribution of particles and waves so $d/dt \rightarrow \partial/\partial t$.

This pair of nonlinear equations must be solved numerically, but their qualitative behavior can be understood analytically without much effort; see Fig. 23.6. Waves resonant with the rising part of the electron distribution function at first grow exponentially, causing the particles to diffuse and flatten the slope of F_0 and thereby reduce the wave-growth rate. Ultimately, the slope $\partial F_0/\partial v$ diminishes to zero and the wave energy density becomes constant, with its integral, by energy conservation (Ex. 23.2), equal to the total kinetic energy lost by the beam. In this way we see that *a velocity-space irregularity in the distribution function leads to the growth of electrostatic waves, which can react back on the particles in such a way as to saturate the instability*. The

evolution equations for bump-in-tail instability of electrons interacting with Langmuir waves that all propagate in the same direction

qualitative description of the evolution

net result is a beam of particles with a much-broadened width propagating through the plasma. The waves will ultimately damp through three-wave processes or other damping mechanisms, converting their energy into heat.

EXERCISES

Exercise 23.7 *Problem: Stability of Isotropic Distribution Function*

For the bump-in-tail instability, the bump must show up in the 1-dimensional distribution function F_0 (after integrating out the electron velocity components orthogonal to the wave vector \mathbf{v}).

Consider an arbitrary, isotropic, 3-dimensional distribution function $f_0 = f_0(|\mathbf{v}|)$ for electron velocities—one that might even have an isotropic bump at large $|\mathbf{v}|$. Show that this distribution is stable against the growth of Langmuir waves (i.e., it produces $\omega_i < 0$ for all wave vectors \mathbf{k}).

23.4.1

23.4.1 Instability of Streaming Cosmic Rays

For a simple illustration of this general type of instability (but one dealing with a different wave mode), we return to the issue of the isotropization of galactic cosmic rays, which we introduced in Sec. 19.7. We argued there that cosmic rays propagating through the interstellar medium are effectively scattered by hydromagnetic Alfvén waves. We did not explain where these Alfvén waves originated. Although often there is an independent turbulence spectrum, sometimes these waves are generated by the cosmic rays themselves.

example of bump-in-tail instability: Alfvén waves generated by Cerenkov emission from cosmic rays' motion along interstellar magnetic field

Suppose we have a beam of cosmic rays propagating through the interstellar gas at high speed. The interstellar gas is magnetized, which allows many more types of wave modes to propagate than in the unmagnetized case. It turns out that the particle distribution is unstable to the growth of Alfvén wave modes satisfying the resonance condition (23.53), modified to account for mildly relativistic protons rather than nonrelativistic electrons:

$$\omega - \mathbf{k}_{\parallel} \cdot \mathbf{v}_{\parallel} = \omega_g. \quad (23.67)$$

Here $\omega_g = \omega_{cp} \sqrt{1 - v^2/c^2}$ is the proton's gyro frequency, equal to its nonrelativistic cyclotron frequency reduced by its Lorentz factor, and we assume that the number of cyclotron (gyro) quanta fed into each emitted Alfvén plasmon is $N = 1$. For pedagogical simplicity, let the wave propagate parallel to the magnetic field so $k = k_{\parallel}$. Then, since cosmic rays travel much faster than the Alfvén waves ($v \gg a = \omega/k$), the wave's frequency ω can be neglected in the resonance condition (23.67); equivalently, we can transform to a reference frame that moves with the Alfvén wave, so ω becomes zero, altering \mathbf{v}_{\parallel} hardly at all. The resonance condition (23.67) then implies that the distance the particle travels along the magnetic field when making one trip around its Larmor orbit is $v_{\parallel}(2\pi/\omega_g) = 2\pi/k$, which is the Alfvén wave's wavelength. This makes sense physically; it enables the wave to resonate with the particle's gyrational motion, absorbing energy from it.

The growth rate of these waves can be studied using a kinetic theory analogous to the one we have just developed for Langmuir waves (Kulsrud, 2005, Chap. 12; Melrose, 1984, Sec. 10.5). Dropping factors of order unity, the growth rate for waves that scatter cosmic rays of energy E is given approximately by

$$\omega_i \simeq \left(\frac{n_{cr}}{n_p} \right) \omega_{cp} \left(\frac{u_{cr}}{a} - 1 \right), \quad (23.68)$$

where n_{cr} is the number density of cosmic rays with energy $\sim E$, n_p is the number density of thermal protons in the background plasma, u_{cr} is the mean speed of the cosmic ray protons through the background plasma, and a is the Alfvén speed; see Ex. 23.8. Therefore, if the particles have a mean speed greater than the Alfvén speed, the waves will grow, exponentially at first.

It is observed that the energy density of cosmic rays in our galaxy builds up until it is roughly comparable with that of the thermal plasma. As more cosmic rays are produced, they escape from the galaxy at a sufficient rate to maintain this balance. Therefore, in a steady state, the ratio of the number density of cosmic rays to the thermal proton density is roughly the inverse of their mean-energy ratio. Adopting a mean cosmic ray energy of ~ 1 GeV and an ambient temperature in the interstellar medium of $T \sim 10^4$ K, this ratio of number densities is $\sim 10^{-9}$. The ion gyro period in the interstellar medium is ~ 100 s for a typical field of strength of ~ 100 pT. Cosmic rays streaming at a few times the Alfvén speed create Alfvén waves in $\sim 10^{10}$ s, of order a few hundred years—long before they escape from the galaxy (e.g., Longair, 2011).

The waves then react back on the cosmic rays, scattering them in momentum space [Eq. (23.51a)]. Now, each time a particle is scattered by an Alfvén-wave quantum, the ratio of its energy change to the magnitude of its momentum change must be the same as that in the waves and equal to the Alfvén speed, which is far smaller than the original energy-to-momentum ratio of the particle ($\sim c$) for a mildly relativistic proton. Therefore, the effect of the Alfvén waves is to scatter the particle directions without changing their energies significantly. As the particles are already gyrating around the magnetic field, the effect of the waves is principally to change the angle between their momenta and the field (known as the *pitch angle*), so as to reduce their mean speed along the magnetic field.

When this mean speed is reduced to a value of order the Alfvén speed, the growth rate diminishes, just like the growth rate of Langmuir waves is diminished after the electron distribution function is flattened. Under a wide variety of conditions, cosmic rays are believed to maintain the requisite energy density in Alfvén-wave turbulence to prevent them from streaming along the magnetic field with a mean speed much faster than the Alfvén speed (which varies between ~ 3 and ~ 30 km s $^{-1}$). This model of their transport differs from spatial diffusion, which we assumed in Sec. 19.7.3, but the end result is similar, and cosmic rays are confined to our galaxy for more than ~ 10 million years. These processes can be observed directly using spacecraft in the interplanetary medium.

Alfvén waves scatter cosmic rays until their speeds along the magnetic field are reduced to Alfvén speed, saturating the bump-in-tail instability

EXERCISES

Exercise 23.8 *Challenge: Alfvén Wave Emission by Streaming Cosmic Rays*

Consider a beam of high-energy cosmic ray protons streaming along a uniform background magnetic field in a collisionless plasma. Let the cosmic rays have an isotropic distribution function in a frame that moves along the magnetic field with speed u , and assume that u is large compared with the Alfvén speed but small compared with the speeds of the individual cosmic rays. Adapt our discussion of the emission of Langmuir waves by a bump-on-tail distribution to show that the growth rate is given to order of magnitude by Eq. (23.68).

For a solution using an order-of-magnitude analysis, see Kulsrud (2005, Sec. 12.2). For a detailed analysis using quasilinear theory, and then a quasilinear study of the diffusion of cosmic rays in the Alfvén waves they have generated, see Kulsrud (2005, Secs. 12.3–12.5).

23.5

23.5 Parametric Instabilities; Laser Fusion

laser fusion

One of the approaches to the goal of attaining commercial nuclear fusion (Sec. 19.3.1) is to compress and heat pellets containing a mixture of deuterium and tritium by using powerful lasers. The goal is to produce gas densities and temperatures large enough, and for long enough, that the nuclear energy released exceeds the energy expended in producing the compression (Box 23.2). At these densities the incident laser radiation behaves like a large-amplitude plasma wave and is subject to a new type of instability that may already be familiar from dynamics, namely, a *parametric instability*.

Consider how the incident light is absorbed by the relatively tenuous ionized plasma around the pellet. The critical density at which the incident wave frequency equals the plasma frequency is $\rho \sim 5\lambda_{\mu\text{m}}^{-2} \text{ kg m}^{-3}$, where $\lambda_{\mu\text{m}}$ is the wavelength measured in microns. For an incident wave energy flux $F \sim 10^{18} \text{ W m}^{-2}$, the amplitude of the wave's electric field $E \sim [F/(\epsilon_0 c)]^{1/2} \sim 2 \times 10^{10} \text{ V m}^{-1}$. The velocity of a free electron oscillating in a wave this strong is $v \sim eE/(m_e \omega) \sim 2,000 \text{ km s}^{-1}$, which is almost 1% of the speed of light. It is therefore not surprising that nonlinear wave processes are important.

stimulated Raman scattering of laser beam parametrically amplifies a Langmuir wave, strengthening the scattering (a parametric instability) and impeding laser fusion

One of the most important such processes is called *stimulated Raman scattering*. In this interaction the coherent electromagnetic wave with frequency ω convects a small preexisting density fluctuation—one associated with a relatively low-frequency Langmuir wave with frequency ω_{pe} —and converts the Langmuir density fluctuation into a current that varies at the beat frequency $\omega - \omega_{pe}$. This creates a new electromagnetic mode with this frequency. The vector sum of the \mathbf{k} vectors of the two modes must also equal the incident \mathbf{k} vector. When this condition can first be met, the new \mathbf{k} is almost antiparallel to that of the incident mode, and so the radiation is backscattered.

The new mode can combine nonlinearly with the original electromagnetic wave to produce a pressure force $\propto \nabla E^2$, which amplifies the original density fluctuation. Provided the growth rate of the wave is faster than the natural damping rates (e.g.,

BOX 23.2. LASER FUSION

In the simplest proposed scheme for laser fusion, solid pellets of deuterium and tritium would be compressed and heated to allow the reaction

to proceed. (We will meet this reaction again in Sec. 28.4.2.) An individual pellet would have mass $m \sim 3 \text{ mg}$ and initial diameter $r_i \sim 2 \text{ mm}$. The total latent nuclear energy in a single pellet is $\sim 1 \text{ GJ}$. So if, optimistically, the useful energy extraction were $\sim 3\%$ of this, pellets would have to burn at a combined rate of $\sim 10^5 \text{ s}^{-1}$ in reactors all around the world to supply, say, a fifth of the *current* (2016) global power usage $\sim 15 \text{ TW}$.

The largest program designed to accomplish this goal is at the National Ignition Facility in Lawrence Livermore National Laboratory in California. Neodymium-glass pulsed lasers are used to illuminate a small pellet from 192 directions at a wavelength of 351 nm. (The frequency is tripled from the initial infrared frequency using KDP crystals; Box 10.2.) The goal is to deliver a power of $\sim 0.5 \text{ PW}$ for a few nanoseconds. The nominal initial laser energy is $\sim 3 \text{ MJ}$ derived from a capacitor bank storing $\sim 400 \text{ MJ}$ of energy. The energy is delivered to a small metal cylinder, called a *hohlraum*, where a significant fraction of the incident energy is converted to X-rays that illuminate the fuel pellet, a technique known as *indirect drive*. The energy absorbed in the surface layers of the pellet is $\sim 150 \text{ kJ}$. This causes the pellet to implode to roughly a tenth of its initial size and a density of $\sim 10^6 \text{ kg m}^{-3}$; nuclear energy releases of 20 MJ are projected. It has recently become possible to create as much fusion energy as the energy deposited in the pellet (Hurricane et al., 2014). The shot repetition rate is currently about one per day. There is clearly a long road ahead to safe commercial reactors supplying a significant fraction of the global power usage, but progress is being made.

that of Landau damping) there can be a strong backscattering of the incident wave at a density well below the critical density of the incident radiation. (A further condition that must be satisfied is that the bandwidth of the incident wave must also be less than the growth rate. This will generally be true for a laser.) This stimulated Raman scattering is an example of a parametric instability. The incident wave frequency is called the *pump* frequency. One difference between parametric instabilities involving waves as opposed to just oscillations is that it is necessary to match spatial as well as temporal frequencies.

Reflection of the incident radiation by this mechanism reduces the ablation of the pellet and also creates a population of suprathermal electrons, which conduct heat

into the interior of the pellet and inhibit compression. Various strategies, including increasing the wave frequency, have been devised to circumvent Raman backscattering (and also a related process called *Brillouin backscattering*, in which the Langmuir mode is replaced by an ion-acoustic mode).

EXERCISES

Exercise 23.9 *Example: Ablation vs. Radiation Pressure in Laser Fusion*

Demonstrate that ablation pressure is necessary to compress a pellet to densities at which nuclear reactions can progress efficiently. More specifically, do the following.

- Assume that a temperature $T \sim 30$ keV is necessary for nuclear reactions to proceed. Using the criteria developed in Sec. 20.2.2, evaluate the maximum density before the electrons become degenerate. Estimate the associated pressure and sound speed.
- Employ the Lawson criterion (19.25) to estimate the minimum size of a pellet for break-even.
- Using the laser performance advertised in Box 23.2, compare the radiation pressure in the laser light with the pressure needed from part (a). Do you think that radiation pressure can create laser fusion?
- Assume instead that the incident laser energy is carried off by an outflow. Show that the associated ablation pressure can be orders of magnitude higher than the laser light pressure, and compute an upper bound on the speed of the outflow for laser fusion to be possible.

23.6

23.6 Solitons and Collisionless Shock Waves

In Sec. 21.4.3, we introduced ion-acoustic waves that have a phase speed $V_{\text{ph}} \sim (k_B T_e / m_p)^{1/2}$, determined by a combination of electron pressure and ion inertia. In Sec. 22.3.6, we argued that these waves would be strongly Landau-damped unless the electron temperature greatly exceeded the proton temperature. However, this formalism was only valid for waves of small amplitude so that the linear approximation could be used. In Ex. 21.6, we considered the profile of a nonlinear wave and found a solution for a single ion-acoustic soliton valid when the waves are weakly nonlinear. We now consider this problem in a slightly different way, one valid for a wave amplitude that is strongly nonlinear. However, we restrict our attention to waves that propagate without change of form and so will not generalize the KdV equation.

Once again we use the fluid model and introduce an ion-fluid velocity u . We presume the electrons are highly mobile and so have a local density $n_e \propto \exp[e\phi / (k_B T_e)]$, where ϕ (not Φ as above) is the electrostatic potential. The ions must satisfy equations of continuity and motion:

$$\begin{aligned}\frac{\partial n}{\partial t} + \frac{\partial}{\partial z}(nu) &= 0, \\ \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} &= -\frac{e}{m_p} \frac{\partial \phi}{\partial z}.\end{aligned}\quad (23.69)$$

We now seek a solution for an ion-acoustic wave moving with constant speed V through the ambient plasma. In this case, all physical quantities must be functions of a single dependent variable: $\xi = z - Vt$. Using a prime to denote differentiation with respect to ξ , Eqs. (23.69) become

$$\begin{aligned}(u - V)n' &= -nu', \\ (u - V)u' &= -\frac{e}{m_p}\phi'.\end{aligned}\quad (23.70)$$

These two equations can be integrated and combined to obtain an expression for the ion density n in terms of the electrostatic potential:

$$n = n_0[1 - 2e\phi/(m_p V^2)]^{-1/2}, \quad (23.71)$$

where n_0 is the ion density, presumed uniform, long before the wave arrives. The next step is to combine this ion density with the electron density and substitute into Poisson's equation to obtain a nonlinear ordinary differential equation for the potential:

$$\phi'' = -\frac{n_0 e}{\epsilon_0} \left\{ \left(1 - \frac{2e\phi}{m_p V^2} \right)^{-1/2} - e^{e\phi/(k_B T_e)} \right\}. \quad (23.72)$$

Now, the best way to think about this problem is to formulate the equivalent dynamical problem of a particle moving in a 1-dimensional potential well $\Phi(\phi)$, with ϕ the particle's position coordinate and ξ its time coordinate. Then Eq. (23.72) becomes $\phi'' = -d\Phi/d\phi$, whence $\frac{1}{2}\phi'^2 + \Phi(\phi) = \mathcal{E}$, where \mathcal{E} is the particle's conserved energy. Integrating $-d\Phi/d\phi = [\text{right-hand side of Eq. (23.72)}]$, and assuming that $\Phi \rightarrow 0$ as $\phi \rightarrow 0$ (i.e., as $\xi \rightarrow \infty$, long before the arrival of the pulse), we obtain

$$\Phi(\phi) = \frac{n_0 k_B T_e}{\epsilon_0} \left\{ \left[1 - (1 - \phi/\phi_o)^{1/2} \right] M^2 - (e^{M^2\phi/(2\phi_o)} - 1) \right\}, \quad (23.73a)$$

where

$$\phi_o = m_p V^2/(2e), \quad M = [m_p V^2/(k_B T_e)]^{1/2}. \quad (23.73b)$$

We have assumed that $0 < \phi < \phi_o$; when $\phi \rightarrow \phi_o$, the proton density $n \rightarrow \infty$ [Eq. (23.71)].

The shape of this potential well $\Phi(\phi)$ is sketched in Fig. 23.7; it is determined by the parameter $M = [m_p V^2/(k_B T_e)]^{1/2}$, which is readily recognizable as the ion-acoustic Mach number (i.e., the ratio of the speed of the soliton to the ion-acoustic speed in the undisturbed medium). A solution for the soliton's potential profile $\phi(\xi)$

two-fluid theory of a strongly nonlinear ion-acoustic soliton with speed V in a plasma with thermalized electrons: ion speed u and electrostatic potential ϕ as functions of $\xi = z - Vt$

FIGURE 23.7 Potential function $\Phi(\phi)$ used for exhibiting the properties of an ion-acoustic soliton for four different values of the ion-acoustic Mach number M .

corresponds to the trajectory of the particle. Physically, a soliton (solitary wave) must be concentrated in a finite region of space at fixed time; that is, $\phi(\xi) = \phi(z - Vt)$ must go to zero as $\xi \rightarrow \pm\infty$. For the particle moving in the potential $\Phi(\phi)$ this is possible only if its total energy \mathcal{E} vanishes, so $\frac{1}{2}\phi'^2 + \Phi(\phi) = 0$. The particle then starts at $\phi = 0$, with zero kinetic energy (i.e., $\phi' = 0$) and then accelerates to a maximum speed near the minimum in the potential before decelerating. If there is a turning point, the particle will come to rest, $\phi(\xi)$ will attain a maximum, and then the particle will return to the origin. This particle trajectory corresponds to a symmetrical soliton, propagating with uniform speed.

Two conditions must be satisfied for a soliton solution. First, the potential well must be attractive. This only happens when $d^2\Phi/d\phi^2(0) < 0$, which implies that $M > 1$. Second, there must be a turning point. This happens if $\Phi(\phi = \phi_o) > 0$. The maximum value of M for which these two conditions are met is a solution of the equation

$$e^{M^2/2} - 1 - M^2 = 0 \quad (23.74)$$

(i.e., $M = 1.58$). Hence, ion-acoustic-soliton solutions only exist for

$$1 < M < 1.59. \quad (23.75)$$

Mach number for ion-acoustic soliton

If $M < 1$, the particle's potential Φ acts as a barrier, preventing it from moving into the $\phi > 0$ region. If $M > 1.59$, the plasma's electrons short out the potential; that is, the electron term $(e^{M^2\phi/(2\phi_o)} - 1)$ in Eq. (23.73a) becomes so negative that it makes $\Phi(\phi_o)$ negative.

This analogy with particle dynamics is not only helpful in understanding large-amplitude solitons. It also assists us to understand a deep connection between these solitons and laminar shock fronts. The equations that we have been solving so far

FIGURE 23.8 Ion-acoustic shock wave. (a) Solution in terms of damped particle motion $\phi(\xi)$ (blue curve) in the equivalent potential $\Phi(\phi)$ (black curve). (b) Electrostatic potential profile $\phi(\xi) = \phi(z - Vt)$ in the shock. The proton number-density variation $n(\xi)$ in the shock can be inferred from this $\phi(\xi)$ using Eq. (23.71).

contain the two key ingredients for a soliton: nonlinearity to steepen the wave profile and dispersion to spread it. However, they do not make provision for any form of dissipation, a necessary condition for a shock front, in which the entropy must increase.

In a real collisionless plasma, this dissipation can take on many forms. It may be associated with anomalous resistivity or perhaps with some viscosity associated with the ions. In many circumstances, some ions are reflected by the electrostatic potential barrier and counterstream against the incoming ions, which they eventually heat. Whatever its origin, the net effect of this dissipation will be to cause the equivalent particle to lose its total energy, so that it can never return to its starting point. Given an attractive and bounded potential well, we find that the particle has no alternative except to sink to the bottom of the well. Depending on the strength of the dissipation, the particle may undergo several oscillations before coming to rest. See Fig. 23.8a.

The structure to which this type of solution corresponds is a laminar shock front. Unlike that for a soliton, the wave profile in a shock wave is not symmetric in this case and instead describes a permanent change in the electrostatic potential ϕ (Fig. 23.8b). Repeating the arguments above, we find that a shock wave can only exist when $M > 1$, that is to say, it must be supersonic with respect to the ion-acoustic sound speed. In addition there is a maximum critical Mach number close to $M = 1.6$, above which a laminar shock becomes impossible.

What happens when the critical Mach number is exceeded? In this case there are several possibilities, which include relying on a more rapidly moving wave to form the shock front or appealing to turbulent conditions downstream from the front to enhance the dissipation rate.

This ion-acoustic shock front is the simplest example of a collisionless shock. Essentially every wave mode can be responsible for the formation of a shock. The dissipation in these shocks is still not very well understood, but we can observe them in several different environments in the heliosphere and also in the laboratory. The

adding dissipation converts soliton into a laminar, collisionless shock

FIGURE 23.9 The form of the collisionless bow shock formed around Earth's magnetosphere. Earth's bow shock has been extensively studied using spacecraft. Alfvén, ion-acoustic, whistler, and Langmuir waves are all generated with large amplitudes in the vicinity of shock fronts by the highly nonthermal particle distributions. Adapted from Parks (2004).

collisionless bow shock at interface of Earth's magnetic field with solar wind

best studied of these shock waves are those based on magnetosonic waves, which were introduced in Sec. 19.7. The solar wind moves with a speed that is typically 5 times the Alfvén speed. It should therefore form a bow shock (one based on the fast magnetosonic mode) when it encounters a planetary magnetosphere. This bow shock forms even though the mean free path of the ions for Coulomb scattering in the solar wind is typically much larger than the thickness of the shock front. The thickness turns out to be a few ion Larmor radii. This is a dramatic illustration of the importance of collective effects in controlling the behavior of essentially collisionless plasmas (Fig. 23.9; see Sagdeev and Kennel, 1991).

EXERCISES

Exercise 23.10 *Derivation: Maximum Mach Number for an Ion-Acoustic Shock Wave* Verify Eq. (23.73a), and show numerically that the maximum Mach number for a laminar shock front is $M = 1.58$.

Exercise 23.11 *Problem: Solar-Wind Termination Shock*

The solar wind is a quasi-spherical outflow of plasma from the Sun. At the radius of Earth's orbit, the mean proton and electron densities are $n_p \sim n_e \sim 4 \times 10^6 \text{ m}^{-3}$, their temperatures are $T_p \sim T_e \sim 10^5 \text{ K}$, and their common radial fluid speed is

$\sim 400 \text{ km s}^{-1}$. The mean magnetic field strength is $\sim 1 \text{ nT}$. Eventually, the radial momentum flux in the solar wind falls to the value of the mean interstellar pressure, $\sim 10^{-13} \text{ N m}^{-2}$, and a shock develops.

- (a) Estimate the radius where the shock develops.
- (b) The solar system moves through the interstellar medium with a speed $\sim 30 \text{ km s}^{-1}$. Sketch the likely flow pattern near this radius.
- (c) How do you expect the magnetic field to vary with radius in the outflowing solar wind? Estimate its value at the termination shock.
- (d) Estimate the electron plasma frequency, the ion-acoustic Mach number, and the proton Larmor radius just ahead of the termination shock front, and comment on the implications of these values for the shock structure.
- (e) The Voyager 1 spacecraft was launched in 1977 and is traveling radially away from the Sun with a terminal speed $\sim 17 \text{ km s}^{-1}$. It was observed to cross the termination shock in 2004, and in 2012 it passed beyond the limit of the shocked solar wind into the interstellar medium. The Voyager 2 spacecraft passed through the termination shock a few years after Voyager 1. How do these observations compare with your answer to part (a)?

Exercise 23.12 *Example: Diffusive Shock Acceleration of Galactic Cosmic Rays*

Cosmic ray particles with energies between $\sim 1 \text{ GeV}$ and $\sim 1 \text{ PeV}$ are believed to be accelerated at the strong shock fronts formed by supernova explosions in the strongly scattering, local, interstellar medium. We explore a simple model of the way in which this happens.

- (a) In a reference frame where the shock is at rest, consider the stationary (time-independent) flow of a medium (a plasma) with velocity $u(x) \mathbf{e}_x$, and consider relativistic cosmic rays, diffusing through the medium, that have reached a stationary state. Assume that the mean free paths of the cosmic rays are so short that their distribution function $f = dN/dV_x dV_p$ is nearly isotropic in the local rest frame of the medium, so $f = f_0(\tilde{p}, x) + f_1(\mathbf{p}, x)$, where \tilde{p} is the magnitude of a cosmic ray's momentum as measured in the medium's local rest frame, $\tilde{p} \equiv |\tilde{\mathbf{p}}|$, $f_0 \equiv \langle f \rangle$ is the average over cosmic-ray propagation direction in the medium's local rest frame, and $|f_1| \ll |f_0|$. Show that in terms of the cosmic ray's momentum $p = |\mathbf{p}|$ and energy $\mathcal{E} = \sqrt{p^2 + m^2}$ as measured in the shock's rest frame, $\tilde{p} = p - u(x)\mathcal{E} \cos \theta$, where θ is the angle between \mathbf{p} and the direction \mathbf{e}_x of the medium's motion. (Here and throughout this exercise we set the speed of light to unity, as in Chap. 2.)
- (b) By expanding the full Vlasov equation to second order in the ratio of the scattering mean free path to the scale on which $u(x)$ varies, it can be shown (e.g., Blandford and Eichler, 1987, Sec. 3.5) that, in the shock's frame,

$$u \frac{\partial f}{\partial x} - u \frac{\partial}{\partial x} \left(D \frac{\partial f}{\partial x} \right) = \frac{\tilde{p}}{3} \frac{\partial f}{\partial \tilde{p}} \frac{\partial u}{\partial x}, \quad (23.76a)$$

where $D(\tilde{p}, x) > 0$ is the spatial diffusion coefficient which arises from f_1 . Explore this *convection-diffusion* equation. For example, by integrating it over momentum space in the shock's frame, show that it conserves cosmic ray particles. Also, show that, when the diffusion term is unimportant, f_0 is conserved moving with the medium's flow in the sense that $u \partial f_0 / \partial x + (d\tilde{p}/dt) \partial f_0 / \partial \tilde{p} = 0$, where $d\tilde{p}/dt$ is the rate of change of cosmic ray momenta due to elastic scattering in the expanding medium (for which a volume element changes as $d \ln \mathcal{V}_x / dt = \partial u / \partial x$).

- (c) Argue that the flux of cosmic-ray particles, measured in the shock's frame, is given by $\int_0^\infty F(p, x) 4\pi p^2 dp$, where $F(p, x) = -D(\partial f_0 / \partial x) - u(p/3)(\partial f / \partial \tilde{p})$; or, to leading order in u/v , where $v = p/\mathcal{E}$ is the cosmic ray speed,

$$F(\tilde{p}, x) = -D \frac{\partial f_0}{\partial x} - u \frac{\tilde{p}}{3} \frac{\partial f}{\partial \tilde{p}} . \quad (23.76b)$$

This F is often called the flux of particles at momentum \tilde{p} .

- (d) Idealize the shock as a planar discontinuity at $x = 0$ in the medium's velocity $u(x)$; idealize the velocity as constant before and after the shock, $u = u_- = \text{constant}$ for $x < 0$, and $u = u_+ = \text{constant}$ for $x > 0$; and denote by $r = u_-/u_+ > 1$ the shock's compression ratio. Show that upstream from the shock, the solution to the convection-diffusion equation (23.76a) is

$$f_0(\tilde{p}, x) = f_-(\tilde{p}) + [f_s(\tilde{p}) - f_-(\tilde{p})] \exp \left[- \int_x^0 \frac{u_- dx'}{D(\tilde{p}, x')} \right] \quad \text{at } x < 0. \quad (23.76c)$$

Here $f_-(\tilde{p}) \equiv f_0(\tilde{p}, x = -\infty)$, and $f_s(\tilde{p}) \equiv f_0(\tilde{p}, x = 0)$ is the value of f_0 at the shock, which must be continuous across the shock. (Why?) Show further that downstream from the shock f_0 cannot depend on x , so

$$f_0(\tilde{p}, x) = f_s(\tilde{p}) \quad \text{at } x > 0 . \quad (23.76d)$$

- (e) By matching the flux of particles at momentum \tilde{p} , $F(\tilde{p}, x)$ [Eq. (23.76b)], across the shock, show that the post-shock distribution function is

$$f_s(\tilde{p}) = q \tilde{p}^{-q} \int_0^{\tilde{p}} d\tilde{p}' f_-(\tilde{p}') \tilde{p}'^{(q-1)} , \quad (23.76e)$$

where $q = 3r/(r - 1)$.

- (f) The fact that this stationary solution to the convection-diffusion equation has a power-law spectrum $f_s \propto \tilde{p}^{-q}$, in accord with observations, suggests that the observed cosmic rays may indeed be accelerated in shock fronts. How, physically, do you think the acceleration occurs and how does this lead to a power-law spectrum? What is the energy source for the acceleration? It may help to explore the manner in which Eq. (23.76c) evolves an arbitrary initial distribution function $f_-(\tilde{p})$ into the power-law distribution (23.76d). [For discussion and details, see, e.g., Blandford and Eichler (1987), and Longair (2011).]

Bibliographic Note

For a concise treatment of the classical quasilinear theory of wave-particle interactions as in Sec. 23.2, see Lifshitz and Pitaevskii (1981, Sec. 49 for quasilinear theory, and Sec. 51 for fluctuations and correlations).

For more detailed and rich, pedagogical, classical treatments of quasilinear theory and some stronger nonlinear effects in plasmas, see Bellan (2006, Chaps. 14, 15), Boyd and Sanderson (2003, Chap. 10), Swanson (2003, Chaps. 7, 8), and Krall and Trivelpiece (1973, Chaps. 10, 11). For a classical treatment of quasilinear theory that is extended to include excitations of magnetized plasmas, see Stix (1992, Chaps. 16–18). For the interactions of cosmic rays with Alfvén waves, see Kulsrud (2005, Chap. 12). For wave-wave coupling parametric instabilities, see Swanson (2003, Sec. 8.4). For ion-acoustic solitons and associated shocks, see Krall and Trivelpiece (1973, Sec. 3.9.4) and Swanson (2003, Sec. 8.2).

A classic text on radiation processes in plasmas is Bekefi (1966). An extensive treatment of nonlinear plasma physics from a quantum viewpoint is contained in Melrose (2008, 2012).

For applications to astrophysical plasmas, see Melrose (1984), Parks (2004), and Kulsrud (2005), and for applications to laser-plasma interactions, see Kruer (1988).

GENERAL RELATIVITY

We have reached the final part of this book, in which we present an introduction to the basic concepts of general relativity and its most important applications. This subject, although a little more challenging than the material that we have covered so far, is nowhere near as formidable as its reputation. Indeed, if you have mastered the techniques developed in the first five parts, the path to the Einstein field equations should be short and direct.

The general theory of relativity is the crowning achievement of classical physics, the last great fundamental theory created prior to the discovery of quantum mechanics. Its formulation by Albert Einstein in 1915 marks the culmination of the great intellectual adventure undertaken by Newton 250 years earlier. Einstein created it after many wrong turns and with little experimental guidance, almost by pure thought. Unlike the special theory, whose physical foundations and logical consequences were clearly appreciated by physicists soon after Einstein's 1905 formulation, the unique and distinctive character of the general theory only came to be widely appreciated long after its creation. Ultimately, in hindsight, rival classical theories of gravitation came to seem unnatural, inelegant, and arbitrary by comparison [see Will (1993b) for a popular account and Pais (1982) for a more scholarly treatment].

Experimental tests of Einstein's theory also were slow to come. Only since 1970 have there been striking tests of high enough precision to convince most empiricists that—in all probability and in its domain of applicability—general relativity is essentially correct. Despite these tests, it is still very poorly tested compared to, for example, quantum electrodynamics.

We begin our discussion of general relativity in Chap. 24 with a review and an elaboration of special relativity as developed in Chap. 2, focusing on those concepts that are crucial for the transition to general relativity. Our elaboration includes (i) an extension of differential geometry to curvilinear coordinate systems and general bases both in the flat spacetime of special relativity and in the curved spacetime that is the venue for general relativity; (ii) an in-depth exploration of the stress-energy tensor, which in general relativity generates the curvature of spacetime; and (iii) construction

and exploration of the reference frames of accelerated observers (e.g., physicists who reside on Earth's surface).

In Chap. 25, we turn to the basic concepts of general relativity, including spacetime curvature, the Einstein field equation that governs the generation of spacetime curvature, the laws of physics in curved spacetime, and weak-gravity limits of general relativity.

In the remaining chapters, we explore applications of general relativity to stars, black holes, gravitational waves, experimental tests of the theory, and cosmology. We begin in Chap. 26 by studying the spacetime curvature around and inside highly compact stars (such as neutron stars). We then discuss the implosion of massive stars and describe the circumstances under which the implosion inevitably produces a black hole. We explore the surprising and, initially, counterintuitive properties of black holes (both nonspinning and spinning holes), and we learn about the many-fingered nature of time in general relativity. In Chap. 27, we study experimental tests of general relativity and then turn to gravitational waves (i.e., ripples in the curvature of spacetime that propagate with the speed of light). We explore the properties of these waves, and their close analogy with electromagnetic waves, and their production by binary stars and merging black holes. We also describe projects to detect them (both on Earth and in space) and the prospects and success for using them to explore observationally the “warped side of the universe” and the nature of ultrastrong spacetime curvature. Finally, in Chap. 28,¹ we draw on all the previous parts of this book, combining them with general relativity to describe the universe on the largest of scales and longest of times: cosmology. It is here, more than anywhere else in classical physics, that we are conscious of reaching a frontier where the still-promised land of quantum gravity beckons.

1. Chapter 28 is very different in style from the rest of the book. It presents a minimalist treatment of the now standard description of the universe at large. This is a huge subject from which we have ruthlessly excised history, observational justification, and didacticism. Our goal is limited to showing that much of what is now widely accepted about the origin and evolution of the cosmos can be explained directly and quantitatively using the ideas developed in this book.

From Special to General Relativity

The Theory of Relativity confers an absolute meaning on a magnitude which in classical theory has only a relative significance: the velocity of light. The velocity of light is to the Theory of Relativity as the elementary quantum of action is to the Quantum Theory: it is its absolute core.

MAX PLANCK (1949)

24.1 Overview

24.1

We begin our discussion of general relativity in this chapter with a review, and elaboration of relevant material already covered in earlier chapters. In Sec. 24.2, we give a brief encapsulation of special relativity drawn largely from Chap. 2, emphasizing those aspects that underpin the transition to general relativity. Then in Sec. 24.3 we collect, review, and extend the fundamental ideas of differential geometry that have been scattered throughout the book and that we shall need as foundations for the mathematics of *spacetime curvature* (Chap. 25). Most importantly, we generalize differential geometry to encompass coordinate systems whose coordinate lines are not orthogonal and bases that are not orthonormal.

Einstein's field equation (to be studied in Chap. 25) is a relationship between the curvature of spacetime and the matter that generates it, akin to the Maxwell equations' relationship between the electromagnetic field and the electric currents and charges that generate it. The matter in Einstein's equation is described by the stress-energy tensor that we introduced in Sec. 2.13. We revisit the stress-energy tensor in Sec. 24.4 and develop a deeper understanding of its properties.

In general relativity one often wishes to describe the outcome of measurements made by observers who refuse to fall freely—for example, an observer who hovers in a spaceship just above the horizon of a black hole, or a gravitational-wave experimenter in an Earthbound laboratory. As a foundation for treating such observers, in Sec. 24.5 we examine measurements made by accelerated observers in the flat spacetime of special relativity.

24.2 Special Relativity Once Again

24.2

Our viewpoint on general relativity is unapologetically geometrical. (Other viewpoints, e.g., those of particle theorists such as Feynman and Weinberg, are quite different.) Therefore, a prerequisite for our treatment of general relativity is understanding special relativity in geometric language. In Chap. 2, we discussed the foundations of

BOX 24.1. READERS' GUIDE

- This chapter relies significantly on:
 - Chap. 2 on special relativity, which now should be regarded as Track One.
 - The discussion of connection coefficients in Sec. 11.8.
- This chapter is a foundation for the presentation of general relativity theory and cosmology in Chaps. 25–28.

special relativity with this in mind. In this section we briefly review the most important points.

We suggest that any reader who has not studied Chap. 2 read Sec. 24.2 first, to get an overview and flavor of what will be important for our development of general relativity, and then (or in parallel with reading Sec. 24.2) read those relevant sections of Chap. 2 that the reader does not already understand.

24.2.1

24.2.1 Geometric, Frame-Independent Formulation

review of the geometric, frame-independent formulation of special relativity

In Secs. 1.1.1 and 2.2.2, we learned that *every law of physics must be expressible as a geometric, frame-independent relationship among geometric, frame-independent objects*. This is equally true in Newtonian physics, in special relativity, and in general relativity. The key difference between the three is the geometric arena: in Newtonian physics, the arena is 3-dimensional Euclidean space; in special relativity, it is 4-dimensional Minkowski spacetime; in general relativity (Chap. 25), it is 4-dimensional curved spacetime (see Fig. 1 in the Introduction to Part I and the associated discussion).

Principle of Relativity—laws as geometric relations between geometric objects

In special relativity, the demand that the laws be geometric relationships among geometric objects that live in Minkowski spacetime is the *Principle of Relativity*; see Sec. 2.2.2. Examples of the geometric objects are:

examples of geometric objects: points, curves, proper time ticked by an ideal clock, vectors, tensors, scalar product

1. A point \mathcal{P} in spacetime (which represents an *event*); Sec. 2.2.1.
2. A parameterized curve in spacetime, such as the world line $\mathcal{P}(\tau)$ of a particle, for which the parameter τ is the particle's *proper time* (i.e., the time measured by an ideal clock¹ that the particle carries; Fig. 24.1); Sec. 2.4.1.

1. Recall that an ideal clock is one that ticks uniformly when compared, e.g., to the period of the light emitted by some standard type of atom or molecule, and that has been made impervious to accelerations. Thus two ideal clocks momentarily at rest with respect to each other tick at the same rate independent of their relative acceleration; see Secs. 2.2.1 and 2.4.1. For greater detail, see Misner, Thorne, and Wheeler (1973, pp. 23–29, 395–399).

FIGURE 24.1 The world line $\mathcal{P}(\tau)$ of a particle in Minkowski spacetime and the tangent vector $\vec{u} = d\mathcal{P}/d\tau$ to this world line; \vec{u} is the particle's 4-velocity. The bending of the world line is produced by some force that acts on the particle, such as the Lorentz force embodied in Eq. (24.3). Also shown is the light cone emitted from the event $\mathcal{P}(\tau = 1)$. Although the axes of an (arbitrary) inertial reference frame are shown, no reference frame is needed for the definition of the world line, its tangent vector \vec{u} , or the light cone. Nor is one needed for the formulation of the Lorentz force law.

3. Vectors, such as the particle's 4-velocity $\vec{u} = d\mathcal{P}/d\tau$ [the tangent vector to the curve $\mathcal{P}(\tau)$] and the particle's 4-momentum $\vec{p} = m\vec{u}$ (with m the particle's rest mass); Secs. 2.2.1 and 2.4.1.
4. Tensors, such as the electromagnetic field tensor $\mathbf{F}(_, _)$; Secs. 1.3 and 2.3.

Recall that a tensor is a linear real-valued function of vectors; when one puts vectors \vec{A} and \vec{B} into the two slots of \mathbf{F} , one obtains a real number (a scalar) $\mathbf{F}(\vec{A}, \vec{B})$ that is linear in \vec{A} and in \vec{B} so, for example: $\mathbf{F}(\vec{A}, b\vec{B} + c\vec{C}) = b\mathbf{F}(\vec{A}, \vec{B}) + c\mathbf{F}(\vec{A}, \vec{C})$. When one puts a vector \vec{B} into just one of the slots of \mathbf{F} and leaves the other empty, one obtains a tensor with one empty slot, $\mathbf{F}(_, \vec{B})$, that is, a vector. The result of putting a vector into the slot of a vector is the scalar product: $\vec{D}(\vec{B}) = \vec{D} \cdot \vec{B} = \mathbf{g}(\vec{D}, \vec{B})$, where $\mathbf{g}(_, _)$ is the metric.

In Secs. 2.3 and 2.4.1, we tied our definitions of the inner product and the spacetime metric to the ticking of ideal clocks: If $\Delta\vec{x}$ is the vector separation of two neighboring events $\mathcal{P}(\tau)$ and $\mathcal{P}(\tau + \Delta\tau)$ along a particle's world line, then

$$\mathbf{g}(\Delta\vec{x}, \Delta\vec{x}) \equiv \Delta\vec{x} \cdot \Delta\vec{x} \equiv -(\Delta\tau)^2. \quad (24.1)$$

This relation for any particle with any timelike world line, together with the linearity of $\mathbf{g}(_, _)$ in its two slots, is enough to determine \mathbf{g} completely and to guarantee that it is symmetric: $\mathbf{g}(\vec{A}, \vec{B}) = \mathbf{g}(\vec{B}, \vec{A})$ for all \vec{A} and \vec{B} . Since the particle's 4-velocity \vec{u} is

$$\vec{u} = \frac{d\mathcal{P}}{d\tau} = \lim_{\Delta\tau \rightarrow 0} \frac{\mathcal{P}(\tau + \Delta\tau) - \mathcal{P}(\tau)}{\Delta\tau} \equiv \lim_{\Delta\tau \rightarrow 0} \frac{\Delta\vec{x}}{\Delta\tau}, \quad (24.2)$$

Eq. (24.1) implies that $\vec{u} \cdot \vec{u} = \mathbf{g}(\vec{u}, \vec{u}) = -1$ (Sec. 2.4.1).

The 4-velocity \vec{u} is an example of a *timelike* vector (Sec. 2.2.3); it has a negative inner product with itself (negative “squared length”). This shows up pictorially in the

spacetime metric

light cone; timelike, null, and spacelike vectors

fact that \vec{u} lies inside the *light cone* (the cone swept out by the trajectories of photons emitted from the tail of \vec{u} ; see Fig. 24.1). Vectors \vec{k} on the light cone (the tangents to the world lines of the photons) are *null* and so have vanishing squared lengths: $\vec{k} \cdot \vec{k} = \mathbf{g}(\vec{k}, \vec{k}) = 0$; vectors \vec{A} that lie outside the light cone are *spacelike* and have positive squared lengths: $\vec{A} \cdot \vec{A} > 0$ (Sec. 2.2.3).

An example of a physical law in 4-dimensional geometric language is the Lorentz force law (Sec. 2.4.2):

Lorentz force law

$$\frac{d\vec{p}}{d\tau} = q\mathbf{F}(_, \vec{u}). \quad (24.3)$$

Here q is the particle's charge (a scalar), and both sides of this equation are vectors, or equivalently, first-rank tensors (i.e., tensors with just one slot). As we learned in Secs. 1.5.1 and 2.5.3, it is convenient to give names to slots. When we do so, we can rewrite the Lorentz force law as

slot-naming index notation

$$\frac{dp^\alpha}{d\tau} = qF^{\alpha\beta}u_\beta. \quad (24.4)$$

Here α is the name of the slot of the vector $d\vec{p}/d\tau$, α and β are the names of the slots of \mathbf{F} , β is the name of the slot of \mathbf{u} . The double use of β with one up and one down on the right-hand side of the equation represents the insertion of \vec{u} into the β slot of \mathbf{F} , whereby the two β slots disappear, and we wind up with a vector whose slot is named α . As we learned in Sec. 1.5, this slot-naming index notation is isomorphic to the notation for components of vectors, tensors, and physical laws in some reference frame. However, no reference frames are needed or involved when one formulates the laws of physics in geometric, frame-independent language as above.

Those readers who do not feel completely comfortable with these concepts, statements, and notation should reread the relevant portions of Chaps. 1 and 2.

EXERCISES

Exercise 24.1 Practice: Frame-Independent Tensors

Let \mathbf{A} , \mathbf{B} be second-rank tensors.

- Show that $\mathbf{A} + \mathbf{B}$ is also a second-rank tensor.
- Show that $\mathbf{A} \otimes \mathbf{B}$ is a fourth-rank tensor.
- Show that the contraction of $\mathbf{A} \otimes \mathbf{B}$ on its first and fourth slots is a second-rank tensor. (If necessary, consult Secs. 1.5 and 2.5 for discussions of contraction.)
- Write the following quantities in slot-naming index notation: the tensor $\mathbf{A} \otimes \mathbf{B}$, and the simultaneous contraction of this tensor on its first and fourth slots and on its second and third slots.

24.2.2

inertial reference frame

24.2.2 Inertial Frames and Components of Vectors, Tensors, and Physical Laws

In special relativity, a key role is played by *inertial reference frames*, Sec. 2.2.1. An inertial frame is an (imaginary) latticework of rods and clocks that moves through spacetime freely (inertially, without any force acting on it). The rods are orthogonal to one another and attached to inertial-guidance gyroscopes, so they do not rotate. These

rods are used to identify the spatial, Cartesian coordinates $(x^1, x^2, x^3) = (x, y, z)$ of an event \mathcal{P} [which we also denote by lowercased Latin indices $x^j(\mathcal{P})$, with j running over 1, 2, 3]. The latticework's clocks are ideal and are synchronized with one another by the Einstein light-pulse process. They are used to identify the temporal coordinate $x^0 = t$ of an event \mathcal{P} : $x^0(\mathcal{P})$ is the time measured by that latticework clock whose world line passes through \mathcal{P} , at the moment of passage. The spacetime coordinates of \mathcal{P} are denoted by lowercased Greek indices x^α , with α running over 0, 1, 2, 3. An inertial frame's spacetime coordinates $x^\alpha(\mathcal{P})$ are called *Lorentz coordinates* or *inertial coordinates*.

Lorentz (inertial) coordinates

In the real universe, spacetime curvature is small in regions well removed from concentrations of matter (e.g., in intergalactic space), so special relativity is highly accurate there. In such a region, frames of reference (rod-clock latticeworks) that are nonaccelerating and nonrotating with respect to cosmologically distant galaxies (and hence with respect to a local frame in which the cosmic microwave radiation looks isotropic) constitute good approximations to inertial reference frames.

Associated with an inertial frame's Lorentz coordinates are basis vectors \vec{e}_α that point along the frame's coordinate axes (and thus are orthogonal to one another) and have unit length (making them orthonormal); see Sec. 2.5. This orthonormality is embodied in the inner products

orthonormal basis vectors of an inertial frame

$$\vec{e}_\alpha \cdot \vec{e}_\beta = \eta_{\alpha\beta}, \quad (24.5)$$

where by definition:

$$\eta_{00} = -1, \quad \eta_{11} = \eta_{22} = \eta_{33} = +1, \quad \eta_{\alpha\beta} = 0 \quad \text{if } \alpha \neq \beta. \quad (24.6)$$

Here and throughout Part VII (as in Chap. 2), we set the speed of light to unity (i.e., we use the geometrized units introduced in Sec. 1.10), so spatial lengths (e.g., along the x -axis) and time intervals (e.g., along the t -axis) are measured in the same units, seconds or meters, with $1 \text{ s} = 2.99792458 \times 10^8 \text{ m}$.

geometrized units

In Sec. 2.5 (see also Sec. 1.5), we used the basis vectors of an inertial frame to build a component representation of tensor analysis. The fact that the inner products of timelike vectors with each other are negative (e.g., $\vec{e}_0 \cdot \vec{e}_0 = -1$), while those of spacelike vectors are positive (e.g., $\vec{e}_1 \cdot \vec{e}_1 = +1$), forced us to introduce two types of components: *covariant* (indices down) and *contravariant* (indices up). The covariant components of a tensor are computable by inserting the basis vectors into the tensor's slots: $u_\alpha = \vec{u}(\vec{e}_\alpha) \equiv \vec{u} \cdot \vec{e}_\alpha$; $F_{\alpha\beta} = \mathbf{F}(\vec{e}_\alpha, \vec{e}_\beta)$. For example, in our Lorentz basis the covariant components of the metric are $g_{\alpha\beta} = \mathbf{g}(\vec{e}_\alpha, \vec{e}_\beta) = \vec{e}_\alpha \cdot \vec{e}_\beta = \eta_{\alpha\beta}$. The contravariant components of a tensor were related to the covariant components via "index lowering" with the aid of the metric, $F_{\alpha\beta} = g_{\alpha\mu} g_{\beta\nu} F^{\mu\nu}$, which simply said that one reverses the sign when lowering a time index and makes no change of sign when lowering a space index. This lowering rule implied that the contravariant components of the metric in a Lorentz basis are the same numerically as the covariant

covariant and contravariant components of vectors and tensors

components, $g^{\alpha\beta} = \eta_{\alpha\beta}$, and that they can be used to raise indices (i.e., to perform the trivial sign flip for temporal indices): $F^{\mu\nu} = g^{\mu\alpha} g^{\nu\beta} F_{\alpha\beta}$. As we saw in Sec. 2.5, tensors can be expressed in terms of their contravariant components as $\vec{p} = p^\alpha \vec{e}_\alpha$, and $\mathbf{F} = F^{\alpha\beta} \vec{e}_\alpha \otimes \vec{e}_\beta$, where \otimes represents the tensor product [Eqs. (1.5)].

We also learned in Chap. 2 that any frame-independent geometric relation among tensors can be rewritten as a relation among those tensors' components in any chosen Lorentz frame. When one does so, the resulting component equation takes precisely the same form as the slot-naming-index-notation version of the geometric relation (Sec. 1.5.1). For example, the component version of the Lorentz force law says $dp^\alpha/d\tau = q F^{\alpha\beta} u_\beta$, which is identical to Eq. (24.4). The only difference is the interpretation of the symbols. In the component equation $F^{\alpha\beta}$ are the components of \mathbf{F} and the repeated β in $F^{\alpha\beta} u_\beta$ is to be summed from 0 to 3. In the geometric relation $F^{\alpha\beta}$ means $\mathbf{F}(_, _)$, with the first slot named α and the second β , and the repeated β in $F^{\alpha\beta} u_\beta$ implies the insertion of \vec{u} into the second slot of \mathbf{F} to produce a single-slotted tensor (i.e., a vector) whose slot is named α .

As we saw in Sec. 2.6, a particle's 4-velocity \vec{u} (defined originally without the aid of any reference frame; Fig. 24.1) has components, in any inertial frame, given by $u^0 = \gamma$, $u^j = \gamma v^j$, where $v^j = dx^j/dt$ is the particle's ordinary velocity and $\gamma \equiv 1/\sqrt{1 - \delta_{ij} v^i v^j}$. Similarly, the particle's energy $E \equiv p^0$ is $m\gamma$, and its spatial momentum is $p^j = m\gamma v^j$ (i.e., in 3-dimensional geometric notation: $\mathbf{p} = m\gamma \mathbf{v}$). This is an example of the manner in which a choice of Lorentz frame produces a "3+1" split of the physics: a split of 4-dimensional spacetime into 3-dimensional space (with Cartesian coordinates x^j) plus 1-dimensional time $t = x^0$; a split of the particle's 4-momentum \vec{p} into its 3-dimensional spatial momentum \mathbf{p} and its 1-dimensional energy $\mathcal{E} = p^0$; and similarly a split of the electromagnetic field tensor \mathbf{F} into the 3-dimensional electric field \mathbf{E} and 3-dimensional magnetic field \mathbf{B} (cf. Secs. 2.6 and 2.11).

The Principle of Relativity (all laws expressible as geometric relations between geometric objects in Minkowski spacetime), when translated into 3+1 language, says that, when the laws of physics are expressed in terms of components in a specific Lorentz frame, the form of those laws must be independent of one's choice of frame. When translated into operational terms, it says that, if two observers in two different Lorentz frames are given identical written instructions for a self-contained physics experiment, then their two experiments must yield the same results to within their experimental accuracies (Sec. 2.2.2).

The components of tensors in one Lorentz frame are related to those in another by a Lorentz transformation (Sec. 2.7), so the Principle of Relativity can be restated as saying that, when expressed in terms of Lorentz-frame components, *the laws of physics must be Lorentz-invariant* (unchanged by Lorentz transformations). This is the version of the Principle of Relativity that one meets in most elementary treatments of special relativity. However, as the above discussion shows, it is a mere shadow of the true Principle of Relativity—the shadow cast into Lorentz frames when one performs

component equations are same as slot-naming-index-notation equations

components of 4-velocity in an inertial frame

3 + 1 split

Principle of Relativity restated: laws take same form in every inertial frame

Lorentz transformations

Principle of Relativity restated: laws are Lorentz invariant

a 3+1 split. The ultimate, fundamental version of the Principle of Relativity is the one that needs no frames at all for its expression: *all the laws of physics are expressible as geometric relations among geometric objects that reside in Minkowski spacetime.*

ultimate version of Principle of Relativity

24.2.3 Light Speed, the Interval, and Spacetime Diagrams

24.2.3

One set of physical laws that must be the same in all inertial frames is Maxwell's equations. Let us discuss the implications of Maxwell's equations and the Principle of Relativity for the speed of light c . (For a more detailed discussion, see Sec. 2.2.2.) According to Maxwell, c can be determined by performing nonradiative laboratory experiments; it is not necessary to measure the time it takes light to travel along some path; see Box 2.2. The Principle of Relativity requires that such experiments must give the same result for c , independent of the reference frame in which the measurement apparatus resides, so the speed of light must be independent of reference frame. It is this frame independence that enables us to introduce geometrized units with $c = 1$.

light speed is the same in all inertial frames

Another example of frame independence (Lorentz invariance) is provided by the *interval between two events* (Sec. 2.2.3). The components $g_{\alpha\beta} = \eta_{\alpha\beta}$ of the metric imply that, if $\Delta\vec{x}$ is the vector separating the two events and Δx^α are its components in some Lorentz coordinate system, then the squared length of $\Delta\vec{x}$ [also called the *interval* and denoted $(\Delta s)^2$] is given by

$$\begin{aligned} (\Delta s)^2 &\equiv \Delta\vec{x} \cdot \Delta\vec{x} = \mathbf{g}(\Delta\vec{x}, \Delta\vec{x}) = g_{\alpha\beta} \Delta x^\alpha \Delta x^\beta \\ &= -(\Delta t)^2 + (\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2. \end{aligned} \quad (24.7)$$

interval between two events

Since $\Delta\vec{x}$ is a geometric, frame-independent object, so must be the interval. This implies that the equation $(\Delta s)^2 = -(\Delta t)^2 + (\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2$ by which one computes the interval between the two chosen events in one Lorentz frame must give the same numerical result when used in any other frame (i.e., this expression must be Lorentz invariant). This *invariance of the interval* is the starting point for most introductions to special relativity—and, indeed, we used it as a starting point in Sec. 2.2.

invariance of the interval

Spacetime diagrams play a major role in our development of general relativity. Accordingly, it is important that the reader feel very comfortable with them. We recommend reviewing Fig. 2.7 and Ex. 2.14.

spacetime diagrams

Exercise 24.2 Example: Invariance of a Null Interval

EXERCISES

You have measured the intervals between a number of adjacent events in spacetime and thereby have deduced the metric \mathbf{g} . Your friend claims that the metric is some other frame-independent tensor $\tilde{\mathbf{g}}$ that differs from \mathbf{g} . Suppose that your correct metric \mathbf{g} and his wrong one $\tilde{\mathbf{g}}$ agree on the forms of the light cones in spacetime (i.e., they agree as to which intervals are null, which are spacelike, and which are timelike), but they give different answers for the value of the interval in the spacelike and timelike cases: $\mathbf{g}(\Delta\vec{x}, \Delta\vec{x}) \neq \tilde{\mathbf{g}}(\Delta\vec{x}, \Delta\vec{x})$. Prove that $\tilde{\mathbf{g}}$ and \mathbf{g} differ solely by

a scalar multiplicative factor, $\tilde{\mathbf{g}} = a\mathbf{g}$ for some scalar a . We say that $\tilde{\mathbf{g}}$ and \mathbf{g} are *conformal to each other*. [Hint: Pick some Lorentz frame and perform computations there, then lift yourself back up to a frame-independent viewpoint.]

Exercise 24.3 *Problem: Causality*

If two events occur at the same spatial point but not simultaneously in one inertial frame, prove that the temporal order of these events is the same in all inertial frames. Prove also that in all other frames the temporal interval Δt between the two events is larger than in the first frame, and that there are no limits on the events' spatial or temporal separation in the other frames. Give *two* proofs of these results, one algebraic and the other via spacetime diagrams.

24.3 **24.3 Differential Geometry in General Bases and in Curved Manifolds**

The differential geometry (tensor-analysis) formalism reviewed in the last section is inadequate for general relativity in several ways.

First, in general relativity we need to use bases \vec{e}_α that are not orthonormal (i.e., for which $\vec{e}_\alpha \cdot \vec{e}_\beta \neq \eta_{\alpha\beta}$). For example, near a spinning black hole there is much power in using a time basis vector \vec{e}_t that is tied in a simple way to the metric's time-translation symmetry and a spatial basis vector \vec{e}_ϕ that is tied to its rotational symmetry. This time basis vector has an inner product with itself $\vec{e}_t \cdot \vec{e}_t = g_{tt}$ that is influenced by the slowing of time near the hole (so $g_{tt} \neq -1$); and \vec{e}_ϕ is not orthogonal to \vec{e}_t ($\vec{e}_t \cdot \vec{e}_\phi = g_{t\phi} \neq 0$), as a result of the dragging of inertial frames by the hole's spin. In this section, we generalize our formalism to treat such nonorthonormal bases.

Second, in the curved spacetime of general relativity (and in any other curved space, e.g., the 2-dimensional surface of Earth), the definition of a vector as an arrow connecting two points (Secs. 1.2 and 2.2.1) is suspect, as it is not obvious on what route the arrow should travel nor that the linear algebra of tensor analysis should be valid for such arrows. In this section, we refine the concept of a vector to deal with this problem. In the process we introduce the concept of a *tangent space* in which the linear algebra of tensors takes place—a different tangent space for tensors that live at different points in the space.

Third, once we have been forced to think of a tensor as residing in a specific tangent space at a specific point in the space, the question arises: how can one transport tensors from the tangent space at one point to the tangent space at an adjacent point? Since the notion of a gradient of a vector depends on comparing the vector at two different points and thus depends on the details of transport, we have to rework the notion of a gradient and the gradient's connection coefficients.

Fourth, when doing an integral, one must add contributions that live at different points in the space, so we must also rework the notion of integration.

We tackle each of these four issues in turn in the following four subsections.

24.3.1 Nonorthonormal Bases

24.3.1

Consider an n -dimensional *manifold*, that is, a space that, in the neighborhood of any point, has the same topological and smoothness properties as n -dimensional Euclidean space, though it might not have a locally Euclidean or locally Lorentz metric and perhaps has no metric at all. If the manifold has a metric (e.g., 4-dimensional spacetime, 3-dimensional Euclidean space, and the 2-dimensional surface of a sphere) it is called “Riemannian.” In this chapter, all manifolds we consider will be Riemannian.

manifold

At some point \mathcal{P} in our chosen n -dimensional manifold with metric, introduce a set of basis vectors $\{\vec{e}_1, \vec{e}_2, \dots, \vec{e}_n\}$ and denote them generally as \vec{e}_α . We seek to generalize the formalism of Sec. 24.2 in such a way that the index-manipulation rules for components of tensors are unchanged. For example, we still want it to be true that covariant components of any tensor are computable by inserting the basis vectors into the tensor’s slots, $F_{\alpha\beta} = \mathbf{F}(\vec{e}_\alpha, \vec{e}_\beta)$, and that the tensor itself can be reconstructed from its contravariant components: $\mathbf{F} = F^{\mu\nu} \vec{e}_\mu \otimes \vec{e}_\nu$. We also require that the two sets of components are computable from each other via raising and lowering with the metric components: $F_{\alpha\beta} = g_{\alpha\mu} g_{\beta\nu} F^{\mu\nu}$. The only thing we do not want to preserve is the orthonormal values of the metric components: we must allow the basis to be nonorthonormal and thus $\vec{e}_\alpha \cdot \vec{e}_\beta = g_{\alpha\beta}$ to have arbitrary values (except that the metric should be nondegenerate, so no linear combination of the \vec{e}_α s vanishes, which means that the matrix $\|g_{\alpha\beta}\|$ should have nonzero determinant).

tensors in a nonorthonormal basis

We can easily achieve our goal by introducing a second set of basis vectors, denoted $\{\vec{e}^1, \vec{e}^2, \dots, \vec{e}^n\}$, which is *dual* to our first set in the sense that

dual sets of basis vectors

$$\vec{e}^\mu \cdot \vec{e}_\beta \equiv \mathbf{g}(\vec{e}^\mu, \vec{e}_\beta) = \delta^\mu_\beta. \quad (24.8)$$

Here δ^α_β is the Kronecker delta. This duality relation actually constitutes a *definition* of the e^μ once the \vec{e}_α have been chosen. To see this, regard \vec{e}^μ as a tensor of rank one. This tensor is defined as soon as its value on each and every vector has been determined. Expression (24.8) gives the value $\vec{e}^\mu(\vec{e}_\beta) = \vec{e}^\mu \cdot \vec{e}_\beta$ of \vec{e}^μ on each of the four basis vectors \vec{e}_β ; and since every other vector can be expanded in terms of the \vec{e}_β s and $\vec{e}^\mu(_)$ is a linear function, Eq. (24.8) thereby determines the value of \vec{e}^μ on every other vector.

The duality relation (24.8) says that \vec{e}^1 is always perpendicular to all the \vec{e}_α s except \vec{e}_1 , and its scalar product with \vec{e}_1 is unity—and similarly for the other basis vectors. This interpretation is illustrated for 3-dimensional Euclidean space in Fig. 24.2. In Minkowski spacetime, if the \vec{e}_α are an orthonormal Lorentz basis, then duality dictates that $\vec{e}^0 = -\vec{e}_0$, and $\vec{e}^j = +\vec{e}_j$.

The duality relation (24.8) leads immediately to the same index-manipulation formalism as we have been using, if one defines the contravariant, covariant, and mixed components of tensors in the obvious manner:

$$F^{\mu\nu} = \mathbf{F}(\vec{e}^\mu, \vec{e}^\nu), \quad F_{\alpha\beta} = \mathbf{F}(\vec{e}_\alpha, \vec{e}_\beta), \quad F^\mu{}_\beta = \mathbf{F}(\vec{e}^\mu, \vec{e}_\beta); \quad (24.9)$$

covariant, contravariant, and mixed components of a tensor

FIGURE 24.2 Nonorthonormal basis vectors \vec{e}_j in Euclidean 3-space and two members \vec{e}^1 and \vec{e}^3 of the dual basis. The vectors \vec{e}_1 and \vec{e}_2 lie in the horizontal plane, so \vec{e}^3 is orthogonal to that plane (i.e., it points vertically upward), and its inner product with \vec{e}_3 is unity. Similarly, the vectors \vec{e}_2 and \vec{e}_3 span a vertical plane, so \vec{e}^1 is orthogonal to that plane (i.e., it points horizontally), and its inner product with \vec{e}_1 is unity.

see Ex. 24.4. Among the consequences of this duality are the following:

covariant and contravariant components of the metric

1. The matrix of contravariant components of the metric is inverse to that of the covariant components, $\|g^{\mu\nu}\| = \|g_{\alpha\beta}\|^{-1}$, so that

$$g^{\mu\beta} g_{\beta\nu} = \delta^{\mu}_{\nu}. \quad (24.10)$$

This relation guarantees that when one raises an index on a tensor $F_{\alpha\beta}$ with $g^{\mu\beta}$ and then lowers it back down with $g_{\beta\mu}$, one recovers one's original covariant components $F_{\alpha\beta}$ unaltered.

reconstructing a tensor from its components

2. One can reconstruct a tensor from its components by lining up the indices in a manner that accords with the rules of index manipulation:

$$\mathbf{F} = F^{\mu\nu} \vec{e}_{\mu} \otimes \vec{e}_{\nu} = F_{\alpha\beta} \vec{e}^{\alpha} \otimes \vec{e}^{\beta} = F^{\mu}_{\beta} \vec{e}_{\mu} \otimes \vec{e}^{\beta}. \quad (24.11)$$

component equations are same as slot-naming-index-notation equations

3. The component versions of tensorial equations are identical in mathematical symbology to the slot-naming-index-notation versions:

$$\mathbf{F}(\vec{p}, \vec{q}) = F^{\alpha\beta} p_{\alpha} q_{\beta}. \quad (24.12)$$

Associated with any coordinate system $x^{\alpha}(\mathcal{P})$ there is a *coordinate basis* whose basis vectors are defined by

coordinate basis

$$\vec{e}_{\alpha} \equiv \frac{\partial \mathcal{P}}{\partial x^{\alpha}}. \quad (24.13)$$

Since the derivative is taken holding the other coordinates fixed, the basis vector \vec{e}_{α} points along the α coordinate axis (the axis on which x^{α} changes and all the other coordinates are held fixed).

FIGURE 24.3 A circular coordinate system $\{\varpi, \phi\}$ and its coordinate basis vectors $\vec{e}_\varpi = \partial\mathcal{P}/\partial\varpi$, $\vec{e}_\phi = \partial\mathcal{P}/\partial\phi$ at several locations in the coordinate system. Also shown is the orthonormal basis vector $\vec{e}_{\hat{\phi}}$.

In an orthogonal curvilinear coordinate system [e.g., circular polar coordinates (ϖ, ϕ) in Euclidean 2-space; Fig. 24.3], this coordinate basis is quite different from the coordinate system's orthonormal basis. For example, $\vec{e}_\phi = (\partial\mathcal{P}/\partial\phi)_\varpi$ is a very long vector at large radii and a very short one at small radii; the corresponding unit-length vector is $\vec{e}_{\hat{\phi}} = (1/\varpi)\vec{e}_\phi = (1/\varpi)\partial/\partial\phi$ (i.e., the derivative with respect to physical distance along the ϕ direction). By contrast, $\vec{e}_\varpi = (\partial\mathcal{P}/\partial\varpi)_\phi$ already has unit length, so the corresponding orthonormal basis vector is simply $\vec{e}_{\hat{\varpi}} = \vec{e}_\varpi$. The metric components in the coordinate basis are readily seen to be $g_{\phi\phi} = \varpi^2$, $g_{\varpi\varpi} = 1$, and $g_{\varpi\phi} = g_{\phi\varpi} = 0$, which are in accord with the equation for the squared distance (interval) between adjacent points: $ds^2 = g_{ij}dx^i dx^j = d\varpi^2 + \varpi^2 d\phi^2$. Of course, the metric components in the orthonormal basis are $g_{\hat{i}\hat{j}} = \delta_{ij}$.

Henceforth, we use hats to identify orthonormal bases; bases whose indices do not have hats will typically (though not always) be coordinate bases.

We can construct the basis $\{\vec{e}^\mu\}$ that is dual to the coordinate basis $\{\vec{e}_\alpha\} = \{\partial\mathcal{P}/\partial x^\alpha\}$ by taking the gradients of the coordinates, viewed as scalar fields $x^\alpha(\mathcal{P})$:

$$\boxed{\vec{e}^\mu = \vec{\nabla} x^\mu.} \quad (24.14)$$

It is straightforward to verify the duality relation (24.8) for these two bases:

$$\vec{e}^\mu \cdot \vec{e}_\alpha = \vec{e}_\alpha \cdot \vec{\nabla} x^\mu = \nabla_{\vec{e}_\alpha} x^\mu = \nabla_{\partial\mathcal{P}/\partial x^\alpha} x^\mu = \frac{\partial x^\mu}{\partial x^\alpha} = \delta^\mu_\alpha. \quad (24.15)$$

In any coordinate system, the expansion of the metric in terms of the dual basis, $\mathbf{g} = g_{\alpha\beta}\vec{e}^\alpha \otimes \vec{e}^\beta = g_{\alpha\beta}\vec{\nabla} x^\alpha \otimes \vec{\nabla} x^\beta$, is intimately related to the line element $ds^2 = g_{\alpha\beta}dx^\alpha dx^\beta$. Consider an infinitesimal vectorial displacement $d\vec{x} = dx^\alpha(\partial/\partial x^\alpha)$. Insert this displacement into the metric's two slots to obtain the interval ds^2 along

orthogonal curvilinear coordinates

the basis dual to a coordinate basis

$d\vec{x}$. The result is $ds^2 = g_{\alpha\beta} \nabla x^\alpha \otimes \nabla x^\beta (d\vec{x}, d\vec{x}) = g_{\alpha\beta} (d\vec{x} \cdot \nabla x^\alpha) (d\vec{x} \cdot \nabla x^\beta) = g_{\alpha\beta} dx^\alpha dx^\beta$:

the line element for the invariant interval along a displacement vector

$$ds^2 = g_{\alpha\beta} dx^\alpha dx^\beta. \quad (24.16)$$

Here the second equality follows from the definition of the tensor product \otimes , and the third from the fact that for any scalar field ψ , $d\vec{x} \cdot \nabla \psi$ is the change $d\psi$ along $d\vec{x}$.

Any two bases $\{\vec{e}_\alpha\}$ and $\{\vec{e}_{\bar{\mu}}\}$ can be expanded in terms of each other:

transformation matrices linking two bases

$$\vec{e}_\alpha = \vec{e}_{\bar{\mu}} L^{\bar{\mu}}_\alpha, \quad \vec{e}_{\bar{\mu}} = \vec{e}_\alpha L^\alpha_{\bar{\mu}}. \quad (24.17)$$

(By convention the first index on L is always placed up, and the second is always placed down.) The quantities $\|L^{\bar{\mu}}_\alpha\|$ and $\|L^\alpha_{\bar{\mu}}\|$ are transformation matrices, and since they operate in opposite directions, they must be the inverse of each other:

$$L^{\bar{\mu}}_\alpha L^\alpha_{\bar{\nu}} = \delta^{\bar{\mu}}_{\bar{\nu}}, \quad L^\alpha_{\bar{\mu}} L^{\bar{\mu}}_\beta = \delta^\alpha_\beta. \quad (24.18)$$

These $\|L^{\bar{\mu}}_\alpha\|$ are the generalizations of Lorentz transformations to arbitrary bases [cf. Eqs. (2.34) and (2.35a)]. As in the Lorentz-transformation case, the transformation laws (24.17) for the basis vectors imply corresponding transformation laws for components of vectors and tensors—laws that entail lining up indices in the obvious manner:

transformation of tensor components between bases

$$A_{\bar{\mu}} = L^\alpha_{\bar{\mu}} A_\alpha, \quad T^{\bar{\mu}\bar{\nu}}_{\bar{\rho}} = L^{\bar{\mu}}_\alpha L^{\bar{\nu}}_\beta L^\gamma_{\bar{\rho}} T^{\alpha\beta}_\gamma, \quad (24.19)$$

and similarly in the opposite direction.

For coordinate bases, these $L^{\bar{\mu}}_\alpha$ are simply the partial derivatives of one set of coordinates with respect to the other:

transformation matrices between coordinate bases

$$L^{\bar{\mu}}_\alpha = \frac{\partial x^{\bar{\mu}}}{\partial x^\alpha}, \quad L^\alpha_{\bar{\mu}} = \frac{\partial x^\alpha}{\partial x^{\bar{\mu}}}, \quad (24.20)$$

as one can easily deduce via

$$\vec{e}_\alpha = \frac{\partial \mathcal{P}}{\partial x^\alpha} = \frac{\partial x^\mu}{\partial x^\alpha} \frac{\partial \mathcal{P}}{\partial x^\mu} = \vec{e}_\mu \frac{\partial x^\mu}{\partial x^\alpha}. \quad (24.21)$$

In many physics textbooks a tensor is *defined* as a set of components $F_{\alpha\beta}$ that obey the transformation laws

$$F_{\alpha\beta} = F_{\mu\nu} \frac{\partial x^\mu}{\partial x^\alpha} \frac{\partial x^\nu}{\partial x^\beta}. \quad (24.22)$$

This definition (valid only in a coordinate basis) is in accord with Eqs. (24.19) and (24.20), though it hides the true and very simple nature of a tensor as a linear function of frame-independent vectors.

Exercise 24.4 *Derivation: Index-Manipulation Rules from Duality*

For an arbitrary basis $\{\vec{e}_\alpha\}$ and its dual basis $\{\vec{e}^\mu\}$, use (i) the duality relation (24.8), (ii) the definition (24.9) of components of a tensor, and (iii) the relation $\vec{A} \cdot \vec{B} = \mathbf{g}(\vec{A}, \vec{B})$ between the metric and the inner product to deduce the following results.

(a) The relations

$$\vec{e}^\mu = \mathbf{g}^{\mu\alpha} \vec{e}_\alpha, \quad \vec{e}_\alpha = \mathbf{g}_{\alpha\mu} \vec{e}^\mu. \quad (24.23)$$

(b) The fact that indices on the components of tensors can be raised and lowered using the components of the metric:

$$F^{\mu\nu} = \mathbf{g}^{\mu\alpha} F_\alpha{}^\nu, \quad p_\alpha = \mathbf{g}_{\alpha\beta} p^\beta. \quad (24.24)$$

(c) The fact that a tensor can be reconstructed from its components in the manner of Eq. (24.11).

Exercise 24.5 *Practice: Transformation Matrices for Circular Polar Bases*

Consider the circular polar coordinate system $\{\varpi, \phi\}$ and its coordinate bases and orthonormal bases as shown in Fig. 24.3 and discussed in the associated text. These coordinates are related to Cartesian coordinates $\{x, y\}$ by the usual relations: $x = \varpi \cos \phi$, $y = \varpi \sin \phi$.

- (a) Evaluate the components (L^x_ϖ , etc.) of the transformation matrix that links the two coordinate bases $\{\vec{e}_x, \vec{e}_y\}$ and $\{\vec{e}_\varpi, \vec{e}_\phi\}$. Also evaluate the components (L^ϖ_x , etc.) of the inverse transformation matrix.
- (b) Similarly, evaluate the components of the transformation matrix and its inverse linking the bases $\{\vec{e}_x, \vec{e}_y\}$ and $\{\vec{e}_\hat{\phi}, \vec{e}_\hat{\phi}\}$.
- (c) Consider the vector $\vec{A} \equiv \vec{e}_x + 2\vec{e}_y$. What are its components in the other two bases?

24.3.2 Vectors as Directional Derivatives; Tangent Space; Commutators

24.3.2

As discussed in the introduction to Sec. 24.3, the notion of a vector as an arrow connecting two points is problematic in a curved manifold and must be refined. As a first step in the refinement, let us consider the tangent vector \vec{A} to a curve $\mathcal{P}(\zeta)$ at some point $\mathcal{P}_o \equiv \mathcal{P}(\zeta = 0)$. We have defined that tangent vector by the limiting process:

$$\vec{A} \equiv \frac{d\mathcal{P}}{d\zeta} \equiv \lim_{\Delta\zeta \rightarrow 0} \frac{\mathcal{P}(\Delta\zeta) - \mathcal{P}(0)}{\Delta\zeta} \quad (24.25)$$

tangent vector to a curve

[Eq. (24.2)]. In this definition the difference $\mathcal{P}(\zeta) - \mathcal{P}(0)$ means the tiny arrow reaching from $\mathcal{P}(0) \equiv \mathcal{P}_o$ to $\mathcal{P}(\Delta\zeta)$. In the limit as $\Delta\zeta$ becomes vanishingly small, these two points get arbitrarily close together. In such an arbitrarily small region of the manifold, the effects of the manifold's curvature become arbitrarily small and

FIGURE 24.4 A curve $\mathcal{P}(\zeta)$ on the surface of a sphere and the curve's tangent vector $\vec{A} = d\mathcal{P}/d\zeta$ at $\mathcal{P}(\zeta = 0) \equiv \mathcal{P}_o$. The tangent vector lives in the tangent space at \mathcal{P}_o (i.e., in the flat plane that is tangent to the sphere there, as seen in the flat Euclidean 3-space in which the sphere's surface is embedded).

negligible (just think of an arbitrarily tiny region on the surface of a sphere), so the notion of the arrow should become sensible. However, before the limit is completed, we are required to divide by $\Delta\zeta$, which makes our arbitrarily tiny arrow big again. What meaning can we give to this?

One way to think about it is to imagine embedding the curved manifold in a higher-dimensional flat space (e.g., embed the surface of a sphere in a flat 3-dimensional Euclidean space, as shown in Fig. 24.4). Then the tiny arrow $\mathcal{P}(\Delta\zeta) - \mathcal{P}(0)$ can be thought of equally well as lying on the sphere, or as lying in a surface that is tangent to the sphere and is flat, as measured in the flat embedding space. We can give meaning to $[\mathcal{P}(\Delta\zeta) - \mathcal{P}(0)]/\Delta\zeta$ if we regard this expression as a formula for lengthening an arrow-type vector in the flat tangent surface; correspondingly, we must regard the resulting tangent vector \vec{A} as an arrow living in the tangent surface.

tangent space at a point

The (conceptual) flat tangent surface at the point \mathcal{P}_o is called the *tangent space* to the curved manifold at that point. It has the same number of dimensions n as the manifold itself (two in the case of the surface of the sphere in Fig. 24.4). Vectors at \mathcal{P}_o are arrows residing in that point's tangent space, tensors at \mathcal{P}_o are linear functions of these vectors, and all the linear algebra of vectors and tensors that reside at \mathcal{P}_o occurs in this tangent space. For example, the inner product of two vectors \vec{A} and \vec{B} at \mathcal{P}_o (two arrows living in the tangent space there) is computed via the standard relation $\vec{A} \cdot \vec{B} = \mathbf{g}(\vec{A}, \vec{B})$ using the metric \mathbf{g} that also resides in the tangent space. (Scalars reside in both the manifold and the tangent space.)

This pictorial way of thinking about the tangent space and vectors and tensors that reside in it is far too heuristic to satisfy most mathematicians. Therefore, mathematicians have insisted on making it much more precise at the price of greater abstraction. Mathematicians define the tangent vector to the curve $\mathcal{P}(\zeta)$ to be the derivative $d/d\zeta$

that differentiates scalar fields along the curve. This derivative operator is well defined by the rules of ordinary differentiation: if $\psi(\mathcal{P})$ is a scalar field in the manifold, then $\psi[\mathcal{P}(\zeta)]$ is a function of the real variable ζ , and its derivative $(d/d\zeta)\psi[\mathcal{P}(\zeta)]$ evaluated at $\zeta = 0$ is the ordinary derivative of elementary calculus. Since the derivative operator $d/d\zeta$ differentiates in the manifold along the direction in which the curve is moving, it is often called the *directional derivative* along $\mathcal{P}(\zeta)$. Mathematicians notice that all the directional derivatives at a point \mathcal{P}_o of the manifold form a vector space (they can be multiplied by scalars and added and subtracted to get new vectors), and so the mathematicians define this vector space to be the tangent space at \mathcal{P}_o .

directional derivative

This mathematical procedure turns out to be isomorphic to the physicists' more heuristic way of thinking about the tangent space. In physicists' language, if one introduces a coordinate system in a region of the manifold containing \mathcal{P}_o and constructs the corresponding coordinate basis $\vec{e}_\alpha = \partial\mathcal{P}/\partial x^\alpha$, then one can expand any vector in the tangent space as $\vec{A} = A^\alpha \partial\mathcal{P}/\partial x^\alpha$. One can also construct, in physicists' language, the directional derivative along \vec{A} ; it is $\partial_{\vec{A}} \equiv A^\alpha \partial/\partial x^\alpha$. Evidently, the components A^α of the physicist's vector \vec{A} (an arrow) are identical to the coefficients A^α in the coordinate-expansion of the directional derivative $\partial_{\vec{A}}$. Therefore a one-to-one correspondence exists between the directional derivatives $\partial_{\vec{A}}$ at \mathcal{P}_o and the vectors \vec{A} there, and a complete isomorphism holds between the tangent-space manipulations that a mathematician performs treating the directional derivatives as vectors, and those that a physicist performs treating the arrows as vectors.

"Why not abandon the fuzzy concept of a vector as an arrow, and *redefine the vector \vec{A} to be the same as the directional derivative $\partial_{\vec{A}}$* ?" mathematicians have demanded of physicists. Slowly, over the past century, physicists have come to see the merit in this approach. (i) It does, indeed, make the concept of a vector more rigorous than before. (ii) It simplifies a number of other concepts in mathematical physics (e.g., the commutator of two vector fields; see below). (iii) It facilitates communication with mathematicians. (iv) It provides a formalism that is useful for calculation. With these motivations in mind, and because one always gains conceptual and computational power by having multiple viewpoints at one's fingertips (see Feynman, 1966, p. 160), we henceforth shall regard vectors both as arrows living in a tangent space and as directional derivatives. Correspondingly, we assert the equalities:

tangent vector as directional derivative along a curve

$$\boxed{\frac{\partial\mathcal{P}}{\partial x^\alpha} = \frac{\partial}{\partial x^\alpha} \quad , \quad \vec{A} = \partial_{\vec{A}},} \quad (24.26)$$

and often expand vectors in a coordinate basis using the notation

$$\boxed{\vec{A} = A^\alpha \frac{\partial}{\partial x^\alpha}.} \quad (24.27)$$

This directional-derivative viewpoint on vectors makes natural the concept of the *commutator* of two vector fields \vec{A} and \vec{B} : $[\vec{A}, \vec{B}]$ is the vector that, when viewed

commutator of two vector fields

FIGURE 24.5 The commutator $[\vec{A}, \vec{B}]$ of two vector fields. The vectors are assumed to be so small that the curvature of the manifold is negligible in the region of the diagram, so all the vectors can be drawn lying in the manifold itself rather than in their respective tangent spaces. In evaluating the two terms in the commutator (24.28), a locally orthonormal coordinate basis is used, so $A^\alpha \partial B^\beta / \partial x^\alpha$ is the amount by which the vector \vec{B} changes when one travels along \vec{A} (i.e., it is the rightward-and-downward pointing dashed arrow in the upper right), and $B^\alpha \partial A^\beta / \partial x^\alpha$ is the amount by which \vec{A} changes when one travels along \vec{B} (i.e., it is the rightward-and-upward pointing dashed arrow). According to Eq. (24.28), the difference of these two dashed arrows is the commutator $[\vec{A}, \vec{B}]$. As the diagram shows, this commutator closes the quadrilateral whose legs are \vec{A} and \vec{B} . If the commutator vanishes, then there is no gap in the quadrilateral, which means that in the region covered by this diagram, one can construct a coordinate system in which \vec{A} and \vec{B} are coordinate basis vectors.

as a differential operator, is given by $[\partial_{\vec{A}}, \partial_{\vec{B}}]$ —where the latter quantity is the same commutator as one meets elsewhere in physics (e.g., in quantum mechanics). Using this definition, we can compute the components of the commutator in a coordinate basis:

$$[\vec{A}, \vec{B}] \equiv \left[A^\alpha \frac{\partial}{\partial x^\alpha}, B^\beta \frac{\partial}{\partial x^\beta} \right] = \left(A^\alpha \frac{\partial B^\beta}{\partial x^\alpha} - B^\alpha \frac{\partial A^\beta}{\partial x^\alpha} \right) \frac{\partial}{\partial x^\beta}. \quad (24.28)$$

This is an operator equation where the final derivative is presumed to operate on a scalar field, just as in quantum mechanics. From this equation we can read off the components of the commutator in any coordinate basis; they are $A^\alpha B^\beta_{,\alpha} - B^\alpha A^\beta_{,\alpha}$, where the comma denotes partial differentiation. Figure 24.5 uses this equation to deduce the geometric meaning of the commutator: it is the fifth leg needed to close a quadrilateral whose other four legs are constructed from the vector fields \vec{A} and \vec{B} . In other words, it is “the change in \vec{B} relative to \vec{A} ,” and as such it is a type of derivative of \vec{B} along \vec{A} , called the *Lie derivative*: $\mathcal{L}_{\vec{A}} \vec{B} \equiv [\vec{A}, \vec{B}]$ (cf. footnote 2 in Chap. 14).

The commutator is useful as a tool for distinguishing between coordinate bases and noncoordinate bases (also called nonholonomic bases). In a coordinate basis, the basis vectors are just the coordinate system’s partial derivatives, $\vec{e}_\alpha = \partial / \partial x^\alpha$, and since partial derivatives commute, it must be that $[\vec{e}_\alpha, \vec{e}_\beta] = 0$. Conversely (as Fig. 24.5 shows), if one has a basis with vanishing commutators $[\vec{e}_\alpha, \vec{e}_\beta] = 0$, then it

coordinate bases have vanishing commutators

is possible to construct a coordinate system for which this is the coordinate basis. In a noncoordinate basis, at least one of the commutators $[\vec{e}_\alpha, \vec{e}_\beta]$ will be nonzero.

24.3.3 Differentiation of Vectors and Tensors; Connection Coefficients

24.3.3

In a curved manifold, the differentiation of vectors and tensors is rather subtle. To elucidate the problem, let us recall how we defined such differentiation in Minkowski spacetime or Euclidean space (Sec. 1.7). Converting to the notation used in Eq. (24.25), we began by defining the directional derivative of a tensor field $\mathbf{F}(\mathcal{P})$ along the tangent vector $\vec{A} = d/d\zeta$ to a curve $\mathcal{P}(\zeta)$:

$$\nabla_{\vec{A}}\mathbf{F} \equiv \lim_{\Delta\zeta \rightarrow 0} \frac{\mathbf{F}[\mathcal{P}(\Delta\zeta)] - \mathbf{F}[\mathcal{P}(0)]}{\Delta\zeta}. \quad (24.29)$$

directional derivative of a tensor field

This definition is problematic, because $\mathbf{F}[\mathcal{P}(\Delta\zeta)]$ lives in a different tangent space than does $\mathbf{F}[\mathcal{P}(0)]$. To make the definition meaningful, we must identify some connection between the two tangent spaces, when their points $\mathcal{P}(\Delta\zeta)$ and $\mathcal{P}(0)$ are arbitrarily close together. That connection is equivalent to identifying a rule for transporting \mathbf{F} from one tangent space to the other.

In flat space or flat spacetime, and when \mathbf{F} is a vector \vec{F} , that transport rule is obvious: keep \vec{F} parallel to itself and keep its length fixed during the transport. In other words, keep constant its components in an orthonormal coordinate system (Cartesian coordinates in Euclidean space, Lorentz coordinates in Minkowski spacetime). This is called the *law of parallel transport*. For a tensor \mathbf{F} , the parallel transport law is the same: keep its components fixed in an orthonormal coordinate basis.

Now, just as the curvature of Earth's surface prevents one from placing a Cartesian coordinate system on it, so nonzero curvature of any other manifold prevents one from introducing orthonormal coordinates; see Sec. 25.3. However, in an arbitrarily small region on Earth's surface, one can introduce coordinates that are arbitrarily close to Cartesian (as surveyors well know); the fractional deviations from Cartesian need be no larger than $O(L^2/R^2)$, where L is the size of the region and R is Earth's radius (see Sec. 25.3). Similarly, in curved spacetime, in an arbitrarily small region, one can introduce coordinates that are arbitrarily close to Lorentz, differing only by amounts quadratic in the size of the region—and similarly for a *local* orthonormal coordinate basis in any curved manifold.

When defining $\nabla_{\vec{A}}\mathbf{F}$, one is sensitive only to first-order changes of quantities, not second, so the parallel transport used in defining it in a flat manifold, based on constancy of components in an orthonormal coordinate basis, must also work in a *local* orthonormal coordinate basis of any curved manifold: In Eq. (24.29), one must transport \mathbf{F} from $\mathcal{P}(\Delta\zeta)$ to $\mathcal{P}(0)$, holding its components fixed in a locally orthonormal coordinate basis (parallel transport), and then take the difference in the tangent space at $\mathcal{P}_o = \mathcal{P}(0)$, divide by $\Delta\zeta$, and let $\Delta\zeta \rightarrow 0$. The result is a tensor at \mathcal{P}_o : the directional derivative $\nabla_{\vec{A}}\mathbf{F}$ of \mathbf{F} .

Having made the directional derivative meaningful, one can proceed as in Secs. 1.7 and 2.10: define the gradient of \mathbf{F} by $\nabla_{\vec{A}}\mathbf{F} = \vec{\nabla}\mathbf{F}(_, _, \vec{A})$ [i.e., put \vec{A} in the last—differentiation—slot of $\vec{\nabla}\mathbf{F}$; Eq. (1.15b)].

As in Chap. 2, in any basis we denote the components of $\vec{\nabla}\mathbf{F}$ by $F_{\alpha\beta;\gamma}$. And as in Sec. 11.8 (elasticity theory), we can compute these components in any basis with the aid of that basis's *connection coefficients*.

In Sec. 11.8, we restricted ourselves to an orthonormal basis in Euclidean space and thus had no need to distinguish between covariant and contravariant indices; all indices were written as subscripts. Now, dealing with nonorthonormal bases in spacetime, we must distinguish covariant and contravariant indices. Accordingly, by analogy with Eq. (11.68), we define the connection coefficients $\Gamma^\mu_{\alpha\beta}$ as

$$\nabla_\beta \vec{e}_\alpha \equiv \nabla_{\vec{e}_\beta} \vec{e}_\alpha = \Gamma^\mu_{\alpha\beta} \vec{e}_\mu. \quad (24.30)$$

The duality between bases $\vec{e}^\nu \cdot \vec{e}_\alpha = \delta^\nu_\alpha$ then implies

$$\nabla_\beta \vec{e}^\mu \equiv \nabla_{\vec{e}_\beta} \vec{e}^\mu = -\Gamma^\mu_{\alpha\beta} \vec{e}^\alpha. \quad (24.31)$$

Note the sign flip, which is required to keep $\nabla_\beta(\vec{e}^\mu \cdot \vec{e}_\alpha) = 0$, and note that the differentiation index always goes last on Γ . Duality also implies that Eqs. (24.30) and (24.31) can be rewritten as

$$\Gamma^\mu_{\alpha\beta} = \vec{e}^\mu \cdot \nabla_\beta \vec{e}_\alpha = -\vec{e}_\alpha \cdot \nabla_\beta \vec{e}^\mu. \quad (24.32)$$

With the aid of these connection coefficients, we can evaluate the components $A_{\alpha;\beta}$ of the gradient of a vector field in any basis. We just compute

$$\begin{aligned} A^\mu_{;\beta} \vec{e}_\mu &= \nabla_\beta \vec{A} = \nabla_\beta (A^\mu \vec{e}_\mu) = (\nabla_\beta A^\mu) \vec{e}_\mu + A^\mu \nabla_\beta \vec{e}_\mu \\ &= A^\mu_{,\beta} \vec{e}_\mu + A^\mu \Gamma^\alpha_{\mu\beta} \vec{e}_\alpha \\ &= (A^\mu_{,\beta} + A^\alpha \Gamma^\mu_{\alpha\beta}) \vec{e}_\mu. \end{aligned} \quad (24.33)$$

In going from the first line to the second, we have used the notation

$$A^\mu_{,\beta} \equiv \partial_{\vec{e}_\beta} A^\mu; \quad (24.34)$$

that is, *the comma denotes the result of letting a basis vector act as a differential operator on the component of the vector*. In going from the second line of (24.33) to the third, we have renamed some summed-over indices. By comparing the first and last expressions in Eq. (24.33), we conclude that

$$A^\mu_{;\beta} = A^\mu_{,\beta} + A^\alpha \Gamma^\mu_{\alpha\beta}. \quad (24.35)$$

The first term in this equation describes the changes in \vec{A} associated with changes of its component A^μ ; the second term *corrects for* artificial changes of A^μ that are induced by turning and length changes of the basis vector \vec{e}_μ . We shall use the short-hand terminology that the second term “corrects the index μ .”

By a similar computation, we conclude that in any basis the covariant components of the gradient are

$$\boxed{A_{\alpha;\beta} = A_{\alpha,\beta} - \Gamma^{\mu}_{\alpha\beta} A_{\mu}}, \quad (24.36)$$

where again $A_{\alpha,\beta} \equiv \partial_{\vec{e}_{\beta}} A_{\alpha}$. Notice that, when the index being corrected is down [α in Eq. (24.36)], the connection coefficient has a minus sign; when it is up [μ in Eq. (24.35)], the connection coefficient has a plus sign. This is in accord with the signs in Eqs. (24.30) and (24.31).

These considerations should make obvious the following equations for the components of the gradient of a second rank tensor field:

$$\begin{aligned} F^{\alpha\beta}_{;\gamma} &= F^{\alpha\beta}_{,\gamma} + \Gamma^{\alpha}_{\mu\gamma} F^{\mu\beta} + \Gamma^{\beta}_{\mu\gamma} F^{\alpha\mu}, \\ F_{\alpha\beta;\gamma} &= F_{\alpha\beta,\gamma} - \Gamma^{\mu}_{\alpha\gamma} F_{\mu\beta} - \Gamma^{\mu}_{\beta\gamma} F_{\alpha\mu}, \\ F^{\alpha}_{\beta;\gamma} &= F^{\alpha}_{\beta,\gamma} + \Gamma^{\alpha}_{\mu\gamma} F^{\mu}_{\beta} - \Gamma^{\mu}_{\beta\gamma} F^{\alpha}_{\mu}. \end{aligned} \quad (24.37)$$

components of the gradient of a tensor field

Notice that each index of \mathbf{F} must be corrected, the correction has a sign dictated by whether the index is up or down, the differentiation index always goes last on the Γ , and all other indices can be deduced by requiring that the free indices in each term be the same and all other indices be summed.

If we have been given a basis, then how can we compute the connection coefficients? We can try to do so by drawing pictures and examining how the basis vectors change from point to point—a method that is fruitful in spherical and cylindrical coordinates in Euclidean space (Sec. 11.8). However, in other situations this method is fraught with peril, so we need a firm mathematical prescription. It turns out that the following prescription works (see Ex. 24.7 for a proof).

1. Evaluate the commutation coefficients $c_{\alpha\beta}{}^{\rho}$ of the basis, which are defined by the two equivalent relations:

$$\boxed{[\vec{e}_{\alpha}, \vec{e}_{\beta}] \equiv c_{\alpha\beta}{}^{\rho} \vec{e}_{\rho}, \quad c_{\alpha\beta}{}^{\rho} \equiv \vec{e}^{\rho} \cdot [\vec{e}_{\alpha}, \vec{e}_{\beta}].} \quad (24.38a)$$

commutation coefficients for a basis

(Note that in a coordinate basis the commutation coefficients will vanish. Warning: Commutation coefficients also appear in the theory of Lie groups; there it is conventional to use a different ordering of indices than here: $c_{\alpha\beta}{}^{\rho}$ here = $c^{\rho}{}_{\alpha\beta}$ Lie groups.)

2. Lower the last index on the commutation coefficients using the metric components in the basis:

$$\boxed{c_{\alpha\beta\gamma} \equiv c_{\alpha\beta}{}^{\rho} g_{\rho\gamma}.} \quad (24.38b)$$

3. Compute the quantities

$$\boxed{\Gamma_{\alpha\beta\gamma} \equiv \frac{1}{2}(g_{\alpha\beta,\gamma} + g_{\alpha\gamma,\beta} - g_{\beta\gamma,\alpha} + c_{\alpha\beta\gamma} + c_{\alpha\gamma\beta} - c_{\beta\gamma\alpha}).} \quad (24.38c)$$

formulas for computing connection coefficients

Here the commas denote differentiation with respect to the basis vectors as though the metric components were scalar fields [as in Eq. (24.34)]. Notice that the pattern of indices is the same on the g s and on the c s. It is a peculiar pattern—one of the few aspects of index gymnastics that cannot be reconstructed by merely lining up indices. In a coordinate basis the c terms will vanish, so $\Gamma_{\alpha\beta\gamma}$ will be symmetric in its last two indices. In an orthonormal basis $g_{\mu\nu}$ are constant, so the g terms will vanish, and $\Gamma_{\alpha\beta\gamma}$ will be antisymmetric in its first two indices. And in a Cartesian or Lorentz coordinate basis, which is both coordinate and orthonormal, both the c terms and the g terms will vanish, so $\Gamma_{\alpha\beta\gamma}$ will vanish.

4. Raise the first index on $\Gamma_{\alpha\beta\gamma}$ to obtain the connection coefficients

$$\Gamma^{\mu}_{\beta\gamma} = g^{\mu\alpha}\Gamma_{\alpha\beta\gamma}. \quad (24.38d)$$

In a coordinate basis, the $\Gamma^{\mu}_{\beta\gamma}$ are sometimes called *Christoffel symbols*, though we will use the name connection coefficients independent of the nature of the basis.

The first three steps in the above prescription for computing the connection coefficients follow from two key properties of the gradient $\vec{\nabla}$. First, the gradient of the metric tensor vanishes:

vanishing gradient of the metric tensor

$$\vec{\nabla} \mathbf{g} = 0. \quad (24.39)$$

Second, for any two vector fields \vec{A} and \vec{B} , the gradient is related to the commutator by

relation of gradient to commutator

$$\nabla_{\vec{A}} \vec{B} - \nabla_{\vec{B}} \vec{A} = [\vec{A}, \vec{B}]. \quad (24.40)$$

For a derivation of these relations and then a derivation of the prescription 1–4, see Exs. 24.6 and 24.7.

The gradient operator $\vec{\nabla}$ is an example of a geometric object that is not a tensor. The connection coefficients $\Gamma^{\mu}_{\beta\gamma} = \vec{e}^{\mu} \cdot (\nabla_{\vec{e}_{\gamma}} \vec{e}_{\beta})$ can be regarded as the components of $\vec{\nabla}$; because it is not a tensor, these components do not obey the tensorial transformation law (24.19) when switching from one basis to another. Their transformation law is far more complicated and is rarely used. Normally one computes them from scratch in the new basis, using the above prescription or some other, equivalent prescription (cf. Misner, Thorne, and Wheeler, 1973, Chap. 14). For most curved spacetimes that one meets in general relativity, these computations are long and tedious and therefore are normally carried out on computers using symbolic manipulation software, such as Maple, Matlab, or Mathematica, or such programs as GR-Tensor and MathTensor that run under Maple or Mathematica. Such software is easily found on the Internet using a search engine. A particularly simple Mathematica program for use with coordinate

bases is presented and discussed in Appendix C of Hartle (2003) and is available on that book's website: <http://web.physics.ucsb.edu/~gravitybook/>.

EXERCISES

Exercise 24.6 *Derivation: Properties of the Gradient $\vec{\nabla}$*

- (a) Derive Eq. (24.39). [Hint: At a point \mathcal{P} where $\vec{\nabla}\mathbf{g}$ is to be evaluated, introduce a locally orthonormal coordinate basis (i.e., locally Cartesian or locally Lorentz). When computing in this basis, the effects of curvature show up only to second order in distance from \mathcal{P} . Show that in this basis, the components of $\vec{\nabla}\mathbf{g}$ vanish, and from this infer that $\vec{\nabla}\mathbf{g}$, viewed as a frame-independent third-rank tensor, vanishes.]
- (b) Derive Eq. (24.40). [Hint: Again work in a locally orthonormal coordinate basis.]

Exercise 24.7 *Derivation and Example: Prescription for Computing Connection Coefficients*

Derive the prescription 1–4 [Eqs. (24.38)] for computing the connection coefficients in any basis. [Hints: (i) In the chosen basis, from $\vec{\nabla}\mathbf{g} = 0$ infer that $\Gamma_{\alpha\beta\gamma} + \Gamma_{\beta\alpha\gamma} = g_{\alpha\beta,\gamma}$. Notice that this determines the part of $\Gamma_{\alpha\beta\gamma}$ that is symmetric in its first two indices. Show that the number of independent components of $\Gamma_{\alpha\beta\gamma}$ thereby determined is $\frac{1}{2}n^2(n+1)$, where n is the manifold's dimension. (ii) From Eq. (24.40) infer that $\Gamma_{\gamma\beta\alpha} - \Gamma_{\gamma\alpha\beta} = c_{\alpha\beta\gamma}$, which fixes the part of Γ antisymmetric in the last two indices. Show that the number of independent components thereby determined is $\frac{1}{2}n^2(n-1)$. (iii) Infer that the number of independent components determined by (i) and (ii) together is n^3 , which is the entirety of $\Gamma_{\alpha\beta\gamma}$. By somewhat complicated algebra, deduce Eq. (24.38c) for $\Gamma_{\alpha\beta\gamma}$. (The algebra is sketched in Misner, Thorne, and Wheeler, 1973, Ex. 8.15.) (iv) Then infer the final answer, Eq. (24.38d), for $\Gamma^\mu{}_{\beta\gamma}$.]

Exercise 24.8 *Practice: Commutation and Connection Coefficients for Circular Polar Bases*

Consider the circular polar coordinates $\{\varpi, \phi\}$ of Fig. 24.3 and their associated bases.

- (a) Evaluate the commutation coefficients $c_{\alpha\beta}{}^\rho$ for the coordinate basis $\{\vec{e}_\varpi, \vec{e}_\phi\}$, and also for the orthonormal basis $\{\vec{e}_{\hat{\varpi}}, \vec{e}_{\hat{\phi}}\}$.
- (b) Compute by hand the connection coefficients for the coordinate basis and also for the orthonormal basis, using Eqs. (24.38). [Note: The answer for the orthonormal basis was worked out pictorially in our study of elasticity theory; Fig. 11.15 and Eq. (11.70).]
- (c) Repeat this computation using symbolic manipulation software on a computer.

Exercise 24.9 *Practice: Connection Coefficients for Spherical Polar Coordinates*

- (a) Consider spherical polar coordinates in 3-dimensional space, and verify that the nonzero connection coefficients, assuming an orthonormal basis, are given by Eq. (11.71).

(b) Repeat the exercise in part (a) assuming a coordinate basis with

$$\mathbf{e}_r \equiv \frac{\partial}{\partial r}, \quad \mathbf{e}_\theta \equiv \frac{\partial}{\partial \theta}, \quad \mathbf{e}_\phi \equiv \frac{\partial}{\partial \phi}. \quad (24.41)$$

(c) Repeat both computations in parts (a) and (b) using symbolic manipulation software on a computer.

Exercise 24.10 *Practice: Index Gymnastics—Geometric Optics*

This exercise gives the reader practice in formal manipulations that involve the gradient operator. In the geometric-optics (eikonal) approximation of Sec. 7.3, for electromagnetic waves in Lorenz gauge, one can write the 4-vector potential in the form $\vec{A} = \vec{A}e^{i\varphi}$, where \vec{A} is a slowly varying amplitude and φ is a rapidly varying phase. By the techniques of Sec. 7.3, one can deduce from the vacuum Maxwell equations that the wave vector, defined by $\vec{k} \equiv \vec{\nabla}\varphi$, is null: $\vec{k} \cdot \vec{k} = 0$.

- (a) Rewrite all the equations in the above paragraph in slot-naming index notation.
 (b) Using index manipulations, show that the wave vector \vec{k} (which is a vector field, because the wave's phase φ is a scalar field) satisfies the geodesic equation $\nabla_{\vec{k}}\vec{k} = 0$ (cf. Sec. 24.5.2). The geodesics, to which \vec{k} is the tangent vector, are the rays discussed in Sec. 7.3, along which the waves propagate.

24.3.4

24.3.4 Integration

Our desire to use general bases and work in curved manifolds gives rise to two new issues in the definition of integrals.

The first issue is that the volume elements used in integration involve the Levi-Civita tensor [Eqs. (2.43), (2.52), and (2.55)], so we need to know the components of the Levi-Civita tensor in a general basis. It turns out (see, e.g., Misner, Thorne, and Wheeler, 1973, Ex. 8.3) that the covariant components differ from those in an orthonormal basis by a factor $\sqrt{|g|}$ and the contravariant by $1/\sqrt{|g|}$, where

$$g \equiv \det ||g_{\alpha\beta}|| \quad (24.42)$$

is the determinant of the matrix whose entries are the covariant components of the metric. More specifically, let us denote by $[\alpha\beta \dots \nu]$ the value of $\epsilon_{\alpha\beta \dots \nu}$ in an orthonormal basis of our n -dimensional space [Eq. (2.43)]:

$$[12 \dots n] = +1, \\ [\alpha\beta \dots \nu] = \begin{cases} +1 & \text{if } \alpha, \beta, \dots, \nu \text{ is an even permutation of } 1, 2, \dots, n \\ -1 & \text{if } \alpha, \beta, \dots, \nu \text{ is an odd permutation of } 1, 2, \dots, n \\ 0 & \text{if } \alpha, \beta, \dots, \nu \text{ are not all different.} \end{cases} \quad (24.43)$$

(In spacetime the indices must run from 0 to 3 rather than 1 to $n = 4$.) Then in a general right-handed basis the components of the Levi-Civita tensor are

$$\boxed{\epsilon_{\alpha\beta\dots\nu} = \sqrt{|g|} [\alpha\beta\dots\nu], \quad \epsilon^{\alpha\beta\dots\nu} = \pm \frac{1}{\sqrt{|g|}} [\alpha\beta\dots\nu]}, \quad (24.44)$$

components of Levi-Civita tensor in an arbitrary basis

where the \pm is plus in Euclidean space and minus in spacetime. In a left-handed basis the sign is reversed.

As an example of these formulas, consider a spherical polar coordinate system (r, θ, ϕ) in 3-dimensional Euclidean space, and use the three infinitesimal vectors $dx^j (\partial/\partial x^j)$ to construct the volume element $d\Sigma$ [cf. Eq. (1.26)]:

$$dV = \epsilon \left(dr \frac{\partial}{\partial r}, d\theta \frac{\partial}{\partial \theta}, d\phi \frac{\partial}{\partial \phi} \right) = \epsilon_{r\theta\phi} dr d\theta d\phi = \sqrt{g} dr d\theta d\phi = r^2 \sin \theta dr d\theta d\phi. \quad (24.45)$$

Here the second equality follows from linearity of ϵ and the formula for computing its components by inserting basis vectors into its slots; the third equality follows from our formula (24.44) for the components. The fourth equality entails the determinant of the metric coefficients, which in spherical coordinates are $g_{rr} = 1$, $g_{\theta\theta} = r^2$, and $g_{\phi\phi} = r^2 \sin^2 \theta$; all other g_{jk} vanish, so $g = r^4 \sin^2 \theta$. The resulting volume element $r^2 \sin \theta dr d\theta d\phi$ should be familiar and obvious.

The second new integration issue we must face is that such integrals as

$$\int_{\partial\mathcal{V}} T^{\alpha\beta} d\Sigma_\beta \quad (24.46)$$

[cf. Eqs. (2.55), (2.56)] involve constructing a vector $T^{\alpha\beta} d\Sigma_\beta$ in each infinitesimal region $d\Sigma_\beta$ of the surface of integration $\partial\mathcal{V}$ and then adding up the contributions from all the infinitesimal regions. A major difficulty arises because each contribution lives in a different tangent space. To add them together, we must first transport them all to the same tangent space at some single location in the manifold. How is that transport to be performed? The obvious answer is “by the same parallel transport technique that we used in defining the gradient.” However, when defining the gradient, we only needed to perform the parallel transport over an infinitesimal distance, and now we must perform it over long distances. When the manifold is curved, long-distance parallel transport gives a result that depends on the route of the transport, and in general there is no way to identify any preferred route (see, e.g., Misner, Thorne, and Wheeler, 1973, Sec. 11.4).

As a result, *integrals such as Eq. (24.46) are ill-defined in a curved manifold. The only integrals that are well defined in a curved manifold are those such as $\int_{\partial\mathcal{V}} S^\alpha d\Sigma_\alpha$, whose infinitesimal contributions $S^\alpha d\Sigma_\alpha$ are scalars (i.e., integrals whose value is a scalar).* This fact will have profound consequences in curved spacetime for the laws of conservation of energy, momentum, and angular momentum (Secs. 25.7 and 25.9.4).

integrals in a curved manifold are well defined only if infinitesimal contributions are scalars

EXERCISES

Exercise 24.11 *Practice: Integration—Gauss's Theorem*

In 3-dimensional Euclidean space Maxwell's equation $\nabla \cdot \mathbf{E} = \rho_e/\epsilon_0$ can be combined with Gauss's theorem to show that the electric flux through the surface $\partial\mathcal{V}$ of a sphere is equal to the charge in the sphere's interior \mathcal{V} divided by ϵ_0 :

$$\int_{\partial\mathcal{V}} \mathbf{E} \cdot d\boldsymbol{\Sigma} = \int_{\mathcal{V}} (\rho_e/\epsilon_0) dV. \quad (24.47)$$

Introduce spherical polar coordinates so the sphere's surface is at some radius $r = R$. Consider a surface element on the sphere's surface with vectorial legs $d\phi\partial/\partial\phi$ and $d\theta\partial/\partial\theta$. Evaluate the components $d\Sigma_j$ of the surface integration element $d\boldsymbol{\Sigma} = \boldsymbol{\epsilon}(\dots, d\theta\partial/\partial\theta, d\phi\partial/\partial\phi)$. (Here $\boldsymbol{\epsilon}$ is the Levi-Civita tensor.) Similarly, evaluate dV in terms of vectorial legs in the sphere's interior. Then use these results for $d\Sigma_j$ and dV to convert Eq. (24.47) into an explicit form in terms of integrals over r , θ , and ϕ . The final answer should be obvious, but the above steps in deriving it are informative.

24.4 The Stress-Energy Tensor Revisited

In Sec. 2.13.1, we defined the stress-energy tensor \mathbf{T} of any matter or field as a symmetric, second-rank tensor that describes the flow of 4-momentum through spacetime. More specifically, the total 4-momentum \vec{P} that flows through some small 3-volume $\vec{\Sigma}$ (defined in Sec. 2.12.1), going from the negative side of $\vec{\Sigma}$ to its positive side, is

$$\mathbf{T}(_, \vec{\Sigma}) = (\text{total 4-momentum } \vec{P} \text{ that flows through } \vec{\Sigma}); \quad T^{\alpha\beta}\Sigma_\beta = P^\alpha \quad (24.48)$$

[Eq. (2.66)]. Of course, this stress-energy tensor depends on the location \mathcal{P} of the 3-volume in spacetime [i.e., it is a tensor field $\mathbf{T}(\mathcal{P})$].

From this geometric, frame-independent definition of the stress-energy tensor, we were able to read off the physical meaning of its components in any inertial reference frame [Eqs. (2.67)]: T^{00} is the total energy density, including rest mass-energy; $T^{j0} = T^{0j}$ is the j -component of momentum density, or equivalently, the j -component of energy flux; and T^{jk} are the components of the stress tensor, or equivalently, of the momentum flux.

In Sec. 2.13.2, we formulated the law of conservation of 4-momentum in a local form and a global form. The local form,

$$\vec{\nabla} \cdot \mathbf{T} = 0, \quad (24.49)$$

says that, in any chosen Lorentz frame, the time derivative of the energy density plus the divergence of the energy flux vanishes, $\partial T^{00}/\partial t + \partial T^{0j}/\partial x^j = 0$, and similarly

stress-energy tensor

local form of 4-momentum conservation

for the momentum, $\partial T^{j0}/\partial t + \partial T^{jk}/\partial x^k = 0$. The global form, $\int_{\partial\mathcal{V}} T^{\alpha\beta} d\Sigma_\beta = 0$ [Eq. (2.71)], says that all the 4-momentum that enters a closed 4-volume \mathcal{V} in spacetime through its boundary $\partial\mathcal{V}$ in the past must ultimately exit through $\partial\mathcal{V}$ in the future (Fig. 2.11). Unfortunately, this global form requires transporting vectorial contributions $T^{\alpha\beta} d\Sigma_\beta$ to a common location and adding them, which cannot be done in a route-independent way in curved spacetime (see the end of Sec. 24.3.4). Therefore (as we shall discuss in greater detail in Secs. 25.7 and 25.9.4), the global conservation law becomes problematic in curved spacetime.

The stress-energy tensor and local 4-momentum conservation play major roles in our development of general relativity. Almost all of our examples will entail perfect fluids.

Recall [Eq. (2.74a)] that in the local rest frame of a perfect fluid, there is no energy flux or momentum density, $T^{j0} = T^{0j} = 0$, but there is a total energy density (including rest mass) ρ and an isotropic pressure P :

$$T^{00} = \rho, \quad T^{jk} = P\delta^{jk}. \quad (24.50)$$

From this special form of $T^{\alpha\beta}$ in the fluid's local rest frame, one can derive a geometric, frame-independent expression for the fluid's stress-energy tensor \mathbf{T} in terms of its 4-velocity \vec{u} , the metric tensor \mathbf{g} , and the rest-frame energy density ρ and pressure P :

$$\mathbf{T} = (\rho + P)\vec{u} \otimes \vec{u} + P\mathbf{g}; \quad T^{\alpha\beta} = (\rho + P)u^\alpha u^\beta + Pg^{\alpha\beta} \quad (24.51)$$

stress-energy tensor for a perfect fluid

[Eq. (2.74b)]; see Ex. 2.26. This expression for the stress-energy tensor of a perfect fluid is an example of a geometric, frame-independent description of physics.

The equations of relativistic fluid dynamics for a perfect fluid are obtained by inserting the stress-energy tensor (24.51) into the law of 4-momentum conservation $\vec{\nabla} \cdot \mathbf{T} = 0$, and augmenting with the law of rest-mass conservation. We explored this in brief in Ex. 2.26, and in much greater detail in Sec. 13.8. Applications that we have explored are the relativistic Bernoulli equation and ultrarelativistic jets (Sec. 13.8.2) and relativistic shocks (Ex. 17.9). In Sec. 13.8.3, we explored in detail the slightly subtle way in which a fluid's nonrelativistic energy density, energy flux, and stress tensor arise from the relativistic perfect-fluid stress-energy tensor (24.51).

These issues for a perfect fluid are so important that readers are encouraged to review them (except possibly the applications) in preparation for our foray into general relativity.

Four other examples of the stress-energy tensor are those for the electromagnetic field (Ex. 2.28), for a kinetic-theory swarm of relativistic particles (Secs. 3.4.2 and 3.5.3), for a point particle (Box 24.2), and for a relativistic fluid with viscosity and diffusive heat conduction (Ex. 24.13). However, we shall not do much with any of these during our study of general relativity, except viscosity and heat conduction in Sec. 28.5.

BOX 24.2. STRESS-ENERGY TENSOR FOR A POINT PARTICLE T2

For a point particle that moves through spacetime along a world line $\mathcal{P}(\zeta)$ [where ζ is the affine parameter such that the particle's 4-momentum is $\vec{p} = d/d\zeta$, Eq. (2.14)], the stress-energy tensor vanishes everywhere except on the world line itself. Correspondingly, \mathbf{T} must be expressed in terms of a Dirac delta function. The relevant delta function is a scalar function of two points in spacetime, $\delta(\mathcal{Q}, \mathcal{P})$, with the property that when one integrates over the point \mathcal{P} , using the 4-dimensional volume element $d\Sigma$ (which in any inertial frame just reduces to $d\Sigma = dt dx dy dz$), one obtains

$$\int_{\mathcal{V}} f(\mathcal{P}) \delta(\mathcal{Q}, \mathcal{P}) d\Sigma = f(\mathcal{Q}). \quad (1)$$

Here $f(\mathcal{P})$ is an arbitrary scalar field, and the region \mathcal{V} of 4-dimensional integration must include the point \mathcal{Q} . One can easily verify that in terms of Lorentz coordinates this delta function can be expressed as

$$\delta(\mathcal{Q}, \mathcal{P}) = \delta(t_{\mathcal{Q}} - t_{\mathcal{P}}) \delta(x_{\mathcal{Q}} - x_{\mathcal{P}}) \delta(y_{\mathcal{Q}} - y_{\mathcal{P}}) \delta(z_{\mathcal{Q}} - z_{\mathcal{P}}), \quad (2)$$

where the deltas on the right-hand side are ordinary 1-dimensional Dirac delta functions. [Proof: Simply insert Eq. (2) into Eq. (1), replace $d\Sigma$ by $dt_{\mathcal{Q}} dx_{\mathcal{Q}} dy_{\mathcal{Q}} dz_{\mathcal{Q}}$, and perform the four integrations.]

The general definition (24.48) of the stress-energy tensor \mathbf{T} implies that the integral of a point particle's stress-energy tensor over any 3-surface \mathcal{S} that slices through the particle's world line just once, at an event $\mathcal{P}(\zeta_0)$, must be equal to the particle's 4-momentum at the intersection point:

$$\int_{\mathcal{S}} T^{\alpha\beta} d\Sigma_{\beta} = p^{\alpha}(\zeta_0). \quad (3)$$

It is a straightforward but sophisticated exercise (Ex. 24.12) to verify that the following frame-independent expression has this property:

$$\mathbf{T}(\mathcal{Q}) = \int_{-\infty}^{+\infty} \vec{p}(\zeta) \otimes \vec{p}(\zeta) \delta[\mathcal{Q}, \mathcal{P}(\zeta)] d\zeta. \quad (4)$$

Here the integral is along the world line $\mathcal{P}(\zeta)$ of the particle, and \mathcal{Q} is the point at which \mathbf{T} is being evaluated. Therefore, Eq. (4) is the point-particle stress-energy tensor.

Exercise 24.12 *Derivation: Stress-Energy Tensor for a Point Particle* T2

Show that the point-particle stress-energy tensor (4) of Box 24.2 satisfies that box's Eq. (3), as claimed.

Exercise 24.13 *Example: Stress-Energy Tensor for a Viscous Fluid with Diffusive Heat Conduction*

This exercise serves two roles: It develops the relativistic stress-energy tensor for a viscous fluid with diffusive heat conduction, and in the process it allows the reader to gain practice in index gymnastics.

In our study of elasticity theory, we introduced the concept of the irreducible tensorial parts of a second-rank tensor in Euclidean space (Box 11.2). Consider a relativistic fluid flowing through spacetime with a 4-velocity $\vec{u}(\mathcal{P})$. The fluid's gradient $\vec{\nabla}\vec{u}$ ($u_{\alpha;\beta}$ in slot-naming index notation) is a second-rank tensor in spacetime. With the aid of the 4-velocity itself, we can break it down into irreducible tensorial parts as follows:

$$u_{\alpha;\beta} = -a_{\alpha}u_{\beta} + \frac{1}{3}\theta P_{\alpha\beta} + \sigma_{\alpha\beta} + \omega_{\alpha\beta}. \quad (24.52)$$

Here: (i)

$$P_{\alpha\beta} \equiv g_{\alpha\beta} + u_{\alpha}u_{\beta} \quad (24.53)$$

is a tensor that projects vectors into the 3-space orthogonal to \vec{u} (it can also be regarded as that 3-space's metric; see Ex. 2.10); (ii) $\sigma_{\alpha\beta}$ is symmetric, trace-free, and orthogonal to the 4-velocity; and (iii) $\omega_{\alpha\beta}$ is antisymmetric and orthogonal to the 4-velocity.

- Show that the rate of change of \vec{u} along itself, $\nabla_{\vec{u}}\vec{u}$ (i.e., the fluid 4-acceleration) is equal to the vector \vec{a} that appears in the decomposition (24.52). Show, further, that $\vec{a} \cdot \vec{u} = 0$.
- Show that the divergence of the 4-velocity, $\nabla \cdot \vec{u}$, is equal to the scalar field θ that appears in the decomposition (24.52). As we shall see in part (d), this is the fluid's rate of expansion.
- The quantities $\sigma_{\alpha\beta}$ and $\omega_{\alpha\beta}$ are the relativistic versions of a Newtonian fluid's shear and rotation tensors, which we introduced in Sec. 13.7.1. Derive equations for these tensors in terms of $u_{\alpha;\beta}$ and $P_{\mu\nu}$.
- Show that, as viewed in a Lorentz reference frame where the fluid is moving with speed small compared to the speed of light, to first order in the fluid's ordinary velocity $v^j = dx^j/dt$, the following statements are true: (i) $u^0 = 1$, $u^j = v^j$; (ii) θ is the nonrelativistic rate of expansion of the fluid, $\theta = \nabla \cdot \mathbf{v} \equiv v^j{}_{,j}$ [Eq. (13.67a)]; (iii) σ_{jk} is the fluid's nonrelativistic shear [Eq. (13.67b)]; and (iv) ω_{jk} is the fluid's nonrelativistic rotation tensor [denoted r_{ij} in Eq. (13.67c)].
- At some event \mathcal{P} where we want to know the influence of viscosity on the fluid's stress-energy tensor, introduce the fluid's local rest frame. Explain why, in that

frame, the only contributions of viscosity to the components of the stress-energy tensor are $T_{\text{visc}}^{jk} = -\zeta\theta g^{jk} - 2\mu\sigma^{jk}$, where ζ and μ are the coefficients of bulk and shear viscosity, respectively; the contributions to T^{00} and $T^{j0} = T^{0j}$ vanish. [Hint: See Eq. (13.73) and associated discussions.]

- (f) From nonrelativistic fluid mechanics, infer that, in the fluid's rest frame at \mathcal{P} , the only contributions of diffusive heat conductivity to the stress-energy tensor are $T_{\text{cond}}^{0j} = T_{\text{cond}}^{j0} = -\kappa\partial T/\partial x^j$, where κ is the fluid's thermal conductivity and T is its temperature. [Hint: See Eq. (13.74) and associated discussion.] Actually, this expression is not fully correct. If the fluid is accelerating, there is a correction term: $\partial T/\partial x^j$ gets replaced by $\partial T/\partial x^j + a^j T$, where a^j is the acceleration. After reading Sec. 24.5 and especially Ex. 24.16, explain this correction.
- (g) Using the results of parts (e) and (f), deduce the following geometric, frame-invariant form of the fluid's stress-energy tensor:

$$T_{\alpha\beta} = (\rho + P)u_\alpha u_\beta + P g_{\alpha\beta} - \zeta\theta g_{\alpha\beta} - 2\mu\sigma_{\alpha\beta} - 2\kappa u_{(\alpha} P_{\beta)}{}^\mu (T_{;\mu} + a_\mu T). \quad (24.54)$$

Here the subscript parentheses in the last term mean to symmetrize in the α and β slots.

From the divergence of this stress-energy tensor, plus the first law of thermodynamics and the law of rest-mass conservation, one can derive the full theory of relativistic fluid mechanics for a fluid with viscosity and heat flow (see, e.g., Misner, Thorne, and Wheeler, 1973, Ex. 22.7). This particular formulation of the theory, including Eq. (24.54), is due to Carl Eckart (1940). Landau and Lifshitz (1959) have given a slightly different formulation. For discussion of the differences, and of causal difficulties with both formulations and the difficulties' repair, see, for example, the reviews by Israel and Stewart (1980), Andersson and Comer (2007, Sec. 14), and López-Monsalvo (2011, Sec. 4).

24.5 24.5 The Proper Reference Frame of an Accelerated Observer

Physics experiments and astronomical measurements almost always use an apparatus that accelerates and rotates. For example, if the apparatus is in an Earthbound laboratory and is attached to the laboratory floor and walls, then it accelerates upward (relative to freely falling particles) with the negative of the “acceleration of gravity,” and it rotates (relative to inertial gyroscopes) because of the rotation of Earth. It is useful, in studying such an apparatus, to regard it as attached to an accelerating, rotating reference frame. As preparation for studying such reference frames in the presence of gravity, we study them in flat spacetime. For a somewhat more sophisticated treatment, see Misner, Thorne, and Wheeler (1973, pp. 163–176, 327–332).

Consider an observer with 4-velocity \vec{U} , who moves along an accelerated world line through flat spacetime (Fig. 24.6) so she has a nonzero 4-acceleration:

$$\vec{a} = \vec{\nabla}_{\vec{U}} \vec{U}. \quad (24.55)$$

FIGURE 24.6 The proper reference frame of an accelerated observer. The spatial basis vectors $\vec{e}_{\hat{x}}$, $\vec{e}_{\hat{y}}$, and $\vec{e}_{\hat{z}}$ are orthogonal to the observer's world line and rotate, relative to local gyroscopes, as they move along the world line. The flat 3-planes spanned by these basis vectors are surfaces of constant coordinate time $x^{\hat{0}} \equiv$ (proper time as measured by the observer's clock at the event where the 3-plane intersects the observer's world line); in other words, they are the observer's slices of simultaneity and "3-space." In each of these flat 3-planes the spatial coordinates $\{\hat{x}, \hat{y}, \hat{z}\}$ are Cartesian, with $\partial/\partial\hat{x} = \vec{e}_{\hat{x}}$, $\partial/\partial\hat{y} = \vec{e}_{\hat{y}}$, and $\partial/\partial\hat{z} = \vec{e}_{\hat{z}}$.

Have that observer construct, in the vicinity of her world line, a coordinate system $\{x^{\hat{\alpha}}\}$ (called her *proper reference frame*) with these properties: (i) The spatial origin is centered on her world line at all times (i.e., her world line is given by $x^{\hat{j}} = 0$). (ii) Along her world line, the time coordinate $x^{\hat{0}}$ is the same as the proper time ticked by an ideal clock that she carries. (iii) In the immediate vicinity of her world line, the spatial coordinates $x^{\hat{j}}$ measure physical distance along the axes of a little Cartesian latticework that she carries (and that she regards as purely spatial, which means it lies in the 3-plane orthogonal to her world line). These properties dictate that, in the immediate vicinity of her world line, the metric has the form $ds^2 = \eta_{\hat{\alpha}\hat{\beta}} dx^{\hat{\alpha}} dx^{\hat{\beta}}$, where $\eta_{\hat{\alpha}\hat{\beta}}$ are the Lorentz-basis metric coefficients, Eq. (24.6); in other words, all along her world line the coordinate basis vectors are orthonormal:

$$g_{\hat{\alpha}\hat{\beta}} = \frac{\partial}{\partial x^{\hat{\alpha}}} \cdot \frac{\partial}{\partial x^{\hat{\beta}}} = \eta_{\hat{\alpha}\hat{\beta}} \quad \text{at } x^{\hat{j}} = 0. \quad (24.56)$$

Moreover, properties (i) and (ii) dictate that along the observer's world line, the basis vector $\vec{e}_{\hat{0}} \equiv \partial/\partial x^{\hat{0}}$ differentiates with respect to her proper time, and thus is identically equal to her 4-velocity \vec{U} :

$$\vec{e}_{\hat{0}} = \frac{\partial}{\partial x^{\hat{0}}} = \vec{U}. \quad (24.57)$$

There remains freedom as to how the observer's latticework is oriented spatially. The observer can lock it to the gyroscopes of an *inertial-guidance system* that she carries (Box 24.3), in which case we say that it is "nonrotating"; or she can rotate it relative to such gyroscopes. For generality, we assume that the latticework rotates.

proper reference frame of an accelerated observer

rotating and nonrotating proper reference frames

BOX 24.3. INERTIAL GUIDANCE SYSTEMS

Aircraft and rockets often carry inertial guidance systems, which consist of an accelerometer and a set of gyroscopes.

The accelerometer measures the system's 4-acceleration \vec{a} (in relativistic language). Equivalently, it measures the system's Newtonian 3-acceleration \mathbf{a} relative to inertial coordinates in which the system is momentarily at rest. As we see in Eq. (24.58), these quantities are two different ways of thinking about the same thing.

Each gyroscope is constrained to remain at rest in the aircraft or rocket by a force that is applied at its center of mass. Such a force exerts no torque around the center of mass, so the gyroscope maintains its direction (does not precess) relative to an inertial frame in which it is momentarily at rest.

As the accelerating aircraft or rocket turns, its walls rotate with some angular velocity $\vec{\Omega}$ relative to these inertial-guidance gyroscopes. This is the angular velocity discussed in the text between Eqs. (24.57) and (24.58).

From the time-evolving 4-acceleration $\vec{a}(\tau)$ and angular velocity $\vec{\Omega}(\tau)$, a computer can calculate the aircraft's (or rocket's) world line and its changing orientation.

Its angular velocity, as measured by the observer (by comparing the latticework's orientation with inertial-guidance gyroscopes), is a 3-dimensional spatial vector $\boldsymbol{\Omega}$ in the 3-plane orthogonal to her world line; and as viewed in 4-dimensional spacetime, it is a 4-vector $\vec{\Omega}$ whose components in the observer's reference frame are $\Omega^{\hat{j}} \neq 0$ and $\Omega^{\hat{0}} = 0$. Similarly, the latticework's acceleration, as measured by an inertial-guidance accelerometer attached to it (Box 24.3), is a 3-dimensional spatial vector \mathbf{a} that can be thought of as a 4-vector with components in the observer's frame:

$$a^{\hat{0}} = 0, \quad a^{\hat{j}} = (\hat{j}\text{-component of the measured } \mathbf{a}). \quad (24.58)$$

This 4-vector is the observer's 4-acceleration, as one can verify by computing the 4-acceleration in an inertial frame in which the observer is momentarily at rest.

Geometrically, the coordinates of the proper reference frame are constructed as follows. Begin with the basis vectors $\vec{e}_{\hat{\alpha}}$ along the observer's world line (Fig. 24.6)—basis vectors that satisfy Eqs. (24.56) and (24.57), and that rotate with angular velocity $\vec{\Omega}$ relative to gyroscopes. Through the observer's world line at time $x^{\hat{0}}$ construct the flat 3-plane spanned by the spatial basis vectors $\vec{e}_{\hat{j}}$. Because $\vec{e}_{\hat{j}} \cdot \vec{e}_{\hat{0}} = 0$, this 3-plane is orthogonal to the world line. All events in this 3-plane are given the same value of coordinate time $x^{\hat{0}}$ as the event where it intersects the world line; thus the 3-plane is a surface of constant coordinate time $x^{\hat{0}}$. The spatial coordinates in this flat 3-plane are ordinary, Cartesian coordinates $x^{\hat{j}}$ with $\vec{e}_{\hat{j}} = \partial/\partial x^{\hat{j}}$.

constructing coordinates
of proper reference frame

It is instructive to examine the coordinate transformation between these proper-reference-frame coordinates $x^{\hat{\alpha}}$ and the coordinates x^{μ} of an inertial reference frame. We pick a very special inertial frame for this purpose. Choose an event on the observer's world line, near which the coordinate transformation is to be constructed; adjust the origin of the observer's proper time, so this event is $x^{\hat{0}} = 0$ (and of course $x^{\hat{j}} = 0$); and choose the inertial frame to be one that, arbitrarily near this event, coincides with the observer's proper reference frame. If we were doing Newtonian physics, then the coordinate transformation from the proper reference frame to the inertial frame would have the form (accurate through terms quadratic in $x^{\hat{\alpha}}$):

$$x^i = x^{\hat{i}} + \frac{1}{2}a^{\hat{i}}(x^{\hat{0}})^2 + \epsilon^{\hat{i}\hat{j}\hat{k}}\Omega^{\hat{j}}x^{\hat{k}}x^{\hat{0}}, \quad x^0 = x^{\hat{0}}. \quad (24.59)$$

Here the term $\frac{1}{2}a^{\hat{i}}(x^{\hat{0}})^2$ is the standard expression for the vectorial displacement produced after time $x^{\hat{0}}$ by the acceleration $a^{\hat{i}}$; and the term $\epsilon^{\hat{i}\hat{j}\hat{k}}\Omega^{\hat{j}}x^{\hat{k}}x^{\hat{0}}$ is the standard expression for the displacement produced by the rotation rate (rotational angular velocity) $\Omega^{\hat{j}}$ during a short time $x^{\hat{0}}$. In relativity theory there is only one departure from these familiar expressions (up through quadratic order): after time $x^{\hat{0}}$ the acceleration has produced a velocity $v^{\hat{j}} = a^{\hat{j}}x^{\hat{0}}$ of the proper reference frame relative to the inertial frame; correspondingly, there is a Lorentz-boost correction to the transformation of time: $x^0 = x^{\hat{0}} + v^{\hat{j}}x^{\hat{j}} = x^{\hat{0}}(1 + a_{\hat{j}}x^{\hat{j}})$ [cf. Eq. (2.37c)], accurate only to quadratic order. Thus, the full transformation to quadratic order is

$$\begin{aligned} x^i &= x^{\hat{i}} + \frac{1}{2}a^{\hat{i}}(x^{\hat{0}})^2 + \epsilon^{\hat{i}\hat{j}\hat{k}}\Omega^{\hat{j}}x^{\hat{k}}x^{\hat{0}}, \\ x^0 &= x^{\hat{0}}(1 + a_{\hat{j}}x^{\hat{j}}). \end{aligned} \quad (24.60a)$$

From this transformation and the form of the metric, $ds^2 = -(dx^0)^2 + \delta_{ij}dx^i dx^j$ in the inertial frame, we easily can evaluate the form of the metric, accurate to linear order in \mathbf{x} , in the proper reference frame:

$$\boxed{ds^2 = -(1 + 2\mathbf{a} \cdot \mathbf{x})(dx^{\hat{0}})^2 + 2(\boldsymbol{\Omega} \times \mathbf{x}) \cdot d\mathbf{x} dx^{\hat{0}} + \delta_{jk}dx^{\hat{j}}dx^{\hat{k}}} \quad (24.60b)$$

(Ex. 24.14a). Here the notation is that of 3-dimensional vector analysis, with \mathbf{x} the 3-vector whose components are $x^{\hat{j}}$, $d\mathbf{x}$ that with components $dx^{\hat{j}}$, \mathbf{a} that with components $a^{\hat{j}}$, and $\boldsymbol{\Omega}$ that with components $\Omega^{\hat{j}}$.

Because the transformation (24.60a) was constructed near an arbitrary event on the observer's world line, the metric (24.60b) is valid near any and every event on the world line (i.e., it is valid all along the world line). In fact, it is the leading order in an expansion in powers of the spatial separation $x^{\hat{j}}$ from the world line. For higher-order terms in this expansion see, for example, Ni and Zimmermann (1978).

inertial coordinates related to those of the proper reference frame of an accelerated, rotating observer

metric in proper reference frame of an accelerated, rotating observer

Notice that precisely on the observer's world line, the metric coefficients $g_{\hat{\alpha}\hat{\beta}}$ [the coefficients of $dx^{\hat{\alpha}}dx^{\hat{\beta}}$ in Eq. (24.60b)] are $g_{\hat{\alpha}\hat{\beta}} = \eta_{\hat{\alpha}\hat{\beta}}$, in accord with Eq. (24.56). However, as one moves farther away from the observer's world line, the effects of the acceleration $a^{\hat{j}}$ and rotation $\Omega^{\hat{j}}$ cause the metric coefficients to deviate more and more strongly from $\eta_{\hat{\alpha}\hat{\beta}}$.

From the metric coefficients of Eq. (24.60b), one can compute the connection coefficients $\Gamma^{\hat{\alpha}}_{\hat{\beta}\hat{\gamma}}$ on the observer's world line, and from these connection coefficients, one can infer the rates of change of the basis vectors along the world line: $\nabla_{\vec{U}}\vec{e}_{\hat{\alpha}} = \nabla_{\vec{0}}\vec{e}_{\hat{\alpha}} = \Gamma^{\hat{\mu}}_{\hat{\alpha}\hat{0}}\vec{e}_{\hat{\mu}}$. The result is (Ex. 24.14b):

$$\nabla_{\vec{U}}\vec{e}_{\hat{0}} \equiv \nabla_{\vec{U}}\vec{U} = \vec{a}, \quad (24.61a)$$

$$\nabla_{\vec{U}}\vec{e}_{\hat{j}} = (\vec{a} \cdot \vec{e}_{\hat{j}})\vec{U} + \epsilon(\vec{U}, \vec{\Omega}, \vec{e}_{\hat{j}}, _). \quad (24.61b)$$

Equation (24.61b) is the general "law of transport" for constant-length vectors that are orthogonal to the observer's world line and that the observer thus sees as purely spatial. For the spin vector \vec{S} of an inertial-guidance gyroscope (Box 24.3), the transport law is Eq. (24.61b) with $\vec{e}_{\hat{j}}$ replaced by \vec{S} and with $\vec{\Omega} = 0$:

$$\nabla_{\vec{U}}\vec{S} = \vec{U}(\vec{a} \cdot \vec{S}). \quad (24.62)$$

This is called *Fermi-Walker transport*. The term on the right-hand side of this transport law is required to keep the spin vector always orthogonal to the observer's 4-velocity: $\nabla_{\vec{U}}(\vec{S} \cdot \vec{U}) = 0$. For any other vector \vec{A} that rotates relative to inertial-guidance gyroscopes, the transport law has, in addition to this "keep-it-orthogonal-to \vec{U} " term, a second term, which is the 4-vector form of $d\mathbf{A}/dt = \boldsymbol{\Omega} \times \mathbf{A}$:

$$\nabla_{\vec{U}}\vec{A} = \vec{U}(\vec{a} \cdot \vec{A}) + \epsilon(\vec{U}, \vec{\Omega}, \vec{A}, _). \quad (24.63)$$

Equation (24.61b) is this general transport law with \vec{A} replaced by $\vec{e}_{\hat{j}}$.

24.5.2

24.5.2 Geodesic Equation for a Freely Falling Particle

Consider a particle with 4-velocity \vec{u} that moves freely through the neighborhood of an accelerated observer. As seen in an inertial reference frame, the particle travels through spacetime on a straight line, also called a *geodesic* of flat spacetime. Correspondingly, a geometric, frame-independent version of its *geodesic law of motion* is

$$\nabla_{\vec{u}}\vec{u} = 0 \quad (24.64)$$

(i.e., the particle parallel transports its 4-velocity \vec{u} along \vec{u}). It is instructive to examine the component form of this geodesic equation in the proper reference frame of the observer. Since the components of \vec{u} in this frame are $u^{\alpha} = dx^{\alpha}/d\tau$, where τ is the particle's proper time (not the observer's proper time), the components $u^{\hat{\alpha}}_{;\hat{\mu}}u^{\hat{\mu}} = 0$ of the geodesic equation (24.64) are

equations for transport of proper reference frame's basis vectors along observer's world line

Fermi-Walker transport for the spin of an inertial-guidance gyroscope

transport law for a vector that is orthogonal to observer's 4-velocity and rotates relative to gyroscopes

geodesic law of motion for freely falling particle

$$u^{\hat{\alpha}}{}_{,\hat{\mu}}u^{\hat{\mu}} + \Gamma^{\hat{\alpha}}{}_{\hat{\mu}\hat{\nu}}u^{\hat{\mu}}u^{\hat{\nu}} = \left(\frac{\partial}{\partial x^{\hat{\mu}}} \frac{dx^{\hat{\alpha}}}{d\tau} \right) \frac{dx^{\hat{\mu}}}{d\tau} + \Gamma^{\hat{\alpha}}{}_{\hat{\mu}\hat{\nu}}u^{\hat{\mu}}u^{\hat{\nu}} = 0; \quad (24.65)$$

or equivalently,

$$\boxed{\frac{d^2x^{\hat{\alpha}}}{d\tau^2} + \Gamma^{\hat{\alpha}}{}_{\hat{\mu}\hat{\nu}} \frac{dx^{\hat{\mu}}}{d\tau} \frac{dx^{\hat{\nu}}}{d\tau} = 0.} \quad (24.66)$$

Suppose, for simplicity, that the particle is moving slowly relative to the observer, so its ordinary velocity $v^{\hat{j}} = dx^{\hat{j}}/dx^{\hat{0}}$ is nearly equal to $u^{\hat{j}} = dx^{\hat{j}}/d\tau$ and is small compared to unity (the speed of light), and $u^{\hat{0}} = dx^{\hat{0}}/d\tau$ is nearly unity. Then to first order in the ordinary velocity $v^{\hat{j}}$, the spatial part of the geodesic equation (24.66) becomes

$$\frac{d^2x^{\hat{i}}}{(dx^{\hat{0}})^2} = -\Gamma^{\hat{i}}{}_{\hat{0}\hat{0}} - (\Gamma^{\hat{i}}{}_{\hat{j}\hat{0}} + \Gamma^{\hat{i}}{}_{\hat{0}\hat{j}})v^{\hat{j}}. \quad (24.67)$$

By computing the connection coefficients from the metric coefficients of Eq. (24.60b) (Ex. 24.14), we bring this low-velocity geodesic law of motion into the form

$$\frac{d^2x^{\hat{i}}}{(dx^{\hat{0}})^2} = -a^{\hat{i}} - 2\epsilon^{\hat{i}}{}_{\hat{j}\hat{k}}\hat{\Omega}^{\hat{j}}v^{\hat{k}}, \quad \text{that is,} \quad \frac{d^2\mathbf{x}}{(dx^{\hat{0}})^2} = -\mathbf{a} - 2\mathbf{\Omega} \times \mathbf{v}. \quad (24.68)$$

This is the standard nonrelativistic form of the law of motion for a free particle as seen in a rotating, accelerating reference frame. The first term on the right-hand side is the inertial acceleration due to the failure of the frame to fall freely, and the second term is the Coriolis acceleration due to the frame's rotation. There would also be a centrifugal acceleration if we had kept terms of higher order in distance away from the observer's world line, but this acceleration has been lost due to our linearizing the metric (24.60b) in that distance.

This analysis shows how the elegant formalism of tensor analysis gives rise to familiar physics. In the next few chapters we will see it give rise to less familiar, general relativistic phenomena.

geodesic equation for slowly moving particle in proper reference frame of accelerated, rotating observer

Exercise 24.14 *Derivation: Proper Reference Frame*

- (a) Show that the coordinate transformation (24.60a) brings the metric $ds^2 = \eta_{\alpha\beta}dx^\alpha dx^\beta$ into the form of Eq. (24.60b), accurate to linear order in separation $x^{\hat{j}}$ from the origin of coordinates.
- (b) Compute the connection coefficients for the coordinate basis of Eq. (24.60b) at an arbitrary event on the observer's world line. Do so first by hand calculations, and then verify your results using symbolic-manipulation software on a computer.
- (c) Using the connection coefficients from part (b), show that the rate of change of the basis vectors $\mathbf{e}_{\hat{\alpha}}$ along the observer's world line is given by Eq. (24.61).

EXERCISES

- (d) Using the connection coefficients from part (b), show that the low-velocity limit of the geodesic equation [Eq. (24.67)] is given by Eq. (24.68).

24.5.3

24.5.3 Uniformly Accelerated Observer

As an important example (cf. Ex. 2.16), consider an observer whose accelerated world line, written in some inertial (Lorentz) coordinate system $\{t, x, y, z\}$, is

$$t = (1/\kappa) \sinh(\kappa\tau), \quad x = (1/\kappa) \cosh(\kappa\tau), \quad y = z = 0. \quad (24.69)$$

Here τ is proper time along the world line, and κ is the magnitude of the observer's 4-acceleration: $\kappa = |\vec{a}|$ (which is constant along the world line; see Ex. 24.15, where the reader can derive the various claims made in this subsection and the next).

The world line (24.69) is depicted in Fig. 24.7 as a thick, solid hyperbola that asymptotes to the past light cone at early times and to the future light cone at late times. The dots along the world line mark events that have proper times $\tau = -1.2, -0.9, -0.6, -0.3, 0.0, +0.3, +0.6, +0.9, +1.2$ (in units of $1/\kappa$). At each of these dots, the 3-plane orthogonal to the world line is represented by a dashed line (with the 2 dimensions out of the plane of the paper suppressed from the diagram). This 3-plane is labeled by its coordinate time $x^{\hat{0}}$, which is equal to the proper time of the dot. The basis vector $\vec{e}_{\hat{1}}$ is chosen to point along the observer's 4-acceleration, so $\vec{a} = \kappa\vec{e}_{\hat{1}}$. The coordinate $x^{\hat{1}}$ measures proper distance along the straight line that starts out tangent to $\vec{e}_{\hat{1}}$. The other two basis vectors $\vec{e}_{\hat{2}}$ and $\vec{e}_{\hat{3}}$ point out of the plane of the figure and are parallel transported along the world line: $\nabla_{\vec{U}}\vec{e}_{\hat{2}} = \nabla_{\vec{U}}\vec{e}_{\hat{3}} = 0$. In addition, $x^{\hat{2}}$ and $x^{\hat{3}}$ are measured along straight lines, in the orthogonal 3-plane, that start out tangent to these vectors. This construction implies that the resulting proper reference frame has vanishing rotation, $\vec{\Omega} = 0$ (Ex. 24.15), and that $x^{\hat{2}} = y$ and $x^{\hat{3}} = z$, where y and z are coordinates in the $\{t, x, y, z\}$ Lorentz frame that we used to define the world line [Eqs. (24.69)].

Usually, when constructing an observer's proper reference frame, one confines attention to the immediate vicinity of her world line. However, in this special case it is instructive to extend the construction (the orthogonal 3-planes and their resulting spacetime coordinates) outward arbitrarily far. By doing so, we discover that the 3-planes all cross at location $x^{\hat{1}} = -1/\kappa$, which means the coordinate system $\{x^{\hat{a}}\}$ becomes singular there. This singularity shows up in a vanishing $g_{\hat{0}\hat{0}}(x^{\hat{1}} = -1/\kappa)$ for the spacetime metric, written in that coordinate system:

$$ds^2 = -(1 + \kappa x^{\hat{1}})^2 (dx^{\hat{0}})^2 + (dx^{\hat{1}})^2 + (dx^{\hat{2}})^2 + (dx^{\hat{3}})^2. \quad (24.70)$$

[Note that for $|x^{\hat{1}}| \ll 1/\kappa$ this metric agrees with the general proper-reference-frame metric (24.60b).] From Fig. 24.7, it should be clear that this coordinate system can only cover smoothly one quadrant of Minkowski spacetime: the quadrant $x > |t|$.

transformation between inertial coordinates and uniformly accelerated coordinates

singularity of uniformly accelerated coordinates

spacetime metric in uniformly accelerated coordinates

FIGURE 24.7 The proper reference frame of a uniformly accelerated observer. All lengths and times are measured in units of $1/\kappa$. We show only 2 dimensions of the reference frame—those in the 2-plane of the observer's curved world line.

24.5.4 Rindler Coordinates for Minkowski Spacetime

24.5.4

The spacetime metric (24.70) in our observer's proper reference frame resembles the metric in the vicinity of a black hole, as expressed in coordinates of observers who accelerate so as to avoid falling into the hole. In preparation for discussing this in

Rindler coordinates

Chap. 26, we shift the origin of our proper-reference-frame coordinates to the singular point and rename them. Specifically, we introduce so-called *Rindler coordinates*:

$$t' = x^{\hat{0}}, \quad x' = x^{\hat{1}} + 1/\kappa, \quad y' = x^{\hat{2}}, \quad z' = x^{\hat{3}}. \quad (24.71)$$

It turns out (Ex. 24.15) that these coordinates are related to the Lorentz coordinates that we began with, in Eqs. (24.69), by

$$t = x' \sinh(\kappa t'), \quad x = x' \cosh(\kappa t'), \quad y = y', \quad z = z'. \quad (24.72)$$

The metric in this Rindler coordinate system, of course, is the same as (24.70) with displacement of the origin:

$$ds^2 = -(\kappa x')^2 dt'^2 + dx'^2 + dy'^2 + dz'^2. \quad (24.73)$$

spacetime metric in Rindler coordinates

The world lines of constant $\{x', y', z'\}$ have uniform acceleration: $\vec{a} = (1/x')\vec{e}_{x'}$. Thus we can think of these coordinates as the reference frame of a family of uniformly accelerated observers, each of whom accelerates away from their *horizon* $x' = 0$ with acceleration equal to $1/(\text{her distance } x' \text{ above the horizon})$. (We use the name “horizon” for $x' = 0$, because it represents the edge of the region of spacetime that these observers are able to observe.) The local 3-planes orthogonal to these observers’ world lines all mesh to form global 3-planes of constant t' . This is a major factor in making the metric (24.73) so simple.

horizon of Rindler coordinates

EXERCISES

Exercise 24.15 *Derivation: Uniformly Accelerated Observer and Rindler Coordinates*

In this exercise you will derive the various claims made in Secs. 24.5.3 and 24.5.4.

- (a) Show that the parameter τ along the world line (24.69) is proper time and that the 4-acceleration has magnitude $|\vec{a}| = 1/\kappa$.
- (b) Show that the unit vectors \vec{e}_j introduced in Sec. 24.5.3 all obey the Fermi-Walker transport law (24.62) and therefore, by virtue of Eq. (24.61b), the proper reference frame built from them has vanishing rotation rate: $\vec{\Omega} = 0$.
- (c) Show that the coordinates $x^{\hat{2}}$ and $x^{\hat{3}}$ introduced in Sec. 24.5.3 are equal to the y and z coordinates of the inertial frame used to define the observer’s world line [Eqs. (24.69)].
- (d) Show that the proper-reference-frame coordinates constructed in Sec. 24.5.3 are related to the original $\{t, x, y, z\}$ coordinates by

$$t = (x^{\hat{1}} + 1/\kappa) \sinh(\kappa x^{\hat{0}}), \quad x = (x^{\hat{1}} + 1/\kappa) \cosh(\kappa x^{\hat{0}}), \quad y = x^{\hat{2}}, \quad z = x^{\hat{3}}; \quad (24.74)$$

and from this, deduce the form (24.70) of the Minkowski spacetime metric in the observer’s proper reference frame.

- (e) Show that, when converted to Rindler coordinates by moving the spatial origin, the coordinate transformation (24.74) becomes (24.72), and the metric (24.70) becomes (24.73).
- (f) Show that observers at rest in the Rindler coordinate system (i.e., who move along world lines of constant $\{x', y', z'\}$) have 4-acceleration $\vec{a} = (1/x')\vec{e}_{x'}$.

Exercise 24.16 *Example: Gravitational Redshift*

Inside a laboratory on Earth's surface the effects of spacetime curvature are so small that current technology cannot measure them. Therefore, experiments performed in the laboratory can be analyzed using special relativity. (This fact is embodied in Einstein's equivalence principle; end of Sec. 25.2.)

- (a) Explain why the spacetime metric in the proper reference frame of the laboratory's floor has the form

$$ds^2 = (1 + 2gz)(dx^{\hat{0}})^2 + dx^2 + dy^2 + dz^2, \quad (24.75)$$

plus terms due to the slow rotation of the laboratory walls, which we neglect in this exercise. Here g is the acceleration of gravity measured on the floor.

- (b) An electromagnetic wave is emitted from the floor, where it is measured to have wavelength λ_o , and is received at the ceiling. Using the metric (24.75), show that, as measured in the proper reference frame of an observer on the ceiling, the received wave has wavelength $\lambda_r = \lambda_o(1 + gh)$, where h is the height of the ceiling above the floor (i.e., the light is *gravitationally redshifted* by $\Delta\lambda/\lambda_o = gh$). [Hint: Show that all crests of the wave must travel along world lines that have the same shape, $z = F(x^{\hat{0}} - x_e^{\hat{0}})$, where F is some function, and $x_e^{\hat{0}}$ is the coordinate time at which the crest is emitted from the floor. You can compute the shape function F if you wish, but it is not needed to derive the gravitational redshift; only its universality is needed.]

The first high-precision experiments to test this prediction were by Robert Pound and his student Glen Rebka and postdoc Joseph Snider, in a tower at Harvard University in the 1950s and 1960s. They achieved 1% accuracy. We discuss this gravitational redshift in Sec. 27.2.1.

Exercise 24.17 *Example: Rigidly Rotating Disk*

Consider a thin disk with radius R at $z = 0$ in a Lorentz reference frame. The disk rotates rigidly with angular velocity Ω . In the early years of special relativity there was much confusion over the geometry of the disk: In the inertial frame it has physical radius (proper distance from center to edge) R and physical circumference $C = 2\pi R$. But Lorentz contraction dictates that, as measured on the disk, the circumference should be $\sqrt{1 - v^2} C$ (with $v = \Omega R$), and the physical radius, R , should be unchanged. This seemed weird. How could an obviously flat disk in flat spacetime have a curved,

non-Euclidean geometry, with physical circumference divided by physical radius smaller than 2π ? In this exercise you will explore this issue.

- (a) Consider a family of observers who ride on the edge of the disk. Construct a circular curve, orthogonal to their world lines, that travels around the disk (at $\sqrt{x^2 + y^2} = R$). This curve can be thought of as lying in a 3-surface of constant time $x^{\hat{0}}$ of the observers' proper reference frames. Show that it spirals upward in a Lorentz-frame spacetime diagram, so it cannot close on itself after traveling around the disk. Thus the 3-planes, orthogonal to the observers' world lines at the edge of the disk, cannot mesh globally to form global 3-planes (by contrast with the case of the uniformly accelerated observers in Sec. 24.5.4 and Ex. 24.15).
- (b) Next, consider a 2-dimensional family of observers who ride on the surface of the rotating disk. Show that at each radius $\sqrt{x^2 + y^2} = \text{const}$, the constant-radius curve that is orthogonal to their world lines spirals upward in spacetime with a different slope. Show this means that even locally, the 3-planes orthogonal to each of their world lines cannot mesh to form larger 3-planes—thus there does not reside in spacetime any 3-surface orthogonal to these observers' world lines. There is no 3-surface that has the claimed non-Euclidean geometry.

Bibliographic Note

For a very readable presentation of most of this chapter's material, from much the same point of view, see Hartle (2003, Chap. 20). For an equally elementary introduction from a somewhat different viewpoint, see Schutz (2009, Chaps. 1–4). A far more detailed and somewhat more sophisticated introduction, largely but not entirely from our viewpoint, will be found in Misner, Thorne, and Wheeler (1973, Chaps. 1–6). More sophisticated treatments from rather different viewpoints than ours are given in Wald (1984, Chaps. 1, 2, and Sec. 3.1), and Carroll (2004, Chaps. 1, 2). A treasure trove of exercises on this material, with solutions, is in Lightman et al. (1975, Chaps. 6–8). See also the bibliography for Chap. 2.

For a detailed and sophisticated discussion of accelerated observers and the measurements they make, see Gourgoulhon (2013).

Fundamental Concepts of General Relativity

The physical world is represented as a four dimensional continuum. If in this I adopt a Riemannian metric, and look for the simplest laws which such a metric can satisfy, I arrive at the relativistic gravitation theory of empty space.

ALBERT EINSTEIN (1934)

25.1 History and Overview

25.1

Newton's theory of gravity is logically incompatible with the special theory of relativity. Newtonian gravity presumes the existence of a universal, frame-independent 3-dimensional space in which lives the Newtonian potential Φ and a universal, frame-independent time t with respect to which the propagation of Φ is instantaneous. By contrast, special relativity insists that the concepts of time and of 3-dimensional space are frame dependent, so that instantaneous propagation of Φ in one frame would mean noninstantaneous propagation in another.

The most straightforward way to remedy this incompatibility is to retain the assumption that gravity is described by a scalar field Φ but modify Newton's instantaneous, action-at-a-distance field equation

$$\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \Phi = 4\pi G\rho \quad (25.1)$$

(where G is Newton's gravitation constant and ρ is the mass density) to read

$$\square\Phi \equiv g^{\alpha\beta}\Phi_{;\alpha\beta} = -4\pi GT^\mu{}_\mu, \quad (25.2a)$$

where $\square \equiv \vec{\nabla} \cdot \vec{\nabla}$ is the squared gradient (i.e., d'Alembertian or wave operator) in Minkowski spacetime, and $T^\mu{}_\mu$ is the trace (i.e., contraction on its two slots) of the stress-energy tensor. This modified field equation at first sight is attractive and satisfactory (but see Ex. 25.1): (i) it satisfies Einstein's Principle of Relativity in that it is expressed as a geometric, frame-independent relationship among geometric objects; and (ii) in any Lorentz frame it takes the form [with factors of $c =$ (speed of light) restored]:

$$\left(-\frac{1}{c^2} \frac{\partial^2}{\partial t^2} + \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \Phi = \frac{4\pi G}{c^2} (T^{00} - T^{xx} - T^{yy} - T^{zz}), \quad (25.2b)$$

which reduces to the Newtonian field equation (25.1) in the kinds of situation contemplated by Newton [energy density predominantly due to rest-mass density, $T^{00} \cong \rho c^2$;

BOX 25.1. READERS' GUIDE

- This chapter relies significantly on:
 - Chap. 2 on special relativity; and
 - Chap. 24 on the transition from special relativity to general relativity.
- This chapter is a foundation for the applications of general relativity theory in Chaps. 26–28.

stress negligible compared to rest mass-energy density, $|T^{jk}| \ll \rho c^2$; and $1/c \times$ (time rate of change of Φ) negligible compared to spatial gradient of Φ].

Not surprisingly, most theoretical physicists in the decade following Einstein's formulation of special relativity (1905–1915) presumed that gravity would be correctly describable, in the framework of special relativity, by this type of modification of Newton's theory, or something resembling it. For a brief historical account, see Pais (1982, Chap. 13). To Einstein, by contrast, it seemed clear that the correct description of gravity should involve a generalization of special relativity rather than an incorporation into special relativity: since an observer in a local, freely falling reference frame near Earth should not feel any gravitational acceleration at all, local freely falling frames (local inertial frames) should in some sense be the domain of special relativity, and gravity should somehow be described by the relative acceleration of such frames.

Although the seeds of this idea were in Einstein's mind as early as 1907 [see the discussion of the equivalence principle in Einstein (1907)], it required 8 years for him to bring them to fruition. A first crucial step, which took half the 8 years, was for Einstein to conquer his initial aversion to Minkowski's geometric formulation of special relativity and to realize that a curvature of Minkowski's 4-dimensional spacetime is the key to understanding the relative acceleration of freely falling frames. The second crucial step was to master the mathematics of differential geometry, which describes spacetime curvature, and using that mathematics, to formulate a logically self-consistent theory of gravity. This second step took an additional 4 years and culminated in Einstein's (1915, 1916a) general theory of relativity. For a historical account of Einstein's 8-year struggle toward general relativity, see, for example, Pais (1982, Part IV). For selected quotations from Einstein's technical papers during this 8-year period, which tell the story of his struggle, see Misner, Thorne, and Wheeler (1973, Sec. 17.7). For his papers themselves with scholarly annotations, see Einstein (1989, vols. 2–4, 6).

It is remarkable that Einstein was led, not by experiment, but by philosophical and aesthetic arguments, to reject the incorporation of gravity into special relativity [Eqs. (25.2) and Ex. 25.1], and to insist instead on describing gravity by curved

key idea of general relativity: gravity described by relative acceleration of local inertial frames

the mathematics of general relativity: differential geometry in curved spacetime

spacetime. Only after the full formulation of his general relativity did experiments begin to confirm that he was right and that the advocates of special-relativistic gravity were wrong, and only a half century after general relativity was formulated did the experimental evidence become extensive and strong. For detailed discussions see, for example, Will (1993a,b, 2014).

The mathematical tools, the diagrams, and the phrases by which we describe general relativity have changed somewhat in the century since Einstein formulated his theory. Indeed, we can even assert that we understand the theory more deeply than did Einstein. However, the basic ideas are unchanged, and general relativity's claim to be the most elegant and aesthetic of physical theories has been reinforced and strengthened by our growing insights.

General relativity is not merely a theory of gravity. Like special relativity before it, the general theory is a framework in which to formulate all the laws of physics, classical and quantum—but now with gravity included. However, there is one remaining, crucial, gaping hole in this framework. It is incapable of functioning—indeed, it fails completely—when conditions become so extreme that space and time themselves must be quantized. In those extreme conditions general relativity must be married in some deep, as-yet-ill-understood way, with quantum theory, to produce an all-inclusive quantum theory of gravity—a theory that, one may hope, will be a “theory of everything.” To this we shall return, briefly, in Chaps. 26 and 28.

In this chapter, we present, in modern language, the foundations of general relativity. Our presentation is proudly geometrical, as this seems to us the most powerful approach to general relativity for most situations. By contrast, some outstanding physicists, particularly Weinberg (1972, especially his preface), prefer a field-theoretic approach. Our presentation relies heavily on the geometric concepts, viewpoint, and formalism developed in Chaps. 2 and 24.

We begin in Sec. 25.2 with a discussion of three concepts that are crucial to Einstein's viewpoint on gravity: a local Lorentz frame (the closest thing there is, in the presence of gravity, to special relativity's “global” Lorentz frame), the extension of the Principle of Relativity to deal with gravitational situations, and Einstein's equivalence principle by which one can “lift” laws of physics out of the flat spacetime of special relativity and into the curved spacetime of general relativity. In Sec. 25.3, we see how gravity prevents the meshing of local Lorentz frames to form global Lorentz frames and infer from this that spacetime must be curved. In Sec. 25.4, we lift into curved spacetime the law of motion for free test particles, and in Sec. 25.5, we see how spacetime curvature pushes two freely moving test particles together or apart, and we use this phenomenon to make contact between spacetime curvature and the Newtonian “tidal gravitational field” (gradient of the Newtonian gravitational acceleration). In Sec. 25.6, we study some mathematical and geometric properties of the tensor field that embodies spacetime curvature: the Riemann tensor. In Sec. 25.7, we examine “curvature coupling delicacies” that plague the lifting of laws of physics from flat spacetime to curved spacetime. In Sec. 25.8, we meet the Einstein field equation, which

general relativity as a framework for all the laws of physics

describes the manner in which spacetime curvature is produced by the total stress-energy tensor of all matter and nongravitational fields. In Sec. 25.9.1, we examine in some detail how Newton's laws of gravity arise as a weak-gravity, slow-motion, low-stress limit of general relativity. In Sec. 25.9.2, we develop an approximation to general relativity called "linearized theory" that is valid when gravity is weak but speeds and stresses may be high, and in Sec. 25.9.3, we use this approximation to deduce the weak relativistic gravitational field outside a stationary (unchanging) source. Finally, in Secs. 25.9.4 and 25.9.5, we examine the conservation laws for energy, momentum, and angular momentum of gravitating bodies that live in "asymptotically flat" regions of spacetime.

EXERCISES

Exercise 25.1 *Example: A Special Relativistic, Scalar-Field Theory of Gravity*

Equation (25.2a) is the field equation for a special relativistic theory of gravity with gravitational potential Φ . To complete the theory, one must describe the forces that the field Φ produces on matter.

- (a) One conceivable choice for the force on a test particle of rest mass m is the following generalization of the familiar Newtonian expression:

$$\nabla_{\vec{u}} \vec{p} = -m \vec{\nabla} \Phi; \quad \text{that is, } \frac{dp_{\alpha}}{d\tau} = -m \Phi_{,\alpha} \quad \text{in a Lorentz frame,} \quad (25.3)$$

where τ is proper time along the particle's world line, \vec{p} is the particle's 4-momentum, \vec{u} is its 4-velocity, and $\vec{\nabla} \Phi$ is the spacetime gradient of the gravitational potential. Show that this equation of motion reduces, in a Lorentz frame and for low particle velocities, to the standard Newtonian equation of motion. Show, however, that this equation of motion is flawed in that the gravitational field will alter the particle's rest mass—in violation of extensive experimental evidence that the rest mass of an elementary particle is unique and conserved.

- (b) Show that the equation of motion (25.3), when modified to read:

$$\begin{aligned} \nabla_{\vec{u}} \vec{p} &= -(\mathbf{g} + \vec{u} \otimes \vec{u}) \cdot m \vec{\nabla} \Phi; \\ \text{that is, } \frac{dp^{\alpha}}{d\tau} &= -(\mathbf{g}^{\alpha\beta} + u^{\alpha} u^{\beta}) m \Phi_{,\beta} \quad \text{in a Lorentz frame,} \end{aligned} \quad (25.4)$$

preserves the particle's rest mass. In this equation of motion \vec{u} is the particle's 4-velocity, \mathbf{g} is the metric, and $\mathbf{g} + \vec{u} \otimes \vec{u}$ projects $\vec{\nabla} \Phi$ into the 3-space orthogonal to the particle's world line (cf. Fig. 24.6 and Ex. 2.10).

- (c) Show, by treating a zero-rest-mass particle as the limit of a particle of finite rest mass ($\vec{p} = m\vec{u}$ and $\zeta = \tau/m$ finite as τ and m go to zero), that the theory sketched in parts (a) and (b) predicts that in any Lorentz reference frame, $p^{\alpha} e^{\Phi}$ (with $\alpha = 0, 1, 2, 3$) are constant along the zero-rest-mass particle's world line. Explain why this prediction implies that there will be no gravitational deflection of light by the Sun, which conflicts severely with experiments that were done after Einstein formulated his general theory of relativity (see Sec. 27.2.3). (There was no way,

experimentally, to rule out this theory in the epoch, ca. 1914, when Einstein was doing battle with his colleagues over whether gravity should be treated by adding a gravitational force to special relativity or should be treated as a geometric extension of special relativity.)

25.2 Local Lorentz Frames, the Principle of Relativity, and Einstein's Equivalence Principle

25.2

One of Einstein's greatest insights was to recognize that special relativity is valid not globally, but only locally, inside local, freely falling (inertial) reference frames. Figure 25.1 shows an example of a *local inertial frame*: the interior of a Space Shuttle in Earth orbit, where an astronaut has set up a freely falling (from his viewpoint "freely floating") latticework of rods and clocks. This latticework is constructed by all the rules appropriate to a special relativistic, inertial (Lorentz) reference frame (Secs. 2.2.1 and 24.2.2): (i) the latticework moves freely through spacetime, so no forces act on it, and its rods are attached to gyroscopes so they do not rotate; (ii) the measuring rods are orthogonal to one another, with their intervals of length uniform compared, for example, to the wavelength of light (orthonormal lattice); (iii) the clocks are densely packed in the lattice, they tick uniformly relative to ideal atomic standards (they are ideal clocks), and they are synchronized by the Einstein light-pulse process. However, there is one crucial change from special relativity: The latticework must be *small enough* that one can neglect the effects of inhomogeneities of gravity (which general relativity will associate with spacetime curvature; and which, e.g., would cause two freely floating particles, one nearer Earth than the other, to gradually move apart, even though initially they are at rest with respect to each other). The necessity for smallness is embodied in the word "local" of "local inertial frame," and we shall quantify it with ever greater precision as we move through this chapter.

local inertial (Lorentz) frame

We use the phrases *local Lorentz frame* and *local inertial frame* interchangeably to describe the above type of synchronized, orthonormal latticework. The spacetime coordinates $\{t, x, y, z\}$ that the latticework provides (in the manner of Sec. 2.2.1) we call, interchangeably, *local Lorentz coordinates* and *local inertial coordinates*.

local inertial (Lorentz) coordinates

FIGURE 25.1 A local inertial frame (local Lorentz frame) inside a Space Shuttle that is orbiting Earth.

Principle of Relativity in presence of gravity

Since in the presence of gravity, inertial reference frames must be restricted to be local, the inertial-frame version of the Principle of Relativity (Sec. 2.2.2) must similarly be restricted: *all the local, nongravitational laws of physics are the same in every local inertial frame, everywhere and everywhen in the universe.* Here, by “local” laws we mean those laws, classical or quantum, that can be expressed entirely in terms of quantities confined to (measurable in) a local inertial frame. The exclusion of gravitational laws from this version of the Principle of Relativity is necessary, because gravity is to be described by a curvature of spacetime, which (by definition; see below) cannot show up in a local inertial frame. This version of the Principle of Relativity can be described in operational terms using the same language as for the special relativistic version (Secs. 2.2.2 and 24.2.2): If two different observers, in two different local Lorentz frames, in different (or the same) regions of the universe, are given identical written instructions for a physics experiment that can be performed within the confines of their local Lorentz frames, then their two experiments must yield the same results to within their experimental accuracies.

It is worth emphasizing that the Principle of Relativity is asserted to hold everywhere and everywhen in the universe: the local laws of physics must have the same form in the early universe, a fraction of a second after the big bang, as they have on Earth today, and as they have at the center of the Sun or inside a black hole.

Einstein’s equivalence principle

It is reasonable to expect that *the specific forms that the local, nongravitational laws of physics take in general relativistic local Lorentz frames are the same as they take in the (global) Lorentz frames of special relativity.* This assertion is a modern version of Einstein’s equivalence principle. (Einstein’s original version states that local physical measurements in a uniformly accelerated reference frame cannot be distinguished from those in a uniform gravitational field. How is this related to the modern version? See Ex. 26.11.) In the next section, we use this principle to deduce some properties of the general relativistic spacetime metric. In Sec. 25.7 we use it to deduce the forms of some nongravitational laws of physics in curved spacetime, and we discover delicacies (ambiguities) in this principle of equivalence triggered by spacetime curvature.

25.3 The Spacetime Metric, and Gravity as a Curvature of Spacetime

The Einstein equivalence principle guarantees that nongravitational physics in a local Lorentz frame can be described using a spacetime metric \mathbf{g} , which gives for the invariant interval between neighboring events with separation vector $\vec{\xi} = \Delta x^\alpha \partial / \partial x^\alpha$, the standard special relativistic expression

$$\vec{\xi}^2 = g_{\alpha\beta} \xi^\alpha \xi^\beta = (\Delta s)^2 = -(\Delta t)^2 + (\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2. \quad (25.5)$$

Correspondingly, in a local Lorentz frame the components of the spacetime metric take on their standard special relativity values:

$$g_{\alpha\beta} = \eta_{\alpha\beta} \equiv \{-1 \text{ if } \alpha = \beta = 0, \quad +1 \text{ if } \alpha = \beta = (x, y, \text{ or } z), \quad 0 \text{ otherwise}\}. \quad (25.6)$$

FIGURE 25.2 (a) A family of local Lorentz frames, all momentarily at rest above Earth's surface. (b) A family of local, 2-dimensional Euclidean coordinate systems on Earth's surface. The nonmeshing of Lorentz frames in (a) is analogous to the nonmeshing of Euclidean coordinates in (b) and motivates attributing gravity to a curvature of spacetime.

Turn, now, to a first look at gravity-induced constraints on the size of a local Lorentz frame. Above Earth, set up a family of local Lorentz frames scattered over the entire region from two Earth radii out to four Earth radii, with all the frames initially at rest with respect to Earth (Fig. 25.2a). From experience—or, if you prefer, from Newton's theory of gravity which after all is quite accurate near Earth—we know that, as time passes, these frames will all fall toward Earth. If (as a pedagogical aid) we drill holes through Earth to let the frames continue falling after reaching its surface, the frames will all pass through Earth's center and fly out the opposite side.

Obviously, two adjacent frames, which initially were at rest with respect to each other, acquire a relative velocity during their fall, which causes them to interpenetrate and pass through each other. Gravity is the cause of their relative velocity.

If these two adjacent frames could be meshed to form a larger Lorentz frame, then as time passes they would always remain at rest relative to each other. Thus, a meshing to form a larger Lorentz frame is impossible. The gravity-induced relative velocity prevents it. In brief: gravity prevents the meshing of local Lorentz frames to form global Lorentz frames.

This situation is closely analogous to the nonmeshing of local, 2-dimensional, Euclidean coordinate systems on the surface of Earth (Figure 25.2b): the curvature of Earth prevents a Euclidean mesh—thereby giving grief to mapmakers and surveyors. This analogy suggested to Einstein in 1912 a powerful new viewpoint on gravity. Just as the curvature of Earth prevents the meshing of local Euclidean coordinates on Earth's surface, so it must be that a curvature of spacetime prevents the meshing of local Lorentz frames in the spacetime above Earth—or anywhere else, for that matter. And since it is already known that gravity is the cause of the nonmeshing of Lorentz frames, it must be that *gravity is a manifestation of spacetime curvature*.

nonmeshing of local Lorentz frames

gravity is a manifestation of spacetime curvature

To make this idea more quantitative, consider, as a pedagogical tool, the 2-dimensional metric of Earth's surface, idealized as spherical and expressed in terms of a spherical polar coordinate system in line-element form [Eq. (2.24)]:

$$ds^2 = R^2 d\theta^2 + R^2 \sin^2 \theta d\phi^2. \quad (25.7a)$$

Here R is the radius of Earth, or equivalently, the “radius of curvature” of Earth's surface. This line element, rewritten in terms of the alternative coordinates

$$x \equiv R\phi, \quad y \equiv R \left(\frac{\pi}{2} - \theta \right), \quad (25.7b)$$

has the form

$$ds^2 = \cos^2(y/R) dx^2 + dy^2 = dx^2 + dy^2 + O(y^2/R^2) dx^2, \quad (25.7c)$$

where as usual, $O(y^2/R^2)$ means “terms of order y^2/R^2 or smaller.” Notice that the metric coefficients have the standard Euclidean form $g_{jk} = \delta_{jk}$ all along the equator ($y = 0$); but as one moves away from the equator, they begin to differ from Euclidean by fractional amounts of $O(y^2/R^2) = O[y^2/(\text{radius of curvature of Earth})^2]$. Thus, local Euclidean coordinates can be meshed and remain Euclidean all along the equator—or along any other great circle—but Earth's curvature forces the coordinates to cease being Euclidean when one moves off the chosen great circle, thereby causing the metric coefficients to differ from δ_{jk} by amounts $\Delta g_{jk} = O[(\text{distance from great circle})^2/(\text{radius of curvature})^2]$.

nonmeshing of local Euclidean coordinates on Earth's curved surface

Turn next to a specific example of curved spacetime: that of a $k = 0$ Robertson-Walker model for our expanding universe (to be studied in depth in Chap. 28). In spherical coordinates $\{\eta, \chi, \theta, \phi\}$, the 4-dimensional metric of this curved spacetime, described as a line element, can take the form

$$ds^2 = a^2(\eta)[-d\eta^2 + d\chi^2 + \chi^2(d\theta^2 + \sin^2 \theta d\phi^2)]. \quad (25.8a)$$

Here a , the “expansion factor of the universe,” is a monotonic increasing function of the “time” coordinate η (not to be confused with the flat metric $\eta_{\alpha\beta}$). This line element, rewritten near $\chi = 0$ in terms of the alternative coordinates

$$t = \int_0^\eta a d\eta + \frac{1}{2} \chi^2 \frac{da}{d\eta}, \quad x = a\chi \sin \theta \cos \phi, \quad y = a\chi \sin \theta \sin \phi, \quad z = a\chi \cos \theta, \quad (25.8b)$$

takes the form (Ex. 25.2)

$$ds^2 = \eta_{\alpha\beta} dx^\alpha dx^\beta + O\left(\frac{x^2 + y^2 + z^2}{\mathcal{R}^2}\right) dx^\alpha dx^\beta, \quad (25.8c)$$

where \mathcal{R} is a quantity that, by analogy with the radius of curvature R of Earth's surface, can be identified as a radius of curvature of spacetime:

cosmological example of nonmeshing

$$\frac{1}{\mathcal{R}^2} = \mathcal{O}\left(\frac{\dot{a}^2}{a^2}\right) + \mathcal{O}\left(\frac{\ddot{a}}{a}\right), \quad \text{where} \quad \dot{a} \equiv \left(\frac{da}{dt}\right)_{x=y=z=0}, \quad \ddot{a} \equiv \left(\frac{d^2a}{dt^2}\right)_{x=y=z=0}. \quad (25.8d)$$

From the form of the metric coefficients in Eq. (25.8d), we see that, all along the world line $x = y = z = 0$, the coordinates are precisely Lorentz, but as one moves away from that world line they cease to be Lorentz, and the metric coefficients begin to differ from $\eta_{\alpha\beta}$ by amounts $\Delta g_{\alpha\beta} = \mathcal{O}[(\text{distance from the chosen world line})^2 / (\text{radius of curvature of spacetime})^2]$. This result is completely analogous to our equatorial Euclidean coordinates on Earth's surface. The curvature of Earth's surface prevented our local Euclidean coordinates from remaining Euclidean as we moved away from the equator; here the curvature of spacetime prevents our local Lorentz coordinates from remaining Lorentz as we move away from the chosen world line.

Notice that the chosen world line is the spatial origin of our local Lorentz coordinates. Thus we can think of those coordinates as provided by a tiny, spatial latticework of rods and clocks, like that of Figure 25.1. The latticework remains locally Lorentz for all time (as measured by its own clocks), but it ceases to be locally Lorentz when one moves a finite spatial distance away from the spatial origin of the latticework.

This behavior is generic. One can show [see, e.g., Misner, Thorne, and Wheeler (1973, Sec. 13.6, esp. item (5) on p. 331)] specialized to vanishing acceleration and rotation] that, if any freely falling observer, anywhere in spacetime, sets up a little latticework of rods and clocks in accord with our standard rules and keeps the latticework's spatial origin on her free-fall world line, then the coordinates provided by the latticework will be locally Lorentz, with metric coefficients

$$g_{\alpha\beta} = \left\{ \begin{array}{l} \eta_{\alpha\beta} + \mathcal{O}\left(\frac{\delta_{jk}x^jx^k}{\mathcal{R}^2}\right), \\ \eta_{\alpha\beta} \quad \text{at spatial origin} \end{array} \right\} \text{ in a local Lorentz frame,} \quad (25.9a)$$

where \mathcal{R} is the radius of curvature of spacetime. Notice that, because the deviations of the metric from $\eta_{\alpha\beta}$ are of second order in the distance from the spatial origin, the first derivatives of the metric coefficients are of first order: $g_{\alpha\beta,k} = \mathcal{O}(x^j/\mathcal{R}^2)$. This, plus the vanishing of the commutation coefficients in our coordinate basis, implies that the connection coefficients of the local Lorentz frame's coordinate basis are [Eqs. (24.38c) and (24.38d)]¹

$$\Gamma^\alpha_{\beta\gamma} = \left\{ \begin{array}{l} \mathcal{O}\left(\frac{\sqrt{\delta_{jk}x^jx^k}}{\mathcal{R}^2}\right), \\ 0 \quad \text{at spatial origin} \end{array} \right\} \text{ in a local Lorentz frame.} \quad (25.9b)$$

1. In any manifold, coordinates for which the metric and connection have the form of Eqs. (25.9) in the vicinity of some chosen geodesic (the "spatial origin") are called *Fermi coordinates* or sometimes *Fermi normal coordinates*.

spacetime curvature forces Lorentz coordinates to be only locally Lorentz

metric coefficients in a local Lorentz frame

connection coefficients in a local Lorentz frame

It is instructive to compare Eq. (25.9a) for the metric in the local Lorentz frame of a freely falling observer in curved spacetime with Eq. (24.60b) for the metric in the proper reference frame of an accelerated observer in flat spacetime. Whereas the spacetime curvature in Eq. (25.9a) produces corrections to $g_{\alpha\beta} = \eta_{\alpha\beta}$ of second order in distance from the world line, the acceleration and spatial rotation of the reference frame in Eq. (24.60b) produce corrections of first order. This remains true when one studies accelerated observers in curved spacetime (e.g., Sec. 26.3.2). In their proper reference frames, the metric coefficients $g_{\alpha\beta}$ contain both the first-order terms of Eq. (24.60b) due to acceleration and rotation [e.g., Eq. (26.26)], and the second-order terms of Eq. (25.9a) due to spacetime curvature.

EXERCISES

Exercise 25.2 *Derivation: Local Lorentz Frame in Robertson-Walker Universe*

By inserting the coordinate transformation (25.8b) into the Robertson-Walker metric (25.8a), derive the metric (25.8c), (25.8d) for a local Lorentz frame.

25.4 25.4 Free-Fall Motion and Geodesics of Spacetime

To make more precise the concept of spacetime curvature, we need to study quantitatively the relative acceleration of neighboring, freely falling particles. Before we can carry out such a study, however, we must understand quantitatively the motion of a single freely falling particle in curved spacetime. That is the objective of this section.

In a global Lorentz frame of flat, special relativistic spacetime, a free particle moves along a straight world line—one with the form

$$(t, x, y, z) = (t_o, x_o, y_o, z_o) + (p^0, p^x, p^y, p^z)\zeta; \quad \text{that is, } x^\alpha = x_o^\alpha + p^\alpha \zeta. \quad (25.10a)$$

Here the p^α are the Lorentz-frame components of the particle's 4-momentum; ζ is the affine parameter such that $\vec{p} = d/d\zeta$, so $p^\alpha = dx^\alpha/d\zeta$ [Eq. (2.10) and subsequent material]; and x_o^α are the coordinates of the particle when its affine parameter is $\zeta = 0$. The straight-line motion (25.10a) can be described equally well by the statement that the Lorentz-frame components p^α of the particle's 4-momentum are constant (i.e., are independent of ζ):

$$\frac{dp^\alpha}{d\zeta} = 0. \quad (25.10b)$$

Even nicer is the frame-independent description, which says that, as the particle moves, it parallel-transport its tangent vector \vec{p} along its world line:

$$\nabla_{\vec{p}} \vec{p} = 0, \quad \text{or equivalently, } p^\alpha{}_{;\beta} p^\beta = 0. \quad (25.10c)$$

For a particle with nonzero rest mass m , which has $\vec{p} = m\vec{u}$ and $\zeta = \tau/m$ (with $\vec{u} = d/d\tau$ its 4-velocity and τ its proper time), Eq. (25.10c) is equivalent to $\nabla_{\vec{u}} \vec{u} = 0$.

This is the *geodesic* form of the particle's law of motion [Eq. (24.64)]; Eq. (25.10c) is the extension of that geodesic law to a particle that may have vanishing rest mass. Recall that the word *geodesic* refers to the particle's straight world line.

This geodesic description of the motion is readily carried over into curved spacetime using the equivalence principle. Let $\mathcal{P}(\zeta)$ be the world line of a freely moving particle in curved spacetime. At a specific event $\mathcal{P}_o = \mathcal{P}(\zeta_o)$ on that world line, introduce a local Lorentz frame (so the frame's spatial origin, carried by the particle, passes through \mathcal{P}_o as time progresses). Then the equivalence principle tells us that the particle's law of motion must be the same in this local Lorentz frame as it is in the global Lorentz frame of special relativity [Eq. (25.10b)]:

$$\left(\frac{dp^\alpha}{d\zeta}\right)_{\zeta=\zeta_o} = 0. \quad (25.11a)$$

More powerful than this local-Lorentz-frame description of the motion is a description that is frame independent. We can easily deduce such a description from Eq. (25.11a). Since the connection coefficients vanish at the spatial origin of the local Lorentz frame where Eq. (25.11a) is being evaluated [cf. Eq. (25.9b)], Eq. (25.11a) can be written equally well, in our local Lorentz frame, as

$$0 = \left(\frac{dp^\alpha}{d\zeta} + \Gamma^\alpha_{\beta\gamma} p^\beta \frac{dx^\gamma}{d\zeta}\right)_{\zeta=\zeta_o} = \left((p^\alpha)_{,\gamma} + \Gamma^\alpha_{\beta\gamma} p^\beta\right) \frac{dx^\gamma}{d\zeta} \Big|_{\zeta=\zeta_o} = (p^\alpha)_{;\gamma} p^\gamma \Big|_{\zeta=\zeta_o}. \quad (25.11b)$$

Thus, as the particle passes through the spatial origin of our local Lorentz coordinate system, the components of the directional derivative of its 4-momentum along itself vanish. Now, if two 4-vectors have components that are equal in one basis, their components are guaranteed [by the tensorial transformation law (24.19)] to be equal in all bases; correspondingly, the two vectors, viewed as frame-independent, geometric objects, must be equal. Thus, since Eq. (25.11b) says that the components of the 4-vector $\nabla_{\vec{p}} \vec{p}$ and the zero vector are equal in our chosen local Lorentz frame, it must be true that

$$\boxed{\nabla_{\vec{p}} \vec{p} = 0} \quad (25.11c)$$

at the moment when the particle passes through the point $\mathcal{P}_o = \mathcal{P}(\zeta_o)$. Moreover, since \mathcal{P}_o is an arbitrary point (event) along the particle's world line, it must be that Eq. (25.11c) is a geometric, frame-independent equation of motion for the particle, valid everywhere along its world line. Notice that this geometric, frame-independent equation of motion $\nabla_{\vec{p}} \vec{p} = 0$ in curved spacetime is precisely the same as that [Eq. (25.10c)] for flat spacetime. We generalize this conclusion to other laws of physics in Sec. 25.7.

Our equation of motion (25.11c) for a freely moving point particle says, in words, that the particle *parallel transports* its 4-momentum along its world line. As in flat

geodesic equation of motion for a freely falling particle in curved spacetime

geodesic equation for particle with finite rest mass

spacetime, so also in curved spacetime, if the particle has finite rest mass, we can rewrite the equation of motion $\nabla_{\vec{p}}\vec{p} = 0$ as

$$\nabla_{\vec{u}}\vec{u} = 0, \quad (25.11d)$$

where $\vec{u} = \vec{p}/m = d/d\tau$ is the particle's 4-velocity, and $\tau = m\zeta$ is proper time along the particle's world line.

In any curved manifold, not just in spacetime, the relation $\vec{\nabla}_{\vec{u}}\vec{u} = 0$ (or $\nabla_{\vec{p}}\vec{p} = 0$) is called the *geodesic equation*, and the curve to which \vec{u} is the tangent vector is called a *geodesic*. If the geodesic is spacelike, its tangent vector can be normalized such that $\vec{u} = d/ds$, with s the proper distance along the geodesic—the obvious analog of $\vec{u} = d/d\tau$ for a timelike geodesic.

On the surface of a sphere, such as Earth, the geodesics are the great circles; they are the unique curves along which local Euclidean coordinates can be meshed, keeping one of the two Euclidean coordinates constant along the curve [cf. Eq. (25.7c)]. They are also the trajectories generated by an airplane's inertial guidance system, which guides the plane along the straightest trajectory it can. Similarly, in spacetime the trajectories of freely falling particles are geodesics. They are the unique curves along which local Lorentz coordinates can be meshed, keeping the three spatial coordinates constant along the curve and letting the time vary, thereby producing a local Lorentz reference frame [Eqs. (25.9)]. They are also the spacetime trajectories along which inertial guidance systems guide a spacecraft.

The geodesic equation $\nabla_{\vec{p}}\vec{p} = 0$ for a particle in spacetime guarantees that the square of the 4-momentum will be conserved along the particle's world line; in slot-naming index notation, we have:

$$(g_{\alpha\beta}p^\alpha p^\beta)_{;\gamma}p^\gamma = 2g_{\alpha\beta}p^\alpha p^\beta_{;\gamma}p^\gamma = 0. \quad (25.12)$$

Here the standard Leibniz rule for differentiating products has been used; this rule follows from the definition (24.29) of the frame-independent directional derivative of a tensor; it also can be deduced in a local Lorentz frame, where $\Gamma^\alpha_{\mu\nu} = 0$, so each gradient with a “;” reduces to a partial derivative with a “,”. In Eq. (25.12) the term involving the gradient of the metric has been discarded, since it vanishes [Eq. (24.39)], and the two terms involving derivatives of p^α and p^β , being equal, have been combined. In index-free notation the frame-independent relation (25.12) says

$$\nabla_{\vec{p}}(\vec{p} \cdot \vec{p}) = 2\vec{p} \cdot \nabla_{\vec{p}}\vec{p} = 0. \quad (25.13)$$

conservation of rest mass for freely falling particle

This is a pleasing result, since the square of the 4-momentum is the negative of the particle's squared rest mass, $\vec{p} \cdot \vec{p} = -m^2$, which surely should be conserved along the particle's free-fall world line! Note that, as in flat spacetime, so also in curved, for a particle of finite rest mass the free-fall trajectory (the geodesic world line) is timelike, $\vec{p} \cdot \vec{p} = -m^2 < 0$, while for a zero-rest-mass particle it is null, $\vec{p} \cdot \vec{p} = 0$. Spacetime

also supports spacelike geodesics [i.e., curves with tangent vectors \vec{p} that satisfy the geodesic equation (25.11c) and are spacelike, $\vec{p} \cdot \vec{p} > 0$]. Such curves can be thought of as the world lines of freely falling “tachyons” (i.e., faster-than-light particles)—though it seems unlikely that such particles exist in Nature. Note that the constancy of $\vec{p} \cdot \vec{p}$ along a geodesic implies that a geodesic can never change its character: if initially timelike, it always remains timelike; if initially null, it remains null; if initially spacelike, it remains spacelike.

The geodesic world line of a freely moving particle has three very important properties:

1. When written in a coordinate basis, the geodesic equation, $\nabla_{\vec{p}}\vec{p} = 0$, becomes the following differential equation for the particle’s world line $x^\alpha(\zeta)$ in the coordinate system (Ex. 25.3):

$$\boxed{\frac{d^2x^\alpha}{d\zeta^2} + \Gamma^\alpha_{\mu\nu} \frac{dx^\mu}{d\zeta} \frac{dx^\nu}{d\zeta} = 0.} \quad (25.14)$$

Here $\Gamma^\alpha_{\mu\nu}$ are the connection coefficients of the coordinate system’s coordinate basis. [Equation (24.66) was a special case of this.] Note that these are four coupled equations ($\alpha = 0, 1, 2, 3$) for the four coordinates x^α as functions of affine parameter ζ along the geodesic. If the initial position, x^α at $\zeta = 0$, and initial tangent vector (particle momentum), $p^\alpha = dx^\alpha/d\zeta$ at $\zeta = 0$, are specified, then these four equations will determine uniquely the coordinates $x^\alpha(\zeta)$ as a function of ζ along the geodesic.

2. Consider a spacetime that possesses a symmetry, which is embodied in the fact that the metric coefficients in some coordinate system are independent of one of the coordinates x^A . Associated with that symmetry there will be a so-called *Killing vector field* $\vec{\xi} = \partial/\partial x^A$ and a conserved quantity $p_A \equiv \vec{p} \cdot \partial/\partial x^A$ for free-particle motion. Exercises 25.4 and 25.5 discuss Killing vector fields, derive this conservation law, and develop a familiar example.
3. Among all timelike curves linking two events \mathcal{P}_0 and \mathcal{P}_1 in spacetime, those whose proper time lapse (timelike length) is stationary under small variations of the curve are timelike geodesics; see Ex. 25.6. In other words, timelike geodesics are the curves that satisfy the action principle (25.19). Now, one can always send a photon from \mathcal{P}_0 to \mathcal{P}_1 by bouncing it off a set of strategically located mirrors, and that photon path is the limit of a timelike curve as the curve becomes null. Therefore, there exist timelike curves from \mathcal{P}_0 to \mathcal{P}_1 with vanishingly small length, so no timelike geodesics can be an absolute minimum of the proper time lapse, but one can be an absolute maximum.

coordinate representation of geodesic equation

Killing vectors and conserved quantities for geodesic motion

action principle of stationary proper time lapse for geodesic motion

Exercise 25.3 *Derivation and Problem: Geodesic Equation in an Arbitrary Coordinate System*

Show that in an arbitrary coordinate system $x^\alpha(\mathcal{P})$ the geodesic equation (25.11c) takes the form of Eq. (25.14).

Exercise 25.4 ***Derivation and Example: Constant of Geodesic Motion in a Spacetime with Symmetry*

- (a) Suppose that in some coordinate system the metric coefficients are independent of some specific coordinate x^A : $g_{\alpha\beta,A} = 0$ (e.g., in spherical polar coordinates $\{t, r, \theta, \phi\}$ in flat spacetime $g_{\alpha\beta,\phi} = 0$, so we could set $x^A = \phi$). Show that

$$p_A \equiv \vec{p} \cdot \frac{\partial}{\partial x^A} \quad (25.15)$$

is a constant of the motion for a freely moving particle [$p_\phi =$ (conserved z -component of angular momentum) in the above, spherically symmetric example]. [Hint: Show that the geodesic equation can be written in the form

$$\frac{dp_\alpha}{d\zeta} - \Gamma_{\mu\alpha\nu} p^\mu p^\nu = 0, \quad (25.16)$$

where $\Gamma_{\mu\alpha\nu}$ is the covariant connection coefficient of Eqs. (24.38c), (24.38d) with $c_{\alpha\beta\gamma} = 0$, because we are using a coordinate basis.] Note the analogy of the constant of the motion p_A with Hamiltonian mechanics: there, if the hamiltonian is independent of x^A , then the generalized momentum p_A is conserved; here, if the metric coefficients are independent of x^A , then the covariant component p_A of the momentum is conserved. For an elucidation of the connection between these two conservation laws, see Ex. 25.7c.

- (b) As an example, consider a particle moving freely through a time-independent, Newtonian gravitational field. In Ex. 25.18, we learn that such a gravitational field can be described in the language of general relativity by the spacetime metric

$$ds^2 = -(1 + 2\Phi)dt^2 + (\delta_{jk} + h_{jk})dx^j dx^k, \quad (25.17)$$

where $\Phi(x, y, z)$ is the time-independent Newtonian potential, and h_{jk} are contributions to the metric that are independent of the time coordinate t and have magnitude of order $|\Phi|$. That the gravitational field is weak means $|\Phi| \ll 1$ (or, in conventional—SI or cgs—units, $|\Phi/c^2| \ll 1$). The coordinates being used are Lorentz, aside from tiny corrections of order $|\Phi|$, and as this exercise and Ex. 25.18 show, they coincide with the coordinates of the Newtonian theory of gravity. Suppose that the particle has a velocity $v^j \equiv dx^j/dt$ through this coordinate system that is $\lesssim |\Phi|^{1/2}$ and thus is small compared to the speed of light. Because the met-

ric is independent of the time coordinate t , the component p_t of the particle's 4-momentum must be conserved along its world line. Since throughout physics, the conserved quantity associated with time-translation invariance is always the energy, we expect that p_t , when evaluated accurate to first order in $|\Phi|$, must be equal to the particle's conserved Newtonian energy, $E = m\Phi + \frac{1}{2}mv^j v^k \delta_{jk}$, aside from some multiplicative and additive constants. Show that this, indeed, is true, and evaluate the constants.

Exercise 25.5 *Example: Killing Vector Field*

A *Killing vector field*² is a coordinate-independent tool for exhibiting symmetries of the metric. It is any vector field $\vec{\xi}$ that satisfies

$$\xi_{\alpha;\beta} + \xi_{\beta;\alpha} = 0 \quad (25.18)$$

(i.e., any vector field whose symmetrized gradient vanishes).

- (a) Let $\vec{\xi}$ be a vector field that might or might not be Killing. Show, by construction, that it is possible to introduce a coordinate system in which $\vec{\xi} = \partial/\partial x^A$ for some coordinate x^A .
- (b) Show that in the coordinate system of part (a) the symmetrized gradient of $\vec{\xi}$ is $\xi_{\alpha;\beta} + \xi_{\beta;\alpha} = \partial g_{\alpha\beta}/\partial x^A$. From this infer that a vector field $\vec{\xi}$ is Killing if and only if there exists a coordinate system in which (i) $\vec{\xi} = \partial/\partial x^A$ and (ii) the metric is independent of x^A .
- (c) Use Killing's equation (25.18) to show, without introducing a coordinate system, that, if $\vec{\xi}$ is a Killing vector field and \vec{p} is the 4-momentum of a freely falling particle, then $\vec{\xi} \cdot \vec{p}$ is conserved along the particle's geodesic world line. This is the same conservation law as we proved in Ex. 25.4a using a coordinate-dependent calculation.

Exercise 25.6 *Problem: Timelike Geodesic as Path of Extremal Proper Time*

By introducing a specific but arbitrary coordinate system, show that among all timelike world lines that a particle could take to get from event \mathcal{P}_0 to event \mathcal{P}_1 , the one or ones whose proper time lapse is stationary under small variations of path are the free-fall geodesics. In other words, an action principle for a timelike geodesic $\mathcal{P}(\lambda)$ [i.e., $x^\alpha(\lambda)$ in any coordinate system x^α] is

$$\delta \int_{\mathcal{P}_0}^{\mathcal{P}_1} d\tau = \delta \int_0^1 \left(-g_{\alpha\beta} \frac{dx^\alpha}{d\lambda} \frac{dx^\beta}{d\lambda} \right)^{\frac{1}{2}} d\lambda = 0, \quad (25.19)$$

2. Named after Wilhelm Killing, the mathematician who introduced it.

where λ is an arbitrary parameter, which by construction ranges from 0 at \mathcal{P}_0 to 1 at \mathcal{P}_1 . [Note: Unless, after the variation, you choose the arbitrary parameter λ to be “affine” ($\lambda = a\zeta + b$, where a and b are constants and ζ is such that $\vec{p} = d/d\zeta$), your equation for $d^2x^\alpha/d\lambda^2$ will not look quite like Eq. (25.14).]

Exercise 25.7 *Problem: Super-Hamiltonian for Free Particle Motion*

- (a) Show that, among all curves $\mathcal{P}(\zeta)$ that could take a particle from event $\mathcal{P}_0 = \mathcal{P}(0)$ to event $\mathcal{P}_1 = \mathcal{P}(\zeta_1)$ (for some ζ_1), those that satisfy the action principle

$$\delta \frac{1}{2} \int_0^{\zeta_1} g_{\alpha\beta} \frac{dx^\alpha}{d\zeta} \frac{dx^\beta}{d\zeta} d\zeta = 0 \quad (25.20)$$

are geodesics, and ζ is the affine parameter along the geodesic related to the particle’s 4-momentum by $\vec{p} = d/d\zeta$. [Note: In this action principle, by contrast with Eq. (25.19), the integration parameter is necessarily affine.]

- (b) The lagrangian $\mathcal{L}(x^\mu, dx^\mu/d\zeta)$ associated with this action principle is $\frac{1}{2}g_{\alpha\beta}(dx^\alpha/d\zeta)(dx^\beta/d\zeta)$, where the coordinates $\{x^0, x^1, x^2, x^3\}$ appear in the metric coefficients and their derivatives appear explicitly. Using standard principles of Hamiltonian mechanics, show that the momentum canonically conjugate to x^μ is $p_\mu = g_{\mu\nu}dx^\nu/d\zeta$ —which in fact is the covariant component of the particle’s 4-momentum. Show, further, that the hamiltonian associated with the particle’s lagrangian is

$$\mathcal{H} = \frac{1}{2}g^{\mu\nu} p_\mu p_\nu. \quad (25.21)$$

Explain why this guarantees that Hamilton’s equations $dx^\alpha/d\zeta = \partial\mathcal{H}/\partial p_\alpha$ and $dp_\alpha/d\zeta = -\partial\mathcal{H}/\partial x^\alpha$ are satisfied if and only if $x^\alpha(\zeta)$ is a geodesic with affine parameter ζ and p_α is the tangent vector to the geodesic.

- (c) Show that Hamilton’s equations guarantee that, if the metric coefficients are independent of some coordinate x^A , then p_A is a conserved quantity. This is the same conservation law as we derived by other methods in Exs. 25.4 and 25.5.

$\mathcal{H} = \frac{1}{2}g^{\mu\nu} p_\mu p_\nu$ is often called the geodesic’s *super-hamiltonian*. It turns out that, often, the easiest way to compute geodesics numerically (e.g., for particle motion around a black hole) is to solve the super-hamiltonian’s Hamilton equations (see, e.g., Levin and Perez-Giz, 2008).

super-hamiltonian for geodesic motion

25.5

25.5 Relative Acceleration, Tidal Gravity, and Spacetime Curvature

Now that we understand the motion of an individual freely falling particle in curved spacetime, we are ready to study the effects of gravity on the relative motions of such particles. Before doing so in general relativity, let us recall the Newtonian description.

FIGURE 25.3 The effects of tidal gravity on the relative motions of two freely falling particles. (a) In Euclidean 3-space using Newton's theory of gravity. (b) In spacetime using Einstein's theory of gravity, general relativity.

25.5.1 Newtonian Description of Tidal Gravity

25.5.1

Consider, as shown in Fig. 25.3a, two point particles, A and B , falling freely through 3-dimensional Euclidean space under the action of an external Newtonian potential Φ (i.e., a potential generated by other masses, not by the particles themselves). At Newtonian time $t = 0$ the particles are separated by only a small distance and are moving with the same velocity: $\mathbf{v}_A = \mathbf{v}_B$. As time passes, however, the two particles, being at slightly different locations in space, experience slightly different gravitational potentials Φ and gravitational accelerations $\mathbf{g} = -\nabla\Phi$ and thence develop slightly different velocities: $\mathbf{v}_A \neq \mathbf{v}_B$. To quantify this, denote by ξ the vector separation of the two particles in Euclidean 3-space. The components of ξ on any Euclidean basis (e.g., that of Fig. 25.3a) are $\xi^j = x_B^j - x_A^j$, where x_I^j is the coordinate location of particle I . Correspondingly, the rate of change of ξ^j with respect to Newtonian time is $d\xi^j/dt = v_B^j - v_A^j$ (i.e., the relative velocity of the two particles is the difference of their velocities). The second time derivative of the relative separation (i.e., the relative acceleration of the two particles) is thus given by

$$\frac{d^2\xi^j}{dt^2} = \frac{d^2x_B^j}{dt^2} - \frac{d^2x_A^j}{dt^2} = -\left(\frac{\partial\Phi}{\partial x^j}\right)_B + \left(\frac{\partial\Phi}{\partial x^j}\right)_A = -\frac{\partial^2\Phi}{\partial x^j\partial x^k}\xi^k, \quad (25.22)$$

accurate to first order in the separation ξ^k . This equation gives the components of the relative acceleration in an arbitrary Euclidean basis. Rewritten in geometric, basis-independent language, this equation is

$$\boxed{\frac{d^2\xi}{dt^2} = -\mathcal{E}(_, \xi); \quad \text{or} \quad \frac{d^2\xi^j}{dt^2} = -\mathcal{E}^j_k \xi^k,} \quad (25.23)$$

relative acceleration of freely falling particles

where \mathcal{E} is a symmetric, second-rank tensor, called the *Newtonian tidal gravitational field*:

$$\mathcal{E} \equiv \nabla\nabla\Phi = -\nabla\mathbf{g}; \quad \text{that is, } \mathcal{E}_{jk} = \frac{\partial^2\Phi}{\partial x^j\partial x^k} \quad \text{in Euclidean coordinates.}$$

(25.24)

The name “tidal gravitational field” comes from the fact that this is the field which, generated by the Moon and the Sun, produces the tides on Earth’s oceans. Note that, since this field is the gradient of the Newtonian gravitational acceleration \mathbf{g} , it is a quantitative measure of the inhomogeneities of Newtonian gravity.

Equation (25.23) shows quantitatively how the tidal gravitational field produces the relative acceleration of our two particles. As a specific application, one can use it to compute, in Newtonian theory, the relative accelerations and thence relative motions of two neighboring local Lorentz frames as they fall toward and through the center of Earth (Fig. 25.2a and associated discussion).

25.5.2 Relativistic Description of Tidal Gravity

Now turn to the general relativistic description of the relative motions of two free particles. As shown in Fig. 25.3b, the particles, labeled A and B , move along geodesic world lines with affine parameters ζ and 4-momentum tangent vectors $\vec{p} = d/d\zeta$. The origins of ζ along the two world lines can be chosen however we wish, so long as events with the same ζ on the two world lines, $\mathcal{P}_A(\zeta)$ and $\mathcal{P}_B(\zeta)$, are close enough to each other that we can perform power-series expansions in their separation, $\vec{\xi}(\zeta) = \mathcal{P}_B(\zeta) - \mathcal{P}_A(\zeta)$, and keep only the leading terms. As in our Newtonian analysis, we require that the two particles initially have vanishing relative velocity, $\nabla_{\vec{p}}\vec{\xi} = 0$, and we compute the tidal-gravity-induced relative acceleration $\nabla_{\vec{p}}\nabla_{\vec{p}}\vec{\xi}$.

As a tool in our calculation, we introduce into spacetime a 2-dimensional surface that contains our two geodesics A and B , and also contains an infinity of other geodesics in between and alongside them. On that surface, we introduce two coordinates, ζ = (affine parameter along each geodesic) and λ = (a parameter that labels the geodesics); see Fig. 25.3b. Geodesic A carries the label $\lambda = 0$; geodesic B is $\lambda = 1$; $\vec{p} = (\partial/\partial\zeta)_{\lambda=\text{const}}$ is a vector field that, evaluated on any geodesic (A , B , or other curve of constant λ), is equal to the 4-momentum of the particle that moves along that geodesic; and $\vec{\xi} \equiv (\partial/\partial\lambda)_{\zeta=\text{const}}$ is a vector field that, when evaluated on geodesic A (i.e., at $\lambda = 0$), we identify as a rigorous version of the separation vector $\mathcal{P}_B(\zeta) - \mathcal{P}_A(\zeta)$ that we wish to study. This identification requires, for good accuracy, that the geodesics be close together and be so parameterized that $\mathcal{P}_A(\zeta)$ is close to $\mathcal{P}_B(\zeta)$.

Our objective is to compute the relative acceleration of particles B and A , $\nabla_{\vec{p}}\nabla_{\vec{p}}\vec{\xi}$, evaluated at $\lambda = 0$. The quantity $\nabla_{\vec{p}}\vec{\xi}$, which we wish to differentiate a second time in

that computation, is one of the terms in the following expression for the commutator of the vector fields \vec{p} and $\vec{\xi}$ [Eq. (24.40)]:

$$\boxed{[\vec{p}, \vec{\xi}] = \nabla_{\vec{p}}\vec{\xi} - \nabla_{\vec{\xi}}\vec{p}.} \quad (25.25)$$

Because $\vec{p} = (\partial/\partial\xi)_\lambda$ and $\vec{\xi} = (\partial/\partial\lambda)_\zeta$, these two vector fields commute, and Eq. (25.25) tells us that $\nabla_{\vec{p}}\vec{\xi} = \nabla_{\vec{\xi}}\vec{p}$. Correspondingly, the relative acceleration of our two particles can be expressed as

$$\nabla_{\vec{p}}\nabla_{\vec{p}}\vec{\xi} = \nabla_{\vec{p}}\nabla_{\vec{\xi}}\vec{p} = (\nabla_{\vec{p}}\nabla_{\vec{\xi}} - \nabla_{\vec{\xi}}\nabla_{\vec{p}})\vec{p}. \quad (25.26)$$

Here the second equality results from adding on, for use below, a term that vanishes because $\nabla_{\vec{p}}\vec{p} = 0$ (geodesic equation).

This first part of our calculation was performed efficiently using index-free notation. The next step will be easier if we introduce indices as names for slots. Then expression (25.26) takes the form

$$(\xi^\alpha{}_{;\beta}p^\beta)_{;\gamma}p^\gamma = (p^\alpha{}_{;\gamma}\xi^\gamma)_{;\delta}p^\delta - (p^\alpha{}_{;\gamma}p^\gamma)_{;\delta}\xi^\delta, \quad (25.27)$$

which can be evaluated by using the rule for differentiating products and then renaming indices and collecting terms. The result is

$$(\xi^\alpha{}_{;\beta}p^\beta)_{;\gamma}p^\gamma = (p^\alpha{}_{;\gamma\delta} - p^\alpha{}_{;\delta\gamma})\xi^\gamma p^\delta + p^\alpha{}_{;\gamma}(\xi^\gamma{}_{;\delta}p^\delta - p^\gamma{}_{;\delta}\xi^\delta). \quad (25.28)$$

The second term in this expression vanishes, since it is just the commutator of $\vec{\xi}$ and \vec{p} [Eq. (25.25)] written in slot-naming index notation, and as we noted above, $\vec{\xi}$ and \vec{p} commute. The resulting equation,

$$(\xi^\alpha{}_{;\beta}p^\beta)_{;\gamma}p^\gamma = (p^\alpha{}_{;\gamma\delta} - p^\alpha{}_{;\delta\gamma})\xi^\gamma p^\delta, \quad (25.29)$$

reveals that the relative acceleration of the two particles is caused by noncommutation of the two slots of a double gradient (slots here named γ and δ). In the flat spacetime of special relativity, the two slots would commute³ and there would be no relative acceleration. Spacetime curvature prevents them from commuting and thereby causes the relative acceleration.

Now, one can show that for any vector field $\vec{p}(\mathcal{P})$, $p^\alpha{}_{;\gamma\delta} - p^\alpha{}_{;\delta\gamma}$ is linear in p^α ; see Ex. 25.8. Thus there must exist a fourth-rank tensor field $\mathbf{R}(_, _, _, _)$ such that

$$\boxed{p^\alpha{}_{;\gamma\delta} - p^\alpha{}_{;\delta\gamma} = -\mathbf{R}^\alpha{}_{\beta\gamma\delta}p^\beta} \quad (25.30)$$

Riemann curvature tensor

3. In flat spacetime, in global Lorentz coordinates, $\Gamma^\alpha{}_{\beta\gamma} = 0$ everywhere, so $p^\alpha{}_{;\gamma\delta} = \partial^2 p^\alpha / \partial x^\gamma \partial x^\delta$. Because partial derivatives commute, expression (25.29) vanishes.

for any \vec{p} . The tensor \mathbf{R} can be regarded as responsible for the failure of gradients to commute, so it must be some aspect of spacetime curvature. It is called the *Riemann curvature tensor*.

Inserting Eq. (25.30) into Eq. (25.29) and writing the result in both slot-naming index notation and abstract notation, we obtain

equation of geodesic deviation

$$\left(\xi^\alpha{}_{;\beta} p^\beta \right)_{;\gamma} p^\gamma = -R^\alpha{}_{\beta\gamma\delta} p^\beta \xi^\gamma p^\delta, \quad \nabla_{\vec{p}} \nabla_{\vec{p}} \vec{\xi} = -\mathbf{R}(_, \vec{p}, \vec{\xi}, \vec{p}). \quad (25.31)$$

This is the equation of relative acceleration for freely moving test particles. It is also called the *equation of geodesic deviation*, because it describes the manner in which spacetime curvature \mathbf{R} forces geodesics that are initially parallel (the world lines of freely moving particles with zero initial relative velocity) to deviate from one another (Fig. 25.3b).

EXERCISES

Exercise 25.8 *Derivation: Linearity of the Commutator of the Double Gradient*

(a) Let a and b be scalar fields with arbitrary but smooth dependence on location in curved spacetime, and let \vec{A} and \vec{B} be vector fields. Show that

$$(aA^\alpha + bB^\alpha)_{;\gamma\delta} - (aA^\alpha + bB^\alpha)_{;\delta\gamma} = a(A^\alpha{}_{;\gamma\delta} - A^\alpha{}_{;\delta\gamma}) + b(B^\alpha{}_{;\gamma\delta} - B^\alpha{}_{;\delta\gamma}). \quad (25.32)$$

[Hint: The double gradient of a scalar field commutes, as one can easily see in a local Lorentz frame.]

(b) Use Eq. (25.32) to show that (i) the commutator of the double gradient is independent of how the differentiated vector field varies from point to point and depends only on the value of the field at the location where the commutator is evaluated, and (ii) the commutator is linear in that value. Thereby conclude that there must exist a fourth-rank tensor field \mathbf{R} such that Eq. (25.30) is true for any vector field \vec{p} .

25.5.3

25.5.3 Comparison of Newtonian and Relativistic Descriptions

It is instructive to compare this relativistic description of the relative acceleration of freely moving particles with the Newtonian description. For this purpose we consider a region of spacetime, such as our solar system, in which the Newtonian description of gravity is highly accurate; and there we study the relative acceleration of two free particles from the viewpoint of a local Lorentz frame in which the particles are both initially at rest.

In the Newtonian description, the transformation from a Newtonian universal reference frame (e.g., that of the center of mass of the solar system) to the chosen local Lorentz frame is achieved by introducing new Euclidean coordinates that are uniformly accelerated relative to the old ones, with just the right uniform acceleration

to annul the gravitational acceleration at the center of the local Lorentz frame. This transformation adds a spatially homogeneous constant to the Newtonian acceleration, $\mathbf{g} = -\nabla\Phi$, but leaves unchanged the tidal field, $\mathcal{E} = \nabla\nabla\Phi$. Correspondingly, the Newtonian equation of relative acceleration in the local Lorentz frame retains its standard Newtonian form, $d^2\xi^j/dt^2 = -\mathcal{E}^j_k \xi^k$ [Eq. (25.23)], with the components of the tidal field computable equally well in the original universal reference frame or in the local Lorentz frame, using the standard relation $\mathcal{E}^j_k = \mathcal{E}_{jk} = \partial^2\Phi/\partial x^j\partial x^k$.

As an aid in making contact between the relativistic and the Newtonian descriptions, we convert from using the 4-momentum \vec{p} as the relativistic tangent vector and ζ as the relativistic parameter along the particles' world lines to using the 4-velocity $\vec{u} = \vec{p}/m$ and the proper time $\tau = m\zeta$. This conversion brings the relativistic equation of relative acceleration (25.31) into the form

$$\nabla_{\vec{u}}\nabla_{\vec{u}}\vec{\xi} = -\mathbf{R}(\dots, \vec{u}, \vec{\xi}, \vec{u}). \quad (25.33)$$

Because the particles are (momentarily) at rest near the origin of the local Lorentz frame, their 4-velocities are $\vec{u} \equiv d/d\tau = \partial/\partial t$, which implies that the components of their 4-velocities are $u^0 = 1, u^j = 0$, and their proper times τ are equal to coordinate time t , which in turn coincides with the time t of the Newtonian analysis: $\tau = t$. In the relativistic analysis, as in the Newtonian, the separation vector $\vec{\xi}$ will have only spatial components, $\xi^0 = 0$ and $\xi^j \neq 0$. (If this were not so, we could make it so by readjusting the origin of proper time for particle B , so $\vec{\xi} \cdot \vec{p} = m\vec{\xi} \cdot \vec{u} = 0$, whence $\xi^0 = 0$; Fig. 25.3b.) These facts, together with the vanishing of all the connection coefficients and derivatives of them ($\Gamma^j_{k0,0} = 0$) that appear in $(\xi^j_{;\beta}u^\beta)_{;\gamma}u^\gamma$ at the origin of the local Lorentz frame [cf. Eqs. (25.9)], imply that the local Lorentz components of the equation of relative acceleration (25.33) take the form

$$\frac{d^2\xi^j}{dt^2} = -R^j_{0k0}\xi^k. \quad (25.34)$$

By comparing this with the Newtonian equation of relative acceleration (25.23), we infer that, in the Newtonian limit, in the local rest frame of the two particles, we have

$$R^j_{0k0} = \mathcal{E}_{jk} = \frac{\partial^2\Phi}{\partial x^j\partial x^k}. \quad (25.35)$$

Thus, the Riemann curvature tensor is the relativistic generalization of the Newtonian tidal field. This conclusion and the above equations make quantitative the statement that gravity is a manifestation of spacetime curvature.

Outside a spherical body with weak (Newtonian) gravity, such as Earth, the Newtonian potential is $\Phi = -GM/r$, where G is Newton's gravitation constant, M is the body's mass, and r is the distance from its center. If we introduce Cartesian coordinates with origin at the body's center and with the point at which the Riemann tensor is to be measured lying on the z -axis at $\{x, y, z\} = \{0, 0, r\}$, then Φ near that point is

geodesic deviation for particles with finite rest mass

space-time-space-time components of Riemann tensor become tidal field in Newtonian limit of general relativity

components of Riemann tensor outside a Newtonian, gravitating body

$\Phi = -GM/(z^2 + x^2 + y^2)^{\frac{1}{2}}$, and on the z -axis the only nonzero R^j_{0k0} components, as computed from Eq. (25.35), are

$$R^z_{0z0} = \frac{-2GM}{r^3}, \quad R^x_{0x0} = R^y_{0y0} = \frac{+GM}{r^3}. \quad (25.36)$$

Correspondingly, for two particles separated from each other in the radial (z) direction, the relative acceleration (25.34) is $d^2\xi^j/dt^2 = (2GM/r^3)\xi^j$ (i.e., the particles are pulled apart by the body's tidal gravitational field). Similarly, for two particles separated from each other in a transverse direction (in the x - y plane), we have $d^2\xi^j/dt^2 = -(GM/r^3)\xi^j$ (i.e., the particles are pushed together by the body's tidal gravitational field). There thus is a radial tidal stretch and a lateral tidal squeeze; the lateral squeeze has half the strength of the radial stretch but occurs in two lateral dimensions compared to the one radial dimension. This stretch and squeeze, produced by the Sun and the Moon, are responsible for the tides on Earth's oceans; Ex. 25.9.

EXERCISES

Exercise 25.9 ***Example: Ocean Tides*

- (a) Place a local Lorentz frame at the center of Earth, and let \mathcal{E}_{jk} be the tidal field there, produced by the Newtonian gravitational fields of the Sun and the Moon. For simplicity, treat Earth as precisely spherical. Show that the gravitational acceleration (relative to Earth's center) at some location on or near Earth's surface (radius r) is

$$g_j = -\frac{GM}{r^2}n^j - \mathcal{E}^j_{\ k}rn^k, \quad (25.37)$$

where M is Earth's mass, and n^j is a unit vector pointing from Earth's center to the location at which g_j is evaluated.

- (b) Show that this gravitational acceleration is minus the gradient of the Newtonian potential

$$\Phi = -\frac{GM}{r} + \frac{1}{2}\mathcal{E}_{jk}r^2n^jn^k. \quad (25.38)$$

- (c) Consider regions of Earth's oceans that are far from any coast and have ocean depth large compared to the heights of ocean tides. If Earth were nonrotating, then explain why the analysis of Sec. 13.3 predicts that the ocean surface in these regions would be a surface of constant Φ . Explain why this remains true to good accuracy also for the rotating Earth.
- (d) Show that in these ocean regions, the Moon creates high tides pointing toward and away from itself and low tides in the transverse directions on Earth; and similarly for the Sun. Compute the difference between high and low tides produced by the Moon and by the Sun, and the difference of the total tide when the Moon and the Sun are in approximately the same direction in the sky. Your answers are

reasonably accurate for deep-ocean regions far from any coast, but near a coast, the tides are typically larger and sometimes far larger, and they are shifted in phase relative to the positions of the Moon and Sun. Why?

25.6 Properties of the Riemann Curvature Tensor

25.6

We now pause in our study of the foundations of general relativity to examine a few properties of the Riemann curvature tensor R .

As a tool for deriving other things, we begin by evaluating the components of the Riemann tensor at the spatial origin of a local Lorentz frame (i.e., at a point where $g_{\alpha\beta} = \eta_{\alpha\beta}$ and $\Gamma^\alpha_{\beta\gamma}$ vanishes, but its derivatives do not). For any vector field \vec{p} , a straightforward computation reveals

$$p^\alpha{}_{;\gamma\delta} - p^\alpha{}_{;\delta\gamma} = (\Gamma^\alpha_{\beta\gamma,\delta} - \Gamma^\alpha_{\beta\delta,\gamma})p^\beta. \quad (25.39)$$

By comparing with Eq. (25.30), we can read off the local-Lorentz components of the Riemann tensor:

$$R^\alpha{}_{\beta\gamma\delta} = \Gamma^\alpha_{\beta\delta,\gamma} - \Gamma^\alpha_{\beta\gamma,\delta} \quad \text{at the spatial origin of a local Lorentz frame.} \quad (25.40)$$

From this expression we infer that, at a spatial distance $\sqrt{\delta_{ij}x^ix^j}$ from the origin of a local Lorentz frame, the connection coefficients and the metric have magnitudes

$$\Gamma^\alpha_{\beta\gamma} = O(R^\mu{}_{\nu\lambda\rho}\sqrt{\delta_{ij}x^ix^j}), \quad g_{\alpha\beta} - \eta_{\alpha\beta} = O(R^\mu{}_{\nu\lambda\rho}\delta_{ij}x^ix^j) \quad (25.41)$$

in a local Lorentz frame.

influence of spacetime curvature on connection and metric in a local Lorentz frame

Comparison with Eqs. (25.9) shows that the radius of curvature of spacetime (a concept defined only semiquantitatively) is of order the inverse square root of the components of the Riemann tensor in a local Lorentz frame:

$$\mathcal{R} = O\left(\frac{1}{|R^\alpha{}_{\beta\gamma\delta}|^{\frac{1}{2}}}\right) \quad \text{in a local Lorentz frame.} \quad (25.42)$$

radius of curvature of spacetime

By comparison with Eq. (25.36), we see that at radius r outside a weakly gravitating body of mass M , the radius of curvature of spacetime is

$$\mathcal{R} \sim \left(\frac{r^3}{GM}\right)^{\frac{1}{2}} = \left(\frac{c^2 r^3}{GM}\right)^{\frac{1}{2}}, \quad (25.43)$$

where the factor c (speed of light) in the second expression makes the formula valid in conventional units. For further discussion, see Ex. 25.10.

Using the components (25.40) of the Riemann tensor in a local Lorentz frame in terms of the connection coefficients, and using expressions (24.38) for the connection coefficients in terms of the metric components and commutation coefficients together

components of Riemann tensor in a local Lorentz frame

with the vanishing of the commutation coefficients (because a local Lorentz frame is a coordinate basis), one easily can show that

$$R_{\alpha\beta\gamma\delta} = \frac{1}{2}(\mathcal{g}_{\alpha\delta,\beta\gamma} + \mathcal{g}_{\beta\gamma,\alpha\delta} - \mathcal{g}_{\alpha\gamma,\beta\delta} - \mathcal{g}_{\beta\delta,\alpha\gamma}) \quad \text{in a local Lorentz frame.}$$

(25.44)

From these expressions, plus the commutation of partial derivatives $\mathcal{g}_{\alpha\gamma,\beta\delta} = \mathcal{g}_{\alpha\gamma,\delta\beta}$ and the symmetry of the metric, one readily can show that in a local Lorentz frame the components of the Riemann tensor have the following symmetries:

three symmetries of Riemann tensor

$$R_{\alpha\beta\gamma\delta} = -R_{\beta\alpha\gamma\delta}, \quad R_{\alpha\beta\gamma\delta} = -R_{\alpha\beta\delta\gamma}, \quad R_{\alpha\beta\gamma\delta} = +R_{\gamma\delta\alpha\beta} \quad (25.45a)$$

(antisymmetry in first pair of indices, antisymmetry in second pair of indices, and symmetry under interchange of the pairs). When one computes the value of the tensor on four vectors, $\mathbf{R}(\vec{A}, \vec{B}, \vec{C}, \vec{D})$ using component calculations in this frame, one trivially sees that these symmetries produce corresponding symmetries under interchange of the vectors inserted into the slots, and thence under interchange of the slots themselves. (This is always the case: any symmetry that the components of a tensor exhibit in any special basis will induce the same symmetry on the slots of the geometric, frame-independent tensor.) The resulting symmetries for \mathbf{R} are given by Eq. (25.45a) with the “Escher mind-flip” (Sec. 1.5.1) in which the indices switch from naming components in a special frame to naming slots. The Riemann tensor is antisymmetric under interchange of its first two slots, antisymmetric under interchange of the last two, and symmetric under interchange of the two pairs.

One additional symmetry can be verified by calculation in the local Lorentz frame [i.e., from Eq. (25.44)]:⁴

a fourth symmetry of Riemann tensor

$$R_{\alpha\beta\gamma\delta} + R_{\alpha\gamma\delta\beta} + R_{\alpha\delta\beta\gamma} = 0. \quad (25.45b)$$

Riemann tensor has 20 independent components generically

One can show that the full set of symmetries (25.45) reduces the number of independent components of the Riemann tensor, in 4-dimensional spacetime, from $4^4 = 256$ to “just” 20.

Of these 20 independent components, 10 are contained in the *Ricci curvature tensor*, which is the contraction of the Riemann tensor on its first and third slots:

Ricci tensor and its symmetry

$$R_{\alpha\beta} \equiv R^{\mu}{}_{\alpha\mu\beta}, \quad (25.46)$$

and which, by the symmetries (25.45) of Riemann, is itself symmetric:

4. Note that this cyclic symmetry is the same as occurs in the second of Maxwell’s equations (2.48), $\epsilon^{\alpha\beta\gamma\delta} F_{\gamma\delta;\beta} = 0$; it is also the same as occurs in the Jacobi identity for commutators $[\vec{B}, [\vec{C}, \vec{D}]] + [\vec{C}, [\vec{D}, \vec{B}]] + [\vec{D}, [\vec{B}, \vec{C}]] = 0$.

$$R_{\alpha\beta} = R_{\beta\alpha}. \quad (25.47)$$

The other 10 independent components of Riemann are contained in the Weyl curvature tensor:

$$C^{\mu\nu}{}_{\rho\sigma} = R^{\mu\nu}{}_{\rho\sigma} - 2g^{[\mu}{}_{[\rho} R^{\nu]}{}_{\sigma]} + \frac{1}{3}g^{[\mu}{}_{[\rho} g^{\nu]}{}_{\sigma]} R. \quad (25.48)$$

Weyl tensor

scalar curvature

Here the square brackets denote antisymmetrization, $A_{[\alpha\beta]} \equiv \frac{1}{2}(A_{\alpha\beta} - A_{\beta\alpha})$, and R is the contraction of the Ricci tensor on its two slots,

$$R \equiv R^{\alpha}{}_{\alpha}, \quad (25.49)$$

and is called the *curvature scalar* or *scalar curvature*. The Weyl curvature tensor $C^{\mu\nu}{}_{\rho\sigma}$ has vanishing contraction on every pair of slots and has the same symmetries as the Riemann tensor; Ex. 25.12.

components of Riemann tensor in an arbitrary basis

One often needs to know the components of the Riemann curvature tensor in some non-local-Lorentz basis. Exercise 25.11 derives the following equation for them in an arbitrary basis:

$$R^{\alpha}{}_{\beta\gamma\delta} = \Gamma^{\alpha}{}_{\beta\delta,\gamma} - \Gamma^{\alpha}{}_{\beta\gamma,\delta} + \Gamma^{\alpha}{}_{\mu\gamma}\Gamma^{\mu}{}_{\beta\delta} - \Gamma^{\alpha}{}_{\mu\delta}\Gamma^{\mu}{}_{\beta\gamma} - \Gamma^{\alpha}{}_{\beta\mu}c_{\gamma\delta}{}^{\mu}. \quad (25.50)$$

Here $\Gamma^{\alpha}{}_{\beta\gamma}$ are the connection coefficients in the chosen basis; $\Gamma^{\alpha}{}_{\beta\gamma,\delta}$ is the result of letting the basis vector \vec{e}_{δ} act as a differential operator on $\Gamma^{\alpha}{}_{\beta\gamma}$, as though $\Gamma^{\alpha}{}_{\beta\gamma}$ were a scalar; and $c_{\gamma\delta}{}^{\mu}$ are the basis vectors' commutation coefficients. Calculations with this equation are usually long and tedious, and so are carried out using symbolic-manipulation software on a computer. See, for example, the simple Mathematica program (specialized to a coordinate basis) in Hartle (2003, Appendix C), also available on that textbook's website: <http://web.physics.ucsb.edu/~gravitybook/mathematica.html>.

EXERCISES

Exercise 25.10 Example: Orders of Magnitude for the Radius of Curvature of Spacetime

With the help of the Newtonian limit (25.35) of the Riemann curvature tensor, show that near Earth's surface the radius of curvature of spacetime has a magnitude $\mathcal{R} \sim (1 \text{ astronomical unit}) \equiv (\text{distance from the Sun to Earth})$. What is the radius of curvature of spacetime near the Sun's surface? Near the surface of a white-dwarf star? Near the surface of a neutron star? Near the surface of a one-solar-mass black hole? In intergalactic space?

Exercise 25.11 Derivation: Components of the Riemann Tensor in an Arbitrary Basis

By evaluating expression (25.30) in an arbitrary basis (which might not even be a coordinate basis), derive Eq. (25.50) for the components of the Riemann tensor. In your derivation keep in mind that commas denote partial derivations *only* in a

coordinate basis; in an arbitrary basis they denote the result of letting a basis vector act as a differential operator [cf. Eq. (24.34)].

Exercise 25.12 *Derivation: Weyl Curvature Tensor*

Show that the Weyl curvature tensor (25.48) has vanishing contraction on all its slots and has the same symmetries as Riemann: Eqs. (25.45). From these properties, show that Weyl has just 10 independent components. Write the Riemann tensor in terms of the Weyl tensor, the Ricci tensor, and the scalar curvature.

Exercise 25.13 *Problem: Curvature of the Surface of a Sphere*

On the surface of a sphere, such as Earth, introduce spherical polar coordinates in which the metric, written as a line element, takes the form

$$ds^2 = a^2(d\theta^2 + \sin^2 \theta d\phi^2), \quad (25.51)$$

where a is the sphere's radius.

(a) Show (first by hand and then by computer) that the connection coefficients for the coordinate basis $\{\partial/\partial\theta, \partial/\partial\phi\}$ are

$$\Gamma^\theta_{\phi\phi} = -\sin \theta \cos \theta, \quad \Gamma^\phi_{\theta\phi} = \Gamma^\phi_{\phi\theta} = \cot \theta, \quad \text{all others vanish.} \quad (25.52a)$$

(b) Show that the symmetries (25.45) of the Riemann tensor guarantee that its only nonzero components in the above coordinate basis are

$$R_{\theta\phi\theta\phi} = R_{\phi\theta\phi\theta} = -R_{\theta\phi\phi\theta} = -R_{\phi\theta\theta\phi}. \quad (25.52b)$$

(c) Show, first by hand and then by computer, that

$$R_{\theta\phi\theta\phi} = a^2 \sin^2 \theta. \quad (25.52c)$$

(d) Show that in the basis

$$\{\vec{e}_{\hat{\theta}}, \vec{e}_{\hat{\phi}}\} = \left\{ \frac{1}{a} \frac{\partial}{\partial \theta}, \frac{1}{a \sin \theta} \frac{\partial}{\partial \phi} \right\}, \quad (25.52d)$$

the components of the metric, the Riemann tensor, the Ricci tensor, the curvature scalar, and the Weyl tensor are

$$g_{\hat{j}\hat{k}} = \delta_{jk}, \quad R_{\hat{\theta}\hat{\phi}\hat{\theta}\hat{\phi}} = \frac{1}{a^2}, \quad R_{\hat{j}\hat{k}} = \frac{1}{a^2} g_{\hat{j}\hat{k}}, \quad R = \frac{2}{a^2}, \quad C_{\hat{\theta}\hat{\phi}\hat{\theta}\hat{\phi}} = 0, \quad (25.52e)$$

respectively. The first of these implies that the basis is orthonormal; the rest imply that the curvature is independent of location on the sphere, as it should be by spherical symmetry. [The θ dependence in the coordinate components of Riemann, Eq. (25.52c), like the θ dependence in the metric component $g_{\phi\phi}$, is a result of the θ dependence in the length of the coordinate basis vector $\vec{e}_{\hat{\phi}}$: $|\vec{e}_{\hat{\phi}}| = a \sin \theta$.]

Exercise 25.14 *Problem: Geodesic Deviation on a Sphere*

Consider two neighboring geodesics (great circles) on a sphere of radius a , one the equator and the other a geodesic slightly displaced from the equator (by $\Delta\theta = b$) and parallel to it at $\phi = 0$. Let $\vec{\zeta}$ be the separation vector between the two geodesics, and note that at $\phi = 0$, $\vec{\zeta} = b\partial/\partial\theta$. Let l be proper distance along the equatorial geodesic, so $d/dl = \vec{u}$ is its tangent vector.

- (a) Show that $l = a\phi$ along the equatorial geodesic.
 (b) Show that the equation of geodesic deviation (25.31) reduces to

$$\frac{d^2\xi^\theta}{d\phi^2} = -\xi^\theta, \quad \frac{d^2\xi^\phi}{d\phi^2} = 0. \quad (25.53)$$

- (c) Solve Eq. (25.53), subject to the above initial conditions, to obtain

$$\xi^\theta = b \cos \phi, \quad \xi^\phi = 0. \quad (25.54)$$

Verify, by drawing a picture, that this is precisely what one would expect for the separation vector between two great circles.

25.7 Delicacies in the Equivalence Principle, and Some Nongravitational Laws of Physics in Curved Spacetime

25.7

Suppose that one knows a local, special relativistic, nongravitational law of physics in geometric, frame-independent form—for example, the expression for the stress-energy tensor of a perfect fluid in terms of its 4-velocity \vec{u} and its rest-frame mass-energy density ρ and pressure P :

$$\mathbf{T} = (\rho + P)\vec{u} \otimes \vec{u} + P\mathbf{g} \quad (25.55)$$

[Eq. (24.51)]. Then the equivalence principle guarantees that in general relativity this law will assume the same geometric, frame-independent form. One can see that this is so by the same method as we used to derive the general relativistic equation of motion $\nabla_{\vec{p}} \vec{p} = 0$ for free particles [Eq. (25.11c) and associated discussion]:

1. Rewrite the special relativistic law in terms of components in a global Lorentz frame [$T^{\alpha\beta} = (\rho + P)u^\alpha u^\beta + P g^{\alpha\beta}$].
2. Infer from the equivalence principle that this same component form of the law will hold, unchanged, in a local Lorentz frame in general relativity.
3. Deduce that this component law is the local-Lorentz-frame version of the original geometric law [$\mathbf{T} = (\rho + P)\vec{u} \otimes \vec{u} + P\mathbf{g}$], now lifted into general relativity.

equivalence principle implies that local nongravitational laws are the same in general relativity as in special relativity

examples of the influence of spacetime curvature on nonlocal laws:

no global conservation of 4-momentum in general relativity, generically

Thus, when the local, nongravitational laws of physics are known in frame-independent form, one need not distinguish between whether they are special relativistic or general relativistic.

In this conclusion the word *local* is crucial. The equivalence principle is strictly valid only at the spatial origin of a local Lorentz frame; correspondingly, it is in danger of failure for any law of physics that cannot be formulated solely in terms of quantities that reside at the spatial origin (i.e., along a timelike geodesic). For the above example, $\mathbf{T} = (\rho + P)\vec{u} \otimes \vec{u} + P\mathbf{g}$, there is no problem; and for the local law of 4-momentum conservation, $\vec{\nabla} \cdot \mathbf{T} = 0$, there is no problem. However, for the global law of 4-momentum conservation

$$\int_{\partial\mathcal{V}} T^{\alpha\beta} d\Sigma_{\beta} = 0 \tag{25.56}$$

[Eq. (2.71) and Fig. 2.11], there is serious trouble. This law is severely nonlocal, since it involves integration over a finite, closed 3-surface $\partial\mathcal{V}$ in spacetime. Thus the equivalence principle fails for it. The failure shows up especially clearly when one notices (as we discussed in Sec. 24.3.4) that the quantity $T^{\alpha\beta} d\Sigma_{\beta}$, which the integral is trying to add up over $\partial\mathcal{V}$, has one empty slot, named α (i.e., it is a vector). This means that, to compute the integral (25.56), we must transport the contributions $T^{\alpha\beta} d\Sigma_{\beta}$ from the various tangent spaces in which they normally live to the tangent space of some single, agreed-on location, where they are to be added. The result of that transport depends on the route used, and in general no preferred route is available. As a result, the integral (25.56) is ill defined, and in general relativity we lose the global conservation law for 4-momentum!—except in special situations, one of which is discussed in Sec. 25.9.5.

25.7.1

25.7.1 Curvature Coupling in the Nongravitational Laws T2

Another instructive example is the law by which a freely moving particle transports its spin angular momentum. The spin angular momentum is readily defined in the instantaneous local Lorentz rest frame of the particle's center of mass; there it is a 4-vector \vec{S} with vanishing time component (so \vec{S} is orthogonal to the particle's 4-velocity), with space components given by the familiar integral

$$S_i = \int_{\text{interior of body}} \epsilon_{ijk} x^j T^{k0} dV, \tag{25.57}$$

where the T^{k0} are components of the momentum density. In special relativity, the law of angular momentum conservation (e.g., Misner, Thorne, and Wheeler, 1973, Sec. 5.11) guarantees that the Lorentz-frame components S^{α} of this spin angular momentum remain constant, so long as no external torques act on the particle. This conservation law can be written in special relativistic, frame-independent notation as Eq. (24.62), specialized to a nonaccelerated particle:

$$\nabla_{\vec{u}} \vec{S} = 0; \tag{25.58}$$

that is, the spin vector \vec{S} is parallel-transported along the world line of the freely falling particle (which has 4-velocity \vec{u}). If this were a local law of physics, it would take this same form, unchanged, in general relativity (i.e., in curved spacetime). Whether the law is local or not clearly depends on the size of the particle. If the particle is vanishingly small in its own rest frame, then the law is local, and Eq. (25.58) will be valid in general relativity. However, if the particle has finite size, the law (25.58) is in danger of failing—and, indeed, it does fail if the particle’s finite size is accompanied by a finite quadrupole moment. In that case, the coupling of the quadrupole moment $\mathcal{I}_{\alpha\beta}$ to the curvature of spacetime $R^\alpha{}_{\beta\gamma\delta}$ produces a torque on the “particle,” so Eq. (25.58) acquires a driving term on the right-hand side:

$$S^\alpha{}_{;\mu} u^\mu = \epsilon^{\alpha\beta\gamma\delta} \mathcal{I}_{\beta\mu} R^\mu{}_{\nu\gamma\zeta} u_\delta u^\nu u^\zeta; \quad (25.59)$$

see Ex. 25.16. Earth is a good example: the Riemann tensor $R^\alpha{}_{\beta\gamma\delta}$ produced at Earth by the Moon and the Sun couples to Earth’s centrifugal-flattening-induced quadrupole moment $\mathcal{I}_{\mu\nu}$. The resulting torque (25.59) causes Earth’s spin axis to precess relative to the distant stars, with a precession period of 26,000 years—sufficiently fast to show up clearly in historical records⁵ as well as in modern astronomical measurements.

This example illustrates the fact that, if a small amount of nonlocality is present in a physical law, then, when lifted from special relativity into general relativity, the law may acquire a small *curvature-coupling* modification.

What is the minimum amount of nonlocality that can produce curvature-coupling modifications in physical laws? As a rough rule of thumb, the minimum amount is double gradients. Because the connection coefficients vanish at the origin of a local Lorentz frame, the local Lorentz components of a single gradient are the same as the components in a global Lorentz frame (e.g., $A^\alpha{}_{;\beta} = \partial A^\alpha / \partial x^\beta$). However, because spacetime curvature prevents the spatial derivatives of the connection coefficients from vanishing at the origin of a local Lorentz frame, any law that involves double gradients is in danger of acquiring curvature-coupling corrections when lifted into general relativity. As an example, it turns out that the vacuum wave equation for the electromagnetic vector 4-potential, which in Lorenz gauge (Jackson, 1999, Sec. 6.3) takes the form $A^{\alpha;\mu}{}_\mu = 0$ in flat spacetime, becomes in curved spacetime:

$$A^{\alpha;\mu}{}_\mu = R^{\alpha\mu} A_\mu, \quad (25.60)$$

where $R^{\alpha\mu}$ is the Ricci curvature tensor; see Ex. 25.15. [In Eq. (25.60)—and always—all indices that follow the semicolon represent differentiation slots: $A^{\alpha;\mu}{}_\mu \equiv A^{\alpha;\mu}{}_{;\mu}$.]

The curvature-coupling ambiguities that occur when one lifts slightly nonlocal laws from special relativity into general relativity using the equivalence principle are very similar to “factor-ordering ambiguities” that occur when one lifts a hamiltonian from classical mechanics into quantum mechanics using the correspondence

5. For example, Earth’s north pole did not point toward the star Polaris in the era of the ancient Egyptian civilization. Hipparchus of Nicaea discovered this precession in 127 BC by comparing his own observations of the stars with those of earlier astronomers.

tidally induced precession of Earth’s spin axis

double gradients as a source of curvature coupling in physical laws

example: curvature coupling in wave equation for electromagnetic 4-potential

curvature-coupling ambiguities in general relativity are analogous to factor-ordering ambiguities in the quantum mechanical correspondence principle

principle. In the case of the equivalence principle, the curvature coupling can be regarded as stemming from double gradients that commute in special relativity but do not commute in general relativity. In the case of the correspondence principle, the factor-ordering difficulties result because quantities that commute classically (e.g., position x and momentum p) do not commute quantum mechanically ($\hat{x}\hat{p} \neq \hat{p}\hat{x}$), so when the products of such quantities appear in a classical hamiltonian one does not know, a priori, their correct order in the quantum hamiltonian [does xp become $\hat{x}\hat{p}$, or $\hat{p}\hat{x}$, or $\frac{1}{2}(\hat{x}\hat{p} + \hat{p}\hat{x})$?]. (However, in each case, general relativity or quantum mechanics, the true curvature coupling or true factor ordering is unambiguous. The ambiguity is solely in the prescription for deducing it via the equivalence principle or the correspondence principle.)

EXERCISES

Exercise 25.15 Example and Derivation: Curvature Coupling

in the Electromagnetic Wave Equation **T2**

Since Maxwell's equations, written in terms of the classically measurable electromagnetic field tensor \mathbf{F} [Eqs. (2.48)] involve only single gradients, it is reasonable to expect them to be lifted into curved spacetime without curvature-coupling additions. Assume this is true. It can be shown that: (i) if one writes the electromagnetic field tensor \mathbf{F} in terms of a 4-vector potential \vec{A} as

$$F_{\alpha\beta} = A_{\beta;\alpha} - A_{\alpha;\beta}, \quad (25.61)$$

then half of the curved-spacetime Maxwell equations, $F_{\alpha\beta;\gamma} + F_{\beta\gamma;\alpha} + F_{\gamma\alpha;\beta} = 0$ [the second of Eqs. (2.48)] are automatically satisfied; (ii) \mathbf{F} is unchanged by gauge transformations in which a gradient is added to the vector potential, $\vec{A} \rightarrow \vec{A} + \vec{\nabla}\psi$; and (iii) by such a gauge transformation one can impose the Lorenz-gauge condition $\vec{\nabla} \cdot \vec{A} = 0$ on the vector potential.

Show that, when the charge-current 4-vector vanishes, $\vec{J} = 0$, the other half of the Maxwell equations, $F^{\alpha\beta}{}_{;\beta} = 0$ [the first of Eqs. (2.48)] become, in Lorenz gauge and in curved spacetime, the wave equation with curvature coupling [Eq. (25.60)].

Exercise 25.16 Example and Derivation: Curvature-Coupling Torque **T2**

(a) In the Newtonian theory of gravity, consider an axisymmetric, spinning body (e.g., Earth) with spin angular momentum S_j and time-independent mass distribution $\rho(\mathbf{x})$, interacting with an externally produced tidal gravitational field \mathcal{E}_{jk} (e.g., that of the Sun and the Moon). Show that the torque around the body's center of mass, exerted by the tidal field, and the resulting evolution of the body's spin are

$$\frac{dS_i}{dt} = -\epsilon_{ijk}\mathcal{I}_{jl}\mathcal{E}_{kl}. \quad (25.62)$$

Here

$$\mathcal{I}_{kl} = \int \rho \left(x_k x_l - \frac{1}{3} r^2 \delta_{kl} \right) dV \quad (25.63)$$

is the body's mass quadrupole moment, with $r = \sqrt{\delta_{ij}x_i x_j}$ the distance from the center of mass.

- (b) For the centrifugally flattened Earth interacting with the tidal fields of the Moon and the Sun, estimate in order of magnitude the spin-precession period produced by this torque. [The observed precession period is 26,000 years.]
- (c) Show that when rewritten in the language of general relativity, and in frame-independent, geometric language, Eq. (25.62) takes the form (25.59) discussed in the text. As part of showing this, explain the meaning of $\mathcal{I}_{\beta\mu}$ in that equation.

For a derivation and discussion of this relativistic curvature-coupling torque when the spinning body is a black hole rather than a Newtonian body, see, for example, Thorne and Hartle (1985).

25.8 The Einstein Field Equation

25.8

One crucial issue remains to be studied in this overview of the foundations of general relativity: What is the physical law that determines the curvature of spacetime? Einstein's search for that law, his *Einstein field equation*, occupied a large fraction of his efforts during the years 1913, 1914, and 1915. Several times he thought he had found it, but each time his proposed law turned out to be fatally flawed; for some flavor of his struggle, see the excerpts from his writings in Misner, Thorne, and Wheeler (1973, Sec. 17.7).

In this section, we briefly examine one segment of Einstein's route toward his field equation: the segment motivated by contact with Newtonian gravity.

The Newtonian potential Φ is a close analog of the general relativistic spacetime metric \mathbf{g} . From Φ we can deduce everything about Newtonian gravity, and from \mathbf{g} we can deduce everything about spacetime curvature. In particular, by differentiating Φ twice we can obtain the Newtonian tidal field \mathcal{E} [Eq. (25.24)], and by differentiating the components of \mathbf{g} twice we can obtain the components of the relativistic generalization of \mathcal{E} : the Riemann curvature tensor [Eq. (25.44) in a local Lorentz frame; Eq. (25.50) in an arbitrary basis].

In Newtonian gravity, Φ is determined by Newton's field equation

$$\nabla^2 \Phi = 4\pi G\rho, \quad (25.64)$$

which can be rewritten in terms of the tidal field, $\mathcal{E}_{jk} = \partial^2 \Phi / \partial x^j \partial x^k$, as

$$\mathcal{E}^j_j = 4\pi G\rho. \quad (25.65)$$

Note that this equates a piece of the tidal field—its contraction or *trace*—to the density of mass. By analogy we can expect the Einstein field equation to equate a piece of the Riemann curvature tensor (the analog of the Newtonian tidal field) to some tensor analog of the Newtonian mass density. Further guidance comes from the demand that in nearly Newtonian situations (e.g., in the solar system), the Einstein field equation

Newtonian gravity

deducing the Einstein field equation from Newtonian gravity

should reduce to Newton's field equation. To exploit that guidance, we can (i) write the Newtonian tidal field for nearly Newtonian situations in terms of general relativity's Riemann tensor, $\mathcal{E}_{jk} = R_{j0k0}$ [Eq. (25.35); valid in a local Lorentz frame], (ii) then take the trace and note that by its symmetries $R^0_{000} = 0$ so that $\mathcal{E}^j_j = R^\alpha_{0\alpha 0} = R_{00}$, and (iii) thereby infer that the Newtonian limit of the Einstein equation should read, in a local Lorentz frame:

$$R_{00} = 4\pi G\rho. \quad (25.66)$$

Here R_{00} is the time-time component of the Ricci curvature tensor, which can be regarded as a piece of the Riemann tensor. An attractive proposal for the Einstein field equation should now be obvious. Since the equation should be geometric and frame independent, and since it must have the Newtonian limit (25.66), it presumably should say $R_{\alpha\beta} = 4\pi G \times$ (a second-rank symmetric tensor that generalizes the Newtonian mass density ρ). The obvious generalization of ρ is the stress-energy tensor $T_{\alpha\beta}$, so a candidate is

$$R_{\alpha\beta} = 4\pi GT_{\alpha\beta}. \quad (25.67)$$

a failed field equation

Einstein flirted extensively with this proposal for the field equation during 1913–1915. However, it, like several others he studied, was fatally flawed. When expressed in a coordinate system in terms of derivatives of the metric components $g_{\mu\nu}$, it becomes (because $R_{\alpha\beta}$ and $T_{\alpha\beta}$ both have 10 independent components) 10 independent differential equations for the 10 $g_{\mu\nu}$. This is too many equations. By an arbitrary change of coordinates, $x_{\text{new}}^\alpha = F^\alpha(x_{\text{old}}^0, x_{\text{old}}^1, x_{\text{old}}^2, x_{\text{old}}^3)$, involving four arbitrary functions F^0, F^1, F^2 , and F^3 , one should be able to impose on the metric components four arbitrary conditions, analogous to gauge conditions in electromagnetism (e.g., one should be able to set $g_{00} = -1$ and $g_{0j} = 0$ everywhere). Correspondingly, the field equations should constrain only 6, not 10 of the components of the metric (the 6 g_{ij} in our example).

the need for a divergence-free curvature tensor

In November 1915, Einstein (1915), and independently Hilbert (1915) [who was familiar with Einstein's struggle as a result of private conversations and correspondence] discovered the resolution of this dilemma. Because the local law of 4-momentum conservation guarantees $T^{\alpha\beta}_{;\beta} = 0$ independent of the field equation, if we replace the Ricci tensor in Eq. (25.67) by a constant (to be determined) times some new curvature tensor $G^{\alpha\beta}$ that is also automatically divergence free independently of the field equation ($G^{\alpha\beta}_{;\beta} \equiv 0$), then the new field equation $G^{\alpha\beta} = \kappa T^{\alpha\beta}$ (with $\kappa = \text{constant}$) will not constrain all 10 components of the metric. Rather, the four equations, $(G^{\alpha\beta} - \kappa T^{\alpha\beta})_{;\beta} = 0$ with $\alpha = 0, 1, 2, 3$, will automatically be satisfied; they will not constrain the metric components in any way, and only six independent constraints on the metric components will remain in the field equation, precisely the desired number.

It turns out, in fact, that from the Ricci tensor and the scalar curvature one can construct a curvature tensor $G^{\alpha\beta}$ with the desired property:

$$G^{\alpha\beta} \equiv R^{\alpha\beta} - \frac{1}{2}Rg^{\alpha\beta}. \quad (25.68)$$

Einstein curvature tensor

Today we call this the *Einstein curvature tensor*. That it has vanishing divergence, independently of how one chooses the metric,

$$\tilde{\nabla} \cdot \mathbf{G} \equiv 0, \quad (25.69)$$

Bianchi identity and contracted Bianchi identity

is called the *contracted Bianchi identity*, since it can be obtained by contracting the following *Bianchi identity* on the tensor $\epsilon_{\alpha}{}^{\beta\mu\nu}\epsilon_{\nu}{}^{\gamma\delta\epsilon}$:

$$R^{\alpha}{}_{\beta\gamma\delta;\epsilon} + R^{\alpha}{}_{\beta\delta\epsilon;\gamma} + R^{\alpha}{}_{\beta\epsilon\gamma;\delta} = 0. \quad (25.70)$$

[This Bianchi identity holds true for the Riemann curvature tensor of any and every manifold (i.e., of any and every smooth space; Ex. 25.17). For an extensive discussion of the Bianchi identities (25.70) and (25.69) and their geometric interpretation, see Misner, Thorne, and Wheeler (1973, Chap. 15).]

The Einstein field equation should then equate a multiple of $T^{\alpha\beta}$ to the Einstein tensor $G^{\alpha\beta}$:

$$G^{\alpha\beta} = \kappa T^{\alpha\beta}. \quad (25.71a)$$

The proportionality constant κ is determined from the Newtonian limit as follows. By rewriting the field equation (25.71a) in terms of the Ricci tensor

$$R^{\alpha\beta} - \frac{1}{2}g^{\alpha\beta}R = \kappa T^{\alpha\beta}, \quad (25.71b)$$

then taking the trace to obtain $R = -\kappa g_{\mu\nu}T^{\mu\nu}$ and inserting this back into (25.71a), we obtain

$$R^{\alpha\beta} = \kappa \left(T^{\alpha\beta} - \frac{1}{2}g^{\alpha\beta}g_{\mu\nu}T^{\mu\nu} \right). \quad (25.71c)$$

In nearly Newtonian situations and in a local Lorentz frame, the mass-energy density $T^{00} \cong \rho$ is far greater than the momentum density T^{j0} and is also far greater than the stress T^{jk} . Correspondingly, the time-time component of the field equation (25.71c) becomes

$$R^{00} = \kappa \left(T^{00} - \frac{1}{2}\eta^{00}\eta_{00}T^{00} \right) = \frac{1}{2}\kappa T^{00} = \frac{1}{2}\kappa\rho. \quad (25.71d)$$

By comparing with the correct Newtonian limit (25.66) and noting that in a local Lorentz frame $R_{00} = R^{00}$, we see that $\kappa = 8\pi G$, whence the Einstein field equation is

$$G^{\alpha\beta} = 8\pi GT^{\alpha\beta}. \quad (25.72)$$

Einstein field equation

EXERCISES

Exercise 25.17 *Derivation and Example: Bianchi Identities*

- (a) Derive the Bianchi identity (25.70) in 4-dimensional spacetime. [Hint: (i) Introduce a local Lorentz frame at some arbitrary event. (ii) In that frame show, from Eq. (25.50), that the components $R_{\alpha\beta\gamma\delta}$ of Riemann have the form of Eq. (25.44) plus corrections that are quadratic in the distance from the origin. (iii) Compute the left-hand side of Eq. (25.70), with index α down, at the origin of that frame, and show that it is zero. (iv) Then argue that because the origin of the frame was an arbitrary event in spacetime, and because the left-hand side of Eq. (25.70) is an arbitrary component of a tensor, the left-hand side viewed as a frame-independent geometric object must vanish at all events in spacetime.]
- (b) By contracting the Bianchi identity (25.70) on $\epsilon_\alpha^{\beta\mu\nu}\epsilon_\nu^{\gamma\delta\epsilon}$, derive the contracted Bianchi identity (25.69).

These derivations are easily generalized to an arbitrary manifold with any dimension by replacing the 4-dimensional local Lorentz frame by a locally orthonormal coordinate system (cf. the third and fourth paragraphs of Sec. 24.3.3).

25.8.1

25.8.1 Geometrized Units

By now the reader should be accustomed to our use of geometrized units in which the speed of light is unity. Just as setting $c = 1$ has simplified greatly the mathematical notation in Chaps. 2 and 24, so also subsequent notation is greatly simplified if we set Newton's gravitation constant G to unity. This further geometrization of our units corresponds to equating mass units to length units via the relation

geometrized units: setting Newton's gravitational constant to one

$$1 = \frac{G}{c^2} = 7.426 \times 10^{-28} \text{ m kg}^{-1}; \quad \text{so} \quad 1 \text{ kg} = 7.426 \times 10^{-28} \text{ m.} \quad (25.73)$$

Any equation can readily be converted from conventional units to geometrized units by removing all factors of c and G ; it can readily be converted back by inserting whatever factors of c and G one needs to make both sides of the equation dimensionally the same. Table 25.1 lists a few important numerical quantities in both conventional units and geometrized units.

In geometrized units, the Einstein field equation (25.72) assumes the following standard form, to which we appeal extensively in the three coming chapters:

the Einstein field equation in geometrized units

$$G^{\alpha\beta} = 8\pi T^{\alpha\beta}; \quad \text{or} \quad \mathbf{G} = 8\pi \mathbf{T}. \quad (25.74)$$

25.9

25.9 Weak Gravitational Fields

All the foundations of general relativity are now in our hands. In this concluding section of the chapter, we explore their predictions for the properties of weak gravitational

TABLE 25.1: Some useful quantities in conventional and geometrized units

Quantity	Conventional units	Geometrized units
Speed of light, c	$2.998 \times 10^8 \text{ m sec}^{-1}$	one
Newton's gravitation constant, G	$6.674 \times 10^{-11} \text{ m}^3 \text{ kg}^{-1} \text{ s}^{-2}$	one
G/c^2	$7.426 \times 10^{-28} \text{ m kg}^{-1}$	one
c^5/G	$3.628 \times 10^{52} \text{ W}$	one
Planck's reduced constant \hbar	$1.055 \times 10^{-34} \text{ kg m}^2 \text{ s}^{-1}$	$(1.616 \times 10^{-35} \text{ m})^2$

Earth's mass, M_{\oplus}	$5.972 \times 10^{24} \text{ kg}$	4.435 mm
Earth's mean radius, R_{\oplus}	$6.371 \times 10^6 \text{ m}$	$6.371 \times 10^6 \text{ m}$

Note: 1 Mpc = 10^6 parsecs (pc), 1 pc = 3.262 light-years (lt-yr), 1 lt-yr = 0.9461×10^{16} m, 1 AU = 1.496×10^{11} m. For other useful astronomical constants, see Cox (2000).

fields, beginning with the Newtonian limit of general relativity and then moving on to other situations.

25.9.1 Newtonian Limit of General Relativity

25.9.1

A general relativistic gravitational field (spacetime curvature) is said to be *weak* if there exist “nearly globally Lorentz” coordinate systems in which the metric coefficients differ only slightly from unity:

$$\boxed{g_{\alpha\beta} = \eta_{\alpha\beta} + h_{\alpha\beta}, \quad \text{with } |h_{\alpha\beta}| \ll 1.} \quad (25.75a)$$

The Newtonian limit requires that gravity be weak in this sense throughout the system being studied. It further requires a slow-motion constraint, which has three aspects:

conditions required for general relativity to become Newton's theory of gravity (the Newtonian limit)

1. The sources of gravity must have slow enough motions that the following holds for some specific choice of the nearly globally Lorentz coordinates:

$$|h_{\alpha\beta,t}| \ll |h_{\alpha\beta,j}|; \quad (25.75b)$$

2. the sources' motions must be slow enough that in this frame the momentum density is very small compared to the energy density:

$$|T^{j0}| \ll T^{00} \equiv \rho; \quad (25.75c)$$

3. and any particles on which the action of gravity is to be studied must move with low velocities, so they must have 4-velocities satisfying

$$|u^j| \ll u^0. \quad (25.75d)$$

Finally, the Newtonian limit requires that the stresses in the gravitating bodies be small compared to their mass densities:

$$|T^{jk}| \ll T^{00} \equiv \rho. \quad (25.75e)$$

When conditions (25.75) are all satisfied, then to leading nontrivial order in the small dimensionless quantities $|h_{\alpha\beta}|$, $|h_{\alpha\beta,t}|/|h_{\alpha\beta,j}|$, $|T^{j0}|/T^{00}$, $|u^j|/u^0$, and $|T^{jk}|/T^{00}$ the laws of general relativity reduce to those of Newtonian theory.

The details of this reduction are an exercise for the reader (Ex. 25.18); here we give an outline.

details of the Newtonian limit:

The low-velocity constraint $|u^j|/u^0 \ll 1$ on the 4-velocity of a particle, together with its normalization $u^\alpha u^\beta g_{\alpha\beta} = -1$ and the near flatness of the metric (25.75a), implies that

$$u^0 \cong 1, \quad u^j \cong v^j \equiv \frac{dx^j}{dt}. \quad (25.76)$$

Since $u^0 = dt/d\tau$, the first of these relations implies that in our nearly globally Lorentz coordinate system the coordinate time is very nearly equal to the proper time of our slow-speed particle. In this way, we recover the “universal time” of Newtonian theory. The universal, Euclidean space is that of our nearly Lorentz frame, with $h_{\mu\nu}$ completely ignored because of its smallness. The universal time and universal Euclidean space become the arena in which Newtonian physics is formulated.

Equation (25.76) for the components of a particle’s 4-velocity, together with $|v^j| \ll 1$ and $|h_{\mu\nu}| \ll 1$, imply that the geodesic equation for a freely moving particle to leading nontrivial order is

$$\frac{dv^j}{dt} \cong \frac{1}{2} \frac{\partial h_{00}}{\partial x^j}, \quad \text{where } \frac{d}{dt} \equiv \frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla. \quad (25.77)$$

(Because our spatial coordinates are Cartesian, we can put the spatial index j up on one side of the equation and down on the other without creating any danger of error.)

By comparing Eq. (25.77) with Newton’s equation of motion for the particle, we deduce that h_{00} must be related to the Newtonian gravitational potential by

$$h_{00} = -2\Phi, \quad (25.78)$$

so the spacetime metric in our nearly globally Lorentz coordinate system must be

spacetime metric in the Newtonian limit

$$ds^2 = -(1 + 2\Phi)dt^2 + (\delta_{jk} + h_{jk})dx^j dx^k + 2h_{0j}dt dx^j. \quad (25.79)$$

Because gravity is weak, only those parts of the Einstein tensor that are linear in $h_{\alpha\beta}$ are significant; quadratic and higher-order contributions can be ignored. Now, by the same mathematical steps as led us to Eq. (25.44) for the components of the Riemann tensor in a local Lorentz frame, one can show that the components of

the linearized Riemann tensor in our nearly global Lorentz frame have that same form (i.e., setting $g_{\alpha\beta} = \eta_{\alpha\beta} + h_{\alpha\beta}$):

$$R_{\alpha\beta\gamma\delta} = \frac{1}{2}(h_{\alpha\delta,\beta\gamma} + h_{\beta\gamma,\alpha\delta} - h_{\alpha\gamma,\beta\delta} - h_{\beta\delta,\alpha\gamma}). \quad (25.80)$$

From this equation and the slow-motion constraint $|h_{\alpha\beta,t}| \ll |h_{\alpha\beta,j}|$, we infer that the space-time-space-time components of Riemann are

$$R_{j0k0} = -\frac{1}{2}h_{00,jk} = \Phi_{,jk} = \mathcal{E}_{jk}. \quad (25.81)$$

tidal gravity in the Newtonian limit

In the last step we have used Eq. (25.78). We have thereby recovered the relation between the Newtonian tidal field $\mathcal{E}_{jk} \equiv \Phi_{,jk}$ and the relativistic tidal field R_{j0k0} . That relation can now be used, via the train of arguments in the preceding section, to show that the Einstein field equation, $G^{\mu\nu} = 8\pi T^{\mu\nu}$, reduces to the Newtonian field equation, $\nabla^2\Phi = 4\pi T^{00} \equiv 4\pi\rho$.

This analysis leaves the details of h_{0j} and h_{jk} unknown, because the Newtonian limit is insensitive to them.

Exercise 25.18 Derivation: Newtonian Limit of General Relativity

Consider a system that can be covered by nearly globally Lorentz coordinates in which the Newtonian-limit constraints (25.75) are satisfied. For such a system, flesh out the details of the text's derivation of the Newtonian limit. More specifically, do the following.

- Derive Eq. (25.76) for the components of the 4-velocity of a particle.
- Show that the geodesic equation reduces to Eq. (25.77).
- Show that to linear order in the metric perturbation $h_{\alpha\beta}$, the components of the Riemann tensor take the form of Eq. (25.80).
- Show that in the slow-motion limit the space-time-space-time components of Riemann take the form of Eq. (25.81).

EXERCISES

25.9.2 Linearized Theory

There are many systems in the universe that have weak gravity [Eq. (25.75a)], but for which the slow-motion approximations (25.75b)–(25.75d) and/or weak-stress approximation (25.75e) fail. Examples are high-speed particles and electromagnetic fields. For such systems, we need a generalization of Newtonian theory that drops the slow-motion and weak-stress constraints but keeps the weak-gravity constraint:

$$g_{\alpha\beta} = \eta_{\alpha\beta} + h_{\alpha\beta}, \quad \text{with } |h_{\alpha\beta}| \ll 1. \quad (25.82)$$

details of linearized theory (weak-gravity limit of general relativity):

spacetime metric and metric perturbation

25.9.2

The obvious generalization is a linearization of general relativity in $h_{\alpha\beta}$, with no other approximations being made—the so-called *linearized theory of gravity*. In this subsection we develop it.

In formulating linearized theory we can regard the metric perturbation $h_{\mu\nu}$ as a gravitational field that lives in flat spacetime, and correspondingly, we can carry out our mathematics as though we were in special relativity. In other words, linearized theory can be regarded as a field theory of gravity in flat spacetime—a variant of the type of theory that Einstein toyed with and then rejected (Sec. 25.1).

In linearized theory, the Riemann tensor takes the form of Eq. (25.80), but we have no right to simplify it further to the form of Eq. (25.81), so we must follow a different route to the linearized Einstein field equation.

Contracting the first and third indices in Eq. (25.80), we obtain an expression for the linearized Ricci tensor $R_{\mu\nu}$ in terms of $h_{\alpha\beta}$. Contracting once again, we obtain the scalar curvature R , and then from Eq. (25.68) we obtain for the Einstein tensor and the Einstein field equation:

linearized Einstein field equation

$$\begin{aligned} 2G_{\mu\nu} &= h_{\mu\alpha,\nu}{}^\alpha + h_{\nu\alpha,\mu}{}^\alpha - h_{\mu\nu,\alpha}{}^\alpha - h_{,\mu\nu} - \eta_{\mu\nu}(h_{\alpha\beta}{}^{,\alpha\beta} - h_{,\alpha}{}^\alpha) \\ &= 16\pi T_{\mu\nu}. \end{aligned} \quad (25.83)$$

Here all indices, subscript or superscript, that follow the comma are partial-derivative indices [e.g., $h_{,\beta}{}^\beta = (\partial^2 h / \partial x^\beta \partial x^\alpha) \eta^{\alpha\beta}$], and

$$h \equiv \eta^{\alpha\beta} h_{\alpha\beta} \quad (25.84)$$

is the “trace” of the metric perturbation. We can simplify the field equation (25.83) by reexpressing it in terms of the quantity

trace-reversed metric perturbation

$$\bar{h}_{\mu\nu} \equiv h_{\mu\nu} - \frac{1}{2} h \eta_{\mu\nu}. \quad (25.85)$$

One can easily check that this quantity has the opposite trace to that of $h_{\mu\nu}$ ($\bar{h} \equiv \bar{h}_{\alpha\beta} \eta^{\alpha\beta} = -h$), so it is called the *trace-reversed metric perturbation*. In terms of it, the field equation (25.83) becomes

$$-\bar{h}_{\mu\nu,\alpha}{}^\alpha - \eta_{\mu\nu} \bar{h}_{\alpha\beta}{}^{,\alpha\beta} + \bar{h}_{\mu\alpha,\nu}{}^\alpha + \bar{h}_{\nu\alpha,\mu}{}^\alpha = 16\pi T_{\mu\nu}. \quad (25.86)$$

We can simplify this field equation further by specializing our coordinates. We introduce a new nearly globally Lorentz coordinate system that is related to the old one by

infinitesimal coordinate transformation (gauge change)

$$x_{\text{new}}^\alpha(\mathcal{P}) = x_{\text{old}}^\alpha(\mathcal{P}) + \zeta^\alpha(\mathcal{P}), \quad (25.87)$$

where ζ^α is a small vectorial displacement of the coordinate grid. This change of coordinates via four arbitrary functions ($\alpha = 0, 1, 2, 3$) produces a change of the functional form of the metric perturbation $h_{\alpha\beta}$ to

influence of gauge change on metric perturbation

$$h_{\mu\nu}^{\text{new}} = h_{\mu\nu}^{\text{old}} - \xi_{\mu,\nu} - \xi_{\nu,\mu} \quad (25.88)$$

(Ex. 25.19), and a corresponding change of the trace-reversed metric perturbation. This is linearized theory's analog of a *gauge transformation* in electromagnetic theory. Just as an electromagnetic gauge change generated by a scalar field ψ alters the vector potential, $A_\mu^{\text{new}} = A_\mu^{\text{old}} - \psi_{,\mu}$, so the linearized-theory gauge change generated by ξ^α alters $h_{\mu\nu}$ and $\bar{h}_{\mu\nu}$; and just as the force-producing electromagnetic field tensor $F_{\mu\nu}$ is unaffected by an electromagnetic gauge change, so the tidal-force-producing linearized Riemann tensor is left unaffected by the gravitational gauge change (Ex. 25.19).

By a special choice of the four functions ξ^α (Ex. 25.19), we can impose the following four gauge conditions on $\bar{h}_{\mu\nu}$:

$$\boxed{\bar{h}_{\mu\nu, \nu} = 0.} \quad (25.89)$$

gravitational Lorenz gauge condition

These are linearized theory's analog of the electromagnetic Lorenz gauge condition $A_{\mu, \mu} = 0$, so they are called the *gravitational Lorenz gauge*. Just as the flat-spacetime Maxwell equations take the remarkably simple wave-equation form $A_{\mu, \alpha}{}^\alpha = 4\pi J_\mu$ in Lorenz gauge, so also the linearized Einstein equation (25.86) takes the corresponding simple wave-equation form in gravitational Lorenz gauge:

$$\boxed{-\bar{h}_{\mu\nu, \alpha}{}^\alpha = 16\pi T_{\mu\nu}.} \quad (25.90)$$

linearized Einstein field equation in Lorenz gauge

By the same method as one uses in electromagnetic theory (e.g., Jackson, 1999, Sec. 6.4), one can solve this gravitational field equation for the field $\bar{h}_{\mu\nu}$ produced by an arbitrary stress-energy-tensor source:

$$\boxed{\bar{h}_{\mu\nu}(t, \mathbf{x}) = \int \frac{4T_{\mu\nu}(t - |\mathbf{x} - \mathbf{x}'|, \mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|} dV_{\mathbf{x}'}.} \quad (25.91)$$

Lorenz-gauge trace-reversed metric perturbation as retarded integral over stress-energy tensor

The quantity in the numerator is the stress-energy source evaluated at the “retarded time” $t' = t - |\mathbf{x} - \mathbf{x}'|$. This equation for the field, and the wave equation (25.90) that underlies it, show explicitly that dynamically changing distributions of stress-energy must generate *gravitational waves*, which propagate outward from their source at the speed of light (Einstein, 1916b; Einstein, 1918). We study these gravitational waves in Chap. 27.

Exercise 25.19 Derivation: Gauge Transformations in the Linearized Theory

EXERCISES

- Show that the “infinitesimal” coordinate transformation (25.87) produces the change (25.88) of the linearized metric perturbation and that it leaves the Riemann tensor (25.80) unchanged.
- Exhibit a differential equation for the ξ^α that brings the metric perturbation into gravitational Lorenz gauge [i.e., that makes $h_{\mu\nu}^{\text{new}}$ obey the Lorenz gauge condition (25.89)].

FIGURE 25.4 The past light cone of an observation event \mathcal{O} , the world line of a particle, and two 4-vectors: the particle's 4-momentum \vec{p} at the point \mathcal{P} where it passes through \mathcal{O} 's past light cone, and the past-directed null vector \vec{k} that reaches from \mathcal{O} to \mathcal{P} .

- (c) Show that in gravitational Lorenz gauge, the Einstein field equation (25.86) reduces to Eq. (25.90).

Exercise 25.20 *Example: Gravitational Field of a Rapidly Moving Particle* T2

In this exercise we illustrate linearized theory by computing the gravitational field of a moving particle with finite rest mass and then that of a zero-rest-mass particle that moves with the speed of light.

- (a) From Eq. (25.91), deduce that, for a particle with mass M at rest at the origin, the only nonvanishing component of $\bar{h}^{\mu\nu}$ is $\bar{h}^{00} = 4M/r$.
- (b) Regarding $\bar{h}^{\mu\nu}$ as a field that lives in flat spacetime, show that it can be written in frame-independent, special relativistic form as

$$\bar{h}^{\mu\nu} = \frac{4p^\mu p^\nu}{\vec{k} \cdot \vec{p}}, \quad (25.92)$$

where \vec{p} is the particle's 4-momentum, and \vec{k} is the past-directed null vector that reaches from the observation event \mathcal{O} to the event \mathcal{P} at which the particle's world line passes through the observer's past light cone; see Fig. 25.4. Equation (25.92) is a very powerful formula. It is an explicit form of the solution (25.91) to the wave equation (25.90) not only for a particle that moves inertially (and thus could be at rest in our original reference frame) but also for an arbitrarily accelerated particle. Explain why.

- (c) In the Lorentz rest frame of the observer, let the particle move along the x -axis with speed v , so its world line is $\{x = vt, y = z = 0\}$, and its 4-momentum has components $p^0 = M\gamma$ and $p^x = Mv\gamma$, with $\gamma = 1/\sqrt{1-v^2}$. Show that, expressed in terms of the observation event's coordinates (t, x, y, z) ,

$$\vec{k} \cdot \vec{p} = \gamma MR, \quad \text{where } R = \sqrt{(1-v^2)(y^2 + z^2) + (x - vt)^2}. \quad (25.93)$$

Show, further, that the linearized spacetime metric is

$$ds^2 = \left(1 + \frac{2M}{\gamma R}\right) (-dt^2 + dx^2 + dy^2 + dz^2) + \frac{4\gamma M}{R} (dt - v dx)^2. \quad (25.94)$$

- (d) Take the limit of a zero-rest-mass particle moving at the speed of light by sending $m \rightarrow 0$, $v \rightarrow 1$, and $M\gamma \rightarrow \mathcal{E}$ (the particle's energy). [The limit of $1/R = 1/\sqrt{(1-v^2)(y^2+z^2) + (x-vt)^2}$ is quite tricky. It turns out to be $1/|x-t| - \delta(x-t) \ln(y^2+z^2)$, where δ is the Dirac delta function (Aichelberg and Sexl, 1971).] Show that the resulting metric is

$$ds^2 = -dt^2 + dx^2 + dy^2 + dz^2 + 4\mathcal{E} \left(\frac{1}{|x-t|} - \ln(y^2+z^2)\delta(x-t) \right) (dx-dt)^2.$$

By a change of coordinates, get rid of the $1/|x-t|$ term, thereby obtaining our final form for the metric of a zero-rest-mass particle:

$$ds^2 = -dt^2 + dx^2 + dy^2 + dz^2 - 4\mathcal{E} \ln(x^2+y^2) \delta(x-t)(dx-dt)^2 \quad (25.95)$$

Equation (25.95) turns out to be an exact solution of the fully nonlinear Einstein field equation for a zero-rest-mass particle; it is called the Aichelberg-Sexl *ultraboost* solution. Just as, when a charged particle is accelerated to near light speed, its electric field lines are compressed into its transverse plane, so the metric (25.95) has all its deviations from flat spacetime concentrated in the particle's transverse plane.

25.9.3 Gravitational Field outside a Stationary, Linearized Source of Gravity T2

25.9.3

Let us specialize to a time-independent source of weak gravity (so $T_{\mu\nu,t} = 0$ in our chosen nearly globally Lorentz frame) and compute its external gravitational field as a power series in $1/(\text{distance to source})$. We place our origin of coordinates at the source's center of mass, so

$$\int x^j T^{00} dV = 0, \quad (25.96)$$

and in the same manner as in electromagnetic theory, we expand

$$\frac{1}{|\mathbf{x} - \mathbf{x}'|} = \frac{1}{r} + \frac{x^j x^{j'}}{r^3} + \dots, \quad (25.97)$$

where $r \equiv |\mathbf{x}|$ is the distance of the field point from the source's center of mass. Inserting Eq. (25.97) into the general solution (25.91) of the Einstein equation and

stationary source of gravity

mass-centered coordinates

taking note of the conservation laws $T^{\alpha j}{}_{,j} = 0$, we obtain for the source's external field:

trace-reversed metric perturbation

$$\bar{h}_{00} = \frac{4M}{r} + \mathcal{O}\left(\frac{1}{r^3}\right), \quad \bar{h}_{0j} = -\frac{2\epsilon_{jkm}J^k x^m}{r^3} + \mathcal{O}\left(\frac{1}{r^3}\right), \quad \bar{h}_{ij} = \mathcal{O}\left(\frac{1}{r^3}\right). \quad (25.98a)$$

Here M and J^k are the source's mass and angular momentum:

source's mass and angular momentum

$$M \equiv \int T^{00} dV, \quad J_k \equiv \int \epsilon_{kab} x^a T^{0b} dV \quad (25.98b)$$

(see Ex. 25.21). This expansion in $1/r$, as in the electromagnetic case, is a multipolar expansion. At order $1/r$ the field is spherically symmetric and the monopole moment is the source's mass M . At order $1/r^2$ there is a "magnetic-type dipole moment," the source's spin angular momentum J_k . These are the leading-order moments in two infinite sets: the "mass multipole" moments (analog of electric moments), and the "mass-current multipole" moments (analog of magnetic moments). For details on all the higher-order moments, see, for example, Thorne (1980).

The metric perturbation can be computed by reversing the trace reversal: $h_{\alpha\beta} = \bar{h}_{\alpha\beta} - \eta_{\alpha\beta}\bar{h}$. Thereby we obtain for the spacetime metric, $g_{\alpha\beta} = \eta_{\alpha\beta} + h_{\alpha\beta}$, at linear order, outside the source:

spacetime metric

$$ds^2 = -\left(1 - \frac{2M}{r}\right) dt^2 - \frac{4\epsilon_{jkm}J^k x^m}{r^3} dt dx^j + \left(1 + \frac{2M}{r}\right) \delta_{jk} dx^j dx^k + \mathcal{O}\left(\frac{1}{r^3}\right) dx^\alpha dx^\beta. \quad (25.98c)$$

In spherical polar coordinates, with the polar axis along the direction of the source's angular momentum, the leading-order terms take the form

$$ds^2 = -\left(1 - \frac{2M}{r}\right) dt^2 - \frac{4J}{r} \sin^2 \theta dt d\phi + \left(1 + \frac{2M}{r}\right) (dr^2 + r^2 d\theta^2 + r^2 \sin^2 \theta d\phi^2), \quad (25.98d)$$

where $J \equiv |\mathbf{J}|$ is the magnitude of the source's angular momentum.

reading off the source's mass and angular momentum from its metric

reading off mass from Keplerian orbits of planets

This is a very important result. It tells us that we can "read off" the mass M and angular momentum J^k from the asymptotic form of the source's metric. More specifically: (i) The mass M shows up in g_{00} in just the way we expect from the Newtonian limit—by comparing Eqs. (25.98c) and (25.79), we see that $\Phi = -M/r$, and from our experience with Newtonian gravity, we conclude that M is the mass that governs the Keplerian orbits of planets around our gravitational source. (ii) The angular momentum J^k shows up in $g_{0j} = -(2/r^3)\epsilon_{jkm}J^k x^m$. The physical manifestation of this g_{0j} is a gravitational torque on gyroscopes.

Consider an inertial-guidance gyroscope whose center of mass is at rest in the coordinate system of Eq. (25.98c) (i.e., at rest relative to the gravitating source). The transport law for the gyroscope's spin is $\nabla_{\vec{u}} \vec{S} = \vec{u}(\vec{a} \cdot \vec{S})$ [Eq. (24.62) boosted from special relativity to general relativity via the equivalence principle]. Here \vec{u} is the gyroscope's 4-velocity (so $u^j = 0$, $u^0 = 1/\sqrt{1 - 2M/r} \simeq 1 + M/r \simeq 1$), and \vec{a} is its 4-acceleration. The spatial components of this transport law are

$$S^j{}_{,t} u^0 \simeq S^j{}_{,t} = -\Gamma^j{}_{k0} S^k u^0 \simeq -\Gamma^j{}_{k0} S^k \simeq -\Gamma^j{}_{jk0} S^k \simeq \frac{1}{2} (g_{0k,j} - g_{0j,k}) S^k. \quad (25.99)$$

Here each “ \simeq ” means “is equal, up to fractional corrections of order M/r .” By inserting g_{0j} from the line element (25.98c) and performing some manipulations with Levi-Civita tensors, we can bring Eq. (25.99) into the form (cf. Ex. 26.19 and Sec. 27.2.5)

$$\boxed{\frac{d\mathbf{S}}{dt} = \boldsymbol{\Omega}_{\text{prec}} \times \mathbf{S}, \quad \text{where } \boldsymbol{\Omega}_{\text{prec}} = \frac{1}{r^3} [-\mathbf{J} + 3(\mathbf{J} \cdot \mathbf{n})\mathbf{n}].} \quad (25.100)$$

reading off angular momentum from gyroscopic precession (frame dragging)

Here $\mathbf{n} = \mathbf{e}_{\hat{r}}$ is the unit radial vector pointing away from the gravitating source.

Equation (25.100) says that the gyroscope's spin angular momentum rotates (precesses) with angular velocity $\boldsymbol{\Omega}_{\text{prec}}$ in the coordinate system (which is attached to distant inertial frames, i.e., to distant galaxies and quasars). This is sometimes called a *gravitomagnetic precession*, because the off-diagonal term g_{j0} in the metric, when thought of as a 3-vector, is $-2\mathbf{J} \times \mathbf{n}/r^2$, which has the same form as the vector potential of a magnetic dipole; and the gyroscopic precession is similar to that of a magnetized spinning body interacting with that magnetic dipole. It is also called a *frame-dragging precession*, because one can regard the source's angular momentum as dragging inertial frames into precession and regard those inertial frames as being locked to inertial-guidance gyroscopes, such as \mathbf{S} . And it is sometimes called Lense-Thirring precession after the physicists who first discovered it mathematically, with Einstein's help (Pfister, 2007).

Figure 25.5 shows this frame-dragging precessional angular velocity $\boldsymbol{\Omega}_{\text{prec}}$ as a vector field attached to the source. Notice that it has precisely the same form as a dipolar magnetic field in electromagnetic theory. In Sec. 27.2.5, we discuss the magnitude of this frame dragging in the solar system and the experiments that have measured it.

For a time-independent body with *strong* internal gravity (e.g., a black hole), the distant gravitational field will have the same general form [Eqs. (25.98)] as for a weakly gravitating body, but the constants M and J^k that appear in the metric will not be expressible as the integrals (25.98b) over the body's interior. Nevertheless, they will be measurable by the same techniques as for a weakly gravitating body (Kepler's laws and frame dragging), and they can be interpreted as the body's total mass and angular momentum. We explore this in the next chapter [Eq. (26.71)], where the body will be a spinning black hole.

FIGURE 25.5 The precessional angular velocity Ω_{prec} [Eq. (25.100)] of an inertial-guidance gyroscope at rest outside a stationary, linearized source of gravity that has angular momentum \mathbf{J} . The arrows are all drawn with the same length rather than proportional to the magnitude of Ω_{prec} .

EXERCISES

Exercise 25.21 *Derivation and Example: External Field of a Stationary, Linearized Source* T2

Derive Eqs. (25.98a) for the trace-reversed metric perturbation outside a stationary (time-independent), linearized source of gravity. More specifically, do the following.

- First derive \bar{h}_{00} . In your derivation identify a dipolar term of the form $4D_j x^j / r^3$, and show that by placing the origin of coordinates at the center of mass, Eq. (25.96), one causes the dipole moment D_j to vanish.
- Next derive \bar{h}_{0j} . The two terms in Eq. (25.97) should give rise to two terms. The first of these is $4P_j / r$, where P_j is the source's linear momentum. Show, using the gauge condition $\bar{h}^{0\mu}_{, \mu} = 0$ [Eq. (25.89)], that if the momentum is nonzero, then the mass dipole term of part (a) must have a nonzero time derivative, which violates our assumption of stationarity. Therefore, the linear momentum must vanish for this source. Show that the second term gives rise to the \bar{h}_{0j} of Eq. (25.98a). [Hint: You will have to add a perfect divergence, $-\frac{1}{2}(T^{0a} x^j x^m)_{, a}$ to the integrand $T^{0j} x^m$.]
- Finally derive \bar{h}_{ij} . [Hint: Show that $T^{ij} = (T^{ia} x^i)_{, a}$ and thence that the volume integral of T^{ij} vanishes; similarly for $T^{ij} x^k$.]

Exercise 25.22 *Derivation and Problem: Differential Precession and Frame-Drag Field* T2

- Derive the equation $\Delta\Omega_i = \mathcal{B}_{ij}\xi^j$ for the precession angular velocity of a gyroscope at the tip of ξ as measured in an inertial frame at its tail. Here \mathcal{B}_{ij} is the frame-drag field introduced in Box 25.2. [For a solution, see Nichols et al. (2011, Sec. III.C).]

BOX 25.2. DECOMPOSITION OF RIEMANN: TIDAL AND FRAME-DRAG FIELDS T2

In any local Lorentz frame, and also in a Lorentz frame of the linearized theory, the electromagnetic field tensor $F_{\mu\nu}$ can be decomposed into two spatial vector fields: the electric field $E_i = F_{i0}$ and magnetic field $B_i = \frac{1}{2}\epsilon_{ipq}F^{pq}$ (Sec. 2.11). Similarly, in vacuum (for simplicity) the Riemann curvature tensor can be decomposed into two spatial tensor fields: the *tidal field* $\mathcal{E}_{ij} = R_{i0j0}$ and the *frame-drag field* $\mathcal{B}_{ij} = \frac{1}{2}\epsilon_{ipq}R^{pq}{}_{j0}$. The symmetries (25.45) of Riemann, and the fact that in vacuum it is trace-free, imply that both \mathcal{E}_{ij} and \mathcal{B}_{jk} are symmetric and trace-free (STF). In the 3-space of the chosen frame, they are the irreducible tensorial parts of the vacuum Riemann tensor (cf. Box 11.2).

In a local Lorentz frame for strong gravity, and also in the linearized theory for weak gravity, the Bianchi identities (25.70) take on the following Maxwell-like form [Nichols et al., 2011, Eqs. (2.4), (2.15)], in which the superscript S means to symmetrize:

$$\nabla \cdot \mathcal{E} = 0, \quad \nabla \cdot \mathcal{B} = 0, \quad \frac{\partial \mathcal{E}}{\partial t} - (\nabla \times \mathcal{B})^S = 0, \quad \frac{\partial \mathcal{B}}{\partial t} + (\nabla \times \mathcal{E})^S = 0. \quad (1)$$

This has motivated some physicists to call the tidal field \mathcal{E} and the frame-drag field \mathcal{B} the “electric” and “magnetic” parts of the vacuum Riemann tensor. We avoid this language because of the possibility of confusing these second-rank tensorial gravitational fields with their truly electromagnetic vector-field counterparts \mathbf{E} and \mathbf{B} .

The tidal and frame-drag fields get their names from the forces they produce. The equation of geodesic deviation (25.34) says that, in a local Lorentz frame or in linearized theory, the relative acceleration of two test particles, separated by the vector ξ , is $\Delta a_i = -\mathcal{E}_{ij}\xi^j$. Similarly, a gyroscope at the tip of ξ precesses relative to an inertial frame at its tail with the differential frame-dragging angular velocity $\Delta\Omega_i = \mathcal{B}_{ij}\xi^j$ (Ex. 25.22). Not surprisingly, in linearized theory, \mathcal{B} is the symmetrized gradient of the angular velocity Ω_{prec} of precession relative to distant inertial frames: $\mathcal{B} = \left(\nabla\Omega_{\text{prec}}\right)^S$.

Just as the electric and magnetic fields can be visualized using field lines that are the integral curves of \mathbf{E} and \mathbf{B} , \mathcal{E} and \mathcal{B} can be visualized using the integral curves of their eigenvectors. Since each field, \mathcal{E} or \mathcal{B} , has three orthogonal eigenvectors, each has a network of three orthogonal sets of field lines. The field lines of \mathcal{B} are called (Nichols et al., 2011) *frame-drag vortex lines* or simply “vortex lines”; those of \mathcal{E} are called *tidal tendex lines* or simply “tendex lines”

(continued)

BOX 25.2. (continued)

(from the Latin *tendere*, meaning “to stretch” by analogy with vortex from *vertere*, meaning “to turn”). For a spinning point mass in linearized theory, \mathcal{E} and \mathcal{B} are given by Eqs. (25.101), and their tendex and vortex lines are as shown below (adapted from Nichols et al., 2011). The red tendex lines (left diagram) stretch; the blue squeeze. The red vortex lines (right) twist a gyroscope at a person’s feet (or head) counterclockwise relative to inertial frames at her head (or feet). The blue vortex lines twist clockwise. We explore these concepts in greater detail in Box 26.3.

- (b) Show that in linearized theory, \mathcal{B} is the symmetrized gradient of the angular velocity Ω_{prec} of precession of a gyroscope relative to distant inertial frames.

Exercise 25.23 *Problem: Spinning Particle in Linearized Theory:*

Tidal and Frame-Drage Fields T2

Show that in linearized theory, for a spinning particle at the origin with mass M and with its spin J along the polar axis, the orthonormal-frame components of \mathcal{E} and \mathcal{B} are

$$\mathcal{E}_{\hat{r}\hat{r}} = -2\mathcal{E}_{\hat{\theta}\hat{\theta}} = -2\mathcal{E}_{\hat{\phi}\hat{\phi}} = -\frac{2M}{r^3}, \quad (25.101a)$$

$$\mathcal{B}_{\hat{r}\hat{r}} = -2\mathcal{B}_{\hat{\theta}\hat{\theta}} = -2\mathcal{B}_{\hat{\phi}\hat{\phi}} = -\frac{6J \cos \theta}{r^4}, \quad \mathcal{B}_{\hat{r}\hat{\theta}} = \mathcal{B}_{\hat{\theta}\hat{r}} = -\frac{3J \sin \theta}{r^4}. \quad (25.101b)$$

What are the eigenvectors of these fields? Convince yourself that these eigenvectors’ integral curves (the tidal tendex lines and frame-drag vortex lines) are as depicted at the bottom of Box 25.2.

25.9.4 Conservation Laws for Mass, Momentum, and Angular Momentum
in Linearized Theory **T2**

25.9.4

T2

Consider a static (unmoving) sphere \mathcal{S} surrounding our time-independent source of gravity, with such a large radius r that the $O(1/r^3)$ corrections in $\bar{h}_{\mu\nu}$ and in the metric [Eqs. (25.98)] can be ignored. Suppose that a small amount of mass-energy E (as measured in the sphere's and source's rest frame) is injected through the sphere, into the source. Then the special relativistic law of mass-energy conservation tells us that the source's mass $M = \int T^{00} dV$ will increase by $\Delta M = E$. Similarly, if an energy flux T^{0j} flows through the sphere, the source's mass will change by

for a stationary source of gravity perturbed by an infalling or outflowing stress-energy tensor:

$$\boxed{\frac{dM}{dt} = - \int_{\mathcal{S}} T^{0j} d\Sigma_j}, \quad (25.102)$$

mass conservation

where $d\Sigma_j$ is the sphere's outward-pointing surface-area element, and the minus sign is because $d\Sigma_j$ points outward, not inward. Since M is the mass that appears in the source's asymptotic gravitational field $\bar{h}_{\mu\nu}$ and metric $g_{\alpha\beta}$, this conservation law can be regarded as describing how the source's gravitating mass changes when energy is injected into it.

From the special relativistic law for angular momentum conservation (e.g., Misner, Thorne, and Wheeler, 1973, Box 5.6), we deduce a similar result. A flux $\epsilon_{ijk} x^j T^{km}$ of angular momentum through the sphere produces the following change in the angular momentum J_i that appears in the source's asymptotic field $\bar{h}_{\mu\nu}$ and metric:

$$\boxed{\frac{dJ_i}{dt} = - \int_{\mathcal{S}} \epsilon_{ijk} x^j T^{km} d\Sigma_m}. \quad (25.103)$$

angular-momentum conservation

There is also a conservation law for a gravitationally measured linear momentum. That linear momentum does not show up in the asymptotic field and metric that we wrote down above [Eqs. (25.98)], because our coordinates were chosen to be attached to the source's center of mass (i.e., they are the Lorentz coordinates of the source's rest frame). However, if linear momentum P_j is injected through our sphere \mathcal{S} and becomes part of the source, then the source's center of mass will start moving, and the asymptotic metric will acquire a new term:

$$\boxed{\delta g_{0j} = -4P_j/r}, \quad (25.104)$$

where (after the injection)

$$\boxed{P_j = P^j = \int T^{0j} dV} \quad (25.105)$$

source's linear momentum

[see Eq. (25.91) with $\bar{h}^{0j} = -\bar{h}_{0j} = -h_{0j} = -\delta g_{0j}$; also see Ex. 25.21b]. More generally, the rate of change of the source's total linear momentum (the P_j term in the

T2

asymptotic g_{0j}) is the integral of the inward flux of momentum (inward component of the stress tensor) across the sphere:

momentum conservation

$$\frac{dP_j}{dt} = - \int_{\mathcal{S}} T^{jk} d\Sigma_k. \quad (25.106)$$

25.9.5

25.9.5 Conservation Laws for a Strong-Gravity Source T2

strong-gravity source surrounded by asymptotically flat spacetime:

For a time-independent source with strong internal gravity, not only does the asymptotic metric, far from the source, have the same form [Eqs. (25.98c), (25.98d), (25.104)] as for a weakly gravitating source, but also the conservation laws for its gravitationally measured mass, angular momentum, and linear momentum [Eqs. (25.102), (25.103), (25.106), respectively] continue to hold true. Of course, the sphere \mathcal{S} must be placed far from the source, in a region where gravity is weak, so spacetime is *asymptotically flat*⁶ and linearized theory is valid in the vicinity of \mathcal{S} . When this is done, then the special relativistic description of inflowing mass, angular momentum, and energy is valid at \mathcal{S} , and the linearized Einstein equation, applied in the vicinity of \mathcal{S} (and not extended into the strong-gravity region), turn out to guarantee that the M , J_j , and P_j appearing in the asymptotic metric evolve in accord with the conservation laws (25.102), (25.103), and (25.106).

in asymptotically flat region, source's mass, momentum, angular momentum, and their conservation are the same as for a weak-gravity source

For strongly gravitating sources, these conservation laws owe their existence to the spacetime's asymptotic time-translation, rotation, and space-translation symmetries. In generic, strong-gravity regions of spacetime there are no such symmetries and correspondingly, no integral conservation laws for energy, angular momentum, or linear momentum.

If a strongly gravitating source is dynamical rather than static, it will emit gravitational waves (Chap. 27). The amplitudes of those waves, like the influence of the source's mass, die out as $1/r$ far from the source, so spacetime retains its asymptotic time-translation, rotation, and space-translation symmetries. These symmetries continue to enforce integral conservation laws on the gravitationally measured mass, angular momentum, and linear momentum [Eqs. (25.102), (25.103), and (25.106)], but with the new requirement that one include, in the fluxes through \mathcal{S} , contributions from the gravitational waves' energy, angular momentum, and linear momentum; see Chap. 27.

For a brief derivation and discussion of these asymptotic conservation laws, see Thorne (1983, Sec. 3.3.2); for far greater detail, see Misner, Thorne, and Wheeler (1973, Chaps. 18 and 19).

6. Our real universe, of course, is not asymptotically flat. However, nearly everywhere the distances between gravitating systems (e.g., between our solar system and the alpha centauri system) are so large that spacetime is very nearly asymptotically flat as one moves outward into the region between the systems. Correspondingly, to very high accuracy all the statements in this section remain true.

Bibliographic Note

For a superb, detailed historical account of Einstein's intellectual struggle to formulate the laws of general relativity, see Pais (1982). For Einstein's papers of that era, in the original German and in English translation, with detailed annotations and explanations by editors with strong backgrounds in both physics and the history of science, see Einstein (1989). For some key papers of that era by other major contributors besides Einstein, in English translation, see Lorentz et al. (1923).

This chapter's pedagogical approach to presenting the fundamental concepts of general relativity is strongly influenced by Misner, Thorne, and Wheeler (1973), where readers will find much greater detail. See, especially, Chap. 8 for the mathematics (differential geometry) of curved spacetime, or Chaps. 9–14 for far greater detail; Chap. 16 for the Einstein equivalence principle and how to lift laws of physics into curved spacetime; Chap. 17 for the Einstein field equations and many different ways to derive them; Chap. 18 for weak gravitational fields (the Newtonian limit and linearized theory); and Chaps. 19 and 20 for the metric in the asymptotically flat region outside a strongly gravitating source and for the source's conservation laws for mass, momentum, and angular momentum.

For an excellent, elementary introduction to the fundamental concepts of general relativity from a viewpoint that is somewhat less mathematical than this chapter or Misner, Thorne, and Wheeler (1973), see Hartle (2003). We also recommend, at a somewhat elementary level, Schutz (2009); and at a more advanced level, Carroll (2004), Straumann (2013), and Zee (2013). At a very advanced and mathematical level, we recommend Wald (1984). For a rather different approach to general relativity, one that emphasizes the connection to field theory over that to geometry, we recommend Weinberg (1972).

Our physicist's approach to differential geometry in this chapter lacks much of the rigor and beauty of a mathematician's approach, for which we recommend Spivak (1999).

Relativistic Stars and Black Holes

All light emitted from such a body would be made to return towards it by its own proper gravity.

JOHN MICHELL (1783)

26.1 Overview

26.1

Having sketched the fundamentals of Einstein's theory of gravity, general relativity, we now illustrate his theory by several concrete applications: stars and black holes in this chapter, gravitational waves in Chap. 27, and the large-scale structure and evolution of the universe in Chap. 28.

While stars and black holes are the central thread of this chapter, we study them less for their own intrinsic interest than for their roles as vehicles by which to understand general relativity. Using them, we elucidate some issues we have already met: the physical and geometric interpretations of spacetime metrics and of coordinate systems, the Newtonian limit of general relativity, the geodesic motion of freely falling particles and photons, local Lorentz frames and the tidal forces measured therein, proper reference frames, the Einstein field equation, the local law of conservation of 4-momentum, and the asymptotic structure of spacetime far from gravitating sources. Stars and black holes also serve to introduce several new physical phenomena that did not show up in our study of the foundations of general relativity: the “many-fingered” nature of time, event horizons, and spacetime singularities.

We begin this chapter, in Sec. 26.2, by studying the geometry of the curved spacetime outside any static star, as predicted by the Einstein field equation. In Sec. 26.3, we study general relativity's description of the interiors of static stars. In Sec. 26.4, we turn attention to the spherically symmetric gravitational implosion by which a nonrotating star is transformed into a black hole, and to the Schwarzschild spacetime geometry outside and inside the resulting static, spherical hole. In Sec. 26.5, we study the Kerr spacetime geometry of a spinning black hole. In Sec. 26.6, we elucidate the nature of time in the curved spacetimes of general relativity. And in Ex. 26.13, we explore the role of the vacuum Schwarzschild solution of the Einstein field equation as a wormhole.

BOX 26.1. READERS' GUIDE

- This chapter relies significantly on:
 - Chap. 2 on special relativity;
 - Chap. 24 on the transition from special relativity to general relativity; and
 - Chap. 25 on the fundamental concepts of general relativity.
- Portions of this chapter are a foundation for the applications of general relativity theory to gravitational waves (Chap. 27) and to cosmology (Chap. 28).

26.2 Schwarzschild's Spacetime Geometry

26.2.1 The Schwarzschild Metric, Its Connection Coefficients, and Its Curvature Tensors

On January 13, 1916, just 7 weeks after formulating the final version of his field equation, $\mathbf{G} = 8\pi \mathbf{T}$, Albert Einstein read to a meeting of the Prussian Academy of Sciences in Berlin a letter from the eminent German astrophysicist Karl Schwarzschild. Schwarzschild, as a member of the German army, had written from the World-War-I Russian front to tell Einstein of a mathematical discovery he had made: he had found the world's first exact solution to the Einstein field equation.

Written as a line element in a special coordinate system (coordinates $\{t, r, \theta, \phi\}$) that Schwarzschild invented for the purpose, Schwarzschild's solution takes the form (Schwarzschild, 1916a)

$$ds^2 = -(1 - 2M/r)dt^2 + \frac{dr^2}{(1 - 2M/r)} + r^2(d\theta^2 + \sin^2\theta d\phi^2), \quad (26.1)$$

where M is a constant of integration. The connection coefficients, Riemann tensor, and Ricci and Einstein tensors for this metric can be computed by the methods of Chaps. 24 and 25; see Ex. 26.1. The results are tabulated in Box 26.2. The key bottom line is that the Einstein tensor vanishes. Therefore, the Schwarzschild metric (26.1) is a solution of the Einstein field equation with vanishing stress-energy tensor.

Many readers know already the lore of this subject. The Schwarzschild metric is reputed to represent the vacuum exterior of a nonrotating, spherical star; and also the exterior of a spherical star as it implodes to form a black hole; and also the exterior and interior of a nonrotating, spherical black hole; and also a wormhole that connects two different universes or two widely separated regions of our own universe.

How does one discover these physical interpretations of the Schwarzschild metric (26.1)? The tools for discovering them—and, more generally, the tools for interpreting

Schwarzschild metric

roles of the Schwarzschild metric: exterior of static star and imploding star; black hole and wormhole

BOX 26.2. CONNECTION COEFFICIENTS AND CURVATURE TENSORS FOR SCHWARZSCHILD SOLUTION

The coordinate basis vectors for the Schwarzschild solution of Einstein's equation are

$$\begin{aligned}\vec{e}_t &= \frac{\partial}{\partial t}, & \vec{e}_r &= \frac{\partial}{\partial r}, & \vec{e}_\theta &= \frac{\partial}{\partial \theta}, & \vec{e}_\phi &= \frac{\partial}{\partial \phi}; \\ \vec{e}^t &= \vec{\nabla}_t, & \vec{e}^r &= \vec{\nabla}_r, & \vec{e}^\theta &= \vec{\nabla}_\theta, & \vec{e}^\phi &= \vec{\nabla}_\phi.\end{aligned}\quad (1)$$

The covariant and contravariant metric coefficients in this coordinate basis are [cf. Eq. (26.1)]

$$g_{tt} = -\left(1 - \frac{2M}{r}\right), \quad g_{rr} = \frac{1}{(1 - 2M/r)}, \quad g_{\theta\theta} = r^2, \quad g_{\phi\phi} = r^2 \sin^2 \theta; \quad (2a)$$

$$g^{tt} = -\frac{1}{(1 - 2M/r)}, \quad g^{rr} = \left(1 - \frac{2M}{r}\right), \quad g^{\theta\theta} = \frac{1}{r^2}, \quad g^{\phi\phi} = \frac{1}{r^2 \sin^2 \theta}. \quad (2b)$$

The nonzero connection coefficients in this coordinate basis are

$$\begin{aligned}\Gamma^t{}_{rt} = \Gamma^t{}_{tr} &= \frac{M}{r^2} \frac{1}{(1 - 2M/r)}, & \Gamma^r{}_{tt} &= \frac{M}{r^2} (1 - 2M/r), & \Gamma^r{}_{rr} &= -\frac{M}{r^2} \frac{1}{(1 - 2M/r)}, \\ \Gamma^r{}_{\theta\theta} &= -r(1 - 2M/r), & \Gamma^\theta{}_{r\theta} = \Gamma^\theta{}_{\theta r} &= \Gamma^\phi{}_{r\phi} = \Gamma^\phi{}_{\phi r} &= \frac{1}{r},\end{aligned}\quad (3)$$

$$\Gamma^r{}_{\phi\phi} = -r \sin^2 \theta (1 - 2M/r), \quad \Gamma^\theta{}_{\phi\phi} = -\sin \theta \cos \theta, \quad \Gamma^\phi{}_{\theta\phi} = \Gamma^\phi{}_{\phi\theta} = \cot \theta.$$

The orthonormal basis associated with the above coordinate basis is

$$\vec{e}_{\hat{t}} = \frac{1}{\sqrt{1 - 2M/r}} \frac{\partial}{\partial t}, \quad \vec{e}_{\hat{r}} = \sqrt{1 - \frac{2M}{r}} \frac{\partial}{\partial r}, \quad \vec{e}_{\hat{\theta}} = \frac{1}{r} \frac{\partial}{\partial \theta}, \quad \vec{e}_{\hat{\phi}} = \frac{1}{r \sin \theta} \frac{\partial}{\partial \phi}. \quad (4)$$

The nonzero connection coefficients in this orthonormal basis are

$$\begin{aligned}\Gamma^{\hat{r}}{}_{\hat{t}\hat{t}} = \Gamma^{\hat{t}}{}_{\hat{r}\hat{t}} &= \frac{M}{r^2 \sqrt{1 - 2M/r}}, & \Gamma^{\hat{\phi}}{}_{\hat{\theta}\hat{\phi}} = -\Gamma^{\hat{\theta}}{}_{\hat{\phi}\hat{\phi}} &= \frac{\cot \theta}{r}, \\ \Gamma^{\hat{\theta}}{}_{\hat{r}\hat{\theta}} = \Gamma^{\hat{r}}{}_{\hat{\theta}\hat{\theta}} &= -\Gamma^{\hat{r}}{}_{\hat{\theta}\hat{\theta}} = -\Gamma^{\hat{\theta}}{}_{\hat{\phi}\hat{\phi}} &= \frac{\sqrt{1 - 2M/r}}{r}.\end{aligned}\quad (5)$$

(continued)

BOX 26.2. (continued)

The nonzero components of the Riemann tensor in this orthonormal basis are

$$R_{\hat{r}\hat{0}\hat{r}\hat{0}} = -R_{\hat{\theta}\hat{\phi}\hat{\theta}\hat{\phi}} = -\frac{2M}{r^3}, \quad R_{\hat{\theta}\hat{0}\hat{\theta}\hat{0}} = R_{\hat{\phi}\hat{0}\hat{\phi}\hat{0}} = -R_{\hat{r}\hat{\phi}\hat{r}\hat{\phi}} = -R_{\hat{r}\hat{\theta}\hat{r}\hat{\theta}} = \frac{M}{r^3}, \quad (6)$$

and those obtainable from these via the symmetries (25.45a) of Riemann. The Ricci tensor, curvature scalar, and Einstein tensor all vanish—which implies that the Schwarzschild metric is a solution of the vacuum Einstein field equation.

physically any spacetime metric that one encounters—are a central concern of this chapter.

EXERCISES

Exercise 26.1 *Practice: Connection Coefficients and the Riemann Tensor for the Schwarzschild Metric*

- Explain why, for the Schwarzschild metric (26.1), the metric coefficients in the coordinate basis have the values given in Eqs. (2a,b) of Box 26.2.
- Using tensor-analysis software on a computer,¹ derive the connection coefficients given in Eq. (3) of Box 26.2.
- Show that the basis vectors in Eqs. (4) of Box 26.2 are orthonormal.
- Using tensor-analysis software on a computer, derive the connection coefficients (5) and Riemann components (6) of Box 26.2 in the orthonormal basis.

26.2.2 26.2.2 The Nature of Schwarzschild's Coordinate System, and Symmetries of the Schwarzschild Spacetime

When presented with a line element such as Eq. (26.1), one of the first questions one is tempted to ask is “What is the nature of the coordinate system?” Since the metric coefficients will be different in some other coordinate system, surely one must know something about the coordinates to interpret the line element.

Remarkably, one need not go to the inventor of the coordinates to find out their nature. Instead, one can turn to the line element itself: the line element (or metric

1. Such as the simple Mathematica program in Hartle (2003, Appendix C), which is available on that book's website: <http://web.physics.ucsb.edu/~gravitybook/mathematical.html>.

coefficients) contain full information not only about the details of the spacetime geometry, but also about the nature of the coordinates. The line element (26.1) is a good example:

Look first at the 2-dimensional surfaces in spacetime that have constant values of t and r . We can regard $\{\theta, \phi\}$ as a coordinate system on each such 2-surface. The spacetime line element (26.1) tells us that the geometry of the 2-surface is given in terms of those coordinates by

$${}^{(2)}ds^2 = r^2(d\theta^2 + \sin^2 \theta d\phi^2) \quad (26.2)$$

(where the prefix ${}^{(2)}$ refers to the dimensionality of the surface). This is the line element (metric) of an ordinary, everyday 2-dimensional sphere expressed in standard spherical polar coordinates. Thus we have learned that the Schwarzschild spacetime is spherically symmetric, and moreover, θ and ϕ are standard spherical polar coordinates. This is an example of extracting from a metric information about both the coordinate-independent spacetime geometry and the coordinate system being used.

Furthermore, note from Eq. (26.2) that the circumferences and surface areas of the spheres $(t, r) = \text{const}$ in Schwarzschild spacetime are given by

$$\boxed{\text{circumference} = 2\pi r, \quad \text{area} = 4\pi r^2.} \quad (26.3)$$

This tells us one aspect of the geometric interpretation of the r coordinate: r is a radial coordinate in the sense that the circumferences and surface areas of the spheres in Schwarzschild spacetime are expressed in terms of r in the standard manner of Eq. (26.3). We must not go further, however, and assert that r is radius in the sense of being the proper distance from the center of one of the spheres to its surface. The center, and the line from center to surface, do not lie on the sphere itself, and they thus are not described by the spherical line element (26.2). Moreover, since we know that spacetime is curved, we have no right to expect that the proper distance from the center of a sphere to its surface will be given by distance = circumference/ 2π = r as in flat spacetime.

26.2.3 Schwarzschild Spacetime at Radii $r \gg M$: The Asymptotically Flat Region

26.2.3

Returning to the Schwarzschild line element (26.1), let us examine several specific regions of spacetime: At “radii” r large compared to the integration constant M , the line element (26.1) takes the form

$$ds^2 = -dt^2 + dr^2 + r^2(d\theta^2 + \sin^2 \theta d\phi^2). \quad (26.4)$$

This is the line element of flat spacetime, $ds^2 = -dt^2 + dx^2 + dy^2 + dz^2$ written in spherical polar coordinates $\{x = r \sin \theta \cos \phi, y = r \sin \theta \sin \phi, z = r \cos \theta\}$. Thus, Schwarzschild spacetime is asymptotically flat in the region of large radii $r/M \rightarrow \infty$. This is just what one might expect physically when one gets far away from all sources of

properties of the Schwarzschild metric and its Schwarzschild coordinates:

spherically symmetric

radial coordinate r is circumference/ 2π , or square root of area/ 4π

asymptotically flat

gravity. Thus, it is reasonable to presume that the Schwarzschild spacetime geometry is that of some sort of isolated, gravitating body that is located in the region $r \sim M$.

The large- r line element (26.4) not only reveals that Schwarzschild spacetime is asymptotically flat; it also shows that in the asymptotically flat region the Schwarzschild coordinate t is the time coordinate of a Lorentz reference frame. Notice that the region of strong spacetime curvature has a boundary (say, $r \sim 100M$) that remains forever fixed relative to the asymptotically Lorentz spatial coordinates $\{x = r \sin \theta \cos \phi, y = r \sin \theta \sin \phi, z = r \cos \theta\}$. This means that the asymptotic Lorentz frame can be regarded as the body's asymptotic rest frame. We conclude, then, that far from the body the Schwarzschild t coordinate becomes the Lorentz time of the body's asymptotic rest frame, and the Schwarzschild $\{r, \theta, \phi\}$ coordinates become spherical polar coordinates in the body's asymptotic rest frame.

As we move inward from $r = \infty$, we gradually begin to see spacetime curvature. That curvature shows up, at $r \gg M$, in slight deviations of the Schwarzschild metric coefficients from those of a Lorentz frame: to first order in M/r the line element (26.1) becomes

$$ds^2 = -\left(1 - \frac{2M}{r}\right) dt^2 + \left(1 + \frac{2M}{r}\right) dr^2 + r^2(d\theta^2 + \sin^2 \theta d\phi^2), \quad (26.5)$$

or, equivalently, in Cartesian spatial coordinates:

$$ds^2 = -\left(1 - \frac{2M}{\sqrt{x^2 + y^2 + z^2}}\right) dt^2 + dx^2 + dy^2 + dz^2 + \frac{2M}{r} \left(\frac{x}{r} dx + \frac{y}{r} dy + \frac{z}{r} dz\right)^2. \quad (26.6)$$

It is reasonable to expect that, at these large radii where the curvature is weak, Newtonian gravity will be a good approximation to Einsteinian gravity. In Sec. 25.9.1, we studied in detail the transition from general relativity to Newtonian gravity, and found that in nearly Newtonian situations, if one uses a nearly globally Lorentz coordinate system (as we are doing), the line element should take the form [Eq. (25.79)]:

$$ds^2 = -(1 + 2\Phi)dt^2 + (\delta_{jk} + h_{jk})dx^j dx^k + 2h_{tj} dt dx^j, \quad (26.7)$$

where the $h_{\mu\nu}$ are metric corrections that are small compared to unity, and Φ (which shows up in the time-time part of the metric) is the Newtonian potential. Direct comparison of Eq. (26.7) with (26.6) shows that a Newtonian description of the body's distant gravitational field will entail a Newtonian potential given by

$$\Phi = -\frac{M}{r} \quad (26.8)$$

($\Phi = -GM/r$ in conventional units). This, of course, is the external Newtonian field of a body with mass M . Thus, the integration constant M in the Schwarzschild line

asymptotic rest frame

Newtonian limit of Schwarzschild metric

element is the mass that characterizes the body's distant, nearly Newtonian gravitational field. This is an example of reading the mass of a body off the asymptotic form of the metric (last paragraph of Sec. 25.9.3).

Notice that the asymptotic metric here [Eq. (26.5)] differs in its spatial part from that in Sec. 25.9.3 [Eq. (25.98d)]. This difference arises from the use of different radial coordinates here. If we define \bar{r} by $r = \bar{r} + M$ at radii $r \gg M$, then to linear order in M/r , the asymptotic Schwarzschild metric (26.5) becomes

$$ds^2 = - \left(1 - \frac{2M}{\bar{r}} \right) dt^2 + \left(1 + \frac{2M}{\bar{r}} \right) [d\bar{r}^2 + \bar{r}^2(d\theta^2 + \sin^2\theta d\phi^2)], \quad (26.9)$$

which is the same as Eq. (25.98d) with vanishing angular momentum $J = 0$. This easy change of the spatial part of the metric reinforces the fact that one reads the asymptotic Newtonian potential and the source's mass M from the time-time components of the metric and not from the spatial part of the metric.

We can describe, in operational terms, the physical interpretation of M as the body's mass as follows. Suppose that a test particle (e.g., a small planet) moves around our central body in a circular orbit with radius $r \gg M$. A Newtonian analysis of the orbit predicts that, as measured using Newtonian time, the period of the orbit will be $P = 2\pi(r^3/M)^{1/2}$ (one of Kepler's laws). Moreover, since Newtonian time is very nearly equal to the time t of the nearly Lorentz coordinates used in Eq. (26.5) (cf. Sec. 25.9.1), and since that t is Lorentz time in the body's relativistic, asymptotic rest frame, the orbital period as measured by observers at rest in the asymptotic rest frame must be $P = 2\pi(r^3/M)^{1/2}$. Thus, M is the mass that appears in Kepler's laws for the orbits of test particles far from the central body. This quantity is sometimes called the body's "active gravitational mass," since it is the mass that characterizes the body's gravitational pull. It is also called the body's "total mass-energy," because it turns out to include all forms of mass and energy that the body possesses (rest mass; internal kinetic energy; and all forms of internal binding energy, including gravitational).

We note in passing that one can use general relativity to deduce the Keplerian role of M without invoking the Newtonian limit: place a test particle in the body's equatorial plane $\theta = \pi/2$ at a radius $r \gg M$, and give it an initial velocity that lies in the equatorial plane. Then symmetry guarantees the particle remains in the equatorial plane: there is no way to prefer going toward north, $\theta < \pi/2$, or toward south, $\theta > \pi/2$. Furthermore, adjust the initial velocity so the particle remains always at a fixed radius. Then the only nonvanishing components $u^\alpha = dx^\alpha/d\tau$ of the particle's 4-velocity are $u^t = dt/d\tau$ and $u^\phi = d\phi/d\tau$. The particle's orbit is governed by the geodesic equation $\nabla_{\vec{u}} \vec{u} = 0$, where \vec{u} is its 4-velocity. The radial component of this geodesic equation, computed in Schwarzschild coordinates, is [cf. Eq. (25.14) with a switch from affine parameter ζ to proper time $\tau = m\zeta$]

$$\frac{d^2 r}{d\tau^2} = -\Gamma^r_{\mu\nu} \frac{dx^\mu}{d\tau} \frac{dx^\nu}{d\tau} = -\Gamma^r_{tt} \frac{dt}{d\tau} \frac{dt}{d\tau} - \Gamma^r_{\phi\phi} \frac{d\phi}{d\tau} \frac{d\phi}{d\tau}. \quad (26.10)$$

M is the mass that characterizes the asymptotic Newtonian gravitational field

M is the mass in Kepler's laws for distant planets

relativistic analysis of Keplerian orbital motion

(Here we have used the vanishing of all $dx^\alpha/d\tau$ except the t and ϕ components and have used the vanishing of $\Gamma^r_{t\phi} = \Gamma^r_{\phi t}$ [Eq. (3) of Box 26.2].) Since the orbit is circular, with fixed r , the left-hand side of Eq. (26.10) must vanish; correspondingly, the right-hand side gives

$$\frac{d\phi}{dt} = \frac{d\phi/d\tau}{dt/d\tau} = \left(-\frac{\Gamma^r_{tt}}{\Gamma^r_{\phi\phi}} \right)^{\frac{1}{2}} = \left(\frac{M}{r^3} \right)^{\frac{1}{2}}, \quad (26.11)$$

where we have used the values of the connection coefficients from Eq. (3) of Box 26.2, specialized to the equatorial plane $\theta = \pi/2$. Equation (26.11) tells us that the amount of coordinate time t required for the particle to circle the central body once, $0 \leq \phi \leq 2\pi$, is $\Delta t = 2\pi(r^3/M)^{\frac{1}{2}}$. Since t is the Lorentz time of the body's asymptotic rest frame, observers in the asymptotic rest frame will measure for the particle an orbital period $P = \Delta t = 2\pi(r^3/M)^{\frac{1}{2}}$. This, of course, is the same result as we obtained from the Newtonian limit—but our relativistic analysis shows it to be true for circular orbits of arbitrary radius r , not just for $r \gg M$.

26.2.4 26.2.4 Schwarzschild Spacetime at $r \sim M$

Next we move inward, from the asymptotically flat region of Schwarzschild spacetime toward smaller and smaller radii. As we do so, the spacetime geometry becomes more and more strongly curved, and the Schwarzschild coordinate system becomes less and less Lorentz. As an indication of extreme deviations from Lorentz, notice that the signs of the metric coefficients,

$$\frac{\partial}{\partial t} \cdot \frac{\partial}{\partial t} = g_{tt} = -\left(1 - \frac{2M}{r}\right), \quad \frac{\partial}{\partial r} \cdot \frac{\partial}{\partial r} = g_{rr} = \frac{1}{(1 - 2M/r)} \quad (26.12)$$

outside $r = 2M$, t is a time coordinate and r a space coordinate; inside, their roles are reversed

reverse as one moves from $r > 2M$ through $r = 2M$ and into the region $r < 2M$. Correspondingly, outside $r = 2M$, world lines of changing t but constant $\{r, \theta, \phi\}$ are timelike, while inside $r = 2M$, those world lines are spacelike. Similarly outside $r = 2M$, world lines of changing r but constant $\{t, \theta, \phi\}$ are spacelike, while inside they are timelike. In this sense, outside $r = 2M$, t plays the role of a time coordinate and r the role of a space coordinate; while inside $r = 2M$, t plays the role of a space coordinate and r the role of a time coordinate. Moreover, this role reversal occurs without any change in the role of r as $1/(2\pi)$ times the circumference of circles around the center [Eq. (26.3)].

For many decades this role reversal presented severe conceptual problems, even to the best experts in general relativity. We return to it in Sec. 26.4. Henceforth we refer to the location of role reversal, $r = 2M$, as the gravitational radius of the Schwarzschild spacetime, henceforth *gravitational radius*. It is also known as the *Schwarzschild radius* and, as we shall see, is the location of an absolute *event horizon*. In Sec. 26.4, we seek a clear understanding of the “interior” region, $r < 2M$; but until then, we confine attention to the region $r > 2M$, outside the gravitational radius.

Notice that the metric coefficients in the Schwarzschild line element (26.1) are all independent of the coordinate t . This means that the geometry of spacetime itself is invariant under the translation $t \rightarrow t + \text{const}$. At radii $r > 2M$, where t plays the role of a time coordinate, $t \rightarrow t + \text{const}$ is a time translation; correspondingly, the Schwarzschild spacetime geometry is time-translation-invariant (i.e., “static”) outside the gravitational radius.

EXERCISES

Exercise 26.2 *Example: The Bertotti-Robinson Solution of the Einstein Field Equation*
Bruno Bertotti (1959) and Ivor Robinson (1959) independently solved the Einstein field equation to obtain the following metric for a universe endowed with a uniform magnetic field:

$$ds^2 = Q^2(-dt^2 + \sin^2 t dz^2 + d\theta^2 + \sin^2 \theta d\phi^2). \quad (26.13)$$

Here

$$Q = \text{const}, \quad 0 \leq t \leq \pi, \quad -\infty < z < +\infty, \quad 0 \leq \theta \leq \pi, \quad 0 \leq \phi \leq 2\pi. \quad (26.14)$$

If one computes the Einstein tensor from the metric coefficients of the line element (26.13) and equates it to 8π times a stress-energy tensor, one finds a stress-energy tensor that is precisely the same as for an electromagnetic field [Eqs. (2.75) and (2.80)] lifted, unchanged, into general relativity. The electromagnetic field is one that, as measured in the local Lorentz frame of an observer with fixed $\{z, \theta, \phi\}$ (a “static” observer), has vanishing electric field and has a magnetic field directed along $\partial/\partial z$ with magnitude independent of where the observer is located in spacetime. In this sense, the spacetime metric (26.13) is that of a homogeneous magnetic universe. Discuss the geometry of this universe and the nature of the coordinates $\{t, z, \theta, \phi\}$. More specifically, do the following.

- Which coordinate increases in a timelike direction and which coordinates in spacelike directions?
- Is this universe spherically symmetric?
- Is this universe cylindrically symmetric?
- Is this universe asymptotically flat?
- How does the geometry of this universe change as t ranges from 0 to π ? [Hint: Show that the curves $\{(z, \theta, \phi) = \text{const}, t = \tau/Q\}$ are timelike geodesics—the world lines of the static observers referred to above. Then argue from symmetry, or use the result of Ex. 25.4a.]
- Give as complete a characterization as you can of the coordinates $\{t, z, \theta, \phi\}$.

26.3

26.3 Static Stars

26.3.1

26.3.1 Birkhoff's Theorem

Birkhoff's theorem:
uniqueness of
Schwarzschild solution

In 1923, George Birkhoff, a professor of mathematics at Harvard, proved a remarkable theorem (Birkhoff, 1923). (For a textbook proof, see Misner, Thorne, and Wheeler, 1973, Sec. 32.2.) The Schwarzschild spacetime geometry is the unique spherically symmetric solution of the vacuum Einstein field equation $\mathbf{G} = 0$. This Birkhoff theorem can be restated in more operational terms as follows. Suppose that you find a solution of the vacuum Einstein field equation, written as a set of metric coefficients $g_{\bar{\alpha}\bar{\beta}}$ in some coordinate system $\{x^{\bar{\mu}}\}$. Suppose, further, that these $g_{\bar{\alpha}\bar{\beta}}(x^{\bar{\mu}})$ coefficients exhibit spherical symmetry but do not coincide with the Schwarzschild expressions [Eqs. (2a) of Box 26.2]. Then the Birkhoff theorem guarantees the existence of a coordinate transformation from your coordinates $x^{\bar{\mu}}$ to Schwarzschild's coordinates x^ν such that, when that transformation is performed, the resulting new metric components $g_{\alpha\beta}(x^\nu)$ have precisely the Schwarzschild form [Eqs. (2a) of Box 26.2]. For an example, see Ex. 26.3. This implies that, thought of as a coordinate-independent spacetime geometry, the Schwarzschild solution is completely unique.

Now consider a static, spherically symmetric star (e.g., the Sun) residing alone in an otherwise empty universe (or, more realistically, residing in our own universe but so far from other gravitating matter that we can ignore all other sources of gravity when studying it). Since the star's interior is spherical, it is reasonable to presume that the exterior will be spherical; since the exterior is also vacuum ($\mathbf{T} = 0$), its spacetime geometry must be that of Schwarzschild. If the circumference of the star's surface is $2\pi R$ and its surface area is $4\pi R^2$, then that surface must reside at the location $r = R$ in the Schwarzschild coordinates of the exterior. In other words, the spacetime geometry will be described by the Schwarzschild line element (26.1) at radii $r > R$, but by something else inside the star, at $r < R$.

Since real atoms with finite rest masses reside on the star's surface, and since such atoms move along timelike world lines, it must be that the world lines $\{r = R, \theta = \text{const}, \phi = \text{const}, t \text{ varying}\}$ are timelike. From the Schwarzschild invariant interval (26.1) we read off the squared proper time, $d\tau^2 = -ds^2 = (1 - 2M/R)dt^2$, along those world lines. This $d\tau^2$ is positive (timelike world line) if and only if $R > 2M$. Thus, a static star with total mass-energy (active gravitational mass) M can never have a circumference smaller than $2\pi R = 4\pi M$. Restated in conventional units:

a static star must have
radius R greater than $2M$

$$\begin{aligned} \frac{\text{circumference}}{2\pi} = R &\equiv \left(\begin{array}{c} \text{radius} \\ \text{of star} \end{array} \right) > 2M = \frac{2GM}{c^2} \\ &= 2.953 \text{ km} \left(\frac{M}{M_\odot} \right) \equiv \left(\begin{array}{c} \text{gravitational} \\ \text{radius} \end{array} \right). \end{aligned} \quad (26.15)$$

Here M_\odot is the mass of the Sun. The Sun satisfies this constraint by a huge margin: $R = 7 \times 10^5 \text{ km} \gg 2.953 \text{ km}$. A 1-solar-mass white-dwarf star satisfies it by a smaller margin: $R \simeq 6 \times 10^3 \text{ km}$. And a 1-solar-mass neutron star satisfies it by only a modest

margin: $R \simeq 10$ km. For a pedagogical and detailed discussion see, for example, Shapiro and Teukolsky (1983).

EXERCISES

Exercise 26.3 *Problem: Schwarzschild Geometry in Isotropic Coordinates*

- (a) It turns out that the following line element is a solution of the vacuum Einstein field equation $\mathbf{G} = 0$:

$$ds^2 = - \left(\frac{1 - M/(2\bar{r})}{1 + M/(2\bar{r})} \right)^2 dt^2 + \left(1 + \frac{M}{2\bar{r}} \right)^4 [d\bar{r}^2 + \bar{r}^2(d\theta^2 + \sin^2\theta d\phi^2)].$$

(26.16)

Since this solution is spherically symmetric, Birkhoff's theorem guarantees it must represent the standard Schwarzschild spacetime geometry in a coordinate system that differs from Schwarzschild's. Show that this is so by exhibiting a coordinate transformation that converts this line element into Eq. (26.1). [Note: The $\{t, \bar{r}, \theta, \phi\}$ coordinates are called *isotropic*, because in them the spatial part of the line element is a function of \bar{r} times the 3-dimensional Euclidean line element, and Euclidean geometry picks out at each point in space no preferred spatial directions (i.e., it is isotropic).]

- (b) Show that at large radii $r \gg M$, the line element (26.16) takes the form (25.98c) discussed in Chap. 25, but with vanishing spin angular momentum $\mathbf{J} = 0$.

Exercise 26.4 ***Example: Gravitational Redshift of Light from a Star's Surface*

Consider a photon emitted by an atom at rest on the surface of a static star with mass M and radius R . Analyze the photon's motion in the Schwarzschild coordinate system of the star's exterior, $r \geq R > 2M$. In particular, compute the "gravitational redshift" of the photon by the following steps.

- (a) Since the emitting atom is nearly an ideal clock, it gives the emitted photon nearly the same frequency ν_{em} , as measured in the emitting atom's proper reference frame (as it would give were it in an Earth laboratory or floating in free space). Thus the proper reference frame of the emitting atom is central to a discussion of the photon's properties and behavior. Show that the orthonormal basis vectors of that proper reference frame are

$$\vec{e}_{\hat{0}} = \frac{1}{\sqrt{1 - 2M/r}} \frac{\partial}{\partial t}, \quad \vec{e}_{\hat{r}} = \sqrt{1 - 2M/r} \frac{\partial}{\partial r}, \quad \vec{e}_{\hat{\theta}} = \frac{1}{r} \frac{\partial}{\partial \theta}, \quad \vec{e}_{\hat{\phi}} = \frac{1}{r \sin \theta} \frac{\partial}{\partial \phi},$$

(26.17)

with $r = R$ (the star's radius).

- (b) Explain why the photon's energy as measured in the emitter's proper reference frame is $\mathcal{E} = h\nu_{\text{em}} = -p_{\hat{0}} = -\vec{p} \cdot \vec{e}_{\hat{0}}$. (Here and below h is Planck's constant, and \vec{p} is the photon's 4-momentum.)

- (c) Show that the quantity $\mathcal{E}_\infty \equiv -p_t = -\vec{p} \cdot \partial/\partial t$ is conserved as the photon travels outward from the emitting atom to an observer at very large radius, which we idealize as $r = \infty$. [Hint: Recall the result of Ex. 25.4a.] Show, further, that \mathcal{E}_∞ is the photon's energy, as measured by the observer at $r = \infty$ —which is why it is called the photon's “energy-at-infinity” and denoted \mathcal{E}_∞ . The photon's frequency, as measured by that observer, is given, of course, by $h\nu_\infty = \mathcal{E}_\infty$.
- (d) Show that $\mathcal{E}_\infty = \mathcal{E}\sqrt{1 - 2M/R}$ and thence that $\nu_\infty = \nu_{\text{em}}\sqrt{1 - 2M/R}$, and that therefore the photon is redshifted by an amount

$$\boxed{\frac{\lambda_{\text{rec}} - \lambda_{\text{em}}}{\lambda_{\text{em}}} = \frac{1}{\sqrt{1 - 2M/R}} - 1.} \quad (26.18)$$

Here λ_{rec} is the wavelength that the photon's spectral line exhibits at the receiver, and λ_{em} is the wavelength that the emitting kind of atom would produce in an Earth laboratory. Note that for a nearly Newtonian star (i.e., one with $R \gg M$), this redshift becomes $\simeq M/R = GM/Rc^2$.

- (e) Evaluate this redshift for Earth, for the Sun, and for a 1.4-solar-mass, 10-km-radius neutron star.

26.3.2 Stellar Interior

We now take a temporary detour from our study of the Schwarzschild geometry to discuss the interior of a static, spherical star. We do so less because of an interest in stars than because the detour will illustrate the process of solving the Einstein field equation and the role of the contracted Bianchi identity in the solution process.

Since the star's spacetime geometry is to be static and spherically symmetric, we can introduce as coordinates in its interior: (i) spherical polar angular coordinates θ and ϕ , (ii) a radial coordinate r such that the circumferences of the spheres are $2\pi r$, and (iii) a time coordinate \bar{t} such that the metric coefficients are independent of \bar{t} . By their geometrical definitions, these coordinates will produce a spacetime line element of the form

$$ds^2 = g_{\bar{t}\bar{t}}d\bar{t}^2 + 2g_{\bar{t}r}d\bar{t}dr + g_{rr}dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2), \quad (26.19)$$

with $g_{\alpha\beta}$ independent of \bar{t} , θ , and ϕ . Metric coefficients $g_{\bar{t}\theta}$, $g_{r\theta}$, $g_{\bar{t}\phi}$, and $g_{r\phi}$ are absent from Eq. (26.19), because they would break the spherical symmetry: they would distinguish the $+\phi$ direction from $-\phi$ or $+\theta$ from $-\theta$, since they would give nonzero values for the scalar products of $\partial/\partial\phi$ or $\partial/\partial\theta$ with $\partial/\partial\bar{t}$ or $\partial/\partial r$. [Recall that the metric coefficients in a coordinate basis are $g_{\alpha\beta} = \mathbf{g}(\partial/\partial x^\alpha, \partial/\partial x^\beta) = (\partial/\partial x^\alpha) \cdot (\partial/\partial x^\beta)$.] We can get rid of the off-diagonal $g_{\bar{t}r}$ term in the line element (26.19) by specializing the time coordinate. The coordinate transformation

$$\bar{t} = t - \int \left(\frac{g_{\bar{t}r}}{g_{\bar{t}\bar{t}}} \right) dr \quad (26.20)$$

brings the line element into the form

$$ds^2 = -e^{2\Phi} dt^2 + e^{2\Lambda} dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2). \quad (26.21)$$

coordinates and line element for interior of a static star

Here, after the transformation (26.20), we have introduced the names $e^{2\Phi}$ and $e^{2\Lambda}$ for the time-time and radial-radial metric coefficients, respectively. The signs of these coefficients (negative for g_{tt} and positive for g_{rr}) are dictated by the fact that inside the star, as on its surface, real atoms move along world lines of constant $\{r, \theta, \phi\}$ and changing t , and thus those world lines must be timelike. The name $e^{2\Phi}$ is chosen because when gravity is nearly Newtonian, the time-time metric coefficient $-e^{2\Phi}$ must reduce to $-(1 + 2\Phi)$, with Φ the Newtonian potential [Eq. (25.79)]. Thus, the Φ used in Eq. (26.21) is a generalization of the Newtonian potential to relativistic, spherical, static gravitational situations.

To solve the Einstein field equation for the star's interior, we must specify the stress-energy tensor. Stellar material is excellently approximated by a perfect fluid, and since our star is static, at any point inside the star the fluid's rest frame has constant $\{r, \theta, \phi\}$. Correspondingly, the 4-velocity of the fluid is

$$\vec{u} = e^{-\Phi} \frac{\partial}{\partial t}. \quad (26.22)$$

fluid 4-velocity inside static star

Here the factor $e^{-\Phi}$ guarantees that the 4-velocity will have $\vec{u}^2 = -1$, as it must.

Of course, this fluid is not freely falling. Rather, for a fluid element to remain always at fixed $\{r, \theta, \phi\}$ it must accelerate relative to local freely falling observers with a 4-acceleration $\vec{a} \equiv \nabla_{\vec{u}} \vec{u} \neq 0$ (i.e., $a^\alpha = u^\alpha{}_{;\mu} u^\mu \neq 0$). Symmetry tells us that this 4-acceleration cannot have any θ or ϕ components, and orthogonality of the 4-acceleration to the 4-velocity tells us that it cannot have any t component. The r component, computed from $a^r = u^r{}_{;\mu} u^\mu = \Gamma^r{}_{00} u^0 u^0$, is $a^r = e^{-2\Lambda} \Phi_{,r}$; and thus we have

$$\vec{a} = e^{-2\Lambda} \Phi_{,r} \frac{\partial}{\partial r}. \quad (26.23)$$

fluid 4-acceleration inside static star

Each fluid element can be thought of as carrying an orthonormal set of basis vectors:

$$\vec{e}_{\hat{0}} = \vec{u} = e^{-\Phi} \frac{\partial}{\partial t}, \quad \vec{e}_{\hat{r}} = e^{-\Lambda} \frac{\partial}{\partial r}, \quad \vec{e}_{\hat{\theta}} = \frac{1}{r} \frac{\partial}{\partial \theta}, \quad \vec{e}_{\hat{\phi}} = \frac{1}{r \sin \theta} \frac{\partial}{\partial \phi}; \quad (26.24a)$$

orthonormal basis vectors of fluid's local rest frame (its proper reference frame)

$$\vec{e}^{\hat{0}} = e^\Phi \vec{\nabla}_t, \quad \vec{e}^{\hat{r}} = e^\Lambda \vec{\nabla}_r, \quad \vec{e}^{\hat{\theta}} = r \vec{\nabla}_\theta, \quad \vec{e}^{\hat{\phi}} = r \sin \theta \vec{\nabla}_\phi. \quad (26.24b)$$

These basis vectors play two independent roles. (i) One can regard the tangent space of each event in spacetime as being spanned by the basis (26.24), specialized to that event. From this viewpoint, Eqs. (26.24) constitute an orthonormal, noncoordinate basis that covers every tangent space of the star's spacetime. This basis is called the

fluid's orthonormal, local-rest-frame basis. (ii) One can focus attention on a specific fluid element, which moves along the world line $r = r_o, \theta = \theta_o, \phi = \phi_o$; and one can construct the proper reference frame of that fluid element in the same manner as we constructed the proper reference frame of an accelerated observer in flat spacetime in Sec. 24.5. That proper reference frame is a coordinate system $\{x^{\hat{\alpha}}\}$ whose basis vectors on the fluid element's world line are equal to the basis vectors (26.24):

$$\frac{\partial}{\partial x^{\hat{\mu}}} = \vec{e}_{\hat{\mu}}, \quad \vec{\nabla}_{x^{\hat{\mu}}} = \vec{e}^{\hat{\mu}} \text{ at } x^{\hat{j}} = 0, \quad \text{with } \hat{1} = \hat{r}, \hat{2} = \hat{\theta}, \hat{3} = \hat{\phi}. \quad (26.25a)$$

More specifically, the proper-reference-frame coordinates $x^{\hat{\mu}}$ are given, to second-order in spatial distance from the fluid element's world line, by

$$\begin{aligned} x^{\hat{0}} &= e^{\Phi_o t}, & x^{\hat{1}} &= \int_{r_o}^r e^{\Lambda} dr - \frac{1}{2} e^{-\Lambda_o} r_o [(\theta - \theta_o)^2 + \sin^2 \theta_o (\phi - \phi_o)^2], \\ x^{\hat{2}} &= r(\theta - \theta_o) - \frac{1}{2} r_o \sin \theta_o \cos \theta_o (\phi - \phi_o)^2, & x^{\hat{3}} &= r \sin \theta (\phi - \phi_o), \end{aligned} \quad (26.25b)$$

from which one can verify relation (26.25a) with the basis vectors given by Eqs. (26.24). [In Eqs. (26.25b) and throughout this discussion all quantities with subscripts $_o$ are evaluated on the fluid's world line.] In terms of the proper-reference-frame coordinates (26.25b), the line element (26.21) takes the following form, accurate to first order in distance from the fluid element's world line:

$$ds^2 = -[1 + 2\Phi_{,r}(r - r_o)](dx^{\hat{0}})^2 + \delta_{ij} dx^{\hat{i}} dx^{\hat{j}}. \quad (26.25c)$$

Notice that the quantity $\Phi_{,r}(r - r_o)$ is equal to the scalar product of (i) the spatial separation $\hat{\mathbf{x}} \equiv (r - r_o)\partial/\partial r + (\theta - \theta_o)\partial/\partial\theta + (\phi - \phi_o)\partial/\partial\phi$ of the "field point" (r, θ, ϕ) from the fluid element's world line, with (ii) the fluid's 4-acceleration (26.23), viewed as a spatial 3-vector $\mathbf{a} = e^{-2\Lambda_o}\Phi_{,r}\partial/\partial r$. Correspondingly, the space-time line element (26.25c) in the fluid element's proper reference frame takes the standard proper-reference-frame form (24.60b):

$$ds^2 = -(1 + 2\mathbf{a} \cdot \hat{\mathbf{x}})(dx^{\hat{0}})^2 + \delta_{jk} dx^{\hat{j}} dx^{\hat{k}}, \quad (26.26)$$

accurate to first order in distance from the fluid element's world line. To second order, as discussed at the end of Sec. 25.3, there are corrections proportional to the spacetime curvature.

In the local rest frame of the fluid [i.e., when expanded on the fluid's orthonormal rest-frame basis vectors (26.24) or equally well (26.25a)], the components $T^{\hat{\alpha}\hat{\beta}} = (\rho + P)u^{\hat{\alpha}}u^{\hat{\beta}} + Pg^{\hat{\alpha}\hat{\beta}}$ of the fluid's stress-energy tensor take on the standard form [Eq. (24.50)]:

$$\boxed{T^{\hat{0}\hat{0}} = \rho, \quad T^{\hat{r}\hat{r}} = T^{\hat{\theta}\hat{\theta}} = T^{\hat{\phi}\hat{\phi}} = P,} \quad (26.27)$$

coordinates of fluid element's proper reference frame

stress-energy tensor in fluid's proper reference frame: fluid density and pressure

corresponding to a rest-frame mass-energy density ρ and isotropic pressure P . By contrast with the simplicity of these local-rest-frame components, the contravariant components $T^{\alpha\beta} = (\rho + P)u^\alpha u^\beta + P g^{\alpha\beta}$ in the $\{t, r, \theta, \phi\}$ coordinate basis are rather more complicated:

$$T^{tt} = e^{-2\Phi} \rho, \quad T^{rr} = e^{-2\Lambda} P, \quad T^{\theta\theta} = r^{-2} P, \quad T^{\phi\phi} = (r \sin \theta)^{-2} P. \quad (26.28)$$

This shows one advantage of using orthonormal bases: the components of vectors and tensors are generally simpler in an orthonormal basis than in a coordinate basis. A second advantage occurs when one seeks the physical interpretation of formulas. Because every orthonormal basis is the proper-reference-frame basis of some local observer (the observer with 4-velocity $\vec{u} = \vec{e}_{\hat{\alpha}}$), components measured in such a basis have an immediate physical interpretation in terms of measurements by that observer. For example, $T^{\hat{0}\hat{0}}$ is the total density of mass-energy measured by the local observer. By contrast, components in a coordinate basis typically do not have a simple physical interpretation.

Exercise 26.5 *Derivation: Proper-Reference-Frame Coordinates*

Show that in the coordinate system $\{x^{\hat{0}}, x^{\hat{1}}, x^{\hat{2}}, x^{\hat{3}}\}$ of Eqs. (26.25b), the coordinate basis vectors at $x^{\hat{j}} = 0$ are Eqs. (26.24), and, accurate through first order in distance from $x^{\hat{j}} = 0$, the spacetime line element is Eq. (26.26); that is, errors are no larger than second order.

EXERCISES

26.3.3 Local Conservation of Energy and Momentum

26.3.3

Before inserting the perfect-fluid stress-energy tensor (26.27) into the Einstein field equation, we impose on it the local law of conservation of 4-momentum: $\vec{\nabla} \cdot \mathbf{T} = 0$. In doing so we require from the outset that, since the star is to be static and spherical, its density ρ and pressure P must be independent of t , θ , and ϕ (i.e., like the metric coefficients Φ and Λ , they must be functions of radius r only).

The most straightforward way to impose 4-momentum conservation is to equate to zero the quantities

$$T^{\alpha\beta}{}_{;\beta} = \frac{\partial T^{\alpha\beta}}{\partial x^\beta} + \Gamma^\beta{}_{\mu\beta} T^{\alpha\mu} + \Gamma^\alpha{}_{\mu\beta} T^{\mu\beta} = 0 \quad (26.29)$$

in our coordinate basis, making use of expressions (26.28) for the contravariant components of the stress-energy tensor, and the connection coefficients and metric components given in Box 26.2.

This straightforward calculation requires a lot of work. Much better is an analysis based on the local proper reference frame of the fluid. The temporal component of $\vec{\nabla} \cdot \mathbf{T} = 0$ in that reference frame [i.e., the projection $\vec{u} \cdot (\vec{\nabla} \cdot \mathbf{T}) = 0$ of this conserva-

tion law onto the time basis vector $\vec{e}_{\hat{0}} = e^{-\Phi} \partial / \partial t = \vec{u}$] represents energy conservation as seen by the fluid—the first law of thermodynamics:

first law of thermodynamics

$$\frac{d(\rho V)}{d\tau} = -P \frac{dV}{d\tau}. \quad (26.30)$$

Here τ is proper time as measured by the fluid element we are following, and V is the fluid element's volume. (This equation is derived in Ex. 2.26b, in a special relativistic context; but since it involves only one derivative, there is no danger of curvature coupling, so that derivation and the result can be lifted without change into general relativity, i.e., into the star's curved spacetime; cf. Ex. 26.6a.) Now, inside this static star, the fluid element sees and feels no changes. Its density ρ , pressure P , and volume V always remain constant along the fluid element's world line, and energy conservation is therefore guaranteed to be satisfied. Equation (26.30) tells us nothing new.

The spatial part of $\vec{\nabla} \cdot \mathbf{T} = 0$ in the fluid's local rest frame can be written in geometric form as $\mathbf{P} \cdot (\vec{\nabla} \cdot \mathbf{T}) = 0$. Here $\mathbf{P} \equiv \mathbf{g} + \vec{u} \otimes \vec{u}$ is the tensor that projects all vectors into the 3-surface orthogonal to \vec{u} , that is, into the fluid's local 3-surface of simultaneity (Exs. 2.10 and 25.1b). By inserting the perfect-fluid stress-energy tensor $\mathbf{T} = (\rho + P)\vec{u} \otimes \vec{u} + P\mathbf{g} = \rho\vec{u} \otimes \vec{u} + P\mathbf{P}$ into $\mathbf{P} \cdot (\vec{\nabla} \cdot \mathbf{T}) = 0$, reexpressing the result in slot-naming index notation, and carrying out some index gymnastics, we must obtain the same result as in special relativity (Ex. 2.26c):

force balance inside the fluid

$$(\rho + P)\vec{a} = -\mathbf{P} \cdot \vec{\nabla} P \quad (26.31)$$

(cf. Ex. 26.6b). Here \vec{a} is the fluid's 4-acceleration. Recall from Ex. 2.27 that for a perfect fluid, $\rho + P$ is the inertial mass per unit volume. Therefore, Eq. (26.31) says that the fluid's inertial mass per unit volume times its 4-acceleration is equal to the negative of its pressure gradient, projected orthogonally to its 4-velocity. Since both sides of Eq. (26.31) are purely spatially directed as seen in the fluid's local proper reference frame, we can rewrite this equation in 3-dimensional language as

$$\boxed{(\rho + P)\mathbf{a} = -\nabla P.} \quad (26.32)$$

A Newtonian physicist, in the proper reference frame, would identify $-\mathbf{a}$ as the local gravitational acceleration, \mathbf{g} , and correspondingly, would rewrite Eq. (26.31) as

Newtonian viewpoint on force balance

$$\nabla P = (\rho + P)\mathbf{g}. \quad (26.33)$$

This is the standard equation of hydrostatic equilibrium for a fluid in an Earthbound laboratory (or swimming pool or lake or ocean), except for the presence of the pressure P in the inertial mass per unit volume (Ex. 2.27). On Earth the typical pressures of fluids, even deep in the ocean, are only $P \lesssim 10^9 \text{ dyne/cm}^2 \simeq 10^{-12} \text{ g cm}^{-3} \lesssim 10^{-12} \rho$. Thus, to extremely good accuracy one can ignore the contribution of pressure to the

inertial mass density. However, deep inside a neutron star, P may be within a factor 2 of ρ , so the contribution of P cannot be ignored.

We can convert the law of force balance (26.31) into an ordinary differential equation for the pressure P by evaluating its components in the fluid's proper reference frame. The 4-acceleration (26.23) is purely radial; its radial component is $a^{\hat{r}} = e^{-\Lambda} \Phi_{,r} = \Phi_{,\hat{r}}$. The gradient of the pressure is also purely radial, and its radial component is $P_{;\hat{r}} = P_{,\hat{r}} = e^{-\Lambda} P_{,r}$. Therefore, the law of force balance reduces to

$$\frac{dP}{dr} = -(\rho + P) \frac{d\Phi}{dr}. \quad (26.34)$$

force balance rewritten

Exercise 26.6 *Practice and Derivation: Local Conservation of Energy and Momentum for a Perfect Fluid*

EXERCISES

- (a) Use index manipulations to show that in general (not just inside a static star), for a perfect fluid with $T^{\alpha\beta} = (\rho + P)u^\alpha u^\beta + P g^{\alpha\beta}$, the law of energy conservation $u_\alpha T^{\alpha\beta}_{;\beta} = 0$ reduces to the first law of thermodynamics (26.30). [Hint: You will need the relation $u^\mu_{;\mu} = (1/V)(dV/d\tau)$; cf. Ex. 2.24.]
- (b) Similarly, show that $P_{\mu\alpha} T^{\alpha\beta}_{;\beta} = 0$ reduces to the force-balance law (26.31).

26.3.4 The Einstein Field Equation

26.3.4

Turn, now, to the Einstein field equation inside a static, spherical star with isotropic pressure. To impose it, we must first compute, in our $\{t, r, \theta, \phi\}$ coordinate system, the components of the Einstein tensor $G_{\alpha\beta}$. In general, the Einstein tensor has 10 independent components. However, the symmetries of the line element (26.21) impose identical symmetries on the Einstein tensor computed from it: The only nonzero components in the fluid's proper reference frame will be $G^{\hat{t}\hat{t}}$, $G^{\hat{r}\hat{r}}$, and $G^{\hat{\theta}\hat{\theta}} = G^{\hat{\phi}\hat{\phi}}$; and these three independent components will be functions of radius r only. Correspondingly, the Einstein equation will produce three independent differential equations for our four unknowns: the metric coefficients ("gravitational potentials") Φ and Λ [Eq. (26.21)], and the radial distribution of density ρ and pressure P .

These three independent components of the Einstein equation will actually be redundant with the law of hydrostatic equilibrium (26.34). One can see this as follows. If we had not yet imposed the law of 4-momentum conservation, then the Einstein equation $\mathbf{G} = 8\pi \mathbf{T}$, together with the Bianchi identity $\vec{\nabla} \cdot \mathbf{G} \equiv 0$ [Eq. (25.69)], would enforce $\vec{\nabla} \cdot \mathbf{T} = 0$. More explicitly, our three independent components of the Einstein equation together would imply the law of radial force balance [i.e., of hydrostatic equilibrium (26.34)]. Since we have already imposed Eq. (26.34), we need evaluate only two of the three independent components of the Einstein equation; they will give us full information.

with force balance imposed, Einstein's equation provides just two additional constraints on the stellar structure

A long and rather tedious calculation (best done on a computer), based on the metric coefficients of Eq. (26.21) and on Eqs. (24.38), (25.50), (25.46), (25.49), and (25.68), produces the following for the time-time and radial-radial components of the Einstein tensor, and thence of the Einstein field equation:

$$G^{\hat{0}\hat{0}} = \frac{1}{r^2} \frac{d}{dr} [r(1 - e^{-2\Lambda})] = 8\pi T^{\hat{0}\hat{0}} = 8\pi\rho, \quad (26.35)$$

$$G^{\hat{r}\hat{r}} = -\frac{1}{r^2}(1 - e^{-2\Lambda}) + \frac{2}{r}e^{-2\Lambda} \frac{d\Phi}{dr} = 8\pi T^{\hat{r}\hat{r}} = 8\pi P. \quad (26.36)$$

We can bring these components of the field equation into simpler form by defining a new metric coefficient $m(r)$ by

$$e^{2\Lambda} \equiv \frac{1}{1 - 2m/r}. \quad (26.37)$$

Note [cf. Eqs. (26.1), (26.21), and (26.37)] that outside the star, m is equal to the star's total mass-energy M . This, plus the fact that in terms of m the time-time component of the field equation (26.35) takes the form

Einstein equation for the mass inside radius r , $m(r)$

$$\frac{dm}{dr} = 4\pi r^2 \rho, \quad (26.38a)$$

motivates the name *mass inside radius r* for the quantity $m(r)$. In terms of m the radial-radial component (26.36) of the field equation becomes

Einstein equation for $\Phi(r)$

$$\frac{d\Phi}{dr} = \frac{m + 4\pi r^3 P}{r(r - 2m)}; \quad (26.38b)$$

combining this with Eq. (26.34), we obtain an alternative form of the equation of hydrostatic equilibrium:

TOV equation of hydrostatic equilibrium

$$\frac{dP}{dr} = -\frac{(\rho + P)(m + 4\pi r^3 P)}{r(r - 2m)}. \quad (26.38c)$$

[This form is called the Tolman-Oppenheimer-Volkoff (or TOV) equation, because it was first derived by Tolman (1939) and first used in a practical calculation by Oppenheimer and Volkoff (1939).] Equations (26.38a), (26.38b), (26.38c) plus an equation of state for the pressure of the stellar material P in terms of its density of total mass-energy ρ ,

$$P = P(\rho), \quad (26.38d)$$

summary: the relativistic equations of stellar structure, Eqs. (26.38)

determine the four quantities Φ , m , ρ , and P as functions of radius. In other words, Eqs. (26.38) are the relativistic equations of stellar structure.

Actually, for full determination, one also needs boundary conditions. Just as the surface of a sphere is everywhere locally Euclidean (i.e., is arbitrarily close to Euclidean

in arbitrarily small regions), so also spacetime must be everywhere locally Lorentz; cf. Eqs. (25.9). For spacetime to be locally Lorentz at the star's center (in particular, for circumferences of tiny circles around the center to be equal to 2π times their radii), it is necessary that m vanish at the center:

$$m = 0 \text{ at } r = 0, \quad \text{and thus} \quad m(r) = \int_0^r 4\pi r^2 \rho dr \quad (26.39)$$

boundary conditions for relativistic equations of stellar structure

[cf. Eqs. (26.21) and (26.37)]. At the star's surface the interior spacetime geometry (26.21) must join smoothly to the exterior Schwarzschild geometry (26.1):

$$m = M \quad \text{and} \quad e^{2\Phi} = 1 - 2M/r \text{ at } r = R. \quad (26.40)$$

26.3.5 Stellar Models and Their Properties

26.3.5

A little thought now reveals a straightforward method of producing a relativistic stellar model.

procedure for constructing a relativistic stellar model

1. Specify an equation of state for the stellar material $P = P(\rho)$, and specify a central density ρ_c or central pressure P_c for the star.
2. Integrate the coupled hydrostatic-equilibrium equation (26.38c) and “mass equation” (26.38a) outward from the center, beginning with the initial conditions $m = 0$ and $P = P_c$ at the center.
3. Terminate the integration when the pressure falls to zero; this is the surface of the star.
4. At the surface read off the value of m ; it is the star's total mass-energy M , which appears in the star's external, Schwarzschild line element (26.1).
5. From this M and the radius $r \equiv R$ of the star's surface, read off the value of the gravitational potential Φ at the surface [Eq. (26.40)].
6. Integrate the Einstein field equation (26.38b) inward from the surface toward the center to determine Φ as a function of radius inside the star.

Just 6 weeks after reading to the Prussian Academy of Science the letter in which Karl Schwarzschild derived his vacuum solution (26.1) of the field equation, Albert Einstein again presented the Academy with results from Schwarzschild's fertile mind: an exact solution for the structure of the interior of a star that has constant density ρ . [And just 4 months after that, on June 29, 1916, Einstein had the sad task of announcing to the Academy that Schwarzschild had died of an illness contracted on the World-War-I Russian front.]

In our notation, Schwarzschild's solution for the interior of a star is characterized by its uniform density ρ , its total mass M , and its radius R , which is given in terms of ρ and M by

details of a relativistic star with constant density ρ

$$M = \frac{4\pi}{3} \rho R^3 \quad (26.41)$$

[Eq. (26.39)]. In terms of these quantities, the mass M inside radius r , the pressure P , and the gravitational potential Φ as functions of r are (Schwarzschild, 1916b)

$$m = \frac{4\pi}{3}\rho r^3, \quad P = \rho \left[\frac{(1 - 2Mr^2/R^3)^{\frac{1}{2}} - (1 - 2M/R)^{\frac{1}{2}}}{3(1 - 2M/R)^{\frac{1}{2}} - (1 - 2Mr^2/R^3)^{\frac{1}{2}}} \right], \quad (26.42a)$$

$$e^\Phi = \frac{3}{2} \left(1 - \frac{2M}{R}\right)^{\frac{1}{2}} - \frac{1}{2} \left(1 - \frac{2Mr^2}{R^3}\right)^{\frac{1}{2}}. \quad (26.42b)$$

We present these details less for their specific physical content than to illustrate the solution of the Einstein field equation in a realistic, astrophysically interesting situation. For discussions of the application of this formalism to neutron stars, where relativistic deviations from Newtonian theory can be rather strong, see, for example, Shapiro and Teukolsky (1983). For the seminal work on the theory of neutron-star structure, see Oppenheimer and Volkoff (1939).

Among the remarkable consequences of the TOV equation of hydrostatic equilibrium (26.38c) for neutron-star structure are the following. (i) If the mass m inside radius r ever gets close to $r/2$, the “gravitational pull” [right-hand side of (26.38c)] becomes divergently large, forcing the pressure gradient that counterbalances it to be divergently large, and thereby driving the pressure quickly to zero as one integrates outward. This protects the static star from having M greater than $R/2$ (i.e., from having its surface inside its gravitational radius). (ii) Although the density of matter near the center of a neutron star is above that of an atomic nucleus ($2.3 \times 10^{17} \text{ kg m}^{-3}$), where the equation of state is ill-understood, we can be confident that there is an upper limit on the masses of neutron stars, a limit in the range $2M_\odot \lesssim M_{\text{max}} \lesssim 3M_\odot$.² This mass limit cannot be avoided by postulating that a more massive neutron star develops an arbitrarily large central pressure and thereby supports itself against gravitational implosion. The reason is that an arbitrarily large central pressure is self-defeating: The “gravitational pull” that appears on the right-hand side of Eq. (26.38c) is quadratic in the pressure at very high pressures (whereas it would be independent of pressure in Newtonian theory). This purely relativistic feature guarantees that, if a star develops too high a central pressure, it will be unable to support itself against the resulting “quadratically too high” gravitational pull.

upper limit on mass of a neutron star, and how it comes about

EXERCISES

Exercise 26.7 *Problem: Mass-Radius Relation for Neutron Stars*

The equation of state of a neutron star is very hard to calculate at the supra-nuclear densities required, because the calculation is a complex, many-body problem and the particle interactions are poorly understood and poorly measured. Observations of

2. Measured neutron star masses range from ~ 1.2 solar masses to more than 2.0 solar masses.

neutron stars' masses and radii can therefore provide valuable constraints on fundamental nuclear physics. As we discuss briefly in the following chapter, various candidate equations of state can already be excluded on these observational grounds.

A necessary step for comparing observation with theory is to compute the stellar structure for candidate equations of state. We can illustrate the approach using a simple functional form, which, around nuclear density ($\rho_{\text{nuc}} \simeq 2.3 \times 10^{17} \text{ kg m}^{-3}$), is a fair approximation to some of the models:

$$P = 3 \times 10^{32} \left(\frac{\rho}{\rho_{\text{nuc}}} \right)^3 \text{ N m}^{-2}. \quad (26.43)$$

For this equation of state, use the equations of stellar structure (26.38a) and (26.38c) to find the masses and radii of stars with a range of central pressures, and hence deduce a mass-radius relation, $M(R)$. You should discover that, as the central pressure is increased, the mass passes through a maximum, while the radius continues to decrease. (Stars with radii smaller than that at the maximum mass are unstable to radial perturbations.)

26.3.6 Embedding Diagrams

26.3.6

We conclude our discussion of static stars by using them to illustrate a useful technique for visualizing the curvature of spacetime: the embedding of the curved spacetime, or a piece of it, in a flat space of higher dimensionality.

The geometry of a curved, n -dimensional manifold is characterized by $\frac{1}{2}n(n+1)$ metric components (since those components form a symmetric $n \times n$ matrix), of which only $\frac{1}{2}n(n+1) - n = \frac{1}{2}n(n-1)$ are of coordinate-independent significance (since we are free to choose arbitrarily the n coordinates of our coordinate system and can thereby force n of the metric components to take on any desired values, e.g., zero). If this n -dimensional manifold is embedded in a flat N -dimensional manifold, that embedding will be described by expressing $N - n$ of the embedding manifold's Euclidean (or Lorentz) coordinates in terms of the other n . Thus, the embedding is characterized by $N - n$ functions of n variables. For the embedding to be possible, in general, this number of choosable functions must be at least as large as the number of significant metric coefficients $\frac{1}{2}n(n-1)$. From this argument we conclude that the dimensionality of the embedding space must be $N \geq \frac{1}{2}n(n+1)$. Actually, this argument analyzes only the local features of the embedding. If one also wants to preserve the global topology of the n -dimensional manifold, one must in general go to an embedding space of even higher dimensionality.

the problem of embedding a curved manifold inside a flat higher-dimensional manifold (the embedding space); number of dimensions needed in the embedding space

Curved spacetime has $n = 4$ dimensions and thus requires for its local embedding a flat space with at least $N = \frac{1}{2}n(n+1) = 10$ dimensions. This is a bit much for 3-dimensional beings like us to visualize. If, as a sop to our visual limitations, we reduce our ambitions and seek only to extract a 3-surface from curved spacetime

embedding the equatorial plane of a static, relativistic star in a flat 3-dimensional embedding space

and visualize it by embedding it in a flat space, we will require a flat space of $N = 6$ dimensions. This is still a bit much. In frustration, we are driven to extract from spacetime $n = 2$ dimensional surfaces and visualize them by embedding in flat spaces with $N = 3$ dimensions. This is doable—and, indeed, instructive.

As a nice example, consider the equatorial “plane” through the spacetime of a static spherical star, at a specific “moment” of coordinate time t [i.e., consider the 2-surface $t = \text{const}, \theta = \pi/2$ in the spacetime of Eqs. (26.21), (26.37)]. The line element on this equatorial 2-surface is

$${}^{(2)}ds^2 = \frac{dr^2}{1 - 2m/r} + r^2 d\phi^2, \quad \text{where } m = m(r) = \int_0^r 4\pi r'^2 \rho dr' \quad (26.44)$$

[cf. Eq. (26.39)]. We seek to construct in a 3-dimensional Euclidean space a 2-dimensional surface with precisely this same 2-geometry. As an aid, we introduce in the Euclidean embedding space a cylindrical coordinate system $\{r, z, \phi\}$, in terms of which the space’s 3-dimensional line element is

$${}^{(3)}ds^2 = dr^2 + dz^2 + r^2 d\phi^2. \quad (26.45)$$

The surface we seek to embed is axially symmetric, so we can describe its embedding by the value of z on it as a function of radius r : $z = z(r)$. Inserting this (unknown) embedding function into Eq. (26.45), we obtain for the surface’s 2-geometry,

$${}^{(2)}ds^2 = [1 + (dz/dr)^2] dr^2 + r^2 d\phi^2. \quad (26.46)$$

Comparing with our original expression (26.44) for the 2-geometry, we obtain a differential equation for the embedding function:

$$\frac{dz}{dr} = \left(\frac{1}{1 - 2m/r} - 1 \right)^{\frac{1}{2}}. \quad (26.47)$$

If we set $z = 0$ at the star’s center, then the solution of this differential equation is

$$z = \int_0^r \frac{dr'}{[r'/(2m) - 1]^{\frac{1}{2}}}. \quad (26.48)$$

shape of embedded equatorial plane in general

shape outside the star where the spacetime geometry is Schwarzschild

Near the star’s center $m(r)$ is given by $m = (4\pi/3)\rho_c r^3$, where ρ_c is the star’s central density; and outside the star $m(r)$ is equal to the star’s r -independent total mass M . Correspondingly, in these two regions Eq. (26.48) reduces to

$$z = \sqrt{(2\pi/3)\rho_c} r^2 \quad \text{at } r \text{ very near zero.}$$

$$z = \sqrt{8M(r - 2M)} + \text{const at } r > R, \quad \text{i.e., outside the star.} \quad (26.49)$$

Figure 26.1 shows the embedded 2-surface $z(r)$ for a star of uniform density $\rho = \text{const}$ (Ex. 26.8). For any other star the embedding diagram will be qualitatively similar, though quantitatively different.

FIGURE 26.1 Embedding diagram depicting an equatorial, 2-dimensional slice $t = \text{const}$, $\theta = \pi/2$ through the spacetime of a spherical star with uniform density ρ and with radius R equal to 2.5 times the gravitational radius $2M$. See Ex. 26.8 for details.

The most important feature of this embedding diagram is its illustration of the fact [also clear in the original line element (26.44)] that, as one moves outward from the star's center, its circumference $2\pi r$ increases less rapidly than the proper radial distance traveled, $l = \int_0^r (1 - 2m/r)^{-\frac{1}{2}} dr$. As a specific example, the distance from the center of Earth to a perfect circle near Earth's surface is more than the circumference/ 2π by about 1.5 mm—a number whose smallness compared to the actual radius, 6.4×10^8 cm, is a measure of the weakness of the curvature of spacetime near Earth. As a more extreme example, the distance from the center of a massive neutron star to its surface is about 1 km greater than its circumference/ 2π —greater by an amount that is roughly 10% of the ~ 10 -km circumference/ 2π . Correspondingly, in the embedding diagram for Earth the embedded surface would be so nearly flat that its downward dip at the center would be imperceptible, whereas the diagram for a neutron star would show a downward dip about like that of Fig. 26.1.

Exercise 26.8 *Example: Embedding Diagram for Star with Uniform Density*

EXERCISES

- Show that the embedding surface of Eq. (26.48) is a paraboloid of revolution everywhere outside the star.
 - Show that in the interior of a uniform-density star, the embedding surface is a segment of a sphere.
 - Show that the match of the interior to the exterior is done in such a way that, in the embedding space, the embedded surface shows no kink (no bend) at $r = R$.
 - Show that, in general, the circumference/ (2π) for a star is less than the distance from the center to the surface by an amount of order one sixth the star's gravitational radius, $M/3$. Evaluate this amount analytically for a star of uniform density, and numerically (approximately) for Earth and for a neutron star.
-

26.4

26.4 Gravitational Implosion of a Star to Form a Black Hole

26.4.1

26.4.1 The Implosion Analyzed in Schwarzschild Coordinates

J. Robert Oppenheimer, on discovering with his student George Volkoff that there is a maximum mass limit for neutron stars (Oppenheimer and Volkoff, 1939), was forced to consider the possibility that, when it exhausts its nuclear fuel, a more massive star will implode to radii $R \leq 2M$. Just before the outbreak of World War II, Oppenheimer and his graduate student Hartland Snyder investigated the details of such an implosion for the idealized case of a perfectly spherical star in which all the internal pressure is suddenly extinguished (Oppenheimer and Snyder, 1939). In this section, we repeat their analysis, though from a more modern viewpoint and using somewhat different arguments.

By Birkhoff's theorem, the spacetime geometry outside an imploding, spherical star must be that of Schwarzschild. This means, in particular, that an imploding, spherical star cannot produce any gravitational waves; such waves would break the spherical symmetry. By contrast, a star that implodes nonspherically can produce a burst of gravitational waves (Chap. 27).

Since the spacetime geometry outside an imploding, spherical star is that of Schwarzschild, we can depict the motion of the star's surface by a world line in a 2-dimensional spacetime diagram with Schwarzschild coordinate time t plotted upward and Schwarzschild coordinate radius r plotted rightward (Fig. 26.2). The world line of the star's surface is an ingoing curve. The region to the left of the world line must be discarded and replaced by the spacetime of the star's interior, while the region to the right, $r > R(t)$, is correctly described by Schwarzschild.

FIGURE 26.2 Spacetime diagram depicting the gravitationally induced implosion of a star in Schwarzschild coordinates. The thick solid curve is the world line of the star's surface, $r = R(t)$, in the external Schwarzschild coordinates. The stippled region to the left of that world line is not correctly described by the Schwarzschild line element (26.1); it requires for its description the spacetime metric of the star's interior. The surface's world line $r = R(t)$ is constrained to lie inside the light cones.

As for a static star, so also for an imploding one: because real atoms with finite rest masses live on the star's surface, the world line of that surface, $\{r = R(t), \theta$ and ϕ constant $\}$, must be timelike. Consequently, at each point along the world line it must lie within the local light cones that are depicted in Fig. 26.2.

The radial edges of the light cones are lines along which the Schwarzschild line element, the ds^2 of Eq. (26.1), vanishes with θ and ϕ held fixed:

$$0 = ds^2 = -(1 - 2M/R)dt^2 + \frac{dr^2}{1 - 2M/R}; \quad \text{that is,} \quad \frac{dt}{dr} = \pm \frac{1}{1 - 2M/R}. \quad (26.50)$$

Therefore, instead of having 45° opening angles $dt/dr = \pm 1$ as they do in a Lorentz frame of flat spacetime, the light cones “squeeze down” toward $dt/dr = \infty$ as the star's surface $r = R(t)$ approaches the gravitational radius: $R \rightarrow 2M$. This is a peculiarity due not to spacetime curvature, but rather to the nature of the Schwarzschild coordinates: If, at any chosen event of the Schwarzschild spacetime, we were to introduce a local Lorentz frame, then in that frame the light cones would have 45° opening angles.

Since the world line of the star's surface is confined to the interiors of the local light cones, the squeezing down of the light cones near $r = 2M$ prevents the star's world line $r = R(t)$ from ever, in any finite coordinate time t , reaching the gravitational radius, $r = 2M$.

This conclusion is completely general; it relies in no way on the details of what is going on inside the star or at its surface. It is just as valid for completely realistic stellar implosion (with finite pressure and shock waves) as for the idealized, Oppenheimer-Snyder case of zero-pressure implosion. In the special case of zero pressure, one can explore the details further:

Because no pressure forces act on the atoms at the star's surface, those atoms must move inward along radial geodesic world lines. Correspondingly, the world line of the star's surface in the external Schwarzschild spacetime must be a timelike geodesic of constant (θ, ϕ) . In Ex. 26.9, the geodesic equation is solved to determine that world line $R(t)$, with a conclusion that agrees with the above argument: only after a lapse of infinite coordinate time t does the star's surface reach the gravitational radius $r = 2M$. A byproduct of that calculation is equally remarkable. Although the implosion to $R = 2M$ requires infinite Schwarzschild coordinate time t , it requires only a finite proper time τ as measured by an observer who rides inward on the star's surface. In fact, the proper time is

$$\tau \simeq \frac{\pi}{2} \left(\frac{R_o^3}{2M} \right)^{\frac{1}{2}} = 15 \mu\text{s} \left(\frac{R_o}{2M} \right)^{3/2} \frac{M}{M_\odot} \quad \text{if } R_o \gg 2M, \quad (26.51)$$

where R_o is the star's initial radius when it first begins to implode freely, M_\odot denotes the mass of the Sun, and proper time τ is measured from the start of implosion. Note that this implosion time is equal to $1/(4\sqrt{2})$ times the orbital period of a test particle at the radius of the star's initial surface. For a star with mass and initial radius equal

the surface of an imploding star reaches the gravitational radius $r = 2M$ in finite proper time τ , but infinite coordinate time t

to those of the Sun, τ is about 30 minutes; for a neutron star that has been pushed over the maximum mass limit by accretion of matter from its surroundings, τ is about $50 \mu\text{s}$. For a hypothetical supermassive star with $M = 10^9 M_\odot$ and $R_o \sim$ a few M , τ would be about a day.

26.4.2 26.4.2 Tidal Forces at the Gravitational Radius

What happens to the star's surface, and an imagined observer on it, when—after infinite coordinate time but a brief proper time—it reaches the gravitational radius? There are two possibilities: (i) the tidal gravitational forces there might be so strong that they destroy the star's surface and any observers on it; or (ii) the tidal forces are not that strong, and so the star and observers must continue to exist, moving into a region of spacetime (presumably $r < 2M$) that is not smoothly joined onto $r > 2M$ in the Schwarzschild coordinate system. In the latter case, the pathology is all due to poor properties of Schwarzschild's coordinates. In the former case, it is due to an intrinsic, coordinate-independent singularity of the tide-producing Riemann curvature.

To see which is the case, we must evaluate the tidal forces felt by observers on the surface of the imploding star. Those tidal forces are produced by the Riemann curvature tensor. More specifically, if an observer's feet and head have a vector separation ξ at time τ as measured by the observer's clock, then the curvature of spacetime will exert on them a relative gravitational acceleration given by the equation of geodesic deviation in the form appropriate to a local Lorentz frame:

$$\frac{d^2 \xi^{\bar{j}}}{d\tau^2} = -R^{\bar{j}}_{\bar{0}\bar{k}\bar{0}} \xi^{\bar{k}} \quad (26.52)$$

[Eq. (25.34)]. Here the barred indices denote components in the observer's local Lorentz frame. The tidal forces will become infinite and will thereby destroy the observer and all forms of matter on the star's surface, if and only if the local Lorentz Riemann components $R^{\bar{j}}_{\bar{0}\bar{k}\bar{0}}$ diverge as the star's surface approaches the gravitational radius. Thus, to test whether the observer and star survive, we must compute the components of the Riemann curvature tensor in the local Lorentz frame of the star's imploding surface.

The easiest way to compute those components is by a transformation from components as measured in the proper reference frames of observers who are "at rest" (fixed r, θ, ϕ) in the Schwarzschild spacetime. At each event on the world tube of the star's surface, then, we have two orthonormal frames: one (barred indices) a local Lorentz frame imploding with the star; the other (hatted indices) a proper reference frame at rest. Since the metric coefficients in these two bases have the standard flat-space form $\mathcal{G}_{\bar{\alpha}\bar{\beta}} = \eta_{\alpha\beta}$, $\mathcal{G}_{\hat{\alpha}\hat{\beta}} = \eta_{\alpha\beta}$, the bases must be related by a Lorentz transformation [cf. Eq. (2.35b) and associated discussion]. A little thought makes it clear that the required transformation matrix is that for a pure boost [Eq. (2.37a)]:

$$L^{\hat{0}}_{\bar{0}} = L^{\hat{r}}_{\bar{r}} = \gamma, \quad L^{\hat{0}}_{\bar{r}} = L^{\hat{r}}_{\bar{0}} = -\beta\gamma, \quad L^{\hat{\theta}}_{\bar{\theta}} = L^{\hat{\phi}}_{\bar{\phi}} = 1; \quad \gamma = \frac{1}{\sqrt{1 - \beta^2}}, \quad (26.53)$$

with β the speed of implosion of the star's surface, as measured in the proper reference frame of the static observer when the surface flies by. The transformation law for the components of the Riemann tensor has, of course, the standard form for any fourth-rank tensor:

$$R_{\bar{\alpha}\bar{\beta}\bar{\gamma}\bar{\delta}} = L^{\hat{\mu}}_{\bar{\alpha}} L^{\hat{\nu}}_{\bar{\beta}} L^{\hat{\lambda}}_{\bar{\gamma}} L^{\hat{\sigma}}_{\bar{\delta}} R_{\hat{\mu}\hat{\nu}\hat{\lambda}\hat{\sigma}}. \quad (26.54)$$

The basis vectors of the proper reference frame are given by Eqs. (4) of Box 26.2, and from that box we learn that the components of Riemann in this basis are

$$\begin{aligned} R_{\hat{0}\hat{r}\hat{0}\hat{r}} &= -\frac{2M}{R^3}, & R_{\hat{0}\hat{\theta}\hat{0}\hat{\theta}} &= R_{\hat{0}\hat{\phi}\hat{0}\hat{\phi}} = +\frac{M}{R^3}, \\ R_{\hat{\theta}\hat{\phi}\hat{\theta}\hat{\phi}} &= \frac{2M}{R^3}, & R_{\hat{r}\hat{\theta}\hat{r}\hat{\theta}} &= R_{\hat{r}\hat{\phi}\hat{r}\hat{\phi}} = -\frac{M}{R^3}. \end{aligned} \quad (26.55)$$

These are the components measured by static observers.

By inserting these static-observer components and the Lorentz-transformation matrix (26.53) into the transformation law (26.54) we reach our goal: the following components of Riemann in the local Lorentz frame of the star's freely imploding surface:

$$\begin{aligned} R_{\bar{0}\bar{r}\bar{0}\bar{r}} &= -\frac{2M}{R^3}, & R_{\bar{0}\bar{\theta}\bar{0}\bar{\theta}} &= R_{\bar{0}\bar{\phi}\bar{0}\bar{\phi}} = +\frac{M}{R^3}, \\ R_{\bar{\theta}\bar{\phi}\bar{\theta}\bar{\phi}} &= \frac{2M}{R^3}, & R_{\bar{r}\bar{\theta}\bar{r}\bar{\theta}} &= R_{\bar{r}\bar{\phi}\bar{r}\bar{\phi}} = -\frac{M}{R^3}. \end{aligned} \quad (26.56)$$

These components are remarkable in two ways. First, they remain perfectly finite as the star's surface approaches the gravitational radius, $R \rightarrow 2M$; correspondingly, tidal gravity cannot destroy the star or the observers on its surface. Second, the components of Riemann are identically the same in the two orthonormal frames, hatted and barred, which move radially at finite speed β with respect to each other [expressions (26.56) are independent of β and are the same as Eqs. (26.55)]. This is a result of the very special algebraic structure that Riemann's components have for the Schwarzschild spacetime; it will not be true in typical spacetimes.

the Riemann tensor (tidal field), as measured on the imploding star's surface, remains finite as the surface approaches radius $r = 2M$

26.4.3 Stellar Implosion in Eddington-Finkelstein Coordinates

26.4.3

From the finiteness of the components of Riemann in the local Lorentz frame of the star's surface, we conclude that something must be wrong with Schwarzschild's $\{t, r, \theta, \phi\}$ coordinate system in the vicinity of the gravitational radius $r = 2M$: although nothing catastrophic happens to the star's surface as it approaches $2M$, those coordinates refuse to describe passage through $r = 2M$ in a reasonable, smooth, finite way. Thus to study the implosion as it passes through the gravitational radius and beyond, we need a new, improved coordinate system.

Several coordinate systems have been devised for this purpose. For a study and comparison of them see, for example, Misner, Thorne, and Wheeler (1973, Chap. 31). In this chapter we confine ourselves to one of them: a coordinate system devised for

FIGURE 26.3 (a) The 3-surfaces of constant Eddington-Finkelstein time coordinate \tilde{t} drawn in a Schwarzschild spacetime diagram, with the angular coordinates $\{\theta, \phi\}$ suppressed. (b) The 3-surfaces of constant Schwarzschild time coordinate t drawn in an Eddington-Finkelstein spacetime diagram, with angular coordinates suppressed.

other purposes by Arthur Eddington (1922), then long forgotten and only rediscovered independently and used for this purpose by Finkelstein (1958). Yevgeny Lifshitz, of Landau-Lifshitz fame, told one of the authors many years later what an enormous impact Finkelstein’s coordinate system had on peoples’ understanding of the implosion of stars. “You cannot appreciate how difficult it was for the human mind before Finkelstein to understand [the Oppenheimer-Snyder analysis of stellar implosion],” Lifshitz said. When, 19 years after Oppenheimer and Snyder, the issue of *Physical Review* containing Finkelstein’s paper arrived in Moscow, suddenly everything was clear.

Finkelstein, a postdoctoral fellow at the Stevens Institute of Technology in Hoboken, New Jersey, found the following simple transformation, which moves the region $\{t = \infty, r = 2M\}$ of Schwarzschild coordinates in to a finite location. His transformation involves introducing a new time coordinate

Eddington-Finkelstein time coordinate

$$\tilde{t} = t + 2M \ln \left| \frac{r}{2M} - 1 \right|, \quad (26.57)$$

but leaving unchanged the radial and angular coordinates. Figure 26.3 shows the surfaces of constant Eddington-Finkelstein time \tilde{t} in Schwarzschild coordinates, and the surfaces of constant Schwarzschild time t in Eddington-Finkelstein coordinates. Notice, as advertised, that $\{t = \infty, r = 2M\}$ is moved to a finite Eddington-Finkelstein location.

By inserting the coordinate transformation (26.57) into the Schwarzschild line element (26.1), we obtain the following line element for Schwarzschild spacetime written in Eddington-Finkelstein coordinates:

3. Sometimes \tilde{t} is also called “ingoing Eddington-Finkelstein time,” because it enables one to analyze infall through the gravitational radius.

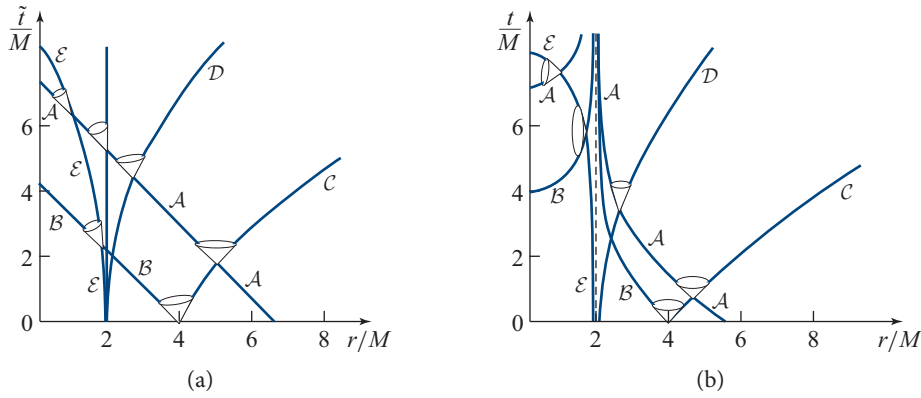

FIGURE 26.4 (a) Radial light rays and light cones for the Schwarzschild spacetime as depicted in Eddington-Finkelstein coordinates [Eq. (26.59)]. (b) The same light rays and light cones as depicted in Schwarzschild coordinates [cf. Fig. 26.2]. \mathcal{A} and \mathcal{B} are ingoing light rays that start far outside $r = 2M$; \mathcal{C} and \mathcal{D} are outgoing rays that start near $r = 2M$; \mathcal{E} is an outgoing ray that is trapped inside the gravitational radius.

$$ds^2 = - \left(1 - \frac{2M}{r}\right) d\tilde{t}^2 + \frac{4M}{r} d\tilde{t} dr + \left(1 + \frac{2M}{r}\right) dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2).$$

(26.58)

Notice that, by contrast with the line element in Schwarzschild coordinates, none of the metric coefficients diverge as r approaches $2M$. Moreover, in an Eddington-Finkelstein spacetime diagram, by contrast with Schwarzschild, the light cones do not pinch down to slivers at $r = 2M$ (compare Figs. 26.4a and 26.4b): The world lines of radial light rays are computable in Eddington-Finkelstein, as in Schwarzschild, by setting $ds^2 = 0$ (null world lines) and $d\theta = d\phi = 0$ (radial world lines) in the line element. The result, depicted in Fig. 26.4a, is

$$\frac{d\tilde{t}}{dr} = -1 \text{ for ingoing rays; and } \frac{d\tilde{t}}{dr} = \left(\frac{1 + 2M/r}{1 - 2M/r}\right) \text{ for outgoing rays.} \quad (26.59)$$

Note that, in the Eddington-Finkelstein coordinate system, the ingoing light rays plunge unimpeded through $r = 2M$ and onward into $r = 0$ along 45° lines. The outgoing light rays, by contrast, are never able to escape outward through $r = 2M$: because of the inward tilt of the outer edge of the light cone, all light rays that begin inside $r = 2M$ are forced forever to remain inside, and in fact are drawn inexorably into $r = 0$, whereas light rays initially outside $r = 2M$ can escape to $r = \infty$.

Now return to the implosion of a star. The world line of the star's surface, which became asymptotically frozen at the gravitational radius when studied in Schwarzschild coordinates, plunges unimpeded through $r = 2M$ and to $r = 0$ when studied in

Schwarzschild metric in Eddington-Finkelstein coordinates

edges of radial light cone in Eddington-Finkelstein coordinates

implosion star passes through the gravitational radius and onward to $r = 0$ in finite Eddington-Finkelstein coordinate time

FIGURE 26.5 World line of an observer on the surface of an imploding star, as depicted (a) in an Eddington-Finkelstein spacetime diagram, and (b) in a Schwarzschild spacetime diagram; see Ex. 26.9.

Eddington-Finkelstein coordinates; see Ex. 26.9 and compare Figs. 26.5b and 26.5a. Thus to understand the star's ultimate fate, we must study the region $r = 0$.

EXERCISES

Exercise 26.9 *Example: Implosion of the Surface of a Zero-Pressure Star Analyzed in Schwarzschild and in Eddington-Finkelstein Coordinates*

Consider the surface of a zero-pressure star, which implodes along a timelike geodesic $r = R(t)$ in the Schwarzschild spacetime of its exterior. Analyze that implosion using Schwarzschild coordinates $\{t, r, \theta, \phi\}$ and the exterior metric (26.1) in those coordinates, and then repeat your analysis in Eddington-Finkelstein coordinates. More specifically, do the following.

- Using Schwarzschild coordinates, show that the covariant time component u_t of the 4-velocity \vec{u} of a particle on the star's surface is conserved along its world line (cf. Ex. 25.4a). Evaluate this conserved quantity in terms of the star's mass M and the radius $r = R_o$ at which it begins to implode.
- Use the normalization of the 4-velocity to show that the star's radius R as a function of the proper time τ since implosion began (proper time as measured on its surface) satisfies the differential equation

$$\frac{dR}{d\tau} = -[\text{const} + 2M/R]^{\frac{1}{2}}, \quad (26.60)$$

and evaluate the constant. Compare this with the equation of motion for the surface as predicted by Newtonian gravity, with proper time τ replaced by Newtonian time. (It is a coincidence that the two equations are identical.)

- Show from the equation of motion (26.60) that the star implodes through the gravitational radius $R = 2M$ and onward to $R = 0$ in a finite proper time given

by Eq. (26.51). Show that this proper time has the magnitudes cited in Eq. (26.51) and the sentences following it.

- (d) Show that the Schwarzschild coordinate time t required for the star to reach its gravitational radius, $R \rightarrow 2M$, is infinite.
- (e) Show, further, that when studied in Eddington-Finkelstein coordinates, the surface's implosion to $R = 2M$ requires only finite coordinate time \tilde{t} ; in fact, a time of the same order of magnitude as the proper time (26.51). [Hint: Derive a differential equation for $d\tilde{t}/d\tau$ along the world line of the star's surface, and use it to examine the behavior of $d\tilde{t}/d\tau$ near $R = 2M$.]
- (f) Show that the world line of the star's surface as depicted in an Eddington-Finkelstein spacetime diagram has the form shown in Fig. 26.5a, and that in a Schwarzschild spacetime diagram it has the form shown in Fig. 26.5b.

26.4.4 Tidal Forces at $r = 0$ —The Central Singularity

26.4.4

As with $r \rightarrow 2M$, there are two possibilities: either the tidal forces as measured on the star's surface remain finite as $r \rightarrow 0$, in which case something must be going wrong with the coordinate system; or else the tidal forces diverge, destroying the star. The tidal forces are computed in Ex. 26.10, with a remarkable result: they diverge. Thus, the region $r = 0$ is a *spacetime singularity*: a region where tidal gravity becomes infinitely large, destroying everything that falls into it.

$r = 0$ is a spacetime singularity; tidal gravity becomes infinite there

This conclusion, of course, is very unsatisfying. It is hard to believe that the correct laws of physics will predict such total destruction. In fact, they probably do not. As we will find in Sec. 28.7.1, in discussing the origin of the universe, when the radius of curvature of spacetime becomes as small as $L_P \equiv (G\hbar/c^3)^{1/2} \simeq 10^{-33}$ cm, space and time must cease to exist as classical entities; they and the spacetime geometry must then become quantized. Correspondingly, general relativity must then break down and be replaced by a quantum theory of the structure of spacetime—a quantum theory of gravity. That quantum theory will describe and govern the classically singular region at $r = 0$. Since, however, only rough hints of the structure of that quantum theory are in hand at this time, it is not known what that theory will say about the endpoint of stellar implosion.

the singularity is governed by the laws of quantum gravity

Exercise 26.10 Example: Gore at the Singularity

EXERCISES

- (a) Show that, as the surface of an imploding star approaches $R = 0$, its world line in Schwarzschild coordinates asymptotes to the curve $\{(t, \theta, \phi) = \text{const}, r \text{ variable}\}$.
- (b) Show that this curve to which it asymptotes [part (a)] is a timelike geodesic. [Hint: Use the result of Ex. 25.4a.]

- (c) Show that the basis vectors of the infalling observer's local Lorentz frame near $r = 0$ are related to the Schwarzschild coordinate basis by

$$\begin{aligned}\vec{e}_{\hat{0}} &= -\left(\frac{2M}{r} - 1\right)^{\frac{1}{2}} \frac{\partial}{\partial r}, & \vec{e}_{\hat{1}} &= \left(\frac{2M}{r} - 1\right)^{-\frac{1}{2}} \frac{\partial}{\partial t}, \\ \vec{e}_{\hat{2}} &= \frac{1}{r} \frac{\partial}{\partial \theta}, & \vec{e}_{\hat{3}} &= \frac{1}{r \sin \theta} \frac{\partial}{\partial \phi}.\end{aligned}\tag{26.61}$$

What are the components of the Riemann tensor in that local Lorentz frame?

- (d) Show that the tidal forces produced by the Riemann tensor stretch an infalling observer in the radial, $\vec{e}_{\hat{1}}$, direction and squeeze the observer in the tangential, $\vec{e}_{\hat{2}}$ and $\vec{e}_{\hat{3}}$, directions. Show that the stretching and squeezing forces become infinitely strong as the observer approaches $r = 0$.
- (e) Idealize the body of an infalling observer to consist of a head of mass $\mu \simeq 20$ kg and feet of mass $\mu \simeq 20$ kg separated by a distance $h \simeq 2$ m, as measured in the observer's local Lorentz frame, and with the separation direction radial. Compute the stretching force between head and feet, as a function of proper time τ , as the observer falls into the singularity. Assume that the hole has the mass $M = 7 \times 10^9 M_{\odot}$, which has been measured by astronomical observations for the black hole at the center of the supergiant elliptical galaxy M87. How long before hitting the singularity (at what proper time τ) does the observer die, if he or she is a human being made of flesh, bone, and blood?

26.4.5

26.4.5 Schwarzschild Black Hole

Unfortunately, the singularity and its quantum mechanical structure are totally invisible to observers in the external universe: the only way the singularity can possibly be seen is by means of light rays, or other signals, that emerge from its vicinity. However, because the future light cones are all directed into the singularity (Fig. 26.5), no light-speed or sub-light-speed signals can ever emerge from it. In fact, because the outer edge of the light cone is tilted inward at every event inside the gravitational radius (Figs. 26.4 and 26.5), no signal can emerge from inside the gravitational radius to tell external observers what is going on there. In effect, the gravitational radius is an *absolute event horizon* for our universe, a horizon beyond which we cannot see—except by plunging through it, and paying the ultimate price for our momentary exploration of the hole's interior: we cannot publish the results of our observations.

As most readers are aware, the region of strong, vacuum gravity left behind by the implosion of the star is called a *black hole*. The horizon, $r = 2M$, is the surface of the hole, and the region $r < 2M$ is its interior. The spacetime geometry of the black hole, outside and at the surface of the star that creates it by implosion, is that of

gravitational radius as an absolute event horizon

black hole, its interior, surface (horizon), and exterior

FIGURE 26.6 Spacetime diagram depicting the formation and evolution of the horizon of a black hole. The coordinates outside the surface of the imploding star are those of Eddington and Finkelstein; those inside are a smooth continuation of Eddington and Finkelstein (not explored in this book). Note that the horizon is the boundary of the region that is unable to send outgoing null geodesics to radial infinity.

Schwarzschild—though, of course, Karl Schwarzschild had no way of knowing this in the few brief months left to him after his discovery of the Schwarzschild line element.

The horizon—defined as the boundary between spacetime regions that can and cannot communicate with the external universe—actually forms initially at the star’s center and then expands to encompass the star’s surface at the precise moment when the surface penetrates the gravitational radius. This evolution of the horizon is depicted in an Eddington-Finkelstein-type spacetime diagram in Fig. 26.6.

Our discussion here has been confined to spherically symmetric, nonrotating black holes created by the gravitational implosion of a spherically symmetric star. Of course, real stars are not spherical, and it was widely believed—perhaps we should say, hoped—in the 1950s and 1960s that black-hole horizons and singularities would be so unstable that small nonsphericities or small rotations of the imploding star would save it from the black-hole fate. However, elegant and very general analyses carried out in the 1960s, largely by the British physicists Roger Penrose and Stephen Hawking, showed otherwise. More recent numerical simulations on supercomputers have confirmed those analyses: singularities are a generic outcome of stellar implosion, as are the black-hole horizons that clothe them.

evolution of the horizon as black hole is formed

genericity of singularities inside black holes

Exercise 26.11 *Example: Rindler Approximation near the Horizon of a Schwarzschild Black Hole*

- (a) Near the event $\{r = 2M, \theta = \theta_o, \phi = \phi_o, t \text{ finite}\}$, on the horizon of a black hole, introduce locally Cartesian spatial coordinates $\{x = 2M \sin \theta_o(\phi - \phi_o), y = 2M(\theta - \theta_o), z = \int_{2M}^r dr/\sqrt{1 - 2M/r}\}$, accurate to first order in distance

EXERCISES

from that event. Show that the metric in these coordinates has the form (accurate to leading order in distance from the chosen event):

$$ds^2 = -(g_H z)^2 dt^2 + dx^2 + dy^2 + dz^2, \quad \text{where } g_H = \frac{1}{4M} \quad (26.62)$$

is the horizon's so-called *surface gravity*, to which we shall return, for a rotating black hole, in Eq. (26.90).

- (b) Notice that the metric (26.62) is the same as that for flat spacetime as seen by a family of uniformly accelerated observers (i.e., as seen in the Rindler coordinates of Sec. 24.5.4). Why is this physically reasonable?

Exercise 26.12 ***Example: Orbits around a Schwarzschild Black Hole*

Around a Schwarzschild black hole, spherical symmetry dictates that every geodesic orbit lies in a plane that bifurcates the $t = \text{const}$ 3-volume. We are free to orient our coordinate system, for any chosen geodesic, so its orbital plane is equatorial: $\theta = \pi/2$. Then the geodesic has three conserved quantities: the orbiting particle's rest mass μ , energy-at-infinity \mathcal{E}_∞ , and angular momentum L , which are given by

$$\mu^2 = -\vec{p}^2 = -g_{\alpha\beta} \frac{dx^\alpha}{d\zeta} \frac{dx^\beta}{d\zeta}, \quad \mathcal{E}_\infty = -p_t = -g_{tt} \frac{dt}{d\zeta}, \quad L = p_\phi = g_{\phi\phi} \frac{d\phi}{d\zeta}, \quad (26.63)$$

respectively. In this exercise we focus on particles with finite rest mass. Zero-rest-mass particles can be analyzed similarly; see the references at the end of this exercise.

- (a) Set the rest mass μ to unity; equivalently, switch from 4-momentum to 4-velocity for the geodesic's tangent vector. Then, by algebraic manipulation of the constants of motion (26.63), derive the following orbital equations:

$$\left(\frac{dr}{d\zeta}\right)^2 + V^2(r) = \mathcal{E}_\infty^2, \quad \text{where } V^2(r) = \left(1 - \frac{2M}{r}\right) \left(1 + \frac{L^2}{r^2}\right), \quad (26.64a)$$

$$\frac{d\phi}{d\zeta} = \frac{L}{r^2}, \quad \frac{dt}{d\zeta} = \frac{\mathcal{E}_\infty}{1 - 2M/r}. \quad (26.64b)$$

- (b) We use a device that we have also encountered in our treatment of ion acoustic solitons in Sec. 23.6. We think of Eq. (26.64a) as an equivalent nonrelativistic energy equation with $\frac{1}{2}V^2$ being the effective potential energy and $\frac{1}{2}\mathcal{E}_\infty^2$ the effective total energy. As the energy we actually care about is \mathcal{E}_∞ , it is more direct to refer to $V(r)$ as our potential and investigate its properties. This $V(r)$ is plotted in Fig. 26.7a for several values of the particle's angular momentum L . Explain why:
- (i) Circular geodesic orbits are at extrema of $V(r)$ —the large dots in the figure. (ii) Each bound orbit can be described by a horizontal line, such as the red one in the figure, with height equal to the orbit's \mathcal{E}_∞ ; and the particle's radial motion is back and forth between the points at which the horizontal line intersects the potential.
- (c) Show that the innermost stable circular orbit (often abbreviated as ISCO) is at $r = 6M$, and it occurs at a saddle point of the potential, for $L = 2\sqrt{3}M$. Show

that all inward-moving particles with $L < 2\sqrt{3}M$ are doomed to fall into the black hole.

- (d) Show that the innermost unstable circular orbit is at $r = 3M$ and has infinite energy for finite rest mass. From this infer that there should be an unstable circular orbit for photons at $r = 3M$.
- (e) The geodesic equations of motion in the form (26.64) are not very suitable for numerical integration: at each radial turning point, where $V(r) = \mathcal{E}_\infty$ and $dr/d\zeta = 0$, the accuracy of straightforward integrations goes bad, and one must switch signs of $dr/d\zeta$ by hand, unless one is sophisticated. For these reasons and others, it is preferable in numerical integrations to use the super-hamiltonian form of the geodesic equation (Ex. 25.7), or to convert Eq. (26.64a) into a second-order differential equation before integrating. Show that Hamilton's equations, for the super-hamiltonian, are

$$\frac{dr}{d\zeta} = \left(1 - \frac{2M}{r}\right) p_r, \quad \frac{dp_r}{d\zeta} = \frac{L^2}{r^3} - \frac{M}{r^2} p_r^2 - \frac{M}{(r-2M)^2} \mathcal{E}_\infty^2, \quad \frac{d\phi}{d\zeta} = \frac{L}{r^2}. \quad (26.65)$$

When integrating these equations, one must make sure that the initial value of p_r satisfies $g^{\alpha\beta} p_\alpha p_\beta = -1$ (for our unit-rest-mass particle). Show that this condition reduces to

$$p_r = \pm \sqrt{\frac{\mathcal{E}_\infty^2 / (1 - 2M/r) - L^2 / r^2 - 1}{1 - 2M/r}}. \quad (26.66)$$

- (f) Integrate the super-hamiltonian equations (26.65) numerically for the orbit described by the red horizontal line in Fig. 26.7a, which has $L = 3.75M$ and

FIGURE 26.7 (a) The potential $V(r)$ for the geodesic radial motion $r(\zeta)$ of finite-rest-mass particles around a Schwarzschild black hole. Each curve is labeled by the particle's orbital angular momentum L . (b) The orbit $r(\phi)$ corresponding to the horizontal red line in (a); it has $L = 3.75M$ and $\mathcal{E}_\infty = 0.9704$. It is called a *zoom-whirl* orbit, because its particle zooms inward from a large radius, whirls around the black hole several times, then zooms back out—and then repeats.

$\mathcal{E}_\infty = 0.9704$. The result should be the zoom-whirl orbit depicted in Fig. 26.7b. (The initial conditions used in that figure were $r = 25M$, $\phi = 0$, and [from Eq. (26.66)] $p_r = 0.0339604$.)

- (g) Carry out other numerical integrations to explore the variety of shapes of finite-rest-mass orbits around a Schwarzschild black hole.

Orbits around a Schwarzschild black hole are treated in most general relativity textbooks; see, for example, Misner, Thorne, and Wheeler (1973, Chap. 25) and Hartle (2003); see also Frolov and Novikov (1998), Sec. 2.8. Analytic solutions to the geodesic equation, expressed in terms of elliptic functions, are given by Darwin (1959).

Exercise 26.13 *Example: Schwarzschild Wormhole* T2

Our study of the Schwarzschild solution of Einstein's equations in this chapter has been confined to situations where, at small radii, the Schwarzschild geometry joins onto that of a star—either a static star or one that implodes to form a black hole. Suppose, by contrast, that there is no matter anywhere in the Schwarzschild spacetime. To get insight into this situation, construct an embedding diagram for the equatorial 2-surfaces $\{t = \text{const}, \theta = \pi/2\}$ of the vacuum Schwarzschild spacetime, using as the starting point the line element of such a 2-surface written in isotropic coordinates (Ex. 26.3):

$${}^{(2)}ds^2 = \left(1 + \frac{M}{2\bar{r}}\right)^4 (d\bar{r}^2 + \bar{r}^2 d\phi^2). \quad (26.67)$$

Show that the region $0 < \bar{r} \ll M/2$ is an asymptotically flat space, that the region $\bar{r} \gg M/2$ is another asymptotically flat space, and that these two spaces are connected by a *wormhole* (“bridge,” “tunnel”) through the embedding space. This exercise reveals that the pure vacuum Schwarzschild spacetime represents a wormhole that connects two different universes—or, with a change of topology, a wormhole that connects two widely separated regions of one universe.

Exercise 26.14 *Example: Dynamical Evolution of Schwarzschild Wormhole* T2

The isotropic-coordinate line element (26.16) describing the spacetime geometry of a Schwarzschild wormhole is independent of the time coordinate t . However, because $g_{tt} = 0$ at the wormhole's throat, $\bar{r} = M/2$, the proper time $d\tau = \sqrt{-ds^2}$ measured by an observer at rest appears to vanish, which cannot be true. Evidently, the isotropic coordinates are ill behaved at the throat.

- (a) Martin Kruskal (1960) and George Szekeres (1960) independently introduced a coordinate system that covers the wormhole's entire spacetime and elucidates its dynamics in a nonsingular manner. The Kruskal-Szekeres time and radial coordinates v and u are related to the Schwarzschild t and r by

$$[r/(2M) - 1] e^{r/(2M)} = u^2 - v^2, \quad (26.68)$$

$$t = 4M \tanh^{-1}(v/u) \quad \text{at } r > 2M, \quad t = 4M \tanh^{-1}(u/v) \quad \text{at } r < 2M.$$

Show that the metric of Schwarzschild spacetime written in these Kruskal-Szekeres coordinates is

$$ds^2 = (32M^3/r)e^{-r/(2M)}(-dv^2 + du^2) + r^2(d\theta^2 + \sin^2\theta d\phi^2), \quad (26.69)$$

where $r(u, v)$ is given by Eq. (26.68).

- (b) Draw a spacetime diagram with v increasing upward and u increasing horizontally and rightward. Show that the radial light cones are 45° lines everywhere. Show that there are two $r = 0$ singularities, one on the past hyperbola, $v = -\sqrt{u^2 + 1}$, and the other on the future hyperbola, $v = +\sqrt{u^2 + 1}$. Show that the gravitational radius, $r = 2M$, is at $v = \pm u$. Show that our universe, outside the wormhole, is at $u \gg 1$, and there is another universe at $u \ll -1$.
- (c) Draw embedding diagrams for a sequence of spacelike hypersurfaces, the first of which hits the past singularity and the last of which hits the future singularity. Thereby show that the metric (26.69) represents a wormhole that is created in the past, expands to maximum throat circumference $4\pi M$, then pinches off in the future to create a pair of singularities, one in each universe.
- (d) Show that nothing can pass through the wormhole from one universe to the other; anything that tries gets crushed in the wormhole's pinch off.

For a solution, see Fuller and Wheeler (1962), or Misner, Thorne, and Wheeler (1973, Chap. 31). For discussions of what is required to hold a wormhole open so it can be traversed, see Morris and Thorne (1988); and for discussions of whether arbitrarily advanced civilizations can create wormholes and hold them open for interstellar travel, see the nontechnical discussions and technical references in Everett and Roman (2011). For a discussion of the possible use of traversable wormholes for backward time travel, see Sec. 2.9, and also Everett and Roman (2011) and references therein. For the visual appearance of wormholes and for guidance in constructing wormhole images by propagating light rays through and around them, see Thorne (2014) and James et al. (2015a).

26.5 Spinning Black Holes: The Kerr Spacetime T2

26.5

26.5.1 The Kerr Metric for a Spinning Black Hole T2

26.5.1

Consider a star that implodes to form a black hole, and assume for pedagogical simplicity that during the implosion no energy, momentum, or angular momentum flows through a large sphere surrounding the star. Then the asymptotic conservation laws discussed in Secs. 25.9.4 and 25.9.5 guarantee that the mass M , linear momentum P_j , and angular momentum J_j of the newborn hole, as encoded in its asymptotic metric, will be identical to those of its parent star. If (as we shall assume) our asymptotic coordinates are those of the star's rest frame ($P_j = 0$), then the hole will also be at rest in those coordinates (i.e., it will also have $P_j = 0$).

If the star was nonspinning ($J_j = 0$), then the hole will also have $J_j = 0$, and a powerful theorem due to Werner Israel (reviewed in Carter 1979) guarantees that—after it has settled down into a quiescent state—the hole’s spacetime geometry will be that of Schwarzschild.

If, instead, the star was spinning ($J_j \neq 0$), then the final, quiescent hole cannot be that of Schwarzschild. Instead, according to powerful theorems due to Stephen Hawking, Brandon Carter, David Robinson, and others (also reviewed in Carter 1979), its spacetime geometry will be that described by the following exact, vacuum solution to the Einstein field equation:

the Kerr metric for a spinning black hole in Boyer-Lindquist coordinates

$$ds^2 = -\alpha^2 dt^2 + \frac{\rho^2}{\Delta} dr^2 + \rho^2 d\theta^2 + \varpi^2 (d\phi - \omega dt)^2, \quad (26.70a)$$

where

$$\Delta = r^2 + a^2 - 2Mr, \quad \rho^2 = r^2 + a^2 \cos^2 \theta, \quad \Sigma^2 = (r^2 + a^2)^2 - a^2 \Delta \sin^2 \theta, \quad (26.70b)$$

$$\alpha^2 = \frac{\rho^2}{\Sigma^2} \Delta, \quad \varpi^2 = \frac{\Sigma^2}{\rho^2} \sin^2 \theta, \quad \omega = \frac{2aMr}{\Sigma^2}.$$

This is called the *Kerr solution*, because it was discovered by the New Zealand mathematician Roy Kerr (1963).

In this line element, $\{t, r, \theta, \phi\}$ are the coordinates, and there are two constants, M and a . The physical meanings of M and a can be deduced from the asymptotic form of the Kerr metric (26.70) at large radii:

$$ds^2 = - \left(1 - \frac{2M}{r} \right) dt^2 - \frac{4Ma}{r} \sin^2 \theta d\phi dt + \left[1 + O \left(\frac{M}{r} \right) \right] [dr^2 + r^2 (d\theta^2 + \sin^2 \theta d\phi^2)]. \quad (26.71)$$

the black hole’s mass M and spin angular momentum Ma

By comparing with the standard asymptotic metric in spherical coordinates [Eq. (25.98d)], we see that M is the mass of the black hole, $Ma \equiv J_H$ is the magnitude of its spin angular momentum, and its spin points along the polar axis, $\theta = 0$. Evidently, then, the constant a is the hole’s angular momentum per unit mass; it has the same dimensions as M : length (in geometrized units).

It is easy to verify that, in the limit $a \rightarrow 0$, the Kerr metric (26.70) reduces to the Schwarzschild metric (26.1), and the coordinates $\{t, r, \theta, \phi\}$ in which we have written it (called “Boyer-Lindquist coordinates”) reduce to Schwarzschild’s coordinates.

Just as it is convenient to read the covariant metric components $g_{\alpha\beta}$ off the line element (26.70a) via $ds^2 = g_{\alpha\beta} dx^\alpha dx^\beta$, so also it is convenient to read the contravariant metric components $g^{\alpha\beta}$ off an expression for the wave operator: $\square \equiv \vec{\nabla} \cdot \vec{\nabla} = g^{\alpha\beta} \nabla_\alpha \nabla_\beta$. (Here $\nabla_\alpha \equiv \nabla_{\vec{e}_\alpha}$ is the directional derivative along the basis vector \vec{e}_α .) For the Kerr metric (26.70), a straightforward inversion of the matrix

$\|g_{\alpha\beta}\|$ gives the $\|g^{\alpha\beta}\|$ embodied in the following equation:

$$\square = -\frac{1}{\alpha^2}(\nabla_t + \omega\nabla_\phi)^2 + \frac{\Delta}{\rho^2}\nabla_r^2 + \frac{1}{\rho^2}\nabla_\theta^2 + \frac{1}{\varpi^2}\nabla_\phi^2. \quad (26.72)$$

T2
the wave operator and contravariant components of the Kerr metric

26.5.2 Dragging of Inertial Frames **T2**

26.5.2

As we saw in Sec. 25.9.3, the angular momentum of a weakly gravitating body can be measured by its frame-dragging, precessional influence on the orientation of gyroscopes. Because the asymptotic metric (26.71) of a Kerr black hole is identical to the weak-gravity metric used to study gyroscopic precession in Sec. 25.9.3, the black hole's spin angular momentum J_{BH} can also be measured via frame-dragging gyroscopic precession.

This frame dragging also shows up in the geodesic trajectories of freely falling particles. For concreteness, consider a particle dropped from rest far outside the black hole. Its initial 4-velocity will be $\vec{u} = \partial/\partial t$, and correspondingly, in the distant, flat region of spacetime, the covariant components of \vec{u} will be $u_t = -1, u_r = u_\theta = u_\phi = 0$.

Now, the Kerr metric coefficients $g_{\alpha\beta}$, like those of Schwarzschild, are independent of t and ϕ : the Kerr metric is symmetric under time translation (it is stationary) and under rotation about the hole's spin axis (it is axially symmetric). These symmetries impose corresponding conservation laws on the infalling particle (Ex. 25.4a): u_t and u_ϕ are conserved (i.e., they retain their initial values $u_t = -1$ and $u_\phi = 0$ as the particle falls). By raising indices— $u^\alpha = g^{\alpha\beta}u_\beta$, using the metric coefficients embodied in Eq. (26.72)—we learn the evolution of the contravariant 4-velocity components: $u^t = -g^{tt} = 1/\alpha^2, u^\phi = -g^{t\phi} = \omega/\alpha^2$. These in turn imply that, as the particle falls, it acquires an angular velocity around the hole's spin axis given by

$$\Omega = \frac{d\phi}{dt} = \frac{d\phi/d\tau}{dt/d\tau} = \frac{u^\phi}{u^t} = \omega. \quad (26.73)$$

frame dragging: angular velocity of a particle that falls in from $r = \infty$

(The coordinates ϕ and t are tied to the rotational and time-translation symmetries of the spacetime, so they are very special; that is why we can use them to define a physically meaningful angular velocity.)

At large radii, $\omega = 2aM/r^3 \rightarrow 0$ as $r \rightarrow \infty$. Therefore, when first dropped, the particle falls radially inward. However, as the particle nears the hole and picks up speed, it acquires a significant angular velocity around the hole's spin axis. The physical cause of this is *frame dragging*: The hole's spin drags inertial frames into rotation around the spin axis, and that inertial rotation drags the inertially falling particle into a circulatory orbital motion.

26.5.3 The Light-Cone Structure, and the Horizon **T2**

26.5.3

Just as for a Schwarzschild hole, so also for Kerr: the light-cone structure is a powerful tool for identifying the horizon and exploring the spacetime geometry near it.

outer and inner edges of light cone

At any event in spacetime, the tangents to the light cone are those displacements $\{dt, dr, d\theta, d\phi\}$ along which $ds^2 = 0$. The outermost and innermost edges of the cone are those for which $(dr/dt)^2$ is maximal. By setting expression (26.70a) to zero, we see that dr^2 has its maximum value, for a given dt^2 , when $d\phi = \omega dt$ and $d\theta = 0$. In other words, the photons that move radially outward or inward at the fastest possible rate are those whose angular motion is that of frame dragging [Eq. (26.73)]. For these extremal photons, the radial motion (along the outer and inner edges of the light cone) is

$$\frac{dr}{dt} = \pm \frac{\alpha\sqrt{\Delta}}{\rho} = \pm \frac{\Delta}{\Sigma}. \quad (26.74)$$

Now, Σ is positive definite, but Δ is not; it decreases monotonically with decreasing radius, reaching zero at

$$r = r_H \equiv M + \sqrt{M^2 - a^2} \quad (26.75)$$

[Eq. (26.70b)]. (We assume that $|a| < M$, so r_H is real; we justify this assumption below.) Correspondingly, the light cone closes up to a sliver and then pinches off as $r \rightarrow r_H$; it pinches onto a null curve (actually, a null geodesic) given by

$$r = r_H, \quad \theta = \text{const}, \quad \phi = \Omega_H t + \text{const}, \quad (26.76)$$

where

$$\Omega_H = \omega(r = r_H) = \frac{a}{2Mr_H}. \quad (26.77)$$

This light-cone structure is depicted in Fig. 26.8a,b. The light-cone pinch-off as shown there is the same as that for Schwarzschild spacetime (Fig. 26.2) except for the light cones' frame-dragging-induced angular tilt $d\phi/dt = \omega$. In the Schwarzschild case, as $r \rightarrow 2M$, the light cones pinch onto the geodesic world lines $\{r = 2M, \theta = \text{const}, \phi = \text{const}\}$ of photons that travel along the horizon. These null world lines are called the horizon's *generators*. In the Kerr case, the light-cone pinch-off reveals that the horizon is at $r = r_H$, and the horizon generators are null geodesics that travel around and around the horizon with angular velocity Ω_H . This motivates us to regard the horizon itself as having the rotational angular velocity Ω_H .

When a finite-rest-mass particle falls into a spinning black hole, its world line, as it nears the horizon, is constrained always to lie inside the light cone. The light-cone pinch-off then constrains its motion asymptotically to approach the horizon generators. Therefore, as seen in Boyer-Lindquist coordinates, the particle is dragged into an orbital motion, just above the horizon, with asymptotic angular velocity $d\phi/dt = \Omega_H$, and it travels around and around the horizon "forever" (for infinite Boyer-Lindquist coordinate time t), and never (as $t \rightarrow \infty$) manages to cross through the horizon.

the horizon, $r = r_H$, and its rotational angular velocity, Ω_H

in Boyer-Lindquist coordinates, infalling particles asymptote to horizon and to its angular velocity

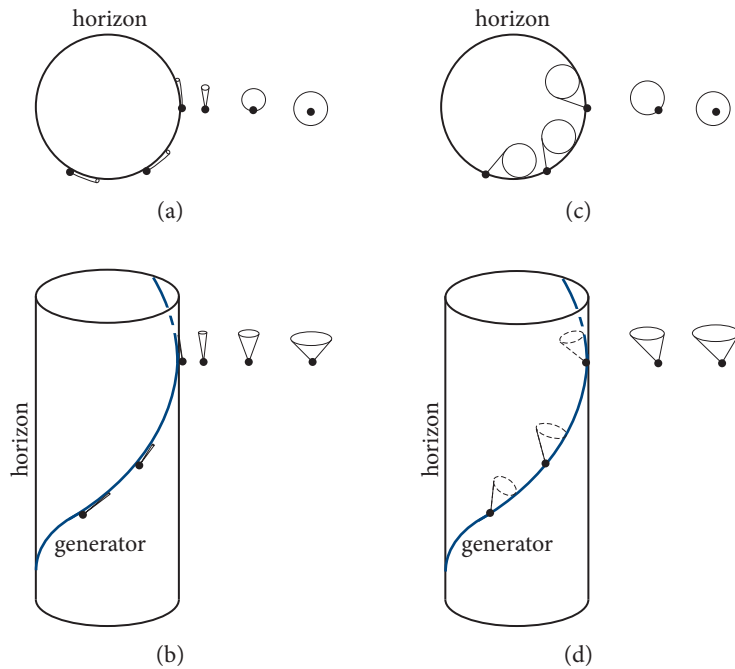

FIGURE 26.8 (a), (b): Light-cone structure of Kerr spacetime depicted in Boyer-Lindquist coordinates. Drawing (b) is a spacetime diagram; drawing (a) is the same diagram as viewed from above. (c), (d): The same light-cone structure in Kerr coordinates.

As in the Schwarzschild case, so also in Kerr: this infall to $r = r_H$ requires only finite proper time τ as measured by the particle, and the particle feels only finite tidal forces (only finite values of the components of Riemann in its proper reference frame). Therefore, as for Schwarzschild spacetime, the “barrier” to infall through $r = r_H$ must be an illusion produced by a pathology of the Boyer-Lindquist coordinates at $r = r_H$.

This coordinate pathology can be removed by a variety of different coordinate transformations. One is the following change of the time and angular coordinates:

$$\tilde{t} = t + \int \frac{2Mr}{\Delta} dr, \quad \tilde{\phi} = \phi + \int \frac{a}{\Delta} dr. \quad (26.78)$$

Kerr coordinates

The new (tilded) coordinates are a variant of a coordinate system originally introduced by Kerr, so we call them “Kerr coordinates.”⁴ By inserting the coordinate transformation (26.78) into the line element (26.70a), we obtain the following form of the Kerr metric in Kerr coordinates:

Kerr metric in Kerr coordinates

4. They are often called “ingoing Kerr coordinates,” because they facilitate analyzing infall through the horizon.

T2

$$\begin{aligned}
 ds^2 = & -\alpha^2 d\tilde{t}^2 + \frac{4Mr\rho^2}{\Sigma^2} dr d\tilde{t} + \frac{\rho^2(\rho^2 + 2Mr)}{\Sigma^2} dr^2 \\
 & + \rho^2 d\theta^2 + \varpi^2 \left[d\tilde{\phi} - \omega d\tilde{t} - \frac{a(\rho^2 + 2Mr)}{\Sigma^2} dr \right]^2.
 \end{aligned}
 \tag{26.79}$$

It is easy to verify that when $a \rightarrow 0$ (so Kerr spacetime becomes Schwarzschild), the Kerr coordinates (26.78) become those of Eddington and Finkelstein [Eq. (26.57)], and the Kerr line element (26.79) becomes the Eddington-Finkelstein one [Eq. (26.58)]. Similarly, when one explores the light-cone structure for a spinning black hole in the Kerr coordinates (Fig. 26.8c,d), one finds a structure like that of Eddington-Finkelstein (Fig. 26.4a): At large radii, $r \gg M$, the light cones have their usual 45° form, but as one moves inward toward the horizon, they begin to tilt inward. In addition to the inward tilt, there is a frame-dragging-induced tilt in the direction of the hole's rotation, $+\phi$. At the horizon, the outermost edge of the light cone is tangent to the horizon generators; in Kerr coordinates, as in Boyer-Lindquist, these generators rotate around the horizon with angular velocity $d\tilde{\phi}/d\tilde{t} = \Omega_H$ [cf. Eq. (26.78), which says that at fixed r , $\tilde{t} = t + \text{const}$ and $\tilde{\phi} = \phi + \text{const}$].

This light-cone structure demonstrates graphically that the horizon is at the radius $r = r_H$. Outside there, the outer edge of the light cone tilts toward increasing r , and so it is possible to escape to radial infinity. Inside r_H the outer edge of the light cone tilts inward, and all forms of matter and energy are forced to move inward, toward a singularity whose structure, presumably, is governed by the laws of quantum gravity.⁵

in Kerr coordinates, infalling particles cross the horizon and are pulled on inward

26.5.4

26.5.4 Evolution of Black Holes—Rotational Energy and Its Extraction T2

When a spinning star collapses to form a black hole, its centrifugal forces will flatten it, and the dynamical growth of flattening will produce gravitational radiation (Chap. 27). The newborn hole will also be flattened and will not have the Kerr shape; but rather quickly, within a time $\Delta t \sim 100M \sim 0.5 \text{ ms } (M/M_\odot)$, the deformed hole will shake off its deformations as gravitational waves and settle down into the Kerr shape. This is the conclusion of extensive analyses, both analytic and numerical.

Many black holes are in binary orbits with stellar companions and pull gas off their companions and swallow it. Other black holes accrete gas from interstellar space. Any such accretion causes a hole's mass and spin to evolve in accord with the conservation laws (25.102) and (25.103). One might have thought that by accreting a large amount of angular momentum, a hole's angular momentum per unit mass a could grow larger than its mass M . If this were to happen, then $r_H = M + \sqrt{M^2 - a^2}$ would cease to

newborn black holes settle down into Kerr form

5. Much hoopla has been made of the fact that in the Kerr spacetime it is possible to travel inward, through a "Cauchy horizon" and then into another universe. However, the Cauchy horizon, located at $r = M - \sqrt{M^2 - a^2}$, is highly unstable against perturbations, which convert it into a singularity with infinite spacetime curvature. For details of this instability and the singularity, see, e.g., Brady, Droz, and Morsink (1998), Marolf and Ori (2013), and references therein.

be a real radius—a fact that signals the destruction of the hole’s horizon: as a grows to exceed M , the inward light-cone tilt gets reduced, so that everywhere the outer edge of the cone points toward increasing r , which means that light, particles, and information are no longer trapped.

Remarkably, however, it appears that the laws of general relativity forbid a ever to grow larger than M . As accretion pushes a/M upward toward unity, the increasing drag of inertial frames causes a big increase of the hole’s cross section to capture material with negative angular momentum (which will spin the hole down) and a growing resistance to capturing any further material with large positive angular momentum. Infalling particles that might try to push a/M over the limit get flung back out by huge centrifugal forces, before they can reach the horizon. A black hole, it appears, is totally resistant to having its horizon destroyed.

In 1969, Roger Penrose discovered that a large fraction of the mass of a spinning black hole is in the form of rotational energy, stored in the whirling spacetime curvature outside the hole’s horizon. Although this rotational energy cannot be localized in any precise manner, it nevertheless can be extracted. Penrose discovered this by the following thought experiment, which is called the *Penrose process*.

From far outside the hole, you throw a massive particle into the vicinity of the hole’s horizon. Assuming you are at rest with respect to the hole, your 4-velocity is $\vec{U} = \partial/\partial t$. Denote by $\mathcal{E}_\infty^{\text{in}} = -\vec{p}^{\text{in}} \cdot \vec{U} = -\vec{p}^{\text{in}} \cdot (\partial/\partial t) = -p_t^{\text{in}}$ the energy of the particle (rest mass plus kinetic), as measured by you—its *energy-at-infinity* in the language of Ex. 26.4 and Sec. 4.10.2. As the particle falls, $\mathcal{E}_\infty^{\text{in}} = -p_t^{\text{in}}$ is conserved because of the Kerr metric’s time-translation symmetry. Arrange that, as the particle nears the horizon, it splits into two particles; one (labeled “plunge”) plunges through the horizon and the other (labeled “out”) flies back out to large radii, where you catch it. Denote by $\mathcal{E}_\infty^{\text{plunge}} \equiv -p_t^{\text{plunge}}$ the conserved energy-at-infinity of the plunging particle and by $\mathcal{E}_\infty^{\text{out}} \equiv -p_t^{\text{out}}$ that of the out-flying particle. Four-momentum conservation at the event of the split dictates that $\vec{p}^{\text{in}} = \vec{p}^{\text{plunge}} + \vec{p}^{\text{out}}$, which implies this same conservation law for all components of the 4-momenta, in particular:

$$\mathcal{E}_\infty^{\text{out}} = \mathcal{E}_\infty^{\text{in}} - \mathcal{E}_\infty^{\text{plunge}}. \quad (26.80)$$

Now, it is a remarkable fact that the Boyer-Lindquist time basis vector $\partial/\partial t$ has a squared length $\partial/\partial t \cdot \partial/\partial t = g_{tt} = -\alpha^2 + \varpi^2 \omega^2$ that becomes positive (so $\partial/\partial t$ becomes spacelike) at radii

$$r < r_{\text{ergo}} \equiv M + \sqrt{M^2 - a^2 \cos^2 \theta}. \quad (26.81)$$

Notice that r_{ergo} is larger than r_H everywhere except on the hole’s spin axis: $\theta = 0, \pi$. The region $r_H < r < r_{\text{ergo}}$ is called the hole’s *ergosphere*. If the split into two particles occurs in the ergosphere, then it is possible to arrange the split such that the scalar product of the *timelike* vector \vec{p}^{plunge} with the *spacelike* vector $\partial/\partial t$ is posi-

accretion of matter onto a black hole pushes its spin parameter a up to a maximum value that is a little less than $a = M$

Penrose process for extracting spin energy from a black hole

black hole’s ergosphere

tive, which means that the plunging particle's conserved energy-at-infinity, $\mathcal{E}_\infty^{\text{plunge}} = -\vec{p}^{\text{plunge}} \cdot (\partial/\partial t)$, is negative; whence [by Eq. (26.80)]

$$\mathcal{E}_\infty^{\text{out}} > \mathcal{E}_\infty^{\text{in}}. \quad (26.82)$$

See Ex. 26.16a.

When the outlying particle reaches your location, $r \gg M$, its conserved energy is equal to its physically measured total energy (rest-mass plus kinetic), and the fact that $\mathcal{E}_\infty^{\text{out}} > \mathcal{E}_\infty^{\text{in}}$ means that you get back more energy (rest-mass plus kinetic) than you put in. The hole's asymptotic energy-conservation law (25.102) implies that the hole's mass has decreased by precisely the amount of energy that you have extracted:

$$\Delta M = -(\mathcal{E}_\infty^{\text{out}} - \mathcal{E}_\infty^{\text{in}}) = \mathcal{E}_\infty^{\text{plunge}} < 0. \quad (26.83)$$

A closer scrutiny of this process (Ex. 26.16f) reveals that the plunging particle must have had negative angular momentum, so it has spun the hole down a bit. The energy you extracted, in fact, came from the hole's enormous store of rotational energy, which makes up part of its mass M . Your extraction of energy has reduced that rotational energy.

Stephen Hawking has used sophisticated mathematical techniques to prove that, independently of how you carry out this thought experiment, and, indeed, independently of what is done to a black hole, general relativity requires that the horizon's surface area A_H never decrease. This is called the *second law of black-hole mechanics*, and it actually turns out to be a variant of the second law of thermodynamics in disguise (Ex. 26.16g). A straightforward calculation (Ex. 26.15) reveals that the horizon surface area is given by

$$A_H = 4\pi(r_H^2 + a^2) = 8\pi M r_H \quad \text{for a spinning hole,} \quad (26.84a)$$

$$A_H = 16\pi M^2 \quad \text{for a nonspinning hole, } a = 0. \quad (26.84b)$$

Dimitrios Christodoulou has shown (cf. Ex. 26.16) that, in the Penrose process described here, the nondecrease of A_H is the only constraint on how much energy one can extract, so by a sequence of optimally designed particle injections and splits that keep A_H unchanged, one can reduce the mass of the hole to

$$M_{\text{irr}} = \sqrt{\frac{A_H}{16\pi}} = \sqrt{\frac{M(M + \sqrt{M^2 - a^2})}{2}}, \quad (26.85)$$

but no smaller. This is called the hole's irreducible mass. The hole's total mass is the sum of its irreducible mass and its rotational energy M_{rot} ; so the rotational energy is

$$M_{\text{rot}} = M - M_{\text{irr}} = M \left[1 - \sqrt{\frac{1}{2} \left(1 + \sqrt{1 - a^2/M^2} \right)} \right]. \quad (26.86)$$

the second law of black-hole mechanics

black hole's irreducible mass and rotational energy

For the fastest possible spin, $a = M$, this gives $M_{\text{rot}} = M(1 - 1/\sqrt{2}) \simeq 0.2929M$. This is the maximum amount of energy that can be extracted, and it is enormous compared to the energy $\sim 0.005M$ that can be released by thermonuclear burning in a star of mass M .

The Penrose process of throwing in particles and splitting them in two is highly idealized, and of little or no importance in Nature. However, Nature seems to have found a very effective alternative method for extracting rotational energy from spinning black holes (Blandford and Znajek, 1977; Thorne, Price, and MacDonald, 1986; McKinney, Tchekhovskoy, and Blandford, 2012; Ex. 26.21) in which magnetic fields, threading through a black hole and held on the hole by a surrounding disk of hot plasma, extract energy electromagnetically. This process is thought to power the gigantic jets that shoot out of the nuclei of some active galaxies. It might also be the engine for some powerful gamma-ray bursts.

Blandford-Znajek process by which magnetic fields extract energy from black holes in Nature

EXERCISES

Exercise 26.15 *Derivation: Surface Area of a Spinning Black Hole* T2

From the Kerr metric (26.70) derive Eqs. (26.84) for the surface area of a spinning black hole's horizon—that is, the surface area of the 2-dimensional surface $\{r = r_H, t = \text{constant}\}$.

Exercise 26.16 ***Example: Penrose Process, Hawking Radiation, and Thermodynamics of Black Holes* T2

This exercise is a foundation for the discussion of black-hole thermodynamics in Sec. 4.10.2.

- (a) Consider the Penrose process, described in the text, in which a particle flying inward toward a spinning hole's horizon splits in two inside the ergosphere, and one piece plunges into the hole while the other flies back out. Show that it is always possible to arrange this process so the plunging particle has negative energy-at-infinity: $\mathcal{E}_\infty^{\text{plunge}} = -\vec{p}^{\text{plunge}} \cdot \partial/\partial t < 0$. [Hint: Perform a calculation in a local Lorentz frame in which $\partial/\partial t$ points along a spatial basis vector, \vec{e}_1 . Why is it possible to find such a local Lorentz frame?]
- (b) Around a spinning black hole consider the vector field

$$\vec{\zeta}_H \equiv \partial/\partial t + \Omega_H \partial/\partial \phi, \quad (26.87)$$

where Ω_H is the horizon's angular velocity. Show that at the horizon (at radius $r = r_H$) this vector field is null and is tangent to the horizon generators. Show that all other vectors in the horizon are spacelike.

- (c) In the Penrose process the plunging particle changes the hole's mass by an amount ΔM and its spin angular momentum by an amount ΔJ_H . Show that

$$\Delta M - \Omega_H \Delta J_H = -\vec{p}^{\text{plunge}} \cdot \vec{\zeta}_H. \quad (26.88)$$

Here \vec{p}^{plunge} and $\vec{\zeta}_H$ are to be evaluated at the event where the particle plunges through the horizon, so they both reside in the same tangent space. [Hint: The angular momentum carried into the horizon is the quantity $p_\phi^{\text{plunge}} = \vec{p}^{\text{plunge}} \cdot \partial/\partial\phi$. Why? This quantity is conserved along the plunging particle's world line. Why?] Note that in Sec. 4.10.2, p_ϕ is denoted $\mathbf{j} \cdot \hat{\Omega}_H$ —the projection of the particle's orbital angular momentum on the black hole's spin axis.

- (d) Show that if \vec{A} is any future-directed timelike vector and \vec{K} is any null vector, both living in the tangent space at the same event in spacetime, then $\vec{A} \cdot \vec{K} < 0$. [Hint: Perform a calculation in a specially chosen local Lorentz frame.] Thereby conclude that $-\vec{p}^{\text{plunge}} \cdot \vec{\zeta}_H$ is positive, whatever may be the world line and rest mass of the plunging particle.
- (e) Show that for the plunging particle to decrease the hole's mass, it must also decrease the hole's angular momentum (i.e., it must spin the hole down a bit).
- (f) Hawking's second law of black-hole mechanics says that, whatever may be the particle's world line and rest mass, when the particle plunges through the horizon, it causes the horizon's surface area A_H to increase. This suggests that the always positive quantity $\Delta M - \Omega_H \Delta J_H = -\vec{p}^{\text{plunge}} \cdot \vec{\zeta}_H$ might be a multiple of the increase ΔA_H of the horizon area. Show that this is indeed the case:

$$\Delta M = \Omega_H \Delta J_H + \frac{g_H}{8\pi} \Delta A_H, \quad (26.89)$$

where g_H is given in terms of the hole's mass M and the radius r_H of its horizon by

$$g_H = \frac{r_H - M}{2Mr_H}. \quad (26.90)$$

(You might want to do the algebra, based on Kerr-metric formulas, on a computer.) The quantity g_H (which we have met previously in the Rindler approximation; Ex. 26.11) is called the hole's "surface gravity" for a variety of reasons. One reason is that an observer who hovers just above a horizon generator, blasting his or her rocket engines to avoid falling into the hole, has a 4-acceleration with magnitude g_H/α and thus feels a "gravitational acceleration" of this magnitude; here $\alpha = g^{tt}$ is a component of the Kerr metric called the *lapse function* [Eqs. (26.70) and (26.72)]. This gravitational acceleration is arbitrarily large for an observer arbitrarily close to the horizon (where Δ and hence α are arbitrarily close to zero); when renormalized by α to make it finite, the acceleration is g_H . Equation (26.89) is called the "first law of black-hole mechanics" because of its resemblance to the first law of thermodynamics.

- (g) Stephen Hawking has shown, using quantum field theory, that a black hole's horizon emits thermal (blackbody) radiation. The temperature of this "Hawking radiation," as measured by the observer who hovers just above the horizon, is proportional to the gravitational acceleration g_H/α that the observer measures,

with a proportionality constant $\hbar/(2\pi k_B)$, where \hbar is Planck's reduced constant and k_B is Boltzmann's constant. As this thermal radiation climbs out of the horizon's vicinity and flies off to large radii, its frequencies and temperature get redshifted by the factor α , so as measured by distant observers the temperature is

$$T_H = \frac{\hbar}{2\pi k_B} g_H. \quad (26.91)$$

This suggests a reinterpretation of the first law of black-hole mechanics (26.89) as the first law of thermodynamics for a black hole:

$$\Delta M = \Omega_H \Delta J_H + T_H \Delta S_H, \quad (26.92)$$

where S_H is the hole's entropy [cf. Eq. (4.62)]. Show that this entropy is related to the horizon's surface area by

$$S_H = k_B \frac{A_H}{4L_P^2}, \quad (26.93)$$

where $L_P = \sqrt{\hbar G/c^3} = 1.616 \times 10^{-33}$ cm is the Planck length (with G Newton's gravitation constant and c the speed of light). Because $S_H \propto A_H$, the second law of black-hole mechanics (nondecreasing A_H) is actually the second law of thermodynamics (nondecreasing S_H) in disguise.⁶

- (h) For a 10-solar-mass, nonspinning black hole, what is the temperature of the Hawking radiation in Kelvins, and what is the hole's entropy in units of the Boltzmann constant?
- (i) Reread the discussions of black-hole thermodynamics and entropy in the expanding universe in Secs. 4.10.2 and 4.10.3, which rely on the results of this exercise.

Exercise 26.17 *Problem: Thin Accretion Disks: Circular, Equatorial, Geodesic Orbits around a Kerr Black Hole* T2

Astronomers find and observe black holes primarily through the radiation emitted by infalling gas. Usually this gas has sufficient angular momentum to form an *accretion disk* around the black hole, lying in its equatorial plane. When the gas can cool efficiently, the disk is physically thin. The first step in describing accretion disks is to compute their equilibrium structure, which is usually approximated by assuming that the fluid elements follow circular geodesic orbits and pressure can be ignored.

6. Actually, the emission of Hawking radiation decreases the hole's entropy and surface area; but general relativity is oblivious to this, because general relativity is a classical theory, and Hawking's prediction of the thermal radiation is based on quantum theory. Thus, the Hawking radiation violates the second law of black-hole mechanics. It does not, however, violate the second law of thermodynamics, because the entropy carried into the surrounding universe by the Hawking radiation exceeds the magnitude of the decrease of the hole's entropy. The total entropy of hole plus universe increases.

The next step is to invoke some form of magnetic viscosity that catalyzes the outward transport of angular momentum through the disk and the slow inspiral of the disk's gas. The final step is to compute the spectrum of the emitted radiation. In this problem, we consider only the first step: the gas's circular geodesic orbits.

- (a) Following Ex. 26.12, we can write the 4-velocity in covariant form as $u_\alpha = \{-\mathcal{E}_\infty, u_r, 0, L\}$, where \mathcal{E}_∞ and L are the conserved energy and angular momentum per unit mass, respectively, and u_r describes the radial motion (which we eventually set to zero). Use $u^\alpha u_\alpha = -1$ and $u^r = dr/d\tau$ to show that, for any equatorial geodesic orbit:

$$\frac{1}{2} \left(\frac{dr}{d\tau} \right)^2 + V_{\text{eff}} = 0, \quad \text{where } V_{\text{eff}} = \frac{1 + u^t u_t + u^\phi u_\phi}{2g_{rr}} \quad (26.94a)$$

is an effective potential that includes \mathcal{E}_∞ and L inside itself [by contrast with the effective potential we used for a Schwarzschild black hole, Eq. (26.64a), from which \mathcal{E}_∞ was pulled out].

- (b) Explain why a circular orbit is defined by the twin conditions, $V_{\text{eff}} = 0$, $\partial_r V_{\text{eff}} = 0$, and use the Boyer-Lindquist metric coefficients plus computer algebra to solve for the conserved energy and angular momentum:

$$\mathcal{E}_\infty = \frac{1 - 2M/r \pm aM^{1/2}/r^{3/2}}{(1 - 3M/r \pm 2aM^{1/2}/r^{3/2})^{1/2}}, \quad L = \frac{\pm M^{1/2}r^{1/2} - 2aM/r \pm M^{1/2}a^2/r^{3/2}}{(1 - 3M/r \pm 2aM^{1/2}/r^{3/2})^{1/2}}, \quad (26.94b)$$

where, in \pm , the $+$ is for a prograde orbit (same direction as hole spins) and $-$ is for retrograde.

- (c) Explain mathematically and physically why the angular velocity $\Omega = u^\phi/u^t$ satisfies

$$\frac{\partial \mathcal{E}_\infty}{\partial r} = \Omega \frac{\partial L}{\partial r}, \quad (26.94c)$$

and show that it evaluates to

$$\Omega = \frac{\pm M^{1/2}}{r^{3/2} \pm aM^{1/2}}. \quad (26.94d)$$

- (d) Modify the argument from Ex. 26.12 to show that the binding energy of a gas particle in its smallest, stable, circular, equatorial orbit around a maximally rotating ($a = M$) Kerr hole is $1 - 3^{-1/2} = 0.423$ per unit mass for prograde orbits and $1 - 5/3^{3/2} = 0.0377$ per unit mass for retrograde orbits. The former is a measure of the maximum power that can be released as gas accretes onto a hole through a thin disk in a cosmic object like a quasar. Note that it is two orders of magnitude larger than the energy typically recoverable from nuclear reactions.

For the visual appearance of a thin accretion disk around a black hole, distorted by gravitational lensing (bending of light rays in the Kerr metric), and for other aspects of

a black hole's gravitational lensing, see, for example, James et al. (2015b) and references therein.

Exercise 26.18 *Problem: Thick Accretion Disks* T2

A quite different type of accretion disk forms when the gas is unable to cool. This can occur when its gas supply rate is either very large or very small. In the former case, the photons are trapped by the inflowing gas; in the latter, the radiative cooling timescale exceeds the inflow timescale. (In practice such inflows are likely to produce simultaneous outflows to carry off the energy released.) Either way, pressure and gravity are of comparable importance. There is an elegant description of gas flow close to the black hole as a sort of toroidal star, where the metric is associated with the hole and not the gas. In this problem we make simple assumptions to solve for the equilibrium flow.

- (a) Treat the gas as a perfect fluid, and use as thermodynamic variables its pressure P and enthalpy density w . When the gas supply rate is large, the pressure is generally dominated by radiation. Show that in this case $w = \rho_o + 4P$, with ρ_o the rest-mass density of the plasma. Show, further, that $w = \rho_o + \frac{5}{2}P$ when the pressure is due primarily to nonrelativistic ions and their electrons.
- (b) Assume that the motion is purely azimuthal, so the only nonzero covariant components of the gas's 4-velocity, in the Boyer-Lindquist coordinate system, are u^t and u^ϕ . (In practice there will also be slow poloidal circulation and slow inflow.) Show that the equation of hydrostatic equilibrium (26.31) can be written in the form

$$\frac{P_{,a}}{w} = u^t u_{t,a} + u^\phi u_{\phi,a}, \quad (26.95a)$$

where $a = r, \theta$, and the commas denote partial derivatives.

- (c) Define for the gas the specific energy at infinity, $\mathcal{E}_\infty = -u_t$; the *specific fluid angular momentum*, $\ell = -u_\phi/u_t$ (which is L/\mathcal{E}_∞ in the notation of the previous exercise); and the angular velocity, $\Omega = d\phi/dt = u^\phi/u^t$. Show that Eq. (26.95a) can be rewritten as

$$-\frac{\vec{\nabla} P}{w} = \vec{\nabla} \ln \mathcal{E}_\infty - \frac{\Omega \vec{\nabla} \ell}{1 - \Omega \ell}, \quad (26.95b)$$

where the spacetime gradient $\vec{\nabla}$ has components only in the r and θ directions, and ℓ and \mathcal{E}_∞ are regarded as scalar fields.

- (d) Now make the first simplifying assumption: the gas obeys a *barotropic* equation of state, $P = P(w)$ (cf. Sec. 14.2.2). Show that this assumption implies that the specific angular momentum ℓ is a function of the angular velocity.
- (e) Show that the nonrelativistic limit of this result—applicable to stars like white dwarfs—is that the angular velocity is constant on cylindrical surfaces, which is von Zeipel's theorem (Ex. 13.8).

- (f) Compute the shape of the surfaces on which Ω and ℓ are constant in the r - θ “plane” (surface of constant t and ϕ) for a spinning black hole with $a = 0.9 M$.
- (g) Now make the second simplifying assumption: the specific angular momentum ℓ is constant. Compute the shape of the isobars, also in the r - θ plane, and show that they exhibit a cusp along a circle in the equatorial plane, whose radius shrinks as ℓ increases.
- (h) Compute the specific energy at infinity, \mathcal{E}_∞ , of the isobar that passes through the cusp, and show that it can vanish if ℓ is large enough. Interpret your answer physically.

Of course it is possible to deal with more realistic assumptions about the equation of state and the angular momentum distribution, but this relatively simple model brings out some salient features of the equilibrium flow.

Exercise 26.19 *Problem: Geodetic and Lense-Thirring Precession* T2

- (a) Consider a pulsar in a circular, equatorial orbit around a massive Kerr black hole, with the pulsar’s spin vector \vec{S} lying in the hole’s equatorial plane. Using the fact that the spin vector is orthogonal to the pulsar’s 4-velocity (Sec. 25.7), show that its only nonzero covariant components are S_r , S_ϕ , and $S_t = -\Omega S_\phi$, where $\Omega = d\phi/dt$ is the pulsar’s orbital angular velocity [Eq. (26.94d)]. Now, neglecting usually negligible quadrupole-curvature coupling forces (Sec. 25.7), the spin is parallel-transported along the pulsar’s geodesic, so $\nabla_{\vec{u}}\vec{S} = 0$. Show that this implies

$$\frac{d^2 S_\alpha}{d\tau^2} = \Gamma^\delta_{\alpha\gamma} \Gamma^\beta_{\delta\epsilon} u^\gamma u^\epsilon S_\beta. \quad (26.96a)$$

- (b) Next use Boyer-Lindquist coordinates and the results from Ex. (26.17) plus computer algebra to show that the spatial part of Eq. (26.96a) takes the remarkably simple form

$$\frac{d^2 S_i}{d\tau^2} = -\frac{M S_i}{r^3}, \quad (26.96b)$$

where $i = r, \phi$. Interpret this equation geometrically. In particular, comment on the absence of the hole’s spin parameter a in the context of the dragging of inertial frames, and consider how two counter-orbiting stars would precess relative to each other.

- (c) Explain why the rate of precession of the pulsar’s spin as measured by a distant observer is given by

$$\Omega_p = \Omega - \frac{M^{1/2}}{r^{3/2} u^t}, \quad (26.96c)$$

where $u^t = dt/d\tau$ is the contravariant time component of the pulsar’s 4-velocity.

- (d) Use computer algebra to evaluate Ω_p , and show that a Taylor expansion for $r \gg M$ gives

$$\Omega_p = \frac{3M^{3/2}}{2r^{5/2}} - \frac{aM}{r^3} + \dots \quad (26.96d)$$

The first term on the right-hand side is known as *geodetic* precession; the second as *Lense-Thirring* precession.

Exercise 26.20 *Challenge: General Orbits around a Kerr Black Hole* T2

By combining the techniques used for general orbits around a Schwarzschild black hole (Ex. 26.12) with those for equatorial orbits around a Kerr black hole (Ex. 26.17), explore the properties and shapes of general, geodesic orbits around a Kerr hole. To make progress on this exercise, note that because the Kerr spacetime is not spherically symmetric, the orbits will not, in general, lie in “planes” (2- or 3-dimensional surfaces) of any sort. Correspondingly, one must explore the orbits in 4 spacetime dimensions rather than 3. In addition to the fairly obvious three constants of motion that the Kerr hole shares with Schwarzschild— μ , \mathcal{E}_∞ , and L [Eqs. (26.63)]—there is a fourth called the *Carter constant* after Brandon Carter, who discovered it:

$$\mathcal{Q} = p_\theta^2 + \cos^2 \theta [a^2(\mu^2 - \mathcal{E}_\infty^2) + \sin^{-2} \theta L^2]. \quad (26.97)$$

The numerical integrations are best carried out using Hamilton’s equations for the super-hamiltonian (Ex. 25.7).

Formulas for the geodesics and some of their properties are given in most general relativity textbooks, for example, Misner, Thorne, and Wheeler (1973, Sec. 33.5) and Straumann (2013, Sec. 8.4). For an extensive numerical exploration of the orbital shapes, based on the super-hamiltonian, see Levin and Perez-Giz (2008)—who present and discuss the Hamilton equations in their Appendix A.

Exercise 26.21 *Challenge: Electromagnetic Extraction of Energy from a Spinning Black Hole* T2

As discussed in the text, spinning black holes contain a considerable amount of rotational energy [Eq. (26.86)]. This exercise sketches how this energy may be extracted by an electromagnetic field: the Blandford-Znajek process.

- (a) Suppose that a Kerr black hole, described using Boyer-Lindquist coordinates $\{t, r, \theta, \phi\}$, is orbited by a thick accretion disk (Ex. 26.18), whose surface near the hole consists of two funnels, axisymmetric around the hole’s rotation axis $\theta = 0$ and $\theta = \pi$. Suppose, further, that the funnels’ interiors contain a stationary, axisymmetric electromagnetic field described by a vector potential $A_\alpha(r, \theta)$. The surface of each funnel contains surface current and charge that keep the disk’s interior free of electromagnetic field, and the disk’s gas supplies pressure across the

funnel's surface to balance the electromagnetic stress. Whatever plasma there may be inside the funnel has such low density that the electromagnetic contribution to the stress-energy tensor is dominant, and so we can write $F_{\alpha\beta}J^\beta = 0$ [cf. Eq. (2.81b)]. Show that the electromagnetic field tensor [Eq. (25.61)] in the Boyer-Lindquist coordinate basis can be written $F_{\alpha\beta} = A_{\beta,\alpha} - A_{\alpha,\beta}$, where the commas denote partial derivatives.

- (b) Write $A_\phi = \Phi/(2\pi)$, $A_t = -V$, and by considering the electromagnetic field for $r \gg M$, interpret Φ and V as the magnetic flux contained in a circle of fixed r, θ and the electrical potential of that circle, respectively. This also remains true near the black hole, where we define the magnetic and electric fields as those measured by observers who move orthogonally to the hypersurfaces of constant Boyer-Lindquist time t , so \vec{E} and \vec{B} can be regarded as spatial vectors \mathbf{E} and \mathbf{B} that lie in those hypersurfaces of constant t . Can you prove all this?
- (c) Explain why it is reasonable to expect the electric field \mathbf{E} to be orthogonal to the magnetic field \mathbf{B} near the hole as well as far away, and use Faraday's law to show that its toroidal component $E_{\hat{\phi}}$ must vanish. Thereby conclude that the equipotential surfaces $V = \text{constant}$ coincide with the magnetic surfaces $\Phi = \text{constant}$.
- (d) Define an angular velocity by $\Omega = -2\pi V_{,\theta}/\Phi_{,\theta}$, show that it, too, is constant on magnetic surfaces, and show that an observer who moves with this angular velocity $d\phi/dt = \Omega$ measures vanishing electric field. Thereby conclude that the magnetic field lines rotate rigidly with this angular velocity, and deduce an expression for the electric field \mathbf{E} in terms of Φ and Ω . (You might want to compare with Ex. 19.11.)
- (e) Use the inhomogeneous Maxwell equations to show that the current density J^α describes a flow of charge along the magnetic field lines. Hence calculate the current I flowing inside a magnetic surface. Express \mathbf{B} in terms of I and Φ .
- (f) Now sketch the variation of the electromagnetic field in the funnel both near the horizon and at a large distance from it, assuming that there is an outward flow of energy and angular momentum.
- (g) Use the fact that $\partial/\partial t$ and $\partial/\partial\phi$ are Killing vectors (Ex. 25.5) to confirm that electromagnetic energy and angular momentum are conserved in the funnels.
- (h) We have derived these general principles without giving an explicit solution that demonstrates energy extraction. In order to do this, we must also specify boundary conditions at the horizon of the black hole and at infinity. The former is essentially that the electromagnetic field be nonsingular when measured by an infalling observer or when expressed in Kerr coordinates, for example. The latter describes the flow of energy and angular momentum as outward. Stable solutions can be exhibited numerically and, typically, they have $\Omega \sim 0.3$ to $0.5\Omega_H$ (McKinney, Tchekhovskoy, and Blandford, 2012). These solutions demonstrate

that energy and angular momentum can flow outward across the event horizon so the mass of the black hole gradually decreases. How can this be?

T2

26.6 The Many-Fingered Nature of Time T2

26.6

We conclude this chapter with a discussion of a concept that John Archibald Wheeler (the person who has most clarified the conceptual underpinnings of general relativity) calls the *many-fingered nature of time*.

In the flat spacetime of special relativity there are preferred families of observers: each such family lives in a global Lorentz reference frame and uses that frame to split spacetime into space plus time. The hypersurfaces of constant time (slices of simultaneity) that result from that split are flat hypersurfaces slicing through all of spacetime (Fig. 26.9a). Of course, different preferred families live in different global Lorentz frames and thus split up spacetime into space plus time in different manners (e.g., the dotted and dashed slices of constant time in Fig. 26.9a in contrast to the solid ones). As a result, no universal concept of time exists in special relativity. But at least there are some strong restrictions on time: each inertial family of observers will agree that another family's slices of simultaneity are flat slices.

in special relativity, different inertial observers slice spacetime into space plus time differently, but all slices are flat

In general relativity (i.e., in curved spacetime), even this restriction is gone. In a generic curved spacetime there are no flat hypersurfaces, and hence no candidates for flat slices of simultaneity. In addition, no global Lorentz frames and thus no preferred families of observers exist in a generic curved spacetime. A family of observers who are all initially at rest with respect to one another, and each of whom moves freely (inertially), will soon acquire relative motion because of tidal forces. As a result, their

in general relativity, the slices of constant time have arbitrary shapes; hence, the “many-fingered nature of time”

FIGURE 26.9 Spacetime diagrams showing the slices of simultaneity as defined by various families of observers. (a) Flat spacetime. The three families (those with solid slices, those with dashed, and those with dotted) are inertial, so their slices of constant time are those of global Lorentz frames. (b) Curved spacetime. The two families' slices of simultaneity illustrate the “many-fingered” nature of time. (c) Curved spacetime. The selection of an arbitrary foliation of spacelike hypersurfaces of simultaneity, and the subsequent construction of the world lines of observers who move orthogonally to those hypersurfaces (i.e., for whom light-ray synchronization will define those hypersurfaces as simultaneities).

slices of simultaneity (defined locally by Einstein light-ray synchronization, and then defined globally by patching together the little local bits of slices) may soon become rather contorted. Correspondingly, as is shown in Fig. 26.9b, different families of observers will slice spacetime up into space plus time in manners that can be quite distorted, relative to one another—with “fingers” of one family’s time slices pushing forward, ahead of the other family’s here, and lagging behind there, and pushing ahead in some other place.

In curved spacetime it is best to not even restrict oneself to inertial (freely falling) observers. For example, in the spacetime of a static star, or of the exterior of a Schwarzschild black hole, the family of static observers [observers whose world lines are $\{(r, \theta, \phi) = \text{const}, t \text{ varying}\}$] are particularly simple; their world lines mold themselves to the static structure of spacetime in a simple, static manner. However, these observers are not inertial; they do not fall freely. This need not prevent us from using them to split up spacetime into space plus time, however. Their proper reference frames produce a perfectly good split. When one uses that split, in the case of a black hole, one obtains a 3-dimensional-space version of the laws of black-hole physics that is a useful tool in astrophysical research; see Thorne, Price, and MacDonald (1986).

For any family of observers, accelerated or inertial, the slices of simultaneity as defined by Einstein light-ray synchronization over small distances (or equivalently by the space slices of the observer’s proper reference frames) are the 3-surfaces orthogonal to the observers’ world lines (cf. Fig. 26.9c). To see this most easily, pick a specific event along a specific observer’s world line, and study the slice of simultaneity there from the viewpoint of a local Lorentz frame in which the observer is momentarily at rest. Light-ray synchronization guarantees that locally, the observer’s slice of simultaneity will be the same as that of this local Lorentz frame. Since the frame’s slice is orthogonal to its own time direction and that time direction is the same as the direction of the observer’s world line, the slice is orthogonal to the observer’s world line. By the discussion in Sec. 24.5, the slice is also locally the same (to first order in distance away from the world line) as a slice of constant time in the observer’s proper reference frame.

If the observers rotate around one another (in curved spacetime or in flat), it is not possible to mesh their local slices of simultaneity, defined in this manner, into global slices of simultaneity (i.e., there are no global 3-dimensional hypersurfaces orthogonal to their world lines). We can protect against this eventuality by choosing the slices first: select any family of nonintersecting spacelike slices through the curved spacetime (Fig. 26.9c). Then there will be a family of timelike world lines that are everywhere orthogonal to these hypersurfaces. A family of observers who move along those orthogonal world lines and who define their 3-spaces of simultaneity by local light-ray synchronization will thereby identify the orthogonal hypersurfaces as their simultaneities. Exercise 26.22 illustrates these ideas using Schwarzschild spacetime, and Box 26.3 uses these ideas to visualize a black hole’s spacetime curvature.

an observer’s local slice of physical simultaneity is orthogonal to the observer’s world line

if observers rotate around one another, their local slices of simultaneity cannot mesh; so best to choose time slices first and then compute observers’ orthogonal world lines

BOX 26.3. TENDEX AND VORTEX LINES OUTSIDE A BLACK HOLE T2

When one uses a family of spacelike slices (a *foliation*) with unit normals (4-velocities of orthogonally moving observers) \vec{w} to split spacetime up into space plus time, the electromagnetic field tensor \mathbf{F} splits into the electric field $E^\alpha = F^{\alpha\beta} w_\beta$ and the magnetic field $B^\beta = \frac{1}{2} \epsilon^{\alpha\beta\gamma\delta} F_{\gamma\delta} w_\alpha$. These are 3-vectors lying in the spacelike slices. In terms of components in the observers' proper reference frames, they are $E^{\hat{j}} = F^{\hat{0}\hat{j}}$ and $B^{\hat{i}} = \epsilon^{\hat{i}\hat{j}\hat{k}} F_{\hat{j}\hat{k}}$ (see Sec. 2.11 and especially Fig. 2.9). Similarly, the foliation splits the vacuum Riemann tensor into the symmetric, trace-free tidal field $\mathcal{E}_{\hat{i}\hat{j}} = R_{\hat{i}\hat{0}\hat{j}\hat{0}}$ (which produces relative accelerations $\Delta a_{\hat{i}} = -\mathcal{E}_{\hat{i}\hat{j}} \xi^{\hat{j}}$ of particles separated by $\xi^{\hat{j}}$), and the frame-drag field $\mathcal{B}_{\hat{i}\hat{j}} = \frac{1}{2} \epsilon_{\hat{i}\hat{p}\hat{q}} R^{\hat{p}\hat{q}}_{\hat{j}\hat{0}}$ (which produces differential frame dragging $\Delta \Omega_{\hat{i}} = \mathcal{B}_{\hat{i}\hat{j}} \xi^{\hat{j}}$). See Box 25.2.

Just as the electromagnetic field can be visualized using electric and magnetic field lines that live in the spacelike slices, so also the tidal field $\mathcal{E}_{\hat{i}\hat{j}}$ and frame-drag field $\mathcal{B}_{\hat{i}\hat{j}}$ can each be visualized using integral curves of its three eigenvector fields: the tidal field's tendex lines and the frame-drag field's vortex lines (Box 25.2). These lines lie in the space slices and are often color coded by their eigenvalues, which are called the lines' *tendicities* and (*frame-drag*) *vorticities*.

For a nonspinning (Schwarzschild) black hole, the frame-drag field vanishes (no spin implies no frame dragging); and the tidal field (with slicing either via Schwarzschild coordinate time t or Eddington-Finkelstein coordinate time \tilde{t}) has proper-reference-frame components $\mathcal{E}_{\hat{r}\hat{r}} = -2M/r^3$, $\mathcal{E}_{\hat{\theta}\hat{\theta}} = \mathcal{E}_{\hat{\phi}\hat{\phi}} = +M/r^3$ [Eq. (6) of Box 26.2]. This tidal field's eigenvectors are $\vec{e}_{\hat{r}}$, $\vec{e}_{\hat{\theta}}$, and $\vec{e}_{\hat{\phi}}$, and their integral curves (the tendex lines) are identical to those shown for a weakly gravitating, spherical body in the figure at the bottom left of Box 25.2.

For a black hole with large spin, $a/M = 0.95$ for example, it is convenient to choose as our space slices, hypersurfaces of constant Kerr coordinate time \tilde{t} [Eq. (26.78)], since these penetrate smoothly through the horizon. The tendex and vortex lines that live in those slices have the following forms (Zhang et al., 2012).

The tendex lines are shown on the left and in the central inset; the vortex lines are shown on the right. The horizon is color coded by the sign of the tendicity (left) and vorticity (right) of the lines that emerge from it: blue for positive and red for negative.

The blue tendex lines have positive tendicity, and the tidal-acceleration equation $\Delta a_{\hat{i}} = -\mathcal{E}_{\hat{i}\hat{j}} \xi^{\hat{j}}$ says that a woman whose body is oriented along them

(continued)

BOX 26.3. (continued)

gets squeezed with relative “gravitational” acceleration between head and foot equal to the lines’ tendicity times her body length. The red lines have negative tendicity, so they stretch a man with a head-to-foot relative acceleration equal to the magnitude of their tendicity times his body length. Notice that near the poles of a fast-spinning black hole, the radial tendex lines are blue, and in the equatorial region they are red. Therefore, a man falling into the polar regions of a fast-spinning hole gets squeezed radially, and one falling into the equatorial regions gets stretched radially.

For a woman with her body oriented along a vortex line, the differential frame-drag equation $\Delta\Omega_i = \mathcal{B}_{ij}\xi^j$ says that a gyroscope at her feet precesses clockwise (blue line, positive vorticity) or counterclockwise (red line, negative vorticity) relative to inertial frames at her head. And a gyroscope at her head precesses in that same direction relative to inertial frames at her feet. Thus, the vortex lines can be regarded as either counterclockwise (red) or clockwise (blue). The precessional angular velocity is equal to the line’s (frame-drag) vorticity times the woman’s body length.

Notice that counterclockwise (red) vortex lines emerge from the north polar region of the horizon, swing around the south pole, and descend back into the north polar region. Similarly, (blue) vortex lines emerge from the horizon’s south polar region, swing around the north pole, and descend back into the south. This is similar to the vortex lines for a spinning body in linearized theory (bottom right figure in Box 25.2). The differential precession is counterclockwise along the (red) near-horizon radial lines in the north polar region, because gyroscopes near the horizon are dragged into precession more strongly by the hole’s spin, the nearer one is to the horizon. This also explains the clockwise precession along the (blue) near-horizon radial lines in the south polar region.

For more details about the tendex and vortex lines of Kerr black holes, see Zhang et al. (2012).

Exercise 26.22 *Practice: Slices of Simultaneity in Schwarzschild Spacetime* T2

- (a) One possible choice of slices of simultaneity for Schwarzschild spacetime is the set of 3-surfaces $\{t = \text{const}\}$, where t is the Schwarzschild time coordinate. Show that the unique family of observers for whom these are the simultaneities are the static observers, with world lines $\{(r, \theta, \phi) = \text{const}, t \text{ varying}\}$. Explain why these slices of simultaneity and families of observers exist only outside the horizon of a black hole and cannot be extended into the interior. Draw a picture of the world lines of these observers and their slices of simultaneity in an Eddington-Finkelstein spacetime diagram.
- (b) A second possible choice of simultaneities is the set of 3-surfaces $\{\tilde{t} = \text{const}\}$, where \tilde{t} is the Eddington-Finkelstein time coordinate. What are the world lines of the observers for whom these are the simultaneities? Draw a picture of those world lines in an Eddington-Finkelstein spacetime diagram. Note that they and their simultaneities cover the interior of the hole as well as its exterior.

Bibliographic Note

In our opinion, the best elementary textbook treatment of black holes and relativistic stars is that in Hartle (2003, Chaps. 12, 13, 15, 24); this treatment is also remarkably complete.

For the treatment of relativistic stars at an elementary level, we also recommend Schutz (2009, Chap. 10), and at a more advanced level (including stellar pulsations), Straumann (2013, Chaps. 4, 9) and Misner, Thorne, and Wheeler (1973, Chaps. 31–34).

For the study of black holes at an intermediate level, see Carroll (2004, Chaps. 5, 6), and Hobson, Efstathiou, and Lasenby (2006, Chaps. 9, 11, 13), and at more advanced levels, Wald (1984, Chap. 12), which is brief and highly mathematical, and Straumann (2013, Chap. 7) and Misner, Thorne, and Wheeler (1973, Chaps. 23, 24, 26), which are long and less mathematical.

The above are all portions of general relativity textbooks. There are a number of books and monographs devoted solely to the theory of black holes and/or relativistic stars. Among these, we particularly recommend the following. Shapiro and Teukolsky (1983) is an astrophysically oriented book at much the same level as this chapter, but with much greater detail and extensive applications; it deals with black holes, neutron stars, and white dwarf stars in astrophysical settings. Meier (2012) is a much more up-to-date and quite comprehensive treatment of the astrophysics and observations of black holes of all sizes. Frolov and Novikov (1998) is a thorough monograph on black holes, including their fundamental theory and their interactions with the rest of the universe; it includes extensive references to the original literature and readable summaries of all the important issues that had been treated by black-hole researchers

as of 1997. Chandrasekhar (1983) is an idiosyncratic but elegant and complete monograph on the theory of black holes and especially small perturbations of them. Thorne, Price, and MacDonald (1986) is an equally idiosyncratic monograph that formulates the theory of black holes in 3+1 language, which facilitates physical understanding.

Gravitational Waves and Experimental Tests of General Relativity

A system of moving bodies emits gravitational waves. . . . We shall assume that the speeds of all the system's bodies are small compared to the speed of light [and that the system's gravity is weak]. . . . Because of the presence of matter, the equation for the radiated waves . . . will have the form $\frac{1}{2}\square\psi_i^k = \kappa\tau_i^k$, . . . where τ_i^k . . . contain, along with the [material stress-energy tensor], also terms of quadratic order from [the Einstein tensor].¹

LEV LANDAU AND EVGENY LIFSHITZ (1941)

27.1 Overview

27.1

In 1915, when Einstein formulated general relativity, human technology was inadequate for testing it definitively. Only a half century later did technology begin to catch up. In the years since then, the best experiments have improved from accuracies of a few tens of percent to a part in 10,000 or 100,000, and general relativity has passed the tests with flying colors. In Sec. 27.2, we describe some of these tests, derive general relativity's predictions for them, and discuss the experimental results.

Observations of gravitational waves are changing the character of research on general relativity. As of 2016, they have enabled observational studies of the large-amplitude, highly nonlinear vibrations of curved spacetime triggered when two black holes collide. Thereby, they have produced, for the first time, tests of general relativity when gravity is ultra strong and dynamical. They are enabling high-accuracy studies of relativistic effects in inspiraling black-hole binaries and soon should do the same for neutron stars—where they may also teach us about the equation of state of high-density nuclear matter. In the future, they will enable us to map the spacetime geometries of quiescent black holes with high precision. And they might provide a window into the physical conditions present during the first moments of the expansion of the universe (Sec. 28.7.1).

In this chapter, we develop the theory of gravitational waves in much detail and describe efforts to detect them and the sources that may be seen. More specifically, in Sec. 27.3, we develop the mathematics of gravitational waves, both classically and quantum mechanically (in the language of gravitons), and we study their propagation through flat spacetime. Then, in Sec. 27.4, we study their propagation through curved spacetime using the tools of geometric optics. In Sec. 27.5, we develop the simplest approximate method for computing the generation of gravitational waves, the “quadrupole-moment formalism.” We also describe and present a few details of

1. By including the quadratic terms from the Einstein tensor, Landau and Lifshitz made their analysis of gravitational-wave generation valid for self-gravitating bodies such as binary stars—a remarkable achievement at this early date in the development of gravitational-wave theory.

BOX 27.1. READERS' GUIDE

- This chapter relies significantly on:
 - Chap. 2 on special relativity;
 - Chap. 24 on the transition from special relativity to general relativity;
 - Chap. 25 on the fundamental concepts of general relativity, especially Sec. 25.9 on weak, relativistic gravitational fields;
 - Chap. 26 on relativistic stars and black holes; and
 - Sec. 7.3 on geometric optics.
- In addition, Sec. 27.2.3 on Fermat's principle and gravitational lenses is closely linked to Sec. 7.3.6 on Fermat's principle, Sec. 7.6 on gravitational lenses, and Sec. 8.6 on diffraction at a caustic.
- Portions of this chapter are a foundation for Chap. 28 on cosmology.

other, more sophisticated and accurate methods based on multipolar expansions, post-Newtonian techniques, and numerical simulations on supercomputers (numerical relativity). In Sec. 27.6, we turn to gravitational-wave detection, focusing especially on the Laser Interferometer Gravitational wave Observatory (LIGO), pulsar timing arrays, and the proposed Laser Interferometer Space Antenna (LISA).

27.2 27.2 Experimental Tests of General Relativity

In this section, we describe briefly some of the most important experimental tests of general relativity. For greater detail and other tests, see Will (1993a, 2014).

27.2.1 27.2.1 Equivalence Principle, Gravitational Redshift, and Global Positioning System

A key aspect of the equivalence principle is the prediction that any object, whose size is extremely small compared to the radius of curvature of spacetime and on which no nongravitational forces act, should move on a geodesic. This means, in particular, that its trajectory through spacetime should be independent of its chemical composition. This is called the *weak equivalence principle*, or the *universality of free fall*.

weak equivalence principle
(i.e., universality of free
fall) and tests of it

Efforts to test the universality of free fall date back to Galileo's (perhaps apocryphal) experiment of dropping objects from the leaning tower of Pisa. Over the past century, a sequence of ever-improving experiments led by Roland von Eötvös (ca. 1920), Robert Dicke (ca. 1964), Vladimir Braginsky (ca. 1972), and Eric Adelberger (ca. 2008) have led to an accuracy $\Delta a/a < 2 \times 10^{-13}$ for the difference of gravitational acceleration toward the Sun for Earthbound bodies with very different chemical compositions (Schlamminger et al., 2008). A planned atom-interferometer experiment is designed to reach $\Delta a/a \lesssim 1 \times 10^{-15}$ (Biedermann et al., 2015). A proposed space experiment called *STEP* has the prospect to increase this accuracy to the phenomenal level of $\Delta a/a \lesssim 1 \times 10^{-18}$ (Overduin et al., 2012).

General relativity predicts that bodies with significant self-gravity (even black holes) should also fall, in a nearly homogeneous external gravitational field, with the same acceleration as a body with negligible self-gravity. This prediction, sometimes called the *strong equivalence principle*, has been tested by comparing the gravitational accelerations of Earth and the Moon toward the Sun. Their fractional difference of acceleration (as determined by tracking the relative motions of the Moon and Earth using laser beams fired from Earth, reflected off mirrors that astronauts and cosmonauts have placed on the Moon, and received back at Earth) has been measured to be $\Delta a/a \lesssim 1 \times 10^{-13}$. Since Earth and the Moon have (gravitational potential energy)/(rest-mass energy) $\simeq -4 \times 10^{-10}$ and $\simeq -2 \times 10^{-11}$, respectively, this verifies that gravitational energy falls with the same acceleration as other forms of energy to within about 2.5 parts in 10,000. A recently discovered pulsar, J0337+1715, is in orbit about a white dwarf binary (Ransom et al. 2014). As the gravitational binding energy of the pulsar is roughly 10% of its mass, this will soon allow a high-accuracy test of the strong equivalence principle. For references and for discussions of a variety of other tests of the equivalence principle, see Merkowitz (2010) and Will (1993a, 2014).

tests for self-gravitating bodies

From the equivalence principle one can deduce that, for an emitter and absorber at rest in a Newtonian gravitational field Φ , light (or other electromagnetic waves) must be gravitationally redshifted by an amount $\Delta\lambda/\lambda = \Delta\Phi$, where $\Delta\Phi$ is the difference in Newtonian potential between the locations of the emitter and receiver. (See Ex. 26.4 for a general relativistic derivation when the field is that of a nonspinning, spherical central body with the emitter on the body's surface and the receiver far from the body; see Ex. 24.16 for a derivation when the emitter and receiver are on the floor and ceiling of an Earthbound laboratory.) Relativistic effects produce a correction to this shift of magnitude $\sim(\Delta\Phi)^2$ [cf. Eq. (26.18)], but for experiments performed in the solar system, the currently available precision is too poor to detect this correction, so such experiments test the equivalence principle and not the details of general relativity.

gravitational redshift, and tests of it

The highest-precision test of this gravitational redshift thus far was NASA's 1976 Gravity-Probe-A Project (led by Robert Vessot), in which several atomic clocks were flown to a height of about 10,000 km above Earth and were compared with atomic clocks on Earth via radio signals transmitted downward. After correcting for special relativistic effects due to the relative motions of the rocket's clocks and the Earth clocks, the measured gravitational redshift agreed with the prediction to within the experimental accuracy of about 2 parts in 10,000.

The Global Positioning System (GPS), by which one can routinely determine one's location on Earth to within an accuracy of about 10 m, is based on signals transmitted from a set of Earth-orbiting satellites. Each satellite's position is encoded on its transmitted signals, together with the time of transmission as measured by atomic clocks onboard the satellite. A person's GPS receiver contains a high-accuracy clock and a computer. It measures the signal arrival time and compares with the encoded transmission time to determine the distance from satellite to receiver. It uses

influence of gravitational redshift on GPS

those distances from several satellites, together with the encoded satellite positions, to determine (by triangulation) the receiver's location on Earth.

The transmission times encoded on the signals are corrected for the gravitational redshift before transmission. Without this redshift correction, the satellite clocks would quickly get out of synchronization with all the clocks on the ground, thereby eroding the GPS accuracy; see Ex. 27.1. Thus a clear understanding of general relativity was crucial to the design of GPS!

EXERCISES

Exercise 27.1 *Practice: Gravitational Redshift for GPS*

The GPS satellites are in circular orbits at a height of 20,200 km above Earth's surface, where their orbital period is 12 sidereal hours. If the ticking rates of the clocks on the satellites were not corrected for the gravitational redshift, roughly how long would it take them to accumulate a time shift, relative to clocks on Earth, large enough to degrade the GPS position accuracy by 10 m? by 1 km?

27.2.2

27.2.2 Perihelion Advance of Mercury

It was known at the end of the nineteenth century that the point in Mercury's orbit closest to the Sun, known as its perihelion, advances at a rate of about 575'' per century with respect to the fixed stars, of which about 532'' can be accounted for by Newtonian perturbations due to the other planets. The remaining $\sim 43''$ per century was a mystery until Einstein showed that it can be accounted for quantitatively by the general theory of relativity.

More specifically (as is demonstrated in Ex. 27.2), if we idealize the Sun as non-rotating and spherical (so its external gravitational field is Schwarzschild), we ignore the presence of the other planets, and we note that the radius of Mercury's orbit is very large compared to the Sun's mass (in geometrized units), then Mercury's orbit will be very nearly an ellipse; and the ellipse's perihelion will advance, from one orbit to the next, by an angle

predicted perihelion or periastron advance

$$\Delta\phi = 6\pi M/p + O(M^2/p^2) \text{ radians.} \quad (27.1)$$

Here M is the Sun's mass,² and p is the ellipse's *semi-latus rectum*, which is related to its semimajor axis a (half its major diameter) and its eccentricity e by $p = a(1 - e^2)$. For the parameters of Mercury's orbit ($M = M_\odot \simeq 1.4766 \text{ km}$, $a = 5.79089 \times 10^7 \text{ km}$, $e = 0.205628$), this advance is 0.10352'' per orbit. Since the orbital period is 0.24085 Earth years, this advance corresponds to 42.98'' per century.

Although the Sun is not precisely spherical, its tiny gravitational oblateness (as inferred from measurements of its spectrum of pulsations; Fig. 16.3) has been shown to contribute negligibly to this perihelion advance. In addition, the frame dragging

2. The same formula is true in a binary whose two masses are comparable, with M the sum of the masses.

due to the Sun's rotational angular momentum is also (sadly!) negligible compared to the experimental accuracy, so 42.98'' per century is the relativistic contribution to Mercury's perihelion advance. Modern observational data agree with this to within the data's accuracy of about 1 part in 1,000.

The advance of periastron has also been measured in several binary pulsars. In the double pulsar, PSR J0737-3039 (see Sec. 27.2.4), the rate is 17° yr^{-1} . In practice this is used to measure the masses of the binary's neutron stars, but it also validates Eq. (27.1) for the advance rate at the same level, $\sim 10^{-3}$, as the Mercury measurement, with the important difference that it is testing the influence of having comparable masses.

Gravity in the solar system is weak. Even at Mercury's orbit, the gravitational potential of the Sun is only $|\Phi| \sim 3 \times 10^{-8}$. Therefore, when one expands the spacetime metric in powers of Φ , current experiments with their fractional accuracies $\sim 10^{-5}$ or worse are able to see only the first-order terms beyond Newtonian theory (i.e., terms of *first post-Newtonian order*). To move on to second post-Newtonian order, $O(\Phi^2)$ beyond Newton, in our solar system will require major advances in technology. However, second- and higher-order effects are beginning to be measured via gravitational waves from inspiraling compact binaries, where $|\Phi|$ is $\gtrsim 0.1$.

measurements of perihelion advance of Mercury's orbit

measurements of periastron advance in binary pulsars

higher-order post-Newtonian corrections to periastron advance

Exercise 27.2 Example: Perihelion Advance

Consider a small satellite in a noncircular orbit about a spherical body with much larger mass M , for which the external gravitational field is Schwarzschild. The satellite will follow a timelike geodesic. Orient the Schwarzschild coordinates so the satellite's orbit is in the equatorial plane: $\theta = \pi/2$.

- (a) Because the metric coefficients are independent of t and ϕ , the satellite's energy-at-infinity $\mathcal{E}_\infty = -p_t$ and angular momentum $L = p_\phi$ must be constants of the satellite's motion (Ex. 25.4a). Show that

$$\mathcal{E}_\infty = \left(1 - \frac{2M}{r}\right) \frac{dt}{d\tau}, \quad L = r^2 \frac{d\phi}{d\tau}. \quad (27.2a)$$

See Ex. 26.12. Here and below we take the satellite to have unit mass, so its momentum and 4-velocity are the same, and its affine parameter ζ and proper time τ are the same.

- (b) Introduce the coordinate $u = r^{-1}$ and use the normalization of the 4-velocity to derive the following differential equation for the orbit:

$$\left(\frac{du}{d\phi}\right)^2 = \frac{\mathcal{E}_\infty^2}{L^2} - \left(u^2 + \frac{1}{L^2}\right) (1 - 2Mu). \quad (27.2b)$$

- (c) Differentiate this equation with respect to ϕ to obtain a second-order differential equation:

$$\frac{d^2u}{d\phi^2} + u - \frac{M}{L^2} = 3Mu^2. \quad (27.2c)$$

EXERCISES

By reinstating the constants G , c , and comparing with the Newtonian orbital equation, argue that the right-hand side represents a relativistic perturbation to the Newtonian equation of motion.

- (d) Henceforth in this exercise, assume that $r \gg M$ (i.e., $u \ll 1/M$), and solve the orbital equation (27.2c) by perturbation theory. More specifically, at zero order (i.e., setting the right-hand side to zero), show that the Kepler ellipse (Goldstein, Poole, and Safko, 2002, Sec. 3.7),

$$u_K = \left(\frac{M}{L^2}\right) (1 + e \cos \phi), \quad (27.2d)$$

is a solution. Here e (a constant of integration) is the ellipse's eccentricity, and L^2/M is the ellipse's *semi-latus rectum*, p . The orbit has its minimum radius at $\phi = 0$.

- (e) By substituting u_K from part (d) into the right-hand side of the relativistic equation of motion (27.2c), show (to first-order in the relativistic perturbation) that in one orbit the angle ϕ at which the satellite is closest to the mass advances by $\Delta\phi \simeq 6\pi M^2/L^2$. [Hint: Try to write the differential equation in the form $d^2u/d\phi^2 + (1 + \epsilon)^2u \simeq \dots$, where $\epsilon \ll 1$.]
- (f) For the planet Mercury, using the parameter values given after Eq. (27.1), deduce that the relativistic contribution to the rate of advance of the perihelion (point of closest approach to the Sun) is $42.98''$ per century.

Exercise 27.3 *Example: Gravitational Deflection of Light*

Repeat the analysis of Ex. 27.2 for a photon following a null geodesic. More specifically, do the following.

- (a) Show that the photon trajectory $u(\phi)$ (with $u \equiv 1/r$) obeys the differential equation

$$\frac{d^2u}{d\phi^2} + u = 3Mu^2. \quad (27.3)$$

- (b) Obtain the zeroth-order solution by ignoring the right-hand side:

$$u = \frac{\sin \phi}{b}, \quad (27.4)$$

where b is an integration constant. Show that this is just a straight line in the asymptotically flat region far from the body, and b is the impact parameter (projected distance of closest approach to the body).

- (c) Substitute this solution (27.4) into the right-hand side of Eq. (27.3), and show that the perturbed trajectory satisfies

$$u = \frac{\sin \phi}{b} + \frac{M}{b^2}(1 - \cos \phi)^2. \quad (27.5)$$

- (d) Hence show that a ray with impact parameter $b \gg M$ will be deflected through an angle

$$\Delta\phi = \frac{4M}{b} \quad (27.6)$$

[cf. Eq. (7.87) and associated discussion].

27.2.3 Gravitational Deflection of Light, Fermat's Principle, and Gravitational Lenses

27.2.3

Einstein not only explained the anomalous perihelion shift of Mercury. He also predicted (Ex. 27.3) that the null rays along which starlight propagates will be deflected, when passing through the curved spacetime near the Sun, by an angle

gravitational deflection of starlight

$$\Delta\phi = 4M/b + O(M^2/b^2) \quad (27.7)$$

relative to their trajectories if spacetime were flat. Here M is the Sun's mass, and b is the ray's impact parameter (distance of closest approach to the Sun's center). For comparison, theories that incorporated a Newtonian-like gravitational field into special relativity (Sec 25.1 and Ex. 25.1) predicted no deflection of light rays; the corpuscular theory of light combined with Newtonian gravity predicted half the general relativistic deflection, as did a 1911 principle-of-equivalence argument by Einstein that was ignorant of the curvature of space. The deflection was measured to an accuracy $\sim 20\%$ during the 1919 solar eclipse and agreed with general relativity rather than with the competing theories—a triumph that helped make Einstein famous. Modern experiments, based on the deflection of radio waves from distant quasars, as measured using very long baseline interferometry (interfering the waves arriving at radio telescopes with transcontinental or transworld separations; Sec. 9.3), have achieved accuracies of about 1 part in 10,000, and they agree completely with general relativity. Similar accuracies are now achievable using optical interferometers in space and may soon be achievable via optical interferometry on the ground.

measurements of gravitational light deflection

These accuracies are so great that, when astronomers make maps of the sky using either radio interferometers or optical interferometers, they must now correct for gravitational deflection of the rays not only when the rays pass near the Sun but also for rays coming in from nearly all directions. This correction is not quite as easy as Eq. (27.7) suggests, since that equation is valid only when the telescope is much farther from the Sun than the impact parameter. In the more general case, the correction is more complicated and must include aberration due to the telescope motion as well as the effects of spacetime curvature.

light deflection for large impact parameters: influences on astronomical observations

The gravitational deflection of light rays passing through or near a cluster of galaxies can produce a spectacular array of distorted images of the light source. In Sec. 7.6, we deduced the details of this gravitational lens effect using a model in which we treated spacetime as flat but endowed with a refractive index $n(\mathbf{x}) = 1 - 2\Phi(\mathbf{x})$, where $\Phi(\mathbf{x})$ is the Newtonian gravitational potential of the lensing system. This model can also be used to compute light deflection in the solar system. We now derive this model from general relativity.

gravitational lensing

The foundation for this model is the following general relativistic version of Fermat's principle [see Eq. (7.46) for the Newtonian version]: Consider any static spacetime geometry [i.e., one for which we can introduce a coordinate system in which $\partial g_{\alpha\beta}/\partial t = 0$ and $g_{jt} = 0$; so the only nonzero metric coefficients are $g_{00}(x^k)$ and $g_{ij}(x^k)$]. In such a spacetime the time coordinate t is special, since it is tied to the spacetime's temporal symmetry. An example is Schwarzschild spacetime and the Schwarzschild time coordinate t . Now, consider a light ray emitted from a spatial point $x^j = a^j$ in the static spacetime and received at a spatial point $x^j = b^j$. Assuming the spatial path along which the ray travels is $x^j(\eta)$, where η is any parameter with $x^j(0) = a^j$, $x^j(1) = b^j$, then the total coordinate time Δt required for the light's trip from a^j to b^j is

general relativistic
Fermat's principle

$$\Delta t = \int_0^1 \sqrt{\gamma_{jk} \frac{dx^j}{d\eta} \frac{dx^k}{d\eta}} d\eta, \quad \text{where } \gamma_{jk} \equiv \frac{g_{jk}}{-g_{00}} \quad (27.8)$$

(computed using the fact that the ray must be null so $ds^2 = g_{00}dt^2 + g_{ij}dx^i dx^j = 0$). Fermat's principle says that *the actual spatial trajectory of the light path, in any static spacetime, is one that extremizes this coordinate time lapse.*

This principle can be proved (Ex. 27.4) by showing that the Euler-Lagrange equation for the action (27.8) is equivalent to the geodesic equation for a photon in the static spacetime with metric $g_{\mu\nu}(x^k)$.

Derivation of Index-of-Refraction Model. The index-of-refraction model used to study gravitational lenses in Sec. 7.6 is easily deduced as a special case of this Fermat principle. In a nearly Newtonian situation, the linearized-theory, Lorenz-gauge, trace-reversed metric perturbation has the form (25.91) with only the time-time component being significantly large: $\bar{h}_{00} = -4\Phi$, $\bar{h}_{0j} \simeq 0$, $\bar{h}_{jk} \simeq 0$. Correspondingly, the metric perturbation [obtained by inverting Eq. (25.85)] is $h_{00} = -2\Phi$, $h_{jk} = -2\Phi\delta_{jk}$, and the full spacetime metric $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$ is

$$ds^2 = -(1 + 2\Phi)dt^2 + (1 - 2\Phi)\delta_{jk}dx^j dx^k. \quad (27.9)$$

This is the standard spacetime metric (25.79) in the Newtonian limit with a special choice of spatial coordinates, those of linearized-theory Lorenz gauge. The Newtonian limit includes the slow-motion constraint that time derivatives of the metric are small compared to spatial derivatives [Eq. (25.75b)], so on the timescale for light to travel through a lensing system, the Newtonian potential can be regarded as static: $\Phi = \Phi(x^j)$. Therefore, the Newtonian-limit metric (27.9) can be regarded as static, and the coordinate time lapse along a trajectory between two spatial points, Eq. (27.8), reduces to

Newtonian limit of
Fermat's principle

$$\Delta t = \int_0^L (1 - 2\Phi)d\ell, \quad (27.10)$$

where $d\ell = \sqrt{\delta_{jk}dx^j dx^k}$ is distance traveled treating the coordinates as though they were Cartesian in flat space and L is that total distance between the two points.

According to the relativistic Fermat principle (27.8), this Δt is extremal for light rays. However, Eq. (27.10) is also the action for the Newtonian, nongravitational version of Fermat's principle [Eq. (7.47)], with index of refraction

$$\boxed{n(x^j) = 1 - 2\Phi(x^j)}. \quad (27.11)$$

Therefore, the spatial trajectories of the light rays can be computed via the Newtonian Fermat principle, with the index of refraction (27.11). ■

Although this index-of-refraction model involves treating a special (Lorenz-gauge) coordinate system as though the spatial coordinates were Cartesian and space were flat (so $d\ell^2 = \delta_{jk}dx^jdx^k$)—which does not correspond to reality—nevertheless, this model predicts the correct gravitational lens images. The reason is that it predicts the correct rays through the Lorenz-gauge coordinates, and when the light reaches Earth, the cumulative lensing has become so great that the slight difference in the coordinates here from truly Cartesian has negligible influence on the images one sees.

refractive-index model for computing gravitational lensing when gravity is weak

Exercise 27.4 *Derivation: Fermat's Principle for a Photon's Path in a Static Spacetime* Show that the Euler-Lagrange equation for the action principle (27.8) is equivalent to the geodesic equation for a photon in the static spacetime metric $g_{00}(x^k)$, $g_{ij}(x^k)$. Specifically, do the following.

EXERCISES

- (a) The action (27.8) is the same as that for a geodesic in a 3-dimensional space with metric γ_{jk} and with t playing the role of proper distance traveled [Eq. (25.19) converted to a positive-definite, 3-dimensional metric]. Therefore, the Euler-Lagrange equation for Eq. (27.8) is the geodesic equation in that (fictitious) space [Eq. (25.14) with t the affine parameter]. Using Eq. (24.38c) for the connection coefficients, show that the geodesic equation can be written in the form

$$\gamma_{jk} \frac{d^2x^k}{dt^2} + \frac{1}{2}(\gamma_{jk,l} + \gamma_{jl,k} - \gamma_{kl,j}) \frac{dx^k}{dt} \frac{dx^l}{dt} = 0. \quad (27.12a)$$

- (b) Take the geodesic equation (25.14) for the light ray in the real spacetime, with spacetime affine parameter ζ , and change parameters to coordinate time t . Thereby obtain

$$\begin{aligned} g_{jk} \frac{d^2x^k}{dt^2} + \Gamma_{jkl} \frac{dx^k}{dt} \frac{dx^l}{dt} - \Gamma_{j00} \frac{g_{kl}}{g_{00}} \frac{dx^k}{dt} \frac{dx^l}{dt} + \frac{d^2t/d\zeta^2}{(dt/d\zeta)^2} g_{jk} \frac{dx^k}{dt} &= 0, \\ \frac{d^2t/d\zeta^2}{(dt/d\zeta)^2} + 2\Gamma_{0k0} \frac{dx^k/dt}{g_{00}} &= 0. \end{aligned} \quad (27.12b)$$

- (c) Insert the second of these equations into the first, and write the connection coefficients in terms of derivatives of the spacetime metric. With a little algebra, bring your result into the form Eq. (27.12a) of the Fermat-principle Euler-Lagrange equation.

Shapiro time delay

In 1964, Irwin Shapiro proposed a new experiment to test general relativity: monitor the round-trip travel time for radio waves transmitted from Earth and bounced off Venus or some other planet, or transponded by a spacecraft. As the line-of-sight between Earth and the planet or spacecraft gradually moves nearer and then farther from the Sun, the waves' rays will pass through regions of greater and then smaller spacetime curvature, which will influence the round-trip travel time by greater and then smaller amounts. From the time evolution of the round-trip time, one can deduce the changing influence of the Sun's spacetime curvature.

One can compute the round-trip travel time with the aid of Fermat's (geometric-optics) principle. The round-trip proper time, as measured on Earth (neglecting, for simplicity, Earth's orbital motion; i.e., pretending Earth is at rest relative to the Sun while a radio-wave's rays go out and back), is $\Delta\tau_{\oplus} = \sqrt{1 - 2M/r_{\oplus}} \Delta t \simeq (1 - M/r_{\oplus})\Delta t$, where M is the Sun's mass, r_{\oplus} is Earth's distance from the Sun's center, Δt is the round-trip coordinate time in the static solar-system coordinates, and we have used $g_{00} = -(1 - 2M/r_{\oplus})$ at Earth. Because Δt obeys Fermat's principle, it is stationary under small perturbations of the ray's spatial trajectory. This allows us to compute it using a straight-line trajectory through the spatial coordinate system. Letting b be the impact parameter (the ray's closest coordinate distance to the Sun) and ℓ be coordinate distance along the straight-line trajectory and neglecting the gravitational fields of the planets, we have $\Phi = -M/\sqrt{\ell^2 + b^2}$, so the coordinate time lapse out and back is [Eq. (27.10)]

$$\Delta t = 2 \int_{-\sqrt{r_{\oplus}^2 - b^2}}^{\sqrt{r_{\text{refl}}^2 - b^2}} \left(1 + \frac{2M}{\sqrt{\ell^2 + b^2}} \right) d\ell. \quad (27.13)$$

Here r_{refl} is the radius of the location at which the ray is reflected (or transponded) back to Earth. Performing the integral and multiplying by $\sqrt{g_{00}} \simeq 1 - M/r_{\oplus}$, we obtain for the round-trip travel time measured on Earth:

$$\Delta\tau_{\oplus} = 2 (a_{\oplus} + a_{\text{refl}}) \left(1 - \frac{M}{r_{\oplus}} \right) + 4M \ln \left[\frac{(a_{\oplus} + r_{\oplus})(a_{\text{refl}} + r_{\text{refl}})}{b^2} \right], \quad (27.14)$$

where $a_{\oplus} = \sqrt{r_{\oplus}^2 - b^2}$, and $a_{\text{refl}} = \sqrt{r_{\text{refl}}^2 - b^2}$.

sharply varying term in Shapiro time delay

As Earth and the reflecting planet or transponding spacecraft move along their orbits, only one term in this round-trip time varies sharply: the term

$$\Delta\tau_{\oplus} = 4M \ln(1/b^2) = -8M \ln b \simeq -40 \mu\text{s} \ln b. \quad (27.15)$$

When the planet or spacecraft passes nearly behind the Sun, as seen from Earth, b plunges to a minimum (on a timescale of hours or days) and then rises back up; correspondingly, the time delay shows a sharp blip. By comparing the observed blip with the

theory in a measurement with the Cassini spacecraft, this Shapiro time delay has been verified to the remarkable precision of 2×10^{-5} (Bertotti, Iess, and Tortora, 2003).

The Shapiro effect has been seen in several binary pulsar systems. The two best examples are the double pulsar PSR J0737-3039 and PSR J1614-2230, where the lines of sight pass within 1° of the orbital plane, very close to the companions. The peak Shapiro delays are $51 \mu\text{s}$ and $21 \mu\text{s}$, respectively. Remarkably, in the second example, the neutron star has a well-measured mass of $2.0 M_\odot$, which is large enough to rule out several candidate equations of state for cold nuclear matter (DeMorest et al., 2010) (cf. Sec. 26.3.5).

measurements of Shapiro time delay in the solar system and in binary pulsars

27.2.5 Geodetic and Lense-Thirring Precession

27.2.5

As we have discussed in Secs. 25.9.3 and 26.5, the mass M and the angular momentum \mathbf{J} of a gravitating body place their imprint on the body's asymptotic spacetime metric:

$$ds^2 = - \left(1 - \frac{2M}{r} \right) dt^2 - \frac{4\epsilon_{jkm} J^k x^m}{r^3} dt dx^j + \left[1 + \mathcal{O} \left(\frac{M}{r} \right) \right] \delta_{jk} dx^j dx^k \quad (27.16)$$

[Eq. (25.98c)]. The mass imprint can be deduced from measurements of the orbital angular velocity $\Omega = \sqrt{M/r^3}$ of an object in a circular orbit, and the angular-momentum imprint, from the precession it induces in an orbiting gyroscope [Eq. (25.100)].

As we deduced in Ex. 26.19, there are actually two precessions: geodetic precession and Lense-Thirring precession. The geodetic precession, like the orbital angular velocity, arises from the spherically symmetric part of the metric; it says that the spin of a gyroscope in a circular orbit of radius r will precess around the orbit's angular momentum vector at a rate $\frac{3}{2}(M/r)\Omega$. The Lense-Thirring precession is the average of Eq. (25.100) around the orbit, which gives $\mathbf{J}/(2r^3)$ for a polar orbit, $-\mathbf{J}/r^3$ for an equatorial orbit, and $(-J_i + \frac{3}{2}P_{ij}J_j)/r^3$ for a general circular orbit, where \mathbf{J} is the central body's angular momentum, r is the orbital radius, and P_{ij} projects into the plane of the orbit.

geodetic precession of a gyroscope

Lense-Thirring precession of a gyroscope

The earth-orbiting experiment Gravity Probe B (GP-B), led by Francis Everitt, has measured these two precessions (Everitt et al., 2011). GP-B comprises four spinning spheres (gyroscopes) in one satellite on a polar orbit, and has verified the geodetic precession of $6.6'' \text{ yr}^{-1}$ to a fractional accuracy of 0.003, and the Lense-Thirring precession of $0.040'' \text{ yr}^{-1}$ to fractional accuracy 0.2. More recently, a combination of three satellites, LAGEOS, LAGEOS2, and LARES, has been used to measure the Lense-Thirring precession of an inclined equatorial orbit (rather than a gyroscope in orbit), where the prediction is $J/r^3 = 0.080'' \text{ yr}^{-1}$. A fractional accuracy of 0.05 has been reported (Ciufolini et al., 2016).

measurements of precessions by GP-B and LAGEOS

Relativistic precession has also been observed in six binary pulsar systems. Here we must take account of the pulsar (p) and its compact companion (c). We can give a heuristic argument for the precession rate. When $m_p \ll m_c$, the dominant precession is geodetic in the gravitational field of the companion at a rate $\Omega_p = \frac{3}{2}(m_c/r)\Omega$. In the opposite limit, the companion undergoes orbital Lense-Thirring precession at a

rate $\Omega_p = 2J_p/r^3$ and so the torque is $(2m_c \vec{J}_p/r) \times \vec{\Omega}$, and the reflex precession of the pulsar, about the total (orbital plus spin) angular momentum, will be at a rate $\Omega_p = (2m_c/r)\Omega$. The simplest interpolation between these two limiting cases is

precession in binary pulsars

$$\Omega_p = \Omega \frac{m_c}{r} \frac{(3m_c + 4m_p)}{2(m_c + m_p)}. \quad (27.17)$$

This turns out to be correct. If the orbit is elliptical, we (again) replace the radius r with the *semi-latus rectum* p .

The best measured example is the double pulsar PSR J0737-3039, where pulses from both pulsars were observed. One pulsar has a spin almost aligned with the orbital angular momentum, and so its precession is hard to measure. The other has an inclined spin, which has now precessed so far that the pulses are no longer detected. However, this precession changes the projected shape of the magnetosphere, which occults the pulses from the nonprecessing pulsar, allowing a measurement of the rate of precession of $4.7 \pm 0.6^\circ \text{ yr}^{-1}$, which is consistent with the predicted value of $5.1^\circ \text{ yr}^{-1}$ (Kramer et al., 2006).

measurements of precession in double pulsars

27.2.6

27.2.6 Gravitational Radiation Reaction

Radio observations of binary pulsars have already provided several indirect detections of gravitational waves, via radiation reaction in the binary.

Hulse-Taylor pulsar

The first binary pulsar (PSR B1913+16) was discovered in 1974 by Russell Hulse and Joseph Taylor. One star is a pulsar that emits radio pulses with a period of ~ 59 ms at predictable times (allowing for the slowing down of the pulsar), and their arrival times can be determined to $\sim 15 \mu\text{s}$. Its companion is almost certainly a neutron star, but it does not pulse. The orbital period is roughly 8 hours, and the orbit's eccentricity is ~ 0.6 . The pulses are received at Earth with Shapiro time delays due to crossing the binary orbit, and with other relativistic effects.

We do not know a priori the orbital inclination or the neutron-star masses. However, we obtain one relation between these three quantities by analyzing the Newtonian orbit. A second relation comes from measuring the consequences of the combined second-order Doppler shift and gravitational redshift as the pulsar moves in and out of its companion's gravitational field. A third relation comes from measuring the relativistic precession of the orbit's periastron. From these three relations, one can solve for the stars' masses and the orbital inclination, and as a check can verify that the Shapiro time delay comes out correctly. One can then use the system's parameters to predict the rate of orbital inspiral due to gravitational radiation reaction—a phenomenon with a magnitude of $\sim |\Phi|^{2.5}$ beyond Newton (i.e., 2.5 post-Newtonian order; Sec. 27.5.3). The prediction agrees with the measurements to an accuracy of $\sim 2 \times 10^{-3}$ (Weissberg, Nice, and Taylor, 2010)—a major triumph for general relativity! The agreement is even better, $< 10^{-3}$, for the double pulsar PSR J0737-3039.

measurement of gravitational radiation reaction in binary pulsars

In LIGO's observations of gravitational waves from the inspiral of binary black holes, the radiation reaction is measured with lower accuracy than this, but because the binary is so compact—with M/a increasing from ~ 0.01 to ~ 0.3 —higher-order corrections to the radiation reaction are readily measured.

For reviews of other tests of general relativity using binary pulsars, see Kaspi and Kramer (2016) and papers cited therein.

27.3 Gravitational Waves Propagating through Flat Spacetime

Gravitational waves are ripples in the curvature of spacetime that are emitted by violent astrophysical events and that propagate with the speed of light. It was clear to Einstein and others, even before general relativity was fully formulated, that his theory would have to predict gravitational waves, and within months after completing the theory, Einstein (1916b, 1918) worked out those waves' basic properties.

It turns out that, after they have been emitted, gravitational waves propagate through matter with near impunity: they propagate as though in vacuum, even when other matter and fields are present. (For a proof and discussion see, e.g., Thorne, 1983, Sec. 2.4.3.) This justifies specializing our analysis to vacuum propagation.

27.3.1 Weak, Plane Waves in Linearized Theory

Once the waves are far from their source, the radii of curvature of their phase fronts are huge compared to a wavelength, as is the radius of curvature of the spacetime through which they propagate. Thus to high accuracy, we can idealize the waves as plane-fronted and as propagating through flat spacetime. The appropriate formalism for describing this is the linearized theory developed in Sec. 25.9.2.

We introduce coordinates that are as nearly Lorentz as possible, so the spacetime metric can be written as

$$\boxed{g_{\alpha\beta} = \eta_{\alpha\beta} + h_{\alpha\beta}, \quad \text{with } |h_{\alpha\beta}| \ll 1} \quad (27.18a)$$

[Eq. (25.82)], and we call $h_{\alpha\beta}$ the waves' *metric perturbation*. We perform an “infinitesimal coordinate transformation” (gauge change):

$$x_{\text{new}}^\alpha(\mathcal{P}) = x_{\text{old}}^\alpha(\mathcal{P}) + \zeta^\alpha(\mathcal{P}), \quad \text{which produces } h_{\mu\nu}^{\text{new}} = h_{\mu\nu}^{\text{old}} - \xi_{\mu,\nu} - \xi_{\nu,\mu} \quad (27.18b)$$

[Eqs. (25.87) and (25.88)], with the gauge-change generators $\zeta^\alpha(\mathcal{P})$ chosen to impose the Lorenz gauge condition

$$\boxed{\bar{h}_{\mu\nu}{}^{,\nu} = 0} \quad (27.18c)$$

[Eq. (25.89)] on the new trace-reversed metric perturbation:

$$\boxed{\bar{h}_{\mu\nu} \equiv h_{\mu\nu} - \frac{1}{2}h \eta_{\mu\nu}, \quad h \equiv \eta^{\alpha\beta} h_{\alpha\beta}} \quad (27.18d)$$

27.3

nature of gravitational waves

penetrating power of gravitational waves

27.3.1

linearized theory of gravitational-wave propagation:

metric perturbation

impose Lorenz gauge

trace-reversed metric perturbation

[Eqs. (25.85) and (25.84)]. In this Lorenz gauge, the vacuum Einstein field equation becomes the flat-space wave equation for $\bar{h}^{\mu\nu}$ and so also for $h^{\mu\nu}$:

wave equation

$$\bar{h}_{\mu\nu,\alpha}{}^\alpha = h_{\mu\nu,\alpha}{}^\alpha = 0 \quad (27.18e)$$

[Eq. (25.90)]. Here all indices after a comma are partial derivatives and they are raised with the flat metric $h_{\mu\nu,\alpha}{}^\alpha = h_{\mu\nu,\alpha\beta}\eta^{\beta\alpha}$.

This is as far as we went in vacuum (far from the waves' source) in Chap. 25. We now go further. We simplify the mathematics by orienting the axes of our nearly Lorenz coordinates so the waves are planar and propagate in the z direction. Then the obvious solution to the wave equation (27.18e) and the consequence of the Lorenz gauge condition (27.18c) are

$$\bar{h}_{\mu\nu} = \bar{h}_{\mu\nu}(t - z), \quad \bar{h}_{\mu 0} = -\bar{h}_{\mu z}. \quad (27.19)$$

There are now six independent components of the trace-reversed metric perturbation: the six spatial \bar{h}_{ij} ; the second of Eqs. (27.19) fixes the time-space and time-time components in terms of them.

Remarkably, these six independent components can be reduced to two by a further specialization of gauge. The original infinitesimal coordinate transformation (27.18b), which brought us into Lorenz gauge, relied on four functions $\xi_\mu(\mathcal{P}) = \xi_\mu(x^\alpha)$ of four spacetime coordinates. A more restricted set of gauge-change generators, $\xi_\mu(t - z)$, that are functions solely of retarded time (and thus satisfy the wave equation) will keep us in Lorenz gauge and can be used to annul the four components \bar{h}_{xz} , \bar{h}_{yz} , \bar{h}_{zz} , and $\bar{h} \equiv \eta^{\mu\nu}\bar{h}_{\mu\nu}$, whence (thanks to the Lorenz conditions $\bar{h}_{\mu 0} = -\bar{h}_{\mu z}$) all the $\bar{h}_{\mu 0}$ are also annulled. See Ex. 27.5. As a result, the trace-reversed metric perturbation $\bar{h}_{\mu\nu}$ and the metric perturbation $h_{\mu\nu}$ are now equal, and their only nonzero components are $h_{xx} = -h_{yy}$ and $h_{xy} = +h_{yx}$.

This special new gauge has the name *transverse-traceless gauge* or *TT gauge*, because in it the metric perturbation is purely spatial, it is transverse to the waves' propagation direction (the z direction), and it is traceless. It is convenient to use the notation $h_{\mu\nu}^{\text{TT}}$ for the metric perturbation in this TT gauge, and convenient to give the names h_+ and h_\times to its two independent, nonzero components (which are associated with two polarization states for the waves, “+” and “ \times ”):

further specialization to TT gauge

for locally plane waves propagating in z direction

the metric perturbation in TT gauge; gravitational-wave fields h_+ and h_\times

$$h_{xx}^{\text{TT}} = -h_{yy}^{\text{TT}} = h_+(t - z), \quad h_{xy}^{\text{TT}} = +h_{yx}^{\text{TT}} = h_\times(t - z). \quad (27.20)$$

The Riemann curvature tensor in this TT gauge, as in any gauge, can be expressed as

Riemann tensor

$$R_{\alpha\beta\gamma\delta} = \frac{1}{2}h_{\{\alpha\beta,\gamma\delta\}}^{\text{TT}} \equiv \frac{1}{2}(h_{\alpha\delta,\beta\gamma}^{\text{TT}} + h_{\beta\gamma,\alpha\delta}^{\text{TT}} - h_{\alpha\gamma,\beta\delta}^{\text{TT}} - h_{\beta\delta,\alpha\gamma}^{\text{TT}}) \quad (27.21)$$

[Eq. (25.80)]. Here the subscript symbol $\{\cdot\}$, analogous to $[\cdot]$ for antisymmetrization and (\cdot) for symmetrization, means the combination of four terms on the right side of the \equiv sign. Of particular interest for physical measurements is the relativistic tidal

field $\mathcal{E}_{ij} = R_{i0j0}$, which produces a relative acceleration of freely falling particles [geodesic deviation; Eq. (25.34)]. Since the temporal components of $h_{\mu\nu}^{\text{TT}}$ vanish, the only nonzero term in Eq. (27.21) for R_{i0j0} is the third one, in which the temporal components are derivatives, whence

$$\boxed{\mathcal{E}_{ij} = R_{i0j0} = -\frac{1}{2}\ddot{h}_{ij}^{\text{TT}}; \quad \text{or}} \quad (27.22)$$

$$\boxed{\mathcal{E}_{xx} = -\mathcal{E}_{yy} = -\frac{1}{2}\ddot{h}_+(t-z), \quad \mathcal{E}_{xy} = +\mathcal{E}_{yx} = -\frac{1}{2}\ddot{h}_\times(t-z).}$$

tidal fields

Here the dots mean time derivatives: $\ddot{h}_+(t-x) \equiv \partial^2 h_+ / \partial t^2$. A useful index-free way to write these equations is

$$\boxed{\mathcal{E} = -\frac{1}{2}\ddot{h}^{\text{TT}} = -\frac{1}{2}\ddot{h}_+\mathbf{e}^+ - \frac{1}{2}\ddot{h}_\times\mathbf{e}^\times,} \quad (27.23a)$$

where

$$\boxed{\mathbf{e}^+ = \vec{e}_x \otimes \vec{e}_x - \vec{e}_y \otimes \vec{e}_y, \quad \mathbf{e}^\times = \vec{e}_x \otimes \vec{e}_y + \vec{e}_y \otimes \vec{e}_x} \quad (27.23b)$$

polarization tensors

are the *polarization tensors* associated with the + and \times polarizations, respectively.

It is a very important fact that the Riemann curvature tensor is gauge invariant. An infinitesimal coordinate transformation $x_{\text{new}}^\alpha(\mathcal{P}) = x_{\text{old}}^\alpha(\mathcal{P}) + \xi^\alpha(\mathcal{P})$ changes it by tiny fractional amounts of order ξ^α , by contrast with the metric perturbation, which is changed by amounts of order itself: $\delta h_{\mu\nu} = -2\xi_{(\mu,\nu)}$ (i.e., by fractional amounts of order unity; Ex. 25.19). This has two important consequences. (i) The gauge-invariant Riemann tensor (or its space-time-space-time part, the tidal field) is an optimal tool for discussing physical measurements (Sec. 27.3.2)—a much better tool than, for example, the gauge-dependent metric perturbation. (ii) The gauge invariance of Riemann motivates us to change our viewpoint on h_{ij}^{TT} in the following way.

gauge invariance of Riemann tensor

We define a dimensionless “gravitational-wave field” h_{ij}^{TT} to be minus twice the double time integral of the wave’s tidal field:

$$\boxed{h_{ij}^{\text{TT}} \equiv -2 \int dt \int dt \mathcal{E}_{ij}.} \quad (27.24)$$

alternative viewpoint: gravitational wave field defined in terms of Riemann tensor’s tidal field

And we regard the computation that led to Eq. (27.22) as a demonstration that it is possible to find a gauge in which the metric perturbation is purely spatial and its spatial part is equal to this gravitational-wave field: $h_{0\mu} = 0$ and $h_{ij} = h_{ij}^{\text{TT}}$.

In Box 27.2, we show that, if we have found a gauge in which the metric perturbation propagates as a plane wave at the speed of light, then we can compute the gravitational-wave field h_{ij}^{TT} from that gauge’s $h_{\alpha\beta}$ or $\bar{h}_{\alpha\beta}$ by a simple projection process. This result is useful in the theory of gravitational-wave generation (see, e.g., Sec. 27.5.2).

BOX 27.2. PROJECTING OUT THE GRAVITATIONAL-WAVE FIELD h_{ij}^{TT}

Suppose that, for some gravitational wave, we have found a gauge (not necessarily TT) in which $h_{\mu\nu} = h_{\mu\nu}(t - z)$. Then a simple calculation with Eq. (25.80) reveals that the only nonzero components of this wave's tidal field are $\mathcal{E}_{ab} = -\frac{1}{2}\ddot{h}_{ab}$, where a and b run over x and y . But by definition, $\mathcal{E}_{ab} = -\frac{1}{2}\ddot{h}_{ab}^{\text{TT}}$. Therefore, in this gauge we can compute the gravitational-wave field by simply throwing away all parts of $h_{\mu\nu}$ except the spatial, transverse parts: $h_{xx}^{\text{TT}} = h_{xx}$, $h_{xy}^{\text{TT}} = h_{xy}$, and $h_{yy}^{\text{TT}} = h_{yy}$.

When computing the generation of gravitational waves, it is often easier to evaluate the trace-reversed metric perturbation $\bar{h}_{\alpha\beta}$ than the metric perturbation itself [e.g., Eq. (25.91)]. But $\bar{h}_{\alpha\beta}$ differs from $h_{\alpha\beta}$ by only a trace, and the gravitational-wave field h_{jk}^{TT} is traceless. Therefore, in any gauge where $\bar{h}_{\mu\nu} = \bar{h}_{\mu\nu}(t - z)$, we can compute the gravitational-wave field h_{jk}^{TT} from $\bar{h}_{\mu\nu}$ by throwing away everything except its spatial, transverse part, and by then removing its trace (i.e., by projecting out the spatial, transverse, traceless part):

$$\begin{aligned} h_{jk}^{\text{TT}} &= (\bar{h}_{jk})^{\text{TT}}; \quad \text{or} \\ h_{+} &= h_{xx}^{\text{TT}} = \bar{h}_{xx} - \frac{1}{2}(\bar{h}_{xx} + \bar{h}_{yy}) = \frac{1}{2}(h_{xx} - h_{yy}), \\ h_{\times} &= h_{xy}^{\text{TT}} = \bar{h}_{xy}. \end{aligned} \quad (1)$$

Here the symbol $(\bar{h}_{jk})^{\text{TT}}$ means “project out the spatial, transverse, traceless part.”

If we rotate the spatial axes so the waves propagate along the unit spatial vector \mathbf{n} instead of along \mathbf{e}_z , then the “speed-of-light-propagation” forms of the metric perturbation and its trace reversal become $h_{\alpha\beta} = h_{\alpha\beta}(t - \mathbf{n} \cdot \mathbf{x})$ and $\bar{h}_{\alpha\beta} = \bar{h}_{\alpha\beta}(t - \mathbf{n} \cdot \mathbf{x})$, respectively, and the TT projection can be achieved with the aid of the transverse projection tensor:

$$P^{jk} \equiv \delta^{jk} - n^j n^k. \quad (2)$$

Specifically, we have

$$h_{jk}^{\text{TT}} = (\bar{h}_{jk})^{\text{TT}} = P_j^l P_k^m \bar{h}_{lm} - \frac{1}{2} P_{jk} P^{lm} \bar{h}_{lm}. \quad (3)$$

Here the notation is that of Cartesian coordinates with $P_j^k = P^{jk} = P_{jk}$.

Exercise 27.5 *Derivation: Bringing $h_{\mu\nu}$ into TT Gauge*

Consider a weak, planar gravitational wave propagating in the z direction, written in a general Lorenz gauge [Eqs. (27.19)]. Show that by appropriate choices of new gauge-change generators that have the plane-wave form $\xi_\mu(t-z)$, one can (i) keep the metric perturbation in Lorenz gauge; (ii) annul \bar{h}_{xz} , \bar{h}_{yz} , \bar{h}_{zz} , and $\bar{h} \equiv \eta^{\mu\nu}\bar{h}_{\mu\nu}$; and (iii) thereby make the only nonzero components of the metric perturbation be $h_{xx} = -h_{yy}$ and $h_{xy} = +h_{yx}$. [Hint: Show that a gauge change (27.18b) produces $\bar{h}_{\mu\nu}^{\text{new}} = \bar{h}_{\mu\nu}^{\text{old}} - \xi_{\mu,\nu} - \xi_{\nu,\mu} + \eta_{\mu\nu}\xi_\alpha{}^\alpha$, and use this in your computations.]

27.3.2 Measuring a Gravitational Wave by Its Tidal Forces

27.3.2

We seek physical insight into gravitational waves by studying the following idealized problem. Consider a cloud of test particles that floats freely in space and is static and spherical before the waves pass. Study the wave-induced deformations of the cloud as viewed in the nearest thing there is to a rigid, orthonormal coordinate system: the local Lorentz frame (in the physical spacetime) of a “fiducial particle” that sits at the cloud’s center. In that frame the displacement vector ζ^j between the fiducial particle and some other particle has components $\zeta^j = x^j + \delta x^j$, where x^j is the other particle’s spatial coordinate before the waves pass, and δx^j is its coordinate displacement produced by the waves. By inserting this into the local-Lorentz-frame variant of the equation of geodesic deviation [Eq. (25.34)], and neglecting the tiny δx^k compared to x^k on the right-hand side, we obtain

$$\frac{d^2\delta x^j}{dt^2} = -R_{j0k0}x^k = -\mathcal{E}_{jk}x^k = \frac{1}{2}\ddot{h}_{jk}^{\text{TT}}x^k, \quad (27.25)$$

gravitational-wave tidal acceleration

which can be integrated twice to give

$$\delta x^j = \frac{1}{2}h_{jk}^{\text{TT}}x^k. \quad (27.26)$$

gravitational-wave tidal displacement

Expression (27.25) is the *gravitational-wave tidal acceleration* that moves the particles back and forth relative to one another. It is completely analogous to the Newtonian tidal acceleration, $-\mathcal{E}_{jk}x^k = -(\partial^2\Phi/\partial x^j\partial x^k)x^k$, by which the Moon raises tides on Earth’s oceans (Sec. 25.5.1).

Now specialize to a wave with $+$ polarization (for which $h_\times = 0$). By inserting expression (27.20) into (27.26), we obtain

$$\delta x = \frac{1}{2}h_+x, \quad \delta y = -\frac{1}{2}h_+y, \quad \delta z = 0. \quad (27.27)$$

tidal displacements produced by h_+

This displacement is shown in Fig. 27.1a,b. Notice that as the gravitational-wave field h_+ oscillates at the spherical cloud’s location, the cloud is left undisturbed in the z -direction (propagation direction), and in transverse planes it gets deformed into an ellipse elongated first along the x -axis (when $h_+ > 0$), then along the y -axis (when

FIGURE 27.1 Physical manifestations, in a particle's local Lorentz frame, of h_+ gravitational waves. (a) Transverse deformation of an initially spherical cloud of test particles in a transverse plane at a phase of the wave when $h_+ > 0$. (b) Deformation of the cloud when $h_+ < 0$. (c) Field lines representing the acceleration field $\delta\ddot{\mathbf{x}}$ that produces the cloud's deformation, at a phase when $\ddot{h}_+ > 0$. (d) Acceleration field lines when $\ddot{h}_+ < 0$.

$h_+ < 0$). Because $\mathcal{E}_{xx} = -\mathcal{E}_{yy}$ (i.e., because \mathcal{E}_{jk} is traceless), the ellipse is squashed along one axis by the same amount as it is stretched along the other (i.e., the area of the ellipse is preserved during the oscillations).

The effects of the h_+ polarization state can also be described in terms of the *tidal acceleration field* that it produces in the central particle's local Lorentz frame:

$$\frac{d^2}{dt^2}\delta\mathbf{x} = -\mathcal{E}_+ \cdot \mathbf{x} = \frac{1}{2}\ddot{h}_+(x\mathbf{e}_x - y\mathbf{e}_y), \quad (27.28)$$

where $\ddot{h}_+ \equiv \partial^2 h_+ / \partial t^2$. Notice that this acceleration vector field $\delta\ddot{\mathbf{x}}$ is divergence free. Because it is divergence free, it can be represented by lines of force analogous to electric field lines, which point along the field and have a density of lines proportional to the magnitude of the field. When this is done, the field lines never end. Figure 27.1c,d shows this acceleration field at the phases of oscillation when \ddot{h}_+ is positive and when it is negative. Notice that the field is quadrupolar in shape, with a field strength (density of lines) that increases linearly with distance from the origin of the local Lorentz frame. The elliptical deformations of the spherical cloud of test particles shown in Fig. 27.1a,b are the responses of that cloud to this quadrupolar acceleration field. The polarization state that produces these accelerations and deformations is called the $+$ state because of the orientation of the axes of the quadrupolar acceleration field (Fig. 27.1c,d).

Next consider the \times polarization state. In this state the deformations of the initially spherical cloud are described by

$$\delta x = \frac{1}{2}h_\times y, \quad \delta y = \frac{1}{2}h_\times x, \quad \delta z = 0. \quad (27.29)$$

These deformations, like those for the $+$ state, are purely transverse; they are depicted in Fig. 27.2a,b. The acceleration field that produces these deformations is

$$\frac{d^2}{dt^2}\delta\mathbf{x} = -\mathcal{E}_\times \cdot \mathbf{x} = \frac{1}{2}\ddot{h}_\times(y\mathbf{e}_x + x\mathbf{e}_y). \quad (27.30)$$

h_+ tidal acceleration described by lines of force

tidal effects of h_\times

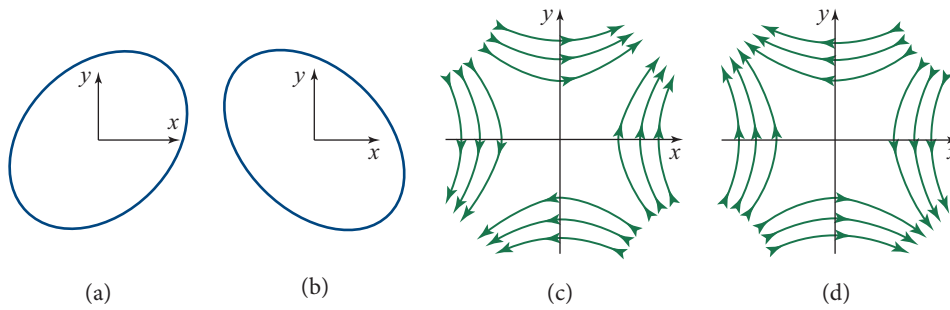

FIGURE 27.2 Physical manifestations, in a particle's local Lorentz frame, of h_{\times} gravitational waves. (a) Deformation of an initially spherical cloud of test particles in a transverse plane at a phase of the wave when $h_{\times} > 0$. (b) Deformation of the sphere when $h_{\times} < 0$. (c) Field lines representing the acceleration field $\delta\ddot{\mathbf{x}}$ that produces the sphere's deformation, at a phase of the wave when $\dot{h}_{\times} > 0$. (d) Acceleration field lines when $\dot{h}_{\times} < 0$.

This acceleration field, like the one for the $+$ polarization state, is divergence free and quadrupolar; the field lines describing it are depicted in Fig. 27.2c,d. The name “ \times polarization state” comes from the orientation of the axes of this quadrupolar acceleration field.

Planar gravitational waves can also be depicted in terms of the tendex and vortex lines associated with their tidal tensor field \mathcal{E} and frame-drag tensor field \mathcal{B} ; see Box 27.3.

When defining the gravitational-wave fields h_{+} and h_{\times} , we have relied on a choice of (local Lorentz) reference frame (i.e., a choice of local Lorentz basis vectors \vec{e}_{α}). Exercise 27.6 explores how these fields change when the basis is changed. The conclusions are simple. (i) When one rotates the transverse basis vectors \vec{e}_x and \vec{e}_y through an angle ψ , then h_{+} and h_{\times} rotate through 2ψ in the sense that:

$$(h_{+} + ih_{\times})_{\text{new}} = (h_{+} + ih_{\times})_{\text{old}} e^{2i\psi}, \quad \text{when } (\vec{e}_x + i\vec{e}_y)_{\text{new}} = (\vec{e}_x + i\vec{e}_y)_{\text{old}} e^{i\psi}. \quad (27.31)$$

(ii) When one boosts from an old frame to a new one moving at some other speed but chooses the old and new spatial bases such that (a) the waves propagate in the z direction in both frames and (b) the plane spanned by \vec{e}_x and $\vec{k} \equiv \vec{e}_0 + \vec{e}_z =$ (propagation direction in spacetime) is the same in both frames, then h_{+} and h_{\times} are the same in the two frames—they are scalars under such a boost! The same is true of the transverse components of the vector potential \mathbf{A} for an electromagnetic wave.

behavior of gravitational wave fields under rotations and boosts

Exercise 27.6 Derivation: Behavior of h_{+} and h_{\times} under Rotations and Boosts

- (a) Derive the behavior [Eq. (27.31)] of h_{+} and h_{\times} under rotations in the transverse plane. [Hint: Write the gravitational-wave field, viewed as a geometric object, as $\mathbf{h}^{\text{TT}} = \Re [(h_{+} + ih_{\times})(\mathbf{e}^{+} - i\mathbf{e}^{\times})]$, where $\mathbf{e}^{+} = (\vec{e}_x \otimes \vec{e}_x - \vec{e}_y \otimes \vec{e}_y)$ and

EXERCISES

BOX 27.3. TENDEX AND VORTEX LINES FOR A GRAVITATIONAL WAVE T2

A plane gravitational wave with + polarization, propagating in the z direction, has as its only nonzero tidal-field components $\mathcal{E}_{xx} = -\mathcal{E}_{yy} = -\frac{1}{2}\ddot{h}_+(t - z)$ [Eq. (27.22)]. This tidal field's eigenvectors are \mathbf{e}_x and \mathbf{e}_y , so its tendex lines (Boxes 25.2 and 26.3) are straight lines pointing along these basis vectors (i.e., the solid lines in the following picture).

These lines' tendicities \mathcal{E}_{xx} and \mathcal{E}_{yy} are equal and opposite, so one set of lines stretches (red) and the other squeezes (blue). As the wave propagates, each line's tendicity oscillates as seen at fixed z , so its color oscillates between red and blue.

From the Maxwell-like Bianchi identity $\partial\mathcal{B}/\partial t = -(\nabla \times \mathcal{E})^S$ (Box 25.2)—with \mathcal{E} a function of $t - \mathbf{n} \cdot \mathbf{x}$, and $\mathbf{n} = \mathbf{e}_z$ the wave's propagation direction—we infer that the wave's frame-drag field and tidal field are related by $\mathcal{B} = (\mathbf{n} \times \mathcal{E})^S$. This means that the nonzero components of \mathcal{B} are $\mathcal{B}_{xy} = \mathcal{B}_{yx} = \mathcal{E}_{xx} = -\mathcal{E}_{yy} = -\frac{1}{2}\ddot{h}_+(t - z)$. Therefore, the gravitational wave's vortex lines are the dashed lines in the figure above (where the propagation direction, $\mathbf{n} = \mathbf{e}_z$, is out of the screen or paper, toward you).

Electric and magnetic field lines are generally drawn with line densities proportional to the magnitude of the field—a convention motivated by flux conservation. Not so for tendex and vortex lines, which have no corresponding conservation law. Instead, their field strengths (tendicities and vorticities) are usually indicated by color coding (see, e.g., Nichols et al., 2011).

Most discussions of gravitational waves (including the text of this chapter) focus on their tidal field \mathcal{E} and its physical stretch and squeeze; they ignore the frame-drag field with its differential precession (twisting) of gyroscopes. The reason is that modern technology is able to detect and monitor the stretch and squeeze, but the precession is far too small to be detected.

$\mathbf{e}^\times = (\vec{e}_x \otimes \vec{e}_y + \vec{e}_y \otimes \vec{e}_x)$ are the polarization tensors associated with + and \times polarized waves, respectively [Eqs. (27.23b)]. Then show that $\mathbf{e}_+ - i\mathbf{e}_\times$ rotates through -2ψ , and use this to infer the desired result.]

- (b) Show that, with the orientations of spatial basis vectors described after Eq. (27.31), h_+ and h_\times are unchanged by boosts.

27.3.3 Gravitons and Their Spin and Rest Mass

27.3.3

Most of the abovementioned features of gravitational waves (though not expressed in this language) were clear to Einstein in 1918. Two decades later, as part of the effort to understand quantum fields, Markus Fierz and Wolfgang Pauli (1939), at the Eidgenössische Technische Hochschule (ETH) in Zurich, Switzerland, formulated a classical theory of linear fields of arbitrary spin so designed that the fields would be quantizable by canonical methods. Remarkably, their canonical theory for a field of spin two and zero rest mass is identical to general relativity with nonlinear effects removed, and the plane waves of that spin-two theory are identical to the waves described above. When quantized by canonical techniques, these waves are carried by zero-rest-mass, spin-two gravitons.

quantization of gravitational waves: gravitons with zero rest mass and spin two

One can see by simple arguments that the gravitons that carry gravitational waves must have zero rest mass and spin two. First, fundamental principles of quantum theory guarantee that any wave that propagates in vacuum with the speed of light must be carried by particles that have that same speed (i.e., particles whose 4-momenta are null, which means particles with zero rest mass). General relativity predicts that gravitational waves propagate with the speed of light. Therefore, its gravitons must have zero rest mass.

elementary explanations of the graviton rest mass and spin

Second, consider any plane-wave field (neutrino, electromagnetic, gravitational, etc.) that propagates at the speed of light in the z -direction of a (local) Lorentz frame. At any moment of time examine any physical manifestation of that field (e.g., the acceleration field it produces on test particles). Rotate that manifestation of the field around the z -axis, and ask what minimum angle of rotation is required to bring the field back to its original configuration. Call that minimum angle, θ_{ret} , the waves' *return angle*. The spin S of the particles that carry the wave will necessarily be related to that return angle by³

$$S = \frac{360^\circ}{\theta_{\text{ret}}}. \quad (27.32)$$

This simple formula corresponds to the elegant mathematical statement that “the waves generate an irreducible representation of order $S = 360^\circ/\theta_{\text{ret}}$ of that subgroup of the Lorentz group that leaves their propagation vector unchanged (the ‘Little group’

3. For spin 0 this formula fails. Spin 0 corresponds to circular symmetry around the spin axis.

of the propagation vector).” For electromagnetic waves, a physical manifestation is the electric field, which is described by a vector lying in the x - y plane; if one rotates that vector about the z -axis (propagation axis), it returns to its original orientation after a return angle $\theta_{\text{ret}} = 360^\circ$. Correspondingly, the spin of the particle that carries the electromagnetic waves (the photon) is one. For neutrinos, the return angle is $\theta_{\text{ret}} = 720^\circ$; and correspondingly, the spin of a neutrino is $\frac{1}{2}$. For gravitational waves, the physical manifestations include the deformation of a sphere of test particles (Figs. 27.1a,b and 27.2a,b) and the acceleration fields (Figs. 27.1c,d and 27.2c,d). Both the deformed, ellipsoidal spheres and the quadrupolar lines of force return to their original orientations after rotation through $\theta_{\text{ret}} = 180^\circ$; correspondingly, the graviton must have spin two. This spin two also shows up in the rotation factor $e^{i2\psi}$ of Eq. (27.31).

Although Fierz and Pauli (1939) showed us how to quantize linearized general relativity, the quantization of full, nonlinear general relativity remains a difficult subject of current research.

27.4 27.4 Gravitational Waves Propagating through Curved Spacetime

Richard Isaacson (1968a,b) has developed a geometric-optics formulation of the theory of gravitational waves propagating through curved spacetime, and as a by-product he has given a rigorous mathematical description of the waves’ stress-energy tensor and thence the energy and momentum carried by the waves. In this section, we sketch the main ideas and results of Isaacson’s analysis.⁴

The foundation for the analysis is a two-lengthscale expansion λ/\mathcal{L} like we used in Sec. 7.3 when formulating geometric optics. For any physical quantity, we identify the wave contribution as the portion that varies on some short lengthscale $\lambda = \lambda/(2\pi)$ (the waves’ reduced wavelength), and the background as the portion that varies on a far longer lengthscale \mathcal{L} (which is less than or of order the background’s spacetime radius of curvature \mathcal{R}); see Fig. 27.3.

To make this idea work, we must use “steady” coordinates (i.e., coordinates that are smooth to as great an extent as the waves permit, on lengthscales shorter than \mathcal{L}). In such coordinates, components of the spacetime metric $g_{\alpha\beta}$ and of the Riemann curvature tensor $R_{\alpha\beta\gamma\delta}$ split into background (B) plus gravitational waves (GW),

$$g_{\alpha\beta} = g_{\alpha\beta}^{\text{B}} + h_{\alpha\beta}, \quad R_{\alpha\beta\gamma\delta} = R_{\alpha\beta\gamma\delta}^{\text{B}} + R_{\alpha\beta\gamma\delta}^{\text{GW}}, \quad (27.33a)$$

where the background quantities are defined as the averages (denoted $\langle \cdot \rangle$) of the full quantities over lengthscales long compared to λ and short compared to \mathcal{L} :

$$g_{\alpha\beta}^{\text{B}} \equiv \langle g_{\alpha\beta} \rangle, \quad R_{\alpha\beta\gamma\delta}^{\text{B}} \equiv \langle R_{\alpha\beta\gamma\delta} \rangle. \quad (27.33b)$$

4. In the 1980s and 1990s, Isaacson, as the Program Director for Gravitational Physics at the U.S. National Science Foundation (NSF), played a crucial role in the creation of the LIGO Project for detecting gravitational waves and in moving LIGO toward fruition.

two-lengthscale expansion for gravitational waves in curved spacetime

steady coordinates

metric and Riemann tensor split into background and gravitational-wave parts

FIGURE 27.3 Heuristic embedding diagram for the decomposition of curved spacetime into a background spacetime plus gravitational waves.

To assist us in solving the Einstein equation, we treat the Einstein tensor $G_{\alpha\beta}$ a bit differently from the metric and Riemann. We begin by expanding $G_{\alpha\beta}$ as a power series in the metric perturbation $h_{\alpha\beta}$: $G_{\alpha\beta} = G_{\alpha\beta}^B + G_{\alpha\beta}^{(1)} + G_{\alpha\beta}^{(2)} + \dots$. Here $G_{\alpha\beta}^B$ is the Einstein tensor computed from the background metric $g_{\alpha\beta}^B$, $G_{\alpha\beta}^{(1)}$ is linear in $h_{\alpha\beta}$, $G_{\alpha\beta}^{(2)}$ is quadratic, and so forth. We then split $G_{\alpha\beta}$ into its rapidly varying part, which is simply $G_{\alpha\beta}^{(1)}$ to leading order, and its smoothly varying part, which through quadratic order is $\langle G_{\alpha\beta} \rangle = G_{\alpha\beta}^B + \langle G_{\alpha\beta}^{(2)} \rangle$. The vacuum Einstein equation $G_{\alpha\beta} = 0$ will be satisfied only if the rapidly and smoothly varying parts both vanish.

In Sec. 27.4.1, by setting the fast-varying part $G_{\alpha\beta}^{(1)}$ to zero, we obtain a wave equation in the background curved spacetime for $h_{\alpha\beta}$ (the gravitational waves), which we can solve (Sec. 27.4.2) using the geometric-optics approximation that underlies this analysis. Then, in Sec. 27.4.3, by setting the slowly varying part $G_{\alpha\beta}^B + \langle G_{\alpha\beta}^{(2)} \rangle$ to zero, we obtain Isaacson's description of gravitational-wave energy and momentum.

27.4.1 Gravitational Wave Equation in Curved Spacetime

27.4.1

The metric perturbation $h_{\alpha\beta}$ can be regarded as a tensor field that lives in the background spacetime.⁵ The rapidly varying part of the Einstein equation, $G_{\alpha\beta}^{(1)} = 0$, gives rise to a wave equation for this tensorial metric perturbation (Isaacson, 1968a; Misner, Thorne, and Wheeler, 1973, Secs. 35.13, 35.14). We can infer this wave equation most easily from a knowledge of the form it takes in any local Lorentz frame of the background (with size $\gg \lambda$ but $\ll \mathcal{L}$). In such a frame, $G_{\alpha\beta}^{(1)} = 0$ must reduce to the field equation of linearized theory [the vacuum version of Eq. (25.83)]. And if we introduce Lorenz gauge [Eq. (27.18c)], then $G_{\alpha\beta}^{(1)} = 0$ must become, in a local Lorentz frame, the vacuum wave equation (27.18e). The frame-invariant versions of these local-Lorentz-frame equations, in the background spacetime, should be obvious. The trace-reversed metric perturbation (27.18d) in frame-invariant form must become

$$\bar{h}_{\mu\nu} \equiv h_{\mu\nu} - \frac{1}{2}h g_{\mu\nu}^B, \quad h \equiv g_B^{\alpha\beta} h_{\alpha\beta}. \quad (27.34a)$$

The Lorenz-gauge condition (27.18c) must become

$$\bar{h}_{\mu\nu|}{}^\nu = 0, \quad (27.34b)$$

Lorenz-gauge condition

5. Actually, this characterization requires that we restrict the coordinates to be steady.

where the $|$ denotes a gradient in the background spacetime (i.e., a covariant derivative computed using connection coefficients constructed from $g_{\mu\nu}^B$) and the index is raised with the background metric, $\bar{h}_{\mu\nu}|^\nu = \bar{h}_{\mu\nu|\alpha} g_B^{\alpha\nu}$. And the gravitational wave equation (Einstein field equation) (27.18e) must become

$$\bar{h}_{\mu\nu|\alpha}{}^\alpha = 0 \quad (27.34c)$$

plus curvature coupling terms, such as $R_{\alpha\mu\beta\nu}^B \bar{h}^{\alpha\beta}$, that result from the noncommutation of the double gradients. The curvature coupling terms have magnitude $h/\mathcal{R}^2 \lesssim h/\mathcal{L}^2$ (where \mathcal{R} is the radius of curvature of the background spacetime; cf. Fig. 27.3), while the terms kept in Eq. (27.34c) have the far-larger magnitude h/λ^2 , so the curvature coupling terms can be (and are) neglected.

27.4.2

27.4.2 Geometric-Optics Propagation of Gravitational Waves

When one solves Eqs. (27.34) using the geometric-optics techniques developed in Sec. 7.3, one obtains precisely the results that one should expect, knowing the solution (27.19) for weak, planar gravitational waves in flat spacetime (linearized theory).

1. If we split $h_{\mu\nu}$ up into two polarization pieces $+$ and \times , each with its own rapidly varying phase φ and slowly varying amplitude $A_{\mu\nu}$, then the Lorenz-gauge, trace-reversed metric perturbation for each piece takes the standard geometric-optics form [eikonal approximation; Eq. (7.20)]:

$$h_{\mu\nu} = \Re(A_{\mu\nu} e^{i\varphi}). \quad (27.35a)$$

2. Because the linearized-theory waves propagate in a straight line (z direction) and travel at the speed of light, the geometric-optics waves propagate through curved spacetime on rays that are null geodesics. More specifically, the wave vector $\vec{k} = \vec{\nabla}\varphi$ is tangent to the null-ray geodesics, and φ is constant along a ray and hence is a rapidly varying function of the retarded time τ_r at which the source (in its own reference frame) emitted the ray:

$$\varphi = \varphi(\tau_r), \quad \vec{k} = \vec{\nabla}\varphi, \quad \vec{k} \cdot \vec{k} = 0, \quad \nabla_{\vec{k}} \vec{k} = 0, \quad \nabla_{\vec{k}} \varphi = 0. \quad (27.35b)$$

3. Because the x - and y -axes that define the two polarizations in linearized theory remain fixed as the wave propagates, for each polarization we can split the amplitude $A_{\mu\nu}$ up into a scalar amplitude A_+ or A_\times , and a polarization tensor \mathbf{e}^+ or \mathbf{e}^\times [like those of Ex. 27.6 and Eqs. (27.23b)], and the polarization tensors are parallel-transported along the rays:

$$A_{\mu\nu} = A e_{\mu\nu}, \quad \nabla_{\vec{k}} \mathbf{e} = 0. \quad (27.35c)$$

4. Because gravitons are conserved (cf. the conservation of quanta in our general treatment of geometric optics, Sec. 7.3.2), the flux of gravitons (which is proportional to the square A^2 of the scalar amplitude) times the cross sectional area \mathcal{A} of a bundle of rays that are carrying the gravitons must be

gravitational wave equation

curvature coupling is negligible

geometric-optics wave propagation

eikonal approximation

rays are null geodesics

polarization tensors are parallel propagated along rays

graviton conservation implies amplitude scales inversely with square root of cross section of a bundle of rays

constant. Therefore, the scalar wave amplitude A must die out as $1/(\text{square root of cross sectional area } \mathcal{A} \text{ of a bundle of rays})$:

$$A \propto 1/\sqrt{\mathcal{A}}. \quad (27.35d)$$

Now, just as the volume of a 3-dimensional fluid element, for a perfect fluid, changes at the rate $d \ln V/d\tau = \vec{\nabla} \cdot \vec{u}$, where \vec{u} is the 4-velocity of the fluid [Eq. (2.65)], so (it turns out) the cross sectional area of a bundle of rays increases as $\vec{\nabla}_{\vec{k}} \mathcal{A} = \vec{\nabla} \cdot \vec{k}$. Therefore, the transport law for the wave amplitude, $A \propto 1/\sqrt{\mathcal{A}}$, becomes

$$\vec{\nabla}_{\vec{k}} A = -\frac{1}{2}(\vec{\nabla} \cdot \vec{k})A. \quad (27.35e)$$

transport law for amplitude

Equations (27.35) are derived more rigorously in Isaacson (1968a) and Misner, Thorne, and Wheeler (1973, Sec. 35.14). They can be used to compute the influence of the cosmological curvature of our universe, and the gravitational fields of intervening bodies, on the propagation of gravitational waves from their sources to Earth. Once the waves have reached Earth, we can compute the measured gravitational-wave fields h_+ and h_\times by projecting out the spatial, transverse-traceless parts of $h_{\mu\nu} = \Re(\mathbf{A}e_{\mu\nu} e^{i\varphi})$, as discussed in Box 27.2.

The geometric-optics propagation of gravitational waves, as embodied in Eqs. (27.35), is essentially identical to that of electromagnetic waves. Both waves, gravitational and electromagnetic, propagate along rays that are null geodesics. Both parallel-transport their polarizations. Both are carried by quanta that are conserved as they propagate along bundles of rays and as a result both have scalar amplitudes that vary as $A \propto 1/\sqrt{\mathcal{A}}$, where \mathcal{A} is the cross sectional area of a ray bundle.

Therefore, gravitational waves must exhibit exactly the same vacuum propagation phenomena as electromagnetic waves: Doppler shifts, cosmological redshifts, gravitational redshifts, gravitational deflection of rays, and gravitational lensing!

In Ex. 27.14, we illustrate this geometric optics propagation of gravitational waves by applying it to the waves from a binary system, which travel outward through our expanding universe.

Exercise 27.7 explores an application where geometric optics breaks down due to diffraction.

gravitational waves exhibit same vacuum propagation phenomena as electromagnetic waves: redshifts, ray deflection, gravitational lensing

Exercise 27.7 ***Example: Gravitational Lensing of Gravitational Waves by the Sun*
Gravitational waves from a distant source travel through the Sun with impunity (negligible absorption and scattering), and their rays are gravitationally deflected. The Sun is quite centrally condensed, so most of the deflection is produced by a central region with mass $M_c \simeq 0.3M_\odot$ and radius $R_c \simeq 10^5 \text{ km} \simeq R_\odot/7$, and the maximum deflection angle is therefore $\Delta\phi \simeq 4M_c/R_c$ [Eq. (27.7)]. A few of the deflected rays, along which the waves propagate according to geometric optics, are shown in Fig. 27.4.

EXERCISES

FIGURE 27.4 Some gravitational-wave rays that pass through the Sun are brought to an imperfect focus at a distance f , the focal length.

- Show that the rays are brought to an imperfect focus and thence produce caustics (Sec. 7.5) at a distance from the Sun (the focal length) $f \sim R_c^2/(4M_c) \sim 38$ AU. A calculation with a more accurate solar model gives $f \sim 20$ AU, which is near the orbit of Uranus.
- If the waves were to have arbitrarily small wavelength λ , then at the caustics, their wave fields h_+ and h_\times would become divergently large (Sec. 7.5). Finite wavelength causes diffraction near the caustics (Sec. 8.6). Explain why the focused field thereby is smeared out over a region with transverse size $\sigma \sim [\lambda/(2R_c)]f \sim [\lambda/(8M_c)]R_c$. [Hint: See Eq. (8.9) and associated discussion.]
- Explain why, if $\sigma \ll R_c$ (i.e., if $\lambda \ll 8M_c \sim 3M_\odot$), substantial focusing occurs, and the field near the caustics is strongly amplified; but if $\sigma \gtrsim R_c$ (i.e., $\lambda \gtrsim 3M_\odot$), there is only slight or no focusing. Explain why it is unlikely that any discrete, strong gravitational-wave sources in the universe emit wavelengths shorter than $3M_\odot \sim 5$ km and therefore are strongly lensed by the Sun.

27.4.3

27.4.3 Energy and Momentum in Gravitational Waves

Now turn from the rapidly varying piece of the vacuum Einstein equation, $G_{\mu\nu}^{(1)} = 0$, to the piece that is averaged over scales long compared to λ and short compared to \mathcal{L} :

$$G_{\alpha\beta}^B + \langle G_{\alpha\beta}^{(2)} \rangle = 0. \quad (27.36)$$

(Recall that $G_{\alpha\beta}^B$ is the Einstein tensor constructed from the slowly varying background metric, and $G_{\alpha\beta}^{(2)}$ is the piece of the full Einstein tensor that is quadratic in the rapidly varying metric perturbation $h_{\mu\nu}$ and that therefore does not average to zero.)

Notice that Eq. (27.36) can be brought into the standard form for Einstein's equation in the background spacetime,

Einstein equation for background metric in vacuum

$$G_{\alpha\beta}^B = 8\pi T_{\alpha\beta}^{\text{GW}}, \quad (27.37)$$

stress-energy tensor for gravitational waves: formal expression

by moving $\langle G_{\alpha\beta}^{(2)} \rangle$ to the right-hand side and then attributing to the waves a stress-energy tensor defined by

$$T_{\alpha\beta}^{\text{GW}} = -\frac{1}{8\pi} \langle G_{\alpha\beta}^{(2)} \rangle. \quad (27.38)$$

Because this stress-energy tensor involves an average over a few wavelengths, its energy density, momentum density, energy flux, and momentum flux are not defined on lengthscales shorter than a wavelength. One cannot say how much energy or momentum resides in the troughs of the waves and how much in the crests. One can only say how much total energy there is in a region containing a few or more wavelengths. However, once reconciled to this amount of nonlocality, one finds that $T_{\alpha\beta}^{\text{GW}}$ has all the other properties expected of any good stress-energy tensor. Most especially, in the absence of coupling of the waves to matter (the situation we are treating), it obeys the standard conservation law:

$$\boxed{T^{\text{GW}}{}^{\alpha\beta}{}_{|\beta} = 0,} \quad (27.39)$$

conservation law for
gravitational-wave energy
and momentum

where, as above, the symbol $|$ denotes the covariant derivative in the background spacetime (i.e., the derivative using the connection coefficients of $g_{\alpha\beta}^{\text{B}}$). This law is a direct consequence of the averaged field equation (27.37) and the contracted Bianchi identity for the background spacetime: $G^{\text{B}}{}^{\alpha\beta}{}_{|\beta} = 0$.

By grinding out the second-order perturbation of the Einstein tensor and inserting it into Eq. (27.38), performing several integrations by parts in the average $\langle \cdot \rangle$, and expressing the result in terms of h_+ and h_\times , one arrives at the following simple expression for $T_{\alpha\beta}^{\text{GW}}$ in terms of the wave fields h_+ and h_\times :

$$\boxed{T_{\alpha\beta}^{\text{GW}} = \frac{1}{16\pi} \langle h_{+, \alpha} h_{+, \beta} + h_{\times, \alpha} h_{\times, \beta} \rangle.} \quad (27.40)$$

stress-energy tensor in
terms of gravitational-
wave fields

[For details of the derivation, see Isaacson (1968b) or Misner, Thorne, and Wheeler (1973, Secs. 35.13, 35.15).]

Let us examine this stress-energy tensor in a local Lorentz frame of the background spacetime where the waves are locally plane and are propagating in the z direction—the kind of frame we used in Sec. 27.3.2 when exploring the properties of gravitational waves. Because in this frame, $h_+ = h_+(t - z)$ and $h_\times = h_\times(t - z)$, the only nonzero components of Eq. (27.40) are

$$\boxed{T^{\text{GW}}{}^{00} = T^{\text{GW}}{}^{0z} = T^{\text{GW}}{}^{z0} = T^{\text{GW}}{}^{zz} = \frac{1}{16\pi} \langle \dot{h}_+^2 + \dot{h}_\times^2 \rangle.} \quad (27.41)$$

This has the same form as the stress-energy tensor for a plane electromagnetic wave propagating in the z direction, and the same form as the stress-energy tensor for any collection of zero-rest-mass particles moving in the z -direction [cf. Eq. (3.32d)], as it must, since the gravitational waves are carried by zero-rest-mass gravitons just as electromagnetic waves are carried by zero-rest-mass photons.

Suppose that the waves have frequency $\sim f$ and that the amplitudes of oscillation of h_+ and h_\times are $\sim h_{\text{amp}}$. Then by inserting factors of G and c into Eq. (27.41) (i.e., by switching from geometrized units to conventional units) and by setting

$\langle (\partial h_+ / \partial t)^2 \rangle \simeq \frac{1}{2} (2\pi f h_{\text{amp}})^2$ and similarly for h_{\times} , we obtain the following approximate expression for the energy flux in the waves:

magnitude of
gravitational-wave
energy flux

$$T^{\text{GW } 0z} \simeq \frac{\pi c^3}{4 G} f^2 h_{\text{amp}}^2 \simeq \frac{0.01 \text{ W}}{\text{m}^2} \left(\frac{f}{200 \text{ Hz}} \right)^2 \left(\frac{h_{\text{amp}}}{10^{-21}} \right)^2. \quad (27.42)$$

The numbers in this equation are those for the first gravitational waves ever detected: LIGO's GW150914 at its peak brightness. Those waves' observed energy flux, $\sim 0.01 \text{ W m}^{-2}$, was several times higher than that from the full moon as seen on Earth, but the waves' source, two $\sim 30 M_{\odot}$ colliding black holes, is ~ 1.2 billion light years away compared to the Moon's distance of 1 light second. Of course, the moon shines steadily, while the holes' collision and this enormous flux lasted for only ~ 20 ms.

For a short gravitational wave burst such as GW150914 (only a few wave cycles, which we shall approximate as just one), the enormous energy flux (27.42) corresponds to a huge mean occupation number for the quantum states of the gravitational-wave field (i.e., a huge value for the number of spin-two, zero-rest-mass gravitons in each quantum state). To compute that occupation number, we evaluate the volume in phase space occupied by the waves and then divide by the volume occupied by each quantum state (cf. Sec. 3.2.5). At a time when the waves have reached a distance r from the source, they occupy a spherical shell of area $4\pi r^2$ and thickness $\sim c/f = 2\pi \lambda$, where $\lambda = 1/(2\pi f)$ is their reduced wavelength, so their volume in physical space is $\mathcal{V}_x \sim 8\pi^2 r^2 \lambda$. As seen by observers whom the waves are passing, they come from a solid angle $\Delta\Omega \sim (2\lambda/r)^2$ centered on the source, and they have a spread of angular frequencies $\Delta\omega \sim \omega = c/\lambda$. Since each graviton carries an energy $\hbar\omega = \hbar c/\lambda$ and a momentum $\hbar\omega/c = \hbar/\lambda$, the volume that they occupy in momentum space is $\mathcal{V}_p \sim (\hbar/\lambda)^3 \Delta\Omega$, or $\mathcal{V}_p \sim 4\hbar^3/(\lambda r^2)$. The gravitons' volume in phase space, then, is

$$\mathcal{V}_x \mathcal{V}_p \sim 32\pi^2 \hbar^3 \sim (2\pi \hbar)^3. \quad (27.43)$$

Since each quantum state for a zero rest-mass particle occupies a volume $(2\pi \hbar)^3$ in phase space [Eq. (3.17) with $g_s = 1$], the total number of quantum states occupied by the gravitons is of order unity! Correspondingly, for a total energy radiated like that of GW150914, $\sim M_{\odot} c^2 \sim 10^{47} \text{ J}$ with each graviton carrying an energy $\hbar c/\lambda \sim 10^{-31} \text{ J}$, the mean occupation number of each occupied state is of order the total number of gravitons emitted:

mean occupation number
for quantum states of
gravitational waves from a
strong gravitational wave
burst

$$\eta \sim \frac{M_{\odot} c^2}{\hbar\omega} \sim 10^{78}. \quad (27.44a)$$

This is the mean occupation number from the viewpoint of the emitter.

A detector on Earth has available to it only those gravitons that pass through a region with transverse size of order their wavelength λ —which means a fraction $(2\pi \lambda)^2/(4\pi r^2)$ of the emitted waves' volume. We can think of the detector as collapsing the gravitons' wave function into that volume. The number of available quantum

states is still of order unity (demonstrate this!), but the number of gravitons occupying them is reduced by this factor, so from the detector's viewpoint, the mean occupation number is

$$\eta_{\text{collapsed}} \sim \frac{M_{\odot} c^2}{\hbar \omega} \frac{(2\pi \lambda)^2}{4\pi r^2} \sim \frac{T^{\text{GW}0z}}{\hbar \omega c} (2\pi \lambda)^3 \sim 10^{39}. \quad (27.44b)$$

Notice that this is the number of gravitons in a cubic wavelength at the wave burst.

Whichever viewpoint one takes, the occupation number is enormous. It guarantees that the waves behave exceedingly classically; quantum-mechanical corrections to the classical theory have fractional magnitude $1/\sqrt{\eta} \sim 10^{-39}$, or $\sim 10^{-20}$.

27.5 The Generation of Gravitational Waves

When analyzing the generation of gravitational waves, it is useful to divide space around the source (in the source's rest frame) into the regions shown in Fig. 27.5.

If the source has size $L \lesssim M$, where M is its mass, then spacetime is strongly curved inside and near it, and we refer to it as a *strong-gravity source*. The region with radii (measured from its center of mass) $r \lesssim 10M$ is called the source's *strong-field region*. Examples of strong-gravity sources are vibrating or spinning neutron stars, and merging binary black holes. The region with radii $10M \lesssim r \lesssim \lambda$ (the reduced wavelength of the emitted waves) is called the source's *weak-field near zone*. In this region, the source's gravity is fairly well approximated by Newtonian theory and a Newtonian gravitational potential Φ . As in electromagnetic theory, the region $\lambda \lesssim r \lesssim \lambda$ is called the *induction zone* or the *intermediate zone*. The *wave zone* begins at $r \sim \lambda = 2\pi \lambda$.

It is useful to divide the wave zone into two parts: a part near the source ($r \lesssim r_o$ for some r_o) called the *local wave zone*, in which the spacetime curvatures of external bodies and of the universe as a whole are unimportant, and the *distant wave zone* ($r \gtrsim r_o$), in which the emitted waves are significantly affected by external bodies and the external universe (i.e., by background spacetime curvature). The theory of

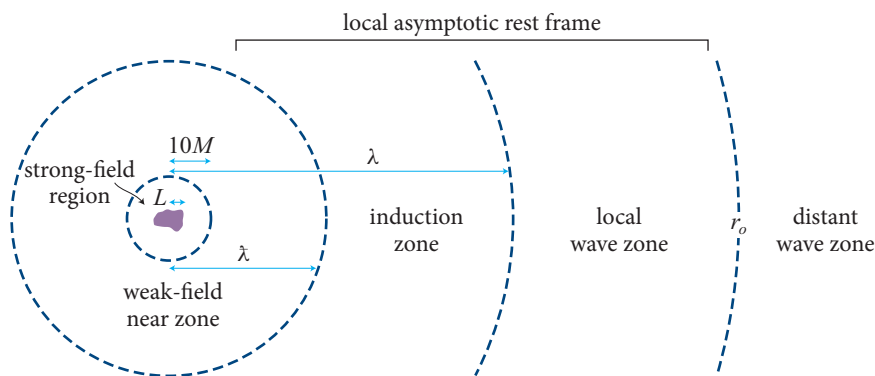

FIGURE 27.5 Regions of space around a source of gravitational waves.

mean occupation number from viewpoint of a detector on Earth

27.5

regions of space around a gravitational-wave source: Fig. 27.5

theory of wave generation predicts waves in source's local wave zone; geometric optics carries them onward through distant wave zone

gravitational-wave generation deals with computing, from the source's dynamics, the gravitational waves in the local wave zone. Propagation of the waves to Earth is dealt with by using geometric optics (or other techniques) to carry the waves from the local wave zone outward, through the distant wave zone, to Earth.

source's local asymptotic rest frame

The entire region in which gravity is weak and the spacetime curvatures of external bodies and the universe are unimportant ($10M \lesssim r \lesssim r_o$)—when viewed in nearly Lorentz coordinates in which the source is at rest—is called the source's *local asymptotic rest frame*.

27.5.1

27.5.1 Multipole-Moment Expansion

The electromagnetic waves emitted by a dynamical charge distribution are usually expressed as a sum over the source's multipole moments. There are two families of moments: the electric moments (moments of the electric-charge distribution) and the magnetic moments (moments of the electric-current distribution).

source's mass moments and current moments

Similarly, the gravitational waves emitted by a dynamical distribution of mass-energy and momentum can be expressed, in the local wave zone, as a sum over multipole moments. Again there are two families of moments: the *mass moments* (moments of the mass-energy distribution) and the *current moments* (moments of the mass-current distribution, i.e., the momentum distribution). The multipolar expansion of gravitational waves is developed in great detail in Blanchet (2014) and Thorne (1980). In this section, we sketch and explain its qualitative and order-of-magnitude features.

In the source's weak-gravity near zone (if it has one), the mass moments show up in the time-time part of the metric in a form familiar from Newtonian theory:

multipolar expansion of metric outside a source

$$g_{00} = -(1 + 2\Phi) = -1 \& \frac{\mathcal{I}_0}{r} \& \frac{\mathcal{I}_1}{r^2} \& \frac{\mathcal{I}_2}{r^3} \& \dots \quad (27.45)$$

[cf. Eq. (25.79)]. Here r is radius, \mathcal{I}_ℓ is the mass moment of order ℓ , and “&” means “plus a term with the form” (i.e., a term whose magnitude and parameter dependence are shown but whose multiplicative numerical coefficients do not interest us, at least not for the moment). The mass monopole moment \mathcal{I}_0 is the source's mass, and the mass dipole moment \mathcal{I}_1 can be made to vanish by placing the origin of coordinates at the center of mass [Eq. (25.96) and Ex. 25.21].

In the source's weak-gravity near zone, its current moments \mathcal{S}_ℓ similarly show up in the space-time part of the metric:

$$g_{0j} = \frac{\mathcal{S}_1}{r^2} \& \frac{\mathcal{S}_2}{r^3} \& \dots \quad (27.46)$$

Just as there is no magnetic monopole moment in classical electromagnetic theory, so there is no current monopole moment in general relativity. The current dipole moment \mathcal{S}_1 is the source's angular momentum J_k , so the leading-order term in the expansion (27.46) has the form (25.98c), which we have used to deduce the angular momenta of gravitating bodies.

If the source has mass M , size L , and internal velocities $\sim v$, then the magnitudes of its moments are

$$\mathcal{I}_\ell \sim ML^\ell, \quad \mathcal{S}_\ell \sim MvL^\ell. \quad (27.47)$$

magnitudes of moments

These formulas guarantee that the near-zone fields g_{00} and g_{0j} , as given by Eqs. (27.45) and (27.46), are dimensionless.

As the source's moments oscillate dynamically, they produce gravitational waves. Mass-energy conservation [Eq. (25.102)] prevents the mass monopole moment $\mathcal{I}_0 = M$ from oscillating; angular-momentum conservation [Eq. (25.103)] prevents the current dipole moment $\mathcal{S}_1 =$ (angular momentum) from oscillating; and because the time derivative of the mass dipole moment \mathcal{I}_1 is the source's linear momentum, momentum conservation [Eq. (25.106)] prevents the mass dipole moment from oscillating. Therefore, the lowest-order moments that can oscillate and thereby contribute to the waves are the quadrupolar ones. The wave fields h_+ and h_\times in the source's local wave zone must (i) be dimensionless, (ii) die out as $1/r$, and (iii) be expressed as a sum over derivatives of the multipole moments. These considerations guarantee that the waves will have the following form:

lowest-order moments that produce gravitational waves are quadrupolar

$$h_+ \sim h_\times \sim \frac{\partial^2 \mathcal{I}_2 / \partial t^2}{r} \& \frac{\partial^3 \mathcal{I}_3 / \partial t^3}{r} \& \dots \& \frac{\partial^2 \mathcal{S}_2 / \partial t^2}{r} \& \frac{\partial^3 \mathcal{S}_3 / \partial t^3}{r} \& \dots$$

(27.48)

multipolar expansion of gravitational waves

(Ex. 27.8).

The timescale on which the moments oscillate is $T \sim L/v$, so each time derivative produces a factor v/L . Correspondingly, the ℓ -pole contributions to the waves have magnitudes

$$\frac{\partial^\ell \mathcal{I}_\ell / \partial t^\ell}{r} \sim \frac{M}{r} v^\ell, \quad \frac{\partial^\ell \mathcal{S}_\ell / \partial t^\ell}{r} \sim \frac{M}{r} v^{(\ell+1)}. \quad (27.49)$$

This means that, for a *slow-motion source* (one with internal velocities v small compared to light, so the reduced wavelength $\lambda \sim L/v$ is large compared to the source size L), the mass quadrupole moment \mathcal{I}_2 will produce the strongest waves. The mass octupole (3-pole) waves and current quadrupole waves will be weaker by $\sim v \sim L/\lambda$; the mass 4-pole and current octupole waves will be weaker by $\sim v^2 \sim L^2/\lambda^2$, and so forth. This is analogous to the electromagnetic case, where the electric dipole waves are the strongest, the electric quadrupole and magnetic dipole are smaller by $\sim L/\lambda$, and so on.

for slow-motion source: relative magnitudes of gravitational waves' multipolar components

In the next section, we develop the theory of mass quadrupole gravitational waves. For the corresponding theory of higher-order multipoles, see, for example, Thorne (1980, Secs. IV and VIII) and Blanchet (2014). In Sec. 27.5.3, we will see that a source's mass quadrupole waves cannot, by themselves, carry net linear momentum. Net wave momentum and the corresponding recoil of the source require a beating of mass quadrupole waves against current quadrupole or mass octupole waves.

EXERCISES

Exercise 27.8 *Derivation: Multipolar Expansion of Gravitational Waves*

Show that conditions (i), (ii), and (iii) preceding Eq. (27.48) guarantee that the multipolar expansion of the gravitational-wave fields will have the form (27.48).

27.5.2 27.5.2 Quadrupole-Moment Formalism

Consider a weakly gravitating, nearly Newtonian system (which is guaranteed to be a slow-motion gravitational-wave source, since Newtonian theory requires internal velocities $v \ll 1$). An example is a binary star system. Write the system's Newtonian potential (in its near zone) in the usual way:

$$\Phi(\mathbf{x}) = - \int \frac{\rho(\mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|} dV_{x'}. \quad (27.50)$$

By using Cartesian coordinates, placing the origin of coordinates at the center of mass so $\int \rho x^j dV_x = 0$, and expanding:

$$\frac{1}{|\mathbf{x} - \mathbf{x}'|} = \frac{1}{r} + \frac{x^j x^{j'}}{r^3} + \frac{x^j x^k (3x^{j'} x^{k'} - r'^2 \delta_{jk})}{2r^5} + \dots, \quad (27.51)$$

we obtain the multipolar expansion of the Newtonian potential:

$$\Phi(\mathbf{x}) = -\frac{M}{r} - \frac{3\mathcal{I}_{jk} x^j x^k}{2r^5} + \dots \quad (27.52)$$

Here

$$M = \int \rho dV_x, \quad \mathcal{I}_{jk} = \int \rho \left(x^j x^k - \frac{1}{3} r^2 \delta_{jk} \right) dV_x \quad (27.53)$$

are the system's mass and mass quadrupole moment. Note that the mass quadrupole moment is equal to the second moment of the mass distribution with its trace removed.

As we have discussed, dynamical oscillations of the quadrupole moment generate the source's strongest gravitational waves. Those waves must be describable, in the source's near zone and local wave zone, by an outgoing-wave solution to the Lorenz-gauge, linearized Einstein equation,

$$\bar{h}_{\mu\nu, \nu} = 0, \quad \bar{h}_{\mu\nu, \alpha}{}^\alpha = 0 \quad (27.54)$$

[Eqs. (25.89) and (25.90)], that has the near-zone Newtonian limit:

$$\frac{1}{2}(\bar{h}_{00} + \bar{h}_{xx} + \bar{h}_{yy} + \bar{h}_{zz}) = h_{00} = -(\text{quadrupole part of } 2\Phi) = \frac{3\mathcal{I}_{jk} x^j x^k}{r^5} \quad (27.55)$$

[cf. Eq. (25.79)].

for nearly Newtonian source: multipolar expansion of Newtonian potential

The desired solution can be written in the form

$$\bar{h}_{00} = 2 \left[\frac{\mathcal{I}_{jk}(t-r)}{r} \right]_{,jk}, \quad \bar{h}_{0j} = 2 \left[\frac{\dot{\mathcal{I}}_{jk}(t-r)}{r} \right]_{,k}, \quad \bar{h}_{jk} = 2 \frac{\ddot{\mathcal{I}}_{jk}(t-r)}{r}, \quad (27.56)$$

where the coordinates are Cartesian, $r \equiv \sqrt{\delta_{jk}x^jx^k}$, and the dots denote time derivatives. To verify that this is the desired solution: (i) Compute its divergence $\bar{h}_{\alpha\beta,}{}^\beta$ and obtain zero almost trivially. (ii) Notice that each Lorentz-frame component of $\bar{h}_{\alpha\beta}$ has the form $f(t-r)/r$ aside from some derivatives that commute with the wave operator, which implies that it satisfies the wave equation. (iii) Notice that in the near zone, the slow-motion assumption inherent in the Newtonian limit makes the time derivatives negligible, so $\bar{h}_{jk} \simeq 0$ and \bar{h}_{00} is twice the right-hand side of Eq. (27.55), as desired.

Because the trace-reversed metric perturbation (27.56) in the local wave zone has the speed-of-light-propagation form, aside from its very slow decay as $1/r$, we can compute the gravitational-wave field h_{jk}^{TT} from it by transverse-traceless projection [Eq. (3) of Box 27.2 with $\mathbf{n} = \mathbf{e}_r$]:

$$h_{jk}^{\text{TT}} = 2 \left[\frac{\ddot{\mathcal{I}}_{jk}(t-r)}{r} \right]^{\text{TT}}. \quad (27.57)$$

This is called the *quadrupole-moment formula for gravitational-wave generation*. Our derivation shows that it is valid for any nearly Newtonian source.

Looking back more carefully at the derivation, one can see that, in fact, it relies only on the linearized Einstein equation and the Newtonian potential in the source's local asymptotic rest frame. Therefore, *this quadrupole formula is also valid for slow-motion sources that have strong internal gravity (e.g., slowly spinning neutron stars), so long as we read the quadrupole moment $\mathcal{I}_{jk}(t-r)$ off the source's weak-field, near-zone Newtonian potential (27.52) and don't try to compute it via the Newtonian volume integral (27.53).*

When the source is nearly Newtonian, so the volume integral (27.53) can be used to compute the quadrupole moment, the computation of the waves is simplified by computing instead the second moment of the mass distribution:

$$I_{jk} = \int \rho x^j x^k dV_x, \quad (27.58)$$

which differs from the quadrupole moment solely in its trace. Then, because the TT projection is insensitive to the trace, the gravitational-wave field (27.57) can be computed as

$$h_{jk}^{\text{TT}} = 2 \left[\frac{\ddot{I}_{jk}(t-r)}{r} \right]^{\text{TT}}. \quad (27.59)$$

Newtonian potential transitions into this linearized-theory gravitational field in transition and local wave zones

resulting quadrupolar gravitational-wave field

validity for strong-gravity slow-motion sources

for Newtonian source: gravitational-wave field in terms of second moment of mass distribution

To get an order-of-magnitude feel for the strength of the gravitational waves, notice that the second time derivative of the quadrupole moment, in order of magnitude, is the nonspherical part of the source's internal kinetic energy, $E_{\text{kin}}^{\text{ns}}$:

magnitude of slow-motion source's quadrupolar gravitational-wave field

$$h_+ \sim h_\times \sim \frac{E_{\text{kin}}^{\text{ns}}}{r} = G \frac{E_{\text{kin}}^{\text{ns}}}{c^4 r}, \quad (27.60)$$

where the second expression is written in conventional units. Although this estimate is based on the slow-motion assumption of source size small compared to reduced wavelength, $L \ll \lambda$, it remains valid in order of magnitude when extrapolated into the realm of the strongest of all realistic astrophysical sources, which have $L \sim \lambda$. In Ex. 27.17 we use Eq. (27.60) to estimate the strongest gravitational waves that might be seen by ground-based gravitational-wave detectors.

Because the gravitational stress-energy tensor $T_{\mu\nu}^{\text{GW}}$ produces background curvature via the Einstein equation $G_{\mu\nu}^{\text{B}} = 8\pi T_{\mu\nu}^{\text{GW}}$, just like nongravitational stress-energy tensors, it must contribute to the rate of change of the source's mass M , linear momentum P_j , and angular momentum J_i [Eqs. (25.102)–(25.106)] just like other stress-energies. When one inserts the quadrupolar $T_{\mu\nu}^{\text{GW}}$ into Eqs. (25.102)–(25.106) and integrates over a sphere in the wave zone of the source's local asymptotic rest frame, one finds that (Ex. 27.11):

source's rate of change of mass, momentum, and angular momentum due to mass quadrupolar gravitational-wave emission

$$\frac{dM}{dt} = -\frac{1}{5} \left\langle \frac{\partial^3 \mathcal{I}_{jk}}{\partial t^3} \frac{\partial^3 \mathcal{I}_{jk}}{\partial t^3} \right\rangle, \quad (27.61)$$

$$\frac{dJ_i}{dt} = -\frac{2}{5} \epsilon_{ijk} \left\langle \frac{\partial^2 \mathcal{I}_{jm}}{\partial t^2} \frac{\partial^3 \mathcal{I}_{km}}{\partial t^3} \right\rangle, \quad (27.62)$$

and $dP_j/dt = 0$. It turns out (cf. Thorne, 1980, Sec. IV) that the dominant linear-momentum change (i.e., the dominant radiation-reaction “kick”) arises from a beating of the mass quadrupole moment against the mass octupole moment, and mass quadrupole against current quadrupole:

$$\frac{dP_i}{dt} = -\frac{2}{63} \left\langle \frac{\partial^3 \mathcal{I}_{jk}}{\partial t^3} \frac{\partial^4 \mathcal{I}_{jki}}{\partial t^4} \right\rangle - \frac{16}{45} \epsilon_{ijk} \left\langle \frac{\partial^3 \mathcal{I}_{jl}}{\partial t^3} \frac{\partial^3 \mathcal{S}_{kl}}{\partial t^3} \right\rangle. \quad (27.63)$$

Here the mass octupole moment \mathcal{I}_{jki} is the trace-free part of the third moment of the mass distribution, and the current quadrupole moment \mathcal{S}_{kp} is the symmetric, trace-free part of the first moment of the vectorial angular momentum distribution. (See, e.g., Thorne, 1980, Secs. IV.C, V.C; Thorne, 1983, Sec. 3.)

The back reaction of the emitted waves on their source shows up not only in changes of the source's mass, momentum, and angular momentum, but also in accompanying changes of the source's internal structure. These structure changes can be deduced fully, in many cases, from dM/dt , dJ_j/dt , and dP_j/dt . A nearly Newtonian binary system is an example (Sec. 27.5.4). However, in other cases (e.g., a compact body orbiting near the horizon of a massive black hole), the only way to compute the structure changes is via a gravitational-radiation-reaction force that acts back on the system.

The simplest example of such a force is one derived by William Burke (1971) for quadrupole waves emitted by a nearly Newtonian system. Burke's quadrupolar radiation-reaction force can be incorporated into Newtonian gravitation theory by simply augmenting the system's near-zone Newtonian potential with a radiation-reaction term, computed from the fifth time derivative of the system's quadrupole moment:

$$\Phi^{\text{react}} = \frac{1}{5} \frac{\partial^5 \mathcal{I}_{jk}}{\partial t^5} x^j x^k. \quad (27.64)$$

gravitational radiation-reaction potential

This potential satisfies the vacuum Newtonian field equation $\nabla^2 \Phi \equiv \delta^{jk} \Phi_{,jk} = 0$, because \mathcal{I}_{jk} is traceless.

This augmentation of the Newtonian potential arises as a result of general relativity's outgoing-wave condition. If one were to switch to an ingoing-wave condition, Φ^{react} would change sign, and if the system's oscillating quadrupole moment were joined onto standing gravitational waves, Φ^{react} would go away. In Ex. 27.12, it is shown that the radiation-reaction force density $-\rho \nabla \Phi^{\text{react}}$ saps energy from the system at the same rate as the gravitational waves carry it away.

radiation-reaction force density in source

Burke's gravitational radiation-reaction potential Φ^{react} and force density $-\rho \nabla \Phi^{\text{react}}$ are close analogs of the radiation-reaction potential [last term in Eq. (16.79)] and acceleration [right-hand side of Eq. (16.82)] that act on an oscillating ball that emits sound waves into a surrounding fluid. Moreover, Burke's derivation of his gravitational radiation-reaction potential is conceptually the same as the derivation, in Sec. 16.5.3, of the sound-wave reaction potential.

Exercise 27.9 *Problem: Gravitational Waves from Arm Waving*

EXERCISES

Wave your arms rapidly, and thereby try to generate gravitational waves.

- Using classical general relativity, compute in order of magnitude the wavelength of the waves you generate and their dimensionless amplitude at a distance of one wavelength away from you.
- How many gravitons do you produce per second? Discuss the implications of your result.

Exercise 27.10 *Example: Quadrupolar Wave Generation in Linearized Theory*

Derive the quadrupolar wave-generation formula (27.59) for a slow-motion, weak-gravity source in linearized theory using Lorenz gauge and beginning with the retarded-integral formula:

$$\bar{h}_{\mu\nu}(t, \mathbf{x}) = \int \frac{4T_{\mu\nu}(t - |\mathbf{x} - \mathbf{x}'|, \mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|} dV_{x'} \quad (27.65)$$

[Eq. (25.91)]. Your derivation might proceed as follows.

- (a) Show that for a slow-motion source, the retarded integral gives for the $1/r \equiv 1/|\mathbf{x}|$ (radiative) part of \bar{h}_{jk} :

$$\bar{h}_{jk}(t, \mathbf{x}) = \frac{4}{r} \int T_{jk}(t - r, \mathbf{x}') dV_{x'}. \quad (27.66)$$

- (b) Show that in linearized theory using Lorenz gauge, the vacuum Einstein equation $-\bar{h}_{\mu\nu,\alpha}{}^\alpha = 16\pi T_{\mu\nu}$ [Eq. (25.90)] and the Lorenz gauge condition $\bar{h}_{\mu\nu,}{}^\nu = 0$ [Eq. (25.89)] together imply that the stress-energy tensor that generates the waves must have vanishing coordinate divergence: $T^{\mu\nu}{}_{,\nu} = 0$. This means that linearized theory is ignorant of the influence of self-gravity on the gravitating $T^{\mu\nu}$!
- (c) Show that this vanishing divergence implies $[T^{00}x^jx^k]_{,00} = [T^{lm}x^jx^k]_{,ml} - 2[T^{lj}x^k + T^{lk}x^j]_{,l} + 2T^{jk}$.
- (d) By combining the results of parts (a) and (c), deduce that

$$\bar{h}_{jk}(t, \mathbf{x}) = \frac{2}{r} \frac{d^2 I_{jk}(t - r)}{dt^2}, \quad (27.67)$$

where I_{jk} is the second moment of the source's (Newtonian) mass-energy distribution $T^{00} = \rho$ [Eq. (27.58)].

- (e) Noticing that the trace-reversed metric perturbation (27.67) has the “speed-of-light-propagation” form, deduce that the gravitational-wave field h_{jk}^{TT} can be computed from Eq. (27.67) by a transverse-traceless projection [Box 27.2].

Part (b) shows that this linearized-theory analysis is incapable of deducing the gravitational waves emitted by a source whose dynamics is controlled by its self-gravity (e.g., a nearly Newtonian binary star system). By contrast, the derivation of the quadrupole formula given in Sec. 27.5.2 is valid for any slow-motion source, regardless of the strength and roles of its internal gravity; see the discussion following Eq. (27.57).

Exercise 27.11 *Problem: Energy and Angular Momentum Carried by Gravitational Waves*

- (a) Compute the net rate at which the quadrupolar waves (27.57) carry energy away from their source, by carrying out the surface integral (25.102) with T^{0j} being Isaacson's gravitational-wave energy flux (27.40). Your answer should be Eq. (27.61). [Hint: Perform the TT projection in Cartesian coordinates using the

projection tensor, Eq. (2) of Box 27.2, and make use of the following integrals over the solid angle on the unit sphere:

$$\begin{aligned} \frac{1}{4\pi} \int n_i d\Omega &= 0, & \frac{1}{4\pi} \int n_i n_j d\Omega &= \frac{1}{3} \delta_{ij}, & \frac{1}{4\pi} \int n_i n_j n_k d\Omega &= 0, \\ \frac{1}{4\pi} \int n_i n_j n_k n_l d\Omega &= \frac{1}{15} (\delta_{ij} \delta_{kl} + \delta_{ik} \delta_{jl} + \delta_{il} \delta_{jk}). \end{aligned} \quad (27.68)$$

These integrals should be obvious by symmetry, aside from the numerical factors out in front. Those factors are most easily deduced by computing the z components (i.e., by setting $i = j = k = l = z$ and using $n_z = \cos \theta$.)

- (b) The computation of the waves' angular momentum can be carried out in the same way, but is somewhat delicate, because a tiny nonradial component of the energy flux, that dies out as $1/r^3$, gives rise to the $O(1/r^2)$ angular momentum flux (see Thorne, 1980, Sec. IV.D).

Exercise 27.12 *Problem: Energy Removed by Gravitational Radiation Reaction*

Burke's radiation-reaction potential (27.64) produces a force per unit volume $-\rho \nabla \Phi^{\text{react}}$ on its nearly Newtonian source. If we multiply this force per unit volume by the velocity $\mathbf{v} = d\mathbf{x}/dt$ of the source's material, we obtain thereby a rate of change of energy per unit volume. Correspondingly, the net rate of change of the system's mass-energy must be

$$\frac{dM}{dt} = - \int \rho \mathbf{v} \cdot \nabla \Phi^{\text{react}} dV_x. \quad (27.69)$$

Show that, when averaged over a few gravitational-wave periods, this formula agrees with the rate of change of mass (27.61) that we derived in Ex. 27.11 by integrating the outgoing waves' energy flux.

27.5.4 Gravitational Waves from a Binary Star System

27.5.4

A very important application of the quadrupole formalism is to wave emission by a nearly Newtonian binary star system. Denote the stars by indices A and B and their masses by M_A and M_B , so their total and reduced mass are (as usual)

$$\boxed{M = M_A + M_B, \quad \mu = \frac{M_A M_B}{M};} \quad (27.70a)$$

and for simplicity, let the binary's orbit be circular, with separation a between the stars' centers of mass. Then Newtonian force balance dictates that the orbital angular velocity Ω is given by Kepler's law:

$$\boxed{\Omega = \sqrt{M/a^3},} \quad (27.70b)$$

dynamics of a Newtonian binary in a circular orbit

and the orbits of the two stars are

$$\begin{aligned} x_A &= \frac{M_B}{M} a \cos \Omega t, & y_A &= \frac{M_B}{M} a \sin \Omega t, \\ x_B &= -\frac{M_A}{M} a \cos \Omega t, & y_B &= -\frac{M_A}{M} a \sin \Omega t. \end{aligned} \quad (27.70c)$$

The second moment of the mass distribution [Eq. (27.58)] is $I_{jk} = M_A x_A^j x_A^k + M_B x_B^j x_B^k$. Inserting the stars' time-dependent positions (27.70c), we obtain as the only nonzero components:

$$I_{xx} = \mu a^2 \cos^2 \Omega t, \quad I_{yy} = \mu a^2 \sin^2 \Omega t, \quad I_{xy} = I_{yx} = \mu a^2 \cos \Omega t \sin \Omega t. \quad (27.70d)$$

Noting that $\cos^2 \Omega t = \frac{1}{2}(1 + \cos 2\Omega t)$, $\sin^2 \Omega t = \frac{1}{2}(1 - \cos 2\Omega t)$, and $\cos \Omega t \sin \Omega t = \frac{1}{2} \sin 2\Omega t$ and evaluating the double time derivative, we obtain:

$$\begin{aligned} \ddot{I}_{xx} &= -2\mu(M\Omega)^{2/3} \cos 2\Omega t, & \ddot{I}_{yy} &= 2\mu(M\Omega)^{2/3} \cos 2\Omega t, \\ \ddot{I}_{xy} &= \ddot{I}_{yx} = -2\mu(M\Omega)^{2/3} \sin 2\Omega t. \end{aligned} \quad (27.70e)$$

We express these components in terms of Ω rather than a , because Ω is a direct gravitational-wave observable: the waves' angular frequency is 2Ω .

To compute the gravitational-wave field (27.59), we must project out the transverse traceless part of this \ddot{I}_{jk} . The projection is most easily performed in an orthonormal spherical basis, since there the transverse part is just the projection onto the plane spanned by $\vec{e}_{\hat{\theta}}$ and $\vec{e}_{\hat{\phi}}$, and the transverse-traceless part has components

$$(\ddot{I}_{\hat{\theta}\hat{\theta}})^{\text{TT}} = -(\ddot{I}_{\hat{\phi}\hat{\phi}})^{\text{TT}} = \frac{1}{2}(\ddot{I}_{\hat{\theta}\hat{\theta}} - \ddot{I}_{\hat{\phi}\hat{\phi}}), \quad (\ddot{I}_{\hat{\theta}\hat{\phi}})^{\text{TT}} = \ddot{I}_{\hat{\theta}\hat{\phi}} \quad (27.70f)$$

[cf. Eq. (1) of Box 27.2]. Now, a little thought will save us much work: We need only compute these quantities at $\phi = 0$ (i.e., in the x - z plane), since their circular motion guarantees that their dependence on t and ϕ must be solely through the quantity $\Omega t - \phi$. At $\phi = 0$, $\vec{e}_{\hat{\theta}} = \vec{e}_x \cos \theta - \vec{e}_z \sin \theta$ and $\vec{e}_{\hat{\phi}} = \vec{e}_y$, so the only nonzero components of the transformation matrices from the Cartesian basis to the transverse part of the spherical basis are $L^x_{\hat{\theta}} = \cos \theta$, $L^z_{\hat{\theta}} = -\sin \theta$, and $L^y_{\hat{\phi}} = 1$. Using this transformation matrix at $\phi = 0$, we obtain: $\ddot{I}_{\hat{\theta}\hat{\theta}} = \ddot{I}_{xx} \cos^2 \theta$, $\ddot{I}_{\hat{\phi}\hat{\phi}} = \ddot{I}_{yy}$, and $\ddot{I}_{\hat{\theta}\hat{\phi}} = \ddot{I}_{xy} \cos \theta$. Inserting these and expressions (27.70e) into Eq. (27.70f), and setting $\Omega t \rightarrow \Omega t - \phi$ to make the formulas valid away from $\phi = 0$, we obtain:

$$\begin{aligned} (\ddot{I}_{\hat{\theta}\hat{\theta}})^{\text{TT}} &= -(\ddot{I}_{\hat{\phi}\hat{\phi}})^{\text{TT}} = -(1 + \cos^2 \theta) \mu(M\Omega)^{2/3} \cos[2(\Omega t - \phi)], \\ (\ddot{I}_{\hat{\theta}\hat{\phi}})^{\text{TT}} &= +(\ddot{I}_{\hat{\phi}\hat{\theta}})^{\text{TT}} = -2 \cos \theta \mu(M\Omega)^{2/3} \sin[2(\Omega t - \phi)]. \end{aligned} \quad (27.70g)$$

The gravitational-wave field (27.59) is $2/r$ times this quantity evaluated at the retarded time $t - r$.

We make the conventional choice for the polarization tensors:

$$\mathbf{e}^+ = (\vec{e}_{\hat{\theta}} \otimes \vec{e}_{\hat{\theta}} - \vec{e}_{\hat{\phi}} \otimes \vec{e}_{\hat{\phi}}), \quad \mathbf{e}^\times = (\vec{e}_{\hat{\theta}} \otimes \vec{e}_{\hat{\phi}} + \vec{e}_{\hat{\phi}} \otimes \vec{e}_{\hat{\theta}});$$

$$\vec{e}_{\hat{\theta}} = \frac{1}{r} \frac{\partial}{\partial \theta}, \quad \vec{e}_{\hat{\phi}} = \frac{1}{r \sin \theta} \frac{\partial}{\partial \phi}. \quad (27.71a)$$

Then Eqs. (27.59) and (27.70g) tell us that the gravitational-wave field is, in slot-naming index notation:

$$h_{\mu\nu}^{\text{TT}} = h_+ e_{\mu\nu}^+ + h_\times e_{\mu\nu}^\times, \quad (27.71b)$$

where

$$h_+ = h_{\hat{\theta}\hat{\theta}}^{\text{TT}} = \frac{2}{r} [\ddot{I}_{\hat{\theta}\hat{\theta}}(t-r)]^{\text{TT}} = -2(1 + \cos^2 \theta) \frac{\mu(M\Omega)^{2/3}}{r} \cos[2(\Omega t - \Omega r - \phi)],$$

(27.71c)

$$h_\times = h_{\hat{\theta}\hat{\phi}}^{\text{TT}} = \frac{2}{r} [\ddot{I}_{\hat{\theta}\hat{\phi}}(t-r)]^{\text{TT}} = -4 \cos \theta \frac{\mu(M\Omega)^{2/3}}{r} \sin[2(\Omega t - \Omega r - \phi)].$$

(27.71d)

We have expressed the amplitudes of these waves in terms of the dimensionless quantity $(M\Omega)^{2/3} = M/a = v^2$, where v is the relative velocity of the two stars.

Notice that, as viewed from the polar axis $\theta = 0$, h_+ and h_\times are identical except for a $\pi/2$ phase delay, which means that the net stretch-squeeze ellipse (the combination of those in Figs. 27.1 and 27.2) rotates with angular velocity Ω . This is the gravitational-wave variant of circular polarization, and it arises because the binary motion as viewed from the polar axis looks circular. By contrast, as viewed by an observer in the equatorial plane $\theta = \pi/2$, h_\times vanishes, so the net stretch-squeeze ellipse just oscillates along the $+$ axes, and the waves have linear polarization. This is natural, since the orbital motion as viewed by an equatorial observer is just a linear, horizontal, back-and-forth oscillation. Notice also that the gravitational-wave frequency is twice the orbital frequency:

$$f = 2 \frac{\Omega}{2\pi} = \frac{\Omega}{\pi}. \quad (27.72)$$

To compute, via Eqs. (27.61) and (27.62), the rate at which energy and angular momentum are lost from the binary, we need to know the double and triple time derivatives of its quadrupole moment \mathcal{I}_{jk} . The double time derivative is just \ddot{I}_{jk} with its trace removed, but Eq. (27.70e) shows that \ddot{I}_{jk} is already traceless so $\ddot{\mathcal{I}}_{jk} = \ddot{I}_{jk}$. Inserting Eq. (27.70e) for this quantity into Eqs. (27.61) and (27.62) and performing

gravitational waves from Newtonian binary

binary's gravitational-wave frequency is twice its orbital frequency

the average over a gravitational-wave period, we find that

$$\frac{dM}{dt} = -\frac{32}{5} \frac{\mu^2}{M^2} (M\Omega)^{10/3}, \quad \frac{dJ_z}{dt} = -\frac{1}{\Omega} \frac{dM}{dt}, \quad \frac{dJ_x}{dt} = \frac{dJ_y}{dt} = 0. \quad (27.73)$$

binary's orbital inspiral due to gravitational-wave emission

This loss of energy and angular momentum causes the binary to spiral inward, decreasing the stars' separation a and increasing their orbital angular velocity Ω . By comparing Eqs. (27.73) with the standard equations for the binary's orbital energy and angular momentum [M – (sum of rest masses of stars) = $E = -\frac{1}{2}\mu M/a = -\frac{1}{2}\mu(M\Omega)^{2/3}$, and $J_z = \mu a^2 \Omega = \mu(M\Omega)^{2/3}/\Omega$], we obtain an equation for $d\Omega/dt$, which we can integrate to give

$$\Omega = \pi f = \left(\frac{5}{256} \frac{1}{\mu M^{2/3}} \frac{1}{t_o - t} \right)^{3/8}. \quad (27.74)$$

Here t_o (an integration constant) is the time remaining until the two stars merge, if the stars are thought of as point masses so their surfaces do not collide sooner. This equation can be inverted to read off the time until merger as a function of gravitational-wave frequency.

These results for a binary's waves and radiation-reaction-induced inspiral are of great importance for gravitational-wave detection (see, e.g., Cutler and Thorne, 2002; Sathyaprakash and Schutz, 2009).

EXERCISES

Exercise 27.13 *Problem: Gravitational Waves Emitted by a Linear Oscillator*

Consider a mass m attached to a spring, so it oscillates along the z -axis of a Cartesian coordinate system, moving along the world line $z = a \cos \Omega t$, $y = x = 0$. Use the quadrupole-moment formalism to compute the gravitational waves $h_+(t, r, \theta, \phi)$ and $h_\times(t, r, \theta, \phi)$ emitted by this oscillator, with the polarization tensors chosen as in Eqs. (27.71a). Pattern your analysis after the computation of waves from a binary in Sec. 27.5.4.

Exercise 27.14 ***Example: Propagation of a Binary's Waves Through an Expanding Universe*

As we shall see in Sec. 28.3, the following line element is a possible model for the large-scale structure of our universe:

$$ds^2 = b^2[-d\eta^2 + d\chi^2 + \chi^2(d\theta^2 + \sin^2 \theta d\phi^2)], \quad \text{where } b = b_o \eta^2, \quad (27.75)$$

and b_o is a constant with dimensions of length. This is an expanding universe with flat spatial slices $\eta = \text{constant}$. Notice that the proper time measured by observers at rest in the spatial coordinate system is $t = b_o \int \eta^2 d\eta = (b_o/3)\eta^3$.

A nearly Newtonian, circular binary is at rest at $\chi = 0$ in an epoch when $\eta \simeq \eta_o$. The coordinates of the binary's local asymptotic rest frame are $\{t, r, \theta, \phi\}$, where $r = b\chi$ and the coordinates cover only a tiny region of the universe: $\chi \lesssim \chi_o \ll \eta_o$. The gravitational waves in this local asymptotic rest frame are described by Eqs. (27.71). Use geometric optics (Sec. 27.4.2) to propagate these waves out through the expanding universe. In particular, do the following.

- (a) Show that the null rays along which the waves propagate are the curves of constant θ , ϕ , and $\eta - \chi$.
- (b) Each ray can be characterized by the retarded time τ_r at which the source emitted it. Show that

$$\tau_r = \frac{1}{3}b_o(\eta - \chi)^3. \quad (27.76a)$$

- (c) Show that in the source's local asymptotic rest frame, this retarded time is $\tau_r = t - r$, and the phase of the wave is $\varphi = 2(\Omega \tau_r + \phi)$ [cf. Eqs. (27.71c) and (27.71d)]. Because the frequency Ω varies with time due to the binary inspiral, a more accurate formula for the wave's phase is $\varphi = 2(\int \Omega d\tau_r + \phi)$. Using Eq. (27.74), show that

$$\varphi = 2\phi - \left(\frac{t_o - \tau_r}{5\mathcal{M}}\right)^{5/8}, \quad \Omega = \frac{d\varphi}{d\tau_r} = \left(\frac{5}{256} \frac{1}{\mathcal{M}^{5/3}} \frac{1}{t_o - \tau_r}\right)^{3/8}, \quad (27.76b)$$

where

$$\mathcal{M} \equiv \mu^{3/5} M^{2/5} \quad (27.76c)$$

(with μ the reduced mass and M the total mass) is called the binary's *chirp mass*, because, as Eqs. (27.76b) show, it controls the rate at which the binary's orbital angular frequency Ω and the gravitational-wave angular frequency 2Ω "chirp upward" as time passes. The quantity τ_r as given by Eq. (27.76a) is constant along rays when they travel out of the local wave zone and into and through the universe. Correspondingly, if we continue to write φ in terms of τ_r on those rays using Eqs. (27.76b), this φ will be conserved along the rays in the external universe and therefore will satisfy the geometric-optics equation: $\nabla_{\vec{k}} \varphi = 0$ [Eqs. (27.35b)].

- (d) Show that the orthonormal basis vectors and polarization tensors

$$\begin{aligned} \vec{e}_{\hat{\theta}} &= \frac{1}{b\chi} \frac{\partial}{\partial \theta}, & \vec{e}_{\hat{\phi}} &= \frac{1}{b\chi \sin \theta} \frac{\partial}{\partial \phi}, \\ \mathbf{e}^+ &= (\vec{e}_{\hat{\theta}} \otimes \vec{e}_{\hat{\theta}} - \vec{e}_{\hat{\phi}} \otimes \vec{e}_{\hat{\phi}}), & \mathbf{e}^\times &= (\vec{e}_{\hat{\theta}} \otimes \vec{e}_{\hat{\phi}} + \vec{e}_{\hat{\phi}} \otimes \vec{e}_{\hat{\theta}}) \end{aligned} \quad (27.76d)$$

in the external universe: (i) are parallel-transported along rays and (ii) when carried backward on rays into the local asymptotic rest frame, become the basis vectors and tensors used in that frame's solution (27.71) for the gravitational

waves. Therefore, these $\mathbf{e}_{\mu\nu}^+$ and $\mathbf{e}_{\mu\nu}^\times$ are the polarization tensors needed for our geometric-optics waves.

- (e) Consider a bundle of rays that, at the source, extends from ϕ to $\phi + \Delta\phi$ and from θ to $\theta + \Delta\theta$. Show that this bundle's cross sectional area, as it moves outward to larger and larger χ , is $\mathcal{A} = r^2 \sin\theta \Delta\theta \Delta\phi$, where r is a function of η and χ given by

$$r = b\chi = b_o\eta^2\chi. \quad (27.76e)$$

Show that in the source's local asymptotic rest frame, this r is the same as the distance r from the source that appears in Eqs. (27.71c) and (27.71d) for h_+ and h_\times .

- (f) By putting together all the pieces from parts (a) through (e), show that the solution to the equations of geometric optics (27.35) for the gravitational-wave field as it travels outward through the universe is

$$\mathbf{h}^{\text{TT}} = h_+ \mathbf{e}^+ + h_\times \mathbf{e}^\times, \quad (27.76f)$$

with \mathbf{e}^+ and \mathbf{e}^\times given by Eqs. (27.76d), with h_+ and h_\times given by

$$h_+ = -2(1 + \cos^2\theta) \frac{\mathcal{M}^{5/3} \Omega^{2/3}}{r} \cos\varphi, \quad h_\times = -4 \cos\theta \frac{\mathcal{M}^{5/3} \Omega^{2/3}}{r} \sin\varphi, \quad (27.76g)$$

and with Ω , φ , and r given by Eqs. (27.76b), (27.76a), and (27.76e). [Hint: Note that all quantities in this solution except r are constant along rays, and r varies as $1/\sqrt{\mathcal{A}}$, where \mathcal{A} is the area of a bundle of rays.]

- (g) The angular frequency of the waves that are emitted at retarded time τ_r is $\omega_e = 2\Omega$. When received at Earth these waves have a cosmologically redshifted frequency $\omega_r = \partial\varphi/\partial t$, where $t = (b_o/3)\eta^3$ is proper time measured at Earth, and in the derivative we must hold fixed the spatial coordinates of Earth: $\{\chi, \theta, \phi\}$. The ratio of these frequencies is $\omega_e/\omega_r = 1 + z$, where z is the so-called cosmological redshift of the waves. Show that $1 + z = (\partial\tau_r/\partial t)^{-1} = \eta^2/(\eta - \chi)^2$.
- (h) Show that the information carried by the binary's waves is the following. (i) From the ratio of the amplitudes of the two polarizations, one can read off the inclination angle θ of the binary's spin axis to the line of sight to the binary. (ii) From the waves' measured angular frequency ω and its time rate of change $d\omega/dt$, one can read off $(1 + z)\mathcal{M}$, the binary's redshifted chirp mass. (iii) From the amplitude of the waves, with θ and $(1 + z)\mathcal{M}$ known, one can read off $(1 + z)r$, a quantity known to cosmologists as the binary's *luminosity distance*. [Note: It is remarkable that gravitational waves by themselves reveal the source's luminosity distance but not its redshift, while electromagnetic observations reveal the redshift but not the

luminosity distance. This complementarity illustrates the importance and power of combined gravitational-wave and electromagnetic observations.]

27.5.5 Gravitational Waves from Binaries Made of Black Holes, Neutron Stars, or Both: Numerical Relativity T2

27.5.5

Among the most interesting sources of gravitational waves are binary systems made of two black holes, a black hole and a neutron star, or two neutron stars—so-called *compact binaries*. When the two bodies are far apart, their motion and waves can be described accurately by Newtonian gravity and the quadrupole-moment formalism: the formulas in Sec. 27.5.4. As the bodies spiral inward, $(M\Omega)^{2/3} = M/a = v^2$ grows larger, h_+ and h_\times grow larger, and relativistic corrections to our Newtonian, quadrupole analysis grow larger. Those relativistic corrections (including current-quadrupole waves, mass-octupole waves, etc.) can be computed using a post-Newtonian expansion of the Einstein field equations (i.e., an expansion in $M/a \sim v^2$). The accuracies of ground-based detectors such as LIGO require that, for compact binaries, the expansion be carried at least to order v^7 beyond our Newtonian, quadrupole analysis! (See Blanchet, 2014.)

compact binaries analyzed by a post-Newtonian expansion

At the end of the inspiral, the binary's bodies come crashing together. To compute the waves from this final merger with an accuracy comparable to the observations, it is necessary to solve the Einstein field equation on a computer. The techniques for doing this are called *numerical relativity* (Baumgarte and Shapiro, 2010; Shibata, 2016) and were pioneered by Bryce DeWitt, Larry Smarr, Saul Teukolsky, Frans Pretorius, and others.

merger analyzed by numerical relativity

For binary black holes with approximately equal masses, simulations using numerical relativity reveal that the total energy radiated in gravitational waves is $\Delta E \sim 0.1Mc^2$, where M is the binary's total mass. Most of this energy is emitted in the last ~ 5 to 10 cycles of waves, at wave periods $P \sim (10 \text{ to } 20)GM/c^3$ [i.e., frequencies $f = 1/P \sim 1,000 \text{ Hz } (10M_\odot/M)$]. The gravitational-wave power output in these last 5–10 cycles is $dE/dt \sim 0.1Mc^2/(100GM/c^3) = 0.001c^5/G$, which is roughly 10^{23} times the luminosity of the Sun, and 100 times the luminosity of all the stars in the observable universe put together! If the holes have masses $\sim 10M_\odot$, this enormous luminosity lasts for only ~ 0.1 s, and the total energy emitted is the rest-mass energy of the Sun. If the holes have masses $\sim 10^9M_\odot$, the enormous luminosity lasts for ~ 1 yr, and the energy emitted is the rest-mass energy of $\sim 10^8$ Suns.

gravitational-wave power output in black hole mergers: 100 universe luminosities

For the simplest case of two identical, nonspinning black holes that spiral together in a circular orbit, both waveforms (both wave shapes) have the simple time evolution shown in Fig. 27.6. As the holes spiral together, their amplitude and phase increase in accord with the Newtonian-quadrupole formulas (27.71), (27.72), and (27.74) but by the time of this figure, post-Newtonian corrections are producing noticeable differences from those formulas. When the holes merge, the gravitational-wave amplitude

FIGURE 27.6 For a binary made of two identical, nonspinning black holes that spiral together and merge: the time evolution of the gravitational-wave tidal field $\mathcal{E}_{ij} \propto \ddot{h}_+$ [Eq. (27.22)] for the + polarization. The \times polarization waveform is the same as this but with a phase shift. The right panel shows the detailed signal just prior to merger. Based on simulations performed by the Caltech/Cornell/CITA numerical relativity group (Mroué et. al. 2013). (CITA is the Canadian Institute for Theoretical Astrophysics.)

reaches a maximum amplitude. The merged hole then vibrates and the waves “ring down” with exponentially decaying amplitude.

Much more interesting are binaries made of black holes that spin. In this case, the angular momentum of each spinning hole drags inertial frames, as does the binary’s orbital angular momentum. This frame-dragging causes the spins and the orbital plane to precess, and those precessions modulate the waves. Figure 27.7 depicts a generic example: a binary whose holes have a mass ratio 6:1, dimensionless spins $a_A/M_A = 0.91$, $a_B/M_B = 0.30$, and randomly chosen initial spin axes and orbital plane. Frame dragging causes the orbital motion to be rather complex, and correspondingly, the two waveforms are much richer than in the nonspinning case. The waveforms carry detailed information about the binary’s masses, spins, and orbital evolution, and also about the geometrodynamics of its merger (Box 27.4).

information in
gravitational waves

EXERCISES

Exercise 27.15 *Problem: Maximum Gravitational-Wave Amplitude* T2

Extrapolating Eqs. (27.71)–(27.73) into the strong-gravity regime, estimate the maximum gravitational-wave amplitude and emitted power for a nonspinning binary black hole with equal masses and with unequal masses. Compare with the results from numerical relativity discussed in the text.

Exercise 27.16 *Problem: Gravitational Radiation from Binary Pulsars in Elliptical Orbits* T2

Many precision tests of general relativity are associated with binary pulsars in elliptical orbits (Sec. 27.2.6).

- (a) Verify that the radius of the relative orbit of the pulsars can be written as $r = p/(1 + e \cos \phi)$, where p is the *semi-latus rectum*, e is the eccentricity, and $d\phi/dt = (Mp)^{1/2}/r^2$ with M the total mass.

FIGURE 27.7 (a) The orbital motion of a small black hole around a larger black hole (mass ratio $M_B/M_A = 1/6$), when the spins are $a_B/M_B = 0.30$ and $a_A/M_A = 0.91$ and the initial spin axes and orbital plane are as shown in panel b. (b) The two gravitational waveforms emitted in the direction toward Earth (blue dashed line). These waveforms are from a catalog of simulations of 174 different binary-black-hole mergers, carried out by the Caltech/Cornell/CITA numerical relativity group (Mroué et al., 2013).

- (b) Show that the traceless mass quadrupole moment, Eq. (27.53), in suitable coordinates, is [cf. Eq. (27.70d)]

$$\mathcal{I}_{jk} = \frac{\mu p^2}{(1 + e \cos \phi)^2} \begin{pmatrix} \cos^2 \phi - \frac{1}{3} & \cos \phi \sin \phi & 0 \\ \cos \phi \sin \phi & \sin^2 \phi - \frac{1}{3} & 0 \\ 0 & 0 & -\frac{1}{3} \end{pmatrix}. \quad (27.77a)$$

- (c) Use computer algebra to evaluate the second and third time derivatives of this tensor, and then use Eqs. (27.61) and (27.62) to calculate the orbit-averaged energy and angular momentum emitted in gravitational waves, per orbit.

BOX 27.4. GEOMETRODYNAMICS T2

When spinning black holes collide, they excite nonlinear vibrations of curved spacetime—a phenomenon that John Wheeler has called *geometrodynamics*. This nonlinear dynamics can be visualized using tidal tendex lines (which depict the tidal field \mathcal{E}_{ij}) and frame-drag vortex lines (which depict the frame-drag field \mathcal{B}_{ij}); see Boxes 25.2 and 26.3. Particularly helpful are the concepts of a *tendex* (a collection of tendex lines with large tendicities) and a (*frame-drag*) *vortex* (a collection of vortex lines with large vorticities). A spinning black hole has a counterclockwise vortex emerging from its north polar region, and a clockwise vortex emerging from its south polar region (right diagram in Box 26.3).

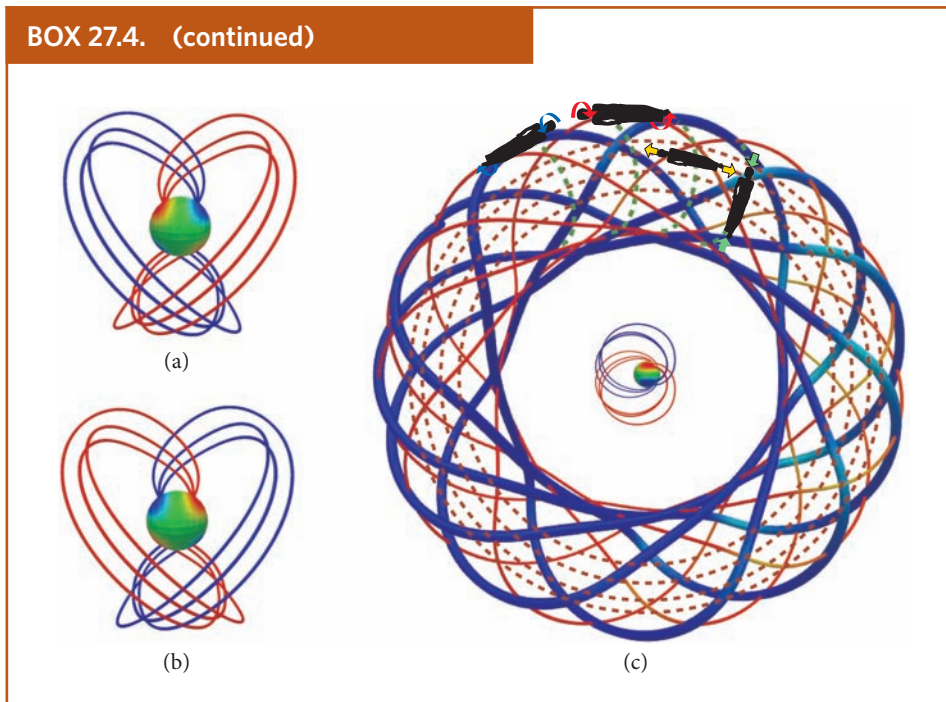

As an example of geometrodynamics, consider two identical black holes that collide head on, with their spins transverse to the collision direction. Numerical-relativity simulations (Owen et al., 2011) reveal that, when the holes collide and merge, each hole deposits its two vortices onto the merged horizon. The four vortices dynamically attach to each other in pairs (panel a in figure below). The pairs then interact, with surprising consequences. The blue (clockwise) vortex disconnects from the hole and forms a set of closed vortex loops that wrap around a torus (thick blue lines in panel c), and the red (counterclockwise) vortex does the same (thin red lines in panel c). This torus expands outward at the speed of light, while energy temporarily stored in near-horizon tendices (not shown) regenerates the new pair of horizon-penetrating vortices shown in panel b, with reversed vorticities (reversed directions of twist). As the torus expands outward, its motion, via the Maxwell-like Bianchi identity $\partial\mathcal{E}/\partial t = (\nabla \times \mathcal{B})^S$ (Box 25.2), generates a set of tendex lines that wrap around the torus at 45° angles to the vortex lines (dashed lines in panel c). The torus's interleaved vortex and tendex lines have become a gravitational wave, which locally looks like the plane wave discussed in Box 27.3. This process repeats, with amplitude damping, generating a sequence of expanding tori. (Figure adapted from Owen et al., 2011.)

(continued)

Your answer should be

$$\Delta E = \frac{64\pi\mu^2 M^{5/2}}{5p^{7/2}} \left(1 + \frac{73}{24}e^2 + \frac{37}{96}e^4 \right), \quad \Delta J = \frac{64\pi\mu^2 M^2}{5p^2} \left(1 + \frac{7}{8}e^2 \right). \quad (27.77b)$$

- (d) Combine the results from part (c) with Kepler's laws to calculate an expression for the rate of increase of pulse period and decrease of the eccentricity (cf. Sec. 27.2.6).

- (e) Consider a parabolic encounter between two stars, and show that the energy and angular momentum radiated are, respectively,

$$\Delta E = \frac{170\pi\mu^2 M^{5/2}}{3p^{7/2}}, \quad \Delta L = \frac{24\pi\mu^2 M^2}{p^2}. \quad (27.78)$$

27.6 The Detection of Gravitational Waves

27.6

27.6.1 Frequency Bands and Detection Techniques

27.6.1

Physicists and astronomers are searching for gravitational waves in four different frequency bands using four different techniques:

- In the extremely low-frequency (ELF) band, $\sim 10^{-18}$ to $\sim 10^{-15}$ Hz, gravitational waves are sought via their imprint on the polarization of the cosmic microwave background (CMB) radiation. There is only one expected ELF source of gravitational waves, but it is a very interesting one: quantum fluctuations in the gravitational field (spacetime curvature) that emerge from the big bang's quantum-gravity regime, the *Planck era*, and that are subsequently amplified to classical, detectable sizes by the universe's early inflationary expansion. We shall study this amplification and the resulting ELF gravitational waves in Sec. 28.7.1 and shall see these waves' great potential for probing the physics of inflation.

gravitational-wave frequency bands: ELF, VLF, LF, and HF; sources and detection techniques in each band

- In the very-low-frequency (VLF) band, $\sim 10^{-9}$ to $\sim 10^{-7}$ Hz, gravitational waves are sought via their influence on the propagation of radio waves emitted by pulsars (spinning neutron stars) and by the resulting fluctuations in the arrival times of the pulsars' radio-wave pulses at Earth (Sec. 27.6.6 and Ex. 27.20). The expected VLF sources are violent processes in the first fraction of a second of the universe's life (Secs. 28.4.1 and 28.7.1) and the orbital motion of extremely massive pairs of black holes in the distant universe.
- In the low-frequency (LF) band, $\sim 10^{-4}$ to ~ 0.1 Hz, gravitational waves have been sought, in the past, via their influence on the radio signals by which NASA tracks interplanetary spacecraft. In the 2020s or 2030s, this technique will likely be supplanted by some variant of the proposed LISA—three “drag-free” spacecraft in a triangular configuration with 5-km-long arms, that track one another via laser beams. LISA is likely to see waves from massive black-hole binaries (hole masses $\sim 10^5$ to $10^7 M_\odot$) out to cosmological distances; from small holes, neutron stars, and white dwarfs spiraling into massive black holes out to cosmological distances; from the orbital motion of white-dwarf binaries, neutron-star binaries, and stellar-mass black-hole binaries in our own galaxy; and possibly from violent processes in the very early universe.
- The high-frequency (HF) band, ~ 10 to $\sim 10^3$ Hz, is where Earth-based detectors operate: laser interferometer gravitational-wave detectors, such as LIGO, and resonant-mass detectors in which a gravitational wave alters the amplitude and phase of vibrations of a normal mode of a large, solid cylinder or sphere. On September 14, 2015, the advanced LIGO gravitational wave detectors made their first detection: a wave burst named GW150914 with amplitude 1.0×10^{-21} , duration ~ 150 ms, and frequency chirping upward from ~ 50 Hz (when it entered the LIGO band) to 240 Hz. By comparing the observed waveform with those from numerical relativity simulations, the LIGO-VIRGO scientists deduced that the waves came from the merger of a $29 M_\odot$ black hole with a $36 M_\odot$ black hole, 1.2 billion light years from Earth, to form a $62 M_\odot$ black hole, with a release of $3 M_\odot c^2$ of energy in gravitational waves. When this textbook went to press, additional black hole binaries were being detected. As LIGO's sensitivity improves and additional interferometers come on line, the LIGO scientists expect to see other sources: waves from spinning, slightly deformed neutron stars (e.g., pulsars) in our Milky Way galaxy, the final inspiral and collisions of binaries made from neutron stars in the more distant universe, the tearing apart of a neutron star by the spacetime curvature of a companion black hole, supernovae, the triggers of gamma-ray bursts, and possibly waves from violent processes in the very early universe.

For detailed discussions of these gravitational-wave sources in all four frequency bands, and of prospects for their detection, see, for example, Cutler and Thorne (2002)

and Sathyaprakash and Schutz (2009) and references therein. It is likely that waves will be seen in all four bands by about 2030.

EXERCISES

Exercise 27.17 *Example: Strongest Gravitational Waves in HF Band*

- (a) Using an order-of-magnitude analysis based on Eq. (27.60), show that the strongest gravitational waves that are likely to occur each year in LIGO's HF band have $h_+ \sim h_\times \sim 10^{-21}$ —which is the actual amplitude of LIGO's first observed wave burst, GW150914. [Hint: The highest nonspherical kinetic energy achievable must be for a highly deformed object (or two colliding objects), in which the internal velocities approach the speed of light—say, for realism, $v \sim 0.3c$. To achieve these velocities, the object's size L must be of order 2 or 3 Schwarzschild radii, $L \sim 5M$, where M is the source's total mass. The emitted waves must have $f \sim 200$ Hz (the frequency at the minimum of Advanced LIGO's noise curve—which is similar to initial LIGO, Fig. 6.7, but a factor ~ 10 lower). Using these considerations, estimate the internal angular frequency of the source's motion, and thence the source's mass, and finally the source's internal kinetic energy. Such a source will be very rare, so to see a few per year, its distance must be some substantial fraction of the Hubble distance. From this, estimate $h_+ \sim h_\times$.]
- (b) As a concrete example, estimate the gravitational-wave strength from the final moments of inspiral and merger of two black holes, as described by Eqs. (27.71) and (27.70b) extrapolated into the highly relativistic domain.

27.6.2 Gravitational-Wave Interferometers: Overview and Elementary Treatment

27.6.2

We briefly discussed Earth-based gravitational-wave interferometers such as LIGO in Sec. 9.5, focusing on optical interferometry issues. In this section we analyze the interaction of a gravitational wave with such an interferometer. This analysis will not only teach us much about gravitational waves, but it will also illustrate some central issues in the physical interpretation of general relativity theory.

idealized gravitational-wave interferometer

To get quickly to the essentials, we examine a rather idealized interferometer: a Michelson interferometer (one without the input mirrors of Fig. 9.13) that floats freely in space, so there is no need to hang its mirrors by wires; see Fig. 27.8. In Sec. 27.6.5, we briefly discuss more realistic interferometers.

If we ignore delicate details, the operation of this idealized interferometer is simple. As seen in a local Lorentz frame of the beam splitter, the gravitational wave changes the length of the x arm by $\delta x = \frac{1}{2}h_+\ell_x$, where ℓ_x is the unperturbed length, and it changes that of the y arm by the opposite amount: $\delta y = -\frac{1}{2}h_+\ell_y$ [Eqs. (27.29)]. The interferometer is operated with unperturbed lengths ℓ_x and ℓ_y that are nearly but not quite equal, so there is a small amount of light going toward the photodetector. The wave-induced change of arm length causes a relative phase shift of the light

FIGURE 27.8 An idealized gravitational-wave interferometer.

returning down the two arms to the beam splitter given by $\Delta\varphi(t) = \omega_o(2\delta y - 2\delta x) = \omega_o(\ell_x + \ell_y)h_+(t)$, where ω_o is the light's angular frequency (and we have set the speed of light to unity); cf. Sec. 9.5. This oscillating phase shift modulates the intensity of the light going into the photodetector by $\Delta I_{\text{PD}}(t) \propto \Delta\varphi(t)$. Setting $\ell_x \simeq \ell_y = \ell$, this modulation is

$$\Delta I_{\text{PD}}(t) \propto \Delta\varphi(t) = 2\omega_o\ell h_+(t). \quad (27.79)$$

Therefore, the photodetector output tells us directly the gravitational waveform $h_+(t)$.

In the following two (Track-Two) subsections, we rederive this result much more carefully in two different coordinate systems (two different gauges). Our two analyses predict the same result (27.79) for the interferometer output, but they appear to attribute that result to two different mechanisms.

In our first analysis (performed in TT gauge; Sec. 27.6.3), the interferometer's test mass remains always at rest in our chosen coordinate system, and the gravitational wave $h_+(t - z)$ interacts with the interferometer's light. The imprint that $h_+(t - z)$ leaves on the light causes a fluctuating light intensity $I_{\text{out}}(t) \propto h_+(t)$ to emerge from the interferometer's output port and be measured by the photodetector.

In our second analysis (a more rigorous version of the above quick analysis, performed in the proper reference frame of the interferometer's beam splitter; Sec. 27.6.4) the gravitational waves interact hardly at all with the light. Instead, they push the end mirrors back and forth relative to the coordinate system, thereby lengthening one arm while shortening the other. These changing arm lengths cause a changing interference of the light returning to the beam splitter from the two arms, and that changing interference produces the fluctuating light intensity $I_{\text{out}}(t) \propto h_+(t)$ measured by the photodetectors.

interferometer's photodetector current output

TT-gauge analysis attributes output signal to influence of waves on interferometer's light

proper-reference-frame analysis attributes output signal to interaction of waves with interferometer mirrors

These differences of viewpoint are somewhat like the differences between the Heisenberg picture and the Schrödinger picture in quantum mechanics. The intuitive pictures associated with two viewpoints appear to be very different (Schrödinger's wave function versus Heisenberg's matrices; gravitational waves interacting with light versus gravitational waves pushing on mirrors). But when one computes the same physical observable from the two different viewpoints (probability for a quantum measurement outcome; light intensity measured by photodetector), the two viewpoints give the same answer.

analogy with Heisenberg and Schrödinger pictures in quantum mechanics

27.6.3 Interferometer Analyzed in TT Gauge T2

27.6.3

For our first analysis, we place the interferometer at rest in the x - y plane of a TT coordinate system, with its arms along the x - and y -axes and its beam splitter at the origin, as shown in Fig. 27.8. For simplicity, we assume that the gravitational wave propagates in the z direction and has $+$ polarization, so the linearized spacetime metric has the TT-gauge form:

interferometer analyzed in TT gauge

$$ds^2 = -dt^2 + [1 + h_+(t - z)]dx^2 + [1 - h_+(t - z)]dy^2 + dz^2 \quad (27.80)$$

spacetime metric

[Eq. (27.20)]. For ease of notation, we omit the subscript $+$ from h_+ in the remainder of this section.

The beam splitter and end mirrors move freely and thus travel along geodesics of the metric (27.80). The splitter and mirrors are at rest in the TT coordinate system before the wave arrives, so initially, the spatial components of their 4-velocities vanish: $u_j = 0$. Because the metric coefficients $g_{\alpha\beta}$ are all independent of x and y , the geodesic equation dictates that the components u_x and u_y are conserved and thus remain zero as the wave passes, which implies (since the metric is diagonal) $u^x = dx/d\tau = 0$ and $u^y = dy/d\tau = 0$. One can also show (see Ex. 27.18) that $u^z = dz/d\tau = 0$ throughout the wave's passage. Thus, in terms of motion relative to the TT coordinate system, the gravitational wave has no influence at all on the beam splitter and mirrors; they all remain at rest (constant x , y , and z) as the waves pass.

mirrors and beam splitter do not move relative to TT coordinates

(Despite this lack of motion, the proper distances between the mirrors and the beam splitter—the interferometer's physically measured arm lengths—do change. If the unchanging coordinate lengths of the two arms are $\Delta x = \ell_x$ and $\Delta y = \ell_y$, then the metric (27.80) says that the physically measured arm lengths are

$$L_x = \left[1 + \frac{1}{2}h(t) \right] \ell_x, \quad L_y = \left[1 - \frac{1}{2}h(t) \right] \ell_y. \quad (27.81)$$

When h is positive, the x arm is lengthened and the y arm is shortened; when negative, L_x is shortened and L_y is lengthened.)

Next turn to the propagation of light in the interferometer. We assume, for simplicity, that the light beams have large enough transverse sizes that we can idealize them, on their optic axes, as plane electromagnetic waves. (In reality, they will be Gaussian

beams, of the sort studied in Sec. 8.5.5.) The light's vector potential A^α satisfies the curved-spacetime vacuum wave equation $A^{\alpha;\mu}{}_\mu = 0$ [Eq. (25.60) with vanishing Ricci tensor]. We write the vector potential in geometric optics (eikonal-approximation) form as

$$A^\alpha = \Re(A^\alpha e^{i\varphi}), \quad (27.82)$$

where A^α is a slowly varying amplitude, and φ is a rapidly varying phase [cf. Eq. (7.20)]. Because the wavefronts are (nearly) planar and the spacetime metric is nearly flat, the light's amplitude A^α will be nearly constant as it propagates down the arms, and we can ignore its variations. Not so the phase. It oscillates at the laser frequency $\omega_o/2\pi \sim 3 \times 10^{14}$ Hz [i.e., $\varphi_{x \text{ arm}}^{\text{out}} \simeq \omega_o(x - t)$ for light propagating outward from the beam splitter along the x arm, and similarly for the returning light and the light in the y arm]. The gravitational wave places tiny deviations from this $\omega_o(x - t)$ onto the phase; we must compute those deviations.

In the spirit of geometric optics, we introduce the light's spacetime wave vector

$$\vec{k} \equiv \vec{\nabla}\varphi, \quad (27.83)$$

and we assume that \vec{k} varies extremely slowly compared to the variations of φ . Then the wave equation $A^{\alpha;\mu}{}_\mu = 0$ reduces to the statement that the wave vector is null: $\vec{k} \cdot \vec{k} = \varphi_{,\alpha}\varphi_{,\beta}g^{\alpha\beta} = 0$. For light in the x arm the phase depends only on x and t ; for that in the y arm it depends only on y and t . Combining this with the TT metric (27.80) and noting that the interferometer lies in the $z = 0$ plane, we obtain

$$\begin{aligned} -\left(\frac{\partial\varphi_{x \text{ arm}}}{\partial t}\right)^2 + [1 - h(t)]\left(\frac{\partial\varphi_{x \text{ arm}}}{\partial x}\right)^2 &= 0, \\ -\left(\frac{\partial\varphi_{y \text{ arm}}}{\partial t}\right)^2 + [1 + h(t)]\left(\frac{\partial\varphi_{y \text{ arm}}}{\partial y}\right)^2 &= 0. \end{aligned} \quad (27.84)$$

influence of waves
on phase of light in
interferometer arms

We idealize the laser as perfectly monochromatic, and we place it at rest in our TT coordinates, arbitrarily close to the beam splitter. Then the outgoing light frequency, as measured by the beam splitter, must be precisely ω_o and cannot vary with time. Since proper time as measured by the beam splitter is equal to coordinate time t [cf. the metric (27.80)], the frequency that the laser and beam splitter measure must be $\omega = -\partial\varphi/\partial t = -k_t$. This dictates the following boundary conditions (initial conditions) on the phase of the light that travels outward from the beam splitter:

$$\frac{\partial\varphi_{x \text{ arm}}^{\text{out}}}{\partial t} = -\omega_o \text{ at } x = 0, \quad \frac{\partial\varphi_{y \text{ arm}}^{\text{out}}}{\partial t} = -\omega_o \text{ at } y = 0. \quad (27.85)$$

It is straightforward to verify that the solutions to Eq. (27.84) (and thence to the wave equation and thence to Maxwell's equations) that satisfy the boundary conditions (27.85) are

$$\begin{aligned}\varphi_{x \text{ arm}}^{\text{out}} &= -\omega_o \left[t - x + \frac{1}{2}H(t - x) - \frac{1}{2}H(t) \right], \\ \varphi_{y \text{ arm}}^{\text{out}} &= -\omega_o \left[t - y - \frac{1}{2}H(t - y) + \frac{1}{2}H(t) \right],\end{aligned}\quad (27.86)$$

where $H(t)$ is the first time integral of the gravitational waveform:

$$H(t) \equiv \int_0^t h(t') dt' \quad (27.87)$$

(cf. Ex. 27.19).

The outgoing light reflects off the mirrors, which are at rest in the TT coordinates at locations $x = \ell_x$ and $y = \ell_y$. As measured by observers at rest in these coordinates, there is no Doppler shift of the light, because the mirrors are not moving. Correspondingly, the phases of the reflected light, returning back along the two arms, have the following forms:

$$\begin{aligned}\varphi_{x \text{ arm}}^{\text{back}} &= -\omega_o \left[t + x - 2\ell_x + \frac{1}{2}H(t + x - 2\ell_x) - \frac{1}{2}H(t) \right], \\ \varphi_{y \text{ arm}}^{\text{back}} &= -\omega_o \left[t + y - 2\ell_y - \frac{1}{2}H(t + y - 2\ell_y) + \frac{1}{2}H(t) \right].\end{aligned}\quad (27.88)$$

The difference of the phases of the returning light, at the beam splitter ($x = y = 0$), is

$$\begin{aligned}\Delta\varphi &\equiv \varphi_{x \text{ arm}}^{\text{back}} - \varphi_{y \text{ arm}}^{\text{back}} = -\omega_o[-2(\ell_x - \ell_y) + \frac{1}{2}H(t - 2\ell_x) + \frac{1}{2}H(t - 2\ell_y) - H(t)] \\ &\simeq +2\omega_o[\ell_x - \ell_y + \ell h(t)] \quad \text{for Earth-based interferometers.}\end{aligned}\quad (27.89)$$

In the final expression we have used the fact that for Earth-based interferometers operating in the HF band, the gravitational wavelength $\lambda_{\text{GW}} \sim c/(100 \text{ Hz}) \sim 3,000 \text{ km}$ is long compared to the interferometers' $\sim 4\text{-km}$ arms, and the arms have nearly the same length: $\ell_y \simeq \ell_x \equiv \ell$.

The beam splitter sends a light field $\propto e^{i\varphi_{x \text{ arm}}^{\text{back}}} + e^{i\varphi_{y \text{ arm}}^{\text{back}}}$ back toward the laser, and a field $\propto e^{i\varphi_{x \text{ arm}}^{\text{back}}} - e^{i\varphi_{y \text{ arm}}^{\text{back}}} = e^{i\varphi_{y \text{ arm}}^{\text{back}}}(e^{i\Delta\varphi} - 1)$ toward the photodetector. The intensity of the light entering the photodetector is proportional to the squared amplitude of the field: $I_{\text{PD}} \propto |e^{i\Delta\varphi} - 1|^2$. We adjust the interferometer's arm lengths so their difference $\ell_x - \ell_y$ is small compared to the light's reduced wavelength $1/\omega_o = c/\omega_o$ but large compared to $|\ell h(t)|$. Correspondingly, $|\Delta\varphi| \ll 1$, so only a tiny fraction of the light goes toward the photodetector (it is the interferometer's "dark port"), and that dark-port light intensity is

$$I_{\text{PD}} \propto |e^{i\Delta\varphi} - 1|^2 \simeq |\Delta\varphi|^2 \simeq 4\omega_o^2(\ell_x - \ell_y)^2 + 8\omega_o^2(\ell_x - \ell_y)\ell h_+(t). \quad (27.90)$$

Here we have restored the subscript $+$ onto h . The time-varying part of this intensity is proportional to the gravitational waveform $h_+(t)$ [in agreement with Eq. (27.79)]. It is this time-varying part that the photodetector reports as the interferometer output.

Exercise 27.18 *Derivation and Practice: Geodesic Motion in TT Coordinates* T2

Consider a particle that is at rest in the TT coordinate system of the gravitational-wave metric (27.80) before the gravitational wave arrives. In the text it is shown that the particle's 4-velocity has $u^x = u^y = 0$ as the wave passes. Show that $u^z = 0$ and $u^t = 1$ as the wave passes, so the components of the particle's 4-velocity are unaffected by the passing gravitational wave, and the particle remains at rest (constant x , y , and z) in the TT coordinate system.

Exercise 27.19 *Example: Light in an Interferometric Gravitational-Wave**Detector in TT Gauge* T2

Consider the light propagating outward from the beam splitter, along the x arm of an interferometric gravitational-wave detector, as analyzed in TT gauge, so (suppressing the subscript “ x arm” and superscript “out”) the electromagnetic vector potential is $A^\alpha = \Re(A^\alpha e^{i\varphi(x,t)})$, with A^α constant and with $\varphi = -\omega_o[t - x + \frac{1}{2}H(t - x) - \frac{1}{2}H(t)]$ [Eqs. (27.86) and (27.87)].

- Show that this φ satisfies the nullness equation (27.84), as claimed in the text—which implies that $A^\alpha = \Re(A^\alpha e^{i\varphi(x,t)})$ satisfies Maxwell's equations in the geometric-optics limit.
- Show that this φ satisfies the initial condition (27.85), as claimed in the text.
- Show that, because the gradient $\vec{k} = \vec{\nabla}\varphi$ of this φ satisfies $\vec{k} \cdot \vec{k} = 0$, it also satisfies $\nabla_{\vec{k}}\vec{k} = 0$. Thus, the wave vector is the tangent vector to geometric-optics rays that are null geodesics in the gravitational-wave metric. Photons travel along these null geodesics and have 4-momenta $\vec{p} = \hbar\vec{k}$.
- Because the gravitational-wave metric (27.80) is independent of x , the p_x component of a photon's 4-momentum must be conserved along its geodesic world line. Compute $p_x = k_x = \partial\varphi/\partial x$, and thereby verify this conservation law.
- Explain why the photon's frequency, as measured by observers at rest in our TT coordinate system, is $\omega = -k_t = -\partial\varphi/\partial t$. Explain why the rate of change of this frequency, as computed moving with the photon, is $d\omega/dt \simeq (\partial/\partial t + \partial/\partial x)\omega$, and show that $d\omega/dt \simeq -\frac{1}{2}\omega_o dh/dt$.

27.6.4

27.6.4 Interferometer Analyzed in the Proper Reference Frame of the Beam Splitter T2

proper-reference-frame
analysis

We now carefully reanalyze our idealized interferometer in the proper reference frame of its beam splitter, denoting that frame's coordinates by \hat{x}^α . Because the beam splitter is freely falling (moving along a geodesic through the gravitational-wave spacetime), its proper reference frame is locally Lorentz (LL), and its metric coefficients have the form $g_{\hat{\alpha}\hat{\beta}} = \eta_{\alpha\beta} + O(\delta_{jk}\hat{x}^j\hat{x}^k/\mathcal{R}^2)$ [Eq. (25.9a)]. Here \mathcal{R} is the radius of curvature of spacetime, and $1/\mathcal{R}^2$ is of order the components of the Riemann tensor, which have

magnitude $\ddot{h}(\hat{t} - \hat{z})$ [Eq. (27.22) with t and z equal to \hat{t} and \hat{z} , aside from fractional corrections of order h]. Thus we have:

$$g_{\hat{\alpha}\hat{\beta}} = \eta_{\alpha\beta} + O[\ddot{h}(\hat{t} - \hat{z})\delta_{jk}\hat{x}^j\hat{x}^k]. \quad (27.91)$$

(Here and below we again omit the subscript $+$ on h for ease of notation.)

The following coordinate transformation takes us from the TT coordinates x^α used in Sec. 27.6.3 to the beam splitter's LL coordinates:

$$\begin{aligned} x &= \left[1 - \frac{1}{2}h(\hat{t} - \hat{z})\right] \hat{x}, & y &= \left[1 + \frac{1}{2}h(\hat{t} - \hat{z})\right] \hat{y}, \\ t &= \hat{t} - \frac{1}{4}\dot{h}(\hat{t} - \hat{z})(\hat{x}^2 - \hat{y}^2), & z &= \hat{z} - \frac{1}{4}\dot{h}(\hat{t} - \hat{z})(\hat{x}^2 - \hat{y}^2). \end{aligned} \quad (27.92)$$

It is straightforward to insert this coordinate transformation into the TT-gauge metric (27.80) and thereby obtain, to linear order in h :

$$ds^2 = -d\hat{t}^2 + d\hat{x}^2 + d\hat{y}^2 + d\hat{z}^2 + \frac{1}{2}(\hat{x}^2 - \hat{y}^2)\ddot{h}(t - z)(d\hat{t} - d\hat{z})^2. \quad (27.93)$$

spacetime metric in proper reference frame of beam splitter

This has the expected LL form (27.91) and, remarkably, it turns out not only to be a solution of the vacuum Einstein equation in linearized theory but also an exact solution to the full vacuum Einstein equation (cf. Misner, Thorne, and Wheeler, 1973, Ex. 35.8)!

Throughout our idealized interferometer, the magnitude of the metric perturbation in these LL coordinates is $|h_{\hat{\alpha}\hat{\beta}}| \lesssim (\ell/\lambda_{\text{GW}})^2 h$, where $\lambda_{\text{GW}} = \lambda_{\text{GW}}/(2\pi)$ is the waves' reduced wavelength, and h is the magnitude of $h(\hat{t} - \hat{z})$. For Earth-based interferometers operating in the HF band (~ 10 to ~ 1000 Hz), λ_{GW} is of order 50–5,000 km, and the arm lengths are $\ell \leq 4$ km, so $(L/\lambda)^2 \lesssim 10^{-6}$ to 10^{-2} . Thus, the metric coefficients $h_{\hat{\alpha}\hat{\beta}}$ are no larger than $h/100$. This has a valuable consequence for the analysis of the interferometer: up to fractional accuracy $\sim (\ell/\lambda_{\text{GW}})^2 h \lesssim h/100$, the LL coordinates are globally Lorentz throughout the interferometer (i.e., \hat{t} measures proper time, and \hat{x}^j are Cartesian and measure proper distance). In the rest of this section, we restrict attention to such Earth-based interferometers but continue to treat them as though they were freely falling. (See Sec. 27.6.5 for the influence of Earth's gravity.)

Being initially at rest at the origin of these LL coordinates, the beam splitter remains always at rest, but the mirrors move. Not surprisingly, the geodesic equation for the mirrors in the metric (27.93) dictates that their coordinate positions are, up to fractional errors of order $(\ell/\lambda_{\text{GW}})^2 h$,

$$\begin{aligned}\hat{x} &= L_x = \left[1 + \frac{1}{2}h(\hat{t})\right] \ell_x, & \hat{y} = \hat{z} = 0 & \text{ for mirror in } x \text{ arm,} \\ \hat{y} &= L_y = \left[1 - \frac{1}{2}h(\hat{t})\right] \ell_y, & \hat{x} = \hat{z} = 0 & \text{ for mirror in } y \text{ arm.}\end{aligned}\tag{27.94}$$

[Equations (27.94) can also be deduced from the gravitational-wave tidal acceleration $-\mathcal{E}_{\hat{j}\hat{k}}\hat{x}^k$, as in Eq. (27.25), and from the fact that to good accuracy \hat{x} and \hat{y} measure proper distance from the beam splitter.] So even though the mirrors do not move in TT coordinates, they do move in LL coordinates. The two coordinate systems predict the same time-varying physical arm lengths (the same proper distances from beam splitter to mirrors), L_x and L_y [Eqs. (27.81) and (27.94)].

As in TT coordinates, so also in LL coordinates, we can analyze the light propagation in the geometric-optics approximation, with $A^{\hat{\alpha}} = \Re(\mathcal{A}^{\hat{\alpha}}e^{i\varphi})$. Just as the wave equation for the vector potential dictates in TT coordinates that the rapidly varying phase of the outward light in the x arm has the form $\varphi_{x \text{ arm}}^{\text{out}} = -\omega_o(t - x) + \mathcal{O}(\omega_o \ell h_{\mu\nu})$ [Eqs. (27.86) with $x \sim \ell \ll \lambda_{\text{GW}}$, so $H(t - x) - H(t) \simeq \dot{H}(t)x = h(t)x \sim h\ell \sim h_{\mu\nu}\ell$], so similarly the wave equation in LL coordinates turns out to dictate that

$$\varphi_{x \text{ arm}}^{\text{out}} = -\omega_o(\hat{t} - \hat{x}) + \mathcal{O}(\omega_o \ell h_{\hat{\mu}\hat{\nu}}) = -\omega_o(\hat{t} - \hat{x}) + \mathcal{O}\left(\omega_o \ell h \frac{\ell^2}{\lambda_{\text{GW}}^2}\right), \tag{27.95}$$

and similarly for the returning light and the light in the y arm. The term $\mathcal{O}(\omega_o \ell h \ell^2 / \lambda_{\text{GW}}^2)$ is the influence of the direct interaction between the gravitational wave and the light, and it is negligible in the final answer (27.96) for the measured phase shift. Aside from this term, the analysis of the interferometer proceeds in exactly the same way as in flat space (because \hat{t} measures proper time and \hat{x} and \hat{y} proper distance): the light travels a round trip distance L_x in one arm and L_y in the other, and therefore acquires a phase difference, on arriving back at the beam splitter, given by

$$\begin{aligned}\Delta\varphi &= -\omega_o[-2(L_x - L_y)] + \mathcal{O}\left(\omega_o \ell h \frac{\ell^2}{\lambda_{\text{GW}}^2}\right) \\ &\simeq +2\omega_o[\ell_x - \ell_y + \ell h(\hat{t})] + \mathcal{O}\left(\omega_o \ell h \frac{\ell^2}{\lambda_{\text{GW}}^2}\right).\end{aligned}\tag{27.96}$$

This net phase difference for the light returning from the two arms is the same as we deduced in TT coordinates [Eq. (27.89)], up to the negligible correction $\mathcal{O}(\omega_o \ell h \ell^2 / \lambda_{\text{GW}}^2)$, and therefore the time-varying intensity of the light into the photodetector will be the same [Eq. (27.90)].

In our TT analysis the phase shift $2\omega_o \ell h(t)$ arose from the interaction of the light with the gravitational waves. In the LL analysis, it is due to the displacements

of the mirrors in the LL coordinates (i.e., the displacements as measured in terms of proper distance) that cause the light to travel different distances in the two arms. The direct LL interaction of the waves with the light produces only the tiny correction $O(\omega_o \ell h \ell^2 / \lambda_{\text{GW}}^2)$ to the phase shift.

It should be evident that the LL description is much closer to elementary physics than the TT description is. This is always the case, when one's apparatus is sufficiently small that one can regard \hat{t} as measuring proper time and \hat{x}^j as Cartesian coordinates that measure proper distance throughout the apparatus. But for a large apparatus (e.g., planned space-based interferometers such as LISA, with arm lengths $\ell \gtrsim \lambda_{\text{GW}}$, and the pulsar timing arrays of Sec. 27.6.6) the LL analysis becomes quite complicated, as one must pay close attention to the $O(\omega_o \ell h \ell^2 / \lambda_{\text{GW}}^2)$ corrections. In such a case, the TT analysis is much simpler.

27.6.5 Realistic Interferometers T2

27.6.5

For realistic, Earth-based interferometers, one must take account of the acceleration of gravity. Experimenters do this by hanging their beam splitters and test masses on wires or fibers. The simplest way to analyze such an interferometer is in the proper reference frame of the beam splitter, where the metric must now include the influence of the acceleration of gravity by adding a term $-2g\hat{z}$ to the metric coefficient $h_{\hat{0}\hat{0}}$ [cf. Eq. (24.60b)]. The resulting analysis, like that in the LL frame of our freely falling interferometer, will be identical to what one would do in an accelerated reference frame of flat spacetime, so long as one takes account of the motion of the test masses driven by the gravitational-wave tidal acceleration $-\mathcal{E}_{\hat{i}\hat{j}}\hat{x}^j$, and so long as one is willing to ignore the tiny effects of $O(\omega_o \ell h \ell^2 / \lambda_{\text{GW}}^2)$.

To make the realistic interferometer achieve high sensitivity, the experimenters introduce a lot of clever complications, such as the input mirrors of Fig. 9.13, which turn the arms into Fabry-Perot cavities. All these complications can be analyzed, in the beam splitter's proper reference frame, using standard flat-spacetime techniques augmented by the gravitational-wave tidal acceleration. The direct coupling of the light to the gravitational waves can be neglected, as in our idealized interferometer.

27.6.6 Pulsar Timing Arrays T2

27.6.6

A rather different approach to direct detection of gravitational waves is by the influence of the waves on the timing of an array of radio pulsars (Hobbs et al., 2010).

As we have discussed in Sec. 27.2.6, many pulsars, especially those with millisecond periods, have pulse arrival times at the radio telescope that can be predicted with high accuracy—30 to 100 ns in the best cases—after correcting for slowing down of the pulsar, propagation effects, and the motion of the telescope relative to the center of mass of the solar system. If the radio pulses travel through a gravitational wave, then they incur tiny variations in arrival time that can be used to detect the wave. This technique is most sensitive to waves with frequency $f \sim 30$ nHz (the gravitational

gravitational-wave searches via pulsar timing arrays in VLF band

VLF band; see Sec. 27.6.1), so a few periods are sampled over the duration of an observation, typically a few years. The most promising sources are supermassive binary black holes in the nuclei of distant galaxies.

Let us consider the idealized problem of radio pulses emitted at a steady rate by a stationary pulsar with position \mathbf{z} relative to a stationary telescope on Earth and traveling at the speed of light. Now, suppose that there is a single, monochromatic, plane gravitational wave, $\mathbf{h} = \mathbf{h}_o \cos[2\pi f(t + \mathbf{x} \cdot \hat{\mathbf{r}})]$, where $\hat{\mathbf{r}}$ is a unit vector pointing toward the source. For the wave, adopt the metric (27.18a) and TT gauge. The pulsar and the telescope will remain at rest with respect to the coordinates (Ex. 27.18), and t measures their proper times.

The wave-induced time delay in the arrival of a pulse, called the *residual* $R(t)$, is then given by integrating along a past directed null geodesic ($ds = 0$) from the telescope to the pulsar:⁶

$$\begin{aligned}
 R(t) &= -\frac{1}{2} \int_0^z dz' \hat{\mathbf{z}} \cdot \mathbf{h}_o \cdot \hat{\mathbf{z}} \cos(2\pi f[t - z'(1 - \hat{\mathbf{z}} \cdot \hat{\mathbf{r}})]) \\
 &= \frac{\hat{\mathbf{z}} \cdot \mathbf{h}_o \cdot \hat{\mathbf{z}} \{ \sin(2\pi f[t - z(1 - \hat{\mathbf{z}} \cdot \hat{\mathbf{r}})]) - \sin(2\pi f t) \}}{4\pi f(1 - \hat{\mathbf{z}} \cdot \hat{\mathbf{r}})}
 \end{aligned} \tag{27.97}$$

influence of gravitational wave on radio pulses' time delay (their "residual")

(Ex. 27.20a). Note that two terms contribute to the residual; the first is associated with the wave as it passes the pulsar, the second is local and associated with the wave passing Earth.

This search for gravitational waves is being prosecuted not just with a single pulsar but also with an array of tens (currently and hundreds in the future) of millisecond pulsars. Programs using different telescopes are being coordinated and combined through the International Pulsar Timing Array (IPTA) collaboration (<http://www.ipta4gw.org>). The local residual (27.97) is correlated between different lines of sight to different pulsars with differing polarization projections $\hat{\mathbf{z}} \cdot \mathbf{h}_o \cdot \hat{\mathbf{z}}$. This facilitates identifying the waves amidst different noises associated with different pulsars, and it allows a coherent addition of the data from many pulsars, which will be particularly valuable in searches for individual sources of gravitational radiation. If and when a source is located, the array can be used to fix its direction $\hat{\mathbf{r}}$ and the polarization of the waves. In addition to extracting astrophysics of the source, there should be a clear affirmation that gravitational waves have spin two and travel at the speed of light.

correlation of residuals between different pulsars

gravitational-wave sources in VLF band

However, unless we are very lucky, it is more likely that the first detection or the most prescriptive upper limit will relate to a stochastic background created by the superposed waves from many black hole binaries (Ex. 27.21). Although the bandwidth from an individual source will be of order the reciprocal of the time it takes the binary

6. Of course the actual null geodesic followed by the radio waves changes in the presence of the gravitational wave but, invoking Fermat's principle, the travel time is unchanged to $O(h)$ if we integrate along the unperturbed trajectory.

frequency to double—in the fHz to pHz range—the randomly phased signals are likely to overlap in frequency, ensuring that the gravitational radiation can be well described by a spectral energy density.

Other more speculative sources of gravitational waves in the VLF frequency band have been proposed, especially cosmic strings. There could be many surprises waiting to be discovered.

EXERCISES

Exercise 27.20 *Example: Pulsar Timing Array* T2

Explore how pulsar timing can be used to detect a plane gravitational wave.

- (a) Derive Eq. (27.97). [Hint: One way to derive this result is from the action

$$\frac{1}{2} \int g_{\alpha\beta} (dx^\alpha/d\zeta)(dx^\beta/d\zeta) d\zeta$$

that underlies the rays' super-hamiltonian; Ex. 25.7. The numerical value of the action is zero, and since it is an extremum along each true ray, if you evaluate it along a path that is a straight line in the TT coordinate system instead of along the true ray, you will still get zero at first order in h_o .]

- (b) Recognizing local and pulsar contributions to the timing residuals, explain how much information about the amplitude, direction, and polarization of a gravitational wave from a single black-hole binary can be obtained using accurate timing data from one, two, three, four, and many pulsars.
- (c) Suppose, optimistically, that 30 pulsars will be monitored with timing accuracy ~ 100 ns, and that arrival times will be measured 30 times a year. Make an estimate of the minimum measurable amplitude of the sinusoidal residual created by a single binary as a function of observing duration and wave frequency f .
- (d) Using the result from part (c) and using the predicted residual averaged over the direction and the orientation of the source from Eqs. (27.71c) and (27.71d), estimate the maximum distance to which an individual source could be detected as a function of the chirp mass \mathcal{M} and the frequency f .

Exercise 27.21 *Problem: Stochastic Background from Binary Black Holes* T2

The most likely signal to be detected using a pulsar timing array is a stochastic background formed by perhaps billions of binary black holes in the nuclei of galaxies.

- (a) For simplicity, suppose that these binaries are all on circular orbits and that they lose energy at a rate given by Eqs. (27.73). Show that for each binary the gravitational wave energy radiated per unit log wave frequency is

$$\frac{dE_{GW}}{d \ln f} = -\frac{dE}{d \ln f} = -\frac{2E}{3} = \frac{\pi^{2/3}}{3} \mathcal{M}^{5/3} f^{2/3}, \quad (27.98a)$$

where \mathcal{M} is the chirp mass given by Eq. (27.76c) and E is its orbital energy given by $-\frac{1}{2}\mu M/a$.

- (b) Suppose that, on astrophysical grounds, binaries only radiate gravitational radiation efficiently if they merge in less than $t_{\text{merge}} \sim 300$ Myr. Show that this requires

$$\mathcal{M} > \left(\frac{5}{256 t_{\text{merge}}} \right)^{3/5} (\pi f)^{-8/5}. \quad (27.98b)$$

This evaluates to ~ 1 million solar masses for $f \sim 30$ nHz. By contrast, measured masses of the large black holes in the nuclei of galaxies range from about 4 million solar masses as in our own modest spiral galaxy to perhaps 20 billion solar masses in the largest galaxies observed.

- (c) Now suppose that these black holes grew mostly through mergers of holes with very different masses. Show that the total energy radiated per unit log frequency over the course of the many mergers that led to a black hole with mass M is

$$\frac{dE_{GW}}{d \ln f} \sim \frac{\pi^{2/3}}{5} M^{5/3} f^{2/3}. \quad (27.98c)$$

- (d) The number density per unit mass dn/dM today of these merging black holes has been estimated to be

$$\frac{dn}{d \ln M} = \frac{\rho_{BH} M^2}{2M_t^3} e^{-M/M_t}, \quad (27.98d)$$

where $\rho_{BH} \sim 2 \times 10^{-15} \text{ J m}^{-3}$ is the contribution of black holes (i.e., of their masses) to the average energy density in the local universe and $M_t = 5 \times 10^7$ solar masses $\sim 10^{38}$ kg. Show that

$$\frac{d\rho_{GW}}{d \ln f} \sim \frac{\pi^{2/3} \Gamma(11/3)}{10} (M_t f)^{2/3} \rho_{BH} \sim 7 \times 10^{-19} \left(\frac{f}{30 \text{ nHz}} \right)^{2/3} \text{ J m}^{-3}. \quad (27.99)$$

This is an overestimate, because most of the black holes were likely assembled in the past, when the universe was about three times smaller than it is today. If one thinks of the gravitational waves as gravitons that lose energy as the universe expands, then this energy density should be reduced by a factor of three. Furthermore, as the black holes are thought to grow through accretion of gas and not by mergers, this estimate should be considered an upper bound.

- (e) Making the same assumptions as in the previous exercise, determine whether it will be possible to detect this background in 5 years of observation.

Bibliographic Note

For an elementary introduction to experimental tests of general relativity in the solar system, we recommend Hartle (2003, Chap. 10). For an enjoyable, popular-level book on experimental tests, see Will (1993b). For a very complete monograph on the theory

underlying experimental tests, see Will (1993a), and for a more nearly up-to-date review of experimental tests, see Will (2014).

For elementary and fairly complete introductions to gravitational waves, we recommend Hartle (2003, Chaps. 16, 23) and Schutz (2009, Chap. 9). For more advanced treatments, we suggest Misner, Thorne, and Wheeler (1973, Sec. 18.2 and Chaps. 35, 36), Thorne (1983), and Straumann (2013, Secs. 5.3–5.7); but Misner, Thorne, and Wheeler (1973, Chap. 37) on gravitational-wave detection is terribly out of date and is not recommended. For fairly complete reviews of gravitational-wave sources for ground-based detectors (LIGO, etc.) and space-based detectors (LISA, etc.), see Cutler and Thorne (2002) and Sathyaprakash and Schutz (2009). For a lovely monograph on the physics of interferometric gravitational-wave detectors, see Saulson (1994).

Because gravitational-wave science is a rapidly maturing and burgeoning field, there are long, in-depth treatments that include considerable experimental detail and much detail on data analysis techniques, as well as on wave sources and the fundamental theory: Thorne, Bondarescu, and Chen (2002), Maggiore (2007), and Creighton and Anderson (2011).

Cosmology

The expansion thus took place in three phases, a first period of rapid expansion in which the atom universe was broken into atomic stars, a period of slowing down, followed by a third period of accelerated expansion.

GEORGES LEMAÎTRE (1933)

28.1 Overview

28.1

The extragalactic sky is isotropic and dark at night. Distant galaxies accelerate away from us. Five-sixths of the matter in the universe is in a “dark” form that we can only detect through its gravitational effects. We are immersed in a bath of blackbody radiation—the *cosmic microwave background* (CMB)—with a temperature of ~ 2.7 K that exhibits tiny fluctuations with fractional amplitude $\sim 10^{-5}$. These four profound observations lead inexorably to a description of the universe that began from a hot big bang nearly 14 billion years ago. Remarkable progress over recent years in making careful measurements of these features has led to a *standard cosmology* that involves mostly classical physics and incorporates many of the ideas and techniques we have discussed in the preceding 27 chapters.

Let us begin by describing the universe. We live on Earth, the “third rock” out from an undistinguished star located in the outskirts of a quite ordinary galaxy—the second largest in a loose federation of galaxies called the *local group* on the periphery of the *local supercluster*. Our neighbors are no more remarkable. Meanwhile, the distant galaxies and microwave background photons that we observe exhibit no preferred directions. In short, we do not appear to be special, and nowhere else that we can see appears to be special. It is therefore reasonable to assume that the universe has no “center” and that it is essentially homogeneous on the largest scales that we observe, so that all parts are equivalent at the same time. By extension, the average observed properties of the universe and its inferred history would be similar if we lived in any other galaxy.

However, it has long been known that the universe cannot also be infinite and static. If it were, then any line of sight would eventually intercept the surface of a star, and the night sky would be bright. Instead, as we observe directly, galaxies and their constituent stars are receding from us, and the speed of recession is now increasing with time, contrary to our Newtonian expectation. This expansion is observed out to distances that are so great that the recession velocities are relativistic, dimming the light from the distant stars and galaxies, and making the night sky between nearby

stars as dark as we observe. Furthermore, the amount of matter in the universe induces gravitational potential differences of order c^2 across the observed universe.

These features require a general relativistic description. However, even if we had tested it adequately in the strong field regime of black holes and neutron stars (which we have only begun to do), there is no more guarantee that general relativity describes the universe at large than that classical mechanics and electromagnetism suffice to describe atoms! Despite this, the best way to proceed is to continue to adopt general relativity and be alert to the possibility that it could fail us. What we shall discover is that it provides a sufficient and successful framework for describing the observations.

The discovery of the CMB in 1964 transformed cosmology. This radiation must have dominated the stress-energy tensor and, consequently, the geometry and dynamics of the universe in the past. More recently, it has been used to show that the spatial curvature of the universe is very small and that the CMB's tiny temperature fluctuations have simple behavior consistent with basic (mostly classical) physics. And the fluctuations can be used to argue that the universe exhibited a brief growth spurt, called *inflation*, when it was very young—a surge that established both the observed uniformity and the structure that we see around us today. No less important has been the quantitative description, mostly developed over the past 20 years, of the two invisible entities (popularly known as *dark matter* and the *cosmological constant* or, more generally, *dark energy*) that account for 95% of the modern universe. In fact, the measurements have become so good that most alternative descriptions of the universe have been ruled out and no longer need to be discussed. This is a good time to benefit from this simplification.

This chapter is longer, more ambitious, and less didactic—there are no practice and derivation exercises—than its predecessors, because we want to take advantage of the opportunity to exhibit modern classical physics in one of its most exciting and currently successful applications. The reader must expect to read slowly and carefully to “connect the dots.” To keep the chapter at a manageable length, we eschew essentially all critical discussion of the observations and measurements, including errors. We also avoid the idiosyncratic terminology and conventions of astronomy. Finally, we stop short of describing the birth and development of galaxies, stars, and planets, as these phenomenological investigations would take us too far away from the direct application of general principles. Despite these limitations, it is striking how much of what is known about the universe can be calculated with passable accuracy using the ideas, principles, and techniques discussed in this book.

We begin in Sec. 28.2 by developing general relativistic cosmology, emphasizing the geometry and the kinematics before turning to the dynamics. In Sec. 28.3, we describe all the major constituents of the universe today and we follow this in Sec. 28.4 with a development of standard cosmology starting from when the temperature was roughly 10^{11} K, distinguishing seven distinct ages. In Sec. 28.5, we develop a theory to describe the growth of perturbations, which ultimately led to clustered galaxies. Most of what we know about the universe comes from observing photons, and so in

Sec. 28.6, we develop the cosmological optics that we need to draw inferences about the birth and growth of the universe. In Sec. 28.7, we conclude by discussing three foci of current research and incipient progress—attempts to understand the origin of the universe, notably inflation, theories of the creation of dark matter and baryons, and speculations about the fate of the universe involving the role of the cosmological constant.

28.2 28.2 General Relativistic Cosmology

28.2.1 28.2.1 Isotropy and Homogeneity

galaxies at a glance

We start by introducing *galaxies* and describing their distribution in space. A typical galaxy, like our own, comprises $\sim 10^{11}$ luminous stars (with a combined luminosity of $\sim 10^{37}$ W)¹ and gas, mostly concentrated in a sphere of radius about 3×10^{20} m ~ 10 kpc located at the center of a sphere about ten times larger dominated by collisionless dark matter (Fig. 28.1). A typical galaxy mass is 10^{42} kg. There is a large range in galaxy masses from less than a millionth of the mass of our galaxy to more than a hundred times its mass.

distribution of galaxies

Roughly a trillion galaxies can be seen over the whole sky (Fig. 28.1; Beckwith et al., 2006). Their distribution appears to be quite isotropic. We can estimate their distances and study their spatial distribution. It is found that the galaxies are strongly clustered on scales of $\lesssim 3 \times 10^{23}$ m ~ 10 Mpc. Especially prominent are clusters of roughly a thousand galaxies. The strength of their relative clustering diminishes with increasing linear scale to $|\delta N/N| \sim 10^{-5}$ when the scale size is comparable with the “size” of the universe (which we will define more carefully below as $\sim 10^{26}$ m ~ 3 Gpc). Insofar as luminous galaxies fairly sample all material in the universe, it seems that on large enough scales, we can regard the matter distribution today as quite homogeneous.

cosmic microwave background

An even more impressive demonstration of this uniformity comes from observations of the CMB (Fig. 28.1; Penzias and Wilson, 1965). Not only does it retain a blackbody spectrum, the temperature fluctuations are also only $|\delta T/T| \lesssim 3 \times 10^{-5}$ on angular scales from radians to arcminutes. (There is a somewhat larger dipolar component, but this is attributable to a Doppler shift caused by the compounded motion of Earth, the Sun, and our galaxy.) This radiation has propagated to us from an epoch when the universe was a thousand times smaller than it is today and, as we shall demonstrate, the temperature was a thousand times greater, roughly 3,000 K. If the universe were significantly inhomogeneous at this time, then we would see far larger fluctuations in its temperature, spectrum, and polarization. We conclude that the young universe was quite homogeneous, just like the contemporary universe appears to be on the largest scales.

1. For calibration, the Sun has a mass of 2.0×10^{30} kg and a luminosity of 3.9×10^{26} W. The standard astronomical distance measure is 1 parsec (pc) = 3.1×10^{16} m.

FIGURE 28.1 Four astronomical images that illustrate recent discoveries about the universe. (a) Image of the whole sky made by the Planck satellite, exhibiting $\sim 10 \mu\text{K}$ fluctuations in the observed $\sim 3 \text{ K}$ temperature of the CMB (Sec. 28.6.1; credit: Planck Collaboration, 2016a). These fluctuations, observed when the universe was $\sim 400,000$ yr old, depict the seeds out of which grew the large structures we see around us today. (b) The deepest image of the sky taken by Hubble Space Telescope, roughly 2 arcmin across (Hubble eXtreme Deep Field, http://en.wikipedia.org/wiki/Hubble_eXtreme_Deep_Field; credit: NASA; ESA; G. Illingworth, and the HUDF09 Team, 2013). The light from the most distant galaxies in this image is estimated to have been emitted when the universe was only ~ 0.08 of its present size and less than 500 Myr old (Sec. 28.4.5). (c) Combined ultraviolet and infrared image of the Andromeda galaxy, the nearest large galaxy to our Milky Way galaxy. (Credit: NASA/JPL-Caltech.) Orbiting hydrogen gas can be seen out to about five times the size of this image, demonstrating that the stars we see form at the bottom of a large potential well of dark matter (Sec. 28.2.1). (d) The Bullet cluster of galaxies. (Credit: X-ray: NASA/CXC/CfA/M. Markevitch et al.; lensing map: NASA/STScI; ESO WFI; Magellan/University of Arizona/D. Clowe et al.; optical: NASA/STScI; Magellan/University of Arizona/D. Clowe et al.) Two clusters, each containing roughly several hundred galaxies, are in the process of merging. The hot gas, in red, can be traced by its X-ray emission and is separated from the dark matter, in blue, which can be located by the weak gravitational lensing distortion it imposes on the images of background galaxies (Sec. 28.6.2). The separation of these concentrations of matter demonstrates that dark matter is effectively collisionless (Sec. 28.3.2).

There is only one conceivable escape from this conclusion. We could live at the origin of a spherically symmetric, radially inhomogeneous universe. The assumption that this is not the case is sometimes known as the *Copernican Principle* by analogy with the proposition that Earth is not at the center of the solar system. According to this principle, the universe would look similarly isotropic from all other vantage points at the same time. If one accepts this hypothesis, then isotropy about us and about all other points at the same time implies homogeneity. This can be demonstrated formally.

homogeneous and isotropic universe

These observational data justify a procedure in modeling the average universe, which was adopted by Einstein (1917) and others with little more than philosophical justification in the early days of relativistic cosmology. Like Einstein, we assume, as a zeroth order approximation, that the universe is homogeneous and isotropic at a given time. This can be stated more carefully as follows. *There exists a family of slices of simultaneity (3-dimensional spacelike hypersurfaces; Fig. 28.2), which completely covers spacetime, with the special property that on a given slice of simultaneity (i) no two points are distinguishable from each other (homogeneity) and (ii) at a given point no one spatial direction is distinguishable from any other (isotropy).*

fundamental observers

So, how do we assign these slices of simultaneity? Fortunately, the universe comes with a clock, the temperature of the CMB. (For the moment, ignore the tiny fluctuations.) We then introduce a set of imaginary *fundamental observers* (FOs; Fig. 28.2) and give them the velocity that removes the dipole anisotropy in the temperature distribution.² (Henceforth when we talk about observations at Earth, we imagine that these are observations made by an FO coincident with Earth today. To get the actual Earth-based observations, we just add a small Doppler shift to these FO observations.) These FOs individually move on world lines that keep the CMB isotropic. We regard the 3-dimensional hypersurfaces that they inhabit when they all measure the same CMB temperature as spaces in their own right, which we approximate as homogeneous. Isotropy guarantees that the FO world lines are orthogonal to these “slices of simultaneity.” Let us focus on the hypersurface that we inhabit today, formed by freezing the action when everyone measures the CMB temperature to be 2.725 K.

28.2.2

28.2.2 Geometry

METRIC TENSOR

We want to explore the geometry of this frozen, 3-dimensional space.³ Our first task is to deduce the form of its metric tensor. Introduce a spherical coordinate system $\{\chi, \theta, \phi\}$, centered on us. Here χ is the radius, the proper distance (measured by a rather large number of meter rules) from us to a distant point; θ, ϕ are spherical polar angles, measured from Earth’s north pole and the direction of

spatial coordinates

2. Roughly 360 km s^{-1} for Earth.

3. For a fuller treatment see, e.g., Misner, Thorne, and Wheeler (1973), Sec. 27.6 and Box 27.2.

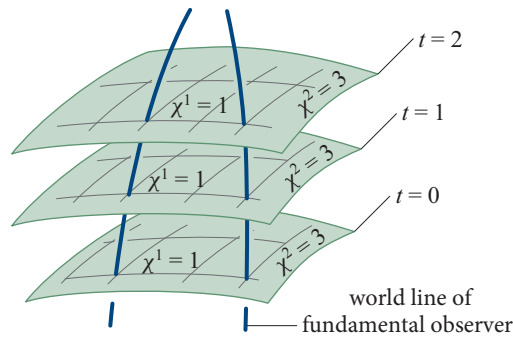

FIGURE 28.2 The slices of simultaneity, world lines of fundamental observers, and synchronous coordinate system for a homogeneous, isotropic model of the universe.

the Sun at the vernal equinox, for example.⁴ We will also find it convenient to introduce an equivalent Cartesian coordinate system (Fig. 28.2): $\chi \equiv \{\chi^1, \chi^2, \chi^3\} = \{\chi \sin \theta \cos \phi, \chi \sin \theta \sin \phi, \chi \cos \theta\}$. We know that the space around us is isotropic, which implies that the angular part of the metric is $d\theta^2 + \sin^2 \theta d\phi^2$ at each radius.⁵ However, we cannot assume that the space is globally flat and that the area of a sphere of constant radius χ is $4\pi \chi^2$. Therefore, we generalize the metric to become

$$^{(3)}ds^2 = d\chi^2 + \Sigma^2(d\theta^2 + \sin^2 \theta d\phi^2), \quad (28.1)$$

where $\Sigma(\chi)$ is a function to be determined. Now we know that $\Sigma \simeq \chi$ for small χ to satisfy the requirement that space be locally flat.

HOMOGENEOUS 2-DIMENSIONAL SPACES

Restrict attention to the 2-dimensional subspace $\phi = \text{const}$, which has metric $^{(2)}ds^2 = d\chi^2 + \Sigma^2(\chi)d\theta^2$, and consider a curve with $\theta = 0$ emanating from us at point O . This is obviously a geodesic—the shortest distance between its start at O and any point we care to choose along it. Let this geodesic pass through two galaxies labeled A , B and end at a third galaxy C (Fig. 28.3). Let the proper distances from O to A , A to B , and B to C , be χ_1 , χ_2 , χ_3 , respectively. Now add a second geodesic, also emanating from O , and inclined to the first geodesic by a small angle θ .⁶ As θ is

4. This is how astronomers set up their equivalent “right ascension”–“declination” coordinate system.
5. The deep, underlying reason it is not possible to cover the surface of a sphere with a metric with constant coefficients is that the vector field $(\partial/\partial\phi)_\theta$ that generates rotations about the polar axis does not commute with the vector field that generates rotations about any other axis. In principle, we could rotate our angular coordinate system from one radius to the next, but this would hide the symmetry that we are so eager to exploit!
6. This is similar in spirit to the description of gravitational lensing in Sec. 7.6.

FIGURE 28.3 Geodesics in a homogeneous 2-dimensional space. We suppose that the angles θ , ψ , ζ are small and compute the transverse displacements η assuming the metric (28.1).

small, the proper separations of these geodesics (measured along short paths perpendicular to the first geodesic at A , B , and C) will be $\eta_A = \theta \Sigma(\chi_1)$, $\eta_B = \theta \Sigma(\chi_1 + \chi_2)$, $\eta_C = \theta \Sigma(\chi_1 + \chi_2 + \chi_3)$, respectively, ignoring terms $O(\theta^3)$, which will vanish in the limit $\theta \rightarrow 0$. Next, introduce a third geodesic backward from C and intersecting with the second geodesic, at a point a perpendicular distance η_A from galaxy A . Denote the (small) angle it makes with the first geodesic at C to be ψ and with the second geodesic near A to be ζ .

derivation of metric tensor

Now, by assumption, the metric must have the same form, with the same metric function $\Sigma(\chi)$ when the origin is at O , A , or C . We can use this to derive a functional relationship that must be satisfied by $\Sigma(\chi)$ by evaluating η_B in two different ways:

$$\begin{aligned} \eta_B &= \theta \Sigma(\chi_1 + \chi_2) = \psi \Sigma(\chi_3) + \zeta \Sigma(\chi_2) \\ &= \theta \left(\frac{\Sigma(\chi_3) \Sigma(\chi_1)}{\Sigma(\chi_2 + \chi_3)} + \frac{\Sigma(\chi_2) \Sigma(\chi_1 + \chi_2 + \chi_3)}{\Sigma(\chi_2 + \chi_3)} \right). \end{aligned} \quad (28.2)$$

(In the last equality, we have used elementary geometry to express ψ and ζ in terms of θ .) Rearranging, we obtain

$$\Sigma(\chi_1 + \chi_2) \Sigma(\chi_2 + \chi_3) = \Sigma(\chi_1) \Sigma(\chi_3) + \Sigma(\chi_1 + \chi_2 + \chi_3) \Sigma(\chi_2), \quad (28.3)$$

for all choices of χ_1, χ_2, χ_3 .⁷

This sort of nonlocal, functional relationship is probably quite unfamiliar and, in general, such equations are hard to solve. However, in this instance we can use the device of solving it in a special case and then showing that the solution satisfies the original equation. If we assume that χ_1 and χ_3 are equal and small, and we expand Eq. (28.3) to second order in χ_1 with $\chi_2 \equiv \chi$ finite, we find that

$$\Sigma'' \Sigma - \Sigma'^2 + 1 = 0. \quad (28.4)$$

Next, multiply the left-hand side by $2\Sigma'/\Sigma^3$, and note that it is the derivative of $(\Sigma'^2 - 1)/\Sigma^2$. Hence, we get

$$\Sigma'^2 + K \Sigma^2 - 1 = 0, \quad (28.5)$$

7. The well-educated reader may notice a similarity to Ptolemy's theorem. The comparison is instructive.

where the integration constant K is known as the *Gaussian curvature* of the 2-dimensional surface, or equivalently, half the scalar curvature (Sec. 25.6). Differentiating this equation leads to the simple harmonic equation

$$\Sigma'' + K\Sigma = 0. \quad (28.6)$$

We need solutions that will be locally Euclidean with $\Sigma(0) = 0$, $\Sigma'(0) = 1$.

There are three cases. If $K = 0$, then $\Sigma = \chi$. If K is positive, we write it as $K = R^{-2}$, where R is the *radius of curvature* and $\Sigma(\chi) = R \sin(\chi/R)$. If $K < 0$, we write it as $K = -R^{-2}$ and $\Sigma(\chi) = R \sinh(\chi/R)$. The final step is to verify that these solutions are valid for general χ_1, χ_2, χ_3 , which they are. We have therefore found three general solutions to the functional equation (28.3). Suppose that there were an additional solution. We could subject it to the same limiting procedure and recover the same nonlinear differential equation (28.4) as $\chi_1 = \chi_3 \rightarrow 0$ for all $\chi_2 = \chi$. However, we know all the locally Euclidean solutions $\Sigma(\chi)$ to this equation, and our hypothetical fourth solution would not be among them. Therefore, it cannot exist, and so we have found all possible distance relations for homogeneous 2-dimensional spaces.

We summarize these three solutions by introducing a parameter $k = \pm 1$ or 0:

$$K = k/R^2; \quad \Sigma = R \sin(\chi/R) \text{ for } k = +1, \quad \chi \text{ for } k = 0, \quad R \sinh(\chi/R) \text{ for } k = -1. \quad (28.7)$$

NON-EUCLIDEAN GEOMETRIES

The $K = 0$ solution is instantly recognizable as describing the geometry of flat, Euclidean space. The $K > 0$ solution describes the 2-dimensional surface of a sphere embedded in 3-dimensional flat space. The circumference of a circle of radius χ is $2\pi R \sin(\chi/R) < 2\pi \chi$ and vanishes at an antipodal point, where $\chi = \pi R$. The space has a natural end—we call it *closed*. The associated area of this space is $2\pi \int_0^{\pi R} d\chi \Sigma = 4\pi R^2$. The geodesics we have been using are simply “great circles” on the 2-sphere.⁸ The theorems of spherical trigonometry, which we could have gone on to prove, are familiar to navigators, astronomers, and crystallographers.

When $K < 0$, the circumference is $2\pi R \sinh(\chi/R) > 2\pi \chi$ and the area is unbounded, so the space is *open*. This 2-dimensional space *cannot* be embedded in 3-dimensional Euclidean space. This discovery, made independently in the nineteenth century by Bolyai, Gauss, and Lobachevsky, was a source of mathematical wonder and philosophical consternation.⁹

homogeneous positive
curvature space

homogeneous negative
curvature space

8. To go from the skinny triangles we have been considering so far to large values of η , we need to construct the geodesic $\chi(\theta)$ by minimizing the length $\int d\theta(\chi'^2 + \Sigma^2)^{1/2}$ of the curve connecting the endpoints. This is a standard exercise in the calculus of variations, and carrying it out opens the door to deriving counterparts to the theorems of Euclidean geometry for non-Euclidean spaces.
9. This *hyperbolic* geometry can be embedded in 3-dimensional Minkowski space, and we could have used our understanding of special relativity to explore it by analogy with what is done with the positively curved space. Had we done so, we would have discovered that it is the same as the mass hyperboloid depicted in Fig. 3.2. However, the spirit of Riemannian geometry is not to do this but instead to explore the space through its *inner* properties.

HOMOGENEOUS 3-DIMENSIONAL SPACES

The generalization to 3 dimensions is straightforward. If space is isotropic, then the geometrical statements we made about the subspace $\phi = \text{const}$ must be true about any 2-dimensional subspace; so we arrive at the same three possibilities for Σ in the 3-dimensional metric (28.1). We replace the circumference of a circle by the area of a sphere of radius χ , which is less than (more than) $4\pi\chi^2$ for positive (negative) curvature. The total volume of the positively curved, closed 3-space is $4\pi \int_0^{\pi R} d\chi \Sigma^2 = 2\pi^2 R^3$.¹⁰

ROBERTSON-WALKER METRIC

Relativistic cosmology is transacted in spacetime, not space (Sec. 25.2). How do we generalize our understanding of these homogeneous subspaces to include a time coordinate and allow for the expansion of the universe? The first step is to assume that the 3-spaces in the past were also homogeneous and so had the same geometry as today. The only thing that can change is the radius of curvature, and so we write

scale factor

$$R(t) = a(t)R_0, \quad (28.8)$$

where R_0 is its value today when $t = t_0$ and $a = 1$. We call $a(t)$ the *scale factor*. (We handle a flat space by taking the limit $R_0 \rightarrow \infty$.) An FO then moves from one spatial hypersurface to the next carrying the same spherical coordinates $\{\chi, \theta, \phi\}$ (Fig. 28.2). We call these three coordinates *comoving coordinates*.

comoving coordinates

The basis vector $\partial_t \equiv \partial/\partial t$ is tangent to the world line of an FO, which is orthogonal to the spatial hypersurface $t = \text{const}$. Thus, $g_{ti} \equiv \partial_t \cdot \partial_i = 0$.¹¹ Next consider g_{tt} . We have so far implicitly measured time using the temperature of the CMB, but as we want to be quantitative, we choose as a time coordinate the *proper time* (or *cosmic time* or simply, *time*) Δt that elapses, as measured by a clock carried by an exceedingly patient FO with $u^\alpha = (1, 0, 0, 0)$, from one hypersurface to the next. (We set $c = 1$ in all subsequent equations.) It is implicit in the assumption of homogeneity that this interval of time will be the same for all FOs, and we can add up all the intervals to make our time coordinate t the *total age of the universe* since the big bang. With this choice, $g_{tt} = -1$.¹²

time coordinate

10. Although homogeneity and isotropy force the cosmological model's hypersurfaces to have one of the three metrics we have described, the topologies of those hypersurfaces need not be the obvious ones adopted here. For example, a flat model could have a closed topology with finite volume rather than an open topology with infinite volume. This could come about in much the same way as a flat piece of paper can be rolled into a cylinder. The geometry is still Euclidean, but one of the two coordinates, say x , is identified with $x + C$, where C is the length of the circumference of the cylinder. In 3 dimensions we can make similar identifications for the y and z coordinates. There are no credible observations to suggest that the universe is like this, but the possibility is worth keeping in mind.

11. Such a coordinate system is termed *synchronous*.

12. Other time coordinates, such as *conformal time*, $\int dt/a$, are in common use for a variety of technical reasons, but we shall eschew these.

Our full metric is then

$$ds^2 = -dt^2 + a(t)^2[d\chi^2 + \Sigma^2(d\theta^2 + \sin^2\theta d\phi^2)]. \quad (28.9)$$

This is known as the *Robertson-Walker metric*.¹³ Using this metric, we can easily verify that the acceleration $\nabla_{\vec{u}}\vec{u}$ of an FO vanishes, so FOs with fixed χ follow geodesics.

The scale factor $a(t)$ is very important. Not only does it measure the size of the universe in the past, it also measures the separation of any two FOs as a fraction of their separation today. Insofar as the universe is well described as homogeneous and isotropic, this single function tells us all we need to know about how the universe expanded and how it will continue to expand. We shall use it—actually, its logarithm—as our independent variable, because physical quantities such as densities and temperatures scale simply with it and because it is closely related to what astronomers commonly measure. Measuring $t(a)$ is the kinematic challenge to observational cosmology; explaining it is the dynamical challenge to general relativity.

meaning of $a(t)$

EINSTEIN TENSOR

Our final geometrical task is to calculate the Einstein tensor (Sec. 25.8). Although the calculation can be simplified by exploiting symmetry, it is best to use computer algebra. The only nonzero elements are

$$\begin{aligned} G^{\hat{t}\hat{t}} &= -G_t{}^t = -\frac{2\Sigma''\Sigma + \Sigma'^2 - 3\Sigma^2\dot{a}^2 - 1}{\Sigma^2a^2}, \\ G^{\hat{\chi}\hat{\chi}} &= G_\chi{}^\chi = \frac{\Sigma'^2 - \Sigma^2(2\ddot{a}a + \dot{a}^2) - 1}{\Sigma^2a^2}, \\ G^{\hat{\theta}\hat{\theta}} &= G_\theta{}^\theta = G^{\hat{\phi}\hat{\phi}} = G_\phi{}^\phi = \frac{\Sigma'' - \Sigma(2\ddot{a}a + \dot{a}^2)}{\Sigma a^2}. \end{aligned} \quad (28.10)$$

components of Einstein tensor in orthonormal basis

Here each dot or prime denotes a derivative with respect to t or χ ; the hatted components are in the proper reference frame of an FO [with orthonormal basis vectors $\vec{e}_{\hat{t}} = \partial_t$, $\vec{e}_{\hat{\chi}} = a^{-1}\partial_\chi$, $\vec{e}_{\hat{\theta}} = (a\Sigma)^{-1}\partial_\theta$, $\vec{e}_{\hat{\phi}} = (a\Sigma \sin\theta)^{-1}\partial_\phi$; cf. the metric (28.9)]; the unhatted components are those of the coordinate basis. The mixed-coordinate components (one index up, the other down) are the easiest to evaluate mathematically, but the orthonormal components are the best for physical interpretation, since they are what an FO measures. The two sets of components are equal up to a sign, because the metric is diagonal.

13. Historically, the three possible choices for the geometry of a homogeneous, isotropic cosmological model were discovered by the Russian meteorologist Alexander Friedmann (1922). These solutions were found independently by a Belgian priest, Georges Lemaître (1927), who included a cosmological constant and discussed the growth of perturbations. The first proof that these three choices are the only possibilities was due to Robertson (1935, 1936a,b) and Walker (1935).

If we now substitute our geometrical conditions (28.4) and (28.5) with $K = kR_0^{-2}$ [Eqs. (28.7) and (28.8)], we obtain

$$G^{\hat{t}\hat{t}} = 3\frac{\dot{a}^2 + kR_0^{-2}}{a^2}, \quad G^{\hat{\lambda}\hat{\lambda}} = G^{\hat{\theta}\hat{\theta}} = G^{\hat{\phi}\hat{\phi}} = -\frac{2\ddot{a}a + \dot{a}^2 + kR_0^{-2}}{a^2}. \quad (28.11)$$

Note that the spatial part of the Einstein tensor is proportional to the 3-metric $g^{\hat{i}\hat{j}} = \delta^{ij}$. In other words, it is isotropic, as we expect.

EXERCISES

Exercise 28.1 *Example: Alternative Derivation of the Spatial Metric*

Not surprisingly, there are several other approaches to deriving the possible forms of $\Sigma(\chi)$.¹⁴ Another derivation exploits the symmetries of the Riemann tensor.

- The 3-dimensional Riemann curvature tensor of the hypersurface must be homogeneous and isotropic. Explain why it should therefore only involve the metric tensor and not any other tensor, for example, not the Levi-Civita tensor.
- Show that the only combination of these quantities that exhibits the full symmetry properties of the Riemann tensor is

$${}^{(3)}R_{ijkl} = K(g_{ik}g_{jl} - g_{il}g_{jk}), \quad (28.12)$$

where K is a constant.

- Write a computer algebra routine to evaluate the Riemann tensor from the metric tensor (28.1) directly. By equating it to Eq. (28.12), show that two differential equations must be satisfied and these are identical to Eqs. (28.5) and (28.6).
- Compute the Ricci tensor, and compare it with the metric tensor. Comment.

Exercise 28.2 *Problem: Area of a Spherical Triangle*

Consider the triangle formed by the three geodesics in Fig. 28.3. In a flat space, the exterior angle ζ must equal $\theta + \psi$. However, if the space is homogeneous and positively curved, then the angle deficit $\Delta \equiv \theta + \psi - \zeta$ will be positive.

- By considering the geometry of the 2-dimensional surface of a sphere embedded in 3-dimensional Euclidean space, show that the area of the triangle is Δ/K . [Hint: We know that the area of a *lune* lying between two lines of longitude separated by an angle ϕ is $2\phi/K$.]
- Make a conjecture (or, better still, devise a demonstration) as to the formula for the area of a triangle in a negatively curved homogeneous space.

These results are special cases of the famous *Gauss-Bonnet* theorem,¹⁵ which allows for the possibility that the topology of the space might not be simple.

14. For example, there is an elegant, group-theoretic approach (e.g., Ryan and Shepley, 1975).

15. See, e.g., Peacock (1999) and Carroll (2004).

RAYS AND WORLD LINES

We are interested in events which lie at the intersection of our past light cone and the world lines of other FOs. Imagine a single wavelength of light emitted in the χ direction at time t_e . Let there be two FOs at either end of the wavelength, and let their comoving radii be χ_e and $\chi_e + d\chi_e$. Their physical separation at the time of emission is λ_e , the emitted wavelength. Their separation in terms of the comoving coordinate is therefore $d\chi = \lambda_e/a(t_e)$. Let the light be observed by us today. Let the front of the wavelength be observed at time t_0 and the end of the wavelength at $t_0 + P_0$, where P_0 is the observed period. Using the metric (28.9) with $ds = d\theta = d\phi = 0$, we see that $\chi_e = \int_{t_e}^{t_0} dt/a$ and $\chi_e + \lambda_e/a(t_e) = \int_{t_e}^{t_0+P_0} dt/a$, from which we deduce that $\lambda_e/a(t_e) = P_e/a(t_e) = P_0$ or in terms of the frequencies, $\nu_0 = a(t_e)\nu_e$.¹⁶ Put another way, as a photon crosses the universe, its frequency, as measured by the FOs, satisfies $\nu \propto a^{-1}$. So, if we observe a spectral line that was emitted by the stars in a distant galaxy with frequency ν_e and we observe it today with frequency ν_0 , then we can deduce immediately that the scale factor a at the time of emission was ν_0/ν_e . The first stars and galaxies to form, and therefore the most distant ones that we can see, emitted their light when $a \sim 0.1$, so that a Lyman α spectral line of hydrogen emitted with a wavelength of $\lambda_e = 122 \text{ nm}$ is observed in the infrared today with $\lambda_0 \sim 1.2 \mu\text{m}$.

cosmological redshift

THERMODYNAMICS

Construct a small, imaginary sphere around us with radius χ and let the sphere's surface be carried by a population of FOs, so it comoves and expands with them. These observers each see isotropic blackbody radiation. Every time a photon leaves the sphere, it will be replaced, on average, by an entering photon. The FOs could therefore construct a spherical mirror, perfectly reflecting on both sides and expanding with the universe. Nothing would change. The radiation inside this sphere will undergo slow adiabatic expansion. If it starts off as thermal blackbody radiation, it will remain so. The blackbody temperature T_γ , photon number density n_γ , pressure P_γ , and energy density ρ_γ will therefore vary as (cf. Secs. 3.2.4 and 3.5.5)

$$T_\gamma \propto a^{-1}; \quad n_\gamma \propto a^{-3}; \quad \rho_\gamma, P_\gamma \propto a^{-4} \propto n_\gamma^{4/3}, \quad (28.13)$$

radiation in an expanding universe

and the specific heat ratio is $4/3$. If the radiation is isotropic but not blackbody, its distribution function $\eta_\gamma(p, a)$ will not change along a trajectory in phase space (Sec. 3.6), and so $\eta_\gamma(p', a') = \eta_\gamma(p = p'a'/a, a)$. Here $p = |\mathbf{p}|$ is the magnitude of the photon's momentum, or equally well its energy $\mathcal{E} = p$.

By parallel arguments, the individual momenta p of massive particles vary as $p \propto a^{-1}$ —their de Broglie wavelengths expand with the universe just like photon

16. This argument neatly avoids a generally unhelpful separation into the Doppler shift and gravitational redshift. The quantity *redshift*, $z = (\nu_e - \nu_0)/\nu_0 = 1/a - 1$, is in common use by astronomers. However, we shall continue to work with the scale factor $a(t)$, as we are focusing on the kinematics of the expansion and not the observations through which this has been inferred.

gas in an expanding universe

wavelengths—so long as their behavior is adiabatic. When nonrelativistic, their kinetic energies and temperatures vary according to $T \propto p^2 \propto a^{-2}$, and their pressure P scales with their number density n as $P \propto nT \propto a^{-5} \propto n^{5/3}$, recovering the familiar specific heat ratio for a monatomic gas.

kinematics of the expansion

EXPANSION, DECELERATION, AND JERK

The kinematic behavior of the homogeneous universe is fully described by the single function $a(t)$. Not surprisingly, its derivatives turn out to be very useful. Adopting standard (if archaic) conventions, we define the *expansion rate* $H(t)$, the *deceleration function* $q(t)$, and the *jerk function* $j(t)$ by

expansion rate H ,
deceleration q and jerk j

$$H = \frac{\dot{a}}{a} \equiv \left(\frac{dt}{d \ln a} \right)^{-1}, \quad q = -\frac{\ddot{a}a}{\dot{a}^2}, \quad j = \frac{\dddot{a}a^2}{\dot{a}^3}, \quad (28.14)$$

respectively. Note that $H^{-1} = dt/d \ln a$ converts a derivative with respect to time (denoted with a dot) to a derivative with respect to $\ln a$ (denoted with a prime), which is our preferred independent variable. The expansion rate H is a reciprocal time; q and j are dimensionless. A galaxy at small radius χ emitted its photons when the scale factor was $a \simeq 1 - \chi \dot{a}$, and so the shift in the wavelengths of spectral lines observed on Earth will satisfy to first order $\delta\lambda/\lambda \equiv v = \dot{a}\chi \equiv H_0\chi$,¹⁷ where v is the inferred recession speed, and the *Hubble constant*¹⁸ $H_0 \equiv H(t_0)$ is the contemporary value of H and is one of the key parameters of observational cosmology. It measures the age and size of the universe. We now know that the universe is accelerating $q_0 \equiv q(t_0) < 0$ and $j_0 \equiv j(t_0) > 0$ (Riess et al., 1998; Perlmutter et al., 1999).

Hubble constant H_0

DISTANCE MEASUREMENT

angular diameter distance
 d_A

There are two common measures of distance in cosmology. The first is based on observing a small source of known physical size, η , perpendicular to the line of sight at radius χ . The source's angular size measured at Earth will be $\theta = \eta/(a\Sigma)$ (Fig. 28.3, where O at $\chi = 0$ is Earth's location). This motivates us to define the angular diameter distance $d_A \equiv a\Sigma$.

The second measure is based on an isotropic source of known luminosity L . If the universe were flat and static, the source's measured flux would be $F = L/(4\pi\chi^2)$. Relativistic cosmology introduces three modifications. First, the area of a sphere centered on the source with comoving radius χ , at the time of observation (today), is $4\pi\Sigma(\chi)^2$. Second, the source emits photons, and their individual energies $h\nu$ as observed at O will be reduced by a factor a from their energies when emitted. Third,

17. The quantity χ must be large enough for the recession speed to exceed the random motion with respect to a local FO.

18. The Hubble "law," that the recession velocity is proportional to the distance, was published in 1929 by Edwin Hubble, following theory by Lemaitre and observations by himself, Slipher, and others. It provided the first compelling demonstration that the universe was expanding, although Hubble's inferred constant of proportionality, $H_0 \sim 500 \text{ km s}^{-1} \text{ Mpc}^{-1}$, was over seven times larger than the contemporary measurement.

the time it takes to emit a fixed number of photons will be shorter by another factor a than the time it takes these same photons to pass the observer on Earth. The flux will therefore be modified to $F = a^2 L / (4\pi \Sigma^2)$. This motivates us to define a *luminosity distance* $d_L = \Sigma/a = a^{-2} d_A$.

luminosity distance d_L

Making cosmological distance measurements is challenging. There are many astronomical candidates for sources of known size or luminosity for use in measuring d_A or d_L . However, they should all be greeted with suspicion, as it is not just the universe that evolves with time; its contents can likewise change. The most natural distance measures use variable and exploding stars. As we discuss below, statistical measures in the CMB and distribution of galaxies as well as gravitational lenses are also important. Many methods are anchored by local trigonometric surveys. Inevitably, there are systematic errors (*inaccuracy*), which are now more limiting than random error (*imprecision*). Remarkably, the spread in measurements of H_0 has been reduced to roughly 10%. For specificity, we shall use cosmological parameters from Planck Collaboration (2016b), starting with $H_0 = 67.7 \text{ km s}^{-1} \text{ Mpc}^{-1} \equiv (4.56 \times 10^{17} \text{ s})^{-1} \equiv (14.4 \text{ Gyr})^{-1} \equiv (1.37 \times 10^{26} \text{ m})^{-1} \equiv (4.43 \text{ Gpc})^{-1}$.

measurement of H_0

HORIZON

The final kinematic quantity we introduce is the *horizon*¹⁹ radius $\chi_H(t)$ of the event on our past world line at time t . This is the comoving radius of a sphere, centered on a point on our past world line, that contains the region of the universe that can have sent signals to the event since the big bang. We also find it useful to introduce the *acoustic horizon radius* $\chi_A = C/\dot{a}$. This is the comoving distance a sound wave can travel at the local sound speed C during one expansion time scale $a/\dot{a} = H^{-1}$:

horizon radius χ_H

acoustic horizon radius χ_A

$$\chi_H(t) = \int_0^t \frac{dt'}{a(t')} = \int_0^{a(t)} \frac{da'}{a'^2 H(a')}; \quad \chi_A = \frac{C}{\dot{a}}. \quad (28.15)$$

When the fluid is ultrarelativistic, C is simply $3^{-1/2}$ and $\chi_A \equiv \chi_R = 3^{-1/2} H^{-1}$.

Exercise 28.3 Example: Mildly Relativistic Particles

EXERCISES

Suppose that the universe contained a significant component in the form of isotropic but noninteracting particles with momentum p and rest mass m . Suppose that they were created with a distribution function $f(p, a) \propto p^{-q}$, with $4 < q < 5$ extending from $p \ll m$ to $p \gg m$ (Sec. 3.5.3).

- Show that the pressure and the internal energy density (not including rest mass) of these particles are both well defined.
- Show that the adiabatic index of this component is $q/3$ and interpret your answer.
- Explain how P and ρ for this component should vary with the scale factor a .

19. Or more properly the *particle horizon*, to distinguish it from an *event horizon* (Sec. 26.4.5).

Exercise 28.4 *Problem: Observations of the Luminosity Distance*

Astronomers find it convenient to use the redshift $z = 1/a - 1$ to measure the size of the universe when the light they observed was emitted.

- (a) Perform a Taylor expansion in z to show that the luminosity distance of a source is given to quadratic order by

$$d_L = H_0^{-1}[z + 1/2(1 - q_0)z^2 + \dots].$$

- (b) The cubic term in this expansion involves the curvature K_0 and the jerk j_0 today. Calculate it.

28.2.4

28.2.4 Dynamics

FRIEDMANN EQUATIONS

Ultimately, we must understand how the universe's individual constituents—matter, photons, neutrinos—behave and interact. However, for the initial purposes of providing an idealized description of the average contents of the universe that can match our idealized description of its geometry and kinematics, we approximate everything as a homogeneous perfect fluid at rest in the FOs' proper reference frame, with pressure $T^{\hat{\lambda}\hat{\lambda}} = T^{\hat{\theta}\hat{\theta}} = T^{\hat{\phi}\hat{\phi}} = P$ (Sec. 2.13). This is related to the Einstein tensor through the Einstein field equation (Sec. 25.8). We start with the time-time part and employ geometrized units (Sec. 25.8.1): $G^{\hat{t}\hat{t}} = 8\pi T^{\hat{t}\hat{t}}$, which becomes, with the aid of Eq. (28.11):

equation of motion

$$\dot{a}^2 = \frac{8\pi}{3}\rho a^2 - \frac{k}{R_0^2}. \quad (28.16)$$

This equation of motion is the foundation of relativistic cosmology. It relates the universe's expansion rate \dot{a} to its mean mass-energy density ρ and curvature k/R_0^2 .

It is illuminating to write Eq. (28.16) in the form

$$\frac{1}{2}(\dot{a}\chi)^2 - \frac{4\pi\rho(a\chi)^3}{3(a\chi)} = -\frac{k\chi^2}{2R_0^2} = \text{const}, \quad (28.17)$$

for fixed χ . Again imagine that we are at the center of a small, imaginary, expanding sphere of radius $a\chi$ carried by FOs. We can regard the first term as the kinetic energy of a unit mass resting on the surface of the sphere and the second as its Newtonian gravitational potential energy. So this looks just like an equation of Newtonian energy conservation. Could we not have written it down without recourse to general relativity? The answer is “No.” Equation (28.16) addresses three crucial issues on which Newtonian cosmology must remain silent. First, it neatly handles the influence of the exterior matter. Second, it relates the total energy of the expansion, the right-hand side of Eq. (28.17), to the spatial curvature. Third, it has taken account of the pressure, which as we saw with neutron stars [(Eqs. 26.38)], can contribute an active gravitational mass. The absence of pressure in Eq. (28.16) is correct but does not

inadequacy of Newtonian treatment

have a simple Newtonian explanation. These three features demonstrate the power of general relativistic cosmology and the inadequacy of a purely Newtonian approach.

Next, consider the spatial part of the Einstein equation $G^{\hat{i}\hat{j}} = 8\pi T^{\hat{i}\hat{j}} = 8\pi P\delta^{\hat{i}\hat{j}}$. With the aid of Eqs. (28.11) and (28.16), this gives a second-order differential equation:

$$\ddot{a} = -\frac{4\pi}{3}(\rho + 3P)a. \quad (28.18)$$

cosmic acceleration

The divergence of the stress-energy tensor must vanish. We have seen many times in this book [Ex. 2.26, Eqs. (13.86), Secs. 13.8.1, 26.3.3] that for any perfect fluid, in the fluid's rest frame (which for cosmology is the same as the FO rest frame), the time component $T^{\hat{i}\hat{\alpha}}_{;\hat{\alpha}} = 0$ is energy conservation, or equivalently, the first law of thermodynamics. For a fluid element with unit comoving volume, the physical volume is a^3 , so the first law states

$$d(\rho a^3) = -Pd(a^3). \quad (28.19)$$

first law of thermodynamics

If the fluid comprises two or more independent components that do not exchange heat and evolve separately, then Eq. (28.19) must apply to each component.

We have also seen many times [Ex. 2.26, Eqs. (13.86), Sec. 26.3.3] that in the fluid's rest frame, the spatial component $T^{\hat{i}\hat{\alpha}}_{;\hat{\alpha}} = 0$ is force balance; it equates the fluid's pressure gradient ∇P to its inertial mass per unit volume $(\rho + P)$ times its 4-acceleration. However, homogeneity and isotropy guarantee that in our cosmological situation, the fluid's pressure gradient and 4-acceleration vanish, so $T^{\hat{i}\hat{\alpha}}_{;\hat{\alpha}} = 0$ is satisfied identically and automatically. It teaches us nothing new.

Equations (28.16), (28.18), and (28.19) are called the *Friedmann equations* in honor of Alexander Friedmann. They are not independent; the contracted Bianchi identity guarantees that from any two of them, one can deduce the third (Sec. 25.8).

CRITICAL DENSITY

Not only does the Hubble constant define a scale of length and of time, it also defines a critical density, ρ_{cr} —the value of ρ for which the universe's spatial curvature $K = k/R_0^2$ vanishes today [Eqs. (28.16) and (28.14)]:

$$\rho_{cr} = \frac{3H_0^2}{8\pi} = 8.6 \times 10^{-27} \text{ kg m}^{-3} \equiv 7.7 \times 10^{-10} \text{ J m}^{-3}. \quad (28.20)$$

It is conventional to express the energy density of constituent i today (e.g., radiation or baryonic matter) as a fraction by introducing

$$\Omega_i = \frac{\rho_i}{\rho_{cr}}; \quad \Omega = \frac{\rho}{\rho_{cr}} = \sum_i \Omega_i = 1 - \Omega_k, \quad (28.21)$$

where Ω refers to the total energy density, and

$$\Omega_k = -\frac{k}{H_0^2 R_0^2} \quad (28.22)$$

takes account of curvature.

density fraction

The kinematic quantities, H , q , j [Eq. (28.14)] are then given by

$$H = H_0 \left(\frac{\rho}{\rho_{cr}} + \frac{\Omega_k}{a^2} \right)^{1/2}; \quad q = \frac{1}{2} \frac{\rho + 3P}{\rho + \frac{\Omega_k \rho_{cr}}{a^2}}; \quad j = \frac{\rho - \frac{3}{2} \frac{dP}{d \ln a}}{\rho + \frac{\Omega_k \rho_{cr}}{a^2}}, \quad (28.23)$$

respectively. Note that if the curvature is negligible, $q = \frac{1}{2}$ when $P = 0$ and $j = 1$ when P is constant.

A FLAT UNIVERSE

At this point we introduce a key simplification. Essentially geometrical arguments, based largely on observations of CMB fluctuations, have shown that the radius of curvature today is $|R_0| \gtrsim 14/H_0$. Equivalently, $\Omega_k \lesssim 0.005$. This is so small, and was even smaller in the past (when we replace R_0 by R) that henceforth we shall set $\Omega_k = 0$ and $\Sigma = \chi$. If significant spatial curvature is measured one day, then small corrections will be required to what follows, while the principles are unaffected. However, none of this absolves us from the obligation to explain *why* the universe is so flat, an issue to which we shall return in Sec. 28.7.1.

SUMMARY

We have described an idealized universe that is homogeneous and isotropic everywhere. We have shown its spatial geometry can take one of three different forms and have invoked observation to restrict attention to the spatially flat case. We have also introduced some useful cosmological measures, most notably the scale factor $a(t)$, to characterize the kinematics of the universe. We have married the universe's geometry to its kinematics to calculate the two independent components of the Einstein tensor, which we then combined with the volume-averaged stress-energy tensor of the contents of the universe to derive the Friedmann equations. We now turn to cataloging the contributions to the stress-energy tensor today.

EXERCISES

Exercise 28.5 *Example: Einstein–de Sitter Universe*

Suppose, as was once thought to be the case, that the universe today is flat and dominated by cold (pressure-free) matter.

- Show that $a \propto t^{2/3}$ and evaluate the age of the universe assuming the Hubble constant given in Sec. 28.2.3: $H_0 = 67.7 \text{ km s}^{-1} \text{ Mpc}^{-1}$.
- Evaluate an expression for the angular diameter distance as a function of a and find its maximum value.
- Calculate the comoving volume within the universe back to very early times.

28.3 The Universe Today

28.3

28.3.1 Baryons

28.3.1

Among all the constituents in our universe, baryonic matter is the easiest form to identify, because it is capable of radiating when hot and absorbing when cool. The baryons from the very early universe are mostly in the form of hydrogen, with mass fraction 0.75, and helium, with mass fraction $0.25 \equiv Y_{\text{He}}$. Some of these baryons found their way into stars, which produced more helium and created about 1% by mass, on average, of heavier elements. Stars have masses ranging from a tenth to more than 100 times that of the Sun. The most massive stars shine for roughly a million years, while the least massive ones will last more than a trillion years, much longer than the age of the universe.

stars at a glance

Very roughly 10^{-4} of the total mass of a typical galaxy is found in a massive, spinning black hole residing in its nucleus. When this black hole is supplied with gas, roughly 10% of the rest mass energy of this gas is converted into radiation. The galaxy is then said to have an *active galactic nucleus*, and when this outshines the entire galaxy, it is called a *quasar*.

active galactic nuclei and quasars

It is common practice to use the luminosity of a galaxy as a measure of its stellar mass. However, this must be done with care, because the answer depends on the relative proportions of low- and high-mass stars. The latter are far more luminous per unit mass. It also depends on the time that has elapsed since the stars were formed. If the stars are old, the luminous high-mass ones will have consumed all their nuclear fuel and evolved to form neutron stars and black holes. Absorption is also an issue. Despite all these difficulties, astronomers estimate that the average fraction of stellar mass today is $\Omega_* \sim 0.005$.

The baryons that are not contained in stars exist as gas. We can assay this gas fraction by measuring the X-ray emission from clusters of galaxies and find that $\Omega_{\text{gas}} \sim 0.05$. More accurate measurements of the total baryon fraction Ω_b are made possible by measuring the tiny fraction of deuterium and other light elements that are created in trace amounts in the early universe (Sec. 28.4.2) and through interpreting the spectrum of CMB fluctuations (Sec. 28.6.1). The best estimate today is $\Omega_b = 0.049$, implying that the mean energy and number densities of baryons in the universe are $\rho_{b0} = 3.8 \times 10^{-11} \text{ J m}^{-3} = 4.2 \times 10^{-28} \text{ kg m}^{-3}$ and $n_{b0} = 0.25 \text{ m}^{-3}$. The equivalent proton, electron, and helium densities (Sec. 28.4.2) are $n_{p0} = 0.19 \text{ m}^{-3}$, $n_{e0} = 0.22 \text{ m}^{-3}$, and $n_{\alpha0} = 0.016 \text{ m}^{-3}$ (Table 28.1). Of course, these densities are substantially higher in galaxies.

measuring Ω_b

Exercise 28.6 Example: Stars and Massive Black Holes in Galaxies

EXERCISES

Assume that a fraction ~ 0.2 of the baryons in the universe is associated with galaxies, split roughly equally between stars and gas. Also assume that a fraction $\sim 10^{-3}$ of the baryons in each galaxy is associated with a massive black hole and that most of the radiation from stars and black holes was radiated when a ~ 0.3 .

TABLE 28.1: The universe today

Geometric	$\Omega_k = 0$		
Kinematic	Hubble constant	Deceleration parameter	Jerk parameter
	$H_0 = 67.7 \text{ km s}^{-1} \text{ Mpc}^{-1}$	$q_0 = -0.54$	$j_0 = 1$
Derived	Hubble time	Hubble distance	Critical density
	$t_H = H_0^{-1} = 4.6 \times 10^{17} \text{ s}$	$d_H = ct_H = 1.4 \times 10^{26} \text{ m}$	$\rho_{cr} = 7.7 \times 10^{-10} \text{ J m}^{-3}$
Constituent	Energy fraction	Energy density (J m^{-3})	Number density (m^{-3})
Baryons	$\Omega_b = 0.049$	$\rho_{b0} = 3.8 \times 10^{-11}$	$n_{b0}, n_{e0} = 0.25, 0.22$
Dark matter	$\Omega_D = 0.26$	$\rho_{D0} = 2.0 \times 10^{-10}$	$n_{D0} = 0.0013 m_{D,12}^{-1}$
Cosmological	$\Omega_\Lambda = 0.69$	$\rho_\Lambda = 5.3 \times 10^{-10}$	
Photons	$\Omega_\gamma = 5.4 \times 10^{-5}$	$\rho_{\gamma 0} = 4.2 \times 10^{-14}$	$n_{\gamma 0} = 4.1 \times 10^8$
Neutrinos	$\Omega_\nu = 0.0014 m_{\nu,-1}$	$\rho_{\nu 0} = 1.1 \times 10^{-12} m_{\nu,-1}$	$n_{\nu 0} = 3.4 \times 10^8$

Note: The notation is explained in the text.

- The current energy density in light from all the galaxies is $\sim 4 \times 10^{-16} \text{ J m}^{-3}$. Estimate what fraction of stellar hydrogen has been converted by nuclear reactions into helium. (You may assume that heat is created by these reactions at a rate of 6.4 MeV per nucleon.)
- The current energy density of light radiated by observed accreting black holes—dominated by quasars—is $\sim 6 \times 10^{-17} \text{ J m}^{-3}$. Estimate the actual efficiency with which the rest mass energy of the accreting gas is released.
- Estimate the total entropy per baryon associated with the horizons of massive black holes today and compare with the entropy per baryon associated with the microwave background and the intergalactic medium (see Sec. 4.10.2).

28.3.2

28.3.2 Dark Matter

clusters of galaxies

After studying the Coma cluster of galaxies, Fritz Zwicky (1933)²⁰ argued that most of the gravitational mass in clusters of galaxies is neither in the form of stars nor of gas but in a *dark* form that has only been detectable through its gravity (Fig. 28.1c). In effect, the gas and the galaxies move in giant gravitational potential wells formed by this dark matter. Careful measurements of the motions of gas and stars have led to an estimate of the dark matter density about five times the baryon density. Again, CMB observations improve the accuracy, and today we find that the dark matter fraction is $\Omega_D = 0.26$ so that $\Omega_b + \Omega_D = 0.31$ is the total matter fraction. It is widely suspected that dark

20. Oort (1932) realized that there is invisible matter in the solar neighborhood. Important subsequent evidence came from optical and radio observations of nearby spiral galaxies by Rubin, Roberts, and others; e.g., Rubin and Ford (1970); and Roberts and Whitehurst (1975).

matter mostly comprises new elementary particles. Furthermore, the development of gravitational clustering on small linear scales points to this matter being collisionless and having negligible pressure when the perturbations grow.²¹ The inferred energy and number density of putative dark matter particles is $\rho_{D0} = 2.0 \times 10^{-10} \text{ J m}^{-3}$, $n_{D0} = 0.0013 m_{D,12}^{-1} \text{ m}^{-3}$, where $m_{D,12}$ is the mass of the hypothesized particle in units of 1 TeV. Of course, the local dark matter density in our galaxy is much larger than this.

EXERCISES

Exercise 28.7 *Challenge: Galaxies*

Make a simple (numerical) model of a spherical galaxy in which the dark matter particles moving in the (Newtonian) gravitational field they create behave like collisionless plasma particles moving in an electromagnetic field. Ignore the baryons.

- Adopt the fluid approximation, treat the pressure P as isotropic and equal to $K\rho^{4/3}$, and use the equation of hydrostatic equilibrium (Sec. 13.3) to solve for the mass and radius. Comment on the answer you get, and make a suitable approximation to define an effective mass and radius.
- Consider a line passing through the galaxy with impact parameter relative to the center given by b . Solve for the dark matter particles' rms velocity along this line as a function of b .
- It is observed that the central densities of galaxies scale as the inverse square of the rms velocity for $b = 0$. How does the mass scale with the velocity?
- Solve for the distribution function of the dark matter particles assuming that it is just a function of the energy (Sec. 22.2).

28.3.3 Photons

28.3.3

The next contributor to the energy density of the universe is the CMB. With its measured temperature of $T_{\gamma 0} = 2.725 \text{ K}$, the energy density is $\rho_{\gamma 0} = 4.2 \times 10^{-14} \text{ J m}^{-3}$ (Sec. 3.5). Equivalently, $\Omega_{\gamma} = 5.4 \times 10^{-5}$. This is dynamically insignificant today but was very important in the past. We can also compute the number density of photons to be $n_{\gamma 0} = 4.1 \times 10^8 \text{ m}^{-3} = 1.6 \times 10^9 n_{b0}$. An equivalent measure, which we need below, is the photon entropy per baryon (Secs. 4.8 and 4.10):

photon number density

$$\sigma_{\gamma 0} = \frac{\rho_{\gamma 0} + P_{\gamma 0}}{n_{b0} T_{\gamma 0}} = \frac{32\pi^5}{45n_{b0}} \left(\frac{k_B T_{\gamma 0}}{h} \right)^3 k_B = 5.9 \times 10^9 k_B. \quad (28.24)$$

entropy of the CMB

The photon entropy per baryon—the entropy in a box that contains, on average, one baryon and expands with the universe—is therefore conserved to high accuracy.

21. It is often called *cold dark matter*. However, “cold” is inappropriate at early times, when the particles are probably relativistic, and at late times, when they virialize in dark matter potential wells with thermal speeds $\sim 100\text{--}1,000 \text{ km s}^{-1}$.

There is also a (currently) undetectable background of neutrinos that was in thermal equilibrium with the photons at early epochs and then became thermodynamically isolated with an approximate Fermi-Dirac distribution. As we show in the next section, the current total neutrino density is $n_{\nu 0} = 3.4 \times 10^8 \text{ m}^{-3}$. There are three *flavors* of neutrinos (ν_e, ν_μ, ν_τ) plus their antiparticles, and they are known to have small masses. The contemporary total neutrino energy density and mass fraction are then $\rho_{\nu 0} = 1.8 \times 10^{-12} m_{\nu, -1} \text{ J m}^{-3}$, $\Omega_\nu = 0.0023 m_{\nu, -1}$, respectively, where $m_{\nu, -1} = (m_{\nu_e} + m_{\nu_\mu} + m_{\nu_\tau})/100 \text{ meV}$. This total m_ν is bounded below through neutrino oscillation measurements (e.g., Cahn and Goldhaber, 2009) at 60 meV and above by cosmological observations at 230 meV. For illustration purposes, we shall assume that there is a single, dominant neutrino of mass 100 meV (i.e., 0.1 eV).

In 1998, it was discovered that the universe is accelerating. This was first inferred from observations of exploding stars called *supernovae*,²² which turn out to be surprisingly good distance indicators. As we know the scale factor at the time of the explosion, we can measure $\chi(a)$ and infer contemporary values for the deceleration and jerk functions: $q_0 = -0.54$ and j_0 consistent with 1. Using Eq. (28.23), we infer that the pressure is also negative, $P = -0.69\rho$, where ρ includes the matter density.

As we have mentioned, Einstein anticipated this possibility in 1917 when he noted that the field equations would remain “covariant”—in our language, would continue to obey the Principle of Relativity (be expressible in geometric language)—if an additional term proportional to the metric tensor \mathbf{g} were added to the field equation (Sec. 25.8):²³

$$\mathbf{G} + \Lambda \mathbf{g} = 8\pi \mathbf{T}. \quad (28.25)$$

The constant of proportionality Λ is known as the *cosmological constant*. As the Einstein tensor involves second derivatives of the metric tensor, a cosmological constant term that is significant on a cosmological scale should be undetectable on the scale of the solar system or a compact object.

Although we might interpret Eq. (28.25) as a modification to the field equation, we can instead incorporate Λ into the stress-energy tensor \mathbf{T} [move $\Lambda \mathbf{g}$ to the right-hand side of Eq. (28.25) and absorb it into $8\pi \mathbf{T}$], resulting in a *cosmological energy density* ρ_Λ and *cosmological pressure* P_Λ satisfying

$$\rho_\Lambda = -P_\Lambda = \frac{\Lambda}{8\pi}. \quad (28.26)$$

22. Perlmutter et al. (1999), Riess et al. (1998).

23. Einstein then went on to propose a static universe, made possible by the cosmological constant Λ . But it was proved wrong when observations revealed the Hubble expansion of the universe, and it was also unstable; so he renounced Λ (Einstein, 1931).

In the absence of another major component of the universe, we deduce that $\Omega_\Lambda = 1 - \Omega_b - \Omega_D - \Omega_\gamma - \Omega_v = 0.69$ and $\rho_\Lambda = -P_\Lambda = 5.3 \times 10^{-10} \text{ J m}^{-3}$.

Although the large negative pressure may seem strange, it is preceded in classical electromagnetism. Consider a uniform magnetic field B permeating a cylinder plus piston and aligned with their axis. The energy density is $\rho_{\text{mag}} = B^2/(2\mu_0)$, and the total stress acting on the piston—the combination of the isotropic magnetic pressure and the magnetic tension—is $P_{\text{mag}} = -B^2/(2\mu_0) = -\rho_{\text{mag}}$. When we withdraw the piston, ρ_{mag} and P_{mag} will not change, in agreement with the first law of thermodynamics, just like the cosmological constant. What is different about the cosmological constant is that the stress is isotropic.

The cosmological constant contribution to the stress-energy tensor is, by assumption, constant on a hypersurface of simultaneity—it is *ubiquitous*. Applying the first law of thermodynamics [Eq. (28.19)], we see that it was the same in the past and will be the same in the future—it is (past and future) *eternal*. In addition, as the contribution to the stress-energy tensor is directly proportional to the metric tensor, it takes the same form in all frames—it is *invariant*. Combining these features, we see that from a relativistic perspective, it is *universal*.

28.3.6 Standard Cosmology

This cosmological energy density ρ_Λ and pressure P_Λ are the most conservative explanation for the universe's acceleration. They motivate us to define a *standard cosmology*, in which there are no other major components of the universe besides ρ_Λ , P_Λ , baryonic matter, dark matter, photons, and neutrinos, and in which the spatial geometry is flat.

Λ as density and negative pressure

Λ is universal

28.3.6

Exercise 28.8 Example: The Pressure of the Rest of the Universe

Calculate three contributions to the pressure of the contemporary universe.

- Baryons. Assume that most of the baryons in the universe outside of stars make up a uniform, hot intergalactic medium with temperature 10^6 K .
- Radiation.
- Neutrinos. Assume that almost all the neutrino pressure is associated with one flavor with an associated mass of 100 meV .

EXERCISES

28.4 Seven Ages of the Universe

28.4

Given this description of the present contents of the universe, we are now in a position to describe its history. As our main purpose is to use cosmology to illustrate and apply many features of classical physics, we do not retrace the tortuous, inferential path that led to the standard description of the universe. Instead, we proceed more or less deductively from the earliest time and describe many of the essentially classical processes that must have occurred along the way. To help us do this, we use the device of dividing the history into seven ages, each dominated by different physical processes.

CONSTITUENTS

As explained at the start of this chapter, the universe began expanding from a very hot, dense state; we commence our story at a time when we still have confidence in essentially classical principles. To be specific, this is when $a \sim 10^{-11}$, $T \sim 10$ MeV $\sim 10^{11}$ K, and $t \sim 10$ ms. At earlier times, thermodynamic equilibrium required the presence of a large density of nucleon-antinucleon pairs and pions at near-nuclear density. A description in terms of quarks and gluons is needed (Cahn and Goldhaber, 2009). However, for $a \gtrsim 10^{-11}$, only a tiny but permanent residue of neutrons n and protons p was present, and it was dynamically and thermodynamically irrelevant. We use the comoving density of these baryons as a reference:

baryon density

$$n_b \equiv n_p + n_n = n_{b0} a^{-3} = 2.5 \times 10^{32} a_{-11}^{-3} \text{ m}^{-3}; \quad a \gtrsim 10^{-11}, \quad (28.27)$$

where $a_{-11} \equiv 10^{11} a$.

pair density

There were also muons and τ s along with their antiparticles, but like the pions, they disappeared from thermodynamic equilibrium and quickly decayed. However, when $a \sim 10^{-11}$, the much lighter electrons and positrons were present with combined density n_e comparable to that of the photons n_γ . The photons and pairs interacted electromagnetically and remained in thermodynamic equilibrium with each other, as well as with the baryons, at a common temperature $T_\gamma(a)$. Neutrinos, with combined density n_ν , were also present at early times. Each of the three neutrino flavors had an approximate Fermi-Dirac distribution with zero chemical potential (Secs. 4.4.3, 5.5.3); and as they were effectively massless, like the photons, the neutrinos' temperature T_ν decreased $\propto a^{-1}$ until comparatively recently, when their finite masses became significant. However, unlike the photons, they did so in thermodynamic isolation (they were *decoupled* from other particles) as the rate at which they self-interacted or exchanged energy with the other constituents quickly became less than the rate of expansion, as we demonstrate below.

neutrino decoupling

ENTROPY AND TEMPERATURE

Prior to neutrino decoupling, the photons and neutrinos were in equilibrium at the same temperature. However, when $T_\gamma \lesssim m_e/k_B \sim 10^{10}$ K, the pairs became non-relativistic; they annihilated, and their number (and entropy) density, relative to that of the photons, quickly declined to a very small value—ultimately just that required to equalize the proton charge density—while the photon entropy [Eq. (28.24)] was augmented. Now, the photon and pair entropies per (conserved) baryon, σ_γ and σ_e , are given by Eq. (28.24) with $T_{\gamma 0}$ replaced by T_γ and n_{b0} by n_b , and by

pair annihilation

$$\sigma_e = \frac{\rho_e + P_e}{n_b T_\gamma} = \frac{16\pi a^3}{n_{b0} h^3 T_\gamma} \int_0^\infty \frac{dp p^2 (E + p^2/(3E))}{e^{E/(k_B T_\gamma)} + 1} = \frac{7}{4} \sigma_\gamma f_{\sigma e}(y), \quad (28.28)$$

where $E = (p^2 + m_e^2)^{1/2}$, $y = m_e/(k_B T_\gamma)$, and

$$f_{\sigma e}(y) = \frac{90y^4}{7\pi^4} \int_0^\infty \frac{dx x^2 (1 + 4x^2/3)}{(1 + x^2)^{1/2} (e^{y(1+x^2)^{1/2}} + 1)} \quad (28.29)$$

FIGURE 28.4 Temperature T and entropy σ variation during the particle age. At early times t (or equivalently, small scale factors a), the photons, electron-positron pairs, and neutrinos (designated by subscripts γ , e , and ν , respectively) were in equilibrium with a common temperature. However, when the temperature approached m_e/k_B , the pairs began to annihilate, and their contribution to the total entropy was taken up by the photons. (The neutrinos had decoupled by this time, and their entropy per baryon remained constant.) The photon temperature T_γ increased relative to the neutrino temperature T_ν by a factor of 1.4.

varies between 1 when $y \rightarrow 0$ ($T_\gamma \rightarrow \infty$) and 0 when $y \rightarrow \infty$ ($T_\gamma \rightarrow 0$) (Secs. 4.8, 4.10.3). Entropy conservation dictates that $\sigma_e + \sigma_\gamma = \sigma_{\gamma 0}$. We can therefore solve for the scale factor $a = (y/y_0)(1 + 7f_{\sigma e}(y)/4)^{-1/3}$, where $y_0 = m_e/(k_B T_{\gamma 0}) = 2.2 \times 10^9$, and hence for the photon temperature as a function of a . At early times and high temperatures, $\sigma_\gamma = (4/11)\sigma_{\gamma 0}$, and so $T_\nu/T_\gamma = (4/11)^{1/3} = 0.71$ at later times.²⁴ The neutrino and photon densities satisfy $n_\nu = \frac{9}{4}(T_\nu/T_\gamma)^3 n_\gamma \propto n_b$, and so n_ν/n_γ decreased from $\frac{9}{4}$ to $\frac{9}{11}$, whence $n_\nu = 3.4 \times 10^{41} a_{-11}^{-3} \text{ m}^{-3}$ (Fig. 28.4).

neutrino density

ENERGY DENSITY

We can now sum ρ_γ , ρ_e , ρ_ν , ρ_D , ρ_b , and ρ_Λ to give the total energy density for $T_\gamma \lesssim 10^{11} \text{ K}$ (Fig. 28.5; Secs. 3.5.4, 3.5.5)

$$\rho = a_B T_\gamma^4 + \frac{7}{4} a_B T_\gamma^4 f_{\rho e}(y) + \frac{21}{8} a_B T_\nu^4 + \rho_{D0} a^{-3} + \rho_{b0} a^{-3} + \rho_\Lambda, \quad (28.30)$$

variation of energy density over cosmic time

where

$$f_{\rho e} = \frac{120y^4}{7\pi^4} \int_0^\infty \frac{dx x^2 (1+x^2)^{1/2}}{(e^{y(1+x^2)^{1/2}} + 1)}. \quad (28.31)$$

24. As neutrinos have mass yet do not interact, they do not maintain a thermal distribution function when they eventually become nonrelativistic, and so $T_{\nu 0}$ is meaningless.

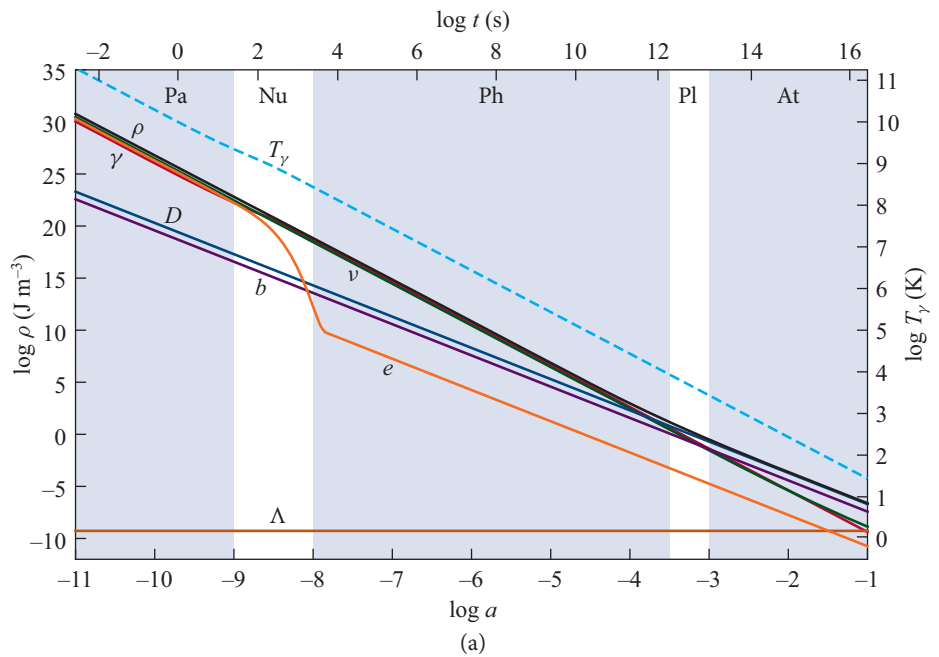

FIGURE 28.5 Energy density in the expanding universe. The energy density ρ (in J m^{-3}) for photons (γ), dark matter (D), baryons (b), and electrons (e) as a function of the scale factor a while the universe evolved. (a) Evolution through the particle (Pa), nuclear (Nu), photon (Ph), plasma (Pl), and atomic (At) ages ending at the *epoch of reionization*, when $a \sim 0.1$. (b) Evolution through the gravitational (Gr) and cosmological (Co) ages. The total energy density is depicted by a thick black line. Also displayed is the cosmic time (proper time) t and the photon temperature T_γ .

Only the first three terms in Eq. (28.30) are significant at early times, but we give the complete expression here.²⁵ We also make a correction for the (unknown) neutrino rest mass density as discussed in Sec. 28.3.4; it has small, observable effects at late times.

AGE

Given the density, we can use the equation of motion to compute the age of the universe (cosmic time) t as a function of the scale factor a :

$$t(a) = \left(\frac{3}{8\pi}\right)^{1/2} \int_0^a \frac{da'}{a'} \rho(a')^{-1/2} \quad (28.32)$$

time as a function of scale factor

[Eq. (28.16)]. The age today ($a = 1$) is $t_0 = 4.4 \times 10^{17}$ s = 13.8 Gyr.

HORIZON

At early times when matter is ultrarelativistic with $T_\gamma \gtrsim 10^{11}$ K, t is proportional to a^2 , ignoring a weak dependence on the number of types of particle contributing to the expansion. In this case, using Eq. (28.15), we find for the horizon radius $\chi_H = 2t/a \propto a$. This tells us that the horizon sphere gets smaller and smaller in terms of comoving baryon mass $M_{Hb} = 4\pi \chi_H^3 \rho_{b0}/3 \propto (t/a)^3$ as we go back in time. When $a \sim 10^{-11}$, $\chi_H \sim 3 \times 10^{16}$ m and $M_H \sim 10^{25}$ kg (roughly an Earth mass). As we have emphasized, the universe that we see around us today grew deterministically out of a hot big bang and is believed to be homogeneous as far as we can see. Yet the regions that were able to establish this smoothness through some form of mixing were comparatively tiny at any time when this could have happened (Fig. 28.6). A plausible resolution of this longstanding paradox, *inflation*, will be discussed in Sec. 28.7.1.

horizon problem

28.4.2 Nuclear Age

28.4.2

NEUTRON-PROTON RATIO

During the early particle age, neutrons and protons were able to establish thermodynamic equilibrium primarily through the weak reactions $n + \nu \leftrightarrow p + e^-$ and $n + e^+ \leftrightarrow p + \bar{\nu}$. When 10^{12} K $\gtrsim T_\gamma \gtrsim 10^{11}$ K, $n_n \sim n_p \sim 0.5n_b$. As the universe cooled, a Boltzmann distribution was established: $n_n/n_p = \exp[-\gamma_{np}m_e/(k_B T)]$, where we write the mass difference $m_n - m_p$ as $\gamma_{np}m_e = 2.53m_e = 1.29$ MeV. However, when $T_\gamma \lesssim 3 \times 10^{10}$ K, the reaction rate became slower than the expansion rate, and n_n/n_p declined slowly to ~ 0.14 . If these were the only possible interactions, then the neutrons would have eventually undergone β -decay, $n \rightarrow p + e^- + \bar{\nu}$, when the universe had expanded further and the age was of order the mean life of a neutron, ~ 15 min. ($\gamma_{np}m_e$ is the maximum electron energy in this decay process.) However, before this happened, strong interactions intervened, and helium was formed.

neutron freeze out

25. Although the free electrons are dynamically insignificant at late times, they are very important for the evolution of the microwave background, and their density evolution is discussed below.

FIGURE 28.6 Comoving horizon radius χ_H as a function of the scale factor a . Also displayed is the associated baryon mass M_{Hb} measured in solar masses (see footnote 1 in this chapter). Note that the mass of baryons in causal contact when $a \sim 10^{-11}$ was equal to only an Earth mass. The mass associated with a cluster of galaxies entered our horizon when $t \sim 300$ yr. The horizon mass when the microwave background was last scattered, $a \sim 10^{-3}$, is equivalent to $\sim 10^4$ galaxy clusters but is only $\sim 10^{-5}$ of the total mass that is observed today, which appears to be impressively homogeneous.

Let us begin analyzing this process by ignoring the expansion of the universe and considering the conversion of n to p through the single reaction $n + \nu \rightarrow p + e^-$ (cf. Sec. 5.5.3). Let us define the *rate constant* $\lambda_{n\nu}$ by the expression

forward reaction

$$\dot{n}_p = -\dot{n}_n = \lambda_{n\nu} n_n, \quad (28.33)$$

where a dot denotes differentiation with respect to t . To compute $\lambda_{n\nu}$, we make some well-justified simplifications. First, we ignore the motion of the nucleons and the mass of the neutrinos, which is justified when $T \sim 10^9$ K. Second, we suppose that all distribution functions are isotropic, which is ensured by frequent scattering. Third, we suppose that the electrons and positrons have a common Fermi-Dirac distribution function $f_e = (e^{\gamma m_e / (k_B T_\gamma)} + 1)^{-1}$ with zero chemical potential and temperature T_γ , which is reasonable, as there were many more electrons than nucleons at this time and they were strongly coupled to the photons through Compton scattering. Likewise, the neutrinos and antineutrinos maintain a similar Fermi-Dirac distribution f_ν with an independent temperature T_ν .

On general grounds [cf. Eqs. (3.28), (23.50), and (23.56)], we expect to be able to write the rate coefficient in the form:

$$\lambda_{n\nu} = \int \left(\frac{d^3 p_\nu}{h^3} f_\nu \right) \left(\frac{h^6 W}{m_e^5} \delta(E_\nu - \gamma m_e + \gamma_{np} m_e) \right) \left(2 \frac{d^3 p_e}{h^3} (1 - f_e) \right). \quad (28.34)$$

The first term in this expression describes the number density of neutrinos. The second is the *rate per state*, defining W and including a delta function to ensure energy conservation, while the third describes the electron density of states, taking account of both spins and including a blocking factor when the states are occupied. The quantity W can be calculated using the theory of electro-weak interactions and can be measured experimentally. It has the value $W = 2.0 \times 10^{-6} \text{ s}^{-1}$ (e.g., Weinberg, 2008). As everything is isotropic, we can write $d^3p = 4\pi(E^2 - m^2)^{1/2}EdE$ and integrate over the delta function to obtain

$$\lambda_{nv} = 32\pi^2 W \int_{\gamma_{np}}^{\infty} d\gamma \frac{\gamma(\gamma^2 - 1)^{1/2}(\gamma - \gamma_{np})^2}{(e^{(\gamma - \gamma_{np})m_e/(k_B T_\nu)} + 1)(e^{-\gamma m_e/(k_B T_\gamma)} + 1)}. \quad (28.35)$$

integration over phase space

The integration is over the range of γ permitted by energy conservation.

Note that if we set $T_\nu = T_\gamma = T$, the neutrons and protons will attain Boltzmann equilibrium (Sec. 4.4), and so the rate constant λ_{pe} for the inverse reaction will be $e^{-\gamma_{np}m_e/(kT)}\lambda_{nv}$.²⁶ This, in turn, implies that W , in the integral corresponding to Eq. (28.34), is the same for the forward and backward reactions. Furthermore, the theory of electro-weak interactions informs us that W is the same for the $n + e^+ \leftrightarrow p + \bar{\nu}$ and $n \rightarrow p + e^- + \bar{\nu}$ reactions. The five relevant rate constants are exhibited in Fig. 28.7(a).

inverse reaction

Including the expansion of the universe is a straightforward matter. We replace the number density of neutrons and protons with the number contained in a fixed volume expanding with the universe. If we set this volume as n_b^{-1} , recalling that baryons are conserved, then we can allow for the expansion by the device of replacing n_p with the proton fraction $X_p \equiv n_p/n_b$, and similarly treating n_n in Eq. (28.33).

including expansion

DEUTERIUM AND HELIUM FORMATION

Neutrons and protons can combine to form deuterons (${}^2\text{H} \equiv d$) through the reactions $p + n \leftrightarrow d + \gamma$ (e.g., Cyburt et al., 2016, and Ex. 4.10). If we just consider the forward reaction and, temporarily, ignore the expansion, d would have formed at the rate $\dot{n}_d = n_p n_n \langle \sigma v \rangle_{np}$. Here the product of the cross section σ and the relative speed v of the nucleons, averaged over the velocity distribution at a given temperature and over the evolution of the universe when these reactions are most significant, is $\langle \sigma v \rangle_{np} = 5 \times 10^{-26} \text{ m}^3 \text{ s}^{-1}$.

deuterium formation

We can now include the inverse reaction by observing that, in equilibrium, we can relate the density n_i of each species i to the chemical potential μ_i through

$$n_i = g_i \int \left(\frac{d^3p}{h^3} \right) e^{(\mu_i - E)/(k_B T_\gamma)} = g_i \left(\frac{2\pi m_i k_B T_\gamma}{h^2} \right)^{3/2} e^{\mu_i/(k_B T_\gamma)} \quad (28.36)$$

including inverse reaction

26. As we could have inferred quantum mechanically.

FIGURE 28.7 (a) Rate coefficients for the five reactions that determine the neutron-proton ratio n/p ; the subscripts on the rates λ correspond to the left-hand side of the reaction. Note that when time $t \gtrsim 300$ ms, the equilibration rate is slower than the Hubble expansion rate H , and the neutron fraction is stabilized. When $t \gtrsim 600$ s, the few remaining neutrons are able to undergo β -decay before being incorporated in α s. (b) Number fractions (number of particles per baryon) for photons γ , protons p , neutrons n , deuterons d , and alpha particles α . When $T_\gamma \lesssim 2 \times 10^{10}$ K, the nucleons depart from thermodynamic equilibrium. The deuterons are produced when $T_\gamma \sim 10^9$ K before being quickly incorporated into α s. These two panels demonstrate that the current deuterium and helium fractions depend sensitively on the expansion rate and the nuclear physics details; the agreement with observation is a nontrivial validation of standard cosmology.

(Sec. 5.2), where g_i is the degeneracy of species i , and we treat the nucleons as nonrelativistic particles with $E = p^2/(2m_i) + \dots$. Under equilibrium conditions, the relativistic chemical potentials satisfy $\tilde{\mu}_p + \tilde{\mu}_n = \tilde{\mu}_d + \tilde{\mu}_\gamma = \tilde{\mu}_d$, and so we can eliminate the chemical potentials to obtain the Saha-like (Ex. 5.10) relation:

$$n_p n_n = S(T_\gamma) n_d, \quad (28.37a)$$

where

$$S(T_\gamma) = 2^{1/2} 3^{-1} \left(\frac{2\pi m_p k_B T_\gamma}{h^2} \right)^{3/2} e^{-\gamma_d m_e / (k_B T_\gamma)}, \quad (28.37b)$$

we have used $g_p = g_n = 2$ and $g_d = 3$ and $\gamma_d m_e = m_n + m_p - m_d = 4.34 m_e$ is the deuteron binding energy. The combined forward-reverse reaction rate must then be described by $dn_d/dt = \langle \sigma v \rangle_{np} [n_p n_n - S(T_\gamma) n_d]$, as this is the only way that we can maintain equilibrium at all temperatures. At early times, $S \langle \sigma v \rangle_{np} \gg H$ and equilibrium must have been maintained.

The final step is to explain how the tritons (nuclei of ${}^3\text{H} \equiv t$), helions (nuclei of ${}^3\text{He} \equiv h$), and alpha particles (nuclei of ${}^4\text{He} \equiv \alpha$) were formed. There are two important pathways: $d + d \rightarrow t + p$, $t + d \rightarrow \alpha + n$; and $d + d \rightarrow h + n$, $h + d \rightarrow \alpha + p$ (cf. Sec. 19.3.1). The effective, combined forward reaction rate is calculated using $\langle \sigma v \rangle_{dd} = 7 \times 10^{-24} \text{ m}^3 \text{ s}^{-1}$. The reverse reaction rates can be calculated using a simple generalization of the argument leading to Eq. (28.37) for reactions involving four or more nucleons. We can now allow for the expansion as before, introducing the d number fraction $X_d = n_d/n_b$, to obtain three coupled rate equations for the proton, neutron, and deuteron number fractions $X_p = n_p/n_b$, $X_n = n_n/n_b$, and $X_d = n_d/n_b$:

$$\begin{aligned} H X'_p &= (\lambda_{nv} + \lambda_{ne} + \lambda_n) X_n - (\lambda_{pe} + \lambda_{pv}) X_p - \langle \sigma v \rangle_{np} (n_b X_p X_n - S(T_\gamma) X_d), \\ H X'_n &= (\lambda_{pe} + \lambda_{pv}) X_p - (\lambda_{nv} + \lambda_{ne} + \lambda_n) X_n - \langle \sigma v \rangle_{np} (n_b X_p X_n - S(T_\gamma) X_d), \\ H X'_d &= \langle \sigma v \rangle_{np} (n_b X_p X_n - S(T_\gamma) X_d) - 2 \langle \sigma v \rangle_{dd} n_b X_d^2, \end{aligned} \quad (28.38)$$

where a prime denotes differentiation with respect to $\ln a$. It is easiest to solve these equations by assuming the neutrons and protons are in equilibrium until $a \sim 10^{-11}$ and the deuterons are in equilibrium until $a \sim 10^{-9}$.

The numerical solution to these equations (Fig. 28.7) shows that the neutrons and protons remained in thermodynamic equilibrium until the temperature fell to $\sim 2 \times 10^{10} \text{ K}$, at which time the neutron fraction declined slowly, reaching a value ~ 0.15 by the time the temperature had fallen to $\sim 10^9 \text{ K}$. At this temperature, the deuteron equilibrium fraction climbed quickly, and the deuteron density became large enough for the $d + d$ reactions to produce α at $T_\gamma = 8 \times 10^8 \text{ K}$, and then declined. Most neutrons were incorporated into helium, though a small fraction was left to decay freely. The final helium fraction is²⁷ $X_\alpha = n_\alpha/n_b = \frac{1}{4}(1 - X_p) = 0.058$ (Fig. 28.7), slightly smaller than the (observed) value $X_\alpha = 0.062$ obtained by more

final helium and deuterium fractions

27. Astronomers reserve the symbol X for hydrogen and use the symbol $Y = 4X_\alpha$ for the helium mass fraction and Z for the mass fraction of all other elements which they call “metals”!

detailed calculations that include about ten more reactions, temperature dependence of the reaction rates, and other refinements. The late-time deuterium number fraction computes to be $X_d = 2.3 \times 10^{-5}$, consistent with the detailed calculations and with observations. Yields of h , ${}^6\text{Li}$, and ${}^7\text{Li}$ are also computed and can be reconciled with observations if one takes account of large astrophysical uncertainty. The t decays.

It is the absence of stable nuclei with $A = 5, 8$ that prevented the build-up of elements beyond helium in the early universe. Instead, the synthesis of these elements had to await the formation and evolution of stars.

28.4.3 Photon Age

Primordial nucleosynthesis was complete by the time the scale factor had increased to $a \sim 10^{-8}$ and the temperature had fallen to $T_\gamma \sim 3 \times 10^8$ K. This marks the beginning of the photon age, during which the energy density of the universe was still dominated by photons (and neutrinos) and $\rho_\gamma \propto a^{-4}$, $a \propto t^{1/2}$. Now is a good time to examine the implicit assumption that we have been making that, with the conspicuous exception of the neutrinos, all major constituents of the universe are maintained in thermal equilibrium during the nuclear and photon ages.

PLASMA EQUILIBRATION

Let us first consider protons and electrons. The plasma frequency $\omega_p = [ne^2/(m\epsilon_0)]^{1/2} \propto a^{-3/2}$ (Sec. 20.3) is very high in comparison with the expansion rate. In fact, $\omega_p H \sim 10^{17} a_{-8}^{1/2}$, where $a_{-8} = a/10^{-8}$. Likewise, the ratio of the Debye length $\lambda_D = [\epsilon_0 k_B T / (ne^2)]^{1/2}$ to the horizon radius is $\lambda_D \chi_H \sim 10^{-18} a_{-8}^{-1}$. Therefore, the use of fluid mechanics in place of plasma physics is amply justified for the whole expansion of the universe.

validity of the fluid approximation

Now let us question our implicit assumption of thermodynamic equilibrium. Using Eqs. (20.23), (28.27), and (28.13), we find that the ratios of the e - e , p - p , and p - e equilibration timescales ($\propto T^{3/2} n^{-1} \propto a^{3/2}$) to the expansion timescale ($\propto a^2$) are given by $H\{t_{ee}, t_{pp}, t_{ep}\} \sim \{1, 40, 1800\} \times 10^{-10} a_{-8}^{-1/2}$ throughout the photon age, ensuring that baryons remained in thermal equilibrium.

equilibration timescales

COMPTON SCATTERING

Next consider the interaction between the plasma and the photons, which is mediated by Compton scattering. If there had been no such interaction, then the (nonrelativistic) plasma would have maintained its Maxwellian distribution with a temperature that would have fallen as $T \propto a^{-2}$ (Sec. 28.2.3). However, each Compton scattering will lead to an energy transfer from the photons to the electrons through a combination of the Doppler effect and Compton recoil. This energy change will then be quickly shared with the protons, so that the plasma is only allowed to become a tiny bit cooler than the radiation. To be quantitative, the mean fractional energy exchange per scattering is $|\Delta \ln E| \sim k_B T / m_e$. Therefore, it will take $\sim m_e / (k_B T)$ scatterings to equilibrate the plasma with the far more numerous photons. The scattering time is $t_{e\gamma} \sim (n_\gamma \sigma_T)^{-1}$, where $\sigma_T = 8\pi r_e^2 / 3 = 6.65 \times 10^{-29} \text{ m}^{-2}$ is the *Thomson cross*

section, and $r_e = 2.8$ fm is the classical electron radius (Sec. 3.7.1). The ratio of the timescale for the plasma to equilibrate with the radiation, to the expansion timescale, is $Ht_{e\gamma} = Hm_e/(\rho_\gamma\sigma_T) \sim 2 \times 10^{-16}a_{-8}^2$. The electrons therefore exchange energy with the radiation field even faster than they share it among themselves and with protons. This justifies our assumption of a common matter and radiation temperature in the early universe. Insofar as the universe is homogeneous, the far more numerous photons will automatically maintain their initial Planck distribution without energy redistribution by electrons. Their response to small, inhomogeneous perturbations is considered below.

electron-photon coupling

28.4.4 Plasma Age

28.4.4

Eventually, the rest-mass energy density of matter (mostly dark matter) exceeded that of radiation and neutrinos, and the plasma age began. This happened when $a = a_{\text{eq}} = 0.00030$, $t = t_{\text{eq}} = 52$ kyr, and $T_\gamma = T_{\text{eq}} = 9,100$ K. Thereafter, according to Eq. (28.30), $\rho \propto a^{-3}$ and $a \propto t^{2/3}$, approximately.²⁸ The Friedmann equation (28.16) can be integrated in this plasma age to give, more precisely,

onset of matter dominance

$$\frac{t}{t_{\text{eq}}} = \left(1 + 2^{-1/2}\right) \left[2 - \left(2 - \frac{a}{a_{\text{eq}}}\right) \left(1 + \frac{a}{a_{\text{eq}}}\right)^{1/2} \right], \quad (28.39)$$

which remains valid until the cosmological age.

Next the helium ions became singly ionized through capturing one electron and then became neutral by taking on a second electron, leaving a proton-electron plasma. After a further interval, the hydrogen recombined.²⁹ Unlike the helium recombination, the details of this process are highly significant.

helium recombination

The total (atomic plus ionized) hydrogen density is $n_{\text{H}+p} = 1.9 \times 10^8 a_{-3}^{-3} \text{ m}^{-3}$, where $a_{-3} = a/10^{-3}$. In equilibrium, the atomic fraction would satisfy the Saha equation (5.68). However, just as happened with nucleosynthesis, the universe expanded too fast for the reactions to keep up. The basic problem is that when an electron and a proton recombine, they emit one or more photons that have a short mean free path and are mostly reabsorbed by neighboring atoms, leading to no net change in ionization. This is especially true of the Lyman α photons emitted with frequency $\nu_\alpha = 2.47 \times 10^{15}$ Hz when a hydrogen atom transitions from its first excited state, designated by quantum number $n = 2$, to its ground state with $n = 1$. A good approximation is to treat the $n = 2$ level as the effective ground state, changing the effective ionization potential from $I_1 = 13.6$ eV to $I_2 = 13.6/4 = 3.4$ eV and modifying the degeneracy in the Saha equation, and then to allow for the slow permanent population of the true, $n = 1$, ground state.

hydrogen recombination

28. The thermal energy density of the plasma was only 6×10^{-10} times the radiation energy density at this time.

29. The use of the term *recombination* is conventional but misleading, because it is the first occurrence of this process.

If we denote by X_1 and X_2 the fraction of the hydrogen in the $n = 1$ and $n = 2$ states, respectively, and ignore higher energy levels,³⁰ then the *ionization fraction* is $x = n_e/n_{\text{H}+p} = 1 - X_1 - X_2$. The rate equations analogous to Eqs. (28.38) are

$$\begin{aligned} HX_2' &= \alpha_2 \left(n_{\text{H}+p} x^2 - \frac{1}{4} X_2 \left(\frac{2\pi m k_B T_\gamma}{h^2} \right)^{3/2} e^{-I_2/(k_B T_\gamma)} \right) - \lambda_{21} X_2, \\ HX_1' &= \lambda_{21} X_2. \end{aligned} \tag{28.40}$$

rate equations

allowing for inverse reactions

The use of fractional densities once again takes account of the expansion of the universe. The quantity $\alpha_2 = 2.8 \times 10^{-19} T_4^{-1/2} \text{ m}^3 \text{ s}^{-1}$ is the *recombination coefficient* into the $n = 2$ level, which is computed by summing over all pathways, excluding transitions to $n = 1$. The $\frac{1}{4}$ takes into account the 2-fold degeneracy of the $n = 1$ level and 8-fold degeneracy of the $n = 2$ level, and the ‘‘Saha’’ factor ensures equilibrium in the absence of transitions to $n = 1$, just like the factor S in Eq. (28.37). The rate constant λ_{21} describes the permanent transitions to the ground state, corrected for reverse transitions.

two-photon deexcitation

We compute λ_{21} as follows. The sublevels of the $n = 2$ level are well mixed by collisions, so one-quarter of the excited atoms will be in the 2s sublevel, while three-quarters will be in the 2p sublevel. The 2s atoms can permanently deexcite by emitting two photons, neither of which is reabsorbed. This process has a *forbidden* spontaneous rate $A_{2s} = 8.2 \text{ s}^{-1}$, and the inverse process can be ignored. The 2p atoms create Lyman α photons with a *permitted* rate $A_{2p} = 4.7 \times 10^8 \text{ s}^{-1}$. The spectral line will have a small, combined natural and Doppler width. The cross section for absorbing a Lyman α photon in the low-frequency wing of the line decreases with decreasing frequency and eventually becomes small enough that the expansion of the universe allows the photon to avoid absorption altogether and therefore leads to the formation of a hydrogen atom in its ground state. Let us define by P_{esc} the probability that one of these photons avoids absorption in this manner. Next let us describe the line profile by $P_\nu(\nu)$, the cumulative probability that an emitted Lyman α photon has frequency less than ν . (See Ex. 28.9 for this and some other details of the analysis.)

escape probability

Kirchhoff’s law of radiation (e.g., Sec. 10.2.1) ensures that the net absorption cross section has the same frequency dependence as the emissivity. Using the Einstein coefficients, we can show that the net absorption cross section associated with the same atoms as those that are emitting the Lyman α photons is $\sigma_\alpha = [A_{2p}/(8\pi\nu_\alpha^2)] dP_\nu/d\nu$.³¹ The probability that a Lyman α photon with any frequency will escape due to expansion is then given by

30. The fractional occupancy of the $n = 2$ level never exceeds $\sim 10^{-13}$, and so this is a good approximation.

31. Another way of expressing this is $\int d\nu \sigma_\alpha = \pi r_e f_\alpha$, where $f_\alpha = 0.42$ is the *oscillator strength* (Cohen-Tannoudji, Diu, and Laloë, 1977).

FIGURE 28.8 Ionization fraction of the universe, x , plotted as a function of the scale factor a . The blue dashed curve shows the result from assuming Saha equilibrium x_S . The solid blue curve shows the actual ionization fraction, x , deduced from Eqs. (28.40) after including in λ_{21} the atomic processes that delay recombination of the electrons. The solid red curve shows the Thomson optical depth τ_T from now back to scale factor a , while the dashed red curve is its derivative with respect to $-\ln a$: $-\tau_T' = n_e \sigma_T H^{-1}$. The shaded region to the left delineates the short interval when τ_T fell from ~ 3 to ~ 1 . The shaded region to the right delineates the poorly understood epoch of reionization (Sec. 28.4.5), when newly formed stars and black holes are thought to have created sufficient ultraviolet photons to change most hydrogen in the universe back to a plasma. The ionization fraction adopted for $0.05 < a < 1$ is $x = 1.16[1 + 1.5(a/0.1)^{-8.7}]^{-1}$, which allows for the presence of helium.

$$P_{\text{esc}} = \int_0^1 dP_\nu e^{-n_1 \int dt \sigma_\alpha} = \int_0^1 dP_\nu e^{-\frac{n_1}{H\nu_\alpha} \int d\nu \sigma_\alpha} = \int_0^1 dP_\nu e^{-\frac{n_1 A_{2p} P_\nu}{8\pi \nu_\alpha^3 H}} \simeq \frac{8\pi \nu_\alpha^3 H}{n_1 A_{2p}}, \quad (28.41)$$

where n_1 is the number density of H atoms in the $n = 1$ state, which is effectively constant in the short time it takes the universe to Doppler shift the frequency of the photon by enough to escape absorption. Therefore $\lambda_{21} = \frac{1}{4}A_{2s} + \frac{3}{4}A_{2p}P_{\text{esc}}$, independent of A_{2p} .

To solve Eqs. (28.40), note that $X_2 \ll X_1$, and so X_2' can be set to zero. The resulting ionization x (solid blue curve in Fig. 28.8) follows the full Saha evolution as long as $T \gtrsim 4,000$ K (Fig. 28.8). Thereafter the ionization fraction is significantly larger. The universe is half-ionized when $T_\gamma \sim 3,500$ as opposed to $\sim 3,700$ K, according to the Saha equation.

We will need the Thomson optical depth τ_I on our past light cone:

$$\tau_T(\ln a) = \int_{\ln a}^0 (d \ln a) n_e \sigma_T / H. \quad (28.42)$$

According to this equation, the average last scattering surface, where $\tau_T = 2/3$, occurred when $a = a_{ls} = 0.00093$, $T_\gamma = 2,920$ K, $t = 1.2 \times 10^{13}$ s = 380 kyr. These values are in good agreement with more careful calculations.

EXERCISES

Exercise 28.9 *Problem: Spectral Line Formation*

In our discussion of recombination, we related the emission of Lyman α photons to their absorption. This involves some important ideas in the theories of radiation and thermodynamics.

- (a) Consider a population of two-state atoms. Let the number of atoms in the lower state be N_1 and in the upper state N_2 . The probability per unit time of an upper-state atom changing to a lower state and releasing a photon of energy $h\nu$ equal to the energy difference of the states is denoted by A . We expect that the rate of upward, $1 \rightarrow 2$ transitions is proportional to the occupation number η_ν of the photons with frequency ν (Sec. 3.2.5). Call this rate $K_u \eta_\nu$. By requiring that the atoms should be able to remain in Boltzmann equilibrium with the Planckian radiation field of the same temperature, show that there must also be downward, *stimulated emission* at a rate per state-2 atom of $K_d \eta_\nu$, and show that $K_u = K_d = A$.
- (b) The absorption cross section σ for an atom at rest can be written in the *Lorentz* or *Breit-Wigner* form as:

$$\sigma = \frac{\pi A^2}{(\nu - \nu_0)^2 + A^2}.$$

Either make a classical model of an atom as an electron oscillator with natural frequency ν_0 , or use time-dependent perturbation theory in quantum mechanics to justify the form of this formula.

- (c) Identify the frequency probability function P_ν introduced in Sec. 28.4.4, and plot the natural line profile for an emission line.
- (d) Atoms also have thermal motions, which Doppler shift the photon frequencies. Modify the line profile by numerically convolving the natural profile with a 1-dimensional Gaussian velocity distribution and replot it, drawing attention to its behavior when A is much more than the thermal Doppler shift.
- (e) We have restricted our attention to a two-state system. It is usually the case that we are dealing with energy levels containing several distinct states, and the formalism we have described has to be modified to include the *degeneracies* g_i of these levels. Make the necessary corrections and recover the formulas used in the text.
- (f) A second complication is polarization (Sec. 7.7). Discuss how to include this.

28.4.5 Atomic Age

The next age is the atomic age.³² If atomic hydrogen were completely decoupled from the radiation field, then it would cool with temperature $T_H \propto a^{-2}$ and eventually become cryogenic! However, this is not what happened, as the electrons that remained were still able to keep in thermal contact with the radiation and with the protons and atomic hydrogen. The plasma was maintained at roughly the electron temperature. Eventually, when $a \sim 0.03$, the temperature had fallen to $T \sim 100$ K, and molecular hydrogen appeared. However, this was also about the time when the very first self-luminous stars and black holes formed and emitted ultraviolet radiation, which caused the molecular hydrogen to dissociate and the atoms to ionize. This is known as the *epoch of reionization* and must have continued until $a \sim 0.14$, because neutral hydrogen is actually detected at this time through Lyman α absorption of quasar light. Characterizing the epoch of reionization is a major goal of modern research and involves many considerations that lie beyond the scope of this book. The evolution adopted in Fig. 28.8 and Sec. 28.5 is consistent with current observations but is not yet well constrained.

28.4.5

electron temperature

first stars and black holes

Exercise 28.10 *Problem: Reionization of the Universe*

- Estimate the minimum fraction of the rest mass energy of the hydrogen that must have undergone nuclear reactions inside stars to have ionized the remaining gas when $a \sim 0.1$.
- Suppose that these stars radiated 30 times this minimum energy at optical frequencies. Estimate the energy density and frequency of this stellar radiation background today.

28.4.6

SCALE FACTOR

As we discuss further in Sec. 28.5, after recombination small inhomogeneities in the early universe grew under the influence of gravity to form galaxies and larger-scale structures. The influence of stars was supplemented by that of accreting massive black holes that formed and grew in the nuclei of galaxies. After reionization this radiative onslaught kept most baryons in the universe in a multiphase, high-temperature state.

However, this is also the time when the influence of the cosmological constant started to become significant. If we ignore photons, neutrinos, and spatial curvature, then Eq. (28.16) describing the expansion of the universe in the gravitational age has

influence of cosmological constant

32. Sometimes called the *dark age*.

a simple analytical solution derived and discussed by Bondi (1952a):

$$t = \frac{2}{3H_0(1 - \Omega_M)^{1/2}} \sinh^{-1} \left[(\Omega_M^{-1} - 1)^{1/2} a^{3/2} \right], \quad (28.43)$$

where Ω_M is the current matter density in units of the critical density. We see that the influence of the cosmological constant is negligible at early enough times, $t \ll t_0$, and the energy density of the matter dominates the expansion. It also dominates any curvature that there might be today. Such a universe is usually called an *Einstein–de Sitter universe* and has $a = (3H_0 t/2)^{2/3}$. Similarly, at late times, $t \gg t_0$, we can ignore the matter and find that $a \propto \exp(Ht)$, where $H = (1 - \Omega_M)^{1/2} H_0$. This is called a *de Sitter universe*. The kinematic properties of our standard universe relative to an Einstein–de Sitter universe and an open ($k = -1$) one are best expressed using the deceleration parameter q [Eqs. (28.14) and (28.23)], which is exhibited in Fig. 28.9. Note that the jerk parameter is $j = 1$ throughout the gravitational and cosmological ages.

Einstein–de Sitter universe

DISTANCE AND VOLUME

Excepting the CMB, most cosmological measurements are made when $a \gtrsim 0.1$. Therefore, now is a good time to calculate distance and volume. The comoving distance to a source whose light was emitted when the expansion parameter was a , $\Sigma(a)$ (equal to the radius $\chi(a)$ in our flat universe), can be computed from the Friedmann equations and is exhibited in Fig. 28.10. We can also compute the angular diameter distance $d_A = a\chi(a)$, which is seen to reach a maximum value of $0.41/H_0 = 5.6 \times 10^{25}$ m at $a = 0.39$. More distant sources of fixed physical length will actually appear progressively larger. By contrast, the luminosity distance $d_L = a^{-1}\chi(a)$ increases rapidly with distance, and individual sources become unobservably faint. The total distance to the early universe is $\chi_H(t_0) = 3.2/H_0 = 14$ Gpc $= 4.4 \times 10^{26}$ m and the associated comoving volume is $V_H(t_0) = 4\pi\chi_H(t_0)^3/3 = 140H_0^{-3} = 1.2 \times 10^4$ Gpc $^3 = 3.6 \times 10^{80}$ m 3 . The universe is a big place!

EXERCISES

Exercise 28.11 *Problem: Type 1a Supernovae and the Accelerating Universe*

Rather surprisingly, it turns out that a certain type of supernova explosion (called “Type 1a” and associated with detonating white-dwarf stars) has a peak luminosity L that can be determined by studying the way its brightness subsequently declines. Astronomers can measure the peak fluxes F for a population of supernovae at a range of distances.

Calculate the flux measured at Earth for a given L as a function of the scale factor $0.3 < a < 1$ at the time of emission for the following.

- An Einstein–de Sitter universe.
- A nonaccelerating universe with $a \propto t$.
- Our standard model universe.

FIGURE 28.9 Expansion of the universe during the gravitational and cosmological ages. (a) The variation of age t with scale factor a is shown for standard cosmology (solid curve). Note that the expansion of the universe initially decelerated under the pull of gravity, but then began to accelerate at age ~ 6 Gyr under the influence of the cosmological constant. If this continues for the next ~ 15 Gyr, then the universe will embark on an exponential growth. (b) This exponential growth is brought out in a plot of the associated deceleration parameter q versus a . Also shown in both panels are the solutions for a (dashed) Einstein-de Sitter (EDS) model, which is flat and matter dominated, with an identical Hubble constant as standard cosmology, and a negatively curved (dotted) open model with the same contemporary density parameter as used in standard cosmology. Neither of these models exhibits acceleration; the former decelerates forever, the latter eventually expands with constant speed.

FIGURE 28.10 Comoving distance χ (in units H_0^{-1}) to a source whose light was emitted when the scale factor was $a < 1$. Also shown are the luminosity distance d_L , the angular diameter distance d_A , and the comoving volume V associated with a sphere of radius χ (red).

Assume the same Hubble constant today, H_0 . How accurately must F be measured to confirm the prediction of the standard model with an error of ~ 0.1 in a single measurement at $a \sim 0.7$? Astronomers do not, in practice, measure the total flux but the flux in a specific spectral band, but this adjustment can be made if the spectrum is known.

28.4.7 28.4.7 Cosmological Age

eschatology!

The final age, which began about 5 Gyr ago, when $a \sim a_\Lambda \sim 0.7$, is called the cosmological age because the energy density is thereafter dominated by the cosmological constant. We are entering a phase of exponential, de Sitter expansion, presaging a future dominated by dilution and decay—an agoraphobic’s worst nightmare! Operationally, the acceleration slows the development of large-scale structure in the distribution of galaxies, which provides one way to measure the value of the cosmological constant. Of course, as a pure cosmological constant is still a weakly constrained fit to the observations, the future could be more subtle, as we discuss in Sec. 28.7.3.

EXERCISES

Exercise 28.12 Problem: Future Evolution of the Universe

Assume that the universe will continue to expand according to Eq. (28.43).

- (a) Calculate the behavior of the angular diameter distance and the associated volume as a function of the scale factor for the next 20 billion years.
- (b) Interpret your answer physically.

(c) Explain qualitatively what will happen if the universe accelerates even faster than this.

We return to this topic in Sec. 28.7.3.

28.5 Galaxy Formation T2

28.5

The universe we have described so far is homogeneous and isotropic and completely ignores the large density fluctuations on small scales, observed today as clustered galaxies. Our task now is to set up a formalism to describe the growth under gravity of the perturbations that produce this structure as the universe ages. Much of this problem can be handled using Newtonian physics, but as the most interesting questions are intrinsically relativistic and as we have already developed the necessary formalism, we shall dive right into a fully relativistic analysis (Peebles and Yu, 1970; Sunyaev and Zel'dovich, 1970).

28.5.1 Linear Perturbations T2

28.5.1

METRIC

We generalize the Robertson-Walker metric [Eq. (28.9)] to include linear perturbations in a manner inspired by our discussions of weak fields (Sec. 25.9) and the Schwarzschild spacetime (Sec. 26.2):

relativistic perturbation theory

$$ds^2 = -(1 + 2\Phi)dt^2 + a^2(1 - 2\Psi)\delta_{ij}d\chi^i d\chi^j. \quad (28.44)$$

Here a is the same function of t as in the unperturbed model, and FOs (by definition) continue to move with fixed comoving coordinate χ . The changes to the spacetime geometry are all contained in the *curvature perturbation* Ψ and in the *potential perturbation* Φ , which agrees with its Newtonian counterpart when it is small in magnitude (relative to unity) and inhomogeneity scale³³ (relative to the horizon).³⁴

curvature and potential perturbations

KINEMATICS

An FO no longer follows a timelike geodesic. We use $\vec{u} \cdot \vec{u} = -1$ to evaluate the components of its 4-velocity and 4-acceleration $a_\alpha = u^\beta u_{\alpha;\beta}$ to first order in the perturbation:

$$u^t = 1 - \Phi, \quad u^j = 0; \quad a^t = 0, \quad a_i = \partial_i \Phi. \quad (28.45)$$

33. Note that Φ does not include the Newtonian potential difference $2\pi\rho r^2/3$ that we might be tempted to associate with two points separated by r in the background medium if we had not appreciated the way that general relativity neatly resolves this ambiguity.

34. The coordinate choice is sometimes called a *gauge* [cf. Eqs. (25.87), (25.88), and (27.18)] by analogy with classical electromagnetism and particle physics and is often motivated by considerations of symmetry. Physical observables should not (and do not) depend on the coordinate/gauge choice. Our choice is known as the *Newtonian gauge* and is useful for perturbations that can be expressed as scalar quantities. (We will encounter tensor perturbations in Sec. 28.7.1.) This gauge choice is appropriate because, when Φ and Ψ are small, it becomes the weak-gravitational-field limit of general relativity (Sec. 25.9), which we need to interpret the actual cosmological observations we make today and which can be used to discuss the initial conditions, as we shall see in Sec. 28.7.1.)

These expressions exhibit gravitational time dilation— $dt/d\tau = 1 - \Phi$ (Sec. 27.2.1)—and Einstein's equivalence principle (Sec. 25.4). A particle that moves with small 3-velocity \mathbf{v} , as measured in an FO's local Lorentz frame, has a 4-velocity $u^t = 1 - \Phi$, $u^i = v_i/a$ and a 4-acceleration $a_t = 0$, $a_i = d(av_i)/dt + \partial_i\Phi$. In the limit $\Phi = 0$, $\mathbf{v} \propto a^{-1}$ if the particle is freely moving (Sec. 28.2.3).

FOURIER MODES

We are interested in the linear evolution of perturbations, and it is convenient to work with the spatial Fourier transform of the perturbed quantities (Sec. 8.3). For the potential, which is our primary concern, we write

$$\Phi(t, \boldsymbol{\chi}) = \int \frac{d^3k}{(2\pi)^3} e^{i\mathbf{k}\cdot\boldsymbol{\chi}} \tilde{\Phi}(t, \mathbf{k}), \quad (28.46)$$

where the \sim denotes spatial Fourier transform, the comoving wave vector \mathbf{k} does not change with time, and we treat t and a as interchangeable coordinates. As Φ is real, $\tilde{\Phi}(t, -\mathbf{k}) = \tilde{\Phi}^*(t, \mathbf{k})$. Implicit in this Fourier expansion is a box, which we presume is much larger than the current horizon but which will not feature in our development. The actual modes can be considered as traveling waves moving in antiparallel directions or as standing modes in quadrature, which is a better way to think about their nonlinear development. In what follows, we shall consider the temporal development of linear perturbations, which can be thought of as either individual wave modes or as continuous Fourier transforms.

PERTURBED EINSTEIN EQUATION

Now focus on a single Fourier oscillation and use computer algebra to evaluate the nonzero, linear perturbations to the Einstein field equations in a local orthonormal basis:

$$\tilde{G}^{\hat{t}\hat{t}} = -2[3H(\dot{\tilde{\Psi}} + H\tilde{\Phi}) + (k/a)^2\tilde{\Psi}] = 8\pi\tilde{T}^{\hat{t}\hat{t}} = 8\pi\tilde{\rho}, \quad (28.47a)$$

$$\tilde{G}^{\hat{t}\hat{\parallel}} = -\frac{2ik}{a}(\dot{\tilde{\Psi}} + H\tilde{\Phi}) = 8\pi\tilde{T}^{\hat{t}\hat{\parallel}} = 8\pi(\rho + P)\tilde{v}, \quad (28.47b)$$

$$\tilde{G}^{\hat{\parallel}\hat{\parallel}} = 2[\ddot{\tilde{\Psi}} + H(\dot{\tilde{\Phi}} + 3\dot{\tilde{\Psi}}) + (1 - 2q)H^2\tilde{\Phi}] = 8\pi\tilde{T}^{\hat{\parallel}\hat{\parallel}}, \quad (28.47c)$$

$$\tilde{G}^{\hat{\perp}\hat{\perp}} = \tilde{G}^{\hat{\parallel}\hat{\parallel}} + \frac{k^2(\tilde{\Psi} - \tilde{\Phi})}{a^2} = 8\pi\tilde{T}^{\hat{\perp}\hat{\perp}}, \quad (28.47d)$$

where \parallel and \perp are components parallel and perpendicular to \mathbf{k} . Equation (28.47b) defines the mean velocity perturbation, which is purely parallel, $\tilde{v} = \tilde{v}^{\parallel}$. Note that if the cosmological fluid is perfect, there is no shear stress ($\tilde{T}^{\hat{\parallel}\hat{\parallel}} = \tilde{T}^{\hat{\perp}\hat{\perp}} = \tilde{P}$) and, consequently, $\tilde{\Psi} = \tilde{\Phi}$. This is a major simplification, echoing our treatment of Schwarzschild spacetime (Sec. 26.2). However, when neutrinos or photons have decoupled from matter and free stream through primordial (dark-matter) density perturbations, their stresses become sufficiently anisotropic to produce a measurable distinction between $\tilde{\Phi}$ and $\tilde{\Psi}$.

Because these equations only involve the component of mean velocity parallel to \mathbf{k} , they describe longitudinal waves, generalizations of the sound waves discussed in Sec. 16.5. This mean velocity is irrotational and can therefore be written as a carefully chosen function of time, multiplied by the gradient of a velocity potential $\tilde{\psi}$ (Sec. 13.5.4):³⁵

$$\tilde{\mathbf{v}} = i\boldsymbol{\beta}\tilde{\psi}. \quad (28.48a)$$

Here we introduce a *scaled wave vector*

$$\boldsymbol{\beta} = \frac{\mathbf{k}}{3^{1/2}\dot{a}}, \quad (28.48b)$$

which can be regarded as a function of either t or a . (Note that $q \equiv (\partial \ln \beta / \partial \ln a)_{\mathbf{k}}$, which is a useful relation.)

We also define the *total relative density perturbation*:

$$\tilde{\delta} \equiv \tilde{\rho}/\rho = (\rho_b\tilde{\delta}_b + \rho_D\tilde{\delta}_D + \rho_\gamma\tilde{\delta}_\gamma + \rho_\nu\tilde{\delta}_\nu)/\rho, \quad \text{with} \quad \tilde{\delta}_{b,D,\gamma,\nu} \equiv \tilde{\rho}_{b,D,\gamma,\nu}/\rho_{b,D,\gamma,\nu}, \quad (28.49)$$

where the subscripts b , D , γ , and ν continue to refer to baryons, dark matter, photons, and neutrinos. Equation (28.47a) then becomes

$$\tilde{\Psi}' + \beta^2\tilde{\Psi} + \tilde{\Phi} = -\frac{1}{2}\tilde{\delta}, \quad (28.50)$$

where the prime denotes a derivative with respect to $\ln a$.

EARLY EVOLUTION

Before neutrino decoupling, when $a \lesssim 10^{-11}$, the stress-energy tensor \mathbf{T} is dominated by a well-coupled, relativistic fluid consisting of radiation, neutrinos, and elementary particles with $P = \rho/3$ and $a \propto t^{1/2}$, so that $q = 1$, $\tilde{\Psi} = \tilde{\Phi}$, and $\tilde{T}^{\parallel\parallel} = \tilde{\rho}/3$. This remains a pretty good approximation until dark matter dominates the density during the plasma era when $a \sim a_{\text{eq}}$, and it can be used to bring out some important features of the general evolution. We can identify β as the ratio of the (relativistic) acoustic horizon χ_R [Eq. (28.15) and subsequent line] to the size of the perturbation, measured by $1/k$, both in comoving coordinates. Further simplification results from changing the independent variable to $\beta \propto a$ and combining Eqs. (28.47b) and (28.47d) to obtain a single second-order, homogeneous differential equation:³⁶

$$\frac{d^2\tilde{\Phi}}{d\beta^2} + \frac{4}{\beta}\frac{d\tilde{\Phi}}{d\beta} + \tilde{\Phi} = 0. \quad (28.51)$$

35. Actually there are modes with vorticity (embodied in the perpendicular part of the velocity $\tilde{\mathbf{v}}^\perp$), and they evolve according to the relativistic generalization of the equations discussed in Sec. 14.2.1. In principle, they could have been created by some sort of primordial turbulence. However, in practice they decay quickly as the universe expands and so will be ignored.

36. This equation, like many other equations describing the evolution of perturbations, has the form of a damped simple harmonic oscillator equation. The first derivative term is then often called a “friction” term. However, this is only a mathematical analogy. Physically, it represents the loss of energy in work done on the expanding medium, not a true dissipation.

velocity potential

scaled wave vector

relative density perturbation

potential evolution equation

evolution under radiation dominance

FIGURE 28.11 Early growth of a single spatial Fourier component of the perturbations. The amplitude of the potential $\tilde{\Phi}$, relative density $\tilde{\delta}$, and velocity potential $\tilde{\psi}$ perturbations are shown as functions of $\beta = k\chi_R$ for a single spatial Fourier component. The perturbations are frozen until they “enter the horizon” when $\beta \sim 1$. The perturbations then convert oscillations in which the amplitude of $\tilde{\delta}$ is constant while $\tilde{\Phi}$ is in antiphase and $\tilde{\psi}$ is in quadrature.

This has a unique solution, nonsingular as $\beta, a \rightarrow 0$ and valid for all scales:

$$\tilde{\Phi}(t, \mathbf{k}) = \frac{3\tilde{\Phi}(0, \mathbf{k})}{\beta^2} \left(\frac{\sin \beta - \beta \cos \beta}{\beta} \right) = \tilde{\Phi}(0, \mathbf{k})(1 - \beta^2/10 + \dots). \quad (28.52)$$

The mode does not evolve significantly until it is contained by the acoustic horizon.³⁷

Using Eq. (28.50), the relative density and velocity potential perturbations are then given by

$$\begin{aligned} \tilde{\delta} &= -6\tilde{\Phi}(0) \left(\frac{2(\beta^2 - 1) \sin \beta - \beta(\beta^2 - 2) \cos \beta}{\beta^3} \right) = -2\tilde{\Phi}(0)(1 + 7\beta^2/10 + \dots), \\ \tilde{\psi} &= \frac{-3^{3/2}\tilde{\Phi}(0)}{2} \left(\frac{(\beta^2 - 2) \sin \beta + 2\beta \cos \beta}{\beta^3} \right) = \frac{-3^{1/2}\tilde{\Phi}(0)}{2}(1 - 3\beta^2/10 + \dots) \end{aligned} \quad (28.53)$$

evolution after entering horizon

(see Fig. 28.11). When $\beta \gg 1$, the wavelength is smaller than the acoustic horizon and the amplitude of the velocity perturbation is $3^{1/2}\delta/4$, in agreement with the expectation for a sound wave in a stationary, relativistic fluid. The angular frequency of the

37. What this really means is that we have chosen a coordinate system in which the expectation is clearly expressed that a physical perturbation not change significantly until a signal can cross it. Even in the absence of a genuine physical perturbation, we could have created the illusion of one simply by changing to a “wrinkled” set of coordinates.

FIGURE 28.12 Evolution of the potential $\tilde{\Phi}$, the matter density perturbation $\tilde{\delta}_M$, and the velocity potential $\tilde{\psi}$ for $-2.0 \leq \log a \leq 0.0$. Note that $\tilde{\Phi}$ and $\tilde{\psi}$ only change slowly during the cosmological era when the cosmological constant is significant. By contrast, the density perturbation $\tilde{\delta}_M$ is $\propto k^2$ and grows rapidly to create the structure we observe today.

wave is $\omega = d\beta/dt = k/(3^{1/2}a)$, just what is expected for a sound wave (Sec. 16.5) in a relativistic fluid. The amplitude of the potential Φ decays as $\sim 3\tilde{\Phi}_0/\beta^2$, in accord with Poisson's equation.

The constancy of the wave amplitude $\tilde{\delta}$ turns out to be a nice illustration of adiabatic invariance (cf. Ex. 7.4). The locally measured wave energy in a single wavelength is $\propto \tilde{\delta}^2 \rho a^3$. This should scale with the wave frequency, implying that $\tilde{\delta}$ is constant (since $\omega \propto a^{-1}$).

LATE EVOLUTION

We can also describe the evolution during the gravitational and cosmological ages, when photons, neutrinos, and pressure can be ignored.³⁸ The space-space part of the Einstein tensor [Eq. (28.47d)] gives

$$\tilde{\Phi}'' + (3 - q)\tilde{\Phi}' + (1 - 2q)\tilde{\Phi} = 0, \quad (28.54)$$

where $q = \frac{1}{2} - 3\rho_\Lambda/2\rho$ is initially $\sim \frac{1}{2}$. This says that the Fourier transform of the potential $\tilde{\Phi}$ is almost constant until the cosmological constant becomes important; then it decreases to ~ 0.80 times its starting value (Fig. 28.12). The density and velocity

slow potential evolution

38. Photons and neutrinos contribute small corrections right after recombination, and there are transients associated with the sudden decrease of the coupling of baryons to photons. These are preserved in the full solution below but can be ignored in this approximate treatment.

potential perturbations for $\beta \gg 1$ [cf. Eqs. (28.53)] are

$$\tilde{\delta}_M \equiv \frac{\tilde{\rho}_M}{\rho_M} = \frac{\tilde{\rho}_D + \tilde{\rho}_b}{\rho_D + \rho_b} \sim -\frac{3\beta^2 \tilde{\Phi}}{1+q}; \quad \tilde{\psi}_M \sim -\frac{3^{1/2}}{1+q}(\tilde{\Phi}' + \tilde{\Phi}) \quad (28.55)$$

for short wavelengths $\beta \gg 1$, where we have introduced the relative matter perturbation $\tilde{\delta}_M$, which grows $\propto \beta^2 \propto a$ in accord with Poisson's equation until ρ_Λ takes over and the growth rate is reduced. The velocity potential $\tilde{\psi}_M$ is that of the matter (baryons and dark matter). Note also that, although this potential is always small, the density fluctuation $\tilde{\delta}_M$ becomes nonlinear for large β . The resulting corrections must be computed numerically.

SUMMARY

We have described the early evolution of linear perturbations that were frozen until they entered the horizon and became sound waves with constant $\tilde{\delta}$ and the universe could no longer be approximated as a single relativistic fluid. We have also outlined the growth of matter perturbations when galaxies are visible—specifically when $0.1 \lesssim a < 1$. To connect these two limits, we must examine the behavior of the separate perturbations to dark matter, neutrinos, photons, and baryons.

28.5.2

28.5.2 Individual Constituents T2

DARK MATTER

Because the nongravitational interactions of dark matter, neutrinos, baryons, and photons are negligible during the epoch of galaxy formation, we handle the evolution of the different constituent perturbations by equating the 4-divergence of their individual stress-energy tensors to zero in the given spacetime.³⁹ Dark matter has no pressure, so the nonzero, mixed, orthonormal stress-energy tensor components are $\tilde{T}_D^{\hat{t}\hat{t}} = \rho_D \tilde{\delta}_D$, $\tilde{T}_D^{\hat{t}\hat{i}} = \rho_D \tilde{v}_D = i\beta \rho_D \tilde{\psi}_D$. Setting its divergence to zero leads to two independent equations:

$$\tilde{\delta}'_D - 3\tilde{\Psi}' - 3^{1/2}\beta^2 \tilde{\psi}'_D = 0; \quad \tilde{\psi}'_D + (1+q)\tilde{\psi}_D + 3^{1/2}\tilde{\Phi} = 0, \quad (28.56)$$

where we have used the conservation law $\rho'_D + 3\rho_D = 0$ [cf. Eq. (28.19)].

Importantly for what follows, we can derive the first of Eqs. (28.56) from the flux of dark matter particles, $(\rho_D/m_D)[1 + \tilde{\delta}_D, \tilde{v}_D]$ in orthonormal coordinates, setting its divergence to zero.

What is the initial dark matter density perturbation? It could have been quite independent of the perturbation to the photons, neutrinos, pairs, etc. However, the simplest assumption to make is that it just depended on local physics and that equilibrium was established on a timescale short compared with the expansion time.⁴⁰

39. The derivations in this section are only sketched. Confirming them will take some work.

40. It is not necessary that the initial conditions be established simultaneously—for example, during inflation—only that they be fixed before the neutrinos start to decouple (when $a \sim 10^{-11}$) and before the pairs annihilate ($a \sim 10^{-9}$).

Equivalently, the number of photons per dark matter particle $\propto \rho_\gamma^{3/4}/\rho_D$ was a fixed number and so, using Eqs. (28.53), $\tilde{\delta}_D(0) = \frac{3}{4}\tilde{\delta}_\gamma(0) = -\frac{3}{2}\tilde{\Phi}(0)$. Using a similar argument we can deduce that $\tilde{\delta}_b(0) = \tilde{\delta}_D(0)$, $\tilde{\delta}_v(0) = \tilde{\delta}_\gamma(0)$. This type of perturbation is called *adiabatic* and is found to describe the observations very accurately, vindicating our trust in basic principles. The initial velocity potential perturbation, common to all constituents, is $\tilde{\psi}_D(0) = -(3^{1/2}/2)\tilde{\Phi}$, from Eqs. (28.53).

adiabatic perturbations

NEUTRINOS

Neutrinos add pressure but are effectively massless and travel at the speed of light until recent epochs, and are collisionless after decoupling. Let us throw caution to the winds and follow our treatment of a warm plasma (Sec. 22.3.5) to develop a fluid model. We set

$$\tilde{T}_v^{\hat{t}\hat{t}} = \rho_v \tilde{\delta}_v, \quad \tilde{T}_v^{\hat{t}\hat{i}} = 4\rho_v \tilde{v}_v/3, \quad \tilde{T}_v^{\hat{i}\hat{i}} = \tilde{T}_v^{\hat{t}\hat{t}} = \rho_v \tilde{\delta}_v/3. \quad (28.57)$$

fluid approximation

When we set the divergence of the neutrino stress-energy tensor to zero, we obtain two equations for the perturbations. These equations are the same as those that we would have gotten if we had treated neutrinos as collisional and would lead to oscillations after the mode entered the horizon. However, the neutrinos can free stream through the mode to damp δ_v and ψ_v . If we ignore the potential $\tilde{\Phi}$ and imagine starting with a simple sine wave, we can use Jeans' theorem to solve approximately for the time evolution of the distribution function. We find that the wave will decay in a time $\sim 2a/k$. A neutrino wave initialized in this fashion and with no other perturbations would then decay according to $\delta'_v \sim -\beta\delta_v$, $\delta\psi'_v \sim -\beta\delta\psi_v$. We therefore add these terms to the perturbation equations to account for free-streaming. The final results are:

$$\tilde{\delta}'_v - 4\tilde{\Psi}' - (4/3^{1/2})\beta^2\tilde{\psi}_v = -\beta\tilde{\delta}_v; \quad \tilde{\psi}'_v + q\tilde{\psi}_v + 3^{1/2}\tilde{\Phi} + (3^{1/2}/4)\tilde{\delta}_v = -\beta\tilde{\psi}_v. \quad (28.58)$$

BARYONS AND PHOTONS

Prior to recombination at the end of the plasma age, the photons and baryons were tightly coupled by Thomson scattering and behaved as a single fluid with the photons dominating the density. The baryons were therefore prevented from falling into dark-matter gravitational potential wells. However, around the time of recombination, the baryon density grew larger than the photon density, and the photon mean free paths lengthened, causing the photon-baryon fluctuations to damp through heat conduction and viscosity (Sec. 18.2). This effect is known as Silk damping (Silk, 1968). If there were no cold dark matter, structure would have been erased on small scales and we would have had to find some other explanation for galaxy formation. Instead, as baryons released themselves from photons, they fell into potential wells formed by the dark matter. It is this complex evolution that we must now try to address.

baryon-photon coupling

Silk damping

The baryons are relatively easy. They can be treated as a cold fluid, just like the dark matter (because their pressure is never significant in the linear regime), with a single fluid velocity $\tilde{\mathbf{v}}_b = i\beta\tilde{\psi}_b$ parallel to \mathbf{k} (because the ions and electrons must have

net zero charge density on all scales larger than the Debye length; Sec. 20.3). Their conservation law can be obtained by setting the divergence of the flux of baryons to zero just like we did for dark matter, Eq. (28.56):

baryon density evolution

$$\tilde{\delta}'_b - 3\tilde{\Psi}' - 3^{1/2}\beta^2\tilde{\psi}_b = 0. \quad (28.59)$$

Now turn to the photons. Just as with the neutrinos, the photons contribute $\rho_\gamma\tilde{\delta}_\gamma$ to the energy density and $\frac{1}{3}\rho_\gamma\tilde{\delta}_\gamma$ to the pressure. Initially, they shared the baryon velocity and so also contributed a term $\frac{4}{3}\rho_\gamma\tilde{v}_b$ to the momentum density/energy flux. Under the diffusive approximation, their heat flux in the baryon rest frame is $-ik\rho_\gamma\tilde{\delta}_\gamma/(3n_e\sigma_T a)$, where we do not have to worry about frequency shifts of the photons. We now define a photon velocity potential, $\tilde{\psi}_\gamma$, in the frame of the FOs, by equating the photon heat flux to $(4i/3)\beta\rho_\gamma(\tilde{\psi}_\gamma - \tilde{\psi}_b)$ [cf. Eq. (28.48a)]. However, this relation breaks down when the photon mean free path approaches the wavelength of the perturbation. The heat flux will then be limited by $\sim\rho_\gamma\tilde{\delta}_\gamma/3$, and we simply modify the photon velocity potential by adding a flux-limiter:

heat flux

$$\tilde{\psi}_\gamma = \tilde{\psi}_b + 3^{1/2}\tilde{\delta}_\gamma/4(\tau'_T - 3^{1/2}\beta), \quad (28.60)$$

substituting the Thomson optical depth from Eq. (28.42). The combined baryon-photon energy flux in the FO frame is then $\tilde{T}_{b\gamma}^{\hat{i}\hat{j}} = i\beta(\rho_b\tilde{\psi}_b + 4\rho_\gamma\tilde{\psi}_\gamma/3)$.

We can now take the divergence of the stress-energy tensor to obtain

$$\begin{aligned} \tilde{\delta}'_\gamma - 4\tilde{\psi}'_\gamma - 4\beta^2\tilde{\psi}_\gamma/3^{1/2} &= 0, \\ \rho_b[\tilde{\psi}'_b + (1+q)\tilde{\psi}_b + 3^{1/2}\tilde{\Phi}] + (4/3)\rho_\gamma[\tilde{\psi}'_\gamma + q\tilde{\psi}_\gamma + 3^{1/2}\tilde{\Phi} + 3^{1/2}\tilde{\delta}_\gamma/4] &= 0. \end{aligned} \quad (28.61)$$

need for kinetic treatment

As with the neutrinos, accurate calculation mandates a kinetic treatment (Ex. 28.12; Sec. 28.6.1), but this simplified treatment captures most of the kinetic results.

SUMMARY

We have now derived a complete set of linear equations describing the evolution of a single mode with wave vector \mathbf{k} . These equations can be used over the observable range, $10^{-4} \lesssim k/H_0 \lesssim 0.3$, and for the whole range of evolution for $10^{-11} < a < 1$, although different terms are significant during different epochs, as we have described. We next turn to the solution of these equations.

EXERCISES

Exercise 28.13 *Challenge: Kinetic Treatment of Neutrino Perturbations* T2

The fluid treatment of the neutrino component would only be adequate if the neutrinos were self-collisional, which they are not.⁴¹ The phenomenon of Landau damping (Sec. 22.3) alerts us to the need for a kinetic approach. We develop this in stages.

41. If we were to introduce shear stress, then viscous damping should also be included (cf. the discussion of stars in Sec. 3.7.1).

Following the discussion in Sec. 3.2.5, we introduce the neutrino distribution function $\eta_\nu(t, x^i, p_j)$, where x^i is the (contravariant) comoving (spatial) coordinate, and p_j is the (covariant) conjugate 3-momentum (Sec. 3.6, Box 3.2, and Ex. 4.1). The function η_ν satisfies the collisionless Boltzmann equation [Eq. (3.65)]:

$$\frac{\partial \eta_\nu}{\partial t} + \frac{dx^i}{dt} \frac{\partial \eta_\nu}{\partial x^i} + \frac{dp_j}{dt} \frac{\partial \eta_\nu}{\partial p_j} = 0. \quad (28.62)$$

We work with this equation to linear order.

(a) Show that the neutrino equation of motion in phase space can be written as

$$\frac{d\chi^i}{dt} = \frac{p_i}{a(t)(p_k p_k)^{1/2}} (1 + \Phi + \Psi); \quad \frac{dp_j}{dt} = -\frac{(p_k p_k)^{1/2}}{a(t)} \frac{\partial(\Phi + \Psi)}{\partial x^j}, \quad (28.63)$$

and explain why it is necessary to express the right-hand sides in terms of t , x^i , and p_i .

(b) Interpret the momentum equation in terms of the expansion of the universe (Sec. 28.2.3) and gravitational lensing (Sec. 7.6.1).

(c) Introduce locally orthonormal coordinates in the rest frame of the FOs, and define $p^{\hat{\alpha}} = \{\mathcal{E}, p^{\hat{1}}, p^{\hat{2}}, p^{\hat{3}}\}$. Carefully interpret the density, velocity, and pressure in this frame, remembering that it is only necessary to work to linear order in Φ .

(d) Multiply the Boltzmann equation successively by 1, \mathcal{E} , and $p^{\hat{i}}$, and integrate over the momentum space volume element $dp^{\hat{1}} dp^{\hat{2}} dp^{\hat{3}}$ to show that

$$\begin{aligned} \tilde{\delta}'_{n_\nu} - 3\tilde{\Psi}' + 3^{1/2} i \boldsymbol{\beta} \cdot \tilde{\mathbf{S}}_\nu &= 0; & \tilde{\delta}'_\nu - 4\tilde{\Psi}' + \frac{4i\boldsymbol{\beta}}{3^{1/2}} \tilde{v}_\nu &= 0; \\ i\tilde{\mathbf{v}}'_\nu - 3^{1/2} \boldsymbol{\beta} \left(\frac{\tilde{\delta}_\nu}{4} + \tilde{\Phi} + \tilde{\Psi} \right) &, \end{aligned} \quad (28.64)$$

where $\tilde{\delta}_{n_\nu}$ is the fractional fluctuation in neutrino number density, and $\tilde{\mathbf{S}}_\nu$ is the associated number flux. In deriving these equations, it is necessary to impose the same closure relation (cf. Sec. 22.2.2) as was used to derive the fluid equations (28.57).⁴² These kinetic equations have the same form as the fluid equations, although the coefficients are different and would change again if we changed the closure relation. This demonstrates that fluid equations can only be approximate, even when derived using the Boltzmann equation.

(e) One standard way to handle the neutrino perturbations accurately is to expand the distribution function in spherical harmonics. Outline how you would carry this out in practice, and how you would then use the more accurate neutrino distribution to improve the evolution equation for the dark-matter, baryon, and photon components.

42. Thus the trace of the stress-energy tensor vanishes in all Lorentz frames.

Exercise 28.14 *Problem: Neutrino Mass* T2

Neutrinos have mass, which becomes measurable at late times through its influence on the growth of structure.

- Explain how the expansion of the universe is changed if there is a single dominant neutrino species of mass 100 meV.
- Modify the equations for neutrino phase-space trajectories described in the preceding problem to allow for neutrino rest mass, and outline how this will affect the growth of perturbations.
- Describe how you could, in principle, measure the individual neutrino masses using cosmological observations. (In practice, this would be extremely difficult.)

28.5.3

28.5.3 Solution of the Perturbation Equations T2

GROWTH VECTOR

If we ignore shear stress and equate Ψ to Φ [as discussed after Eq. (28.47d)], we have eight first-order, coupled, linear differential equations [Eqs. (28.50), (28.56), (28.58), (28.59), and (28.61)] plus an algebraic equation (28.60), describing the evolution of small perturbations in the presence of a single wave mode. A simple reorganization gives

$$\tilde{\mathbf{Y}}' = \mathcal{M}\tilde{\mathbf{Y}}, \quad (28.65)$$

where $\tilde{\mathbf{Y}} = \{\tilde{\Phi}, \tilde{\delta}_D, \tilde{\psi}_D, \tilde{\delta}_v, \tilde{\psi}_v, \tilde{\delta}_b, \tilde{\Psi}_b, \tilde{\delta}_\gamma, \tilde{\psi}_\gamma\}$ is dimensionless, and the elements of the matrix \mathcal{M} are all real functions of a that we have already calculated and that describe the unperturbed universe. The solution of Eq. (28.65) can be written as $\tilde{\mathbf{Y}} = \mathbf{\Gamma}(a, \mathbf{k})\tilde{\Phi}(0, \mathbf{k})$, where $\mathbf{\Gamma}$ is the *growth vector* for adiabatic perturbations, initialized by

$$\mathbf{\Gamma}(0, k) = \left\{ 1, -\frac{3}{2}, -\frac{3^{1/2}}{2}, -2, -\frac{3^{1/2}}{2}, -\frac{3}{2}, -\frac{3^{1/2}}{2}, -2, -\frac{3^{1/2}}{2} \right\}. \quad (28.66)$$

[Note that we here switch from the scaled wave vector $\boldsymbol{\beta}$, Eq. (28.48b), to its unscaled, comoving form \mathbf{k} , as that is what we will need in using the growth vector.]

In the above equations and analysis, we have neither allowed for uncertainty in the governing parameters nor the addition of speculative physical processes (Ex. 28.26). We have also ignored nonlinear corrections (cf. Sec. 23.2, Ex. 28.15). Nonetheless, in their domain of applicability, these equations allow us to exhibit much that is observed and measured (Fig. 28.13).

POTENTIAL POWER SPECTRUM

What determined the initial amplitudes $\tilde{\Phi}(0, \mathbf{k})$? It turns out that a simple early conjecture⁴³ accounts very well for a large number of independent cosmological mea-

43. First proposed by Harrison (1970), who considered the mode amplitudes when they entered the horizon, not when they were initialized much earlier, as we shall do. The idea was put on a more general footing by Zel'dovich (1972); see also Peebles and Yu (1970).

FIGURE 28.13 Variation of the growth vector Γ for one choice of wave number $k_{\text{eq}} = 78H_0$, which enters the horizon, $\beta = 1$, when the universe becomes matter dominated ($a = a_{\text{eq}} = 0.00030$; $\log a_{\text{eq}} = -3.52$). The solid black line is the potential perturbation; the dashed lines are the density perturbations, δ ; the dotted lines are the velocity potential perturbations. The potential decreases slowly as the universe expands through the radiation, plasma, and atomic ages. The dark matter density perturbation starts to grow $\propto a$ after it enters the horizon. By contrast, the neutrino and photon perturbations, being hot, do not fall into the dark matter potential wells. The baryon perturbations are initially coupled to the photon perturbations, as can be seen by their common velocity potentials, but after recombination, they are released to fall into the dark matter potential wells. The model for the neutrino and photon perturbations is decreasingly realistic after recombination but irrelevant for our purpose here, and so is not shown.

measurements. The conjecture is that the initial metric perturbations were *scale invariant and isotropic*. To explain what this means, adopt the formalism developed in Sec. 6.4, and imagine an ensemble of universes⁴⁴ defining a dimensionless *power spectrum* of potential fluctuations $P_\Phi(a, k)$. Specifically, we define [cf. Eq. (6.31)]

$$\langle \tilde{\Phi}(a, \mathbf{k}) \tilde{\Phi}^*(a, \mathbf{k}') \rangle = (2\pi)^3 P_\Phi(a, k) \delta(\mathbf{k} - \mathbf{k}') = (2\pi)^3 \Gamma_1(a, k)^2 P_\Phi(0, k) \delta(\mathbf{k} - \mathbf{k}'). \quad (28.67)$$

Henceforth, we use $\langle \cdot \rangle$ to denote an ensemble average; all other averages that can be computed by integrating known functions over position, angle, frequency, etc. will

ensemble average

44. Of course, we only have one universe to observe, but when we study many small regions, the average properties are well defined. By contrast, when we examine large regions, the *cosmic variance* is also large, and no matter how precisely we make our measurements, there is a limit to how much we can learn about the statistical properties of the ensemble.

be denoted by an overbar. Scale invariance is the assertion that $P_\Phi(0, k) \propto k^{-3}$.⁴⁵ Equivalently, the primordial contribution to $\langle \Phi^2 \rangle$ from each octave of k is a constant:

$$\langle \Phi^2 \rangle_k \equiv \left(\frac{k}{2\pi} \right)^3 P_\Phi(k) \equiv \mathcal{Q} = \text{const.} \quad (28.68)$$

initial cosmic noise

Observations of the CMB and galaxies imply that the dimensionless quantity \mathcal{Q} , the *initial cosmic noise*, is 1.8×10^{-10} .⁴⁶

Gaussian fluctuation spectrum

In general, a power spectrum does not capture all possible statistical properties of noise. However, in this case a stronger statement was conjectured—that the initial amplitudes of individual Fourier modes had a Gaussian distribution with zero mean, constant variance, and random phases (implying no covariance and no need for any other independent statistical measures beyond \mathcal{Q} ; cf. Secs 6.3.2 and 6.3.3).

We can now employ the Wiener-Khinchine theorem (Sec. 6.4) to obtain a symmetric *correlation matrix*:

correlation matrix

$$C_{ij}(\mathbf{s}, a) \equiv \langle \Upsilon_i(a, \boldsymbol{\chi} + \mathbf{s}) \Upsilon_j(a, \boldsymbol{\chi}) \rangle = \mathcal{Q} \int \frac{d^3k}{4\pi k^3} e^{i\mathbf{k}\cdot\mathbf{s}} \Gamma_i(a, \mathbf{k}) \Gamma_j(a, \mathbf{k}) \quad (28.69)$$

(cf. Ex. 9.8). Many entries in this matrix have been verified observationally, thereby validating the remarkably simple physical model that we have outlined. The birth of the universe was accompanied by a hum, not a fanfare!

SUMMARY

We have set up a general formalism for describing, approximately and linearly, the growth of perturbations under general relativity in the expanding universe all the way from neutrino decoupling to the present day. The principal output is the evolution of the potential functions Ψ , Φ and the accompanying density perturbations through recombination and after reionization. This provides a basis for a more careful treatment of the photons, to which we turn in Sec. 28.6, and the observed clustering of galaxies, which we now address.

28.5.4

28.5.4 Galaxies T2

observations of galaxies

SURVEYS

Much of what we have learned about cosmology has come from systematic surveys of distant galaxies over large areas of sky. As we have emphasized (cf. Sec. 28.2.1), galaxies are not well standardized; they are more like people than elementary particles! However, it is possible to average over this diversity to study their clustering. To date,

45. This spectrum may be thought of as the (3-dimensional) spatial generalization of flicker or “1/f” noise that is commonly measured in time series, such as music (Sec. 6.6.1). The common property is that there are no characteristic spectral features, and the power diverges logarithmically at both small and large scales. The measured spectrum has slightly more power at small k , as we discuss in Sec. 28.7.1.

46. For reasons that make perfect sense to astronomers, the conventional normalization is expressed as the rms relative density fluctuation in a sphere of radius 11 Mpc, assuming linear evolution of the perturbations. This quantity, known as σ_8 , has the value ~ 0.82 .

roughly a billion galaxies (out of the roughly one trillion that are observable) have had their positions, shapes, and fluxes measured in a few spectral bands. Over a million of these have had their spectra taken, so their distances can be determined using the Hubble law.

GALAXY POWER SPECTRUM

The power spectrum of density perturbations in the gravitational and cosmological ages, $P_M(a, k)$, defined by $\langle \tilde{\delta}_M(a, \mathbf{k}) \tilde{\delta}_M^*(a, \mathbf{k}') \rangle = (2\pi)^3 P_M(a, k) \delta(\mathbf{k} - \mathbf{k}')$, can be simply related to the power spectrum for the gravitational perturbations $P_\Phi(a, k)$ [the evolved Eq. (28.68)] using Eqs. (28.55). If we also assume that, despite the different evolution of baryons and dark matter, the space density of galaxies is directly proportional to their combined density,⁴⁷ then we can use galaxy counts to measure the total matter power spectrum. The computed power spectrum is exhibited in Fig. 28.14, and its high- k region is explored in Ex. 6.7. Note that after recombination, the small-scale (large k) structure was relatively more important than the larger-scale structure in comparison with today. In other words, smaller *groups* of protogalaxies merged to create larger groups as the universe expanded. This principle is also apparent before reionization, when smaller, pregalactic dark matter *halos* merged to form larger halos, which eventually made observable galaxies when the gas was able to cool and form luminous stars.

To describe merging requires that we handle the perturbations nonlinearly. Mild nonlinearity can be handled by a variety of analytical techniques, but the best approach is to assume that the dark matter is collisionless and to perform N -body numerical simulations, which can now (2016) follow over a trillion test particles. These calculations can then be supplemented with prescriptions for handling the non-gravitational behavior of the baryons on the smallest length scales as they cool to form stars and massive black holes. This happened most vigorously when $a \sim 0.3$. The current incidence of small structure appears to be significantly less than expected. This may be a result of nongravitational effects, or it could signify a high- k cutoff in the initial potential power spectrum [Eq. (28.68)].

BARYON ACOUSTIC OSCILLATIONS

The perturbations at recombination are basically sound waves whose amplitude depends on the phase of the oscillation measured since the time when the wave mode entered the horizon. As a result, at recombination (380 kyr), the amplitude oscillates with the (comoving) wavelength. These oscillations are observed directly in angular fluctuations of the CMB (see Fig. 28.15), where they are known as *acoustic peaks*. Baryons were released from the grip of photons during recombination and fell into dark matter potential wells. There should thus be preferred scales imprinted on the

merging of galaxies and groups

nonlinearity of evolution

47. This turns out to be a better approximation than might be imagined, but it fails on small scales, where cooling and stellar activity become more important than gravity in determining what we see. These effects are addressed by attempting to compute *bias* factors.

FIGURE 28.14 Matter fluctuation power spectrum $P_M(k)$ for $\log a = -1, -0.5$, and 0 , corresponding to recombination, reionization, the epoch of maximal galaxy and star formation, and today, respectively. The spectrum demonstrates clearly that structure grows first on small scales, and it provides a fair description of the results of large-scale galaxy surveys. Note the wiggles in the power spectrum for $2 < \log(k/H_0) < 2.7$, shown more clearly in the inset for $\log a = 0$. These are baryon acoustic oscillations—echoes of the acoustic oscillations observed using CMB measurements at recombination.

distribution of galaxies we see around us today. These *baryon acoustic oscillations* are very important, because they allow astronomers to follow the expansion of a comoving ruler over time—in other words, to measure $a(t)$. As we shall see, the calibration length at recombination is very well determined by observations of the radiation (Sec. 28.6.1). Baryon acoustic oscillations can be seen in the angular correlation functions measured in large galaxy surveys and also in studies of the radial velocities of these galaxies.

EXERCISES

Exercise 28.15 Example: Nonlinearity T2

Explore nonlinear effects in the growth of perturbations in the gravitational age—when radiation and the cosmological constant can be ignored—by considering the evolution of a sphere in which the matter density is uniform and exceeds the external density by a small quantity.

- (a) Use the Friedmann equations (28.16), (28.18), and (28.19) to show that the sphere behaves like a universe with density greater than the critical density and stops expanding when its density exceeds the external value by a factor of $9\pi^2/16$.

- (b) Assume that the perturbation remains strictly spherical, and determine by what additional scale factor the external universe will have expanded when the perturbation collapses to a point.
- (c) Argue that realistic perturbations behave quite differently, that non-spherical perturbations grow during the collapse, and that the infall kinetic energy effectively randomizes during the collapse. Show that the collapse stops when the radius of the sphere is roughly half its maximum value and that this occurs when the average density exceeds that in the still-expanding external universe by a factor of ~ 150 .

T2

28.6 Cosmological Optics T2

28.6

28.6.1 Cosmic Microwave Background T2

28.6.1

OVERVIEW

So far, we have emphasized the dynamical effects that govern the evolution of small perturbations in the expanding universe and have shown how these lead to a statistical description of the potential, density, and velocity perturbations. We now consider the effect of these perturbations on extragalactic observations where the radiation propagates passively through them. We start with the CMB. As we have explained in Sec. 28.4.4, most of the action happens at recombination—over an interval of time short compared with the age of the universe—when free electrons are rapidly captured and retained by protons and the rate of Thomson scattering plummets. We need to describe photons as they transition from belonging to a perfect fluid to uninterrupted, free propagation along null geodesics. We then discuss the statistical properties of the relative temperature and polarization fluctuations.

radiative transfer

MONTE CARLO RADIATIVE TRANSFER

The standard way to compute the radiative transfer is to generalize the moments of the Boltzmann equation (28.64) to include baryon motion and the potentials $\tilde{\Phi}$ and $\tilde{\Psi}$. Hundreds of spherical harmonics are necessary to achieve the requisite accuracy. As we have already discussed many calculations of this general character in the preceding chapters, we shall elucidate the underlying physical processes by using a Monte Carlo description (cf. Sec. 5.8.4). Monte Carlo methods are often used for problems that are too complex for a Boltzmann approach.

To do this, we first ignore the perturbations and follow backward in time a photon observed by us, today (at time t_0), with initial direction \mathbf{n} and polarization (electric field unit vector) $\hat{\mathbf{E}}$. (The backward transition probabilities are just the same as for the actual, forward path.) We then assign the Thomson optical depth to the first scattering (going backward) according to $\tau_T = -\ln R_1$, where R_1 is a random number distributed uniformly in $[0, 1]$. Using the discussion in Sec. 28.4.4, we associate this optical depth with the location of the scatterer in spacetime, which is

Thomson optical depth

specified by t_1 and $\chi_1 = \mathbf{n} \int_{t_1}^{t_0} dt/a$. The differential cross section for electron scattering into direction \mathbf{n}_1 is $d\sigma/d\Omega = r_e^2(1 - \mu_s^2)$, where r_e is the classical electron radius, and $\mu_s = \hat{\mathbf{E}} \cdot \mathbf{n}_1$ (e.g., Jackson, 1999).⁴⁸ The cumulative probability distribution for μ_s is $(3\mu_s/4 - \mu_s^3/4 + 1/2)$, and so we equate this to another uniformly distributed random number R_2 and solve for μ_s . The scattered photon's azimuth is likewise assigned as $2\pi R_3$, with R_3 a third random number uniform on $[0, 1]$, and the new polarization vector $\hat{\mathbf{E}}_1$ is along the direction of $(\hat{\mathbf{E}} \times \mathbf{n}_1) \times \mathbf{n}_1$. We iterate and trace the photon path backward until the scatterings were so frequent that the evolution of the radiation can be treated as adiabatic. This happened at time t_{ad} and location χ_{ad} .

Having determined the path, we consider a photon traveling forward along it. According to Eq. (28.63) with $\Phi = \Psi = 0$, the covariant momentum p_i is constant between scatterings, and so the photon's frequency is $\nu \propto a^{-1}$. This frequency is unchanged by scattering, as the electrons are assumed to be at rest with respect to the FOs. When we repeat this exercise many times, we find no net polarization to statistical accuracy, as we must.

We now switch on a single perturbation with wave vector \mathbf{k} . [It is helpful to express the perturbation's Ψ and Φ as standing waves rather than running waves; cf. the passage following Eq. (28.46).] And we make the approximation that $\Psi = \Phi$ [i.e., we neglect gravitational effects of anisotropies in the free-streaming photon and neutrino stresses; see passage following Eq. (28.47d).] We need to calculate the linear relative frequency shift $\delta_\nu \equiv \delta\nu/\nu$ induced by the perturbation for a photon propagating forward in time along the above path, superposing four effects. The first is that the perturbation mode changes the *initial* frequency through the radiation density perturbation, the Doppler shift associated with the baryon velocity, and the gravitational frequency shift (Sec. 25.9). Specifically, $\delta_\nu = \frac{1}{4}\tilde{\delta}_\nu(t_{\text{ad}}) - \mathbf{n}_{\text{ad}} \cdot \tilde{\mathbf{v}}_b(t_{\text{ad}}) + \tilde{\Phi}(t_{\text{ad}})$. The second effect is more subtle. The proper time (age of the universe) at the start of the path differs from that of an FO in a homogeneous universe by $\delta\tilde{t} = \int_0^{t_{\text{ad}}} dt \tilde{\Phi}(t)$ (cf. Eq. 28.44). Since the universe is expanding according to local laws, the local scale factor (as measured, for example, by the local temperature) is modified by $\delta\tilde{a}/a = H\delta\tilde{t}$; and correspondingly, the frequency of the photon moving along the above Monte Carlo path is modified by $\delta_\nu = -H(t_{\text{ad}}) \int_0^{t_{\text{ad}}} dt \tilde{\Phi}(t)$.⁴⁹

The third effect is related to the second one. The scattering rate is $n_e\sigma(1 - \mathbf{n}_i \cdot \tilde{\mathbf{v}}_b)$, and its perturbation leads to a change in the propagation time and consequently to

48. The Compton recoil is ignorable, and so the Thomson cross section suffices.

49. This is known as the Sachs-Wolfe effect (Sachs and Wolfe, 1967). The largest influence on the photon frequency comes from long-wavelength (low- k) gravitational perturbations, for which $\tilde{\Phi}$ —which arises from dark matter—is nearly time independent during $0 < t < t_{\text{ad}}$. Combining this with the value $H(t_{\text{ad}}) = 2/(3t_{\text{ad}})$ in the plasma age, we obtain for the second effect $\delta_\nu = -\frac{2}{3}\tilde{\Phi}(t_{\text{ad}})$. And adding this to our first effect's gravitational frequency shift $\delta_\nu = +\tilde{\Phi}(t_{\text{ad}})$, we obtain a combined direct gravitational frequency shift $\delta_\nu = +\frac{1}{3}\tilde{\Phi}(t_{\text{ad}})$.

the time and frequency at the start of the path. The baryon density perturbations $\tilde{\delta}_b$ induce relative electron density perturbations $\tilde{\delta}_e$. They can be estimated using

$$\tilde{\delta}_e = \left(\frac{\partial \ln(n_p x)}{\partial \ln n_b} \right) \tilde{\delta}_b + \frac{1}{4} \left(\frac{\partial \ln(n_p x)}{\partial \ln T_\gamma} \right) \tilde{\delta}_\gamma, \quad (28.70)$$

ionization shift

where x is the ionization fraction (Sec. 28.4.4), and the partial derivatives are computed at the recombination surface using the formalism of Sec. 28.4.4. (A more careful treatment includes many more atomic processes.) When the scattering rate increased and the total duration of the path decreased, the universe became colder, which contributes a negative frequency shift $\delta_\nu = - \int_{t_{\text{ad}}}^{t_0} dt H \tau_T' [\tilde{\delta}_e + \mathbf{n}(t) \cdot \tilde{\mathbf{v}}_b] / \tau_T'(t_{\text{ad}})$. The fourth and final effect is the Doppler shift applied at each scattering: $\delta_\nu = \sum_i (\mathbf{n}_i - \mathbf{n}_{i-1}) \cdot \tilde{\mathbf{v}}(t_i)$.

Doppler shift

Now, the point of the Boltzmann equation is that the photon distribution function $\eta_\gamma = \{\exp[h\nu/(k_B T_\gamma)] - 1\}^{-1}$ is conserved along a trajectory in phase space (Sec. 3.6). Furthermore, it is not changed by scattering in the electron rest frame or by Lorentz transformation into and out of this frame. Therefore, the relative temperature fluctuation, which is what is actually measured, satisfies $\delta_{T_\gamma} \equiv \delta_T = \langle \delta_\nu \rangle$, averaging over the sum of the four contributions.

temperature fluctuation

We can also consider the effect on the polarization. The natural basis for the electric vector is $\mathbf{e}_a = \mathbf{k} \times \mathbf{n} / |\mathbf{k} \times \mathbf{n}|$ and $\mathbf{e}_b = \mathbf{n} \times \mathbf{e}_a$, and we expect any measured polarization to be perpendicular or parallel to the projection of \mathbf{k} on the sky. (See Ex. 28.16.) However, \mathbf{v}_b is along \mathbf{k} , and transforming into and out of the electron rest frame does not rotate the polarization vector in the $\{\mathbf{e}_a, \mathbf{e}_b\}$ basis. And the influence of gravitational deflections on the polarization is also negligible.

polarization

SPHERICAL HARMONIC EXPANSION

The Monte-Carlo calculation that we have just outlined allows us to compute the expected temperature fluctuation and write it in the form

$$\tilde{\delta}_T(\mathbf{n}, \mathbf{k}) = \mathcal{T}_k(\mathbf{n} \cdot \hat{\mathbf{k}}) \tilde{\Phi}(0, \mathbf{k}) \quad (28.71)$$

where \mathcal{T}_k is the *initial potential-temperature transfer function*. As \mathcal{T}_k is defined on a sphere, it is natural to expand it in Legendre polynomials, the functional equivalent of a Fourier series:

$$\mathcal{T}_k(\mathbf{n} \cdot \hat{\mathbf{k}}) = \sum_{l=0}^{\infty} \mathcal{T}_{kl} P_l(\mathbf{n} \cdot \hat{\mathbf{k}}), \quad \text{where} \quad \mathcal{T}_{kl} = \frac{(2l+1)}{2} \int_{-1}^1 d(\mathbf{n} \cdot \hat{\mathbf{k}}) \mathcal{T}_k P_l(\mathbf{n} \cdot \hat{\mathbf{k}}). \quad (28.72)$$

We are interested in the cross correlation of the temperature fluctuations $\langle \delta_T(\mathbf{n}) \delta_T(\mathbf{n}') \rangle$, where the average is over all directions \mathbf{n}, \mathbf{n}' separated by a fixed angle and we take the ensemble average over perturbations using Eqs. (28.67), (28.68). This

must depend only on that angle and can therefore be expanded as another sum over Legendre polynomials:⁵⁰

$$\begin{aligned}\langle \delta_T(\mathbf{n})\delta_T(\mathbf{n}') \rangle &= \int \frac{d^3k}{(2\pi)^3} P_\Phi(0, k) \sum_{l, l'} \mathcal{T}_{kl} \mathcal{T}_{kl'}^* \langle P_l(\hat{\mathbf{k}} \cdot \mathbf{n}) P_{l'}(\hat{\mathbf{k}} \cdot \mathbf{n}') \rangle \\ &= \int \frac{d^3k}{(2\pi)^3} P_\Phi(0, k) \sum_{l=0}^{\infty} |\mathcal{T}_{kl}|^2 \frac{P_l(\mathbf{n} \cdot \mathbf{n}')}{2l+1}.\end{aligned}\quad (28.73)$$

This is the functional equivalent of the Wiener-Khintchine theorem (Sec. 6.4.4). It is conventional to express $\langle \delta_T(\mathbf{n})\delta_T(\mathbf{n}') \rangle$ in terms of the total *multipole coefficient* C_l :

$$\langle \delta_T(\mathbf{n})\delta_T(\mathbf{n}') \rangle = \sum_{l=0}^{\infty} \frac{2l+1}{4\pi T_{\gamma 0}^2} C_l P_l(\mathbf{n} \cdot \mathbf{n}') ; \quad (28.74a)$$

$$\begin{aligned}C_l &= \frac{4\pi T_{\gamma 0}^2}{(2l+1)^2} \int \frac{d^3k}{(2\pi)^3} P_\Phi(0, k) |\mathcal{T}_{lk}|^2 \\ &= \frac{16\pi^2 Q T_{\gamma 0}^2}{(2l+1)^2} \int_0^\infty d \ln k |\mathcal{T}_{lk}|^2 ,\end{aligned}\quad (28.74b)$$

where we have used the scale-invariant form (28.68) of the initial perturbation spectrum $P_\Phi(0, k)$.

REIONIZATION SCATTERING

The rapid increase in electron density and Thomson scattering following reionization at the end of the atomic age (see Fig. 28.8) can actually be detected in the observations of the CMB and is described by essentially the same equations that we used for recombination. The Thomson optical depth, backward in time from us through reionization (as defined in Sec. 28.4.4) averages to $\tau_T \sim 0.066$.

INTEGRATED SACHS-WOLFE EFFECT

Another late-time effect is better described in configuration space. Consider a photon crossing a large negative gravitational potential well, associated with an excess of matter during the cosmological age. The cosmological constant causes the potential perturbation to decrease [cf. Eq. (28.54)] while the photon crosses it and so the photon loses less energy climbing out of it than it gained by falling into it, so there is a net positive temperature fluctuation. This is most apparent at long wavelengths and is most easily detected by cross-correlating the matter distribution with the temperature fluctuations.

GRAVITATIONAL LENSING

As we describe in more detail in Sec. 28.6.2, the gravitational deflection of rays crossing the universe leads to the distortion of the images of background sources. Of

50. To verify this identity, consider the special case $\mathbf{n} = \mathbf{n}'$.

FIGURE 28.15 Theoretical spectra for anisotropy of the microwave background fluctuations as measured by the coefficients C_l , where l is the spherical harmonic quantum number as defined in Eqs. (28.74). The curve labeled TT shows the C_l s for the temperature fluctuations [Eqs. (28.74); multiplied by $l(l+1)/(2\pi)$]; that labeled EE shows the C_l s for the E-mode polarization fluctuations; and that labeled TE shows the C_l s for the temperature-polarization cross correlation. These curves are adapted from theoretical calculations by Planck Collaboration (2016b) for parameter values that best fit the observations. The low- l portion of the TT curve can be reproduced with the formalism presented in this section. The fluctuations' angular scale on the top axis is $\vartheta = 180^\circ/l$. Note the prominence of the first “acoustic peak” at $l \sim 200$, which corresponds to waves that have reached maximum amplitude at recombination. The large-angle fluctuations with $l \lesssim 70$ are basically gravitational redshifts associated with perturbations that have not yet entered the horizon at the time of recombination. Modes with $l \gtrsim 300$ are dominated by density changes. Velocity effects contribute heavily to intermediate l harmonics. Ten of the predicted acoustic peaks have been measured in the TT spectrum out to $l \sim 3,000$. The observations agree extremely well with these predictions after correcting for some additional effects listed in the text.

course this makes no difference to the appearance of a uniform background radiation. However, it will change the fluctuation spectrum. The formalism used is an adaption of that developed below. This has turned out to be a powerful probe of intervening structure and, consequently, an important consistency check on the standard model.

TEMPERATURE FLUCTUATION SPECTRUM

The theoretical temperature fluctuation spectrum computed using more detailed calculations than ours (Planck Collaboration, 2016b) is shown in Fig. 28.15. It fits the observational data extremely well with only six adjustable parameters. Our Monte Carlo results (not shown) roughly recover this spectrum for low l . The detailed fit of the observations to the theory is responsible for many of the features of the standard model described earlier in this chapter.

the spectrum of temperature fluctuations

POLARIZATION

A very important recent development has been the calculation and measurement of polarization in the CMB. The calculation outlined above predicts that a single wave perturbation will produce roughly 10% polarization along the projected direction of \mathbf{k} on the sky and also predicts that the polarization observed along neighboring directions will be correlated (Ex. 28.22). When we sum over all modes, expand in spherical harmonics, and average over the sky, there is a net polarization signal of a few percent and a cross correlation with the temperature spectrum (Fig. 28.15). Measurements of these effects are used to refine the standard model. A simple generalization of Eq. (28.74b) gives the multipole coefficients for the polarization as well as the cross correlation with the temperature fluctuations (Fig. 28.15).

Because this polarization arises from photon scattering in the presence of density fluctuations, it turns out to have a pattern described by tensor spherical harmonics that are double gradients (on the sky) of scalar spherical harmonics; these are sometimes called “electric-type” spherical harmonics, and polarization patterns constructed from them are called *E-modes*. Primordial gravitational waves, interacting with the plasma during recombination, can catalyze a second type of polarization pattern called *B-modes*, whose “magnetic-type” spherical harmonics are constructed by operating on a scalar spherical harmonic with one gradient ∇ and one angular momentum operator $\mathbf{L} = \mathbf{e}_\hat{r} \times \nabla$. For some details of E-modes, B-modes, and other aspects of the predicted polarization, see Ex. 28.22.

RADIATION STRESS-ENERGY TENSOR

The least satisfactory aspect of our treatment of the growth of perturbations is the approximation of the radiation as a perfect fluid. Our treatment of radiative transfer allows one to refine this approximation by including in Eq. (28.61) an estimate of the anisotropic part of the photon stress-energy tensor.

EXERCISES

Exercise 28.16 *Example: Stokes' Parameters* T2

There are many ways to represent the polarization of electromagnetic radiation (Sec. 7.7). A convenient one that is used in the description of CMB fluctuations was introduced by Stokes.

- (a) Consider a monochromatic wave propagating along \mathbf{e}_z with electric vector $\mathbf{E} = \{E_x, E_y\}e^{i\omega t}$, where the components are complex numbers. Explain why this wave is completely polarized, and introduce the *Stokes' parameters* (following Jackson, 1999) $I = E_x E_x^* + E_y E_y^*$, $Q = E_x E_x^* - E_y E_y^*$, $U = 2\Re(E_x E_y^*)$, and $V = -2\Im(E_x E_y^*)$. Sketch the behavior of the electric vector as the complex ratio $r = E_y/E_x$ is varied, and hence associate Q , U , and V with different states of polarization.

- (b) Derive the transformation laws for the Stokes' parameters if we rotate the \mathbf{e}_x , \mathbf{e}_y directions about \mathbf{e}_z through an angle ψ .
- (c) Show that $Q^2 + U^2 + V^2 = I^2$ and that the polarization of the wave may be represented as a point on a sphere, which you should identify.
- (d) Now suppose that the wave is polychromatic and partially polarized, and replace the definitions of I , Q , U , and V with the time averages $\langle E_x E_x^* \rangle$, and so forth. Show that $Q^2 + U^2 + V^2 < I^2$, and give expressions for the degree of polarization and the associated position angle in terms of I , Q , U , and V .

Exercise 28.17 *Problem: Cosmic Variance* T2

The precision with which the low- l spherical harmonic power spectrum can be determined observationally is limited because of the low number of independent measurements that can be averaged over. Give an approximate expression for the *cosmic variance* that should be associated with the CMB fluctuation spectrum.

Exercise 28.18 *Problem: Acoustic Peaks* T2

We have explained how the peaks in the CMB temperature fluctuation spectrum arise because the sound waves all began at the same time and are all effectively observed at the same time, while they entered the horizon at different times. Suppose that the universe had been radiation dominated up to recombination, so that Eq. (28.51) is valid and oscillatory waves of constant amplitude were created with different values of k . Calculate the total relative density perturbation $\tilde{\delta}(k)$ at recombination. Describe the main changes in standard cosmology that are introduced.

Exercise 28.19 *Example: Cosmic Dawn* T2

The cosmic dawn that preceded the epoch of reionization can be probed by low-frequency CMB observations using a special radio hyperfine line emitted and absorbed by hydrogen atoms. This line is associated with a flip in direction of the magnetic dipole associated with the central proton relative to the magnetic field created by the orbiting electron. The line's frequency and strength can be calculated using quantum mechanics. For our purposes, all that we need to know is that the frequency associated with the transition is $\nu_H = 1.42$ GHz, the degeneracy of the ground/upper state is 1/3, and the rate of spontaneous transition is $A = 3 \times 10^{-15} \text{ s}^{-1}$ (Ex. 28.9).

- (a) Explain why these hyperfine transitions should produce a change in the measured CMB spectrum over a range of frequencies ~ 20 – 150 MHz, where the lower limit is due to the practicality of making the measurement.
- (b) Consider hydrogen atoms with total number density n_1 in the ground state and $n_2 = 3n_1 \exp(-h\nu_H/k_B T_S)$ in the excited state, where T_S defines the *spin temperature*, and we measure frequencies and rates locally. Show that the net creation rate

of photons per unit volume and frequency can be written as $3n_1 A \delta(\nu - \nu_H)(1 - T_\gamma/T_S)$. [Hint: $T_S, T_\gamma \gg h\nu_H/k_B$.]

- (c) Hence, show that the CMB temperature fluctuation at frequency $\nu_0 = \nu_H/a$, produced when the expansion factor was a , is

$$\delta_T = \left(\frac{3}{32\pi} \right) \left(\frac{n_H}{\nu_H^3} \right) \left(\frac{A}{H(a)} \right) [1 - T_{\gamma 0}/T_S(a)],$$

where n_H is the atomic hydrogen density, $H(a)$ is the expansion rate, and $T_{\gamma 0}$ is the CMB temperature today while T_γ is the CMB temperature at the point of emission.

- (d) It is predicted that $T_S \sim 10$ K when $a \sim 0.05$. Estimate the associated temperature perturbation, δ_T .

The spin temperature T_s will follow the nonrelativistic gas and fall faster than the radiation temperature T_γ (Sec. 28.2.3), creating absorption above ~ 10 MHz. The first stars will heat the gas and create Lyman alpha photons (Sec. 28.4.4), which end up populating the upper hyperfine state (cf. Sec. 10.2.1), increasing the spin temperature and reducing the absorption above ~ 50 MHz. Black holes are expected to create highly penetrating X-rays, which may make $T_s > T_\gamma$ and lead to emission above 100 MHz. Eventually the gas will be fully ionized, so that the spectrum above ~ 200 MHz should be unaffected.

At the lowest frequencies observable today, the radiation from our galaxy is ~ 300 times brighter than the CMB and has to be carefully removed, along with the influence of the ionosphere (cf. Sec. 21.5.4). Most attention is now (2016) focused on measuring a signal associated with the growing density perturbations from the time just before reionization. If the measurements are successful, we will have another powerful probe of the growth of matter perturbations (Sec. 28.5.3).

28.6.2

28.6.2 Weak Gravitational Lensing T2

NULL GEODESIC CONGRUENCE

We introduced strong gravitational lensing in Sec. 7.6. Such lensing is important for rare lines of sight where the galaxy-induced gravitational deflections of light rays are strong enough to image background sources more than once. There is a complementary effect called *weak gravitational lensing*, which is a consequence of the growth of perturbations in the universe and is present for all images (e.g., Schneider, Ehlers, and Falco, 1992). Basically, the tidal actions of gravitational perturbations distort galaxy images, inducing a correlated ellipticity that we can measure if we assume that the galaxies' intrinsic shapes are randomly oriented on the sky. To quantify this effect, we need to consider the propagation of neighboring rays through the inhomogeneous universe, under the geometrical optics approximation.

What we actually do is a little more subtle and much more powerful. We consider one *fiducial* ray and a *congruence* of rays that encircle it—a generalization of the paraxial optics developed in Sec. 7.4. We imagine this congruence as propagating backward in time from us, now (in a scholastically correct manner!), toward a distant galaxy. We label rays that belong to the congruence by the vectorial angle ψ they make with the fiducial ray here and now—what an astronomer observes. The fiducial ray will follow a crooked path, but we are concerned with the proper transverse separations of neighboring rays $\xi(\chi; \psi)$. This is a job for the equation of geodesic deviation [Eq. (25.31)]. (For a more detailed analysis along the lines of the following, see Blandford et al., 1991.)

As we have discussed in Sec. 25.4, we parameterize distance along a null geodesic using an affine parameter ζ , which must satisfy $dt/d\zeta \propto p^0$ [cf. Eq. (2.14)]. Now, p^0 is the energy of a photon measured by an FO; in the homogeneous universe, this will vary $\propto a^{-1}$. A convenient choice for ζ is therefore

$$\zeta(a) = \int_{t(a)}^{t_0} dt' a(t') = \int_a^1 \frac{da'}{H(a')} = \int_0^{\chi(a)} d\chi' a(\chi')^2. \quad (28.75)$$

Note that we use the scale factor appropriate to the unperturbed universe in defining ζ , because the overall expansion of the universe is dictated by the behavior of the stress-energy tensor \mathbf{T} on the largest scales where it is, by assumption, homogeneous. The associated tangent vector to use in the equation of geodesic deviation is $dx^\alpha/d\zeta = \{a^{-1}, 0, 0, a^{-2}\}$.

The Riemann tensor for the perturbed metric (28.44), like the Einstein tensor (28.47), is easily computed to linear order in the perturbations and then inserted into the equation of geodesic deviation (25.31). In contrast to our treatment of the CMB, for weak lensing we explicitly assume that the relevant perturbations are of short wavelength and are effectively static when crossed by the photons we see today, allowing us to use local Lorentz coordinates parallel-propagated along the ray with \hat{e}_3 aligned along the ray. Assuming that $\Phi = \Psi$ as dictated by the Einstein equations (28.47d) for a perfect fluid, and just retaining lowest order terms, the equation of geodesic deviation becomes

$$a^2 \frac{d^2 \xi^i}{d\zeta^2} - \dot{H} \xi^i = - \left(\Phi_{,3}{}^3 \xi^i + 2\Phi_{,j}{}^i \xi^j \right) = - \left(4\pi \delta \rho_M \xi^i + 2\bar{\Phi}_{,j}{}^i \xi^j \right),$$

for $i, j = 1, 2,$ (28.76)

where we have used Poisson's equation $\Phi_{,k}{}^k + \Phi_{,3}{}^3 = 4\pi \delta \rho_M$ and have introduced the trace-free *tidal tensor* $\bar{\Phi}_{,j}{}^i \equiv \Phi_{,j}{}^i - \frac{1}{2} \Phi_{,k}{}^k \delta_j^i$; and where spatial indices are raised and lowered with the flat metric, and all indices following a comma represent partial derivatives.

ray congruence

affine parameter

equation of geodesic deviation

CONVERGENCE AND SHEAR

It is instructive and helpful to express this equation in terms of comoving coordinates. Substituting $\xi \rightarrow a\eta$ and $d\zeta \rightarrow a^2d\chi$, we obtain⁵¹

$$\frac{d^2\eta^i}{d\chi^2} = - \left(4\pi\delta\rho_M\delta_{,j}^i + 2\bar{\Phi}_{,j}{}^i \right) a^2\eta^j. \quad (28.77)$$

The right-hand side vanishes in the absence of perturbations, which is what we expect, as the 3-space associated with the homogeneous universe is flat (Sec. 28.2.2). Equation (28.77), made linear by inserting the unperturbed η^i on the right-hand side, admits a Green function solution:

$$\eta = \frac{\xi}{a} = \chi[(1-\kappa)\mathbf{I} - \boldsymbol{\gamma}] \cdot \boldsymbol{\psi};$$

$$\{\kappa, \gamma_j^i\} = \int_0^\chi d\chi' \left(\chi' - \frac{\chi'^2}{\chi} \right) a(\chi')^2 \left\{ 4\pi\delta\rho_M(\chi'), 2\bar{\Phi}_{,j}{}^i(\chi') \right\}. \quad (28.78)$$

Here $\boldsymbol{\psi} = (d\xi/d\zeta)_0 = (d\xi/d\chi)_0$ is the observed angular displacement from the fiducial ray, and \mathbf{I} is the 2-dimensional unit tensor (metric). Also, we introduce the convergence κ ; it is the analog of the expansion that appears in the theory of elastostatics (Sec. 11.2), and it is produced by matter density perturbations inside the congruence. The quantity $\boldsymbol{\gamma}$ is the trace-free *cosmic shear tensor* produced by matter distributed anisotropically outside the congruence.

If we replace χ with d_A/a , Eq. (28.78) appears to be a simple linear generalization of the formalism introduced in our discussion of strong gravitational lensing (Sec. 7.6). However, the equation of geodesic deviation is necessary to justify the neglect of the cosmological constant, to handle the potential derivatives along the ray, and to include large density perturbations.

Now we jump into \mathbf{k} -space, write $\bar{\Phi}$ in terms of the Fourier transform $\tilde{\Phi}$, and express the two components of the distortion as:

$$\{\kappa, \gamma_j^i\} = - \int_0^\chi d\chi' \left(\chi' - \frac{\chi'^2}{\chi} \right) \int \frac{d^3k}{(2\pi)^3} \left\{ k^2, k_j k^i - \frac{1}{2} k_l k^l \delta_j^i \right\} \tilde{\Phi} e^{i\mathbf{k} \cdot \boldsymbol{\chi}'}. \quad (28.79)$$

The first component is a scalar; the second is a tensor.⁵²

CORRELATION FUNCTIONS

The ensemble average distortion vanishes, because the wave phases are random. When we consider the convergence and shear along two congruences labeled 1, 2,

51. The cosmological constant does not contribute to the focusing, but we should include radiation and neutrinos when considering weak lensing of the CMB.

52. Formally, κ should be a tensor with an antisymmetric part describing image rotation. In the case of elastostatics, this term is dropped, because it induces no stress. Weak lensing rotation vanishes in the linear, scalar approximation, but there is a tiny nonlinear contribution. In principle, an antisymmetric part of κ could be created by a hypothetical cosmic torsion field, which has been sought (unsuccessfully!) using polarization observations.

and separated by an angle ϑ , the contribution from the products of different waves likewise vanishes. Even the contribution from a single wave is small except when it is directed almost perpendicular to the line of sight and we are integrating along its crest or trough. We formalize these expectations by using the potential power spectrum [Eq. (28.67)] and keeping faith with the magic of delta functions. Let us assume that $\vartheta \ll 1$, so the sky can be treated as flat, and introduce local basis vectors \mathbf{e}_{\parallel} parallel to the separation of the congruences and \mathbf{e}_{\perp} perpendicular to the separation. We then define two independent components of shear by $\gamma_{+} \equiv \gamma_{\parallel}^{\parallel} - \gamma_{\perp}^{\perp}$ and $\gamma_{\times} \equiv 2\gamma_{\perp}^{\parallel}$. The convergence correlation function is $C_{\kappa\kappa} = \langle \kappa_1 \kappa_2 \rangle$, where the average is over all pairs of rays on the sky separated by an angle ϑ . We can likewise define correlation functions involving the shear. Then the values of the nonzero correlation functions are

$$\begin{pmatrix} C_{\kappa\kappa} \\ C_{\kappa+} \\ C_{++} \\ C_{\times\times} \end{pmatrix} = \int_0^{\chi} d\chi' \int_0^{\chi} d\chi'' \left(\chi' - \frac{\chi'^2}{\chi} \right) \left(\chi'' - \frac{\chi''^2}{\chi} \right) \times \\ \int \frac{d^3k}{(2\pi)^3} e^{i(k_{\parallel}\vartheta\chi' + k_3(\chi' - \chi''))} P_{\Phi}(a, k) \begin{pmatrix} k^4 \\ k^2(k_{\parallel}^2 - k_{\perp}^2) \\ (k_{\parallel}^2 - k_{\perp}^2)^2 \\ 4k_{\parallel}^2 k_{\perp}^2 \end{pmatrix}. \quad (28.80)$$

(The vanishing of the two remaining averages provides a check on the accuracy of the measurements.) As $k\chi \gg 1$, we approximate the integral over χ'' by an infinite integral over $\chi'' - \chi'$ to produce a delta function, which can then be integrated over to obtain

$$\begin{pmatrix} C_{\kappa\kappa} \\ C_{\kappa+} \\ C_{++} \\ C_{\times\times} \end{pmatrix} = \int_0^{\chi} d\chi' \left(\chi' - \frac{\chi'^2}{\chi} \right)^2 \int \frac{dk}{2\pi} k^5 P_{\Phi}(a, k) \int_0^{2\pi} \frac{d\phi_k}{2\pi} e^{ik\vartheta\chi' \cos\phi_k} \begin{pmatrix} 1 \\ \cos 2\phi_k \\ \cos^2 2\phi_k \\ \sin^2 2\phi_k \end{pmatrix} \\ = (2\pi)^2 \mathcal{Q} \int_0^{\chi} d\chi' \left(\chi' - \frac{\chi'^2}{\chi} \right)^2 \int dk k^2 \Gamma_1^2(a, k) \begin{pmatrix} J_0(k\chi\vartheta) \\ -J_2(k\chi\vartheta) \\ \frac{1}{2}[J_0(k\chi\vartheta) + J_4(k\chi\vartheta)] \\ \frac{1}{2}[J_0(k\chi\vartheta) - J_4(k\chi\vartheta)] \end{pmatrix}, \quad (28.81)$$

where we have substituted the initial cosmic noise [Eq. (28.68)] for P_{Φ} , $\Gamma_1(a, k)$ is the first component of the growth vector Eq. (28.66), and J_0, J_2, J_4 are Bessel functions. The remaining integrals must be performed numerically; see Fig. 28.16. Note that

FIGURE 28.16 Two-point correlation functions for weak gravitational lensing for sources located at $\log a = -0.5$, calculated from Eq. (28.81) and adopting the growth factor $\Gamma_1(a, k)$ calculated numerically from Eq. (28.65). The cross correlation of magnification fluctuations is $C_{\kappa\kappa}$. The correlation function for parallel stretching of galaxy images is C_{++} . The correlation function for stretching along a direction inclined at 45° to the separation vector is $C_{\times\times}$. The magnification-shear cross correlation is $C_{\kappa+}$.

shear correlation

$C_{++} + C_{\times\times}$, the total shear cross correlation, equals $C_{\kappa\kappa}$, as can be seen directly from Eq. (28.80) if we recall that $k_3 \sim 0$. Note also that $C_{\times\times}(\vartheta)$ can change sign. This effect has been observed. The calculation is performed here in the linear approximation, which breaks down for small scales, and so numerical simulations must be used in practice.

tomography

These four correlation functions refer to galaxies at a fixed distance. In practice, a given survey averages over a range of distances and, by varying this range, can make a *tomographic* examination of the growth of the potential power spectrum P_Φ .

STATISTICAL MEASUREMENT

How do we actually use observations of galaxies to measure convergence and shear? Weak lensing does not change the intensity of radiation. Therefore a source's flux F is determined by the solid angle it subtends. Using Eq. (28.78) to linear order, we see that $\Delta F/F = 2\kappa$. Now, we do not know the intrinsic galaxy luminosities. However, their distribution should be the same in different directions at the same distance if the universe is homogeneous, and the predicted magnifications have been measured. Unfortunately, absorption in our galaxy and other problems limit the utility of this approach. Conversely, $C_{\kappa\kappa}(0)$ is a measure of the variance of a flux measurement and a limit on how precisely a measurement need be made in a single case when

flux perturbation

attempting to use “standard candles” (sources of known luminosity) to measure the universe.

Statistical shear measurements are more useful. We expect the orientations of galaxies to be uncorrelated,⁵³ and so, if we associate the fiducial ray with the center of an observed galaxy, the tensor $\langle \xi \otimes \xi \rangle$ should be proportional to the unit tensor. Inverting the first part of Eq. (28.78) then provides a linear estimator of the shear:

$$\{\gamma_+, \gamma_\times\} = \frac{\langle \{\psi_\parallel^2 - \psi_\perp^2, 2\psi_\parallel\psi_\perp\} \rangle}{\langle \psi_\parallel^2 + \psi_\perp^2 \rangle}, \quad (28.82)$$

where the averages are over the photons associated with observed images of individual galaxies and then over galaxies adjacent on the sky but at differing distances. This estimator is quite general, and different types of source⁵⁴ and weighting can be employed in evaluating it observationally.

There are many observational challenges. For example, the dominance of Fourier modes with \mathbf{k} almost perpendicular to the line of sight means that occasional structures elongated along the line of sight can hinder the measurement of an unbiased estimate of the ensemble-averaged correlations. Despite this, cosmic shear measurements are consistent with the predicted perturbation spectrum (28.68) and its evolution and show great promise for future surveys that will image 20 billion galaxies.

Exercise 28.20 *Example: Weak Lensing in an Empty Universe* T2

Consider an extended congruence propagating through an otherwise homogeneous universe, from which all matter has been removed. Show that the affine distance functions as an effective angular diameter distance in this congruence. Now reinstate the matter as compact galaxies and modify Eq. (28.79) for the convergence and shear. Bookkeep the average density of matter as purely positive density perturbations. Explain qualitatively how the convergence and shear are changed when the ray passes through one or more galaxies, when it misses all of them, and on average.

Exercise 28.21 *Problem: Mean Deviation* T2

Consider a single light ray propagating across the universe from a source at $\log a = -0.5$ to us. The cumulative effect of all the deflections caused by large-scale inhomogeneities makes the observed direction of this ray deviate by a small angle from the direction it would have had in the absence of the inhomogeneities. Estimate this deviation angle. Is it large enough to be observable?

53. In fact, neighboring galaxies are systematically aligned, but provided we average over large enough volumes, this is ignorable. In addition, systematic biases associated with telescope and atmospheric distortion must be removed carefully.

54. For example, the CMB fluctuations and the galaxy correlation function at the smallest angular scales can be used.

EXERCISES

T2

Exercise 28.22 *Challenge: CMB Polarization* T2

Polarization observations of the CMB provide an extremely important probe of fluctuations in the early universe.

- By invoking the electromagnetic features of Thomson scattering by free electrons, give a heuristic demonstration of why a net linear polarization signal is expected.
- Using the Monte Carlo formalism sketched in Sec. 28.6.1, calculate the polarization expected from a single fluctuational mode $\tilde{\Phi}e^{i\mathbf{k}\cdot\boldsymbol{\chi}}$ of given amplitude.
- The description of polarization has many similarities with the formalism we have outlined to describe cosmic shear. Linear polarization is unchanged by rotation through π just like a shear deformation. In addition, the polarization pattern that should be seen from a single inhomogeneity mode should have an electric vector that alternates between parallel and perpendicular to the projection of the mode's wave vector \mathbf{k} on the sky, just like the elongation of the images of background galaxies in weak gravitational lensing. We do not expect to produce a signal in either case along a direction at 45° to the projection of \mathbf{k} . These predicted polarization/shear patterns are commonly called "E-modes." However, as we discuss in Sec. 28.7.1, primordial gravitational wave modes may also be present. Explain qualitatively how a single gravitational wave mode can produce a "B-mode" polarization pattern with electric vectors inclined at $\pm 45^\circ$ to the direction of the projection of \mathbf{k} on the sky.
- When one sums over inhomogeneity modes, and over gravitational-wave modes, the resulting polarization E-modes and B-modes have distinctive patterns that differ from each other. In what ways do they differ? Read, explain, and elaborate the discussion of E-modes and B-modes near the end of Sec. 28.6.1.
- Outline how our perturbed metric, Eq. (28.44), would have to be modified to accommodate the presence of primordial gravitational waves.

28.6.3

28.6.3 Sunyaev-Zel'dovich Effect T2

When we discussed CMB radiative transfer in Sec. 28.6.1, we assumed that the plasma was cold. This was appropriate when the temperature was $T_e \sim 3,000$ K. However, the gas that settles in rich clusters of galaxies (see Sec. 28.2.1 and Fig. 28.1) has a temperature of $\sim 10^8$ K, and thermal effects are very important. To understand these important effects in general, consider a homogeneous and isotropic radiation field with distribution function $\eta_\gamma(v)$. Every time a photon is scattered by an electron, its energy changes through small increments by Doppler shifting and Compton recoil. This problem is ideally suited for a Fokker-Planck treatment (Sec. 6.9.1). If we ignore emission and absorption, photons are conserved, and the Fokker-Planck equation must have the form

$$\frac{\partial \eta_\gamma}{\partial t} + \frac{1}{v^2} \frac{\partial}{\partial v} \left(v^2 \mathcal{F}_\gamma \right) = 0, \quad (28.83)$$

clusters of galaxies

Fokker-Planck formalism

where the flux \mathcal{F}_γ in frequency space depends on η_γ and its frequency derivative. When the electrons are very cold, each scattering produces a Compton recoil with average frequency change $\langle \Delta v \rangle = -hv^2/m_e$, and so $\mathcal{F}_\gamma = -(n_e \sigma_T hv^2/m_e) \eta_\gamma$. Now, our experience with the Fokker-Planck equation suggests that we add a term proportional to $\partial \eta_\gamma / \partial v$ to account for the heating of the photons by hot electrons with temperature T_e . However, \mathcal{F}_γ must vanish when η_γ is Planckian with temperature T_e . A quick inspection shows that to deal with this, we must also add a term quadratic in η_γ :

$$\mathcal{F}_\gamma = -\frac{n_e \sigma_T hv^2}{m_e} \left(\eta_\gamma + \eta_\gamma^2 + \frac{k_B T_e}{h} \frac{\partial \eta_\gamma}{\partial v} \right). \quad (28.84)$$

Kompaneets equation

This \mathcal{F}_γ vanishes when η_γ has the Bose-Einstein form $\{\exp[(hv - \mu)/(k_B T_e)] - 1\}^{-1}$, with μ the chemical potential. This is entirely reasonable, as the total photon number density is fixed in pure electron scattering and the equilibrium photon distribution function under these conditions has the Bose-Einstein form, not the Planck form (Sec. 4.4). The kinetic equation (28.83), adopting the flux \mathcal{F}_γ of Eq. (28.84), is known as the *Kompaneets equation* (Kompaneets, 1957). The third term in parentheses in Eq. (28.84) describes the diffusion of photons in frequency space due to the Doppler shift $\Delta v \sim v(k_B T_e/m_e)^{1/2}$, leading to the familiar second-order frequency increase. The diffusion coefficient in frequency space, $D_{vv} = n_e \sigma_T v^2 k_B T_e/m_e$, can be calculated explicitly by averaging over all electron velocities, assuming a Maxwell-Boltzmann distribution function.

The quadratic term in parentheses in Eq. (28.84) describes the *induced Compton effect*, in which the scattering rate between two photon states (from unprimed to primed) is $\propto \eta_\gamma (1 + \eta'_\gamma)$. To lowest order, the product term is canceled by inverse scattering. However, when we make allowance for the electron recoil, there is a finite effect, which is important at low frequency. This term is also derivable from classical electrodynamics without recourse to quantum mechanics.⁵⁵

induced Compton scattering

Now return to what happens in a galaxy cluster. The radiation is still effectively isotropic, and time should be interpreted as path length through the cluster. The derivative term in \mathcal{F}_v dominates at high T_e , and so the observed CMB relative temperature change measured at a fixed frequency is given by

$$\begin{aligned} \delta_T SZ &= \left(\frac{\partial \eta_\gamma}{\partial \ln T_\gamma} \right)_v^{-1} \left(\frac{k_B T_e \tau_T}{m_e v^2} \right) \left[\frac{\partial}{\partial v} \left(v^4 \frac{\partial \eta_\gamma}{\partial v} \right) \right]_{T_\gamma} \\ &= \left(\frac{k_B T_e \tau_T}{m_e} \right) \left[\left(\frac{hv}{k_B T_\gamma} \right) \coth \left(\frac{hv}{2k_B T_\gamma} \right) - 4 \right]. \end{aligned} \quad (28.85)$$

frequency shift

55. The first realization that *induced* Compton scattering could be important was by Kapitsa and Dirac (1933).

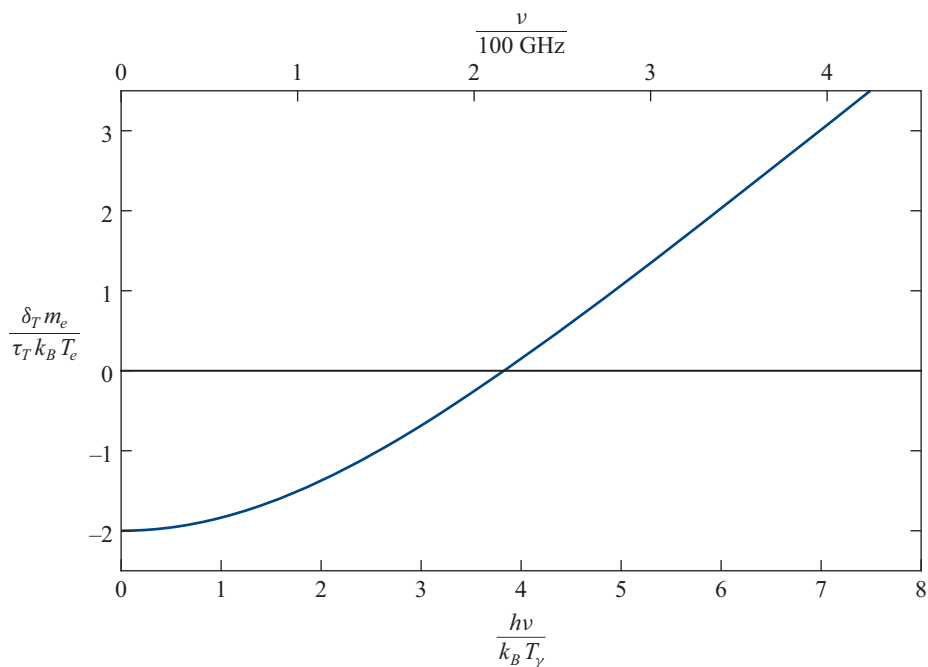

FIGURE 28.17 Sunyaev-Zeldovich effect: Distortion of the CMB blackbody spectrum by passage of radiation through a cluster of galaxies, where the hot electrons Doppler boost (on average) the frequencies of individual photons. At frequencies well below the peak in the spectrum, the intensity decreases, while at high frequencies, it increases.

This is known as the *Sunyaev-Zeldovich (1970) effect* (Fig. 28.17). In a typical cluster, the optical depth is $\tau_T \sim 0.1$ and $\delta_{T\text{SZ}} \sim 10^{-3}$. The photon temperature decreases by a fractional amount $\delta_T = -2k_B T_e \tau_T / m_e$ in the Rayleigh-Jeans part of the spectrum and increases in the Wien part. The crossover occurs at $\nu = 3.83k_B T_\gamma / h = 217 \text{ GHz}$, as observed.

EXERCISES

Exercise 28.23 *Example and Challenge: The Music of the Sphere* T2

We have hitherto focused on the statistical properties of the cosmological perturbations as probed by a variety of observations. However, we on Earth occupy a unique location in a specific realization of wave modes that we have argued are drawn from a specific set of waves with particular amplitudes and phases, despite these supposedly being drawn from a statistical distribution (in much the same way that different pieces of music are distinct despite having similar power spectra). It should not be too long before we can produce a 3-dimensional “map” of our universe out to recombination based on a suite of observations, presuming that our standard cosmology and theory for the evolution of perturbations is correct.

- (a) Calculate the comoving radii of recombination, reionization, and the most distant galaxies and quasars.

- (b) Suppose that we have noise-free CMB fluctuation maps in temperature and polarization up to spherical harmonic quantum number $l = 100$. How many numbers would be contributed by these measurements?
- (c) How many numbers would we need to measure to describe the potential and the associated density perturbations out to the radius of recombination with comparable resolution?
- (d) Would these modes still be in the linear regime today?
- (e) *Challenge.* Explore some of the practical challenges of carrying out this program, paying attention to the investigations we have described in Sec. 28.6 and assuming them to be carried out over the whole sky.

28.7 Three Mysteries T2

28.7

The cosmology that we have described depends on the application of basic physical laws, mostly classical—including (among others) general relativity with a cosmological constant—in locales where the laws are not independently tested; and it also depends on the “simplest” assumptions, including flatness and an initial, scale-free spectrum of adiabatic fluctuations. In this cosmology’s most elementary version, on which we have focused, what we observe follows from just four dimensionless parameters, which we can choose to be Ω_b , Ω_D , Ω_γ , and \mathcal{Q} , plus a single length/timescale which we can choose to be t_0 ; and we learn these parameters by fitting observations. In a more comprehensive version of this cosmology, one must also fit additional astrophysical parameters associated with reionization and galaxy formation.

We conclude this chapter with a brief summary of contemporary views on the more fundamental processes that presumably determine this cosmology’s assumptions and parameters.

28.7.1 Inflation and the Origin of the Universe T2

28.7.1

KINEMATICS

Early in our discussion of cosmology, we introduced the horizon and emphasized that it was smaller and smaller when the universe was younger and younger, so less and less of the universe was in causal contact at early times (Fig. 28.6). However, the universe we observe today is nearly homogeneous and isotropic. In particular, large-scale, spatially coherent fluctuations in the CMB are seen at recombination, when the horizon was less than 1% of their size. We have argued that the universe began in thermodynamic equilibrium at a very high temperature and that key properties (such as the net number of baryons and dark matter particles per photon and the amplitude of the potential perturbations) were determined by specific, though unknown, local physical laws. If this is so, how can there be spacelike slices of simultaneity that are homogeneous on the largest scale? It is also surprising that the universe is as flat as

horizon problem

it appears to be.⁵⁶ As was realized surprisingly early in the development of modern cosmology, these mysteries may have a common explanation called *inflation*.⁵⁷

Under the inflationary scenario, it is proposed that the material of the universe we see today was initially in causal contact and was well mixed and therefore homogeneous. There followed an epoch of runaway expansion—inflation—when parts of the universe on different world lines from our own exited our horizon and lost contact with us. After this phase ended, these parts independently followed the evolution we described in Sec. 28.4 and, primed with the same features as us, their world lines then reentered our horizon, the last to leave being the first to return. “Hello, goodbye, hello!”

We have not demonstrated that the universe had such an origin, but all recent observations are consistent with the simplest version of inflation, and nothing that we have learned is in conflict with it. At the very least, the theory of inflation illustrates some fascinating features of general relativity, bringing out clearly the challenge that will have to be met by any rational description of the very early universe.⁵⁸

We do not understand the physics that underlies inflation, but let us make a guess, inspired by observation. We have explained that the inferred initial amplitude of a potential perturbation is almost independent of its comoving length scale (scale invariance). We presume that each perturbation was laid down by local physics just prior to that scale exiting the horizon and argue that the physical conditions were therefore constant in time. The one homogeneous cosmology that has this character is a de Sitter expansion with $\rho = \text{const}$ and $a \propto e^{H_i t}$ for $t_i < t < t_h$, with a constant *inflation Hubble constant* H_i and where the subscript h denotes the end of inflation.

It is commonly supposed that inflation began during the epoch of “grand unification” of the electroweak and strong forces, when $t \sim t_i \sim H_i^{-1} \sim 10^{-36}$ s. If we also assume that the universe was homogeneous on the scale of the horizon $\sim t_i$, and inflation went on for long enough to encompass our horizon, then $a_i \sim t_i / \chi_{0H} \sim 3 \times 10^{-55}$. However, we also know that $a_h \sim a_i \exp(H_i t_h)$; and if we denote the start of the particle era by $a_p \sim 10^{-11}$ when $t_p \sim 3$ ms, then we also have that $a_h \sim a_p (t_h / t_p)^{1/2}$. These two relations and the above numbers imply that $t_h \sim 64 t_i$, $a_h \sim 2 \times 10^{-27}$. In this simple example, 64 e -foldings of inflationary expansion suffice to explain the homogeneity of our universe today.

Furthermore, any significant curvature that may have been present when the universe started to inflate would have made a fractional contribution to the Friedmann equation (28.16) $\sim (a_i / a_h)^2 \sim 10^{-56}$ at t_h . This fractional contribution would then

56. There are additional quantum field theory puzzles, especially the apparent scarcity of topological defects like monopoles, strings, and domain walls that are addressed by this theory.

57. Pioneers of these ideas included Kazanas (1980), Starobinsky (1980), Guth (1981), Sato (1981), Albrecht and Steinhardt (1982), and Linde (1982).

58. We exclude “Just So” stories—for example, flood geology—that assert that the world began at a specific time in the relatively recent past with just the right initial conditions necessary to evolve to the world of today.

grow by a factor $\sim (a_{\text{eq}}/a_h)^2 \sim 10^{46}$ by the end of the radiation era and by a further factor $\sim a_{\Lambda}/a_{\text{eq}} \sim 3,000$ by the start of the cosmological era. In this example it is only $\sim 10^{-56} \times 10^{46} \times 3,000 \sim 3 \times 10^{-7}$ in the early cosmological age (today). However, with other plausible assumptions, it may just be detectable. Therefore, the observed flatness, which otherwise requires very careful fine tuning of the initial conditions, also has a natural explanation.

CLASSICAL ELECTROMAGNETIC FIELD THEORY

The constant energy density that we have argued is needed to drive inflation is commonly associated with a classical scalar field, sometimes called the *inflaton*. To describe its properties necessitates a short digression into classical field theory (cf. Ex. 7.4).

inflaton field

Lagrangian methods were devised to solve problems in celestial mechanics and turned out to be useful for a larger class of classical problems (Goldstein, Poole, and Safko, 2002). To summarize the approach (with which the reader is presumed to be quite familiar), the coordinates \mathbf{x} of all particles are replaced by a sufficient number of generalized coordinates $\mathbf{q}(\mathbf{x}, t)$ —for example, three Euler angles for a spinning top—to describe the system. A scalar *lagrangian* $L(\mathbf{q}, \dot{\mathbf{q}}, t)$ is introduced as the difference of the kinetic and potential energies, and the system evolves so as to make the *action* $\int dt L$ stationary.⁵⁹ This implies the Euler-Lagrange equations $\partial_{\mathbf{q}} L = d(\partial_{\dot{\mathbf{q}}} L)/dt$, where $\partial_{\mathbf{q}}$ is shorthand notation for $\partial/\partial q^i$. A *hamiltonian*, $\partial_{\dot{\mathbf{q}}} L \cdot \dot{\mathbf{q}} - L$, is introduced, which equals the conserved energy if the system does not interact with its environment and evolve explicitly with time.

Lagrangian dynamics

This Lagrangian approach was generalized to describe the classical electromagnetic field⁶⁰ (where it is not very much used in practice; Jackson, 1999).⁶¹ For this, three changes need to be made to the particle lagrangian. First, as we are dealing with a relativistic theory, we work in spacetime coordinates. Second, we use the lagrangian density \mathcal{L} , so that the action is $\int dt dV \mathcal{L}$; \mathcal{L} must be a Lorentz-invariant scalar (cf. Sec. 2.12 and Ex. 7.4). Third, we treat the electromagnetic field itself as a generalized coordinate. However, instead of being an N -dimensional vector, we take the limit $N \rightarrow \infty$ and treat it as a continuous variable.

The natural choice of field coordinate is the 4-vector potential A^α constrained by the Lorenz gauge condition $\partial_\alpha A^\alpha = 0$. (We use indices here to avoid notational confusion, we use ∂_α for partial derivatives, $\partial_\alpha A^\alpha \equiv \partial A^\alpha / \partial x^\alpha$, and for simplicity we assume spacetime is flat.) For the free electromagnetic field, the only choice for the

59. In a phrase that captures the philosophical, political, theological, and literary context in which this revolutionary approach to physics was created, we live “in the best of all possible worlds.”

60. Faraday first conceptualized a field description of electromagnetism and gravity in the 1820s, contrasting it with the Newtonian “action at a distance” and gradually developed this idea (Faraday, 1846). Although Maxwell and others sought a variational description of electromagnetism, it was the astronomer Karl Schwarzschild (1903) who first got it right, 2 years before the advent of special relativity.

61. It is, of course, indispensable for understanding quantum mechanics, quantum electrodynamics, and quantum field theory and is extremely useful for probing the fundamental character of general relativity.

lagrangian density (except for an additive or multiplicative constant) consistent with these requirements is $\mathcal{L}_{\text{EM}} = \frac{1}{4\pi} \partial^{[\alpha} A^{\beta]} \partial_{[\beta} A_{\alpha]}$, in Gaussian units. Comparing with the particle lagrangian, we recognize this as kinetic energy–like with no potential energy–like contribution. Varying the action leads to the Euler-Lagrange equations:

$$\frac{\delta \mathcal{L}_{\text{EM}}}{\delta A_{\alpha}} \equiv -\partial_{\beta} \left(\frac{\partial \mathcal{L}_{\text{EM}}}{\partial (\partial_{\beta} A_{\alpha})} \right) = 0 \Rightarrow F^{\alpha\beta}{}_{,\beta} = 0 \quad \text{where } F_{\alpha\beta} = 2\partial_{[\beta} A_{\alpha]}. \quad (28.86)$$

These are the free-field Maxwell equations.⁶²

The electromagnetic stress-energy tensor is a natural generalization of the hamiltonian for particle dynamics:⁶³

$$T_{\beta}{}^{\alpha} = \mathcal{L}_{\text{EM}} \delta_{\beta}{}^{\alpha} - \left(\frac{\partial \mathcal{L}_{\text{EM}}}{\partial (\partial_{\alpha} A_{\gamma})} \right) \partial_{\beta} A_{\gamma} = \frac{1}{4\pi} \left(\partial^{[\gamma} A^{\delta]} \partial_{[\delta} A_{\gamma]} \delta_{\beta}^{\alpha} - 4\partial^{[\alpha} A^{\gamma]} \partial_{[\gamma} A_{\beta]} \right). \quad (28.87)$$

This agrees with the standard form, Eq. (2.75).

SCALAR FIELD THEORY

The observed isotropy of the universe suggests that the fundamental inflaton field we seek—henceforth designated as φ —is a real scalar and not a vector field (as in electromagnetism) or a tensor field (as in general relativity) or a complex or spinorial quantum field (like the Higgs field). In this section we set $G = c = 1$, so that φ is dimensionless and we deal with the real universe where spacetime is curved. The simplest form for the lagrangian density, by analogy with \mathcal{L}_{EM} , is $\mathcal{L} = -\frac{1}{2} \vec{\nabla} \varphi \cdot \vec{\nabla} \varphi - V(\varphi)$ (where we no longer need to use indices, as the field is a scalar). The first term is the only invariant choice we have for the kinetic energy–like part (except that the $-\frac{1}{2}$ is a convention); the second term is the simplest potential energy–like part, which is absent for classical electromagnetism but necessary here. Continuing the analogy, the stress-energy tensor is given by

$$\mathbf{T} = \mathcal{L} \mathbf{g} - \frac{\partial \mathcal{L}}{\partial (\vec{\nabla} \varphi)} \otimes \vec{\nabla} \varphi = \mathcal{L} \mathbf{g} + \vec{\nabla} \varphi \otimes \vec{\nabla} \varphi. \quad (28.88)$$

Now consider a harmonic potential $V = \frac{1}{2} \omega_h^2 (\varphi - \varphi_h)^2$, in which φ_h is the (vacuum) value of the field, where the potential vanishes. The (Euler-Lagrange) field equation for our lagrangian density is $\nabla_{\alpha} \nabla^{\alpha} \varphi = dV/d\varphi$. If we seek a wave solution in a local Lorentz frame, then we recover the dispersion relation: $\omega^2 - k^2 = \omega_h^2$, where ω_h is Lorentz invariant. This describes a longitudinal scalar wave propagating in vacuo but has a similar dispersion relation to a transverse vector wave propagating in an unmagnetized plasma [cf. Eq. (21.24)]. Note that we can Lorentz transform into a frame

62. Including a current source requires the addition of an interaction lagrangian, which is straightforward but need not concern us here.

63. The formal justification of this heuristic argument hinges on the celebrated theorem (Noether, 1918) that relates conserved quantities to symmetry.

in which $\omega = \omega_h$ and $k = 0$, and the wave becomes a pure oscillation with no spatial gradients. In this frame, the field is directly analogous to a classical particle moving in a stationary potential well. In a general frame, the stress tensor for an individual wave is anisotropic and oscillatory.

Next, consider a potential maximum $V = V_i - \frac{1}{2}\omega_i^2\varphi^2$, and transform into the frame where there are no spatial gradients. The equation of motion for the field is $\ddot{\varphi} - \omega_i^2\varphi = 0$. It is simplest to imagine the field as starting with $\varphi(0) = 0$ and a small positive velocity $\dot{\varphi}(0)$, so that $\dot{\varphi}(t) = \dot{\varphi}(0) \cosh \omega_i t$, which soon increases exponentially with time.

SLOW-ROLL INFLATION

We have now introduced all the ideas we need to design a potential that allows the universe to *slow roll* and inflate for ~ 64 e -foldings before transitioning classically to a decelerating expansion. Qualitatively, we require a potential maximum with small enough curvature for sufficient inflation to take place, joined to a potential minimum into which the field can settle and allow fundamental particles to take over the dynamics.⁶⁴

A convenient and illustrative choice for the potential is $V = V_i[1 - (\varphi/\varphi_h)^2]^2$ (Fig. 28.18a). The two parameters V_i and φ_h measure the height and the width of the potential and ought to be derivable from basic physics. Let us work in the frame in which $\varphi = \varphi(t)$ with no spatial gradients, which will define and evolve into the sequence of homogeneous spatial hypersurfaces that we have been using. Using Eq. (28.88) and comparing with the perfect fluid stress-energy tensor, we can identify the energy density ρ and the pressure P :

$$\rho_\varphi = V + \frac{1}{2}\dot{\varphi}^2, \quad P_\varphi = -V + \frac{1}{2}\dot{\varphi}^2. \quad (28.89)$$

If we ignore all other possible contributions and insert these expressions into the first law of thermodynamics [Eq. (28.19)], we obtain the cosmological scalar field equation:

$$\ddot{\varphi} + 3H\dot{\varphi} + dV/d\varphi = 0, \quad (28.90)$$

where $H^2 = 8\pi\rho_\varphi/3$. We set $V_i = 3H_i^2/8\pi = 1.6 \times 10^{98} \text{ J m}^{-3}$ and we choose $\varphi_h = 1.5$ and the value of the scalar field $\dot{\varphi}(0)$ so as to prolong inflation for 64 e -foldings and to match the expansion during the particle age (Fig. 28.18).

Now, this model thus far is seriously incomplete, because its evolution asymptotes to an empty, static universe with $H = 0$ and $a = \text{const}$. We have completely ignored the relativistic, fundamental particles that drive the post-inflationary expansion. These cannot be primordial, because their contribution would have inflated away; instead, they must have been generated at the end of inflation, specifically, as the field oscillates in the potential well. From a quantum mechanical perspective, this is quite reasonable,

64. In the original theory, this transition—called the *graceful exit*—was attributed, unsuccessfully, to quantum mechanical tunneling.

particle production

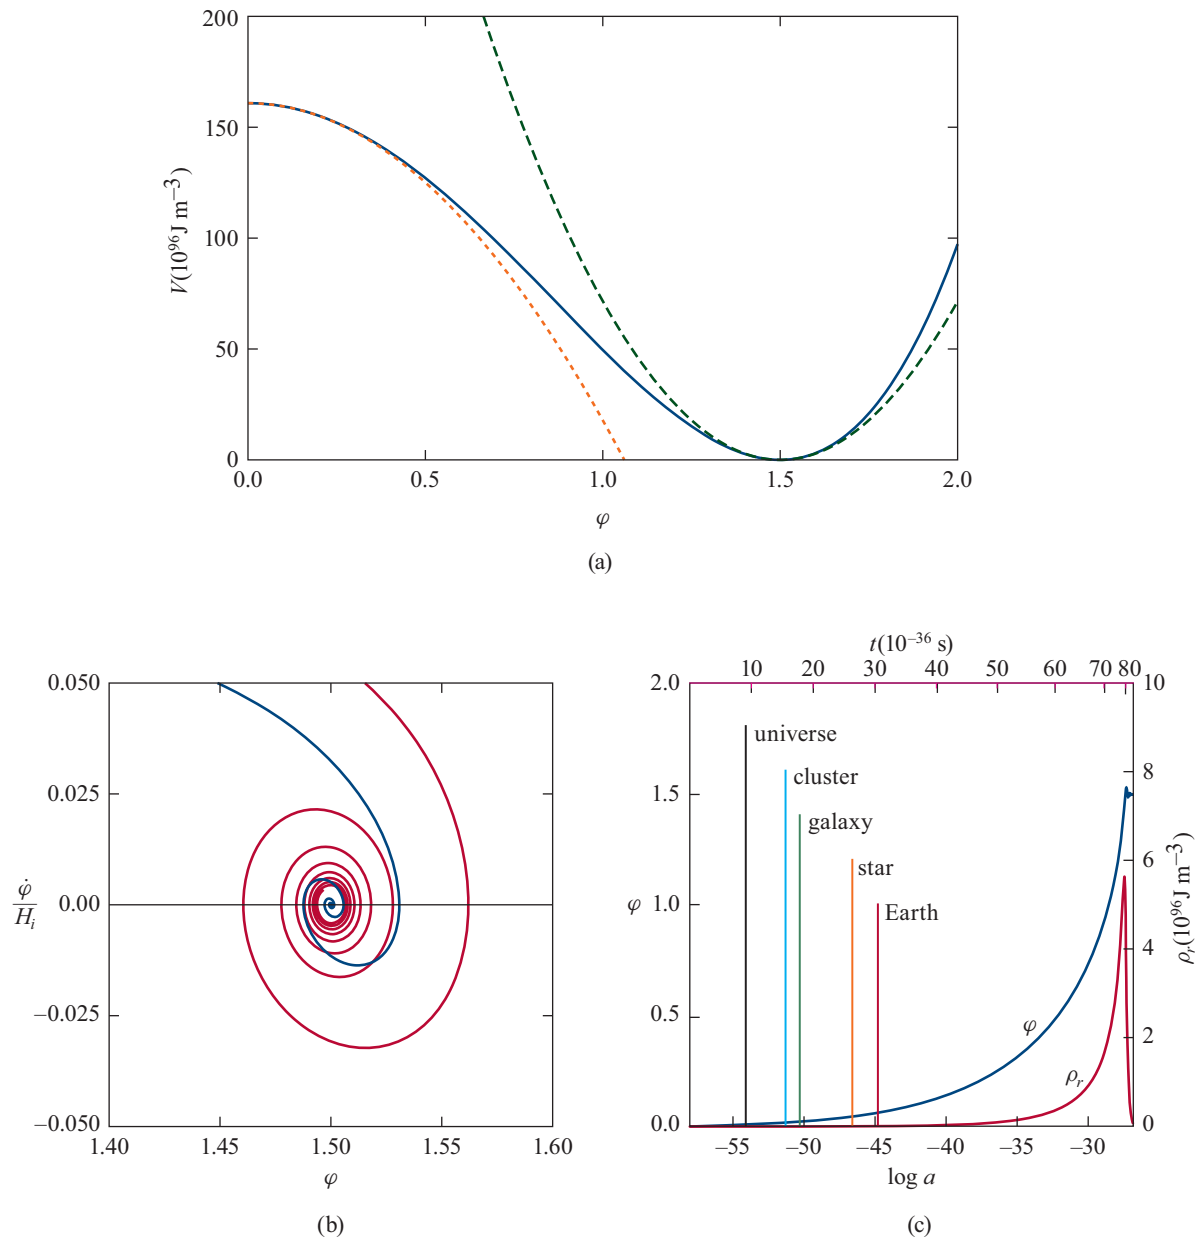

FIGURE 28.18 (a) The three types of potential considered in the text. The dashed line is a (shifted) potential minimum, the dotted line is a potential maximum, and the solid line is the simple model inflaton potential that joins these two solutions. (b) Variation of φ as it oscillates about the potential minimum exhibited in the φ - $\dot{\varphi}$ plane. The red curve is the free field variation; the blue curve includes the ad hoc particle production. (c) Variation of the field φ , the scale factor a , and the relativistic particle energy density ρ_r as a function of a . The rapid decline in ρ_r at late time is due to expansion. The times at which perturbations, on the comoving scale of various cosmic structures, leave the horizon are indicated by vertical lines.

though the detailed mechanisms are not understood.⁶⁵ The production of particles is irreversible, and this is where the entropy of today's universe, mostly carried by CMB photons, would have originated.

So (inspired by the treatment of collisionless shocks in Sec. 23.6), let us make an ad hoc modification to Eq. (28.90) by changing the “friction” term from $3H\dot{\phi}$ to $(3H + k_r H_i)\dot{\phi}$ with $k_r > 0$, to include some genuine dissipation. The equation for the production of relativistic particle energy density ρ_r is then

$$\dot{\rho}_r + 4H\rho_r = k_r H_i \dot{\phi}^2, \quad (28.91)$$

where the source term on the right is the negative of the dissipative rate of loss of inflaton energy, $\dot{\rho}_{\phi \text{ diss}}$. The results from adding this particle production to our evolution equation are shown in Fig. 28.18b. We see that a choice of $k_r = 0.2$ leads to a scale factor evolution similar to what we suggest may have happened.

One of the more serious issues glossed over in this abbreviated account of inflation is the value of the potential at its minimum. Our model potential has $V(\phi_h) = 0$. What this really means is that after inflation is over, the finite scalar field contributed nothing to the stress-energy tensor and generated no spacetime curvature. This must be essentially forever, because all other contributions to ρ diminish with time, at least until the cosmological age. Quantum mechanically, the issue is even murkier. We return to this point when we discuss the fate of the universe.

PERTURBATIONS

We have not yet explained why the primordial potential perturbations have their inferred amplitude. It is widely argued that these perturbations are quantum mechanical in origin, and to describe the associated theory goes beyond the scope of this book. See, for example, Mukhanov (2005) for details. However, we can give a heuristic semi-classical argument that captures the essence of the calculations.

In the early stages of inflation, when the perturbations that we measure leave our horizon, the inflaton field ϕ is very small, V and H_i are almost constant, and the end of inflation is far in the future. There is a limit to how far a photon can travel in comoving coordinate χ , since $dt = a d\chi \propto e^{H_i t} d\chi$. The de Sitter spacetime therefore has an effective *event horizon*. It should therefore come as no surprise to discover that there is an associated temperature similar to the Hawking temperature for a black hole, $T_i = \hbar H_i / (2\pi k_B) \sim 10^{24}$ K as H_i is the effective acceleration (Secs. 4.10.2 and 4.10.3). This temperature is too low for excited states to be important, so we are only interested in zero-point fluctuations in ϕ (Sec. 12.5). We can estimate the magnitude $\delta\phi$ of the fluctuations by equating the energy associated with it, $\sim (H_i \delta\phi)^2 (1/H_i)^3 / G$, to the zero-point energy in a mode $\sim \hbar H_i$, temporarily abandoning geometrized units and reinstating G for clarity. We deduce that $\delta\phi \sim (G\hbar)^{1/2} H_i$.

65. The production of electron-positron pairs by a rapidly varying electromagnetic field is an analogous process. The most developed explanations involve parametric resonance, as discussed in Secs. 23.5 and 10.7.2.

particle production ansatz

potential must asymptote to 0

de Sitter horizon

relation to Hawking radiation

The quantity $(G\hbar)^{1/2}$ is known as the *Planck length*, denoted $L_P \sim 10^{-35}$ m, and is equivalent to the Planck time $t_P \sim 10^{-43}$ s. It marks the scale when gravitational, relativistic, and quantum mechanical effects should be comparably important and it makes no sense to invoke classical physics alone. The physics must be described by some future complete theory of quantum gravity, perhaps derived from *string theory*. Associated with the Planck length/time is a *Planck mass* $m_P \sim (\hbar/G)^{1/2} \sim 10^{-8}$ kg $\sim 10^{28}$ eV, and a *Planck energy density* $\sim (G^2\hbar)^{-1} \sim 10^{114}$ J m⁻³. The associated Planck temperature is $\sim 10^{32}$ K. In our model for inflation, $t_{\text{start}} \sim 10^7 t_P$, and this justifies a semi-classical treatment.

The way these field fluctuations $\delta\phi$ are transformed into density and potential fluctuations is a bit more subtle. Spatial gradients can no longer be ignored when there are perturbations. Positive fluctuations develop faster than negative fluctuations, just as we saw in the gravitational age. However, we can ignore $\ddot{\phi}$ so the rate of change of ϕ is $\dot{\phi} \sim -(dV/d\phi)/(3H_i)$ from Eq. (28.90), and the time interval to change the field is $\delta t \sim \delta\phi/\dot{\phi}$. The absolute values of the relative density and potential fluctuations on a given scale are then estimated by $\delta \sim \Phi \sim H_i \delta t$ (Peacock, 1999, pp. 338–340). Now allowing ϕ to be dynamical and to evolve means that the production of the potential fluctuations from quantum fluctuations is not completely scale free, and the detailed shape of the potential $V(\phi)$ should be reflected in the observed fluctuation spectrum.

We mentioned at the start of our discussion of perturbations (Sec. 28.5.1) that we were confining our attention to scalar perturbations. If the inflationary mechanism for creating them is basically correct, then they should also be accompanied by tensor perturbations, which take the form of gravitational wave modes whose wavelengths expand with the universe in just the same way. Repeating the zero-point energy calculation using an estimate of the gravitational wave energy of $\sim (H_i \delta h)^2 (1/H_i)^3 / G$, where δh is the amplitude of the wave (cf. Sec. 27.4.3), we find that $\delta h \sim H_i t_P$. A full discussion of the growth of the tensor perturbations requires the addition of extra terms to the perturbed Robertson-Walker metric, and care must be taken to deal only with physical quantities that are independent of the choice of coordinate system/gauge.

TESTING INFLATION

We have addressed several cosmological riddles by invoking an inflaton scalar field accompanied by a specific potential for which we have no experimental evidence. Although this may seem quite unscientific, there are many precedents for astronomical observations anticipating laboratory measurement, including the deduction of an inverse square law of gravitation, the discovery of helium, and the prediction of the excited state of carbon that allowed stellar nucleosynthesis to proceed. Although there is a limit to what we can hope to learn, the recent determination that the spectrum of potential perturbations was not quite scale-free—specifically, that $P^\Phi(0, k) \propto k^{-3.04}$, so the longer-wavelength modes have slightly larger amplitudes—is encouraging. As

can be appreciated from the preceding discussion, this is a fairly general feature of simple, slow-roll potentials, because the vacuum fluctuations diminish as the field “rolls” down the potential.

As outlined in Ex. 28.22, gravitational waves are detectable through the polarization patterns that they produce in the CMB. Specifically, the B-modes, which have specific handedness locally, have been sought observationally and have been found with levels that are attributable to gravitational lensing and interstellar dust. More sensitive measurements are planned to seek the primordial signal.

INITIAL CONDITIONS

Even if we accept uncritically—on theoretical or observational grounds—that inflation happened roughly as just described,⁶⁶ the mechanism has not explained the birth of the universe. It has only translated the discussion of this question to earlier times. The simplest explanation of the origin of the universe is that there is only one universe that began as quantum mechanical decay of a Planck-scale entity.⁶⁷ Discussion of “outside” or “before” is relegated to metaphysics. More appealing ideas are that the initial state was chaotic, that it involved extra spatial dimensions, or that the evolution of the inflaton was not semi-classical.

However, the most discussed and intriguing possibility is that our universe is just one member of an ensemble of universes—the *multiverse*—that may be both past and future eternal. Members of this ensemble—also called the *landscape*—correspond to a large number⁶⁸ of possible vacuum states that are continuously created and destroyed—most on Planckian timescales. The initial conditions (Kachru et al., 2003; Susskind, 2005) mandated by the existence of our universe (e.g., that it has existed for 14 billion years) are highly specialized and will arise extremely rarely. These unusual circumstances may also extend beyond the starting requirements to the actual laws of physics that come into play as the universe expands. They may need to be fine-tuned as well to allow dark matter, baryons, nuclei, atoms, molecules, galaxies, stars, planets, and life to have developed.

The apparent improbability of this outcome has been turned on its head by conjecturing that our very existence actually selects, as opposed to just allows us to infer, the initial conditions and perhaps also the laws of physics. This is known as the *anthropic principle* (Dicke, 1961). Things were as they were because we are as we are! Many physicists are repelled by such a principle, arguing that it is basically

multiverse
landscape

anthropic principle

66. A minority of cosmologists argue that the inflation theory creates more problems than it solves.

67. If we try to do away with inflation altogether and assume that there were only relativistic particles present, then the scale factor at the Planck time is $a \sim 10^{-32}$, and we would have to explain how a region $\sim 1 \mu\text{m}$ (or $\sim 10^{29}$ Planck lengths) across could be homogenized and synchronized!

68. Over 10^{500} in some formulations! This is sufficient for adopting the precepts of statistical mechanics. The problem is that we do not have a Liouville equation for assigning a priori probabilities to individual states.

T2

extension of scientific method

teleological—a belief in the existence of final causes—and an abandonment of the quest to understand the foundations of science. Others see it as an important extension of the scientific method to accommodate the discussion of hypotheses that cannot be tested experimentally⁶⁹ and as the only practical way to advance our understanding of physics at energies well beyond current experimental reach. It will be interesting to see which of these viewpoints holds sway as our measurement of cosmological parameters continues to improve. What is undeniable, though, is that the contemplation of a universe in which, for example, P_ϕ or Ω_b have very different values or a physics under which planets obey an inverse cube law of gravitation, nuclear interactions fail to produce carbon or even helium, or the fine structure constant is 0.1⁷⁰ greatly sharpens our appreciation of the laws that we otherwise take for granted.

EXERCISES

Exercise 28.24 *Example: Blind Cosmologist* T2

A blind (but hearing) cosmologist observed the radiation-dominated universe. He detected faint tones and noted that their frequencies declined as $t^{-1/2}$ and believed (correctly) that the sound speed is constant. As he was blind, he knew nothing of photons but did understand classical scalar field theory. What did he conclude about $V(\varphi)$?

28.7.2

28.7.2 Dark Matter and the Growth of Structure T2

The material content of the modern universe is dominated by dark matter and baryons. The existence of each of these constituents is puzzling. Let us consider them in turn.

DARK PARTICLES

It is widely conjectured that dark matter comprises one or more new elementary particles. For specificity, let us suppose that there is a single particle that is neutral (like a neutron), fermionic with spin $\frac{1}{2}$ (like an electron), its own antiparticle (like a photon), weakly interacting (like a neutrino), and stable (like a proton appears to be).⁷¹ Introduce $Z_D \equiv n_D/n_\nu$, the ratio of its density n_D to the neutrino density n_ν , and let its mass be $m_D \equiv m_{D,12}$ TeV. When $T \gg m_D/k_B \sim 10^{16}m_{D,12}$ K, the dark particles were presumably created and destroyed freely in thermal equilibrium with other particles and with zero chemical potential, so that $Z_D = \frac{1}{3}$, as there are three

WIMPs

69. It can be argued that many of the most important modern applications of classical physics (e.g., geophysics, climate change, and astrophysics) are of this character, although when we understand the governing principles, we substitute simulation for experiment and Bayesian likelihood for frequentist statistics.

70. In some extreme formulations, even the laws of arithmetic are allowed to vary!

71. Such dark matter particles are often called Weakly Interacting Massive Particles or WIMPs!

neutrino species. Using the current dark matter and neutrino densities from Table 28.1, we find that today $Z_D = 4 \times 10^{-12} m_{D,12}^{-1}$ (Table 28.1).

So, most of the dark matter particles must have vanished. The simplest explanation is that during binary collisions they annihilated to form less massive, relativistic particles when they became mildly relativistic, like electrons and positrons annihilated, consistent with thermodynamic equilibrium (cf. Sec 28.4.1). Eventually the annihilation rate fell below the Hubble expansion rate, and a small relict density was left over, out of equilibrium, constituting the dark matter we see today (Lee and Weinberg, 1977). Using the principles we established in our discussion of nucleosynthesis (Sec. 28.4.2), we can write down immediately a kinetic equation for the dark particles that balances annihilation with the reverse reactions:

$$\dot{Z}_D = n_\nu \langle \sigma_{DD} v_D \rangle \left(\frac{n_{D\text{th}}^2}{n_\nu^2} - Z_D^2 \right), \quad (28.92a)$$

$$\text{where } n_{D\text{th}}(T, m_D) = 2 \int_0^\infty \frac{4\pi p^2 dp}{h^3} \frac{1}{e^{(m_D^2 + p^2)^{1/2}/(k_B T)} + 1} \quad (28.92b)$$

[cf. Eqs. (28.38)], and where $\langle \sigma_{DD} v_D \rangle$ is the annihilation rate, $n_{D\text{th}}(m_D, T)$ is the density the dark particles would have in thermal equilibrium, and the neutrino density is $n_\nu(T) = 3n_{D\text{th}}(0, T)$. (The particle speeds v_D are nonrelativistic when they stop annihilating and typically, $\sigma_{DD} \propto v_D^{-1}$.) We assume that the dark particles are kept at the same temperature as the rest of the universe and that the expansion obeyed the same $t \propto a^2$ law as at the start of the photon age. Eq. (28.92a) is now easily solved numerically for different masses to derive the relation $\sigma_{DD}(m_D)$ needed to produce the contemporary value of Z_D . More simply, though less accurately, we note that $\langle \sigma_{DD} v_D \rangle \sim H/n_D \propto m_D a_D$ when $a \sim a_D$ and annihilation ceased. Guided by pair annihilation, we estimate that the associated temperature was $T_D \sim 0.1 m_D/k_B \propto a_D^{-1}$. In order for this to be the origin of dark matter, we require that $\langle \sigma_{DD} v_D \rangle \sim 3 \times 10^{-32} \text{ m}^3 \text{ s}^{-1}$, which is also the result from the more careful calculation and is pretty insensitive to the more detailed assumptions and entirely consistent with the expectations from particle physics.

We do not understand the properties of the dark particle, and the choices we have just made look like they have been delivered by a committee! (Indeed, every single one of them can be negated and still lead to a viable explanation.) However, these choices do describe the most widely supported explanation for dark matter, namely, that it is the lightest supersymmetric particle.⁷² *Supersymmetry* is a promising extension of the standard model of particle physics that postulates the existence of fermionic partners to the bosons of the standard model and vice versa. A major experimental program

relict density

"WIMP miracle"

supersymmetry

72. Alternatives that have been seriously considered and sought include axions (Peccei and Quinn, 1977) and sterile neutrinos (Pontecorvo, 1968).

under way at the Large Hadron Collider seeks evidence for it. Many *direct* searches are also being conducted in deep mines (to filter out the cosmic ray background) for very rare collisions between dark particles and atomic nuclei. Finally, the small rate of annihilations still going on today might lead to γ -rays and positrons that can be seen, indirectly, by astronomers. All three searches—below, on, and above ground—are under way or are being undertaken in 2016. What is interesting and encouraging is that the sensitivity attainable, in each case, is roughly compatible with the value of $\langle\sigma_{DD}v\rangle$ inferred on the basis of cosmology observations and theoretical calculations.

To date, despite exquisite experiments, no convincing evidence for dark particles has been found. Instead, significant constraints on their properties are being measured by all three techniques, and improvements in sensitivity should be forthcoming over the next several years. Only Nature knows whether we are now on the threshold of identifying most of the matter in the universe and exploring a second standard model of particle physics or if we must look elsewhere for an explanation, but the hunt is on.

BARYOGENESIS

The puzzle over baryons is why there are any of them at all! Protons have antiparticles with which they can annihilate with very large cross sections, so symmetry would seem to suggest that none should have been left over after the temperature fell far below $\sim m_p/k_B \sim 10^{13}$ K. The only way residual baryons could have been created is if some imbalance were created between baryons and antibaryons.⁷³ The protons (and neutrons, which decay into protons) derived from quarks and primordial asymmetry can be preserved through the quark phase of the universe by a conserved quantum number—the *baryon number*. Essentially, what we seek is some process occurring during the very early universe and involving a significant constituent that creates such an asymmetry. Any serious discussion of this topic involves highly speculative high-energy-physics considerations that we cannot go into here. However, there are essentially classical considerations that should underlie any proposed mechanism, and these we now discuss.

Let us suppose that a particle—one with a distinct antiparticle—undergoes a decay that creates a net baryon number. Such a possibility is permitted—and indeed, suggested—by the existence of finite neutrino masses, though it has never been observed. The problem is that on quite general grounds, an antiparticle will create the opposite baryon number and so we have to explain why there is a difference between the amounts of matter and antimatter. Now, the laws of classical physics are tacitly assumed to be the same when the spatial coordinates are inverted: $\mathbf{x} \rightarrow -\mathbf{x}$. In the language of particle physics, we say that they are invariant under a *parity* (P) transformation. Likewise, the laws of classical electromagnetism are unchanged if we change

73. Equally effective would be a process that created and maintained an asymmetry between electrons and positrons, so that a baryon asymmetry would be needed to preserve charge neutrality. However, baryogenesis is thought to be more likely than *leptogenesis*.

the signs of all the charges. This is invariance under a *charge* (C) transformation. Finally, the microscopic classical laws (e.g., those describing collisions of particles or the evolution of an electromagnetic field) are invariant under time reversal—a *time* (T) transformation. This last observation does not imply that all physical phenomena are reversible. As discussed in Sec. 4.7, the act of averaging (or “coarse graining”) introduces the arrow of time, embodied in the second law of thermodynamics.

This need not have been the case and is not true in particle physics. Specifically, it was shown in the 1950s that β decay—a weak interaction—produces left-handed (not right-handed) neutrinos, which violates P symmetry. This was a surprise to many physicists. Likewise, if we were to change the signs of all charges in this decay, we would expect to produce a left-handed antineutrino, and this is not seen either, so C symmetry is violated as well. However, combined C and P transformations lead to the preservation of CP symmetry in β decay. This is important, because a fundamental theorem states that CPT symmetry must be respected, and so a violation of CP would imply a violation of T.

It therefore came as a second, even greater, shock when in the 1960s, experimental measurements of neutral K mesons showed that their decay into two channels that were CP equivalent occurred at different rates. CP symmetry is violated, and Nature can distinguish matter from antimatter and forward from backward in time. For the universe to have actually made this distinction also requires a departure from thermodynamic equilibrium in the past. If this did not happen, the particles and antiparticles would have had identical distribution functions with zero chemical potentials, and no net baryons would have been made. Now, thermodynamic equilibrium would not have been maintained had the expansion been too fast for the particle reactions (cf. Secs. 28.4.1 and 28.4.2). An alternative possibility is that the particles did not scatter, so that their momenta evolved according to $p \propto a^{-1}$ (cf. Sec. 28.2.3). This automatically leads to a nonthermal distribution function⁷⁴ and allows baryon asymmetry to proceed. We are probably a long way from understanding the detailed particle physics of baryogenesis, but determining that its general requirements could plausibly have been satisfied is a good first step.

Exercise 28.25 *Challenge: Including More Details* T2

EXERCISES

We have made many simplifying assumptions in this chapter to demonstrate the strong connection to the principles and techniques developed in the preceding 27 chapters. It is possible to improve on our standard cosmological model by being more careful without introducing anything fundamentally new. (The research frontier, of course, is advancing fast and contains much we have not attempted to explain.) Consider how to implement the following corrections to standard cosmology that

74. That all three violations—baryon number, C/CP symmetry, and thermal equilibrium—were necessary was first recognized by Sakharov (1965).

are mandated by observation, and then repeat the calculations with these changes, comparing with the research literature.

- (a) Changing the slope of the initial cosmic noise spectrum (Sec. 28.5.3).
- (b) Including more spherical harmonics in the description of the radiation field and using the Boltzmann equation instead of a Monte Carlo simulation (Sec. 28.6.1).
- (c) Including tensor perturbations in the Robertson-Walker metric (Secs. 28.5.1, 28.5.3, and 28.7.1).
- (d) Accounting for neutrino mass (Sec. 28.3.4).

Exercise 28.26 *Challenge: Testing Standard Cosmology* T2

There are many elaborations of standard cosmology either involving new features following from known physics or involving new physics. While no convincing evidence exists for any of them as of this writing, they are all being actively sought. Explain how to generalize standard cosmology to accommodate these possibilities and to test for them, repeating calculations, where possible.

- (a) Space curvature (Sec. 28.2.2).
- (b) Dark energy. Adopt an empirical equation of state with the parameter w being constant and slightly greater than -1 (Sec. 28.7.3).
- (c) Additional neutrino flavors, including *sterile* neutrinos (Secs. 28.4.1 and 28.4.2).
- (d) Nonadiabatic and non-Gaussian initial fluctuations (Sec. 28.5.3). [Hint: Consulting an advanced textbook is recommended.]

28.7.3

28.7.3 The Cosmological Constant and the Fate of the Universe T2

Einstein's cosmological constant, Λ

We have explained (Sec. 28.3.5) that the observed acceleration of the universe requires an effective negative pressure in the stress-energy tensor, and how such a possibility was anticipated by Einstein (1917). Furthermore, we have explained that Einstein's cosmological constant is consistent with the data. This is important, because it is a simple prescription whose consequences can be computed without too many extraneous assumptions and is therefore readily falsifiable. However, there are also theoretical reasons for questioning this interpretation; they, too, lie at the interface between quantum and classical physics.

The earliest view of the cosmological constant (implicitly, that of Einstein) was that its presence in the field equations is an expression of the true law of gravitation necessary on a large scale, in an analogous fashion to Newton proposing the inverse square law for planets and expanding our understanding of gravitational force beyond what is needed on the surface of Earth. The ultimate connection between the general relativity of, say, stellar-mass black holes and that of the universe at large has yet to be divined, but it should exist independent of the messy details of our cosmic environment. Many interesting ideas have been proposed, in particular those involving

extra spatial dimensions and oscillating universes. There have even been proposals to dispense with dark matter particles altogether and to interpret the observed motions of stars and galaxies in terms of modified Newtonian gravity or entanglement.

Today it is more common to view the field equations (Sec. 25.8) as providing a complete framework for describing gravitation and the cosmological constant as being just one of several contributions to the stress-energy tensor. This is the approach we followed in Sec. 28.3.5. Its most natural identification is with the quantum mechanical vacuum. Having $T_\Lambda \propto g$ ensures that the vacuum looks the same in all local Lorentz frames, consistent with the principle of relativity. However, attempts to develop this relationship quantitatively have mostly foundered on the tiny size of Λ relative to the Planck scale of quantum gravity⁷⁵— $G^2\hbar\rho_\Lambda \sim 10^{-122}$. Either this represents an unprecedented degree of fine tuning, or the cosmological constant has even less to do with quantum mechanics than, say, oceanography, and it is instead some ungrasped expression of the “fabric” of spacetime on a supraclassical scale.⁷⁶ If so, it throws down a challenge to the *reductionist* view of physics, under which physics at essentially all scales (especially classical physics) is viewed as being derivative of physics at the smallest lengthscales and highest energies. The properties of materials depend on the behavior of atoms and molecules, which depend on electrons and nuclei, which depend on quantum electrodynamics and the interactions of quarks, and so on. This does not preclude the existence, interest, or importance of *emergent* phenomena (e.g., ferromagnetism, shock fronts, or astrophysical black holes) that require appealing to the properties of matter in bulk, but it is a statement of faith that ultimately, the governing principles of these phenomena are reducible to the physics of the smallest scales, even if this is not useful in describing what we observe. In this sense Λ might be like ferromagnetism.

However, the square peg of quantum field theory need not be forced into the round hole of Riemannian geometry. The very existence of something like a cosmological constant should also cause us to inquire whether some physics is derivative of the largest scales and lowest energies instead of the smallest scales and the highest energies. Consider, allegorically, a bug in a still pond, living its low-Reynolds-number life. A fish swims by, and the bug finds itself in the fish’s turbulent wake. It observes that its food is moving more rapidly with an average speed that increases as the cube root of its distance [Eq. (15.23)] and, if it is very sensitive, it might find the water

Λ as a contribution to the stress-energy tensor

Λ as the vacuum

reductionist view of physics

Λ as emergent phenomena

75. A more intriguing possibility is that the natural, quantum mechanical mass scale for Λ is $\sim(\hbar^3\rho_\Lambda/c^3)^{1/4} \sim 10$ meV, similar to the neutrino mass scale. However, there is no known good reason for this.

76. It is interesting that the cosmological constant was taken very seriously before the 1980s (e.g., Lemaître, 1934; Tolman, 1934; Bondi, 1952a; Zel’dovich, 1968) because it allowed the universe to be older than its contents and because it provided a scale distinct from those associated with atoms, nuclei, and elementary particles (e.g., Eddington, 1933). However, the challenge of reconciling it with quantum field theory then led to its near abandonment. The subsequent discovery of cosmic acceleration therefore came as a surprise to many physicists.

Λ as a “situational” phenomenon

heating up a little. While it is true that the Navier-Stokes equations can be derived by suitable averaging of a kinetic theory, if the bug desires to reconcile its observations with their causes, it is to the outer scale of a turbulent spectrum that it should turn, not the properties of water molecules. The speculations involving the anthropic principle and the multiverse contain some of this spirit. Perhaps Λ is “situational”—our first glimpse of physics on the large scale—just like blackbody radiation and the photoelectric effect opened the door to the physics of small scales and quantum mechanics more than a century ago. Of course, this physics, dependent on conditions at and beyond our current horizon, might reflect what happened immediately prior to our observable universe leaving the horizon during inflation; alternatively, it might reflect the accidental properties of our contemporary cosmological environment.

dark energy

A more pragmatic approach is to consider generalizations of the cosmological constant. These include *dark energy* (or *quintessence*; Perlmutter et al., 1999). In particular, the behavior of the stress-energy tensor has been parameterized by introducing an equation of state $P_\Lambda = w\rho_\Lambda$, where w is negative, although there is no compelling theoretical reason for doing this. Several observational studies have concluded that $|w + 1| \lesssim 0.08$, and more accuracy is in the works. Another common approach is to invoke classical field theory (just as we did for inflation) and to use the same formalism to develop a description of contemporary inflation. It is tempting to suppose that there have been many instances of inflation over the history of the universe, and that Nature has managed to find graceful exits from every one of these expansions in the past and, in the fullness of time, it will do so again. However, there is no requirement that this will ever happen. Another way to connect to inflation is to suppose that the bottom of the inflaton potential well is associated with some sort of quantum mechanical zero-point energy or a classical offset, and that this is what the universe is experiencing now.

big rip

A particularly interesting outcome would be if future observations demonstrated that $-P_\Lambda > \rho_\Lambda > 0$; for example, if $w < -1$.⁷⁷ This condition corresponds to negative cosmological enthalpy and negative kinetic energy for a scalar field (cf. Sec. 28.7.1). Not only would it exclude a simple scalar field; it would also, if taken literally, predict an unusual fate for the universe. If $w = \text{const}$, then the first law of thermodynamics implies that eventually $\rho \propto a^{-3(w+1)}$. The energy density increases as the universe expands if $w < -1$; the universe reaches infinite size in finite time, while the horizon shrinks and closer and closer neighbors disappear, a behavior dubbed “the big rip.” Despite its eschatological fascination, many cosmologists reject this outcome on grounds of physics inconsistency and regard $w \geq -1$ as a prediction.

future measurements

As with the experimental searches for dark matter, the prospects for learning more about the expansion and fate of the universe from astronomical studies over the next decade are bright, and the observations will presumably continue to corral speculative

77. This is sometimes known as a violation of the *weak energy condition*.

interpretation. At present, progress in cosmology seems to be following that in the standard model of particle physics, where a relatively simple physical model suffices to account for essentially all data pertaining to questions addressed by the model, while leaving other questions to be confronted by new physics and future experiments. Three familiar constituents, baryons, neutrinos, and photons—supplemented by dark matter, zero curvature, and a cosmological constant and imprinted with an almost scale-free spectrum of adiabatic, Gaussian potential perturbations—suffice to account for most of what we measure. It will be fascinating to see whether this apparent simplicity is maintained through the next phase of cosmological exploration, when the true nature of inflation, dark matter, and the cosmological constant will likely be a focus of attention.

Bibliographic Note

The literature on cosmology is enormous, and it is not hard to find excellent texts and research papers to elaborate on the many topics we have touched on in this chapter. Arguably, the most useful advanced text is Weinberg (2008). Other books that are helpful on the physics but are rather out of date observationally are Padmanabhan (1993); Peebles (1993); Kolb and Turner (1994); Peacock (1999); Dodelson (2003); and Hobson, Efstathiou, and Lasenby (2006). Texts that emphasize the early universe include Liddle and Lyth (2000) and Mukhanov (2005). An especially lucid and up-to-date textbook accessible to undergraduates that emphasizes observational cosmology is Schneider (2015). Excellent discussions of cosmology from a more elementary standpoint include Ryden (2002) and Hartle (2003). Among the most important contemporary observations are the CMB results from the Planck (Planck Collaboration, 2016a, 2016b) and Wilkinson Microwave Anisotropy Probe (WMAP) (Komatsu et al., 2011) satellites, one of several careful analyses of weak-lensing observations (Heymans et al., 2012), and the preliminary results on galaxy clustering from the Baryon Oscillation Spectroscopic Survey (BOSS) galaxy survey (Anderson et al., 2014).

SUBJECT INDEX

Second and third level entries are not ordered alphabetically. Instead, the most important or general entries come first, followed by less important or less general ones, with specific applications last.

Page numbers for entries in boxes are followed by “b,” those for epigraphs at the beginning of a chapter by “e,” those for figures by “f,” for notes by “n,” and for tables by “t.”

- $\mathbf{E} \times \mathbf{B}$ drift, 1025, 1026f, 1039
- \ominus -pinch for plasma confinement, 961f, 962–963, 971
 - stability of, 978–979
- \ominus -pinch, toroidal, for plasma confinement, 978
 - flute instability of, 978–979, 978f
- 3+1 split
 - of spacetime into space plus time, 60, 1158
 - of electromagnetic field tensor, 72–74
 - of stress-energy tensor, 82–84, 120
 - of 4-momentum conservation, 60, 85–88
- 4-acceleration related to acceleration that is felt, 69, 1182
- 4-force
 - as a geometric object, 51
 - orthogonal to 4-velocity, 52
- 4-momentum
 - as a geometric object, 50
 - components in Lorentz frame: energy and momentum, 58–59
 - and affine parameter, 51
 - related to 4-velocity, 50
 - related to quantum wave vector, 50
 - related to stress-energy tensor, 82–84
- 4-momentum conservation (energy-momentum conservation)
 - 3+1 split: energy and momentum conservation, 60, 85–88
 - expressed in terms of stress-energy tensor, 84–85
 - global, for asymptotically flat system, 1237–1238
 - global version fails in generic curved spacetime, 1177, 1218
 - for particles, 51, 52f, 60
 - for perfect fluid, 86–87
 - for electromagnetic field and charged matter, 88
- 4-momentum density, 82
- 4-vector. *See* vector in spacetime
- 4-velocity
 - as a geometric object, 49
 - 3+1 split: components in Lorentz frame, 58
- Abbé condition, 373n
- aberration of photon propagation direction, 107, 1305
- aberrations of optical instruments, 395–396
 - of Hubble space telescope 426–427
- absorption of radiation, 115–116, 131, 260, 341–342, 515–516, 937, 1017, 1054, 1057, 1126–1130, 1394–1397
- accelerated observer
 - proper reference frame of, 1180–1186, 1181f, 1200, 1254, 1274
 - uniformly, 1186–1189, 1187f
- acceleration of universe, 1382, 1398–1401, 1444, 1445n
- accretion disk around spinning black hole, 784, 969
 - thin, 1287–1289
 - thick, 1289–1290
- accretion of gas onto neutron star or black hole, 205, 890–891, 1266, 1282–1283

acoustic horizon radius, χ_A , 1375
 ultrarelativistic, χ_R , 1375, 1403–1404

acoustic peaks, in CMB anisotropy spectrum, 1413, 1419f, 1421

action principles
 Hamilton's, in analytical mechanics, 15
 for geodesic equation, 1203, 1205–1206, 1357
 for rays in geometric optics, 371–373
 for elastic stress, 584
 for eigenfrequencies of normal modes, 980–981

active galactic nuclei, 1379

adaptive optics, 470b–471b, 472

adiabatic index
 definition, 243, 724b
 polytropic, 878
 for ideal gas: ratio of specific heats, 244, 678, 681b, 724b
 influence of molecules' internal degrees of freedom, 879–880
 for air, as function of temperature, 880f
 in plasma: anisotropic, 1020–1024

adiabatic invariants
 accuracy of, 1030
 failure of, 1030
 for charged particle in magnetic field, 1028–1030
 wave action of a classical wave, 365–366

advective (convective) time derivative, 32, 692, 724b, 892

affine parameter, 50–51, 99–100, 133, 136b, 1178b, 1200, 1203, 1206, 1208, 1247, 1303, 1307, 1423

Aichelberg-Sexl ultraboost metric of a light-speed particle, 1231

airplane wing or airfoil, lift on, 743f, 743–744, 824

Airy diffraction pattern for circular aperture, 426–428, 437, 442

Airy disk
 for diffraction pattern of a circular aperture, 426–427, 437, 471
 for low-pass filter to clean laser beam, 441
 in phase-contrast microscopy, 442–443, 442f
 in Strehl ratio for a telescope's performance, 472

Airy function, for diffraction near a caustic, 451–454, 452f

Alcator C-Mod, 963

Alfvén waves, 354, 990–991, 1053f
 two-fluid analysis of, 1055–1058
 dispersion relation of, 354, 990
 phase velocity of, 354, 990
 group velocity of, 355f, 356
 polarization of, 405
 relativistic corrections for, 1055–1056

as plasma-laden, plucked magnetic field lines, 990, 1056–1057
 in magnetosphere, 370f
 in solar wind, 970–971
 generated near shock fronts, 1146f
 interaction with cosmic rays. *See* cosmic rays

Allan variance of clocks, 310f, 320–21

allometry, 587, 609

ALMA (Atacama Large Millimeter Array), 480, 482

Andromeda galaxy, 305, 1365f

angular momentum
 and moment of inertia tensor, 6
 of fundamental particles (spin), 22
 of a Kerr black hole, 204–205, 226n, 1278, 1282–1283, 1285–1286, 1342. *See also* frame dragging by spinning bodies
 of a relativistic, spinning body, 1218, 1220, 1232–1234, 1237–1238, 1328
 in accretion disks, 1287–1292
 carried by gravitational waves, 1332–1333, 1335, 1338, 1345
 in statistical mechanics, 169, 172–173, 179
 in elastodynamics, 644, 661–662
 in fluid mechanics, 702, 729, 732, 733, 784, 826, 849

angular momentum conservation, Newtonian, 14–15
 in circulating water, 729, 732–733

angular momentum conservation, relativistic
 global, for asymptotically flat system, 1237–1238
 for geodesic orbits around a black hole, 1274, 1303

angular-diameter distance, d_A , 1374, 1378, 1398–1400, 1427

anthropic principle, 1439–1440, 1446

aperture synthesis, in radio astronomy, 480

Appleton-Hartree dispersion relation, 1059–1060

Archimedes law, 675, 684–685, 692

artery, blood flow in, 716–719

astigmatism, 390, 395

astronomical seeing, 425, 464–472, 481, 511

asymptotic rest frame, 1237, 1246–1248
 local, 1328, 1331, 1332, 1339–1340

asymptotically flat system in general relativity, 1194, 1238, 1238n
 imprint of mass and angular momentum on exterior metric, 1232–1233, 1238
 conservation laws for mass and angular momentum, 1237–1238, 1332, 1338

atmosphere of Earth. *See also* tornados; winds
 structure of, 683–684, 684f
 chemical reactions in, 256–258
 and greenhouse effect, 138, 748–749
 storms in, 768, 769b
 excitation of ocean waves by, 783

billow clouds in, 783, 783f
 sedimentation in, 748–755

- turbulence of
 - and astronomical seeing, 425, 464–472, 481, 511
 - excitation of earth's normal modes by, 816–817
- atomic bomb, 153, 912–914, 1009
- B-modes, of CMB polarization, 1420, 1428, 1439
- Babinet's principle, 428–429, 523
- bacterium, swimming, 747b–748b, 756–757
- baffles, to control scattered light, 448–451
- balls, physics of flight, 817, 823–825
- bandwidth of a filter, 315–318
- barotropic fluid, 681b, 724b
- baryogenesis, 1442–1443
- baryons in universe
 - origin of: baryogenesis, 1442–1443
 - evolution of, 1407–1408, 1410–1414
 - observations today, 1379
- basis vectors in Euclidean space
 - orthogonal transformation of, 20–21
 - Cartesian, 16–17
 - spherical and Cartesian, orthonormal, 614
- basis vectors in spacetime
 - dual sets of, 1161
 - coordinate, 1162–1163, 1167
 - orthonormal (Lorentz), 54, 1157
 - Lorentz transformation of, 63–65
 - nonorthonormal, 1160–1163
 - transformation between, 1164
- baths for statistical-mechanical systems
 - concept of, 160
 - general, 172
 - tables summarizing, 160t, 221t, 251t
- BBGKY hierarchy of kinetic equations, 803, 1103–1106, 1109
- BD, 530, 531
- beam, bent. *See* bent beam
- bending modulus (flexural rigidity), 594
- bending torque, 593f, 594, 596, 600, 602, 603, 608, 611, 612
- bent beam, elastostatics of, 592–596
 - elastostatic force-balance equation for, 595
 - solutions of force-balance equation
 - for clamped cantilever pulled by gravity, 596–597
 - for Foucault pendulum, 597–598
 - for elastica, 600–601, 601f
- bent plate, elastostatics of, 609–613
 - elastostatic force-balance equation: shape equation, 610
- Bernoulli function, 698–700, 702, 721, 722, 724b
- Bernoulli's theorem
 - most general version: for any ideal fluid, 698
 - for steady flow of an ideal fluid, 698, 700
 - for irrotational flow of an ideal, isentropic fluid, 701
 - relativistic, 722
- Berry's phase (geometric phase), 406–409
- BGK waves in a plasma, 1100–1101
- Bianchi identities, 1223–1224
 - in Maxwell-like form, 1235b, 1318b
- bifurcation of equilibria
 - formal mathematical foundations for, 384
 - onset of dynamical instability at bifurcation
 - in general, in absence of dissipation, 648
 - for beam under compression, 647–648
 - for convection, Rayleigh-Bénard, 931
 - for beam under compression, 603–605
 - for rapidly spinning star, 607
 - for rotating Couette flow, 826–827
 - for Venus fly trap, 607
 - for whirling shaft, 607
- big rip, 1446
- biharmonic equation, 589, 610, 754, 756
- billow clouds, 783, 783f
- binary black holes, 1341–1342, 1342f, 1343f, 1344b–1345b
- binary pulsars
 - Hulse-Taylor: B1913+16, 502, 1310

 - evolution of, 1282–1287
 - quantum thermal atmosphere of, 204–205
 - Hawking radiation from, 204–205, 1286–1287
 - accretion of gas onto, 205, 784, 890–891, 969, 1282–1283, 1287–1290
 - binary, 1341–1342, 1342f, 1343f, 1344b–1345b
 - collisions of and their gravitational waves, 1341–1342, 1342f, 1343f, 1344b–1345b
 - in the universe, 1379–1380, 1397
- blackbody (Planck) distribution and specific intensity, 113, 128, 132
- Blandford-Znajek process, 1285, 1291–1293
- Blasius profile for laminar boundary layer, 758–764
- blast wave. *See* explosion and blast wave
- blood flow in arteries, 717–719
- boat waves, 846–848
- boat, stability of, 685–686
- Boltzmann distribution (mean occupation number), 113, 177
- entropy of, 187
- Boltzmann equation, collisionless, 134–135, 167, 169. *See also* Vlasov equation
- derivation from Hamiltonian, 136b–137b
 - implies conservation of particles and 4-momentum, 135
- Boltzmann transport equation, 135, 139
- for photons scattered by thermalized electrons, 144–148
 - accuracy of solutions, 140–141
 - order-of-magnitude solution, 143–144
 - solution via Fokker-Planck equation, 343
 - solution via Monte Carlo methods, 1415–1418, 1428
 - solution via two-lengthscale expansion, 145–148
- boost, Lorentz, 64–65
- Bose-Einstein condensate, 193–201
- condensation process, 193, 196, 197f, 198–200
 - critical temperature, 196
 - specific heat change, 200
 - in cubical box, 201
- Bose-Einstein ensemble
- probabilistic distribution function for, 176
 - mean occupation number of, 112–113, 176–177
 - entropy of, 187
- bosons, 110
- boundary layers
- laminar, 757–766
 - Blasius profile, 758–764
 - sublayer of turbulent boundary layer, 818
 - Ekman, for rotating flow, 772–777
 - vorticity creation in, 758
 - diffusion of vorticity in, 741–742, 741f, 758
 - instability of, 822–823
 - in a pipe, 766
 - near curved surface, 764–765
 - separation from boundary, 764, 793
 - turbulent, 817–825
 - profile of, 818–820, 818f
 - separation from boundary, 821f, 820–821
 - thermal, 923
 - influence on flight of sports balls, 823–825
- Boussinesq approximation, 923–925
- bow shock around Earth, 876f, 957, 1090, 1146–1147, 1146f
- bremsstrahlung, 142, 260, 1009, 1017
- brightness temperature, 482
- Brillouin scattering, 1142
- Brownian motion, 296, 309, 313–315. *See also* random walk
- spectral density and correlation function for, 313–314
 - relaxation time for, 328
 - fluctuation-dissipation theorem applied to, 327–329
- Brunt-Väisälä frequency for internal waves in stratified fluid, 941
- bubbles
- in water, collapse of, 703
 - in water, rising, 937
 - soap, 846
- buckling of compressed beam or card, 602
- onset of buckling at bifurcation of equilibria, 603–605
 - onset of elastostatic instability at bifurcation of equilibria, 648
 - elementary theory of, 602–605, 608–609
 - free energy for, 604
 - applications
 - collapse of World Trade Center buildings, 605–607
 - mountain building, 609
 - thermal expansion of pipes, 609
- bulk modulus, for elasticity, 581
- values of, 586t, 651t
 - atomic origin of, 649f
 - relation to equation of state, 650
- bump-in-tail instability, 1136–1137, 1138–1139
- bunching of bosons, 511, 511n, 1117
- canonical ensemble, 160t, 169–172, 221t
- distribution function, 171, 173
- canonical transformation, 162, 164, 166
- cantilever, 566, 592–593, 596–597
- capillary waves, 844–848
- Cartesian coordinates, 16, 26, 28
- local, on curved surface, 1198
- catastrophe theory
- caustics as examples of catastrophes, 384

state variables, 385
 control parameters, 386
 five elementary catastrophes
 fold catastrophe, 386–388, 393f
 cusp catastrophe, 389, 392, 391f, 393f
 swallowtail catastrophe, 389–390, 391f, 393f
 hyperbolic umbilic catastrophe, 389–390, 391f, 393f
 elliptic umbilic catastrophe, 391f, 392, 393f
 applications
 to caustics of light propagation, 384–394
 to elliptic gravitational lens, 403
 to van der Waals equation, 394–395
 to buckling of a beam, 606–607
 caustics, 351, 384–394. *See also* catastrophe theory
 diffraction near, 451–454
 examples
 sunlight on bottom of swimming pool, 384, 384n, 385f
 sunlight reflected onto bottom of a cup, 385f
 cavitation, 702–703
 CD, 530, 531
 central limit theorem, 292–294
 examples and applications of, 261, 294–295, 322, 465, 510
 centrifugal acceleration, 689, 767
 Cerenkov emission of plasmons by fast electrons in a plasma,
 1127–1129, 1131, 1133, 1138
 CGL equations of state, 1024
 chaos in dynamical systems, 832–834
 Lyapunov exponent, 833
 Lyapunov time, 832
 strange attractors, 833–834
 examples of, 832, 1030
 quantum chaos, 832
 chaos, onset of in dynamical systems, 825–833. *See also*
 turbulence, onset of
 in idealized equations and mathematical maps
 logistic equation and Feigenbaum sequence, 828–831
 Lorenz equations, 834
 universality of routes to chaos, 830
 Chapman-Kolmogorov equation. *See* Smoluchowski
 equation
 characteristics of a dynamical fluid flow, 852, 892–893, 893f,
 894–896
 charge density
 as integral over plasma distribution function, 1072
 as time component of charge-current 4-vector, 74
 charge-current 4-vector
 geometric definition, 78
 components: charge and current density, 78
 local (differential) conservation law for, 79
 global (integral) conservation law for, 79, 79f
 evaluation in a Lorentz frame, 81
 relation to nonrelativistic conservation of charge, 81
 charged-particle motion in electromagnetic field, 1024–1032
 chemical free energy (Gibbs potential), 246–249. *See also*
 under fundamental thermodynamic potentials;
 fundamental thermodynamic potentials out of
 statistical equilibrium
 chemical potential, excluding rest mass, μ , 112, 173
 chemical potential, including rest mass, $\bar{\mu}$, 112, 172–173
 chemical reactions, including nuclear and particle, 256
 direction controlled by Gibbs potential (chemical-
 potential sum), 256–258
 partial statistical equilibrium for, 256
 examples
 water formation from hydrogen and oxygen, 256–257
 electron-positron pair formation, 258–259, 1001
 emission and absorption of photons, 115–116
 ionization of hydrogen: Saha equation, 259–260,

 relativistic, 902–903
 rarefaction wave, 895–896

Rayleigh criterion for instability of rotating flows, 784
 Rayleigh number, 928
 Rayleigh principle, 980. *See also* action principles
 Rayleigh scattering, 471
 Rayleigh waves at surface of a homogeneous solid, 654–657, 659, 661, 839–840, 941
 Rayleigh-Bénard convection. *See under* convection
 Rayleigh-Jeans spectrum, 482, 1430
 Rayleigh-Taylor instability, 783–784
 reciprocity relations for reflection and transmission coefficients, 485, 486–488
 recombination in early universe, 1392–1396
 redshift, cosmological, 1373
 redshift, gravitational
 in proper reference frame of accelerated observer, 1189
 from surface of spherical star, to infinity, 1251–1252
 influence on GPS, 1301–1302
 experimental tests of, 70, 1301
 reference beam for holography, 525, 525f
 reflection and transmission coefficients
 reciprocity relations for, 485, 486–488
 for an interface between dielectric media, 489
 for a locally planar optical device, 486–488
 for an etalon, 484, 485, 486–488
 for a Fabry-Perot interferometer, 490
 modulus squared: power reflectivity and transmissivity, 486
 refractive-index surface, 1062–1063, 1062f
 reionization of universe, 193, 1386f, 1395f, 1397, 1418, 1431
 relaxation (correlation) time, 297, 298f
 renormalization group
 idea of, 273
 applied to 2-dimensional Ising model for ferromagnetism, 273–278
 applied to the onset of chaos in the logistic equation, 831
 resistance
 in electrical circuit, 324
 in an oscillator, 326
 in Stokes fluid flow, 328, 753
 as real part of complex impedance, 332
 resonance conditions in wave-wave mixing, 542, 543–544, 1132
 rest frame
 momentary, 49
 local, 85, 86, 366, 677, 719–720
 asymptotic, 1237, 1246–1248
 local asymptotic, 1327f, 1328, 1331, 1332, 1339–1340
 rest mass, 34, 58–59
 global and local conservation laws for, 80, 82
 rest-mass density, relativistic, 81
 rest-mass-flux 4-vector
 geometric definition of, 80
 components: rest-mass density and flux, 81
 Reynolds number, 716, 726b
 as ratio of inertial to viscous acceleration, 746
 magnetic, 950, 987
 Reynolds stress for turbulence, 802
 and turbulent viscosity, 804
 Ricci (curvature) tensor, 1214–1215
 Richardson criterion for instability of shear flows, 785–786
 Richardson number, 785–786
 Riemann curvature tensor
 definition, 1209
 symmetries of, 1214
 components of
 in an arbitrary basis, 1215–1216
 in local Lorentz frame, 1214
 Bianchi identity for, 1223
 decomposition into tidal and frame-drag fields, in vacuum, 1235b–1236b
 components in specific spacetimes or spaces
 surface of a sphere, 1216
 general linearized metric, 1227
 Schwarzschild metric, 1244b, 1267
 Newtonian limit of, 1227
 magnitude of, 1213
 outside Newtonian, gravitating body, 1212–1213
 Riemann invariants, 852, 891–897, 901–902
 right modes, for plasma electromagnetic waves parallel to magnetic field, 1052–1056
 rigidly rotating disk, relativistic, 1189–1190
 Rindler approximation, 1273–1274
 Rindler coordinates
 in flat spacetime, 1187–1189
 near black-hole horizon, 1273–1274
 Robertson-Walker metric for a homogeneous, isotropic universe, 1371
 coordinates for, 1370
 derivation of, 1366–1372
 Einstein tensor for, 1371–1372
 perturbations of, and their evolution, 1401–1422
 rocket engines, fluid flow through, 887–890
 rod. *See* bent beam, elastostatics of
 Rossby number, 768
 Rossby waves in rotating fluid, 858–861
 rotating disk, relativistic, 1189–1190
 rotating reference frame, fluid dynamics in, 766–777
 rotation, rate of, in fluid mechanics, 711, 726b
 as vorticity in disguise, 711
 rotation group, 21, 572b–574b
 rotation matrix, 21, 65

rotation tensor and vector, in elasticity theory, 571, 573b–574b, 575–576, 577
 rupture point, in elasticity, 580, 581f
 Rutherford scattering, 1006–1007

Sackur-Tetrode equation for entropy of a perfect gas, 189
 Sagnac interferometer, 501–502, 502f
 Saha equation for ionization equilibrium, 259–260, 999–1000
 Saint-Venant's principle, for elastostatic equilibrium, 590b
 salt fingers due to double diffusion of salt and heat, 937–940
 sausage instability, of magnetostatic equilibria, 977
 scale factor, in cosmology, 1370
 as a function of time, 1387, 1388f, 1390f, 1399f, 1400f
 scaling relations in fluid flows
 between similar flows, 791–792
 for drag force on an object, 765
 for Kolmogorov turbulence spectrum, 789, 810–814
 scaling relations near a catastrophe (caustic), 392
 scattering of light. *See also under* radiative processes
 by large, opaque particle, 429
 in LIGO, 448–451

Schrödinger equation
 energy eigenstates (modes) of, 175n, 194–195, 848–849
 and Coulomb wave functions, 1009
 propagation speed of waves, 44b
 geometric optics for, 375, 409
 nonlinear variant of, and solitons, 856–857

Schwarzschild criterion for onset of convection in a star, 935, 935f

Schwarzschild metric, 1242. *See also* black holes; horizon,
 black-hole event; stars; wormhole
 uniqueness of: Birchoff's theorem, 1250
 in Schwarzschild coordinates, 1242
 bases, connection coefficients, and Riemann tensor, 1243b–1244b
 Schwarzschild coordinate system and symmetries, 1244–1249
 in isotropic coordinate system, 1251
 in ingoing Eddington-Finkelstein coordinates, 1269
 gravitational (horizon) radius of, 1250
 Rindler approximation near horizon, 1273–1274
 geodesic orbits in, 1247–1248, 1274–1276
 Newtonian limit of, 1246
 roles of
 exterior metric of static star, 1250–1252
 exterior metric of imploding star, 1264–1266, 1269
 metric of nonspinning black hole, 1272–1276
 metric of wormhole, 1276–1277

second quantization, 175
 secondary fluid flows, 775–776
 sedimentation, 749, 754–755

Sedov-Taylor blast wave, 909–912
 seeing, atmospheric, 425, 465, 466b–471b, 471–472
 seismic waves. *See* elastodynamic waves in Earth

 - large dissipation, 799
 - intermittency, 798–799, 807, 814, 831
- onset of. *See* turbulence, onset of

vorticity in, 799–800
 drives energy from large scales to small, 799f
 semiquantitative analysis of, 800–817
 Kolmogorov spectrum, 467, 810–813, 813f, 815. *See also* Kolmogorov spectrum for turbulence
 weak turbulence formalism, 800–810. *See also* weak turbulence formalism
 generation of sound by, 869
 turbulence, 2-dimensional analog of, 801b
 inverse cascade of energy, 799n
 transition to (3-dimensional) turbulence, 800
 turbulence, onset of. *See also* chaos, onset of in dynamical systems
 critical Reynolds number for, 787, 794, 822, 826
 in convection, 830, 831
 in flow past a cylinder, 789–794, 800
 in rotating Couette flow, 825–828
 routes to turbulence
 one frequency, two frequencies, turbulence, 825–828
 one frequency, two frequencies, phase locking, turbulence, 831
 one frequency, two frequencies, three frequencies, turbulence, 831
 period doubling sequence, 830–831
 intermittency, 831
 twins paradox, 67–70
 two-fluid formalism, for plasma physics, 1037–1068
 fundamental equations, 1037–1038
 deduced from kinetic theory, 1073–1074
 two-lengthscale expansion, 146b
 bookkeeping parameter for, 360b
 and statistical independence in statistical mechanics, 170n
 for solving Boltzmann transport equation, 145
 for geometric optics, 357–358, 359–360
 for quasi-linear theory in plasma physics, 1113–1114
 for gravitational waves in curved spacetime, 1320–1321, 1321f
 two-point correlation function, 305, 1104–1107, 1424–1426
 for Coulomb corrections to pressure in a plasma, 1107–1108
 for electron antibunching in a plasma, 1104–1107
 for galaxy clustering, 305, 306f
 for weak gravitational lensing, 1424–1426
 two-stream instability
 in two-fluid formalism, 1065–1068
 in kinetic theory, 1079–1080, 1137
 ultrasound, 663–664
 universe, evolution of
 expansion, kinematics of, 1373–1376
 evolution of radiation and gas properties during, 1373–1375
 expansion, dynamics of, 1376–1378
 Friedman equations, 1376–1377
 graphical summaries of
 entire life: distances as functions of scale factor, 1400f
 entire life: energy densities of constituents, 1386f
 particle age: temperatures and entropies of particle constituents, 1385f
 nuclear age: reaction rates; nuclear and particle abundances, 1390f
 plasma and atomic ages: ionization fraction and optical depths, 1395f
 gravitational and cosmological ages: scale factor and deceleration function, 1399f
 perturbations, evolution of, 1404f, 1405f, 1411f, 1414f
 formation of structure
 origin of primordial perturbations, 1437–1440
 perturbations, initial spectrum, 1410–1412
 evolution of perturbations, 1401–1422
 statistical mechanics of, 210–211
 seven ages
 before the particle age, 1431–1440
 particle age, before nucleosynthesis, 1384–1387
 nuclear age, primordial nucleosynthesis, 192–193, 1387–1392
 photon age, from nucleosynthesis to matter dominance, 1392–1393
 plasma age, from matter dominance through recombination, 1393–1396
 atomic age, from recombination through reionization, 193, 1394
 gravitational age, from reionization to dark-energy influence, 1394–1400
 cosmological age, the era of dark-energy influence, 1400–1401
 galaxy formation, 210–211, 1401–1415
 universe, observed properties of
 isotropy and homogeneity, 1364–1366
 spatial flatness, 1378
 parameter values today, 1380t
 age of, 1387
 volume of, 1398
 constituents of
 baryons, 1379. *See also* baryons in universe
 neutrinos, 1382
 photons: cosmic microwave background, 1381. *See also* cosmic microwave background
 dark matter, 1380–1381. *See also* dark matter
 dark energy or cosmological constant, 1382–1383, 1444–1447
