$$l_c \equiv \frac{w_c(q)}{q\epsilon(q)}.$$

The correction due to the temperature gradient in the capillary wave peak heights is the corresponding fractional difference, which can be obtained by evaluating $\Delta(\vec{q}, w = w_c)$. The result is simple:

$$\Delta(\vec{q}, w = w_c) = 3 \frac{l_c(q)}{L_\nabla}.$$

For the system in thermal equilibrium, one can compute the time-dependent mean square displacement $\langle |\zeta|^2 \rangle$

(q, t) , from the damped forced harmonic oscillator equation for ζ , [equation \(A3.3.30\)](#). The result is

$$\langle |\zeta|^2 \rangle(q, t) = \frac{kT_0}{\sigma q^2} \left[1 - \exp\left(-\frac{4\eta}{\rho} q^2 t\right) \right] \quad (\text{A3.3.39})$$

-16-

which goes to $S^0(q)$ as $t \rightarrow \infty$ as required. By integrating it over the two-dimensional wavevector \vec{q} , one can find the mean square displacement of the interface:

$$\langle \zeta^2 \rangle(t) = \frac{kT_0}{4\sigma} [\ln \tau + E_1(\tau) + C]$$

where $\tau = (4\eta q_{\max}^2 / \rho)t$ with $q_{\max} = 2\pi/a$, with a being a typical molecular size (diameter), E_1 is Euler's integral and $C \sim 0.577$ is Euler's number. Thus, as $t \rightarrow \infty$, $\langle \zeta^2 \rangle(t)$ diverges as $\ln t$, which is the dynamic analogue of the well known infrared divergence of the interfacial thickness. Numerically, the effect is small: at $t \sim 10^{18}$ s we find using typical values of T , σ , η and ρ such that $[\langle \zeta^2 \rangle(t)]^{1/2} \sim 9 \text{ \AA}$. From [equation \(A3.3.39\)](#) one can also proceed by first taking the $t \rightarrow \infty$ limit and then integrating over \vec{q} , with the result

$$\langle \zeta^2 \rangle = \frac{kT_0}{2\pi\sigma} \ln \frac{q_{\max}}{q_{\min}}$$

where $q_{\min} = 2\pi/L$. Again $\langle \zeta^2 \rangle$ shows a logarithmic infrared divergence as $2\pi/L \rightarrow 0$ which is the conventional result obtained from equilibrium statistical mechanics. This method hides the fact, which is transparent in the dynamic treatment, that the source of the divergence is the spontaneous random force fluctuations in the bulk, which drive the oscillations of the surface ζ . The equilibrium description of capillary wave excitations of a surface are often introduced in the framework of the so-called capillary wave model: the true free energy is functionally expanded around a 'bare' free energy in terms of the suppressed density fluctuations $\delta\rho$, and these 'capillary wave fluctuations' are assumed to be of the form

$$\delta\rho_{\text{cwf}} = -\zeta(x) \frac{d\rho(z)}{dz}. \quad (\text{A3.3.40})$$

It can be shown that this form leads to an unphysical dispersion relation for capillary waves: $w_c^2 \sim q^4$, rather than $\sim q^3$. This is precisely because of the neglect of the surface-bulk coupling in the above assumed form. One can show that a fluctuation *consistent* with capillary wave dispersion is

$$\delta\rho(\vec{x}, z, t) = -\zeta(x, t) \left[\frac{d\rho(z)}{dz} - \frac{q^2\sigma}{c^2} e^{qz} \right] \quad (\text{A3.3.41})$$

for $z > \xi$, where one neglects the vapour density, and where c is the speed of sound in the bulk phase coupled to the surface. Thus, if one wants to introduce density fluctuations into the description, the entire fluid has to be self-consistently treated as compressible. Physically, the first term $\zeta(d\rho(z)/dz)$ corresponds to a perturbation, or kick, of the interface, and the second term self-consistently accounts for the pressure fluctuations in the bulk due to that kick. Neglecting the second term amounts to violating momentum conservation, resulting in an incorrect 'energy-momentum relation' for the capillary wave excitations.

A3.3.3 NON-EQUILIBRIUM TIME-EVOLVING SYSTEMS

There are many examples in nature where a system is not in equilibrium and is evolving in time towards a thermodynamic equilibrium state. (There are also instances where non-equilibrium and time variation appear to be a persistent feature. These include chaos, oscillations and strange attractors. Such phenomena are not considered here.)

A pervasive natural phenomenon is the growth of order from disorder which occurs in a variety of systems. As a result, an interdisciplinary area rich in problems involving the formation and evolution of spatial structures has developed, which combines non-equilibrium dynamics and nonlinear analysis. An important class of such problems deals with the kinetics of phase ordering and phase separation, which are characteristics of any first-order phase transition. Examples of such growth processes occur in many diverse systems, such as chemically reacting systems, biological structures, simple and binary fluids, crystals, polymer melts and metallic alloys. It is interesting that such a variety of systems, which display growth processes, have common characteristics. In the remainder of chapter A3.3 we focus our attention on such common features of kinetics, and on the models which attempt to explain them. Substantial progress has occurred over the past few decades in our understanding of the kinetics of domain growth during first-order phase transitions.

Consider an example of phase separation. It is typically initiated by a rapid change (quench) in a thermodynamic variable (often temperature, and sometimes pressure) which places a disordered system in a post-quench initial non-equilibrium state. The system then evolves towards an inhomogeneous ordered state of coexisting phases, which is its final equilibrium state. Depending on the nature of the quench, the system can be placed in a post-quench state which is thermodynamically unstable or metastable (see [figure A3.3.2](#)). In the former case, the onset of separation is spontaneous, and the kinetics that follows is known as *spinodal decomposition*. For the metastable case, the nonlinear fluctuations are required to initiate the separation process; the system is said to undergo phase separation through *homogeneous nucleation* if the system is pure and through *heterogeneous nucleation* if system has impurities or surfaces which help initiate nucleation. The phase transformation kinetics of supercooled substances via homogeneous nucleation is a fundamental topic. It is also important in science and technology: gases can be compressed way beyond their equilibrium pressures without forming liquids, and liquids can be supercooled several decades below their freezing temperature without crystallizing.

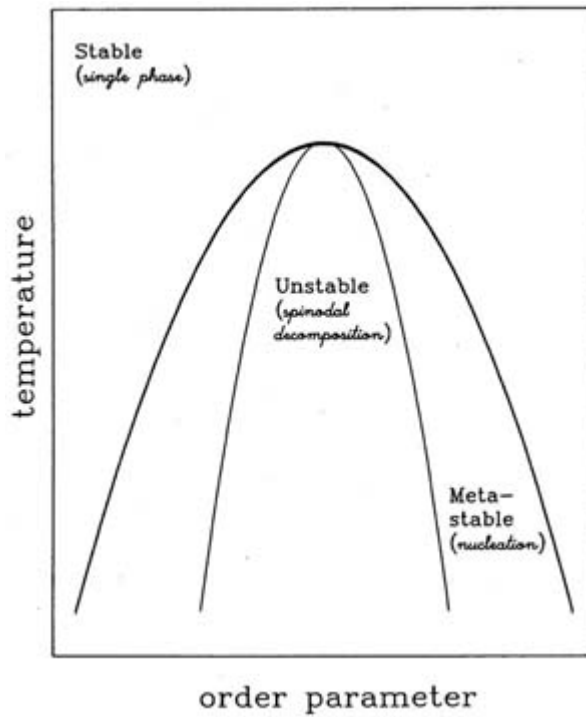

Figure A3.3.2 A schematic phase diagram for a typical binary mixture showing stable, unstable and metastable regions according to a van der Waals mean field description. The coexistence curve (outer curve) and the spinodal curve (inner curve) meet at the (upper) critical point. A critical quench corresponds to a sudden decrease in temperature along a constant order parameter (concentration) path passing through the critical point. Other constant order parameter paths ending within the coexistence curve are called off-critical quenches.

In both cases the late stages of kinetics show power law domain growth, the nature of which does not depend on the initial state; it depends on the nature of the fluctuating variable(s) which is (are) driving the phase separation process. Such a fluctuating variable is called the order parameter; for a binary mixture, the order parameter $\phi(\vec{r}, t)$ is the relative concentration of one of the two species and its fluctuation around the mean value is $\delta c(\vec{r}, t) = c(\vec{r}, t) - c_0$. In the disordered phase, the system's concentration is homogeneous and the order parameter fluctuations are microscopic. In the ordered phase, the inhomogeneity created by two coexisting phases leads to a macroscopic spatial variation in the order parameter field near the interfacial region. In a magnetic system, the average magnetization characterises the para-ferro magnetic transition and is the order parameter. Depending on the system and the nature of the phase transition, the order parameter may be scalar, vector or complex, and may be conserved or non-conserved.

Here we shall consider two simple cases: one in which the order parameter is a non-conserved scalar variable and another in which it is a conserved scalar variable. The latter is exemplified by the binary mixture phase separation, and is treated here at much greater length. The former occurs in a variety of examples, including some order-disorder transitions and antiferromagnets. The example of the para-ferro transition is one in which the magnetization is a conserved quantity in the absence of an external magnetic field, but becomes non-conserved in its presence.

For a one-component fluid, the vapour-liquid transition is characterized by density fluctuations; here the order parameter, mass density ρ , is also conserved. The equilibrium structure factor $S(\vec{k})$ of a one component fluid is

discussed in [section A2.2.5.2](#) and is the Fourier transform of the density–density correlation function. For each of the examples above one can construct the analogous order parameter correlation function. Its spatial Fourier transform (often also denoted by $S(\vec{k})$) is, in most instances, measurable through an appropriate elastic scattering experiment. In a quench experiment which monitors the kinetics of phase transition, the relevant structure evolves in time. That is, the *equal-time* correlation function of the order parameter fluctuations $\langle \delta\phi(\vec{r}, t)\delta\phi(0, t) \rangle_{\text{noneq}}$, which would be time independent in equilibrium, acquires time dependence associated with the growth of order in the non-equilibrium system. Its spatial Fourier transform, $S(\vec{k}, t)$ is called the time-dependent structure factor and is experimentally measured.

The evolution of the system following the quench contains different stages. The early stage involves the emergence of macroscopic domains from the initial post-quench state, and is characterized by the formation of interfaces (domain walls) separating regions of space where the system approaches one of its final coexisting states (domains). Late stages are dominated by the motion of these interfaces as the system acts to minimize its surface free energy. During this stage the mean size of the domains grows with time while the total amount of interface decreases. Substantial progress in the understanding of late stage domain growth kinetics has been inspired by the discovery of *dynamical scaling*, which arises when a single length dominates the time evolution. Then various measures of the morphology depend on time only through this length (an instantaneous snapshot of the order parameter’s space dependence is referred to as the system’s morphology at that time). The evolution of the system then acquires self-similarity in the sense that the spatial patterns formed by the domains at two different times are statistically identical apart from a global change of the length scale.

The time-dependent structure factor $S(\vec{k}, t)$, which is proportional to the intensity $I(k, t)$ measured in an elastic scattering experiment, is a measure of the strength of the spatial correlations in the ordering system with wavenumber k at time t . It exhibits a peak whose position is inversely proportional to the average domain size. As the system phase separates (orders) the peak moves towards increasingly smaller wavenumbers (see [figure A3.3.3](#)).

-20-

Figure A3.3.3 Time-dependent structure factor as measured through light scattering experiments from a phase separating mixture of polystyrene (PS) ($M = 1.5 \times 10^5$) and poly(vinylmethylether) (PVME) ($M = 4.6 \times 10^4$) following a fast quench from a homogeneous state to $T = 101$ °C located in the two-phase region. The time in

seconds following the quench is indicated for each structure factor curve. Taken from [11].

A signature of the dynamical scaling is evidenced by the collapse of the experimental data to a scaled form, for a d -dimensional system:

$$S(k, t) = (R(t))^d S_0(kR(t)) \tag{A3.3.42}$$

where S_0 is a time-independent function and $R(t)$ is a characteristic length (such as the average domain size) (see figure A3.3.4). To the extent that other lengths in the system, such as the interfacial width, play important roles in the kinetics, the dynamical scaling may be valid only asymptotically at very late times.

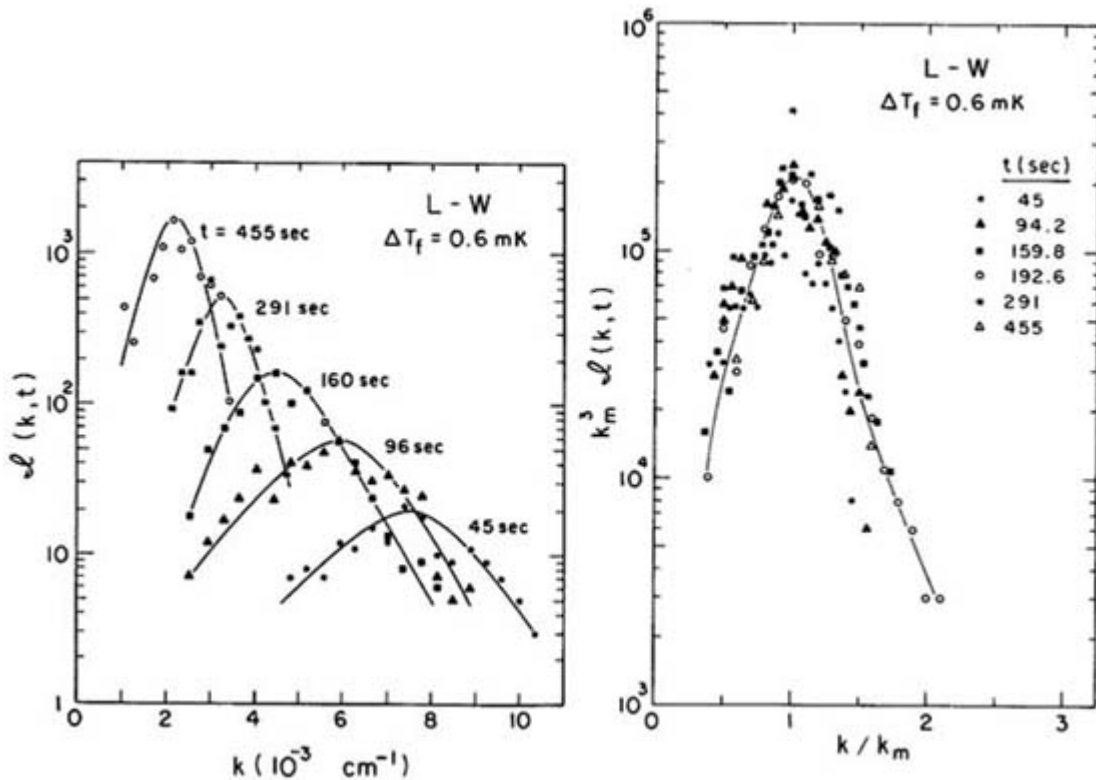

Figure A3.3.4 Time-dependent structure factor as measured through light scattering experiments from a phase separating mixture of 2,6-lutidine and water, following a fast quench from a homogeneous state through the critical point to a temperature 0.6 mK below the critical temperature. The time in seconds, following the quench is indicated for each structure factor curve. In the figure on the right-hand side the data collapse indicates dynamic scaling. Taken from [12].

Another important characteristic of the late stages of phase separation kinetics, for asymmetric mixtures, is the cluster size distribution function of the minority phase clusters: $n(R, \tau) dR$ is the number of clusters of minority phase per unit volume with radii between R and $R + dR$. Its zeroth moment gives the mean number of clusters at time τ and the first moment is proportional to the mean cluster size.

A3.3.3.1 LANGEVIN MODELS FOR PHASE TRANSITION KINETICS

Considerable amount of research effort has been devoted, especially over the last three decades, on various issues in domain growth and dynamical scaling. See the reviews [13, 14, 15, 16 and 17].

Although in principle the microscopic Hamiltonian contains the information necessary to describe the phase separation kinetics, in practice the large number of degrees of freedom in the system makes it necessary to construct a reduced description. Generally, a subset of slowly varying macrovariables, such as the hydrodynamic modes, is a useful starting point. The equation of motion of the macrovariables can, in principle, be derived from the microscopic

Hamiltonian, but in practice one often begins with a phenomenological set of equations. The set of macrovariables are chosen to include the order parameter and all other slow variables to which it couples. Such slow variables are typically obtained from the consideration of the conservation laws and broken symmetries of the system. The remaining degrees of freedom are assumed to vary on a much faster timescale and enter the phenomenological description as random thermal noise. The resulting coupled nonlinear stochastic differential equations for such a chosen ‘relevant’ set of macrovariables are collectively referred to as the Langevin field theory description.

In two of the simplest Langevin models, the order parameter ϕ is the only relevant macrovariable; in model A it is non-conserved and in model B it is conserved. (The labels A, B, etc have historical origin from the Langevin models of critical dynamics; the scheme is often referred to as the Hohenberg–Halperin classification scheme.) For model A, the Langevin description assumes that, on average, the time rate of change of the order parameter is proportional to (the negative of) the thermodynamic force that drives the phase transition. For this single variable case, the thermodynamic force is canonically conjugate to the order parameter: i.e. in a thermodynamic description, if ϕ is a state variable, then its canonically conjugate force is $\partial f/\partial\phi$ (see figure A3.3.5), where f is the free energy.

Figure A3.3.5 Thermodynamic force as a function of the order parameter. Three equilibrium isotherms (full curves) are shown according to a mean field description. For $T < T_c$, the isotherm has a van der Waals loop, from which the use of the Maxwell equal area construction leads to the horizontal dashed line for the equilibrium isotherm. Associated coexistence curve (dotted curve) and spinodal curve (dashed line) are also shown. The spinodal curve is the locus of extrema of the various van der Waals loops for $T < T_c$. The states within the spinodal curve are thermodynamically unstable, and those between the spinodal and coexistence

curves are metastable according to the mean field description.

In a field theory description, the thermodynamic free energy f is generalized to a free energy functional $\mathcal{F}[\phi(\vec{r}, t)]$, leading to the thermodynamic force as the analogous functional derivative. The Langevin equation for model A is then

$$\frac{\partial \phi}{\partial t} = -M \frac{\delta \mathcal{F}}{\delta \phi} + \eta(\vec{r}, t) \quad (\text{A3.3.43})$$

-23-

where the proportionality coefficient M is the mobility coefficient, which is related to the random thermal noise η through the fluctuation dissipation theorem:

$$\langle \eta(\vec{r}, t) \eta(\vec{r}', t') \rangle = kT M \delta(\vec{r} - \vec{r}') \delta(t - t'). \quad (\text{A3.3.44})$$

The phenomenology of model B, where ϕ is conserved, can also be outlined simply. Since ϕ is conserved, it obeys a conservation law (continuity equation):

$$\frac{\partial \phi}{\partial t} = -\vec{\nabla} \cdot \vec{j}(\vec{r}, t) \quad (\text{A3.3.45})$$

where (provided \vec{j} itself is not a conserved variable) one can write the transport law

$$\vec{j}(\vec{r}, t) = -[M \vec{\nabla} \mu(\vec{r}, t) + \vec{\zeta}^*] \quad (\text{A3.3.46})$$

with $\vec{\zeta}^*$ being the order parameter current arising from thermal noise, and $\mu(\vec{r}, t)$, which is the local chemical potential, being synonymous with the thermodynamic force discussed above. It is related to the free energy functional as

$$\mu(\vec{r}, t) = \frac{\delta \mathcal{F}}{\delta \phi} \quad (\text{A3.3.47})$$

Putting it all together, one has the Langevin equation for model B:

$$\frac{\partial \phi}{\partial t} = +M \nabla^2 \left(\frac{\delta \mathcal{F}}{\delta \phi} \right) + \zeta \quad (\text{A3.3.48})$$

where $\zeta = \vec{\nabla} \cdot \vec{\zeta}^*$ is the random thermal noise which satisfies the fluctuation dissipation theorem:

$$\langle \zeta(\vec{r}, t) \zeta(\vec{r}', t') \rangle = -2kT M \nabla^2 \delta(\vec{r} - \vec{r}') \delta(t - t'). \quad (\text{A3.3.49})$$

As is evident, the free energy functional \mathcal{F} plays a crucial role in the model A/B kinetics. It contains a number of terms. One of these is the local free energy term $f(\phi)$ which can be thought of as a straightforward generalization of the thermodynamic free energy function in which the global thermodynamic variable ϕ is

replaced by its local field value $\phi(\vec{r}, t)$. Many universal features of kinetics are insensitive to the detailed shape of $f(\phi)$. Following Landau, one often uses for it a form obtained by expanding around the value of ϕ at the critical point, ϕ_c . If the mean value of ϕ is $\bar{\phi}$, then

$$\delta\phi \equiv (\phi - \bar{\phi}) = (\phi - \phi_c) + (\phi_c - \bar{\phi}) \equiv \phi^* + \phi_0 \quad (\text{A3.3.50})$$

-24-

with $\phi^* = (\phi - \phi_c)$ and $\phi_0 = (\phi_c - \bar{\phi})$. The Landau expansion is written in terms of ϕ^* as

$$f(\phi) = \frac{1}{2}a_0(T - T_c)\phi^{*2} + \frac{1}{4}u\phi^{*4} - \mathcal{H}\phi \quad (\text{A3.3.51})$$

where an external field \mathcal{H} is assumed to couple linearly to ϕ . In the absence of \mathcal{H} , $f(\phi)$ has a single minimum for temperatures above T_c at $\phi^* = 0$, and two minima below T_c at $\phi^* = \pm[a_0(T_c - T)/u]^{1/2} \equiv \pm\phi_{\min}^*$ corresponding to the two coexisting ordered phases in equilibrium (see figure A3.3.6).

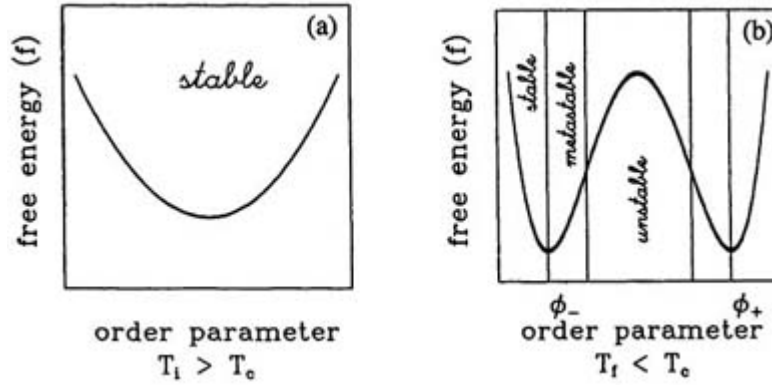

Figure A3.3.6 Free energy as a function of the order parameter ϕ^* for the homogeneous single phase (a) and for the two-phase regions (b), $\mathcal{H}=0$.

The free energy functional also contains a square gradient term which is the cost of the inhomogeneity of the order parameter at each point in the system. Such a surface energy cost term occurs in many different contexts; it was made explicit for binary mixtures by Cahn and Hilliard [18], for superconductors by Ginzburg, and is now commonplace. It is often referred to as the Ginzburg term. This Landau–Ginzburg free energy functional is

$$\mathcal{F}[\phi(\vec{r}, t)] = \int d^d r \left[f(\phi) + \frac{\kappa}{2}(\nabla\phi)^2 \right] \quad (\text{A3.3.52})$$

where the coefficient κ of the square gradient term is related to the interfacial (domain wall) tension σ through the mean field expression

$$\sigma = \kappa \int_{-\infty}^{\infty} dz \left(\frac{d\phi}{dz} \right)^2 \quad (\text{A3.3.53})$$

where z is the direction of the local normal to the interface, and $\phi(z)$ is the equilibrium order parameter profile.

-25-

There is a class of systems where, in addition to the above two terms, there is a non-local free energy functional term in \mathcal{F} . This can arise due to elastic fields, or due to other long-range repulsive interactions (LRRI) originating from the coherent action of molecular dipoles (electric or magnetic). The square gradient (Ginzburg) term is a short-range attractive term which then competes with the LRRI, resulting in a rich variety of structures often termed supercrystals. For such systems, which include Langmuir monolayers and uniaxial magnetic garnet films, the kinetics is much richer. It will not be considered here. See [19, 20] for reviews.

With the form of free energy functional prescribed in equation (A3.3.52), equation (A3.3.43) and equation (A3.3.48) respectively define the problem of kinetics in models A and B. The Langevin equation for model A is also referred to as the time-dependent Ginzburg–Landau equation (if the noise term is ignored); the model B equation is often referred to as the Cahn–Hilliard–Cook equation, and as the Cahn–Hilliard equation in the absence of the noise term.

For deep quenches, where the post-quench T is far below T_c , the equations are conveniently written in terms of scaled (dimensionless) variables: $\psi(\vec{x}, \tau) = \phi^*/\phi_{\min}^*$ and $\vec{x} = \vec{r}/\xi$, where the correlation length $\xi = (\kappa/(a_0|T_c - T|))^{1/2}$, and the dimensionless time τ is defined as equal to $[(2Ma_0|T_c - T)t]$ for model A and equal to $[(2Ma_0^2(T_c - T)^2/\kappa)t]$ for model B. In terms of these variables the model B Langevin equation can be written as

$$\frac{\partial \psi}{\partial \tau} = -\frac{1}{2} \nabla_x^2 (\nabla_x^2 \psi + \psi - \psi^3) + \epsilon^{1/2} \mu(\vec{x}, \tau) \quad (\text{A3.3.54})$$

where

$$\epsilon = \frac{kTu}{a_0^2(T_c - T)^2} \left(\frac{a_0|T_c - T|}{\kappa} \right)^{d/2} \quad (\text{A3.3.55})$$

is the strength of the random thermal noise μ which satisfies

$$\langle \mu(\vec{x}, \tau) \mu(\vec{x}', \tau') \rangle = -\nabla_x^2 \delta(\vec{x} - \vec{x}') \delta(\tau - \tau'). \quad (\text{A3.3.56})$$

Similarly, the dimensionless model A Langevin equation can also be obtained. The result is recovered by replacing the outermost ∇_x^2 by (-1) in equation (A3.3.54) and by $(-\frac{1}{2})$ in equation (A3.3.56).

Using the renormalization group techniques, it has been shown, by Bray [16], that the thermal noise is irrelevant in the deep-quench kinetics. This is because the free energy has two stable fixed points to which the system can flow: for $T > T_c$ it is the infinite temperature fixed point, and for $T < T_c$ it is the zero-temperature strong coupling fixed point. Since at $T = 0$, the strength of the noise ϵ vanishes, the thermal noise term μ can be neglected in model B phase separation kinetics during which $T < T_c$. The same conclusion was also obtained, earlier, [21] from a numerical simulation of equation (A3.3.54) and equation (A3.3.56). In what follows, we ignore the thermal noise term. One must note, however, that there are many examples of kinetics

where the thermal noise can play an important role. See for example a recent monograph [22].

-26-

For critical quench experiments there is a symmetry $\phi_0 = 0$ and from equation (A3.3.50) $\delta\phi = \phi^*$, leading to a symmetric local free energy (figure A3.3.6) and a scaled order parameter whose average is zero, $\delta\psi = \psi$. For off-critical quenches this symmetry is lost. One has $\delta\phi = \phi^* + \phi_0$ which scales to $\delta\psi = \psi + \psi_0$ with $\psi_0 = \phi_0/\phi_{\min}^*$. ψ_0 is a measure of how far off-critical the system is. For $\psi_0 = \pm 1$ the system will be quenched to the coexistence curve and $\psi_0 = 0$ corresponds to a quench through the critical point. In general, one has to interpret the dimensionless order parameter ψ in (A3.3.54) as a mean value plus the fluctuations. If one replaces ψ in (A3.3.54) by $\psi + \psi_0$, the mean value of the order parameter ψ_0 becomes explicit and the average of such a replaced ψ becomes zero, so that now ψ is the order parameter fluctuation. The conservation law dictates that the average value of the order parameter remains equal to ψ_0 throughout the time evolution. Since the final equilibrium phase corresponds to $\psi_{\pm} = \pm 1$, non-zero ψ_0 reflects an asymmetry in the spatial extent of these two phases. The degree of asymmetry is given by the lever rule. A substitution of ψ by $\psi + \psi_0$ in (A3.3.54) yields the following nonlinear partial differential equation (we ignore the noise term):

$$\frac{\partial\psi}{\partial\tau} = -\frac{1}{2}\nabla_x^2([q_c^2 + \nabla_x^2]\psi - 3\psi_0\psi^2 - \psi^3) \quad (\text{A3.3.57})$$

where $q_c^2 = (1 - 3\psi_0^2)$. For a critical quench, when $\psi_0 = 0$, the bilinear term vanishes and q_c^2 becomes one, so that the equation reduces to the symmetric equation (A3.3.54). In terms of the scaled variables, it can be shown that the equation of the classical spinodal, shown in figure A3.3.2 and figure A3.3.5 is $q_c^2 = 0$ or $|\psi_0| = 1/\sqrt{3}$. For states within the classical mean field spinodal, $q_c^2 > 0$.

Equation (A3.3.57) must be supplied with appropriate initial conditions describing the system prior to the onset of phase separation. The initial post-quench state is characterized by the order parameter fluctuations characteristic of the pre-quench initial temperature T_i . The role of these fluctuations has been described in detail in [23]. However, again using the renormalization group arguments, any initial short-range correlations should be irrelevant, and one can take the initial conditions to represent a completely disordered state at $T = \infty$. For example, one can choose the white noise form $\langle\psi(\vec{x}, 0)\psi(\vec{x}', 0)\rangle = \varepsilon_0\delta(\vec{x} - \vec{x}')$, where $\langle\cdots\rangle$ represents an average over an ensemble of initial conditions, and ε_0 controls the size of the initial fluctuations in ψ ; $\varepsilon_0 \ll 1$.

The fundamental problem of understanding phase separation kinetics is then posed as finding the nature of late-time solutions of deterministic equations such as (A3.3.57) subject to random initial conditions.

A linear stability analysis of (A3.3.57) can provide some insight into the structure of solutions to model B. The linear approximation to (A3.3.57) can be easily solved by taking a spatial Fourier transform. The result for the k th Fourier mode is

$$\psi(\vec{k}, \tau) = e^{\gamma_k\tau}\psi(\vec{k}, 0) \quad (\text{A3.3.58})$$

where the exponential growth exponent γ_k is given by

$$\gamma_k = \frac{1}{2}k^2(q_c^2 - k^2). \quad (\text{A3.3.59})$$

For $0 < k < q_c$, γ_k is positive, and the corresponding Fourier mode fluctuations grow in time, i.e. these are the *linearly* unstable modes of the system. The maximally unstable mode occurs at $k_m = q_c/\sqrt{2}$ and overwhelms all other growing modes due to exponential growth in the linear approximation. The structure factor can also be computed analytically in this linear approximation, and has a time invariant maximum at $k = k_m$. In binary polymer mixtures (polymer melts), the early time experimental observations can be fitted to a structure factor form obtained from a linear theory on account of its slow dynamics.

The limitations and range of validity of the linear theory have been discussed in [17, 23, 24]. The linear approximation to [equation \(A3.3.54\)](#) and [equation \(A3.3.57\)](#) assumes that the nonlinear terms are small compared to the linear terms. As $\psi(\vec{k}, \tau)$ increases with time, at some crossover time t_{cr} the linear approximation becomes invalid. This occurs roughly when $\langle \psi^2 \rangle$ becomes comparable to $(\psi_{sp} - \psi_o)^2 = \psi_{sp}^2 q_c^2$. One can obtain t_{cr} using [equation \(A3.3.58\)](#), in which k can be replaced by k_m , since the maximally unstable mode grows exponentially faster than other modes. Then the dimensionless crossover time $\tau_{cr} \equiv t_{cr}(2M\kappa/\xi_o^4)$ is obtained from

$$(\psi_{sp} - \psi_o)^2 = \langle |\psi(\vec{k}_m, \tau_{cr})|^2 \rangle = e^{2\gamma_{k_m} \tau_{cr}} \langle |\psi(\vec{k}_m, 0)|^2 \rangle$$

where the initial fluctuation spectrum is to be determined from the Ornstein–Zernicke theory, at the pre-quench temperature T_o :

$$\langle |\psi(\vec{k}, 0)|^2 \rangle = \frac{\epsilon_o}{(k_m^2 + q_c^2)}.$$

Here ϵ_o is given by [equation \(A3.3.55\)](#) evaluated at T_o , and can be written as $\epsilon_o = kT_o u \kappa^{-2} \xi_o^{4-d/2}$. Using the values $k_m^2 = q_c^2/2$, $\psi_{sp}^2 = 1/3$, and $\kappa = \kappa/[a_o(T_o - T_c)]$, one obtains

$$2\gamma_{k_m} \tau_{cr} = \frac{d}{4} \ln(\kappa) + \ln(q_c^4) + \ln\left(\frac{[a_o(T_o - T_c)]^{(2-d/4)}}{2kT_o u}\right).$$

As is evident from the form of the square gradient term in the free energy functional, [equation \(A3.3.52\)](#), κ is like the square of the effective range of interaction. Thus, the dimensionless crossover time depends only weakly on the range of interaction as $\ln(\kappa)$. For polymer chains of length N , $\kappa \sim N$. Thus for practical purposes, the dimensionless crossover time τ_{cr} is not very different for polymeric systems as compared to the small molecule case. On the other hand, the scaling of t_{cr} to τ_{cr} is through a characteristic time which itself increases linearly with κ , and one has

$$t_{cr} = \frac{2\kappa[(d/4) \ln(\kappa) + \ln(q_c^4) + \ln([a_o(T_o - T_c)]^{(2-d/4)})/2kT_o u]}{q_c^4 M a_o^2 (T_o - T_c)^2}$$

which behaves like $\kappa \ln(\kappa) \sim N \ln(N)$ for polymeric systems. It is clear that the longer time for the validity of linear theory for polymer systems is essentially a longer characteristic time phenomenon.

For initial post-quench states in the metastable region between the classical spinodal and coexistence curves, q_c^2

is negative and so is γ_k for all values of k . Linear stability analysis is not adequate for the metastable region, since it predicts that all modes are stable. Nonlinear terms are important and cannot be ignored in the kinetics leading to either nucleation or spinodal decomposition. The transition from spinodal decomposition to nucleation is also not well defined because nonlinear instabilities play an increasingly more important role as the ‘classical spinodal’ is approached from within.

A3.3.3.2 UNSTABLE STATES AND KINETICS OF SPINODAL DECOMPOSITION

Equation (A3.3.57) is an interesting nonlinear partial differential equation, but it is mathematically intractable. It contains quadratic and cubic nonlinear terms. The cubic term treats both phases in a symmetric manner; for a symmetric binary mixture only this term survives and leads to a labyrinthian morphology in which both phases have an equal share of the system volume. This term is the source of spinodal decomposition. For the symmetric case the partial differential equation is parameter free and there is no convenient small expansion parameter, especially during early times (the linear approximation loses its validity around $\tau \sim 10$). At late times, the ratio of the interfacial width to the time-dependent domain size $\xi/R(\tau)$ was used as a small parameter by Pego [25] in a matched asymptotic expansion method. It leads to useful connections of this nonlinear problem to the Mullins–Sekerka instability for the slowest timescale and to the classic Stefan problem on a faster timescale. The quadratic term treats the two phases in an asymmetric manner and is the source of nucleation-like morphology. As the off criticality ψ_0 increases, the quadratic term gradually assumes a greater role compared to the cubic nonlinear term. Nucleation-like features in the kinetics occur even for a 49–51 mixture in principle, and are evident at long enough times, since the minority phase will form clusters within the majority background phase for any asymmetric mixture.

While approximate analytical methods have played a role in advancing our understanding of the model B kinetics, complimentary information from laboratory experiments and numerical simulations have also played an important role. Figure A3.3.3 and figure A3.3.4 show the time-dependent structure factors from laboratory experiments on a binary polymer melt and a small molecule binary mixture, respectively. Compared to the conceptual model B Langevin equation discussed above, real binary mixtures have additional physical effects: for a binary polymer melt, hydrodynamic interactions play a role at late times [17]; for a small molecule binary fluid mixture, hydrodynamic flow effects become important at late times [26]; and for a binary alloy, the elastic effects play a subsidiary, but important, role [37]. In each of these systems, however, there is a broad range of times when model B kinetics are applicable. Comparing the approximate theory of model B kinetics with the experimental results from such systems may not be very revealing, since the differences may be due to effects not contained in model B. Comparing an approximate theory to computer simulation results provides a good test for the theory, provided a good estimate of the numerical errors in the simulation can be made.

In the literature there are numerical simulations of equation (A3.3.57) for both two- and three-dimensional systems [21, 23, 28, 29, 30 and 31]. For a two-dimensional system, morphology snapshots of the order parameter field ψ are shown in figure A3.3.7 for late times, as obtained from the numerical simulations of (A3.3.57). The light regions correspond to positive values of ψ and the dark regions to negative values. For the critical quench case (figure A3.3.7(a) and (b)), the (statistical) symmetry of ψ between the two phases is apparent. The topological difference between the critical and off-critical quench evolutions at late times is also clear: bicontinuous for critical quench and isolated closed cluster topology for asymmetric off-critical quench. Domain coarsening is also evident from these snapshots for each of the two topologies. For the off-critical quench, from such snapshots one can obtain the time evolution of the cluster size distribution.

Figure A3.3.7 The order parameter field morphology, for $\psi_0 = 0.0$ at (a) $\tau = 500$ and (b) $\tau = 5000$; and for $\psi_0 = 0.4$ at (c) $\tau = 500$ and (d) $\tau = 5000$. The dark regions have $\psi < 0$. From [28].

From a snapshot at time τ , the spatial correlation function $G(x, \tau) \equiv \langle \psi(\vec{x}, \tau) \psi(0, \tau) \rangle$ can be computed, where $\langle \dots \rangle$ includes the angular average assuming the system to be spatially isotropic. Repeating this for various snapshots yields the full space-and-time-dependent correlation function $G(x, \tau)$. Its spatial Fourier transform is essentially the time-dependent structure factor $S(k, t)$ measured in light scattering experiments (see [figure A3.3.3](#) and [figure A3.3.4](#)). There are a number of ways to obtain the time-dependent domain size, $R(\tau)$: (i) first zero of $G(x, \tau)$, (ii) first moment of $S(k, t)$, (iii) value k_m where $S(k, t)$ is a maximum. The result that is now firmly established from experiments and simulations, is that

$$R(\tau) \sim \tau^{1/3} \quad (\text{A3.3.60})$$

independent of the system dimensionality d . In the next section ([section A3.3.4](#)) we describe the classic theory of Lifshitz, Slyozov and Wagner, which is one of the cornerstone for understanding the $\tau^{1/3}$ growth law and asymptotic cluster size distribution for quenches to the coexistence curve.

As in the experiments, the simulation results also show dynamic scaling at late times. The scaling function $S_0(kR(\tau))$ at late times has the large k behaviour $S_0(y) \sim y^{-(d+1)}$ known as Porod's law [13, 16]. This result is understood to be the consequence of the sharp interfaces at late times. The small k behaviour, $S_0(y) \sim y^4$ was independently predicted in [32, 33], and was put on a firm basis in [34].

Interfaces play a central role in phase transition kinetics of both models A and B. [Figure A3.3.8](#) shows the interfacial structure corresponding to [Figure A3.3.7](#) (b). One can see the relationship between the interfacial width and the domain size for a late-stage configuration. The upper part of the figure demarks the interfacial

regions of the system where $0.75\psi_- > \psi > 0.75\psi_+$. The lower plot gives a cross sectional variation of ψ as the system is traversed. The steep gradients in ψ in the lower plot clearly indicates the sharpness of interfaces at late times.

Figure A3.3.8 Interface structure for $\tau = 5000$, $\psi_0 = 0$. In (a) the shaded regions correspond to interfaces separating the domains. In (b) a cross sectional view of the order parameter ψ is given. The location of the cross section is denoted by the horizontal line in (a). From [35].

In [figure A3.3.9](#) the early-time results of the interface formation are shown for $\psi_0 = 0.48$. The classical spinodal corresponds to $\psi_0 \sim 0.58$. Interface motion can be simply monitored by defining the domain boundary as the location where $\psi = 0$. Surface tension smooths the domain boundaries as time increases. Large interconnected clusters begin to break apart into small circular droplets around $\tau = 160$. This is because the quadratic nonlinearity eventually outpaces the cubic one when off-criticality is large, as is the case here.

Figure A3.3.9 Time dependence of the domain boundary morphology for $\psi_0 = 0.48$. Here the domain boundary is the location where $\psi = 0$. The evolution is shown for early-time τ values of (a) 50, (b) 100, (c) 150, (d) 200, (e) 250 and (f) 300. From [29].

Some features of late-stage interface dynamics are understood for model B and also for model A. We now proceed to discuss essential aspects of this interface dynamics. Consider the Langevin equations without noise. Equation (A3.3.57) can be written in a more general form:

$$\frac{\partial \psi}{\partial \tau} = -\nabla_x^2 (\xi^2 \nabla_x^2 \psi - f'(\psi)) \quad (\text{A3.3.61})$$

where we have absorbed the factor $\frac{1}{2}$ in the time units of τ , introduced ξ even though it is one, in order to keep track of characteristic lengths, and denoted the thermodynamic force (chemical potential) by f' . At late times the domain size $R(\tau)$ is much bigger than the interfacial width ξ . Locally, therefore, the interface appears to be planar. Let its normal be in direction u , and let $u = u_0$ at the point within the interface where $\psi = 0$. Then $\psi = \psi(u, \vec{s}, \tau)$ where \vec{s} refers to the $(d-1)$ coordinates parallel to the interface at point \vec{x} . In essence, we have used the interface specific coordinates: $\vec{x} = \vec{R}(\vec{s}) + u\hat{n}(s)$, where $\hat{n}(s)$ is a unit normal at the interface, pointing from the ψ_- phase into the ψ_+ phase.

The stationary solution of (A3.3.61), when $\xi/R(\tau)$ is very small, satisfies

$$\xi^2 \frac{d^2 \psi_0}{du^2} = \frac{\partial f}{\partial \psi_0} \quad (\text{A3.3.62})$$

which has a kink profile solution $\psi_0(u) = \pm \tanh((u - u_0)/(\sqrt{2}\xi))$ for the double well free energy $f(\psi_0) = \psi_0^4/4 - \psi_0^2/2$. By linearizing around such a kink solution, one obtains a linear eigenvalue problem. Its lowest eigenmode is $\zeta_0(u) \equiv d\psi_0(u)/du$ and the corresponding eigenvalue is zero. It is localized within the interface and is called the Goldstone mode arising out of the broken translational symmetry at the interface. The higher eigenmodes, which are constructed to be orthogonal to the Goldstone mode, are the capillary wave fluctuation modes with the dispersion relation that is a generalised version [35] of that discussed in [section A3.3.2.4](#). The orthogonality to the Goldstone mode leads to a constraint which is used to show an important relation between the local interface velocity $v(\vec{x})$ and local curvature $K(\vec{s})$. It is, to the lowest order in ξ K ,

$$\sigma \xi^2 K(s) = \int du d\vec{x}' G(\vec{x}, \vec{x}') \zeta_0(u) \zeta_0(u') v(\vec{x}') \quad (\text{A3.3.63})$$

where $G(\vec{x}, \vec{x}')$ is the diffusion Green's function satisfying $\nabla^2 G(\vec{x}, \vec{x}') = \delta(\vec{x} - \vec{x}')$. The mean field surface tension σ , defined in [equation \(A3.3.53\)](#), is the driving force for the interface dynamics. The diffusion Green's function couples the interface motion, at two points (\vec{x}, \vec{x}') on the interface, inextricably to the bulk dynamics. For a conserved order parameter, the interface dynamics and late-stage domain growth involve the *evaporation–diffusion–condensation mechanism* whereby large droplets (small curvature) grow at the expense of small droplets (large curvature). This is also the basis for the Lifshitz–Slyozov analysis which is discussed in [section A3.3.4](#).

If the order parameter is not conserved, the results are much simpler and were discussed by Lifshitz and by Allen and Cahn [36]. For model A, [equation \(A3.3.61\)](#) is to be replaced by the time-dependent Ginzburg–Landau equation which is obtained by removing the overall factor of $(-\nabla_x^2)$ from the right-hand side. This has the consequence that, in the constraint, [equation \(A3.3.63\)](#), the diffusion Green's function is replaced by $\delta(\vec{x} - \vec{x}')$ and the integrals can be performed with the right-hand side reducing to $-\sigma v(s)$. The surface tension then cancels from both sides and one gets the Allen–Cahn result:

$$-\xi^2 K(s) = v(s). \quad (\text{A3.3.64})$$

For model A, the interfaces decouple from the bulk dynamics and their motion is driven entirely by the local curvature, and the surface tension plays only a background, but still an important, role. From this model A interface dynamics result, one can also simply deduce that the domains grow as $R(\tau) \sim \tau^{1/2}$: at some late time, a spherical cluster of radius R grows; since $K \sim (d-1)/R$ and $v \sim -dR/d\tau$, one has $R^2 \sim (d-1)\tau$.

A3.3.4 LATE-STAGE GROWTH KINETICS AND OSTWALD RIPENING

Late stages of model B dynamics for asymmetric quenches may be described by the Lifshitz–Slyozov–Wagner (LSW) theory of coarsening. When the scalar order parameter is conserved, the late-stage coarsening is referred to as Ostwald ripening. The LSW analysis is valid for late-stage domain growth following either spinodal decomposition or nucleation. A recent paper [37] has combined the steady-state homogeneous nucleation theory described in the next [section, A3.3.5](#), with the LSW analysis in a new model for the entire process of phase separation. If the initial condition places the post-quench system just inside and quite near

the coexistence curve, the conservation law dictates that one (minority) phase will occupy a much smaller ‘volume’ fraction than the other (majority) phase in the final equilibrium state.

The dynamics is governed by interactions between different domains of the minority phase. At late times these will have attained spherical (circular) shape for a three (two)-dimensional system. For model B systems, the classic work of Lifshitz and Slyozov [38] and the independent work by Wagner [39] form the theoretical cornerstone. The late-stage dynamics is mapped onto a diffusion equation with sources and sinks (i.e. domains) whose boundaries are time dependent. The Lifshitz–Slyozov (LS) treatment of coarsening is based on a mean field treatment of the diffusive interaction between the domains and on the assumption of an infinitely sharp interface with well defined boundary conditions. The analysis predicts the onset of dynamical scaling. As in [section A3.3.3.1](#) we shall denote the extent of the off-criticality by $\psi_0 > 0$. The majority phase equilibrates at $\psi_+ = +1$ and the minority phase at $\psi_- = -1$. At late times, the minority clusters have radius $R(\tau)$ which is much larger than the interface width ξ . An important coupling exists between the interface and the majority phase through the surface tension σ . This coupling is manifested through a Gibbs–Thomson boundary condition, which is given later.

The LS analysis is based on the premise that the clusters of the minority phase compete for growth through an evaporation–condensation mechanism, whereby larger clusters grow at the expense of smaller ones. (Material (of the minority phase) evaporates from a smaller cluster, diffuses through the majority phase background matrix and condenses on a larger cluster.) That is, the dominant growth mechanism is the transport of the order parameter from interfaces of high curvature to regions of low curvature by diffusion through the intervening bulk phases. The basic model B equations, [\(A3.3.48\)](#) and [\(A3.3.52\)](#), can be linearized around the majority phase bulk equilibrium value of the order parameter, $\psi_+ = 1$ (which corresponds to the off-criticality $\psi_0 = -1$), by using $\psi = 1 + \delta\psi$ and keeping only up to first-order terms in $\delta\psi$. The result in dimensionless form is

$$\frac{\partial}{\partial \tau} \delta\psi = -\xi^2 \nabla^4 \delta\psi + \left(\frac{\delta^2 f}{\delta \psi^2} \right)_{\psi=1} \nabla^2 \delta\psi \quad (\text{A3.3.65})$$

where we have kept the interfacial width ξ as a parameter to be thought of as one; we retain it in order to keep track of the length scales in the problem. Since at late times the characteristic length scales are large compared to ξ , the ∇^4 term is negligible and $\delta\psi$ satisfies a diffusion equation,

$$\frac{\partial}{\partial \tau} \delta\psi = f''(1) \nabla^2 \delta\psi. \quad (\text{A3.3.66})$$

-34-

Due to the conservation law, the diffusion field $\delta\psi$ relaxes in a time much shorter than the time taken by significant interface motion. If the domain size is $R(\tau)$, the diffusion field relaxes over a time scale $\tau_D \sim R^2$. However a typical interface velocity is shown below to be $\sim R^{-2}$. Thus in time τ_D , interfaces move a distance of about one, much smaller compared to R . This implies that the diffusion field $\delta\psi$ is essentially always in equilibrium with the interfaces and, thus, obeys Laplace’s equation

$$\nabla^2 \delta\psi = 0 \quad (\text{A3.3.67})$$

in the bulk.

A3.3.4.1 GIBBS–THOMSON BOUNDARY CONDITION

To derive the boundary condition, it is better to work with the chemical potential instead of the diffusion field. We have

$$\frac{\partial \psi}{\partial \tau} = -\nabla \cdot \vec{j} \quad (\text{A3.3.68})$$

$$\vec{j} = -\nabla \mu \quad (\text{A3.3.69})$$

and

$$\mu = f'(\psi) - \xi^2 \nabla^2 \psi. \quad (\text{A3.3.70})$$

In the bulk, linearizing μ leads to $\mu = f''(\psi_*)\delta\psi - \xi^2 \nabla^2 \delta\psi$, where the ∇^2 term is again negligible, so that μ is proportional to $\delta\psi$. Thus μ also obeys Laplace's equation

$$\nabla^2 \mu = 0. \quad (\text{A3.3.71})$$

Let us analyse μ near an interface. The Laplacian in the curvilinear coordinates (u, \vec{s}) can be written such that (A3.3.71) becomes (near the interface)

$$\mu = f'(\psi) - \xi^2 \left(\frac{\partial \psi}{\partial u} \right)_\tau K - \xi^2 \left(\frac{\partial^2 \psi}{\partial u^2} \right)_\tau \quad (\text{A3.3.72})$$

where $K = \vec{\nabla} \cdot \hat{n}$ is the total curvature. The value of μ at the interface can be obtained from (A3.3.72) by multiplying it with $(\partial\psi/\partial u)_\tau$ (which is sharply peaked at the interface) and integrating over u across the interface.

Since μ and K vary smoothly through the interface, one obtains a general result that, at the interface,

$$\mu \Delta \psi = \Delta f - \xi^2 \sigma K \quad (\text{A3.3.73})$$

where $\Delta \psi$ is the change in ψ across the interface and Δf is the difference in the minima of the free energy f for the two bulk phases. For the symmetric double well, $\Delta f = 0$ and $\Delta \psi = 2$. Thus

$$\mu = -\frac{1}{2} \xi^2 \sigma K. \quad (\text{A3.3.74})$$

We make two side remarks.

- (1) If the free energy minima have unequal depths, then this calculation can also be done. See [14].

(2) Far away from the interface, $\mu = f'(\psi_{\pm})\delta\psi = 2\delta\psi$ for the ψ^4 form. Then one also has for the supersaturation

$$\delta\psi(\infty) = - \lim_{u \rightarrow \infty} \delta\psi(u) = -\mu/2 = +\xi^2\sigma K/4. \quad (\text{A3.3.75})$$

The supersaturation $\varepsilon \equiv \delta\psi(\infty)$ is the mean value of $\delta\psi$, which reflects the presence of other subcritical clusters in the system.

Equation (A3.3.73) is referred to as the Gibbs–Thomson boundary condition. equation (A3.3.74) determines μ on the interfaces in terms of the curvature, and between the interfaces μ satisfies Laplace's equation, [equation \(A3.3.71\)](#). Now, since $\vec{j} = -\vec{\nabla}\mu$, an interface moves due to the imbalance between the current flowing into and out of it. The interface velocity is therefore given by

$$j_{\text{out}} - j_{\text{in}} = v\Delta\psi \quad (\text{A3.3.76})$$

and also from [equation \(A3.3.69\)](#),

$$j_{\text{out}} - j_{\text{in}} = - \left[\frac{\partial\mu}{\partial u} \right] = -[\hat{n} \cdot \nabla\mu]. \quad (\text{A3.3.77})$$

Here [...] denotes the discontinuity in ... across the interface. [Equation \(A3.3.71\)](#), [equation \(A3.3.74\)](#), [equation \(A3.3.76\)](#) and [equation \(A3.3.77\)](#) together determine the interface motion.

Consider a single spherical domain of minority phase ($\psi_- = -1$) in an infinite sea of majority phase ($\psi_+ = +1$). From the definition of μ in [\(A3.3.70\)](#), $\mu = 0$ at infinity. Let $R(\tau)$ be the domain radius. The solution of Laplace's equation, [\(A3.3.71\)](#), for $d > 2$, with a boundary condition at ∞ and [equation \(A3.3.74\)](#) at $r = R$, is spherically symmetric and is, using $K = (d - 1)/R$,

$$\mu = - \frac{(d - 1)\sigma\xi^2}{2r} \quad \text{for } r \geq R \quad (\text{A3.3.78})$$

and

$$\mu = - \frac{(d - 1)\sigma\xi^2}{2R} \quad \text{for } r \leq R. \quad (\text{A3.3.79})$$

Then, using [equation \(A3.3.76\)](#) and [equation \(A3.3.77\)](#), we obtain, since $\Delta\psi = 2$,

$$\frac{dR}{d\tau} = v = - \frac{1}{2} \left[\frac{\partial\mu}{\partial r} \right]_{R-\epsilon}^{R+\epsilon} = - \frac{(d - 1)\xi^2\sigma}{4R^2}. \quad (\text{A3.3.80})$$

Integrating equation (A3.3.80), we get (setting $\xi = 1$)

$$R^3(\tau) = R^3(0) - \frac{3}{4}(d-1)\sigma\tau \quad (\text{A3.3.81})$$

which leads to a ' R^3 proportional to τ ' time dependence of the evaporating domain: the domain evaporates in time τ proportional to $R^3(0)$.

A3.3.4.2 LS ANALYSIS FOR GROWING DROPLETS

Again consider a single spherical droplet of minority phase ($\psi_- = -1$) of radius R immersed in a sea of majority phase. But now let the majority phase have an order parameter at infinity that is (slightly) smaller than +1, i.e. $\psi(\infty) \equiv \psi_0 < 1$. The majority phase is now 'supersaturated' with the dissolved minority species, and if the minority droplet is large enough it will grow by absorbing material from the majority phase. Otherwise it will evaporate as above. The two regimes are separated by a critical radius R_c .

Let $f(\pm 1) = 0$ by convention, then the Gibbs–Thomson boundary condition, [equation \(A3.3.73\)](#), becomes at $r = R$,

$$(1 + \psi_0)\mu = f(\psi_0) - \frac{(d-1)\sigma}{R}. \quad (\text{A3.3.82})$$

At $r = \infty$, from [equation \(A3.3.70\)](#),

$$\mu = f'(\psi_0). \quad (\text{A3.3.83})$$

-37-

The solution of Laplace's equation, [\(A3.3.71\)](#), with these boundary conditions is, for $d = 3$,

$$\mu = \begin{cases} f'(\psi_0) + \left(\frac{f(\psi_0)}{1 + \psi_0} - f'(\psi_0) \right) \frac{R}{r} - \frac{2\sigma}{(1 + \psi_0)} \frac{1}{r} & r \geq R \\ \frac{f(\psi_0)}{1 + \psi_0} - \frac{2\sigma}{(1 + \psi_0)} \frac{1}{R} & r \leq R. \end{cases} \quad (\text{A3.3.84})$$

(A3.3.85)

Using [equation \(A3.3.76\)](#), [equation \(A3.3.77\)](#) and [equation \(A3.3.84\)](#), one finds the interface velocity $v \equiv dR/d\tau$ as

$$\frac{dR}{d\tau} = \left(\frac{f(\psi_0)}{(1 + \psi_0)^2} - \frac{f'(\psi_0)}{(1 + \psi_0)} \right) \frac{1}{R} - \frac{2\sigma}{(1 + \psi_0)^2} \frac{1}{R^2}. \quad (\text{A3.3.86})$$

For a small supersaturation, $\psi_0 = 1 - \varepsilon$ with $\varepsilon \ll 1$. To leading (non-trivial) order in ε , [equation \(A3.3.86\)](#) reduces to

$$v(R) \equiv \frac{dR}{d\tau} = \frac{\sigma}{2R} \left(\frac{1}{R_c} - \frac{1}{R} \right) \quad (\text{A3.3.87})$$

with $R_c = \sigma/(f''(1)\epsilon)$ as the critical radius.

The form of $v(R)$ in (A3.3.87) is valid only for $d = 3$. If we write it as

$$\frac{dR}{d\tau} = \frac{\alpha_d}{R} \left(\frac{1}{R_c} - \frac{1}{R} \right) \quad (\text{A3.3.88})$$

then the general expression (see [40]) for α_d is $\alpha_d = (d-1)(d-2)\sigma/4$. For $d = 2$, α_d vanishes due to the singular nature of the Laplacian in two-dimensional systems. For $d = 2$ and in the limit of a small (zero) volume fraction of the minority phase, equation (A3.3.87) is modified to (see the appendix of [28]),

$$\frac{dR}{d\tau} = \frac{\sigma}{4R \ln(4\tau)} \left(\frac{1}{R_c} - \frac{1}{R} \right) \quad (\text{A3.3.89})$$

with $R_c = \sigma/(2f''(1)\epsilon)$. A change of variable $\tau^* = \tau/\ln(4\tau)$ converts (A3.3.89) into the same form as (A3.3.87), but now the time-like variable has a logarithmic modification.

In the LS analysis, an assembly of drops is considered. Growth proceeds by evaporation from drops with $R < R_c$ and condensation onto drops $R > R_c$. The supersaturation ϵ changes in time, so that $\epsilon(\tau)$ becomes a sort of mean field due to all the other droplets and also implies a time-dependent critical radius $R_c(\tau) = \sigma/[f''(1)\epsilon(\tau)]$. One of the starting equations in the LS analysis is equation (A3.3.87) with $R_c(\tau)$.

-38-

For a general dimension d , the cluster size distribution function $n(R, \tau)$ is defined such that $n(R, \tau)dR$ equals the number of clusters per unit 'volume' with a radius between R and $R + dR$. Assuming no nucleation of new clusters and no coalescence, $n(R, \tau)$ satisfies a continuity equation

$$\frac{\partial n}{\partial \tau} + \frac{\partial}{\partial R}(vn) = 0 \quad (\text{A3.3.90})$$

where $v \equiv dR/d\tau$ is given by equation (A3.3.87). Finally, the conservation law is imposed on the entire system as follows. Let the spatial average of the conserved order parameter be $(1 - \epsilon_0)$. At late times the supersaturation $\epsilon(\tau)$ tends to zero giving the constraint

$$\epsilon_0 = \epsilon(\tau) + V_d \int_0^\infty dR R^d n(R, \tau) \sim V_d \int_0^\infty dR R^d n(R, \tau) \quad (\text{A3.3.91})$$

where V_d is the volume of the d -dimensional unit sphere. Equation (A3.3.88), equation (A3.3.90) and equation (A3.3.91) constitute the LS problem for the cluster size distribution function $n(R, \tau)$. The LS analysis of these equations starts by introducing a scaling distribution of droplet sizes. For a d -dimensional system, one writes

$$n(R, \tau) = R_c^{-(d+1)} f\left(\frac{R}{R_c}\right). \quad (\text{A3.3.92})$$

Equation (A3.3.91) becomes, denoting R/R_c by x ,

$$\epsilon_0 = 2V_d \int_0^\infty dx x^d f(x) \quad (\text{A3.3.93})$$

and fixes the normalization of $f(x)$. If equation (A3.3.92) is substituted into equation (A3.3.90) we obtain, using the velocity [equation \(A3.3.88\)](#),

$$\frac{\dot{R}_c}{R_c^{d+2}} \left[(d+1)f(x) + x \frac{df}{dx} \right] = \frac{\alpha_d}{R_c^{d+4}} \left[\left(\frac{2}{x^3} - \frac{1}{x^2} \right) f(x) + \left(\frac{1}{x} - \frac{1}{x^2} \right) \frac{df}{dx} \right]. \quad (\text{A3.3.94})$$

For the consistency of the scaling form, equation (A3.3.92), R_c dependence should drop out from equation (A3.3.94); i.e.

$$R_c^2 \dot{R}_c = \alpha_d \gamma \quad (\text{A3.3.95})$$

-39-

which integrates to

$$R_c(\tau) = (3\alpha_d \gamma \tau)^{1/3}. \quad (\text{A3.3.96})$$

[Equation \(A3.3.94\)](#) simplifies to

$$\left[\frac{2}{x^3} - \frac{1}{x^2} - \gamma(d+1) \right] f(x) = \left[\gamma x - \frac{1}{x} + \frac{1}{x^2} \right] \frac{df}{dx} \quad (\text{A3.3.97})$$

which integrates to

$$\ln f(x) = \int^x \frac{dy}{y} \frac{(2-y-\gamma(d+1)y^3)}{(\gamma y^3 - y + 1)}. \quad (\text{A3.3.98})$$

Due to the normalization integral, [equation \(A3.3.93\)](#), $f(x)$ cannot be non-zero for arbitrarily large x ; $f(x)$ must vanish for x greater than some cut-off value x_0 , which must be a pole of the integrand in [equation \(A3.3.98\)](#) on the positive real axis. For this to occur $\gamma \leq \frac{4}{27} \equiv \gamma_0$. [Equation \(A3.3.88\)](#) and [equation \(A3.3.96\)](#) together yield an equation for $x = R/R_c$:

$$\frac{dx}{d\tau} = \frac{1}{3\gamma\tau} \left(\frac{1}{x} - \frac{1}{x^2} - \gamma x \right) \quad (\text{A3.3.99})$$

$$(\text{A3.3.100})$$

The form of $g(x)$ is shown in [figure A3.3.10](#). For $\gamma < \gamma_0$, all drops with $x > x_1$ will asymptotically approach the size $x_2 R_c(\tau)$, which tends to infinity with τ as $\tau^{1/3}$ from equation (A3.3.96). For $\gamma > \gamma_0$, all points move to the origin and the conservation condition again cannot be satisfied. The only allowed solution consistent with conservation condition, [equation \(A3.3.93\)](#), is that γ asymptotically approaches γ_0 from above. In doing this it takes an infinite time. (If it reaches γ_0 in finite time, all drops with $x > \frac{3}{2}$ would eventually arrive at $x = \frac{3}{2}$ and become stuck and one has a repeat of the $\gamma > \gamma_0$ case.) $\gamma = \gamma_0 = \frac{4}{27}$ then corresponds to a double pole in the integrand in (A3.3.98). LS show that $\gamma(\tau) = \gamma_0 [1 - \tilde{\epsilon}^2(\tau)]$ with $\tilde{\epsilon}(\tau) \rightarrow 0$ as $\tau \rightarrow \infty$ as $\tau \rightarrow \infty$. For an asymptotic scaled distribution, one uses $\gamma = \gamma_0 = \frac{4}{27}$ and evaluates the integral in (A3.3.98) to obtain

$$f(x) = \begin{cases} \text{constant } x^2 (3+x)^{-(1+\frac{d}{\gamma})} \left(\frac{3}{2}-x\right)^{-(2+\frac{d}{\gamma})} \exp\left(-\frac{d}{3-2x}\right) & \text{for } x < \frac{3}{2} \\ 0 & \text{for } x \geq \frac{3}{2} \end{cases} \quad (\text{A3.3.101})$$

where the normalization constraint, [equation \(A3.3.93\)](#), can be used to determine the constant. $f(x)$ is the scaled LS cluster distribution and is shown in [figure A3.3.11](#) for $d = 3$.

-40-

Figure A3.3.10 $g(x)$ as a function of x for the three possible classes of γ .

Figure A3.3.11 The asymptotic cluster size distribution $f(x)$ from LS analysis for $d = 3$.

In [section A3.3.3](#) the Langevin models that were introduced for phase transition kinetics utilized the Landau mean field expansion of the free energy, [equation \(A3.3.50\)](#) and [equation \(A3.3.51\)](#). In spite of this, many of the subsequent results based on [\(A3.3.57\)](#) as a starting point are more broadly valid and are dependent only on the existence of a double-well nature of the free energy functional as shown in [figure A3.3.6](#). Also, as the renormalization group analysis shows, the role of thermal noise is irrelevant for the evolution of the initially unstable state. Thus, apart from the random fluctuations in the initial state, which are essential for the subsequent growth of unstable modes, the mean field description is a good theoretical starting point in understanding spinodal decomposition and the ensuing growth. The late-stage growth analysis given in this section is a qualitatively valid starting point for quenches with sufficient off-criticality, and becomes correct asymptotically as the off-criticality ψ_0 increases, bringing the initial post-quench state closer to the coexistence curve, where it is one. In general, one has to add to the LS analysis the cluster–cluster interactions. The current states of such extensions (which are non-trivial) are reviewed in [[37](#), [40](#), [41](#)].

-41-

The main results are that the universal scaling form of the LS cluster distribution function $f(x)$ given above acquires a dependence on $\delta\psi_0 \equiv (1-\psi_0)$ which measures the proximity to the coexistence curve (it is essentially the volume fraction for the vapour–liquid nucleation); also, the $\tau^{1/3}$ growth law for the domain size has the form: $R(\tau) = [K(\delta\psi_0)\tau]^{1/3}$, where $K(\delta\psi_0)$ is a monotonically increasing function of $\delta\psi_0$.

A3.3.5 NUCLEATION KINETICS—METASTABLE SYSTEMS

In this section, we restrict our discussion to homogeneous nucleation, which has a illustrious history spanning at least six decades (see [[37](#), [42](#)] and references therein). Heterogeneous nucleation occurs more commonly in nature, since suspended impurities or imperfectly wetted surfaces provide the interface on which the growth of the new phase is initiated. Heterogeneous nucleation is treated in a recent book by Debenedetti (see [section 3.4](#) of this book, which is listed in Further Reading); interesting phenomena of breath figures and dew formation are related to heterogeneous nucleation, and are discussed in [[43](#), [44](#) and [45](#)].

In contrast to spinodal decomposition, where small-amplitude, long-wavelength fluctuations initiate the growth, the kinetics following an initial metastable state requires large-amplitude (nonlinear) fluctuations for the stable phase to nucleate. A qualitative picture for the nucleation event is as follows. For the initial metastable state, the two minima of the local free energy functional are not degenerate, in contrast to the initially unstable case shown in [figure A3.3.6](#). The metastable system is initially in the higher of the two minimum energy states and has to overcome a free energy barrier (provided by the third extremum which is a maximum) in order to go over to the absolute minimum, which is the system's ground state. For this, it requires an activation energy which is obtained through rarely occurring large-amplitude fluctuations of the order parameter, in the form of a critical droplet. Physically, the rarity of the nonlinear fluctuation introduces large characteristic times for nucleation to occur.

The central quantity of interest in homogeneous nucleation is the nucleation rate J , which gives the number of droplets nucleated per unit volume per unit time for a given supersaturation. The free energy barrier is the dominant factor in determining J ; J depends on it exponentially. Thus, a small difference in the different model predictions for the barrier can lead to orders of magnitude differences in J . Similarly, experimental measurements of J are sensitive to the purity of the sample and to experimental conditions such as temperature. In modern field theories, J has a general form

(A3.3.102)

$$J = \frac{1}{\tau^*} \Omega e^{(E_c/kT)}$$

where τ^* is the time scale for the macroscopic fluctuations and Ω is the volume of phase space accessible for fluctuations. The barrier height to nucleation E_c is described below.

A homogeneous metastable phase is always stable with respect to the formation of infinitesimal droplets, provided the surface tension σ is positive. Between this extreme and the other thermodynamic equilibrium state, which is inhomogeneous and consists of two coexisting phases, a critical size droplet state exists, which is in unstable equilibrium. In the ‘classical’ theory, one makes the capillarity approximation: the critical droplet is assumed homogeneous up to the boundary separating it from the metastable background and is assumed to be the same as the new phase in the bulk. Then the work of formation $W(R)$ of such a droplet of arbitrary radius R is the sum of the

-42-

free energy gain of the new stable phase droplet and the free energy cost due to the new interface that is formed:

$$W(R) = 4\pi R^2 \sigma - \frac{4}{3}\pi R^3 \Delta f \quad (\text{A3.3.103})$$

where Δf is the positive bulk free energy difference per unit volume between the stable and metastable phases. From this, by maximizing $W(R)$ with respect to R , one obtains the barrier height to nucleation $W(R_c) \equiv E_c$ and the critical radius R_c : $R_c = 2\sigma/(\Delta f)$ and $E_c = (16\pi/3)\sigma^3/(\Delta f)^2$. For a supercooled vapour nucleating into liquid drops, Δf is given by $kT\rho_1 \ln(\varepsilon)$, where ρ_1 is the bulk liquid density and $\varepsilon = P/P_e$ is the supersaturation ratio, which is the ratio of the actual pressure P to the equilibrium vapour pressure P_e of the liquid at the same T . For the case of the nucleation of a crystal from a supercooled liquid, $\Delta f = \Delta\mu/v$, where v is the volume per particle of the solid and $\Delta\mu$ is the chemical potential difference between the bulk solid and the bulk liquid. These results, given here for three-dimensional systems, can be easily generalized to an arbitrary d -dimensional case [37]. Often, it is useful to use the capillary length $l_c = (2\sigma v)/(kT)$ as the unit of length: the critical radius is $R_c = l_c/\varepsilon(t)$, where the supersaturation $\varepsilon(t) = \Delta\mu/(kT)$, and the nucleation barrier is $(E_c/kT) = (\varepsilon_0/\varepsilon(t))^2$, where the dimensionless quantity $\varepsilon_0 = l_c[(4\pi\sigma)/(3kT)]^{1/2}$.

Early (classical) theories of homogeneous nucleation are based on a microscopic description of cluster dynamics (see reference (1) in [37]). A kinetic equation for the droplet number density $n_i(t)$ of a given size i at time t is written, in which its time rate of change is the difference between J_{i-1} and J_i , where J_i is the rate at which droplets of size i grow to size $i+1$ by gaining a single molecule [13]. By providing a model for the forward and backward rates at which a cluster gains or loses a particle, J_i is related to $\{n_i(t)\}$, and a set of coupled rate equations for $\{n_i(t)\}$ is obtained. The nucleation rate is obtained from the steady-state solution in which $J_i = J$ for large i . The result is in the form of equation (A3.3.102), with specific expressions for $J_0 \equiv \Omega/\tau^*$ obtained for various cases such as vapour–liquid and liquid–solid transitions. Classical theories give nucleation rates that are low compared to experimental measurements. Considerable effort has gone into attempts to understand ‘classical’ theories, and compare their results to experiments (see references in 42).

In two classic papers [18, 46], Cahn and Hilliard developed a field theoretic extension of early theories of nucleation by considering a spatially inhomogeneous system. Their free energy functional, equations (A3.3.52), has already been discussed at length in section A3.3.3. They considered a two-component incompressible fluid. The square gradient approximation implied a slow variation of the concentration on the

coarse-graining length scale ξ (i.e. a diffuse interface). In their 1959 paper [46], they determined the saddle point of this free energy functional and analysed the properties of a critical nucleus of the minority phase within the metastable binary mixture. While the results agree with those of the early theories for low supersaturation, the properties of the critical droplet change as the supersaturation is increased: (i) the work required to form a critical droplet becomes progressively less compared to ‘classical’ theory result, and approaches zero continuously as spinodal is approached; (ii) the interface with the exterior phase becomes more diffuse and the interior of the droplet becomes inhomogeneous in its entirety; (iii) the concentration at the droplet centre approaches that of the exterior phase; and (iv) the radius and excess concentration in the droplet at first decrease, pass through a minimum and become infinite at the spinodal. These papers provide a description of the spatially inhomogeneous critical droplet, which is not restricted to planar interfaces, and yields, for $W(R)$, an expression that goes to zero at the mean field spinodal. The Cahn–Hilliard theory has been a useful starting point in the development of modern nucleation theories.

A full theory of nucleation requires a dynamical description. In the late 1960s, the early theories of homogeneous nucleation were generalized and made rigorous by Langer [47]. Here one starts with an appropriate Fokker–Planck

-43-

(or its equivalent Langevin) equation for the probability distribution function $P(\{\psi_i\}, t)$ for the set of relevant field variables $\{\psi_i\}$ which are semi-macroscopic and slowly varying:

$$\frac{\partial P}{\partial t} = - \sum_i \frac{\delta J_i}{\delta \psi_i} \quad (\text{A3.3.104})$$

where the probability current J_i is given by

$$J_i = \sum_j M_{ij} \left[\frac{\delta \mathcal{F}}{\delta \psi_j} + kT \frac{\delta P}{\delta \psi_j} \right]. \quad (\text{A3.3.105})$$

\mathcal{F} is the free energy functional, for which one can use equation (A3.3.52). The summation above corresponds to both the sum over the semi-macroscopic variables and an integration over the spatial variable \vec{r} . The mobility matrix M_{ij} consists of a symmetric dissipative part and an antisymmetric non-dissipative part. The symmetric part corresponds to a set of generalized Onsager coefficients.

The decay of a metastable state corresponds to passing from a local minimum of \mathcal{F} to another minimum of lower free energy which occurs only through improbable free energy fluctuations. The most probable path for this passage to occur when the nucleation barrier is high is via the saddle point. The saddle point corresponds to a critical droplet of the stable phase in a metastable phase background. The nucleation rate is given by the steady-state solution of the Fokker–Planck equation that describes a finite probability current across the saddle point. The result is of the form given in (A3.3.102). The quantity $1/\tau^*$ is also referred to as a dynamical prefactor and Ω as a statistical prefactor.

Within this general framework there have been many different systems modelled and the dynamical, statistical prefactors have been calculated. These are detailed in [42]. For a binary mixture, phase separating from an initially metastable state, the work of Langer and Schwartz [48] using the Langer theory [47] gives the nucleation rate as

$$J(t) = (l_c^3 t_c)^{-1} \frac{3\epsilon_0^6}{4\pi} \left(\frac{\epsilon(t)}{\epsilon_0} \right)^{2/3} \left(1 + \frac{\epsilon(t)}{\epsilon_0} \right)^{3.55} \exp \left[- \left(\frac{\epsilon_0}{\epsilon(t)} \right)^2 \right] \quad (\text{A3.3.106})$$

where l_c is the capillary length defined above and the characteristic time $t_c = l_c^2/[DvC_{\text{eq}}(\infty)]$ with D as the diffusion coefficient and $C_{\text{eq}}(\infty)$ the solute concentration in the background matrix at a planar interface in the phase separated system [37].

One can introduce a distributed nucleation rate $j(R, t)dR$ for nucleating clusters of radius between R and $R + dR$. Its integral over R is the total nucleation rate $J(t)$. Equation (A3.3.103) can be viewed as a radius-dependent droplet energy which has a maximum at $R = R_c$. If one assumes $j(R, t)$ to be a Gaussian function, then

$$j(R, t) = \frac{J(t)}{\sqrt{2\pi}(\delta R)} \exp \left[- \frac{(R - R_c)^2}{2(\delta R)^2} \right] \quad (\text{A3.3.107})$$

where $(\delta R)^2 = 2[E_c - W(R)]/|E_c''|$, with E_c and E_c'' being, respectively, the values of $W(R)$ and its second derivative evaluated at $R = R_c$. Langer [47] showed that the droplet energy is not only a function of R but can also depend on the capillary wavelength fluctuations w ; i.e. $W(R) \rightarrow E(R, w)$. Then, the droplets appear at the saddle point in the surface of $E(R, w)$. The $2 - d$ surface area of the droplet is given by $4\pi(R^2 + w^2)$, which gives the change in the droplet energy due to non-zero w , as $\Delta E(R) = 4\pi\sigma w^2$. Both approaches lead to the same Gaussian form of the distributed nucleation rate with $w \equiv (\delta R)$ estimated from an uncertainty in the required activation energy of the order of $kT/2$.

Just as is the case for the LSW theory of Ostwald ripening, the Langer–Schwartz theory is also valid for quenches close to the coexistence curve. Its extension to non-zero volume fractions requires that such a theory take into account cluster–cluster correlations. A framework for such a theory has been developed [37] using a multi-droplet diffusion equation for the concentration field. This equation has been solved analytically using (i) a truncated multipole expansion and (ii) a mean field Thomas–Fermi approximation. The equation has also been numerically simulated. Such studies are among the first attempts to construct a unified model for the entire process of phase separation that combines steady-state homogeneous nucleation theory with the LSW mechanism for ripening, modified to account for the inter-cluster correlations.

A3.3.6 SUMMARY

In this brief review of dynamics in condensed phases, we have considered dense systems in various situations. First, we considered systems in equilibrium and gave an overview of how the space–time correlations, arising from the thermal fluctuations of slowly varying physical variables like density, can be computed and experimentally probed. We also considered capillary waves in an inhomogeneous system with a planar interface for two cases: an equilibrium system and a NESS system under a small temperature gradient. Finally, we considered time evolving non-equilibrium systems in which a quench brings a homogeneous system to an initially unstable (spinodal decomposition) or metastable state (nucleation) from which it evolves to a final inhomogeneous state of two coexisting equilibrium phases. The kinetics of the associated processes provides rich physics involving nonlinearities and inhomogeneities. The early-stage kinetics associated with the formation of interfaces and the late-stage interface dynamics in such systems continues to provide

challenging unsolved problems that have emerged from the experimental observations on real systems and from the numerical simulations of model systems.

A 3.4 Gas-phase kinetics

David Luckhaus and Martin Quack

A3.4.1 INTRODUCTION

Gas-phase reactions play a fundamental role in nature, for example atmospheric chemistry [1, 2, 3, 4 and 5] and interstellar chemistry [6], as well as in many technical processes, for example combustion and exhaust fume cleansing [7, 8 and 9]. Apart from such practical aspects the study of gas-phase reactions has provided the basis for our understanding of chemical reaction mechanisms on a microscopic level. The typically small particle densities in the gas phase mean that reactions occur in well defined elementary steps, usually not involving more than three particles.

At the limit of extremely low particle densities, for example under the conditions prevalent in interstellar space, ion–molecule reactions become important (see [chapter A3.5](#)). At very high pressures gas-phase kinetics approach the limit of condensed phase kinetics where elementary reactions are less clearly defined due to the large number of particles involved (see [chapter A3.6](#)).

Here, we mainly discuss homogeneous gas-phase reactions at intermediate densities where ideal gas behaviour can frequently be assumed to be a good approximation and diffusion is sufficiently fast that transport processes are not rate determining. The focus is on thermally activated reactions induced by collisions at well defined temperatures, although laser induced processes are widely used for the experimental study of such gas-phase reactions (see [chapter B2.1](#)). The aim of the present chapter is to introduce the basic concepts at our current level of understanding. It is not our goal to cover the vast original literature on the general topic of gas reactions. We refer to the books and reviews cited as well as to [chapter B2.1](#) for specific applications.

Photochemical reactions ([chapter A3.13](#)) and heterogeneous reactions on surfaces ([chapter A3.10](#)) are discussed in separate chapters.

A3.4.2 DEFINITIONS OF THE REACTION RATE

There are many ways to define the rate of a chemical reaction. The most general definition uses the rate of change of a thermodynamic state function. Following the second law of thermodynamics, for example, the change of entropy S with time t would be an appropriate definition under reaction conditions at constant energy U and volume V :

$$v_S(t) = \left(\frac{\partial S}{\partial t} \right)_{U,V} \geq 0. \quad (\text{A3.4.1})$$

An alternative rate quantity under conditions of constant temperature T and volume, frequently realized in gas kinetics, would be

$$v_A(t) = - \left(\frac{\partial A}{\partial t} \right)_{T,V} \geq 0, \quad (\text{A3.4.2})$$

where A is the Helmholtz free energy.

For non-zero v_S and v_A the problem of defining the thermodynamic state functions under non-equilibrium conditions arises (see [chapter A3.2](#)). The definition of rate of change implied by [equation \(A3.4.1\)](#) and [equation \(A3.4.2\)](#) includes changes that are not due to chemical reactions.

In *reaction kinetics* it is conventional to define *reaction rates* in the context of chemical reactions with a well defined stoichiometric equation

$$0 = \sum_i \nu_i B_i \quad (\text{A3.4.3})$$

where ν_i are the stoichiometric coefficients of species B_i ($\nu_i < 0$ for reactants and $\nu_i > 0$ for products, by convention). This leads to the conventional definition of the ‘rate of conversion’:

$$v_\xi(t) = \frac{d\xi}{dt} = \nu_i^{-1} \frac{dn_i}{dt}, \quad (\text{A3.4.4})$$

The ‘extent of reaction’ ξ is defined in terms of the amount n_i of species B_i (i.e. the amount of substance or enplethy n_p , usually expressed in moles [10]):

$$\xi(t) = \frac{n_i(t) - n_i(t=0)}{\nu_i}; \quad (\text{A3.4.5})$$

v_ξ is an extensive quantity, i.e. for two independent subsystems I and II we have $v_\xi(I + II) = v_\xi(I) + v_\xi(II)$. For homogeneous reactions we obtain the conventional definition of the ‘reaction rate’ v_c as rate of conversion per volume

$$v_c(t) = V^{-1} v_\xi(t) = \nu_i^{-1} \frac{dc_i}{dt} \quad (\text{A3.4.6})$$

where c_i is the concentration of species B_p , for which we shall equivalently use the notation $[B_i]$ (with the common unit mol dm^{-3} and the unit of v_c being $\text{mol dm}^{-3} \text{s}^{-1}$). In gas kinetics it is particularly common to use the quantity particle

density for concentration, for which we shall use C_i (capital letter) with

$$v_c(t) = N_A V^{-1} v_\xi(t) = v_i^{-1} \frac{dc_i}{dt}.$$

N_A is Avogadro's constant. The most commonly used unit then is $\text{cm}^{-3} \text{s}^{-1}$, sometimes inconsistently written ($\text{molecule cm}^{-3} \text{s}^{-1}$). v_c is an intensive quantity. Table A3.4.1 summarizes the definitions.

Table A3.4.1 Definitions of the reaction rate.

Constraint	Extensive quantity	Intensive quantity	Reaction rate
$U, V = \text{constant}$ adiabatic	Entropy S (thermodynamics of irreversible processes)	Local entropy $S_V = \frac{\delta S}{\delta V}$	$v_S = \frac{dS}{dt} \geq 0$ unit: $\text{J K}^{-1} \text{s}^{-1}$ $v_{S_V} = \frac{dS_V}{dt} \geq 0$ unit: $\text{J K}^{-1} \text{s}^{-1} \text{cm}^{-3}$
$T, V = \text{constant}$ isothermal	Helmholtz energy $A = U - TS$	Local A $A_V = \frac{\delta A}{\delta V}$	$v_A = -\frac{dA}{dt} \geq 0$ unit: J s^{-1} $v_{A_V} = \frac{dA_V}{dt} \geq 0$ unit: $\text{J s}^{-1} \text{cm}^{-3}$
$V = \text{constant}$ isothermal or adiabatic, fixed stoichiometry	Amount of substance n_i , number of particles N_i $0 = \sum_i \nu_i B_i$ extent of reaction ξ $d\xi = \nu_i^{-1} dn_i$	Concentration $c_i = n_i / V$ $\frac{\delta \xi}{\delta V} \simeq \frac{\xi}{V}$ $c_i = \frac{N_i}{V}$	$\frac{dn_i}{dt}$ or $\frac{dc_i}{dt}$ unit: mol s^{-1} or $\text{mol cm}^{-3} \text{s}^{-1}$ $\frac{d\xi}{dt}$ or $\frac{1}{V} \frac{d\xi}{dt} = \frac{1}{\nu_i} \frac{dc_i}{dt}$ unit: mol s^{-1} , $\text{mol cm}^{-3} \text{s}^{-1}$ or $\text{molecule cm}^{-3} \text{s}^{-1}$ $v_c = \frac{1}{\nu_i} \frac{dc_i}{dt}$

Figure A3.4.1 shows as an example the time dependent concentrations and entropy for the simple decomposition reaction of chloroethane:

The slopes of the functions shown provide the reaction rates according to the various definitions under the reaction conditions specified in the figure caption. These slopes are similar, but not identical (nor exactly proportional), in this simple case. In more complex cases, such as oscillatory reactions ([chapter A3.14](#) and [chapter C3.6](#)), the simple definition of an overall rate law through [equation \(A3.4.6\)](#) loses its usefulness, whereas [equation \(A3.4.1\)](#) could still be used for an isolated system.

Figure A3.4.1. Concentration and entropy as functions of time for reaction equation (A3.4.8). S_m is the maximum value of the entropy ([20]).

A3.4.3 EMPIRICAL RATE LAWS AND REACTION ORDER

A general form of the ‘rate law’, i.e. the differential equation for the concentrations is given by

$$v_c(t) = v_i^{-1} \frac{dc_i}{dt} = f(c_1, c_2, \dots). \quad (\text{A3.4.9})$$

The functional dependence of the reaction rate on concentrations may be arbitrarily complicated and include species not appearing in the stoichiometric equation, for example, catalysts, inhibitors, etc. Sometimes, however, it takes a particularly simple form, for example, under certain conditions for elementary reactions and for other relatively simple reactions:

$$v_c(t) = k \prod_i c_i^{m_i} \quad (\text{A3.4.10})$$

with a concentration-independent and frequently time-independent ‘rate coefficient’ or ‘rate constant’ k . m_i is the order of the reaction with respect to the species B_i and the total order of the reaction m is given by

$$m = \sum_i m_i \quad (\text{A3.4.11})$$

where m and m_i are real numbers. Table A3.4.2 summarizes a few examples of such rate laws. In general, one may allow for rate coefficients that depend on time (but not on concentration) [11].

Table A3.4.2 Rate laws, reaction order, and rate constants.

Reaction	Rate law	Reaction order	Dimension of rate constant [k]
Isomerization $\text{CH}_3\text{NC} = \text{CH}_3\text{CN}$ excess of inert gas	$-\frac{d[\text{CH}_3\text{NC}]}{dt} = k[\text{CH}_3\text{NC}]$	First order in CH_3NC . First-order total	$[\text{s}^{-1}]$
Atom transfer $\text{F} + \text{CHF}_3 = \text{HF} + \text{CF}_3$	$-\frac{d[\text{F}]}{dt} = k[\text{F}][\text{CHF}_3]$	First order in F. First order in CHF_3 . Second-order total	$[\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}]$ or $[\text{cm}^3 \text{s}^{-1}]$
Radical recombination $2\text{CH}_3 = \text{C}_2\text{H}_6$	$-\frac{1}{2} \frac{d[\text{CH}_3]}{dt} = k[\text{CH}_3]^2$	Second order in CH_3 . Second-order total	$[\text{cm}^3 \text{mol}^{-1} \text{s}^{-1}]$ or $[\text{cm}^3 \text{s}^{-1}]$
Decomposition $\text{CH}_3\text{CHO} = \text{CH}_4 + \text{CO}$	$-\frac{d[\text{CH}_3\text{CHO}]}{dt} = k[\text{CH}_3\text{CHO}]^{3/2}$	Order 3/2 in CH_3CHO and total	$[\text{cm}^{3/2} \text{mol}^{-1/2} \text{s}^{-1}]$

If certain species are present in large excess, their concentration stays approximately constant during the course of a reaction. In this case the dependence of the reaction rate on the concentration of these species can be included in an effective rate constant k_{eff} . The dependence on the concentrations of the remaining species then defines the *apparent order of the reaction*. Take for example [equation \(A3.4.10\)](#) with $c_{i>1} \gg c_1$. The result would be a *pseudo m_1 th order* effective rate law:

$$v_c(t) = k_{\text{eff}} c_1^{m_1} \quad (\text{A3.4.12})$$

$$k_{\text{eff}} = k \prod_{i>1} c_i^{m_i}. \quad (\text{A3.4.13})$$

This is the situation exploited by the so-called *isolation* method to determine the order of the reaction with respect to each species (see [chapter B2.1](#)). It should be stressed that the rate coefficient k in [\(A3.4.10\)](#) depends upon the definition of the v_i in the stoichiometric equation. It is a conventionally defined quantity to within multiplication of the stoichiometric equation by an arbitrary factor (similar to reaction enthalpy).

The definitions of the empirical rate laws given above do not exclude empirical rate laws of another form. Examples are reactions, where a reverse reaction is important, such as in the *cis-trans* isomerization of 1,2-dichloroethene:

$$-\frac{d[\text{cis}]}{dt} = k_a[\text{cis}] - k_b[\text{trans}] \quad (\text{A3.4.15})$$

or the classic example of hydrogen bromide formation:

$$-\frac{d[\text{HBr}]}{dt} = k_a[\text{H}_2][\text{Br}_2]^{1/2} \left(1 + k_b \frac{[\text{HBr}]}{[\text{Br}_2]} \right)^{-1} \quad (\text{A3.4.17})$$

Neither (A3.4.15) nor (A3.4.17) is of the form (A3.4.10) and thus neither reaction order nor a unique rate coefficient can be defined. Indeed, the number of possible rate laws that are *not* of the form of (A3.4.10) greatly exceeds those cases following (A3.4.10). However, certain particularly simple reactions necessarily follow a law of type of (A3.4.10). They are particularly important from a mechanistic point of view and are discussed in the next section.

A3.4.4 ELEMENTARY REACTIONS AND MOLECULARITY

Sometimes the reaction orders m_i take on integer values. This is generally the case, if a chemical reaction

or

takes place on a microscopic scale through direct interactions between particles as implied by equation (A3.4.18) or equation (A3.4.19). Thus, the coefficients of the substances in (A3.4.18) and (A3.4.19) represent the actual number of particles involved in the reaction, rather than just the stoichiometric coefficients. To keep the distinction clear we shall reserve the reaction arrow ‘ \rightarrow ’ for such *elementary reactions*. Sometimes the inclusion of the reverse elementary reaction will be signified by a double arrow ‘ \rightleftharpoons ’. Other, *compound reactions* can always be decomposed into a set of—not necessarily consecutive—elementary steps representing the *reaction mechanism*.

-7-

Elementary reactions are characterized by their *molecularity*, to be clearly distinguished from the reaction order. We distinguish *uni-* (or *mono-*), *bi-*, and *trimolecular* reactions depending on the number of particles involved in the ‘essential’ step of the reaction. There is some looseness in what is to be considered ‘essential’, but in gas kinetics the definitions usually are clearcut through the number of particles involved in a reactive collision; plus, perhaps, an additional convention as is customary in unimolecular reactions.

A3.4.4.1 UNIMOLECULAR REACTIONS

Strictly unimolecular processes—sometimes also called *monomolecular*—involve only a single particle:

(A3.4.20)

A → products.

Classic examples are the spontaneous emission of light or spontaneous radioactive decay. In chemistry, an important class of monomolecular reactions is the predissociation of metastable (excited) species. An example is the formation of oxygen atoms in the upper atmosphere by predissociation of electronically excited O₂ molecules [12, 13 and 14]:

Excited O₂^{*} molecules are formed by UV light absorption. Monomolecular reactions (e.g., $c = [\text{O}_2^*]$) show a first-order rate law:

$$-\frac{dc}{dt} = kc(t). \quad (\text{A3.4.22})$$

Integration of the differential equation with time-independent k leads to the familiar exponential decay:

$$c(t) = c(0) \exp\{-kt\}. \quad (\text{A3.4.23})$$

The rate constant in this case is of the order of 10¹¹ s⁻¹ depending on the rovibronic level considered.

Another example of current interest is the *vibrational predissociation* of hydrogen bonded complexes such as (HF)₂:

-8-

With one quantum of non-bonded (HF)-stretching excitation (*) the internal energy (~50 kJ mol⁻¹) is about four times in excess of the hydrogen bond dissociation energy (12.7 kJ mol⁻¹). At this energy the rate constant is about $k \approx 5 \times 10^7 \text{ s}^{-1}$ [15]. With two quanta of (HF)-stretching (at about seven times the dissociation energy) the rate constant is $k \approx 7.5 \times 10^8 \text{ s}^{-1}$ in all cases, depending on the rovibrational level considered [16, 17].

While monomolecular collision-free predissociation excludes the preparation process from explicit consideration, thermal unimolecular reactions involve collisional excitation as part of the unimolecular mechanism. The simple mechanism for a thermal chemical reaction may be formally decomposed into three (possibly reversible) steps (with rovibronically excited (CH₃NC)*):

The inert collision partner M is assumed to be present in large excess:

$$[\text{M}] \gg [\text{CH}_3\text{NC}] \quad (\text{A3.4.28})$$

$$[\text{M}] \approx \text{constant}. \quad (\text{A3.4.29})$$

This mechanism as a whole is called ‘unimolecular’ since the essential isomerization step equation (A3.4.26) only involves a single particle, *viz.* CH_3NC . Therefore it is often simply written as follows:

Experimentally, one finds the same first-order rate law as for monomolecular reactions, but with an effective rate constant k that now depends on $[\text{M}]$.

$$-\frac{dc}{dt} = k([\text{M}]c(t)). \quad (\text{A3.4.31})$$

The correct treatment of the mechanism (equation (A3.4.25), equation (A3.4.26) and equation (A3.4.27), which goes back to Lindemann [18] and Hinshelwood [19], also describes the pressure dependence of the effective rate constant in the low-pressure limit ($[\text{M}] \leq [\text{CH}_3\text{NC}]$, see [section A3.4.8.2](#)).

The unimolecular rate law can be justified by a probabilistic argument. The number ($N_{\text{A}} Vdc \propto dc$) of particles which react in a time dt is proportional both to this same time interval dt and to the number of particles present ($N_{\text{A}} Vc \propto c$). However, this probabilistic argument need not always be valid, as illustrated in figure A3.4.2 for a simple model [20]:

A number of particles perform periodic rotations in a ring-shaped container with a small opening, through which some particles can escape. Two situations can now be distinguished.

Figure A3.4.2. A simple illustration of limiting dynamical behaviour: case 1 statistical, case 2 coherent (after [20]).

Case 1. The particles are statistically distributed around the ring. Then, the number of escaping particles will be proportional both to the time interval (opening time) dt and to the total number of particles in the container. The result is a first-order rate law.

Case 2. The particles rotate in small packets ('coherently' or 'in phase'). Obviously, the first-order rate law no longer holds. In [chapter B2.1](#) we shall see that this simple consideration has found a deeper meaning in some of the most recent kinetic investigations [21].

A3.4.4.2 BIMOLECULAR REACTIONS

Bimolecular reactions involve two particles in their essential step. In the so-called *self-reactions* they are of the same species:

with the stoichiometric equation

Typical examples are radical recombinations:

-10-

Here the initially formed excited species $(\text{C}_2\text{H}_6)^*$ is sufficiently long lived that the deactivation step (equation (A3.4.35)) is not essential and one writes

The rate is given by the second-order law ($c \equiv [\text{CH}_3]$ or $c \equiv [\text{A}]$)

$$-\frac{1}{2} \frac{dc}{dt} = kc^2. \quad (\text{A3.4.37})$$

Integration leads to

$$\frac{1}{c(t)} = 2kt + \frac{1}{c(0)}. \quad (\text{A3.4.38})$$

Bimolecular reactions between different species

lead to the second-order rate law

$$-\frac{dc_A}{dt} = kc_Ac_B. \quad (\text{A3.4.40})$$

For $c_B(0) \neq c_A(0)$ the solution of this differential equation is

$$\ln \left(\frac{c_B(t)}{c_A(t)} \right) - \ln \left(\frac{c_B(0)}{c_A(0)} \right) = (c_B(0) - c_A(0))kt. \quad (\text{A3.4.41})$$

The case of equal concentrations, $c_B = c_A = c(t)$, is similar to the case A + A in equation (A3.4.37), except for the stoichiometric factor of two. The result thus is

$$\frac{1}{c(t)} = kt + \frac{1}{c(0)}. \quad (\text{A3.4.42})$$

If one of the reactants is present in large excess $c_B \gg c_A$ its concentration will essentially remain constant throughout the reaction. Equation (A3.4.41) then simplifies to

$$c_A(t) = c_A(0) \exp\{-k_{\text{eff}}t\} \quad (\text{A3.4.43})$$

with the effective *pseudo first-order* rate constant $k_{\text{eff}} = kc_B$.

One may justify the differential equation (A3.4.37) and equation (A3.4.40) again by a probability argument. The number of reacting particles $N_A Vdc \propto dc$ is proportional to the frequency of encounters between two particles and to the time interval dt . Since not every encounter leads to reaction, an additional reaction probability P_R has to be introduced. The frequency of encounters is obtained by the following simple argument. Assuming a statistical distribution of particles, the probability for a given particle to occupy a

volume element δV is proportional to the concentration c . If the particles move independently from each other (ideal behaviour) the same is true for a second particle. Therefore the probability for two particles to occupy the same volume element (an encounter) is proportional to c^2 . This leads to the number of particles reacting in the time interval dt :

$$N_A V dc \propto P_R c^2 dt. \quad (\text{A3.4.44})$$

In the case of bimolecular gas-phase reactions, ‘encounters’ are simply collisions between two molecules in the framework of the general collision theory of gas-phase reactions (section A3.4.5.2). For a random thermal distribution of positions and momenta in an ideal gas reaction, the probabilistic reasoning has an exact foundation. However, as noted in the case of unimolecular reactions, in principle one must allow for deviations from this ideal behaviour and, thus, from the simple rate law, although in practice such deviations are rarely taken into account theoretically or established empirically.

The second-order rate law for bimolecular reactions is empirically well confirmed. Figure A3.4.3 shows the example of methyl radical recombination (equation (A3.4.36)) in a graphical representation following equation (A3.4.38) [22, 23 and 24]. For this example the bimolecular rate constant is

$$k = 4.4 \times 10^{-11} \text{ cm}^3 \text{ s}^{-1} \quad (\text{A3.4.45})$$

or

$$k = 2.6 \times 10^{13} \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1}. \quad (\text{A3.4.46})$$

It is clear from figure A3.4.3 that the second-order law is well followed. However, in particular for recombination reactions at low pressures, a transition to a third-order rate law (second order in the recombining species and first order in some collision partner) must be considered. If the non-reactive collision partner M is present in excess and its concentration $[M]$ is time-independent, the rate law still is pseudo-second order with an effective second-order rate coefficient proportional to $[M]$.

Figure A3.4.3. Methyl radical recombination as a second-order reaction (after [22, 23]).

A3.4.4.3 TRIMOLECULAR REACTIONS

Trimolecular reactions require the simultaneous encounter of three particles. At the usually low particle densities of gas phase reactions they are relatively unlikely. Examples for trimolecular reactions are atom recombination reactions

with the stoichiometric equation

In contrast to the bimolecular recombination of polyatomic radicals (equation (A3.4.34)) there is no long-lived intermediate AB^* since there are no extra intramolecular vibrational degrees of freedom to accommodate the excess energy. Therefore, the formation of the bond and the deactivation through collision with the inert collision partner M have to occur simultaneously (within 10–100 fs). The rate law for trimolecular recombination reactions of the type in equation (A3.4.47) is given by

$$-\frac{dc_A}{dt} = k[M]c_Ac_B \quad (\text{A3.4.49})$$

as can be derived by a probability argument similar to bimolecular reactions (and with similar limitations). Generally, collisions with different collision partners M_i may have quite different efficiencies. The rate law actually observed is therefore given by

$$-\frac{dc_A}{dt} = \sum_i k_i[M_i]c_Ac_B. \quad (\text{A3.4.50})$$

If the dominant contributions $k_i[M_i]$ are approximately constant, this leads to pseudo second-order kinetics with an effective rate constant

$$k_{\text{eff}} = \sum_i k_i[M_i]. \quad (\text{A3.4.51})$$

The recombination of oxygen atoms affords an instructive example:

with the common stoichiometric equation

Here $k_{\text{O}} \gg k_{\text{O}_2}$ because (A3.4.52) proceeds through a highly-excited molecular complex O_3^* with particularly efficient redistribution pathways for the excess energy. As long as $[\text{O}] \geq [\text{O}_2]$ the rate law for this trimolecular reaction is given by $(c(t) = [\text{O}], k = k_{\text{O}})$:

$$-\frac{1}{2} \frac{dc}{dt} = kc^3. \quad (\text{A3.4.55})$$

Integration leads to

$$\frac{1}{c(t)^2} = 4kt + \frac{1}{c(0)^2}. \quad (\text{A3.4.56})$$

Trimolecular reactions have also been discussed for molecular reactions postulating concerted reactions via cyclic intermediate complexes, for example

-14-

Empirically, one indeed finds a third-order rate law

$$-\frac{1}{2} \frac{d[\text{NO}]}{dt} = k[\text{NO}]^2[\text{O}_2]. \quad (\text{A3.4.58})$$

However, the postulated trimolecular mechanism is highly questionable. The third-order rate law would also be consistent with mechanisms arising from consecutive bimolecular elementary reactions, such as

or

In fact, the bimolecular mechanisms are generally more likely. Even the atom recombination reactions sometimes follow a mechanism consisting of a sequence of bimolecular reactions

This so-called complex mechanism has occasionally been proven to apply [25, 26].

A3.4.5 THEORY OF ELEMENTARY GAS-PHASE REACTIONS

A3.4.5.1 GENERAL THEORY

The foundations of the modern theory of elementary gas-phase reactions lie in the time-dependent molecular quantum dynamics and molecular scattering theory, which provides the link between time-dependent quantum dynamics and chemical kinetics (see also [chapter A3.11](#)). A brief outline of the steps in the development is as follows [27].

We start from the time-dependent Schrödinger equation for the state function (wave function $\Psi(t)$) of the reactive molecular system with Hamiltonian operator \hat{H} :

$$i\hbar \frac{\partial \Psi(t)}{\partial t} = \hat{H} \Psi(t). \quad (\text{A3.4.65})$$

Its solution can be written in terms of the time evolution operator \hat{U}

$$\Psi(t) = \hat{U}(t, t_0) \Psi(t_0) \quad (\text{A3.4.66})$$

which satisfies a similar differential equation

$$i\hbar \frac{\partial \hat{U}}{\partial t} = \hat{H} \hat{U}. \quad (\text{A3.4.67})$$

For time-independent Hamiltonians we have

$$\hat{U}(t, t_0) = \exp[-i\hat{H}(t - t_0)/\hbar]. \quad (\text{A3.4.68})$$

For strictly monomolecular processes the general theory would now proceed by analysing the time-dependent

wavefunction as a function of space (and perhaps spin) coordinates $\{q_i\}$ of the particles in terms of time-dependent probability densities.

$$P(\{q_i\}, t) = |\Psi(\{q_i\}, t)|^2 \quad (\text{A3.4.69})$$

which are integrated over appropriate regions of coordinate space assigned to reactants and products. These time-dependent probabilities can be associated with time-dependent concentrations, reaction rates and, if applicable, rate coefficients.

-16-

For thermal unimolecular reactions with bimolecular collisional activation steps and for bimolecular reactions, more specifically one takes the limit of the time evolution operator for $t_0 \rightarrow -\infty$ and $t \rightarrow +\infty$ to describe isolated binary collision events. The corresponding matrix representation of \hat{U} is called the scattering matrix or S-matrix with matrix elements

$$S_{fi} = U_{fi}(t \rightarrow +\infty, t_0 \rightarrow -\infty). \quad (\text{A3.4.70})$$

The physical interpretation of the scattering matrix elements is best understood in terms of its square modulus

$$P_{fi} = |S_{fi}|^2 \quad (\text{A3.4.71})$$

which is the transition probability between an initial fully specified quantum state $|i\rangle$ before the collision and a final quantum state $|f\rangle$ after the collision.

In a third step the S-matrix is related to state-selected reaction cross sections σ_{fi} , in principle observable in beam scattering experiments [28, 29, 30, 31, 32, 33, 34 and 35], by the fundamental equation of scattering theory

$$\sigma_{fi} = \frac{\pi}{k_i^2} |\delta_{fi} - S_{fi}|^2. \quad (\text{A3.4.72})$$

Here $\delta_{fi} = 1(0)$ is the Kronecker delta for $f=i$ ($f \neq i$) and k_i is the wavenumber for the collision, related to the initial relative centre of mass translational energy $E_{t,i}$ before the collision

$$k_i = \hbar^{-1} \sqrt{2\mu E_{t,i}} \quad (\text{A3.4.73})$$

with reduced mass μ for the collision partners of mass m_A and m_B :

$$\mu = \frac{m_A m_B}{m_A + m_B}. \quad (\text{A3.4.74})$$

Actually equation (A3.4.72) for σ_{fi} is still formal, as practically observable cross sections, even at the highest quantum state resolution usually available in molecular scattering, correspond to certain sums and averages of

the individual σ_{fi} . We use capital indices for such coarse-grained state-selected cross sections

$$\sigma_{FI} = \langle \sigma_{fi} \rangle. \quad (\text{A3.4.75})$$

-17-

In a fourth step the cross section is related to a state-selected specific bimolecular rate coefficient

$$k_{FI}(E_I) = \sigma_{FI}(E_{t,I}) \sqrt{2E_{t,I}/\mu}. \quad (\text{A3.4.76})$$

This rate coefficient can be averaged in a fifth step over a translational energy distribution $P(E_I)$ appropriate for the bulk experiment. In principle, any distribution $P(E_I)$ as applicable in the experiment can be introduced at this point. If this distribution is a thermal Maxwell–Boltzmann distribution one obtains a partially state-selected thermal rate coefficient

$$k_{FI}(T) = \left(\frac{8k_{\text{B}}T}{\pi\mu} \right)^{1/2} \int_0^\infty \left(\frac{E_{t,I}}{k_{\text{B}}T} \right) \sigma_{FI}(E_{t,I}) \exp \left\{ -\frac{E_{t,I}}{k_{\text{B}}T} \right\} \left(\frac{dE_{t,I}}{k_{\text{B}}T} \right). \quad (\text{A3.4.77})$$

In a final, sixth step one may also average (sum) over a thermal (or other) quantum state distribution I (and F) and obtain the usual thermal rate coefficient

$$k(T) = \langle k_{FI}(T) \rangle. \quad (\text{A3.4.78})$$

[Figure A3.4.4](#) summarizes these steps in one scheme. Different theories of elementary reactions represent different degrees of approximations to certain averages, which are observed in experiments.

There are two different aspects to these approximations. One consists in the approximate treatment of the underlying many-body quantum dynamics; the other, in the statistical approach to observable average quantities. An exhaustive discussion of different approaches would go beyond the scope of this introduction. Some of the most important aspects are discussed in separate chapters (see [chapter A3.7](#), [chapter A3.11](#), [chapter A3.12](#), [chapter A3.13](#)).

Here, we shall concentrate on basic approaches which lie at the foundations of the most widely used models. Simplified collision theories for bimolecular reactions are frequently used for the interpretation of experimental gas-phase kinetic data. The general transition state theory of elementary reactions forms the starting point of many more elaborate versions of quasi-equilibrium theories of chemical reaction kinetics [[27](#), [36](#), [37](#) and [38](#)].

-18-

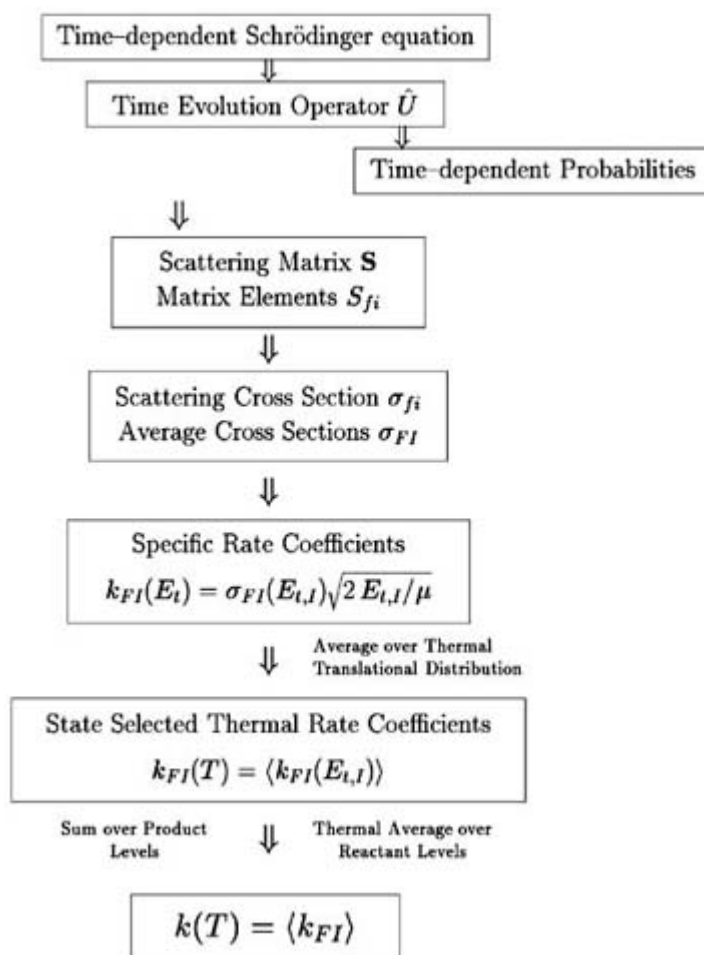

Figure A3.4.4. Steps in the general theory of chemical reactions.

In practice, one of the most important aspects of interpreting experimental kinetic data in terms of model parameters concerns the temperature dependence of rate constants. It can often be described phenomenologically by the Arrhenius equation [39, 40 and 41]

$$k(T) = A(T) \exp\{-E_A(T)/RT\} \quad (\text{A3.4.79})$$

where the *pre-exponential Arrhenius factor* A and the *Arrhenius activation energy* E_A generally depend on the temperature. R is the gas constant. This leads to the *definition* of the Arrhenius parameters:

$$E_A(T) \stackrel{\text{def}}{=} RT^2 \frac{d \ln(k(T))}{dT} \quad (\text{A3.4.80})$$

-19-

$$A(T) \stackrel{\text{def}}{=} k(T) \exp\left\{\frac{E_A(T)}{RT}\right\}. \quad (\text{A3.4.81})$$

The usefulness of these definitions is related to the usually weak temperature dependence of E_A and A . In the simplest models they are constant, whereas $k(T)$ shows a very strong temperature dependence.

A3.4.5.2 SIMPLE COLLISION THEORIES OF BIMOLECULAR REACTIONS

A bimolecular reaction can be regarded as a reactive collision with a reaction cross section σ that depends on the relative translational energy E_t of the reactant molecules A and B (masses m_A and m_B). The *specific rate constant* $k(E_t)$ can thus formally be written in terms of an effective reaction cross section σ , multiplied by the relative centre of mass velocity v_{rel}

$$k(E_t) = \sigma(E_t)v_{\text{rel}} = \sigma(E_t)\sqrt{2E_t/\mu}. \quad (\text{A3.4.82})$$

Simple collision theories neglect the internal quantum state dependence of σ . The rate constant as a function of temperature T results as a thermal average over the Maxwell–Boltzmann velocity distribution $p(E_t)$:

$$k(T) = \int_0^\infty p(E_t)k(E_t) dE_t = \langle v_{\text{rel}} \rangle \langle \sigma \rangle. \quad (\text{A3.4.83})$$

Here one has the thermal average centre of mass velocity

$$\langle v_{\text{rel}} \rangle = \sqrt{\frac{8k_B T}{\pi \mu}} \quad (\text{A3.4.84})$$

and the thermally averaged reaction cross section

$$\langle \sigma \rangle \stackrel{\text{def}}{=} \int_0^\infty \left(\frac{E_t}{k_B T} \right) \sigma(E_t) \exp \left\{ -\frac{E_t}{k_B T} \right\} \left(\frac{dE_t}{k_B T} \right). \quad (\text{A3.4.85})$$

We use the symbol k_B for Boltzmann's constant to distinguish it from the rate constant k . Equation (A3.4.85) defines the thermal average reaction cross section $\langle \sigma \rangle$.

In principle, the reaction cross section not only depends on the relative translational energy, but also on individual reactant and product quantum states. Its sole dependence on E_t in the simplified effective expression (equation (A3.4.82)) already implies unspecified averages over reactant states and sums over product states. For practical purposes it is therefore appropriate to consider simplified models for the energy dependence of the effective reaction cross section. They often form the basis for the interpretation of the temperature dependence of thermal cross sections. Figure A3.4.5 illustrates several cross section models.

Figure A3.4.5. Simple models for effective collision cross sections σ : hard sphere without threshold (dotted line) hard sphere with threshold (dashed line) and hyperbolic threshold (full curve). E_t is the (translational) collision energy and E_0 is the threshold energy. σ_0 is the hard sphere collision cross section. The dashed--dotted curve is of the generalized type $\sigma_R(E_t > E_0) = \sigma_0 (1 - E_0/E_t) \exp[(1 - E_t/E_0)/(aE_0)]$ with the parameter $a = 3 E_0$.

(A) HARD SPHERE COLLISIONS

The reactants are considered as hard spheres with radii r_A and r_B , respectively. A (reactive) collision occurs on contact yielding a constant cross section σ_0 independent of the energy:

$$\sigma_0 = \pi(r_A + r_B)^2 \quad (\text{A3.4.86})$$

$$k(T) = \sigma_0 \sqrt{\frac{8k_B T}{\pi \mu}} \quad (\text{A3.4.87})$$

(B) CONSTANT CROSS SECTION WITH A THRESHOLD

The reaction can only occur once the collision energy reaches at least a value E_0 . The reaction cross section remains constant above this threshold:

$$\sigma = \begin{cases} 0 & \text{for } E_t < E_0 \\ \sigma_0 & \text{for } E_t \geq E_0 \end{cases} \quad (\text{A3.4.88})$$

$$k(T) = \sigma_0 \sqrt{\frac{8k_B T}{\pi \mu}} \left(1 + \frac{E_0}{k_B T}\right) \exp\left\{-\frac{E_0}{k_B T}\right\}. \quad (\text{A3.4.89})$$

(C) CROSS SECTION WITH A HYPERBOLIC THRESHOLD

Again, the reaction requires a minimum collision energy E_0 , but increases only gradually above the threshold towards a finite, high-energy limit σ_0 :

$$\sigma = \begin{cases} 0 & \text{for } E_t < E_0 \\ \sigma_0 \left(1 - \frac{E_0}{E_t}\right) & \text{for } E_t \geq E_0 \end{cases} \quad (\text{A3.4.90})$$

$$k(T) = \sigma_0 \sqrt{\frac{8k_B T}{\pi \mu}} \exp\left\{-\frac{E_0}{k_B T}\right\}. \quad (\text{A3.4.91})$$

(D) GENERALIZED COLLISION MODEL

The hyperbolic cross section model can be generalized further by introducing a function $f(\Delta E)$ ($\Delta E = E_t - E_0$) to describe the reaction cross section above a threshold:

$$\sigma = \begin{cases} 0 & \text{for } E_t < E_0 \\ \sigma_0 \left(1 - \frac{E_0}{E_t}\right) f(\Delta E) & \text{for } E_t \geq E_0 \end{cases} \quad (\text{A3.4.92})$$

$$k(T) = \sigma_0 \sqrt{\frac{8k_B T}{\pi \mu}} g(T) \exp\left\{-\frac{E_0}{k_B T}\right\} \quad (\text{A3.4.93})$$

$$g(T) = \int_0^\infty \frac{\Delta E}{k_B T} f(\Delta E) \exp\left\{-\frac{\Delta E}{k_B T}\right\} d\left(\frac{\Delta E}{k_B T}\right). \quad (\text{A3.4.94})$$

A3.4.6 TRANSITION STATE THEORY

Transition state theory or ‘activated complex theory’ has been one of the most fruitful approximations in reaction kinetics and has had a long and complex history [42, 43 and 44]. Transition state theory is originally based on the idea that reactant molecules have to pass a bottleneck to reach the product side and that they stay in quasi-equilibrium on the reactant side until this bottleneck is reached. The progress of a chemical reaction can often be described by the motion along a *reaction path* in the multidimensional molecular configuration space. Figure A3.4.6 shows typical potential energy profiles along such paths for uni- and bimolecular reactions. The effective potential energy $V(r_q)$ includes the zero point energy due to the motion orthogonal to the reaction coordinate r_q . The bottleneck is located at r_q^\ddagger , usually coinciding with an effective potential barrier, i.e. a first-order saddle point of the multidimensional potential hypersurface. Its height with respect to the reactants’ zero point level is E_0 . In its canonical form the transition state theory assumes a thermal

equilibrium between the reactant molecules A and molecules X moving in some infinitesimal range δ over the barrier towards the product side. For the unimolecular case this yields the equilibrium concentration:

$$[X] = \frac{q_X}{q_A} \exp\{-E_0/k_B T\}[A] \quad (\text{A3.4.95})$$

$$q_X = \frac{1}{2} q^\ddagger \delta \sqrt{2\pi\mu k_B T/h^2} \quad (\text{A3.4.96})$$

where h is Planck's constant. q stands for molecular partition functions referred to the corresponding zero point level. Thus q_A is the partition function for the reactant A. q^\ddagger is the restricted partition function for fixed reaction coordinate $r = r^\ddagger$ referring to the top of the effective (i.e. zero point corrected) barrier. It is often called the 'partition function of the transition state' bearing in mind that—in contrast to the X molecules—it does not correspond to any observable species. Rather, it defines the meaning of the purely technical term 'transition state'. Classically it corresponds to a $(3N - 7)$ -dimensional hypersurface in the $(3N - 6)$ -dimensional internal coordinate space of an N atomic system. The remainder of (A3.4.96) derives from the classical partition function for the motion in a one-dimensional box of length δ with an associated reduced mass μ . The factor of one half accounts for the fact that, in equilibrium, only half of the molecules located within $r^\ddagger \pm \delta/2$ move towards the product side.

-23-

Figure A3.4.6. Potential energy along the reaction coordinate r_q for an unimolecular isomerization (left) and a bimolecular reaction (right). r_q^\ddagger is the location of the transition state at the saddle point. $[X]$ is the concentration of molecules located within δ of r_q^\ddagger moving from the reactant side to the product side (indicated by the arrow, which is omitted in the text).

Assuming a thermal one-dimensional velocity (Maxwell–Boltzmann) distribution with average velocity $\sqrt{2k_B T/\pi\mu}$ the reaction rate is given by the equilibrium flux if (1) the flux from the product side is neglected and (2) the thermal equilibrium is retained throughout the reaction:

$$-\frac{d[A]}{dt} = [X] \frac{\sqrt{2k_B T/\pi\mu}}{\delta} \quad (\text{A3.4.97})$$

Combining [equation \(A3.4.95\)](#), [equation \(A3.4.96\)](#) and [equation \(A3.4.97\)](#) one obtains the *first Eyring equation* for unimolecular rate constants:

$$k_{\text{uni}}(T) = \frac{k_{\text{B}}T}{h} \frac{q^{\ddagger}}{q_{\text{A}}} \exp\{-E_0/k_{\text{B}}T\}. \quad (\text{A3.4.98})$$

A completely analogous derivation leads to the rate coefficient for bimolecular reactions, where \tilde{q} are partition functions *per unit volume*:

$$k_{\text{bi}}(T) = \frac{k_{\text{B}}T}{h} \frac{\tilde{q}^{\ddagger}}{\tilde{q}_{\text{A}}\tilde{q}_{\text{B}}} \exp\{-E_0/k_{\text{B}}T\}. \quad (\text{A3.4.99})$$

In the high barrier limit, $E_0 \gg k_{\text{B}}T$, E_0 is approximately equal to the Arrhenius activation energy. The ratio of the partition functions is sometimes called the ‘statistical’ or ‘entropic’ factor. Its product with the ‘universal frequency factor’ $k_{\text{B}}T/h$ corresponds approximately to Arrhenius’ pre-exponential factor $A(T)$.

-24-

The quasi-equilibrium assumption in the above canonical form of the transition state theory usually gives an upper bound to the real rate constant. This is sometimes corrected for by multiplying [\(A3.4.98\)](#) and [\(A3.4.99\)](#) with a *transmission coefficient* $0 \leq \kappa \leq 1$.

In a *formal* analogy to the expressions for the thermodynamical quantities one can now *define* the standard *enthalpy* $\Delta^{\ddagger} H^{\ominus}$ and *entropy* $\Delta^{\ddagger} S^{\ominus}$ of activation. This leads to the *second Eyring equation*:

$$k(T) = \frac{k_{\text{B}}T}{h} \exp\{\Delta^{\ddagger} S^{\ominus}/R\} \exp\{-\Delta^{\ddagger} H^{\ominus}/RT\} \left(\frac{k_{\text{B}}T}{p^{\ominus}}\right)^j \quad (\text{A3.4.100})$$

where p^{\ominus} is the standard pressure of the ideal gas ($j=0$ for unimolecular and $j=1$ for bimolecular reactions). As a definition [\(A3.4.100\)](#) is strictly identical to [\(A3.4.98\)](#) and [\(A3.4.99\)](#) if considered as a theoretical equation. Since neither $\Delta^{\ddagger} S^{\ominus}$ nor $\Delta^{\ddagger} H^{\ominus}$ are connected to observable species, [equation \(A3.4.100\)](#) may also be taken as an empirical equation, *viz.* an alternative representation of Arrhenius’ equation ([equation \(A3.4.79\)](#)). In the field of thermochemical kinetics [43] one tries, however, to estimate $\Delta^{\ddagger} H^{\ominus}$ and $\Delta^{\ddagger} S^{\ominus}$ on the basis of molecular properties.

There is an immediate connection to the collision theory of bimolecular reactions. Introducing internal partition functions q_{int} , excluding the (separable) degrees of freedom for overall translation,

$$q = q_{\text{int}}q_{\text{trans}} \quad (\text{A3.4.101})$$

with

$$(\text{A3.4.102})$$

$$q_{\text{trans}} = V \left(\frac{2\pi M k_B T}{h^2} \right)^{3/2}$$

and comparing with [equation \(A3.4.83\)](#) the transition state theory expression for the effective thermal cross section of reaction becomes

$$\langle \sigma \rangle = \frac{h^2}{8\pi \mu_{AB} k_B T} \frac{q_{\text{int}}^\ddagger}{q_{\text{int},A} q_{\text{int},B}} \exp\{-E_0/k_B T\} \quad (\text{A3.4.103})$$

where V is the volume, $M = m_A + m_B$ is the total mass, and μ_{AB} is the reduced mass for the relative translation of A and B. One may interpret [equation \(A3.4.103\)](#) as the transition state version of the collision theory of bimolecular reactions: Transition state theory is used to calculate the thermally averaged reaction cross section to be inserted into [equation \(A3.4.83\)](#).

A3.4.7 STATISTICAL THEORIES BEYOND CANONICAL TRANSITION STATE THEORY

Transition state theory may be embedded in the more general framework of statistical theories of chemical reactions, as summarized in [figure A3.4.7](#) [27, 36]. Such theories have aimed at going beyond canonical transition state theory in several ways. The first extension concerns reaction systems with potential energy schemes depicted in [figure A3.4.8](#) (in analogy to [figure A3.4.6](#)), where one cannot identify a saddle point on the potential hypersurface to be related to a transition state. The left-hand diagram corresponds to a complex forming bimolecular reaction, and the right-hand to a direct barrierless bimolecular reaction. The individual sections (the left- and right-hand parts) of the left diagram correspond to the two unimolecular dissociation channels for the intermediate characterized by the potential minimum. These unimolecular dissociation channels correspond to simple bond fissions. The general types of reactions shown in [figure A3.4.8](#) are quite abundant in gas kinetics. Most ion molecule reactions as well as many radical-radical reactions are of this type. Thus, most of the very fast reactions in interstellar chemistry, atmospheric and combustion chemistry belong to this class of reaction, where standard canonical transition state theory cannot be applied and extension is clearly necessary. A second extension of interest would apply the fundamental ideas of transition state theory to state-selected reaction cross sections (see [section A3.4.5.1](#)). This theoretical program is carried out in the framework of phase space theory [45, 46] and of the statistical adiabatic channel model [27, 47], the latter being more general and containing phase space theory as a special case. In essence, the statistical adiabatic channel model is a completely state-selected version of the transition state theory. Here, the starting point is the \mathbf{S} -matrix element ([equation \(A3.4.104\)](#)), which in the statistical limit takes the statistically averaged form

$$\langle |S_{fi}|^2 \rangle_{F,I,\Delta E} = \begin{cases} W(E, J)^{-1} & \text{for strongly coupled channels} \\ \delta_{f,i} & \text{for weakly coupled channels} \end{cases} \quad (\text{A3.4.104})$$

where $W(E, J)$ is the total number of adiabatically open reaction channels for a given total angular momentum quantum number J (or any other good quantum number). $\langle \rangle_{F, I, \Delta E}$ refers to the averaging over groups of final and initial states ('coarse graining') and over suitably chosen collision energy intervals ΔE . Following the

lines of the general theory of reaction cross sections, [section A3.4.5.1](#), and starting from equation (A3.4.104) one can derive all the relevant kinetic specific reaction cross sections, specific rate constants and lifetimes in unimolecular reactions and the thermal rate constants analogous to transition state theory.

-26-

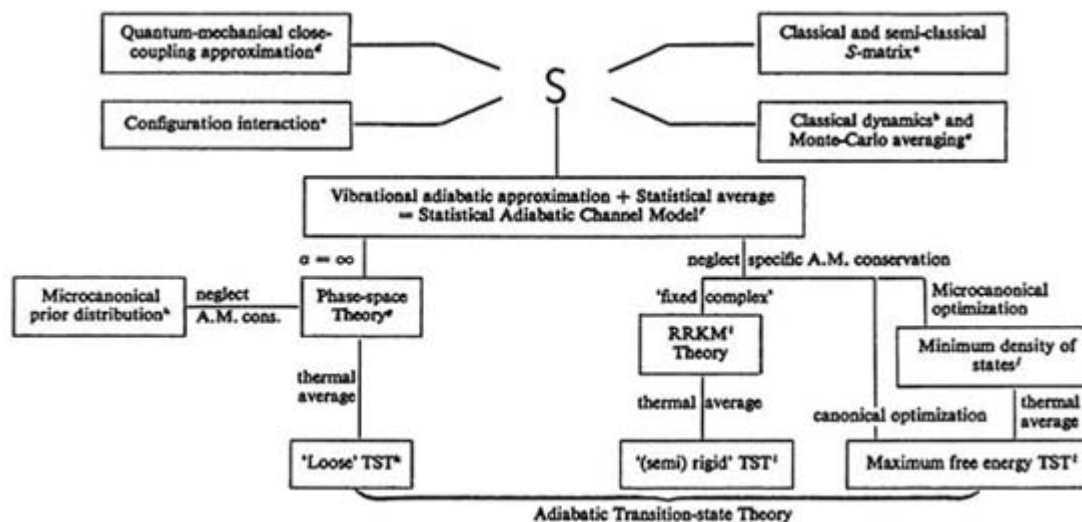

Figure A3.4.7. Summary of statistical theories of gas kinetics with emphasis on complex forming reactions (in the figure A.M. is the angular momentum, after Quack and Troe [27, 36, 74]). The indices refer to the following references: (a) [75, 76 and 77]; (b) [78]; (c) [79, 80 and 81]; (d) [82, 83, 84 and 85]; (e) [86, 87 and 88]; (f) [36, 37, 47, 89 and 90]; (g) [45, 46, 91]; (h) [92, 93, 94 and 95]; (i) [96, 97, 98, 99, 100, 101, 102, 103, 104 and 105]; (j) [106, 107, 108 and 109]; (k) [88, 94, 98, 99]; and (l) [94, 106, 107, 108, 109, 110, 111, 112].

Figure A3.4.8. Potential energy profiles for reactions without barrier. Complex forming bimolecular reaction (left) and direct barrierless bimolecular reaction (right).

We summarize here only the main results of the theory and refer to a recent review [27] for details. The total number of adiabatically open channels is computed by searching for channel potential maxima $V_{a,\max}$. The channel potentials $V_a(r_q)$ are obtained by following the quantum energy levels of the reaction system along the reaction path r_q . An individual adiabatic channel connects an asymptotic scattering channel (corresponding to a reactant or to a product quantum level) with the reaction complex. One has the total number of open channels as a function of energy E , angular momentum J and other good quantum numbers:

$$W(E, J, \dots) = \sum_{a(J\dots)} h(E - V_{a,\max}). \quad (\text{A3.4.105})$$

Here $h(x)$ is the Heaviside step function with $h(x > 0) = 1$ and $h(x \geq 0) = 0$ (not to be confused with Planck's constant). The limit $a(J \dots)$ indicates that the summation is restricted to channel potentials with a given set of good quantum numbers ($J \dots$).

A state-to-state integral reaction cross section from reactant level a to product level b takes the form

$$\sigma_{ba} = \frac{\pi}{g_a k_a^2} \sum_{J=0}^{\infty} (2J+1) \frac{W(E, J, a)W(E, J, b)}{W(E, J)}. \quad (\text{A3.4.106})$$

Here the levels consist of several states. g_a is the reactant level degeneracy and k_a is the collision wavenumber (see [equation \(A3.4.73\)](#)).

A specific unimolecular rate constant for the decay of a highly excited molecule at energy E and angular momentum J takes the form

$$k(E, J, \dots) = \gamma \frac{W(E, J, \dots)}{h\rho(E, J, \dots)} \quad (\text{A3.4.107})$$

where γ is a dimensionless transmission coefficient (usually $0 \leq \gamma \leq 1$) and $\rho(E, J, \dots)$ is the density of molecular states. These expressions are relevant in the theory of thermal and non-thermal unimolecular reactions and are generalizations of the Rice–Ramsperger–Kassel–Marcus (RRKM) theory (see [chapter A3.12](#)).

Finally, the generalization of the partition function q^\ddagger in transition state theory ([equation \(A3.4.96\)](#)) is given by

$$Q_{\text{int}}^* = \sum_a \exp(-V_{a,\text{max}}/k_B T) = \int_0^\infty W(E) \exp(-E/k_B T) \left(\frac{dE}{k_B T} \right) \quad (\text{A3.4.108})$$

with the total number of open channels

$$W(E) = \sum_a \sum_{J=0}^{\infty} (2J+1)W(E, J, a). \quad (\text{A3.4.109})$$

These equations lead to forms for the thermal rate constants that are perfectly similar to transition state theory, although the computations of the partition functions are different in detail. As described in [figure A3.4.7](#) various levels of the theory can be derived by successive approximations in this general state-selected form of the transition state theory in the framework of the statistical adiabatic channel model. We refer to the literature cited in the diagram for details.

It may be useful to mention here one currently widely applied approximation for barrierless reactions, which is now frequently called microcanonical and canonical variational transition state theory (equivalent to the ‘minimum density of states’ and ‘maximum free energy’ transition state theory in [figure A3.4.7](#) . This type of theory can be understood by considering the partition functions $Q(r_q)$ as functions of r_q similar to [equation \(A3.4.108\)](#) but with $V_a(r_q)$ instead of $V_{a,\max}$. Obviously $Q(r_q) \geq Q^*$ so that the best possible choice for a transition state results from minimizing the partition function along the reaction coordinate r_q :

$$Q^\ddagger(T) = \min_{r_q} Q(r_q, T) = Q(r_q^\ddagger, T). \quad (\text{A3.4.110})$$

Equation (A3.4.110) represents the canonical form ($T = \text{constant}$) of the ‘variational’ theory. Minimization at constant energy yields the analogous microcanonical version. It is clear that, in general, this is only an approximation to the general theory, although this point has sometimes been overlooked. One may also define a free energy

$$A(r_q) = -k_B T \ln Q(r_q) \quad (\text{A3.4.111})$$

which leads to a maximum free energy condition

$$A^\ddagger(T) = \max_{r_q} A(r_q, T) = A(r_q^\ddagger, T). \quad (\text{A3.4.112})$$

The free energy as a function of reaction coordinates has been explicitly represented by Quack and Troe [[36, 112](#)] for the reaction

but the general concept goes back to Eyring (see [[27, 36](#)]).

A3.4.8 GAS-PHASE REACTION MECHANISMS

The kinetics of a system of elementary reactions forming a reaction mechanism are described by a system of coupled differential equations. Disregarding transport processes there is one differential equation for each species involved. Few examples for these systems of coupled differential equations can be solved exactly in closed form. The accurate solution more generally requires integration by numerical methods. In the simplest case of reversible elementary reactions the stoichiometry is sufficient to decouple the differential equations leading to simple rate laws. For more complicated compound reaction mechanisms this can only be achieved with more or less far reaching approximations, usually concerning reactive intermediates. The most important are *quasi-equilibrium* (or partial equilibrium) and the *quasi-stationarity* (or quasi-steady-state), whose practical importance goes far beyond gas-phase kinetics.

A3.4.8.1 ELEMENTARY REACTIONS WITH BACK-REACTION

The simplest possible gas-phase reaction mechanisms consist of an elementary reaction and its back reaction.

Here we consider uni- and bimolecular reactions yielding three different combinations. The resulting rate laws can all be integrated in closed form.

(A) UNIMOLECULAR REACTIONS WITH UNIMOLECULAR BACK REACTION

The equation

is the elementary mechanism of reversible isomerization reactions, for example

The rate law is given by

$$-\frac{dc_A}{dt} = k_1 c_A - k_{-1} c_C. \quad (\text{A3.4.115})$$

Exploiting the stoichiometric equation one can eliminate c_C . Integration yields the simple relaxation of the initial concentrations into the equilibrium, $c_A^{\text{eq}} = (c_A(\infty))$, with a relaxation time τ :

$$c_A(t) - c_A^{\text{eq}} = (c_A(t) - c_A^{\text{eq}}) \exp\{-t/\tau\} \quad (\text{A3.4.116})$$

$$\tau = \frac{1}{k_1 + k_{-1}}. \quad (\text{A3.4.117})$$

(B) BIMOLECULAR REACTIONS WITH UNIMOLECULAR BACK REACTION

For example

The rate law is given by

$$-\frac{1}{2} \frac{dc_A}{dt} = k_2 c_A^2 - k_{-1} c_{A_2}. \quad (\text{A3.4.118})$$

After transformation to the turnover variable $x = (c_A(0) - c_A(t))/2 = c_{A_2}(t) - c_{A_2}(0)$, integration yields

$$\ln\left(\frac{x+x_e-c_A(0)-K/4}{x-x_e}\right) - \ln\left(\frac{c_A(0)+K/4-x_e}{x_e}\right) = k_2(4c_A(0)+K-8x_e)t \quad (\text{A3.4.119})$$

$$x_e = \frac{c_A(0)}{2} + \frac{K}{8} - \left(\frac{K}{4}\left(c_{A_2}(0) + \frac{c_A(0)}{2}\right) + \left(\frac{K}{8}\right)^2\right)^{1/2} \quad (\text{A3.4.120})$$

where $K = k_2/k_{-1}$ is the equilibrium constant.

(C) BIMOLECULAR REACTIONS WITH BIMOLECULAR BACK-REACTION

For example

The rate law is given by

$$-\frac{dc_A}{dt} = k_2c_Ac_B - k_{-2}c_Cc_D \quad (\text{A3.4.121})$$

After transformation to the turnover variable $x = c_A(0) - c_A(t)$, integration yields

$$\ln\left(\frac{1 - [x/(a+b)]}{1 - [x/(a-b)]}\right) = 2k_2(1 - K^{-1})bt \quad (\text{A3.4.122})$$

$$a = \frac{c_A(0) + c_B(0) + K^{-1}[c_C(0) + c_D(0)]}{2(1 - K^{-1})} \quad (\text{A3.4.123})$$

$$b = \left(a^2 - \frac{c_A(0)c_B(0) - K^{-1}c_C(0)c_D(0)}{1 - K^{-1}}\right)^{1/2} \quad (\text{A3.4.124})$$

where $K = k_2/k_{-2}$ is the equilibrium constant.

Bimolecular steps involving identical species yield correspondingly simpler expressions.

A3.4.8.2 THE LINDEMANN-HINSHELWOOD MECHANISM FOR UNIMOLECULAR REACTIONS

The system of coupled differential equations that result from a compound reaction mechanism consists of several different (reversible) elementary steps. The kinetics are described by a system of coupled differential equations rather than a single rate law. This system can sometimes be decoupled by assuming that the concentrations of the intermediate species are small and quasi-stationary. The *Lindemann mechanism of thermal unimolecular reactions* [18, 19] affords an instructive example for the application of such approximations. This mechanism is based on the idea that a molecule A has to pick up sufficient energy

before it can undergo a monomolecular reaction, for example, bond breaking or isomerization. In thermal reactions this energy is provided by collisions with other molecules M in the gas to produce excited species A*:

Two important points must be noted here.

- (1) The collision partners may be any molecule present in the reaction mixture, i.e., inert bath gas molecules, but also reactant or product species. The activation (k_a) and deactivation (k_d) rate constants in equation (A3.4.125) therefore represent the effective average rate constants.
- (1) The collision (k_a, k_d) and reaction (k_r) efficiencies may significantly differ between different excited reactant states. This is essentially neglected in the Lindemann–Hinshelwood mechanism. In particular, the *strong collision* assumption implies that so much energy is transferred in a collision that the collision efficiency can be regarded as effectively independent of the energy.

With $k_1 = k_a[M]$ and $k_{-1} = k_d[M]$ the resulting system of differential equations is

$$-\frac{d[A]}{dt} = k_1[A] - k_{-1}[A^*] \quad (\text{A3.4.127})$$

$$-\frac{d[A^*]}{dt} = -k_1[A] + k_r[A^*] + k_{-1}[A^*] \quad (\text{A3.4.128})$$

$$\frac{d[\text{products}]}{dt} = k_r[A^*]. \quad (\text{A3.4.129})$$

If the excitation energy required to form activated species A* is much larger than $k_B T$ its concentration will remain small. This is fulfilled if $k_a \ll k_d$. Following Bodenstein, [A*] is then assumed to be quasi-stationary, i.e. after some initialization phase the concentration of activated species remains approximately constant (strictly speaking the ratio [A*]/[A] remains approximately constant (see [section A3.4.8.3](#))):

$$-\frac{d[A^*]}{dt} \approx 0 \quad (\text{A3.4.130})$$

$$\Rightarrow [A^*]_{\text{QS}} = \frac{k_1[A]}{k_{-1} + k_r} \quad (\text{A3.4.131})$$

This yields the quasi-stationary reaction rate with an effective unimolecular rate constant

$$v_c = \frac{d[\text{products}]}{dt} = k_{\text{eff}}[A] = k_r[A^*]_{\text{QS}} \quad (\text{A3.4.132})$$

$$k_{\text{eff}} = \frac{k_1 k_r}{k_{-1} + k_r} = \frac{k_a[M]k_r}{k_d[M] + k_r}. \quad (\text{A3.4.133})$$

The effective rate law correctly describes the pressure dependence of unimolecular reaction rates at least qualitatively. This is illustrated in [figure A3.4.9](#). In the limit of high pressures, i.e. large $[M]$, k_{eff} becomes independent of $[M]$ yielding the high-pressure rate constant k_{∞} of an effective first-order rate law. At very low pressures, product formation becomes much faster than deactivation. k_{eff} now depends linearly on $[M]$. This corresponds to an effective second-order rate law with the pseudo first-order rate constant k_0 :

$$k_{\infty} = \frac{k_a}{k_d} k_r \quad (\text{A3.4.134})$$

$$k_0 = k_a[M]. \quad (\text{A3.4.135})$$

In addition to $[A^*]$ being quasi-stationary the *quasi-equilibrium* approximation assumes a virtually unperturbed equilibrium between activation and deactivation ([equation \(A3.4.125\)](#)):

$$\frac{[A^*]}{[A]} = \frac{k_a}{k_d}. \quad (\text{A3.4.136})$$

-33-

This approximation is generally valid if $k_r \ll k_{-1}$. For the Lindemann mechanism of unimolecular reactions this corresponds to the high-pressure limit $k_{\text{eff}} = k_{\infty}$.

Figure A3.4.9. Pressure dependence of the effective unimolecular rate constant. Schematic fall-off curve for the Lindemann–Hinshelwood mechanism. k_{∞} is the (constant) high-pressure limit of the effective rate constant

k_{eff} and k_0 is the low-pressure limit, which depends linearly on the concentration of the inert collision partner [M].

The approximate results can be compared with the long time limit of the exact stationary state solution derived in section A3.4.8.3:

$$k_{\text{eff}} = \frac{1}{2} \{k_1 + k_{-1} + k_r - [(k_1 + k_{-1} + k_r)^2 - 4k_1k_r]^{1/2}\}. \quad (\text{A3.4.137})$$

This leads to the quasi-stationary rate constant of equation (A3.4.133) if $4k_1k_r \ll (k_1 + k_{-1} + k_r)^2$, which is more general than the Bodenstein condition $k_a \ll k_d$.

A3.4.8.3 GENERALIZED FIRST-ORDER KINETICS

The Lindemann mechanism for thermally activated unimolecular reactions is a simple example of a particular class of compound reaction mechanisms. They are mechanisms whose constituent reactions individually follow first-order rate laws [11, 20, 36, 48, 49, 50, 51, 52, 53, 54, 55 and 56]:

where N is the number of different species involved. With $c_i = [A_i]$ this leads to the following system of N coupled differential equations called *generalized first-order kinetics*:

-34-

$$-\frac{dc_i}{dt} = \sum_{j=1}^N K_{ij}c_j \quad i = 1, \dots, N. \quad (\text{A3.4.139})$$

The individual reactions need not be unimolecular. It can be shown that the relaxation kinetics after small perturbations of the equilibrium can always be reduced to the form of (A3.4.138) in terms of extension variables from equilibrium, even if the underlying reaction system is not of first order [51, 52, 57, 58].

Generalized first-order kinetics have been extensively reviewed in relation to technical chemical applications [59] and have been discussed in the context of copolymerization [53]. From a theoretical point of view, the general class of coupled kinetic equation (A3.4.138) and equation (A3.4.139) is important, because it allows for a general closed-form solution (in matrix form) [49]. Important applications include the Pauli master equation for statistical mechanical systems (in particular gas-phase statistical mechanical kinetics) [48] and the investigation of certain simple reaction systems [49, 50, 55]. It is the basis of the many-level treatment of thermal unimolecular reactions in terms of the appropriate master equations for energy transfer [36, 55, 60, 61, 62 and 63]. Generalized first-order kinetics also form the basis for certain statistical limiting cases of multiphoton induced chemical reactions and laser chemistry [54, 56].

Written in matrix notation, the system of first-order differential equations, (A3.4.139) takes the form

$$-\frac{d\mathbf{c}(t)}{dt} = \mathbf{K}\mathbf{c}(t) \quad (\text{A3.4.140})$$

With time independent matrix \mathbf{K} it has the general solution

$$\mathbf{c}(t) = \exp\{-\mathbf{K}t\}\mathbf{c}(0). \quad (\text{A3.4.141})$$

The exponential function of the matrix can be evaluated through the power series expansion of $\exp()$. \mathbf{c} is the column vector whose elements are the concentrations c_i . The matrix elements of the *rate coefficient matrix* \mathbf{K} are the first-order rate constants K_{ij} . The system is called *closed* if all reactions and back reactions are included. Then \mathbf{K} is of rank $N - 1$ with positive eigenvalues, of which exactly one is zero. It corresponds to the equilibrium state, with concentrations c_i^{eq} determined by the principle of microscopic reversibility:

$$\frac{K_{ij}}{K_{ji}} = \frac{c_i^{\text{eq}}}{c_j^{\text{eq}}}. \quad (\text{A3.4.142})$$

In this case \mathbf{K} is similar to a real symmetric matrix and equation (A3.4.141) can easily be solved by diagonalization of \mathbf{K} .

-35-

If some of the reactions of (A3.4.138) are neglected in (A3.4.139), the system is called open. This generally complicates the solution of (A3.4.141). In particular, the system no longer has a well defined equilibrium. However, as long as the eigenvalues of \mathbf{K} remain positive, the kinetics at long times will be dominated by the smallest eigenvalue. This corresponds to a stationary state solution.

As an example we take again the Lindemann mechanism of unimolecular reactions. The system of differential equations is given by equation (A3.4.127), equation (A3.4.128) and equation (A3.4.129). The rate coefficient matrix is

$$\mathbf{K} = \begin{pmatrix} k_1 & -k_{-1} & \vdots & 0 \\ -k_1 & k_{-1} + k_r & \vdots & 0 \\ \dots & \dots & \dots & \dots \\ 0 & -k_r & & 0 \end{pmatrix}. \quad (\text{A3.4.143})$$

Since the back reaction, products $\rightarrow A^*$, has been neglected this is an open system. Still \mathbf{K} has a trivial zero eigenvalue corresponding to complete reaction, i.e. pure products. Therefore we only need to consider (A3.4.127) and (A3.4.128) and the corresponding (2×2) submatrix indicated in equation (A3.4.143).

The eigenvalues $\lambda_1 < \lambda_2$ of \mathbf{K} are both positive

$$\lambda_{1,2} = \frac{1}{2} \left\{ k_1 + k_{-1} + k_r \pm [(k_1 + k_{-1} + k_r)^2 - 4k_1k_r]^{1/2} \right\} > 0. \quad (\text{A3.4.144})$$

For long times, the smaller eigenvalue λ_1 will dominate (A3.4.141), yielding the stationary solution

$$\begin{pmatrix} c_A(t) \\ c_{A^*}(t) \end{pmatrix} = \exp\{-\lambda_1 t\} \begin{pmatrix} a \\ b \end{pmatrix} \quad (\text{A3.4.145})$$

where a and b are time-independent functions of the initial concentrations. With the condition $\lambda_1 \ll \lambda_2$ one obtains the effective unimolecular rate constant

$$k_{\text{eff}} = -\frac{d \ln(c_A + c_{A^*})}{dt} = \lambda_1 \stackrel{\lambda_1 \ll \lambda_2}{\approx} \frac{k_1 k_r}{k_1 + k_{-1} + k_r}. \quad (\text{A3.4.146})$$

For $k_a \ll k_d$ this is identical to the quasi-stationary result, [equation \(A3.4.133\)](#), although only the ratio $[A^*]/[A] = b/a$ ([equation \(A3.4.145\)](#)) is stationary and not $[A^*]$ itself. This suggests $d[A^*]/dt \ll d[A]/dt$ as a more appropriate formulation of quasi-stationarity. Furthermore, the general stationary state solution ([equation \(A3.4.144\)](#)) for the Lindemann mechanism contains cases that are not usually retained in the Bodenstein quasi-steady-state solution.

An important example for the application of general first-order kinetics in gas-phase reactions is the master equation treatment of the fall-off range of thermal unimolecular reactions to describe non-equilibrium effects in the weak collision limit when activation and deactivation cross sections ([equation \(A3.4.125\)](#)) are to be retained in detail [[60](#)].

General first-order kinetics also play an important role for the so-called *local eigenvalue analysis* of more complicated reaction mechanisms, which are usually described by nonlinear systems of differential equations. Linearization leads to effective general first-order kinetics whose analysis reveals information on the time scales of chemical reactions, species in steady states (quasi-stationarity), or partial equilibria (quasi-equilibrium) [[64](#), [65](#) and [66](#)].

A3.4.8.4 GENERAL COMPOUND REACTION MECHANISMS

More general compound reaction mechanisms lead to systems of differential equations of different orders. They can sometimes be treated by applying a quasi-stationarity or a quasi-equilibrium approximation. Often, this may even work for simple chain reactions. Chain reactions generally consist of four types of reaction steps: In the *chain initiation* steps, reactive species (radicals) are produced from stable species (reactants or catalysts). They react with stable species to form other reactive species in the *chain propagation*. Reactive species recovered in the chain propagation steps are called *chain carriers*. Propagation steps where one reactive species is replaced by another less-reactive species are sometimes termed *inhibiting*. *Chain branching* occurs if more than one reactive species are formed. Finally, the chain is *terminated* by reactions of reactive species, which yield stable species, for example through recombination in the gas phase or at the surface of the reaction vessel.

The assumption of quasi-stationarity can sometimes be justified if there is no significant chain branching, for example in HBr formation at 200–300°C:

Chain carriers are indicated by an asterisk. Assuming quasi-stationarity for $[\text{H}^*]$ and $[\text{Br}^*]$ and neglecting (6) and (7) (because $[\text{H}^*] \ll [\text{Br}^*]$) yields

$$\frac{d[\text{HBr}]}{dt} = \frac{2k_2(k_1/k_5)^{1/2}[\text{H}_2][\text{Br}_2]^{1/2}}{1 + (k_4[\text{HBr}]/k_3[\text{Br}_2])}. \quad (\text{A3.4.148})$$

The resulting rate law agrees with the form found experimentally. Of course the postulated mechanism can only be proven by measuring the rate constants of the individual elementary steps separately and comparing calculated rates of equation (A3.4.148) with observed rates of HBr formation.

-37-

In general, the assumption of quasi-stationarity is difficult to justify *a priori*. There may be several possible choices of intermediates for which the assumption of quasi-stationary concentrations appears justified. It is possible to check for consistency, for example $[\text{A}^*]_{\text{QS}} \ll [\text{A}]$, but the final justification can only come from a comparison with the exact solution. These have usually to be obtained with numerical solvers for systems of differential equations [7, 8 and 9]. In particular, if transport phenomena with complicated boundary conditions must be taken into account this is the only viable solution. Modern fields of application include atmospheric chemistry and combustion chemistry [67, 68]. A classic example is the H_2/O_2 reaction. The mechanism includes more than 60 elementary steps and has been discussed in great detail [69]. A recent analysis of the explosion limits of this system in the range of 0.3–15.7 atm and 850–1040 K included 19 reversible elementary reactions [67]. Table A3.4.3 summarizes some of the major reactions for the hydrogen–oxygen reaction. A simplified mechanism involves only six reactions:

Reaction (5) proceeds mostly heterogeneously, reaction (6) mostly homogeneously. This mechanism can be integrated with simplifying assumptions to demonstrate the main features of gas-phase explosion kinetics [8].

The importance of numerical treatments, however, cannot be overemphasized in this context. Over the decades enormous progress has been made in the numerical treatment of differential equations of complex gas-phase reactions [8, 70, 71]. Complex reaction systems can also be seen in the context of nonlinear and self-organizing reactions, which are separate subjects in this encyclopedia (see [chapter A3.14](#), [chapter C3.6](#)).

-38-

Table A3.4.3. Rate constants for the reaction of H₂ with O₂ [73]. The rate constants are given in terms of the following expression: $k(T) = A(T/K)^b \exp(-E/RT)$.

Reaction	A (cm ³ mol ⁻¹ s ⁻¹)	b	E (kJ mol ⁻¹)
OH + H ₂ → H ₂ O + H	1.2 × 10 ⁹	1.3	15.2
H + H ₂ O → OH + H ₂	4.5 × 10 ⁹	1.3	78.7
H + O ₂ → OH + O	2.2 × 10 ¹⁴	0	70.4
OH + O → H + O ₂	1.0 × 10 ¹³	0	0
O + H ₂ → OH + H	1.8 × 10 ¹⁰	1.0	37.3
OH + H → O + H ₂	8.3 × 10 ⁹	1.0	29.1
OH + OH → H ₂ O + O	1.5 × 10 ⁹	1.14	0
O + H ₂ O → OH + OH	1.6 × 10 ¹⁰	1.14	72.4
H + HO ₂ → OH + OH	1.5 × 10 ¹⁴	0	4.2
H + HO ₂ → H ₂ + O ₂	2.5 × 10 ¹³	0	2.9
OH + HO ₂ → H ₂ O + O	1.5 × 10 ¹³	0	0
O + HO ₂ → OH + O ₂	2.0 × 10 ¹³	0	0
	cm ⁶ mol ⁻² s ⁻¹		
H + H + M → H ₂ + M	9.0 × 10 ¹⁶	-0.6	0
O + OH + M → HO ₂ + M	2.2 × 10 ²²	-2.0	0
H + O ₂ + M → HO ₂ + M	2.3 × 10 ¹⁸	-0.8	0

-39-

A3.4.9 SUMMARIZING OVERVIEW

Although the field of gas-phase kinetics remains full of challenges it has reached a certain degree of maturity. Many of the fundamental concepts of kinetics, in general take a particularly clear and rigorous form in gas-phase kinetics. The relation between fundamental quantum dynamical theory, empirical kinetic treatments, and experimental measurements, for example of combustion processes [72], is most clearly established in gas-phase kinetics. It is the aim of this article to review some of these most basic aspects. Details can be found in the sections on applications as well as in the literature cited.

Ion chemistry A3.5

A A Viggiano and Thomas M Miller

A3.5.1 INTRODUCTION

Ion chemistry is a product of the 20th century. J J Thomson discovered the electron in 1897 and identified it as a constituent of all matter. Free positive ions (as distinct from ions deduced to exist in solids or electrolytes) were first produced by Thomson just before the turn of the century. He produced beams of light ions, and measured their mass-to-charge ratios, in the early 1900s, culminating in the discovery of two isotopes of neon in 1912 [1]. This year also marked Thomson's discovery of H_3^+ , which turns out to be the single most important astrophysical ion and which may be said to mark the beginning of the study of the *chemistry* of ions. Thomson noted that 'the existence of this substance is interesting from a chemical point of view', and the problem of its structure soon attracted the distinguished theorist Niels Bohr [2]. (In 1925, the specific reaction producing H_3^+ was recognized [2].) The mobilities of electrons and ions drifting in weak electric fields were first measured by Thomson, Rutherford and Townsend at the Cavendish Laboratory of Cambridge University in the closing years of the 19th century. The average mobility of the negative charge carrier was observed to increase dramatically in some gases, while the positive charge carrier mobility was unchanged—the *anomalous mobility problem*—which led to the hypothesis of electron attachment to molecules to form negative ions [3]. In 1936, Eyring, Hirschfelder and Taylor calculated the rate constant for an ion–molecule reaction (the production of H_3^+ !), showing it to be 100 times greater than for a typical neutral reaction, but it was not until 20 years later that any ion–molecule rate constant was measured experimentally [4]. Negative ion–molecule reactions were not studied at all until 1957 [5].

In this section, the wide diversity of techniques used to explore ion chemistry and ion structure will be outlined and a sampling of the applications of ion chemistry will be given in studies of lamps, lasers, plasma processing, ionospheres and interstellar clouds.

Note that chemists tend to refer to positive ions as *cations* (attracted to the cathode in electrolysis) and negative ions as *anions* (attracted to an anode). In this section of the encyclopedia, the terms *positive ion* and *negative ion* will be used for the sake of clarity.

A3.5.2 METHODOLOGIES

A3.5.2.1 SPECTROSCOPY

(A) ACTION SPECTROSCOPY

The term *action spectroscopy* refers to how a particular ‘action’, or process, depends on photon energy. For example, the photodissociation of O_2^- with UV light leads to energetic $\text{O}^- + \text{O}$ fragments; the kinetic energy released has been

-2-

studied as a function of photon energy by Lavrich *et al* [6, 7]. Many of the processes discussed in this section may yield such an action spectrum and we will deal with the processes individually.

(B) LASER INDUCED FLUORESCENCE

Laser induced fluorescence (LIF) detection of molecules has served as a valuable tool in the study of gas-phase processes in combustion, in the atmosphere, and in plasmas [8, 9, 10, 11 and 12]. In the LIF technique, laser light is used to excite a particular level of an atom or molecule which then radiates (fluoresces) to some lower excited state or back to the ground state. It is the fluorescence photon which signifies detection of the target. Detection may be by measurement of the total fluorescence signal or by resolved fluorescence, in which the various rovibrational populations are separated. LIF is highly selective and may be used to detect molecules with densities as low as 10^5 cm^{-3} in low pressure situations ($<0.1 \text{ Pa}$) where collisional quenching is negligible. In the presence of an atmosphere of air, the detection limit is about 10^{10} cm^{-3} . The use of LIF for ions is more difficult than for neutrals because a typical ion number density may be orders of magnitude lower than for neutrals. Nevertheless, important LIF work with ions has been reported.

LIF has been used to study state-selected ion–atom and ion–molecule collisions in gas cells. Ar^+ reactions with N_2 and CO were investigated by Leone and colleagues in the 1980s [13, 14] and that group has continued to contribute new understanding of the drifting and reaction of ions in gases, including studies of velocity distributions and rotational alignment [15, 16, 17, 18 and 19]. The vibrational state dependence of the charge transfer reaction

where $\text{X} = \text{Ar}$ or O_2 and the collisional deactivation reaction

were studied by this group using LIF [20]. They showed that charge transfer is enhanced by vibrational excitation and that vibrational deactivation is much more likely with O_2 than with Ar . We also consider here a reaction that displays both electron-transfer and proton-transfer channels,

and

studied via LIF of the $\text{A}^2\Sigma - \text{X}^2\Pi_{1/2,3/2}$ (0,0) bands of HBr^+ , using photons in the range 358–378 nm [21, 22]. For the electron transfer reaction, it was found that any excess energy in the process was statistically partitioned among all degrees of freedom of the complex and was manifested in the LIF spectra as rotational heating. Flow tube experiments tuned to different Br isotopes also showed a hydrogen-atom transfer channel in the $\text{HBr}^+ + \text{HBr}$ reaction.

LIF is also used with liquid and solid samples. For example, LIF is used to detect UO_2^{2+} ions in minerals; the uranyl ion is responsible for the bright green fluorescence given off by minerals such as autunite and opal upon exposure to UV light [23].

(C) PHOTODISSOCIATION OF IONS

Photodissociation of molecular ions occurs when a photon is absorbed by the ion and the energy is released (at least partly) by the breaking of one of the molecular bonds. The photodissociation of a molecular ion is conceptually similar to that for neutral molecules, but the experimental techniques differ. Photodissociation events are divided into two categories: *direct dissociation*, in which the photoexcitation is from a bound state to a repulsive state and *predissociation*, in which a quasi-bound state is accessed in the excitation. Direct dissociation takes place rapidly (fs to ps timescale). The shape of the direct dissociation cross section curve against photon energy is governed by the (Franck–Condon) overlap of wavefunctions of the initial state (usually the ground state) and the final, repulsive state. It will normally consist of peaks corresponding to vibrational structure in the initial level of the target ion with shapes skewed by the overlap with the repulsive state. One can model these shapes to obtain the potential curves of both the initial and repulsive states. Predissociation, in contrast, may take place over a much longer timescale; the lifetime of a particular predissociating state may be determined from the width of the resonance observed. Measurements of the lifetime for a series of predissociating states gives a picture of the predissociation mechanism. Photodissociation cross sections tend to peak in the 10^{-18} cm² range and hence are often given in Mb (megabarn) units.

There are many experimental methods by which photodissociation of ions have been studied. The earliest were crossed-beams experiments on H_2^+ beginning in the late 1960s [24, 25 and 26] and experiments on a variety of ions in the 1970s using drift tubes [27, 28 and 29]. Later techniques allowed more detailed information to be obtained on state symmetries and kinetic energy releases [30, 31 and 32]. [Figure A3.5.1](#) shows the fast ion beam photofragment spectrometer at SRI International; similar apparatus is in use at other institutions [33]. The apparatus consists of an ion source and mass selector, two electrostatic quadrupole benders that allow a laser beam to interact coaxially with the ion beam, a product-ion (photofragment) energy analyser and a particle detector. An interesting feature of the coaxial beam technique, aside from the long interaction region, is that sub-Doppler line widths can be obtained because of a thousandfold or more narrowing of the ion velocity distribution in the centre-of-mass reference frame for typical keV ion energies. By the same token, photofragment ions that differ in energy by a tenth of an electron volt in the centre-of-mass frame will be separated by typically 10–20 eV in the laboratory frame. This simplifies the job of the photofragment energy analyser. An example of a photofragment kinetic energy spectrum is shown in [figure A3.5.2](#). If the laser beam is sent at right angles to the ion beam (instead of coaxially), the optical polarization vector can be rotated to map out angular distributions of photofragments. (In the coaxial arrangement, the optical polarization is necessarily always perpendicular to the ion beam direction.)

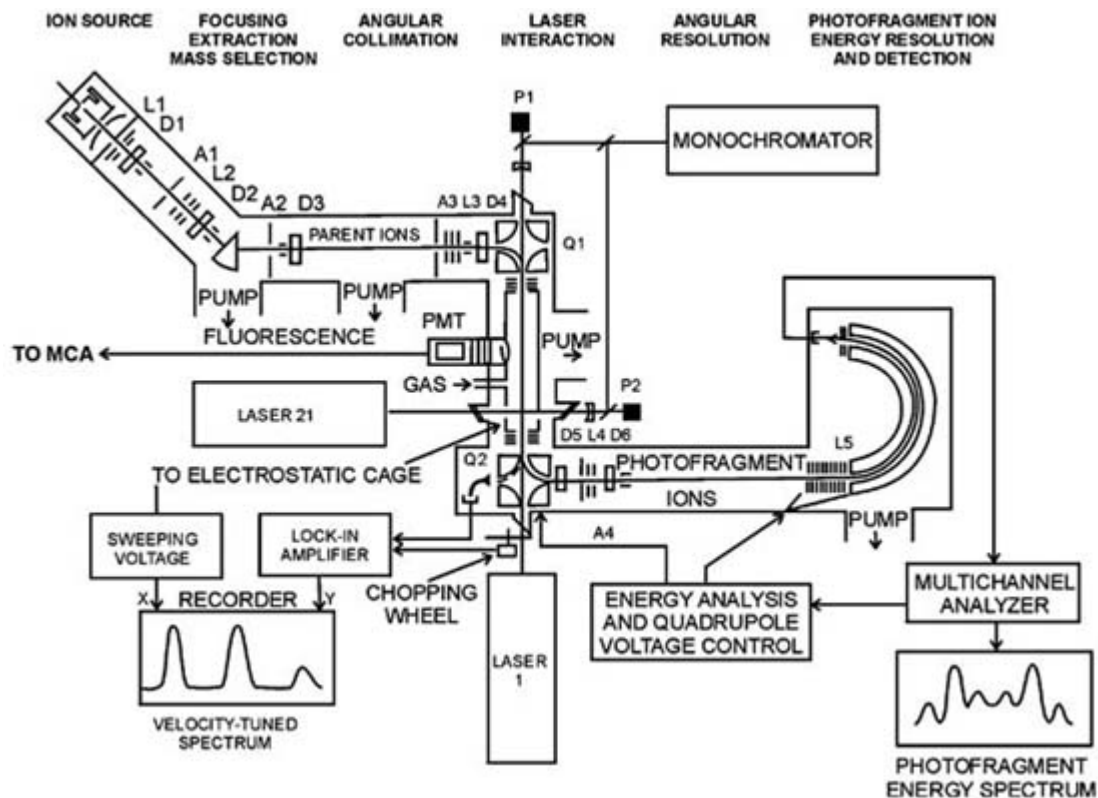

Figure A3.5.1. The fast ion beam photofragment spectrometer at SRI International. ‘L’ labels electrostatic lenses, ‘D’ labels deflectors and ‘A’ labels apertures.

-5-

Figure A3.5.2. The Ar^+ photofragment energy spectrum for the dissociation of $3 \text{ keV } \text{Ar}_2^+$ ions at 752.5 nm . The upper scale gives the kinetic energy release in the centre-of-mass reference frame, both parallel and antiparallel to the ion beam velocity vector in the laboratory.

In the past decade there has been photodissociation work on doubly charged positive ions, e.g., N_2^{2+} , NO_2^{2+} , CF_3^{2+} , CCl_3^{2+} , SiF_2^{2+} and SiF_3^{2+} [34]. Interestingly, the result of photoexcitation of the latter four molecular ions is the loss of neutrals, as a consequence of the electronic structures. There are two possible scenarios, illustrated by

There has been much activity in the study of photodissociation of cluster ions, dating back to the 1970s when it was realized that most ions in the earth's lower atmosphere were heavily clustered [7, 35, 36].

-6-

(D) PHOTOELECTRON SPECTROSCOPY

Photoelectron spectroscopy (PES) of negative ions involves irradiation of an ion beam with laser light and energy analysis of the electrons liberated when the photon energy exceeds the binding energy of the electron. The kinetic energy of the detached electron is the difference between the photon energy and the binding energy of the electron [37, 38, 39, 40, 41, 42, 43, 44, 45, 46 and 47]. Analysis of the electron energy thus gives a direct measurement of the electron affinity of the corresponding neutral atom or molecule, a very important thermochemical quantity. Generally speaking, PES yields more information about the *neutral* atom or molecule than the corresponding negative ion, because the target ion is ideally in its ground state and the electron kinetic energy is then dependent on the final state of the neutral product. The energy resolution of a PES experiment is usually adequate (often 5–10 meV) to resolve vibrational structure due to the neutral molecule, certainly for low-mass systems of few atoms and likewise electronic structure, including singlet–triplet splittings and fine structure separations. In a few cases, rotational energy levels have been resolved. Features may appear in a photoelectron spectrum due to excited levels of the target negative ion and give valuable information about the structure of the negative ion, but at the cost of complicating the spectrum.

An example of a PES apparatus is shown in [figure A3.5.3](#). A PES apparatus consists of (a) an ion source, (b) a fixed-frequency laser, (c) an interaction region, (d) an electron energy analyser and (e) an electron detector. Ion sources include gas discharge, sputtering, electron-impact and flowing afterglow. The laser may be cw (the argon-ion laser operated at 488 nm is common) or pulsed (which allows frequency doubling etc.). Recent trends have been toward UV laser light because the negative ions of importance in practical chemistry (e.g., atmospheric chemistry and biochemistry) tend to be strongly bound and because the more energetic light allows one to access more electronic and vibrational states. The interaction region may include a magnetic field that routes detached electrons toward the energy analyser. The energy analyser is either a hemispherical electrostatic device or a time-of-flight energy analyser; the latter is especially suited to a pulsed-laser system.

-7-

Figure A3.5.3. The negative ion photoelectron spectrometer used at the University of Colorado. The apparatus now contains a UV-buildup cavity inside the vacuum system (not shown in this sketch).

Data obtained with a PES apparatus are shown in [figure A3.5.4](#) [48]. Interpretation of the spectrum for a diatomic molecule is particularly straightforward. Peaks to the left of the origin band (each band containing unresolved rotational structure) are spaced by the vibrational separation in the neutral molecule, and their relative intensities are determined by the amount of spatial overlap between wavefunctions for the negative ion and the neutral molecule (Franck–Condon factors). Peaks to the right of the origin band are spaced by the vibrational separation in the negative ion and their relative intensities give the effective temperature of the ion source. Subtracting the electron kinetic energy

corresponding to the origin band from the photon energy yields the electron affinity of the molecule. The energy of the maximum of the envelope of neutral molecule peaks is referred to as the *vertical detachment energy*, i.e., the energy required from the ground vibrational state of the negative ion to the neutral molecule with no change in nuclear geometry. Photoelectron spectra are often far more complicated than the example shown, especially for polyatomic molecules. The origin band may have zero intensity, making the electron

affinity difficult to determine directly. Fine structure at least doubles the number of peaks in the spectrum. PES experiments have been carried out for doubly charged negative ions [49] and using multiphoton detachment [37].

Figure A3.5.4. The 488 nm photoelectron spectrum of NaCl^- . The arrow marks the origin band, for transitions from $\text{NaCl}^- (v=0)$ to $\text{NaCl} (v=0)$, from which the electron affinity of NaCl is obtained.

It is advantageous if the laser system permits rotation of the optical polarization. Detached electrons correlated with different final electronic states of the neutral molecule will generally be emitted with different angular distributions about the direction of polarization. Measurement of the angular distribution helps in the interpretation of complex photoelectron spectra. The angular distribution $f(\theta)$ of photoelectrons is [50]

$$f(\theta) = [1 + \beta P_2(\cos \theta)]/4\pi$$

where θ is the angle between the optical polarization vector and the direction of emission of a photoelectron, β is the asymmetry parameter (β is in the range -1 to 2 and in general depends on photon energy) and $P_2(\cos \theta)$ is the second-order Legendre polynomial, $(3 \cos^2 \theta - 1)/2$. $P_2(\cos \theta)$ is zero if $\theta = 54.7^\circ$, in which case the detected electron signal is proportional to the angle-averaged detachment cross section. The distribution function is independent of the azimuthal angle.

ZEKE (zero kinetic energy) photoelectron spectroscopy has also been applied to negative ions [51]. In ZEKE work, the laser wavelength is swept through photodetachment thresholds and only electrons with near-zero kinetic energy are

allowed into a detector, resulting in narrow threshold peaks. The resulting resolution ($2\text{--}3 \text{ cm}^{-1}$) is superior to that commonly encountered with PES ($40\text{--}300 \text{ cm}^{-1}$).

PES of neutral molecules to give positive ions is a much older field [52]. The information is valuable to chemists because it tells one about unoccupied orbitals in the neutral that may become occupied in chemical reactions. Since UV light is needed to ionize neutrals, UV lamps and synchrotron radiation have been used as well as UV laser light. With suitable electron-energy resolution, vibrational states of the positive ions can be

resolved, as with the negative-ion PES described above. The angular distribution of photoelectrons can be also determined as described above.

(E) ABSORPTION

In absorption spectroscopy, the attenuation of light as it passes through a sample is measured as a function of wavelength. The attenuation is due to rovibrational or electronic transitions occurring in the sample. Mapping out the attenuation versus photon frequency gives a description of the molecule or molecules responsible for the absorption. The attenuation at a particular frequency follows the Beer–Lambert law,

$$I = I_0 \exp(-\sigma nL)$$

where I and I_0 are the attenuated and unattenuated intensities, σ is the cross section, n is the number density of target molecules and L is the path length. Broadening of spectral lines may be observed, and is classed as *homogeneous broadening* (e.g., collisions with other molecules and laser power effects) or *inhomogeneous broadening* (e.g., Doppler broadening) [53, 54]. So-called ‘UV/vis’ absorption spectroscopy is a standard tool for analysis of chemical samples. In organic samples, absorption by functional groups in the sample aids in identification of the species because it is strongly dependent upon the relative number of single, double, and triple bonds.

Microwave spectra (giving pure rotational spectra) are especially useful for the detection of interstellar molecular ions (in some cases the microwave spectrum has first been observed in interstellar spectra!).

Typically a DC glow discharge tube is used to produce the target ion (e.g., HCO^+) [55, 56]. If the photons travel parallel or antiparallel to the electric field direction, there is a small but measurable Doppler shift in frequencies. This is due to the drift velocity of ions in the electric field, which may aid in distinguishing ion spectra from neutral spectra, but in any case must be accounted for [55, 58]. Infrared spectroscopy has also been carried out on ions in a glow discharge tube using the beat frequency between a fixed-frequency visible laser and a tunable dye laser. The difference frequency laser, in the IR, irradiates a long discharge tube. The method was first used to study the important astrophysical ion H_3^+ [59]. *Velocity modulation spectroscopy* utilizes an audio frequency glow discharge coupled with phase synchronous demodulation of the absorbed IR laser radiation to take advantage of the Doppler shift occurring for ions drifting in glow discharge tubes. Many important positive ions, such as H_3O^+ , NH_4^+ and H_3^+ , have been studied with this technique with the high precision common to IR spectroscopy [58, 60].

Far-infrared spectra of great sensitivity may be obtained with *laser magnetic resonance* (LMR). The sensitivity comes about because the gas sample is located inside the long cavity of the laser where the circulating power is typically 100 times that used in extracavity work. A discharge in the gas cell produces the radical species to be studied, and an axial magnetic field is varied to bring energy levels into resonance with one of many laser lines. HBr^+ was the first ion to be observed with LMR, in 1979. OH^- was one of the first negative ions to have been detected by direct absorption spectroscopy [61].

Strictly speaking, the term absorption spectroscopy refers to measurements of light intensity. In practice, the absorption may be deduced from the detection of electrons or ions produced in the process, such as in absorption of light leading to photodetachment or photodissociation, i.e., action spectra. In the absorption spectroscopy of ions, this is a natural tack to take as the charged-particle production can be detected with greater precision than is possible for a measurement of a small change in the light intensity. The most important of such experiment types is the coaxial beams spectrometer, one of which is described in detail in the section on dissociation of ions. In these experiments, the ions are identified by mass and collimated, and interact with the laser beam over a long distance (0.25–1 m). The method was first used with ions in 1976 for HD^+ , with the absorption events detected via enhanced production of buffer gas ions as a result of charge

transfer reactions [62]. Since this time many small ions have been studied in great detail, notably H_3^+ , O_2^+ , CH^+ , H_2O^+ , and CO^+ [31, 32, 63]. A few negative ions have been studied using coaxial fast-ion/laser beams. The high-resolution IR spectrum of NH^- , for example, was studied in this manner. The negative ion was excited to an autodetaching state with a photon energy greater than the electron affinity of NH . Detection of autodetached electrons signified an absorption event. Aside from determination of spectroscopic constants for NH^- , information on autodetachment dynamics was obtained [64].

A3.5.2.2 KINETICS AND DYNAMICS

In principle the study of ion–molecule kinetics and dynamics is no different from studies of the same processes in neutral species; however, there are additional forces that govern reactivity, often leading to behaviour that is fundamentally different from neutral processes. An important factor in determining ion–molecule rate constants and cross sections is the rate at which the reactants collide, i.e. the collision rate. In contrast to neutral kinetics, the collision rate at low energies or temperatures is determined not by the size of the molecule but by electrical forces. The ion–molecule collision rate is determined by the classical capture cross section for a point charge interacting with a structureless multipole. This was first described analytically for a point charge interacting with a polarizable species with no other multipole. In this case, the collisional value of the rate constant is independent of temperature [65]. The only other force of any significance is from the ion–permanent dipole interaction. Other forces, such as those between the ion and the quadrupole moment of the neutral, and between the neutral dipole and the induced dipole of the ion, have been shown to be of minor importance [58, 59, 60, 61, 62 and 63]. If the physical size of the reactants is greater than the capture radius, e.g. at translational energies of several tenths of an electron volt and greater, more conventional notions apply. Except for species with very small polarizabilities and systems of large mass, ion–molecule collision rates are above 10^{-9} molecules $\text{cm}^{-3} \text{s}^{-1}$, or about a factor of ten larger than neutral collision rates.

Several processes are unique to ions. A common reaction type in which no chemical rearrangement occurs but rather an electron is transferred to a positive ion or from a negative ion is termed charge transfer or electron transfer. Proton transfer is also common in both positive and negative ion reactions. Many proton- and electron-transfer reactions occur at or near the collision rate [72]. A reaction pertaining only to negative ions is associative detachment [73, 74],

Associative detachment reactions are important in controlling the electron concentration in the earth's mesosphere [75]. Reactions in which more than one neutral product are formed also occur and are sometimes referred to as reactive detachment [76].

Several reactivity trends are worth noting. Reactions that are rapid frequently stay rapid as the temperature or centre-of-mass kinetic energy of the reactants is varied. Slow exothermic reactions almost always show behaviour such that

the rate constant decreases with increasing temperature at low temperature or kinetic energies and then increases at higher temperature. As an example, figure A3.5.5 shows rate constants for the charge-transfer reaction of Ar^+ with O_2 as a function of temperature. The data are from five separate experiments and four experimental techniques [77, 78, 79, 80 and 81] and cover the extremely wide temperature range of 0.8 K to 1400 K. The extremely low temperature data are relatively flat. At approximately 20 K, the rate constants decrease. The decrease is described by a power law. A minimum is found at 800–900 K and a steep increase is found above 1000 K. The position of the minimum varies considerably for other reactions.

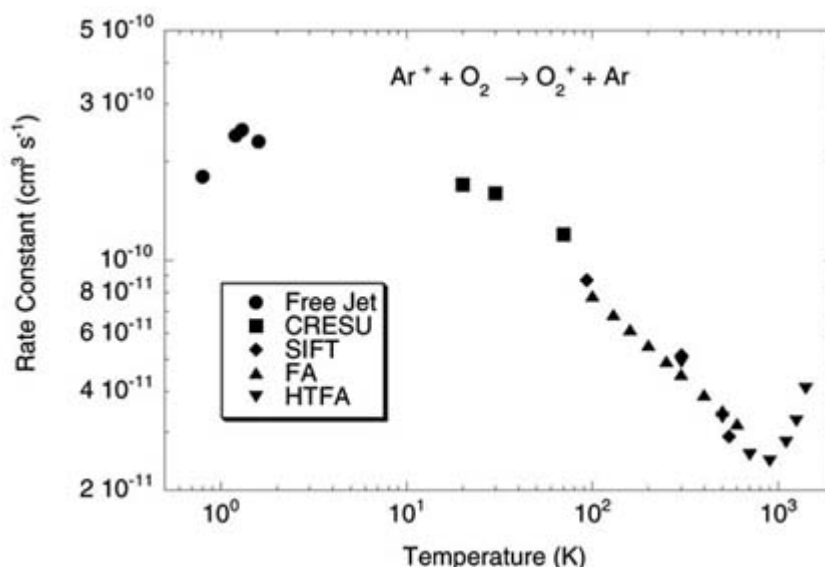

Figure A3.5.5. Rate constants for the reaction of Ar^+ with O_2 as a function of temperature. CRESU stands for the French translation of reaction kinetics at supersonic conditions, SIFT is selected ion flow tube, FA is flowing afterglow and HTFA is high temperature flowing afterglow.

The decrease in reactivity with increasing temperature is due to the fact that many low-energy ion–molecule reactions proceed through a double-well potential with the following mechanism [82]:

The minimum energy pathway for the reaction of Cl^- with CH_3Br is shown in [figure A3.5.6](#) [83]. As the reactants approach they are attracted by the ion–dipole and ion–induced-dipole forces and enter the entrance channel complex. As the reaction proceeds along the minimum energy path, the potential energy increases due to the forces necessary for rearrangement. The species then enter the product well and finally separate into products. The two wells are separated by a barrier that is often below the energy of the reactants but still plays an important role in controlling reactivity. The decrease in the overall rate constant with increasing temperature is due to the rate constant for collision complex

dissociation to reactants, k_b , increasing more rapidly with temperature than the rate constant for the complex going to products, k_{prod} [68]. The increase at higher energies and temperatures is often due to new channels opening, including new vibrational and electronic states as well as new chemical channels.

Figure A3.5.6. Minimum energy pathway for the reaction of Cl^- with CH_3Br .

Rotational and translational energy have been shown to be equivalent in controlling most reactions [84]. Vibrational energy often increases reactivity; however, sometimes it does not affect reactivity, or occasionally decreases reactivity. The following sections describe several of the more common techniques used to measure ion–molecule rate constants or cross sections.

(A) FLOW TUBES

Flow tube studies of ion–molecule reactions date back to the early 1960s, when the flowing afterglow was adapted to study ion kinetics [85]. This represented a major advance since the flowing afterglow is a thermal device under most situations and previous instruments were not. Since that time, many iterations of the ion–molecule flow tube have been developed and it is an extremely flexible method for studying ion–molecule reactions [86, 87, 88, 89, 90, 91 and 92].

The basic flow system is conceptually straightforward. A carrier gas, often helium, flows into the upstream end of a tube approximately 1 m long with a radius of several centimetres. This buffer gas pressure is approximately 100 Pa. Ions are created either in the flow tube or injected from an external source at the upstream end of the pipe. The carrier gas transports the ions downstream at approximately 100 m s^{-1} . Part way down the tube, a neutral reactant is added and the ions created in the source region are transformed into products. Conditions are chosen so that all ion chemistry leading to the reactant ion is complete and the ions are thermalized before they encounter the neutral reagent gas. The rate constant is determined by sampling a small portion of the gas with a quadrupole mass spectrometer and monitoring the disappearance of the primary ion and the appearance of product ions. For the reaction of $\text{A}^+ + \text{B} \rightarrow \text{products}$, the rate constant is given by

-13-

$$k = 1/[\text{B}]\tau \ln([\text{A}_0^+]/[\text{A}^+])$$

A3.5.1

where $[\text{B}]$ is the reactant neutral concentration in the flow tube, τ is the reaction time and $[\text{A}_0^+]$ and $[\text{A}^+]$ are the ion concentrations with and without reactant neutrals in the flow tube. This equation assumes that the

concentration of B is much greater than that of A^+ , i.e. first order kinetics apply. This situation applies to all ion kinetics since it is difficult to make large quantities of ions. Fortunately, the derivation of the rate constant depends only on the relative ion concentration, which is much easier to measure than the absolute concentration. The reaction time is determined from the flow velocity of the carrier gas. The average ion flow velocity is approximately 1.6 times the average neutral flow velocity [87], a result of ion diffusion, ions being neutralized on the flow tube walls and the carrier gas having a parabolic flow profile characteristic of laminar flow.

The basic system described above can be easily modified to study many processes. Figure A3.5.7 shows an example of a modern ion–molecule flow tube [93] with a number of interesting features. First, ions are created external to the flow tube. Any suitable ion source can be used, including high- and low-pressure electron-impact ion sources, a supersonic-expansion source (shown) or a flow-tube source. Once created the ions are injected into a quadrupole mass spectrometer and only ions with the proper mass are injected into the flow tube through a Venturi inlet. Under favourable circumstances, only one ion species enters the flow tube. This configuration is called the selected-ion flow tube (SIFT) [89, 90 and 91]. Alternatively, ions can be created in the carrier-gas flow by a filament or discharge. Neutral reagents are added through a variety of inlets. Unstable species such as O, H and N atoms, molecular radicals and vibrationally excited diatomics can be injected by passing the appropriate gas through a microwave discharge. In a SIFT, the chemistry is usually straightforward since there is only one reactant ion and one neutral present in the flow tube.

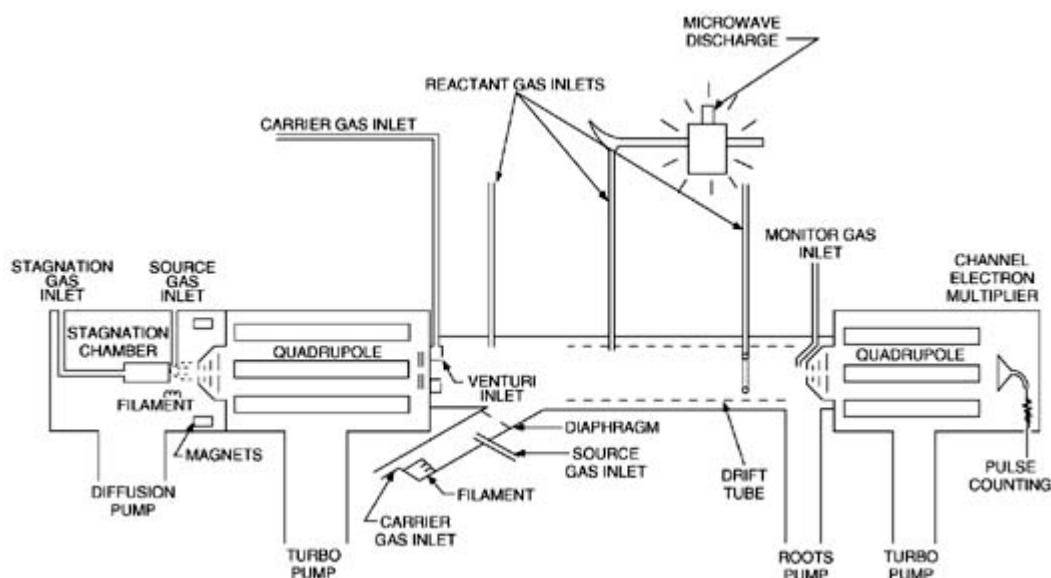

Figure A3.5.7. Schematic diagram of a selected ion flow drift tube with supersonic expansion ion source.

Flowing afterglows and SIFTs have been operated between 80 K and 1800 K. In addition, the ion kinetic energy can be varied by adding a drift tube either at room temperature [94, 95, 96 and 97] or with temperature variability [84]. A drift tube is a series of rings electrically connected by uniform resistors. Applying a voltage to the resistor chain forms a uniform electric field in the flow tube. Ions are accelerated by the electric field and decelerated by collisions so that a steady-state velocity results. The ion kinetic energy in the centre of mass, $\langle KE \rangle_{cm}$, is given by the Wannier expression [98]

$$\langle KE \rangle_{cm} = \frac{(m_i + m_b)m_n}{2(m_i + m_n)} v_d^2 + 3/2kT$$

where m_i , m_n and m_b are the mass of the ion, neutral and buffer respectively, v_d is the velocity of the ion due to the electric field and T is the temperature. Equation (A3.5.2) shows that the kinetic energy in a drift tube is the sum of a thermal component ($\frac{3}{2}kT$) and a drift field component. At a fixed kinetic energy, varying the contribution of each term yields information on rotational and vibrational effects [84]. Excited-state effects can be studied in a number of other ways. Electronic excitation often occurs in SIFT studies of atomic ions. Vibrational effects can be studied by exciting neutral diatomics in a microwave discharge. Ion vibrations can be excited in the source and monitored by LIF or judicious choice of a reactant neutral, i.e. one that reacts differently with excited states than for ground states. Often one looks for a reaction that is endothermic with respect to the ground state and energetically allowed for the excited state. Product-state information can be obtained by the monitor method or through optical spectroscopy. This list of possibilities is not exhaustive but it does give a sample of the type of information that can be obtained.

(B) TRAPS

Another powerful class of instrumentation used to study ion–molecule reactivity is trapping devices. Traps use electric and magnetic fields to store ions for an appreciable length of time, ranging from milliseconds to thousands of seconds. Generally, these devices run at low pressure and thus can be used to obtain data at pressures well below the range in which flow tubes operate.

The most widely used type of trap for the study of ion–molecule reactivity is the ion-cyclotron-resonance (ICR) [99] mass spectrometer and its successor, the Fourier-transform mass spectrometer (FTMS) [100, 101]. Figure A3.5.8 shows the cubic trapping cell used in many FTMS instruments [101]. Ions are created in or injected into a cubic cell in a vacuum of 10^{-2} Pa or lower. A magnetic field, B , confines the motion in the x – y plane through ion-cyclotron motion. The frequency of motion, ω , is given as $1.537 \times 10^7 B e/m$ where B is the magnetic field in tesla (typically 1–7 T), e is the charge of an electron and m the mass in atomic mass units. To trap ions in the z direction, a potential is placed on the two end electrodes. The ions oscillate in the z direction until their motion is damped by collisions. The magnetic field adds little energy to the motion, and the ions can be described as thermal. Ions are detected by applying a radio frequency (RF) pulse (a chirp) to the transmitter plates. The RF pulse causes ions with the matching cyclotron frequency to absorb energy. The ions are not only energized but quickly move coherently. Image currents on the receiver plates are detected. By putting a rapidly varying RF pulse (0–2 MHz) on the transmitter plate one obtains image currents as a function of time. A fast Fourier transform yields the frequency spectrum that is directly related to the mass spectrum by the equation described above.

Figure A3.5.8. Schematic diagram of the cell used in a Fourier transform mass spectrometer.

Kinetics measurements are made by adding a known concentration of reactant gas to the cell and monitoring the time evolution of the ion intensities. Rate constants are derived from [equation \(A3.5.1\)](#). Many useful tricks can be employed. The most useful is to chirp the cell so that all ions except those with the correct mass are excited out of the cell. In this manner the kinetics are simplified; only one ion and one neutral exist at time zero, and product information is easily obtained. A mass-specific excitation pulse adds energy such that ions may acquire enough energy to dissociate upon collision with background gas. The pattern of the dissociation often yields structural information. The ICR is particularly suited to the study of radiative association [\[101\]](#) and radiative cooling [\[102\]](#) of ions since the pressure is low and the trapping time can be long.

Another class of trapping device that is gaining importance is the radiofrequency trap [\[103\]](#). Quadrupole ion traps (also called Paul traps) are three-dimensional traps with rotationally symmetric ring and endcap electrodes. An RF voltage of opposite phase is applied to the ring and endcaps, respectively, to create a quadrupolar RF field. This type of trap suffers from electric field heating of the ions and can be classified as a nonthermal device. More innovative traps in limited use are the ring electrode trap and 22-pole trap. Both of these devices trap ions in a large field-free region and produce thermal ions. Reactions at very low temperatures have been studied with these types of trap [\[81, 103\]](#).

(C) BEAMS

The guided-ion beam has become the instrument of choice for studying ion–molecule reactions at elevated kinetic energies [\[103\]](#). In many guided-ion beam systems the lowest energy obtainable is slightly above thermal energy ($\sim 0.1\text{--}0.2$ eV), although it can be as low as the thermal energy of the target gas. The upper range varies but is generally in the tens of electron volts.

In essence, a guided-ion beam is a double mass spectrometer. [Figure A3.5.9](#) shows a schematic diagram of a guided-ion beam apparatus [\[104\]](#). Ions are created and extracted from an ion source. Many types of source have been used and the choice depends upon the application. Combining a flow tube such as that described in this chapter has proven to be versatile and it ensures the ions are thermalized [\[105\]](#). After extraction, the ions are mass selected. Many types of mass spectrometer can be used; a Wien ExB filter is shown. The ions are then injected into an octopole ion trap. The octopole consists of eight parallel rods arranged on a circle. An RF

voltage is applied to alternating sets of rods to trap ions in the centre of the octopole in an approximately square well potential. Little energy is transferred to the ions. The surrounding part of the octopole is a chamber where reactive gas is added. Typical pressures of added gas are of the order of 10^{-2} Pa. Pressure is kept low so single-collision conditions apply; the primary ions collide at most once with the reactant gas. The collision cell is generally run at room temperature although cooled and heated versions have been used. The main advantage of the octopole collision cell arrangement, over the arrangement used in early beam apparatuses, is greater collection efficiency of the product ions since products scattering in all directions are collected. The primary ions react with the reactant neutral and the resulting mix of ions exits the octopole to be mass analysed and detected. A quadrupole mass filter is often used for mass analysis although other mass spectrometers can be used. The reaction cross section is derived from the Beer–Lambert law, $I = I_0 \exp(-\sigma nL)$ where I and I_0 are the reactant ion signals with and without the reactant gas, n is the number density in the gas, L is the length of the collision cell. In the single-collision limit, I is taken as the product ion signal and I_0 as the primary ion signal.

Figure A3.5.9. Schematic diagram of a guided-ion beam.

As with most methods for studying ion–molecule kinetics and dynamics, numerous variations exist. For low-energy processes, the collision cell can be replaced with a molecular beam perpendicular to the ion beam [106]. This greatly reduces the thermal energy spread of the reactant neutral. Another approach for low energies is to use a merged beam [103]. In this system the supersonic expansion is aimed at the throat of the octopole, and the ions are passed through

a quadrupole bender and merged with the neutral beam. Exceedingly low collision energies can be obtained with this arrangement. Another important modification is obtained by adding a second octopole between the collision cell and the mass analyser. This allows the product-ion flight times to be measured, thus yielding the kinetic-energy release in the reaction to provide important dynamical information. Laser radiation can be introduced into the octopole to measure product distributions or to study dissociative processes. One valuable use of guided-ion beams has been the study of thresholds for endothermic processes in order to measure bond strengths and other thermodynamic quantities.

Two techniques exist for measuring the angular distribution of products. In the crossed-beam setup, the

octopole/collision cell is replaced with an interaction zone defined by the overlap of an ion beam and a supersonic neutral beam [106]. The angular distribution is measured by moving a mass spectrometer to detect ions at various angles. A simpler approach is to measure the product transmission as a function of trapping potential on the octopole [103]. The derivative of the signal yields the angular information but with limited resolution. Angular distributions are often used to determine the extent of collision complex formation.

(D) OTHER TECHNIQUES

While the techniques described above are the most common and versatile for measuring ion–molecule kinetics, several other techniques are worth mentioning. An important technique for measuring ion energetics is the pulsed, high-pressure mass spectrometer (PHPMS) [107]. In PHPMS, a pulsed beam of 2 keV electrons enters a small chamber containing reactants and a buffer gas. The chamber is maintained at ~500 Pa. Ion signals are then recorded as a function of time until equilibrium is established. Knowledge of the ion signals and partial pressures of the reactant neutral(s) yields the equilibrium constant. Temperature variation allows the enthalpy and entropy of reaction to be derived. Important thermodynamic information obtained by this technique includes ligand bond strengths, proton affinities, gas phase basicities, electron affinities and ionization energies. Information on kinetics can also be obtained.

Several instruments have been developed for measuring kinetics at temperatures below that of liquid nitrogen [81]. Liquid helium cooled drift tubes and ion traps have been employed, but this apparatus is of limited use since most gases freeze at temperatures below about 80 K. Molecules can be maintained in the gas phase at low temperatures in a free jet expansion. The CRESU apparatus (acronym for the French translation of reaction kinetics at supersonic conditions) uses a Laval nozzle expansion to obtain temperatures of 8–160 K. The merged ion beam and molecular beam apparatus are described above. These techniques have provided important information on reactions pertinent to interstellar-cloud chemistry as well as the temperature dependence of reactions in a regime not otherwise accessible. In particular, information on ion–molecule collision rates as a function of temperature has proven valuable in refining theoretical calculations.

Most ion–molecule techniques study reactivity at pressures below 1000 Pa; however, several techniques now exist for studying reactions above this pressure range. These include time-resolved, atmospheric-pressure, mass spectrometry; optical spectroscopy in a pulsed discharge; ion-mobility spectrometry [108] and the turbulent flow reactor [109].

A3.5.3 APPLICATIONS

A3.5.3.1 ION STRUCTURE AND ENERGETICS

The molecular constants that describe the structure of a molecule can be measured using many optical techniques described in [section A3.5.1](#) as long as the resolution is sufficient to separate the rovibrational states [110, 111 and 112]. Absorption spectroscopy is difficult with ions in the gas phase, hence many ion species have been first studied by matrix isolation methods [113], in which the IR spectrum is observed for ions trapped within a frozen noble gas on a liquid-helium cooled surface. The measured frequencies may be shifted as much as 1% from gas phase values because of the weak interaction with the matrix.

These days, remarkably high-resolution spectra are obtained for positive and negative ions using coaxial-beam spectrometers and various microwave and IR absorption techniques as described earlier. Information on molecular bond strengths, isomeric forms and energetics may also be obtained from the techniques discussed earlier. The kinetics of cluster-ion formation, as studied in a selected-ion flow tube (SIFT) or by high-pressure

mass spectrometry, may be interpreted in terms of cluster bond strengths [114]. In addition, the chemistry of ions may be used to identify the structure. For example, the ionic product of reaction between O_2^+ and CH_4 at 300 K has been identified as CH_2OOH^+ from its chemistry; the reaction mechanism is insertion [115]. Collision-induced dissociation (in a SIFT apparatus, a triple-quadrupole apparatus, a guided-ion beam apparatus, an ICR or a beam-gas collision apparatus) may be used to determine ligand-bond energies, isomeric forms of ions and gas-phase acidities.

Photoelectron spectra of cluster ions yields cluster-bond strengths, because each added ligand increases the binding energy of the extra electron in the negative ion by the amount of the ligand bond strength (provided the bond is electrostatic and does not appreciably affect the chromophore ion) [116].

One example of the determination of molecular constants can be taken from the photoelectron spectrum for NaCl^- shown in figure A3.5.4 [48]. The peak spacing to the left of the origin band is 45 meV: the nominal vibrational frequency ω_e in neutral NaCl . The spectral resolution is not good enough to specify the small anharmonic correction, $\omega_e x_e$, or the rotational constant, B_e , but these, along with the equilibrium separation, r_e ($=2.361 \text{ \AA}$), are accurately known from optical spectra. The spectrum in figure A3.5.4 also provides new information about the negative ion: the peaks to the right of the origin band are spaced by 33 meV, the nominal vibrational spacing in NaCl^- . The distribution of peak heights everywhere is determined by the Franck–Condon overlap of wavefunctions for NaCl and NaCl^- vibrational states, so the data give the ion temperature and the magnitude of the change in r_e between the neutral and negative ion (0.136 \AA in this case). Vibrational frequencies and bond-energy considerations imply that $r_e(\text{NaCl}^-) > r_e(\text{NaCl})$. Therefore, $r_e(\text{NaCl}^-) = 2.497 \text{ \AA}$, and $B_e = 0.195 \text{ cm}^{-1}$. Finally, the position of the origin peak gives the electron binding energy (the electron affinity of NaCl , 0.727 eV) and a thermochemical cycle allows one to calculate the bond energy of NaCl^- (all other quantities being known):

$$D_0(\text{Na-Cl}^-) = D_0(\text{Na-Cl}) + \text{EA}(\text{NaCl}) - \text{EA}(\text{Cl})$$

-19-

yielding $D_0(\text{Na-Cl}^-) = 1.34 \text{ eV}$. Admittedly, this is a simple spectrum to interpret. Had the system involved a Π state instead of Σ states, additional peaks would have complicated the spectrum (but yielded additional information if resolved). Had the molecules been polyatomic, where vibrations may be bending modes or stretches and combinations, the spectra and interpretation become more complex—the systems must be described in terms of normal modes instead of the more intuitive, but coupled, stretches and bends.

A.3.5.3.2 THERMOCHEMISTRY

The principles of ion thermochemistry are the same as those for neutral systems; however, there are several important quantities pertinent only to ions. For positive ions, the most fundamental quantity is the adiabatic ionization potential (IP), defined as the energy required at 0 K to remove an electron from a neutral molecule [117, 118 and 119].

Positive ions also form readily by adding a proton to a neutral atom or molecule [120]

The proton affinity, PA, is defined (at 298 K) as [117]

$$\text{PA} = \Delta H_f^0(\text{M}) + \Delta H_f(\text{H}^+) - \Delta H_f(\text{MH}^+).$$

Negative ions also have two unique thermodynamic quantities associated with them: the electron affinity, EA, defined as the negative of the enthalpy change for addition of an electron to a molecule at 0 K [117, 121, 122]

and the gas-phase acidity of a molecule, defined as the Gibbs energy change at 298 K, $\Delta G_{\text{acid}}(\text{AH})$, for the process [117, 121]

The enthalpy for this process is the proton affinity of the negative ion.

Much effort has gone into determining these quantities since they are fundamental to ionic reactivity. Examples include thermodynamic equilibrium measurements for all quantities and photoelectron studies for determination of EAs and IPs. The most up-to-date tabulation on ion thermochemistry is the *NIST Chemistry WebBook* (webbook.nist.gov/chemistry) [123].

Neutral thermochemistry can be determined by studying ion thermochemistry. For example, the following cycle can be used to determine a neutral bond strength,

-20-

where $D(\text{A-H})$ is the bond dissociation energy or enthalpy for dissociating a hydrogen atom from AH. Often it is easier to determine the EA and anionic proton affinity than it is to determine the bond strength directly, especially when AH is a radical. The IP of hydrogen is well known. As an example, this technique has been used to determine all bond strengths in ethylene and acetylene [124].

A3.5.3.3 CLUSTER PROPERTIES

A gas phase ionic cluster can be described as a core ion solvated by one or more neutral atoms or molecules and it is often represented as $\text{A}^{\pm}(\text{B})_n$ or $\text{A}^{\pm} \cdot \text{B}_n$, where A^{\pm} is the core ion and B are the ligand molecules. Of course, the core and the ligand can be the same species, e.g. the hydrated electron. The interactions governing the properties of these species are often similar to those governing liquid-phase ionic solvation. Modern techniques allow clusters with a specific number of neutral molecules to be studied, providing information on the evolution of properties as a function of solvation number. This leads to insights into the fundamental properties of solutions and has made this field an active area of research.

The most fundamental of cluster properties are the bond strengths and entropy changes for the process [125]

The thermodynamic quantities are derived from equilibrium measurements as a function of temperature. The measurements are frequently made in a high-pressure mass spectrometer [107]. The pertinent equation is ln

$(K_{n,n+1}) = -\Delta G^0/RT = -\Delta H^0/RT + \Delta S^0/T$. Another important method to determine bond strengths is from threshold measurements in collisional dissociation experiments [126]. Typically, ΔH^0 changes for $n = 0$ are 1.5 to several times the solution value [127]. The value usually drops monotonically with increasing n . The step size can have discontinuities as solvent shells are filled. The discontinuities in the thermodynamic properties appear as magic numbers in the mass spectra, i.e. ions of particular stability such as those with a closed solvation shell tend to be more abundant than those with one more or less ligand. A graph of bond strengths for H_2O bonding to several ions against cluster size is shown in figure A3.5.10 [125].

-21-

Figure A3.5.10. Bond strengths of water clustering to various core ions as a function of the number of water molecules.

Clusters can undergo a variety of chemical reactions, some relevant only to clusters. The simplest reaction involving clusters is association, namely the sticking of ligands to an ionic core. For association to occur, the ion-neutral complex must release energy either by radiating or by collision with an inert third body. The latter is an important process in the earth's atmosphere [128, 129, 130 and 131] and the former in interstellar clouds [101]. Cluster ions can be formed by photon or electron interaction with a neutral cluster produced in a supersonic expansion [132]. Another process restricted to clusters is ligand-switching or the replacement of one ligand for another. Often exothermic ligand-switching reactions take place at rates near the gas kinetic limit, especially for small values of n [72, 133]. Chemical-reactivity studies as a function of cluster size show a variety of trends [93, 127, 133]. Proton-transfer reactions are often unaffected by solvation, while nucleophilic-displacement reactions are often shut down by as few as one or two solvent molecules.

Increasing solvation number can also change the type of reactivity. A good example is the reaction of $NO^+(H_2O)_n$ with H_2O . These associate for small n but react to form $H_3O^+(H_2O)_n$ ions for $n = 3$. This is an important process in much of the earth's atmosphere. Neutral reactions have been shown to proceed up to 30 orders of magnitude faster when clustered to inert alkali ions than in the absence of the ionic clustering [134].

Caging is an important property in solution and insight into this phenomenon has been obtained by studying photodestruction of $Br_2^-(M)_n$ and $I_2^-(M)_n$ clusters, where M is a ligand such as Ar or CO_2 . When the X_2^- core is

photoexcited above the dissociation threshold of X_2^- , the competition between the two processes forming $X^-(M)_m$ and $X_2^-(M)_m$ indicates when caging is occurring. For $I_2^-(CO_2)_n$ the caging is complete at $n = 16$ [127, 135].

-22-

An important class of molecule often described as clusters may better be referred to as micro-particles. This class includes metal, semiconductor and carbon clusters. Particularly interesting are the carbon clusters, C_n^+ . Mass spectra from a carbon cluster ion source show strong magic numbers at C_{60}^+ and C_{70}^+ [136]. This led to the discovery of the class of molecules called buckminsterfullerenes. Since that time, other polyhedra have been discovered, most notably metallocarbohedrenes [137]. The first species of this type discovered was $Ti_8C_{12}^+$. Much of the work done on metal clusters has been focused on the transition from cluster properties to bulk properties as the clusters become larger, e.g. the transition from quantum chemistry to band theory [127].

A3.5.3.4 ATMOSPHERIC CHEMISTRY

Atmospheric ions are important in controlling atmospheric electrical properties and communications and, in certain circumstances, aerosol formation [128, 130, 131, 138, 139, 140, 141, 142, 143, 144 and 145]. In addition, ion composition measurements can be used to derive trace neutral concentrations of the species involved in the chemistry. Figure A3.5.11 shows the total-charged-particle concentration as a function of altitude [146]. The total density varies between 10^3 and 10^6 ions cm^{-3} . The highest densities occur above 100 km. Below 100 km the total ion density is roughly constant even though the neutral density changes by a factor of approximately 4×10^6 . Most negative charge is in the form of electrons above 80 km, while negative ions dominate below this altitude.

Above approximately 80 km, the prominent bulge in electron concentration is called the ionosphere. In this region ions are created from UV photoionization of the major constituents—O, NO, N_2 and O_2 . The ionosphere has a profound effect on radio communications since electrons reflect radio waves with the same frequency as the plasma frequency, $f = 8.98 \times 10^3 n_e^{1/3}$, where n_e is the electron density in cm^{-3} [147]. The large gradient in electron density ensures that a wide variety of frequencies are absorbed. It is this phenomenon that allows one to hear distant radio signals. Ion chemistry plays a major role in determining the electron density. Diatomic ions recombine rapidly with electrons while monatomic ions do not. Monatomic positive ions do not destroy electrons until they are converted to diatomic ions. The most important reaction in the ionosphere is the reaction of O^+ with N_2 ,

Although this reaction is exothermic, the reaction has a small rate constant. This is one of the most studied ion-molecule reactions, and dependences on many parameters have been measured [148].

-23-

Figure A3.5.11. Charged particle concentrations in the atmosphere.

More complex ions are created lower in the atmosphere. Almost all ions below 70–80 km are cluster ions. Below this altitude range free electrons disappear and negative ions form. Three-body reactions become important. Even though the complexity of the ions increases, the determination of the final species follows a rather simple scheme. For positive ions, formation of $\text{H}^+(\text{H}_2\text{O})_n$ is rapid, occurring in times of the order of milliseconds or shorter in the stratosphere and troposphere. After formation of $\text{H}^+(\text{H}_2\text{O})_n$, the chemistry involves reaction with species that have a higher proton affinity than that of H_2O . The resulting species can be written as $\text{H}^+(\text{X})_m(\text{H}_2\text{O})_n$. The main chemical processes include ligand exchange and proton transfer as well as association and dissociation of H_2O ligands. Examples of species X include NH_3 [149], CH_3COCH_3 [150] and CH_3CN [151]. The rate constants are large, so the proton hydrates are transformed even when the concentration of X is low.

The negative ion chemistry is equally clear. $\text{NO}_3^-(\text{HNO}_3)_m(\text{H}_2\text{O})_n$ ions are formed rapidly. Only acids, HX, stronger than HNO_3 react with this series of ions producing $\text{X}^-(\text{HX})_m(\text{H}_2\text{O})_n$. Most regions of the atmosphere have low concentrations of such acids. The two exceptions are a layer of H_2SO_4 in the 30–40 km region [152, 153] and H_2SO_4 and $\text{CH}_3\text{SO}_3\text{H}$ which play an important role near the ground under some circumstances [154].

Ion-composition measurements can be used to derive the concentrations of X and HX involved in the chemistry. This remains the only practical method of monitoring abundances of H_2SO_4 and CH_3CN in the upper atmosphere. Concentrations as low as 10^4 molecules cm^{-3} have been measured.

A3.5.3.5 ASTROCHEMISTRY

The astrochemistry of ions may be divided into topics of interstellar clouds, stellar atmospheres, planetary atmospheres and comets. There are many areas of astrophysics (stars, planetary nebulae, novae, supernovae) where highly ionized species are important, but beyond the scope of ‘ion chemistry’. (Still, molecules, including H₂O, are observed in solar spectra [155] and a surprise in the study of Supernova 1987A was the identification of molecular species, CO, SiO and possibly H₃⁺[156, 157].) In the early universe, after expansion had cooled matter to the point that molecules could form, the small fraction of positive and negative ions that remained was crucial to the formation of molecules, for example [156]

The formation of molecules was the first step toward local gravitational collapses which led to, among other things, the production of this encyclopedia.

Interstellar clouds of gases contain mostly H, H₂ and He, but the minority species are responsible for the interesting chemistry that takes place, just as in the earth’s atmosphere. Interstellar clouds are divided into two types: *diffuse*, with atomic or molecular concentrations in the neighbourhood of 100 cm⁻³ and temperatures of 100–200 K, in which ionization is accomplished primarily by stellar UV light, and *dense* (or dark) clouds, with densities of 10⁴–10⁶ cm⁻³ and temperatures of 10–20 K, in which ionization is a result of galactic cosmic rays since visible and UV light cannot penetrate the dense clouds [156, 158]. The dense clouds also contain particulate matter (referred to as dust or grains). Close to 100 molecular species, as large as 13-atomic, have been detected in interstellar clouds by RF and MM spectroscopy; among these are nine types of molecular positive ion. It is assumed that the neutral molecular species (except H₂) are mainly synthesized through ion–molecule reactions, followed by electron–ion recombination, since neutral–neutral chemical reactions proceed very slowly in the cold temperatures of the clouds, except on grain surfaces. Ion–molecule reactions are typically even faster at lower temperatures. Extensive laboratory studies of ion–molecule reactions, including work at very low temperatures, have mapped out the reaction schemes that take place in interstellar clouds. In dense clouds the reactions

are of paramount importance. These reactions are followed by reactions with C and H₂ to produce CH₃⁺, that subsequently undergoes reaction with many neutral molecules to give ion products such as CH₅⁺, C₂H₅OH₂⁺ and CH₃CNH⁺. Many of the reactions involve radiative association. Dissociative electron–ion recombination then yields neutrals such as CH₄ (methane), C₂H₅OH (ethanol) and CH₃CN (acetonitrile) [158]. It is often joked that diffuse interstellar clouds contain enough grain alcohol to keep space travellers happy on their long journeys. In diffuse clouds, the reaction scheme is more varied and leads to smaller molecules in general.

solute surface which, under the assumption of slip boundary conditions, gives for the correction factor *C* in equation (A3.6.35):

$$C_{\text{size}} = \frac{f_{\text{slip}} V_h}{f_{\text{slip}} V_h + BkT\kappa_T\eta(4/\sigma_r^2 + 1)} \quad (\text{A3.6.36})$$

with isothermal compressibility κ_T , ratio of radii of solvent to solute σ_r and a temperature-dependent parameter *B*. If one compares equation (A3.6.36) with the empirical friction model mentioned above, one

realizes that both contain a factor of the form $C = 1/1 + a\eta$, suggesting that these models might be physically related.

Another, purely experimental possibility to obtain a better estimate of the friction coefficient for rotational motion γ_{rot} in chemical reactions consists of measuring rotational relaxation times τ_{rot} of reactants and calculating it according to equation (A3.6.35) as $\gamma_{\text{rot}} = 6kT\tau_{\text{rot}}$.

A3.6.4 SELECTED REACTIONS

A3.6.4.1 PHOTOISOMERIZATION

According to Kramers' model, for flat barrier tops associated with predominantly small barriers, the transition from the low- to the high-damping regime is expected to occur in low-density fluids. This expectation is borne out by an extensively studied model reaction, the photoisomerization of *trans*-stilbene and similar compounds [70, 71] involving a small energy barrier in the first excited singlet state whose decay after photoexcitation is directly related to the rate coefficient of *trans-cis*-photoisomerization and can be conveniently measured by ultrafast laser spectroscopic techniques.

(A) PRESSURE DEPENDENCE OF PHOTOISOMERIZATION RATE CONSTANTS

The results of pressure-dependent measurements for *trans*-stilbene in supercritical *n*-pentane [46] (figure A3.6.5) and the prediction from the model described by equation (A3.6.29), using experimentally determined microcanonical rate coefficients in jet-cooled *trans*-stilbene to calculate k_{∞} , show two marked discrepancies between model calculation and measurement: (1) experimental values of k are an order of magnitude higher already at low pressure and (2) the decrease of k due to friction is much less pronounced than predicted. As interpretations for the first observation, several ideas have been put forward that will not be further discussed here, such as a decrease of the effective potential barrier height due to electrostatic solute–solvent interactions enhanced by cluster formation at relatively low pressures [72, 73], or incomplete intramolecular vibrational energy redistribution in the isolated molecule [74, 75, 76, 77, 78, 79 and 80], or Franck–Condon cooling in the excitation process [79, 80]. The second effect, the weak viscosity dependence, which was first observed in solvent series experiments in liquid solution [81, 82 and 83], has also led to controversial interpretations: (i) the macroscopic solvent viscosity is an inadequate measure for microscopic friction acting along the reaction path [84, 85], (ii) the multidimensional character of the barrier crossing process leads to a fractional power dependence of k on $1/\eta$ [54, 81, 86, 87], (iii) as the reaction is very fast, one has to take into account the finite response time of the solvent, i.e. consider frequency-dependent friction [81, 87] and (iv) the effective barrier

Depending on the electron and ion temperatures in a plasma, all of the processes mentioned in this section of the encyclopedia may be taking place simultaneously in the plasma [163]. Understanding, or modelling, the plasma may be quite complicated [164]. Flame chemistry involves charged particles [165]. Most of the early investigations and classifications of electron and ion interactions came about in attempts to understand electric discharges, and these continue today in regard to electric power devices, such as switches and high-intensity lamps [166]. Often the goal is to prevent discharges in the face of high voltages. Military applications involving the earth's ionosphere funded refined work during and following the Second World War. Newer applications such as gas discharge lasers have driven recent studies of plasma chemistry. The rare-gas halide excimer laser is a marvellous example of plasma chemistry, because the lasing molecule may be formed in

recombination between a positive and a negative ion, for example [167, 168 and 169]

or

The Ar_2^+ is formed from $\text{Ar}^+ + \text{Ar}$, where the metastable Ar^* is a product of electron-impact or charge-transfer collisions. The F^- is formed by dissociative electron attachment to F_2 or NF_3 . The population inversion required for light amplification is simple to obtain in the ArF laser since the ground state of the lasing molecule is not bound, except by van der Waals forces and quickly dissociates upon emission of the laser light.

A3.6 Chemical kinetics in condensed phases

Jorg Schroeder

A3.6.1 INTRODUCTION

The transition from the low-pressure gas to the condensed phase is accompanied by qualitative changes in the kinetics of many reactions caused by the presence of a dense solvent environment permanently interacting with reactants (also during their motion along the reaction path). Though this solvent influence in general may be a complex phenomenon as contributions of different origin tend to overlap, it is convenient to single out aspects that dominate the kinetics of certain types of reactions under different physical conditions.

Basic features of solvent effects can be illustrated by considering the variation of the rate constant k_{uni} of a unimolecular reaction as one gradually passes from the low-pressure gas phase into the regime of liquid-like densities [1] (see [figure A3.6.1](#).) At low pressures, where the rate is controlled by thermal activation in isolated binary collisions with bath gas molecules, k_{uni} is proportional to pressure, i.e. it is in the low-pressure limit k_0 . Raising the pressure further, one reaches the fall-off region where the pressure dependence of k_{uni} becomes increasingly weaker until, eventually, it attains the constant so-called high-pressure limit k_∞ . At this stage, collisions with bath gas molecules, which can still be considered as isolated binary events, are sufficiently frequent to sustain an equilibrium distribution over rotational and vibrational degrees of freedom of the reactant molecule, and k_∞ is determined entirely by the intramolecular motion along the reaction path. k_∞ may be calculated by statistical theories (see [chapter A3.4](#)) if the potential-energy (hyper)surface (PES) for the reaction is known. What kind of additional effects can be expected, if the density of the compressed bath gas approaches that of a dense fluid? Ideally, there will be little further change, as equilibration becomes even more effective because of permanent energy exchange with the dense heat bath. So, even with more confidence than in the gas phase, one could predict the rate constant using statistical reaction rate theories such as, for example, transition state theory (TST). However, this ideal picture may break down if (i) there is an appreciable change in charge distribution or molar volume as the system moves along the reaction path from reactant to product state, (ii) the reaction entails large-amplitude structural changes that are subject to solvent frictional forces retarding the motion along the reaction path or (iii) motion along the reaction path is sufficiently fast that thermal equilibrium over all degrees of freedom of the solute and the bath cannot be maintained.

- (i) This situation can still be handled by quasi-equilibrium models such as TST, because the solvent only influences the equilibrium energetics of the system. The ensuing phenomena may be loosely referred to as ‘static’ solvent effects. These may be caused by electronic solute–solvent interactions that change the effective PES by shifting intersection regions of different electronic states or by lowering or raising potential-energy barriers, but also by solvent structural effects that influence the

free-energy change along the reaction path associated with variations in molar volume.

- (ii) The decrease of the rate constant due to the viscous drag exerted by the solvent medium requires an extension of statistical rate models to include diffusive barrier crossing, because the no-recrossing postulate of TST is obviously violated. In the so-called Smoluchowski limit, one would expect an inverse dependence of k_{uni} on solvent viscosity η at sufficiently high pressure. A reaction rate constant is still well defined and kinetic rate equations may be used to describe the course of the reaction.

-2-

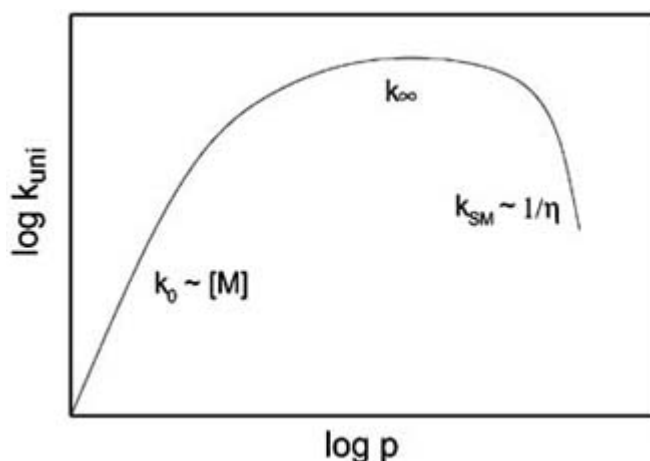

Figure A3.6.1. Pressure dependence of unimolecular rate constant k_{uni} .

This is no longer the case when (iii) motion along the reaction path occurs on a time scale comparable to other relaxation times of the solute or the solvent, i.e. the system is partially non-relaxed. In this situation dynamic effects have to be taken into account explicitly, such as solvent-assisted intramolecular vibrational energy redistribution (IVR) in the solute, solvent-induced electronic surface hopping, dephasing, solute–solvent energy transfer, dynamic caging, rotational relaxation, or solvent dielectric and momentum relaxation.

The introductory remarks about unimolecular reactions apply equivalently to bimolecular reactions in condensed phase. An essential additional phenomenon is the effect the solvent has on the rate of approach of reactants and the lifetime of the collision complex. In a dense fluid the rate of approach evidently is determined by the mutual diffusion coefficient of reactants under the given physical conditions. Once reactants have met, they are temporarily trapped in a solvent cage until they either diffusively separate again or react. It is common to refer to the pair of reactants trapped in the solvent cage as an encounter complex. If the ‘unimolecular’ reaction of this encounter complex is much faster than diffusive separation: i.e., if the effective reaction barrier is sufficiently small or negligible, the rate of the overall bimolecular reaction is diffusion controlled.

As it has appeared in recent years that many fundamental aspects of elementary chemical reactions in solution can be understood on the basis of the dependence of reaction rate coefficients on solvent density [2, 3, 4 and 5], increasing attention is paid to reaction kinetics in the gas-to-liquid transition range and supercritical fluids under varying pressure. In this way, the essential differences between the regime of binary collisions in the low-pressure gas phase and that of a dense environment with typical many-body interactions become apparent. An extremely useful approach in this respect is the investigation of rate coefficients, reaction yields and concentration–time profiles of some typical model reactions over as wide a pressure range as possible, which permits the continuous and well controlled variation of the physical properties of the solvent. Among these the most important are density, polarity and viscosity in a continuum description or collision frequency,

Progress in the theoretical description of reaction rates in solution of course correlates strongly with that in other theoretical disciplines, in particular those which have profited most from the enormous advances in computing power such as quantum chemistry and equilibrium as well as non-equilibrium statistical mechanics of liquid solutions where Monte Carlo and molecular dynamics simulations in many cases have taken on the traditional role of experiments, as they allow the detailed investigation of the influence of intra- and intermolecular potential parameters on the microscopic dynamics not accessible to measurements in the laboratory. No attempt, however, will be made here to address these areas in more than a cursory way, and the interested reader is referred to the corresponding chapters of the encyclopedia.

In the sections below a brief overview of static solvent influences is given in A3.6.2, while in A3.6.3 the focus is on the effect of transport phenomena on reaction rates, i.e. diffusion control and the influence of friction on intramolecular motion. In A3.6.4 some special topics are addressed that involve the superposition of static and transport contributions as well as some aspects of dynamic solvent effects that seem relevant to understanding the solvent influence on reaction rate coefficients observed in homologous solvent series and compressed solution. More comprehensive accounts of dynamics of condensed-phase reactions can be found in [chapter A3.8](#), [chapter A3.13](#), [chapter B3.3](#), [chapter C3.1](#), [chapter C3.2](#) and [chapter C3.5](#).

A3.6.2 STATIC SOLVENT EFFECTS

The treatment of equilibrium solvation effects in condensed-phase kinetics on the basis of TST has a long history and the literature on this topic is extensive. As the basic ideas can be found in most physical chemistry textbooks and excellent reviews and monographs on more advanced aspects are available (see, for example, the recent review article by Truhlar *et al* [6] and references therein), the following presentation will be brief and far from providing a complete picture.

A3.6.2.1 SEPARATION OF TIME SCALES

A reactive species in liquid solution is subject to permanent random collisions with solvent molecules that lead to statistical fluctuations of position, momentum and internal energy of the solute. The situation can be described by a reaction coordinate X coupled to a huge number of solvent bath modes. If there is a reaction barrier E_0^\pm ('+' refers to the forward direction and '-' to the reverse reaction), in a way similar to what is common in gas phase reaction kinetics, one may separate the reaction into the elementary steps of activation of A or B, barrier crossing, and equilibration of B or A, respectively (see [figure A3.6.2](#).) The time scale τ_r^\pm for mounting and crossing the barrier is determined by the magnitude of statistical fluctuations $X(t) = \langle X(t) \rangle$ at temperature T , where $\langle \rangle$ indicates ensemble average. In a canonical ensemble this is mainly the Boltzmann factor $\tau_r^\pm \sim e^{E_0^\pm/kT}$, where k denotes Boltzmann's constant. Obviously, the reaction is a rare event if the barrier is large. On the other hand, the time scale for energy relaxation τ_s in a potential well is inversely proportional to the curvature of the potential V along X ,

$$\tau_s \sim \sqrt{\mu / \left. \frac{\partial^2 V}{\partial X^2} \right|_{X=A,B}}$$

where μ denotes reduced mass. So the overall time scale for the reaction

$$\tau_r^\pm \approx \tau_{s(A,B)} \exp(E_0^\pm/kT) \gg \tau_{s(A,B)}$$

for $E_0^\pm \gg kT$. If at the same time τ_r^\pm is also significantly larger than all other relevant time constants of the solute–bath system (correlation time of the bath, energy and momentum relaxation time, barrier passage time), X may be considered to be a random variable and the motion of the reacting species along this reaction coordinate a stochastic Markov process under the influence of a statistically fluctuating force. This simply means that before, during and after the reaction all degrees of freedom of the solute–solvent system but X are in thermodynamic equilibrium. In this case quasi-equilibrium models of reaction rates are applicable. If the additional requirements are met that (i) each trajectory crossing the transition state at the barrier top never recrosses and (ii) the Born–Oppenheimer approximation is fulfilled, TST can be used to calculate the reaction rate and provide an upper limit to the real rate coefficient (see [chapter A3.12](#)).

Figure A3.6.2. Activation and barrier crossing.

A3.6.2.2 THERMODYNAMIC FORMULATION OF TST AND REFERENCE STATES

For analysing equilibrium solvent effects on reaction rates it is common to use the thermodynamic formulation of TST and to relate observed solvent-induced changes in the rate coefficient to variations in Gibbs free-energy differences between solvated reactant and transition states with respect to some reference state. Starting from the simple one-dimensional expression for the TST rate coefficient of a unimolecular reaction $A \xrightarrow{k_{\text{TST}}} P$

$$k_{\text{TST}} = \frac{kT}{h} \frac{Q^\ddagger}{Q_A} \exp(-E_0/kT) = \frac{kT}{h} \frac{[A^\ddagger]}{[A]} \quad (\text{A3.6.1})$$

where Q_A and Q^\ddagger denote the partition functions of reactant and transition state per volume, respectively, E_0 is the barrier height, and $[A]$, $[A^\ddagger]$ stand for equilibrium concentration of reactant and, in a formal not physical sense, the transition state, respectively. Defining an equilibrium constant in terms of activities a

-5-

$$K_a^\ddagger \equiv \frac{a^\ddagger}{a_A} = \frac{\gamma^\ddagger [A^\ddagger]}{\gamma_A [A]} = \frac{Q^\ddagger}{Q_A} \exp(-E_0/kT) \quad (\text{A3.6.2})$$

with corresponding activity coefficients denoted by γ , one obtains for the rate coefficient from [equation](#)

(A3.6.1) and equation (A3.6.2)

$$k_{\text{TST}} = \frac{kT}{h} \frac{[A^\ddagger]}{[A]} = \frac{kT}{h} \frac{Q^\ddagger}{Q_A} \exp(-E_0/kT) \frac{\gamma_A}{\gamma^\ddagger} \equiv k_{\text{TST}}^0 \frac{\gamma_A}{\gamma^\ddagger} \quad (\text{A3.6.3})$$

where k_{TST}^0 is a standard rate coefficient which depends on the reference state chosen. If one uses the dilute-gas phase as reference, i.e. $k_{\text{TST}}^0 = k_{\text{gas}}$, all equilibrium solvation effects according to equation (A3.6.3) are included in the ratio of activity coefficients γ_A/γ^\ddagger which is related to the Gibbs free energy of activation for the reaction in the gas $\Delta G_{\text{gas}}^\ddagger$ and in solution $\Delta G_{\text{solution}}^\ddagger$;

$$kT \ln \left(\frac{k_{\text{solution}}}{k_{\text{gas}}} \right) = kT \ln \left(\frac{\gamma_A}{\gamma^\ddagger} \right) = \Delta G_{\text{gas}}^\ddagger - \Delta G_{\text{solution}}^\ddagger. \quad (\text{A3.6.4})$$

Since $\Delta G_{\text{gas}}^\ddagger - \Delta G_{\text{solution}}^\ddagger$ in equation (A3.6.4) is equal to the difference between the Gibbs free energy of solvation of reactant and transition state, $\Delta G_{\text{sol}}(A) - \Delta G_{\text{sol}}(A^\ddagger)$, one has a direct correlation between equilibrium solvation free enthalpies and rate coefficient ratios. It is common practice in physical organic chemistry to use as a reference state not the gas phase, but a suitable reference solvent M, such that one correlates measured rate coefficient ratios of equation (A3.6.4) to relative changes in Gibbs free energy of solvation

$$[\Delta G_{\text{sol,S}}(A) - \Delta G_{\text{sol,S}}(A^\ddagger)] - [\Delta G_{\text{sol,M}}(A) - \Delta G_{\text{sol,M}}(A^\ddagger)] \equiv \delta_M \Delta G^\ddagger. \quad (\text{A3.6.5})$$

The shorthand notation in the rhs of equation (A3.6.5) is frequently referred to as the Leffler–Grunwald operator [7].

Considering a bimolecular reaction $A+B \xrightarrow{k_{\text{TST}}} P$, one correspondingly obtains for the rate constant ratio

$$k_{\text{solution}}/k_{\text{gas}} = \gamma_A \gamma_B / \gamma^\ddagger. \quad (\text{A3.6.6})$$

In the TST limit, the remaining task strictly speaking does not belong to the field of reaction kinetics: it is a matter of obtaining sufficiently accurate reactant and transition state structures and charge distributions from quantum chemical calculations, constructing sufficiently realistic models of the solvent and the solute–solvent interaction potential, and calculating from these ingredients values of Gibbs free energies of solvation and activity coefficients. In many cases, a microscopic description may prove a task too complex, and one rather has to use simplifying approximations to characterize influences of different solvents on the kinetics of a reaction in terms of some macroscopic physical or empirical solvent parameters. In many cases, however, this approach is sufficient to capture the kinetically significant contribution of the solvent–solute interactions.

A3.6.2.3 EQUILIBRIUM SOLVATION—MACROSCOPIC DESCRIPTION

(A) NAÏVE VIEW OF SOLVENT CAVITY EFFECTS

Considering equation (A3.6.3), if activity coefficients of reactant and transition state are approximately equal, for a unimolecular reaction one should observe $k_{\text{solution}} \approx k_{\text{gas}}$. This in fact is observed for many unimolecular reactions where the reactant is very similar to the transition state, i.e. only a few bond lengths and angles change by a small amount and there is an essentially constant charge distribution. There are, however, also large deviations from this simplistic prediction, in particular for dissociation reactions that require separation

of fragments initially formed inside a common solvent cavity into individually solvated products.

For a bimolecular reaction in such a case one obtains from equation (A3.6.6) $k_{\text{solution}} \approx \gamma \cdot k_{\text{gas}}$, so one has to estimate the activity coefficient of a reactant to qualitatively predict the solvent effect. Using *ad hoc* models of solvation based on the free-volume theory of liquids or the cohesive energy density of a solvent cavity, purely thermodynamic arguments yield $\gamma \sim 10^2 - 10^3$ [8, 9 and 10].

The reason for this enhancement is intuitively obvious: once the two reactants have met, they temporarily are trapped in a common solvent shell and form a short-lived so-called encounter complex. During the lifetime of the encounter complex they can undergo multiple collisions, which give them a much bigger chance to react before they separate again, than in the gas phase. So this effect is due to the microscopic solvent structure in the vicinity of the reactant pair. Its description in the framework of equilibrium statistical mechanics requires the specification of an appropriate interaction potential.

(B) ELECTROSTATIC EFFECTS—ONSAGER AND BORN MODELS

If the charge distribution changes appreciably during the reaction, solvent polarity effects become dominant and in liquid solution often mask the structural influences mentioned above. The calculation of solvation energy differences between reactant and transition state mainly consists of estimating the Gibbs free energies of solvation ΔG_{sol} of charges, dipoles, quadrupoles etc in a polarizable medium. If the solute itself is considered non-polarizable and the solvent a continuous linear dielectric medium without internal structure, then $\Delta G_{\text{sol}} = \frac{1}{2} E_{\text{int}}$, where E_{int} is the solute-solvent interaction energy [11]. Reactant and transition state are modelled as point charges or point dipoles situated at the centre of a spherical solvent cavity. The point charge or the point dipole will polarize the surrounding dielectric continuum giving rise to an electric field which in turn will act on the charge distribution inside the cavity. The energy of the solute in this so-called reaction field may be calculated by a method originally developed by Onsager. Using his reaction field theory [12, 13], one obtains the molar Gibbs free energy of solvation (with respect to vacuum) of an electric point dipole μ_{el} in a spherical cavity of radius r embedded in a homogeneous dielectric of dielectric constant ϵ as

$$\Delta G_{\text{sol,dip}} = -N_{\text{A}} \frac{\epsilon - 1}{2\epsilon + 1} \frac{\mu_{\text{el}}^2}{4\pi \epsilon_0 r^3} \quad (\text{A3.6.7})$$

with ϵ_0 and N_{A} denoting vacuum permittivity and Avogadro's constant, respectively. The dielectric constant inside the cavity in this approximation is assumed to be unity. Applying this expression to a solvent series study of a reaction

-7-

involving large charge separation, such as the Menshutkin reaction of triethylamine with ethyliodide

one obtains

$$\delta_M \Delta G^\ddagger = -N_A \frac{\epsilon - 1}{2\epsilon + 1} \frac{1}{4\pi \epsilon_0} \left(\frac{(\mu_{ab}^\ddagger)^2}{(r_{ab}^\ddagger)^3} - \frac{\mu_a^2}{r_a^3} - \frac{\mu_b^2}{r_b^3} \right)$$

predicting a linear relationship between $\ln(k_{\text{solvent}}/k_{\text{reference}})$ and $(\epsilon - 1)/(2\epsilon + 1)$ which is only approximately reflected in the experimental data covering a wide range of solvents [14] (see figure A3.6.3). This is not surprising, in view of the approximate character of the model and, also, because a change of solvent does not only lead to a variation in the dielectric constant, but at the same time may be accompanied by a change in other kinetically relevant properties of the medium, demonstrating a general weakness of this type of experimental approach.

Figure A3.6.3. Solvent polarity dependence of the rate constant for the Menshutkin reaction (data from [14]).

Within the framework of the same dielectric continuum model for the solvent, the Gibbs free energy of solvation of an ion of radius r_{ion} and charge $z_{\text{ion}}e$ may be estimated by calculating the electrostatic work done when hypothetically charging a sphere at constant radius r_{ion} from $q = 0 \rightarrow q = z_{\text{ion}}e$. This yields the Born equation [13]

$$\Delta G_{\text{sol,ion}} = -N_A \frac{z_{\text{ion}}^2 e^2}{8\pi \epsilon_0 r_{\text{ion}}} \left(1 - \frac{1}{\epsilon} \right) \quad (\text{A3.6.8})$$

-8-

such that for a reaction of the type

the change in effective barrier height (difference of Gibbs free energy of solvation changes between transition state and reactants) according to equation (A3.6.7) and equation (A3.6.8) equals

$$\delta_M \Delta G^\ddagger = -\frac{N_A}{8\pi \epsilon_0} \left[(ze)^2 \left(1 - \frac{1}{\epsilon} \right) \left(\frac{1}{r^\ddagger} - \frac{1}{r_A} \right) - \frac{\mu_B^2}{r_B^3} \frac{2(\epsilon - 1)}{2\epsilon + 1} \right].$$

This formula does not include the charge–dipole interaction between reactants A and B. The correlation between measured rate constants in different solvents and their dielectric parameters in general is of a similar quality as illustrated for neutral reactants. This is not, however, due to the approximate nature of the Born model itself which, in spite of its simplicity, leads to remarkably accurate values of ion solvation energies, if the ionic radii can be reliably estimated [15].

Onsager’s reaction field model in its original form offers a description of major aspects of equilibrium solvation effects on reaction rates in solution that includes the basic physical ideas, but the inherent simplifications seriously limit its practical use for quantitative predictions. It since has been extended along several lines, some of which are briefly summarized in the next section.

(C) IMPROVED DIELECTRIC CONTINUUM MODELS

Onsager’s original reaction field method imposes some serious limitations: the description of the solute as a point dipole located at the centre of a cavity, the spherical form of the cavity and the assumption that cavity size and solute dipole moment are independent of the solvent dielectric constant.

Kirkwood generalized the Onsager reaction field method to arbitrary charge distributions and, for a spherical cavity, obtained the Gibbs free energy of solvation in terms of a multipole expansion of the electrostatic field generated by the charge distribution [12, 13]

$$\Delta G_{\text{sol,K}} = \frac{N_A e^2}{8\pi \epsilon_0} \sum_{n=0}^{\infty} \frac{(n+1)(1-\epsilon)}{(n+1)\epsilon+n} \frac{1}{r^{2n+1}} \sum_{k=1}^N \sum_{l=1}^N z_k z_l \mathbf{r}_k^n \mathbf{r}_l^n P_n(\cos \vartheta_{kl}) \quad (\text{A3.6.9})$$

where N is the number of point charges in the cavity, vectors \mathbf{r}_i denote their position, ϑ_{ij} the angle between respective vectors, and P_n are the Legendre polynomials. This expression reduces to [equation \(A3.6.8\)](#) and [equation \(A3.6.7\)](#) for $n = 0$ and $n = 1$, respectively. It turns out that usually it is sufficient to consider terms up to $n \approx 4$ to achieve convergence of the expansion. The absolute value of the solvation energy calculated from [equation \(A3.6.9\)](#), however, critically depends on the size and the shape of the cavity. Even when the charge distribution of reactants and transition state can be calculated to sufficient accuracy by advanced quantum chemical methods, this approach only will give

useful quantitative information about the solvent dependence of reaction rates, if the cavity does not change appreciably along the reaction path from reactants to transition state and if it is largely solvent independent.

As this condition usually is not met, considerable effort has gone into developing methods to calculate solvation energies for cavities of arbitrary shape that as closely as possible mimic the topology of the interface between solute molecule and solvent continuum. Among these are various implementations of boundary element methods [16], in which a cavity surface of arbitrary shape is divided into surface elements carrying a specified surface charge. In one of the more simple variants, a virtual charge scheme as proposed by Miertuš [17], the charge distribution of the solute $\rho^0(\mathbf{r}_i)$ reflects itself in corresponding polarization surface charge densities at the cavity interface $\sigma(\mathbf{s}_i)$ that are assigned to each of m surface elements \mathbf{s}_i and assumed to be constant across the respective surface areas ΔS_i . The electric potential generated by these virtual charges is

$$V_\sigma = \sum_{i=1}^m \Delta S_i \frac{\sigma(\mathbf{s}_i)}{4\pi \epsilon_0 r_i} \quad (\text{A3.6.10})$$

The surface charge density on each surface element is determined by the boundary condition

$$\sigma(\mathbf{s}_i) = \frac{\epsilon_0(\epsilon - 1)}{\epsilon} \left(\frac{dV}{dn_i} \right)_{\mathbf{s}_i} \quad (\text{A3.6.11})$$

where ϵ denotes the static dielectric constant of the solvent, and the derivative of the total electrical potential V at the interface is taken with respect to the normal vector \mathbf{n}_i of each surface element \mathbf{s}_i . V is the sum of contributions from the solute charges ρ^0 and the induced polarization surface charges $\sigma(\mathbf{s}_i)$. Using equation (A3.6.10) and equation (A3.6.11), the virtual surface charge densities $\sigma(\mathbf{s}_i)$ can be calculated iteratively, and the Gibbs free energy of solvation is then half the electrostatic interaction energy of the solute charge distribution in the electric potential generated by the induced polarization surface charges

$$\Delta G_{\text{sol}} = \frac{1}{2} \int V_{\sigma}(\mathbf{r}) \rho^0(\mathbf{r}) d\mathbf{r}. \quad (\text{A3.6.12})$$

Of course, one has to fix the actual shape and size of the cavity, before one can apply equation (A3.6.12). Since taking simply ionic or van der Waals radii is too crude an approximation, one often uses basis-set-dependent *ab initio* atomic radii and constructs the cavity from a set of intersecting spheres centred on the atoms [18, 19]. An alternative approach, which is comparatively easy to implement, consists of using an electrical equipotential surface to define the solute–solvent interface shape [20].

The most serious limitation remaining after modifying the reaction field method as mentioned above is the neglect of solute polarizability. The reaction field that acts back on the solute will affect its charge distribution as well as the cavity shape as the equipotential surface changes. To solve this problem while still using the polarizable continuum model (PCM) for the solvent, one has to calculate the surface charges on the solute by quantum chemical methods and represent their interaction with the solvent continuum as in classical electrostatics. The Hamiltonian of the system thus is written as the sum of the Hamilton operator for the isolated solute molecule and its interaction with the macroscopic

electrostatic reaction field. The coupled equations of the solute subject to the reaction field induced in the solvent are then solved self-consistently to obtain the electron density of the solute in the presence of the polarizable dielectric—the basis of self-consistent reaction field (SCRF) models [21]. Whether this is done in the framework of, for example, Hartree–Fock theory or density functional theory, is a question of optimizing quantum chemical techniques outside the topics addressed here.

If reliable quantum mechanical calculations of reactant and transition state structures in vacuum are feasible, treating electrostatic solvent effects on the basis of SRCF-PCM using cavity shapes derived from methods mentioned above is now sufficiently accurate to predict variations of Gibbs free energies of activation $\delta\Delta G^{\ddagger}$ with solvent polarity reliably, at least in the absence of specific solute–solvent interactions. For instance, considering again a Menshutkin reaction, in this case of pyridine with methylbromide, $\text{Pyr} + \text{MeBr} \rightarrow \text{MePyr}^+ + \text{Br}^-$, in cyclohexane and di-*n*-butyl ether, the difference between calculated and experimental values of ΔG^{\ddagger} is only about 2% and 4%, respectively [22, 23].

As with SCRF-PCM only macroscopic electrostatic contributions to the Gibbs free energy of solvation are taken into account, short-range effects which are limited predominantly to the first solvation shell have to be considered by adding additional terms. These correct for the neglect of effects caused by solute–solvent electron correlation including dispersion forces, hydrophobic interactions, dielectric saturation in the case of

multiply charged ions and solvent structural influences on cavitation. In many cases, however, the electrostatic contribution dominates and dielectric continuum models provide a satisfactory description.

A3.6.2.4 EQUILIBRIUM SOLVENT EFFECTS—MICROSCOPIC VIEW

Specific solute–solvent interactions involving the first solvation shell only can be treated in detail by discrete solvent models. The various approaches like point charge models, supermolecular calculations, quantum theories of reactions in solution, and their implementations in Monte Carlo methods and molecular dynamics simulations like the Car–Parrinello method are discussed elsewhere in this encyclopedia. Here only some points will be briefly mentioned that seem of relevance for later sections.

(A) POINT CHARGE DISTRIBUTION MODEL [11]

Considering, for simplicity, only electrostatic interactions, one may write the solute–solvent interaction term of the Hamiltonian for a solute molecule surrounded by S solvent molecules as

$$\hat{H}_{\text{elstat}} = \sum_{s=1}^S \left[\sum_{\lambda=1}^N \sum_{\alpha=1}^{N_s} \frac{1}{r_{\lambda\alpha s}} - \sum_{\lambda=1}^N \sum_{a=1}^{M_s} \frac{Z_a}{r_{\lambda\alpha s}} + \sum_{l=1}^M \sum_{a=1}^{M_s} \frac{Z_l Z_a}{r_{l\alpha s}} - \sum_{l=1}^M \sum_{\alpha=1}^{N_s} \frac{Z_l}{r_{l\alpha s}} \right] \quad (\text{A3.6.13})$$

where the solute contains N electrons and M nuclei with charges Z_l and the solvent molecules N_s electrons and M_s nuclei with charge Z_a . In the point charge method equation (A3.6.13) reduces to

$$\hat{H}_{\text{pc}} = \sum_{p=1}^P \sum_{\lambda=1}^N \frac{q_p}{r_{\lambda p}} - \sum_{p=1}^P \sum_{l=1}^M \frac{q_p Z_l}{r_{lp}}. \quad (\text{A3.6.14})$$

-11-

Here the position r_{ip} of the point charges located on the solvent molecules q_p is determined by the structure of the solvent shell and the electron density distribution within the solvent molecule. In this type of model, the latter is assumed to be fixed, i.e. the solvent molecules are considered non-polarizable while solving the Schrödinger equation for the coupled system.

Instead of using point charges one may also approximate the interaction Hamiltonian in terms of solute electrons and nuclei interacting with solvent point dipoles μ_d

$$\hat{H}_{\text{pd}} = \sum_{d=1}^D \sum_{\lambda=1}^N \frac{\mu_d r_{d\lambda}}{r_{d\lambda}^3} - \sum_{d=1}^D \sum_{l=1}^M \frac{\mu_d r_{dl} Z_l}{r_{dl}^3}. \quad (\text{A3.6.15})$$

In either case, the structure of the solvation shell has to be calculated by other methods supplied or introduced *ad hoc* by some further model assumptions, while charge distributions of the solute and within solvent molecules are obtained from quantum chemistry.

(B) SOLVATION SHELL STRUCTURE

The quality of the results that can be obtained with point charge or dipole models depends critically on the input solvation shell structure. In view of the computer power available today, taking the most rigorous route

is feasible in many cases, i.e. using statistical methods to calculate distribution functions in solution. In this way the average structure of solvation shells is accessible, that is, to be used in equilibrium solvation calculations required to obtain, for example, TST rate constants.

Assuming that additive pair potentials are sufficient to describe the inter-particle interactions in solution, the local equilibrium solvent shell structure can be described using the pair correlation function $g^{(2)}(\mathbf{r}_1, \mathbf{r}_2)$. If the potential only depends on inter-particle distance, $g^{(2)}(\mathbf{r}_1, \mathbf{r}_2)$ reduces to the radial distribution function $g(r) \equiv g^{(2)}(|\mathbf{r}_1 - \mathbf{r}_2|)$ such that $\rho \cdot 4\pi r^2 dr g(r)$ gives the number of particles in a spherical shell of thickness dr at distance r from a reference particle (ρ denotes average particle density). The local particle density is then simply $\rho \cdot g(r)$. The radial distribution function can be obtained experimentally in neutron scattering experiments by measuring the angular dependence of the scattering amplitude, or by numerical simulation using Monte Carlo methods.

(C) POTENTIAL OF MEAN FORCE

At low solvent density, where isolated binary collisions prevail, the radial distribution function $g(r)$ is simply related to the pair potential $u(r)$ via $g_0(r) = \exp[-u(r)/kT]$. Correspondingly, at higher density one defines a function $w(r) \equiv -kT \ln[g(r)]$. It can be shown that the gradient of this function is equivalent to the mean force between two particles obtained by holding them at fixed distance r and averaging over the remaining $N - 2$ particles of the system. Hence $w(r)$ is called the potential of mean force. Choosing the low-density system as a reference state one has the relation

$$\lim_{\rho \rightarrow 0} g(r) = g_0(r) \Rightarrow \lim_{\rho \rightarrow 0} w(r) = u(r)$$

-12-

and $\Delta w(r) \equiv w(r) - u(r)$ describes the average many-body contribution such as, for example, effects due to solvation shell structure. In the language of the thermodynamic formulation of TST, the ratio of rate constants in solution and dilute-gas phase consequently may be written as

$$kT \ln \frac{k_{\text{solution}}}{k_{\text{gas}}} = -\delta \Delta w^\ddagger \equiv -[\Delta w(r^\ddagger) - \Delta w(r_{\text{react}})]. \quad (\text{A3.6.16})$$

A3.6.2.5 PRESSURE EFFECTS

The inherent difficulties in interpreting the effects observed in solvent series studies of chemical reaction rates, which offer little control over the multitude of parameters that may influence the reaction, suggest rather using a single liquid solvent and varying the pressure instead, thereby changing solvent density and polarity in a well known way. One also may have to consider, of course, variations in the local solvent shell structure with increasing pressure.

(A) ACTIVATION VOLUME

In the thermodynamic formulation of TST the pressure dependence of the reaction rate coefficient defines a volume of activation [24, 25 and 26]

$$\left(\frac{\partial \ln k}{\partial p} \right)_T = -\frac{1}{RT} \left(\frac{\partial \Delta G^\ddagger}{\partial p} \right)_T \equiv -\frac{\Delta V^\ddagger}{RT} \quad (\text{A3.6.17})$$

with $\Delta V^\ddagger = \bar{V}^\ddagger - \sum_i^{\text{reactants}} \bar{V}_i$, the difference of the molar volume of transition state and the sum over molar volumes of reactants. Experimental evidence shows that $|\Delta V^\ddagger|$ is of the order of $10^0 - 10^1 \text{ cm}^3 \text{ mol}^{-1}$ and usually pressure dependent [27]. It is common practice to interpret it using geometric arguments considering reactant and transition state structures and by differences in solvation effects between reactant and transition state. If one uses a molar concentration scale (standard state 1 mol dm^{-3}), an additional term $+\kappa_{\text{solv}} \Delta v^\ddagger$ appears in the rhs of equation (A3.6.16), the product of isothermal solvent compressibility and change in sum over stoichiometric coefficients between reactants and transition state.

There is one important *caveat* to consider before one starts to interpret activation volumes in terms of changes of structure and solvation during the reaction: the pressure dependence of the rate coefficient may also be caused by transport or dynamic effects, as solvent viscosity, diffusion coefficients and relaxation times may also change with pressure [2]. Examples will be given in subsequent sections.

(B) ACTIVATION VOLUME IN A DIELECTRIC CONTINUUM

If, in analogy to equation (A3.6.5), one denotes the change of activation volume with respect to some reference solvent as $\delta_M \Delta V^\ddagger$ and considers only electrostatic interactions of reactant and transition state with a dielectric continuum solvent, one can calculate it directly from

-13-

$$\delta_M \Delta V^\ddagger = \left(\frac{\partial(\delta_M \Delta G^\ddagger)}{\partial p} \right)_T \quad (\text{A3.6.18})$$

by using any of the models mentioned above. If the amount of charge redistribution is significant and the solvent is polar, the dielectric contribution to ΔV^\ddagger by far dominates any so-called intrinsic effects connected with structural changes between reactant and transition state. For the Menshutkin reaction, for example, equation (A3.6.17) gives

$$\delta_M \Delta V^\ddagger = \frac{-N_A}{4\pi \epsilon_0} \left[\frac{3}{(2\epsilon(p) + 1)^2} \left(\frac{\partial \epsilon}{\partial p} \right)_T \right] \left(\frac{(\mu_{ab}^\ddagger)^2}{(r_{ab}^\ddagger)^3} - \frac{\mu_a^2}{r_a^3} - \frac{\mu_b^2}{r_b^3} \right)$$

which includes a positive term resulting from the pressure dependence of the dielectric constant (in square brackets) and represents the experimentally observed pressure dependence of the activation volume quite satisfactorily [25]. For the Menshutkin reaction, only the large dipole moment of the transition state needs to be considered, resulting in a negative activation volume, a typical example of electrostriction. If one assumes that the neglect of solute polarizability is justified and, in addition, the cavity radius is constant, one may use this kind of expression to estimate transition state dipole moments. Improved continuum models as outlined in the preceding sections may, of course, also be applied to analyse activation volumes.

(C) ACTIVATION VOLUME AND LOCAL SOLVENT STRUCTURE

In a microscopic equilibrium description the pressure-dependent local solvent shell structure enters through variations of the potential of mean force, $(\partial \delta \Delta w^\ddagger / \partial p)_T$, such that the volume of activation contains a contribution related to the pressure dependence of radial distribution functions for reactants and transition state, i.e.

$$\Delta V_{\text{local}}^{\ddagger} = -kT \left\{ \frac{\partial}{\partial p} \left[\ln \left(\frac{g(r^{\ddagger})g_0(r_{\text{react.}})}{g_0(r^{\ddagger})g(r_{\text{react.}})} \right) \right] \right\}_{\text{T}}$$

This contribution of local solvent structure to ΔV^{\ddagger} may be quite significant and, even in nonpolar solvents, in many cases outweigh the intrinsic part. It essentially describes a caging phenomenon, as with increasing pressure the local solvent density or packing fraction of solvent molecules around reactants and transition state increases, thereby enhancing the stability of the solvent cage. This constitutes an equilibrium view of caging in contrast to descriptions of the cage effect in, for example, photodissociation where solvent friction is assumed to play a central role.

How large the magnitude of this packing effect can be was demonstrated in simple calculations for the atom transfer reaction $\text{CH}_3 + \text{CH}_4 \rightarrow \text{CH}_4 + \text{CH}_3$ using a binary solution of hard spheres at infinite dilution as the model system [28]. Allowing spheres to partially overlap in the transition state, i.e. assuming a common cavity, reaction rates were calculated by variational TST for different solute-to-solvent hard-sphere ratios $r_{\text{G}} = \sigma_{\text{M}}/\sigma_{\text{S}}$ and solvent densities $\rho_{\text{S}}\sigma_{\text{S}}^3$. Increasing the latter from 0.70 to 0.95 led to an enhancement of the relative rate constant $k_{\text{solution}}/k_{\text{gas}}$ by factors of 8.5, 15.5 and 53 for r_{G} equal to 0.93, 1.07 and 1.41, respectively, thus clearly showing the effect of local packing density. With respect to the calculated gas phase value the rate constants at the highest density were 95, 280 and

-14-

2670 times larger, respectively. This behaviour is typical for ‘tight’ transition states, whereas for loose transition states as they appear, for example, in isomerization reactions, this caging effect is orders of magnitude smaller.

A3.6.3 TRANSPORT EFFECTS

If reactant motion along the reaction path in the condensed phase involves significant displacement with respect to the surrounding solvent medium and there is non-negligible solute–solvent coupling, frictional forces arise that oppose the reactive motion. The overall rate of intrinsically fast reactions for which, for example, the TST rate constant is sufficiently large, therefore, may be influenced by the viscous drag that the molecules experience on their way from reactants to products. As mentioned in the introduction, dynamic effects due to other partially non-relaxed degrees of freedom will not be considered in this section.

For a bimolecular reaction, this situation is easily illustrated by simply writing the reaction as a sequence of two steps

where brackets denote common solvent cage (encounter complex), k_{diff} is the rate constant of diffusive approach of reactants, sometimes called the ‘encounter rate’, k_{sep} is that of diffusive separation of the unreacted encounter pair and k_{mol} that of the reactive step in the encounter complex. If $k_{\text{mol}} \gg k_{\text{sep}}$, the overall reaction rate constant k essentially equals k_{diff} and the reaction is said to be diffusion controlled. One important implicit assumption of this phenomenological description is that diffusive approach and separation

are statistically independent processes, i.e. the lifetime of the encounter pair is sufficiently long to erase any memory about its formation history. Examples of processes that often become diffusion controlled in solution are atom and radical recombination, electron and proton transfer, fluorescence quenching and electronic energy transfer.

In a similar phenomenological approach to unimolecular reactions involving large-amplitude motion, the effect of friction on the rate constant can be described by a simple transition formula between the high-pressure limit k_∞ of the rate constant at negligible solvent viscosity and the so-called Smoluchowski limit of the rate constant, k_{SM} , approached in the high-damping regime at large solvent viscosity [2]:

$$\frac{1}{k} = \frac{1}{k_\infty} + \frac{1}{k_{SM}}. \quad (\text{A3.6.20})$$

As k_{SM} is inversely proportional to solvent viscosity, in sufficiently viscous solvents the rate constant k becomes equal to k_{SM} . This concerns, for example, reactions such as isomerizations involving significant rotation around single or double bonds, or dissociations requiring separation of fragments, although it may be difficult to experimentally distinguish between effects due to local solvent structure and solvent friction.

Systematic experimental investigations of these transport effects on reaction rates can either be done by varying solvents in a homologous series to change viscosity without affecting other physicochemical or chemical properties

-15-

(or as little as possible) or, much more elegantly and experimentally demanding, by varying pressure and temperature in a single solvent, maintaining control over viscosity, polarity and density at the same time. As detailed physical insight is gained by the latter approach, the few examples shown all will be from pressure-dependent experimental studies. Computer experiments involving stochastic trajectory simulations or classical molecular dynamics simulations have also been extremely useful for understanding details of transport effects on chemical reaction rates, though they have mostly addressed dynamic effects and been less successful in actually providing a quantitative connection with experimentally determined solvent or pressure dependences of rate constants or quantum yields of reactions.

A3.6.3.1 DIFFUSION AND BIMOLECULAR REACTIONS

(A) DIFFUSION-CONTROLLED RATE CONSTANT

Smoluchowski theory [29, 30] and its modifications form the basis of most approaches used to interpret bimolecular rate constants obtained from chemical kinetics experiments in terms of diffusion effects [31]. The Smoluchowski model is based on Brownian motion theory underlying the phenomenological diffusion equation in the absence of external forces. In the standard picture, one considers a dilute fluid solution of reactants A and B with $[A] \ll [B]$ and asks for the time evolution of $[B]$ in the vicinity of A, i.e. of the density distribution $\rho(r,t) \equiv [B](r,t)/[B]_{t=0} \simeq [B](r(t))/[B]_{t=0}$ ($[B]$ is assumed not to change appreciably during the reaction). The initial distribution and the outer and inner boundary conditions are chosen, respectively, as

$$\rho(r, 0) = \begin{cases} 0 & \text{for } r \leq R \\ 1 & \text{for } r > R \end{cases}$$

$$\rho(r \rightarrow \infty, t) = 1 \quad \text{for } t \geq 0 \quad (\text{A3.6.21})$$

$$k_{\text{mol}}\rho(R) = 4\pi R^2 D_{\text{AB}} \left. \frac{\partial \rho}{\partial r} \right|_R$$

where R is the encounter radius and D_{AB} the mutual diffusion coefficient of reactants. The reflecting boundary condition [32] at the encounter distance R ensures that, once a stationary concentration of encounter pairs is established, the intrinsic reaction rate in the encounter pair, $k_{\text{mol}}\rho(R)$, equals the rate of diffusive formation of encounter pairs. In this formulation k_{mol} is a second-order rate constant. Solving the diffusion equation

$$\frac{\partial \rho}{\partial t} = D_{\text{AB}} \left[\frac{\partial^2 \rho}{\partial r^2} + \frac{2}{r} \frac{\partial \rho}{\partial r} \right] \quad (\text{A3.6.22})$$

subject to conditions (A3.6.21) and realizing that the observed reaction rate coefficient $k(t)$ equals $k_{\text{mol}}\rho(R, t)$, one obtains

$$k(t) = \frac{k_{\text{mol}}}{1+x} \{1 + x \exp[y^2(1+x)^2 t] \text{erfc}[y(1+x)\sqrt{t}]\} \quad (\text{A3.6.23})$$

-16-

using the abbreviations $x \equiv k_{\text{mol}}/4\pi R D_{\text{AB}}$ and $y \equiv \sqrt{D_{\text{AB}}}R$. The time-dependent terms reflect the transition from the initial to the stationary distribution. After this transient term has decayed to zero, the reaction rate attains its stationary value

$$k = \frac{k_{\text{mol}}}{1+x} = \frac{4\pi R D_{\text{AB}} k_{\text{mol}}}{4\pi R D_{\text{AB}} + k_{\text{mol}}} = \frac{k_{\text{diff}} k_{\text{mol}}}{k_{\text{diff}} + k_{\text{mol}}} \quad (\text{A3.6.24})$$

such that for $k_{\text{mol}} \gg k_{\text{diff}}$ one reaches the diffusion limit $k \simeq k_{\text{diff}}$. Comparing equation (A3.6.24) with the simple kinetic scheme (A3.6.19), one realizes that at this level of Smoluchowski theory one has $k_{\text{sep}} = k_{\text{diff}}\rho(R)$, i.e. there is no effect due to caging of the encounter complex in the common solvation shell. There exist numerous modifications and extensions of this basic theory that not only involve different initial and boundary conditions, but also the inclusion of microscopic structural aspects [31]. Among these are hydrodynamic repulsion at short distances that may be modelled, for example, by a distance-dependent diffusion coefficient

$$D_{\text{AB}}(r) \simeq D_{\text{AB}} \left[1 - \frac{1}{2} \exp\left(1 - \frac{r}{R}\right) \right]$$

or the potential of mean force *via* the radial distribution function $g(r)$, which leads to a significant reduction of the steady-state rate constant by about one-third with respect to the Smoluchowski value [33, 34]:

$$k = k_{\text{mol}} g(R) \left[1 + k_{\text{mol}} g(R) \int \frac{dr}{4\pi r^2 D_{AB}(r) g(r)} \right]^{-1}.$$

Diffusion-controlled reactions between ions in solution are strongly influenced by the Coulomb interaction accelerating or retarding ion diffusion. In this case, the diffusion equation for ρ concerning motion of one reactant about the other stationary reactant, the Debye–Smoluchowski equation,

$$\frac{\partial \rho}{\partial t} = D_{AB} \nabla \cdot \left[\nabla \rho + \frac{\rho}{kT} \nabla V(r) \right] \quad (\text{A3.6.25})$$

includes the gradient of the potential energy $V(r)$ of the ions in the Coulomb field. Using boundary conditions equivalent to equation (A3.6.21) and an initial condition corresponding to a Boltzmann distribution of interionic distances

$$\rho(r, 0) = e^{-V(r)/kT} = e^{-R_C/r} \quad R_C = \frac{z_A z_B e^2}{4\pi \epsilon \epsilon_0 kT}$$

and solving equation (A3.6.25), one obtains the steady-state solution

-17-

$$k = 4\pi R_C D_{AB} \left[\left(1 + \frac{4\pi R_C D_{AB}}{k_{\text{mol}}} \right) e^{R_C/R} - 1 \right]^{-1}.$$

Many additional refinements have been made, primarily to take into account more aspects of the microscopic solvent structure, within the framework of diffusion models of bimolecular chemical reactions that encompass also many-body and dynamic effects, such as, for example, treatments based on kinetic theory [35]. One should keep in mind, however, that in many cases the practical value of these advanced theoretical models for a quantitative analysis or prediction of reaction rate data in solution may be limited.

(B) TRANSITION FROM GASEOUS TO LIQUID SOLVENT—ONSET OF DIFFUSION CONTROL

Instead of concentrating on the diffusion limit of reaction rates in liquid solution, it can be instructive to consider the dependence of bimolecular rate coefficients of elementary chemical reactions on pressure over a wide solvent density range covering gas and liquid phase alike. Particularly amenable to such studies are atom recombination reactions whose rate coefficients can be easily investigated over a wide range of physical conditions from the dilute-gas phase to compressed liquid solution [3, 4].

As discussed above, one may try to represent the density dependence of atom recombination rate coefficients k in the spirit of equation (A3.6.24) as

$$\frac{1}{k} \approx \frac{1}{k_{\text{rec}}^g} + \frac{1}{k_{\text{diff}}} \quad (\text{A3.6.26})$$

where k_{rec}^g denotes the low-pressure second-order rate coefficient proportional to bath gas density, and k_{diff} is

the second-order rate coefficient of diffusion-controlled atom recombination as discussed in the previous section. In order to apply equation (A3.6.26), a number of items require answers specific to the reaction under study: (i) the density dependence of the diffusion coefficient D_{AA} , (ii) the magnitude of the encounter radius R , (iii) the possible participation of excited electronic states and (iv) the density dependence of $k_{\text{rec}}^{\text{g}}$. After these have been dealt with adequately, it can be shown that for many solvent bath gases, the phenomenon of the turnover from a molecular reaction into a diffusion-controlled recombination follows equation (A3.6.26) without any apparent discontinuity in the rate coefficient k at the gas–liquid phase transition, as illustrated for iodine atom recombination in argon [36, 37]. For this particular case, D_{AA} is based on and extrapolated from experimental data, R is taken to be one-half the sum of the Lennard-Jones radii of iodine atom and solvent molecule, and the density-dependent contribution of excited electronic states is implicitly considered by making the transition from the measured $k_{\text{rec}}^{\text{g}}$ in dilute ethane gas to k_{diff} in dense liquid ethane.

A more subtle point concerns scaling of $k_{\text{rec}}^{\text{g}}$ with density. Among the various possibilities that exist, either employing local densities obtained from numerically calculated radial distribution functions [38]

$$k_{\text{rec}}^{\text{g}}(\rho) = k_{\text{rec}}^{\text{g}}(\rho_0) \frac{\rho g(r; \rho)}{\rho_0 g(r; \rho_0)}$$

-18-

or taking into account that in the gas phase the reaction is controlled to a large extent by the energy transfer mechanism, such that $k_{\text{rec}}^{\text{g}} \approx \beta_c Z_{\text{LJ}}$ where β_c is a collision efficiency and Z_{LJ} the Lennard-Jones collision frequency, are probably the most practical. As $Z_{\text{LJ}} \sim 1/D_{\text{AM}}$ throughout the whole density range, $k_{\text{rec}}^{\text{g}}(\rho)$ in the latter case may be estimated by scaling with the diffusion coefficient [37]

$$k_{\text{rec}}^{\text{g}}(\rho) = k_{\text{rec}}^{\text{g}}(\rho_0) \frac{D_{\text{AM}}(\rho_0)}{D_{\text{AM}}(\rho)}$$

Although the transition to diffusion control is satisfactorily described in such an approach, even for these apparently simple elementary reactions the situation in reality appears to be more complex due to the participation of weakly bonding or repulsive electronic states which may become increasingly coupled as the bath gas density increases. These processes manifest themselves in iodine atom and bromine atom recombination in some bath gases at high densities where marked deviations from ‘normal’ behaviour are observed [3, 4]. In particular, it is found that the transition from $k_{\text{rec}}^{\text{g}}$ to k_{diff} is significantly broader than predicted by equation (A3.6.26), the reaction order of iodine recombination in propane is higher than 3, and S-shaped curves are observed with He as a bath gas [36] (see figure A3.6.4). This is in contrast to the recombination of the methyl radicals in Ar which can be satisfactorily described by a theory of particle encounter kinetics using appropriate interaction potentials and a modified friction for relative motion [39]. The only phenomena that cannot be reproduced by such treatments were observed at moderate gas pressures between 1 and 100 bar. This indicates that the kinetics of the reaction in this density regime may be influenced to a large extent by reactant–solute clustering or even chemical association of atoms or radicals with solvent molecules.

Figure A3.6.4. Pressure dependence of atom recombination rate constant of iodine in argon: experiment (points) [36] and theory (full line) [120].

-19-

This problem is related to the question of appropriate electronic degeneracy factors in chemical kinetics. Whereas the general belief is that, at very low gas pressures, only the electronic ground state participates in atom recombination and that, in the liquid phase, at least most of the accessible states are coupled somewhere ‘far out’ on the reaction coordinate, the transition between these two limits as a function of solvent density is by no means understood. Direct evidence for the participation of different electronic states in iodine geminate recombination in the liquid phase comes from picosecond time-resolved transient absorption experiments in solution [40, 41] that demonstrate the participation of the low-lying, weakly bound iodine A and A' states, which is also taken into account in recent mixed classical–quantum molecular dynamics simulations [42, 43].

A3.6.3.2 UNIMOLECULAR REACTIONS AND FRICTION

So far the influence of the dense solvent environment on the barrier crossing process in a chemical reaction has been ignored. It is evident from the typical pressure dependence of the rate coefficient k of a unimolecular reaction from the low-pressure gas phase to the compressed-liquid phase that the prerequisites of TST are only met, if at all, in a narrow density regime corresponding to the plateau region of the curve. At low pressures, where the rate is controlled by thermal activation in binary collisions with the solvent molecules, k is proportional to pressure. This regime is followed by a plateau region where k is pressure independent and controlled by intramolecular motion along the reaction coordinate. Here k attains the so-called high-pressure limit k_∞ which can be calculated by statistical theories if the PES for the reaction is known. If the reaction entails large-amplitude structural changes, further increasing the pressure can lead to a decrease of k as a result of frictional forces retarding the barrier crossing process. In the simplest approach, k eventually approaches an inverse dependence on solvent friction, the so-called Smoluchowski limit k_{SM} of the reaction rate.

The transition from k_0 to k_∞ on the low-pressure side can be constructed using multidimensional unimolecular rate theory [1, 44], if one knows the barrier height for the reaction and the vibrational frequencies of the reactant and transition state. The transition from k_∞ to k_{SM} can be described in terms of Kramers’ theory [45]

which, in addition, requires knowledge of the pressure dependence of the solvent friction acting on the molecule during the particular barrier crossing process. The result can be compared with rate coefficients measured over a wide pressure range in selected solvents to test the theoretical models that are used to describe this so-called Kramers' turnover of the rate coefficient.

(A) KRAMERS' THEORY

Kramers' solution of the barrier crossing problem [45] is discussed at length in [chapter A3.8](#) dealing with condensed-phase reaction dynamics. As the starting point to derive its simplest version one may use the Langevin equation, a stochastic differential equation for the time evolution of a slow variable, the reaction coordinate \mathbf{r} , subject to a rapidly statistically fluctuating force \mathbf{F} caused by microscopic solute–solvent interactions under the influence of an external force field generated by the PES V for the reaction

$$M\dot{\mathbf{u}} = -\gamma\mathbf{u} + \mathbf{F}(t) - \nabla_{\mathbf{r}}V \quad (\text{A3.6.27})$$

where dots denote time derivative, M is the mass moving with velocity \mathbf{u} along the reaction path and γ is the constant friction coefficient for motion along that path. The assumption is that there are no memory effects in the solvent bath,

-20-

i.e. one considers a Markov process such that for the ensemble average $\langle \mathbf{F}(t) \cdot \mathbf{F}(t') \rangle \sim \delta(t - t')$. The corresponding two-dimensional Fokker–Planck equation for the probability distribution in phase space can be solved for the potential-barrier problem involving a harmonic well and a parabolic barrier in the limit of low and large friction. Since the low-friction limit, corresponding to the reaction in the gas phase, is correctly described by multidimensional unimolecular rate theory, only the solution in the large-friction limit is of interest in this context. One obtains a correction factor F_{Kr} to the high-pressure limit of the reaction rate constant k_{∞}

$$F_{\text{Kr}} = \left[\left(\left(\frac{\gamma/M}{2\omega_{\text{B}}} \right)^2 - 1 \right)^{1/2} - \frac{\gamma/M}{2\omega_{\text{B}}} \right] \quad (\text{A3.6.28})$$

which contains as an additional parameter the curvature of the parabolic barrier top, the so-called imaginary barrier frequency ω_{B} . F_{Kr} is less than unity and represents the dynamic effect of trajectories recrossing the barrier top, in contrast to the central assumption of canonical and microcanonical statistical theories, like TST or RRKM theory. In the high-damping limit, when $\gamma/M \gg \omega_{\text{B}}$, F_{Kr} reduces to $\omega_{\text{B}}M/\gamma$ which simply represents the Smoluchowski limit where velocities relax much faster than the barrier is crossed. As γ approaches zero, F_{Kr} goes to unity and the rate coefficient becomes equal to the high-pressure limit k_{∞} . In contrast to the situation in the Smoluchowski limit, the velocities do not obey a Maxwell–Boltzmann distribution.

(B) PRESSURE DEPENDENCE OF REACTION RATES

If other fall-off broadening factors arising in unimolecular rate theory can be neglected, the overall dependence of the rate coefficient on pressure or, equivalently, solvent density may be represented by the expression [1, 2]

$$k(\rho) = \frac{k_0 \rho k_\infty}{k_0 \rho + k_\infty} F_{\text{Kr}}(\rho). \quad (\text{A3.6.29})$$

This ensures the correct connection between the one-dimensional Kramers model in the regime of large friction and multidimensional unimolecular rate theory in that of low friction, where Kramers' model is known to be incorrect as it is restricted to the energy diffusion limit. For low damping, equation (A3.6.29) reduces to the Lindemann–Hinshelwood expression, while in the case of very large damping, it attains the Smoluchowski limit

$$k_{\text{SM}} = k_\infty \frac{\omega_{\text{B}}}{\gamma/M}. \quad (\text{A3.6.30})$$

Sometimes it may be convenient to use an even simpler interpolation formula that connects the different rate coefficient limits [4]

$$\frac{1}{k} \approx \frac{1}{k_0 \rho} + \frac{1}{k_\infty} + \frac{1}{k_{\text{SM}}} \Rightarrow k \approx \frac{k_0 \rho k_\infty}{k_\infty + k_0(1 + \gamma/M\omega_{\text{B}})} \quad (\text{A3.6.31})$$

for which numerical simulations have shown that it is accurate to within 10–20%.

-21-

Predicting the solvent or density dependence of rate constants by [equation \(A3.6.29\)](#) or [equation \(A3.6.31\)](#) requires the same ingredients as the calculation of TST rate constants plus an estimate of ω_{B} and a suitable model for the friction coefficient γ and its density dependence. While in the framework of molecular dynamics simulations it may be worthwhile to numerically calculate friction coefficients from the average of the relevant time correlation functions, for practical purposes in the analysis of kinetic data it is much more convenient and instructive to use experimentally determined macroscopic solvent parameters.

As in the case of atom recombination, a convenient ‘pressure scale’ to use across the entire range is the inverse of the binary diffusion coefficient, D_{AM}^{-1} , of reactant A in solvent M, as compared to density ρ in the low-pressure gas and the inverse of solvent viscosity η^{-1} in liquid solution [46]. According to kinetic theory the diffusion coefficient in a dilute Lennard-Jones gas is given by

$$D_{\text{AM}} = \frac{3}{2\sqrt{2}} \frac{kT}{\mu_{\text{AM}}} \frac{\Omega^{(2,2)*}}{\Omega^{(1,1)*}} \frac{1}{Z_{\text{LJ}}\rho} \equiv \frac{A_{\text{D}}}{Z_{\text{LJ}}\rho}$$

with reduced collision integrals $\Omega^{(l,j)*}$ for Lennard-Jones well depths $\epsilon_{\text{AM}} = \sqrt{\epsilon_{\text{A}}\epsilon_{\text{M}}}$ and reduced mass μ_{AM} , such that the low-pressure rate coefficient is

$$k_0 = \frac{A_{\text{D}}}{D_{\text{AM}}} \int_{E_0}^{\infty} f(E) dE \equiv \frac{A_{\text{D}}}{D_{\text{AM}} k_{00}}.$$

In liquid solution, Brownian motion theory provides the relation between diffusion and friction coefficient

$D_{AM} = kT/\gamma$. Substituting correspondingly in equation (A3.6.31), one arrives at an expression representing the pressure dependence of the rate constant in terms of the pressure-dependent diffusion coefficient:

$$k \approx \frac{k_{00} A_D k_{\infty} D_{AM}}{k_{\infty} + k_{00} A_D (D_{AM} + kT/\mu_{AM} \omega_B)}. \quad (\text{A3.6.32})$$

As data of the binary diffusion coefficient $D_{AM}(\rho, T)$ are not available in many cases, one has to resort to taking the solvent self-diffusion coefficient $D_M(\rho, T)$ which requires rescaling in the low-pressure regime according to

$$\frac{D_M}{D_{AM}} = \left[\frac{2\mu_{AM}}{M} \right]^{1/2} \left[\frac{\sigma_M}{\sigma_{AM}} \right]^2 \frac{\Omega_M^{(1,1)*}}{\Omega_{AM}^{(1,1)*}}.$$

In the Smoluchowski limit, one usually assumes that the Stokes–Einstein relation $(D\eta/kT)\sigma = C$ holds, which forms the basis of taking the solvent viscosity as a measure for the zero-frequency friction coefficient appearing in Kramers' expressions. Here C is a constant whose exact value depends on the type of boundary conditions used in deriving Stokes' law. It follows that the diffusion coefficient ratio is given by $D_M/D_{AM} = C_M \sigma_{AM}/C_{AM} \sigma_M$, which may be considered as approximately pressure independent.

(C) EXTENSIONS OF KRAMERS' BASIC MODEL

As extensions of the Kramers theory [47] are essentially a topic of condensed-phase reaction dynamics, only a few remarks are in place here. These concern the barrier shape and the dimensionality in the high-damping regime. The curvature at the parabolic barrier top obviously determines the magnitude of the friction coefficient at which the rate constant starts to decrease below the upper limit defined by the high-pressure limit: for relatively sharp barriers this 'turnover' will occur at comparatively high solvent density corresponding almost to liquid phase densities, whereas reactions involving flat barriers will show this phenomenon in the moderately dense gas, maybe even in the unimolecular fall-off regime before they reach k_{∞} .

Non-parabolic barrier tops cause the prefactor to become temperature dependent [48]. In the Smoluchowski limit, $k_{SM} \propto T^n$, $|n| \sim 1$, with $n > 0$ and $n < 0$ for curvatures smaller and larger than parabolic, respectively. For a cusp-shaped barrier top, i.e. in the limit $\omega_B \rightarrow \infty$ as might be applicable to electron transfer reactions, one obtains [45]

$$k_{SM} = k_{\infty} \frac{\omega_A M \sqrt{\pi}}{\gamma} \sqrt{\frac{E_0}{kT}}$$

where ω_A is the harmonic frequency of the potential well in this one-dimensional model. In the other limit, for an almost completely flat barrier top, the transition curve is extremely broad and the maximum of k is far below k_{∞} [49]. A qualitatively different situation arises when reactant and product well are no longer separated by a barrier, but one considers escape out of a Lennard-Jones potential well. In this case, dynamics inside the well and outside on top of the 'barrier' plateau are no longer separable and, in a strict sense, the Smoluchowski limit is not reached any more. The stationary rate coefficient in the high-damping limit turns

out to be [50]

$$\left(\frac{k}{k_\infty}\right)^{\text{LJ}} = \frac{1}{\gamma\sigma_{\text{LJ}}} \sqrt{\frac{\pi M k T}{2}} \frac{1}{L/\sigma_{\text{LJ}} - 2^{1/6}} \left[1 - \frac{2\varepsilon_{\text{LJ}} M}{(L\gamma)^2} + \dots \right].$$

The original Kramers model is restricted to one-dimensional barriers and cannot describe effects due to the multidimensional barrier topology that may become important in cases where the system does not follow the minimum energy path on the PES but takes a detour across a higher effective potential energy barrier which is compensated by a gain in entropy. Considering a two-dimensional circular reaction path, the Smoluchowski limit of the rate coefficient obtained by solving the two-dimensional Fokker–Planck equation in coordinate space was shown to be [51]

$$k_{\text{SM}}^{2\text{D}} = k_{\text{SM}} \left[1 + \frac{kT}{M(\omega_\perp r_c)^2} \right]$$

where ω_\perp is the harmonic frequency of the transverse potential well and r_c the radius of curvature of the reaction path. This result is in good agreement with corresponding Langevin simulations [52]. A related concept is based on the picture that with increasing excitation of modes transverse to the reaction path the effective barrier curvature may increase according to $\omega_{\text{B}}^{\text{eff}}(E_\perp) \propto (E_\perp/b)^a$, where a and b are dimensionless parameters [53]. Approximating the

topology of the saddle point region by a combination of a parabolic barrier top and a transverse parabolic potential, one arrives at a rate constant in the Smoluchowski limit given by

$$k_{\text{SM}}^{2\text{D}} = \frac{k_\infty}{\gamma/M} \omega_{\text{B}}(T) \quad \text{with } \omega_{\text{B}}(T) \propto \left(\frac{T}{a}\right)^b \Gamma\left(b + \frac{1}{2}\right).$$

Multidimensionality may also manifest itself in the rate coefficient as a consequence of anisotropy of the friction coefficient [54]. Weak friction transverse to the minimum energy reaction path causes a significant reduction of the effective friction and leads to a much weaker dependence of the rate constant on solvent viscosity. These conclusions based on two-dimensional models also have been shown to hold for the general multidimensional case [55, 56, 57, 58, 59, 60 and 61].

To conclude this section it should be pointed out again that the friction coefficient has been considered to be frequency independent as implied in assuming a Markov process, and that zero-frequency friction as represented by solvent viscosity is an adequate parameter to describe the effect of friction on observed reaction rates.

(D) FREQUENCY-DEPENDENT FRICTION

For very fast reactions, as they are accessible to investigation by pico- and femtosecond laser spectroscopy, the separation of time scales into slow motion along the reaction path and fast relaxation of other degrees of freedom in most cases is no longer possible and it is necessary to consider dynamical models, which are not the topic of this section. But often the temperature, solvent or pressure dependence of reaction rate

coefficients determined in chemical kinetics studies exhibit a signature of underlying dynamic effects, which may justify the inclusion of some remarks at this point.

The key quantity in barrier crossing processes in this respect is the barrier curvature ω_B which sets the time window for possible influences of the dynamic solvent response. A sharp barrier entails short barrier passage times during which the memory of the solvent environment may be partially maintained. This non-Markov situation may be expressed by a generalized Langevin equation including a time-dependent friction kernel $\gamma(t)$ [62]

$$M\ddot{u} = - \int_0^t \gamma(t - \tau) \mathbf{u}(\tau) d\tau + \mathbf{F}(t) = \nabla_{\mathbf{r}} V$$

in which case the autocorrelation function of the randomly fluctuating force is no longer a δ -function but obeys $\langle \mathbf{F}(t) \cdot \mathbf{F}(t') \rangle = kT\gamma(t - t')$. This ensures that a Maxwell–Boltzmann distribution is re-established after decay of the solvent response. Adding the assumption of a Gaussian friction kernel, a generalized Fokker–Planck equation with time-dependent friction may be set up, and for a piecewise parabolic potential one obtains an expression for the rate coefficient, the so-called Grote–Hynes formula [63]:

$$k_{GH} = \frac{k_{\infty}}{\omega_B} \lambda_r. \quad (\text{A3.6.33})$$

-24-

λ_r is the reactive frequency or unstable mode which is related to the friction coefficient by the implicit equation

$$\lambda_r = \frac{\omega_B^2}{\lambda_r + (\gamma(\lambda_r)/M)} \quad (\text{A3.6.34})$$

with $\gamma(\lambda_r)$ being the Laplace transform of the time-dependent friction, $\hat{\gamma}(\lambda_r) = \int_0^{\infty} \exp(-\lambda_r t) \gamma(t) dt$. It is obvious that calculation of k_{GH} requires knowledge of potential barrier parameters and the complete viscoelastic response of the solvent, demonstrating the fundamental intimate link between condensed-phase reaction dynamics and solvation dynamics. This kind of description may be equivalently transferred to the dielectric response of the solvent causing dielectric friction effects in reactions with significant and fast charge rearrangement [64, 65 and 66].

In the Smoluchowski limit the reaction is by definition the slow coordinate, such that $\hat{\gamma}(\lambda_r) \approx \hat{\gamma}(0) = \int_0^{\infty} \gamma(t) dt$, $\hat{\gamma}(0) \gg \lambda_r$ and $k_{GH} \approx k_{SM} = k_{\infty} \omega_B M / \hat{\gamma}(0)$. Though the time-dependent friction in principle is accessible *via* molecular dynamics simulations, for practical purposes in chemical kinetics in most cases analytical friction models have to be used including a short-time Gaussian ‘inertial’ component and a hydrodynamic tail at longer times. In the Grote–Hynes description the latter term only comes into play when the barrier top is sufficiently flat. As has been pointed out, the reactive mode frequency λ_r can be interpreted as an effective barrier curvature such that coupling of the reaction coordinate to the solvent changes position and shape of the barrier in phase space.

Because of the general difficulty encountered in generating reliable potentials energy surfaces and estimating reasonable friction kernels, it still remains an open question whether by analysis of experimental rate constants one can decide whether non-Markovian bath effects or other influences cause a particular solvent or pressure dependence of reaction rate coefficients in condensed phase. From that point of view, a purely

empirical friction model might be a viable alternative, in which the frequency-dependent friction is replaced by a state-dependent friction $\hat{\gamma}(\omega) \rightarrow K^2 = \omega_B^2/(A/\eta + B)$ that is described in terms of properties of PES and solute–solvent interaction, depicting the reaction as occurring in a frozen environment of fixed microscopic viscosity [67, 68].

(E) MICROSCOPIC FRICTION

The relation between the microscopic friction acting on a molecule during its motion in a solvent environment and macroscopic bulk solvent viscosity is a key problem affecting the rates of many reactions in condensed phase. The sequence of steps leading from friction to diffusion coefficient to viscosity is based on the general validity of the Stokes–Einstein relation and the concept of describing friction by hydrodynamic as opposed to microscopic models involving local solvent structure. In the hydrodynamic limit the effect of solvent friction on, for example, rotational relaxation times of a solute molecule is [69]

$$\tau_{\text{rot}} = 1/6D_{\text{rot}} = (V_h/kT)\eta f_{\text{bc}}C + \tau_0 \quad (\text{A3.6.35})$$

where V_h is the hydrodynamic volume of the solute in the particular solvent, whereas f_{bc} and C are parameters describing hydrodynamic boundary conditions and correcting for aspherical shape, respectively. τ_0 in turn may be related to the relaxation time of the free rotor. Though in many cases this equation correctly reproduces the viscosity dependence of τ_{rot} , in particular when solute and solvent molecules are comparable in size there are quite a number of significant deviations. One may incorporate this size effect by explicitly considering the first solvation shell on the

-25-

solute surface which, under the assumption of slip boundary conditions, gives for the correction factor C in equation (A3.6.35):

$$C_{\text{size}} = \frac{f_{\text{slip}}V_h}{f_{\text{slip}}V_h + BkT\kappa_T\eta(4/\sigma_r^2 + 1)} \quad (\text{A3.6.36})$$

with isothermal compressibility κ_T , ratio of radii of solvent to solute σ_r and a temperature-dependent parameter B . If one compares equation (A3.6.36) with the empirical friction model mentioned above, one realizes that both contain a factor of the form $C = 1/1 + a\eta$, suggesting that these models might be physically related.

Another, purely experimental possibility to obtain a better estimate of the friction coefficient for rotational motion γ_{rot} in chemical reactions consists of measuring rotational relaxation times τ_{rot} of reactants and calculating it according to equation (A3.6.35) as $\gamma_{\text{rot}} = 6kT\tau_{\text{rot}}$.

A3.6.4 SELECTED REACTIONS

A3.6.4.1 PHOTOISOMERIZATION

According to Kramers' model, for flat barrier tops associated with predominantly small barriers, the transition from the low- to the high-damping regime is expected to occur in low-density fluids. This expectation is borne

out by an extensively studied model reaction, the photoisomerization of *trans*-stilbene and similar compounds [70, 71] involving a small energy barrier in the first excited singlet state whose decay after photoexcitation is directly related to the rate coefficient of *trans-cis*-photoisomerization and can be conveniently measured by ultrafast laser spectroscopic techniques.

(A) PRESSURE DEPENDENCE OF PHOTOISOMERIZATION RATE CONSTANTS

The results of pressure-dependent measurements for *trans*-stilbene in supercritical *n*-pentane [46] (figure A3.6.5) and the prediction from the model described by equation (A3.6.29), using experimentally determined microcanonical rate coefficients in jet-cooled *trans*-stilbene to calculate k_∞ , show two marked discrepancies between model calculation and measurement: (1) experimental values of k are an order of magnitude higher already at low pressure and (2) the decrease of k due to friction is much less pronounced than predicted. As interpretations for the first observation, several ideas have been put forward that will not be further discussed here, such as a decrease of the effective potential barrier height due to electrostatic solute–solvent interactions enhanced by cluster formation at relatively low pressures [72, 73], or incomplete intramolecular vibrational energy redistribution in the isolated molecule [74, 75, 76, 77, 78, 79 and 80], or Franck–Condon cooling in the excitation process [79, 80]. The second effect, the weak viscosity dependence, which was first observed in solvent series experiments in liquid solution [81, 82 and 83], has also led to controversial interpretations: (i) the macroscopic solvent viscosity is an inadequate measure for microscopic friction acting along the reaction path [84, 85], (ii) the multidimensional character of the barrier crossing process leads to a fractional power dependence of k on $1/\eta$ [54, 81, 86, 87], (iii) as the reaction is very fast, one has to take into account the finite response time of the solvent, i.e. consider frequency-dependent friction [81, 87] and (iv) the effective barrier

-26-

height decreases further with increasing electronic polarizability and polarity of the solvent, and the observed phenomenon is a manifestation of the superposition of a static solvent effect and hydrodynamic solvent friction correctly described by η [88]. One may test these hypotheses by studying molecular rotational motion and reaction independently in compressed sample solutions. A few examples will serve here to illustrate the main conclusions one can draw from the experimental results.

Figure A3.6.5. Photoisomerization rate constant of *trans*-stilbene in *n*-pentane versus inverse of the self-diffusion coefficient. Points represent experimental data, the dashed curve is a model calculation based on an

RRKM fit to microcanonical rate constants of isolated *trans*-stilbene and the solid curve a fit that uses a reaction barrier height reduced by solute–solvent interaction [46].

(B) MICROSCOPIC AND FREQUENCY-DEPENDENT FRICTION

Rotational relaxation times τ_{rot} of *trans*-stilbene and E,E-diphenylbutadiene (DPB) in liquid solvents like subcritical ethane and *n*-octane show a perfectly linear viscosity dependence with a slope that depends on the solvent [89] (figure A3.6.6), showing that microscopic friction acting during molecular rotational diffusion is proportional to the macroscopic solvent viscosity and that the relevant solute–solvent coupling changes with solvent. It seems reasonable to assume, therefore, that a corresponding relation also holds for microscopic friction governing diffusive motion along the reaction path.

Figure A3.6.6. Viscosity dependence of rotational relaxation times of *trans*-stilbene in ethane (open circles) and *n*-octane (full circles) [89].

The validity of this assumption is apparent in the viscosity dependence of rate coefficients for S_1 -photoisomerization reactions in a number of related molecules such as *cis*-stilbene [90] (see figure A3.6.7), tetraphenylethylene (TPE) [91], DPB [92] and ‘stiff’ *trans*-stilbene [93] (where the phenyl ring is fixed by a five-membered ring to the ethylenic carbon atom). In all these cases a study of the pressure dependence reveals a linear correlation between k and $1/\eta$ in *n*-alkane and *n*-alkanol solvents, again with a solvent-dependent slope. The time scale for motion along the reaction path extends from several hundred picoseconds in DPB to a couple of hundred femtoseconds in *cis*-stilbene. There is no evidence for a frequency dependence of the friction coefficient in these reactions. As the time scale for the similar reaction in *trans*-stilbene is between 30 and 300 ps, one may conclude that also in this case the dynamics is mainly controlled by the zero-frequency friction which, in turn, is adequately represented by the macroscopic solvent viscosity. Therefore, the discrepancy between experiment and model calculation observed for *trans*-stilbene in compressed-liquid *n*-alkanes does not indicate a breakdown of the simple friction model in the Kramers–Smoluchowski theory. This result is in contrast to the analysis of solvent series study in linear alkanes, in which a solvent size effect of the microviscosity was made responsible for weak viscosity dependence [94]. Surprisingly, in a different type of non-polar solvent like methylcyclohexane, an equally weak viscosity dependence was found when the pressure was varied [95]. So the details of the viscosity influence are still posing puzzling questions.

Figure A3.6.7. Viscosity dependence of reduced S_1 -decay rate constants of *cis*-stilbene in various solvents [90]. The rate constants are divided by the slope of a linear regression to the measured rate constants in the respective solvent.

(C) EFFECTIVE BARRIER HEIGHT

Measuring the pressure dependence of k at different temperatures shows that the apparent activation energy at constant viscosity decreases with increasing viscosity [46, 89] (figure A3.6.8). From a detailed analysis one can extract an effective barrier height E_0 along the reaction path that decreases linearly with increasing density of the solvent. The magnitude of this barrier shift effect is more than a factor of two in nonpolar solvents like *n*-hexane or *n*-pentane [46]. It is interesting to note that in compressed-liquid *n*-propanol one almost reaches the regime of barrierless dynamics [96]. This is also evident in the room-temperature $k(\eta)$ isotherm measured in *n*-butanol (figure A3.6.9) which turns into linear k versus $1/\eta$ dependence at higher pressures, indicating that there is no further decrease of the effective barrier height. Thus the unexpected dependence of the reaction rate on solvent viscosity is connected with specific properties of the PES of *trans*-stilbene in its first excited singlet state, because corresponding measurements for, for example, DPB or TPE in *n*-alkanes and *n*-alkanols do not show any evidence for deviations from standard Kramers–Smoluchowski behaviour.

Figure A3.6.8. Isotherms of $k(\eta)$ for *trans*-stilbene photoisomerization in *n*-hexane at temperatures between

300 K (bottom) and 480 K (top). The curvature of the isotherms is interpreted as a temperature-dependent barrier shape [89].

Figure A3.6.9. Viscosity dependence of photoisomerization rate constants of *trans*-stilbene (open circles) and *E,E*-diphenylbutadiene (full circles) in *n*-butanol. The broken line indicates a η^{-1} -dependence of k [96].

As a multidimensional PES for the reaction from quantum chemical calculations is not available at present, one does not know the reason for the surprising barrier effect in excited *trans*-stilbene. One could suspect that *trans*-stilbene possesses already a significant amount of zwitterionic character in the conformation at the barrier top, implying a fairly ‘late’ barrier along the reaction path towards the twisted perpendicular structure. On the other hand, it could also be possible that the effective barrier changes with viscosity as a result of a multidimensional barrier crossing process along a curved reaction path.

(D) SOLVATION DYNAMICS

The dependence of k on viscosity becomes even more puzzling when the time scale of motion along the reaction coordinate becomes comparable to that of solvent dipole reorientation around the changing charge distribution

within the reacting molecule—in addition to mechanical, one also has to consider dielectric friction. For *trans*-stilbene in ethanol, the $k(\eta)$ curve exhibits a turning point which is caused by a crossover of competing solvation and reaction time scales [97] (figure A3.6.10): as the viscosity increases the dielectric relaxation time of the solvent increases more rapidly than the typical time necessary for barrier crossing. Gradually, the solvation dynamics starts to freeze out on the time scale of reactive motion, the polar barrier is no longer decreased by solvent dipole reorientation and the rate coefficient drops more rapidly with increasing viscosity. As soon as the solvent dipoles are completely ‘frozen’, one has the same situation as in a non-polar solvent: i.e. only the electronic polarizability of the solvent causes further decrease of the barrier height.

Figure A3.6.10. Viscosity dependence of photoisomerization rate constants of *trans*-stilbene (open circles) and *E,E*-diphenylbutadiene (full circles) in ethanol. The dashed line indicates a η^{-1} -dependence of k , the dotted line indicates the viscosity dependence of the dielectric relaxation time of ethanol and the solid curve is the result of a kinetic model describing the parallel processes of reaction and solvent relaxation [97].

A3.6.4.2 CHAIR-BOAT INVERSION OF CYCLOHEXANE

As mentioned above, in liquid solution most reactions are expected to have passed beyond the low-damping regime where the dynamics is dominated by activating and deactivating collisions between reactants' solvent molecules. In general, this expectation is met, as long as there is a sufficiently strong intramolecular coupling of the reaction coordinate to a large number of the remaining modes of the reactant at the transition state which leads to fast IVR within the reactant. In this case, the high-pressure limit of unimolecular rate theory is reached, and additional coupling to the liquid solvent environment leads to a decrease of the rate coefficient through the factor F_{KR} . From this point of view, the observation of rate coefficient maxima in liquid solution would appear to signal a breakdown of RRKM theory. In particular it has been argued that, for the case of weak *intramolecular* coupling, a strong coupling of the reaction coordinate to the solvent could effectively decrease the volume of phase space accessible to the reactant in

the liquid with respect to the gas phase [98, 99]. As the relative strength of *intra*- and *intermolecular* coupling may change with solvent properties, the breakdown of the RRKM model might be accompanied by the appearance of a rate coefficient maximum in liquid solution as a function of solvent friction.

Among the few reactions for which an increase of a reaction rate coefficient in liquid solution with increasing reactant–solvent coupling strength has been observed, the most notable is the thermal chair-boat isomerization reaction of cyclohexane (figure A3.6.11) and 1,1-difluorocyclohexane [100, 101, 102 and 103]. The observed pressure dependence of the rate coefficients along different isotherms was analysed in terms of one-dimensional transition state theory by introducing a transmission coefficient κ describing the effect of solvent friction $k_{\text{obs}} = \kappa k_{\text{TST}}$. In the intermediate- to high-damping regime, κ can be identified with the Kramers term F_{KR} . The observed pressure-dependent activation volumes $\Delta V_{\text{OBS}}^{\ddagger}$ were considered to represent the sum of a

pressure-independent intrinsic activation volume $\Delta V_{\text{TST}}^\ddagger$ and a pressure-dependent formal collisional activation volume $\Delta V_{\text{COLL}}^\ddagger$ arising from the increase of that reactant–solvent coupling with pressure which corresponds to viscous effects

$$RT \left(\frac{\partial \ln k_{\text{TST}}}{\partial p} \right)_T = -\Delta V_{\text{TST}}^\ddagger$$

$$RT \left(\frac{\partial \ln \kappa}{\partial p} \right)_T = -\Delta V_{\text{COLL}}^\ddagger.$$

The intrinsic volume of activation was estimated to correspond to the molar volume difference between cyclohexene and cyclohexane, adding the molar volume difference between ethane and ethene to account for the two missing protons and shortened double bond in cyclohexane. This yields a value of $\Delta V_{\text{TST}}^\ddagger = -1.5 \text{ cm}^3 \text{ mol}^{-1}$. Then, knowing the pressure dependence of the solvent viscosity, the viscosity dependence of the relative transmission coefficient κ was estimated from

$$\frac{\kappa(\eta)}{\kappa(1.5 \text{ cP})} = \frac{k_{\text{obs}}(\eta)}{k_{\text{obs}}(1.5 \text{ cP})} \exp \left[\frac{p \Delta V_{\text{TST}}^\ddagger}{RT} \right].$$

The experimental values of $\kappa(\eta)$ have a maximum at a viscosity close to 3 cP and varies by about 15% over the entire viscosity range studied. As discussed above, this unexpected dependence of κ on solvent friction in liquid CS_2 is thought to be caused by a relatively weak intramolecular coupling of the reaction coordinate to the remaining modes in cyclohexane. At viscosities below the maximum, motion along the reaction coordinate due to the reduction of the accessible phase space region is fast. The barrier passage is still in the inertial regime, and the strong coupling to the solvent leads to increasingly rapid stabilization in the product well. With increasing solvent friction, the barrier crossing enters the diffusive regime and begins to show a slowdown with further increasing solvent viscosity.

Figure A3.6.11. Viscosity dependence of transmission coefficient of the rate of cyclohexane chair-boat inversion in liquid solution (data from [100]).

This interpretation of the experimentally determined pressure dependence of the isomerization rate rests on

the assumptions that (i) the barrier height for the reaction is independent of pressure and (ii) the estimate of the intrinsic volume of activation is reliable to within a factor of two and $\Delta V_{\text{TST}}^\ddagger$ does not change with pressure. As pointed out previously, due to the differences in the pressure dependences of solvent viscosity and density, a change of the barrier height with solvent density can give rise also to an apparent maximum of the rate coefficient as a function of viscosity. In particular, a decrease of E_0 with pressure by about 1 kJ mol^{-1} could explain the observed non-monotonic viscosity dependence. Therefore, the constancy to within 0.05 kJ mol^{-1} of the isoviscous activation energy over a limited viscosity range from 1.34 to 2.0 cP lends some support to the first assumption.

From stochastic molecular dynamics calculations on the same system, in the viscosity regime covered by the experiment, it appears that *intra*- and *intermolecular* energy flow occur on comparable time scales, which leads to the conclusion that cyclohexane isomerization in liquid CS_2 is an activated process [99]. Classical molecular dynamics calculations [104] also reproduce the observed non-monotonic viscosity dependence of κ . Furthermore, they also yield a solvent contribution to the free energy of activation for the isomerization reaction which in liquid CS_2 *increases* by about 0.4 kJ mol^{-1} , when the solvent density is increased from 1.3 to 1.5 g cm^{-3} . Thus the molecular dynamics calculations support the conclusion that the high-pressure limit of this unimolecular reaction is not attained in liquid solution at ambient pressure. It has to be remembered, though, that the analysis of the measured isomerization rates depends critically on the estimated value of $\Delta V_{\text{TST}}^\ddagger$. What is still needed is a reliable calculation of this quantity in CS_2 .

A3.6.4.3 PHOTOLYTIC CAGE EFFECT AND GEMINATE RECOMBINATION

For very fast reactions, the competition between geminate recombination of a pair of initially formed reactants and its escape from the common solvent cage is an important phenomenon in condensed-phase kinetics that has received considerable attention both theoretically and experimentally. An extremely well studied example is the

-33-

photodissociation of iodine for which the quantum yield Φ_d decreases from unity in the dilute-gas phase by up to a factor of ten or more in compressed-liquid solution. An intuitively appealing interpretation of this so-called photolytic cage effect, predicted by Franck and Rabinovitch in the 1930s [105], is based on models describing it as diffusive escape of the pair [106], formed instantaneously at t_0 with initial separation \mathbf{r}_0 , from the solvent cage under the influence of Stokes friction subject to inner boundary conditions similar to equation (A3.6.21) [31],

$$\frac{\partial \rho}{\partial t} = D_{AA} \nabla^2 \rho + \delta(\mathbf{r} - \mathbf{r}_0) \delta(t - t_0) \quad k_{\text{mol}} \rho(\mathbf{r}, t) = 4\pi R D_{AA} \left. \frac{\partial \rho}{\partial r} \right|_R.$$

Solving this diffusion problem yields an analytical expression for the time-dependent escape probability $q(t)$:

$$q(t) = 1 - \frac{x}{z(1+x)} \left\{ \text{erfc} \left(\frac{z-1}{2y\sqrt{t}} \right) - \exp[(z-1)(1+x) + y^2 t (1+x)^2] \text{erfc} \left[y\sqrt{t}(1+x) + \frac{z-1}{2y\sqrt{t}} \right] \right\}$$

where x and y are as defined above and $z = r_0/R$. This equation can be compared with time-resolved measurements of geminate recombination dynamics in liquid solution [107, 108] if the parameters r_0 , R , D_{AA} and k_{mol} are known or can be reliably estimated. This simple diffusion model, however, does not satisfactorily represent the observed dynamics, which is in part due to the participation of different electronic states. Direct evidence for this comes from picosecond time-resolved transient absorption experiments in solution that demonstrate the involvement of the low-lying, weakly bound iodine A and A' states. In these experiments it was possible to separate geminate pair dynamics and vibrational energy relaxation of the initially formed hot iodine molecules [40, 41, 109]. The details of the complex steps of recombination dynamics are still only partially understood and the subject of mixed quantum–classical molecular dynamics simulations [110].

In order to probe the importance of van der Waals interactions between reactants and solvent, experiments in the gas–liquid transition range appear to be mandatory. Time-resolved studies of the density dependence of the cage and cluster dynamics in halogen photodissociation are needed to extend earlier quantum yield studies which clearly demonstrated the importance of van der Waals clustering at moderate gas densities [37, 111] (see figure A3.6.12). The pressure dependence of the quantum yield established the existence of two different regimes for the cage effect: (i) at low solvent densities, excitation of solvent-clustered halogen molecules leads to predissociation of the van der Waals bond and thereby to stabilization of the halogen molecule, whereas (ii), at high liquid phase densities, the hard-sphere repulsive caging takes over which leads to a strong reduction in the photodissociation quantum yield.

Figure A3.6.12. Photolytic cage effect of iodine in supercritical ethane. Points represent measured photodissociation quantum yields [37] and the solid curve is the result of a numerical simulation [111].

Attractive long-range and repulsive short-range forces both play a role in the cage effect, though each type dominates in a different density range. Whereas the second component has traditionally been recognized as being responsible for caging in liquid solution and solids, theoretical models and molecular dynamics calculations [112, 113] have confirmed the idea that complex formation between halogen and solvent molecules in supercritical solvents is important in photodissociation dynamics and responsible for the lowering of quantum yields at moderate gas densities [114, 115].

The traditional diffusion model permits estimation of the magnitude of the cage effect in solution according to [37]

$$\lim_{t \rightarrow \infty} q(t) = 1 - \frac{x}{z(1+x)}$$

which should directly represent overall photodissociation quantum yields measured in dense solvents, as in this quantity dynamical effects are averaged out as a consequence of multiple collisions in the cage and effective collision-induced hopping between different electronic states at large interatomic distances. The initial separation of the iodine atom pair in the solvent cage may be calculated by assuming that immediately after excitation, the atoms are spherical particles subject to Stokes friction undergoing a damped motion on a repulsive potential represented by a parabolic branch. This leads to an excitation energy dependence of the initial separation [37]

$$z - 1 = \frac{\sqrt{1 - c^2}}{2c} \exp\left(-\frac{\pi c}{\sqrt{1 - c^2}}\right) \quad \text{with } c = \frac{6\pi\eta\sigma_1 R}{\sqrt{m_1(h\nu - D_0)}} \text{ for } c < 1$$

where σ_1 and m_1 are radius and mass of the iodine atom, respectively, $h\nu$ is the photon energy and D_0 the dissociation energy of iodine molecules. Obviously, $c \geq 1$ corresponds to the overdamped case for which $r_0 = R$ irrespective of

-35-

initial energy. As in experiments a fairly weak dependence of Φ_d on excitation wavelength was found, it seems that, at least at liquid phase densities, separation of the iodine pair is overdamped, a finding corroborated by recent classical molecular dynamics simulations using simple model potentials [38].

The simple diffusion model of the cage effect again can be improved by taking effects of the local solvent structure, i.e. hydrodynamic repulsion, into account in the same way as discussed above for bimolecular reactions. The consequence is that the potential of mean force tends to favour escape at larger distances ($r_0 > 1.5R$) more than it enhances caging at small distances, leading to larger overall photodissociation quantum yields [116, 117].

The analysis of recent measurements of the density dependence of Φ_d has shown, however, that considering only the variation of solvent structure in the vicinity of the atom pair as a function of density is entirely sufficient to understand the observed changes in Φ_d with pressure and also with size of the solvent molecules [38]. Assuming that iodine atoms colliding with a solvent molecule of the first solvation shell under an angle α less than α_{\max} (the value of α_{\max} is solvent dependent and has to be found by simulations) are reflected back onto each other in the solvent cage, Φ_d is given by

$$\Phi_d = 1 - 4\pi\rho(1 - \cos\alpha_{\max}) \int_0^{r_{\text{shell}}} r^2 g(r) dr$$

where the solvation shell radius shell is obtained from Lennard-Jones radii (figure A3.6.13).

Figure A3.6.13. Density dependence of the photolytic cage effect of iodine in compressed liquid *n*-pentane (circles), *n*-hexane (triangles), and *n*-heptane (squares) [38]. The solid curves represent calculations using the diffusion model [37], the dotted and dashed curves are from ‘static’ caging models using Carnahan–Starling packing fractions and calculated radial distribution functions, respectively [38].

-36-

As these examples have demonstrated, in particular for fast reactions, chemical kinetics can only be appropriately described if one takes into account dynamic effects, though in practice it may prove extremely difficult to separate and identify different phenomena. It seems that more experiments under systematically controlled variation of solvent environment parameters are needed, in conjunction with numerical simulations that as closely as possible mimic the experimental conditions to improve our understanding of condensed-phase reaction kinetics. The theoretical tools that are available to do so are covered in more depth in other chapters of this encyclopedia and also in comprehensive reviews [6, 118, 119].

A3.7 Molecular reaction dynamics in the gas phase

Daniel M Neumark

A3.7.1 INTRODUCTION

The field of gas phase reaction dynamics is primarily concerned with understanding how the microscopic forces between atoms and molecules govern chemical reactivity. This goal is targeted by performing exacting experiments which yield measurements of detailed attributes of chemical reactions, and by developing state-of-the-art theoretical techniques in order to calculate accurate potential energy surfaces for reactions and determine the molecular dynamics that occur on these surfaces. It has recently become possible to compare experimental results with theoretical predictions on a series of benchmark reactions. This convergence of experiment and theory is leading to significant breakthroughs in our understanding of how the peaks and valleys on a potential energy surface can profoundly affect the measurable properties of a chemical reaction.

In most of gas phase reaction dynamics, the fundamental reactions of interest are bimolecular reactions,

and unimolecular photodissociation reactions,

There are significant differences between these two types of reactions as far as how they are treated experimentally and theoretically. Photodissociation typically involves excitation to an excited electronic state, whereas bimolecular reactions often occur on the ground-state potential energy surface for a reaction. In addition, the initial conditions are very different. In bimolecular collisions one has no control over the reactant orbital angular momentum (impact parameter), whereas in photodissociation one can start with cold molecules with total angular momentum $J \approx 0$. Nonetheless, many theoretical constructs and experimental methods can be applied to both types of reactions, and from the point of view of this chapter their similarities are more important than their differences.

The field of gas phase reaction dynamics has been extensively reviewed elsewhere [1, 2 and 3] in considerably greater detail than is appropriate for this chapter. Here, we begin by summarizing the key theoretical concepts and experimental techniques used in reaction dynamics, followed by a ‘case study’, the reaction $F + H_2 \rightarrow HF + H$, which serves as an illustrative example of these ideas.

A3.7.2 THEORETICAL BACKGROUND: THE POTENTIAL ENERGY SURFACE

Experimental and theoretical studies of chemical reactions are aimed at obtaining a detailed picture of the potential

-2-

energy surface on which these reactions occur. The potential energy surface represents the single most important theoretical construct in reaction dynamics. For N particles, this is a $3N - 6$ dimensional function $V(q_1 \dots q_{3N-6})$ that gives the potential energy as a function of nuclear internal coordinates. The potential energy surface for any reaction can, in principle, be found by solving the electronic Schrödinger equation at many different nuclear configurations and then fitting the results to various functional forms, in order to obtain a smoothly varying surface in multiple dimensions. In practice, this is extremely demanding from a computational perspective. Thus, much of theoretical reaction dynamics as recently as a few years ago was performed on highly approximate model surfaces for chemical reactions which were generated using simple empirical functions (the London–Eyring–Polanyi–Sato potential, for example [4]). The $H + H_2$ reaction was the first for which an accurate surface fitted to *ab initio* points was generated [5, 6]. However, recent conceptual and computational advances have made it possible to construct accurate surfaces for a small number of benchmark systems, including the $F + H_2$, $Cl + H_2$ and $OH + H_2$ reactions [7, 8 and 9]. Even in these systems, one must be concerned with the possibility that a single Born–Oppenheimer potential energy surface is insufficient to describe the full dynamics [10].

Let us consider the general properties of a potential energy surface for a bimolecular reaction involving three atoms, i.e. equation (A3.7.1) with A , B and C all atomic species. A three-atom reaction requires a three-dimensional function. It is more convenient to plot two-dimensional surfaces in which all coordinates but two are allowed to vary. Figure A3.7.1 shows a typical example of a potential energy surface contour plot for a collinear three-atom reaction. The dotted curve represents the minimum energy path, or reaction coordinate, that leads from reactants on the lower right to products on the upper left. The reactant and product valleys (often referred to as the entrance and exit valleys, respectively) are connected by the transition-state region, where the transformation from reactants to products occurs, and ends in the product valley at the upper left. The potential energy surface shown in Figure A3.7.1 is characteristic of a ‘direct’ reaction, in that there is a single barrier (marked by ‡ in Figure A3.7.1) along the minimum energy path in the transition-state region. In the other general class of bimolecular reaction, a ‘complex’ reaction, one finds a well rather than a barrier in the transition-state region.

Figure A3.7.1. Two-dimensional contour plot for direct collinear reaction $A + BC \rightarrow AB + C$. Transition state is indicated by ‡.

-3-

The barrier on the surface in [figure A3.7.1](#) is actually a saddle point; the potential is a maximum along the reaction coordinate but a minimum along the direction perpendicular to the reaction coordinate. The classical transition state is defined by a slice through the top of the barrier perpendicular to the reaction coordinate. This definition holds for multiple dimensions as well; for N particles, the classical transition state is a saddle point that is unbound along the reaction coordinate but bound along the $3N - 7$ remaining coordinates. A cut through the surface at the transition state perpendicular to the reaction coordinate represents a $3N - 7$ dimensional dividing surface that acts as a ‘bottleneck’ between reactants and products. The nature of the transition state and, more generally, the region of the potential energy in the vicinity of the transition state (referred to above as the transition-state region) therefore plays a major role in determining many of the experimental observables of a reaction such as the rate constant and the product energy and angular distributions. For this reason, the transition-state region is the most important part of the potential energy surface from a computational (and experimental) perspective.

Once such an *ab initio* potential energy surface for a reaction is known, then all properties of the reaction can, in principle, be determined by carrying out multidimensional quantum scattering calculations. This is again computationally very demanding, and for many years it was more useful to perform classical and quasi-classical trajectory calculations to explore dynamics on potential energy surfaces [11]. The simpler calculations led to very valuable generalizations about reaction dynamics, showing, for example, that for an exothermic reaction with an entrance channel barrier, reactant translation was far more effective than vibration in surmounting the barrier and thus forming products, and are still very useful, since quantum effects in chemical reactions are often relatively small. However, recent conceptual and computational advances [12, 13 and 14] have now made it possible to carry out exact quantum scattering calculations on multidimensional potential energy surfaces, including the benchmark surfaces mentioned above. Comparison of such calculations with experimental observables provides a rigorous test of the potential energy surface.

A3.7.3 EXPERIMENTAL TECHNIQUES IN REACTION DYNAMICS

We now shift our focus to a general discussion of experimental chemical reaction dynamics. Given that the goal of these experiments is to gain an understanding of the reaction potential energy surface, it is important to perform experiments that can be interpreted as cleanly as possible in terms of the underlying surface. Hence, bimolecular and unimolecular reactions are often studied under ‘single-collision’ conditions, meaning

that the number density in the experiment is sufficiently low that each reactant atom or molecule undergoes at most one collision with another reactant or a photon during the course of the experiment, and the products are detected before they experience any collisions with bath gases, walls, etc. One can therefore examine the results of single-scattering events without concern for the secondary collisions and reactions that often complicate the interpretation of more standard chemical kinetics experiments. Moreover, the widespread use of supersonic beams in reaction dynamics experiments [15, 16] allows one to perform reactions under well defined initial conditions; typically the reactants are rotationally and vibrationally very cold, and the spread in collision energies (for bimolecular reactions) is narrow. The study of photodissociation reactions [2, 17] has been greatly facilitated by recent developments in laser technology, which now permit one to investigate photodissociation at virtually any wavelength over a spectral range extending from the infrared to vacuum ultraviolet (VUV).

What attributes of bimolecular and unimolecular reactions are of interest? Most important is the identity of the products, without which any further characterization is impossible. Once this is established, more detailed issues can be addressed. For example, in any exothermic reaction, one would like to determine how the excess energy is

-4-

partitioned among the translational, rotational, vibrational and electronic degrees of freedom of the products. Under the ideal of 'single-collision' conditions, one can measure the 'nascent' internal energy distribution of the products, i.e. the distribution resulting from the reaction before any relaxation (collisional or otherwise) has occurred. Measurements of the product angular distribution provide considerable insight into the topology and symmetry of the potential energy surface(s) on which the reaction occurs. More recently, the measurement of product alignment and orientation has become an area of intense interest; in photodissociation reactions, for example, one can determine if the rotational angular momentum of a molecular fragment is randomly oriented or if it tends to be parallel or perpendicular to the product velocity vector.

An incredible variety of experimental techniques have been developed over the years to address these issues. One of the most general is the crossed molecular beams method with mass spectrometric detection of the products, an experiment developed by Lee, Herschbach and co-workers [18, 19]. A schematic illustration of one version of the experiment is shown in figure A3.7.2. Two collimated beams of reactants cross in a vacuum chamber under single-collision conditions. The scattered products are detected by a rotatable mass spectrometer, in which the products are ionized by electron impact and mass selected by a quadrupole mass spectrometer. By measuring mass spectra as a function of scattering angle, one obtains angular distributions for all reaction products. In addition, by chopping either the products or one of the reactant beams with a rapidly spinning slotted wheel, one can determine the time of flight of each product from the interaction region, where the two beams cross, to the ionizer, and from this the product translational energy E_T can be determined at each scattering angle. The resulting product translational energy distributions $P(E_T)$ also contain information on the internal energy distribution of the products via conservation of energy, so long as the reactant collision energy is well defined.

Figure A3.7.2. Schematic illustration of crossed molecular beams experiment for F + H₂ reaction.

-5-

In an important variation of this experiment, one of the reactant beams is replaced by a pulsed laser which photodissociates molecules in the remaining reactant beam. Use of a pulsed laser makes it straightforward to determine the product translational energy distribution by time of flight. This experiment, photofragment translational spectroscopy, was first demonstrated by Wilson [20, 21] and is now used in many laboratories [17].

Mass spectrometry, the primary detection method in the above crossed beams experiments, is a particularly general means of analysing reaction products, since no knowledge of the optical spectroscopy of the products is required. On the other hand, electron impact ionization often leads to extensive fragmentation, thereby complicating identification of the primary products. Very recently, tunable VUV radiation from synchrotrons has been used to ionize scattered products from both photodissociation [22] and bimolecular reactions [23]; other than the ionization mechanism, the instrument is similar in principle to that shown in figure A3.7.2. By choosing the VUV wavelength to lie above the ionization potential of the product of interest but below the lowest dissociative ionization threshold (i.e. the minimum energy for $AB + h\nu \rightarrow A^+ B + e^-$) one can eliminate fragmentation and thus simplify interpretation of the experiments.

A complementary approach to reaction dynamics centres on probing reaction products by optical spectroscopy. Optical spectroscopy often provides higher resolution on the product internal energy distribution than the measurement of translational energy distributions, but is less universally applicable than mass spectrometry as a detection scheme. If products are formed in electronically excited states, their emission spectra (electronic chemiluminescence) can be observed, but ground-state products are more problematic. Polanyi [24] made a seminal contribution in this field by showing that vibrationally excited products in their ground electronic state could be detected by spectrally resolving their spontaneous emission in the infrared; this method of 'infrared chemiluminescence' has proved of great utility in determining product vibrational and, less frequently, rotational distributions.

However, with the advent of lasers, the technique of 'laser-induced fluorescence' (LIF) has probably become the single most popular means of determining product-state distributions; an early example is the work by Zare and co-workers on Ba + HX ($X = F, Cl, Br, I$) reactions [25]. Here, a tunable laser excites an electronic transition of one of the products (the BaX product in this example), and the total fluorescence is detected as a

function of excitation frequency. This is an excellent means of characterizing molecular products with bound-bound electronic transitions and a high fluorescence quantum yield; in such cases the LIF spectra are often rotationally resolved, yielding rotational, vibrational and, for open shell species, fine-structure distributions. LIF has been used primarily for diatomic products since larger species often have efficient non-radiative decay pathways that deplete fluorescence, but there are several examples in which LIF has been used to detect polyatomic species as well.

LIF can provide more detail than the determination of the product internal energy distribution. By measuring the shape LIF profile for individual rotational lines, one can obtain Doppler profiles which yield information on the translational energy distribution of the product as well [26, 27]. In photodissociation experiments where the photolysis and probe laser are polarized, the Doppler profiles yield information on product alignment, i.e. the distribution of m_J levels for products in a particular rotational state J [28]. Experiments of this type have shown, for example, that the rotational angular momentum of the OH product from H_2O photodissociation tends to be perpendicular to \mathbf{v} [29], the vector describing the relative velocity of the products, whereas for H_2O_2 photodissociation [30] one finds J tends to be parallel to \mathbf{v} . These ‘vector correlation’ measurements [31, 32 and 33] are proving very useful in unravelling the detailed dynamics of photodissociation and, less frequently, bimolecular reactions.

The above measurements are ‘asymptotic’, in that they involve looking at the products of reaction long after the collision has taken place. These very valuable experiments are now complemented by ‘transition-state spectroscopy’

-6-

experiments, in which one uses frequency- or time-domain experiments to probe the very short-lived complex formed when two reactants collide [34]. For example, in our laboratory, we have implemented a transition-state spectroscopy experiment based on negative-ion photodetachment [35]. The principle of the experiment, in which a stable negative ion serves as a precursor for a neutral transition state, is illustrated in figure A3.7.3. If the anion geometry is similar to that of the transition state, then photodetachment of the anion will access the transition-state region on the neutral surface. The resulting photoelectron spectrum can give a vibrationally resolved picture of the transition-state dynamics, yielding the frequencies of the bound vibrational modes of the transition state (i.e. those perpendicular to the reaction coordinate) and thereby realizing the goal of transition-state spectroscopy. An example of the successful application of this technique is given below in the discussion of the $\text{F} + \text{H}_2$ reaction.

Figure A3.7.3. Principle of transition-state spectroscopy via negative-ion photodetachment.

Alternatively, one can take advantage of the developments in ultrafast laser technology and use femtosecond lasers to follow the course of a reaction in real time. In this approach, pioneered by Zewail [36], a unimolecular or bimolecular reaction is initiated by a femtosecond pump pulse, and a femtosecond probe pulse monitors some aspect of the reaction as a function of pump–probe delay time. The first example of such an experiment was the photodissociation of ICN [37]. Here the pump pulse excited ICN to a repulsive electronic state correlating to ground state $I + CN(X^2 \Sigma^+)$ products. The probe pulse excited the dissociating ICN to a second repulsive state correlating to excited $I + CN(B^2 \Sigma^+)$ products, and progress of the dissociation was monitored via LIF. If the probe pulse is tuned to be resonant with the $CN B \leftarrow X$ transition, the LIF signal rises monotonically on a 200 fs time scale, attributed to the time delay for the formation of CN product. On the other hand, at slightly redder probe wavelengths, the LIF signal rises then falls, indicative of the transient ICN^* species formed by the pump pulse. This experiment thus represented the first observation of a molecule in the act of falling apart.

In an elegant application of this method to bimolecular reactions, the reaction $H + CO_2 \rightarrow OH + CO$ was studied by forming the $CO_2 \cdot HI$ van der Waals complex, dissociating the HI moiety with the pump pulse, allowing the resulting H atom to react with the CO_2 , and then using LIF to probe the OH signal as a function of time [38]. This experiment represents the ‘real-time clocking’ of a chemical reaction, as it monitors the time interval between initiation of a bimolecular reaction and its completion.

-7-

The above discussion represents a necessarily brief summary of the aspects of chemical reaction dynamics. The theoretical focus of this field is concerned with the development of accurate potential energy surfaces and the calculation of scattering dynamics on these surfaces. Experimentally, much effort has been devoted to developing complementary asymptotic techniques for product characterization and frequency- and time-resolved techniques to study transition-state spectroscopy and dynamics. It is instructive to see what can be accomplished with all of these capabilities. Of all the benchmark reactions mentioned in [section A3.7.2](#), the reaction $F + H_2 \rightarrow HF + H$ represents the best example of how theory and experiment can converge to yield a fairly complete picture of the dynamics of a chemical reaction. Thus, the remainder of this chapter focuses on this reaction as a case study in reaction dynamics.

A3.7.4 CASE STUDY: THE F + H₂ REACTION

The energetics for the $F + H_2$ reaction is shown in figure A3.7.4. The reaction is exothermic by 32.07 kcal mol⁻¹, so that at collision energies above 0.5 kcal mol⁻¹, enough energy is available to populate HF vibrational levels up to and including $v = 3$. Hence the determination of the HF vibration–rotation distribution from this reaction has been of considerable interest. How might one go about this? Since HF does not have an easily accessible bound excited state, LIF is not an appropriate probe technique. On the other hand, the HF vibrational transitions in the infrared are exceedingly strong, and this is the spectral region where characterization of the HF internal energy distribution has been carried out.

Figure A3.7.4. Energetics of the $F + H_2$ reaction. All energies in kcal mol^{-1} .

The first information on the HF vibrational distribution was obtained in two landmark studies by Pimentel [39] and Polanyi [24] in 1969; both studies showed extensive vibrational excitation of the HF product. Pimentel found that the $F + H_2$ reaction could pump an infrared chemical laser, i.e. the vibrational distribution was inverted, with the $HF(v = 2)$ population higher than that for the $HF(v = 1)$ level. A more complete picture was obtained by Polanyi by measuring and spectrally analysing the spontaneous emission from vibrationally excited HF produced by the reaction. This ‘infrared chemiluminescence’ experiment yielded relative populations of 0.29, 1 and 0.47 for the $HF(v = 1, 2$ and $3)$

-8-

vibrational levels, respectively. While improvements in these measurements were made in subsequent years, the numbers describing the vibrational populations have stayed approximately constant. The highly inverted vibrational distributions are characteristic of a potential energy surface for an exothermic reaction with a barrier in the entrance channel.

Spectroscopic determination of the HF rotational distribution is another story. In both the chemical laser and infrared chemiluminescence experiments, rotational relaxation due to collisions is faster or at least comparable to the time scale of the measurements, so that accurate determination of the nascent rotational distribution was not feasible. However, Nesbitt [40, 41] has recently carried out direct infrared absorption experiments on the HF product under single-collision conditions, thereby obtaining a full vibration–rotation distribution for the nascent products.

These spectroscopic probes have been complemented by studies using the crossed molecular beams technique. In these experiments, two well collimated and nearly monoenergetic beams of H_2 and F atoms cross in a large vacuum chamber. The scattered products are detected by a rotatable mass spectrometer, yielding the angular distribution of the reaction products. The experiment measures the transitional energy of the products via time of flight. Thus, one obtains the full transitional energy and angular distribution, $P(E_T, \theta)$, for the HF products. The first experiments of this type on the $F + D_2$ reaction were carried out by Lee [42] in 1970. Subsequent work by the Lee [43, 44] and Toennies [45, 46] groups on the $F + H_2$, D_2 and HD reactions has yielded a very complete characterization of the $P(E, \theta)$ distribution.

As an example, [figure A3.7.5](#) shows a polar contour plot of the HF product velocity distribution at a reactant collision energy of $E_{\text{coll}} = 1.84 \text{ kcal mol}^{-1}$ [43]. *p*- H_2 refers to *para*-hydrogen, for which most of the rotational population is in the $J = 0$ level under the experimental conditions used here. This plot is in the centre-of-mass (CM) frame of reference. F atoms are coming from the right, and H_2 from the left, and the

scattering angle θ is reference to the H_2 beam. The dashed circles ('Newton circles') represent the maximum speed of the HF product in a particular vibrational state, given by

$$v_{\max} = \frac{m_H}{M} \sqrt{\frac{2(\Delta E + E_{\text{coll}} - E_v)}{\mu}} \quad (\text{A3.7.3})$$

where ΔE is the exothermicity, E_v the vibrational energy, M is the total mass ($M = m_H + m_{\text{HF}}$) and $\mu = m_F m_H / M$ the reduced mass of the products. Thus, all the signal inside the $\nu = 3$ circle is from HF($\nu = 3$), all the signal inside the $\nu = 2$ circle is from HF($\nu = 2$) or HF($\nu = 3$), etc.

-9-

Figure A3.7.5. Velocity–flux contour plot for HF product from the reaction $F + \textit{para}\text{-}H_2 \rightarrow HF + H$ at a reactant collision energy of $1.84 \text{ kcal mol}^{-1}$.

An important feature of figure A3.7.5 is that the contributions from different HF vibrational levels, particularly the $\nu = 2$ and 3 levels, are very distinct, a result of relatively little rotational excitation of the HF ($\nu = 2$) products (i.e. if these products had sufficient rotational excitation, they would have the same translational energy as HF($\nu = 3$) product in low J levels). As a consequence, from figure A3.7.5 one can infer the angular distribution for each HF vibrational state, in other words, vibrationally state-resolved differential cross sections. These are quite different depending on the vibrational level. The HF($\nu = 2$) and ($\nu = 1$) products are primarily back-scattered with their angular distributions peaking at $\theta = \pi$, while the HF($\nu = 3$) products are predominantly forward-scattered, peaking sharply at $\theta = 0^\circ$. In general, backward-scattered products result from low impact parameter, head-on collisions, while forward-scattered products are a signature of higher impact parameter, glancing collisions. To understand the significance of these results, it is useful to move away from experimental results and consider the development of potential energy surfaces for this reaction.

Many potential energy surfaces have been proposed for the $F + H_2$ reaction. It is one of the first reactions for which a surface was generated by a high-level *ab initio* calculation including electron correlation [47]. The resulting surface (restricted to collinear geometries) was imperfect, but it had a low barrier ($1.66 \text{ kcal mol}^{-1}$) lying in the entrance channel, as expected for an exothermic reaction with a low activation energy ($\sim 1.0 \text{ kcal mol}^{-1}$). In the 1970s, several empirical surfaces were developed which were optimized so that classical trajectory calculations performed on these surfaces reproduced experimental results, primarily the rate

constant and HF vibrational energy distribution. One of these, the Muckerman V surface [48], was used in many classical and quantum mechanical scattering calculations up until the mid-1980s and provided a generally accepted theoretical foundation for the $F + H_2$ reaction. However, one notable feature of this surface was its rather stiff bend potential near the transition state. With such a potential, only near-collinear collisions were likely to lead to reaction. As a consequence, the HF product angular distribution found by scattering calculations on this surface was strongly back-scattered for all vibrational states. This is in marked disagreement with the experimental results in figure A3.7.5 which show the HF($\nu = 3$) distribution to be strongly forward-scattered.

-10-

At the time the experiments were performed (1984), this discrepancy between theory and experiment was attributed to quantum mechanical resonances that led to enhanced reaction probability in the HF($\nu = 3$) channel for high impact parameter collisions. However, since 1984, several new potential energy surfaces using a combination of *ab initio* calculations and empirical corrections were developed in which the bend potential near the barrier was found to be very flat or even non-collinear [49, 51], in contrast to the Muckerman V surface. In 1988, Sato [52] showed that classical trajectory calculations on a surface with a bent transition-state geometry produced angular distributions in which the HF($\nu = 3$) product was peaked at $\theta = 0^\circ$, while the HF($\nu = 2$) product was predominantly scattered into the backward hemisphere ($\theta \geq 90^\circ$), thereby qualitatively reproducing the most important features in figure A3.7.5.

At this point it is reasonable to ask whether comparing classical or quantum mechanical scattering calculations on model surfaces to asymptotic experimental observables such as the product energy and angular distributions is the best way to find the 'true' potential energy surface for the $F + H_2$ (or any other) reaction. From an experimental perspective, it would be desirable to probe the transition-state region of the $F + H_2$ reaction in order to obtain a more direct characterization of the bending potential, since this appears to be the key feature of the surface. From a theoretical perspective, it would seem that, with the vastly increased computational power at one's disposal compared to 10 years ago, it should be possible to construct a chemically accurate potential energy surface based entirely on *ab initio* calculations, with no reliance upon empirical corrections. Quite recently, both developments have come to pass and have been applied to the $F + H_2$ reaction.

The transition-state spectroscopy experiment based on negative-ion photodetachment described above is well suited to the study of the $F + H_2$ reaction. The experiment is carried out through measurement of the photoelectron spectrum of the anion FH_2^- . This species is calculated to be stable with a binding energy of about 0.20 eV with respect to $F^- + H_2$ [53]. Its calculated equilibrium geometry is linear and the internuclear distances are such that good overlap with the entrance barrier transition state is expected.

The photoelectron spectrum of FH_2^- is shown in figure A3.7.6 [54]. The spectrum is highly structured, showing a group of closely spaced peaks centred around 1 eV, and a smaller peak at 0.5 eV. We expect to see vibrational structure corresponding to the bound modes of the transition state perpendicular to the reaction coordinate. For this reaction with its entrance channel barrier, the reaction coordinate at the transition state is the $F \cdots H_2$ distance, and the perpendicular modes are the F–H–H bend and H–H stretch. The bend frequency should be considerably lower than the stretch. We therefore assign the closely spaced peaks to a progression in the F–H–H bend and the small peak at 0.5 eV to a transition-state level with one quantum of vibrational excitation in the H_2 stretch.

-11-

Figure A3.7.6. Photoelectron spectrum of FH_2^- . Here the F^- is complexed to *para*- H_2 . Solid curve: experimental results. Dashed curve: simulated spectrum from scattering calculation on *ab initio* surface.

The observation of a bend progression is particularly significant. In photoelectron spectroscopy, just as in electronic absorption or emission spectroscopy, the extent of vibrational progressions is governed by Franck–Condon factors between the initial and final states, i.e. the transition between the anion vibrational level ν'' and neutral level ν' is given by

$$I_{\nu''-\nu'} \propto |\langle \psi_{\nu''} | \psi_{\nu'} \rangle|^2 \quad (\text{A3.7.4})$$

where $\psi_{\nu'}$ and $\psi_{\nu''}$ are the neutral and anion vibrational wavefunctions, respectively. Since the anion is linear, a progression in a bending mode of the neutral species can only occur if the latter is bent. Hence the FH_2^- photoelectron spectrum implies that the FH_2^\ddagger transition state is bent.

While this experimental work was being carried out, an intensive theoretical effort was being undertaken by Werner and co-workers to calculate an accurate $\text{F} + \text{H}_2$ potential energy surface using purely *ab initio* methods. The many previous unsuccessful attempts indicated that an accurate calculation of the barrier height and transition-state properties requires both very large basis sets and a high degree of electron correlation; Werner incorporated both elements in his calculation. The resulting Stark–Werner (SW) surface [7] has a bent geometry at the transition state and a barrier of $1.45 \pm 0.25 \text{ kcal mol}^{-1}$. A two-dimensional contour plot of this potential near the transition state is shown in figure A3.7.7. The reason for the bent transition state is illuminating. The F atom has one half-filled p orbital and one might expect this to react most readily with H_2 by collinear approach of the reactants with the half-filled p orbital lined up with the internuclear axis of the H_2 molecule. On the other hand, at longer $\text{F} \cdots \text{H}_2$ distances, where electrostatic forces dominate, there is a minimum in the potential energy surface at a T-shaped geometry with the half-filled orbital perpendicular to the H–H bond. (This arises from the quadrupole–quadrupole interaction between the F and H_2 .)

The interplay between favourable reactivity at a collinear geometry and electrostatic forces favouring a T-shaped geometry leads to a bent geometry at the transition state.

Figure A3.7.7. Two-dimensional contour plot of the Stark–Werner potential energy surface for the $F + H_2$ reaction near the transition state. Θ is the F–H–H bend angle.

How good is this surface? The first test was to simulate the FH_2 photoelectron spectrum. This calculation was carried out by Manolopoulos [54] and the result is shown as a dashed curve in figure A3.7.6. The agreement with experiment is excellent considering that no adjustable parameters are used in the calculation. In addition, Castillo *et al* [55, 56] and Aoiz *et al* [57] have performed quasi-classical and quantum scattering calculations on the SW surface to generate angular distributions for each HF product vibrational state for direct comparison to the molecular beam scattering results in figure A3.7.5. The state-specific forward-scattering of the HF($v = 3$) product is indeed reproduced in the quantum calculations and, to a somewhat lesser extent, in the quasi-classical calculations. The experimental product vibrational populations are also reproduced by the calculations. It therefore appears that scattering calculations on the SW surface agree with the key experimental results for the $F + H_2$ reaction.

What is left to understand about this reaction? One key remaining issue is the possible role of other electronic surfaces. The discussion so far has assumed that the entire reaction takes place on a single Born–Oppenheimer potential energy surface. However, three potential energy surfaces result from the interaction between an F atom and H_2 . The spin–orbit splitting between the $^2P_{3/2}$ and $^2P_{1/2}$ states of a free F atom is 404 cm^{-1} . When an F atom interacts with H_2 , the $^2P_{3/2}$ state splits into two states with A' and A'' symmetry ($^2\Sigma^+$ and $^2\Pi_{3/2}$, respectively, for collinear geometry) while the higher-lying $^2P_{1/2}$ state becomes an A' state ($^2\Pi_{1/2}$ for collinear geometry). Only the lower A' state correlates adiabatically to ground-state HF + H products; the other two states correlate to highly excited products and are therefore non-reactive in the adiabatic limit. In this limit, the excited $F(^2P_{1/2})$ state is completely unreactive.

Since this state is so low in energy, it is likely to be populated in the F atom beams typically used in scattering experiments (where pyrolysis or microwave/electrical discharges are used to generate F atoms), so the issue of its reactivity is important. The molecular beam experiments of Lee [43] and Toennies [45] showed no evidence for

reaction from the $F(^2P_{1/2})$ state. However, the recent work of Nesbitt [40, 41], in which the vibrational and rotational HF distribution was obtained by very high-resolution IR spectroscopy, shows more rotational excitation of the HF($v = 3$) product than should be energetically possible from reaction with the $F(^2P_{3/2})$ state. They therefore suggested that this rotationally excited product comes from the $F(^2P_{1/2})$ state. This work prompted an intensive theoretical study of spin–orbit effects on the potential energy surface and reaction

dynamics. A recent study by Alexander and co-workers [58] does predict a small amount of reaction from the $F(^2P_{1/2})$ state but concludes that the adiabatic picture is largely correct. The issue of whether a reaction can be described by a single Born–Oppenheimer surface is of considerable interest in chemical dynamics [10], and it appears that the effect of multiple surfaces must be considered to gain a complete picture of a reaction even for as simple a model system as the $F + H_2$ reaction.

A3.7.5 CONCLUSIONS AND PERSPECTIVES

This chapter has summarized some of the important concepts and results from what has become an exceedingly rich area of chemical physics. On the other hand, the very size of the field means that the vast majority of experimental and theoretical advances have been left out; the books referenced in the introduction provide a much more complete picture of the field.

Looking toward the future, two trends are apparent. First, the continued study of benchmark bimolecular and photodissociation reactions with increasing levels of detail is likely to continue and be extremely productive. Although many would claim that the ‘three-body problem’ is essentially solved from the perspective of chemical reaction dynamics, the possibility of multiple potential surfaces playing a role in the dynamics adds a new level of complexity even for well studied model systems such as the $F + H_2$ reaction considered here. Slightly more complicated benchmark systems such as the $OH + H_2$ and $OH + CO$ reactions present even more of a challenge to both experiment and theory, although considerable progress has been achieved in both cases.

However, in order to deliver on its promise and maximize its impact on the broader field of chemistry, the methodology of reaction dynamics must be extended toward more complex reactions involving polyatomic molecules and radicals for which even the primary products may not be known. There certainly have been examples of this: notably the crossed molecular beams work by Lee [59] on the reactions of O atoms with a series of hydrocarbons. In such cases the spectroscopy of the products is often too complicated to investigate using laser-based techniques, but the recent marriage of intense synchrotron radiation light sources with state-of-the-art scattering instruments holds considerable promise for the elucidation of the bimolecular and photodissociation dynamics of these more complex species.

A3.8 Molecular reaction dynamics in condensed phases

Gregory A Voth

A3.8.0 INTRODUCTION

The effect of the condensed phase environment on chemical reaction rates has been extensively studied over the past few decades. The central framework for understanding these effects is provided by the transition state theory (TST) [1, 2] developed in the 1930s, the Kramers theory [3] of 1940, the Grote–Hynes [4] and related theories [5] of the 1980s and 1990s and the Yamamoto reactive flux correlation function formalism [6] as extended and further developed by a number of workers [7, 8]. Each of these seminal theoretical breakthroughs has, in turn, generated an enormous amount of research in its own right. There are many good reviews of this body of literature, some of which are cited in [5, 9, 10, 11 and 12]. It therefore serves no useful purpose to review the field again in the present chapter. Instead, the key issues involving condensed phase effects on chemical reactions will be organized around the primary theoretical concepts as they stand at the present time. Even more importantly, the gaps in our understanding and prediction of these effects will be highlighted. From this discussion it will become evident that, despite the large body of theoretical work in this field, there are significant questions that remain unanswered, as well as a need for greater contact between theory and experiment. The discussion here is by no means intended to be exhaustive, nor is the reference list comprehensive.

A3.8.1 THE REACTIVE FLUX

To begin, consider a system which is at equilibrium and undergoing a forward and reverse chemical reaction. For simplicity, one can focus on an isomerization reaction, but the discussion also applies to other forms of unimolecular reactions as well as to bimolecular reactions that are not diffusion limited. The equilibrium of the reaction is characterized by the mole fractions x_R and x_P of reactants and products, respectively, and an equilibrium constant K_{eq} . For gas phase reactions, it is commonplace to introduce the concept of the *minimum energy path* along some reaction coordinate, particularly if one is interested in microcanonical reaction rates. In condensed phase chemical dynamics, however, this concept is not useful. In fact, a search for the minimum energy path in a liquid phase reaction would lead one to the solid state! Instead, one considers a *free energy path* along the reaction coordinate q , and the dominant effect of a condensed phase environment is to change the nature of this path (i.e. its barriers and reactant and product wells, or minima). To illustrate this point, the free energy function along the reaction coordinate of an isomerizing molecule in the gas phase is shown by the full curve in [figure A3.8.1](#). In the condensed phase, the free energy function will almost always be modified by the interaction with the solvent, as shown by the broken curve in [figure A3.8.1](#). (It should be noted that, in the spirit of TST, the definition of the optimal reaction coordinate should probably be redefined for the condensed phase reaction, but for simplicity it can be taken to be the same coordinate as in the gas phase.) As can be seen from [figure A3.8.1](#), the solvent can modify the barrier height for the reaction, the location of the barrier along q , and the reaction free energy (i.e. the difference between the reactant and product minima). It may also introduce dynamical effects that are not apparent from the curve, and it is noted here that a classical framework has been implicitly used—the generalization to the quantum regime will be addressed in a later section.

Figure A3.8.1 A schematic diagram of the PMF along the reaction coordinate for an isomerizing solute in the gas phase (full curve) and in solution (broken curve). Note the modification of the barrier height, the well positions, and the reaction free energy due to the interaction with the solvent.

It is worth discussing the fact that a free energy can be directly relevant to the rate of a *dynamical* process such as a chemical reaction. After all, a free energy function generally arises from an ensemble average over configurations. On the other hand, most condensed phase chemical rate constants are indeed thermally averaged quantities, so this fact may not be so surprising after all, although it should be quantified in a rigorous fashion. Interestingly, the free energy curve for a condensed phase chemical reaction (cf figure A3.8.1) can be viewed, in effect, as a natural consequence of Onsager's linear regression hypothesis as it is applied to condensed phase chemical reactions, along with some additional analysis and simplifications [7].

In the spirit of Onsager, if one imagines a relatively *small* perturbation of the populations of reactants and products away from their equilibrium values, then the regression hypothesis states that the decay of these populations back to their equilibrium values will follow the same time-dependent behaviour as the decay of correlations of *spontaneous* fluctuations of the reactant and product populations in the equilibrium system. In the condensed phase, it is this powerful principle that connects a macroscopic dynamical quantity such as a kinetic rate constant with equilibrium quantities such as a free energy function along a reaction pathway and, in turn, the underlying microscopic interactions which determine this free energy function. The effect of the condensed phase environment can therefore be largely understood in the equilibrium, or quasi-equilibrium, context in terms of the modifications of the free energy curve as shown in figure A3.8.1. As will be shown later, the remaining condensed phase effects which are not included in the equilibrium picture may be defined as being 'dynamical'.

The Onsager regression hypothesis, stated mathematically for the chemically reacting system just described, is given in the classical limit by

$$\frac{\Delta N_{\text{R}}(t)}{\Delta N_{\text{R}}(0)} = \frac{\langle \delta N_{\text{R}}(0) \delta N_{\text{R}}(t) \rangle}{\langle \delta N_{\text{R}}(0)^2 \rangle} \quad (\text{A 3.8.1})$$

where $\Delta N_{\text{R}}(t) = \bar{N}_{\text{R}}(t) - \langle N_{\text{R}} \rangle$ is the time-dependent difference between the number of reactant molecules $\bar{N}_{\text{R}}(t)$ arising from an initial non-equilibrium (perturbed) distribution and the final equilibrium number of the reactants $\langle N_{\text{R}} \rangle$. On the right-hand side of the equation, $\langle \delta N_{\text{R}}(t) = N_{\text{R}}(t) - \langle N_{\text{R}} \rangle$ is the instantaneous fluctuation

in the number of reactant molecules away from its equilibrium value in the canonical ensemble, and the notation $\langle \dots \rangle$ denotes the ensemble average over initial conditions.

The solution to the usual macroscopic kinetic rate equations for the reactant and product concentrations yields an expression for the left-hand side of (A3.8.1) that is equal to $\Delta N_R(t) = \Delta N_R(0) \exp(-t/\tau_{rxn})$, where τ_{rxn}^{-1} is the sum of the forward and reverse rate constants, k_f and k_r , respectively. The connection with the microscopic dynamics of the reactant molecule comes about from the right-hand side of (A3.8.1). In particular, in the dilute solute limit, the reactant and product states of the reacting molecule can be identified by the reactant and product population of functions $h_R[q(t)] = 1 - h_P[q(t)]$ and $h_P[q(t)]$, respectively, where $h_P[q(t)] \equiv h[q^* - q(t)]$ and $h(x)$ is the Heaviside step function. The product population function abruptly switches from a value of zero to one as the reaction coordinate trajectory $q(t)$ passes through the barrier maximum at q^* (cf. [Figure A3.8.1](#)). The important connection between the macroscopic (exponential) rate law and the decay of spontaneous fluctuations in the reactant populations, as specified by the function $h_R[q(t)] = 1 - h_P[q(t)]$ and in terms of the microscopic reaction coordinate q , is valid in a ‘coarse-grained’ sense in time, i.e. after a period of molecular-scale transients usually of the order of a few tens of femtoseconds. From the theoretical point of view, the importance of the connection outlined above cannot be overstated because it provides a link between the macroscopic (experimentally observed) kinetic phenomena and the molecular scale dynamics of the reaction coordinate in the equilibrium ensemble.

However, further analysis of the linear regression expression in A3.8.1 is required to achieve a useful expression for the rate constant both from a computational and a conceptual points of view. Such an expression was first provided by Yamamoto [6], but others have extended, validated, and expounded upon his analysis in considerable detail [7, 8]. The work of Chandler [7] in this regard is followed most closely here in order to demonstrate the places in which condensed phase effects can appear in the theory, and hence in the value of the thermal rate constant. The key mathematical step is to differentiate both sides of the linear regression formula in (A3.8.1) and then carefully analyse its expected behaviour for systems having a barrier height of at least several times $k_B T$. The resulting expression for the classical forward rate constant in terms of the so-called ‘reactive flux’ time correlation function is given by [6, 7 and 8]

$$\begin{aligned} k_f &= x_R^{-1} \langle \dot{h}_P[q(0)] h_P[q(t_{pl})] \rangle \\ &= x_R^{-1} \langle \dot{q}(0) \delta[q^* - q(0)] h_P[q(t_{pl})] \rangle \end{aligned} \quad (\text{A 3.8.2})$$

where x_R is the equilibrium mole fraction of the reactant. The classical rate constant is obtained from (A3.8.2) when the correlation function reaches a ‘plateau’ value at the time $t = t_{pl}$ after the molecular-scale transients have ended [7]. Upon inspection of the above expression, it becomes apparent that the classical rate constant can be calculated by averaging over trajectories initiated at the barrier top with a velocity Boltzmann distribution for the reaction coordinate and an equilibrium distribution in all other degrees of freedom of the system. Those trajectories are then weighted by their initial velocity and the initial flux over the barrier is correlated with the product state population function $h_P[q(t)]$. The time dependence of the correlation function is computed until the plateau value is reached, at which point it

becomes essentially constant and the numerical value of the thermal rate constant can be evaluated. An example of such a correlation function obtained through molecular dynamics simulations is shown in figure A3.8.2.

Figure A3.8.2 The correlation function $\kappa(t)$ for particular case of the reaction of methyl vinyl ketone with cyclopentadiene in water. The leveling-off of this function to reach a constant value at the plateau time t_{pl} is clearly seen.

It is important to recognize that the time-dependent behaviour of the correlation function during the molecular transient time seen in figure A3.8.2 has an important origin [7, 8]. This behaviour is due to trajectories that recross the transition state and, hence, it can be proven [7] that the classical TST approximation to the rate constant is obtained from A3.8.2 in the $t \rightarrow 0^+$ limit:

$$\begin{aligned} k_f^{\text{TST}} &= x_R^{-1} \lim_{t \rightarrow 0^+} \langle \dot{q}(0) \delta[q^* - q(0)] h_P[q(t)] \rangle \\ &= x_R^{-1} \langle h[\dot{q}(0)] \dot{q}(0) \delta[q^* - q(0)] \rangle. \end{aligned} \quad (\text{A } 3.8.3)$$

It is, of course, widely considered that the classical TST provides the central framework for the understanding of thermal rate constants (see the review article by Truhlar *et al* [13]) and also for quantifying the dominant effects of the considered phase in chemical reactions (see below).

In order to segregate the theoretical issues of condensed phase effects in chemical reaction dynamics, it is useful to rewrite the exact classical rate constant in (A3.8.2) as [5, 6, 7, 8, 9, 10 and 11]

$$k_f = \kappa k_f^{\text{TST}} \quad (\text{A } 3.8.4)$$

where κ is the dynamical correction factor (or ‘transmission coefficient’) which is given by

$$\begin{aligned} \kappa &= \frac{\langle \dot{q}(0) \delta[q^* - q(0)] h_P[q(t_{pl})] \rangle}{\langle h[\dot{q}(0)] \dot{q}(0) \delta[q^* - q(0)] \rangle} \\ &= \langle h_P[q(t_{pl})] \rangle_+ - \langle h_P[q(t_{pl})] \rangle_-. \end{aligned} \quad (\text{A } 3.8.5)$$

Here, the symbol $\langle \dots \rangle_{\pm}$ denotes an averaging over the flux-weighted distribution [7, 8] for positive or negative initial velocities of the reaction coordinate. In figure A3.8.2 is shown the correlation function $\kappa(t)$ for the particular case of the reaction of methyl vinyl ketone with cyclopentadiene in water. The leveling-off of this

function to reach a constant value at the plateau time t_{pl} is clearly seen. The effect of the condensed phase environment in a thermal rate constant thus appears *both* in the value of the TST rate constant and in the value of the dynamical correction factor in (A3.8.4). These effects will be described separately in the following sections, but it should be noted that the two quantities are not independent of each other in that they both depend on the choice of the reaction coordinate q . The ‘variational’ choice of q amounts to finding a definition of that coordinate that causes the value of κ to be as close to unity as possible, i.e. to minimize the number of recrossing trajectories. It seems clear that an important area of research for the future will be to define theoretically the ‘best’ reaction coordinate in a condensed phase chemical reaction—one in which the solvent is explicitly taken into account. In charge transfer reactions, for example, a collective solvent polarization coordinate can be treated as being coupled to a solute coordinate (see, for example, 14), but a more detailed and rigorous microscopic treatment of the full solution—phase reaction coordinate is clearly desirable for the future (see, for example, 15 for progress in this regard). Before describing the effects of a solvent on the thermal rate constants, it is worthwhile to first reconsider the above analysis in light of current experimental work on condensed phase dynamics and chemical reactions. The formalism outlined above, while exceptionally powerful in that it provides a link between microscopic dynamics and macroscopic chemical kinetics, is intended to help us calculate and analyse *only* thermal rate constants in *equilibrium* systems. The linear regression hypothesis provides the key line of analysis for this problem. To the extent that the thermal rate constant is the quantity of interest—and many times it *is* the primary quantity of interest—this theoretical approach would appear to be the best. However, in many experiments, for example nonlinear optical experiments involving intense laser pulses and/or photoinitiated chemical reactions, the system may initially be far from equilibrium and the above theoretical analysis may not be completely applicable. Furthermore, experimentally measured quantities such as vibrational or phase relaxation rates are often only indirectly related to the thermal rate constant. It would therefore appear that more theoretical effort will be required in the future to relate experimental measurements to the particular microscopic dynamics in the liquid phase that influence the outcome of such measurements and, in turn, to the more standard quantities such as the thermal rate constant.

A3.8.2 THE ACTIVATION FREE ENERGY AND CONDENSED PHASE EFFECTS

Having separated the dynamical from equilibrium (or, more accurately, quasi-equilibrium) effects, one can readily discover the origin of the activation free energy and define the concept of the potential of mean force by analysis of the expression for the TST rate constant, k_f^{TST} in (A3.8.3). The latter can be written as [7]

$$k_f^{\text{TST}} = \frac{(2\pi m\beta)^{-1/2}}{\int_{-\infty}^{q^*} dq \exp[-\beta V_{\text{eq}}(q)]} \exp[-\beta V_{\text{eq}}(q^*)] \quad (\text{A 3.8.6})$$

-6-

where $\beta = 1/k_B T$ and $V_{\text{eq}}(q)$ is the *potential of mean force* (PMF) along the reaction coordinate q . The latter quantity is all important for quantifying and understanding the effect of the condensed phase on the value of the thermal rate constant. It is defined as

$$V_{\text{eq}}(q) = -k_B T \ln \left[\int dq' d\mathbf{x} \delta(q - q') \exp[-\beta V'(q', \mathbf{x})] \right] + \text{constant} \quad (\text{A 3.8.7})$$

where \mathbf{x} are all coordinates of the condensed phase system other than the reaction coordinate, and $V(q, \mathbf{x})$ is the total potential energy function. The additive constant in (A3.8.7) is irrelevant to the value of the thermal rate constant in (A3.8.6). If the PMF around its minimum in the reactant state (cf. Figure A3.8.1) is expanded

quadratically, i.e. $V_{\text{eq}}(q) \approx V_{\text{eq}}(q_0) + (1/2)m\omega_0^2(q - q_0)^2$, then (A3.8.6) simplifies to [5, 7]

$$k_f^{\text{TST}} = \frac{\omega_0}{2\pi} \exp(-\beta \Delta F_{\text{cl}}^*) \quad (\text{A 3.8.8})$$

where the *activation free energy* of the system is defined as $\Delta F_{\text{cl}}^* = V_{\text{eq}}(q^*) - V_{\text{eq}}(q_0)$. The PMF is often decomposed as $V_{\text{eq}}(q) = v(q) + W_{\text{eq}}(q)$, where $v(q)$ is the intrinsic contribution to the PMF from the solute potential energy function and, therefore, by definition, $W_{\text{eq}}(q)$ is the contribution arising from the solute–solvent coupling. Figure A3.8.1 illustrates how the latter coupling is responsible for the condensed phase-induced change in the activation free energy, the reaction free energy, and the position of the reactant and product wells. Thus, within the context of the TST, one can conclude that the condensed phase enters into the picture in a ‘simple’ way through the aforementioned modifications of the reaction coordinate free energy profile in figure A3.8.1.

In principle, nothing more is necessary to understand the influence of the solvent on the TST rate constant than the modification of the PMF, and the resulting changes in the free energy barrier height should be viewed as the dominant effect on the rate since these changes appear in an exponential form. As an example, an error in calculating the solvent contribution to the barrier of 1 kcal mol^{-1} will translate into an error of a factor of four in the rate constant—a factor which is often larger than any dynamical and/or quantum effects such as those described in later sections. This is a compelling fact for the theorist, so it is therefore no accident that the accurate calculation of the solvent contribution to the activation free energy has become the primary focus of many theoretical and computational chemists. The successful completion of such an effort requires four things: (1) an accurate representation of the solute potential, usually from highly demanding *ab initio* electronic structure calculations; (2) an accurate representation of both the solvent potential and the solute–solvent coupling; (3) an accurate computational method to compute, with good statistics, the activation free energy in condensed phase systems; and (4) improved theoretical techniques, both analytical and computational, to identify the *microscopic origin* of the dominant contributions to the activation free energy and the relationship of these effects to experimental parameters such as pressure, temperature, solvent viscosity and polarity, etc. Each of these areas has in turn generated a significant number of theoretical papers over the past few decades—too many in fact to fairly cite them here—and many of these efforts have been major steps forward. There seems to be little dispute, however, that much work remains to be done in all of these areas. Indeed, one of the computational ‘grand challenges’ facing theoretical chemistry over the coming decades will surely be the *quantitative prediction* (better than a factor of two) of chemical reaction rates in highly complex systems. Some of this effort may, in fact, be driven by the needs of industry and government in, for example, the environmental fate prediction of pollutants.

A3.8.3 THE DYNAMICAL CORRECTION AND SOLVENT EFFECTS

While the TST estimate of the thermal rate constant is usually a good approximation to the true rate constant and contains most of the dominant solvent effects, the dynamical corrections to the rate can be important as well. In the classical limit, these corrections are responsible for a value of the dynamical correction factor κ in A3.8.4 that drops below unity. A considerable theoretical effort has been underway over the past 50 years to develop a general theory for the dynamical correction factor (see, for example, [5, 6, 7, 8, 9, 10, 11 and 12]). One approach to the problem is a direct calculation of κ using molecular dynamics simulation and the reactive flux correlation function formalism [7, 8, 16]. This approach obviously requires the numerically exact integration of Newton’s equations for the many-body potential energy surface and a good microscopic model of the condensed phase interactions. However, another approach [5, 9, 10, 11 and 12] has been to employ a *model* for the reaction coordinate dynamics around the barrier top, for example, the generalized Langevin

equation (GLE) given by

$$m\ddot{q}(t) = -\frac{dV_{\text{eq}}(q)}{dq} - \int_0^t dt' \eta(t-t'; q^*)\dot{q}(t') + \delta F(t). \quad (\text{A 3.8.9})$$

In this equation, m is the effective mass of the reaction coordinate, $\eta(t-t'; q^*)$ is the friction kernel calculated with the reaction coordinate ‘clamped’ at the barrier top, and $\delta F(t)$ is the fluctuating force from all other degrees of freedom with the reaction coordinate so configured. The friction kernel and force fluctuations are related by the fluctuation–dissipation relation

$$\eta(t; q^*) = \beta \langle \delta F(0)\delta F(t) \rangle_{q^*}. \quad (\text{A 3.8.10})$$

In the limit of a very rapidly fluctuating force, the above equation can sometimes be approximated by the simpler Langevin equation

$$m\ddot{q}(t) = -\frac{dV_{\text{eq}}(q)}{dq} - \hat{\eta}(0)\dot{q}(t) + \delta F(t) \quad (\text{A 3.8.11})$$

where $\hat{\eta}(0)$ is the so-called ‘static’ friction, $\hat{\eta}(0) = \int_0^\infty dt \eta(t; q^*)$

The GLE can be derived by invoking the linear response approximation for the response of the solvent modes coupled to the motion of the reaction coordinate.

It should be noted that the friction kernel is not in general independent of the reaction coordinate motion [17], i.e. a nonlinear response, so the GLE may have a limited range of validity [18, 19 and 20]. Furthermore, even if the equation is valid, the strength of the friction might be so great that the second and third terms on the right-hand side of (A3.8.9) could dominate the dynamics much more so than the force generated by the PMF. It should also be noted that, even though the friction in (A3.8.9) may be adequately approximated to be dynamically independent of the value of the reaction coordinate, the equation is still in general nonlinear, depending on the nature of the PMF. For non-quadratic

forms of the PMF, $V_{\text{eq}}(q)$, even the solution of the reactive dynamics from the model perspective of the GLE becomes a non-trivial problem.

Two central results have arisen from the GLE-based perspective on the dynamical correction factor. The first is the Kramers theory of 1940 [3], based on the simpler Langevin equation, while the second is the Grote–Hynes theory of 1980 [4]. Both have been extensively discussed and reviewed in the literature [5, 9, 10, 11 and 12]. The important insight of the Kramers theory is that the transmission coefficient for an isomerization or metastable escape reaction undergoes a ‘turnover’ as one increases the static friction from zero to large values. For weak damping (friction), the transmission coefficient is proportional to the friction, i.e. $\kappa \propto \hat{\eta}(0)$. This dependence arises because the barrier recrossings are caused by the slow energy diffusion (equilibration) in the reaction coordinate motion as it leaves the barrier region. For strong damping, on the other hand, the transmission coefficient is inversely proportional to the friction, i.e. $\kappa \propto 1/\hat{\eta}(0)$, because the barrier crossings are caused by the diffusive spatial motion of the reaction coordinate in the barrier region. For systems such as atom exchange reactions that do not involve a bound reactant state, only the spatial diffusion regime is predicted. The basic phenomenology of condensed phase activated rate processes, as mapped out by Kramers, captures the essential physics of the problem and remains the seminal work to this day.

The second key insight into the dynamical corrections to the TST was provided by the Grote–Hynes theory [4]. This theory highlights the importance of the time dependence of the friction and demonstrates how it may be taken into account at the leading order. In the overdamped regime this is done so through the insightful and compact Grote–Hynes (subscript GH) formula for the transmission coefficient [4].

$$\kappa_{\text{GH}} = \frac{\lambda_0^\ddagger}{\omega_{b,\text{eq}}} \quad \lambda_0^\ddagger = \frac{\omega_{b,\text{eq}}^2}{\lambda_0^\ddagger + \hat{\eta}(\lambda_0^\ddagger)/m} \quad (\text{A 3.8.12})$$

where $\hat{\eta}(z)$ is the Laplace transform of the friction kernel, i.e. $\hat{\eta}(z) = \int_0^\infty dt e^{-zt} \eta(t)$, and $\omega_{b,\text{eq}}$ is the magnitude of the unstable PMF barrier frequency. Importantly, the derivation of this formula assumes a quadratic approximation to the barrier $V_{\text{eq}}(q) \approx V_{\text{eq}}(q^*) - (1/2)m\omega_{b,\text{eq}}^2 (q - q^*)^2$ that may not always be a good one.

Research over the past decade has demonstrated that a multidimensional TST approach can also be used to calculate an even more accurate transmission coefficient than κ_{GH} for systems that can be described by the full GLE with a non-quadratic PMF. This approach has allowed for variational TST improvements [21] of the Grote–Hynes theory in cases where the nonlinearity of the PMF is important and/or for systems which have general nonlinear couplings between the reaction coordinate and the bath force fluctuations. The Kramers turnover problem has also been successfully treated within the context of the GLE and the multidimensional TST picture [22]. A multidimensional TST approach has even been applied [15] to a realistic model of an $S_{\text{N}}2$ reaction and may prove to be a promising way to elaborate the explicit microscopic origins of solvent friction. While there has been great progress toward an understanding and quantification of the dynamical corrections to the TST rate constant in the condensed phase, there are several quite significant issues that remain largely open at the present time. For example, even if the GLE were a valid model for calculating the dynamical corrections, it remains unclear how an accurate and predictive microscopic theory can be developed for the friction kernel $\eta(t)$ so that one does not have to resort to a molecular dynamics simulation [17] to calculate this quantity. Indeed, if one could compute the solvent friction along the reaction coordinate in such a manner, one could instead just calculate the exact rate

-9-

constant using the reactive-flux formalism. A microscopic theory for the friction is therefore needed to relate the friction along the reaction coordinate to the parameters varied by experimentalists such as pressure or solvent viscosity. No complete test of Kramers theory will ever be possible until such a theoretical effort is completed. Two possible candidates in the latter vein are the instantaneous normal mode theory of liquids [23] and the damped normal mode theory [24] for liquid state dynamics.

Another key issue remaining to be resolved is whether a one-dimensional GLE as in [A3.8.11](#) is the optimal choice of a dynamical model in the case of strong damping, or whether a two- or multi-dimensional GLE that explicitly includes coupling to solvation and/or intramolecular modes is more accurate and/or more insightful. Such an approach might, for example, allow better contact with nonlinear optical experiments that could measure the dynamics of such additional modes. It is also entirely possible that the GLE may not even be a good approximation to the true dynamics in many cases because, for example, the friction strongly depends on the position of the reaction coordinate. In fact, a strong solvent modification of the PMF usually ensures that the friction will be spatially dependent [25]. Several analytical studies have dealt with this issue (see, for example, [26, 27 and 28] and literature cited therein). Spatially-dependent friction is found to have an important effect on the dynamical correction in some instances, but in others the Grote–Hynes estimate is predicted to be robust [29]. Nevertheless, the question of the nonlinearity and the accurate modelling of real activated rate processes by the GLE remains an open one.

Another important issue has been identified by several authors [30, 31] which involves the participation of

intramolecular solute modes in defining the range of the energy diffusion-limited regime of condensed phase activated dynamics. In particular, if the coupling between the reaction coordinate and such modes is strong, then the Kramers turnover behaviour as a function of the solvent friction occurs at a significantly lower value of the friction than for the simple case of the reaction coordinate coupled to the solvent bath alone. In fact, the issue of whether the turnover can be experimentally observed at all in the condensed phase hinges on this issue. To date, it has remained a challenge to calculate the effective number of intramolecular modes that are strongly coupled to the reaction coordinate; no general theory yet exists to accomplish this important goal.

As a final point, it should again be emphasized that many of the quantities that are measured experimentally, such as relaxation rates, coherences and time-dependent spectral features, are complementary to the thermal rate constant. Their information content in terms of the underlying microscopic interactions may only be indirectly related to the value of the rate constant. A better theoretical link is clearly needed between experimentally measured properties and the common set of microscopic interactions, if any, that also affect the more traditional solution phase chemical kinetics.

A3.8.4 QUANTUM ACTIVATED RATE PROCESSES AND SOLVENT EFFECTS

The discussion thus far in this chapter has been centred on classical mechanics. However, in many systems, an explicit quantum treatment is required (not to mention the fact that it is the correct law of physics). This statement is particularly true for proton and electron transfer reactions in chemistry, as well as for reactions involving high-frequency vibrations.

The exact quantum expression for the activated rate constant was first derived by Yamamoto [6]. The resulting quantum reactive flux correlation function expression is given by

-10-

$$k_f = \frac{1}{x_R \hbar \beta} \int_0^{\hbar \beta} d\tau \langle \dot{h}_P(-i\tau) h_P(t_{pl}) \rangle \quad (\text{A 3.8.13})$$

where $h_P(t)$ is the Heisenberg product state population operator. As opposed to the classical case, however, the $t \rightarrow 0^+$ limit of this expression is always equal to zero [32] which ensures that an *entirely different* approach from the classical analysis must be adopted in order to formulate a quantum TST (QTST), as well as a theory for its dynamical corrections. An article by Truhlar *et al* [13] describes many of the efforts over the past 60 years to develop quantum versions of the TST, and many, if not most, of these efforts have been applicable to primarily low-dimensional gas phase systems. A QTST that is useful for condensed phase reactions is an extremely important theoretical goal since a direct numerical attack on the time-dependent Schrödinger equation for many-body systems is computationally prohibitive, if not impossible. (The latter fact seems to be true in the fundamental sense, i.e. there is an exponential scaling of the numerical effort with system size for the exact solution.) In this section, some of the leading candidates for a viable condensed phase QTST will now be briefly described. The discussion should by no means be considered complete.

As a result of several complementary theoretical efforts, primarily the path integral centroid perspective [33, 34 and 35], the periodic orbit [36] or instanton [37] approach and the ‘above crossover’ quantum activated rate theory [38], one possible candidate for a unifying perspective on QTST has emerged [39] from the ideas from [39, 40, 41 and 42]. In this theory, the QTST expression for the forward rate constant is expressed as [39]

$$k_f \approx \nu \frac{\text{Im } Q_b}{Q_R} \quad (\text{A 3.8.14})$$

where ν is a simple frequency factor, Q_R is the reactant partition function, and Q_b is the barrier ‘partition function’ which is to be interpreted in the appropriate asymptotic limit [39, 40, 41 and 42]. The frequency factor has the piecewise continuous form [39]

$$\nu = \begin{cases} \lambda_0^\ddagger/2\pi & \hbar\beta\lambda_0^\ddagger < 2\pi \\ (\hbar\beta)^{-1} & \hbar\beta\lambda_0^\ddagger \geq 2\pi \end{cases} \quad (\text{A 3.8.15})$$

while the barrier partition function is defined under most conditions as 39

$$Q_b = \int_{q_c \rightarrow i q_c} dq_c \rho_c(q_c). \quad (\text{A 3.8.16})$$

The quantity $\rho_c(q_c)$ is the Feynman path integral centroid density [43] that is understood to be expressed asymptotically as

$$\rho_c(q_c) \approx \rho_c(q^*) \exp[-\beta V_c''(q^*)(q_c - q^*)^2/2] \quad (\text{A 3.8.17})$$

where the quantum centroid potential of mean force is given by $V_c(q_c) = -k_B T \ln[\rho_c(q_c)] + \text{constant}$ and q^* is *defined*

-11-

to be the value of the reaction coordinate that gives the maximum value of $V_c(q)$ in the barrier region (i.e. it may differ [33, 35] from the maximum of the classical PMF along q). The path integral centroid density along the reaction coordinate is given by the Feynman path integral expression

$$\rho_c(q_c) = \int \cdots \int Dq(\tau) D\mathbf{x}(\tau) \delta(q_c - \tilde{q}_0) \exp\{-S[q(\tau), \mathbf{x}(\tau)]/\hbar\} \quad (\text{A 3.8.18})$$

which is a functional integral over all possible cyclic paths of the system coordinates weighted by the imaginary time action function [43]:

$$S[q(\tau), \mathbf{x}(\tau)] = \int_0^{\hbar\beta} d\tau \left\{ \frac{m}{2} \dot{q}(\tau)^2 + \sum_{i=1}^N \frac{m_i}{2} \dot{x}_i(\tau)^2 + V[q(\tau), \mathbf{x}(\tau)] \right\}. \quad (\text{A 3.8.19})$$

The key feature of A3.8.18 is that the centroids of the reaction coordinate Feynman paths are constrained to be at the position q_c . The centroid \tilde{q}_0 of a particular reaction coordinate path $q(\tau)$ is given by the zero-frequency Fourier mode, i.e.

$$\tilde{q}_0 = \frac{1}{\hbar\beta} \int_0^{\hbar\beta} d\tau q(\tau) \quad (\text{A 3.8.20})$$

Under most conditions, the sign of $V_c''(q^*)$ in (A3.8.17) is negative. In such cases, the centroid variable *naturally* appears in the theory 39, and the equation for the quantum thermal rate constant from (A3.8.14) – (A3.8.17) is then given by [39]

$$k_{\text{f}} \approx v \frac{\sqrt{2\pi/\beta|V_{\text{c}}''(q^*)|}}{Q_{\text{R}}} \exp[-\beta V_{\text{c}}(q^*)]. \quad (\text{A } 3.8.21)$$

It should be noted that in the cases where $V_{\text{c}}''(q^*) > 0$, the centroid variable becomes irrelevant to the quantum activated dynamics as defined by (A3.8.14) and the instanton approach [37] to evaluate Q_{b} based on the steepest descent approximation to the path integral becomes the approach one may take. Alternatively, one may seek a more generalized saddle point coordinate about which to evaluate A3.8.14. This approach has also been used to provide a unified solution for the thermal rate constant in systems influenced by non-adiabatic effects, i.e. to bridge the adiabatic and non-adiabatic (Golden Rule) limits of such reactions.

In the limit of reasonably high temperatures (above the so-called ‘crossover’ temperature), i.e. $\hbar\beta\lambda_{\text{0}}^{\ddagger} < 2\pi$, the above formula in A3.8.21 is best simplified further and approximately written as

$$k_{\text{f}} \approx k_{\text{GH}} \frac{(2\pi m\beta)^{-1/2}}{\int_{-\infty}^{q^*} dq_{\text{c}} \exp[-\beta V_{\text{c}}(q_{\text{c}})]} \exp[-\beta V_{\text{c}}(q^*)]. \quad (\text{A } 3.8.22)$$

-12-

This formula, aside from the prefactor κ_{GH} , is often referred to as the path integral quantum transition state theory (PI–QTST) formula 33. One clear strength of this formula is its clear analogy with and generalization of the classical TST formula in A3.8.6. In turn, this allows for an interpretation of solvent effects on quantum activated rate constants in terms of the quantum centroid potential of mean force in a fashion analogous to the classical case. The quantum activation free energy for highly-non-trivial systems can also be directly calculated with imaginary time path integral Monte Carlo techniques 44. Many such studies have now been carried out, but a single example will be described in the following section.

The preceding discussion has focused on the path integral centroid picture of condensed phase quantum activated dynamics, primarily because of its strong analogy with the classical case, the PMF, etc, as well as its computational utility for realistic problems. However, several recent complementary developments must be mentioned. The first is due to Pollak, Liao and Shao 45 who have significantly extended an earlier idea 30 in which the exact Heisenberg population operator in $h_{\text{p}}(t)$ in A3.8.13 is replaced by one for a parabolic barrier (plus some other important manipulations, such as symmetrization of the flux operator, that were not done in 30). The dynamical population operator then has an analytic form which in turn leads one to a purely analytic ‘quantum transition state theory’ approximation to A3.8.13. This approach, which in principle can be systematically improved upon through perturbation theory, has been demonstrated to be as accurate as the path integral centroid-based formulae in A3.8.21 and A3.8.22 above the crossover temperature.

A second recent development has been the application 46 of the initial value representation 47 to semiclassically calculate A3.8.13 (and/or the equivalent time integral of the ‘flux–flux’ correlation function). While this approach has to date only been applied to problems with simplified harmonic baths, it shows considerable promise for applications to realistic systems, particularly those in which the real solvent ‘bath’ may be adequately treated by a further classical or quasiclassical approximation.

A3.8.5 SOLVENT EFFECTS IN QUANTUM CHARGE TRANSFER PROCESSES

In this section, the results of a computational study 48 will be used to illustrate the effects of the solvent—and the significant *complexity* of these effects—in quantum charge transfer processes. The particular example

described here is for a ‘simple’ modelistic proton transfer reaction in a polar solvent. This study, while useful in its own right, also illustrates the level of detail and theoretical formalism that is likely to be necessary in the future to accurately study solvent effects in condensed phase charge transfer reactions, even at the equilibrium (quantum PMF) level.

Some obvious targets for quantum activated rate studies are proton, hydride, and hydrogen transfer reactions because they are of central importance in the solution phase and acid–base chemistry, as well as in biochemistry. These reactions are particularly interesting because they can involve large quantum mechanical effects and, since there is usually a redistribution of solute electronic charge density during the reaction, a substantial contribution to the activation free energy may have its origin from the solvent reorganization process. It is thought that intramolecular vibrations may also play a crucial role in modulating the reactive process by lowering the intrinsic barrier for the reaction.

Many of the condensed phase effects mentioned above have been studied computationally using the PI–QTST approach outlined in the first part of the last section. One such study [48](#) has focused on the model symmetric

-13-

three-body proton transfer reaction in a polar fluid with its dipole moment chosen to model methanol. The molecular group ‘A’ represents a generic proton donor/acceptor group.

After some straightforward manipulations of [A3.8.22](#), the PI–QTST estimate of the proton transfer rate constant can be shown to be given by [48](#)

$$k_f^{\text{PI-QTST}} = \frac{\omega_{c,0}}{2\pi} \exp(-\beta \Delta F_c^*) \quad (\text{A 3.8.23})$$

where $\omega_{c,0} = [V''_c(q_0)/m]^{1/2}$ and the quantum activation free energy is given by [48](#)

$$\begin{aligned} \Delta F_c^* &= -k_B T \ln[\rho_c(q^*)/\rho_c(q_0)] \\ &= -k_B T \ln[P_c(q_0 \rightarrow q^*)]. \end{aligned} \quad (\text{A 3.8.24})$$

The probability $P_c(q_0 \rightarrow q^*)$ to move the reaction coordinate centroid variable from the reactant configuration to the transition state is calculated [48](#) by path integral Monte Carlo techniques [44](#) combined with umbrella sampling [[48](#), [49](#)]. From the calculations on the model proton transfer system above, the quantum activation free energy curves are shown in [figure A3.8.3](#) for both a rigid and non-rigid (vibrating) intra-complex A–A (donor/acceptor) distance. Shown are both the activation curves for the complex in isolation and in the solvent. The effect of the solvent in the total activation free energy is immediately obvious, contributing 2–4 kcal mol⁻¹ to its overall value. One effect of the A–A distance fluctuations is a lowering of the quantum activation free energy (i.e. increased tunnelling) both when the solvent is present and when it is not. A second interesting effect becomes evident from a comparison of the curves for the systems with the rigid versus flexible A–A distance. The contribution to the quantum activation free energy from the solvent is reduced when the A–A distance can fluctuate, resulting in a rate that is 20 times higher than in the rigid case. This novel behaviour was found to arise from a *nonlinear* coupling between the intra-complex fluctuations and the solvent activation, resulting in a reduced dipole moment of the solute when there is an inward fluctuation of the A–A distance.

Figure A3.8.3 Quantum activation free energy curves calculated for the model A–H–A proton transfer reaction described 45. The full line is for the classical limit of the proton transfer solute in isolation, while the other curves are for different fully quantized cases. The rigid curves were calculated by keeping the A–A distance fixed. An important feature here is the direct effect of the solvent activation process on both the solvated rigid and flexible solute curves. Another feature is the effect of a fluctuating A–A distance which both lowers the activation free energy and reduces the influence of the solvent. The latter feature enhances the rate by a factor of 20 over the rigid case.

From the above PI–QTST studies, it was found that, in order to fully quantify the solvent effects for even a ‘simple’ model proton transfer reaction, one must deal with a number of complex, nonlinear interactions. Examples of other such interactions include the nonlinear dependence of the solute dipole on the position of the proton and the intrinsically nonlinear interactions arising from both solute and solvent polarizability effects 48. In the latter context, it was found that the solvent electronic polarizability modes *must* be treated quantum mechanically when studying their influence on the proton transfer activation free energy 48. (In general, the adequate treatment of electronic polarizability in a variety of condensed phase contexts is emerging as an extremely important problem in many contexts; condensed phase reactions may never be properly described until this problem is addressed.) The detailed calculations described above, while only for a model proton transfer system, clearly illustrate the significant challenge that lies ahead for those who hope to *quantitatively* predict the rates of computation phase chemical reactions through computer simulation.

A3.8.6 CONCLUDING REMARKS

In this chapter many of the basic elements of condensed phase chemical reactions have been outlined. Clearly, the material presented here represents just an overview of the most important features of the problem. There is an extensive literature on all of the issues described herein and, more importantly, there is still much work to be done before a complete understanding of the effects of condensed phase environments on chemical reactions can be achieved. The theorist and experimentalist alike can therefore look forward to many more years of exciting and challenging research in this important area of physical chemistry.

A3.9 Molecular reaction dynamics: surfaces

George R Darling, Stephen Holloway and Charles Rettner

A3.9.1 INTRODUCTION

Molecular reaction dynamics is concerned with understanding elementary chemical reactions in terms of the individual atomic and molecular forces and the motions that occur during the process of chemical change. In gas phase and condensed phase reactions (discussed in [section A3.7](#) and [section A3.8](#)) the reactants, products and all intermediates are in the same phase. This ‘reduces’ the complexity of such systems such that we need ‘only’ develop experimental and theoretical tools to treat one medium. In a surface reaction, the reactants derive from the gas phase, to which the products may or may not return, but the surface is a condensed phase exchanging energy with reactants and products and any intermediates in a nontrivial fashion. The electronic states of the surface may also play a role by changing the bonding within and between the various species, affecting the reaction as a heterogeneous catalyst (see [section A3.10](#)). Of course, the surface itself may be one of the reactants, as in the etching of silicon surfaces by halide molecules. Indeed, it might be argued that if the

reactants achieve thermal equilibrium with the surface, they have become part of a new surface, with properties differing from those of the clean surface.

An individual surface reaction may be the result of several steps occurring on very different timescales. For example, a simple bimolecular reaction $A(\text{gas}) + B(\text{gas}) \rightarrow AB(\text{gas})$ might proceed as follows: A strikes the surface, losing enough energy to stick (i.e. adsorb), B also adsorbs, A and B diffuse across the surface and meet to form AB, after some time AB acquires enough energy to escape (i.e. desorb) from the surface. Each part of this schematic process is itself complicated. In the initial collisions with the surface, the molecules can lose or gain energy, and this can be translational energy (i.e. from the centre-of-mass motion) or internal (rotational, vibrational etc) energy, or both. Internal energy can be exchanged for translational energy, or *vice versa*, or the molecule can simply fragment on impact. Thermalization (i.e. the attainment of thermal equilibrium with the surface) is a slower process, requiring possibly tens of bounces of the molecule on the surface. The subsequent diffusion of A and B towards each other is even slower, while the desorption of the product AB might occur as soon as it is formed, leaving the molecule with some of the energy released in the association step.

Why should we be interested in the dynamics of such complex systems? Apart from the intellectual rewards offered by this field, understanding reactions at surfaces can have great practical and economic value. Gas–surface chemical reactions are employed in numerous processes throughout the chemical and electronic industries. Heterogeneous catalysis lies at the heart of many synthetic cycles, and etching and deposition are key steps in the fabrication of microelectronic components. Gas–surface reactions also play an important role in the environment, from acid rain to the chemistry of the ozone hole. Energy transfer at the gas–surface interface influences flight, controls spacecraft drag, and determines the altitude of a slider above a computer hard disk. Any detailed understanding of such processes needs to be built on fundamental knowledge of the dynamics and kinetics at the molecular level.

For any given gas–surface reaction, the various elementary steps of energy transfer, adsorption, diffusion, reaction and desorption are inextricably linked. Rather than trying to study all together in a single system where they cannot easily be untangled, most progress has been made by probing the individual steps in carefully chosen systems [1, 2 and 3].

-2-

For example, energy transfer in molecule–surface collisions is best studied in nonreactive systems, such as the scattering and trapping of rare-gas atoms or simple molecules at metal surfaces. We follow a similar approach below, discussing the dynamics of the different elementary processes separately. The surface must also be ‘simplified’ compared to technologically relevant systems. To develop a detailed understanding, we must know exactly what the surface looks like and of what it is composed. This requires the use of surface science tools (section B1.19-26) to prepare very well-characterized, atomically clean and ordered substrates on which reactions can be studied under ultrahigh vacuum conditions. The most accurate and specific experiments also employ molecular beam techniques, discussed in [section B2.3](#).

A3.9.2 REACTION MECHANISMS

The basic paradigms of surface reaction dynamics originate in the pioneering studies of heterogeneous catalysis by Langmuir [4, 5 and 6]. Returning to our model bimolecular reaction $A(\text{gas}) + B(\text{gas}) \rightarrow AB(\text{gas})$, let us assume first that A adsorbs on, and comes into thermal equilibrium with, the surface. We categorize the reaction according to the behaviour of molecule B. For most surface reactions, B adsorbs and thermalizes on the surface before meeting and reacting with A, by way of a Langmuir–Hinshelwood mechanism. However, in some systems, AB can only be formed as a result of a direct collision of the incoming B with the adsorbed A. Such reactions, which are discussed in further detail in [section A3.9.6](#), are

said to occur by an Eley–Rideal mechanism. A schematic illustration of these processes is shown in [figure A3.9.1](#).

For a Langmuir–Hinshelwood reaction, we can expect the surface temperature to be an important variable determining overall reactivity because it determines how fast A and B diffuse across the surface. If the product AB molecules thermalize before desorption, the distribution of internal and translational energies in the gas phase will also reflect the surface temperature (yielding Boltzmann distributions that are modified by a dynamical factor related by the principle of detailed balance to the energetics of adsorption [7]). The main factor discriminating between the reaction schemes is that for a Langmuir–Hinshelwood reaction, the AB molecule can have no memory of the initial state and motion of the B molecule, but these should be evident in the AB products if the mechanism is of the Eley–Rideal type. These simple divisions are of course too black and white. In all probability, the two paradigms are actually extremes, with real systems reflecting aspects of both mechanisms [8].

-3-

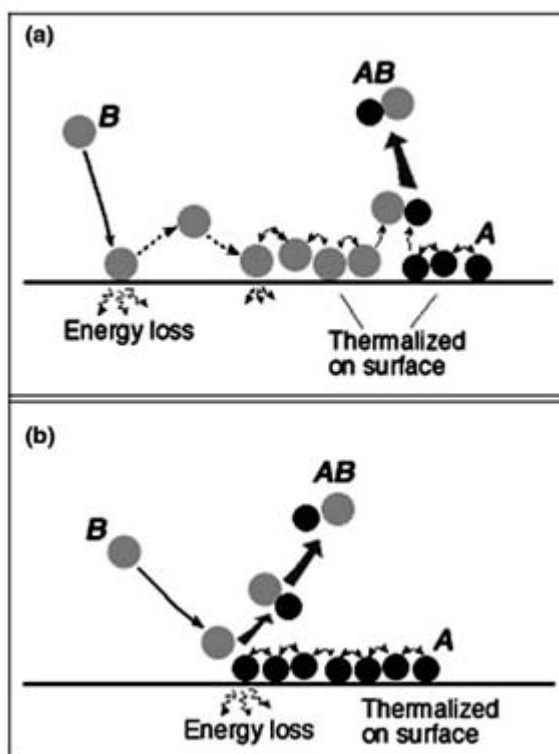

Figure A3.9.1. Schematic illustrations of (a) the Langmuir–Hinshelwood and (b) Eley–Rideal mechanisms in gas–surface dynamics.

A3.9.3 COLLISION DYNAMICS AND TRAPPING IN NONREACTIVE SYSTEMS

As with any collision process, to understand the dynamics of collisions we need an appreciation of the relevant forces and masses. Far from the surface, the incoming atom or molecule will experience the van der Waals attraction of the form

$$V(z) = -C/z^3 \tag{A3.9.1}$$

where z is the distance from the surface, and C is a constant dependent on the polarizability of the particle and the dielectric properties of the solid [9]. Close to the surface, where z is 0.1 nm for a nonreactive system, this attractive interaction is overwhelmed by repulsive forces (Pauli repulsion) due to the energy cost of orthogonalizing the overlapping electronic orbitals of the incoming molecule and the surface. The net result of van der Waals attraction and Pauli repulsion is a potential with a shallow well, the physisorption well, illustrated in figure A3.9.2. The depth of this well ranges from a few meV for He adsorption to ~ 30 meV for H_2 molecules on noble metal surfaces, and to ~ 100 meV for Ar or Xe on metal surfaces.

-4-

Figure A3.9.2. Interaction potential for an atom or molecule physisorbed on a surface. A convenient model is obtained by ‘squaring off’ the potential, which facilitates solution of the Schrödinger equation for the scattering of a quantum particle.

The van der Waals attraction arises from the interaction between instantaneous charge fluctuations in the molecule and surface. The molecule interacts with the surface as a whole. In contrast the repulsive forces are more short-range, localized to just a few surface atoms. The repulsion is, therefore, not homogeneous but depends on the point of impact in the surface plane, that is, the surface is corrugated.

A3.9.3.1 BINARY COLLISION (HARD-CUBE) MODEL

We can obtain an approximate description of the molecule–surface encounter using a binary collision model, with the projectile of mass m as one collision partner and a ‘cube’ having an effective mass, M , related to that of a surface atom, as the other partner. M depends on how close the projectile approaches the atoms of the surface, on the stiffness of the surface, and on the degree of corrugation of the repulsive potential. For rare-gas atoms interacting with metal surfaces, the surface electronic orbitals are delocalized and the repulsive interaction is effectively with a large cluster. The effective mass is correspondingly large, some 3–9 times the mass of a surface atom [10]. In other cases, such as O_2 colliding with Ag(111), the degree of corrugation and the effective mass may be closer to that expected for one atom [11].

Approximating the real potential by a square well and infinitely hard repulsive wall, as shown in figure A3.9.2 we obtain the hard cube model. For a well depth of W , conservation of energy and momentum lead [11, 12] to the very useful Baule formula for the translational energy loss, δE , to the substrate

$$\delta E = \frac{4\mu}{(1 + \mu)^2} (E + W) \quad (\text{A3.9.2})$$

where E is the initial translational energy of the projectile and μ is the ratio m/M . This formula shows us that the energy transfer increases with the mass of the projectile, reaching a maximum when projectile and cube masses are equal.

-5-

Of course the real projectile–surface interaction potential is not infinitely hard (cf figure A3.9.2). As E increases, the projectile can penetrate deeper into the surface, so that at its turning point (where it momentarily stops before reversing direction to return to the gas phase), an energetic projectile interacts with fewer surface atoms, thus making the effective cube mass smaller. Thus, we expect $\delta E/E$ to increase with E (and also with W since the well accelerates the projectile towards the surface).

The effect of surface temperature, T_S , can be included in this model by allowing the cube to move [12]. E becomes the translational energy in the frame of the centre-of-mass of projectile and cube; then we average the results over E , weighting with a Boltzmann distribution at T_S . This causes δE to decrease with increasing T_S , and when the thermal energy of the cube, kT_S , substantially exceeds E , the projectile actually gains energy in the collision! This is qualitatively consistent with experimental observations of the scattering of beams of rare-gas atoms from metal surfaces [14, 15].

A3.9.3.2 SCATTERING AND TRAPPING–DESORPTION DISTRIBUTIONS

Projectiles leaving the surface promptly after an inelastic collision have exchanged energy with the surface, yet their direction of motion and translational and internal energies are clearly related to their initial values. This is called direct-inelastic (DI) scattering. At low E , the projectile sees a surface in thermal motion. This motion dominates the final energy and angular distributions of the scattering, and so this is referred to as thermal scattering. As E becomes large, the projectile penetrates the surface more deeply, seeing more of the detailed atomic structure, and the interaction comes to be dominated by scattering from individual atoms. Eventually E becomes so large that the surface thermal motion becomes negligible, and the energy and angular distributions depend only on the atomic structure of the surface. This is known as the structure-scattering regime. Comparing experimental results with those of detailed classical molecular dynamics modelling of these phenomena can allow one to construct good empirical potentials to describe the projectile-surface interaction, as has been demonstrated for the Xe/Pt(111) [16] and Ar/Ag(111) [17] systems.

From equation (A3.9.2), we can see that at low E , the acceleration into the well dominates the energy loss, that is, δE does not reduce to zero with decreasing E . Below a critical translational energy, given by

$$E_c = \frac{4\mu W}{(1 - \mu)^2} \quad (\text{A3.9.3})$$

the projectile has insufficient energy remaining to escape from the well and it traps at the surface. Inclusion of surface temperature (cube motion) leads to a blurring of this cut-off energy so that trapping versus energy curves are predicted to be smoothed step functions. In fact, true trapping versus energy curves are closer to exponential in form, due to the combined effects of additional averaging over variations of W with surface site and with the orientation of the incident molecule. Additionally, transfer of motion normal to the surface to motion parallel to the surface, or into internal motions (rotations) can also lead to trapping, as we shall discuss below.

Trapped molecules can return to the gas phase once the thermal energy, kT_S , becomes comparable to the well depth. Having equilibrated with the surface, they have velocity, angular distribution and internal energies determined by T_S . This is visible in experiment as a scattering component (the trapping–desorption (TD) scattering component) with a very different appearance to the DI component, being peaked at and symmetrical about the surface normal, independently of the incidence conditions of the beam of projectiles.

Such behaviour has been seen in many systems, for example in the scattering of Ar from Pt(111) [10] as illustrated in [figure A3.9.3](#).

-6-

Figure A3.9.3. Time-of-flight spectra for Ar scattered from Pt(111) at a surface temperature of 100 K [10]. Points in the upper plot are actual experimental data. Curve through points is a fit to a model in which the bimodal distribution is composed of a sharp, fast moving (hence short flight time), direct-inelastic (DI) component and a broad, slower moving, trapping–desorption (TD) component. These components are shown separately in the lower curves. Parameters: $E = 12.5 \text{ kJ mol}^{-1}$; $\theta_i = 60^\circ$; $\theta_f = 40^\circ$; $T_s = 100 \text{ K}$.

A3.9.3.3 SELECTIVE ADSORPTION

Light projectiles impinging on a cold surface exhibit strong quantum behaviour in the scattering and trapping dynamics. Motion in the physisorption well is quantized normal to the surface, as indicated in [figure A3.9.2](#). Although in the gas phase the projectile can have any parallel momentum, when interacting with a perfect surface, the parallel momentum can only change by whole numbers of reciprocal lattice vectors (the wavevectors corresponding to wavelengths fitting within the surface lattice) [9]. The scattering is thus into special directions, forming a diffraction pattern, which is evident even for quite massive particles such as Ar [18]. These quantizations couple to yield maxima in the trapping probability when, to accommodate the gain in parallel momentum, the projectile must drop into one of the bound states in the z -direction. In other words, the quantized gain in parallel motion leaves the projectile with more translational energy than it had initially, but the excess is cancelled by the negative energy of the bound state [19]. This is an entirely elastic phenomenon, no energy loss to the substrate is required, simply a conversion of normal for parallel motion. The trapping is undone if the parallel momentum gain is reversed.

The energies of the selective adsorption resonances are very sensitive to the details of the physisorption potential. Accurate measurement allied to computation of bound state energies can be used to obtain a very accurate quantitative form for the physisorption potential, as has been demonstrated for helium atom scattering. For molecules, we have

-7-

the additional possibility of exchanging normal translations for rotational motion (the vibrational energies of light molecules are much larger than typical physisorption energies). Parallel momentum changes are effected by the surface corrugation, giving rise to corrugation mediated selective adsorption (CMSA). By analogy, rotational excitations produce rotation mediated selective adsorption (RMSA). Together these yield the acronym CRMSA. All such processes have been identified in the scattering of H_2 and its isotopomers from noble and simple metal surfaces [20]. Typical results are shown in [figure A3.9.4](#). The selective adsorption resonances show up as peaks in the trapping (minima in the reflectivity) because the long residence time at the surface increases the amount of energy lost to the substrate, resulting in sticking [21].

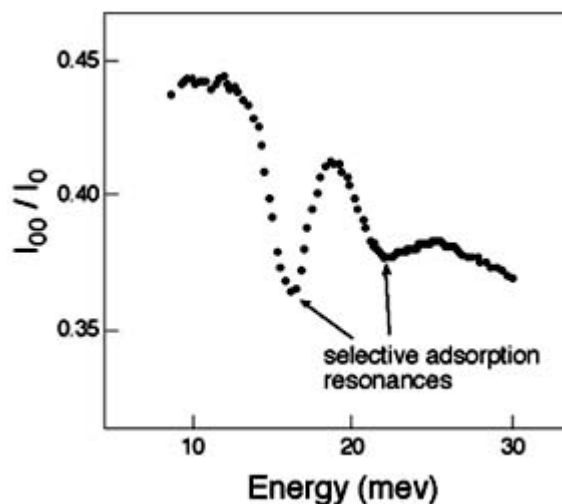

Figure A3.9.4. The ratio of specular reflectivity to incident beam intensity ratio for D_2 molecules scattering from a Cu(100) surface at 30 K [21].

A3.9.4 MOLECULAR CHEMISORPTION AND SCATTERING

Unlike physisorption, chemisorption results from strong attractive forces mediated by chemical bonding between projectile and surface [9]. There is often significant charge transfer between surface and molecule, as in the adsorption of O_2 on metal surfaces [22]. The characteristics, well depth, distance of minimum above the surface etc. can vary greatly with surface site [23]. The degree of charge transfer can also differ, such that in many systems we can speak of there being more than one chemisorbed species [24].

The chemisorption interaction is also very strongly dependent on the molecular orientation, especially for heteronuclear molecules. This behaviour is exemplified by NO adsorption on metal surfaces, where the N end is the more strongly bound. These anisotropic interactions lead to strong steric effects and consequent rotational excitation in the scattering dynamics. Rainbows are evident in the rotational distributions [25], as can be seen in [figure A3.9.5](#). These steric effects show up particularly strongly when the incident molecules are aligned prior to scattering (by magnetic fields) [26, 27].

Figure A3.9.5. Population of rotational states versus rotational energy for NO molecules scattered from an Ag (111) surface at two different incidence energies and at $T_S = 520$ K [25]: (a) $E = 0.85$ eV, $\theta_i = 15^\circ$ and (b) $E = 0.09$ eV, $\theta_i = 15^\circ$. Results at $E = 0.85$ eV show a pronounced rotational rainbow.

The change of charge state of an adsorbed molecule leads to a change in the intramolecular bonding, usually a lengthening of the bond, which can result in vibrational excitation of the scattered molecule. Once again, this shows up in the scattering of NO from the Ag(111) surface [28], as shown in [figure A3.9.6](#). In this case, the vibrational excitation probability is dependent on both the translational energy and the surface temperature. The translational energy dependence is probably due to the fact that the closer the molecule is to a surface, the more extended the molecular bond becomes, that is, in the language of [section A3.9.5](#), the NO is trying to get round the elbow (see [figure A3.9.8](#)) to dissociate. It fails, and returns to the gas phase with increased vibrational energy. Surface temperature can enhance this process by supplying energy from the thermal motion of a surface atom towards the molecule [29, 30], but interaction with electronic excitations in the metal has also been demonstrated to be an efficient and likely source of energy transfer to the molecular vibrations [29, 30].

Figure A3.9.6. Population of the first excited vibrational state ($v = 1$) versus inverse of surface temperature for NO scattering from an Ag(111) surface [28]. Curves: (a) $E = 102 \text{ kJ mol}^{-1}$ and (b) $E = 9 \text{ kJ mol}^{-1}$.

A3.9.4.1 CHEMISORPTION AND PRECURSOR STATES

The chemisorption of a molecule is often a precursor [31] to further reactions such as dissociation (see section A3.9.5.2), that is, the molecule must reside in the precursor state exploring many configurations until finding that leading to a reaction. Where there is more than one distinct chemisorption state, one can act as a precursor to the other [32]. The physisorption state can also act as a precursor to chemisorption, as is observed for the $\text{O}_2/\text{Ag}(110)$ system [33].

The presence of a precursor breaks the dynamical motion into three parts [34]. First, there is the dynamics of trapping into the precursor state; secondly, there is (at least partial) thermalization in the precursor state; and, thirdly, the reaction to produce the desired species (possibly a more tightly bound chemisorbed molecule). The first two of these we can readily approach with the knowledge gained from the studies of trapping and sticking of rare-gas atoms, but the long timescales involved in the third process may perhaps more usefully be addressed by kinetics and transition state theory [35].

A3.9.5 DYNAMICS OF DISSOCIATION REACTIONS

A3.9.5.1 DIRECT DISSOCIATION OF DIATOMICS

The direct dissociation of diatomic molecules is the most well studied process in gas–surface dynamics, the one for which the combination of surface science and molecular beam techniques allied to the computation of total energies and detailed and painstaking solution of the molecular dynamics has been most successful. The result is a substantial body of knowledge concerning the importance of the various degrees of freedom (e.g. molecular rotation) to the reaction dynamics, the details of which are contained in a number of review articles [2, 36, 37, 38, 39, 40 and 41].

(A) LENNARD-JONES MODEL OF HYDROGEN DISSOCIATION

In the 1930s Lennard-Jones [42] introduced a model that is still in use today in discussions of the dissociation of molecules at surfaces. He proposed a description based on two potential energy curves. The first, describing the interaction of the intact molecule with the surface as a physisorption potential, is shown as curve (a) in figure A3.9.7. Coupled with this, there is a second potential describing the interaction of the two separately chemisorbed atoms with the surface (curve (b) in figure A3.9.7). In equilibrium the adsorbed atoms are located at the minimum, L, of curve (b). The difference between (a) and (b) far from the surface is the gas-phase molecular dissociation energy, D . A dissociation event occurs if a molecule approaches the surface until K, where it makes a radiationless transition from (a) to (b) becoming adsorbed as atoms.

Figure A3.9.7. A representation of the Lennard-Jones model for dissociative adsorption of H_2 . Curves: (a) interaction of intact molecule with surface; (b) interaction of two separately chemisorbed atoms with surface.

There is an inconsistency in the model in that when changing from (a) to (b) the molecular bond is instantaneously elongated. Lennard-Jones noted that although one-dimensional potential energy curves (such as shown in figure A3.9.7 can prove of great value in discussions, ‘they do not lend themselves to generalization when more than one coordinate is necessary to specify a configuration’. In a quantitative theory there should be a number of additional curves between (a) and (b) corresponding to rotational and vibrational states of the molecule. In modern terms, we try to describe each

-11-

degree-of-freedom relevant to the problem with a separate dimension. The potential energy curves of [figure A3.9.7](#) then become a multidimensional surface, the potential energy surface (PES).

The model illustrated in [figure A3.9.7](#) is primarily diabatic, the molecule jumps suddenly from one type of bonding, represented by a potential energy curve, to another. However, much of the understanding in gas-surface dynamics derives from descriptions based on motion on a single adiabatic PES, usually the ground-state PES. In the Lennard-Jones model, this would approximately correspond to whichever of (a) and (b) has the lower energy. Although this approach is successful in describing H_2 dissociation, it will not be adequate for reactions involving very sudden changes of electronic state [43]. These may occur, for example, in the O_2 reaction with simple metal surfaces [44]; they are so energetic that they can lead to light or electron emission during reaction [45].

(B) INFLUENCE OF MOLECULAR VIBRATION ON REACTION

Dissociation involves extension of a molecular bond until it breaks and so it might seem obvious that the more energy we can put into molecular vibration, the greater the reactivity. However, this is not always so: the

existence of a vibrational enhancement of dissociation reveals something about the shape, or topography of the PES itself. This is illustrated in figure A3.9.8 which shows a generic elbow PES [37]. This two-dimensional PES describes the dynamics in the molecule–surface and intramolecular bond length coordinates only. Far from the surface, it describes the intramolecular bonding of the projectile by, for example, a Morse potential. Close to the surface at large bond length, the PES describes the chemisorption of the two atoms to the surface in similar fashion to curve (b) in figure A3.9.7. The curved region linking these two extremes is the interaction region (shaded in figure A3.9.8), where the bonding is changing from one type to another. It corresponds roughly to the curve crossing point, K, in the Lennard-Jones model.

Figure A3.9.8. An elbow potential energy surface representing the dissociation of a diatomic in two dimensions—the molecular bond length and the distance from the molecule to the surface.

For vibrational effects in the dynamics, the location of the dissociation barrier within the curved interaction region of figure A3.9.8 is crucial. If the barrier occurs largely before the curved region, it is an ‘early’ barrier at point E, then vibration will not promote reaction as it occurs largely at right angles to the barrier. In contrast, if the barrier occurs when the bond is already extended, say at L (a ‘late’ barrier) in the figure, the vibration is now clearly helping the molecule to attack this barrier, and can substantially enhance reaction.

The consequences of these effects have been fully worked out, and agree with the Polanyi rules used in gas-phase scattering [46, 47]. Experimental observations of both the presence and absence of vibrational enhancement have been made, most clearly in hydrogen dissociation on metal surfaces. For instance, H₂ dissociation on Ni surfaces shows no vibrational enhancement [48, 49]. On Cu surfaces, however, vibrational enhancement of dissociation has been clearly demonstrated by using molecular beam techniques (section B2.6) to vary the internal and translational energies independently [50] and by examining the energy and state distributions of molecules undergoing the reverse of dissociation, the associative desorption reaction [51]. Figure A3.9.9 shows typical results presented in the form of dissociation versus translational energy curves backed out from the desorption data [52]. The curves corresponding to the vibrationally excited states clearly lie at lower energy than those for the vibrational ground-state, implying that some of the energy for the reaction comes from the H₂ vibration.

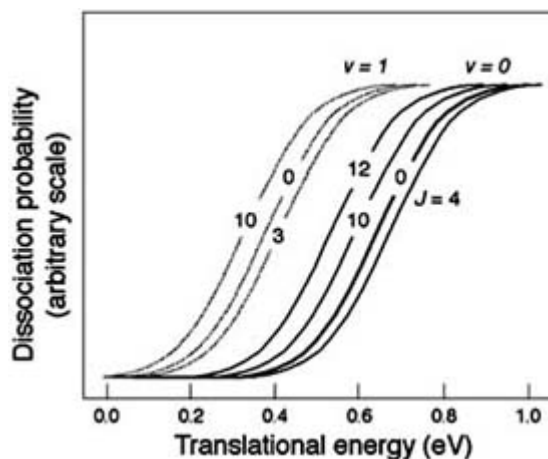

Figure A3.9.9. Dissociation probability versus incident energy for D_2 molecules incident on a Cu(111) surface for the initial quantum states indicated (v indicates the initial vibrational state and J the initial rotational state) [100]. For clarity, the saturation values have been scaled to the same value irrespective of the initial state, although in reality the saturation value is higher for the $v = 1$ state.

An important further consequence of curvature of the interaction region and a late barrier is that molecules that fail to dissociate can return to the gas-phase in vibrational states different from the initial, as has been observed experimentally in the H_2/Cu system [53, 55]. To undergo vibrational (de-)excitation, the molecules must round the elbow part way, but fail to go over the barrier, either because it is too high, or because the combination of vibrational and translational motions is such that the molecule moves across rather than over the barrier. Such vibrational excitation and de-excitation constrains the PES in that we require the elbow to have high curvature. Dissociation is not necessary, however, for as we have pointed out, vibrational excitation is observed in the scattering of NO from Ag(111) [55].

(C) ROTATIONAL EFFECTS: STERIC HINDRANCE AND CENTRIFUGAL ENHANCEMENT

Molecular rotation has two competing influences on the dissociation of diatomics [56, 57 and 58]. A molecule will only be able to dissociate if its bond is oriented correctly with respect to the plane of the surface. If the bond is parallel to the plane, then dissociation will take place, whereas if the molecule is end-on to the surface, dissociation requires one atom to be ejected into the gas phase. In most cases, this ‘reverse Eley–Rideal’ process is energetically very

unfavourable (although it does occur for very energetic reactions such as halide adsorption on Si surfaces, and possibly for O_2 adsorbing on reactive metals [59]). In general, molecules cannot dissociate when oriented end-on. The PES is, thus, highly corrugated in the molecular orientation coordinate. In consequence, increasing the rapidity of motion in this coordinate (i.e. increasing the rotational state) will make it more likely for the molecule to race past the small dissociation window at the parallel orientation, strike-off a more repulsive region of the PES and return to the gas phase. Therefore, dissociation is inhibited by increasing the rotational energy of the molecule. In opposition to this effect, the rotational motion can enhance reactivity when the dissociation barrier is late (i.e. occurs at extended bond length). As the molecule progresses through the interaction region, its bond begins to extend. This increases the moment of inertia and thus reduces the rotational energy. The rotational energy thus ‘lost’ feeds into the reaction coordinate, further stretching the molecular bond and enhancing the reaction. The combination of these two competing effects has been demonstrated in the $H_2/Cu(111)$ system. For the first few rotational states, increases in rotation reduce the dissociation (i.e. shift the dissociation curve to higher energy) as can be seen in [figure A3.9.9](#). Eventually, however, centrifugal enhancement wins out, and for the higher rotational states the dissociation curves are pushed to lower translational energies.

The strong dependence of the PES on molecular orientation also leads to strong coupling between rotational states, and hence rotational excitation/de-excitation in the scattering. This has been observed experimentally for H₂ scattering from Cu surfaces. Recent work has shown that for H₂ the changes in rotational state occur almost exclusively when the molecular bond is extended, that is, longer than the gas-phase equilibrium value [60].

(D) SURFACE CORRUGATION AND SITE SPECIFICITY OF REACTION

The idea that certain sites on a surface are especially active is common in the field of heterogeneous catalysis [61]. Often these sites are defects such as dislocations or steps. But surface site specificity for dissociation reactions also occurs on perfect surfaces, arising from slight differences in the molecule–surface bonding at different locations. This is so not only of insulator and semiconductor surfaces where there is strongly directional bonding, but also of metal surfaces where the electronic orbitals are delocalized. The site dependence of the reactivity manifests itself as a strong corrugation in the PES, which has been shown to exist by *ab initio* computation of the interaction PES for H₂ dissociation on some simple and noble metal surfaces [62, 63 and 64].

The dynamical implications of this corrugation appear straightforward: surface sites where the dissociation barrier is high (unfavourable reaction sites) should shadow those sites where the barrier is low (the favoured reaction sites) if the reacting molecule is incident at an angle to the surface plane. If we assume that the motion normal to the surface is important in traversing the dissociation barrier, then those molecules approaching at an angle should have lower dissociation probability than those approaching at normal incidence. This has indeed been observed in a number of dissociation systems [37], but a far more common observation is that the dissociation scales with the ‘normal energy’, $E_p = E \cos^2 \theta$, where E is the translational energy, and θ the angle of incidence of the beam with respect to the surface normal. Normal energy scaling, shown in [figure A3.9.10](#) implies that the motion parallel to the surface does not affect dissociation, and the surface appears flat.

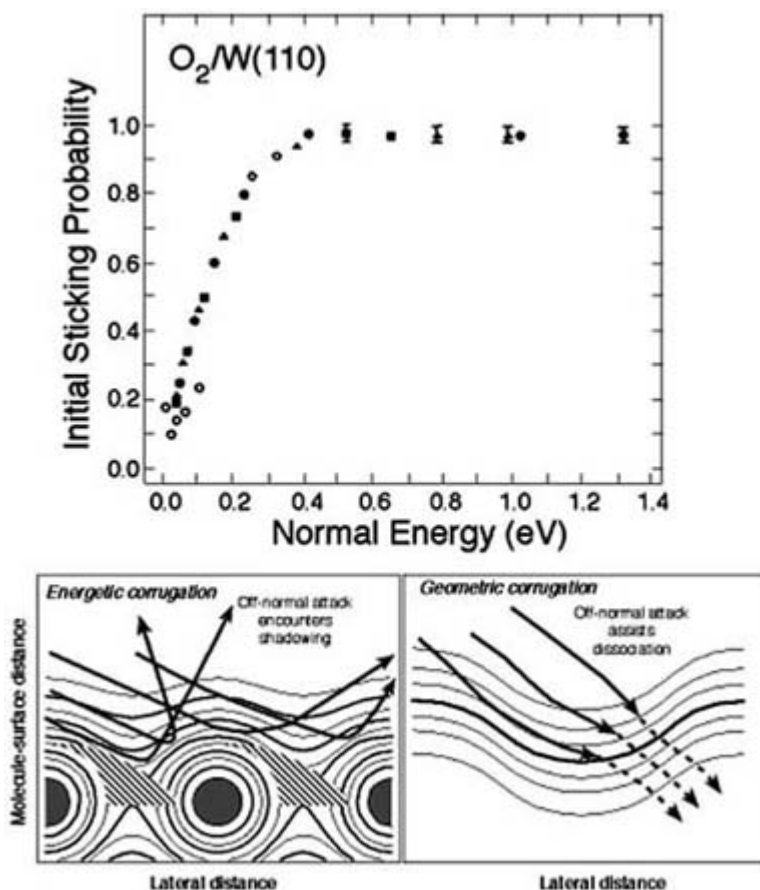

Figure A3.9.10. The dissociation probability for O₂ on W(110) [101] as a function of the normal energy, (upper). $T_g = 800$ K; θ : (●) 0°, (▲) 30° (■) 45° and (○) 60°. The normal energy scaling observed can be explained by combining the two surface corrugations indicated schematically (lower diagrams).

This difficulty has been resolved with the realization that the surface corrugation is not merely of the barrier energy, but of the distance of the barrier above the surface [65]. We then distinguish between *energetic corrugation* (the variation of the energetic height of the barrier) and *geometric corrugation* (a simple variation of the barrier location or shape). The two cases are indicated in figure A3.9.10. For energetic corrugation, the shadowing does lead to lower dissociation at off-normal incidence, but this can be counterbalanced by geometric corrugation, for which the parallel motion helps the molecule to attack the facing edge of the PES [65].

The site specificity of reaction can also be a state-dependent site specificity, that is, molecules incident in different quantum states react more readily at different sites. This has recently been demonstrated by Kroes and co-workers for the H₂/Cu(100) system [66]. Additionally, we can find reactivity dominated by certain sites, while inelastic collisions leading to changes in the rotational or vibrational states of the scattering molecules occur primarily at other sites. This spatial separation of the active site according to the change of state occurring (dissociation, vibrational excitation etc) is a very surface specific phenomenon.

(E) STEERING DOMINATED REACTION

A very extreme version of surface corrugation has been found in the nonactivated dissociation reactions of H₂ on W [67, 68], Pd and Rh systems. In these cases, the very strong chemisorption bond of the H atoms gives rise to a very large energy release when the molecule dissociates. In consequence, at certain sites on the surface, the molecule accelerates rapidly downhill into the dissociation state. At the unfavourable sites, there

are usually small dissociation barriers and, of course, molecules oriented end-on to the surface cannot dissociate. When we examine the dynamics of motion on such PESs, we find that the molecules are steered into the attractive downhill regions [69], away from the end-on orientation and away from the unfavourable reaction sites.

Steering is a very general phenomenon, caused by gradients in the PES, occurring in every gas–surface system [36]. However, for these nonactivated systems showing extreme variations in the PES, the steering dominates the dissociation dynamics. At the very lowest energies, most molecules have enough time to steer into the most favourable geometry for dissociation hence the dissociation probability is high. At higher E , there is less time for steering to be effective and the dissociation decreases. The general signature of a steering dominated reaction is, therefore, a dissociation probability that falls with increasing E [49, 70, 71], as shown in figure A3.9.11. This can be contrasted with the curve usually expected for direct dissociation, figure A3.9.10, one which increases with E because, as E increases, it is easier to overcome the barriers in unfavourable geometries.

Figure A3.9.11. Dissociation of H_2 on the $W(100)-c(2 \times 2)-Cu$ surface as a function of incident energy [71]. The steering dominated reaction [102] is evident at low energy, confirmed by the absence of a significant surface temperature.

(F) SURFACE TEMPERATURE DEPENDENCE

Direct dissociation reactions are affected by surface temperature largely through the motion of the substrate atoms [72]. Motion of the surface atom towards the incoming molecule increases the likelihood of (activated) dissociation, while motion away decreases the dissociation probability. For low dissociation probabilities, the net effect is an enhancement of the dissociation by increasing surface temperature, as observed in the system $O_2/Pt\{100\}-hex-R0.7^\circ$ [73].

This interpretation is largely based on the results of cube models for the surface motion. It may also be that

the thermal disorder of the surface leads to slightly different bonding and hence different barrier heights. Increasing temperature also changes the populations of the excited electronic states in the surface, which may affect bonding. The contribution of these effects to the overall surface temperature dependence of reaction is presently not clear.

A3.9.5.2 DIRECT DISSOCIATION OF POLYATOMIC MOLECULES

Although understanding the dissociation dynamics of diatomic molecules has come a long way, that of polyatomic molecules is much less well-developed. Quite simply, this is due to the difficulty of computing adequate PESs on which to perform suitable dynamics, when there are many atoms. Quantum dynamics also becomes prohibitively expensive as the dimensionality of the problem increases. The dissociation of CH_4 (to $\text{H} + \text{CH}_3$) on metal surfaces is the most studied to date [74]. This shows dependences on molecular translational energy and internal state, as well as a strong surface temperature dependence, which has been interpreted in terms of thermally assisted quantum tunnelling through the dissociation barrier. More recent experimental work has shown complicated behaviour at low E , with the possible involvement of steering or trapping [75].

A3.9.5.3 PRECURSOR-MEDIATED DISSOCIATION

Precursor-mediated dissociation involves trapping in a molecularly chemisorbed state (or possibly several states) prior to dissociation. If the molecule thermalizes before dissociation, we can expect to observe the signature of trapping in the dissociation dynamics, that is, we expect increasing E and increasing surface temperature to decrease the likelihood of trapping, and hence of dissociation. This is exemplified by the dissociation of N_2 on $\text{W}(100)$ in the low energy regime [76], shown in figure A3.9.12.

The thermalization stage of this dissociation reaction is not amenable to modelling at the molecular dynamics level because of the long timescales required. For some systems, such as $\text{O}_2/\text{Pt}(111)$, a kinetic treatment is very successful [77]. However, in others, thermalization is not complete, and the internal energy of the molecule can still enhance reaction, as observed for $\text{N}_2/\text{Fe}(111)$ [78, 79] and in the dissociation of some small hydrocarbons on metal surfaces [80]. A detailed explanation of these systems is presently not available.

-17-

Figure A3.9.12. The dissociation probability of N_2 on the $\text{W}(100)$ surface as a function of the energy of the

molecular beam. The falling trend and pronounced surface temperature dependence are indicative of a precursor mediated reaction at low energies.

A3.9.6 ELEY–RIDEAL DYNAMICS

The idea that reactions can occur directly when an incident reagent strikes an adsorbate is strongly supported by detailed theoretical calculations. From early classical simulations on model PESs (e.g. for H on H/tungsten [81] and O on C/platinum [82]), to more recent theoretical studies of ER reactions employing quantum-mechanical models, it has been clearly established that product molecules should show a high degree of internal excitation. As noted in [section A3.9.2](#), certain highly facile gas–surface reactions can occur directly at the point of impact between an incident gas-phase reagent and an adsorbate; however, it is more likely that the incident reagent will ‘bounce’ a few times before reaction, this being to some degree accommodated in the process. A more useful working definition of an ER reaction is that it should occur before the reagents have become equilibrated at the surface. With this definition, we encompass hot-atom dynamics and what Harris and Kasemo have termed *precursor dynamics* [8]. Since the heat of adsorption of the incident reagent is not fully accommodated, ER reactions are far more exothermic than their LH counterparts.

Until relatively recently, the experimental evidence for the ER mechanism came largely from kinetic measurements, relating the rate of reaction to the incident flux and to the surface coverage and temperature [83]. For example, it has been found that the abstraction of halogens from Si(100) by incident H proceeds with a very small activation barrier, consistent with an ER mechanism. To *prove* that a reaction can occur on essentially a single gas–surface collision, however, dynamical measurements are required. The first definitive evidence for an ER mechanism was obtained in 1991, in a study showing that hyperthermal $\text{N}(\text{C}_2\text{H}_4)_3\text{N}$ can pick up a proton from a H/Pt(111) surface to give an ion with translational energy dependent on that of the incident molecule [84]. A year later, a study was reported of the formation of HD from H atoms incident on D/Cu(111), and from D incident on H/Cu(111) [85]. The angular

-18-

distribution of the HD was found to be asymmetrical about the surface normal and peaked on the opposite side of the normal to that of the incident atom. This behaviour proved that the reaction must occur before the incident atom reaches equilibrium with the surface. Moreover, the angular distribution was found to depend on the translational energy of the incident atom and on which isotope was incident, firmly establishing the operation of an ER mechanism for this elementary reaction.

Conceptually similar studies have since been carried out for the reaction of H atoms with Cl/Au(111). More recently, quantum-state distributions have been obtained for both the H + Cl/Au(111) [86, 87 and 88] and H(D) + D (H)/Cu(111) systems. The results of these studies are in good qualitative agreement with calculations. Even for the H(D) + D (H)/Cu(111) system [89], where we know that the incident atom cannot be significantly accommodated prior to reaction, reaction may not be direct. Detailed calculations yield much smaller cross sections for direct reaction than the overall experimental cross section, indicating that reaction may occur only after trapping of the incident atom [90].

Finally, it should also be clear that ER reactions do not necessarily yield a gas-phase product. The new molecule may be trapped on the surface. There is evidence for an ER mechanism in the addition of incident H atoms to ethylene and benzene on Cu(111) [91], and in the abstraction of H atoms from cyclohexane by incident D atoms [92], and the direct addition of H atoms to CO on Ru(001) [93].

A3.9.7 PHOTOCHEMISTRY

The interaction of light with both clean surfaces and those having adsorbed species has been a popular research topic over the past 10 years [94]. Our understanding of processes such as photodesorption, photodissociation and photoreaction is still at a very early stage and modelling has been largely performed on a system-by-system basis rather than any general theories being applicable. One of the most important aspects of performing photochemical reactions on surfaces, which has been well documented by Polanyi and co-workers is that it is possible to align species before triggering reactions that cannot be done in the gas phase. This is frequently referred to as surface aligned photochemistry [95]. One of the key issues when light, such as that from a picosecond laser, impinges a surface covered with an adsorbate is where the actual absorption takes place. Broadly speaking there are two possible choices either in the adsorbate molecule or the surface itself. Unfortunately, although it may seem that unravelling microscopic reaction mechanisms might be quite distinct depending on what was absorbing, this is not the case and considerable effort has been spent on deciding what the dynamical consequences are for absorption into either localized or extended electronic states [96].

Of lesser interest here for a laser beam incident upon a surface are the processes that occur due to surface heating. Of greater interest are those occasions when an electronic transition is initiated and a process occurs, for in these circumstances it becomes possible to ‘tune’ reactivity by an external agent. A good example of this is the UV photodissociation of a range of carbonyls on Si surfaces [97]. Here it was shown explicitly that 257 nm light can selectively excite the adsorbate and then dissociation ensues. An alternative story unfolds when NO is photodesorbed from Pt surfaces. Detailed experiment and modelling shows that, in this case, the initial excitation (absorption) event occurs in the metal substrate. Following this, the excess energy is transferred to the adsorbate by a hot electron which resides for about 10–12 fs before returning to the substrate. During this time, it is possible for the NO to gain sufficient energy to overcome the adsorption bond [98].

-19-

Finally, and most recently, femtosecond lasers have been employed to investigate reactions on surfaces, one good example is the oxidation of CO on a Ru surface [99]. One of the long outstanding problems in surface dynamics is to determine the energy pathways that are responsible for irreversible processes at the surface. Both phonons and electrons are capable of taking energy from a prethermalized adsorbate and because of the time required for converting electronic motion to nuclear motion, there is the possibility that measurements employing ultrashort-pulsed lasers might be able to distinguish the dominant pathway.

A3.9.8 OUTLOOK

Despite the considerable progress over the 1990s, the field of gas–surface reaction dynamics is still very much in its infancy. We have a relatively good understanding of hydrogen dissociation on noble metals but our knowledge of other gas–surface systems is far from complete. Even for other diatomic reagents such as N₂ or O₂ a great deal yet remains to be learned. Nevertheless, we believe that progress will take place even if in a slightly different fashion to that which is described here.

In parallel with the remarkable increase in computing power, particularly in desktop workstations, there have been significant advances also in the algorithmic development of codes that can calculate the potential energy (hyper-)surfaces that have been mentioned in this article. Most of the theoretical work discussed here has relied to a greater or lesser extent on potential energy surfaces being available from some secondary agency

and this, we believe, will not be the case in the future. Software is now available which will allow the dynamicist to calculate new potentials and then deploy them to evaluate state-to-state cross sections and reaction probabilities. Although new, detailed experimental data will provide guidance, a more general understanding of gas–surface chemistry will develop further as computational power continues to increase.

A3.10 Reactions on surfaces: corrosion, growth, etching and catalysis

Todd P St Clair and D Wayne Goodman

A3.10.1 INTRODUCTION

The impact of surface reactions on society is often overlooked. How many of us pause to appreciate integrated circuitry before checking email? Yet, without growth and etching reactions, the manufacturing of integrated circuits would be quite impractical. Or consider that in 1996, the United States alone consumed 123 billion gallons of gasoline [1]. The production of this gasoline from crude petroleum is accomplished by the petroleum industry using heterogeneous catalytic reactions. Even the control of automobile exhaust emissions, an obvious environmental concern, is achieved *via* catalytic reactions using ‘three-way catalysts’ that eliminate hydrocarbons, CO and NO_x. The study of these types of surface reactions and others is an exciting and rapidly changing field. Nevertheless, much remains to be understood at the atomic level regarding the interaction of gases and liquids with solid surfaces.

Surface science has thrived in recent years primarily because of its success at providing answers to fundamental questions. One objective of such studies is to elucidate the basic mechanisms that control surface reactions. For example, a goal could be to determine if CO dissociation occurs prior to oxidation over Pt catalysts. A second objective is then to extrapolate this microscopic view of surface reactions to the

corresponding macroscopic phenomena.

How are fundamental aspects of surface reactions studied? The surface science approach uses a simplified system to model the more complicated 'real-world' systems. At the heart of this simplified system is the use of well defined surfaces, typically in the form of oriented single crystals. A thorough description of these surfaces should include composition, electronic structure and geometric structure measurements, as well as an evaluation of reactivity towards different adsorbates. Furthermore, the system should be constructed such that it can be made increasingly more complex to more closely mimic macroscopic systems. However, relating surface science results to the corresponding real-world problems often proves to be a stumbling block because of the sheer complexity of these real-world systems.

Essential to modern surface science techniques is the attainment and maintenance of ultrahigh vacuum (UHV), which corresponds to pressures of the order of 10^{-10} Torr ($\sim 10^{-13}$ atm). At these pressures, the number of collisions between gas phase molecules and a surface are such that a surface can remain relatively contaminant-free for a period of hours. For example, in air at 760 Torr and 298 K the collision frequency is 3×10^{23} collisions $\text{cm}^{-2} \text{s}^{-1}$. Assuming a typical surface has 10^{15} atoms cm^{-2} , then each surface atom undergoes $\sim 10^8$ collisions per second. Clearly, a surface at 760 Torr has little chance of remaining clean. However, by lowering the pressure to 10^{-10} Torr, the collision frequency decreases to approximately 10^{10} collisions $\text{cm}^{-2} \text{s}^{-1}$, corresponding to a collision with a surface atom about every 10^5 s. Decreasing the pressure is obviously a solution to maintaining a clean sample, which itself is crucial to sustaining well characterized surfaces during the course of an experiment.

Modern UHV chambers are constructed from stainless steel. The principal seals are metal-on-metal, thus the use of greases is avoided. A combination of pumps is normally used, including ion pumps, turbomolecular pumps, cryopumps and mechanical (roughing) pumps. The entire system is generally heatable to ~ 500 K. This 'bakeout' for a period of

-2-

10–20 h increases gas desorption rates from the internal surfaces, ultimately resulting in lower pressure. For further reading on vacuum technology, including vacuum and pump theory, see [2, 3].

The importance of low pressures has already been stressed as a criterion for surface science studies. However, it is also a limitation because real-world phenomena do not occur in a controlled vacuum. Instead, they occur at atmospheric pressures or higher, often at elevated temperatures, and in conditions of humidity or even contamination. Hence, a major thrust in surface science has been to modify existing techniques and equipment to permit detailed surface analysis under conditions that are less than ideal. The scanning tunnelling microscope (STM) is a recent addition to the surface science arsenal and has the capability of providing atomic-scale information at ambient pressures and elevated temperatures. Incredible insight into the nature of surface reactions has been achieved by means of the STM and other *in situ* techniques.

This chapter will explore surface reactions at the atomic level. A brief discussion of corrosion reactions is followed by a more detailed look at growth and etching reactions. Finally, catalytic reactions will be considered, with a strong emphasis on the surface science approach to catalysis.

A3.10.2 CORROSION

A3.10.2.1 INTRODUCTION

Corrosion is a frequently encountered phenomenon in which a surface undergoes changes associated with

exposure to a reactive environment. While materials such as plastics and cement can undergo corrosion, the term corrosion more commonly applies to metal surfaces. Rust is perhaps the most widely recognized form of corrosion, resulting from the surface oxidation of an iron-containing material such as steel. Economically, corrosion is extremely important. It has been estimated that annual costs associated with combating and preventing corrosion are 2–3% of the gross national product for industrialized countries. Equipment damage is a major component of the costs associated with corrosion. There are also costs related to corrosion prevention, such as implementation of anti-corrosive paints or other protective measures. Finally, there are indirect losses, such as plant shutdowns, when equipment or facilities need repair or replacement.

Most metals tend to corrode in an environment of air and/or water, forming metal oxides or hydrated oxides. Whether or not such a reaction is possible is dictated by the thermodynamics of the corrosion reaction. If the reaction has a negative Gibbs free energy of formation, then the reaction is thermodynamically favoured. While thermodynamics determines whether a particular reaction can occur or not, the *rate* of the corrosion reaction is determined by kinetic factors. A number of variables can affect the corrosion rate, including temperature, pH and passivation, which is the formation of a thin protective film on a metal surface. Passivation can have a tremendous influence on the corrosion rate, often reducing it to a negligible amount.

Since metals have very high conductivities, metal corrosion is usually electrochemical in nature. The term electrochemical is meant to imply the presence of an electrode process, i.e. a reaction in which free electrons participate. For metals, electrochemical corrosion can occur by loss of metal atoms through anodic dissolution, one of the fundamental corrosion reactions. As an example, consider a piece of zinc, hereafter referred to as an electrode, immersed in water. Zinc tends to dissolve in water, setting up a concentration of Zn^{2+} ions very near the electrode

-3-

surface. The term *anodic dissolution* arises because the area of the surface where zinc is *dissolving* to form Zn^{2+} is called the *anode*, as it is the source of positive current in the system. Because zinc is oxidized, a concentration of electrons builds up on the electrode surface, giving it a negative charge. This combination of negatively charged surface region with positively charged near-surface region is called an electrochemical double layer. The potential across the layer, called the electrode potential, can be as much as ± 1 V.

In moist environments, water is present either at the metal interface in the form of a thin film (perhaps due to condensation) or as a bulk phase. Figure A3.10.1 schematically illustrates another example of anodic dissolution where a droplet of slightly acidic water (for instance, due to H_2SO_4) is in contact with an Fe surface in air [4]. Because Fe is a conductor, electrons are available to reduce O_2 at the edges of the droplets. The electrons are then replaced by the oxidation reaction of Fe to Fe^{2+} (forming $FeSO_4$ if H_2SO_4 is the acid), and the rate of corrosion is simply the current induced by metal ions leaving the surface.

Figure A3.10.1 (a) A schematic illustration of the corrosion process for an oxygen-rich water droplet on an iron surface. (b) The process can be viewed as a short-circuited electrochemical cell [4].

Corrosion protection of metals can take many forms, one of which is passivation. As mentioned above, passivation is the formation of a thin protective film (most commonly oxide or hydrated oxide) on a metallic surface. Certain metals that are prone to passivation will form a thin oxide film that displaces the electrode potential of the metal by +0.5–2.0 V. The film severely hinders the diffusion rate of metal ions from the electrode to the solid–gas or solid–liquid interface, thus providing corrosion resistance. This decreased corrosion rate is best illustrated by anodic polarization curves, which are constructed by measuring the net current from an electrode into solution (the corrosion current) under an applied voltage. For passivable metals, the current will increase steadily with increasing voltage in the so-called active region until the passivating film forms, at which point the current will rapidly decrease. This behaviour is characteristic of metals that are susceptible to passivation.

Another method by which metals can be protected from corrosion is called alloying. An alloy is a multi-component solid solution whose physical and chemical properties can be tailored by varying the alloy composition.

-4-

For example, copper has relatively good corrosion resistance under non-oxidizing conditions. It can be alloyed with zinc to yield a stronger material (brass), but with lowered corrosion resistance. However, by alloying copper with a passivating metal such as nickel, both mechanical and corrosion properties are improved. Another important alloy is steel, which is an alloy between iron (>50%) and other alloying elements such as carbon.

Although alloying can improve corrosion resistance, brass and steel are not completely resistant to attack and often undergo a form of corrosion known as selective corrosion (also called de-alloying or leaching). De-alloying consists of the segregation of one alloy component to the surface, followed by the removal of this surface component through a corrosion reaction. De-zincification is the selective leaching of zinc from brasses in an aqueous solution. The consequences of leaching are that mechanical and chemical properties change with compositional changes in the alloy.

As an example of the effect that corrosion can have on commercial industries, consider the corrosive effects of salt water on a seagoing vessel. Corrosion can drastically affect a ship's performance and fuel consumption over a period of time. As the hull of a steel boat becomes corroded and fouled by marine growths, the

performance of the ship declines because of increased frictional drag. Therefore, ships are drydocked periodically to restore the smoothness of the hull. Figure A3.10.2 shows the loss of speed due to corrosion and marine fouling between annual drydockings for a ship with a steel hull [5]. As corrosion effects progressively deteriorated the hull and as marine growth accumulated, the ship experienced an overall loss of speed even after drydocking and an increased fuel consumption over time. It is clear that there is strong economic motivation to implement corrosion protection.

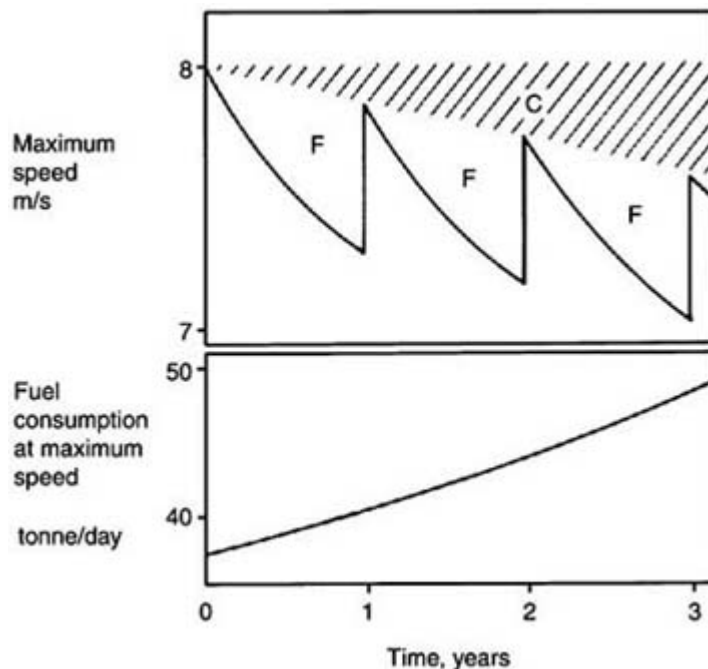

Figure A3.10.2 The influence of corrosion (C) and marine fouling (F) on the performance of a steel ship drydocked annually for cleaning and painting [5].

Surface science studies of corrosion phenomena are excellent examples of *in situ* characterization of surface reactions. In particular, the investigation of corrosion reactions with STM is promising because not only can it be used to study solid–gas interfaces, but also solid–liquid interfaces.

A3.10.2.2 SURFACE SCIENCE OF CORROSION

(A) THE ROLE OF SULFUR IN CORROSION

STM has been used to study adsorption on surfaces as it relates to corrosion phenomena [6, 7]. Sulfur is a well known corrosion agent and is often found in air (SO_2 , H_2S) and in aqueous solution as dissolved anions (HSO_3^-) or dissolved gas (H_2S). By studying the interaction of sulfur with surfaces, insights can be gained into the fundamental processes governing corrosion phenomena. A Ni(111) sample with 10 ppm sulfur bulk impurity was used to study sulfur adsorption by annealing the crystal to segregate the sulfur to the surface [8]. Figure A3.10.3 shows a STM image of a S-covered Ni(111) surface. It was found that sulfur formed islands preferentially near step edges, and that the Ni surface reconstructed under the influence of sulfur adsorption. This reconstruction results in surface sites that have fourfold symmetry rather than threefold symmetry as on the unreconstructed (111) surface. Furthermore, the fourfold symmetry sites are similar to those found on unreconstructed Ni(100), demonstrating the strong influence that sulfur adsorption has on this surface. The mechanism by which sulfur leads to corrosion of nickel surfaces is clearly linked to the ability of sulfur to weaken Ni–Ni bonds.

Figure A3.10.3 STM images of the early stages of sulfur segregation on Ni(111). Sulfur atoms are seen to preferentially nucleate at step edges [8].

-6-

(B) ANODIC DISSOLUTION IN ALLOYS

This weakening of Ni–Ni surface bonds by adsorbed sulfur might lead one to expect that the corrosion rate should increase in this case. In fact, an increased anodic dissolution rate was observed for Ni₃Fe (100) in 0.05 M H₂SO₄ [9]. Figure A3.10.4 shows the anodic polarization curves for clean and S-covered single-crystal alloy surfaces. While both surfaces show the expected current increase with potential increase, the sulfur-covered surface clearly has an increased rate of dissolution. In addition, the sulfur coverage (measured using radioactive sulfur, ³⁵S) does not decrease even at the maximum dissolution rate, indicating that adsorbed sulfur is not consumed by the dissolution reaction. Instead, surface sulfur simply enhances the rate of dissolution, as expected based on the observation above that Ni–Ni bonds are significantly weakened by surface sulfur.

Figure A3.10.4 The effect of sulfur on the anodic polarization curves from a Ni_{0.25}Fe(100) alloy in 0.05 M H₂SO₄. θ is the sulfur (³⁵S) coverage [6].

The nature of copper dissolution from CuAu alloys has also been studied. CuAu alloys have been shown to have a surface Au enrichment that actually forms a protective Au layer on the surface. The anodic polarization curve for CuAu alloys is characterized by a critical potential, E_c , above which extensive Cu dissolution is observed [10]. Below E_c , a smaller dissolution current arises that is approximately potential-independent. This critical potential depends not only on the alloy composition, but also on the solution composition. STM was used to investigate the mechanism by which copper is selectively dissolved from a CuAu₃ electrode in solution [11], both above and below the critical potential. At potentials below E_c , it was found that, as copper dissolves, vacancies agglomerate on the surface to form voids one atom deep. These voids grow two-dimensionally with increasing Cu dissolution while the second atomic layer remains undisturbed. The fact that the second atomic layer is unchanged suggests that Au atoms from the first layer are filling

-7-

in holes left by Cu dissolution. In sharp contrast, for potentials above E_c , massive Cu dissolution results in a rough surface with voids that grow both parallel and perpendicular to the surface, suggesting a very fast dissolution process. These *in situ* STM observations lend insight into the mechanism by which Cu dissolution occurs in CuAu₃ alloys.

The characterization of surfaces undergoing corrosion phenomena at liquid–solid and gas–solid interfaces remains a challenging task. The use of STM for *in situ* studies of corrosion reactions will continue to shape the atomic-level understanding of such surface reactions.

A3.10.3 GROWTH

A3.10.3.1 INTRODUCTION

Thin crystalline films, or overlayers, deposited onto crystalline substrates can grow in such a way that the substrate lattice influences the overlayer lattice. This phenomenon is known as *epitaxy*; if the deposited material is different from (the same as) the substrate, the process is referred to as heteroepitaxy (homoepitaxy). Epitaxial growth is of interest for several reasons. First, it is used prevalently in the semiconductor industry for the manufacture of III/V and II/VI semiconductor devices. Second, novel phases have been grown epitaxially by exploiting such phenomena as lattice mismatch and strain. These new phases have physical and chemical properties of interest to science and engineering. Finally, fundamental catalytic studies often focus on modelling oxide-supported metal particles by depositing metal films on oxide single crystals and thin films and, in many cases, these oxide and metal films grow epitaxially.

When considering whether growth will occur epitaxially or not, arguments can be made based on geometrical considerations, or row matching. This concept is based on the idea that the overlayer must sit on minima of the substrate corrugation potential to minimize the interaction energy. For example, consider the illustration of epitaxial growth in [figure A3.10.5](#) where an fcc(111) monolayer has been overlaid on a bcc(110) surface [12]. [Figure A3.10.5\(a\)](#) shows that the overlayer must be expanded or contracted in two directions to obtain row matching. [Figure A3.10.5\(b\)](#) shows, however, that rotation of the overlayer by 5.26° results in row matching along the most close-packed row of the lattices. Epitaxial growth clearly provides a pathway to energetically favourable atomic arrangements.

Figure A3.10.5 An fcc(111) monolayer (full circles) overlaid onto a bcc(110) substrate (open circles). (a) fcc [011] parallel to bcc[001]. (b) 5.26° rotation relative to (a). The lattice constants were chosen to produce row-matching in (b) [12].

The influence of the substrate lattice makes it energetically favourable for two materials to align lattices. On the other hand, if two lattices are misaligned or mismatched in some other way, then lattice strain may result. This lattice strain can lead to a metastable atomic arrangement of the deposited material. In other words, an overlayer can respond to lattice strain by adopting a crystal structure that differs from its normal bulk structure in order to row-match the substrate lattice. This phenomenon is known as pseudomorphy. For example, Cu (fcc) deposited on a Pd(100) surface will grow epitaxially to yield a pseudomorphic fcc overlayer [13]. However, upon increasing the copper film thickness, a body-centred tetragonal (bct) metastable phase, one not normally encountered for bulk copper, was observed. This phase transformation is due to a high degree of strain in the fcc overlayer.

Another example of epitaxy is tin growth on the (100) surfaces of InSb or CdTe ($a = 6.49 \text{ \AA}$) [14]. At room temperature, elemental tin is metallic and adopts a bct crystal structure ('white tin') with a lattice constant of 5.83 \AA . However, upon deposition on either of the two above-mentioned surfaces, tin is transformed into the diamond structure ('grey tin') with $a = 6.49 \text{ \AA}$ and essentially no misfit at the interface. Furthermore, since grey tin is a semiconductor, then a novel heterojunction material can be fabricated. It is evident that epitaxial growth can be exploited to synthesize materials with novel physical and chemical properties.

A3.10.3.2 FILM GROWTH TECHNIQUES

There are several design parameters which distinguish film growth techniques from one another, namely generation of the source atom/molecule, delivery to the surface and the surface condition. The source molecule can be generated in a number of ways including vapour produced thermally from solid and liquid sources, decomposition of organometallic

compounds and precipitation from the liquid phase. Depending on the pressures used, gas phase atoms and

molecules impinging on the surface may be in viscous flow or molecular flow. This parameter is important to determining whether atom–atom (molecule–molecule) collisions, which occur in large numbers at pressures higher than UHV, can affect the integrity of the atom (molecule) to be deposited. The condition of the substrate surface may also be a concern: elevating the surface temperature may alter the growth kinetics, or the surface may have to be nearly free of defects and/or contamination to promote the proper growth mode. Two film growth techniques, molecular beam epitaxy (MBE) and vapour phase epitaxy (VPE) will be briefly summarized below. These particular techniques were chosen because of their relevance to UHV studies. The reader is referred elsewhere for more detailed discussions of the various growth techniques [15, 16 and 17].

MBE is accomplished under UHV conditions with pressures of the order of $\sim 10^{-10}$ Torr. By using such low pressures, the substrate surface and deposited thin films can be kept nearly free of contamination. In MBE, the material being deposited is usually generated in UHV by heating the source material to the point of evaporation or sublimation. The gas phase species is then focused in a molecular beam onto the substrate surface, which itself may be at an elevated temperature. The species flux emanating from the source can be controlled by varying the source temperature and the species flux arriving at the surface can be controlled by the use of mechanical shutters. Precise control of the arrival of species at the surface is a very important characteristic of MBE because it allows the growth of epitaxial films with very abrupt interfaces. Several sources can be incorporated into a single vacuum chamber, allowing doped semiconductors, compounds or alloys to be grown. For instance, MBE is used prevalently in the semiconductor industry to grow GaAs/Al_xGa_{1-x}As layers and, in such a situation, a growth chamber would be outfitted with Ga, As and Al deposition sources. Because of the compatibility of MBE with UHV surface science techniques, it is often the choice of researchers studying fundamentals of thin-film growth.

A second technique, VPE, is also used for surface science studies of overlayer growth. In VPE, the species being deposited can be generated in several ways, including vaporization of a liquid precursor into a flowing gas stream or sublimation of a solid precursor. VPE generates an unfocused vapour or cloud of the deposited material, rather than a collimated beam as in MBE. Historically, VPE played a major role in the development of III/V semiconductors. Currently, VPE is used as a tool for studying metal growth on oxides, an issue of importance to the catalysis community.

The following two sections will focus on epitaxial growth from a surface science perspective with the aim of revealing the fundamentals of thin-film growth. As will be discussed below, surface science studies of thin-film deposition have contributed greatly to an atomic-level understanding of nucleation and growth.

A3.10.3.3 THERMODYNAMICS

The number of factors affecting thin-film growth is largely dependent upon the choice of growth technique. The overall growth mechanism may be strongly influenced by three factors: mass transport, thermodynamics and kinetics. For instance, for an exothermic (endothermic) process, increasing (decreasing) the surface temperature will decrease (increase) the growth rate for a thermodynamically limited process. On the other hand, if temperature has no effect on the growth rate, then the process may be limited by mass transport, which has very little dependence on the substrate temperature. Another test of mass transport limitations is to increase the total flow rate to the surface while keeping the partial pressures constant—if the growth rate is influenced, then mass transport limitations should be considered. Alternatively, if the substrate orientation is found to influence the growth rates, then the process is very likely kinetically limited. Thus, through a relatively straightforward analysis of the parameters affecting macroscopic

quantities, such as growth rate, a qualitative description of the growth mechanism can be obtained. The

growth of epitaxial thin films by vapour deposition in UHV is a non-equilibrium kinetic phenomenon. At thermodynamic equilibrium, atomic processes are required to proceed in opposite directions at equal rates. Hence, a system at equilibrium must have equal adsorption and desorption rates, as well as equal cluster growth and cluster decay rates. If growth were occurring under equilibrium conditions, then there would be no net change in the amount of deposited material on the surface. Typical growth conditions result in systems far from equilibrium, so film growth is usually limited by kinetics considerations. Thermodynamics does play an important role, however, as will be discussed next.

Thermodynamics can lend insight into the expected growth mode by examination of energetics considerations. The energies of importance are the surface free energy of the overlayer, the interfacial energy between the substrate and the overlayer, and the surface free energy of the substrate. Generally, if the free energy of the overlayer plus the interface energy is greater than the free energy of the substrate, then Frank–van der Merwe (FM) growth will occur [18]. FM growth, also known as layer-by-layer growth, is characterized by the completion of a surface overlayer before the second layer begins forming. However, if the free energy of the overlayer plus the interface energy is less than the free energy of the substrate then the growth mode is Volmer–Weber (VW) [18]. VW, or three-dimensional (3D), growth yields 3D islands or clusters that coexist with bare patches of substrate. There is also a third growth mode, called Stranski–Krastanov (SK), which can be described as one or two monolayers of growth across the entire surface subsequently followed by the growth of 3D islands [18]. In SK growth, the sum of the surface free energy of the overlayer plus interface energy is initially greater than that of the substrate, resulting in the completion of the first monolayer, after which the surface free energy of the overlayer plus interface energy becomes greater than that of the substrate, resulting in 3D growth. It should be stressed that the energetic arguments for these growth modes are only valid for equilibrium processes. However, these descriptions provide good models for the growth modes experimentally observed even under non-equilibrium conditions.

A3.10.3.4 NUCLEATION AND GROWTH

The process of thin-film growth from an atomic point of view consists of the following stages: adsorption, diffusion, nucleation, growth and coarsening. Adsorption is initiated by exposing the substrate surface to the deposition source. As described above, this is a non-equilibrium process, and the system attempts to restore equilibrium by forming aggregates. The adatoms randomly walk during the diffusion process until two or more collide and subsequently nucleate to form a small cluster. A rate-limiting step is the formation of some critical cluster size, at which point cluster growth becomes more probable than cluster decay. The clusters increase in size during the growth stage, with the further addition of adatoms leading to island formation. Growth proceeds at this stage according to whichever growth mode is favoured. Once deposition has ceased, further island morphological changes occur during the coarsening stage, whereby atoms in small islands evaporate and add to other islands or adsorb onto available high-energy adsorption sites such as step edge sites. For an excellent review on the atomic view of epitaxial metal growth, see [19].

Experimentally, the variable-temperature STM has enabled great strides to be made towards understanding nucleation and growth kinetics on surfaces. The evolution of overlayer growth can be followed using STM from the first stages of adatom nucleation through the final stages of island formation. The variable-temperature STM has also been crucial to obtaining surface diffusion rates. In such cases, however, the importance of tip–sample interactions must be considered. Typically, low tunnelling currents are best because under these conditions the tip is further from the surface, thereby reducing the risk of tip–sample interactions.

Much effort in recent years has been aimed at modelling nucleation at surfaces and several excellent reviews exist [20, 21 and 22]. Mean-field nucleation theory is one of these models and has a simple picture at its core.

In the nucleation stage, an atom arriving at the surface from the gas phase adsorbs and then diffuses at a particular rate until it collides with another surface adatom to form a dimer. If the dimers are assumed to be stable (so that no decay occurs) and immobile (so that no diffusion occurs) then, as deposition proceeds, the concentration of dimers will increase approximately linearly until it is roughly equal to the concentration of monomers. At this point, the probability of an atom colliding with a dimer is comparable to the probability of an adatom colliding with another adatom, hence growth and nucleation compete. Once the island density has saturated, i.e. no more clusters are being formed, then the adatom mean free path is equal to the mean island separation and further deposition results in island growth. At coverages near 0.5 monolayers (ML), islands begin to coalesce and the island density decreases.

This simple and idealistic picture of nucleation and growth from mean field nucleation theory was found to be highly descriptive of the Ag/Pt(111) system at 75 K (figure A3.10.6) [23]. Figure A3.10.6 shows a series of STM images of increasing Ag coverage on Pt(111) and demonstrates the transition from nucleation to growth. At very low coverages ((a) and (b)), the average cluster size is 2.4 and 2.6 atoms, respectively, indicating that dimers and trimers are the predominant surface species. However, when the coverage was more than doubled from (a) to (b), the mean island size remained relatively constant. This result clearly indicates that deposition at these low coverages is occurring in the nucleation regime. By increasing the coverage to 0.03 ML, the Ag mean island size doubled to 6.4 atoms and the island density increased, indicating that nucleation and growth were competing. Finally, after increasing the coverage even further (d), the mean island size doubled again, while the island density saturated, suggesting that a pure growth regime dominated, with little or no nucleation occurring.

Growth reactions at surfaces will certainly continue to be the focus of much research. In particular, the synthesis of novel materials is an exciting field that holds much promise for the nanoscale engineering of materials. Undoubtedly, the advent of STM as a means of investigating growth reactions on the atomic scale will influence the future of nanoscale technology.

Figure A3.10.6 A series of STM images for Ag/Pt(111) at 75 K showing the transition from nucleation to growth [23]. Coverages (Θ) and mean island sizes (\bar{n}) are indicated.

A3.10.4 ETCHING

A3.10.4.1 INTRODUCTION

Etching is a process by which material is removed from a surface. The general idea behind etching is that by interaction of an etch atom or molecule with a surface, a surface species can be formed that is easily removed. The use of a liquid to etch a surface is known as *wet etching*, while the use of a gas to etch a surface is known as *dry etching*. Wet etching has been employed since the late Middle Ages. The process then was rather simple and could be typified as follows. The metal to be etched was first coated with a wax, or in modern vernacular, a mask. Next, a pattern was cut into the wax to reveal the metal surface beneath. Then, an acid was used to etch the exposed metal, resulting in a patterned surface. Finally, the mask was removed to reveal the finished product. Modern methods are considerably more technologically advanced, although the general principles behind etching remain unchanged.

Both wet and dry etching are used extensively in the semiconductor processing industry. However, wet etching has limitations that prevent it being used to generate micron or submicron pattern sizes for GaAs etching. The most serious of these limitations is called substrate undercutting, which is a phenomenon where etch rates parallel and perpendicular to the surface are approximately equal (isotropic etching). Substrate

undercutting is much less prevalent for silicon surfaces than GaAs surfaces, thus wet etching is more commonly used to etch silicon surfaces. Generally, when patterning surfaces, anisotropic etching is preferred, where etch rates perpendicular to the surface exceed etch rates parallel to the surface. Hence, in cases of undercutting, an ill defined pattern typically results. In the early 1970s, dry etching (with CF_4/O_2 , for example) became widely used for patterning. Dry methods have a distinct advantage over wet methods, namely anisotropic etching.

A form of anisotropic etching that is of some importance is that of orientation-dependent etching, where one particular crystal face is etched at a faster rate than another crystal face. A commonly used orientation-dependent wet etch for silicon surfaces is a mixture of KOH in water and isopropanol. At approximately 350 K, this etchant has an etch rate of $0.6 \mu\text{m min}^{-1}$ for the Si(100) plane, $0.1 \mu\text{m min}^{-1}$ for the Si(110) plane and $0.006 \mu\text{m min}^{-1}$ for the Si(111) plane [24]. These different etch rates can be exploited to yield anisotropically etched surfaces.

Semiconductor processing consists of a number of complex steps, of which etching is an integral step. [Figure A3.10.7](#) shows an example of the use of etching [25] in which the goal of this particular process is to remove certain parts of a film, while leaving the rest in a surface pattern to serve as, for example, interconnection paths. This figure illustrates schematically how etching paired with a technique called photolithography can be used to manufacture a semiconductor device. In this example, the substrate enters the manufacturing stream covered with a film (for example, a SiO_2 film on a Si wafer). A liquid thin-film called a photoresist (denoted 'positive resist' or 'negative resist', as explained below) is first placed on the wafer, which is then spun at several thousand rotations per minute to spread out the film and achieve a uniform coating. Next, the wafer is exposed through a mask plate to an ultraviolet (UV) light source. The UV photons soften certain resists (positive resists) and harden others (negative resists). Next, a developer solution is used to remove the susceptible area, leaving behind the remainder according to the mask pattern. Then, the wafer is etched to remove all of the surface film not protected by the photoresist. Finally, the remaining photoresist is removed, revealing a surface with a patterned film. Thus the role of etching in semiconductor processing is vital and it is evident that motivation exists to explore etching reactions on a fundamental level.

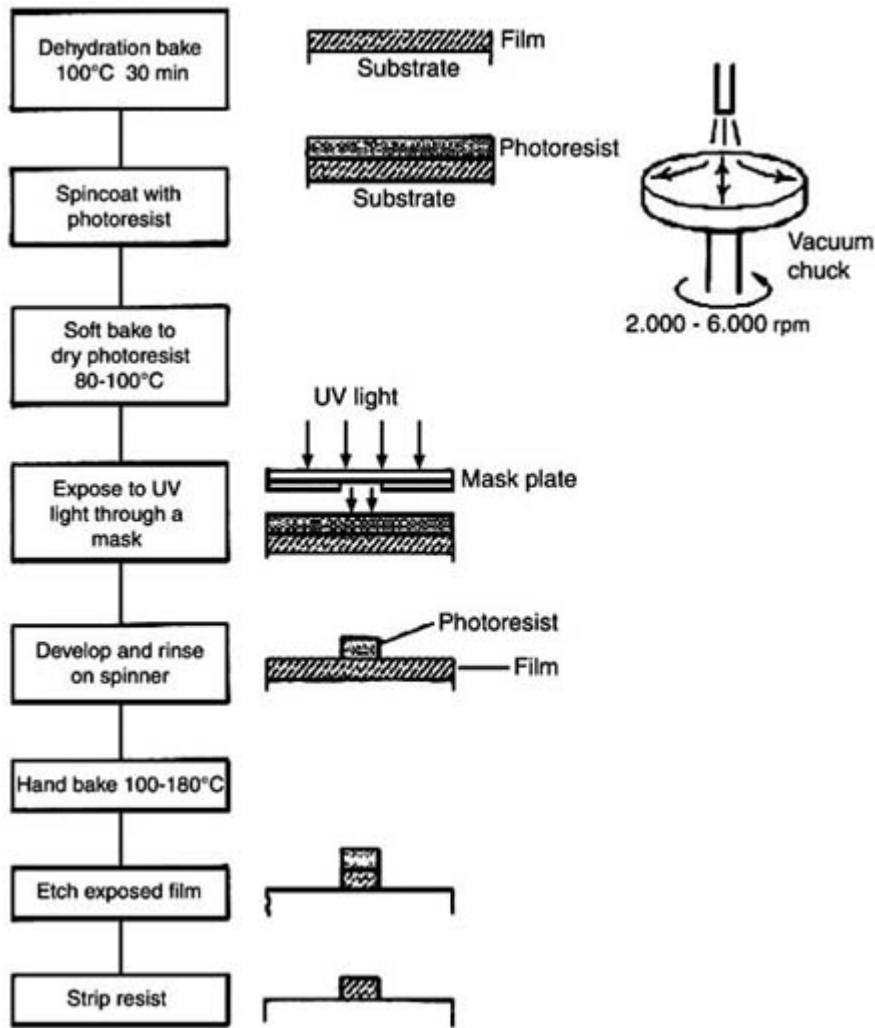

Figure A3.10.7 The role of etching in photolithography [25].

A3.10.4.2 DRY ETCHING TECHNIQUES

It has already been mentioned that dry etching involves the interaction of gas phase molecules/atoms with a surface. More specifically, dry etching utilizes either plasmas that generate reactive species, or energetic ion beams to etch surfaces. Dry etching is particularly important to GaAs processing because, unlike silicon, there are no wet etching methods that result in negligible undercutting. Dry etching techniques can be characterized by either chemical or physical etching mechanisms. The chemical mechanisms tend to be more selective, i.e. more anisotropic, and tend to depend strongly on the specific material being etched. Several dry etch techniques will be briefly discussed below. For a more comprehensive description of these and other techniques, the reader is referred to the texts by Williams [26] or Sugawara [27].

Ion milling is a dry etch technique that uses a physical etching mechanism. In ion milling, ions of an inert gas are generated and then accelerated to impinge on a surface. The etching mechanism is simply the bombardment of these energetic ions on the surface, resulting in erosion. The energy of the ions can be controlled by varying the accelerating voltage, and it may be possible to change the selectivity by varying the angle of incidence.

Plasma etching is a term used to describe any dry etching process that utilizes reactive species generated from a gas plasma. For semiconductor processing, a low-pressure plasma, also called a glow discharge, is used. The glow discharge is characterized by pressures in the range 0.1–5 Torr and electron energies of 1–10 eV. The simplest type of plasma reactor consists of two parallel plates in a vacuum chamber filled with a gas at low pressure. A radio frequency (RF) voltage is applied between the two plates, generating plasma that emits a characteristic glow. Reactive radicals are produced by the plasma, resulting in a collection of gas phase species that are the products of collisions between photons, electrons, ions and atoms or molecules. These chemically reactive species can then collide with a nearby surface and react to form a volatile surface species, thereby etching the surface.

Reactive ion etching (RIE) is distinguished from plasma etching by the fact that the surface reactions are enhanced by the kinetic energy of the incoming reactive species. This type of chemical mechanism is referred to as a kinetically assisted chemical reaction, and very often results in highly anisotropic etching. RIE is typically performed at low pressures (0.01–0.1 Torr) and is used industrially to etch holes in GaAs.

Dry etching is a commonly used technique for creating highly anisotropic, patterned surfaces. The interaction of gas phase etchants with surfaces is of fundamental interest to understanding such phenomena as undercutting and the dependence of etch rate on surface structure. Many surface science studies aim to understand these interactions at an atomic level, and the next section will explore what is known about the etching of silicon surfaces.

A3.10.4.3 ATOMIC VIEW OF ETCHING

On the atomic level, etching is composed of several steps: diffusion of the etch molecules to the surface, adsorption to the surface, subsequent reaction with the surface and, finally, removal of the reaction products. The third step, that of reaction between the etchant and the surface, is of considerable interest to the understanding of surface reactions on an atomic scale. In recent years, STM has given considerable insight into the nature of etching reactions at surfaces. The following discussion will focus on the etching of silicon surfaces [28].

Figure A3.10.8 schematically depicts a Si(100) surface (a) being etched to yield a rough surface (b) and a more regular surface (c). The surfaces shown here are seen to consist of steps, terraces and kinks, and clearly have a three-dimensional character, rather than the two-dimensional character of an ideally flat, smooth surface. The general etching mechanism is based on the use of halogen molecules, the principal etchants used in dry etching. Upon adsorption on silicon at room temperature, Br₂ dissociates to form bromine atoms, which react with surface silicon atoms. Then, if an external source of energy is provided, for example by heating Si (100) to 900 K, SiBr₂ forms and desorbs, revealing the silicon atom(s) beneath and completing the etching process. Depending upon the relative desorption energies from various surface sites, the surface could be etched quite differently, as seen in figure A3.10.8(b) and figure A3.10.8(c).

Figure A3.10.8 Depiction of etching on a Si(100) surface. (a) A surface exposed to Br_2 as well as electrons, ions and photons. Following etching, the surface either becomes highly anisotropic with deep etch pits (b), or more regular (c), depending on the relative desorption energies for different surface sites [28].

Semiconductors such as silicon often undergo rearrangements, or reconstructions, at surface boundaries to lower their surface free energy. One way of lowering the surface free energy is the reduction of dangling bonds, which are non-bonding orbitals that extend (dangle) into the vacuum. Si(111) undergoes a complex (7×7) reconstruction that was ultimately solved using STM. [Figure A3.10.9\(a\)](#) shows an STM image of the reconstructed Si(111) surface [29]. This reconstruction reduces the number of dangling bonds from 49 to 19 per unit cell.

The (7×7) reconstruction also affects the second atomic layer, called the rest layer. The rest layer is composed of silicon atoms arranged in triangular arrays that are separated from one another by rows of silicon dimers. [Figure A3.10.9\(b\)](#) shows the exposed rest layer following bromine etching at 675 K [29]. It is noteworthy that the rest layer does not reconstruct to form a new (7×7) surface. The stability of the rest layer following etching of (7×7)-Si(111) is due to the unique role of the halogen. The silicon adlayer is removed by insertion of bromine atoms into Si–Si dimer bonds. Once this silicon adlayer is gone, the halogen stabilizes the silicon rest layer by reacting with the dangling bonds, effectively inhibiting surface reconstruction to a (7×7) phase. Unfortunately, the exposure of the rest layer makes etching more difficult because to form SiBr_2 , bromine atoms must insert into stronger Si–Si bonds.

Figure A3.10.9 STM images of Si(111) surfaces before (a) and after (b) etching by bromine at 675 K. In (a) the (7×7) reconstructed surface is seen. In (b), the rest layer consisting of triangular arrays of Si atoms has been exposed by etching [28]. Both images show a $17 \times 17 \text{ nm}^2$ area.

Si(100) reconstructs as well, yielding a (1×2) surface phase that is formed when adjacent silicon atoms bond through their respective dangling bonds to form a more stable silicon dimer. This reconstructed bonding results in a buckling of the surface atoms. Furthermore, because Si–Si dimer bonds are weaker than bulk silicon bonds, the reconstruction actually facilitates etching. For a comprehensive discussion on STM studies of reconstructed silicon surfaces, see [30].

Si(100) is also etched by Br_2 , although in a more dramatic fashion. [Figure A3.10.10](#) shows a STM image of a Si(100) surface after etching at 800 K [28]. In this figure, the dark areas are etch pits one atomic layer deep. The bright rows running perpendicular to these pits are silicon dimer chains, which are composed of silicon atoms that were released from terraces and step edges during etching. The mechanism by which Si(100) is etched has been deduced from STM studies. After Br_2 dissociatively adsorbs to the surface, a bromine atom bonds to each silicon atom in the dimer pairs. SiBr_2 is the known desorption product and so the logical next step is the formation of a surface SiBr_2 species. This step can occur by the breaking of the Si–Si dimer bond and the transfer of a bromine atom from one of the dimer atoms to the other. Then, if enough energy is available to overcome the desorption barrier, SiBr_2 will desorb, leaving behind a highly uncoordinated silicon atom that will migrate to a terrace and eventually re-dimerize. On the other hand, if there is not enough energy to desorb SiBr_2 , then the Br atom would transfer back to the original silicon atom, and a silicon dimer bond would again be formed. In this scenario, SiBr_2 desorption is essential to the etching process.

Figure A3.10.10 STM image ($55 \times 55 \text{ nm}^2$) of a Si(100) surface exposed to molecular bromine at 800 K. The dark areas are etch pits on the terraces, while the bright rows that run perpendicular to the terraces are Si dimer chains. The dimer chains consist of Si atoms released from terraces and step edges during etching [28].

Another view of the Si(100) etching mechanism has been proposed recently [28]. Calculations have revealed that the most important step may actually be the escape of the bystander silicon atom, rather than SiBr_2 desorption. In this way, the SiBr_2 becomes trapped in a state that otherwise has a very short lifetime, permitting many more desorption attempts. Preliminary results suggest that indeed this vacancy-assisted desorption is the key step to etching Si(100) with Br_2 .

The implementation of tools such as the STM will undoubtedly continue to provide unprecedented views of etching reactions and will deepen our understanding of the phenomena that govern these processes.

A3.10.5 CATALYTIC REACTIONS

A3.10.5.1 INTRODUCTION

A catalyst is a material that accelerates a reaction rate towards thermodynamic equilibrium conversion without itself being consumed in the reaction. Reactions occur on catalysts at particular sites, called ‘active sites’, which may have different electronic and geometric structures than neighbouring sites. Catalytic reactions are at the heart of many chemical industries, and account for a large fraction of worldwide chemical production. Research into fundamental aspects of catalytic reactions has a strong economic motivating factor: a better understanding of the catalytic process

may lead to the development of a more efficient catalyst. While the implementation of a new catalyst based on surface science studies has not yet been realized, the investigation of catalysis using surface science methods has certainly shaped the current understanding of catalytic reactions. Several recommended texts on catalysis

can be found in [31, 32 and 33].

Fundamental studies in catalysis often incorporate surface science techniques to study catalytic reactions at the atomic level. The goal of such experiments is to characterize a catalytic surface before, during and after a chemical reaction; this is no small task. The characterization of these surfaces is accomplished using a number of modern analytical techniques. For example, surface compositions can be determined using x-ray photoelectron spectroscopy (XPS) or Auger electron spectroscopy (AES). Surface structures can be probed using low-energy electron diffraction (LEED) or STM. In addition, a number of techniques are available for detecting and identifying adsorbed species on surfaces, such as infrared reflection absorption spectroscopy, high-resolution electron energy-loss spectroscopy (HREELS) and sum frequency generation (SFG).

As with the other surface reactions discussed above, the steps in a catalytic reaction (neglecting diffusion) are as follows: the adsorption of reactant molecules or atoms to form bound surface species, the reaction of these surface species with gas phase species or other surface species and subsequent product desorption. The global reaction rate is governed by the slowest of these elementary steps, called the rate-determining or rate-limiting step. In many cases, it has been found that either the adsorption or desorption steps are rate determining. It is not surprising, then, that the surface structure of the catalyst, which is a variable that can influence adsorption and desorption rates, can sometimes affect the overall conversion and selectivity.

Industrial catalysts usually consist of one or more metals supported on a metal oxide. The supported metal can be viewed as discrete single crystals on the support surface. Changes in the catalyst structure can be achieved by varying the amount, or 'loading', of the metal. An increased loading should result in a particle size increase, and so the relative population of a particular crystal face with respect to other crystal faces may change. If a reaction rate on a per active site basis changes as the metal loading changes, then the reaction is deemed to be structure sensitive. The surface science approach to studying structure-sensitive reactions has been to examine the chemistry that occurs over different crystal orientations. In general, these studies have shown that close-packed, atomically smooth metal surfaces such as (111) and (100) fcc and (110) bcc surfaces are less reactive than more open, rough surfaces such as fcc(110) and bcc(111). The remaining task is then to relate the structure sensitivity results from single-crystal studies to the activity results over real-world catalysts.

Surface science studies of catalytic reactions certainly have shed light on the atomic-level view of catalysis. Despite this success, however, two past criticisms of the surface science approach to catalysis are that the pressure regimes (usually 10^{-10} Torr) and the materials (usually low-surface-area single crystals) are far removed from the high pressures and high-surface-area supported catalysts used industrially. These criticisms have been termed the 'pressure gap' and the 'materials gap'. To combat this criticism, much research in the last 30 years has focused on bridging these gaps, and many advances have been made that now suggest these criticisms are no longer warranted.

A3.10.5.2 EXPERIMENTAL

(A) BRIDGING THE PRESSURE GAP

The implementation of high-pressure reaction cells in conjunction with UHV surface science techniques allowed the first true *in situ* postmortem studies of a heterogeneous catalytic reaction. These cells permit exposure of a sample to ambient pressures without any significant contamination of the UHV environment. The first such cell was internal to the main vacuum chamber and consisted of a metal bellows attached to a reactor cup [34]. The cup could be translated using a hydraulic piston to envelop the sample, sealing it from

the surrounding UHV by means of a copper gasket. Once isolated from the vacuum, the activity of the enclosed sample for a given reaction could be measured at elevated pressures. Following the reaction, the high-pressure cell was evacuated and then retracted, exposing the sample again to the UHV environment, at which point any number of surface science techniques could be used to study the 'spent' catalyst surface.

Shortly thereafter, another high-pressure cell design appeared [35]. This design consisted of a sample mounted on a retractable bellows, permitting the translation of the sample to various positions. The sample could be retracted to a high-pressure cell attached to the primary chamber and isolated by a valve, thereby maintaining UHV in the primary chamber when the cell was pressurized for catalytic studies. The reactor could be evacuated following high-pressure exposures before transferring the sample back to the main chamber for analysis.

A modification to this design appeared several years later (figure A3.10.11) [36, 37]. In this arrangement, the sample rod can be moved easily between the UHV chamber and the high-pressure cell without any significant increase in chamber pressure. Isolation of the reaction cell from UHV is achieved by a differentially pumped sliding seal mechanism (figure A3.10.12) whereby the sample rod is pushed through the seals until it is located in the high-pressure cell. Three spring-loaded, differentially pumped Teflon seals are used to isolate the reaction chamber from the main chamber by forming a seal around the sample rod. Differential pumping is accomplished by evacuating the space between the first and second seals (on the low-pressure side) by a turbomolecular pump and the space between the second and third seals (on the high-pressure side) by a mechanical (roughing) pump. Pressures up to several atmospheres can be maintained in the high-pressure cell while not significantly raising the pressure in the attached main chamber.

The common thread to these designs is that a sample can be exposed to reaction conditions and then studied using surface science methods without exposure to the ambient. The drawback to both of these designs is that the samples are still being analysed under UHV conditions *before* and *after* the reaction under study. The need for *in situ* techniques is clear.

-21-

Figure A3.10.11 Side view of a combined high-pressure cell and UHV surface analysis system [37].

Figure A3.10.12 Side view of the high-pressure cell showing the connections to the UHV chamber, the turbomolecular pump and the gas handling system. The differentially pumped sliding seal is located between the high-pressure cell and the UHV chamber [37].

Two notable *in situ* techniques are at the forefront of the surface science of catalysis: STM and SFG. STM is used to investigate surface structures while SFG is used to investigate surface reaction intermediates. The significance of both techniques is that they can operate over a pressure range of 13 orders of magnitude, from 10^{-10} to 10^3 Torr, i.e. they are truly *in situ* techniques. STM has allowed the visualization of surface structures under ambient conditions and has shed light on adsorbate-induced morphological changes that occur at surfaces, for both single-crystal metals and metal clusters supported on oxide single crystals. Studies of surface reactions with SFG have given insight into reaction mechanisms previously investigated under non-ideal pressure or temperature constraints. Both SFG and STM hold promise as techniques that will contribute greatly to the understanding of catalytic reactions under *in situ* conditions.

(B) BRIDGING THE MATERIALS GAP

Single crystals are traditionally used in UHV studies because they provide an opportunity to well characterize a surface. However, as discussed above, single crystals are quite different from industrial catalysts. Typically, such catalysts consist of supported particles that can have multiple crystal orientations exposed at the surface. Therefore, an obstacle in attempting surface science studies of catalysis is the preparation of a surface in such a way that it mimics a real-world catalyst.

One criterion necessary for using charged-particle spectroscopies such as AES and EELS is that the material being investigated should be conductive. This requisite prevents problems such as charging when using electron spectroscopies and ensures homogeneous heating during thermal desorption studies. A problem then with investigating oxide surfaces for use as metal supports is that many are insulators or semiconductors. For example, alumina and silica are often used as oxide supports for industrial catalysts, yet both are insulators at room temperature, severely hindering surface science studies of these materials. However, thin-films of these and other oxides can be deposited onto metal substrates, thus providing a conductive substrate (*via* tunnelling)

for use with electron spectroscopies and other surface science techniques.

Thin oxide films may be prepared by substrate oxidation or by vapour deposition onto a suitable substrate. An example of the former method is the preparation of silicon oxide thin-films by oxidation of a silicon wafer. In general, however, the thickness and stoichiometry of a film prepared by this method are difficult to control. On the other hand, vapour deposition, which consists of evaporating the parent metal in an oxidizing environment, allows precise control of the film thickness. The extent of oxidation can be controlled by varying the O_2 pressure (lower O_2 pressures can lead to lower oxides) and the film thickness can be controlled by monitoring the deposition rate. A number of these thin metal oxide films have been prepared by vapour deposition, including SiO_2 , Al_2O_3 , MgO , TiO_2 and NiO [38].

MgO films have been grown on a $Mo(100)$ substrate by depositing Mg onto a clean $Mo(100)$ sample in O_2 ambient at 300 K [39, 40]. LEED results indicated that MgO grows epitaxially at an optimum O_2 pressure of 10^{-7} Torr, with the (100) face of MgO parallel to the $Mo(100)$ surface. Figure A3.10.13 shows a ball model illustration of the $MgO(100)$ overlayer on $Mo(100)$. The chemical states of Mg and O were also probed as a function of the O_2 pressure during deposition by AES and XPS. It was found that as the O_2 pressure was increased, the metallic Mg^0 ($L_{2,3}VV$) Auger transition at 44.0 eV decreased while a new transition at 32.0 eV increased. The transition at 32.0 eV was assigned to a Mg^{2+} ($L_{2,3}VV$) transition due to the formation of MgO . When the O_2 pressure reached 10^{-7} Torr, the Mg^{2+} feature dominated the AES spectrum while the Mg^0 feature completely diminished. XPS studies confirmed the LEED and AES results, verifying that MgO was formed at the optimal O_2 pressure. Furthermore, the Mg 2p and O 1s XPS peaks from the MgO film had the same binding energy (BE) and peak shape as the Mg 2p and O 1s peaks from an MgO single crystal. Both AES and XPS indicated that the stoichiometry of the film was MgO . Further annealing in O_2 did

-23-

not increase the oxygen content of the film, which supports the fact that no evidence of Mg suboxides was found. This MgO film was successfully used to study the nature of surface defects in Li -doped MgO as they relate to the catalytic oxidative coupling of methane.

Figure A3.10.13 Ball model illustration of an epitaxial MgO overlayer on $Mo(100)$ [38].

The deposition of titanium oxide thin-films on $Mo(110)$ represents a case where the stoichiometry of the film is sensitive to the deposition conditions [41]. It was found that both TiO_2 and Ti_2O_3 thin-films could be made,

depending on the Ti deposition rate and the O₂ background pressure. Lower deposition rates and higher O₂ pressures favoured the formation of TiO₂. The two compositionally different films could be distinguished in several ways. Different LEED patterns were observed for the different films: TiO₂ exhibited a (1 × 1) rectangular periodicity, while Ti₂O₃ exhibited a (1 × 1) hexagonal pattern. XPS Ti 2p data clearly differentiated the two films as well, showing narrow peaks with a Ti 2p_{3/2} BE of 459.1 eV for TiO₂ and broad peaks with a Ti 2p_{3/2} BE of 458.1 eV for Ti₂O₃. From LEED and HREELS results, it was deduced that the surfaces grown on Mo(110) were TiO₂(100) and Ti₂O₃(0001). Therefore, it is clear that vapour deposition allows control over thickness and extent of oxidation and is certainly a viable method for producing thin oxide films for use as model catalyst supports.

Metal vapour deposition is a method that can be used to conveniently prepare metal clusters for investigation under UHV conditions. The deposition is accomplished using a doser constructed by wrapping a high-purity wire of the metal to be deposited around a tungsten or tantalum filament that can be resistively heated. After sufficient outgassing, which is the process of heating the doser to remove surface and bulk impurities, then a surface such as an oxide can be exposed to the metal emanating from the doser to yield a model oxide-supported metal catalyst.

Model catalysts such as Au/TiO₂(110) have been prepared by metal vapour deposition [42]. [Figure A3.10.14](#) shows a STM image of 0.25 ML (1 ML = 1.387 × 10¹⁵ atoms cm⁻²) Au/TiO₂(110). These catalysts were tested for CO oxidation to compare to conventional Au catalysts. It is well known that for conventional Au catalysts there is an optimal Au cluster size (~3 nm) that yields a maximum CO oxidation rate. This result was duplicated by measuring the CO oxidation rate over model Au/TiO₂(110), where the cluster sizes were varied by manipulating the deposition

amounts. There is a definite maximum in the CO oxidation activity at a cluster size of approximately 3.5 nm. Furthermore, investigation of the cluster electronic properties using scanning tunnelling spectroscopy (STS) revealed a correlation between the cluster electronic structure and the maximum in CO oxidation activity. Pd/SiO₂/Mo(100) model catalysts were also prepared and were found to have remarkably similar kinetics for CO oxidation when compared to Pd single crystals and conventional silica-supported Pd catalysts [43]. These results confirm that metal vapour deposition on a suitable substrate is a viable method for producing model surfaces for UHV studies.

Figure A3.10.14 STM image of 0.25 ML Au vapour-deposited onto $\text{TiO}_2(110)$. Atomic resolution of the substrate is visible as parallel rows. The Au clusters are seen to nucleate preferentially at step edges.

Another method by which model-supported catalysts can be made is electron beam lithography [44]. This method entails spin-coating a polymer solution onto a substrate and then using a collimated electron beam to damage the polymer surface according to a given pattern. Next, the damaged polymer is removed, exposing the substrate according to the electron beam pattern, and the sample is coated with a thin metal film. Finally, the polymer is removed from the substrate, taking with it the metal film except where the metal was bound to the substrate, leaving behind metal particles of variable size. This technique has been used to prepare Pt particles with 50 nm diameters and 15 nm heights on an oxidized silicon support [44]. It was found that ethylene hydrogenation reaction rates on the model catalysts agreed well with turnover rates on Pt single crystals and conventional Pt-supported catalysts.

A3.10.5.3 ATOMIC-LEVEL VIEWS OF CATALYSIS

(A) NH_3 SYNTHESIS: $\text{N}_2 + 3\text{H}_2 \leftrightarrow 2\text{NH}_3$

Ammonia has been produced commercially from its component elements since 1909, when Fritz Haber first demonstrated the viability of this process. Bosch, Mittasch and co-workers discovered an excellent promoted Fe catalyst in 1909 that was composed of iron with aluminium oxide, calcium oxide and potassium oxide as promoters. Surprisingly, modern ammonia synthesis catalysts are nearly identical to that first promoted iron catalyst. The reaction is somewhat exothermic and is favoured at high pressures and low temperatures, although, to keep reaction rates high, moderate temperatures are generally used. Typical industrial reaction conditions for ammonia synthesis are 650–750 K and 150–300 atm. Given the technological importance of the

ammonia synthesis reaction, it is not surprising that surface science techniques have been used to thoroughly study this reaction on a molecular level [45, 46].

As mentioned above, a structure-sensitive reaction is one with a reaction rate that depends on the catalyst structure. The synthesis of ammonia from its elemental components over iron surfaces is an example of a structure-sensitive reaction. Figure A3.10.15 demonstrates this structure sensitivity by showing that the rate of NH_3 formation at 20 atm and 600–700 K has a clear dependence on the surface structure [47]. The (111) and (211) Fe faces are much more active than the (100), (210) and (110) faces. Figure A3.10.16 depicts the different Fe surfaces for which ammonia synthesis was studied in figure A3.10.15. The coordination of the different surface atoms is denoted in each drawing. Surface roughness is often associated with higher catalytic activity, however in this case the (111) and (210) surfaces, both of which can be seen to be atomically rough, have distinctly different catalytic activities. Closer inspection of these surfaces reveals that the (111) and (211) faces have a C_7 site in common, i.e. a surface Fe atom with seven nearest neighbours. The high catalytic activity of the (111) and (211) Fe faces has been proposed to be due to the presence of these C_7 sites.

-26-

Figure A3.10.15 NH_3 synthesis activity of different Fe single-crystal orientations [32]. Reaction conditions were 20 atm and 600–700 K.

-27-

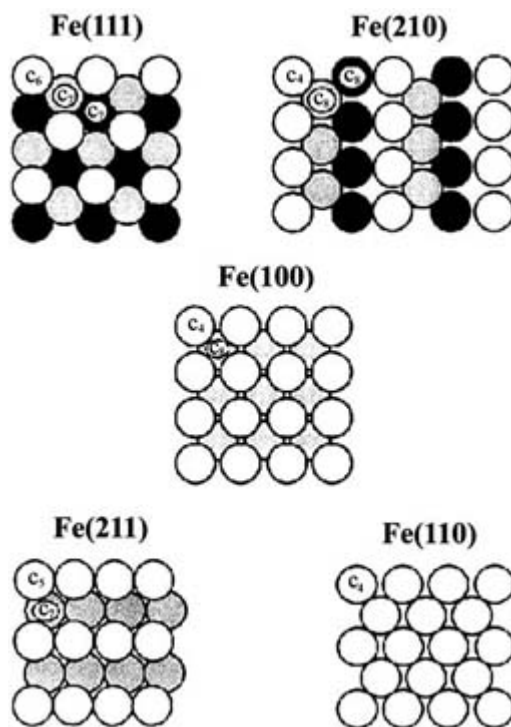

Figure A3.10.16 Illustrations of the surfaces in [figure A3.10.15](#) for which ammonia synthesis activity was tested. The coordination of the surface atoms is noted in the figure [32].

It is widely accepted that the rate-determining step in NH_3 synthesis is the dissociative adsorption of N_2 , depicted in a Lennard-Jones potential energy diagram in [figure A3.10.17](#) [46]. This result is clearly illustrated by examining the sticking coefficient (the adsorption rate divided by the collision rate) of N_2 on different Fe crystal faces ([figure A3.10.18](#)) [48]. The concentration of surface nitrogen on the Fe single crystals at elevated temperatures in UHV was monitored with AES as a function of N_2 exposure. The sticking coefficient is proportional to the slope of the curves in [figure A3.10.18](#). The initial sticking coefficients increase in the order $(110) < (100) < (111)$, which is the same trend observed for the ammonia synthesis catalytic activity at high-pressure (20 atm). This result indicates that the pressure gap for ammonia synthesis can be overcome: the kinetics results obtained in UHV conditions can be readily extended to the kinetics results obtained under high-pressure reaction conditions.

-28-

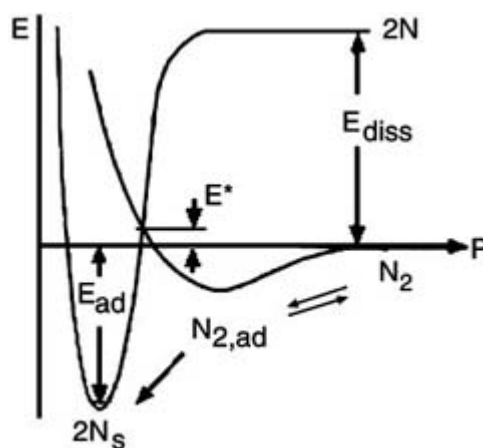

Figure A3.10.17 Potential energy diagram for the dissociative adsorption of N_2 [46].

Figure A3.10.18 Surface concentration of nitrogen on different Fe single crystals following N_2 exposure at elevated temperatures in UHV [48].

Further work on modified Fe single crystals explored the role of promoters such as aluminium oxide and potassium [49, 50 and 51]. It was found that the simple addition of aluminium oxide to Fe single crystal surfaces decreased the ammonia synthesis rate proportionally to the amount of Fe surface covered, indicating no favourable interaction between Fe and aluminium oxide under those conditions. However, by exposing an aluminium-oxide-modified Fe surface to water vapour, the surface was oxidized, inducing a favourable interaction between Fe and the Al_xO_y . This interaction resulted in a 400-fold increase in ammonia synthesis activity for $Al_xO_y/Fe(110)$ as compared to Fe(110) and an activity for $Al_xO_y/Fe(110)$ comparable to that of Fe(111). Interestingly, aluminium-oxide-modified Fe(111) showed no change in activity. The increase in activity for $Al_xO_y/Fe(110)$ to that of Fe(111) suggests a possible reconstruction

of the catalyst surface, in particular that Fe(111) and Fe(211) surfaces may be formed. These surfaces have C_7 sites and so the formation of crystals with these orientations could certainly lead to an enhancement in catalytic activity. Thus, the promotion of Fe ammonia synthesis catalysts by Al_xO_y appears to be primarily a geometric effect.

The addition of potassium to Fe single crystals also enhances the activity for ammonia synthesis. Figure A3.10.19 shows the effect of surface potassium concentration on the N_2 sticking coefficient. There is nearly a 300-fold increase in the sticking coefficient as the potassium concentration reaches $\sim 1.5 \times 10^{14}$ K atoms cm^{-2} . Not only does the sticking coefficient increase, but with the addition of potassium as a promoter, N_2 molecules are bound more tightly to the surface, with the adsorption energy increasing from 30 to 45 $kJ\ mol^{-1}$. A consequence of the lowering of the N_2 potential well is that the activation energy for dissociation (E^* in Figure A3.10.17) also decreases. Thus, the promotion of Fe ammonia synthesis catalysts by potassium appears to be primarily an electronic effect.

Figure A3.10.19 Variation of the initial sticking coefficient of N_2 with increasing potassium surface concentration on Fe(100) at 430 K [50].

(B) ALKANE HYDROGENOLYSIS

Alkane hydrogenolysis, or cracking, involves the dissociation of a larger alkane molecule to a smaller alkane molecule. For example, ethane hydrogenolysis in the presence of H_2 yields methane:

Cracking (or hydrocracking, as it is referred to when carried out in the presence of H_2) reactions are an integral part of petroleum refining. Hydrocracking is used to lower the average molecular weight (MW) of a higher MW hydrocarbon mixture so that it can then be blended and sold as gasoline. The interest in the fundamentals of catalytic cracking reactions is strong and it has been thoroughly researched.

Ethane hydrogenolysis has been shown to be structure sensitive over nickel catalysts [43], as seen in figure A3.10.20 where methane formation rates are plotted for both nickel single crystals and a conventional, supported nickel catalyst. There is an obvious difference in the rates over Ni(111) and Ni(100), and it is evident that the rate also changes as a function of particle size for the supported Ni catalysts. In addition, differences in activation energy were observed: for Ni(111) the activation energy is 192 kJ mol^{-1} , while for Ni(100) the activation energy is 100 kJ mol^{-1} . It is noteworthy that there is overlap between the hydrogenolysis rates over supported Ni catalysts with the Ni single crystals. The data suggest that small Ni particles are composed primarily of Ni(100) facets while large Ni particles are composed primarily of Ni(111) facets. In fact, this has been observed for fcc materials where surfaces with a (111) orientation are more commonly observed after thermally induced sintering. The structure sensitivity of this reaction over Ni surfaces has been clearly demonstrated.

Figure A3.10.20 Arrhenius plot of ethane hydrogenolysis activity for Ni(100) and Ni(111) at 100 Torr and $\text{H}_2/\text{C}_2\text{H}_6 = 100$. Also included is the hydrogenolysis activity on supported Ni catalysts at 175 Torr and $\text{H}_2/\text{C}_2\text{H}_6 = 6.6$ [43].

The initial step in alkane hydrogenolysis is the dissociative adsorption, or ‘reactive sticking’ of the alkane. One might suspect that this first step may be the key to the structure sensitivity of this reaction over Ni surfaces. Indeed, the reactive sticking of alkanes has been shown to depend markedly on surface structure [52]. Figure A3.10.21 shows the buildup of surface carbon due to methane decomposition ($P_{\text{methane}} = 1.00$ Torr) over three single-crystal Ni surfaces at 450 K. The rate of methane decomposition is obviously dependent upon the surface structure with the decomposition rate increasing in the order (111) < (100) < (110). It can be seen that, initially, the rates of methane decomposition are

similar for Ni(100) and (110), while Ni(111) has a much lower reaction rate. With increasing reaction time, i.e. increasing carbon coverage, the rate over Ni(110) continues to increase linearly while both Ni(111) and (100) exhibit a nonlinear dependence. This linear dependence over Ni(111) may be due to either the formation of carbon islands or a reduced carbon coverage dependence as compared to Ni(111) and (100).

Figure A3.10.21 Methane decomposition kinetics on low-index Ni single crystals at 450 K and 1.00 Torr methane [43].

Hydrogenolysis reactions over Ir single crystals and supported catalysts have also been shown to be structure sensitive [53, 54 and 55]. In particular, it was found that the reactivity tracked the concentration of low-coordination surface sites. Figure A3.10.22 shows ethane selectivity (selectivity is reported here because both ethane and methane are products of butane cracking) for *n*-butane hydrogenolysis over Ir(111) and the reconstructed surface Ir(110)-(1 × 2), as well as two supported Ir catalysts. There are clear selectivity differences between the two Ir surfaces, with Ir(110)-(1 × 2) having approximately three times the ethane selectivity of Ir(111). There is also a similarity seen between the ethane selectivity on small Ir particles and Ir(110)-(1 × 2), and between the ethane selectivity on large Ir particles and Ir(111).

Figure A3.10.22 Relationship between selectivity and surface structure for *n*-butane hydrogenolysis on iridium. (a) Illustrations of the Ir(110)-(1 × 2) and Ir(111) surfaces. The *z*-axis is perpendicular to the plane of the surface. (b) Selectivity for C₂H₆ production (mol% total products) for *n*-butane hydrogenolysis on both Ni single crystals and supported catalysts at 475 K. The effective particle size for the single crystal surfaces is based on the specified geometric shapes [43]. Δ Ir/Al₂O₃; \square Ir/SiO₂.

The mechanisms by which *n*-butane hydrogenolysis occurs over Ir(110)-(1 × 2) and Ir(111) are different. The high ethane selectivity of Ir(110)-(1 × 2) has been attributed to the ‘missing row’ reconstruction that the (110) surface undergoes (figure A3.10.22). This reconstruction results in the exposure of a highly uncoordinated C₇ site that is sterically unhindered. These C₇ sites are capable of forming a metallocyclopentane (a five-membered ring consisting of four carbons and an Ir atom) which, based on kinetics and surface carbon coverages, has been suggested as the intermediate for this reaction [56, 57]. It has been proposed that the crucial step in this reaction mechanism over the reconstructed (110) surface is the reversible cleavage of the central C–C bond. On the other hand, the hydrogenolysis of *n*-butane over Ir(111) is thought to proceed by a different mechanism, where dissociative chemisorption of *n*-butane and hydrogen are the first steps. Then, the adsorbed hydrocarbon undergoes the irreversible cleavage of the terminal C–C bond. It is evident that surface structure plays an important role in hydrogenolysis reactions over both nickel and iridium surfaces.

(C) CO OXIDATION: $2\text{CO} + \text{O}_2 \rightarrow 2\text{CO}_2$

The oxidation of CO to CO₂, which is essential to controlling automobile emissions, has been extensively studied because of the relative simplicity of this reaction. CO oxidation was the first reaction to be studied using the surface science approach and is perhaps the most well understood heterogeneous catalytic reaction [58]. The simplicity of CO oxidation by O₂ endears itself to surface science studies. Both reactants are diatomic molecules whose adsorption

on single-crystal surfaces has been widely studied, and presumably few steps are necessary to convert CO to CO₂. Surface science studies of CO and O₂ adsorption on metal surfaces have provided tremendous insight

into the mechanism of the CO–O₂ reaction. The mechanism over platinum surfaces has been unequivocally established and the reaction has shown structure insensitivity over platinum [59], palladium [55, 59, 60] and rhodium surfaces [61, 62].

Although dissociative adsorption is sometimes observed, CO adsorption on platinum group metals typically occurs molecularly and this will be the focus of the following discussion. Figure A3.10.23 illustrates schematically the donor–acceptor model (first proposed by Blyholder [63]) for molecular CO chemisorption on a metal such as platinum. The bonding of CO to a metal surface is widely accepted to be similar to bond formation in a metal carbonyl. Experimental evidence indicates that the 5σ highest occupied molecular orbital (HOMO), which is regarded as a lone pair on the carbon atom, bonds to the surface by donating charge to unoccupied density of states (DOS) at the surface. Furthermore, this surface bond can be strengthened by back-donation, which is the transfer of charge from the surface to the 2π* lowest unoccupied molecular orbital (LUMO). An effect of this backbonding is that the C–O bond weakens, as seen by a lower C–O stretch frequency for adsorbed CO (typically <2100 cm⁻¹) than for gas phase CO (2143 cm⁻¹).

Figure A3.10.23 Schematic diagram of molecular CO chemisorption on a metal surface. The model is based on a donor–acceptor scheme where the CO 5σ HOMO donates charge to surface unoccupied states and the surface back-donates charge to the CO 2π LUMO [58].

Ultraviolet photoelectron spectroscopy (UPS) results have provided detailed information about CO adsorption on many surfaces. Figure A3.10.24 shows UPS results for CO adsorption on Pd(110) [58] that are representative of molecular CO adsorption on platinum surfaces. The difference result in (c) between the clean surface and the CO-covered surface shows a strong negative feature just below the Fermi level (E_F), and two positive features at ~8 and 11 eV below E_F . The negative feature is due to suppression of emission from the metal d states as a result of an anti-resonance phenomenon. The positive features can be attributed to the 4σ molecular orbital of CO and the overlap of the 5σ and 1π molecular orbitals. The observation of features due to CO molecular orbitals clearly indicates that CO molecularly adsorbs. The overlap of the 5σ and 1π levels is caused by a stabilization of the 5σ molecular orbital as a consequence of forming the surface–CO chemisorption bond.

Figure A3.10.24 UPS data for CO adsorption on Pd(110). (a) Clean surface. (b) CO-dosed surface. (c) Difference spectrum (b-a). This spectrum is representative of molecular CO adsorption on platinum metals [58].

The adsorption of O₂ on platinum surfaces is not as straightforward as CO adsorption because molecular and dissociative adsorption can occur, as well as oxide formation [58]. However, molecular adsorption has been observed only at very low temperatures, where CO oxidation rates are negligible, hence this form of adsorbed oxygen will not be discussed here. UPS data indicate dissociative adsorption of O₂ on platinum surfaces at temperatures >100 K, and isotopic exchange measurements support this finding as well. The oxygen atoms resulting from O₂ dissociation can be either chemisorbed oxygen or oxygen in the form of an oxide. The two types of oxygen are distinguished by noting that oxide oxygen is located beneath the surface ('subsurface') while chemisorbed oxygen is located on the surface. Experimentally, the two types of oxygen are discernible by AES, XPS and UPS. In general, it has been found that as long as pressure and temperature are kept fairly low, the most likely surface oxygen species will be chemisorbed. Therefore, when formulating a mechanism for reaction under these general conditions, only chemisorbed oxygen needs to be considered.

The mechanism for CO oxidation over platinum group metals has been established from a wealth of data, the analysis of which is beyond the scope of this chapter. It is quite evident that surface science provided the foundation for this mechanism by directly showing that CO adsorbs molecularly and O₂ adsorbs

dissociatively. The mechanism is represented below (* denotes an empty surface site):

The first step consists of the molecular adsorption of CO. The second step is the dissociation of O₂ to yield two adsorbed oxygen atoms. The third step is the reaction of an adsorbed CO molecule with an adsorbed oxygen atom to form a CO₂ molecule that, at room temperature and higher, desorbs upon formation. To simplify matters, this desorption step is not included. This sequence of steps depicts a Langmuir–Hinshelwood mechanism, whereby reaction occurs between two adsorbed species (as opposed to an Eley–Rideal mechanism, whereby reaction occurs between one adsorbed species and one gas phase species). The role of surface science studies in formulating the CO oxidation mechanism was prominent.

CO oxidation by O₂ is a structure-insensitive reaction over rhodium catalysts [61, 62]. Figure A3.10.25 illustrates this structure insensitivity by demonstrating that the activation energies over supported Rh catalysts and a Rh(111) single crystal (given by the slope of the line) were nearly identical. Furthermore, the reaction rates over both supported Rh/Al₂O₃ and single crystal Rh (111) surfaces were also remarkably similar. Thus, the reaction kinetics were quite comparable over both the supported metal particles and the single crystal surfaces, and no particle size effect (structure sensitivity) was observed.

-36-

Figure A3.10.25 Arrhenius plots of CO oxidation by O₂ over Rh single crystals and supported Rh/Al₂O₃ at P_{CO} = P_{O₂} = 0.01 atm [43]. The dashed line in the figure is the predicted behaviour based on the rate constants for CO and O₂ adsorption and desorption on Rh under UHV conditions.

The study of catalytic reactions using surface science techniques has been fruitful over the last 30 years. Great strides have been made towards understanding the fundamentals of catalytic reactions, particularly by

bridging the material and pressure gaps. The implementation of *in situ* techniques and innovative model catalyst preparation will undoubtedly shape the future of catalysis.

A3.11 Quantum mechanics of interacting systems: scattering theory

George C Schatz

A3.11.1 INTRODUCTION

Quantum scattering theory is concerned with transitions between states which have a continuous energy spectrum, i.e., which are unbound. The most common application of scattering theory in chemical physics is to collisions involving atoms, molecules and/or electrons. Such collisions can produce many possible results, ranging from elastic scattering to reaction and fragmentation. Scattering theory can also be used to describe collisions of atoms, molecules and/or electrons with solid surfaces and it also has application to many kinds of dynamical process in solids. These latter include collisions of conduction electrons in a metal with impurities or with particle surfaces, or collisions of collective wave motions such as phonons with impurities, or adsorbates. Scattering theory is also involved in describing the interaction of light with matter, including applications to elastic and inelastic light scattering, photoabsorption and emission. Additionally, there are many processes where continuum states of particles are coupled to continuum states of electromagnetic radiation, including photodissociation of molecules and photoemission from surfaces.

While the basic formalism of quantum scattering theory can be found in a variety of general physics textbooks [1, 2, 3, 4, 5, 6 and 7] and textbooks that are concerned with scattering theory in a broad sense [8, 9, 10 and 11], many problems in chemical physics require special adaptation of the theory. For example, in collisions of particles with surfaces, angular momentum conservation is not important, but linear momentum conservation can be crucial. Also, in many collision problems involving atoms and molecules, the de Broglie wavelength is short compared to the distances over which the particles interact strongly, making classical or semiclassical theory useful. One especially important feature associated with scattering theory applications in chemical physics is that the forces between the interacting particles can usually be determined with reasonable accuracy (in principle to arbitrary accuracy), so explicit forms for the Hamiltonian governing particle motions are

available. Often these forces are quite complicated, so it is not possible to develop analytical solutions to the scattering theory problem. However, numerical solutions are possible, so a significant activity among researchers in this field is the development of numerical methods for solving scattering problems. There are a number of textbooks which consider scattering theory applications of more direct relevance to problems in chemical physics [[12](#), [13](#), [14](#), [15](#), [16](#), [17](#) and [18](#)], as well as numerous monographs that have a narrower focus within the field [[19](#), [20](#), [21](#), [22](#), [23](#), [24](#), [25](#), [26](#), [27](#), [28](#) and [29](#)].

Much of what one needs to know about scattering theory can be understood by considering a particle moving in one dimension governed by a potential that allows it to move freely except for a range of coordinates where there is a feature such as a barrier or well that perturbs the free particle motion. Our discussion will therefore begin with this simple problem ([section A3.11.2](#)). Subsequently ([section A3.11.3](#)) more complete versions of scattering theory will be developed that apply to collisions involving particles having internal degrees of freedom. There are both time dependent and time independent versions of scattering theory, and both of these theories will be considered. In [section A3.11.4](#), the numerical methods that are used to calculate scattering theory properties are considered, including time dependent and independent approaches. Also presented ([section A3.11.5](#)) are scattering theory methods for determining information that has been summed and averaged over many degrees of freedom (such as in a Boltzmann distribution).

-2-

Finally, in [section A3.11.6](#), scattering theory methods based on classical and semiclassical mechanics are described.

There are a variety of topics that will not be considered, but it is appropriate to provide references for further reading. The development in this paper assumes that the Born–Oppenheimer approximation applies in collisions between atoms and molecules and thus the nuclear motion is governed by a single potential energy surface. However there are many important problems where this approximation breaks down and multiple coupled potential energy surfaces are involved, with nonadiabatic transitions taking place during the scattering process. The theory of such processes is described in many places, such as [[14](#), [15](#), [23](#), [25](#)].

Other topics that have been omitted include the description of scattering processes using Feynman path integrals [[18](#), [19](#)] and the description of scattering processes with more than two coupled continua (i.e., where three or more independent particles are produced, as in electron impact ionization [[30](#)] or collision induced dissociation) [[31](#)]. Our treatment of resonance effects in scattering processes (i.e., the formation of metastable intermediate states) is very brief as this topic is commonly found in textbooks and one monograph is available [[26](#)]. Finally, it should be mentioned that the theory of light scattering is not considered; interested readers should consult textbooks such as that by Newton [[8](#)].

A3.11.2 QUANTUM SCATTERING THEORY FOR A ONE-DIMENSIONAL POTENTIAL FUNCTION

A3.11.2.1 HAMILTONIAN; BOUNDARY CONDITIONS

The problem of interest in this section is defined by the simple one-dimensional Hamiltonian

$$\hat{H} = \frac{\hat{p}^2}{2m} + V(x) \tag{A3.11.1}$$

where $V(x)$ is the potential energy function, examples of which are pictured in [figure A3.11.1](#). The potentials

shown are of two general types: those which are constant in the limit of $x \rightarrow \pm\infty$ [figure A3.11.1\(a\)](#) and [figure A3.11.1\(b\)](#), and those which are constant in the limit of $x \rightarrow -\infty$ and are infinite in the limit of $x \rightarrow +\infty$ [figure A3.11.1\(c\)](#) (of course this potential could be flipped around if one wants). In the former case, one can have particles moving at constant velocity in both asymptotic limits ($x \rightarrow \pm\infty$), so there are two physically distinct processes that can be described, namely, scattering in which the particle is initially moving to the right in the limit $x \rightarrow -\infty$, and scattering in which the particle is initially moving to the left in the limit $x \rightarrow +\infty$. In the latter case [figure A3.11.1\(c\)](#), the only physically interesting situation involves the particle initially moving to the left in the limit $x \rightarrow +\infty$. The former case is appropriate for describing a chemical reaction where there is either a barrier [figure A3.11.1\(a\)](#) or a well [figure A3.11.1\(b\)](#). It is also relevant to the scattering of an electron from the surface of a metal, where either transmission or reflection can occur. In [figure A3.11.1\(c\)](#), only reflection can occur, such as happens in elastic collisions of atoms, or low energy collisions of molecules with surfaces.

-3-

Figure A3.11.1. Potential associated with the scattering of a particle in one dimension. The three cases shown are (a) barrier potential, (b) well potential and (c) scattering off a hard wall that contains an intermediate well.

The physical question to be answered for [figure A3.11.1\(a\)](#) and [figure A3.11.1\(b\)](#) is: what is the probability P that a particle incident with an energy E from the left at $x \rightarrow -\infty$ will end up moving to the right at $x \rightarrow +\infty$? In the case of [figure A3.11.1\(c\)](#) only reflection can occur. However the change in phase of the wavefunction that occurs in this reflection is often of interest. In the following treatment the detailed theory associated with [figure A3.11.1\(a\)](#) and [figure A3.11.1\(b\)](#) will be considered. Eventually we will see that [figure A3.11.1\(c\)](#) is a subset of this theory.

The classical expression for the transmission probability associated with [figure A3.11.1\(a\)](#) or [figure A3.11.1\(b\)](#) is straightforward, namely

(1) $P(E) = 0$ if $V(x) \geq E$ for any x

(2) $P(E) = 1$ if $V(x) < E$ for all x .

The quantum solution to this problem is much more difficult for a number of reasons. First, it is important to know how to define what we mean by a particle moving in a given direction when $V(x)$ is constant. Secondly, one must determine the probability that the particle is moving in any specified direction at any desired

location and, third, we need to be able to solve the Schrödinger equation for the potential $V(x)$.

A3.11.2.2 WAVEPACKETS IN ONE DIMENSION

To understand how to describe a particle moving in a constant potential, consider the case of a free particle for which $V(x) = 0$. In this case the time-dependent Schrödinger equation is

-4-

$$i\hbar \frac{\partial \psi}{\partial t} = -\frac{\hbar^2}{2m} \frac{\partial^2 \psi}{\partial x^2} \quad (\text{A3.11.2})$$

and if one invokes the usual procedure for separating the time and spatial parts of this equation, it can readily be shown that one possible solution is

$$\psi_k(x, t) = e^{-iEt/\hbar} e^{ikx} \quad (\text{A3.11.3})$$

where

$$E = \frac{\hbar^2 k^2}{2m} \quad (\text{A3.11.4})$$

is the particle's energy and $\hbar k$ is its linear momentum. Note that both energy and momentum of the particle are exactly specified in this solution. As might be expected from the uncertainty principle, the location of the particle is therefore completely undetermined. As a result, this solution to the Schrödinger equation, even though correct, is not useful for describing the scattering processes of interest.

In order to localize the particle, it is necessary to superimpose wavefunctions ψ^k with different momenta k . A very general way to do this is to construct a wavepacket, defined through the integral

$$\begin{aligned} \psi_{\text{wp}}(x, t) &= \int_{-\infty}^{\infty} dk C(k) \psi_k(x, t) \\ &= \int_{-\infty}^{\infty} dk C(k) e^{ikx} e^{-i\hbar k^2 t/2m} \end{aligned} \quad (\text{A3.11.5})$$

where $C(k)$ is a function which tells us how much of each momentum $\hbar k$ is contained in the wavepacket. If the particle is to move with roughly a constant velocity, $C(k)$ must be peaked at some k which is taken to be k_0 .

One function which accomplishes this is the Gaussian

$$C(k) = \sqrt{\frac{a}{2\pi^{3/2}}} \exp[-a^2(k - k_0)^2/2] \quad (\text{A3.11.6})$$

where a measures the width of the packet. Substituting this into equation (A3.11.5), the result is:

$$(\text{A3.11.7})$$

$$\psi_{\text{wp}}(x, t) = \pi^{-1/4} [a(1 + i\hbar t/ma^2)]^{-1/2} \exp \left[-\frac{(x - \hbar k_0 t/m)^2}{2a^2(1 + i\hbar t/ma^2)} + ik_0 x - \frac{i\hbar t}{2ma^2} \right].$$

-5-

The absolute square of this wavefunction is $|\psi_{\text{wp}}(x, t)|^2$

$$|\psi_{\text{wp}}|^2 = \pi^{-1/2} a^{-1} (1 + \hbar^2 t^2/m^2 a^4)^{-1/2} \exp \left[-\frac{(x - \hbar k_0 t/m)^2}{a^2(1 + \hbar^2 t^2/m^2 a^4)} \right]. \quad (\text{A3.11.8})$$

This is a Gaussian function which peaks at $x = \hbar k_0 t/m$, moving to the right with a momentum $\hbar k_0$. The width of this peak is

$$\Delta = a[(\ln 2)(1 + \hbar^2 t^2/m^2 a^4)]^{1/2} \quad (\text{A3.11.9})$$

which starts out at $\Delta = a(\ln 2)^{1/2}$ at $t = 0$ and increases linearly with time for large t . This increase in width means that wavepacket spreads as it moves. This is an inevitable consequence of the fact that the wavepacket was constructed with a distribution of momentum components, and is a natural consequence of the uncertainty principle. Note that the wavefunction in [equation \(A3.11.7\)](#) still satisfies the Schrödinger [equation \(A3.11.2\)](#).

One can show that the expectation value of the Hamiltonian operator for the wavepacket in [equation \(A3.11.7\)](#) is:

$$\langle \hat{H} \rangle = \frac{\hbar^2 k_0^2}{2m} + \frac{\hbar^2}{4ma^2}. \quad (\text{A3.11.10})$$

The first term is what one would expect to obtain classically for a particle of momentum $\hbar k_0$, and it is much bigger than the second term provided $k_0 a \gg 1$. Since the de Broglie wavelength λ is $2\pi/k_0$, this condition is equivalent to the statement that the size of the wavepacket be much larger than the de Broglie wavelength.

It is also notable that the spreading of the wavepacket can be neglected for times t such that $t \ll ma^2/\hbar$. In this time interval the centre of the wavepacket will have moved a distance $(k_0 a)a$. Under the conditions noted above for which $k_0 a \gg 1$, this distance will be many times larger than the width of the packet.

A3.11.2.3 WAVEPACKETS FOR THE COMPLETE SCATTERING PROBLEM

The generalization of the treatment of the previous section to the determination of a wavepacket for the Hamiltonian in [equation \(A3.11.1\)](#) is accomplished by writing the solution as follows:

$$\psi_{\text{wp}}(x, t) = \int_{-\infty}^{\infty} dk C(k) \psi_k(x) e^{-iE_k t/\hbar} \quad (\text{A3.11.11})$$

where ψ_k is the solution of the time-independent Schrödinger equation

-6-

$$\hat{H}\psi_k = E_k\psi_k \quad (\text{A3.11.12})$$

for an energy E_k . By substituting [equation \(A3.11.11\)](#) into the time-dependent Schrödinger equation one can readily show that ψ_{wp} is a solution.

However, it is important to make sure that ψ_{wp} satisfies the desired boundary conditions initially and finally. Part of this is familiar already, since we have already demonstrated in [equation \(A3.11.3\)](#), [equation \(A3.11.5\)](#) and [equation \(A3.11.7\)](#) that use of $\psi_k = e^{ikx}$ and a Gaussian $C(k)$ gives a Gaussian wavepacket which moves with momentum $\hbar k_0$. This is the behaviour that is of interest initially ($t \rightarrow -\infty$) in the limit of $x \rightarrow -\infty$.

At the end of the collision ($t \rightarrow +\infty$) one expects to see part of the wavepacket moving to the right for $x \rightarrow \infty$ (the transmitted part) and part of it moving to the left for $x \rightarrow -\infty$ (the reflected part). Both this and the $t \rightarrow -\infty$ boundary condition can be satisfied by requiring that

$$\psi_k(x) \underset{x \rightarrow -\infty}{=} e^{ikx} + R e^{-ikx} \quad (\text{A3.11.13a})$$

$$\underset{x \rightarrow +\infty}{=} T e^{-i\bar{k}x} \quad (\text{A3.11.13b})$$

where R and T are as yet undetermined coefficients that will be discussed later and $\bar{k} = (2m(E - V_0)/\hbar^2)^{1/2}$ where V_0 is the value of the potential in the limit $x \rightarrow \infty$. Note that V_0 specifies the energy difference between the potential in the right and left asymptotic limits, and it has been assumed that $E > V_0$, as otherwise there could not be travelling waves in the $x \rightarrow \infty$ limit.

To prove that [equation \(A3.11.13\)](#) gives a wavepacket which satisfies the desired boundary conditions, we note that substitution of [equation \(3.11.13\)](#) into [equation \(A3.11.11\)](#) gives us two wavepackets which roughly speaking are given by

$$\psi_{\text{wp}} \underset{x \rightarrow -\infty}{\approx} e^{-(x - \hbar k_0 t/m)^2/2a^2} + R e^{-(x + \hbar k_0 t/m)^2/2a^2}. \quad (\text{A3.11.14a})$$

In the $t \rightarrow -\infty$ limit, only the first term, representing a packet moving to the right, has a peak in the $x \rightarrow -\infty$ region (the left asymptotic region). The second term peaks in the right asymptotic region but this is irrelevant as [equation A3.11.14](#) does not apply there. Thus, in the left asymptotic region the second term is negligible and all we have is a packet moving to the right. For $t \rightarrow +\infty$, [equation A3.11.14](#) still applies in the left asymptotic region, but now it is the second term which peaks and this packet moves to the left.

Now substitute [equation A3.11.13](#) into [equation \(A3.11.11\)](#). Ignoring various unimportant terms, we obtain

$$\psi_{\text{wp}} \underset{x \rightarrow +\infty}{\approx} T e^{-(x - \hbar \bar{k}_0 t/m)^2/2a^2}. \quad (\text{A3.11.14b})$$

This formula represents a packet moving to the right centred at $x = \hbar \bar{k}_0 t/m$. For $t \rightarrow -\infty$, this is negligible in the right asymptotic region, so the wavefunction is zero there, while for $t \rightarrow +\infty$ this packet is large for $x \rightarrow +\infty$ just as we wanted.

A3.11.2.4 FLUXES AND PROBABILITIES

Now let us use the wavepackets just discussed to extract the physically measurable information about our problem, namely, the probabilities of reflection and transmission. As long as the wavepackets do not spread much during the collision, these probabilities are given by the general definition:

$$\text{probability} = \frac{|\text{total flux outgoing for process of interest}|}{|\text{total flux incident}|} \quad (\text{A3.11.15})$$

where the flux is the number of particles per unit time that cross a given point (that cross a given surface in three dimensions), and the total flux is the spatial integral of the instantaneous flux. Classically the flux is just ρv where ρ is the density of particles (particles per unit length in one dimension) and v is the velocity of the particles. In quantum mechanics, the flux I is defined as

$$I = \text{Re}[\psi^* \hat{v} \psi] \quad (\text{A3.11.16})$$

where \hat{v} is the velocity operator ($\hat{v} = (-i\hbar/m)\partial/\partial x$ in one dimension) and Re implies that only the real part of $\psi^* \hat{v} \psi$ is to be used.

To see how equation (A3.11.16) works, substitute [equation \(A3.11.7\)](#) into (A3.11.16). Under the condition that wavepacket spreading is small (i.e., $\hbar t/ma^2 \ll 1$) we obtain

$$I = \left(\frac{\hbar k_0}{m} \right) \pi^{-1/2} a^{-1} \exp[-(x - \hbar k_0 t/m)^2/a^2] \quad (\text{A3.11.17})$$

which is just $v_0 |\psi_{\text{wp}}|^2$ where v_0 is the initial most probable velocity ($v_0 = \hbar k_0/m$). In view of [equation A3.11.14\(a\)](#), this is just the incident flux. The integral of this quantity over all space (the total flux) is $I_{\text{tot}}^{\text{inc}} = v_0$.

For the reflected wave associated with [equation \(A3.11.13a\)](#), the total outgoing flux is $I_{\text{tot}}^{\text{out}} = |R|^2 v_0$ so the reflection probability P_R is

$$P_R = |R|^2. \quad (\text{A3.11.18a})$$

-8-

A similar calculation of the transmission probability gives

$$P_T = \frac{\bar{v}_0}{v_0} |T|^2 \quad (\text{A3.11.18b})$$

where

$$\bar{v}_0 \equiv \frac{\hbar \bar{k}}{m}. \quad (\text{A3.11.19})$$

A3.11.2.5 TIME-INDEPENDENT APPROACH TO SCATTERING

Note from [equation \(A3.11.18a\)](#), [equation \(A3.11.18\)](#) that all of the physically interesting information about the scattering process involves the coefficients R and T which are properties of the time *independent* wavefunction ψ_k obtained from [equations \(A3.11.12\)](#) with the boundary conditions in [equations \(A3.11.13\)](#). As a result, we can use scattering theory completely in a time independent picture. This picture can be thought of as related to the time dependent picture by the superposition of many Gaussian incident wavepackets to form a plane wave. The important point to remember in using time independent solutions is that the asymptotic solution given by [equations \(A3.11.13\)](#) involves waves moving to the left and right that should be treated *separately* in calculating fluxes since these solutions do not contribute at the same time to the evolution of $\psi_{\text{wp}}(x, t)$ in the $t \rightarrow \pm\infty$ limits. As a result, fluxes are evaluated by substituting either the left or right moving wavepacket parts of [equations \(A3.11.13\)](#) into [\(A3.11.16\)](#).

A3.11.2.6 SCATTERING MATRIX

It is useful to rewrite the asymptotic part of the wavefunction as

$$\psi_k(x) \underset{x \rightarrow -\infty}{=} e^{ikx} + S_{11} e^{-ikx} \quad (\text{A3.11.20a})$$

$$\underset{x \rightarrow +\infty}{=} S_{12} (k/\bar{k})^{1/2} e^{-i\bar{k}x} \quad (\text{A3.11.20b})$$

where the coefficients S_{11} and S_{12} are two elements of a 2×2 matrix known as the scattering (S) matrix. The other two elements are associated with a different scattering solution in which the incident wave at $t \rightarrow -\infty$ moves to the left in the $x \rightarrow +\infty$ region. The boundary conditions on this solution are

$$\begin{aligned} \psi_{\bar{k}} \underset{x \rightarrow +\infty}{=} e^{-i\bar{k}x} + S_{22} e^{+i\bar{k}x} \\ \underset{x \rightarrow -\infty}{=} S_{21} (\bar{k}/k)^{1/2} e^{-i\bar{k}x}. \end{aligned} \quad (\text{A3.11.21})$$

-9-

The S matrix has a number of important properties, one of which is that it is *unitary*. Mathematically this means that $\mathbf{S}^+ \mathbf{S} = 1$ where \mathbf{S}^+ is the Hermitian conjugate (transpose of complex conjugate) of \mathbf{S} . This property comes from the equation of continuity, which says that for any solution ψ to the time dependent Schrödinger equation,

$$\frac{\partial |\psi|^2}{\partial t} + \frac{\partial I}{\partial x} = 0 \quad (\text{A3.11.22})$$

where I is the flux from [equation \(A3.11.16\)](#). [equation \(A3.11.22\)](#) can be proved by substitution of [equation \(A3.11.16\)](#) and the time dependent Schrödinger equation into [\(A3.11.22\)](#).

If $\psi = \psi_k(x)e^{iEt/\hbar}$, $|\psi|^2$ is time independent, so equation (A3.11.22) reduces to $\partial I/\partial x = 0$, which implies I is a constant (i.e., flux is conserved), independent of x . If so then the evaluation of I at $x \rightarrow +\infty$ and at $x \rightarrow -\infty$ should give the same result. By directly substituting equations (A3.11.13) into (A3.11.16) one finds

$$\begin{aligned} I &= \frac{\hbar k}{m} (1 - |S_{11}|^2) \\ &= \frac{\hbar k}{m} |S_{12}|^2 \end{aligned} \quad (\text{A3.11.23})$$

and since these two have to be equal, we find that

$$|S_{11}|^2 + |S_{12}|^2 = 1 \quad (\text{A3.11.24})$$

which indicates that the sum of the reflected and transmitted probabilities has to be unity. This is one of the equations that is implied by unitarity of the S matrix. The other equations can be obtained by using the solution ψ_k (equation (A3.11.21)) and by using a generalized flux that is defined by

$$I_{k\bar{k}} = \text{Re}(\psi_k^* \hat{v} \psi_{\bar{k}}). \quad (\text{A3.11.25})$$

Another useful property of the S matrix is that it is *symmetric*. This property follows from conservation of the fluxlike expression

$$\tilde{I}_{k\bar{k}} = \text{Re}(\psi_k v \psi_{\bar{k}}) \quad (\text{A3.11.26})$$

which differs from equation (A3.11.25) in the absence of a complex conjugate in the wavefunction ψ_k . The symmetry property of \mathbf{S} implies that S_{12} in equation (A3.11.20b) equals S_{21} in equation (A3.11.21). Defining the probability matrix \mathbf{P} by the relation

$$P_{ij} = |S_{ij}|^2 \quad (\text{A3.11.27})$$

we see that symmetry of \mathbf{S} implies equal probabilities for the $i \rightarrow j$ and $j \rightarrow i$ transitions. This is a statement of the principle of *microscopic reversibility* and it arises from the time reversal symmetry associated with the Schrödinger equation.

The probability matrix plays an important role in many processes in chemical physics. For chemical reactions, the probability of reaction is often limited by tunnelling through a barrier, or by the formation of metastable states (resonances) in an intermediate well. Equivalently, the conductivity of a molecular wire is related to the probability of transmission of conduction electrons through the junction region between the wire and the electrodes to which the wire is attached.

A3.11.2.7 GREEN'S FUNCTIONS FOR SCATTERING

Now let us write down the Schrödinger equation (A3.11.12) using equation (A3.11.1) for H and assuming that V_0 in figure A3.11.1 is zero. The result can be written

$$\left(\frac{d^2}{dx^2} + k^2\right) \psi_k(x) = \frac{2m}{\hbar^2} V(x) \psi_k(x). \quad (\text{A3.11.28})$$

One way to solve this is to invert the operator on the left hand side, thereby converting this differential equation into an integral equation. The general result is

$$\psi_k(x) = \varphi_k(x) + \frac{2m}{\hbar^2} \int_{-\infty}^{\infty} G_0(x, x') V(x') \psi_k(x') dx' \quad (\text{A3.11.29})$$

where G_0 is called the Green function associated with the operator $d^2/dx^2 + k^2$ and φ_k is a solution of the homogeneous equation that is associated with equation (A3.11.28), namely

$$\left(\frac{d^2}{dx^2} + k^2\right) \varphi_k(x) = 0. \quad (\text{A3.11.30})$$

To determine $G_0(x, x')$, it is customary to reexpress equation (A3.11.28) in a Fourier representation. Let $F_k(k')$ be the Fourier transform of $\psi_k(x)$. Taking the Fourier transform of equation (A3.11.28), we find

$$\frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{ik'x} (k^2 - k'^2) F_k(k') dk' = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{ik'x} B(k') dk' \quad (\text{A3.11.31})$$

-11-

where

$$B(k') = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{-ik'x} \frac{2m}{\hbar^2} V(x) \psi_k(x) dx. \quad (\text{A3.11.32})$$

Equation (A3.11.31) implies

$$F_k(k') = \frac{B(k')}{k^2 - k'^2} \quad (\text{A3.11.33})$$

and upon inverting the Fourier transform we find

$$\psi_k(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{ik'x} \frac{B(k')}{k^2 - k'^2} dk' = \frac{2m}{\hbar^2} \int_{-\infty}^{\infty} G_0(x, x') V(x') \psi_k(x') dx' \quad (\text{A3.11.34})$$

where the Green function is given by

$$G_0(x, x') = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{ik'(x-x')} (k^2 - k'^2)^{-1} dk'. \quad (\text{A3.11.35})$$

The evaluation of the integral in equation (A3.11.35) needs to be done carefully as there is a pole at $k' = \pm k$. A standard trick to do it involves replacing k by $k \pm i\varepsilon$ where ε is a small positive constant that will be set to zero in the end. This reduces equation (A3.11.35) to

$$G_0(x, x') = \frac{1}{4\pi k} \lim_{\varepsilon \rightarrow 0} \int_{-\infty}^{\infty} \exp[ik'(x - x')] \left(\frac{1}{k - k' \pm i\varepsilon} + \frac{1}{k + k' \pm i\varepsilon} \right) dk'. \quad (\text{A3.11.36})$$

This integral can be done by contour integration using the contours in figure A3.11.2. For the $+i\varepsilon$ choice, the contour in figure A3.11.2(a) is appropriate for $x < x'$ as the circular part has a negative imaginary k' which makes $e^{ik'(\xi - \xi')}$ vanish for $|k'| \rightarrow \infty$. Likewise for $x > x'$, we want to use the contour in figure A3.11.2(b) as this makes the imaginary part of k' positive along the circular part. In either case, the integral along the real axis equals the full contour integral, and the latter is determined by the residue theorem to be $2\pi i$ times the residue at the pole which is encircled by the contour.

-12-

Figure A3.11.2. Integration contours used to evaluate equation (A3.11.36) (a) for $x < x'$, (b) for $x > x'$.

The pole is at $k' = -k - i\varepsilon$ for the contour in figure A3.11.2(a) and at $k' = k + i\varepsilon$ for figure A3.11.2(b). This gives us

$$G_0^+(x, x') = \begin{cases} \left(\frac{-i}{2k} \right) e^{-ik(x-x')} & \text{for } x < x' \\ \left(\frac{-i}{2k} \right) e^{ik(x-x')} & \text{for } x > x' \end{cases} \quad (\text{A3.11.37})$$

which we will call the ‘plus’ wave free particle Green function G_0^+ . A different Green function (‘minus’ wave) is obtained by using $-i\varepsilon$ in the above formulas. It is

$$G_0^-(x, x') = \begin{cases} \left(\frac{i}{2k} \right) e^{ik(x-x')} & \text{for } x < x' \\ \left(\frac{i}{2k} \right) e^{-ik(x-x')} & \text{for } x > x'. \end{cases} \quad (\text{A3.11.38})$$

Upon substitution of G_0 into equation (A3.11.29) we generate the following integral equation for the solution ψ_k^* that is associated with G_0^+ :

$$(\text{A3.11.39})$$

$$\begin{aligned}\psi_k^+(x) = \varphi_k(x) - \int_{-\infty}^x \left(\frac{i}{2k}\right) e^{ik(x-x')} \frac{2m}{\hbar^2} V(x') \psi_k^+(x') dx' \\ - \int_x^{\infty} \left(\frac{i}{2k}\right) e^{-ik(x-x')} \frac{2m}{\hbar^2} V(x') \psi_k^+(x') dx' .\end{aligned}$$

For $x \rightarrow \pm\infty$, it is possible to make ψ_k^+ look like [equation \(A3.11.20\)](#) by setting $\varphi_k(x) = e^{ikx}$. This shows that the plus Green function is associated with scattering solutions in which outgoing waves move to the right in the $x \rightarrow \infty$ limit. For $x \rightarrow -\infty$, [equation \(A3.11.39\)](#) becomes

$$\psi_k^+ \underset{x \rightarrow -\infty}{=} e^{ikx} - e^{-ikx} \int_{-\infty}^{\infty} \left(\frac{i}{2k}\right) e^{ikx'} \frac{2m}{\hbar^2} V(x') \psi_k^+(x') dx' . \quad (\text{A3.11.40})$$

-13-

By comparison with [equation A3.11.20\(a\)](#), we see that

$$S_{11} = -\frac{i}{2k} \int_{-\infty}^{\infty} e^{ikx'} \frac{2m}{\hbar^2} V(x') \psi_k^+(x') dx' \quad (\text{A3.11.41})$$

which is an integral that can be used to calculate S_{11} provided that ψ_k^+ is known. One can similarly show that

$$S_{12} = 1 - \frac{i}{2k} \int_{-\infty}^{\infty} e^{ikx'} \frac{2m}{\hbar^2} V(x') \psi_k^+(x') dx' . \quad (\text{A3.11.42})$$

The other S matrix components S_{21} and S_{22} can be obtained from the G_0^- Green function.

A3.11.2.8 BORN APPROXIMATION

If $V(x)$ is ‘small’, ψ_k^+ will not be perturbed much from what it would be if $V(x) = 0$. If so, then we can approximate ψ_k^+ and obtain

$$S_{11} = -\frac{i}{2k} \int_{-\infty}^{\infty} e^{2ikx'} \frac{2m}{\hbar^2} V(x') dx' \quad (\text{A3.11.43a})$$

$$S_{12} = 1 - \frac{i}{2k} \int_{-\infty}^{\infty} \frac{2m}{\hbar^2} V(x') dx' . \quad (\text{A3.11.43b})$$

This is the one dimensional version of what is usually called the *Born approximation* in scattering theory. The transition probability obtained from [equation A3.11.43\(b\)](#) is

$$P_{11} = \frac{m^2}{\hbar^2 p^2} \left| \int_{-\infty}^{\infty} e^{2ikx'} V(x') dx' \right|^2 \quad (\text{A3.11.44})$$

where $p = \hbar k$ is the momentum. Note that this approximation simplifies the evaluation of transition probabilities to performing an integral.

A number of improvements to the Born approximation are possible, including *higher order* Born approximations (obtained by inserting lower order approximations to ψ_k^* into equation (A3.11.40), then the result into (A3.11.41) and (A3.11.42)), and the *distorted wave* Born approximation (obtained by replacing the free particle approximation for ψ_k^* by the solution to a Schrödinger equation that includes part of the interaction potential). For chemical physics

-14-

applications, the distorted wave Born approximation is the most often used approach, as the approximation of ψ_k^* by a plane wave is rarely of sufficient accuracy to be even qualitatively useful. However, even the distorted wave Born approximation is poorly convergent for many applications, so other exact and approximate methods need to be considered.

A3.11.2.9 VARIATIONAL METHODS

A completely different approach to scattering involves writing down an expression that can be used to obtain S directly from the wavefunction, and which is stationary with respect to small errors in the wavefunction. In this case one can obtain the scattering matrix element by variational theory. A recent review of this topic has been given by Miller [32]. There are many different expressions that give S as a functional of the wavefunction and, therefore, there are many different variational theories. This section describes the Kohn variational theory, which has proven particularly useful in many applications in chemical reaction dynamics. To keep the derivation as simple as possible, we restrict our consideration to potentials of the type plotted in figure A3.11.1(c) where the wavefunction vanishes in the limit of $x \rightarrow -\infty$, and where the S matrix is a scalar property so we can drop the matrix notation.

The Kohn variational approximation states that for a trial wavefunction $\tilde{\Psi}$ which has the asymptotic form

$$\tilde{\Psi} \underset{x \rightarrow \infty}{\sim} v^{-1/2} (e^{-ikx} - e^{-ikx} \tilde{S}) \quad (\text{A3.11.45})$$

that the quantity

$$S = \tilde{S} + \frac{i}{\hbar} \langle \tilde{\Psi} | \hat{H} - E | \tilde{\Psi} \rangle \quad (\text{A3.11.46})$$

is stationary with respect to variations in $\tilde{\Psi}$, and $S = S_{\text{ex}}$ where S_{ex} is the exact scattering matrix when $\tilde{\Psi} = \psi_{\text{exact}}$. Note that $\tilde{\Psi}$ is not complex conjugated in calculating $\langle \tilde{\Psi} |$.

To prove this we expand $\tilde{\Psi}$ about the exact wavefunction ψ_{ex} , that is, we let

$$\tilde{\Psi} = \psi_{\text{ex}} + \delta\Psi. \quad (\text{A3.11.47})$$

ψ_{ex} here is assumed to have the asymptotic form

$$\Psi_{\text{ex}} \underset{x \rightarrow \infty}{\sim} -v^{-1/2}(e^{-ikx} - e^{-ikx} S_{\text{ex}}). \quad (\text{A3.11.48})$$

-15-

This means that

$$S\Psi \underset{x \rightarrow \infty}{\sim} v^{-1/2} e^{-ikx} \delta S \quad (\text{A3.11.49})$$

where $\delta S = S - S_{\text{ex}}$. Then we see that

$$\begin{aligned} S &= S_{\text{ex}} + \delta S + \frac{i}{\hbar} \langle \Psi_{\text{ex}} + \delta\Psi | \hat{H} - E | \Psi_{\text{ex}} + \delta\Psi \rangle \\ &= S_{\text{ex}} + \delta S + \frac{i}{\hbar} \langle \Psi_{\text{ex}} | \hat{H} - E | \delta\Psi \rangle + \mathcal{O}(\delta\Psi^2) \end{aligned} \quad (\text{A3.11.50})$$

since $\langle \hat{H} - E | \Psi_{\text{ex}} \rangle = 0$.

Now use integration by parts twice to show that

$$\left\langle \Psi_{\text{ex}} \left| \frac{d^2}{dx^2} \right| \delta\Psi \right\rangle = +(\Psi_{\text{ex}} \delta\Psi' - \Psi_{\text{ex}}' \delta\Psi) \Big|_{-\infty}^{\infty} + \left\langle \delta\Psi \left| \frac{d^2}{dx^2} \right| \Psi_{\text{ex}} \right\rangle \quad (\text{A3.11.51})$$

which means that

$$\langle \Psi_{\text{ex}} | \hat{H} - E | \delta\Psi \rangle = \frac{-\hbar^2}{2\mu} (\Psi_{\text{ex}} \delta\Psi' - \Psi_{\text{ex}}' \delta\Psi) \Big|_{-\infty}^{\infty} + \langle \delta\Psi | \hat{H} - E | \Psi_{\text{ex}} \rangle. \quad (\text{A3.11.52})$$

The last term vanishes, and so does the first at $x = -\infty$. The nonzero part is then

$$\begin{aligned} \frac{-\hbar^2}{2\mu} (-v^{-1/2}(e^{-ikx} - e^{ikx} S_{\text{ex}})v^{-1/2}(ik) e^{-ikx} \delta S + v^{-1/2}(-ik) \\ (e^{-ikx} + e^{ikx} S_{\text{ex}})v^{-1/2} e^{ikx} \delta S) \\ = \frac{-\hbar^2}{2\mu} \left(2 \frac{-ik}{v} \delta S \right) = i\hbar \delta S. \end{aligned} \quad (\text{A3.11.53})$$

So overall

$$S = S_{\text{ex}} + \delta S + \frac{i}{\hbar} (i\hbar \delta S) + \mathcal{O}(\delta\Psi^2) = S_{\text{ex}} + \mathcal{O}(\delta\Psi^2) \quad (\text{A3.11.54})$$

-16-

which means that the deviations from the exact result are of second order. This means that S is stationary with respect to variations in the trial function. Later ([section A3.11.4](#)) we will show how the variational approach can be used in practical applications where the scattering wavefunction is expanded in terms of basis functions.

A3.11.3 MULTICHANNEL QUANTUM SCATTERING THEORY; SCATTERING IN THREE DIMENSIONS

In this section we consider the generalization of quantum scattering theory to problems with many degrees of freedom, and to problems where the translational motion takes place in three dimensions rather than one. The simplest multidimensional generalization is to consider two degrees of freedom, and we will spend much of our development considering this, as it contains the essence of the complexity that can arise in what is called ‘multichannel’ scattering theory. Moreover, models containing two degrees of freedom are of use throughout the field of chemical physics. For example, this model can be used to describe the collision of an atom with a diatomic molecule with the three atoms constrained to be collinear so that only vibrational motion in the diatomic molecule needs to be considered in addition to translational motion of the atom relative to the molecule. This model is commonly used in studies of *vibrational energy transfer* [29] where the collision causes changes in the vibrational state of the molecule. In addition, this model can be used to describe *reactive* collisions wherein an atom is transferred to form a new diatomic molecule [23, 23 and 24]. We will discuss both of these processes in the following two sections ([A3.11.3.1](#) and [A3.11.3.2](#)).

The treatment of translational motion in three dimensions involves representation of particle motions in terms of plane waves $e^{i\mathbf{k}\cdot\mathbf{r}}$ where the wavevector \mathbf{k} specifies the direction of motion in addition to the magnitude of the velocity. For problems involving the motion of isolated particles, i.e., gas phase collisions, all problems can be represented in terms of eigenfunctions of the total angular momentum, which is a conserved quantity. The relationship between these eigenfunctions and the plane wave description of particle motions leads to the concept of a *partial wave expansion*, something that is used throughout the field of chemical physics. This is described in the third part of this [section \(A3.11.3.3\)](#).

Problems in chemical physics which involve the collision of a particle with a surface do not have rotational symmetry that leads to partial wave expansions. Instead they have two dimensional translational symmetry for motions parallel to the surface. This leads to expansion of solutions in terms of diffraction eigenfunctions. This theory is described in the literature [33].

A3.11.3.1 MULTICHANNEL SCATTERING—COUPLED CHANNEL EQUATIONS

Consider the collision of an atom (denoted A) with a diatomic molecule (denoted BC), with motion of the atoms constrained to occur along a line. In this case there are two important degrees of freedom, the distance R between the atom and the centre of mass of the diatomic, and the diatomic internuclear distance r . The Hamiltonian in terms of these coordinates is given by:

$$\hat{H} = \frac{\hat{p}_R^2}{2\mu_{A,BC}} + \frac{\hat{p}_r^2}{2\mu_{BC}} + V(R, r) \quad (\text{A3.11.55})$$

where $\mu_{A,BC}$ is the reduced mass associated with motion in the R coordinate, and μ_{BC} is the corresponding diatom reduced mass. Note that this Hamiltonian can be derived by starting with the Hamiltonian of the

independent atoms and separating out the motion of the centre of mass. The second form (A3.11.56) arises by replacing the momentum operators by their usual quantum mechanical expressions.

$$= -\frac{\hbar^2}{2\mu_{A,BC}} \frac{\partial^2}{\partial R^2} - \frac{\hbar^2}{2\mu_{BC}} \frac{\partial^2}{\partial r^2} + V(R, r) \quad (\text{A3.11.56})$$

We concentrate in this section on solving the time-independent Schrödinger equation, which, as we learned from [section A3.11.2.5](#), is all we need to do to generate the physically meaningful scattering information. If BC does not dissociate then it is reasonable to use the BC eigenfunctions as a basis for expanding the scattering wavefunction. Assume that as $R \rightarrow \infty$, $V(R, r) \rightarrow V_{BC}(r)$. Then the BC eigenfunctions are solutions to

$$\left(\frac{-\hbar^2}{2\mu_{BC}} \frac{d^2}{dr^2} + V_{BC}(r) \right) \varphi_v(r) = \epsilon_v \varphi_v(r) \quad (\text{A3.11.57})$$

where ϵ_v is the vibrational eigenvalue. The expansion of Ψ in terms of the BC eigenfunctions is thus given by

$$\Psi(R, r) = \sum_v \varphi_v(r) g_v(R) \quad (\text{A3.11.58})$$

where the g_v are unknown functions to be determined. This equation is called a *coupled channel* expansion. Substituting this into the Schrödinger equation, we find

$$\begin{aligned} \frac{-\hbar^2}{2\mu_{A,BC}} \sum_v \varphi_v(r) \frac{d^2 g_v}{dR^2} + \sum_v g_v(R) \left[\frac{-\hbar^2}{2\mu_{BC}} \frac{d^2}{dr^2} + V_{BC}(r) \right] \varphi_v(r) \\ + \sum_v (V(R, r) - V_{BC}(r)) g_v(R) \varphi_v(r) \\ = E \sum_v g_v(R) \varphi_v(r). \end{aligned} \quad (\text{A3.11.59})$$

Now rearrange, multiply by $\varphi_{v'}$, and integrate to obtain

$$\frac{-\hbar^2}{2\mu_{A,BC}} \frac{d^2 g_v}{dR^2} = (E - \epsilon_v) g_v - \sum_{v'} \langle \varphi_v | V - V_{BC} | \varphi_{v'} \rangle g_{v'} \quad (\text{A3.11.60})$$

or

$$\frac{d^2 g_v(R)}{dR^2} = \sum_{v'} U_{vv'}(R) g_{v'}(R) \quad (\text{A3.11.61})$$

where

$$U_{vv'} = \frac{2\mu_{A,BC}}{\hbar^2}(E - \epsilon_v) \delta_{vv'} + \frac{2\mu_{BC}}{\hbar^2} \langle \phi_v | V - V_{BC} | \phi_{v'} \rangle. \quad (\text{A3.11.62})$$

In matrix–vector form these *coupled-channel* equations are

$$\frac{d^2 \mathbf{g}}{dR^2} = \mathbf{U} \mathbf{g} \quad (\text{A3.11.63})$$

where \mathbf{g} is the vector formed using the g_v as elements and \mathbf{U} is a matrix whose elements are $U_{vv'}$. Note that the internal states may be either *open* or *closed*, depending on whether the energy E is above or below the internal energy ϵ_v . Only the open states (often termed *open channels*) have measurable scattering properties, but the closed channels can be populated as intermediates during the collision, sometimes with important physical consequences. In the following discussion we confine our discussion to the open channels. The boundary conditions on the open channel solutions are:

$$\mathbf{g}(R) \rightarrow \mathbf{0} \text{ as } R \rightarrow 0 \quad (\text{A3.11.64})$$

provided that the potential is repulsive at short range, and

$$\mathbf{g}(R) \rightarrow \mathbf{v}^{-1/2} (\mathbf{e}^{-ikR} - \mathbf{e}^{ikR} \mathbf{S}) \text{ as } R \rightarrow \infty. \quad (\text{A3.11.65})$$

Here we have collected the N independent g that correspond to different incoming states for N open channels into a matrix \mathbf{g} (where the *sans serif* bold notation is again used to denote a square matrix). Also we have the matrices

$$(\mathbf{v})_{vv'} = v_v \delta_{vv'} \quad (\text{A3.11.66})$$

$$(\mathbf{k})_{vv'} = k_v \delta_{vv'} \quad (\text{A3.11.67})$$

where

$$k_v = \frac{\sqrt{2\mu_{A,BC}}}{\hbar^2} (E - \epsilon_v) \quad (\text{A3.11.68})$$

-19-

$$v_v = \frac{\hbar k_v}{\mu_{A,BC}} \quad (\text{A3.11.69})$$

$$\mathbf{S} = S_{vv'}. \quad (\text{A3.11.70})$$

\mathbf{S} is the *scattering matrix*, analogous to that defined earlier. As before, the probabilities for transitions between states v and v' are

$$P_{vv'} = |S_{vv'}|^2. \quad (\text{A3.11.71})$$

Often in numerical calculations we determine solutions $\mathbf{g}(R)$ that solve the Schrödinger equations but do not satisfy the asymptotic boundary condition in (A3.11.65). To solve for \mathbf{S} , we rewrite equation (A3.11.65) and its derivative with respect to R in the more general form:

$$\mathbf{g} = (\mathbf{I} - \mathbf{O}\mathbf{S})\mathbf{A} \quad (\text{A3.11.72})$$

$$\mathbf{g}' = (\mathbf{I}' - \mathbf{O}'\mathbf{S})\mathbf{A} \quad (\text{A3.11.73})$$

where the incoming and outgoing asymptotic solutions are:

$$\mathbf{I} = \kappa^{-1/2} e^{-i\kappa R} \quad (\text{A3.11.74})$$

$$\mathbf{O} = \kappa^{-1/2} e^{i\kappa R}. \quad (\text{A3.11.75})$$

\mathbf{A} is a coefficient matrix that is designed to transform between solutions that obey arbitrary boundary conditions and those which obey the desired boundary conditions. \mathbf{A} and \mathbf{S} can be regarded as unknowns in equation (A3.11.72) and equation (A3.11.73). This leads to the following expression for \mathbf{S} :

$$\mathbf{S} = \mathbf{W}^{-1}(\mathbf{I}'\mathbf{g} - \mathbf{I}\mathbf{g}')(\mathbf{O}'\mathbf{g} - \mathbf{O}\mathbf{g}')^{-1}\mathbf{W} \quad (\text{A3.11.76})$$

where

$$\mathbf{W} = \mathbf{O}\mathbf{I}' - \mathbf{O}'\mathbf{I}. \quad (\text{A3.11.77})$$

The present derivation can easily be generalized to systems with an arbitrary number of internal degrees of freedom, and it leads to coupled channel equations identical with equation (A3.11.63), where the coupling terms (A3.11.62) are expressed as matrix elements of the interaction potential using states which depend on these internal degrees of

-20-

freedom. These internal states could, in principle, have a continuous spectrum but, in practice, if there are multiple continuous degrees of freedom then it is most useful to reformulate the problem to take this into account. One particularly important case of this sort arises in the treatment of reactive collisions, where the atom B is transferred from C to A, leading to the formation of a new arrangement of the atoms with its own scattering boundary conditions. We turn our attention to this situation in the next section.

A3.11.3.2 REACTIVE COLLISIONS

Let us continue with the atom–diatom collinear collision model, this time allowing for the possibility of the reaction $A + BC \rightarrow AB + C$. We first introduce *mass-scaled* coordinates, as these are especially convenient to describe rearrangements, using

$$(\text{A3.11.78})$$

$$R' = \left(\frac{\mu_{A,BC}}{m} \right)^{1/2} R$$

$$r' = \left(\frac{\mu_{BC}}{m} \right)^{1/2} r. \quad (\text{A3.11.79})$$

The choice of m in these formulas is arbitrary, but it is customary to take either $m = 1$ or

$$m = \sqrt{\frac{m_A m_B m_C}{m_A + m_B + m_C}} = \sqrt{\mu_{A,BC} \mu_{BC}}. \quad (\text{A3.11.80})$$

Either choice is invariant to permutation of the atom masses.

In terms of these coordinates, the Hamiltonian of [equation \(A3.11.55\)](#) becomes

$$H = \frac{\hat{P}_R^2}{2\mu_{A,BC}} + \frac{\hat{P}_r^2}{2\mu_{BC}} + V = \frac{\hat{P}_R'^2 + \hat{P}_r'^2}{2m} + V. \quad (\text{A3.11.81})$$

One nice thing about H in mass-scaled coordinates is that it is identical to the Hamiltonian of a mass point moving in two dimensions. This is convenient for visualizing trajectory motions or wavepackets, so the mass-scaled coordinates are commonly used for plotting data from scattering calculations.

Another reason why mass-scaled coordinates are useful is that they simplify the transformation to the Jacobi coordinates that are associated with the products $AB + C$. If we define S as the distance from C to the centre of mass of AB , and s as the AB distance, mass scaling is accomplished via

$$S' = \sqrt{\frac{\mu_{C,AB}}{m}} S \quad (\text{A3.11.82})$$

-21-

$$s' = \sqrt{\frac{\mu_{AB}}{m}} s. \quad (\text{A3.11.83})$$

The Hamiltonian in terms of product coordinates is

$$\hat{H} = \frac{\hat{P}_{S'}^2 + \hat{P}_{s'}^2}{2m} + V \quad (\text{A3.11.84})$$

and the transformation between reagent and product coordinates is given by:

$$\begin{aligned} S' &= r' \sin \beta + R' \cos \beta \\ s' &= -r' \cos \beta + R' \sin \beta \end{aligned} \quad (\text{A3.11.85})$$

where the angle β is defined by:

$$\tan \beta = \sqrt{\frac{m_B(m_A + m_B + m_C)}{m_A m_C}}. \quad (\text{A3.11.86})$$

Equation (A3.11.85) implies that the $R', r' \rightarrow S', s'$ transformation is orthogonal, a point which is responsible for the similarities between the Hamiltonian expressed in terms of reagent and product mass-scaled coordinates ((A3.11.81) and (A3.11.84)). In fact, the reagent to product transformation can be thought of as a rotation by an angle β followed by a flip in the sign of s' . The angle β is sometimes called the 'skew' angle, and it can vary between 0 and 90°, as determined by equation (A3.11.86). If $m_A = m_B = m_C$ (i.e., all three masses are identical, as in the reaction $\text{H} + \text{H}_2$), then $\beta = 60^\circ$, while for $m_B \gg m_A, m_C$, $\beta \rightarrow 90^\circ$ and $m_B \ll m_A m_C$ gives $\beta \rightarrow 0$.

Although the Schrödinger equation associated with the $\text{A} + \text{BC}$ reactive collision has the same form as for the nonreactive scattering problem that we considered previously, it *cannot* be solved by the coupled-channel expansion used then, as the reagent vibrational basis functions cannot directly describe the product region (for an expansion in a finite number of terms). So instead we need to use alternative schemes of which there are many.

One possibility is to use *hyperspherical coordinates*, as these enable the use of basis functions which describe reagent and product internal states in the same expansion. Hyperspherical coordinates have been extensively discussed in the literature [34, 35 and 36] and in the present application they reduce to polar coordinates (ρ, η) defined as follows:

$$\rho = \sqrt{R'^2 + r'^2} = \sqrt{S'^2 + s'^2} \quad 0 \leq \rho \leq \infty \quad (\text{A3.11.87})$$

$$\eta = \tan^{-1} \frac{r'}{R'} \quad 0 \leq \eta \leq \beta. \quad (\text{A3.11.88})$$

-22-

Hyperspherical coordinates have the properties that η motion is always bound since $\eta = 0$ and $\eta = \beta$ correspond to cases where two of the three atoms are on top of one another, yielding a very repulsive potential. Also, $\rho \rightarrow 0$ is a repulsive part of the potential, while large ρ takes us to the reagent and product valleys.

To develop coupled-channel methods to solve the Schrödinger equation, we first transform the Hamiltonian (A3.11.81) to hyperspherical coordinates, yielding:

$$\hat{H} = \frac{-\hbar^2}{2m} \left(\frac{\partial^2}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2}{\partial \eta^2} \right) + V. \quad (\text{A3.11.89})$$

Now define a new wavefunction $\chi = \rho^{+1/2} \psi$. Then

$$\hat{H} \psi = \frac{-\hbar^2}{2m} \left(\frac{\partial^2}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2}{\partial \eta^2} \right) \rho^{-1/2} \chi + V \rho^{-1/2} \chi. \quad (\text{A3.11.90})$$

After cancelling out a factor $\rho^{-1/2}$ and regrouping, we obtain a new version of the Schrödinger equation in which the first derivative term has been eliminated.

$$\left\{ \frac{-\hbar^2}{2m} \left[\frac{\partial^2}{\partial \rho^2} + \frac{1}{4\rho^2} + \frac{1}{\rho^2} \frac{\partial^2}{\partial \eta^2} \right] + V \right\} \chi = E \chi. \quad (\text{A3.11.91})$$

Now select out the η -dependent part to define vibrational functions at some specific ρ which we call $\bar{\rho}$.

$$-\frac{\hbar^2}{2m\bar{\rho}^2} \frac{d^2}{d\eta^2} \varphi_n + V(\bar{\rho}, \eta) \varphi_n = \varepsilon_n \varphi_n \quad (\text{A3.11.92})$$

with the boundary condition that $\varphi_n \rightarrow 0$ as $\eta \rightarrow 0$ and $\eta \rightarrow \beta$. For large $\bar{\rho}$ the φ_n will become eigenfunctions of the reagent and product diatomics.

To set up coupled-channel equations, use the expansion

$$\psi = \rho^{-1/2} \sum_n \varphi_n(\eta) g_n(\rho). \quad (\text{A3.11.93})$$

This leads to

$$\frac{-\hbar^2}{2m} \frac{d^2}{d\rho^2} \sum_n \varphi_n g_n + \frac{-\hbar^2}{2m\rho^2} \sum_n g_n \frac{d^2 \varphi_n}{d\eta^2} + \left(V - \frac{\hbar^2}{8m\rho^2} \right) \sum_n \varphi_n g_n = E \sum_n \varphi_n g_n. \quad (\text{A3.11.94})$$

-23-

Now substitute the $\rho = \bar{\rho}$ solution for $d^2 \varphi_n / d\eta^2$ from above, multiply by φ_n and integrate over η . This gives

$$\frac{d^2 \mathbf{g}}{d\rho^2} = \mathbf{U} \mathbf{g} \quad (\text{A3.11.95})$$

where

$$U_{nn'} = \frac{2m}{\hbar^2} \left\langle \varphi_n \left| V(\rho, \eta) - \frac{\bar{\rho}^2}{\rho^2} V(\bar{\rho}, \eta) \right| \varphi_{n'} \right\rangle + \frac{2m}{\hbar^2} \delta_{nn'} \left(\varepsilon_n \frac{\bar{\rho}^2}{\rho^2} - \frac{\hbar^2}{8m\rho^2} - E \right). \quad (\text{A3.11.96})$$

This equation may be solved by the same methods as used with the nonreactive coupled-channel equations (discussed later in [section A3.11.4.2](#)). However, because $V(\rho, \eta)$ changes rapidly with ρ , it is desirable to periodically change the expansion basis set φ_n . To do this we divide the range of ρ to be integrated into 'sectors' and within each sector choose a $\bar{\rho}$ (usually the midpoint) to define local eigenfunctions. The coupled-channel equations just given then apply within each sector, but at sector boundaries we change basis sets. Let $\bar{\rho}_1$ and $\bar{\rho}_2$ be the $\bar{\rho}$ associated with adjacent sectors. Then, at the sector boundary ρ_b we require

$$\Psi_1(\eta, \rho_b) = \Psi_2(\eta, \rho_b) \quad (\text{A3.11.97})$$

or

$$\sum_n \varphi_n(\eta, \bar{\rho}_1) g_{nn_i}^{(1)}(\rho_b) = \sum_n \varphi_n(\eta, \bar{\rho}_2) g_{nn_i}^{(2)}(\rho_b). \quad (\text{A3.11.98})$$

Multiply by $\varphi_n(\varepsilon, \bar{\rho}_2)$ and integrate to obtain

$$\mathbf{g}^{(2)} = \mathbf{S}^{21} \mathbf{g}^{(1)} \quad (\text{A3.11.99})$$

where

$$S_{nn'}^{21} = \langle \varphi_n(\eta, \bar{\rho}_2) | \varphi_{n'}(\eta, \bar{\rho}_1) \rangle. \quad (\text{A3.11.100})$$

The corresponding derivative transformation is:

$$\frac{d\mathbf{g}^{(2)}}{d\rho} = \mathbf{S}^{21} \frac{d\mathbf{g}^{(1)}}{d\rho}. \quad (\text{A3.11.101})$$

-24-

This scheme makes it possible to propagate \mathbf{g} from small ρ where \mathbf{g} should vanish to large ρ where an asymptotic analysis can be performed.

To perform the asymptotic analysis we need to first write down the proper asymptotic solution. Clearly we want some solutions with incoming waves in the reagents, then outgoing waves in both reagents and products and other solutions with the reagent and product labels interchanged. One way to do this is to define a matrix of incoming waves \mathbf{I} and outgoing waves \mathbf{O} such that

$$I_{\alpha v' \alpha' v} = \delta_{\alpha \alpha'} \delta_{v v'} \begin{cases} e^{-ik_v R'} & \alpha = 1 \\ e^{-ik_v S'} & \alpha = 2 \end{cases} \quad (\text{A3.11.102a})$$

$$O_{\alpha v \alpha' v'} = \delta_{\alpha \alpha'} \delta_{v v'} \begin{cases} e^{ik_v R'} & \alpha = 1 \\ e^{ik_v S'} & \alpha = 2 \end{cases} \quad (\text{A3.11.102b})$$

where α is an arrangement channel label such that $\alpha = 1$ and 2 correspond to the ‘reagents’ and ‘products’. Also let $\varphi_{\alpha v}$ be the reagent or product vibrational function. Then the asymptotic solution is

$$\Psi_{R' S' \rightarrow \infty} \sim \sum_{\alpha v} \varphi_{\alpha v}(v_\alpha)^{-1/2} \left(I_{\alpha v \alpha' v'} - \sum_{\alpha'' v''} S_{\alpha v \alpha'' v''} O_{\alpha'' v'' \alpha v} \right). \quad (\text{A3.11.103})$$

We have expressed Ψ in terms of Jacobi coordinates as this is the coordinate system in which the vibrations and translations are separable. The separation does not occur in hyperspherical coordinates except at $\rho = \infty$, so it is necessary to interrelate coordinate systems to complete the calculations. There are several approaches for doing this. One way is to project the hyperspherical solution onto Jacobi’s before performing the asymptotic analysis, i.e.

$$(\text{A3.11.104})$$

$$\rho^{-1/2} \sum_v \varphi_v(\eta) g_{vv'}(\rho) = \sum_v \varphi_v(r) G_{vv'}(R).$$

The \mathbf{G} matrix is then obtained by performing the quadrature

$$G_{vv'} = \int dr \varphi_v(r) \sum_{v''} \rho^{-1/2} \varphi_{v''}(\eta) g_{v''v'}(\rho) \quad (\text{A3.11.105})$$

where $\rho(R, r)$, $\eta(R, r)$ are to be substituted as needed into the right hand side.

A3.11.3.3 SCATTERING IN THREE DIMENSIONS

All the theory developed up to this point has been limited in the sense that translational motion (the continuum degree of freedom) has been restricted to one dimension. In this section we discuss the generalization of this to three dimensions for collision processes where space is isotropic (i.e., collisions in homogeneous phases, such as in a

-25-

vacuum, but not collisions with surfaces). We begin by considering collisions involving a single particle in three dimensions; the multichannel case is considered subsequently.

The biggest change associated with going from one to three dimensional translational motion refers to asymptotic boundary conditions. In three dimensions, the initial scattering wavefunction for a single particle is represented by a plane wave $e^{i\mathbf{k}\cdot\mathbf{r}}$ moving in a direction which we denote with the wavevector \mathbf{k} . Scattering then produces outgoing spherical waves as $t \rightarrow \infty$ weighted by an amplitude $f_k(\theta)$ which specifies the scattered intensity as a function of the angle θ between \mathbf{k} and the observation direction. Mathematically the time independent boundary condition analogous to [equation \(A3.11.13a\)](#), [equation \(A3.11.13b\)](#) is:

$$\psi_{\mathbf{k}}(\mathbf{r}) \underset{r \rightarrow \infty}{=} e^{i\mathbf{k}\cdot\mathbf{r}} + f_k(\theta) \frac{e^{ikr}}{r}. \quad (\text{A3.11.106})$$

Note that for potentials that depend only on the scalar distance r between the colliding particles, the amplitude $f_k(\theta)$ does not depend on the azimuthal angle associated with the direction of observation.

The measurable quantity in a three dimensional scattering experiment is the differential cross section $d\sigma_k(\theta)/d\Omega$. This is defined as

$$\frac{d\sigma_k(\theta)}{d\Omega} = \frac{|\text{outgoing radial flux}|}{|\text{total incident flux}|} \quad (\text{A3.11.107})$$

where outgoing flux refers to the radial velocity operator $\hat{v}_r = -i\hbar\partial/\partial r$. Substitution of [equation \(A3.11.106\)](#) into [\(A3.11.107\)](#) using [\(A3.11.16\)](#) yields

$$d\sigma_k(\theta)/d\Omega = |f_k(\theta)|^2. \quad (\text{A3.11.108})$$

It is convenient to expand $f_k(\theta)$ in a basis of Legendre polynomials $P_\ell(\cos \theta)$ (as these define the natural

angular eigenfunctions associated with motion in three dimensions). Here we write:

$$I(\theta) = \sum_n \frac{b_n}{\sin \theta} \left(\frac{db}{d\theta} \right)_n. \quad (\text{A3.11.109})$$

We call this a *partial wave expansion*. To determine the coefficients a_ℓ^k , one matches asymptotic solutions to the radial Schrödinger equation with the corresponding partial wave expansion of equation (A3.11.106). It is customary to write the asymptotic radial Schrödinger equation solution as

$$\psi_{\ell m}(r, \theta, \varphi) \underset{r \rightarrow \infty}{=} \frac{1}{r} Y_{\ell m}(\theta, \varphi) (e^{-i(kr - \ell\pi/2)} - S_\ell e^{i(kr - \ell\pi/2)}) \quad (\text{A3.11.110})$$

-26-

where S_ℓ is the scattering matrix for the ℓ th partial wave and m is the projection quantum number associated with ℓ . Unitarity of the scattering matrix implies that S_ℓ can be written as $\exp(2i\delta_\ell)$ where δ_ℓ is a real quantity known as the *phase shift*.

The asymptotic partial wave expansion of [equation \(A3.11.106\)](#) can be developed using the identity

$$e^{ik \cdot r} = e^{ikr \cos \theta} = \sum_{\ell=0}^{\infty} i^\ell (2\ell + 1) j_\ell(kr) P_\ell(\cos \theta) \quad (\text{A3.11.111})$$

where $j_\ell(kr)$ is a spherical Bessel function. At large r , the spherical Bessel function reduces to

$$j_\ell(kr) \underset{r \rightarrow \infty}{=} \frac{\sin(kr - \ell\pi/2)}{kr}. \quad (\text{A3.11.112})$$

If equation (A3.11.112) is then used to evaluate (A3.11.111) after substitution of the latter into [\(A3.11.106\)](#) and if [equation \(A3.11.109\)](#) is also substituted into [\(A3.11.106\)](#) and the result for each ℓ and m is equated to [\(A3.11.110\)](#), one finds that only $m = 0$ contributes, and that

$$a_\ell^k = \frac{(2\ell + 1)}{2ik} (S_\ell - 1). \quad (\text{A3.11.113})$$

From [equation \(A3.11.108\)](#), [equation \(A3.11.109\)](#) and [equation \(A3.11.113\)](#) one then finds

$$\frac{d\sigma_k(\theta)}{d\Omega} = \frac{1}{4k^2} \left| \sum_{\ell} (2\ell + 1) P_\ell(\cos \theta) (S_\ell - 1) \right|^2 \quad (\text{A3.11.114a})$$

$$= \frac{1}{k^2} \left| \sum_{\ell} (2\ell + 1) P_\ell(\cos \theta) e^{i\delta_\ell} \sin \delta_\ell \right|^2. \quad (\text{A3.11.114b})$$

This differential cross section may be integrated over scattering angles to define an integral cross section σ as follows:

$$\sigma = 2\pi \int_0^\pi \frac{d\sigma_\ell(\theta)}{d\Omega} \sin\theta d\theta = \frac{\pi}{k^2} \sum_\ell (2\ell + 1) |S_\ell - 1|^2 \quad (\text{A3.11.115a})$$

$$= \frac{4\pi}{k^2} \sum_\ell (2\ell + 1) \sin^2 \delta_\ell. \quad (\text{A3.11.115b})$$

-27-

Equations [A3.11.114\(b\)](#) and [A3.11.115\(b\)](#) are in a form that is convenient to use for potential scattering problems. One needs only to determine the phase shift δ_ℓ for each ℓ , then substitute into these equations to determine the cross sections. Note that in the limit of large ℓ , δ_ℓ must vanish so that the infinite sum over partial waves ℓ will converge. For most potentials of interest to chemical physics, the calculation of δ_ℓ must be done numerically.

Equation [A3.11.115\(a\)](#) is also useful as a form that enables easy generalization of the potential scattering theory that we have just derived to multistate problems. In particular, if we imagine that we are interested in the collision of two molecules A and B starting out in states n_A and n_B and ending up in states n'_A and n'_B , then the asymptotic wavefunction analogous to [equation \(A3.11.106\)](#) is

$$\psi_{n_A n_B \rightarrow n'_A n'_B} = \exp(i\mathbf{k}_{n_A n_B} \cdot \mathbf{r}) |n_A n_B\rangle + r^{-1} \sum_{n'_A n'_B} f_{n_A n_B \rightarrow n'_A n'_B}(\theta) \exp(i\mathbf{k}_{n'_A n'_B} \cdot \mathbf{r}) |n'_A n'_B\rangle \quad (\text{A3.11.116})$$

where the scattering amplitude f is now labelled by the initial and final state indices. Integral cross sections are then obtained using the following generalization of [equation A3.11.115\(a\)](#):

$$\sigma_{n_A n_B \rightarrow n'_A n'_B} = \frac{\pi}{k_{n_A n_B}^2} \sum_J (2J + 1) |S_{n_A n_B \rightarrow n'_A n'_B}^J - \delta_{n_A n_B, n'_A n'_B}|^2 \quad (\text{A3.11.117})$$

where S is the multichannel scattering matrix, δ is the Kronecker delta function and J is the total angular momentum (i.e., the vector sum of the orbital angular momentum ℓ plus the angular momenta of the molecules A and B). Here the sum is over J rather than ℓ , because ℓ is not a conserved quantity due to coupling with angular momenta in the molecules A and B.

A3.11.4 COMPUTATIONAL METHODS AND STRATEGIES FOR SCATTERING PROBLEMS

In this section we present several numerical techniques that are commonly used to solve the Schrödinger equation for scattering processes. Because the potential energy functions used in many chemical physics problems are complicated (but known to reasonable precision), new numerical methods have played an important role in extending the domain of application of scattering theory. Indeed, although much of the formal development of the previous sections was known 30 years ago, the numerical methods (and computers) needed to put this formalism to work have only been developed since then.

This section is divided into two sections: the first concerned with time-dependent methods for describing the evolution of wavepackets and the second concerned with time-independent methods for solving the time independent Schrödinger equation. The methods described are designed to be representative of what is in use,

but not exhaustive. More detailed discussions of time-dependent and time-independent methods are given in the literature [37, 38].

-28-

A3.11.4.1 TIME-DEPENDENT WAVEPACKET METHODS

(A) OVERALL STRATEGY

The methods described here are all designed to determine the time evolution of wavepackets that have been previously defined. This is only one of several steps for using wavepackets to solve scattering problems. The overall procedure involves the following steps:

- (a) First, choose an initial wavepacket $\psi(x,t)$ that describes the range of energies and initial conditions that we want to simulate and which is numerically as well behaved as possible. Typically, this is chosen to be a Gaussian function of the translational coordinate x , with mean velocity and width chosen to describe the range of interest. In making this choice, one needs to consider how the spatial part of the Schrödinger equation is to be handled, i.e., whether the dependence of the wavepacket on spatial coordinates is to be represented on a grid, or in terms of basis functions.
- (b) Second, one propagates this wavepacket in time using one of the methods described below, for a sufficient length of time to describe the scattering process of interest.
- (c) Third, one calculates the scattering information of interest, such as the outgoing flux.

Typically, the ratio of this to the incident flux determines the transition probability. This information will be averaged over the energy range of the initial wavepacket, unless one wants to project out specific energies from the solution. This projection procedure is accomplished using the following expression for the energy resolved (time-independent) wavefunction in terms of its time-dependent counterpart:

$$\psi^+(E) = \frac{1}{a(E)} \int_{-\infty}^{\infty} e^{iEt} \psi(t) dt \quad (\text{A3.11.118})$$

where

$$a(E) = \frac{1}{v^{1/2}} \langle e^{-ikR} | \psi(0) \rangle. \quad (\text{A3.11.119})$$

(B) SECOND ORDER DIFFERENCING

A very simple procedure for time evolving the wavepacket is the second order differencing method. Here we illustrate how this method is used in conjunction with a fast Fourier transform method for evaluating the spatial coordinate derivatives in the Hamiltonian.

If we write the time-dependent Schrödinger equation as $\partial\psi/\partial t = -(i/\hbar)\hat{H}\psi$, then, after replacing the time derivative by a central difference, we obtain

$$\frac{\partial\psi}{\partial t} = \frac{\psi(t + \Delta t) - \psi(t - \Delta t)}{2\Delta t}. \quad (\text{A3.11.120})$$

After rearranging this becomes

$$\psi(t + \Delta t) = \psi(t - \Delta t) - \frac{2i\Delta t}{\hbar} \hat{H} \psi(t). \quad (\text{A3.11.121})$$

To invoke this algorithm, we need to evaluate $\hat{H}\psi = (\hat{T} + \hat{V})\psi$. If ψ is represented on a uniform grid in coordinate x , an effective scheme is to use fast Fourier transforms (FFTs) to evaluate $\hat{T}\psi$. Thus, in one dimension we have, with n points on the grid,

$$\tilde{\psi}(k_j, t) = \sum_{m=1}^n e^{ik_j x_m} \psi(x_m, t) \quad (\text{A3.11.122})$$

where the corresponding momentum grid is

$$k_j = \frac{2\pi j}{n\Delta x}. \quad (\text{A3.11.123})$$

Differentiation of (A3.11.122) then gives

$$\hat{T} \tilde{\psi}(k_j, t) = \frac{p_j^2}{2m} \tilde{\psi}(k_j, t) \quad (\text{A3.11.124a})$$

where $p_j = \hbar k_j$. This expression can be inverted to give

$$\hat{T} \psi(x_\ell) = \frac{1}{n} \sum_{j=-n/2}^{n/2-1} e^{-ik_j x_\ell} \frac{p_j^2}{2m} \tilde{\psi}(k_j, t). \quad (\text{A3.11.124b})$$

This expression, in combination with (A3.11.122), determines the action of the kinetic energy operator on the wavefunction at each grid point. The action of \hat{V} is just $V(x_\ell)\psi(x_\ell)$ at each grid point.

(C) SPLIT-OPERATOR OR FEIT-FLECK METHOD

A more powerful method for evaluating the time derivative of the wavefunction is the split-operator method [39]. Here we start by formally solving $i\hbar\partial\psi/\partial t = \hat{H}\psi$ with the solution $\psi(t) = e^{-i\hat{H}t/\hbar}\psi(0)$. Note that H is assumed to be time-independent. Now imagine evaluating the propagator $e^{-i\hat{H}t/\hbar}$ over a short time interval.

$$e^{-i\hat{H}\Delta t/\hbar} = e^{-i(\hat{T}+\hat{V})\Delta t/\hbar} \approx e^{-i\hat{V}\Delta t/2\hbar} e^{-i\hat{T}\Delta t/\hbar} e^{-i\hat{V}\Delta t/2\hbar}. \quad (\text{A3.11.125})$$

Evidently, this formula is not exact if \hat{T} and \hat{V} do not commute. However for short times it is a good approximation, as can be verified by comparing terms in Taylor series expansions of the middle and right-hand expressions in (A3.11.125). This approximation is intrinsically unitary, which means that scattering information obtained from this calculation automatically conserves flux.

The complete propagator is then constructed by piecing together N time steps, leading to

$$e^{-i\hat{H}\Delta t/\hbar} = e^{-i\hat{V}\Delta t/2\hbar} e^{-i\hat{T}\Delta t/\hbar} e^{-i\hat{V}\Delta t/\hbar} \dots e^{-i\hat{V}\Delta t/\hbar} e^{-i\hat{T}\Delta t/\hbar} e^{-i\hat{V}\Delta t/2\hbar}. \quad (\text{A3.11.126})$$

To evaluate each term we can again do it on a grid, using FFTs as described above to evaluate $e^{-i\hat{T}\Delta t/\hbar}$.

(D) CHEBYSHEV METHOD

Another approach [40] is to expand $e^{-i\hat{H}\Delta t/\hbar}$ in terms of Chebyshev polynomials and to evaluate each term in the polynomial at the end of the time interval. Here a Chebyshev expansion is chosen as it gives the most uniform convergence in representing the exponential over the chosen time interval. The time interval Δt is typically chosen to be several hundred of the time steps that would be used in the second order differencing or split-operator methods. Although the Chebyshev method is not intrinsically unitary, it is capable of much higher accuracy than the second order differencing or split-operator methods [41].

In order to apply this method it is necessary to scale \hat{H} to lie in a certain finite interval which is usually chosen to be $(-1, 1)$. Thus, if V_{\max} and V_{\min} are estimates of the maximum and minimum potentials and T_{\max} is the maximum kinetic energy, we use

$$\hat{H}_{\text{norm}} = [\hat{H} - (R + V_{\min})]/R = \frac{\hat{H} - V_{\min}}{R} - 1 \quad (\text{A3.11.127})$$

where

$$R = (T_{\max} + V_{\max} - V_{\min})/2. \quad (\text{A3.11.128})$$

This choice restricts the range of values of \hat{H}_{norm} to the interval $(0, 1)$. Then the propagator becomes

$$e^{-i\hat{H}\Delta t/\hbar} = e^{-i\hat{H}_{\text{norm}}R\Delta t/\hbar} e^{-i(R+V_{\min})\Delta t/\hbar}. \quad (\text{A3.11.129})$$

Now we replace the first exponential in the right-hand side of (A3.11.129) by a Chebyshev expansion as follows:

$$e^{-i\hat{H}\Delta t/\hbar} = e^{-i(R+V_{\min})\Delta t/\hbar} \sum_{k=0}^N C_k J_k(R\Delta t/\hbar) i^k T_k(-\hat{H}_{\text{norm}}) \quad (\text{A3.11.130})$$

where T_k is a Chebyshev polynomial, and J_k is a Bessel function. The coefficients C_k are fixed at $C_0 = 1$, $C_k = 2$, $k < 0$.

To apply this method, the J_k are calculated once and stored while the T_k are generated using the recursion formula:

$$T_{k+1}(x) = 2xT_k(x) - T_{k-1}(x) \quad (\text{A3.11.131})$$

with $T_0 = 1$, $T_1 = x$. Actually the T_k are never explicitly stored, as all we really want is T_k operating onto a wavefunction. However, the recursion formula is still used to generate this, so the primary computational step involves \hat{H}_{norm} operating onto wavefunctions. This can be done using FFTs as discussed previously.

(E) SHORT ITERATIVE LANCZOS METHOD

Another approach involves starting with an initial wavefunction ψ_0 , represented on a grid, then generating $\hat{H}\psi_0$, and consider that this, after orthogonalization to ψ_0 , defines a new state vector. Successive applications \hat{H} can now be used to define an orthogonal set of vectors which defines as a *Krylov space* via the iteration: ($n = 0, \dots, N$)

$$\beta_{n+1}|\psi_{n+1}\rangle = (\hat{H} - \alpha_n)|\psi_n\rangle - \beta_n|\psi_{n-1}\rangle \quad (\text{A3.11.132})$$

where

$$\alpha_n = \langle \psi_n | \hat{H} | \psi_n \rangle \quad \beta_{n+1} = \langle \psi_n | \hat{H} | \psi_{n+1} \rangle. \quad (\text{A3.11.133})$$

The Hamiltonian in this vector space is

$$\mathbf{H} = \begin{pmatrix} \alpha_0 & \beta_1 & 0 & 0 & 0 \\ \beta_1 & \alpha_1 & \beta_2 & 0 & 0 \\ 0 & \beta_2 & \alpha_2 & \beta_3 & 0 \\ 0 & 0 & \beta_2 & \alpha_3 & \beta_4 \\ \cdot & \cdot & \cdot & \cdot & \cdot \end{pmatrix}. \quad (\text{A3.11.134})$$

Here \mathbf{H} forms an $N \times N$ matrix, where N is the dimensionality of the space and is generally much smaller than the number of grid points.

Now diagonalize \mathbf{H} , calling the eigenvalues λ_k and eigenvectors $T_{\ell k}$. Numerically, this is a very efficient process due to the tridiagonal form of (A3.11.134). The resulting eigenvalues and eigenvectors are then used to propagate for a short time Δt via

$$[\psi(t + \Delta t)]_j = [\psi_0^+(t)\psi_0(t)]_j^{1/2} \sum_{\ell=0}^N \sum_{k=0}^{\ell} \frac{(\psi(t)_\ell)_j}{[\psi(t)_\ell^+ \psi(t)_\ell]_j^{1/2}} T_{\ell k} e^{-i\lambda_k \Delta t/\hbar} T_{0k} \quad (\text{A3.11.135})$$

where $(\psi_\ell)_j$ are coefficients that transfer between the j th grid point and the ℓ th order Krylov space in (A3.11.132).

A3.11.4.2 TIME-INDEPENDENT METHODS

Here we discuss several methods that are commonly used to propagate coupled-channel equations, and we also present a linear algebra method for applying variational theory. The coupled-channel equations are coupled ordinary differential equations, so they can in principle be solved using any one of a number of standard methods for doing this (Runge–Kutta, predictor–corrector etc). However these methods are very inefficient for this application and a number of alternatives have been developed which take advantage of specific features of the problems being solved.

(A) GORDON-TYPE METHODS

In many kinds of atomic and molecular collision problem the wavefunction has many oscillations because the energy is high (i.e., $g(R) \approx e^{ikR}$ and k is large). In this case it is useful to expand $g(R)$ in terms of oscillatory solutions to some reference problem that is similar to the desired one and then regard the expansion coefficients as the quantity being integrated, thereby removing most or all of the oscillations from the time dependence of the coefficients.

For example, suppose that we divide coordinate space into steps ΔR , then evaluate \mathbf{U} (in equation (A3.11.61)) at the middle of each step and regard this as the reference for propagation within this step. Further, let us diagonalize \mathbf{U} , calling the eigenvalues u_k and eigenvectors \mathbf{T} . Then, as long as the variation in eigenvalues and eigenvectors can be neglected in each step, the Schrödinger equation solution within each step is easily expressed in terms of sin and cos $w_k \Delta R$, where $w_k = \sqrt{-u_k}$ (or exponential solutions if $u_k < 0$). In particular, if $\mathbf{g}(R_0)$ is the solution at the beginning of each step, then $\mathbf{T}\mathbf{g}$ transforms into the diagonalized representation and $\mathbf{T}\mathbf{g}'$ is the corresponding derivative. The complete solution at the end of each step would then be

$$\mathbf{g}(R_1) = \mathbf{T}^{-1}(\mathbf{w}^{-1} \sin(\mathbf{w}\Delta R)\mathbf{T}\mathbf{g}'(R_0) + \cos(\mathbf{w}\Delta R)\mathbf{T}\mathbf{g}(R_0)) \quad (\text{A3.11.136})$$

$$\mathbf{g}'(R_1) = \mathbf{T}^{-1}(\cos(\mathbf{w}\Delta R)\mathbf{T}\mathbf{g}'(R_0) - \mathbf{w} \sin(\mathbf{w}\Delta R)\mathbf{T}\mathbf{g}(R_0)). \quad (\text{A3.11.137})$$

In principle, one can do better by allowing for R -dependence to \mathbf{U} and \mathbf{T} . If we allow them to vary linearly with R , then we have Gordon's method [42]. However, the higher order evaluation in this case leads to a much more cumbersome theory that is often less efficient even though larger steps can be used.

One problem with using this method (or any method that propagates ψ) is that in regions where $u_k > 0$, the so-called 'closed' channels, the solutions increase exponentially. If such solutions exist for some channels while others are still open, the closed-channel solutions can become numerically dominant (i.e., so much bigger that they overwhelm the open-channel solutions to within machine precision and, after a while, all channels propagate as if they are closed).

To circumvent this, it is necessary to 'stabilize' the solutions periodically. Typically this is done by multiplying $\mathbf{g}(R)$ and $\mathbf{g}'(R)$ by some matrix \mathbf{h} that 'orthogonalizes' the solutions as best one can. For example, this can be done using $\mathbf{h} = \mathbf{g}^{-1}(R_s)$ where R_s is the value of R at the end of the 'current' step. Thus, after stabilization, the new \mathbf{g} and \mathbf{g}' are:

$$\mathbf{g}_{\text{new}}(R_s) = \mathbf{g}_{\text{old}}(R_s)\mathbf{g}_{\text{old}}^{-1}(R_4) = \mathbf{I} \quad (\text{A3.11.138})$$

$$\mathbf{g}'_{\text{new}}(R_s) = \mathbf{g}'_{\text{old}}(R_s)\mathbf{g}_{\text{old}}^{-1}(R_4). \quad (\text{A3.11.139})$$

One consequence of performing the stabilization procedure is that the initial conditions that correspond to the current $\mathbf{g}(R)$ are changed each time stabilization is performed. However this does not matter as long the initial $\mathbf{g}(R)$ value corresponds to the limit $R \rightarrow 0$ as then all one needs is for $\mathbf{g}(R)$ to be small (i.e., the actual value is not important).

(B) LOG DERIVATIVE PROPAGATION

One way to avoid the stabilization problem just mentioned is to propagate the log derivative matrix $\mathbf{Y}(R)$ [43]. This is defined by

$$\mathbf{Y}(R) = \mathbf{g}'(R)\mathbf{g}^{-1}(R) \quad (\text{A3.11.140})$$

and it remains well behaved numerically even when $\mathbf{g}(R)$ grows exponentially. The differential equation obeyed by \mathbf{Y} is

$$\mathbf{Y}'(R) = \mathbf{g}''(R)\mathbf{g}^{-1}(R) - \mathbf{g}'(R)\mathbf{g}^{-1}(R)\mathbf{g}'(R)\mathbf{g}^{-1}(R) = \mathbf{U}\mathbf{g}(R)\mathbf{g}^{-1}(R) - \mathbf{Y}^2(R) = \mathbf{U} - \mathbf{Y}^2(R). \quad (\text{A3.11.141})$$

It turns out that one cannot propagate \mathbf{Y} using standard numerical methods because $|\mathbf{Y}|$ blows up whenever $|\mathbf{g}|$ is zero. To circumvent this one must propagate \mathbf{Y} by ‘invariant imbedding’. The basic idea here is to construct a propagator \mathbf{Y} which satisfies

$$\begin{pmatrix} \mathbf{g}'(R') \\ \mathbf{g}'(R'') \end{pmatrix} = \begin{pmatrix} \mathbf{Y}_1(R', R'') & \mathbf{Y}_2(R', R'') \\ \mathbf{Y}_3(R', R'') & \mathbf{Y}_4(R', R'') \end{pmatrix} \begin{pmatrix} -\mathbf{g}(R') \\ \mathbf{g}(R'') \end{pmatrix} \quad (\text{A3.11.142})$$

where R' and R'' might form the beginning and end of a propagation step. Assuming for the moment that we know what the \mathbf{Y}_i are, then the evolution of \mathbf{Y} is as follows

$$\mathbf{Y}(R'') = \mathbf{g}'(R'')\mathbf{g}^{-1}(R'') = -\mathbf{Y}_3\mathbf{g}(R')\mathbf{g}^{-1}(R'') + \mathbf{Y}_4\mathbf{g}(R'')\mathbf{g}^{-1}(R'') \quad (\text{A3.11.143})$$

$$\mathbf{Y}(R') = \mathbf{g}'(R')\mathbf{g}^{-1}(R') = -\mathbf{Y}_1\mathbf{g}(R')\mathbf{g}^{-1}(R') + \mathbf{Y}_2\mathbf{g}(R'')\mathbf{g}^{-1}(R'). \quad (\text{A3.11.144})$$

So the overall result is

$$\mathbf{Y}(R'') = \mathbf{Y}_4 - \mathbf{Y}_3[\mathbf{Y}(R') + \mathbf{Y}_1]^{-1}\mathbf{Y}_2. \quad (\text{A3.11.145})$$

To solve for the \mathbf{Y} , we begin by solving a reference problem wherein the coupling matrix is assumed diagonal with constant couplings within each step. (These could be accomplished by diagonalizing \mathbf{U} , but it would be better to avoid this work and use the diagonal \mathbf{U} matrix elements.) Then, in terms of the reference \mathbf{U} (which we call \mathbf{U}_d), we have

$$\mathbf{g}(R_1) = \mathbf{U}_d^{-1} \sin(\mathbf{U}_d \Delta R) \mathbf{g}'(R_0) + \cos(\mathbf{U}_d \Delta R) \mathbf{g}(R_0) \quad (\text{A3.11.146})$$

$$\mathbf{g}'(R_1) = \cos \mathbf{U}_d \Delta R \mathbf{g}'(R_0) - \mathbf{U}_d \sin \mathbf{U}_d \Delta R \mathbf{g}(R_0) \quad (\text{A3.11.147})$$

Now rearrange these to:

$$\mathbf{g}'(R_0) = \mathbf{U}_d (\sin^{-1} \mathbf{U}_d \Delta R)^{-1} \mathbf{g}(R_1) - \mathbf{U}_d \cot \mathbf{U}_d \Delta R \mathbf{g}(R_0) \quad (\text{A3.11.148})$$

$$\mathbf{g}'(R_1) = \mathbf{U}_d \cot \mathbf{U}_d \Delta R \mathbf{g}(R_1) - \mathbf{U}_d (\sin \mathbf{U}_d \Delta R)^{-1} \mathbf{g}(R_0) \quad (\text{A3.11.149})$$

which can be written:

$$\begin{pmatrix} \mathbf{g}'(R_0) \\ \mathbf{g}'(R_1) \end{pmatrix} = \begin{pmatrix} \mathbf{U}_d \cot \mathbf{U}_d \Delta R & \mathbf{U}_d (\sin \mathbf{U}_d \Delta R)^{-1} \\ \mathbf{U}_d (\sin \mathbf{U}_d \Delta R)^{-1} & \mathbf{U}_d \cot \mathbf{U}_d \Delta R \end{pmatrix} \begin{pmatrix} -\mathbf{g}(R_0) \\ \mathbf{g}(R_1) \end{pmatrix}. \quad (\text{A3.11.150})$$

Note that $|\mathbf{U}_d \Delta R| < 0$ is required for meaningful results and thus ΔR cannot be too large. By comparing equation (A3.11.142) and equation (A3.11.150), we find:

$$\mathbf{Y}_1 = \mathbf{Y}_4 = \mathbf{U}_d \cot \mathbf{U}_d \Delta R \quad (\text{A3.11.151})$$

$$\mathbf{Y}_2 = \mathbf{Y}_3 = \mathbf{U}_d (\sin \mathbf{U}_d \Delta R)^{-1}. \quad (\text{A3.11.152})$$

The standard log-derivative propagator now corrects for the difference between \mathbf{U} and \mathbf{U}_d using a Simpson-rule integration. The specific formulas are

$$\mathbf{y}_1 \rightarrow \mathbf{y}_1 + \mathbf{Q}(R_0) \quad (\text{A3.11.153})$$

$$\mathbf{y}_2 \rightarrow \mathbf{y}_2 \quad (\text{A3.11.154})$$

$$\mathbf{y}_3 \rightarrow \mathbf{y}_3 \quad (\text{A3.11.155})$$

$$\mathbf{y}_4 \rightarrow \mathbf{y}_4 + \mathbf{Q}(R_1). \quad (\text{A3.11.156})$$

Then for a step divided into two halfsteps, at $R = a, c, b$, write $c = 1/2(a+b)$, $\Delta R = (b-a)/2$, $\Delta \mathbf{u} = \mathbf{U} - \mathbf{U}_d$, $a = R_0$, $b = R_1$. This leads to the following expression for \mathbf{Q} :

$$\mathbf{Q}(a) = \frac{\Delta R}{e} \Delta \mathbf{u}(a) \quad (\text{A3.11.157})$$

$$\mathbf{Q}(c) = \frac{1}{2} \left(1 - \frac{\Delta R^2}{6} \Delta \mathbf{u}(c) \right)^{-1} \frac{4\Delta R}{3} \Delta \mathbf{u}(c) \quad (\text{A3.11.158})$$

$$\mathbf{Q}(b) = \frac{\Delta R}{3} \Delta \mathbf{u}(b). \quad (\text{A3.11.159})$$

Propagation then proceeds from $R \rightarrow 0$ to large R , then the scattering matrix is easily connected to \mathbf{Y} at large R .

(C) VARIATIONAL CALCULATIONS

Now let us return to the Kohn variational theory that was introduced in [section A3.11.2.8](#). Here we demonstrate how [equation \(A3.11.46\)](#) may be evaluated using basis set expansions and linear algebra. This discussion will be restricted to scattering in one dimension, but generalization to multidimensional problems is very similar.

To construct $\tilde{\Psi}$, we use the basis expansion

$$\tilde{\Psi} = -u_0 + \sum_{t=1}^N u_t(r) C_t \quad (\text{A3.11.160})$$

where $u_0(r)$ is a special basis function which asymptotically looks like $u_0(r) \sim v^{-1/2} e^{-ikr}$, and $\mathbf{u}_1 = \mathbf{u}_0^*$ is the outgoing wavepart, multiplied by a coefficient C_1 which is \tilde{S} . Typically the complete form of u_0 is chosen to be

$$u_0 = v^{-1/2} f(r) e^{-ikr} \quad (\text{A3.11.161})$$

where $f(r)$ is a function which is unity at larger r and vanishes at small r . The functions u_2, u_3, \dots are taken to be square integrable and the coefficients C_1, \dots, C_N are to be variationally modified. Now substitute $\tilde{\Psi}$ into the expression for S . This gives

$$\begin{aligned} S &= \tilde{S} + \frac{i}{\hbar} \left\langle -u_0 + \sum_t u_t C_t \left| \hat{H} - E \right| -u_0 + \sum_t u_t C_t \right\rangle \\ &= \tilde{S} + \frac{i}{\hbar} \langle u_0 | \hat{H} - E | u_0 \rangle - \frac{i}{\hbar} \sum_t \langle u_0 | \hat{H} - E | u_t \rangle C_t \\ &\quad - \frac{i}{\hbar} \sum_t \langle u_t | \hat{H} - E | u_0 \rangle C_t + \frac{i}{\hbar} \sum_t \sum_{t'} \langle u_t | \hat{H} - E | u_{t'} \rangle C_t C_{t'}. \end{aligned} \quad (\text{A3.11.162})$$

Let us define a matrix \mathbf{M} via

$$M_{0,0} = \langle u_0 | \hat{H} - E | u_0 \rangle \quad (\text{A3.11.163})$$

$$(M_0)_t = \langle u_t | \hat{H} - E | u_0 \rangle \quad (\text{A3.11.164})$$

$$(M)_{t,t'} = \langle u_t | \hat{H} - E | u_{t'} \rangle. \quad (\text{A3.11.165})$$

Also, employ integration by parts to convert (plus $\tilde{S} = C_1$), yielding

$$\frac{-i}{\hbar} \sum_t \langle u_0 | \hat{H} - E | u_t \rangle C_t = \frac{-i}{\hbar} \sum_t \langle u_t | \hat{H} - E | u_0 \rangle C_t - \frac{-i}{\hbar} (i\hbar \tilde{S}). \quad (\text{A3.11.166})$$

This replaces (A3.11.162) with

$$S = \frac{i}{\hbar} \left(M_{0,0} - 2 \sum_t C_t M_{t,0} + \sum_{t,t'} C_t C_{t'} M_{t,t'} \right). \quad (\text{A3.11.167})$$

Now apply the variational criterion as follows:

$$\frac{\partial}{\partial C_t} S = 0 = \frac{i}{\hbar} \left(-2M_{t,0} + 2 \sum_{t'} C_{t'} M_{t,t'} \right). \quad (\text{A3.11.168})$$

This leads to:

$$\mathbf{M}\mathbf{C} = M_0 \quad (\text{A3.11.169})$$

and thus:

$$\mathbf{C} = \mathbf{M}^{-1} M_0 \quad (\text{A3.11.170})$$

and the S matrix is given by:

$$S = \frac{i}{\hbar} (M_{0,0} - 2M_0^+ \mathbf{M}^{-1} M_0 + M_0^+ \mathbf{M}^{-1} \mathbf{M} \mathbf{M}^{-1} M_0) = \frac{i}{\hbar} (M_{0,0} - M_0^+ \mathbf{M}^{-1} M_0). \quad (\text{A3.11.171})$$

This converts the calculation of S to the evaluation of matrix elements together with linear algebra operations. Generalizations of this theory to multichannel calculations exist and lead to a result of more or less the same form.

A3.11.5 CUMULATIVE REACTION PROBABILITIES

A special feature of quantum scattering theory as it applies to chemical reactions is that in many applications

it is only the cumulative reaction probability (CRP) that is of interest in determining physically measurable properties such as the reactive rate constant. This probability P_{cum} (also denoted $N(E)$) is obtained from the S matrix through the formula:

$$P_{\text{cum}} = \sum_i \sum_f |S_{if}|^2. \quad (\text{A3.11.172})$$

Note that the sums are restricted to the portion of the full S matrix that describes reaction (or the specific reactive process that is of interest). It is clear from this definition that the CRP is a highly averaged property where there is no information about individual quantum states, so it is of interest to develop methods that determine this probability directly from the Schrödinger equation rather than indirectly from the scattering matrix. In this section we first show how the CRP is related to the physically measurable rate constant, and then we discuss some rigorous and approximate methods for directly determining the CRP. Much of this discussion is adapted from Miller and coworkers [44, 45].

A3.11.5.1 RATE CONSTANTS

Consider first a gas phase bimolecular reaction ($A + B \rightarrow C + D$). If we consider that the reagents are approaching each other with a relative velocity v , then the total flux of A moving toward B is just vC_A where C_A is the concentration of A (number of A per unit volume (or per unit length in one dimension)). If σ is the integral cross section for reaction between A and B for a given velocity v (σ is the reaction probability in one dimension), then for every B, the number of reactive collisions per unit time is $\sigma v C_A$. The total number of reactive collisions per unit time per unit volume (or per unit length in one dimension) is then $\sigma v C_A C_B$ where C_B is the concentration of B. Equating this to the rate constant k times $C_A C_B$ leads us to the conclusion that

$$k = \sigma v. \quad (\text{A3.11.173})$$

This rate constant refers to reactants which all move with a velocity v whereas the usual situation is such that we have a Boltzmann distribution of velocities. If so then the rate constant is just the average of (A3.11.173) over a Boltzmann distribution P_B :

$$k(T) = \int_0^\infty P_B(v) v \sigma(v) dv. \quad (\text{A3.11.174})$$

This expression is still oversimplified, as it ignores the fact that the molecules A and B have internal states and that the cross section σ depends on these states; σ depends also on the internal states of the products C and D. Letting the indices i and f denote the internal states of the reagents and products respectively, we find that σ in equation (A3.11.174) must be replaced by $\sum_f \sigma_{if}$ and the Boltzmann average must now include the internal states.

Thus, equation (A3.11.174) becomes:

$$k(T) = \sum_i p_B(i) \int_0^\infty P_B(v_i) v_i \sum_f \sigma_{if}(v_i) dv_i$$

where $p_B(i)$ is the internal state Boltzmann distribution.

Now let us write down explicit expressions for $p_B(i)$, $P_B(v_i)$ and σ_{if} . Denoting the internal energy for a given state i as ε_i and the relative translational energy as $E_i = 1/2\mu v_i^2$, we have (in three dimensions)

$$p_B(i) = e^{-\varepsilon_i/kT} / Q_{\text{int}} \quad (\text{A3.11.176})$$

and

$$P_B = 4\pi(\mu/2\pi kT)^{3/2} v_i^2 \exp(-\mu v_i^2/2kT) \quad (\text{A3.11.177})$$

where Q_{int} is the internal state partition function.

The cross section σ_{if} is related to the partial wave reactive scattering matrix $\times S_{if}^J$ through the partial wave sum (i.e., [equation \(A3.11.117\)](#) evaluated for $n_A n_B \neq n_A n_B$).

$$\sigma_{if} = \frac{\pi}{k_i^2} \sum_J (2J+1) |S_{if}^J|^2 \quad (\text{A3.11.178})$$

where $k_i = \mu v_i / \hbar$. Now substitute [equation \(A3.11.176\)](#), [equation \(A3.11.177\)](#) and [equation \(A3.11.178\)](#) into [\(A3.11.175\)](#). Replacing the integral over v_i by one over E_i leads us to the expression

$$k(T) = \frac{(2\pi\hbar)^2}{Q_{\text{int}}(2\pi\mu kT)^{3/2}} \sum_i e^{-\varepsilon_i/kT} \int_0^\infty e^{-E_i/kT} \sum_J (2J+1) \sum_f |S_{if}^J|^2 dE_i. \quad (\text{A3.11.179})$$

If we now change the integration variable from E_i to the total energy $E = E_i + \varepsilon_i$, we can rewrite [equation \(A3.11.179\)](#) as

$$k(T) = \frac{kT}{h} \frac{1}{Q_{\text{int}} Q_{\text{trans}}} \int_0^\infty e^{-E/kT} P_{\text{cum}}(E) dE/kT \quad (\text{A3.11.180})$$

where Q_{trans} is the translational partition function per unit volume:

$$Q_{\text{trans}} = \left(\frac{2\pi\mu kT}{h^2} \right)^{3/2} \quad (\text{A3.11.181})$$

and P_{cum} is the cumulative reaction probability that we wrote down in [equation \(A3.11.172\)](#), but generalized to include a sum over the conserved total angular momentum J weighted by the usual $2J + 1$ degeneracy:

$$P_{\text{cum}}(E) = \sum_J (2J + 1) \sum_i \sum_f |S_{if}^J|^2. \quad (\text{A3.11.182})$$

Note that in deriving [equation \(A3.11.180\)](#), we have altered the lower integration limit in [equation \(A3.11.182\)](#) from zero to $-\varepsilon_i$ by defining S_{if}^J to be zero for $E_i < 0$.

In one physical dimension, [equation \(A3.11.180\)](#) still holds, but Q_{trans} is given by its one dimensional counterpart and [\(A3.11.172\)](#) is used for the CRP.

A3.11.5.2 TRANSITION STATE THEORY

The form of [equation \(A3.11.182\)](#) is immediately suggestive of statistical approximations. If we assume that the total reaction probability $\sum_f |S_{if}^J|^2$ is zero for $E < E_i^\ddagger$ and unity for $E \geq E_i^\ddagger$ where E_i^\ddagger is the energy of a critical bottleneck (commonly known as the transition state) then

$$P_{\text{cum}}^\ddagger = \sum_J (2J + 1) \sum_i h(E - E_i^\ddagger) \quad (\text{A3.11.183})$$

where h is a Heaviside (step) function which is unity for positive arguments and zero for negative arguments, and we have added the subscript i to E_i^\ddagger since the bottleneck energies will in general be dependent on internal state.

[Equation \(A3.11.183\)](#) is simply a formula for the number of states energetically accessible at the transition state and [equation \(A3.11.180\)](#) leads to the thermal average of this number. If we imagine that the states of the system form a continuum, then $P_{\text{cum}}^\ddagger(E)$ can be expressed in terms of a density of states ρ as in

$$P_{\text{cum}}^\ddagger(E) = \int_0^E \rho^\ddagger(\varepsilon) d\varepsilon. \quad (\text{A3.11.184})$$

Substituting this into the integral in [equation \(A3.11.180\)](#) and inverting the order of integration, one obtains

-40-

$$\int_0^\infty e^{-E/kT} \left(\int_0^E \rho^\ddagger(\varepsilon) d\varepsilon \right) dE/kT = \int_0^\infty \rho^\ddagger(\varepsilon) \left(\int_\varepsilon^\infty e^{-E/kT} dE/kT \right) d\varepsilon. \quad (\text{A3.11.185})$$

The inner integral on the right-hand side is just $e^{-\varepsilon/kT}$, so [equation \(A3.11.185\)](#) reduces to the transition state partition function (leaving out relative translation):

$$Q^\ddagger = \int_0^\infty e^{-\varepsilon/kT} \rho^\ddagger(\varepsilon) d\varepsilon. \quad (\text{A3.11.186})$$

Using this in [equation \(A3.11.180\)](#) gives the following

$$k(T) = \frac{kT}{h} \frac{Q^\ddagger}{Q_{\text{int}} Q_{\text{trans}}}. \quad (\text{A3.11.187})$$

This is commonly known as the *transition state theory* approximation to the rate constant. Note that all one needs to do to evaluate (A3.11.187) is to determine the partition function of the reagents and transition state, which is a problem in statistical mechanics rather than dynamics. This makes transition state theory a very useful approach for many applications. However, what is left out are two potentially important effects, tunnelling and barrier recrossing, both of which lead to CRPs that differ from the sum of step functions assumed in [\(A3.11.183\)](#).

A3.11.5.3 EXACT QUANTUM EXPRESSIONS FOR THE CUMULATIVE REACTION PROBABILITY

An important development in the quantum theory of scattering in the last 20 years has been the development of exact expressions which directly determine either $P_{\text{cum}}(E)$ or the thermal rate constant $k(T)$ from the Hamiltonian H . Formally, at least, these expressions avoid the determination of scattering wavefunctions and any information related to the internal states of the reagents or products. The fundamental derivations in this area have been presented by Miller [44] and by Schwartz *et al* [45].

The basic expression of $P_{\text{cum}}(E)$ is

$$P_{\text{cum}}(E) = \frac{1}{2} (2\pi\hbar)^2 \text{Tr}[\hat{F} \delta(E - \hat{H}) \hat{F} \delta(E - \hat{H})] \quad (\text{A3.11.188})$$

where \hat{F} is the symmetrized flux operator:

$$\hat{F} = \frac{1}{2} \left\{ \frac{\hat{p}}{m} \delta(s) + \delta(s) \frac{\hat{p}}{m} \right\}. \quad (\text{A3.11.189})$$

Note that [equation \(A3.11.188\)](#) includes a quantum mechanical trace, which implies a sum over states. The states used for this evaluation are arbitrary as long as they form a complete set and many choices have been considered in recent work. Much of this work has been based on wavepackets [46] or grid point basis functions [47].

An exact expression for the thermal rate constant is given by:

$$k = Q^{-1} \int_0^\infty dt C_f(t) \quad (\text{A3.11.190})$$

where $C_f(t)$ is a flux–flux correlation function

$$C_f(t) = \text{Tr}(\hat{F} e^{i\hat{H}t_c/\hbar} \hat{F} e^{-i\hat{H}t_c/\hbar}). \quad (\text{A3.11.191})$$

Here t_c is a complex time which is given by $t_c = t - i\hbar/2kT$. Methods for evaluating this equation have included path integrals [45], wavepackets [48, 49] and direct evaluation of the trace in square integrable basis sets [50].

A3.11.6 CLASSICAL AND SEMICLASSICAL SCATTERING THEORY

Although the primary focus of this article is on quantum scattering theory, it is important to note that classical and semiclassical approximations play an important role in the application of scattering theory to problems in chemical physics. The primary reason for this is that the de Broglie wavelength associated with motions of atoms and molecules is typically short compared to the distances over which these atoms and molecules move during a scattering process. There are exceptions to this of course, in the limits of low temperature and energy, and for light atoms such as hydrogen atoms, but for a very broad sampling of problems the dynamics is close to the classical limit.

A3.11.6.1 CLASSICAL SCATTERING THEORY FOR A SINGLE PARTICLE

Consider collisions between two molecules A and B. For the moment, ignore the structure of the molecules, so that each is represented as a particle. After separating out the centre of mass motion, the classical Hamiltonian that describes this problem is

$$H = \frac{1}{2}\mu \dot{r}^2 + V(r) \quad (\text{A3.11.192})$$

where the reduced mass is $\mu = m_A m_B / (m_A + m_B)$ and the potential V only depends on the distance r between the particles. Because of the spherical symmetry of the potential, motion of the system is confined to a plane. It is convenient to use polar coordinates, r, θ, ϕ and to choose the plane of motion such that $\phi = 0$. In this case the orbital angular momentum is:

$$|L| = |r \times p_r| = \mu r^2 \dot{\theta}. \quad (\text{A3.11.193})$$

-42-

Since angular momentum is conserved, [equation \(A3.11.192\)](#) may be rearranged to give the following implicit equation for the time dependence of r :

$$\int_{r_1}^{r_2} \frac{dr}{\sqrt{(E - L^2/2\mu r^2 - V)2/\mu}} = t_2 - t_1. \quad (\text{A3.11.194})$$

The time dependence of θ can then be obtained by integrating [\(A3.11.193\)](#).

The physical situation of interest in a scattering problem is pictured in [figure A3.11.3](#). We assume that the initial particle velocity v is coincident with the z axis and that the particle starts at $z = -\infty$, with $x = b = \text{impact parameter}$, and $y = 0$. In this case, $L = \mu v b$. Subsequently, the particle moves in the x, z plane in a trajectory that might be as pictured in [figure A3.11.4](#) (here shown for a hard sphere potential). There is a point of closest approach, i.e., $r = r_2$ (inner turning point for r motions) where

$$E = \frac{L^2}{2\mu r_{\infty}^2} + V(r_{\infty}). \quad (\text{A3.11.195})$$

If we define $t_1 = 0$ at $r = r_{\infty}$, then the explicit trajectory motion is determined by

$$t = \int_{r_{\infty}}^{r(t)} \frac{dr}{\sqrt{(E - L^2/2\mu r^2 - V(r))2/\mu}} \quad (\text{A3.11.196})$$

$$\theta(t) = \pi + L \int_{-\infty}^t \frac{dr}{\mu r(t')^2}. \quad (\text{A3.11.197})$$

The final scattering angle θ is defined using $\theta = \theta(t = \infty)$. There will be a correspondence between b and θ that will tend to look like what is shown in [figure A3.11.5](#) for a repulsive potential (here given for the special case of a hard sphere potential).

Figure A3.11.3. Coordinates for scattering of a particle from a central potential.

Figure A3.11.4. Trajectory associated with a particle scattering off a hard sphere potential.

-44-

Figure A3.11.5. Typical dependence of b on τ (shown for a hard sphere potential).

In an ensemble of collisions, the impact parameters are distributed randomly on a disc with a probability distribution $P(b)$ that is defined by $P(b) db = 2\pi b db$. The *cross section* $d\sigma$ is then defined by

$$d\sigma = 2\pi b db. \quad (\text{A3.11.198})$$

Now $d\sigma = (d\sigma/d\Omega) d\Omega$ or $(d\sigma/2\pi d \cos\theta) 2\pi d \cos\theta = [d\sigma/2\pi d(\cos\theta)] 2\pi \sin\theta d\theta = I(\omega) 2\pi \sin\theta d\theta$ where $I(\omega)$ is the differential cross section. Therefore

$$I(\omega) = \frac{b db}{\sin\theta d\theta} = \frac{b}{\sin\theta} \left| \frac{db}{d\theta} \right| \quad (\text{A3.11.199})$$

where the absolute value takes care of the case when $db/d\theta < 0$. The integral cross section is

$$\sigma = 2\pi \int_0^\pi I \sin\theta d\theta = 2\pi \int_0^{b_{\max}} b db \quad (\text{A3.11.200})$$

-45-

where b_{\max} is the value of the impact parameter that is associated with a scattering angle of 0 (i.e., scattering in the forward direction). Note that for a potential with infinite range (one that does not go to zero until $r = \infty$), the cross section predicted by (A3.11.200) is infinite. This is not generally correct, except for a Coulomb ($1/r$) potential. This is a classical artifact; the corresponding quantum mechanical result is finite.

A simple example of a finite range potential is the *hard sphere*, for which $V(r) = 0$ for $r > a$, $V(r) = \infty$ for $r < a$. By geometry one can show that $2\phi + \theta = \pi$ and $\sin\phi = b/a$. Therefore

$$b = a \sin\left(\frac{\pi}{2} - \frac{\theta}{2}\right) = a \cos\theta/2 \quad (\text{A3.11.201})$$

$$\frac{db}{d\theta} = \frac{-a}{2} \sin\theta/2 \quad (\text{A3.11.202})$$

$$I(\omega) = \frac{a \cos\theta/2 (a/2) \sin\theta/2}{\sin\theta} = \frac{a^2}{4} \quad (\text{A3.11.203})$$

and

$$\sigma = 2\pi \frac{a^2}{4} \int \sin\theta d\theta = \pi a^2. \quad (\text{A3.11.204})$$

This shows that the differential cross section is independent of angle for this case, and the integral cross section is, just as expected, the area of the circle associated with the radius of the sphere. More generally it is important to note that there can be many trajectories which give the same θ for different b' . In this case the DCS is just the sum over trajectories.

$$f_k(\theta) = \sum_l a_l^k P_l(\cos\theta). \quad (\text{A3.11.205})$$

An explicit result for the differential cross section (DCS) can be obtained by substituting $L = pb = \mu vb$ into the

following expression:

$$\frac{\dot{\theta}}{\dot{r}} = \frac{d\theta}{dr} = \frac{L/\mu r^2}{\sqrt{(2/\mu)(E - V - L^2/2\mu r^2)}} = \frac{b/r^2}{\sqrt{(1 - V/E - (2\mu E)b^2/2\mu E r^2)}} \quad (\text{A3.11.206})$$

$$= \frac{b/r^2}{\sqrt{1 - V/E - b^2/r^2}}$$

To integrate this expression, we note that θ starts at π when $r = \infty$, then it decreases while r decreases to its turning point, then r retraces back to ∞ while θ continues to evolve back to π . The *total change* in θ is then *twice* the integral

-46-

$$\theta = \pi - 2b \int_{r_c}^{\infty} \frac{dr}{r^2} \left(1 - \frac{V}{E} - \frac{b^2}{r^2}\right)^{-1/2}. \quad (\text{A3.11.207})$$

Note that θ obtained this way can be negative. Because of cylindrical symmetry, only $|\theta|$ (or $\theta \bmod \pi$) means anything.

For a typical interatomic potential such as a 6-12 potential, $\theta(b)$ looks like figure A3.11.6 rather than A3.11.5. This shows that for some θ there are three b (one for positive θ and two for negative θ) that contribute to the DCS. The θ where the number of contributing trajectories changes value are sometimes called *rainbow angles*. At these angles, the classical differential cross sections have singularities.

Figure A3.11.6. Dependence of scattering angle τ on impact parameter for a 6-12 potential.

To generalize what we have just done to reactive and inelastic scattering, one needs to calculate numerically integrated trajectories for motions in many degrees of freedom. This is most convenient to develop in space-fixed Cartesian coordinates. In this case, the classical equations of motion (Hamilton's equations) are given by:

$$\dot{x}_i = \frac{\partial H}{\partial p_i} = \frac{p_i}{m_i} \quad (\text{A3.11.208})$$

-47-

$$\dot{p}_i = \frac{\partial H}{\partial x_i} = -\frac{\partial V}{\partial x_i} \quad (\text{A3.11.209})$$

where m_i is the mass associated with the i th degree of freedom and the second equality applies to Cartesian coordinates. Methods for solving these equations of motion have been described in review articles, as have procedures for defining initial conditions [27]. Note that for most multidimensional problems it is necessary to average over initial conditions that represent the internal motions of the species undergoing collision. These averages are often determined by Monte Carlo integration (i.e., randomly sampling the coordinates that need to be averaged over). The initial conditions may be chosen from canonical or microcanonical ensembles, or they may be chosen to mimic an initially prepared quantum state. In the latter case, the trajectory calculation is called a 'quasiclassical' trajectory calculation.

A3.11.6.3 SEMICLASSICAL THEORY

The obvious defect of classical trajectories is that they do not describe quantum effects. The best known of these effects is tunnelling through barriers, but there are others, such as effects due to quantization of the reagents and products and there are a variety of interference effects as well. To circumvent this deficiency, one can sometimes use semiclassical approximations such as WKB theory. WKB theory is specifically for motion of a particle in one dimension, but the generalizations of this theory to motion in three dimensions are known and will be mentioned at the end of this section. More complete descriptions of WKB theory can be found in many standard texts [1, 2, 3, 4 and 5, 18].

(A) WKB THEORY

In WKB theory, one generates a wavefunction that is valid in the $\hbar \rightarrow 0$ limit using a linear combination of exponentials of the form

$$\psi(x) = A(x) e^{iS(x)/\hbar} \quad (\text{A3.11.210})$$

where $A(x)$ and $S(x)$ are real (or sometimes purely imaginary) functions that are derived from the Hamiltonian. This expression is, of course, very familiar from scattering theory applications described above (A3.11.2), where $A(x)$ is a constant, and $S(x)$ is kx . More generally, by substituting (A3.11.210) into the time independent Schrödinger equation in one dimension, and expanding $A(x)$ and $S(x)$ in powers of \hbar , one can show that the leading terms representing $S(x)$ have the form:

$$(\text{A3.11.211})$$

$$A(x) = [E - V(x)]^{-1/4}$$

$$S(x) = \pm \int \sqrt{\frac{2m}{\hbar^2} (E - V(x))} dx.$$

Note that the integrand in $S(x)$ is just the classical momentum $p(x)$, so $S(x)$ is the classical *action* function. In addition, $A(x)$ is proportional to $p^{-1/2}$, which means that $|\psi|_2$ is proportional to the inverse of the classical velocity of the particle.

-48-

This is just the usual classical expression for the probability density. Note that $A(x)$ and $S(x)$ are real as long as motion is classically allowed, meaning that $E > V(x)$. If $E < V(x)$, then $S(x)$ becomes imaginary and $\psi(x)$ involves real rather than complex exponentials. At the point of transition between allowed and forbidden regions, i.e., at the so-called *turning points* of the classical motion, $A(x)$ becomes infinite and the solutions above are not valid. However, it is possible to ‘connect’ the solutions on either side of the turning point using ‘connection formulas’ that are determined from exact solutions to the Schrödinger equation near the turning point. The reader should consult the standard textbooks [1, 2, 3, 4 and 5, 18] for a detailed discussion of this.

In applications to scattering theory, one takes linear combinations of functions of the form (A3.11.210) to satisfy the desired boundary conditions and one uses the connection formulas to determine wavefunctions that are valid for all values of x . By examining the asymptotic forms of the wavefunction, scattering information can be determined. For example, in applications to scattering from a central potential, one can solve the radial Schrödinger equation using WKB theory to determine the phase shift for elastic scattering. The explicit result depends on how many turning points there are in the radial motion.

(B) SCATTERING THEORY FOR MANY DEGREES OF FREEDOM

For multidimensional problems, the generalization of WKB theory to the description of scattering problems is often called Miller–Marcus or classical S -matrix theory [51]. The reader is referred to review articles for a more complete description of this theory [52].

Another theory which is used to describe scattering problems and which blends together classical and quantum mechanics is the semiclassical wavepacket approach [53]. The basic procedure comes from the fact that wavepackets which are initially Gaussian remain Gaussian as a function of time for potentials that are constant, linear or quadratic functions of the coordinates. In addition, the centres of such wavepackets evolve in time in accord with classical mechanics. We have already seen one example of this with the free particle wavepacket of equation (A3.11.7). Consider the general quadratic Hamiltonian (still in one dimension but the generalization to many dimensions is straightforward)

$$\hat{H} = -\frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2} + V_0 + V_x(x - x_t) + \frac{1}{2} V_{xx}(x - x_t)^2. \quad (\text{A3.11.212})$$

The Gaussian wavepacket is written as

$$\psi(x, t) = \exp[(i/\hbar)\alpha_t(x - x_t)^2 + (i/\hbar)p_t(x - x_t) + (i/\hbar)\gamma_t]. \quad (\text{A3.11.213})$$

Here x_t and p_t are real time dependent quantities that specify the average position and momentum of the wavepacket ($p_t = \langle p \rangle, x_t = \langle x \rangle$) and α_t and γ_t are complex functions which determine the width, phase and normalization of the wavepacket.

Inserting equation (A3.11.213) into $\hat{H}\psi = i\hbar\partial\psi/\partial t$, and using equation (A3.11.212), leads to the following relation:

-49-

$$-\dot{\alpha}_t(x-x_t)^2 + (2\alpha_t\dot{x}_t - \dot{p}_t)(x-x_t) - \dot{\gamma}_t + p_t\dot{x}_t] \psi = \left[\left(\frac{2}{m} \right) \alpha_t^2 + \frac{1}{2} V_{xx} \right] (x-x_t)^2 + (2\alpha_t p_t/m + V_x)(x-x_t) + V_0 - i\hbar\alpha_t/m + p_t^2/2m \} \psi. \quad (\text{A3.11.214})$$

Comparing coefficients of like powers of $(x-x_t)$ then gives us three equations involving the four unknowns:

$$\dot{\alpha}_t = -(2/m)\alpha_t^2 - V_{xx}/2 \quad (\text{A3.11.215a})$$

$$2\alpha_t\dot{x}_t - \dot{p}_t = 2\alpha_t p_t/m + V_x \quad (\text{A3.11.215b})$$

$$\dot{\gamma}_t = i\hbar\alpha_t/m + p_t\dot{x}_t - V_0 - p_t^2/2m. \quad (\text{A3.11.215c})$$

To develop an additional equation, we simply make the *ansatz* that the first term on the left-hand side of equation (3.11.215b) equals the first term on the right-hand side and similarly with the second term. This immediately gives us Hamilton's equations

$$\dot{x}_t = p_t/m \quad (\text{A3.11.216a})$$

$$\dot{p}_t = -V_x \quad (\text{A3.11.216b})$$

from which it follows that x_t and p_t are related through the classical Hamiltonian function

$$H = p_t^2/2m + V_0 = E. \quad (\text{A3.11.217})$$

Equations (A3.11.216) can then be cast in the general form

$$\dot{x}_t = \partial H / \partial p_t \quad (\text{A3.11.218a})$$

$$-\dot{p}_t = \partial H / \partial x_t \quad (\text{A3.11.218b})$$

and the remaining two equations in equation (A3.11.215) become

$$\dot{\alpha}_t = -(2/m)\alpha_t^2 - \frac{1}{2} V_{xx} \quad (\text{A3.11.219a})$$

$$\dot{\gamma}_t = i\hbar\alpha_t/m + p_t\dot{x}_t - E. \quad (\text{A3.11.219b})$$

It is not difficult to show that, for a constant potential, equation (A3.11.218) and equation (A3.11.219) can be solved to give the free particle wavepacket in [equation \(A3.11.7\)](#). More generally, one can solve equation (A3.11.218) and equation (A3.11.219) numerically for *any* potential, even potentials that are not quadratic, but the solution obtained will be exact only for potentials that are constant, linear or quadratic. The deviation between the exact and Gaussian wavepacket solutions for other potentials depends on how close they are to being *locally quadratic*, which means

-50-

how well the potential can be approximated by a quadratic potential over the width of the wavepacket. Note that although this theory has many classical features, the $\hbar \rightarrow 0$ limit has not been used. This circumvents problems with singularities in the wavefunction near classical turning points that cause trouble in WKB theory.

A3.12 Statistical mechanical description of chemical kinetics: RRKM

William L Hase

A3.12.1 INTRODUCTION

As reactants transform to products in a chemical reaction, reactant bonds are broken and reformed for the products. Different theoretical models are used to describe this process ranging from time-dependent classical or quantum dynamics [1,2], in which the motions of individual atoms are propagated, to models based on the postulates of statistical mechanics [3]. The validity of the latter models depends on whether statistical mechanical treatments represent the actual nature of the atomic motions during the chemical reaction. Such a statistical mechanical description has been widely used in unimolecular kinetics [4] and appears to be an accurate model for many reactions. It is particularly instructive to discuss statistical models for unimolecular reactions, since the model may be formulated at the elementary microcanonical level and then averaged to obtain the canonical model.

Unimolecular reactions are important in chemistry, physics, biochemistry, materials science, and many other areas of science and are denoted by

where the asterisk denotes that the unimolecular reactant A contains sufficient internal vibrational/rotational energy to decompose. (Electronic excitation may also promote decomposition of A, but this topic is outside the purview of this presentation.) The energy is denoted by E and must be greater than the unimolecular decomposition threshold energy E_0 . There are three general types of potential energy profiles for unimolecular reactions (see figure A3.12.1). One type is for an isomerization reaction, such as cyclopropane isomerization

for which there is a substantial potential energy barrier separating the two isomers. The other two examples are for unimolecular dissociation. In one case, as for formaldehyde dissociation

there is a potential energy barrier for the reverse association reaction. In the other, as for aluminium cluster dissociation

there is no barrier for association.

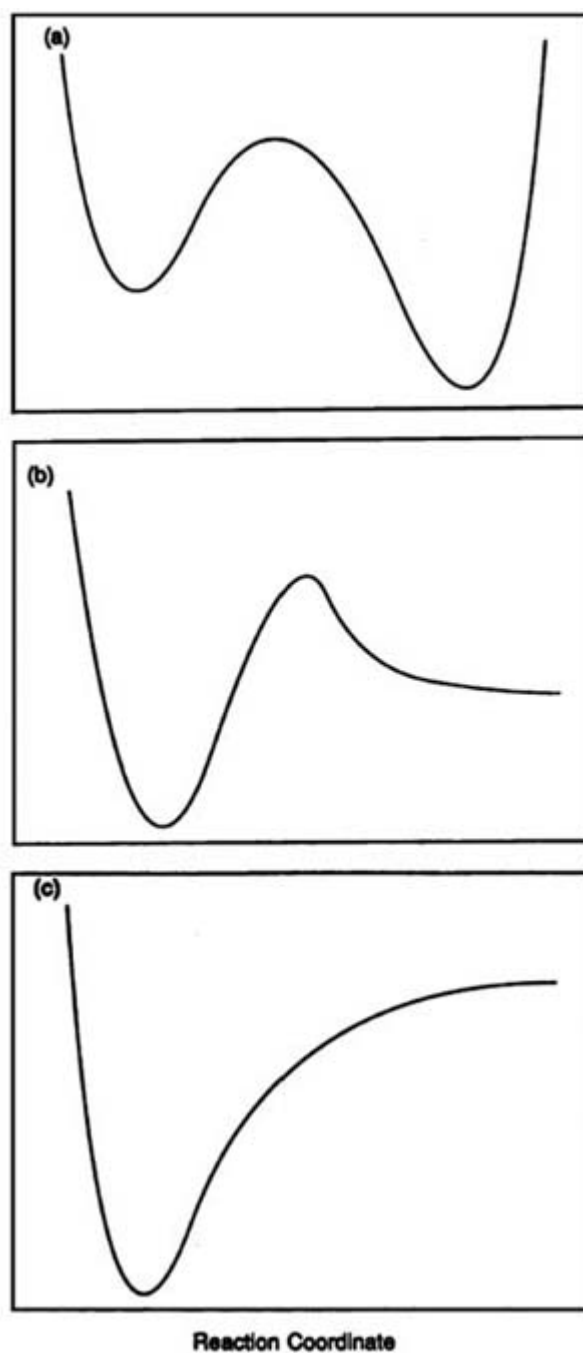

Figure A3.12.1. Schematic potential energy profiles for three types of unimolecular reactions. (a) Isomerization. (b) Dissociation where there is an energy barrier for reaction in both the forward and reverse directions. (c) Dissociation where the potential energy rises monotonically as for rotational ground-state species, so that there is no barrier to the reverse association reaction. (Adapted from [5].)

A number of different experimental methods may be used to energize the unimolecular reactant A. For example, energization can take place by the potential energy release in chemical reaction, i.e.

or by absorption of a single photon,

Extensive discussions of procedures for energizing molecules are given elsewhere [5].

Quantum mechanically, the time dependence of the initially prepared state of A^* is given by its wavefunction $\Psi(t)$, which may be determined from the equation of motion

$$i\hbar \frac{d\Psi(t)}{dt} = \hat{H}\Psi(t). \quad (\text{A3.12.2})$$

At the unimolecular threshold of moderate to large size molecules (e.g. C_2H_6 to peptides), there are many vibrational/rotational states within the experimental energy resolution dE and the initial state of A^* may decay by undergoing transitions to other states and/or decomposing to products. The former is called intramolecular vibrational energy redistribution (IVR) [6]. The probability amplitude versus time of remaining in the initially prepared state is given by

$$C(t) = \langle \Psi(0) | \Psi(t) \rangle \quad (\text{A3.12.3})$$

and is comprised of contributions from both IVR and unimolecular decomposition. The time dependence of the unimolecular decomposition may be constructed by evaluating $|\Psi(t)|^2$ inside the potential energy barrier, within the reactant region of the potential energy surface.

In the statistical description of unimolecular kinetics, known as Rice–Ramsperger–Kassel–Marcus (RRKM) theory [4,7,8], it is assumed that complete IVR occurs on a timescale much shorter than that for the unimolecular reaction [9]. Furthermore, to identify states of the system as those for the reactant, a dividing surface [10], called a transition state, is placed at the potential energy barrier region of the potential energy surface. The assumption implicit in RRKM theory is described in the next section.

A3.12.2 FUNDAMENTAL ASSUMPTION OF RRKM THEORY: MICROCANONICAL ENSEMBLE

RRKM theory assumes a microcanonical ensemble of A^* vibrational/rotational states within the energy interval $E \rightarrow E + dE$, so that each of these states is populated statistically with an equal probability [4]. This assumption of a microcanonical distribution means that the unimolecular rate constant for A^* only depends on energy, and not on the manner in which A^* is energized. If $N(0)$ is the number of A^* molecules excited at $t = 0$ in accord with a microcanonical ensemble, the microcanonical rate constant $k(E)$ is then defined by

$$\left. \frac{-dN(t)}{dt} \right|_{t=0} = k(E)N(t)|_{t=0}. \quad (\text{A3.12.4})$$

The rapid IVR assumption of RRKM theory means that a microcanonical ensemble is maintained as the A* molecules decompose so that, at any time t , $k(E)$ is given by

$$\frac{-dN(t)}{dt} = k(E)N(t). \quad (\text{A3.12.5})$$

As a result of the fixed time-independent rate constant $k(E)$, $N(t)$ decays exponentially, i.e.

$$N(t) = N(0) \exp[-k(E)t]. \quad (\text{A3.12.6})$$

A RRKM unimolecular system obeys the ergodic principle of statistical mechanics[11].

The quantity $-dN(t)/[N(t)dt]$ is called the lifetime distribution $P(t)$ [12] and according to RRKM theory is given by

$$P(t) = k(E) \exp[-k(E)t]. \quad (\text{A3.12.7})$$

[Figure A3.12.2\(a\)](#) illustrates the lifetime distribution of RRKM theory and shows random transitions among all states at some energy high enough for eventual reaction (toward the right). In reality, transitions between quantum states (though coupled) are not equally probable: some are more likely than others. Therefore, transitions between states must be sufficiently rapid and disorderly for the RRKM assumption to be mimicked, as qualitatively depicted in [figure A3.12.2\(b\)](#). The situation depicted in these figures, where a microcanonical ensemble exists at $t = 0$ and rapid IVR maintains its existence during the decomposition, is called *intrinsic* RRKM behaviour [9].

Figure A3.12.2. Relation of state occupation (schematically shown at constant energy) to lifetime distribution for the RRKM theory and for various actual situations. Dashed curves in lifetime distributions for (d) and (e) indicate RRKM behaviour. (a) RRKM model. (b) Physical counterpart of RRKM model. (c) Collisional state selection. (d) Chemical activation. (e) Intrinsically non-RRKM. (Adapted from [9].)

The lifetime distribution will depend in part on the manner in which the energy needed for reaction is supplied. In many experiments, such as photoactivation and chemical activation, the molecular vibrational/rotational states are excited non-randomly. Regardless of the pattern of the initial energizing, the RRKM model of rapid IVR requires the distribution of states to become microcanonical in a negligibly short time. Three different possible lifetime distributions are represented by figure A3.12.2(d). As shown in the middle, the lifetime distribution may be similar to that of RRKM theory. In other cases, the probability of a short lifetime with respect to reaction may be enhanced or reduced, depending on the location of the initial excitation within the molecule. These are examples of *apparent* non-RRKM behaviour [9] arising from the initial non-random excitation. If there are strong internal couplings, $P(t)$ will become

that of RRKM theory, (equation A3.12.5), after rapid IVR. A classic example of apparent non-RRKM behaviour is described below in section A3.12.8.1.

A situation that arises from the intramolecular dynamics of A^* and completely distinct from apparent non-RRKM behaviour is *intrinsic* non-RRKM behaviour [9]. By this, it is meant that A^* has a non-random $P(t)$ even if the internal vibrational states of A^* are prepared randomly. This situation arises when transitions between individual molecular vibrational/rotational states are slower than transitions leading to products. As a result, the vibrational states do not have equal dissociation probabilities. In terms of classical phase space dynamics, slow transitions between the states occur when the reactant phase space is *metrically decomposable* [13,14] on the timescale of the unimolecular reaction and there is at least one *bottleneck* [9] in the molecular phase space other than the one defining the transition state. An intrinsic non-RRKM molecule decays non-exponentially with a time-dependent unimolecular rate constant or exponentially with a rate constant different from that of RRKM theory.

The above describes the fundamental assumption of RRKM theory regarding the intramolecular dynamics of A^* . The RRKM expression for $k(E)$ is now derived.

A3.12.3 THE RRKM UNIMOLECULAR RATE CONSTANT

A3.12.3.1 DERIVATION OF THE RRKM $k(E)$

As discussed above, to identify states of the system as those for the reactant A^* , a dividing surface is placed at the potential energy barrier region of the potential energy surface. This is a classical mechanical construct and classical statistical mechanics is used to derive the RRKM $k(E)$ [4].

In the vicinity of the dividing surface, it is assumed that the Hamiltonian for the system may be separated into the two parts

$$H = H_1 + H' \quad (\text{A3.12.8})$$

where H_1 defines the energy for the conjugate coordinate and momentum pair q_1, p_1 and H' gives the energy for the remaining conjugate coordinates and momenta. This special coordinate q_1 is called the *reaction coordinate*. Reactive systems which have a total energy $H = E$ and a value for q_1 which lies between q_1^\ddagger and $q_1^\ddagger + dq_1^\ddagger$ called microcanonical transition states. The reaction coordinate potential at the transition state is E_0 . The RRKM $k(E)$ is determined from the rate at which these transition states form products.

The hypersurface formed from variations in the system's coordinates and momenta at $H(p, q) = E$ is the microcanonical system's phase space, which, for a Hamiltonian with $3n$ coordinates, has a dimension of $6n - 1$. The assumption that the system's states are populated statistically means that the population density over the whole surface of the phase space is uniform. Thus, the ratio of molecules at the dividing surface to the total molecules $[dN(q_1^\ddagger, p_1^\ddagger)/N]$

may be expressed as a ratio of the phase space at the dividing surface to the total phase space. Thus, at any instant in time, the ratio of molecules whose reaction coordinate and conjugate momentum have values that range from q_1^\ddagger to $q_1^\ddagger + dq_1^\ddagger$ and from p_1^\ddagger to $p_1^\ddagger + dp_1^\ddagger$ to the total number of molecules is given by

$$\frac{dN(q_1^\ddagger, p_1^\ddagger)}{N} = \frac{dq_1^\ddagger dp_1^\ddagger \int \dots \int_{H=E-E_1^\ddagger-E_0} dq_2^\ddagger \dots dq_{3n}^\ddagger dp_2^\ddagger \dots dp_{3n}^\ddagger}{\int \dots \int_{H=E} dq_1 \dots dq_{3n} dp_1 \dots dp_{3n}} \quad (\text{A3.12.9})$$

where E_1^\ddagger is the translational energy in the reaction coordinate. One can think of this expression as a reactant–transition state equilibrium constant for a microcanonical system. The term $dq_1^\ddagger dp_1^\ddagger$ divided by Planck's constant is the number of translational states in the reaction coordinate and the surface integral in the numerator divided by h^{3n-1} is the density of states for the $3n - 1$ degrees of freedom orthogonal to the reaction coordinate. Similarly, the surface integral in the denominator is the reactant density of states multiplied by h^{3n} .

To determine $k(E)$ from equation (A3.12.9) it is assumed that transition states with positive p_1^\ddagger form products. Noting that $p_1^\ddagger = \mu_1 dq_1^\ddagger/dt$, where μ_1 is the reduced mass of the separating fragments, all transition states that lie within q_1^\ddagger and $q_1^\ddagger + dq_1^\ddagger$ with positive p_1^\ddagger will cross the transition state toward products in the time interval $dt = \mu_1 dq_1^\ddagger/p_1^\ddagger$. Inserting this expression into equation (A3.12.9), one finds that the reactant-to-product rate (i.e. flux) through the transition state for momentum p_1^\ddagger is

$$\frac{dN(q_1^\ddagger, p_1^\ddagger)}{dt} = \frac{N \frac{p_1^\ddagger dq_1^\ddagger}{\mu_1} \int \dots \int_{H=E-E_1^\ddagger-E_0} dq_2^\ddagger \dots dq_{3n}^\ddagger dp_2^\ddagger \dots dp_{3n}^\ddagger}{\int \dots \int_{H=E} dq_1 \dots dq_{3n} dp_1 \dots dp_{3n}} \quad (\text{A3.12.10})$$

Since the energy in the reaction coordinate is $E_1^\ddagger = p_1^{\ddagger 2}/2\mu_1$, its derivative is $dE_1^\ddagger = p_1^\ddagger dp_1^\ddagger/\mu_1$ so that equation (A3.12.10) can be converted into

$$\frac{dN(q_1^\ddagger, p_1^\ddagger)}{dt} = \frac{N dE_1^\ddagger \int \dots \int_{H=E-E_1^\ddagger-E_0} dq_2^\ddagger \dots dq_{3n}^\ddagger dp_2^\ddagger \dots dp_{3n}^\ddagger}{\int \dots \int_{H=E} dq_1 \dots dq_{3n} dp_1 \dots dp_{3n}} \quad (\text{A.12.11})$$

This equation represents the reaction rate at total energy E with a fixed energy in the reaction coordinate E_1^\ddagger and may be written as

$$dN(E, E_1^\ddagger)/dt = k(E, E_1^\ddagger) N dE_1^\ddagger \quad (\text{A3.12.12})$$

-8-

where $k(E, E_1^\ddagger)$ is a unimolecular rate constant. As discussed above, the integrals in [equation \(A3.12.11\)](#) are densities of states ρ , so $k(E, E_1^\ddagger)$ becomes

$$k(E, E_1^\ddagger) = \frac{\rho^\ddagger(E - E_0 - E_1^\ddagger)}{h\rho(E)} \quad (\text{A3.12.13})$$

To find the total reaction flux, [equation \(A3.12.12\)](#) must be integrated between the limits E_1^\ddagger equal to 0 and $E - E_0$, so that

$$\frac{dN}{dt} = \frac{\int_0^{E-E_0} dN(E, E_1^\ddagger)}{dt} = N \int_0^{E-E_0} k(E, E_1^\ddagger) dE_1^\ddagger = k(E)N \quad (\text{A3.12.14})$$

where, using equation (A3.12.13), $k(E)$ is given by

$$k(E) = \frac{\int_0^{E-E_0} \rho^\ddagger(E - E_0 - E_1^\ddagger) dE_1^\ddagger}{h\rho(E)} = \frac{N^\ddagger(E - E_0)}{h\rho(E)}. \quad (\text{A3.12.15})$$

The term $N^\ddagger(E - E_0)$ is the sum of states at the transition state for energies from 0 to $E - E_0$. Equation (A3.12.15) is the RRKM expression for the unimolecular rate constant.

Only in the high-energy limit does classical statistical mechanics give accurate sums and densities of state [15]. Thus, in general, quantum statistical mechanics must be used to calculate a RRKM $k(E)$ which may be compared with experiment [16]. A comparison of classical and quantum harmonic (see below) RRKM rate constants for $\text{C}_2\text{H}_5 \rightarrow \text{H} + \text{C}_2\text{H}_4$ is given in figure A3.12.3 [17]. The energies used for the classical calculation are with respect to the reactant's and transition state's potential minima. For the quantum calculation the energies are with respect to the zero-point levels. If energies with respect to the zero-point levels were used in the classical calculation, the classical $k(E)$ would be appreciably smaller than the quantum value [16].

-9-

Figure A3.12.3. Harmonic RRKM unimolecular rate constants for $\text{C}_2\text{H}_5 \rightarrow \text{H} + \text{C}_2\text{H}_4$ dissociation: classical state counting (solid curve), quantum state counting (dashed curve). Rate constant is in units of s^{-1} and energy in kcal mol^{-1} . (Adapted from [17].)

RRKM theory allows some modes to be uncoupled and not exchange energy with the remaining modes [16]. In quantum RRKM theory, these uncoupled modes are not *active*, but are *adiabatic* and stay in fixed quantum states n during the reaction. For this situation, equation (A3.12.15) becomes

$$k(E, \mathbf{n}) = \frac{N^\ddagger[E - E_0(\mathbf{n}), \mathbf{n}]}{h\rho(E, \mathbf{n})}. \quad (\text{A3.12.16})$$

In addition to affecting the number of active degrees of freedom, the fixed n also affects the unimolecular threshold $E_0(n)$. Since the total angular momentum j is a constant of motion and quantized according to

$$j = \sqrt{J(J+1)}\hbar \quad (\text{A3.12.17})$$

the quantum number J is fixed during the unimolecular reaction. This may be denoted by explicitly including J in equation (A3.12.16), i.e.

$$k(E, J, \mathbf{n}) = \frac{N^\ddagger(E, J, \mathbf{n})}{\rho(E, J, \mathbf{n})}. \quad (\text{A3.12.18})$$

-10-

The treatment of angular momentum is discussed in detail below in [section A3.12.4.3](#).

A3.12.3.2 K(E) AS AN AVERAGE FLUX

The RRKM rate constant is often expressed as an average classical flux through the transition state [18, 19 and 20]. To show that this is the case, first recall that the density of states $\rho(E)$ for the reactant may be expressed as

$$\rho(E) = \frac{d}{dE} \int \dots \int dq_1 \dots dq_{3n} dp_1 \dots dp_{3n} \theta(E - H) / h^{3n} \quad (\text{A3.12.19})$$

where θ is the Heaviside function, i.e. $\theta(x) = 1$ for $x > 0$ and $\theta(x) = 0$ for $x < 0$. Since the delta and Heaviside functions are related by $\delta(x) = d\theta(x)/dx$, equation (A3.12.19) becomes

$$\rho(E) = \int \dots \int dq_1 \dots dq_{3n} dp_1 \dots dp_{3n} \delta(E - H) / h^{3n}. \quad (\text{A3.12.20})$$

From [equation \(A3.12.11\)](#), [equation \(A3.12.12\)](#), [equation \(A3.12.13\)](#), [equation \(A3.12.14\)](#) and [equation \(A3.12.15\)](#) and the discussion above, the RRKM rate constant may be written as

$$k(E) = \frac{\int_0^{E-E_0} \left[\int \dots \int dq_2^\ddagger \dots dq_{3n}^\ddagger dp_2^\ddagger \dots dp_{3n}^\ddagger \delta(E' - H) \right] dH}{\int \dots \int dq_1 \dots dq_{3n} dp_1 \dots dp_{3n} \delta(E - H)}. \quad (\text{A3.12.21})$$

The inner multiple integral is the transition state's density of states at energy E' , and also the numerator in [equation \(A3.12.13\)](#), which gives the transition states sum of states $N^\ddagger(E - E_0)$ when integrated from $E' = 0$ to $E' = E - E_0$. Using Hamilton's equation $dH/dp_1 = q_1$, dH in the above equation may be replaced by $q_1 dp_1$. Also, from the definition of the delta function

$$\int \delta(q_1 - q_1^\ddagger) dq_1 = 1. \quad (\text{A3.12.22})$$

This expression may be inserted into the numerator of the above equation, without altering the equation. Making the above two changes and noting that $\delta(q_1 - q_1^\ddagger)$ specifies the transition state, so that the \ddagger superscript to the transition state's coordinates and momenta may be dropped, equation (A3.12.21) becomes

$$k(E) = \frac{\int \dots \int \dot{q}_1 dq_1 \dots dq_{3n} dp_1 \dots dp_{3n} \delta(q_1 - q_1^\ddagger) \delta(E - H)}{\int \dots \int dq_1 \dots dq_{3n} dp_1 \dots dp_{3n} \delta(E - H)}. \quad (\text{A3.12.23})$$

-11-

The rate constant is an average of $\dot{q}_1 \delta(q_1 - q_1^\ddagger)$, with positive \dot{q}_1 , for a microcanonical ensemble $H = E$ and may be expressed as

$$k(E) = \langle \dot{q}_1 \delta(q_1 - q_1^\ddagger) \rangle. \quad (\text{A3.12.24})$$

The RRKM rate constant written this way is seen to be an average flux through the transition state.

A3.12.3.3 VARIATIONAL RRKM THEORY

In deriving the RRKM rate constant in section A3.12.3.1, it is assumed that the rate at which reactant molecules cross the transition state, in the direction of products, is the same rate at which the reactants form products. Thus, if any of the trajectories which cross the transition state in the product direction return to the reactant phase space, i.e. recross the transition state, the actual unimolecular rate constant will be smaller than that predicted by RRKM theory. This one-way crossing of the transition state, with no recrossing, is a fundamental assumption of transition state theory [21]. Because it is incorporated in RRKM theory, this theory is also known as microcanonical transition state theory.

As a result of possible recrossings of the transition state, the classical RRKM $k(E)$ is an upper bound to the correct classical microcanonical rate constant. The transition state should serve as a bottleneck between reactants and products, and in *variational RRKM theory* [22] the position of the transition state along q_1 is varied to minimize $k(E)$. This minimum $k(E)$ is expected to be the closest to the truth. The quantity actually minimized is $N^\ddagger(E - E_0)$ in equation (A3.12.15), so the operational equation in variational RRKM theory is

$$\frac{dN^\ddagger[E - E_0(q_1)]}{dq_1} = 0 \quad (\text{A3.12.25})$$

where $E_0(q_1)$ is the potential energy as a function of q_1 . The minimum in $N^\ddagger[E - E_0(q_1)]$ is identified by $q_1 = q_1^\ddagger$ and this value for q_1 , with the smallest sum of states, is expected to be the best bottleneck for the reaction.

For reactions with well defined potential energy barriers, as in figure A3.12.1(a) and figure A3.12.1(b) the variational criterion places the transition state at or very near this barrier. The variational criterion is particularly important for a reaction where there is no barrier for the reverse association reaction: see figure A3.12.1(c). There are two properties which gave rise to the minimum in $N^\ddagger[E - E_0(q_1)]$ for such a reaction.

As q_1 is decreased the potential energy $E_0(q_1)$ decreases and the energy available to the transition state $E - E_0(q_1)$ increases. This has the effect of increasing the sum of states. However, as q_1 is decreased, the intermolecular anisotropic forces between the dissociating fragments increase, which has the effect of decreasing the available phase space and, thus, the sum of states. The combination of these two effects gives rise to a minimum in $N^\ddagger[E - E_0(q_1)]$. Plots of the sum of states versus q_1 are shown in [figure A3.12.4](#) for three model potentials of the $C_2H_6 \rightarrow 2CH_3$ dissociation reaction [23].

-12-

Figure A3.12.4. Plots of $N^\ddagger[E - E_0(q_1)]$ versus q_1 for three models of the $C_2H_6 \rightarrow 2CH_3$ potential energy function. r^\ddagger represents q_1 and the term on the abscissa represents N^\ddagger . (Adapted from [23].)

Variational RRKM theory is particularly important for unimolecular dissociation reactions, in which vibrational modes of the reactant molecule become translations and rotations in the products [22]. For $CH_4 \rightarrow CH_3 + H$ dissociation there are three vibrational modes of this type, i.e. the C---H stretch which is the reaction coordinate and the two degenerate H---CH₃ bends, which first transform from high-frequency to low-frequency vibrations and then hindered rotors as the H---C bond ruptures. These latter two degrees of freedom are called transitional modes [24,25]. $C_2H_6 \rightarrow 2CH_3$ dissociation has five transitional modes, i.e. two pairs of degenerate CH₃ rocking/rotational motions and the CH₃ torsion.

To calculate $N^\ddagger(E - E_0)$, the non-torsional transitional modes have been treated as vibrations as well as rotations [26]. The former approach is invalid when the transitional mode's barrier for rotation is low, while the latter is inappropriate when the transitional mode is a vibration. Harmonic frequencies for the transitional modes may be obtained from a semi-empirical model [23] or by performing an appropriate normal mode analysis as a function of the reaction path for the reaction's potential energy surface [26]. Semiclassical quantization may be used to determine anharmonic energy levels for the transitional modes [27].

The intermolecular Hamiltonian of the product fragments is used to calculate the sum of states of the transitional modes, when they are treated as rotations. The resulting model [28] is nearly identical to phase space theory [29].

if the distance between the product fragments' centres-of-mass is assumed to be the reaction coordinate [30]. A more complete model is obtained by using a generalized reaction coordinate, which may contain contributions from different motions, such as bond stretching and bending, as well as the above relative centre-of-mass motion [31].

Variational RRKM calculations, as described above, show that a unimolecular dissociation reaction may have two variational transition states [32, 33, 34, 35 and 36], i.e. one that is a tight vibrator type and another that is a loose rotator type. Whether a particular reaction has both of these variational transition states, at a particular energy, depends on the properties of the reaction's potential energy surface [33, 34 and 35]. For many dissociation reactions there is only one variational transition state, which smoothly changes from a loose rotator type to a tight vibrator type as the energy is increased [26].

A3.12.4 APPROXIMATE MODELS FOR THE RRKM RATE CONSTANT

A3.12.4.1 CLASSICAL HARMONIC OSCILLATORS: RRK THEORY

The classical mechanical RRKM $k(E)$ takes a very simple form, if the internal degrees of freedom for the reactant and transition state are assumed to be harmonic oscillators. The classical sum of states for s harmonic oscillators is [16]

$$N(E) = \frac{E^s}{s! \prod_{i=1}^s h \nu_i}. \quad (\text{A3.12.26})$$

The density $\rho(E) = dN(E)/dE$ is then

$$\rho(E) = \frac{E^{s-1}}{(s-1)! \prod_{i=1}^s h \nu_i}. \quad (\text{A3.12.27})$$

The reactant density of states in [equation \(A3.12.15\)](#) is given by the above expression for $\rho(E)$. The transition state's sum of states is

$$N^\ddagger(E - E_0) = \frac{(E - E_0)^{s-1}}{(s-1)! \prod_{i=1}^{s-1} h \nu_i^\ddagger}. \quad (\text{A3.12.28})$$

Inserting [equation \(A3.12.27\)](#) and [equation \(A3.12.28\)](#) into [equation \(A3.12.15\)](#) gives

$$k(E) = \frac{\prod_{i=1}^s \nu_i}{\prod_{i=1}^{s-1} \nu_i^\ddagger} \left(\frac{E - E_0}{E} \right)^{s-1}. \quad (\text{A3.12.29})$$

If the ratio of the products of vibrational frequencies is replaced by v , [equation \(A3.12.29\)](#) becomes

$$k(E) = v \left(\frac{E - E_0}{E} \right)^{s-1} . \quad (\text{A3.12.30})$$

which is the Rice–Ramsperger–Kassel (RRK) unimolecular rate constant [16,37]. Thus, the $k(E)$ of RRK theory is the classical harmonic limit of RRKM theory.

A3.12.4.2 QUANTUM HARMONIC OSCILLATORS

Only in the high-energy limit does classical statistical mechanics give accurate values for the sum and density of states terms in [equation \(A3.12.15\)](#) [3,14]. Thus, to determine an accurate RRKM $k(E)$ for the general case, quantum statistical mechanics must be used. Since it is difficult to make anharmonic corrections, both the molecule and transition state are often assumed to be a collection of harmonic oscillators for calculating the sum $N^\ddagger(E - E_0)$ and density $\rho(E)$. This is somewhat incongruous since a molecule consisting of harmonic oscillators would exhibit intrinsic non-RRKM dynamics.

With the assumption of harmonic oscillators, the molecule's quantum energy levels are

$$E(\mathbf{n}) = \sum_{i=1}^s n_i h\nu_i . \quad (\text{A3.12.31})$$

The same expression holds for the transition state, except that the sum is over $s - 1$ oscillators and the frequencies are the ν_i^\ddagger . The Beyer–Swinehart algorithm [38] makes a very efficient direct count of the number of quantum states between an energy of zero and E . The molecule's density of states is then found by finite difference, i.e.

$$\rho(E) = \frac{N(E + \Delta E/2) - N(E - \Delta E/2)}{\Delta E} \quad (\text{A3.12.32})$$

where $N(E + \Delta E/2)$ is the sum of states at energy $E + \Delta E/2$. The transition state's harmonic $N^\ddagger(E - E_0)$ is counted directly by the Beyer–Swinehart algorithm. This harmonic model is used so extensively to calculate a value for the RRKM $k(E)$ that it is easy to forget that RRKM theory is not a harmonic theory.

A3.12.4.3 OVERALL ROTATION

Regardless of the nature of the intramolecular dynamics of the reactant A^* , there are two constants of the motion in a unimolecular reaction, i.e. the energy E and the total angular momentum j . The latter ensures the rotational quantum number J is fixed during the unimolecular reaction and the quantum RRKM rate constant is specified as $k(E, J)$.

(A) SEPARABLE VIBRATION/ROTATION

For a RRKM calculation without any approximations, the complete vibrational/rotational Hamiltonian for the unimolecular system is used to calculate the reactant density and transition state's sum of states. No approximations are made regarding the coupling between vibration and rotation. However, for many molecules the exact nature of the coupling between vibration and rotation is uncertain, particularly at high energies, and a model in which rotation and vibration are assumed separable is widely used to calculate the quantum RRKM $k(E, J)$ [4,16]. To illustrate this model, first consider a linear polyatomic molecule which decomposes via a linear transition state. The rotational energy for the reactant is assumed to be that for a rigid rotor, i.e.

$$E_r = J(J + 1)\hbar^2/2I. \quad (\text{A3.12.33})$$

The same expression applies to the transition state's rotational energy $E_r^\ddagger(J)$ except that the moment of inertia I is replaced by I^\ddagger . Since the quantum number j is fixed, the active energies for the reactant and transition state are $[E - E_r(J)]$ and $[E - E_0 - E_r^\ddagger(J)]$, respectively. The RRKM rate constant is denoted by

$$k(E, J) = \frac{N[E - E_0 - E_r^\ddagger(J)]}{h\rho[E - E_r(J)]} \quad (\text{A3.12.34})$$

where N^\ddagger and ρ are the sum and density of states for the vibrational degrees of freedom. Each j level is $(2J + 1)^2$ degenerate, which cancels for the sum and density.

(B) THE K QUANTUM NUMBER: ADIABATIC OR ACTIVE

The degree of freedom in [equation \(A3.12.18\)](#), which has received considerable interest regarding its activity or adiabaticity, is the one associated with the K rotational quantum number for a symmetric or near-symmetric top molecule [39,40]. The quantum number K represents the projection of J onto the molecular symmetry axis. Coriolis coupling can mix the $2J + 1$ K levels for a particular J and destroy K as a good quantum number. For this situation K is considered an active degree of freedom. On the other hand, if the Coriolis coupling is weak, the K quantum number may retain its integrity and it may be possible to measure the unimolecular rate constant as a function of K as well as of E and J . For this case, K is an adiabatic degree of freedom.

It is straightforward to introduce active and adiabatic treatments of K into the widely used RRKM model which represents vibration and rotation as separable and the rotations as rigid rotors [41,42]. For a symmetric top, the rotational energy is given by

$$E_r(J, K) = \frac{J(J + 1)\hbar^2}{2I_a} + \left(\frac{1}{I_c} - \frac{1}{I_a} \right) K^2\hbar^2. \quad (\text{A3.12.35})$$

If K is adiabatic, a molecule containing total vibrational-rotational energy E and, in a particular J, K level, has a vibrational density of states $\rho[E - E_r(J, K)]$. Similarly, the transition state's sum of states for the same E, J , and K is $N^\ddagger[E - E_0 - E_r^\ddagger(J, K)]$. The RRKM rate constant for the K adiabatic model is

$$k(E, J, K) = \frac{N^\ddagger[E - E_0 - E_t^\ddagger(J, K)]}{h\rho[E - E_r(J, K)]}. \quad (\text{A3.12.36})$$

Mixing the $2J + 1$ K levels, for the K active model, results in the following sums and densities of states:

$$N^\ddagger(E, J) = \sum_{K=-J}^J N^\ddagger[E - E_0 - E_t^\ddagger(J, K)] \quad (\text{A3.12.37})$$

$$\rho(E, J) = \sum_{K=-J}^J \rho[E - E_r(J, K)]. \quad (\text{A3.12.38})$$

The RRKM rate constant for the K active model is

$$k(E, J) = \frac{\sum_{K=-J}^J N^\ddagger[E - E_0 - E_t^\ddagger(J, K)]}{h \sum_{K=-J}^J \rho[E - E_r(J, K)]}. \quad (\text{A3.12.39})$$

In these models the treatment of K is the same for the molecule and transition state. It is worthwhile noting that *mixed mode RRKM models* are possible in which K is treated differently in the molecule and transition state [39].

A3.12.5 ANHARMONIC EFFECTS

In the above section a harmonic model is described for calculating RRKM rate constants with harmonic sums and densities of states. This rate constant, denoted by $k_h(E, J)$, is related to the actual anharmonic RRKM rate constant by

$$k(E, J) = f_{\text{anh}}(E, J)k_h(E, J) = f_{\text{anh}}(E, J) \frac{N_h^\ddagger(E, J)}{h\rho_h(E, J)} \quad (\text{A3.12.40})$$

where $NN_h^\ddagger(E, J)$ and $\rho_h(E, J)$ are the harmonic approximations to the sum and density of states. The anharmonic correction, $f_{\text{anh}}(E, J)$, is obviously

$$f_{\text{anh}}(E, J) = \frac{N_{\text{anh}}^\ddagger(E, J)/N_h^\ddagger(E)}{\rho_{\text{anh}}(E, J)/\rho_h(E, J)} = \frac{f_{\text{anh}, N^\ddagger}(E, J)}{f_{\text{anh}, \rho}(E, J)} \quad (\text{A3.12.41})$$

the ratio of anharmonic corrections for the sum and density. For energies near the unimolecular threshold, where the transition state energy $E - E_0$ is small, anharmonicity in the transition state may be negligible, so

that $f_{\text{anh}}(E)$ may be well approximated by $1/f_{\text{anh},\rho(E)}$ [43]. However, for higher energies, anharmonicity is expected to become important also for the transition state.

There is limited information available concerning anharmonic corrections to RRKM rate constants. Only a few experimental studies have investigated the effect of anharmonicity on the reactant's density of states (see below). To do so requires spectroscopic information up to very high energies. It is even more difficult to measure anharmonicities for transition state energy levels [44,45]. If the potential energy surface is known for a unimolecular reactant, anharmonic energy levels for both the reactant and transition state may be determined in principle from large-scale quantum mechanical variational calculations. Such calculations are more feasible for the transition state with energy $E - E_0$ than for the reactant with the much larger energy E . Such calculations have been limited to relatively small molecules [4].

The bulk of the information about anharmonicity has come from classical mechanical calculations. As described above, the anharmonic RRKM rate constant for an analytic potential energy function may be determined from either equation (A3.12.4) [13] or equation (A3.12.24) [46] by sampling a microcanonical ensemble. This rate constant and the one calculated from the harmonic frequencies for the analytic potential give the anharmonic correction $f_{\text{anh}}(E, J)$ in equation (A3.12.41). The transition state's anharmonic classical sum of states is found from the phase space integral

$$N_{\text{anh}}^{\ddagger}(E, J) = \int \dots \int dq_2 \dots dq_{3n} dp_2 \dots dp_{3n} \theta(E - H) / h^{3n-1} \quad (\text{A3.12.42})$$

which may be combined with the harmonic sum $NN_{\text{h}}^{\ddagger}(E, J)$ to give $f_{\text{anh},N_{\text{h}}^{\ddagger}}(E, J)$. The classical anharmonic correction to the reactant's density of states, $f_{\text{anh},\rho}(E, J)$, may be obtained in a similar manner.

A3.12.5.1 MOLECULES WITH A SINGLE MINIMUM

Extensive applications of RRKM theory have been made to unimolecular reactions, for which there is a single potential energy minimum for the reactant molecule [4,47]. For such reactions, the anharmonic correction $f_{\text{anh}}(E, J)$ is usually assumed to be unity and the harmonic model is used to calculate the RRKM $k(E, J)$. Though this is a widely used approach, uncertainties still remain concerning its accuracy. Anharmonic densities of states for formaldehyde [48] and acetylene [49] obtained from high-resolution spectroscopic experiments at energies near their unimolecular thresholds, are 11 and 6 times larger, respectively, than their harmonic densities. From calculations with analytic potential energy functions at energies near the unimolecular thresholds, the HCN quantum anharmonic density of states is 8 times larger than the harmonic value [50] and the classical anharmonic density of states for the model alkyl radical HCC is 3–5 times larger than the harmonic value [51]. There is a sense that the anharmonic correction may become less important for larger molecules, since the average energy per mode becomes smaller [4]. However, as shown below, this assumption is clearly not valid for large fluxional molecules with multiple minima.

Analytic expressions have been proposed for making anharmonic corrections for molecules with a single potential minimum [52,53,54,55 and 56]. Haarhoff [52] derived an expression for this correction factor by describing the molecules' degrees of freedom as a collection of Morse oscillators. One of the limitations of this model is that it is difficult to assign Morse parameters to non-stretching degrees of freedom. Following the spirit of Haarhoff's work, Troe [54] formulated the correction factor

$$f_{\text{anh},\rho}(E) = \prod_{i=1}^m \left(1 + \frac{E/D_i}{2s-3} \right) \quad (\text{A3.12.43})$$

for a molecule with s degrees of freedom, m of which are Morse stretches. The remaining $s - m$ degrees of freedom are assumed to be harmonic oscillators. The D_i are the individual Morse dissociation energies. To account for bend–stretch coupling, i.e. the attenuation of bending forces as bonds are stretched [51], Troe amended equation (A3.12.43) to give [55]

$$f_{\text{anh},\rho}(E) = \sum_{i=1}^m \left(1 + \frac{E/D_i}{2s-3} \right)^2. \quad (\text{A3.12.44})$$

The above expressions are empirical approaches, with m and D_i as parameters, for including an anharmonic correction in the RRKM rate constant. The utility of these equations is that they provide an analytic form for the anharmonic correction. Clearly, other analytic forms are possible and may be more appropriate. For example, classical sums of states for H–C–C, H–C=C, and H–C≡C hydrocarbon fragments with Morse stretching and bend–stretch coupling anharmonicity [51] are fit accurately by the exponential

$$f_{\text{anh},N}(E) = \exp(bE). \quad (\text{A3.12.45})$$

The classical anharmonic density of states is then [56]

$$f_{\text{anh},\rho}(E) = \exp(bE)[1 + bE/s]. \quad (\text{A3.12.46})$$

Modifying equation (A3.12.45) to represent the transition state's sum of states, the anharmonic correction to the RRKM rate constant becomes

$$f_{\text{anh}}(E) = \frac{\exp[b^*(E - E_0)]}{\exp(bE)[1 + bE/s]}. \quad (\text{A3.12.47})$$

This expression, and variations of it, have been used to fit classical anharmonic microcanonical $k(E, J)$ for unimolecular decomposition [56].

A3.12.5.2 FLUXIONAL MOLECULES WITH MULTIPLE MINIMA

Anharmonic corrections are expected to be very important for highly fluxional molecules such as clusters and macromolecules [30]. Figure A3.12.5 illustrates a possible potential energy curve for a fluxional molecule. There are multiple minima (i.e. conformations) separated by barriers much lower than that for dissociation. Thus, a moderately excited fluxional molecule may undergo rapid transitions between its many conformations, and all will contribute to the molecule's unimolecular rate constant. Many different conformations are expected for the products, but near the dissociation threshold E_0 , only one set of product conformations is accessible. As the energy is increased, thresholds for other product conformations are reached. For energies near E_0 , there is very little excess energy in the transition state and the harmonic approximation for the lowest energy product conformation should be very good for the transition state's sum

of states. Thus, for $E \approx E_0$ the anharmonic correction in [equation \(A3.12.40\)](#) is expected to primarily result from anharmonicity in the reactant density of states.

Figure A3.12.5. A model reaction coordinate potential energy curve for a fluxional molecule. (Adapted from [30].)

The classical anharmonic RRKM rate constant for a fluxional molecule may be calculated from classical trajectories by following the initial decay of a microcanonical ensemble of states for the unimolecular reactant, as given by [equation \(A3.12.4\)](#). Such a calculation has been performed for dissociation of the Al_6 and Al_{13} clusters using a model analytic potential energy function written as a sum of Lennard–Jones and Axelrod–Teller potentials [30]. Structures of some of the Al_6 minima, for the potential function, are shown in [figure A3.12.6](#). The deepest potential minimum has

C_{2h} symmetry and a classical $\text{Al}_6 \rightarrow \text{Al}_5 + \text{Al}$ dissociation energy E_0 of $43.8 \text{ kcal mol}^{-1}$. For energies 30–80 kcal mol^{-1} in excess of this E_0 , the value of f_{anh} determined from the trajectories varies from 200 to 130. The harmonic RRKM rate constants are based on the deepest potential energy minima for the reactant and transition state, and calculated for a reaction path degeneracy of 6. As discussed above, even larger corrections are expected at lower energies, particularly for $E \approx E_0$, where anharmonicity in the transition state does not contribute $B_{\text{anh}}(E)$. However, because of the size of Al_6 and its long unimolecular lifetime, it becomes impractical to simulate the classical dissociation of Al_6 for energies in excess of E_0 much smaller than 30 kcal mol^{-1} . For the bigger cluster Al_{13} , the anharmonic correction varies from 5500 to 1200 for excess energies in the range of 85–185 kcal mol^{-1} [30]. These calculations illustrate the critical importance of including anharmonic corrections when calculating accurate RRKM rate constants for fluxional molecules.

Figure A3.12.6. Structures for some of the potential energy minima for Al_6 . The unimolecular thresholds for the C_{2h} , D_{3h} , C_s , O_h , C_{4v} , and D_h minima are 43.8, 40.0, 39.6, 38.8, 31.4 and 20.9 kcal mol $^{-1}$, respectively. (Adapted from [40].)

In the above discussion it was assumed that the barriers are low for transitions between the different conformations of the fluxional molecule, as depicted in [figure A3.12.5](#) and therefore the transitions occur on a timescale much shorter than the RRKM lifetime. This is the rapid IVR assumption of RRKM theory discussed in [section A3.12.2](#). Accordingly, an initial microcanonical ensemble over all the conformations decays exponentially. However, for some fluxional molecules, transitions between the different conformations may be slower than the RRKM rate, giving rise to bottlenecks in the unimolecular dissociation [4,57]. The ensuing lifetime distribution, [equation \(A3.12.7\)](#), will be non-exponential, as is the case for *intrinsic* non-RRKM dynamics, for an initial microcanonical ensemble of molecular states.

A3.12.6 CLASSICAL DYNAMICS OF INTRAMOLECULAR MOTION AND UNIMOLECULAR DECOMPOSITION

A3.12.6.1 NORMAL-MODE HAMILTONIAN: SLATER THEORY

The classical mechanical model of unimolecular decomposition, developed by Slater [18], is based on the normal-mode harmonic oscillator Hamiltonian. Although this Hamiltonian is rigorously exact only for small displacements from the molecular equilibrium geometry, Slater extended it to the situation where molecules are highly vibrationally energized, undergo large amplitude motions and decompose. Since there are no couplings in the normal-mode Hamiltonian, the energies in the individual normal modes do not vary with time. This is the essential difference from the RRKM theory which treats a molecule as a collection of coupled modes which freely exchange energy.

The normal-mode harmonic oscillator classical Hamiltonian is

$$H = \sum_{i=1}^s \frac{(P_i^2 + \lambda_i Q_i^2)}{2} \quad (\text{A3.12.48})$$

where $\lambda_i = 4\pi^2\nu_i^2$. Solving the classical equations of motion for this Hamiltonian gives rise to quasiperiodic motion [58] in which each normal-mode coordinate Q_i varies with time according to

$$Q_i = Q_i^0 \cos(2\pi\nu_i t + \delta_i) \quad (\text{A3.12.49})$$

where Q_i^0 is the amplitude and δ_i the phase of the motion. Thus, if an energy $E_i = (p_i^2 + \lambda_i Q_i^2)/2$ and phase δ_i are chosen for each normal mode, the complete intramolecular motion of the energized molecule may be determined for this particular initial condition.

Reaction is assumed to have occurred if a particular internal coordinate q , such as a bond length, attains a critical extension q^\ddagger . In the normal-mode approximation, the displacement d of internal coordinates and normal-mode coordinates Q are related through the linear transformation

$$d = LQ. \quad (\text{A3.12.50})$$

The transformation matrix L is obtained from a normal-mode analysis performed in internal coordinates [59,60]. Thus, as the evolution of the normal-mode coordinates versus time is evaluated from equation (A3.12.49), displacements in the internal coordinates and a value for q are found from equation (A3.12.50). The variation in q with time results from a superposition of the normal modes. At a particular time, the normal-mode coordinates may phase together so that q exceeds the critical extension q^\ddagger , at which point decomposition is assumed to occur.

-22-

The preceding discussion gives the essential details of the Slater theory. Energy does not flow freely within the molecule and attaining the critical reaction coordinate extension is not a statistically random process as in RRKM theory, but depends on the energies and phases of the specific normal modes excited. If a microcanonical ensemble is chosen at $t = 0$, Slater theory gives an initial decay rate which agrees with the RRKM value. However, Slater theory gives rise to intrinsic non-RRKM behaviour [12,13]. The trajectories are quasiperiodic and each trajectory is restricted to a particular type of motion and region of phase space. Thus, as specific trajectories react, other trajectories cannot fill up unoccupied regions of phase space. As a result, a microcanonical ensemble is not maintained during the unimolecular decomposition. In addition, some of the trajectories may be unreactive and trapped in the reactant region of phase space.

Overall, the Slater theory is unsuccessful in interpreting experiments. Many unimolecular rate constants and reaction paths are consistent with energy flowing randomly within the molecule [4,36]. If one considers the nature of classical Hamiltonians for actual molecules, it is not surprising that the Slater theory performs so poorly. For example, in Slater theory, the intramolecular and unimolecular dynamics of the molecule conform to the symmetry of the molecular vibrations. Thus, if normal modes of a particular symmetry type are excited (e.g. in-plane vibrations) a decomposition path of another symmetry type (e.g. out-of-plane dissociation) cannot occur. This path requires excitation of out-of-plane vibrations. Normal modes of different symmetry types for actual molecules are coupled by *Coriolis* vibrational-rotational interactions [61]. Similarly, nonlinear resonance interactions couple normal modes of vibration, allowing transfer of energy [62,63]. Not including these effects is a severe shortcoming of Slater theory. Clearly, understanding the classical intramolecular motion of vibrationally excited molecules requires one to go beyond the normal-mode model.

A3.12.6.2 COUPLED ANHARMONIC HAMILTONIANS

The first classical trajectory study of unimolecular decomposition and intramolecular motion for realistic anharmonic molecular Hamiltonians was performed by Bunker [12,13]. Both intrinsic RRKM and non-RRKM dynamics was observed in these studies. Since this pioneering work, there have been numerous additional studies [9,17,30,64,65,66 and 67] from which two distinct types of intramolecular motion, chaotic and quasiperiodic [14], have been identified. Both are depicted in figure A3.12.7. Chaotic vibrational motion is not regular as predicted by the normal-mode model and, instead, there is energy transfer between the modes. If all the modes of the molecule participate in the chaotic motion and energy flow is sufficiently rapid, an initial microcanonical ensemble is maintained as the molecule dissociates and RRKM behaviour is observed [9]. For non-random excitation initial apparent non-RRKM behaviour is observed, but at longer times a microcanonical ensemble of states is formed and the probability of decomposition becomes that of RRKM theory.

-23-

Figure A3.12.7. Two trajectories for a model HCC Hamiltonian. Top trajectory is for $n_{\text{HC}}=0$ and $n_{\text{CC}}=2$, and

is quasiperiodic. Bottom trajectory is for $n_{\text{HC}}=5$ and $n_{\text{CC}}=0$, and is chaotic. R_1 is the HC bond length and R_2 the CC bond length. Distance is in Å ngstroms (Å). (Adapted from [121] and [4].)

-24-

Quasiperiodic motion is regular as assumed by the Slater theory. The molecule's vibrational motion may be represented by a superposition of individual modes, each containing a fixed amount of energy. For some cases these modes resemble normal modes, but they may be identifiably different. Thus, although actual molecular Hamiltonians contain potential and kinetic energy coupling terms, they may still exhibit regular vibrational motion with no energy flow between modes as predicted by the Slater theory. The existence of regular motion for coupled systems is explained by the Kolmogorov–Arnold–Moser (KAM) theorem [4,68].

Extensive work has been done to understand quasiperiodic and chaotic vibrational motion of molecular Hamiltonians [14,58,63,68,69]. At low levels of excitation, quasiperiodic normal mode motion is observed. However, as the energy is increased, nonlinear resonances [14,62,63,68] result in the flow of energy between the normal modes, giving rise to chaotic trajectories. In general, the fraction of the trajectories, which are chaotic at a fixed energy, increases as the energy is increased. With increase in energy the nature of the quasiperiodic trajectories may undergo a transition from normal mode to another type of motion, e.g. local mode [70,71]. In many cases the motion becomes totally chaotic before the unimolecular threshold energy is reached, so that the intramolecular dynamics is ergodic. Though this implies intrinsic RRKM behaviour for energies above the threshold, the ergodicity must occur on a timescale much shorter than the RRKM lifetime for a system to be intrinsically RRKM.

For some systems quasiperiodic (or nearly quasiperiodic) motion exists above the unimolecular threshold, and intrinsic non-RRKM lifetime distributions result. This type of behaviour has been found for Hamiltonians with low unimolecular thresholds, widely separated frequencies and/or disparate masses [12,62,65]. Thus, classical trajectory simulations performed for realistic Hamiltonians predict that, for some molecules, the unimolecular rate constant may be strongly sensitive to the modes excited in the molecule, in agreement with the Slater theory. This property is called *mode specificity* and is discussed in the next section.

It is of interest to consider the classical/quantal correspondence for the above different types of classical motion. If the motion within the classical phase space is ergodic so that the decomposing molecules can be described by a microcanonical ensemble, classical RRKM theory will be valid. However, the classical and quantal RRKM rate constants may be in considerable disagreement. This results from an incorrect treatment of zero-point energy in the classical calculations [17,72] and is the reason quantum statistical mechanics is needed to calculate an accurate RRKM rate constant: see the discussion following equation (A3.12.15). With the energy referenced at the bottom of the well, the total internal energy of the dissociating molecule is $E = E^* + E_z^*$ where E^* is the internal energy of the molecule and E_z^* is its zero-point energy. The classical dissociation energy is D_e , and the energy available to the dissociating molecule at the classical barrier is $E - D_e$. Because the quantal threshold is $D_e + E_z^\ddagger$ where E_z^\ddagger is the zero-point energy at the barrier, the classical threshold is lower than the quantal one by E_z^\ddagger . For large molecules with a large E_z^\ddagger and/or for low levels of excitation the classical RRKM rate constant is significantly larger than the quantal one. Only in the high-energy limit are they equal; see figure A3.12.3.

Quasiperiodic trajectories, with an energy greater than the unimolecular threshold, are trapped in the reactant region of phase space and will not dissociate. These trajectories correspond to quantum mechanical compound-state resonances $|n\rangle$ (discussed in the next section), which have complex eigenvalues. Applying semiclassical mechanics to the trajectories [73, 74, 75 and 76] gives energies E_n , wavefunctions ψ_n , and unimolecular rate constants k_n for these resonances. A classical microcanonical ensemble for an energized

molecule may consist of quasiperiodic, chaotic, and ‘vague tori’ trajectories [77]. The lifetimes of trajectories for the latter may yield correct quantum k_n for resonance states[4].

A3.12.7 STATE-SPECIFIC UNIMOLECULAR DECOMPOSITION

The quantum dynamics of unimolecular decomposition may be studied by solving the time-dependent Schrödinger equation, i.e. equation (A3.12.2). For some cases the dissociation probability of the molecule is sufficiently small that one can introduce the concept of quasi-stationary states. Such states are commonly referred to as resonances, since the energy of the unimolecular product(s) in the continuum is in resonance with (i.e. matches) the energy of a vibrational/rotational level of the unimolecular reactant. For unimolecular reactions there are two types of resonance states. A shape resonance occurs when a molecule is temporarily trapped by a fairly high and wide potential energy barrier and decomposes by tunnelling. The second type of resonance, called a Feshbach or compound-state resonance, arises when energy is initially distributed between molecular vibrational/rotational degrees of freedom which are not strongly coupled to the decomposition reaction coordinate motion, so that there is a time lag for unimolecular dissociation.

In a time-dependent picture, resonances can be viewed as localized wavepackets composed of a superposition of continuum wavefunctions, which qualitatively resemble bound states for a period of time. The unimolecular reactant in a resonance state moves within the potential energy well for a considerable period of time, leaving it only when a fairly long time interval τ has elapsed; τ may be called the lifetime of the almost stationary resonance state.

Solving the time-dependent Schrödinger equation for resonance states [78] one obtains a set of complex eigenvalues, which may be written in the form

$$E_n^0 = E_n - i\Gamma_n/2 \quad (\text{A3.12.51})$$

where E_n and Γ_n are positive constants. The constant E_n , the real component to the eigenvalue, gives the position of the resonance in the spectrum. It is easy to see the physical significance of complex energy values. The time factor in the wavefunction of a quasi-stationary state is of the form

$$\exp[-(i/\hbar)E_n^0 t] = \exp[-(i/\hbar)E_n t] \exp[-(\Gamma_n/2\hbar)t]. \quad (\text{A3.12.52})$$

Hence, all probabilities given by the squared modulus of the wavefunction decrease as $\exp[-(\Gamma_n/\hbar)t]$ with time, that is

$$|\psi_n(t)|^2 = |\psi_n(0)|^2 \exp[-(\Gamma_n/\hbar)t]. \quad (\text{A3.12.53})$$

In particular, the probability of finding the unimolecular reactant within its potential energy well decreases according to this law. Thus Γ_n determines the lifetime of the state and the state specific unimolecular rate constant is

$$k_n = \Gamma_n/\hbar = 1/\tau_n \quad (\text{A3.12.54})$$

where τ_n is the state's lifetime.

-26-

The energy spectrum of the resonance states will be quasi-discrete; it consists of a series of broadened levels with Lorentzian lineshapes whose full-width at half-maximum Γ is related to the lifetime by $\Gamma = \hbar\tau$. The resonances are said to be isolated if the widths of their levels are small compared with the distances (spacings) between them, that is

$$\Gamma_n \ll 1/\rho(E) \quad (\text{A3.12.55})$$

where $\rho(E)$ is the density of states for the energized molecule. A possible absorption spectrum for a molecule with isolated resonances is shown in figure A3.12.8. Below the unimolecular threshold E_0 , the absorption lines for the molecular eigenstates are very narrow and are only broadened by interaction of the excited molecule with the radiation field. However, above E_0 the excited states leak toward product space, which gives rise to widths for the resonances in the spectrum. Each resonance has its own characteristic width (i.e. lifetime). As the linewidths broaden and/or the number of resonance states in an energy interval increases, the spectrum may no longer be quasi-discrete since the resonance lines may overlap, that is

$$\Gamma_n \gg 1/\rho(E). \quad (\text{A3.12.56})$$

It is of interest to determine when the linewidth $\Gamma(E)$ associated with the RRKM rate constant $k(E)$ equals the average distance $\rho(E)^{-1}$ between the reactant energy levels. From equation (A3.12.54) $\Gamma(E) = \hbar k(E)$ and from the RRKM rate constant expression equation (A3.12.15) $\rho(E)^{-1} = \hbar 2\pi K(E)/N^\ddagger(E - E_0)$. Equating these two terms gives $N^\ddagger(E - E_0) = 2\pi$, which means that the linewidths, associated with RRKM decomposition, begin to overlap when the transition state's sum of states exceeds six.

Figure A3.12.8. Possible absorption spectrum for a molecule which dissociates via isolated compound-state resonances. E_0 is the unimolecular threshold. (Adapted from [4].)

The theory of isolated resonances is well understood and is discussed below. Mies and Krauss [79,80] and Rice [81] were pioneers in treating unimolecular rate theory in terms of the decomposition of isolated Feshbach resonances.

A3.12.7.1 ISOLATED REACTANT RESONANCE STATES MODE SPECIFICITY

The observation of decomposition from isolated compound-state resonances does not necessarily imply mode-specific unimolecular decomposition. Nor is mode specificity established by the presence of fluctuations in state-specific rate constants for resonances within a narrow energy interval. What is required for mode-specific unimolecular decomposition is a distinguishable and, thus, assignable pattern (or patterns) in the positions of resonance states in the spectrum. Identifying such patterns in a spectrum allows one to determine which modes in the molecule are excited when forming the resonance state. It is, thus, possible to interpret particularly large or small state-specific rate constants in terms of mode-specific excitations. Therefore, mode specificity means there are exceptionally large or small state-specific rate constants depending on which modes are excited.

The ability to assign a group of resonance states, as required for mode-specific decomposition, implies that the complete Hamiltonian for these states is well approximated by a zero-order Hamiltonian with eigenfunctions $\phi_i(m)$ [58]. The ϕ_i are product functions of a zero-order orthogonal basis for the reactant molecule and the quantity m represents the quantum numbers defining ϕ_i . The wavefunctions ψ_n for the compound state resonances are given by

$$\psi_n = \sum_i c_{in} \phi_i(m). \quad (\text{A3.12.57})$$

Resonance states in the spectra, which are assignable in terms of zero-order basis $\phi_i(m)$, will have a predominant expansion coefficient c_{in} . Hose and Taylor [58] have argued that for an assignable level $c_{in}^2 > 0.5$ for one of the expansion coefficients. The quasiperiodic and ‘vague tori’ trajectories for energies above the unimolecular threshold, discussed in the previous section, are the classical analogue of these quantum mode specific resonance states.

Mode specificity has been widely observed in the unimolecular decomposition of van der Waals molecules [82], e.g.

A covalent bond (or particular normal mode) in the van der Waals molecule (e.g. the I_2 bond in $\text{I}_2\text{-He}$) can be selectively excited, and what is usually observed experimentally is that the unimolecular dissociation rate constant is orders of magnitude smaller than the RRKM prediction. This is thought to result from weak coupling between the excited high-frequency intramolecular mode and the low-frequency van der Waals intermolecular modes [83]. This coupling may be highly mode specific. Exciting the two different HF stretch modes in the $(\text{HF})_2$ dimer with one quantum results in lifetimes which differ by a factor of 24 [84]. Other van der Waals molecules studied include $(\text{NO})_2$ [85], NO-HF [86], and $(\text{C}_2\text{H}_4)_2$ [87].

There are fewer experimental examples of mode specificity for the unimolecular decomposition of covalently bound molecules. One example is the decomposition of the formyl radical HCO, namely

Well defined progressions are seen in the stimulated emission pumping spectrum (SEP) [88,89] so that quantum numbers may be assigned to the HCO resonance states, and lifetimes for these states may be associated with the degree of excitation in the HC stretch, CO stretch and HCO bend vibrational modes, denoted by quantum numbers ν_1 , ν_2 , and ν_3 , respectively. States with large ν_1 and large excitations in the HC stretch have particularly short lifetimes, while states with large ν_2 and large excitations in the CO stretch have particularly long lifetimes. Short lifetimes for states with a large ν_1 might be expected, since the reaction coordinate for dissociation is primarily HC stretching motion. The mode specific effects are illustrated by the nearly isoenergetic (ν_1, ν_2, ν_3) resonance states (0, 4, 5), (1, 5, 1) and (0, 7, 0) whose respective energies (i.e. position in spectrum) are 12373, 12487 and 12544 cm^{-1} and whose respective linewidths Γ are 42, 55 and 0.72 cm^{-1} .

Time-dependent quantum mechanical calculations have also been performed to study the HCO resonance states [90,91]. The resonance energies, linewidths and quantum number assignments determined from these calculations are in excellent agreement with the experimental results.

Mode specificity has also been observed for $\text{HOCl} \rightarrow \text{Cl} + \text{OH}$ dissociation [92, 93 and 94]. For this system, many of the states are highly mixed and unassignable (see below). However, resonance states with most of the energy in the OH bond, e.g. $\nu_{\text{OH}} = 6$, are assignable and have unimolecular rate constants orders of magnitude smaller than the RRKM prediction [92, 93 and 94]. The lifetimes of these resonances have a very strong dependence on the J and K quantum numbers of HOCl.

(A) STATISTICAL STATE SPECIFICITY

In contrast to resonance states which may be assigned quantum numbers and which may exhibit mode-specific decomposition, there are states which are intrinsically unassignable. Because of extensive couplings, a zero-order Hamiltonian and its basis set cannot be found to represent the wavefunctions ψ_n for these states. The spectrum for these states is irregular without patterns, and fluctuations in the k_n are related to the manner in which the ψ_n are randomly distributed in coordinate space. Thus, the states are intrinsically unassignable and have no good quantum numbers apart from the total energy and angular momentum. Energies for these resonance states do not fit into a pattern, and states with particularly large or small rate constants are simply random occurrences in the spectrum. For the most statistical (i.e. non-separable) situation, the expansion coefficients in [equation \(A3.12.56\)](#) are random variables, subject only to the normalization and orthogonality conditions

$$\sum_n c_{in}^2 = 1 \quad \text{and} \quad \sum_i c_{in} c_{im} = 0. \quad (\text{A3.12.58})$$

If all the resonance states which form a microcanonical ensemble have random ψ_n , and are thus intrinsically unassignable, a situation arises which is called *statistical state-specific behaviour* [95]. Since the wavefunction coefficients of the ψ_n are Gaussian random variables when projected onto ϕ_i basis functions for any zero-order representation [96], the distribution of the state-specific rate constants k_n will be as statistical as possible. If these k_n within the energy interval $E \rightarrow E + dE$ form a continuous distribution, Levine [97] has argued that the probability of a particular k is given by the Porter–Thomas [98] distribution

$$P(k) = \frac{\nu}{2\bar{k}} \left(\frac{\nu k}{2\bar{k}} \right)^{((\nu-2)/2)} \frac{\exp(-\nu k/2\bar{k})}{\Gamma(1/2\nu)} \quad \text{A3.12.59}$$

where \bar{k} is the average state-specific unimolecular rate constant within the energy interval $E \rightarrow E + dE$,

$$\bar{k} = \int_0^\infty k P(k) dk \quad \text{(A3.12.60)}$$

and ν is the ‘effective number of decay channels’. Equation (A3.12.59) is derived in statistics as the probability distribution

$$X_\nu^2 = x_1^2 + x_2^2 + \dots + x_\nu^2 \quad \text{(A3.12.61)}$$

where the νx_i are each independent Gaussian distributions [96]. Increasing ν reduces the variance of the distribution $P(k)$.

The connection between the Porter–Thomas $P(k)$ distribution and RRKM theory is made through the parameters \bar{k} and ν . Waite and Miller [99] have studied the relationship between the average of the statistical state-specific rate constants k and the RRKM rate constant $k(E)$ by considering a separable (uncoupled) two-dimensional Hamilton, $H = H_x + H_y$, whose decomposition path is tunnelling through a potential energy barrier along the x -coordinate. They found that the average of the state-specific rate constants for a microcanonical ensemble \bar{k} is the same as the RRKM rate constant $k(E)$. Though insightful, this is not a general result since the tunnelling barrier defines the dividing surface, with no recrossings, which is needed to derive RRKM from classical (not quantum) mechanical principles (see section A3.12.3). For state-specific decomposition which does not occur by tunnelling, a dividing surface cannot be constructed for a quantum calculation. However, the above analysis is highly suggestive that \bar{k} may be a good approximation to the RRKM $k(E)$.

The parameter ν in equation (A3.12.59) has also been related to RRKM theory. Polik *et al* [80] have shown that for decomposition by quantum mechanical tunnelling

$$\nu = \left[\sum_n \kappa(E - E_n^\ddagger) \right]^2 / \sum_n \kappa(E - E_n^\ddagger)^2 \quad \text{(A3.12.62)}$$

where $\kappa(E - E_n^\ddagger)$ is a one-dimensional tunnelling probability through a potential barrier and E_n^\ddagger is the vibrational energy in the $3N - 7$ modes orthogonal to the tunnelling coordinate. If the energy is sufficiently low that all the tunnelling probabilities are much less than 1 and one makes a parabolic approximation to the tunnelling probabilities [96,100], equation (A3.12.62) becomes

$$\nu = \prod_{k=1}^{3N-7} \coth(\pi \omega_k^\ddagger / \omega_b) \quad \text{(A3.12.63)}$$

where the ω_k^\ddagger are the $3N - 7$ frequencies for the modes orthogonal to the tunnelling coordinate and ω_b is the

barrier frequency. The interesting aspect of [equation \(A3.12.63\)](#) is that it shows ν to be energy independent in the tunnelling region. On the other hand, for energies significantly above the barrier so that $\kappa(E - E_{\ddagger}^{\ddagger}) = 1$, it is easy to show [\[96,100\]](#) that

$$\nu = N^{\ddagger}(E) \quad (\text{A3.12.64})$$

where $N^{\ddagger}(E)$ is the sum of states for the transition state. In this energy region, ν rapidly increases with increase in energy and the $P(k)$ distribution becomes more narrowly peaked. Statistical state-specific behaviour has been observed in experimental SEP studies of $\text{H}_2\text{CO} \rightarrow \text{H}_2 + \text{CO}$ dissociation [\[44,48\]](#) and quantum mechanical scattering calculations of $\text{HO}_2 \rightarrow \text{H} + \text{O}_2$ dissociation [\[101,102\]](#). The state-specific rate constants for the latter calculation are plotted in [figure A3.12.9](#). For both of these dissociations the RRKM rate constant and the average of the state-specific quantum rate constants for a small energy interval ΔE are in good agreement. Similarly, the fluctuations in the resonance rate constants are well represented by the Porter–Thomas distribution. That HO_2 dissociation is statistical state-specific, while HCO dissociation is mode specific, is thought to arise from the deeper potential energy well and associated greater couplings and density of states for HO_2 .

Figure A3.12.9. Comparison of the unimolecular dissociation rates for $\text{HO}_2 \rightarrow \text{H} + \text{O}_2$ as obtained from the quantum mechanical resonances (k_{qm} , open circles) and from variational transition state RRKM (k_{RRKM} , step function). E_{thr} is the threshold energy for dissociation. Also shown is the quantum mechanical average (solid line) as well as the experimental prediction for $J=0$ derived from a simplified SACM analysis of high pressure unimolecular rate constants. (Adapted from [\[101\]](#).)

A microcanonical ensemble of isolated resonances decays according to

$$N(t, E) = \sum_n \exp(-k_n t).$$

If the state-specific rate constants are assumed continuous, equation (A3.12.65) can be written as [103]

$$N(t, E) = N_0 \int_0^\infty \exp(-kt) P(k) \mathbf{d}(k) \quad (\text{A3.12.66})$$

where N_0 is the total number of molecules in the microcanonical ensemble. For the Porter–Thomas $P(k)$ distribution, $N(t, E)$ becomes [103,104]

$$N(t, E)/N_0 = (1 + 2\bar{k}t/v)^{-v/2}. \quad (\text{A3.12.67})$$

The expression for $N(t, E)$ in equation (A3.12.67) has been used to study [103,104] how the Porter–Thomas $P(k)$ affects the collision-averaged monoenergetic unimolecular rate constant $k(\omega, E)$ [105] and the Lindemann–Hinshelwood unimolecular rate constant $k_{\text{uni}}(\omega, T)$ [47]. The Porter–Thomas $P(k)$ makes $k(\omega, E)$ pressure dependent [103]. It equals \bar{k} in the high-pressure $\omega \rightarrow \infty$ limit and $[(v-2)/v]\bar{k}$ in the $\omega \rightarrow 0$ low-pressure limit. $P(k)$ only affects $k_{\text{uni}}(\omega, T)$ in the intermediate pressure regime [40,104], and has no effect on the high- and low-pressure limits. This type of analysis has been applied to $\text{HO}_2 \rightarrow \text{H} + \text{O}_2$ resonance states [106], which decay in accord with the Porter–Thomas $P(k)$. Deviations between the $k_{\text{uni}}(\omega, T)$ predicted by the Porter–Thomas and exponential $P(k)$ are more pronounced for the model in which the rotational quantum number K is treated as adiabatic than the one with K active.

A3.12.7.2 INDIVIDUAL TRANSITION STATE LEVELS

The prediction of RRKM theory is that at low energies, where $N^\ddagger(E)$ is small, there are incremental increases in $N^\ddagger(E)$ and resulting in steps in $k(E)$. The minimum rate constant is at the threshold where $N^\ddagger(E) = 1$, i.e. $k(E_0) = 1/\rho(E_0)$. Steps are then expected in $k(E)$ as $N^\ddagger(E)$ increases by unit amounts. This type of behaviour has been observed in experiments for $\text{NO}_2 \rightarrow \text{NO} + \text{O}$ [107,108], $\text{CH}_2\text{CO} \rightarrow \text{CH}_2 + \text{CO}$ [44] and $\text{CH}_3\text{CHO} \rightarrow \text{CH}_3 + \text{HCO}$ [109] dissociation. These experiments do not directly test the rapid IVR assumption of RRKM theory, since steps are expected in $N^\ddagger(E)$ even if all the states of the reactant do not participate in $\rho(E)$. However, if the measured threshold rate constant $k(E_0)$ equals the inverse of the accurate anharmonic density of states for the reactant (difficult to determine), RRKM theory is verified.

If properly interpreted [110], the above experiments provide information about the energy levels of the transition state, i.e. figure A3.12.10. For $\text{NO}_2 \rightarrow \text{NO} + \text{O}$ dissociation, there is no barrier for the reverse association reaction, and it has been suggested that the steps in its $k(E)$ may arise from quantization of the transition state's O---NO bending mode [107,108]. Ketene (CH_2CO) dissociates on both singlet and triplet surfaces. The triplet surface has a saddlepoint, at which the transition state is located, and the steps in $k(E)$ for this surface are thought to result from excitation in the transition state's CH_2 wag and C---CO bending vibrations [44]. The singlet ketene surface does not have a barrier for the reverse $^1\text{CH}_2 + \text{CO}$ association and the small steps in $k(E)$ for dissociation on this surface are attributed to CO free

rotor energy levels for a loose transition state [44]. The steps for acetaldehyde dissociation [109] have been associated with the torsional and C---CO bending motions at the transition state.

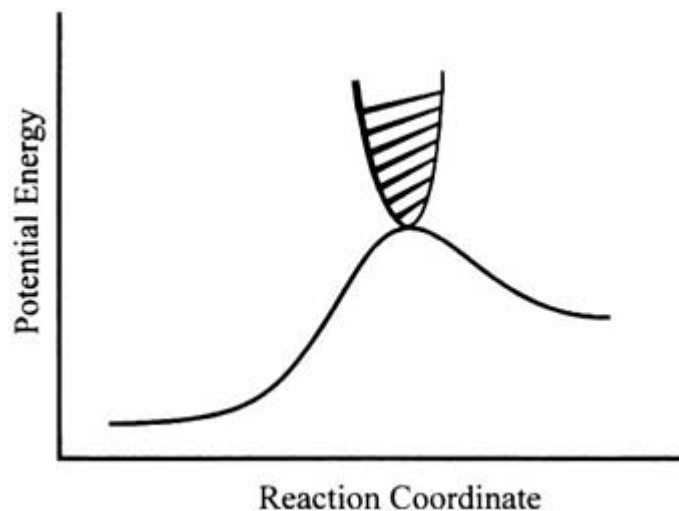

Figure A3.12.10. Schematic diagram of the one-dimensional reaction coordinate and the energy levels perpendicular to it in the region of the transition state. As the molecule's energy is increased, the number of states perpendicular to the reaction coordinate increases, thereby increasing the rate of reaction. (Adapted from [4].)

Detailed analyses of the above experiments suggest that the apparent steps in $k(E)$ may not arise from quantized transition state energy levels [110,111]. Transition state models used to interpret the ketene and acetaldehyde dissociation experiments are not consistent with the results of high-level *ab initio* calculations [110,111]. The steps observed for NO_2 dissociation may originate from the opening of electronically excited dissociation channels [107,108]. It is also of interest that RRKM-like steps in $k(E)$ are not found from detailed quantum dynamical calculations of unimolecular dissociation [91,101,102,112]. More studies are needed of unimolecular reactions near threshold to determine whether there are actual quantized transition states and steps in $k(E)$ and, if not, what is the origin of the apparent steps in the above measurements of $k(E)$.

A3.12.8 EXAMPLES OF NON-RRKM DECOMPOSITION

A3.12.8.1 APPARENT NON-RRKM

Apparent non-RRKM behaviour occurs when the molecule is excited non-randomly and there is an initial non-RRKM decomposition before IVR forms a microcanonical ensemble (see section A3.12.2). Reaction pathways, which have non-competitive RRKM rates, may be promoted in this way. Classical trajectory simulations were used in early studies of apparent non-RRKM dynamics [113,114].

To detect the initial apparent non-RRKM decay, one has to monitor the reaction at short times. This can be performed by studying the unimolecular decomposition at high pressures, where collisional stabilization competes with the rate of IVR. The first successful detection of apparent non-RRKM behaviour was accomplished by Rabinovitch and co-workers [115], who used chemical activation to prepare vibrationally excited hexafluorobicyclopropyl- d_2 :

The molecule decomposes by elimination of CF_2 , which should occur with equal probabilities from each ring when energy is randomized. However, at pressures in excess of 100 Torr there is a measurable increase in the fraction of decomposition in the ring that was initially excited. From an analysis of the relative product yield *versus* pressure, it was deduced that energy flows between the two cyclopropyl rings with a rate of only $3 \times 10^9 \text{ s}^{-1}$. In a related set of experiments Rabinovitch *et al* [116] studied the series of chemically activated fluoroalkyl cyclopropanes:

The chemically activated molecules are formed by reaction of $^1\text{CH}_2$ with the appropriate fluorinated alkene. In all these cases apparent non-RRKM behaviour was observed. As displayed in [figure A3.12.11](#) the measured unimolecular rate constants are strongly dependent on pressure. The large rate constant at high pressure reflects an initial excitation of only a fraction of the total number of vibrational modes, i.e. initially the molecule behaves smaller than its total size. However, as the pressure is decreased, there is time for IVR to compete with dissociation and energy is distributed between a larger fraction of the vibrational modes and the rate constant decreases. At low pressures each rate constant approaches the RRKM value.

-34-

Figure A3.12.11. Chemical activation unimolecular rate constants *versus* ω for fluoroalkyl cyclopropanes. The \square , \circ and \blacktriangle points are for $R=\text{CF}_3$, C_3F_7 , and C_5F_{11} , respectively. (Adapted from [116].)

Apparent non-RRKM dynamics has also been observed in time-resolved femtosecond (fs) experiments in a collision-free environment [117]. An experimental study of acetone illustrates this work. Acetone is dissociated to the CH_3 and CH_3CO (acetyl) radicals by a fs laser pulse. The latter which dissociates by the channel

is followed in real time by fs mass spectrometry to measure its unimolecular rate constant. It is found to be $2 \times 10^{12} \text{ s}^{-1}$ and ~ 10 times smaller than the RRKM value, which indicates the experimental excitation process does not put energy in the C–C reaction coordinate and the rate constant value and short timescale reflects restricted IVR and non-RRKM kinetics.

A3.12.8.2 INTRINSIC NON-RRKM

As discussed in section A3.12.2, intrinsic non-RRKM behaviour occurs when there is at least one bottleneck for transitions between the reactant molecule's vibrational states, so that IVR is slow and a microcanonical ensemble over the reactant's phase space is not maintained during the unimolecular reaction. The above discussion of mode-specific decomposition illustrates that there are unimolecular reactions which are intrinsically non-RRKM. Many van der Waals molecules behave in this manner [4,82]. For example, in an initial microcanonical ensemble for the $(\text{C}_2\text{H}_4)_2$ van der Waals molecule both the $\text{C}_2\text{H}_4 \cdots \text{C}_2\text{H}_4$ intermolecular modes and C_2H_4 intramolecular modes are excited with equal probabilities. However, this microcanonical ensemble is not maintained as the dimer dissociates. States with energy in the intermolecular modes react more rapidly than do those with the C_2H_4 intramolecular modes excited [85].

-35-

Furthermore, IVR is not rapid between the C_2H_4 intramolecular modes and different excitation patterns of these modes result in different dissociation rates. As a result of these different timescales for dissociation, the relative populations of the vibrational modes of the C_2H_4 dimer change with time.

Similar behaviour is observed in both experiments and calculations for $\text{HCO} \rightarrow \text{H} + \text{CO}$ dissociation [88, 89, 90 AND 91] and in calculations for the $\text{X}^- \cdots \text{CH}_3\text{Y}$ ion–dipole complexes, which participate in $\text{S}_{\text{N}}2$ nucleophilic substitution reactions [118]. HCO states with HC excitation dissociate more rapidly than do those with CO excitation and, thus, the relative population of HC to CO excitation decreases with time. The unimolecular dynamics of the $\text{X}^- \cdots \text{CH}_3\text{Y}$ complex is similar to that for van der Waals complexes. There is weak coupling between the $\text{X}^- \cdots \text{CH}_3\text{Y}$ intermolecular modes and the CH_3Y intramolecular modes, and the two sets of modes react on different timescales.

Definitive examples of intrinsic non-RRKM dynamics for molecules excited near their unimolecular thresholds are rather limited. Calculations have shown that intrinsic non-RRKM dynamics becomes more pronounced at very high energies, where the RRKM lifetime becomes very short and dissociation begins to compete with IVR [119]. There is a need for establishing quantitative theories (i.e. not calculations) for identifying which molecules and energies lead to intrinsic non-RRKM dynamics. For example, at thermal energies the unimolecular dynamics of the $\text{Cl}^- \cdots \text{CH}_3\text{Cl}$ complex is predicted to be intrinsically non-RRKM [118], while experiments have shown that simply replacing one of the H-atoms of CH_3Cl with a CN group leads to intrinsic RRKM dynamics for the $\text{Cl}^- \cdots \text{ClCH}_2\text{CN}$ complex [120]. This difference is thought to arise from a deeper potential energy well and less of a separation between vibrational frequencies for the $\text{Cl}^- \cdots \text{ClCH}_2\text{CN}$ complex. For the $\text{Cl}^- \cdots \text{CH}_3\text{Cl}$ complex the three intermolecular vibrational frequencies are 64(2) and 95 cm^{-1} , while the lowest intramolecular frequency is the C–Cl stretch of 622 cm^{-1} [118]. Thus, very

high-order resonances are required for energy transfer from the intermolecular to intramolecular modes. In contrast, for the $\text{Cl}^- \cdots \text{ClCH}_2\text{CN}$ complex there is less of a hierarchy of frequencies, with 44, 66 and 118 cm^{-1} for the intermolecular modes and 207, 367, 499, 717, ... for the intramolecular ones [120]. Here there are low-order resonances which couple the intermolecular and intramolecular modes. It would be very useful if one could incorporate such molecular properties into a theoretical model to predict intrinsic RRKM and non-RRKM behaviour.

ACKNOWLEDGMENTS

The author wishes to thank the many graduate students, post-doctorals and collaborators who have worked with him on this topic. Of particular importance are the many discussions the author has had with Tom Baer, Reinhard Schinke and Jürgen Troe concerning unimolecular dynamics. Special thanks are given to Fleming Crim, Martin Quack and Kihyung Song for their valuable comments in preparing this chapter.

A 3.13 Energy redistribution in reacting systems

Roberto Marquardt and Martin Quack

A 3.13.1 INTRODUCTION

Energy redistribution is the key primary process in chemical reaction systems, as well as in reaction systems quite generally (for instance, nuclear reactions). This is because many reactions can be separated into two steps:

(a) activation of the reacting species R, generating an energized species R*:

(b) reaction of the energized species to give products.

The first step (A3.13.1) is a general process of energy redistribution, whereas the second step (A3.13.2) is the genuine reaction step, occurring with a specific rate constant at energy E . This abstract reaction scheme can take a variety of forms in practice, because both steps may follow a variety of quite different mechanisms. For instance, the reaction step could be a barrier crossing of a particle, a tunnelling process or a nonadiabatic crossing between different potential hypersurfaces to name just a few important examples in chemical reactions.

The first step, which is the topic of the present chapter, can again follow a variety of different mechanisms. For instance, the energy transfer could happen within a molecule, say from one initially excited chemical bond to another, or it could involve radiative transfer. Finally, the energy transfer could involve a collisional transfer of energy between different atoms or molecules. All these processes have been recognized to be important for a very long time. The basic idea of collisional energization as a necessary primary step in chemical reactions can be found in the early work of van't Hoff [1] and Arrhenius [2, 3], leading to the famous Arrhenius equation for thermal chemical reactions (see also [chapter A3.4](#))

$$k(T) = A(T) \exp\left(-\frac{E_A(T)}{RT}\right). \quad (\text{A 3.13.3})$$

This equation results from the assumption that the actual reaction step in thermal reaction systems can happen only in molecules (or collision pairs) with an energy exceeding some threshold energy E_0 which is close, in general, to the Arrhenius activation energy defined by equation (A3.13.3). Radiative energization is at the basis of classical photochemistry (see e.g. [4, 3 and 7] and [chapter B2.5](#)) and historically has had an interesting sideline in the radiation

theory of unimolecular reactions [8], which was later superseded by the collisional Lindemann mechanism [9]. Recently, radiative energy redistribution has received new impetus through coherent and incoherent multiphoton excitation [10].

In this chapter we shall first outline the basic concepts of the various mechanisms for energy redistribution, followed by a very brief overview of collisional intermolecular energy transfer in chemical reaction systems. The main part of this chapter deals with true intramolecular energy transfer in polyatomic molecules, which is a topic of particular current importance. Stress is placed on basic ideas and concepts. It is not the aim of this chapter to review in detail the vast literature on this topic; we refer to some of the key reviews and books [11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, and 32] and the literature cited therein. These cover a variety of aspects of the topic and further, more detailed references will be given throughout this review. We should mention here the energy transfer processes, which are of fundamental importance but are beyond the scope of this review, such as electronic energy transfer by mechanisms of the Förster type [33, 34] and related processes.

A 3.13.2 BASIC CONCEPTS FOR INTER- AND INTRAMOLECULAR ENERGY TRANSFER

The processes summarized by equation (A3.13.1) can follow quite different mechanisms and it is useful to classify them and introduce the appropriate nomenclature as well as the basic equations.

A3.13.2.1 PROCESSES INVOLVING INTERACTION WITH THE ENVIRONMENT (BIMOLECULAR AND RELATED)

(a) The first mechanism concerns bimolecular, collisional energy transfer between two molecules or atoms and molecules. We may describe such a mechanism by

or more precisely by defining quantum energy levels for both colliding species, e.g.

This is clearly a process of intermolecular energy transfer, as energy is transferred between two molecular species. Generally one may, following chapter A.3.4.5, combine the quantum labels of M and R into one level index (I for initial and F for final) and define a cross section σ_{FI} for this energy transfer. The specific rate constant $k_{FI}(E_{tI})$ for the energy transfer with the collision energy E_{tI} is given by:

$$k_{FI}(E_{tI}) = \sigma_{FI}(E_{tI}) \sqrt{\frac{2E_{tI}}{\mu}} \quad (\text{A 3.13.6})$$

with the reduced mass:

$$E_{Mi} + E_{Ri} + E_{t,I} = E_{Mf} + E_{Rf} + E_{t,F}. \quad (\text{A } 3.13.7)$$

We note that, by energy conservation, the following equation must hold:

$$E_{Mi} + E_{Ri} + E_{t,I} = E_{Mf} + E_{Rf} + E_{t,F}. \quad (\text{A } 3.13.8)$$

Some of the internal (rovibronic) energy of the atomic and molecular collision partners is transformed into extra translational energy $\Delta E_t = E_{t,F} - E_{t,I}$ (or consumed, if ΔE_t is negative). If one averages over a thermal distribution of translational collision energies, one obtains the thermal rate constant for collisional energy transfer:

$$k_{FI}(T) = \left(\frac{8k_B T}{\pi \mu} \right)^{1/2} \int_0^\infty x \exp(-x) \sigma_{FI}(k_B T x) dx. \quad (\text{A } 3.13.9)$$

We note here that the quantum levels denoted by the capital indices I and F may contain numerous energy eigenstates, i.e. are highly degenerate, and refer to [chapter A3.4](#) for a more detailed discussion of these equations. The integration variable in equation (A3.13.9) is $x = E_{t,I} / k_B T$.

(b) The second mechanism, which is sometimes distinguished from the first although it is similar in kind, is obtained when we assume that the colliding species M does not change its internal quantum state. This special case is frequently realized if M is an inert gas atom in its electronic ground state, as the energies needed to generate excited states of M would then greatly exceed the energies available in ordinary reaction systems at modest temperatures. This type of mechanism is frequently called *collision induced intramolecular energy transfer*, as internal energy changes occur only *within the molecule* R. One must note that in general there is transfer of energy between *intermolecular translation* and intramolecular rotation and vibration in such a process, and thus the nomenclature ‘intramolecular’ is somewhat unfortunate. It is, however, widely used, which is the reason for mentioning it here. In the following, we shall not make use of this nomenclature and shall summarize mechanisms (a) and (b) as one class of bimolecular, intermolecular process. We may also note that, for mechanism (b) one can define a cross section σ_{FI} and rate constant k_{FI} between individual, nondegenerate quantum states *i* and *f* and obtain special equations analogous to [equation \(A3.13.5\)](#), [equation \(A3.13.4\)](#) and [equation \(A3.13.3\)](#), which we shall not repeat in detail. Indeed, one may then have cross sections and rates between different individual quantum states *i* and *f* of the same energy and thus no transfer of energy to translation. In this very special case, the redistribution of energy would indeed be entirely ‘intramolecular’ within R.

-4-

(c) The third mechanism would be transfer of energy between molecules and the radiation field. These processes involve absorption, emission or Raman scattering of radiation and are summarized, in the simplest case with one or two photons, in [equation \(A3.13.10\)](#), [equation \(A3.13.11\)](#) and [equation \(A3.13.12\)](#):

$$R_{i^{\nu}} + h\nu_i \rightarrow R_{f^{\nu}} + h\nu_f \quad (\text{Raman scattering}). \quad (\text{A 3.13.12})$$

In the case of polarized, but otherwise incoherent statistical radiation, one finds a rate constant for radiative energy transfer between initial molecular quantum states i and final states f :

$$k_{\bar{f}i} = \frac{8\pi^3}{h^2} \frac{I_{\nu}^z}{(4\pi\epsilon_0)c} |M_{\bar{f}i}^z|^2 \quad (\text{A 3.13.13})$$

where $I_{\nu}^z = dI^z / d\nu$ is the intensity per frequency bandwidth of radiation and $M_{\bar{f}i}^z$ is the electric dipole transition moment in the direction of polarization. For unpolarized random spatial radiation of density $\rho(\nu)$ per volume and frequency, I_{ν}^z / c must be replaced by $\rho(\nu) / 3$, because of random orientation, and the rate of induced transitions (absorption or emission) becomes:

$$\begin{aligned} k_{\bar{f}i}^{\text{induced}} &= B_{\bar{f}i} \rho(\nu) \\ &= \frac{8\pi^3}{3h^2(4\pi\epsilon_0)} \rho(\nu) |M_{\bar{f}i}|^2. \end{aligned} \quad (\text{A 3.13.14})$$

$B_{\bar{f}i}$ is the Einstein coefficient for induced emission or absorption, which is approximately related to the absolute value of the dipole transition moment $|M_{\bar{f}i}|$, to the integrated cross section $G_{\bar{f}i}$ for the transition and to the Einstein coefficient $A_{\bar{f}i}$ for spontaneous emission [10]:

$$B_{\bar{f}i} = \frac{c}{h} G_{\bar{f}i} = \frac{c^3}{8\pi h\nu_{\bar{f}i}^3} A_{\bar{f}i} \quad (\text{A 3.13.15})$$

with

$$G_{\bar{f}i} = \int_{\text{line}} \sigma_{\bar{f}i}(\nu) \nu^{-1} d\nu \quad (\text{A 3.13.16})$$

-5-

and $\sigma_{\bar{f}i}(\nu)$ the frequency dependent absorption cross section. In [equation \(A3.13.15\)](#), $\nu_{\bar{f}i} = |E_f - E_i| / h$. Equation (A3.13.17) is a simple, useful formula relating the integrated cross section and the electric dipole transition moment as dimensionless quantities, in the electric dipole approximation [10, 100]:

$$\frac{G_{\bar{f}i}}{\text{pm}^2} \approx 41.624 \left| \frac{M_{\bar{f}i}}{\text{Debye}} \right|^2. \quad (\text{A 3.13.17})$$

From these equations one also finds the rate coefficient matrix for thermal radiative transitions including absorption, induced and spontaneous emission in a thermal radiation field following Planck's law [35]:

$$k_{\bar{f}i} = A_{\bar{f}i} \frac{\text{sign}(E_f - E_i)}{\exp((E_f - E_i)/k_B T) - 1}. \quad (\text{A 3.13.18})$$

Finally, if one has a condition with incoherent radiation of a small band width $\Delta\nu$ exciting a broad absorption band with $\sigma(\nu \pm \Delta\nu) \approx \sigma(\nu)$, one finds:

$$k_{fi}^{\text{induced}} = \frac{\sigma(\nu)}{h\nu} I \quad (\text{A 3.13.19})$$

where I is the radiation intensity. For a detailed discussion refer to [10]. The problem of coherent radiative excitation is considered in [section A3.13.4](#) and [section A3.13.5](#) in relation to intramolecular vibrational energy redistribution.

(d) The fourth mechanism is purely intramolecular energy redistribution. It is addressed in the next section.

A3.13.2.2 STRICTLY MONOMOLECULAR PROCESSES IN ISOLATED MOLECULES

Purely intramolecular energy transfer occurs when energy migrates within an isolated molecule from one part to another or from one type of motion to the other. Processes of this type include the vast field of molecular electronic radiationless transitions which emerged in the late 1960s [36], but more generally any type of intramolecular motion such as intramolecular vibrational energy redistribution (IVR) or intramolecular vibrational–rotational energy redistribution (IVRR) and related processes [37, 38 and 39]. These processes will be discussed in [section A3.13.5](#) in some detail in terms of their full quantum dynamics. However, in certain situations a statistical description with rate equations for such processes can be appropriate [38].

[Figure A3.13.1](#) illustrates our general understanding of intramolecular energy redistribution in isolated molecules and shows how these processes are related to ‘intermolecular’ processes, which may follow any of the mechanisms discussed in the previous section. The horizontal bars represent levels of nearly degenerate states of an isolated molecule.

-6-

Figure A3.13.1. Schematic energy level diagram and relationship between ‘intermolecular’ (collisional or radiative) and intramolecular energy transfer between states of isolated molecules. The fat horizontal bars indicate thin energy shells of nearly degenerate states.

Having introduced the basic concepts and equations for various energy redistribution processes, we will now

discuss some of them in more detail.

A 3.13.3 COLLISIONAL ENERGY REDISTRIBUTION PROCESSES

A3.13.3.1 THE MASTER EQUATION FOR COLLISIONAL RELAXATION REACTION PROCESSES

The fundamental kinetic master equations for collisional energy redistribution follow the rules of the kinetic equations for all elementary reactions. Indeed an energy transfer process by inelastic collision, [equation \(A3.13.5\)](#), can be considered as a somewhat special ‘reaction’. The kinetic differential equations for these processes have been discussed in the general context of [chapter A3.4](#) on gas kinetics. We discuss here some special aspects related to collisional energy transfer in reactive systems. The general master equation for relaxation and reaction is of the type [[11](#), [12](#) and [13](#), [15](#), [25](#), [40](#), [41](#)]:

$$\frac{dc_j(t)}{dt} = F(\{c_k(t)\}) \quad (\text{A 3.13.20})$$

$$c_j(t = 0) = c_{j0}. \quad (\text{A 3.13.21})$$

-7-

The index j can label quantum states of the same or different chemical species. [Equation \(A3.13.20\)](#) corresponds to a generally stiff initial value problem [[42](#), [43](#)]. In matrix notation one may write:

$$\frac{dc(t)}{dt} = F[c(t)] \quad (\text{A 3.13.22})$$

$$c(t = 0) = c_0. \quad (\text{A 3.13.23})$$

There is no general, simple solution to this set of coupled differential equations, and thus one will usually have to resort to numerical techniques [[42](#), [43](#)] (see also [chapter A3.4](#)).

A3.13.3.2 THE MASTER EQUATION FOR COLLISIONAL AND RADIATIVE ENERGY REDISTRIBUTION UNDER CONDITIONS OF GENERALIZED FIRST-ORDER KINETICS

There is one special class of reaction systems in which a simplification occurs. If collisional energy redistribution of some reactant occurs by collisions with an excess of ‘heat bath’ atoms or molecules that are considered kinetically structureless, and if furthermore the reaction is either unimolecular or occurs again with a reaction partner M having an excess concentration, then one will have generalized first-order kinetics for populations p_j of the energy levels of the reactant, i.e. with

$$\frac{dp_j}{dt} = \sum_{k \neq j} (K'_{jk} p_k - K'_{kj} p_j) - k_j p_j \quad (\text{A 3.13.24})$$

$$\frac{dp}{dt} = \mathbf{K}p \quad (\text{A 3.13.25})$$

In equation (A3.13.24), k_j is the specific rate constant for reaction from level j , and K'_{jk} are energy transfer rate coefficients. With appropriate definition of a rate coefficient matrix \mathbf{K} one has, in matrix notation,

$$\frac{dp}{dt} = \mathbf{K}p \quad (\text{A 3.13.26})$$

where for $j \neq i$

$$K_{ji}(T) = \left(\frac{8k_B T}{\pi \mu} \right)^{1/2} [M] \int_0^\infty x \exp(-x) \sigma_{ji}(k_B T x) dx. \quad (\text{A 3.13.27})$$

-8-

(see [equation \(A3.13.9\)](#)) and

$$-K_{jj}(T) = k_j + \sum_{k \neq j} K_{kj}(T). \quad (\text{A3.13.28})$$

The master [equation \(A3.13.26\)](#) applies also, under certain conditions, to radiative excitation with rate coefficients for radiative energy transfer being given by [equation \(A3.13.13\)](#), [equation \(A3.13.14\)](#), [equation \(A3.13.15\)](#), [equation \(A3.13.16\)](#), [equation \(A3.13.17\)](#), [equation \(A3.13.18\)](#) and [equation \(A3.13.19\)](#), depending on the case, or else by more general equations [10]. Finally, the radiative and collisional rate coefficients may be considered together to be important at the same time in a given reaction system, if time scales for these processes are of the appropriate order of magnitude. The solution of [equation \(A3.13.26\)](#) is given by:

$$p(t) = \exp(\mathbf{K}t)p(0). \quad (\text{A 3.13.29})$$

This solution can be obtained explicitly either by matrix diagonalization or by other techniques (see [chapter A3.4](#) and [42, 43]). In many cases the discrete quantum level labels in [equation \(A3.13.24\)](#) can be replaced by a continuous energy variable and the populations by a population density $p(E)$, with replacement of the sum by appropriate integrals [11]. This approach can be made the starting point of useful analytical solutions for certain simple model systems [11, 19, 44, 45 and 46].

While the time dependent populations $p_j(t)$ may generally show a complicated behaviour, certain simple limiting cases can be distinguished and characterized by appropriate parameters:

(a) The long time steady state limit (formally $t \rightarrow \infty$) is described by the largest eigenvalue λ_1 of \mathbf{K} . Since all λ_j are negative, λ_1 has the smallest absolute value [35, 47]. In this limit one finds [47] (with the reactant fraction $F_R = \sum_j p_j$):

$$-\frac{d \ln(F_R(t))}{dt} = -\frac{d \ln(\sum_j p_j(t))}{dt} = k_{\text{uni}} = -\lambda_1. \quad (\text{A3.13.30})$$

Thus, this eigenvalue λ_1 determines the unimolecular steady-state reaction rate constant.

(b) The second largest eigenvalue λ_2 determines ideally the relaxation time towards this steady state, thus:

$$\tau_{\text{relax}}^{-1} = -\lambda_2. \quad (\text{A 3.13.31})$$

More generally, further eigenvalues must be taken into account in the relaxation process.

-9-

(c) It is sometimes useful to define an incubation time τ_{inc} by the limiting equation for steady state:

$$-\ln(F_{\text{R}}^{\text{st}}(t)) = -\lambda_1(t - \tau_{\text{inc}}). \quad (\text{A 3.13.32})$$

Figure A3.13.2 illustrates the origin of these quantities. Refer to [47] for a detailed mathematical discussion as well as the treatment of radiative laser excitation, in which incubation phenomena are important. Also refer to [11] for some classical examples in thermal systems.

Figure A3.13.2. Illustration of the analysis of the master equation in terms of its eigenvalues λ_1 and λ_2 for the example of IR-multiphoton excitation. The dashed lines give the long time straight line limiting behaviour. The full line to the right-hand side is for $x = F_{\text{R}}(t)$ with a straight line of slope $-\lambda_1 = k_{\text{uni}}^{-1}$. The intercept of the corresponding dashed line (F_{R}^{st}) indicates τ_{inc} (see equation (A3.13.32)). The left-hand line is for $x = |F_{\text{R}} - F_{\text{R}}^{\text{st}}|$ with limiting slope $-\lambda_2 = \tau_{\text{relax}}^{-1}$ (see text and [47]).

As a rule, in thermal unimolecular reaction systems at modest temperatures, λ_1 is well separated from the other eigenvalues, and thus the time scales for incubation and ‘relaxation’ are well separated from the steady-state reaction time scale $\tau_{\text{reaction}} = k_{\text{uni}}^{-1}$. On the other hand, at high temperatures, k_{uni} , τ_{relax}^{-1} and τ_{inc}^{-1} may merge. This is illustrated in figure A3.13.3 for the classic example of thermal unimolecular dissociation [48, 49, 50 and 51]:

Note that in the ‘low pressure limit’ of unimolecular reactions ([chapter A3.4](#)), the unimolecular rate constant k_{uni} is entirely dominated by energy transfer processes, even though the relaxation and incubation rates (τ_{relax}^{-1} and τ_{inc}^{-1}) may be much faster than k_{uni} .

Figure A3.13.3. Dissociation ($k_{\text{uni}} = k_{\text{diss}}$), incubation (τ_{inc}^{-1}) and relaxation (τ_{relax}^{-1}) rate constants for the reaction $N_2O \rightarrow N_2 + O$ at low pressure in argon (from [11], see discussion in the text for details and references to the experiments).

The master equation treatment of energy transfer in even fairly complex reaction systems is now well established and fairly standard [52]. However, the rate coefficients k_{ij} for the individual energy transfer processes must be established and we shall discuss some aspects of this matter in the following section.

A3.13.3.3 MECHANISMS OF COLLISIONAL ENERGY TRANSFER

Collisional energy transfer in molecules is a field in itself and is of relevance for kinetic theory ([chapter A3.1](#)), gas phase kinetics ([chapter A3.4](#)), RRKM theory ([chapter A3.12](#)), the theory of unimolecular reactions in general,

as well as the kinetics of laser systems [53]. [Chapter C3.3](#), [Chapter C3.4](#) and [Chapter C3.5](#) treat these subjects in detail. We summarize those aspects that are of importance for mechanistic considerations in chemically reactive systems.

We start from a model in which collision cross sections or rate constants for energy transfer are compared with a reference quantity such as average Lennard-Jones collision cross sections or the usually cited Lennard-Jones collision frequencies [54]

$$Z_{LJ} = \pi \sigma_{AB}^2 \left(\frac{8k_B T}{\pi \mu_{AB}} \right)^{1/2} \Omega_{AB}^{(2,2)*} \quad (\text{A3.13.34})$$

where σ_{AB} is the Lennard-Jones parameter and $\Omega_{AB}^{(2,2)*}$ is the reduced collision integral [54], calculated from the binding energy ϵ and the reduced mass μ_{AB} for the collision in the Lennard-Jones potential

$$V(r) = 4\epsilon \left[\left(\frac{\sigma_{AB}}{r} \right)^{12} - \left(\frac{\sigma_{AB}}{r} \right)^6 \right]. \quad (\text{A3.13.35})$$

Given such a reference, we can classify various mechanisms of energy transfer either by the probability that a certain energy transfer process will occur in a ‘Lennard-Jones reference collision’, or by the average energy transferred by one ‘Lennard-Jones collision’.

With this convention, we can now classify energy transfer processes either as resonant, if $|\Delta E_t|$ defined in [equation \(A3.13.8\)](#) is small, or non-resonant, if it is large. Quite generally the rate of resonant processes can approach or even exceed the Lennard-Jones collision frequency (the latter is possible if other long-range potentials are actually applicable, such as by permanent dipole–dipole interaction).

Resonant processes of some importance include resonant electronic to electronic energy transfer (E–E), such as the pumping process of the iodine atom laser

Another near resonant process is important in the hydrogen fluoride laser, [equation \(A3.13.37\)](#), where vibrational to vibrational energy transfer is of interest:

where Δv is the number of vibrational quanta exchanged. If HF were a harmonic oscillator, ΔE_t would be zero (perfect resonance). In practice, because of anharmonicity, the most important process is exothermic, leading to increasing excitation v' of some of the HF molecules with successive collisions [55, 56], because the exothermicity drives this process to high v' as long as plenty of HF(v'') with low v'' are available.

Resonant rotational to rotational (R–R) energy transfer may have rates exceeding the Lennard-Jones collision frequency because of long-range dipole–dipole interactions in some cases. Quasiresonant vibration to rotation transfer (V–R) has recently been discussed in the framework of a simple model [57].

‘Non-resonant’ processes include vibration–translation (V–T) processes with transfer probabilities decreasing to very small values for diatomic molecules with very high vibrational frequencies, of the order of 10^{-4} and less for the probability of transferring a quantum in a collision. Also, vibration to rotation (V–R) processes frequently have low probabilities, of the order of 10^{-2} , if ΔE_t is relatively large. Rotation to translation (R–T)

processes are generally fast, with probabilities near 1. Also, the R–V–T processes in collisions of large polyatomic molecules have high probabilities, with average energies transferred in one Lennard-Jones collision being of the order of a few kJ mol^{-1} [11, 25], or less in collisions with rare gas atoms. As a general rule one may assume collision cross sections to be small, if ΔE_t is large [11, 58, 59].

In the experimental and theoretical study of energy transfer processes which involve some of the above mechanisms, one should distinguish processes in atoms and small molecules and in large polyatomic molecules. For small molecules a full theoretical quantum treatment is possible and even computer program packages are available [60, 62 and 63], with full state to state characterization. A good example are rotational energy transfer theory and experiments on $\text{He} + \text{CO}$ [64]:

On the experimental side, small molecule energy transfer experiments may use molecular beam techniques [65, 66 and 67] (see also [chapter C3.3](#) for laser studies).

In the case of large molecules, instead of the detailed quantum state characterization implied in the cross sections σ_{fi} and rate coefficients K_{fi} of the master [equation \(A3.13.24\)](#), one derives more coarse grained information on ‘levels’ covering a small energy bandwidth around E and E' (with an optional notation $K_{fi}(E', E)$) or finally energy transfer probabilities $P(E', E)$ for a transition from energy E to energy E' in a highly excited large polyatomic molecule where the density of states $\rho(E')$ is very large, for example in a collision with a heat bath inert gas atom [11]. Such processes can currently be modelled by classical trajectories [68, 69 and 70].

Experimental access to the probabilities $P(E', E)$ for energy transfer in large molecules usually involves techniques providing just the first moment of this distribution, i.e. the average energy $\langle \Delta E \rangle$ transferred in a collision. Such methods include UV absorption, infrared fluorescence and related spectroscopic techniques [11, 28, 71, 72, 73 and 74]. More advanced techniques, such as kinetically controlled selective ionization (KCSI [74]) have also provided information on higher moments of $P(E', E)$, such as $\langle (\Delta E)^2 \rangle$.

The standard mechanisms of collisional energy transfer for both small and large molecules have been treated extensively and a variety of scaling laws have been proposed to simplify the complicated body of data [58, 59, 75]. To conclude, one of the most efficient special mechanisms for energy transfer is the quasi-reactive process involving chemically bound intermediates, as in the example of the reaction:

-13-

Such processes transfer very large amounts of energy in one collision and have been treated efficiently by the statistical adiabatic channel model [11, 19, 30, 76, 77, 78 and 79]. They are quite similar mechanistically to chemical activation systems. One might say that in such a mechanism one may distinguish three phases:

(a) Formation of a bound collision complex AB:

(b) IVRR in this complex:

(c) Finally, dissociation of the internally, statistically equilibrated complex:

That is, rapid IVR in the long lived intermediate is an essential step. We shall treat this important process in the next section, but mention here in passing the observation of so-called ‘supercollisions’ transferring large average amounts of energy $\langle \Delta E \rangle$ in one collision [80], even if intermediate complex formation may not be important.

A 3.13.4 INTRAMOLECULAR ENERGY TRANSFER STUDIES IN POLYATOMIC MOLECULES

In this section we review our understanding of IVR as a special case of intramolecular energy transfer. The studies are based on calculations of the time evolution of vibrational wave packets corresponding to middle size and large amplitude vibrational motion in polyatomic molecules. An early example for the investigation of wave packet motion as a key to understanding IVR and its implication on reaction kinetics using experimental data is given in [81]. Since then, many other contributions have helped to increase our knowledge using realistic potential energy surfaces, mainly for two- and three-dimensional systems, and we give a brief summary of these results below.

A3.13.4.1 IVR AND CLASSICAL MECHANICS

Before undergoing a substantial and, in many cases, practically irreversible, change of geometrical structure within a chemical reaction, a molecule may often perform a series of vibrations in the multidimensional space around its equilibrium structure. This applies in general to reactions that take place entirely in the bound electronic ground state and in many cases to reactions that start in the electronic ground state near the equilibrium structure, but evolve into highly excited states above the reaction threshold energy. In the latter case, within the general scheme of [equation \(A3.13.1\)](#) a reaction is thought to be induced by a sufficiently energetic pulse of electromagnetic radiation or by collisions with adequate high-energy collision partners. In the first case, a reaction is thought to be the last step after

-14-

a chain of excitation steps has transferred enough energy into the molecule to react either thermally, by collisions, or coherently, for instance by irradiation with infrared laser pulses. These pulses can be tuned to adequately excite vibrations along the reaction coordinate, the amplitudes of which become gradually larger until the molecule undergoes a sufficiently large structural change leading to the chemical reaction.

Vibrational motion is thus an important primary step in a general reaction mechanism and detailed investigation of this motion is of utmost relevance for our understanding of the dynamics of chemical reactions. In classical mechanics, vibrational motion is described by the time evolution $\vec{q}(t)$ and $\vec{p}(t)$ of general internal position and momentum coordinates. These time dependent functions are solutions of the classical equations of motion, e.g. Newton’s equations for given initial conditions $\vec{q}(t_0) = q_0$ and $\vec{p}(t_0) = p_0$. The definition of initial conditions is generally limited in precision to within experimental uncertainties Δq_0 and Δp_0 , more fundamentally related by the Heisenberg principle $\Delta q_0 \Delta p_0 \gtrsim h/4\pi$. Therefore, we need to

consider an initial distribution $F_0(q-q_0, p-p_0)$, with widths Δq_0 and Δp_0 and the time evolution $F_t(q-\tilde{q}(t), p-\tilde{p}(t))$, which may be quite different from the initial distribution F_0 , depending on the integrability of the dynamical system. Ideally, for classical, integrable systems, vibrational motion may be understood as the motion of narrow, well localized distributions $F(q-\tilde{q}(t), p-\tilde{p}(t))$ (ideally δ -functions in a strict mathematical sense), centred around the solutions of the classical equations of motion. In this picture we wish to consider initial conditions that correspond to localized vibrational motion along specific manifolds, for instance a vibration that is induced by elongation of a single chemical bond (local mode vibrations) as a result of the interaction with some external force, but it is also conceivable that a large displacement from equilibrium might be induced along a single normal coordinate. Independent of the detailed mechanism for the generation of localized vibrations, harmonic transfer of excitation may occur when such a vibration starts to extend into other manifolds of the multidimensional space, resulting in trajectories that draw Lissajous figures in phase space, and also in configuration space [82] (see also [83]). Furthermore, if there is anharmonic interaction, IVR may occur. In [84, 85] this type of IVR was called classical intramolecular vibrational redistribution (CIVR).

A3.13.4.2 IVR AND QUANTUM MECHANICS

In time-dependent quantum mechanics, vibrational motion may be described as the motion of the wave packet $|\psi(q, t)\rangle^2$ in configuration space, e.g. as defined by the possible values of the position coordinates q . This motion is given by the time evolution of the wave function $\psi(q, t)$, defined as the projection $\langle q | \psi(t) \rangle$ of the time-dependent quantum state $|\psi(t)\rangle$ on configuration space. Since the quantum state is a complete description of the system, the wave packet defining the probability density can be viewed as the quantum mechanical counterpart of the classical distribution $F(q-\tilde{q}(t), p-\tilde{p}(t))$. The time dependence is obtained by solution of the time-dependent Schrödinger equation

$$i \frac{\hbar}{2\pi} \frac{d|\psi(t)\rangle}{dt} = \hat{H}|\psi(t)\rangle \quad (\text{A 3.13.43})$$

where \hbar is the Planck constant and \hat{H} is the Hamiltonian of the system under consideration. Solutions depend on initial conditions $|\psi(t_0)\rangle$ and may be formulated using the time evolution operator $\hat{U}(t, t_0)$:

$$|\psi(t)\rangle = \hat{U}(t, t_0)|\psi(t_0)\rangle. \quad (\text{A 3.13.44})$$

-15-

Alternatively, in the case of incoherent (e.g. statistical) initial conditions, the density matrix operator $\hat{P}(t) = |\psi(t)\rangle \langle \psi(t)|$ at time t can be obtained as the solution of the Liouville–von Neumann equation:

$$\hat{P}(t) = \hat{U}(t, t_0) \hat{P}(t_0) \hat{U}^\dagger(t, t_0) \quad (\text{A 3.13.45})$$

where $\hat{U}^\dagger(t, t_0)$ is the adjoint of the time evolution operator (in strictly conservative systems, the time evolution operator is unitary and $\hat{U}^\dagger(t, t_0) = \hat{U}^{-1}(t, t_0) = \hat{U}(t_0, t)$).

The calculation of the time evolution operator in multidimensional systems is a formidable task and some results will be discussed in this section. An alternative approach is the calculation of semi-classical dynamics as demonstrated, among others, by Heller [86, 87 and 88], Marcus [89, 90], Taylor [91, 92], Metiu [93, 94] and coworkers (see also [83] as well as the review by Miller [95] for more general aspects of semiclassical dynamics). This method basically consists of replacing the δ -function distribution in the true classical calculation by a Gaussian distribution in coordinate space. It allows for a simulation of the vibrational

quantum dynamics to the extent that interference effects in the evolving wave packet can be neglected. While the application of semi-classical methods might still be of some interest for the simulation of quantum dynamics in large polyatomic molecules in the near future, as a natural extension of classical molecular dynamics calculations [68, 96], full quantum mechanical calculations of the wave packet evolution in smaller polyatomic molecules are possible with the currently available computational resources. Following earlier spectroscopic work and three-dimensional quantum dynamics results [81, 97, 98, 99 and 100], Wyatt and coworkers have recently demonstrated applications of full quantum calculations to the study of IVR in fluoroform, with nine degrees of freedom [101, 102] and in benzene [103], considering all 30 degrees of freedom [104]. Such calculations show clearly the possibilities in the computational treatment of quantum dynamics and IVR. However, remaining computational limitations restrict the study to the lower energy regime of molecular vibrations, when all degrees of freedom of systems with more than three dimensions are treated. Large amplitude motion, which shows the inherently quantum mechanical nature of wave packet motion and is highly sensitive to IVR, cannot yet be discussed for such molecules, but new results are expected in the near future, as indicated in recent work on ammonia [105, 106], formaldehyde and hydrogen peroxide [106, 107 and 108], and hydrogen fluoride dimer [109, 110 and 111] including all six internal degrees of freedom.

A key feature in quantum mechanics is the dispersion of the wave packet, i.e. the loss of its Gaussian shape. This feature corresponds to a delocalization of probability density and is largely a consequence of anharmonicities of the potential energy surface, both the ‘diagonal’ anharmonicity, along the manifold in which the motion started, and ‘off diagonal’, induced by anharmonic coupling terms between different manifolds in the Hamiltonian. Spreading of the wave packet into different manifolds is thus a further important feature of IVR. In [84, 85] this type of IVR was called delocalization quantum intramolecular vibrational redistribution (DIVR). DIVR plays a central role for the understanding of statistical theories for unimolecular reactions in polyatomic molecules [84, 97], as will be discussed below.

A3.13.4.3 IVR WITHIN THE GENERAL SCHEME OF ENERGY REDISTRIBUTION IN REACTIVE SYSTEMS

As in classical mechanics, the outcome of time-dependent quantum dynamics and, in particular, the occurrence of IVR in polyatomic molecules, depends both on the Hamiltonian and the initial conditions, i.e. the initial quantum mechanical state $|\psi(t_0)\rangle$. We focus here on the time-dependent aspects of IVR, and in this case such initial conditions always correspond to the preparation, at a time t_0 , of superposition states of molecular (spectroscopic) eigenstates involving at least two distinct vibrational energy levels. Strictly, IVR occurs if these levels involve at least two distinct

-16-

vibrational manifolds in terms of which the total (vibrational) Hamiltonian is not separable [84]. In a time-independent view, this requirement states that the wave functions belonging to the two spectroscopic states are spread in a non-separable way over the configuration space spanned by at least two different vibrational modes. The conceptual framework for the investigation of IVR may be sketched within the following scheme, which also mirrors the way we might investigate IVR in the time-dependent approach, both theoretically and experimentally:

$$|\psi(t_{-1})\rangle \xrightarrow{\hat{U}_{\text{prep}}(t_0, t_{-1})} |\psi(t_0)\rangle \xrightarrow{\hat{U}_{\text{free}}(t, t_0)} |\psi(t)\rangle. \quad (\text{A 3.13.46})$$

In a first time interval $[t_{-1}, t_0]$ of the scheme (A3.13.46), a superposition state is prepared. This step corresponds to the step in [equation \(A3.13.1\)](#). One might think of a time evolution $|\psi(t_{-1})\rangle \rightarrow |\psi(t_0)\rangle = \hat{U}_{\text{prep}}(t_0, t_{-1})|\psi(t_{-1})\rangle$, where $|\psi(t_{-1})\rangle$ may be a molecular eigenstate and \hat{U}_{prep} is the time evolution operator obtained from the interaction with an external system, to be specified below. The probability distribution $|\psi(q, t_n)|^2$ is expected to be approximatively localized in configuration space, such that $|\psi(q^*, t_n)|^2 > 0$ for

position coordinates $q^* \in \mathcal{M}^*$ belonging to some specific manifold \mathcal{M}^* and $|\psi(q, t_0)|^2 \approx 0$ for coordinates $q \in \mathcal{M}$ belonging to the complementary manifold $\mathcal{M} = \overline{\mathcal{M}^*}$. In a second time interval $[t_0, t_1]$, the superposition state $|\psi(t_0)\rangle$ has a free evolution into states $|\psi(t)\rangle = \hat{U}_{\text{free}}(t, t_0)|\psi(t_0)\rangle$. This step corresponds to the intermediate step equation (A3.13.47), occurring between the steps described before by equation (A3.13.1) and equation (A3.13.2) (see also equation (A3.13.41)):

$$\mathbf{R}^* \rightarrow \mathbf{R}^{**}. \quad (\text{A } 3.13.47)$$

IVR is present if $|\psi(q, t)|^2 > 0$ is observed for $t > t_0$ also for $q \in \mathcal{M}$. IVR may of course also occur during the excitation process, if its time scale is comparable to that of the excitation.

In the present section, we concentrate on coherent preparation by irradiation with a properly chosen laser pulse during a given time interval. The quantum state at time t_{-1} may be chosen to be the vibrational ground state $|\phi_0^{(g)}\rangle$ in the electronic ground state. In principle, other possibilities may also be conceived for the preparation step, as discussed in section A3.13.1, section A3.13.2 and section A3.13.3. In order to determine superposition coefficients within a realistic experimental set-up using irradiation, the following questions need to be answered: (1) What are the eigenstates? (2) What are the electric dipole transition matrix elements? (3) What is the orientation of the molecule with respect to the laboratory fixed (linearly or circularly) polarized electric field vector of the radiation? The first question requires knowledge of the potential energy surface, or the Hamiltonian $\hat{H}_0(p, q)$ of the isolated molecule, the second that of the vector valued surface $\vec{\mu}(q)$ of the electric dipole moment. This surface yields the operator, which couples spectroscopic states by the impact of an external irradiation field and thus directly affects the superposition procedure. The third question is indeed of great importance for comparison with experiments aiming at the measurement of internal wave packet motion in polyatomic molecules and has recently received much attention in the treatment of molecular alignment and orientation [112, 113], including non-polar molecules [114, 115]. To the best of our knowledge, up to now explicit calculations of multidimensional wave packet evolution in polyatomic molecules have been performed upon neglect of rotational degrees of freedom, i.e. only internal coordinates have been considered, although calculations on coherent excitation in ozone level structures with rotation exist [116, 117], which could be interpreted in terms of wave packet evolution. A more detailed discussion of this point will be given below for a specific example.

-17-

A3.13.4.4 CONCEPTS OF COMPUTATIONAL METHODS

There are numerous methods for solving the time dependent Schrödinger equation (A3.13.43), and some of them were reviewed by Kosloff [118] (see also [119, 120]). Whenever projections of the evolving wave function on the spectroscopic states are useful for the detailed analysis of the quantum dynamics (and this is certainly the case for the detailed analysis of IVR), it is convenient to express the Hamiltonian based on spectroscopic states $|\phi_n\rangle$:

$$\hat{H}_0 = \sum_n \frac{\hbar}{2\pi} \omega_n |\phi_n\rangle \langle \phi_n| \quad (\text{A3.13.48})$$

where ω_n are the eigenfrequencies. For an isolated molecule $\hat{H} = \hat{H}_0$ in equation (A3.13.43) and the time evolution operator is of the form

$$(\text{A3.13.49})$$

$$\hat{U}(t, t_0) = \sum_n \exp(-i\omega_n(t - t_0)) |\phi_n\rangle \langle \phi_n|.$$

The time-dependent wave function is then given by the expression:

$$\psi(q, t) = \sum_n c_n^0 \exp(-i\omega_n t) \phi_n(q). \quad (\text{A3.13.50})$$

Here, $\phi_n(q) = \langle q | \phi_n \rangle$ are the wave functions of the spectroscopic states and the coefficients c_n^0 are determined from the initial conditions

$$\psi(q, t_0) = \sum_n c_n^0 \phi_n(q), \quad c_n^0 = \langle \phi_n | \psi(t_0) \rangle. \quad (\text{A3.13.51})$$

Equation (A3.13.49) describes the spectroscopic access to quantum dynamics. Clearly, when the spectral structure becomes too congested, i.e. when there are many close lying frequencies ω_n , calculation of all spectroscopic states becomes difficult. However, often it is not necessary to calculate all states when certain model assumptions can be made. One assumption concerns the separation of time scales. When there is evidence for a clear separation of time scales for IVR, only part of the spectroscopic states need to be considered for fast evolution. Typically, these states have large frequency separations, and considering only such states means neglecting the fine-grained spectral structure as a first approximation. An example for separation of time scales is given by the dynamics of the alkyl CH chromophore in CHXYZ compounds, which will be discussed below. This group span a three-dimensional linear space of stretching and bending vibrations. These vibrations are generally quite strongly coupled, which is manifested by the occurrence of a Fermi resonance in the spectral structure throughout the entire vibrational energy space. As we will see, the corresponding time evolution and IVR between these modes takes place in less than 1 ps, while other modes become involved in the dynamics on much longer time scales (10 ps to ns, typically). The assumption for time scale separation and IVR on the subpicosecond time scale for the alkyl CH chromophore was founded on the basis of

-18-

spectroscopic data nearly 20 years ago [98, 121]. The first results on the nature of IVR in the CH chromophore system and its role in IR photochemistry were also reported by that time [122, 123], including results for the acetylenic CH chromophore [124] and results obtained from first calculations of the wave packet motion [81]. The validity of this assumption has recently been confirmed in the case of CHF_3 both experimentally, from the highly resolved spectral structure of highly excited vibrational overtones [125, 126], and theoretically, including all nine degrees of freedom for modestly excited vibrational overtones up to 6000 cm^{-1} [102].

A3.13.4.5 IVR DURING AND AFTER COHERENT EXCITATION: GENERAL ASPECTS

Modern photochemistry (IR, UV or VIS) is induced by coherent or incoherent radiative excitation processes [4, 5, 6 and 7]. The first step within a photochemical process is of course a preparation step within our conceptual framework, in which time-dependent states are generated that possibly show IVR. In an ideal scenario, energy from a laser would be deposited in a spatially localized, large amplitude vibrational motion of the reacting molecular system, which would then possibly lead to the cleavage of selected chemical bonds. This is basically the central idea behind the concepts for a ‘mode selective chemistry’, introduced in the late 1970s [127], and has continuously received much attention [10, 117, 122, 128, 129, 130, 131, 132, 133, 134

and 135]. In a recent review [136], IVR was interpreted as a ‘molecular enemy’ of possible schemes for mode selective chemistry. This interpretation is somewhat limited, since IVR represents more complex features of molecular dynamics [37, 84, 134], and even the opposite situation is possible. IVR can indeed be selective with respect to certain structural features [85, 97] that may help mode selective reactive processes after tailored laser excitation [137].

To be more specific, we assume that for a possible preparation step the Hamiltonian might be given during the preparation time interval $[t_{-1}, t_0]$ by the expression:

$$\hat{H} = \hat{H}_0 + \hat{H}_1(t) \quad (\text{A 3.13.52})$$

where \hat{H}_0 is the Hamiltonian of the isolated molecule and \hat{H}_1 is the interaction Hamiltonian between the molecule and an external system. In this section, we limit the discussion to the case where the external system is the electromagnetic radiation field. For the interaction with a classical electromagnetic field with electric field vector $\vec{E}(t)$, the interaction Hamiltonian is given by the expression:

$$\hat{H}_1(t) = -\hat{\mu}\vec{E}(t). \quad (\text{A 3.13.53})$$

where $\hat{\mu}$ is the operator of the electric dipole moment. When we treat the interaction with a classical field in this way, we implicitly assume that the field will remain unaffected by the changes in the molecular system under consideration. More specifically, its energy content is assumed to be constant. The energy of the radiation field is thus not explicitly considered in the expression for the total Hamiltonian and all operators acting on states of the field are replaced by their time-dependent expectation values. These assumptions are widely accepted, whenever the number of photons in each field mode is sufficiently large. For a coherent, monochromatic, polarized field with intensity $I = \sqrt{\epsilon_0/\mu_0}|\vec{E}|^2 \approx 1 \text{ MW cm}^{-2}$ *in vacuo*, which is a typical value used in laser chemical experiments in the gas phase at low pressures, the number N_v of mid infrared photons existing in a cavity of volume $V = 1 \text{ m}^3$ is [138, p498]:

-19-

$$N_v = \frac{IV}{c_0 h \nu} \approx 10^{21}. \quad (\text{A 3.13.54})$$

Equation (A3.13.54) legitimates the use of this semi-classical approximation of the molecule–field interaction in the low-pressure regime. Since $\hat{H}_1(t)$ is explicitly time dependent, the time evolution operator is more complicated than in equation A3.13.49. However, the time-dependent wave function can still be written in the form

$$\psi(q, t) = \sum_n c_n(t) \phi_n(q) \quad (\text{A 3.13.55})$$

with time-dependent coefficients that are obtained by solving the set of coupled differential equations

$$i \frac{dc_n(t)}{dt} = \sum_{n'} \{W_{nn'} + V_{nn'}(t)\} c_{n'}(t) \quad (\text{A 3.13.56})$$

where $W_{nn'} = \delta_{nn'} \omega_n$ ($\delta_{nn'}$ is the Kronecker symbol, ω_n were defined in equation (A3.13.48)) and

$$\begin{aligned}
V_{nn'}(t) &= \frac{2\pi}{h} \langle \phi_n | \hat{H}_i(t) | \phi_{n'} \rangle \\
&= -\frac{2\pi}{h} \langle \phi_n | \hat{\mu} | \phi_{n'} \rangle \vec{E}(t).
\end{aligned}
\tag{A 3.13.57}$$

The matrix elements $\langle \phi_n | \hat{\mu} | \phi_{n'} \rangle$ are multidimensional integrals $\int \phi_n^*(q) \vec{\mu}(q) \phi_{n'}(q) d\mathbf{r}$ of the vector valued dipole moment surface. The time-independent part of the coupling matrix elements in equation (A3.13.57) can also be cast into the practical formula

$$V_{nn'}^0 / (2\pi c_0 \text{ cm}^{-1}) = -0.46093 \langle \phi_n | \hat{\mu}_\alpha | \phi_{n'} \rangle \sqrt{I_0 / \text{MW cm}^{-2}},
\tag{A 3.13.58}$$

where α is the direction of the electric field vector of the linearly polarized radiation field with maximal intensity I_0 . The solution of equation (A3.13.56) may still be quite demanding, depending on the size of the system under consideration. However, it has become a practical routine procedure to use suitable approximations such as the QRA (quasiresonant approximation) or Floquet treatment [35, 122, 129] and programmes for the numerical solution are available [139, 140].

A3.13.4.6 ELECTRONIC EXCITATION IN THE FRANCK–CONDON LIMIT AND IVR

At this stage we may distinguish between excitation involving different electronic states and excitation occurring within the same electronic (ground) state. When the spectroscopic states are located in different electronic states, say the ground (g) and excited (e) states, one frequently assumes the Franck–Condon approximation to be applicable:

$$\langle \phi_n^{(g)} | \hat{\mu} | \phi_{n'}^{(e)} \rangle \approx \vec{\mu}_{ge} \langle \phi_n^{(g)} | \phi_{n'}^{(e)} \rangle.
\tag{A 3.13.59}$$

Such electronic excitation processes can be made very fast with sufficiently intense laser fields. For example, if one considers monochromatic excitation with a wavenumber in the UV region ($60\,000 \text{ cm}^{-1}$) and a coupling strength $(\vec{\mu}_{ge} \vec{E}) / hc \approx 4000 \text{ cm}^{-1}$ (e.g. $\mu_{ge} \approx 1 \text{ Debye}$ in equation (A3.13.59), $I \approx 50 \text{ TW cm}^{-2}$), excitation occurs within 1 fs [141]. During such a short excitation time interval the relative positions of the nuclei remain unchanged (Franck approximation). Within these approximations, if one starts the preparation step in the vibrational ground state $|\phi_0^g\rangle$, the resulting state $|\psi(t_0)\rangle$ at time t_0 has the same probability distribution as the vibrational ground state. However, it is now transferred into the excited electronic state where it is no longer stationary, since it is a superposition state of vibrational eigenstates in the excited electronic state:

$$|\psi(t_0)\rangle = \sum_n \langle \phi_n^{(e)} | \phi_0^g \rangle |\phi_n^{(e)}\rangle.
\tag{A 3.13.60}$$

Often the potential energy surfaces for the ground and excited states are fairly different, i.e. with significantly different equilibrium positions. The state $|\psi(t_0)\rangle$ will then correspond to a wave packet, which has nearly a Gaussian shape with a centre position that is largely displaced from the minimal energy configuration on the excited surface and, since the Franck approximation can be applied, the expectation value of the nuclear linear momentum vanishes. In a complementary view, the superposition state of equation (A3.13.60) defines the manifold \mathcal{M}^* in configuration space. It is often referred to as the ‘bright’ state, since its probability density defines a region in configuration space, the Franck–Condon region, which has been reached by the irradiation

field through mediation by the electric dipole operator. After the preparation step, the wave packet most likely starts to move along the steepest descent path from the Franck–Condon region. One possibility is that it proceeds to occupy other manifolds, which were not directly excited. The occupation of the remaining, ‘dark’ manifolds (e.g. $\overline{\mathcal{M}^*}$) by the time-dependent wave packet is a characteristic feature of IVR.

Studies of wave packet motion in excited electronic states of molecules with three and four atoms were conducted by Schinke, Engel and collaborators, among others, mainly in the context of photodissociation dynamics from the excited state [142, 143 and 144] (for an introduction to photodissociation dynamics, see [7], and also more recent work [145, 146, 147, 148 and 149] with references cited therein). In these studies, the dissociation dynamics is often described by a time-dependent displacement of the Gaussian wave packet in the multidimensional configuration space. As time goes on, this wave packet will occupy different manifolds (from where the molecule possibly dissociates) and this is identified with IVR. The dynamics may be described within the Gaussian wave packet method [150], and the vibrational dynamics is then of the classical IVR type (CIVR [84]). The validity of this approach depends on the dissociation rate on the one hand, and the rate of delocalization of the wave packet on the other hand. The occurrence of DIVR often receives less attention in the discussions of photodissociation dynamics mentioned above. In [148], for instance, details of the wave packet motion by means of snapshots of the probability density are missing, but a delocalization of the wave packet probably takes place, as may be concluded from inspection of [figure 5](#) therein.

A 3.13.5 IVR IN THE ELECTRONIC GROUND STATE: THE EXAMPLE OF THE CH CHROMOPHORE

A3.13.5.1 REDISTRIBUTION DURING AND AFTER COHERENT EXCITATION

A system that shows IVR with very fast spreading of the wave packet, i.e. DIVR in the subpicosecond time range, is that of the infrared alkyl CH chromophore, which will be used in the remaining part of this chapter to discuss IVR as a result of a mode specific excitation within the electronic ground state. The CH stretching and bending modes of the alkyl CH chromophore in CHXYZ compounds are coupled by a generally strong Fermi resonance [100, 151]. [Figure A3.13.4](#) shows the shape of the potential energy surface for the symmetrical compound CHD_3 as contour line representations of selected one- and two-dimensional sections (see figure caption for a detailed description). The important feature is the curved shape of the $V(Q_s, Q_b)$ potential section ($V(Q_s, Q_b)$ being similarly curved), which indicates a rather strong anharmonic coupling. This feature is characteristic for compounds of the type CHXYZ [84, 100, 151, 152 and 153]. Q_s , Q_b and Q_{b_2} are (mass weighted) normal coordinates of the CH stretching and bending motion, with symmetry A_1 and E, respectively, in the C_{3v} point group of symmetrical CHD_3 . A change of Q_s is a concerted motion of all atoms along the z -axis, defined in [figure A3.13.5](#). However, displacements along Q_s are small for the carbon and deuterium atoms, and large for the hydrogen atom. Thus, this coordinate essentially describes a stretching motion of the CH bond (along the z -axis). In the same way, Q_b and Q_{b_2} describe bending motions of the CH bond along the x - and y -axis, respectively (see [figure A3.13.5](#)). In the one-dimensional sections the positions of the corresponding spectroscopic states are drawn as horizontal lines. On the left-hand side, in the potential section $V(Q_{b_2})$, a total of 800 states up to an energy equivalent wave number of $25\,000\text{ cm}^{-1}$ has been considered. These energy levels may be grouped into semi-isoenergetic shells defined by multiplets of states with a constant chromophore quantum number $N = v_s + \frac{1}{2}v_b = 0, \frac{1}{2}, 1, \frac{3}{2}, 2, \frac{5}{2}, \dots$, where v_s and v_b are quantum numbers of effective basis states (‘Fermi modes’ [97, 152, 154]) that are strongly coupled by a 2:1 Fermi resonance. These multiplets give rise to spectroscopic polyads and can be well distinguished in the lower energy region, where the density of states is low.

Figure A3.13.4. Potential energy cuts along the normal coordinate subspace pertaining to the CH chromophore in CHD_3 . Q_{b1} is the A' coordinate in C_s symmetry, essentially changing structure along the x -axis see also [Figure A3.13.5](#), and Q_{b2} is the A'' coordinate, essentially changing structure along the y -axis. Contour lines show equidistant energies at wave number differences of 3000 cm^{-1} up to $30\,000 \text{ cm}^{-1}$. The upper curves are one-dimensional cuts along Q_{b2} (left) and Q_s (right). The dashed curves in the two upper figures show harmonic potential curves (from [154]).

Figure A3.13.5. Coordinates and axes used to describe the wave packet dynamics of the CH chromophore in

CHX₃ or CHXYZ compounds.

In the potential section $V(Q_s)$, shown on the right hand side of [figure A3.13.4](#) the subset of A_1 energy states is drawn. This subset contains only multiplets with integer values of the chromophore quantum number $N = 0, 1, 2, \dots$. This reduction allows for an easier visualization of the multiplet structure and also represents the subset of states that are strongly coupled by the parallel component of the electric dipole moment (see discussion in the following paragraph). The excitation dynamics of the CH chromophore along the stretching manifold can indeed be well described by restriction to this subset of states [[97](#), [154](#)].

Excitation specificity is a consequence of the shape of the electric dipole moment surface. For the alkyl CH chromophore in CHX₃ compounds, the parallel component of the dipole moment, i.e. the component parallel to the symmetry axis, is a strongly varying function of the CH stretching coordinate, whereas it changes little along the bending manifolds [[155](#), [156](#)]. Excitation along this component will thus induce preparation of superposition states lying along the stretching manifold, preferentially. These states thus constitute the ‘bright’ manifold in this example. The remaining states define the ‘dark’ manifolds and any substantial population of these states during or after such an excitation process can thus be directly linked to the existence of IVR. On the other hand, the perpendicular components of the dipole moment vector are strongly varying functions of the bending coordinates. For direct excitation along one of these components, states belonging to the bending manifolds become the ‘bright’ states and any appearance of a subsequent stretching motion can be interpreted as arising from IVR.

The following discussion shall illustrate our understanding of structural changes along ‘dark’ manifolds in terms of wave packet motion as a consequence of IVR. [Figure A3.13.6](#) shows the evolution of the wave packet for the CH chromophore in CHF₃ during the excitation step along the parallel (stretching) coordinate [[97](#)]. The potential surface in the CH chromophore subspace is similar to that for CHD₃ ([figure A3.13.4](#) above), with a slightly more curved form in the stretching–bending representation (figures are shown in [[97](#), [151](#)]). The laser is switched on at a given time t_{-1} , running thereafter as a continuous, monochromatic irradiation up to time t_0 , when it is switched off. Thus, the electric field vector is given as

-24-

$$\vec{E}(t) = h(t - t_{-1})h(t_0 - t)\vec{E}_0 \cos(\omega_L t), \quad (\text{A3.13.61})$$

where $h(t)$ is the Heaviside unit step function, \vec{E}_0 is the amplitude of the electric field vector and $\omega_L = 2\pi c\tilde{\nu}_L$ its angular frequency. Excitation parameters are the irradiation intensity $I_0 = 30 \text{ TW cm}^{-2}$, which corresponds to a maximal electric field strength $E_0 \approx 3.4 \times 10^{10} \text{ V m}^{-1}$, and wave number $\tilde{\nu}_L = 2832.42 \text{ cm}^{-1}$, which lies in the region of the fundamental for the CH stretching vibration (see arrows in the potential cut $V(Q_s)$ of [figure \(A3.13.4\)](#) . The figure shows snapshots of the time evolution of the wave packet between 50 and 70 fs after the beginning of the irradiation ($t_{-1} = 0$ here). On the left-hand side, contour maps of the time-dependent, integrated probability density

$$|\psi(Q_s, Q_b, t)|^2 = \int_{\varphi_b} |\psi(Q_s, Q_b, \varphi_b, t)|^2 d\varphi_b \quad (\text{A3.13.62})$$

are shown, where Q_s is the coordinate for the stretching motion and $Q_b = \sqrt{Q_{b_1}^2 + Q_{b_2}^2}$, $\varphi_b = \arctan(Q_{b_2} / Q_{b_1})$ are polar representations of the bending coordinates Q_{b_1} and Q_{b_2} . Additionally, contour curves of the potential energy surface are drawn at the momentary energy of the wave packet. This energy is defined as:

$$(\text{A3.13.63})$$

$$E(t) = \sum_n E_n p_n(t)$$

where

$$p_n(t) = c_n^*(t)c_n(t) \quad (\text{A3.13.64})$$

are the time-dependent populations of the spectroscopic states during the preparation step (the complex coefficients $c_n(t)$ in equation (A3.13.64) are calculated according to equation (A3.13.55), the spectroscopic energies $E_n = \frac{h}{2\pi}\omega_n$ are defined in equation (A3.13.48); the dashed curves indicate the quantum mechanical uncertainty which arises from the superposition of molecular eigenstates). The same evolution is repeated on the right-hand side of the figure as a three-dimensional representation.

-25-

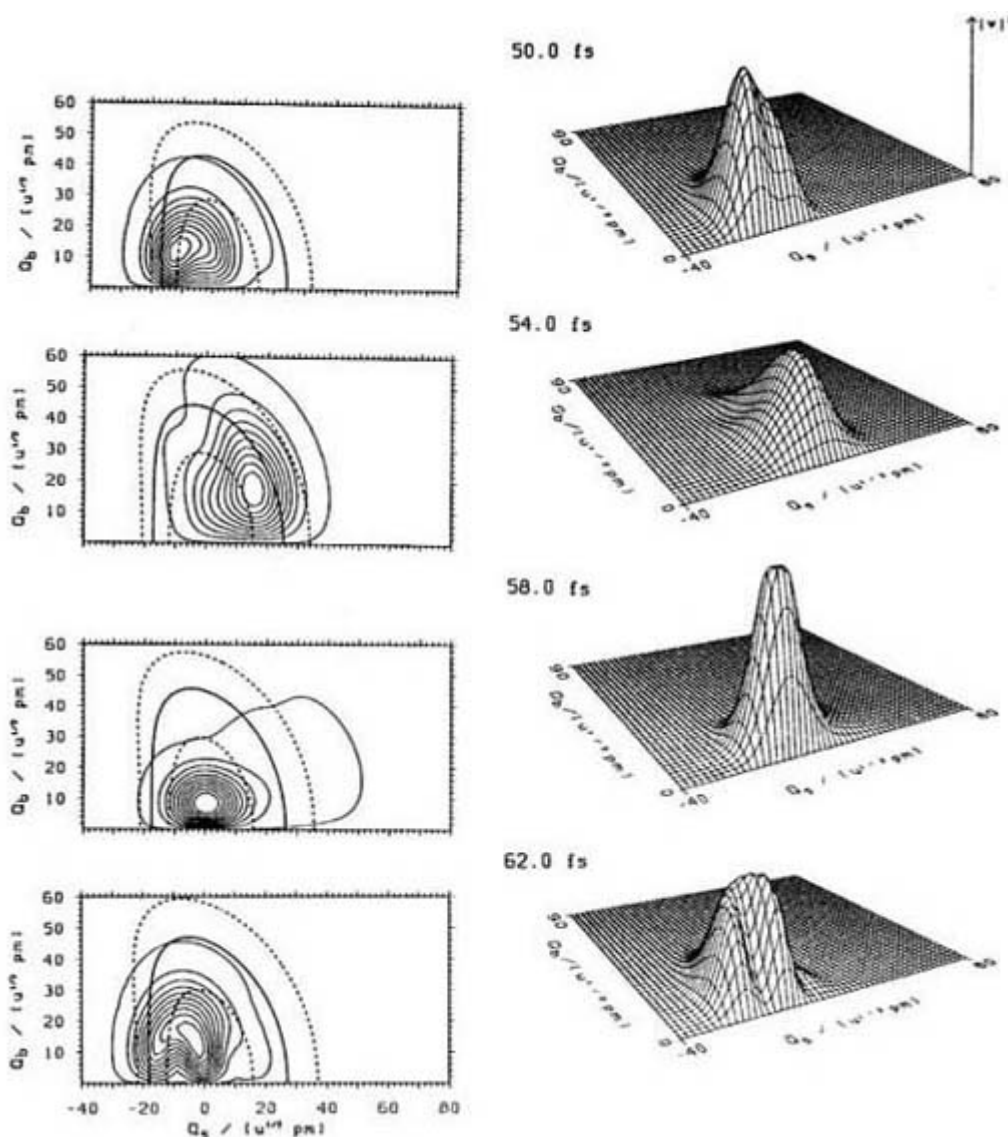

Figure A3.13.6. Time evolution of the probability density of the CH chromophore in CHF_3 after 50 fs of irradiation with an excitation wave number $\tilde{\nu}_L = 2832.42 \text{ cm}^{-1}$ at an intensity $I_0 = 30 \text{ TW cm}^{-2}$. The contour lines of equiprobability density in configuration space have values $2 \times 10^{-5} \text{ u}^{-1} \text{ pm}^{-2}$ for the lowest line shown and distances between the lines of 24, 15, 29 and $20 \times 10^{-5} \text{ u}^{-1} \text{ pm}^{-2}$ in the order of the four images

shown. The averaged energy of the wave packet corresponds to 6000 cm^{-1} (roughly 3100 cm^{-1} absorbed) with a quantum mechanical uncertainty of $\pm 3000 \text{ cm}^{-1}$ (from [97]).

-26-

In the treatment adopted in [97], the motion of the CF_3 frame is implicitly considered in the dynamics of the normal modes. Indeed, the integrand $|\psi(Q_s, Q_b, \phi_b, t)|^2$ in equation (A3.13.62) is to be interpreted as probability density for the change of the CHF_3 structure in the subspace of the CH chromophore, as defined by the normal coordinates Q_s , Q_b and ϕ_b , irrespective of the molecular structure and its change in the remaining space. This interpretation is also valid beyond the harmonic approximation, as long as the structural change in the CH chromophore space can be dynamically separated from that of the rest of the molecule. The assumption of dynamical separation is well confirmed, both from experiment and theory, at least during the first 1000 fs of motion of the CH chromophore.

When looking at the snapshots in figure A3.13.6 we see that the position of maximal probability oscillates back and forth along the stretching coordinate between the walls at $Q_s = -20$ and $+25 \sqrt{u}$ pm, with an approximate period of 12 fs, which corresponds to the classical oscillation period $\tau = 1/\nu$ of a pendulum with a frequency $\nu = c_0 \tilde{\nu} \approx 8.5 \times 10^{13} \text{ s}^{-1}$ and wave number $\tilde{\nu} = 2850 \text{ cm}^{-1}$. Indeed, the motion of the whole wave packet approximately follows this oscillation and, when it does so, the wave packet motion is semiclassical. In harmonic potential wells the motion of the wave packet is always semiclassical [157, 158 and 159]. However, since the potential surface of the CH chromophore is anharmonic, some gathering and spreading out of the wave packet is observable on top of the semiclassical motion. It is interesting to note that, at this ‘initial’ stage of the excitation step, the motion of the wave packet is nearly semiclassical, though with modest amplitudes of the oscillations, despite the anharmonicity of the stretching potential.

The later time evolution is shown in figure A3.13.7 between 90 and 100 fs, and in figure A3.13.8, between 390 and 400 fs, after the beginning of the excitation (time step t_{-1}). Three observations are readily made: first, the amount of energy absorbed by the chromophore has increased, from 3000 cm^{-1} in figure A3.13.6, to 6000 cm^{-1} in figure A3.13.7 and $12\,000 \text{ cm}^{-1}$ in figure A3.13.8. Second, the initially semiclassical motion has been replaced by a more irregular motion of probability density, in which the original periodicity is hardly visible. Third, the wave packet starts to occupy nearly all of the energetically available region in configuration space, thus escaping from the initial, ‘bright’ manifolds into the ‘dark’ manifolds. From these observations, the following conclusions may be directly drawn: IVR of the CH chromophore in fluoroform is fast (in the subpicosecond time scale); IVR sets in already during the excitation process, i.e. when an external force field is driving the molecular system along a well prescribed path in configuration space (the ‘bright’ manifold); IVR is of the delocalization type (DIVR). Understanding these observations is central for the understanding of IVR and they are discussed as follows:

(a) A more detailed analysis of quantum dynamics shows that the molecular system, represented by the group of vibrations pertaining to the CH chromophore in this example, absorbs continuously more energy as time goes on. Let the absorbed energy be $E_{\text{abs}} = N_{\text{v,abs}}(h/2\pi)\omega_L$, where $N_{\text{v,abs}}$ is the mean number of absorbed photons. Since the carrier frequency of the radiation field is kept constant at a value close to the fundamental of the stretching oscillation, $\omega_L \approx \omega_N = 1 - \omega_N = 0$ (N being the chromophore quantum number here), this means that the increase in absorbed energy is a consequence of the stepwise multiphoton excitation process, in which each vibrational level serves as a new starting level for further absorption of light after it has itself been significantly populated. This process is schematically represented, within the example for CHD_3 , by the sequence of upright arrows shown on the right-hand side of figure A3.13.4 $N_{\text{v}, \alpha\beta\sigma}$ is thus a smoothly increasing function of time.

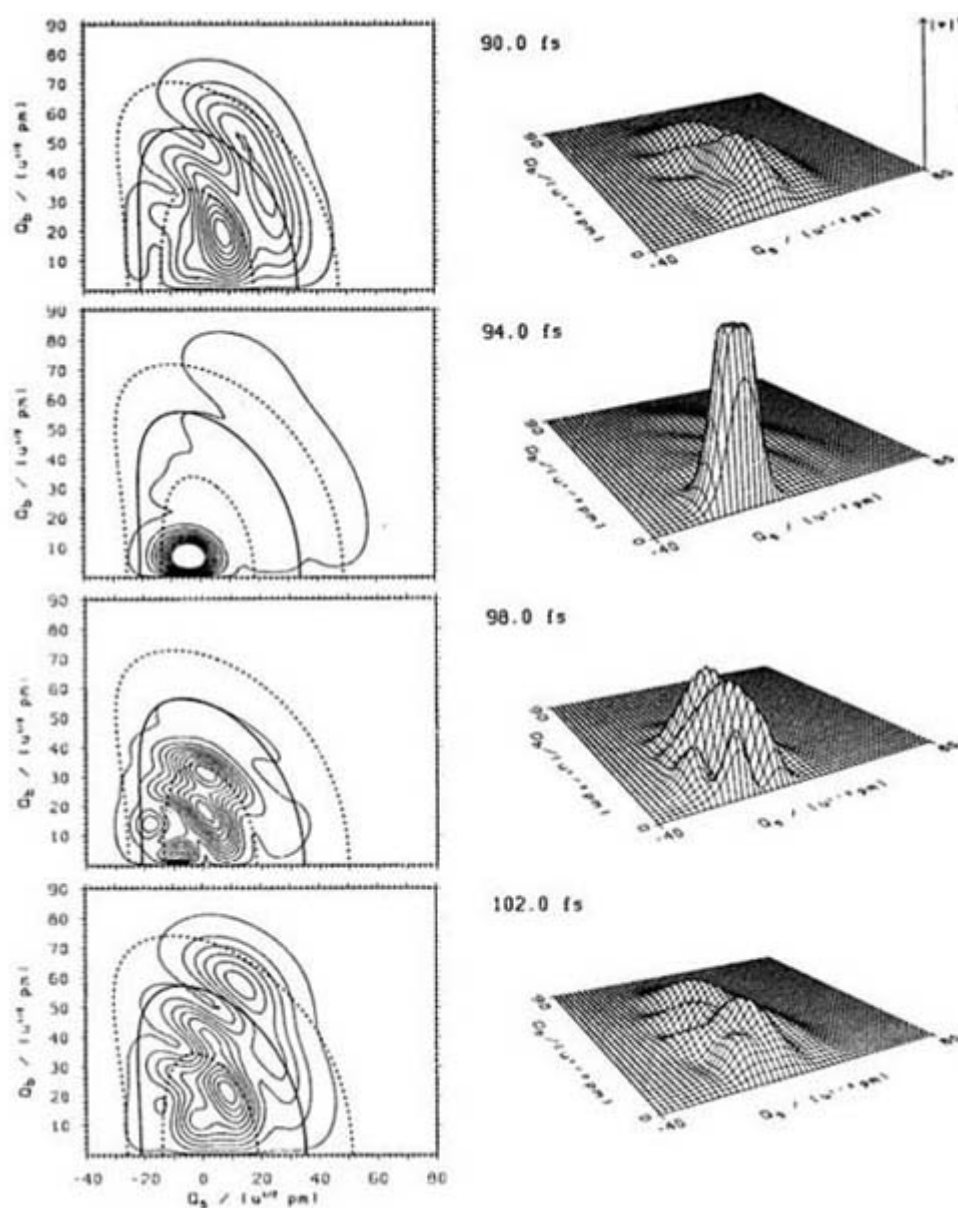

Figure A3.13.7. Continuation of the time evolution for the CH chromophore in CHF_3 after 90 fs of irradiation (see also figure A3.13.6). Distances between the contour lines are $10, 29, 16$ and $9 \times 10^{-5} \text{ u}^{-1} \text{ pm}^{-2}$ in the order of the four images shown. The averaged energy of the wave packet corresponds to 9200 cm^{-1} (roughly 6300 cm^{-1} absorbed) with a quantum mechanical uncertainty of $\pm 5700 \text{ cm}^{-1}$ (from [97]).

(b) The disappearance of the semiclassical type of motion and, thus, the delocalization of the wave packet, is understood to follow the onset of dephasing. With increasing energy, both the effective anharmonic couplings between the ‘bright’ stretching mode and the ‘dark’ bending modes, as well as the diagonal anharmonicity of

the ‘bright’ mode increase. The larger the anharmonicity, the larger the deviation from a purely harmonic behaviour, in which the wave packet keeps on moving in a semiclassical way. In quantum mechanics, the increase in anharmonicity of an oscillator leads to an effective broadening $\Delta\nu_{\text{eff}} > 0$ in the distribution of frequencies of high-probability transitions—for transitions induced by the electric dipole operator usually those with a difference of ± 1 in the oscillator quantum number (for the harmonic oscillator $\Delta\nu_{\text{eff}} = 0$). On the other hand, these are the transitions which play a major role in the stepwise multiphoton excitation of molecular vibrations. A broadening of the frequency distribution invariably leads to a broadening of the distribution of relative phases of the time-dependent coefficients $c_n(t)$ in [equation \(A3.13.55\)](#). Although the sum in [equation \(A3.13.55\)](#) is entirely coherent, one might introduce an effective coherence time defined by:

$$\tau_{c,\text{eff}} = 1/\Delta\nu_{\text{eff}}. \quad (\text{A 3.13.65})$$

For the stretching oscillations of the CH chromophore in CHF_3 $\tau_{c,\text{eff}} \approx 100$ fs. Clearly, typical coherence time ranges depend on both the molecular parameters and the effectively absorbed amount of energy during the excitation step, which in turn depends on the coupling strength of the molecule–radiation interaction. A more detailed study of the dispersion of the wave packet and its relationship with decoherence effects was carried out in [106]. In [97] an excitation process has been studied for the model of two anharmonically coupled, resonant harmonic oscillators (i.e. with at least one cubic coupling term) but under similar conditions as for the CH chromophore in fluoroform discussed here. When the cubic coupling parameter is chosen to be very small compared with the diagonal parameters of the Hamilton matrix, the motion of the wave packet is indeed semiclassical for very long times (up to 600 ps) and, moreover, the wave packet does probe the bending manifold without significantly changing its initial shape. This means that, under appropriate conditions, IVR can also be of the classical type within a quantum mechanical treatment of the dynamics. Such conditions require, for instance, that the band width $h\Delta\nu_{\text{eff}}$ be smaller than the resonance width (power broadening) of the excitation process.

(c) The third observation, that the wave packet occupies nearly all of the energetically accessible region in configuration space, has a direct impact on the understanding of IVR as a rapid promotor of microcanonical equilibrium conditions. Energy equipartition preceding a possible chemical reaction is the main assumption in quasiequilibrium statistical theories of chemical reaction dynamics (‘RRKM’ theory [161, 162 and 163], ‘transition state’ theory [164, 165] but also within the ‘statistical adiabatic channel model’ [76, 77]; see also [chapter A3.12](#) and further recent reviews on varied and extended forms of statistical theories in [25, 166, 167, 168, 169, 170, 171 and 172]). In the case of CHF_3 one might conclude from inspection of the snapshots at the later stage of the excitation dynamics (see [figure A3.13.8](#)) that after 400 fs the wave packet delocalization is nearly complete. Moreover, this delocalization arises here from a fully coherent, isolated evolution of a system consisting of one molecule and a coherent radiation field (laser). Of course, within the common interpretation of the wave packet as a probability distribution in configuration space, this result means that, for an ensemble of identically prepared molecules, vibrational motion is essentially delocalized at this stage and vibrational energy is nearly equipartitioned.

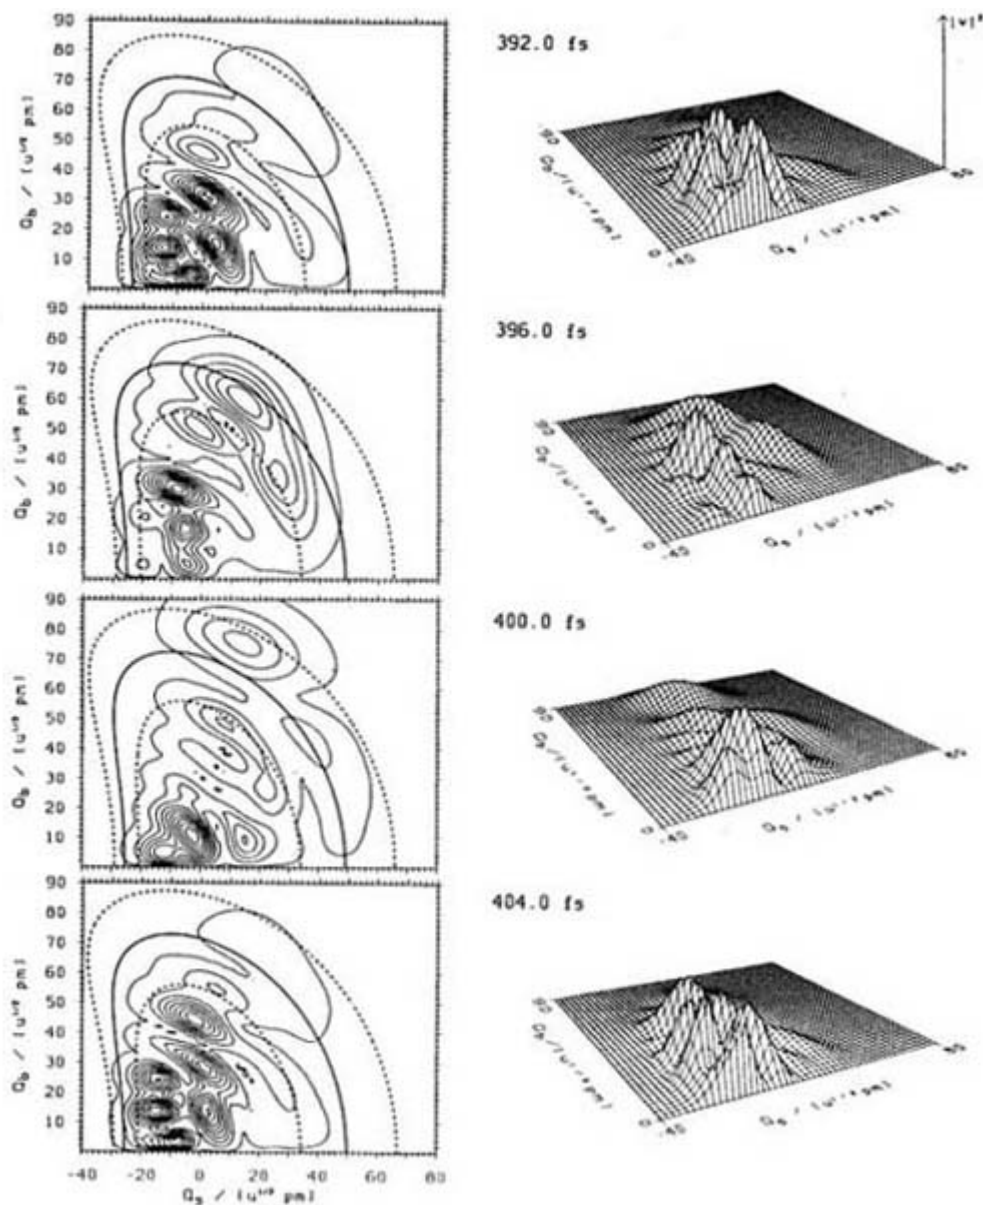

Figure A3.13.8. Continuation of the time evolution for the CH chromophore in CHF_3 after 392 fs of irradiation (see also [figure A3.13.6](#) and [figure A3.13.7](#)). Distances between the contour lines are 14 , 12 , 13 and $14 \times 10^{-5} u^{-1} \text{ pm}^{-2}$ in the order of the four images shown. The averaged energy of the wave packet corresponds to $15\,000 \text{ cm}^{-1}$ (roughly $12\,100 \text{ cm}^{-1}$ absorbed) with a quantum mechanical uncertainty of $\pm 5800 \text{ cm}^{-1}$ (from [97]).

-30-

However, the wave packet does not occupy all of the energetically accessible region. A more detailed analysis of populations [97, table IV] reveals that, during the excitation process, the absorbed energy is inhomogeneously distributed among the set of molecular eigenstates of a given energy shell (such a shell is represented by all nearly iso-energetic states belonging to one of the multiplets shown on the right-hand side of [figure A3.13.4](#)). Clearly, equipartition of energy is attained, if all states of an energy shell are equally populated. The microcanonical probability distribution in configuration space may then be represented by a typical member of the microcanonical ensemble, defined e.g. by the wave function

$$\psi_{\text{micro}} \approx \frac{1}{\sqrt{N_{\text{shell}}}} \sum_{n \in \text{shell}} \exp(-i\varphi_n^{\text{random}}) \phi_n \quad (\text{A3.13.66})$$

where N_{shell} denotes the number of nearly iso-energetic states ϕ_n of a shell and ϕ_n^{random} is a random phase. Such a state is shown in [figure A3.13.9](#). When comparing this state with the state generated by multiphoton excitation, the two different kinds of superposition that lead to these wave packets must, of course, be distinguished. In the stepwise multiphoton excitation, the time evolved wave packet arises from a superposition of many states in several multiplets (with roughly constant averaged energy after some excitation time and a large energy uncertainty). The microcanonical distribution is given by the superposition of states in a single multiplet (of the same averaged energy but much smaller energy uncertainty). In the case of the CH chromophore in CHF_3 studied in this example, the distribution of populations within a molecular energy shell is not homogeneous during the excitation process because the multiplets are not ideally centred at the multiphoton resonance levels and their energy range is effectively too large when compared to the resonance width of the excitation process (power broadening). If molecular energy shells fall entirely within the resonance width of the excitation, such as in the model systems of two harmonic oscillators studied in [97], population distribution within a shell becomes more homogeneous [97, table V]. However, as discussed in that work, equidistribution of populations does not imply that the wave packet is delocalized. Indeed, the contrary was shown to occur. If the probability distribution in configuration space is to delocalize, the relative phases between the superposition states must follow an irregular evolution, such as in a random phase ensemble, in addition to equidistribution of population. Thus, one statement would therefore be that IVR is not complete, although very fast, during the multiphoton excitation of CHF_3 . Excitation and redistribution are indeed two concurring processes. In the limit of weak field excitation, in the spectroscopic regime, the result is a superposition of essentially two eigenstates (the ground and an excited state, for instance). Within the ‘bright’ state concept, strong IVR will be revealed by an instantaneous delocalization of probability density, both in the ‘bright’ and the ‘dark’ manifolds, as soon as the excited state is populated, because the excited state is, of course, a superposition state of states from both manifolds. On the other hand, strong field stepwise IR multiphoton excitation promotes, in a first step, the deposition of energy in a spatially localized, time-dependent molecular structure. Simultaneously, IVR starts to induce redistribution of this energy among other modes. The redistribution becomes apparent after some time has passed and is expected to be of the DIVR type, at least on longer time scales. DIVR may lead to a complete redistribution in configuration space, if the separation between nearly iso-energetic states is small compared to the power broadening of the excitation field. However, under such conditions, at least during an initial stage of the dynamics, CIVR will dominate.

-31-

Figure A3.13.9. Probability density of a microcanonical distribution of the CH chromophore in CHF_3 within the multiplet with chromophore quantum number $N = 6$ ($N_{\text{shell}} = N + 1 = 7$). Representations in configuration space of stretching (Q_s) and bending (Q_b) coordinates (see text following (equation (A3.13.62)) and [figure A3.13.10](#)). Left-hand side: typical member of the microcanonical ensemble of the multiplet with $N = 6$ (random phases, (equation (A3.13.66))). Right-hand side: microcanonical density $P_{\text{micro}} = \frac{1}{N_{\text{shell}}} \sum_{n \in \text{shell}} |\phi_n|^2$ for the multiplet with $N = 6$ ($N_{\text{shell}} = 7$). Adapted from [81].

In view of the foregoing discussion, one might ask what is a typical time evolution of the wave packet for the *isolated* molecule, what are typical time scales and, if initial conditions are such that an entire energy shell participates, does the wave packet resulting from the coherent dynamics look like a microcanonical

distribution? Such studies were performed for the case of an initially pure stretching ‘Fermi mode’ ($v_s, v_b = 0$), with a high stretching quantum number, e.g. $v_s = 6$. It was assumed that such a state might be prepared by irradiation with some hypothetical laser pulse, without specifying details of the pulse. The energy of that state is located at the upper end of the energy range of the corresponding multiplet [81, 152, 154], which has a total of $N_{\text{shell}} = 7$ states. Such a state couples essentially to all remaining states of that multiplet. The corresponding evolution of the isolated system is shown as snapshots after the preparation step ($t_0 = 0$) in [figure A3.13.10](#). The wave packet starts to spread out from the initially occupied stretching manifold (along the coordinate axis denoted by Q_s) into the bending manifold (Q_b) within the first 30–45 fs of evolution (left-hand side). Later on, it remains delocalized most of the time (as shown at the time steps 80, 220 and 380 fs, on the right-hand side) with exceptional partial recovery of the initial conditions at some isolated times (such as at 125 fs). The shape of the distribution at 220 fs is very similar to that of a typical member of the microcanonical ensemble in [figure A3.13.9](#) above. However, in [figure A3.13.9](#), the relative phases between the seven superposition states were drawn from a random number generator, whereas in [figure A3.13.10](#) they result from a fully coherent and deterministic propagation of a wave function.

-32-

Figure A3.13.10. Time-dependent probability density of the isolated CH chromophore in CHF_3 . Initially, the system is in a ‘Fermi mode’ with six quanta of stretching and zero of bending motion. The evolution occurs within the multiplet with chromophore quantum number $N = 6$ ($N_{\text{shell}} = N + 1 = 7$). Representations are given in the configuration space of stretching (Q_s) and bending (Q_b) coordinates (see text following [equation \(A3.13.62\)](#)): Q_b is strictly a positive quantity, and there is always a node at $Q_b = 0$; the mirrored representation at $Q_b = 0$ is artificial and serves to improve visualization). Adapted from [81].

IVR in the example of the CH chromophore in CHF_3 is thus at the origin of a redistribution process which is, despite its coherent nature, of a statistical character. In CHD_3 , the dynamics after excitation of the stretching manifold reveals a less complete redistribution process in the same time interval [97]. The reason for this is a smaller effective coupling constant k'_{sbb} between the ‘Fermi modes’ of CHD_3 (by a factor of four) when

compared to that of CHF_3 . In [97] it was shown that redistribution in CHD_3 becomes significant in the picosecond time scale. However, on that time scale, the dynamical separation of time scales is probably no longer valid and couplings to modes pertaining to the space of CD_3 vibrations may become important and have additional influence on the redistribution process.

-33-

A3.13.5.2 IVR AND TIME-DEPENDENT CHIRALITY

IVR in the CH chromophore system may also arise from excitation along the bending manifolds. Bending motions in polyatomic molecules are of great importance as primary steps for reactive processes involving isomerization and similar, large amplitude changes of internal molecular structure. At first sight, the one-dimensional section of the potential surface along the out-of-plane CH bending normal coordinate in CHD_3 , shown in [figure A3.13.4](#) is clearly less anharmonic than its one-dimensional stretching counterpart, also shown in that figure, even up to energies in the wave number region of $30\,000\text{ cm}^{-1}$. This suggests that coherent sequential multiphoton excitation of a CH bending motion, for instance along the x -axis in [figure A3.13.5](#) may induce a quasiclassical motion of the wave packet along that manifold [159, 160], which is significantly longer lived than the motion induced along the stretching manifold under similar conditions (see discussion above). Furthermore, the two-dimensional section in the CH bending subspace, spanned by the normal coordinates in the lower part of [figure A3.13.4](#) is approximately isotropic. This corresponds to an almost perfect $C_{\infty\omega}$ symmetry with respect to the azimuthal angle φ (in the xy plane of [figure A3.13.5](#), and is related to the approximate conservation of the bending vibration angular momentum ℓ_b [152, 173]. This implies that the direct anharmonic coupling between the degenerate bending manifolds is weak. However, IVR between these modes might be mediated by the couplings to the stretching mode. An interesting question is then to what extent such a coupling scheme might lead to a motion of the wave packet with quasiclassical exchange of vibrational energy between the two bending manifolds, following paths which could be described by classical vibrational mechanics, corresponding to CIVR. Understanding quasiclassical exchange mechanisms of large amplitude vibrational motion opens one desirable route of exerting control over molecular vibrational motion and reaction dynamics. In [154] these questions were investigated by considering the CH bending motion in CHD_3 and the asymmetric isotopomers CHD_2T and CHDT_2 . The isotopic substitution was investigated with the special goal of a theoretical study of the coherent generation of dynamically chiral, bent molecular structures [174] and of the following time evolution. It was shown that IVR is at the origin of a coherent racemization dynamics which is superposed to a very fast, periodic exchange of left- and right-handed chiral structures ('stereomutation' reaction, period of roughly 20 fs, comparable to the period of the bending motion) and sets in after typically 300–500 fs. The main results are reviewed in the discussion of [figure A3.13.11](#) [figure A3.13.12](#) and [figure A3.13.13](#).

-34-

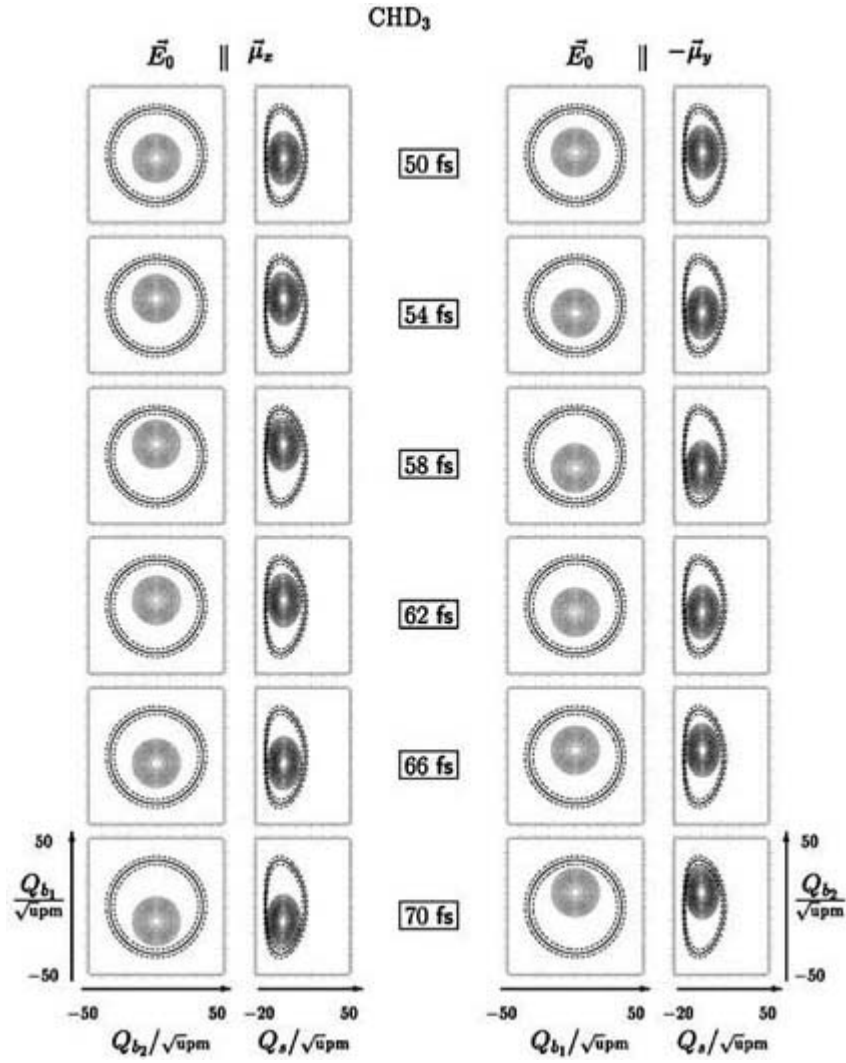

Figure A3.13.11. Illustration of the time evolution of reduced two-dimensional probability densities $|\psi_{bb}|^2$ and $|\psi_{sb}|^2$, for the excitation of CHD₃ between 50 and 70 fs (see [154] for further details). The full curve is a cut of the potential energy surface at the momentary absorbed energy corresponding to 3000 cm⁻¹ during the entire time interval shown here (≈ 6000 cm⁻¹, if zero point energy is included). The dashed curves show the energy uncertainty of the time-dependent wave packet, approximately 500 cm⁻¹. Left-hand side: excitation along the x -axis (see figure A3.13.5). The vertical axis in the two-dimensional contour line representations is the Q_{b1} -axis, the horizontal axes are Q_{b2} and Q_s , for $|\psi_{bb}|^2$ and $|\psi_{sb}|^2$, respectively. Right-hand side: excitation along the y -axis, but with the field vector pointing into the negative y -axis. In the two-dimensional contour line representations, the vertical axis is the Q_{b2} -axis, the horizontal axes are Q_{b1} and Q_s , for $|\psi_{bb}|^2$ and $|\psi_{sb}|^2$, respectively. The lowest contour line has the value $44 \times 10^{-5} \text{ u}^{-1} \text{ pm}^{-2}$, the distance between them is $7 \times 10^{-5} \text{ u}^{-1} \text{ pm}^{-2}$. Maximal values are nearly constant for all the images in this figure and correspond to $140 \times 10^{-5} \text{ u}^{-1} \text{ pm}^{-2}$ for $|\psi_{bb}|^2$ and $180 \times 10^{-5} \text{ u}^{-1} \text{ pm}^{-2}$ for $|\psi_{sb}|^2$.

The wave packet motion of the CH chromophore is represented by simultaneous snapshots of two-dimensional representations of the time-dependent probability density distribution

$$|\psi_{sb}(t, Q_s, Q_{b_i})|^2 = \int_{Q_{b_j}} dQ_{b_j} |\psi(t, Q_s, Q_{b_i}, Q_{b_j})|^2 \quad (i \neq j) \quad (\text{A3.13.67})$$

and

$$|\psi_{bb}(t, Q_{b_1}, Q_{b_2})|^2 = \int_{Q_s} dQ_s |\psi(t, Q_s, Q_{b_1}, Q_{b_2})|^2. \quad (\text{A3.13.68})$$

Such a sequence of snapshots, calculated in intervals of 4 fs, is shown as a series of double contour line plots on the left-hand side of [figure A3.13.11](#) (the outermost row shows the evolution of $|\psi_{bb}|^2$, equation (A3.13.68), the innermost row is $|\psi_{sb}|^2$, equation (A3.13.67), at the same time steps). This is the wave packet motion in CHD₃ for excitation with a linearly polarized field along the x -axis at 1300 cm⁻¹ and 10 TW cm⁻² after 50 fs of excitation. At this point a more detailed discussion regarding the orientational dynamics of the molecule is necessary. Clearly, the polarization axis is defined in a laboratory fixed coordinate system, while the bending axes are fixed to the molecular frame. Thus, exciting internal degrees of freedom along specific axes in the internal coordinate system requires two assumptions: the molecule must be oriented or aligned with respect to the external polarization axis, and this state should be stationary, at least during the relevant time scale for the excitation process. It is possible to prepare oriented states [[112](#), [114](#), [115](#)] in the gas phase, and such a state can generally be represented as a superposition of a large number of rotational eigenstates. Two questions become important then: How fast does such a rotational superposition state evolve? How well does a purely vibrational wave packet calculation simulate a more realistic calculation which includes rotational degrees of freedom, i.e. with an initially oriented rotational wave packet? The second question was studied recently by full dimensional quantum dynamical calculations of the wave packet motion of a diatomic molecule during excitation in an intense infrared field [[175](#)], and it was verified that rotational degrees of freedom may be neglected whenever vibrational–rotational couplings are not important for intramolecular rotational–vibrational redistribution (IVRR) [[84](#)]. Regarding the first question, because of the large rotational constant of methane, the time scales on which an initially oriented state of the free molecule is maintained are likely to be comparatively short and it would also be desirable to carry out calculations that include rotational states explicitly. Such calculations were done, for instance, for ozone at modest excitations [[116](#), [117](#)], but they would be quite difficult for the methane isotopomers at the high excitations considered in the present example.

The multiphoton excitation scheme corresponding to excitation along the x -axis is shown by the upright arrows on the left-hand side of [figure A3.13.4](#). In the convention adopted in [[154](#)], nuclear displacements along Q_{b_1} occur along the x -axis, displacements along Q_{b_2} are directed along the y -axis. One observes a semiclassical, nearly periodic motion of the wave packet along the excited manifold with a period of approximately 24 fs, corresponding to the frequency of the bending vibrations in the wave number region around 1500 cm⁻¹. At this stage of the excitation process, the motion of the wave packet is essentially one-dimensional, as seen from the trajectory followed by the maximum of the probability distribution and its practically unchanged shape during the oscillations back and forth between the turning points. The latter lie on the potential energy section defined by the momentary energy $E(t)$ of the wave packet, as described above,

and describe the classically accessible region in configuration space. These potential energy sections are shown by the continuous curves in the figures, which are surrounded by dotted curves describing the energy uncertainty.

The sequence on the right-hand side of [figure A3.13.11](#) shows wave packets during the excitation along the y -axis. Here, excitation was chosen to be antiparallel to the y -axis ($E_0 \parallel -\mu_y$). This choice induces a phase shift of π between the two wave packets shown in the figure, in addition to forcing oscillations along different directions. Excitation along the y -axis can be used to generate dynamically chiral structures. If the excitation laser field is switched off, e.g. at time step 70 fs after beginning the excitation, the displacement of the wave packet clearly corresponds to a bent molecular structure with angle $\vartheta \approx 10^\circ$ (e.g. in the xy plane of figure

A3.13.5 . This structure will, of course, also change with time for the isolated molecule, and one expects this change to be oscillatory, like a pendulum, at least initially. Clearly, IVR will play some role, if not at this early stage, then at some later time. One question is, will it be CIVR or DIVR? When studying this question with the isotopically substituted compounds CHD_2T and CHDT_2 , the y -axis being perpendicular to the C_s mirror plane, a bent CH chromophore corresponds to a chiral molecular structure with a well defined chirality quantum number, say R . As time evolves, the wave packet moves to the other side of the symmetry plane, $Q_{b_2} = 0$, implying a change of chirality. In this context, the enantiomeric excess can be defined by the probability

$$P_R(t) = \int_{-\infty}^0 dQ_{b_2} |\psi_{b_2}(t, Q_{b_2})|^2 \quad (\text{A3.13.69})$$

for right-handed ('R') chiral structures ($P_L(t) = 1 - P_R(t)$ is the probability for left-handed ('L') structures), where

$$|\psi_{b_2}(t, Q_{b_2})|^2 = \int_{Q_s} \int_{Q_{b_1}} dQ_s dQ_{b_1} |\psi(t, Q_s, Q_{b_1}, Q_{b_2})|^2. \quad (\text{A3.13.70})$$

The time evolution of $P_R(t)$ is shown in [figure A3.13.12](#) for the field free motion of wave packets for CHD_2T and CHDT_2 prepared by a preceding excitation along the y -axis.

In the main part of each figure, the evolution of P_R calculated within the stretching and bending manifold of states for the CH chromophore is shown (full curve). The dashed curve shows the evolution of P_R within a one-dimensional model, in which only the Q_{b_2} bending manifold is considered during the dynamics. Within this model there is obviously no IVR, and comparison of the full with the dashed curves helps to visualize the effect of IVR. The insert on the left-hand side shows a survey of the evolution of P_R for the one-dimensional model during a longer time interval of 2 ps, while the insert on the right-hand side shows the evolution of P_R for the calculation within the full three-dimensional stretching and bending manifold of states during the same time interval of 2 ps. The three-dimensional calculations yield a fast, initially nearly periodic, evolution, with an approximate period of 20 fs, which is superimposed by a slower decay of probability corresponding to an overall decay of enantiomeric excess $|D_{\text{abs}}(t)| = |1 - 2P_R(t)|$ on a time scale of 300–400 fs for both CHD_2T and CHDT_2 . The decay is clearly more pronounced for CHD_2T ([figure A3.13.12](#)a)). The first type of evolution corresponds to a stereomutation reaction, while the second can be interpreted as racemization. A further question is then related to the origin of this racemization.

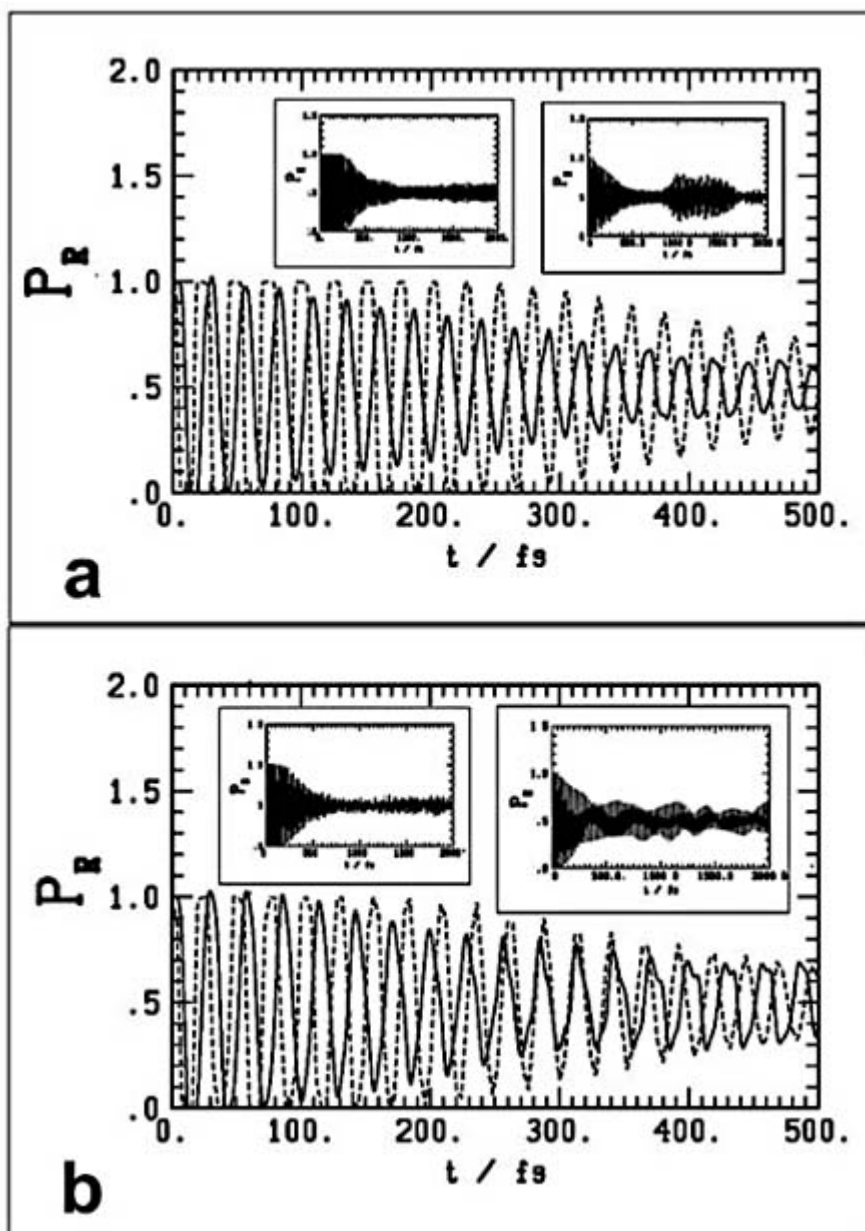

Figure A3.13.12. Evolution of the probability for a right-handed chiral structure $P_R(t)$ (full curve, see (equation (A3.13.69))) of the CH chromophore in CHD_2T (a) and CHDT_2 (b) after preparation of chiral structures with multiphoton laser excitation, as discussed in the text (see also [154]). For comparison, the time evolution of P_R according to a one-dimensional model including only the Q_{b2} bending mode (dashed curve) is also shown. The left-hand side insert shows the time evolution of P_R within the one-dimensional calculations for a longer time interval; the right-hand insert shows the P_R time evolution within the three-dimensional calculation for the same time interval (see text).

Figure A3.13.13. Illustration of the time evolution of reduced two-dimensional probability densities $|\psi_{bb}|^2$ and $|\psi_{sb}|^2$, for the isolated CHD_2T (left-hand side) and CHDT_2 (right-hand side) after 800 fs of free evolution. At time 0 fs the wave packets corresponded to a localized, chiral molecular structure (from [154]). See also text and figure A3.13.11.

Figure A3.13.14 shows the wave packet motion for CHD_2T and CHDT_2 , roughly 800 fs after the initially localized, chiral structure has been generated. Comparison with the wave packet motion allows for the conclusion that racemization is induced by the presence of DIVR between all vibrational modes of the CH chromophore. However, while DIVR is quite complete for CHD_2T , after excitation along the y axis, it is only two-dimensional for CHDT_2 . A localized exchange of vibrational energy in terms of CIVR has not been observed at any intermediate time step. Racemization is stronger for CHD_2T , for which DIVR occurs in the full three-dimensional subspace of the CH chromophore, under the present conditions. It is less pronounced for CHDT_2 , which has a higher degree of localization of the wave packet motion. In comparison with the one-dimensional calculations in figure A3.13.12, it becomes evident that there is a decay of the overall

enantiomeric excess for CHD_2T , as well as for CHDT_2 , also in the absence of IVR. The decay takes place on a time scale of 500–1000 fs and is a consequence of the dephasing of the wave packet due to the diagonal anharmonicity of the bending motion. This decay may, of course, also be interpreted as racemization. However, it is much less complete than racemization in the three-dimensional case and clearly of secondary importance for the enantiomeric decay in the first 200 fs.

Figure A3.13.14. Illustration of the quantum evolution (points) and Pauli master equation evolution (lines) in quantum level structures with two levels (and 59 states each, left-hand side) and three levels (and 39 states each, right-hand side) corresponding to a model of the energy shell IVR (horizontal transition in [figure A3.13.1](#)). From [38]. The two-level structure (left) has two models: $|V_{ij}|^2 = \text{const}$ and random signs (upper part), random V_{ij} , but $-V_m \leq V_{ij} \leq V_m$ (lower part). The right-hand side shows an evolution with initial diagonal density matrix (upper part) and a single trajectory (lower part).

A 3.13.6 STATISTICAL MECHANICAL MASTER EQUATION TREATMENT OF INTRAMOLECULAR ENERGY REDISTRIBUTION IN REACTIVE MOLECULES

The previous sections indicate that the full quantum dynamical treatment of IVR in an intermediate size molecule even under conditions of ‘coherent’ excitation shows phenomena reminiscent of relaxation and equilibration. This suggests that, in general, at very high excitations in large polyatomic molecules with densities of states easily exceeding the order of 10^{10} cm^{-1} (or about 10^9 molecular states in an energy interval corresponding to 1 J mol^{-1}), a statistical master equation treatment may be possible [38, 122]. Such an approach has been justified by quantum simulations in model systems as well as analytical considerations [38], following early ideas in the derivation of the statistical mechanical Pauli equation [176]. [Figure A3.13.14](#) shows the kinetic behaviour in such model systems. The ‘coarse grained’ populations of groups of quantum states (‘levels’ with less than 100 states, indexed by capital letters I and J) at the same total energy show very similar behaviour if calculated from the Schrödinger equation, e.g. [equation \(A3.13.43\)](#), or the Pauli equation [\(A3.13.71\)](#),

$$p(t) = \mathbf{Y}(t)p(0), \quad (\text{A 3.13.71})$$

with \mathbf{Y} being given by:

$$\mathbf{Y}(t) = \exp(\mathbf{K}t), \quad (\text{A 3.13.72})$$

and the rate coefficient matrix elements in the limit of perturbation theory

$$K_{IJ} = 2\pi |V_{IJ}|^2 / \delta_I. \quad (\text{A 3.13.73})$$

In equation (A3.13.73), δ_I is the average angular frequency distance between quantum states within level I and $|V_{ij}|^2$ is the average square coupling matrix element (as angular frequency) between the quantum states in levels I and J (of total number of states N_I and N_J , respectively) and is given by:

$$|V_{IJ}|^2 = \frac{1}{N_I} \frac{1}{N_J} \sum_{i=1}^{N_I} \sum_{j=1}^{N_J} |V_{ij}|^2. \quad (\text{A 3.13.74})$$

Figure A3.13.14 seems to indicate that the Pauli equation is a strikingly good approximation for treating IVR under these conditions, involving even relatively few quantum states. This is, however, only true in this simple manner because we assume in the model that all the couplings are randomly distributed around their ‘typical’ values. This excludes any symmetry selection rules for couplings within the set of quantum states considered [177]. More generally, one has to consider only sets of quantum states with the same set of good (conserved) quantum numbers in such a master equation treatment. It is now well established that even in complex forming collisions leading to maximum energy transfer by IVR (section A3.13.3.3), conserved quantum numbers such as nuclear spin symmetry

-41-

and parity lead to considerable restrictions [177, 178]. More generally, one has to identify approximate symmetries on short time scales, which lead to further restrictions on the density of strongly coupled states [179]. Thus, the validity of a statistical master equation treatment for IVR in large polyatomic molecules is not obvious *a priori* and has to be established individually for at least classes of molecular systems, if not on a case by case basis.

Figure A3.13.15 shows a scheme for such a Pauli equation treatment of energy transfer in highly excited ethane, e.g. equation (A3.13.75), formed at energies above both thresholds for dissociation in chemical activation:

The figure shows the migration of energy between excited levels of the ultimately reactive C–C oscillator, the total energy being constant at $E/hc = 41\,000\text{ cm}^{-1}$ with a CC dissociation threshold of $31\,000\text{ cm}^{-1}$. The energy balance is thus given by:

(A 3.13.76)

$$E_{\text{tot}} = E_{\text{C-C}} + \sum_{i=1}^{17} E_i.$$

The microcanonical equilibrium distributions are governed by the densities ρ_{s-1} in the $(s-1) = 17$ oscillators (figure A3.13.15):

$$p_{\text{micro}}(n) = \rho_{s-1}^{(n)} \left\{ \sum_k \rho_{s-1}^{(k)} \right\}^{-1} \quad (\text{A 3.13.77})$$

where the 17 remaining degrees of freedom of ethane form essentially a ‘heat bath’. The kinetic master equation treatment of this model leads to steady-state populations shown in figure A3.13.16. This illustrates that the steady-state populations under conditions where reaction equation (A3.13.75) competes with IVR differ from the microcanonical equilibrium populations at high energy, and both differ from thermal distributions shown as lines (quantum or classical). Whereas the deviation from a thermal distribution is well understood and handled by standard statistical theories such as RRKM (chapter A3.12) and the statistical adiabatic channel model [76], the deviation from the microcanonical distribution would lead to an intramolecular nonequilibrium effect on the rates of reaction which so far has not been well investigated experimentally [37, 38 and 39].

-42-

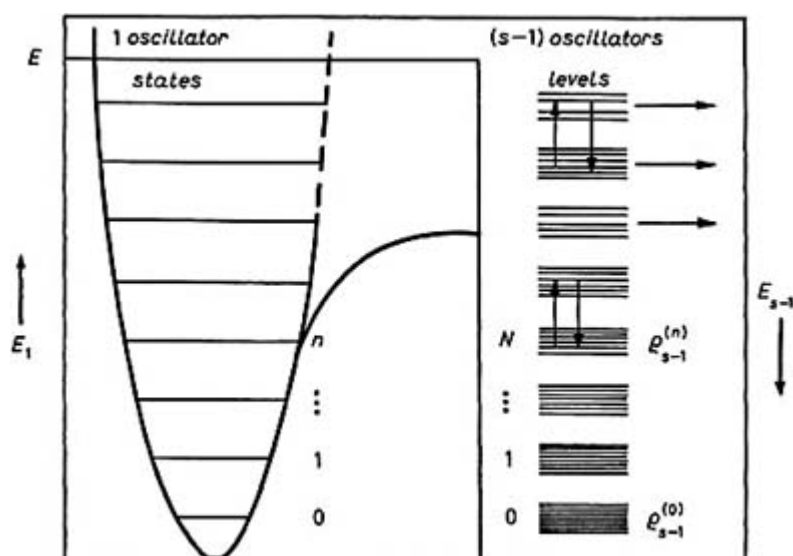

Figure A3.13.15. Master equation model for IVR in highly excited C_2H_6 . The left-hand side shows the quantum levels of the reactive CC oscillator. The right-hand side shows the levels with a high density of states from the remaining 17 vibrational (and torsional) degrees of freedom (from [38]).

Figure A3.13.16. Illustration of the level populations (corresponding to the C–C oscillator states) from various treatments in the model of figure A3.13.15 for C_2H_6 at a total energy $E = (hc) 41\,000\text{ cm}^{-1}$ and a threshold energy $E_0 = (hc) 31\,000\text{ cm}^{-1}$. The points are microcanonical equilibrium distributions. The crosses result from the solution of the master equation for IVR at steady state and the lines are thermal populations at the temperatures indicated (from [38]: quant. is calculated with quantum densities of states, class. with classical mechanical densities.).

A 3.13.7 SUMMARIZING OVERVIEW ON ENERGY REDISTRIBUTION IN REACTING SYSTEMS

It has been understood for more than a century that energy redistribution is a key process in chemical reactions, including in particular the oldest process of chemical technology used by mankind: fire or combustion, where both radiative and collisional processes are relevant. Thus one might think that this field has reached a stage of maturity and saturation. Nothing could be further from the truth. While collisional energy transfer is now often treated in reaction systems in some detail, as is to some extent routine in unimolecular reactions, there remain plenty of experimental and theoretical challenges. In the master equation treatments, which certainly should be valid here, one considers a statistical, macroscopic reaction system consisting of reactive molecules in a mixture, perhaps an inert gas heat bath.

The understanding of the second process considered in this chapter, intramolecular energy redistribution within a single molecular reaction system, is still in its infancy. It is closely related to the challenge of finding possible schemes to control the dynamics of atoms in molecules and the related change of molecular structure during the course of a chemical reaction [10, 117, 154, 175], typically in the femtosecond time scale, which has received increasing attention in the last few decades [180, 181 and 182]. The border between fully quantum dynamical treatments, classical mechanical theories and, finally, statistical master equations for IVR type processes needs to be explored further experimentally and theoretically in the future. Unravelling details of the competition between energy redistribution and reaction in individual molecules remains an important task for the coming decades [37, 38, 39 and 40].

A3.14 Nonlinear reactions, feedback and self-organizing reactions

Stephen K Scott

A3.14.1 INTRODUCTION

A3.14.1.1 NONLINEARITY AND FEEDBACK

In the reaction kinetics context, the term 'nonlinearity' refers to the dependence of the (overall) reaction rate on the concentrations of the reacting species. Quite generally, the rate of a (simple or complex) reaction can be defined in terms of the rate of change of concentration of a reactant or product species. The variation of this rate with the extent of reaction then gives a 'rate–extent' plot. Examples are shown in [figure A3.14.1](#). In

the case of a first-order reaction, curve (i) in [figure A3.14.1\(a\)](#), the rate–extent plot gives a straight line: this is the only case of ‘linear kinetics’. For all other concentration dependences, the rate–extent plot is ‘nonlinear’: curves (ii) and (iii) in [figure A3.14.1\(a\)](#) correspond to second-order and half-order kinetics respectively. For all the cases in [figure A3.14.1\(a\)](#), the reaction rate is maximal at zero extent of reaction, i.e. at the beginning of the reaction. This is characteristic of ‘deceleratory’ processes. A different class of reaction types, [figure A3.14.1\(b\)](#), show rate–extent plots for which the reaction rate is typically low for the initial composition, but increases with increasing extent of reaction during an ‘acceleratory’ phase. The maximum rate is then achieved for some non-zero extent, with a final deceleratory stage as the system approaches complete reaction (chemical equilibrium). Curves (i) and (ii) in [figure A3.14.1\(b\)](#) are idealized representations of rate–extent curves observed in isothermal processes exhibiting ‘chemical feedback’. Feedback arises when a chemical species, typically an intermediate species produced from the initial reactants, influences the rate of (earlier) steps leading to its own formation. Positive feedback arises if the intermediate accelerates this process; negative feedback (or inhibition) arises if there is a retarding effect. Such feedback may arise chemically through ‘chain-branching’ or ‘autocatalysis’ in isothermal systems. Feedback may also arise through thermal effects: if the heat released through an exothermic process is not immediately lost from the system, the temperature of the reacting mixture will rise. A reaction showing a typical overall Arrhenius temperature dependence will thus show an increase in overall rate, potentially giving rise to further self-heating. Curve (iii) in [figure A3.14.1\(b\)](#) shows the rate–extent curve for an exothermic reaction under adiabatic conditions. Such feedback is the main driving force for the process known as combustion: endothermic reactions can similarly show self-cooling and inhibitory feedback. Specific examples of the origin of feedback in a range of chemical systems are presented below.

-2-

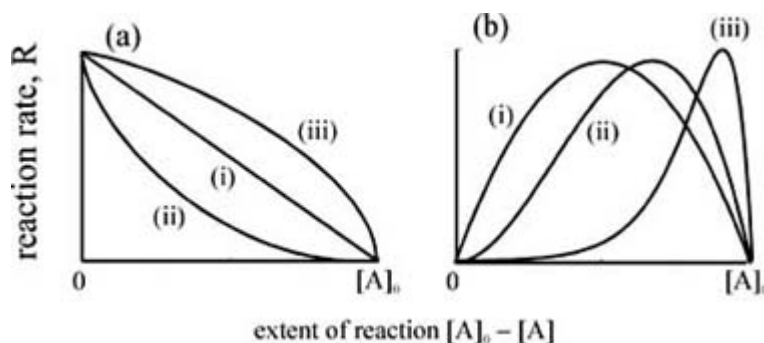

Figure A3.14.1. Rate-extent plots for (a) deceleratory and (b) acceleratory systems.

The branching cycle involving the radicals H, OH and O in the $\text{H}_2 + \text{O}_2$ reaction involves the three elementary steps

In step (1) and step (2) there is an increase from one to two ‘chain carriers’. (For brevity, step (x) is used to refer to equation (A3.14.x) throughout.) Under typical experimental conditions close to the first and second explosion limits (see [section A3.14.2.3](#)), step (2) and step (3) are fast relative to the rate determining step (1).

Combining (1) + (2) + 2 × (3) gives the overall stoichiometry

so there is a net increase of 2 H atoms per cycle. The rate of this overall step is governed by the rate of step (1), so we obtain

$$d[\text{H}]/dt = +2k_1[\text{O}_2][\text{H}]$$

where the + sign indicates that the rate of production of H atoms increases proportionately with that concentration.

-3-

In the bromate–iron clock reaction, there is an autocatalytic cycle involving the species intermediate species HBrO_2 . This cycle is comprised of the following non-elementary steps:

Step (5) is rapid due to the radical nature of BrO_2 , so the overall stoichiometric process given by (4) + 2 × (5), has the form

and an effective rate law

$$d[\text{HBrO}_2]/dt = +k_4[\text{BrO}_3^-][\text{H}^+][\text{HBrO}_2]$$

again showing increasing rate of production as the concentration of HBrO_2 increases.

In ‘Landolt’-type reactions, iodate ion is reduced to iodide through a sequence of steps involving a reductant species such as bisulfite ion (HSO_3^-) or arsenous acid (H_3AsO_3). The reaction proceeds through two overall stoichiometric processes. The Dushman reaction involves the reaction of iodate and iodide ions

with an empirical rate law $R_\alpha = (k_1 + k_2[\text{I}^-])[\text{IO}_3^-][\text{I}^-][\text{H}^+]^2$.

The iodine produced in the Dushman process is rapidly reduced to iodide via the Roebuck reaction

If the initial concentrations are such that $[H_3AsO_3]_0/[IO_3^-]_0 > 3$, the system has excess reductant. In this case, the overall stoichiometry is given by (6) + 3 × (7) to give

-4-

i.e. there is a net production of one iodide ion, with an overall rate given by R_α . At constant pH and for conditions such that $k_2[I^-] \gg k_1$, this can be approximated by

$$d[I^-]/dt = k[IO_3^-][I^-]^2$$

where $k = k_2[H^+]^2$. This again has the autocatalytic form, but now with the growth proportional to the square of the autocatalyst (I^-) concentration. Generic representations of autocatalytic processes in the form

where a and b are the concentrations of the reactant A and autocatalyst B respectively, are represented in [figure A3.14.1\(b\)](#) as curves (i) and (ii). The bromate–iron reaction corresponds to the quadratic type and the Landolt system to the cubic form.

A3.14.1.2 SELF-ORGANIZING SYSTEMS

‘Self-organization’ is a phrase referring to a range of behaviours exhibited by reacting chemical systems in which nonlinear kinetics and feedback mechanisms are operating. Examples of such behaviour include ignition and extinction, oscillations and chaos, spatial pattern formation and chemical wave propagation. There is a formal distinction between thermodynamically closed systems (no exchange of matter with the surroundings) and open systems [1]. In the former, the reaction will inevitably attain a unique state of chemical equilibrium in which the forward and reverse rates of every step in the overall mechanism become equal (detailed balance). This equilibrium state is temporally stable (the system cannot oscillate about equilibrium) and spatially uniform (under uniform boundary conditions). However, nonlinear responses such as oscillation in the concentrations of intermediate species can be exhibited as a transient phenomenon, provided the system is assembled with initial species concentrations sufficiently ‘far from’ the equilibrium composition (as is frequently the case). The ‘transient’ evolution may last for an arbitrary long (perhaps even a geological timescale), but strictly finite, period.

A3.14.2 CLOCK REACTIONS, CHEMICAL WAVES AND IGNITION

A3.14.2.1 CLOCK REACTIONS

The simplest manifestation of nonlinear kinetics is the clock reaction—a reaction exhibiting an identifiable ‘induction period’, during which the overall reaction rate (the rate of removal of reactants or production of final products) may be practically indistinguishable from zero, followed by a comparatively sharp ‘reaction event’ during which reactants are converted more or less directly to the final products. A schematic evolution of the reactant, product and intermediate species concentrations and of the reaction rate is represented in [figure A3.14.2](#). Two typical mechanisms may operate to produce clock behaviour.

Figure A3.14.2. Characteristic features of a clock reaction, illustrated for the Landolt reaction, showing (a) variation of product concentration with induction period followed by sharp ‘reaction event’; (b) variation of overall reaction rate with course of reaction.

The Landolt reaction (iodate + reductant) is prototypical of an autocatalytic clock reaction. During the induction period, the absence of the feedback species (here iodide ion, assumed to have virtually zero initial concentration and formed from the reactant iodate only via very slow ‘initiation’ steps) causes the reaction mixture to become ‘kinetically frozen’. There is reaction, but the intermediate species evolve on concentration scales many orders of magnitude less than those of the reactant. The induction period depends on the initial concentrations of the major reactants in a manner predicted by integrating the overall rate cubic autocatalytic rate law, given in [section A3.14.1.1](#).

The bromate–ferroin reaction has a quadratic autocatalytic sequence, but in this case the induction period is determined primarily by the time required for the concentration of the ‘inhibitor’ bromide ion to fall to a critical low value through the reactions

Bromide ion acts as an inhibitor through step (9) which competes for HBrO₂ with the rate determining step for the autocatalytic process described previously, [step \(4\)](#) and [step \(5\)](#), Step (8) and Step (9) constitute a pseudo-first-order removal of Br[−] with HBrO₂ maintained in a low steady-state concentration. Only once [Br[−]] < [Br[−]]_{cr} = k₃[BrO₃[−]]/k₂ does [step \(3\)](#) become effective, initiating the autocatalytic growth and oxidation.

Clock-type induction periods occur in the spontaneous ignition of hydrocarbon–oxygen mixtures [2], in the setting of concrete and the curing of polymers [3]. A related phenomenon is the induction period exhibited

during the self-heating of stored material leading to thermal runaway [4]. A wide variety of materials stored in bulk are capable of undergoing a slow, exothermic oxidation at ambient temperatures. The consequent self-heating (in the absence of efficient heat transfer) leads to an increase in the reaction rate and, therefore, in the subsequent rate of heat release. The Semenov and Frank–Kamenetskii theories of thermal runaway address the relative rates of heat release and heat loss under conditions where the latter is controlled by Newtonian cooling and by thermal conductivity respectively. In the Frank–Kamenetskii form, the heat balance equation shows that the following condition applies for a steady-state balance between heat transfer and heat release:

$$\kappa \nabla^2 T - (-\Delta H)c^n A e^{-E/RT} = 0$$

where κ is the thermal conductivity and ∇^2 is the Laplacian operator appropriate to the particular geometry. The boundary condition specifies that the temperature must have some fixed value equal to the surrounding temperature T_a at the edge of the reacting mass: the temperature will then exceed this value inside the reacting mass, varying from point to point and having a maximum at the centre. Steady-state solutions are only possible if the group of quantities $(-\Delta H)a_0^2 c^n E A e^{-E/RT_a} / \kappa R T_a^2$, where a_0 is the half-width of the pile, is less than some critical value. If this group exceeds the critical value, thermal runaway occurs. For marginally supercritical situations where thermal balance is almost achieved, the runaway is preceded by an induction period as the temperature evolves on the Fourier time scale, $t_F = c_p a_0^2 / \kappa$, where c_p is the heat capacity. For large piles of low thermal conductivity, this may be of the order of months.

A3.14.2.2 REACTION–DIFFUSION FRONTS

A ‘front’ is a thin layer of reaction that propagates through a mixture, converting the initial reactants to final products. It is essentially a clock reaction happening in space. If the mixture is one of fuel and oxidant, the resulting front is known as a flame. In each case, the unreacted mixture is held in a kinetically frozen state due to the virtual absence of the feedback species (autocatalyst or temperature). The reaction is initiated locally to some point; for example, by seeding the mixture with the autocatalyst or providing a ‘spark’. This causes the reaction to occur locally, producing a high autocatalyst concentration/high temperature. Diffusion/conduction of the autocatalyst/heat then occurs into the surrounding mixture, initiating further reaction there. Front/flames propagate through this combination of diffusion and reaction, typically adopting a constant velocity which depends on the diffusion coefficient/thermal diffusivity and the rate coefficient for the reaction [5]. In each case, the speed c has the form $c \propto \sqrt{Dk}$. In gravitational fields, convective effects may arise due to density differences between the reactants ahead and the products behind the front. This difference may arise from temperature changes due to an exothermic/endothermic reaction or due to changes in molar volume between reactants and products—in some cases the two processes occur and may compete. In solid-phase combustion systems, such as those employed in self-propagating high-temperature synthesis (SHS) of materials, the steady flame may become unstable and a pulsing or oscillating flame develop—a feature also observed in propagating polymerization fronts [6].

A3.14.2.3 IGNITION, EXTINCTION AND BISTABILITY

In flow reactors there is a continuous exchange of matter due to the inflow and outflow. The species concentrations do not now attain the thermodynamic chemical equilibrium state—the system now has steady states which constitute a balance between the reaction rates and the flow rates. The steady-state concentrations (and temperature if the reaction is exo/endothermic) depend on the operating conditions through experimental parameters such as the flow rate. A plot of this dependence gives the steady-state locus, see [figure A3.14.3](#). With feedback reactions, this locus may fold back on itself, the fold points corresponding to critical conditions

for ignition or extinction—the plot is also then known as a ‘bifurcation diagram’. Between these points, the system exhibits bistability, as either the upper or the lower branch can be accessed; so the system may have different net reaction rates for identical operating conditions. Starting with a long residence time (low flow rates), the system lies on the ‘thermodynamic branch’, with a steady-state composition close to the equilibrium state. As the residence time is decreased (flow rate is increased), so the steady-state extent of conversion decreases, but at the turning point in the locus a further decrease in residence time causes the system to drop onto the lower, flow branch. This jump is known as ‘washout’ for solution-phase reactions and ‘extinction’ in combustion. The system now remains on the flow branch, even if the residence time is increased: there is hysteresis, with the system jumping back to the thermodynamic branch at the ‘ignition’ turning point in the locus. Many reactions exhibiting clock behaviour in batch reactors show ignition and extinction in flow systems. The determination of such bifurcation diagrams is a classic problem in chemical reactor engineering and of great relevance to the safe and efficient operation of flow reactors in the modern chemical industry. More complex steady-state loci, with isolated branches or multiple fold points leading to three accessible competing states have been observed in systems ranging from autocatalytic solution-phase reactions, smouldering combustion and in catalytic reactors [7]. Bistability has been predicted from certain models of atmospheric chemistry [8]. In the $\text{H}_2 + \text{O}_2$ and other branched-chain reactions, a balance equation for the radical species expresses the condition for a steady-state radical concentration. The condition for an ‘ignition limit’, i.e. for the marginal existence of a steady state, is that the branching and termination rates just balance. This can be expressed in terms of a ‘net branching factor’, $\phi = k_b - k_t$ where k_b and k_t are the pseudo-first-order rate constants for branching and termination respectively. For the hydrogen–oxygen system at low pressures, this has the form

$$2k_b[\text{O}_2] = k_{t1}[\text{O}_2][\text{M}] + k_{t2}$$

where k_{t1} corresponds to a three-body termination process (with [M] being the total gas concentration) and k_{t2} to a surface removal of H-atoms. This condition predicts a folded curve on the pressure–temperature plane—the first and second explosion limits, see [figure A3.14.4](#).

-8-

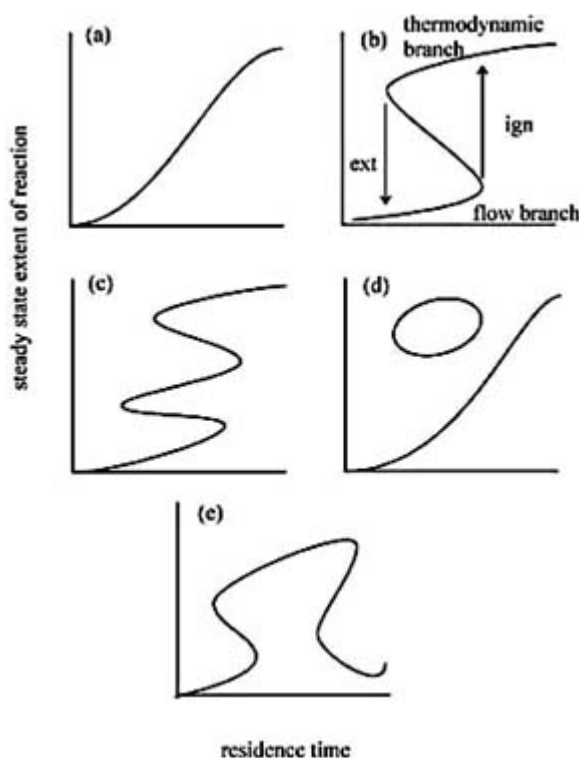

Figure A3.14.3. Example bifurcation diagrams, showing dependence of steady-state concentration in an open system on some experimental parameter such as residence time (inverse flow rate): (a) monotonic dependence; (b) bistability; (c) tristability; (d) isola and (e) mushroom.

Figure A3.14.4. $P-T_a$ ignition limit diagram for $H_2 + O_2$ system showing first, second and third limits as appropriate to a closed reactor. The first and second limits have similar positions in a typical flow reactor, for which there is also a region of oscillatory ignition as indicated.

A3.14.3 OSCILLATIONS AND CHAOS

Despite previous worries about restrictions imposed by thermodynamics, the ability of homogeneous isothermal chemical systems to support long-lived (although strictly transient) oscillations in the concentrations of *intermediate* species even in closed reactors is now clearly established [9]. The reaction system studied in greatest detail is the Belousov–Zhabotinsky (BZ) reaction [10, 11 and 12], although the CIMA/CDIMA system involving chlorine dioxide, iodine and malonic acid is also of importance [13]. In flow reactors, oscillations amongst the concentrations of all species, including the reactants and products, are possible.

A3.14.3.1 THE BELOUSOV–ZHABOTINSKY REACTION

The BZ reaction involves the oxidation of an organic molecule (citric acid, malonic acid (MA)) by an acidified bromate solution in the presence of a redox catalyst such as the ferroin/ferrin or Ce^{3+}/Ce^{4+} couples. For a relatively wide range of initial reactant concentrations in a well-stirred beaker, the reaction may exhibit a short induction period, followed by a series of oscillations in the concentration of several intermediate species and also in the colour of the solution. The response of a bromide-ion-selective electrode and of a Pt electrode (responding to the redox couple) for such a system is shown in figure A3.14.5. Under optimal conditions, several hundred excursions are observed. In the redox catalyst concentrations, the oscillations are of apparently identical amplitude and only minutely varying period: the bromide ion concentration increases slowly with each complete oscillation and it is the slow build-up of this inhibitor, coupled with the consumption of the initial reactants, that eventually causes the oscillations to cease (well before the system approaches its equilibrium concentration).

Figure A3.14.5. Experimental records from Pt and Br⁻-ion-sensitive electrode for the BZ reaction in batch showing regular oscillatory response.

-10-

The basic features of the oscillatory mechanism of the BZ reaction are given by the Field–Koros–Noyes (FKN) model [14]. This involves three ‘processes’—A, B and C. Process A involves [step \(8\)](#) and [step \(9\)](#) from [section A3.14.2.1](#), leading to removal of ‘inhibitor’ bromide ion. Process B involves [step \(3\)](#) and [step \(4\)](#) from [Section A3.14.1.1](#) and gives the autocatalytic oxidation of the catalyst. This growth is limited partly by the disproportionation reaction

The ‘clock’ is reset through process C. Bromomalonic acid, BrMA, is a by-product of processes A and B (possibly from HOBr) which reacts with the oxidized form of the redox catalyst. This can be represented as

Here, f is a stoichiometric factor and represents the number of bromide ions produced through this overall process for each two catalyst ions reduced. Because of the complex nature of this process, involving various radical species, f can lie in a range between 0 and ~ 3 depending on the $[\text{BrO}_3^-]/[\text{MA}]$ ratio and the $[\text{H}^+]$ concentration (note that these may change during the reaction).

The behaviour of the BZ system can be modelled semi-quantitatively by the ‘oregonator’ model [15]:

$$\frac{dx}{dt} = \frac{1}{\varepsilon} \left\{ x(1-x) - fz \frac{(x-q)}{(x+q)} \right\}$$

$$\frac{dz}{dt} = x - z$$

$$\frac{dx}{dt} = \frac{1}{\varepsilon} \left\{ x(1-x) - fz \frac{(x-q)}{(x+q)} \right\}$$

$$\frac{dz}{dt} = x - z$$

where x and z are (scaled) concentrations of HBrO_2 and M_{ox} respectively, and $\varepsilon = k_{11}[\text{Org}]/k_5[\text{BrO}_3^-][\text{H}^+]$ and $q = 2k_8k_{10}/k_9k_4$ are parameters depending on the rate coefficients and the initial concentrations [16], with $[\text{Org}]$ being the total concentration of organic species ($\text{MA} + \text{BrMA}$). Oscillations are observed in this model for $0.5 < f < 1 + \sqrt{2}$. More advanced models and detailed schemes account for the difference between systems with ferrion and cerium ion catalysts and for the effect of oxygen on the reaction [17].

Under some conditions, it is observed that complex oscillatory sequences develop even in batch systems, typically towards the end of the oscillatory phase of the reaction. Transient ‘chaos’—see [section A3.14.3.3](#)—appears to be established [18].

-11-

In flow reactors, both simple period-1 oscillations (every oscillation has the same amplitude and period as its predecessor) and more complex periodic states can be established and sustained indefinitely. The first report of chemical chaos stemmed from the BZ system [19] (approximately contemporaneously with observations in the biochemical peroxidase reaction [20]). These observations were made in systems with relatively high flow rate and show complexity increasing through a sequence of ‘mixed-mode’ wave forms comprising one large excursion followed by n small peaks, with n increasing as the flow rate is varied. Subsequent period-doubling and other routes to chaos have been found in this system at low flow rates [21]. A relatively simple two-variable extension of the oregonator model can adequately describe these complex oscillations and chaos.

A3.14.3.2 THE CIMA/CDIMA SYSTEM

The reaction involving chlorite and iodide ions in the presence of malonic acid, the CIMA reaction, is another that supports oscillatory behaviour in a batch system (the chlorite–iodide reaction being a classic ‘clock’ system: the CIMA system also shows reaction–diffusion wave behaviour similar to the BZ reaction, see [section A3.14.4](#)). The initial reactants, chlorite and iodide are rapidly consumed, producing ClO_2 and I_2 which subsequently play the role of ‘reactants’. If the system is assembled from these species initially, we have the CDIMA reaction. The chemistry of this oscillator is driven by the following overall processes, with the empirical rate laws as given:

The concentrations of the major reactants ClO_2 and I_2 , along with H^+ , are treated as constants, so this is a two-variable scheme involving the concentrations of ClO_2^- and I^- . Step (12) constitutes the main feedback

process, which here is an inhibitory channel, with the rate decreasing as the concentration of iodide ion increases (for large $[I^-]$ the rate is inversely proportional to the concentration). Again, exploiting dimensionless terms, the governing rate equations for u (a scaled $[I^-]$) and v (scaled $[ClO_2^-]$) can be written as [22, 23]:

$$\frac{du}{dt} = a - u - \frac{4uv}{1+u^2} \frac{dv}{dt} = b \left(u - \frac{uv}{1+u^2} \right)$$

where a and b are constants depending on the rate coefficients and the initial concentrations of the reactants.

-12-

Another important reaction supporting nonlinear behaviour is the so-called FIS system, which involves a modification of the iodate–sulfite (Landolt) system by addition of ferrocyanide ion. The Landolt system alone supports bistability in a CSTR: the addition of an extra feedback channel leads to an oscillatory system in a flow reactor. (This is a general and powerful technique, exploiting a feature known as the ‘cross-shaped diagram’, that has led to the design of the majority of known solution-phase oscillatory systems in flow reactors [25].) The FIS system is one member of the important class of pH oscillators in which H^+ acts as an autocatalyst in the oxidation of a weak acid to produce a strong acid. Elsewhere, oscillations are observed in important chemical systems such as heterogeneously catalysed reactions or electrochemical and electrodisolution reactions [26].

A3.14.3.3 COMBUSTION SYSTEMS

Oscillatory behaviour occurs widely in the oxidation of simple fuels such as H_2 , CO and hydrocarbons. Even in closed reactors, the $CO + O_2$ reaction shows a ‘lighthouse effect’, with up to 100 periodic emissions of chemiluminescence accompanying the production of electronically excited CO_2 . Although also described as ‘oscillatory ignition’, each ‘explosion’ is associated with less than 1% fuel consumption and can be effectively isothermal, even for this strongly exothermic reaction. Many hydrocarbons exhibit ‘cool flame’ oscillations in closed reactors, with typically between two and seven ‘bursts’ of light emission (from excited HCHO) and reaction, accompanied by self-heating of the reacting mixture. In continuous flow reactors, these modes can be sustained indefinitely. Additionally, true periodic ignitions occur for both the $CO + O_2$ and $H_2 + O_2$ systems [27, 28]. The $p-T_a$ ‘ignition’ diagram for the $CO + O_2$ reaction under typical experimental conditions is shown in figure A3.14.6. Example oscillations observed at various locations on this diagram are displayed in figure A3.14.7. Within the region marked ‘complex oscillations’ the simple period-1 oscillation is replaced by waveforms that have different numbers of excursions in the repeating unit. The complexity develops through a ‘period-doubling’ sequence, with the waveform having 2^n oscillations per repeating unit, with n increasing with T_a . The range of experimental conditions over which the higher-order periodicities exist decreases in a geometric progression, with $n \rightarrow \infty$ leading to an oscillation with no repeating unit at some finite ambient temperature. Such *chaotic* responses exist over a finite range of experimental conditions and differ fundamentally from stochastic responses. Plotting the amplitude of one excursion against the amplitude of the next gives rise to a ‘next-maximum map’ (figure A3.14.8). This has a definite structure—a single-humped maximum—characteristic of a wide class of physical systems showing the period-doubling route to chaos.

Figure A3.14.6. P - T_a ignition limit diagram for CO + O₂ system in a flow reactor showing location of ignition limits and regions of simple and complex (shaded area) oscillations.

-13-

Figure A3.14.7. Example oscillatory time series for CO + O₂ reaction in a flow reactor corresponding to different P - T_a locations in [figure A3.14.6](#): (a) period-1; (b) period-2; (c) period-4; (d) aperiodic (chaotic) trace; (e) period-5; (f) period-3.

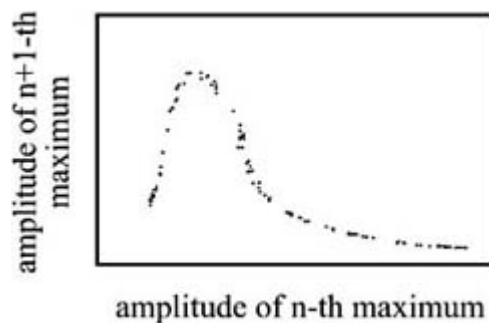

Figure A3.14.8. Next-maximum map obtained by plotting maximum temperature in one ignition against maximum in next ignition from trace (d) of [figure A3.14.7](#).

The mechanistic origin of simple and complex oscillation in the $\text{H}_2 + \text{O}_2$ system is well established. The basic oscillatory clockwork involves the self-acceleration of the reaction rate through the chain-branching cycle, [step \(1\)](#), [step \(2\)](#) and [step \(3\)](#) in [section A3.14.1.1](#) and the ‘self-inhibitory’ effect of H_2O production. Water is an inhibitor of the $\text{H}_2 + \text{O}_2$ system under these pressure and temperature conditions through its role in the main chain-termination step

where M is a ‘third-body’ species which removes energy, stabilizing the newly-formed HO_2 bond. H_2 and O_2 have third body efficiencies of 1 and 0.3 respectively (these are measured relative to H_2), but H_2O is substantially more effective, with an efficiency of ~ 6.3 relative to H_2 . Following an ignition, then, the rate of [step \(A3.14.13\)](#) is enhanced relative to the branching cycle, due to the now high concentration of H_2O , and further reaction is inhibited. The effect of the flow to the reactor, however, is to replace H_2O with H_2 and O_2 , thus lowering the overall third-body effectiveness of the mixture in the reactor. Eventually, the rate of [step \(A3.14.13\)](#) relative to the branching rate becomes sufficiently small for another ignition to occur. Complex oscillations require the further feedback associated with the self-heating accompanying ignition. A ‘minimal’ complex oscillator mechanism for this system has been determined [\[28\]](#).

Surprisingly, the origin of the complex oscillations and chaos in the $\text{CO} + \text{O}_2$ system (where trace quantities of H-containing species have a major influence on the reaction and, consequently, many of the reactions of the $\text{H}_2 + \text{O}_2$ system predominate) are far from established to date.

The ‘cool flames’ associated with the low-temperature oxidation of hydrocarbon have great relevance, being the fundamental cause of knock in internal combustion engines. Their mechanistic origin arises through a thermokinetic feedback [\[2\]](#). The crucial feature is the reaction through which O_2 reacts by addition to an alkyl radical R^\cdot

Under typical operating conditions, in the absence of self-heating from the reaction, the equilibrium for this step lies in favour of the product RO_2^\cdot . This species undergoes a series of intramolecular hydrogen-abstraction and further O_2 -addition steps before fragmentation of the carbon chain. This final step produces three radical

species, leading to a delayed, but overall branching of the radical chain ('degenerate branching'). This channel is overall an exothermic process, and the acceleration in rate associated with the branching leads to an increase in the gas temperature. This increase causes the equilibrium of [step \(A3.14.14\)](#) to shift to the left, in favour of the R' radical. The subsequent reaction channel for this species involves H-atom abstraction by O₂, producing the conjugate alkene. This is a significantly less exothermic channel, and the absence of branching means that the overall reaction rate and the rate of heat release fall. The temperature of the reacting mixture, consequently, decreases, causing a shift of the equilibrium back to the right. Complex oscillations have been observed in hydrocarbon oxidation in a flow reactor, although chaotic responses have not yet been reported.

A3.14.3.4 CONTROLLING CHAOS

The simple shape of the next-maximum map has been exploited in approaches to 'control' chaotic systems. The basic idea is that a system in a chaotic state is coexisting with an infinite number of unstable periodic states—indeed the chaotic 'strange attractor' is comprised of the period-1, period-2, period-4 and all other periodic solutions which have now become unstable. Control methods seek to select one of these unstable periodic solutions and to 'stabilize' it by applying appropriate but very small perturbations to the experimental operating conditions. Such control methods can also be adapted to allow an unstable state, such as the period-1 oscillation, to be 'tracked' through regions of operating conditions for which it would be naturally unstable. These techniques have been successfully employed for the BZ chaos as well as for chaos in lasers and various other physical and biological systems. For a full review and collection of papers see [\[29\]](#).

A3.14.4 TARGETS AND SPIRAL WAVES

The BZ and other batch oscillatory systems are capable of supporting an important class of reaction–diffusion structures. As mentioned earlier, clock reactions support one-off travelling wave fronts or flame, converting reactants to products. In an oscillatory system, the 'resetting' process can be expected to produce a 'wave back' following the front, giving rise to a propagating wave pulse. Furthermore, as the system is then returned more or less to its initial state, further wave initiation may be possible. A series of wave pulses travelling one after the other forms a wave train. If the solution is spread as a thin film, for example in a Petri dish, and initiation is from a point source, the natural geometry will be for a series of concentric, circular wave pulses—a *target 'pattern'* [\[16, 30, 31\]](#). An example of such reaction–diffusion structures in the BZ system is shown in [figure A3.14.9\(a\)](#). For such studies, the reactant solution is typically prepared with initial composition such that the system lies just outside the range for which it is spontaneously oscillatory (i.e. for f marginally in excess of $1 + \sqrt{2}$, see [section A3.14.3.1](#)) by increasing the initial malonic acid concentration relative to bromate. The system then sits in a stable steady state corresponding to the reduced form of the catalyst, and has the property of being *excitable*. An excitable system is characterized by (i) having a steady state; (ii) the steady state is stable to small perturbations and (iii) if the perturbation exceeds some critical or threshold value, the system responds by exhibiting an *excitation event*. For the BZ system, this excitation event is the oxidation of the redox catalyst, corresponding to process B with a local colour change in the vicinity of the perturbation (initiation) site.

This response is typically large compared with the critical stimulus, so the system acts as a 'nonlinear amplifier' of the perturbing signal. Following the excitation, the system eventually returns to the initial steady state and recovers its excitability. There is, however, a finite period, the *refractory period*, between the excitation and the recovery during which the system is unresponsive to further stimuli. These basic characteristics are summarized in [figure A3.14.10](#). Excitability is a feature not just of the BZ system, but is found widely throughout physical and, in particular, biological systems, with important examples in nerve signal transmission and co-ordinated muscle contraction [\[32\]](#).

Figure A3.14.9. Reaction–diffusion structures for an excitable BZ system showing (a) target and (b) spiral waves. (Courtesy of A F Taylor.)

Figure A3.14.10. Schematic representation of important features of an excitable system (see the text for details).

The target structures shown in figure A3.14.9(a) reveal several levels of detail. Each ‘pacemaker site’ at the centre of a target typically corresponds to a position at which the system exhibits some heterogeneity, in some cases due to the presence of dust particles or defects of the dish surface. It is thought that these alter the local pH, so as to produce a composition in that vicinity such that the system is locally oscillatory, the spontaneous oscillations then serving as initiation events. Different sites have differing natural oscillatory frequencies, leading to the differing observed wavelengths of the various target structures. The speed of the waves also depends on the frequency of the pacemaker, through the so-called dispersion relation. The underlying cause of this for the BZ system is that the speed of a given front is dependent on the bromide ion (inhibitor) concentration into which it is propagating: the higher the pacemaker frequency, the less time the bromide ion concentration has to fall, so high-frequency (low-period) structures have lower propagation speeds.

-17-

If a wave pulse is broken, for example through mechanical disturbance, another characteristic feature of excitable media is that the two ‘ends’ then serve as sites around which the wave may develop into a pair of counter-rotating spirals, see figure A3.14.9(b). Once created, the spiral core is a persistent structure (in contrast to the target, in which case removal of the pacemaker heterogeneity prevents further initiation). The spiral structures have a wavelength determined by the composition of the bulk solution rather than the local properties at the core (although other features such as the *meandering* of the core may depend more crucially on local properties).

Targets and spirals have been observed in the CIMA/CDIMA system [13] and also in dilute flames (i.e. flames close to their lean flammability limits) in situations of enhanced heat loss [33]. In such systems, substantial fuel is left unburnt. Spiral waves have also been implicated in the onset of cardiac arrhythmia [32]: the normal contractive events occurring across the atria in the mammalian heart are, in some sense, equivalent to a wave pulse initiated from the sino-atrial node, which acts as a pacemaker. If this pulse becomes fragmented, perhaps by passing over a region of heart muscle tissue of lower excitability, then spiral structures (in 3D, these are *scroll waves*) or ‘re-entrant waves’ may develop. These have the incorrect

sequencing of contractions to squeeze blood from the atria to the ventricles and impair the operation of the heart. Similar waves have been observed in neuronal tissue and there are suggested links to pathological behaviour such as epilepsy and migraine [34]. Spirals and targets have also been observed accompanying the oxidation of CO on appropriate single-crystal catalysts, such as Pt(110), and in other heterogeneously catalysed systems of technological relevance [35] (see figure A3.14.11). The light-sensitive nature of the Ru (bipy)₂-catalysed BZ system has been exploited in many attempts to ‘control’ or influence spiral structures (for example to remove spirals). The excitable properties of the BZ system have also been used to develop generic methods for devising routes through complex mazes or to construct chemical equivalents of logic gates [36].

A3.14.5 TURING PATTERNS AND OTHER STRUCTURES

A3.14.5.1 TURING PATTERNS

Diffusive processes normally operate in chemical systems so as to disperse concentration gradients. In a paper in 1952, the mathematician Alan Turing produced a remarkable prediction [37] that if *selective* diffusion were coupled with chemical feedback, the opposite situation may arise, with a spontaneous development of sustained spatial distributions of species concentrations from initially uniform systems. Turing’s paper was set in the context of the development of form (morphogenesis) in embryos, and has been adopted in some studies of animal coat markings. With the subsequent theoretical work at Brussels [1], it became clear that oscillatory chemical systems should provide a fertile ground for the search for experimental examples of these Turing patterns.

The basic requirements for a Turing pattern are:

- (i) the chemical reaction must exhibit feedback kinetics;

- (ii) the diffusivity of the feedback species must be less than those of the other species;
- (iii) for the patterns to be sustained, the system must be open to the inflow and outflow of reactants and products.

Requirement (i) is met particularly well by the BZ and CIMA/CDIMA reactions, although many chemical reactions with feedback are known. Requirements (ii) and (iii) were met almost simultaneously through the use of ‘continuous flow unstirred reactors’ (CFURs) in which the reaction is carried out in a dilute gel or membrane, with reactant free flows across the edges or faces of the gel. The incorporation of large indicator molecules such as starch into the gel is the key. This indicator is used with the CIMA/CDIMA system for which I_3^- is formed where the I^- concentration is high, and this binds as a complex to the starch to produce the characteristic blue colour. The complexed ion is temporarily immobilized compared with the free ion, thus reducing the effective diffusion coefficient in a kind of ‘reactive chromatography’ [24]. In this way the first laboratory examples of Turing patterns were produced in Bordeaux [38] and in Texas [39]: examples are shown in figure A3.14.12 and figure A3.14.13. Turing patterns have not been unambiguously observed in the BZ system as no similar method of reducing the diffusivity of the autocatalytic species $HBrO_2$ has been devised.

Figure A3.14.12. The first experimental observation of a Turing pattern in a gel strip reactor. Solutions containing separate components of the CIMA/CDIMA reaction are flowed along each edge of the strip and a spatial pattern along the horizontal axis develops for a range of experimental conditions. (Reprinted with permission from [38], © The American Physical Society.)

Figure A3.14.13. Further examples of the various Turing patterns observable in a 2D gel reactor. (a) and (b) spots, (c) and (d) stripes, (e) and (f): wider field of view showing long-range defects in basic structure. The scale bar alongside each figure represents 1 mm. (Reprinted with permission from [39], © The American Institute of Physics.)

A3.14.5.2 CELLULAR FLAMES

Such ‘diffusion-driven instabilities’ have been observed earlier in combustion systems. As early as 1892, Smithells reported the observation of ‘cellular flames’ in fuel-rich mixtures [40]. An example is shown in [figure A3.14.14](#). These were explained theoretically by Sivashinsky in terms of a ‘thermodiffusive’ mechanism [41]. The key feature here involves the role played by the Lewis number, Le , the ratio of the thermal to mass diffusivity. If $Le < 1$, which may arise with fuel-rich flame, for which H-atoms are the relevant species, of relatively low thermal conductivity (due to the high hydrocarbon content), a planar flame is unstable to spatial perturbations along the front. This mechanism has also been shown to operate for simple one-off chemical wave fronts, such as the iodate–arsenite system [42] and for various pH-driven fronts [43], if the diffusivity of I^- or H^+ are reduced via complexing strategies similar to that described above for the CIMA system.

A3.14.5.3 OTHER REACTION–DIFFUSION STRUCTURES

The search for Turing patterns led to the introduction of several new types of chemical reactor for studying reaction–diffusion events in feedback systems. Coupled with huge advances in imaging and data analysis capabilities, it is now possible to make detailed quantitative measurements on complex spatiotemporal behaviour. A few of the reactor configurations of interest will be mentioned here.

The Turing instability is specific in requiring the feedback species to be selectively immobilized. An related instability, the differential flow-induced chemical instability or DIFICI requires only that one active species be immobilized relative to the others [44]. The experimental configuration is simple: a column of ion exchange beads is loaded with one chemical component, for example, ferrion for the BZ system. The remaining species are prepared in solution and flowed through this column. Above some critical flow rate, a travelling spatial structure with narrow bands of oxidized reagent (in the BZ system) separated by a characteristic wavelength and propagating with a characteristic velocity (not equal to the liquid flow velocity) is established. This effect has been realized experimentally—see [figure A3.14.15](#).

Figure A3.14.15. The differential flow-induced chemical instability (DIFICI) in the BZ reaction. (Reprinted with permission from [44], © The American Physical Society.)

If a fluid is placed between two concentric cylinders, and the inner cylinder rotated, a complex fluid dynamical motion known as Taylor–Couette flow is established. Mass transport is then by exchange between eddy vortices which can, under some conditions, be imagined as a substantially enhanced diffusivity (typically with ‘effective diffusion coefficients several orders of magnitude above molecular diffusion coefficients) that can be altered by varying the rotation rate, and with all species having the same diffusivity. Studies of the BZ and CIMA/CDIMA systems in such a Couette reactor [45] have revealed bifurcation through a complex sequence of front patterns, see [figure A3.14.16](#).

-22-

Spatiotemporal complexity in a Couette reactor: space–time plots showing the variation of position with time of fronts corresponding to high concentration gradients of IO_3^- in the CIMA/CDIMA reaction. (Reprinted with permission from Ouyang *et al* [45], © Elsevier Science Publishers 1989.)

The FIS reaction (section A3.14.3.2) has been studied in a CFUR and revealed a series of structures known as ‘serpentine patterns’; also, the birth, self-replication and death of ‘spots’, corresponding to regions of high concentration of particular species (see [figure A3.14.17](#) have been observed [46]).

Figure A3.14.17. Self-replicating spots in the FIS reaction in a CFUR, comparing an experimental time sequence with numerical simulation based on a simple autocatalytic scheme. (Reprinted with permission from Lee *et al* [46], © Macmillan Magazines Ltd. 1994.)

A3.14.6 THEORETICAL METHODS

Much use has been, and continues to be, made of simplified model schemes representative of general classes of chemical or thermal feedback. The Oregonator and Lengyel–Epstein models for the BZ and CDIMA systems have been given earlier. Pre-eminent among the more abstracted caricature models is the Brusselator introduced by Prigogine and Lefever [47] which has the following form:

Here, A and B are regarded as ‘pool chemicals’, with concentrations regarded as imposed constants. The concentrations of the intermediate species X and Y are the variables, with D and E being product species whose concentrations do not influence the reaction rates. The reaction rate equations for [X] and [Y] can be written in the following dimensionless form:

$$\frac{dx}{dt} = A - Bx + yx^2 - x \quad \frac{dy}{dt} = Bx - yx^2.$$

Oscillations are found in this model if $B < B^* = 1 + A^2$.

A variation on this theme introduced by Gray and Scott, known as the ‘autocatalator’, is also widely exploited. This is often written in the form

so here A and B are equivalent to the Y and X in the brusselator and the main clockwork again involves the cubic autocatalytic [step \(15c\)](#) or step (16). The dimensionless equations here are

$$\frac{da}{dt} = \mu - \kappa a - ab^2 \quad \frac{db}{dt} = \kappa a + ab^2 - b \quad (\text{A3.14.17})$$

where μ is a scaled concentration of the reactant P and κ is a dimensionless rate coefficient for the ‘uncatalysed’ conversion of A to B in step (16). In this form, the model has oscillatory behaviour over a range of experimental conditions:

$$\mu_1^* < \mu < \mu_2^* \quad \text{with} \quad (\mu_{1,2}^*)^2 = \frac{1}{2}[1 - 2\kappa \pm (1 - 8\kappa)^{1/2}]. \quad (\text{A3.14.18})$$

Outside this range, the system approaches the steady state obtained by setting $da/dt = db/dt = 0$:

$$(a_{ss}, b_{ss}) = (\mu/(\mu^2 + \kappa), \mu). \quad (\text{A3.14.19})$$

The existence of an upper and a lower limit to the range of oscillatory behaviour is more typical of observed behaviour in chemical systems.

The autocatalytic driving [step \(16c\)](#) can also be taken on its own, or with the ‘decay’ [step \(16d\)](#) in models of open systems such as a CSTR, with an inflow of species A and, perhaps, of B. This system is then one of the simplest to show bistability and more complex steady-state loci of the type described in [section A3.14.2.3](#). Also, generic features of wave front propagation can be studied on the basis of this scheme [7]. A comprehensive account can be found in the book by Gray and Scott (see [Further Reading](#)). Essentially, this model has been used in the context of modelling the broad features of oscillations in glycolysis and, with some modification, for animal coat patterning through Turing-like mechanisms.

The main theoretical methods have in common the determination of the *stability* of steady-state or other

simple solutions to the appropriate form of the governing mass balance equations. Bifurcations from simple to more complex responses occur when such a solution loses its stability. Thus, the steady state given in [equation \(A3.14.19\)](#) does not cease to exist in the oscillatory region defined by [\(A3.14.18\)](#), but is now unstable, so that, if the system is perturbed, it departs from the steady state and moves to the (stable) oscillatory state which is also a solution of the reaction rate [equations \(A3.14.17\)](#).

In the generalized representation of the rate equations

$$da/dt = f(a, b) \quad db/dt = g(a, b)$$

where f and g are functions of the species concentrations, a determining role is played by the eigenvalues of the Jacobian matrix J defined by

$$J = \begin{pmatrix} \partial f/\partial a & \partial f/\partial b \\ \partial g/\partial a & \partial g/\partial b \end{pmatrix}$$

evaluated with the steady-state concentrations. (This is readily generalized to n -variable systems, with J then being an $n \times n$ matrix.) Bifurcations corresponding to a turning or fold point in a steady-state locus (ignition or extinction point) occur if a real eigenvalue passes through zero. Equivalently, this arises if the determinant $\det J = 0$. This is known as a ‘saddle-node’ bifurcation. The oscillatory instability, or Hopf bifurcation, occurs if the real part of an imaginary pair of eigenvalues passes through zero (provided all other eigenvalues are negative or have negative real parts). For a two-variable system, this occurs if the trace $\text{Tr } J = 0$, and is the origin of the result in [equation \(A3.14.18\)](#).

The autocatalator model is in many ways closely related to the FONI system, which has a single first-order exothermic reaction step obeying an Arrhenius temperature dependence and for which the role of the autocatalyst is taken by the temperature of the system. An extension of this is the Sal’nikov model which supports ‘thermokinetic’ oscillations in combustion-like systems [48]. This has the form:

-26-

The reactant P is again taken as a pool chemical, so the first step has a constant rate. The rate of the second step depends on the concentration of the intermediate A and on the temperature T and this step is taken as exothermic. (In the simplest case, k_0 is taken to be independent of T and the first step is thermoneutral.) Again, the steady state is found to be unstable over a range of parameter values, with oscillations being observed.

The approach to investigating spatial structure is similar—usually some simple solutions, such as a spatially uniform steady state exists and the condition for instability to spatial perturbations is determined in terms of eigenvalues of an extended Jacobian matrix. For conditions marginally beyond a bifurcation point (whether the instability is temporal or spatial), amplitude equations, such as the complex Ginsburg–Landau equation, are exploited [49]. For conditions far from bifurcation points, however, recourse to numerical integration is generally required. Frequently these will involve reaction–diffusion (and perhaps advection) equations, although representations of such systems in terms of cellular automata or gas-lattice models can be advantageous [50].

B1.1 Electronic spectroscopy

S J Strickler

B1.1.1 INTRODUCTION

Optical spectroscopy is the study of the absorption and emission of light by atoms, molecules, or larger assemblies. Electronic spectroscopy is the branch of the field in which the change produced by the absorption or emission is a rearrangement of the electrons in the system. These changes are interpreted in terms of the quantum theory of electronic structure. To a first approximation, the rearrangements usually correspond to an electron being transferred from one orbital to another, and a transition will be described in terms of those orbitals. The wavelengths or frequencies of transitions help identify atoms and molecules and give information about their energy levels and hence their electronic structure and bonding. Intensities of absorption or emission give information about the nature of the electronic states and help to determine concentrations of species. In the case of molecules, along with the rearrangements of electrons there are usually changes in nuclear motions, and the vibrational and rotational structure of electronic bands give valuable insights into molecular structure and properties. For all these reasons, electronic spectroscopy is one of the most useful tools in chemistry and physics.

Most electronic transitions of interest fall into the visible and near-ultraviolet regions of the spectrum. This range of photon energies commonly corresponds to electrons being moved among valence orbitals. These orbitals are important to an understanding of bonding and structure, so are of particular interest in physical chemistry and chemical physics. For this reason, most of this chapter will concentrate on visible and near-UV spectroscopy, roughly the region between 200 and 700 nm, but there are no definite boundaries to the wavelengths of interest. Some of the valence orbitals will be so close in energy as to give spectra in the near-infrared region. Conversely, some valence transitions will be at high enough energy to lie in the vacuum ultraviolet, below about 200 nm, where air absorbs strongly and instrumentation must be evacuated to allow light to pass. In this region are also transitions of electrons to states of higher principal quantum number, known as Rydberg states. At still higher energies, in the x-ray region, are transitions of inner-shell electrons, and their spectroscopy has become an extremely useful tool, especially for studying solids and their surfaces. However, these other regions will not be covered in detail here.

Section B1.1.2 provides a brief summary of experimental methods and instrumentation, including definitions of some of the standard measured spectroscopic quantities. Section B1.1.3 reviews some of the theory of spectroscopic transitions, especially the relationships between transition moments calculated from wavefunctions and integrated absorption intensities or radiative rate constants. Because units can be so confusing, numerical factors with their units are included in some of the equations to make them easier to use. Vibrational effects, the Franck–Condon principle and selection rules are also discussed briefly. In the final section, B1.1.4, a few applications are mentioned to particular aspects of electronic spectroscopy.

B1.1.2 EXPERIMENTAL METHODS

B1.1.2.1 STANDARD INSTRUMENTATION

There are two fundamental types of spectroscopic studies: absorption and emission. In absorption spectroscopy an atom or molecule in a low-lying electronic state, usually the ground state, absorbs a photon to go to a higher state. In emission spectroscopy the atom or molecule is produced in a higher electronic state by some excitation process, and emits a photon in going to a lower state. In this section we will consider the traditional instrumentation for studying the resulting spectra. They define the quantities measured and set the standard for experimental data to be considered.

(A) EMISSION SPECTROSCOPY

Historically, emission spectroscopy was the first technique to be extensively developed. An electrical discharge will break up most substances into atoms and small molecules and their ions. It also excites these species into nearly all possible stable states, and the higher states emit light by undergoing transitions to lower electronic states. In typical classical instruments light from the sample enters through a slit, is collimated by a lens or mirror, is dispersed by a prism or grating so that different colours or wavelengths are travelling in different directions and is focused on a detector. Gratings are generally favoured over prisms. A concave grating may do the collimation, dispersion and focusing all in one step. The angle at which the light is reflected by a plane grating is simply related to the spacing, d , of the grooves ruled on the grating and the wavelength, λ , of the light:

$$\pm n\lambda = d(\sin \alpha + \sin \beta)$$

where α and β are the angles of incidence and reflection measured from the normal, and n is the order of the reflection, i.e. the number of cycles by which wave fronts from successive grooves differ for constructive interference. (The angles may be positive or negative depending on the experimental arrangement.) The first determinations of the absolute wavelengths of light and most of our knowledge of energies of excited states of atoms and molecules came from measuring these angles. In everyday use now the wavelength scale of an instrument can be calibrated using the wavelengths of known atomic lines. Grating instruments do have the disadvantage in comparison with prism spectrometers that different orders of light may overlap and need to be sorted out.

The earliest detector was the human eye observing the different colours. More versatile is a photographic plate, where each wavelength of light emitted shows up as a dark line (an image of the entrance slit) on the plate. It has the advantage that many wavelengths are measured simultaneously. Quantitative measurements are easier with a photomultiplier tube placed behind an exit slit. The spectrum is obtained as the different wavelengths are scanned across the slit by rotating the grating. The disadvantage is that measurements are made one wavelength at a time. With the advent of solid-state electronics, array detectors have become available that will measure many wavelengths at a time much like a photographic plate, but which can be read out quickly and quantitatively into a computer or other data system.

The design and use of spectrographs or spectrometers involves a compromise between resolution—how close in wavelength two lines can be and still be seen as separate—and sensitivity—how weak a light can be observed or how

long it takes to make a measurement. Books have been written about the design of such instruments [1], and the subject cannot be pursued in this work.

Larger molecules generally cannot be studied in quite the same way, as an electric discharge merely breaks them up into smaller molecules or atoms. In such a case excited states are usually produced by optical excitation using light of the same or higher energy. Many modern fluorimeters are made with two

monochromators, one to select an excitation wavelength from the spectrum of a suitable lamp, and the other to observe the emission as discussed above. Most studies of large molecules are done on solutions because vapour pressures are too low to allow gaseous spectra.

The fundamental measurements made in emission spectroscopy are the wavelengths or frequencies and the intensities of emission lines or bands. The problem with intensity measurements is that the efficiency of a dispersing and detecting system varies with wavelength. Relative intensities at a single wavelength are usually quite easily measured and can be used as a measure of concentration or excitation efficiency. Relative intensities of lines at nearly the same wavelength, say different rotational lines in a given band, can usually be obtained by assuming that the efficiency is the same for all. But the absolute intensity of a band or relative intensities of well separated bands require a calibration of the sensitivity of the instrument as a function of wavelength. In favourable cases this may be done by recording the spectrum of a standard lamp that has in turn been calibrated to give a known spectrum at a defined lamp current. For critical cases it may be necessary to distinguish between intensities measured in energy flow per unit time or in photons per unit time.

(B) ABSORPTION SPECTROSCOPY

Absorption spectroscopy is a common and well developed technique for studying electronic transitions between the ground state and excited states of atoms or molecules. A beam of light passes through a sample, and the amount of light that is absorbed during the passage is measured as a function of the wavelength or frequency of the light. The absorption is measured by comparing the intensity, I , of light leaving the sample with the intensity, I_0 , entering the sample. The transmittance, T , is defined as the ratio

$$T = I/I_0.$$

It is often quoted as a percentage. In measuring the spectra of gases or solutions contained in cells, I_0 is usually taken to be the light intensity passing through an empty cell or a cell of pure solvent. This corrects well for reflection at the surfaces, absorption by the solvent or light scattering, which are not usually the quantities of interest.

It is usually convenient to work with the decadic absorbance, A , defined by

$$A = \log(I_0/I) = -\log T.$$

The unmodified term absorbance usually means this quantity, though some authors use the Napierian absorbance $B = -\ln T$. The absorbance is so useful because it normally increases linearly with path length, l , through the sample and with the concentration, c , of the absorbing species within the sample. The relationship is usually called Beer's law:

-4-

$$A = \epsilon cl.$$

The quantity ϵ is called the absorption coefficient or extinction coefficient, more completely the molar decadic absorption coefficient; it is a characteristic of the substance and the wavelength and to a lesser extent the solvent and temperature. It is common to take path length in centimetres and concentration in moles per litre, so ϵ has units of $\text{l mol}^{-1} \text{cm}^{-1}$. The electronic absorption spectrum of a compound is usually shown as a plot of ϵ versus wavelength or frequency.

Another useful quantity related to extinction coefficient is the cross section, σ , defined for a single atom or molecule. It may be thought of as the effective area blocking the beam at a given wavelength, and the value

may be compared with the size of the molecule. The relationship is

$$\sigma = (\ln 10)\epsilon/N_A$$

where N_A is Avogadro's number. If ϵ is in $\text{l mol}^{-1} \text{cm}^{-1}$ and σ is desired in cm^2 the relationship may be written

$$\sigma = (3.8235 \times 10^{-21} \text{ cm}^3 \text{ mol l}^{-1})\epsilon.$$

The standard instrument for measuring an absorption spectrum is a double-beam spectrophotometer. A typical instrument uses a lamp with a continuous spectrum to supply the light, usually a tungsten lamp for the visible, near-infrared, and near-ultraviolet regions and a discharge lamp filled with hydrogen or deuterium for farther in the ultraviolet. Light from the source passes through a monochromator to give a narrow band of wavelengths, and is then split into two beams. One beam passes through a cell containing the sample, the other through an identical reference cell filled with solvent. These beams define I and I_0 , respectively. The beams are monitored by a detection system, usually a photomultiplier tube. An electronic circuit measures the ratio of the two intensities and displays the transmittance or absorbance. The wavelength is varied by scanning the monochromator, and the spectrum may be plotted on a chart recorder.

A different design of instrument called a diode array spectrometer has become popular in recent years. In this instrument the light from the lamp passes through the sample, then into a spectrometer to be dispersed, and then is focused onto an array of solid-state detectors arranged so that each detector element measures intensity in a narrow band of wavelengths—say one detector for each nanometre of the visible and ultraviolet regions. The output is digitized and the spectrum displayed on a screen, and it can be read out in digital form and processed with a computer. The complete spectrum can be recorded in a few seconds. This is not formally a double-beam instrument, but because a spectrum is taken so quickly and handled so easily, one can record the spectrum of a reference cell and the sample cell and then compare them in the computer, so it serves the same purpose. The available instruments do not give quite the resolution or versatility of the standard spectrophotometers, but they are far quicker and easier to use.

B1.1.2.2 SOME MODERN TECHNIQUES

The traditional instruments for measuring emission and absorption spectra described above set the standard for the types of information which can be obtained and used by spectroscopists. In the more recent past, several new

-5-

techniques have become available which have extended the range of spectroscopic measurements to higher resolution, lower concentrations of species, weaker transitions, shorter time scales, etc. Many studies in electronic spectroscopy as a branch of physical chemistry or chemical physics are now done using these new techniques. The purpose of this section is to discuss some of them.

(A) LASERS

The foremost of the modern techniques is the use of lasers as spectroscopic tools. Lasers are extremely versatile light sources. They can be designed with many useful properties (not all in the same instrument) such as high intensity, narrow frequency bandwidth with high-frequency stability, tunability over reasonable frequency ranges, low-divergence beams which can be focused into very small spots, or pulsed beams with

very short time durations. There are nearly as many different experimental arrangements as there are experimenters, and only a few examples will be mentioned here.

While a laser beam can be used for traditional absorption spectroscopy by measuring I and I_0 , the strength of laser spectroscopy lies in more specialized experiments which often do not lend themselves to such measurements. Other techniques are commonly used to detect the absorption of light from the laser beam. A common one is to observe fluorescence excited by the laser. The total fluorescence produced is normally proportional to the amount of light absorbed. It can be used as a measurement of concentration to detect species present in extremely small amounts. Or a measurement of the fluorescence intensity as the laser frequency is scanned can give an absorption spectrum. This may allow much higher resolution than is easily obtained with a traditional absorption spectrometer. In other experiments the fluorescence may be dispersed and its spectrum determined with a traditional spectrometer. In suitable cases this could be the emission from a single electronic–vibrational–rotational level of a molecule and the experimenter can study how the spectrum varies with level.

Other methods may also be useful for detecting the absorption of laser radiation. For example, the heat generated when radiation is absorbed can be detected in several ways. One way observes the defocusing of the laser beam when the medium is heated and its refractive index changes. Another way, called photoacoustic spectroscopy, detects sound waves or pressure pulses when light is absorbed from a pulsed laser. Still another method useful with high-intensity pulsed lasers is to measure light absorption by the excited states produced. This is often useful for studying the kinetics of the excited species as they decay or undergo reactions.

Another example of a technique for detecting absorption of laser radiation in gaseous samples is to use multiphoton ionization with intense pulses of light. Once a molecule has been electronically excited, the excited state may absorb one or more additional photons until it is ionized. The electrons can be measured as a current generated across the cell, or can be counted individually by an electron multiplier; this can be a very sensitive technique for detecting a small number of molecules excited.

(B) EXCITED-STATE LIFETIMES

Measurements of the decay rates of excited states are important, both for the fundamental spectroscopic information they can give, and for studies of other processes such as energy transfer or photochemistry. The techniques used vary greatly depending on the time scale of the processes being studied. For rather long time scales, say of the order of a millisecond or longer, it is rather simple to excite the molecules optically, cut off the exciting light, and watch the decay of emission or some other measurement of excited-state concentration.

-6-

For fluorescent compounds and for times in the range of a tenth of a nanosecond to a hundred microseconds, two very successful techniques have been used. One is the phase-shift technique. In this method the fluorescence is excited by light whose intensity is modulated sinusoidally at a frequency f , chosen so its period is not too different from the expected lifetime. The fluorescent light is then also modulated at the same frequency but with a time delay. If the fluorescence decays exponentially, its phase is shifted by an angle $\Delta\phi$ which is related to the mean life, τ , of the excited state. The relationship is

$$\tan \Delta\phi = 2\pi f\tau.$$

The phase shift is measured by comparing the phase of the fluorescence with the phase of light scattered by a cloudy but non-fluorescent solution.

The other common way of measuring nanosecond lifetimes is the time-correlated single-photon counting

technique [2]. In this method the sample is excited by a weak, rapidly repeating pulsed light source, which could be a flashlamp or a mode-locked laser with its intensity reduced. The fluorescence is monitored by a photomultiplier tube set up so that current pulses from individual photons can be counted. It is usually arranged so that at most one fluorescence photon is counted for each flash of the excitation source. A time-to-amplitude converter and a multichannel analyser (equipment developed for nuclear physics) are used to determine, for each photon, the time between the lamp flash and the photon pulse. A decay curve is built up by measuring thousands of photons and sorting them by time delay. The statistics of such counting experiments are well understood and very accurate lifetimes and their uncertainties can be determined by fitting the resulting decay curves.

One advantage of the photon counting technique over the phase-shift method is that any non-exponential decay is readily seen and studied. It is possible to detect non-exponential decay in the phase-shift method too by making measurements as a function of the modulation frequency, but it is more cumbersome.

At still shorter time scales other techniques can be used to determine excited-state lifetimes, but perhaps not as precisely. Streak cameras can be used to measure faster changes in light intensity. Probably the most useful techniques are pump-probe methods where one intense laser pulse is used to excite a sample and a weaker pulse, delayed by a known amount of time, is used to probe changes in absorption or other properties caused by the excitation. At short time scales the delay is readily adjusted by varying the path length travelled by the beams, letting the speed of light set the delay.

(C) PHOTOELECTRON SPECTROSCOPY

Only brief mention will be made here of photoelectron spectroscopy. This technique makes use of a beam of light whose energy is greater than the ionization energy of the species being studied. Transitions then occur in which one of the electrons of the molecule is ejected. Rather than an optical measurement, the kinetic energy of the ejected electron is determined. Some of the technology is described in [section B1.6](#) on electron energy-loss spectroscopy. The ionization energy of the molecule is determined from the difference between the photon energy and the kinetic energy of the ejected electron.

A useful light source is the helium resonance lamp which produces light of wavelength 58.4 nm or a photon energy of 21.2 eV, enough to ionize any neutral molecule. Often several peaks can be observed in the photoelectron spectrum

-7-

corresponding to the removal of electrons from different orbitals. The energies of the peaks give approximations to the orbital energies in the molecule. They are useful for comparison with theoretical calculations.

An interesting variation on the method is the use of a laser to photodetach an electron from a negative ion produced in a beam of ions. Since it is much easier to remove an electron from a negative ion than from a neutral molecule, this can be done with a visible or near-ultraviolet laser. The difference between the photon energy and the electron energy, in this case, gives the electron affinity of the neutral molecule remaining after the photodetachment, and may give useful energy levels of molecules not easily studied by traditional spectroscopy [3].

(D) OTHER TECHNIQUES

Some other extremely useful spectroscopic techniques will only be mentioned here. Probably the most important one is spectroscopy in free jet expansions. Small molecules have often been studied by gas-phase spectroscopy where sharp rotational and vibrational structure gives detailed information about molecular

states and geometries. The traditional techniques will often not work for large molecules because they must be heated to high temperatures to vaporize them and then the spectra become so broad and congested that detailed analysis is difficult or impossible. In jet spectroscopy the gaseous molecules are mixed with an inert gas and allowed to expand into a vacuum. The nearly adiabatic expansion may cool them rapidly to temperatures of a few degrees Kelvin while leaving them in the gas phase. The drastic simplification of the spectrum often allows much more information to be extracted from the spectrum.

Fourier-transform instruments can also be used for visible and ultraviolet spectroscopy. In this technique, instead of dispersing the light with a grating or prism, a wide region of the spectrum is detected simultaneously by splitting the beam into two components, one reflected from a stationary mirror and one from a movable mirror, and then recombining the two beams before they enter the detector. The detected intensity is measured as a function of the position of the movable mirror. Because of interference between the two beams, the resulting function is the Fourier transform of the normal spectrum as a function of wavelength. This offers some advantages in sensitivity and perhaps resolution because the whole spectrum is measured at once rather than one wavelength at a time. The technique is not too common in electronic spectroscopy, but is very widely used for the infrared. It is described more fully in the chapter on vibrational spectroscopy, [section B1.2](#). While the light sources and detectors are different for the visible and ultraviolet region, the principles of operation are the same.

B1.1.3 THEORY

The theory of absorption or emission of light of modest intensity has traditionally been treated by time-dependent perturbation theory [4]. Most commonly, the theory treats the effect of the oscillating electric field of the light wave acting on the electron cloud of the atom or molecule. The instantaneous electric field is assumed to be uniform over the molecule but it oscillates in magnitude and direction with a frequency ν . The energy of a system of charges in a uniform electric field, \mathbf{E} , depends on its dipole moment according to

$$E = -\boldsymbol{\mu} \cdot \mathbf{E}$$

-8-

where the dipole moment is defined by

$$\boldsymbol{\mu} = \sum_i q_i \mathbf{r}_i$$

and the q_i and \mathbf{r}_i are the charges and positions of the particles, i.e. the electrons and nuclei. The result of the time-dependent perturbation theory is that the transition probability for a transition between one quantum state i and another state j is proportional to the absolute value squared of the matrix element of the electric dipole operator between the two states

$$\mu_{ij} = \int \Psi_i^* \boldsymbol{\mu} \Psi_j \, d\tau$$

(B1.1.1)

transition probability $\propto |\mu_{ij}|^2$.

The transition occurs with significant probability only if the frequency of the light is very close to the familiar resonance condition, namely $h\nu = \Delta E$, where h is Planck's constant and ΔE is the difference in energy of the

two states. However, transitions always occur over a range of frequencies because of various broadening effects; if nothing else, as required by the uncertainty principle, the states will not have precisely defined energies if they have finite lifetimes.

B1.1.3.1 ABSORPTION SPECTROSCOPY

(A) INTEGRATED ABSORPTION INTENSITY

The relationship between the theoretical quantity μ_{ij} and the experimental parameter ϵ of absorption spectroscopy involves, not the value of ϵ at any one wavelength, but its integral over the absorption band. The relationship is

$$\int \epsilon \, d\tilde{\nu} = \frac{2\pi^2 N_A \tilde{\nu}}{3hc\epsilon_0 \ln 10} |\mu_{ij}|^2 = (2.512 \times 10^{19} \text{ l mol}^{-1} \text{ cm}^{-3}) \frac{\tilde{\nu}}{e^2} |\mu_{ij}|^2. \quad (\text{B1.1.2})$$

We will quote a numerical constant in some of these equations to help with actual calculations. The units can be very confusing because it is conventional to use non-SI units for several quantities. The wavenumber value, $\tilde{\nu}$, is usually taken to be in cm^{-1} . The extinction coefficient is conveniently taken in units of $\text{l mol}^{-1} \text{ cm}^{-1}$. We have inserted the factor e^2 into the equation because values of μ_{ij} are usually calculated with the charges measured in units of the electron charge. For the sake of consistency, we have quoted the numerical factor appropriate for μ/e taken in centimetres, but the values are easily converted to use other length units such as Ångstroms or atomic units. The value of $\tilde{\nu}$ in the right-hand side of the equation is to be interpreted as a suitable average frequency for the transition. This causes no difficulty unless the band is very broad. Some of the difficulties with different definitions of intensity terms have been discussed by Hilborn [5].

-9-

(B) OSCILLATOR STRENGTH

A related measure of the intensity often used for electronic spectroscopy is the oscillator strength, f . This is a dimensionless ratio of the transition intensity to that expected for an electron bound by Hooke's law forces so as to be an isotropic harmonic oscillator. It can be related either to the experimental integrated intensity or to the theoretical transition moment integral:

$$(\text{B1.1.3})$$

or

$$(\text{B1.1.4})$$

The harmonically bound electron is, in a sense, an ideal absorber since its harmonic motion can maintain a perfect phase relationship with the oscillating electric field of the light wave. Strong electronic transitions have oscillator strengths of the order of unity, but this is not, as sometimes stated, an upper limit to f . For example, some polyacetylenes have bands with oscillator strengths as high as 5 [6]. There is a theorem, the Kuhn–Thomas sum rule, stating that the sum of the oscillator strengths of all electronic transitions must be equal to the number of electrons in an atom or molecule [7].

In the above discussion we have used the electric dipole operator μ . It is also sometimes possible to observe electronic transitions occurring due to interaction with the magnetic field of the light wave. These are called magnetic dipole transitions. They are expected to be weaker than electric dipole transitions by several orders of magnitude. If account is taken of a variation of the field of the light wave over the size of the molecule it is possible to treat quadrupole or even higher multipole transitions. These are expected to be even weaker than typical magnetic dipole transitions. We will concentrate on the more commonly observed electric dipole

transitions.

[Equation \(B1.1.1\)](#) for the transition moment integral is rather simply interpreted in the case of an atom. The wavefunctions are simply functions of the electron positions relative to the nucleus, and the integration is over the electronic coordinates. The situation for molecules is more complicated and deserves discussion in some detail.

(C) TRANSITION MOMENTS FOR MOLECULES

Electronic spectra are almost always treated within the framework of the Born–Oppenheimer approximation [8] which states that the total wavefunction of a molecule can be expressed as a product of electronic, vibrational, and rotational wavefunctions (plus, of course, the translation of the centre of mass which can always be treated separately from the internal coordinates). The physical reason for the separation is that the nuclei are much heavier than the electrons and move much more slowly, so the electron cloud normally follows the instantaneous position of the nuclei quite well. The integral of [equation \(B1.1.1\)](#) is over all internal coordinates, both electronic and nuclear. Integration over the rotational wavefunctions gives rotational selection rules which determine the fine structure and band shapes of electronic transitions in gaseous molecules. Rotational selection rules will be discussed below. For molecules in condensed phases the rotational motion is suppressed and replaced by oscillatory and diffusional motions.

-10-

In this section we concentrate on the electronic and vibrational parts of the wavefunctions. It is convenient to treat the nuclear configuration in terms of normal coordinates describing the displacements from the equilibrium position. We call these nuclear normal coordinates Q_j and use the symbol Q without a subscript to designate the whole set. Similarly, the symbol x_i designates the coordinates of the i th electron and x the whole set of electronic coordinates. We also use subscripts l and u to designate the lower and upper electronic states of a transition, and subscripts a and b to number the vibrational states in the respective electronic states. The total wavefunction Ψ can be written

$$\Psi_{la}(x, Q) = \psi_l(x, Q)\phi_a(Q) \quad \Psi_{ub}(x, Q) = \psi_u(x, Q)\phi_b(Q).$$

Here each $\phi(Q)$ is a vibrational wavefunction, a function of the nuclear coordinates Q , in first approximation usually a product of harmonic oscillator wavefunctions for the various normal coordinates. Each $\psi(x, Q)$ is the electronic wavefunction describing how the electrons are distributed in the molecule. However, it has the nuclear coordinates within it as parameters because the electrons are always distributed around the nuclei and follow those nuclei whatever their position during a vibration. The integration of [equation \(B1.1.1\)](#) can be carried out in two steps—first an integration over the electronic coordinates x , and then integration over the nuclear coordinates Q . We define an electronic transition moment integral which is a function of nuclear position:

$$\mu_{lu}(Q) = \int \psi_l^*(x, Q)\mu\psi_u(x, Q) dx. \quad (\text{B1.1.5})$$

We then integrate this over the vibrational wavefunctions and coordinates:

$$\mu_{lu,ab} = \int \Psi_{la}^*\mu\Psi_{ub} d\tau = \int \phi_{la}^*(Q)\mu_{lu}(Q)\phi_{ub}(Q) dQ. \quad (\text{B1.1.6})$$

This last transition moment integral, if plugged into [equation \(B1.1.2\)](#), will give the integrated intensity of a vibronic band, i.e. of a transition starting from vibrational state a of electronic state l and ending on vibrational level b of electronic state u .

(D) THE FRANCK—CONDON PRINCIPLE

The electronic transition moment of [equation \(B1.1.5\)](#) is related to the intensity that the transition would have if the nuclei were fixed in configuration Q , but its value may vary with that configuration. It is often useful to expand $\mu_{lu}(Q)$ as a power series in the normal coordinates, Q_i :

$$\mu_{lu}(Q) = \mu_{lu}(0) + \sum_i \left(\frac{\partial \mu_{lu}}{\partial Q_i} \right)_0 Q_i + \dots \quad (\text{B1.1.7})$$

-11-

Here $\mu_{lu}(0)$ is the value at the equilibrium position of the initial electronic state.

In many cases the variation is not very strong for reasonable displacements from equilibrium, and it is sufficient to use only the zero-order term in the expansion. If this is inserted into [equation \(B1.1.6\)](#) we get

$$\mu_{la,ub} = \mu_{lu}(0) \int \phi_{la}^*(Q) \phi_{ub}(Q) dQ$$

and using this in [equation \(B1.1.2\)](#) for the integrated intensity of a vibronic band we get the relationship

$$\int \varepsilon d\tilde{\nu} = \frac{2\pi^2 N_A \tilde{\nu}_{la \rightarrow ub}}{3hc\varepsilon_0 \ln 10} |\mu_{lu}(0)|^2 \left| \int \phi_{la}^*(Q) \phi_{ub}(Q) dQ \right|^2. \quad (\text{B1.1.8})$$

The last factor, the square of the overlap integral between the initial and final vibrational wavefunctions, is called the Franck—Condon factor for this transition.

The Franck—Condon principle says that the intensities of the various vibrational bands of an electronic transition are proportional to these Franck—Condon factors. (Of course, the frequency factor must be included for accurate treatments.) The idea was first derived qualitatively by Franck through the picture that the rearrangement of the light electrons in the electronic transition would occur quickly relative to the period of motion of the heavy nuclei, so the position and momentum of the nuclei would not change much during the transition [9]. The quantum mechanical picture was given shortly afterwards by Condon, more or less as outlined above [10].

The effects of the principle are most easily visualized for diatomic molecules for which the vibrational potential can be represented by a potential energy curve. A typical absorption starts from the lowest vibrational level of the ground state (actually a thermal distribution of low-lying levels). A useful qualitative statement of the Franck—Condon principle is that vertical transitions should be favoured. [Figure B1.1.1\(a\)](#) illustrates the case where the potential curve for the excited state lies nearly directly above that for the ground state. Then by far the largest overlap of excited state wavefunctions with the lowest level of the ground state will be for the $v = 0$ level, and we expect most intensity to be in the so-called 0–0 band, i.e. from $v = 0$ in the lower state to $v = 0$ in the upper state. A case in point is the transition of the O_2 molecule at about 750 nm in the near-infrared. (This is actually a magnetic dipole transition rather than electric dipole, so it is very weak,

but the vibrational effects are the same.) Both ground and excited state have a $(\pi^*)^2$ electron configuration and nearly the same equilibrium bond length, only 0.02 Å different. The spectrum shows most of the intensity in the 0–0 band with less than one tenth as much in the 1–0 band [11].

Figure B1.1.1. (a) Potential curves for two states with little or no difference in the equilibrium position of the upper and lower states. A transition of O_2 , with displacement only 0.02 Å, is shown as an example. Data taken from [11]. Most of the intensity is in the 0–0 vibrational band with a small intensity in the 1–0 band. (b) Potential curves for two states with a large difference in the equilibrium position of the two states. A transition in I_2 , with a displacement of 0.36 Å, is shown as an example. Many vibrational peaks are observed.

Figure B1.1.1(b) shows a contrasting case, where the potential curve for the excited state is displaced considerably relative to the ground-state curve. Then a vertical transition would go to a part of the excited-state curve well displaced from the bottom, and the maximum overlap and greatest intensity should occur for high-lying levels. There results a long progression of bands to various vibrational levels. The spectrum of I_2 is shown as an illustration; here the displacement between the two minima is about 0.36 Å. Many vibronic transitions are seen. One can observe the excited-state levels getting closer together and converging as the dissociation limit is approached, and part of the absorption goes to continuum states above the dissociation energy. (The long-wavelength part of the spectrum is complicated by transitions starting from thermally excited vibrational levels of the ground state.)

(E) BEYOND FRANCK—CONDON

There are cases where the variation of the electronic transition moment with nuclear configuration cannot be neglected. Then it is necessary to work with equation (B1.1.6) keeping the dependence of μ_{lu} on Q and integrating it over the vibrational wavefunctions. In most such cases it is adequate to use only the terms up to first-order in equation (B1.1.7). This results in ‘modified Franck–Condon factors’ for the vibrational intensities [12].

(F) TOTAL INTENSITY OF AN ELECTRONIC TRANSITION

Equation (B1.1.8) gives the intensity of one vibronic band in an absorption spectrum. It is also of interest to consider

the total integrated intensity of a whole electronic transition, i.e. the sum of all the vibronic bands corresponding to the one electronic change. In the most common absorption spectroscopy experiment we can assume that all transitions originate in the lowest vibrational level of the ground electronic state, which we can designate as level 10. The transitions can go to various levels ub of the upper electronic state. The total integrated intensity is then obtained by summing over the index b which numbers the excited state vibrational levels.

$$\int \varepsilon d\tilde{\nu} = \frac{2\pi^2 N_A}{3hc\varepsilon_0 \ln 10} \sum_b \tilde{\nu}_{10 \rightarrow ub} \left| \int \phi_{10}^*(Q) \mu_{lu}(Q) \phi_{ub}(Q) dQ \right|^2. \quad (\text{B1.1.9})$$

This equation can be simplified if the frequency term $\tilde{\nu}_{10 \rightarrow ub}$ is removed from the summation. One way to do this is to incorporate it into the integral on the left-hand side by writing $\int \varepsilon d \ln \tilde{\nu}$. The alternative is to use an appropriate average $\langle \tilde{\nu} \rangle$ outside the sum, choosing the proper average by making the expressions equal. Often it is enough to pick an average by eye, but if high accuracy is important the value to use is given by

$$\langle \tilde{\nu} \rangle = \frac{\int \varepsilon d\tilde{\nu}}{\int \varepsilon d \ln \tilde{\nu}}.$$

With the frequency removed from the sum, (B1.1.9) has just a sum over vibrational integrals. Because all the vibrational wavefunctions for a given potential surface will form a complete set, it is possible to apply a sum rule to simplify the resulting expression:

$$\sum_b \left| \int \phi_{10}^*(Q) \mu_{lu}(Q) \phi_{ub}(Q) dQ \right|^2 = \int \phi_{10}^*(Q) |\mu_{lu}(Q)|^2 \phi_{10}(Q) dQ$$

i.e. the sum is just the mean value of $|\mu_{lu}(Q)|^2$ in the initial vibrational state. Then the total integrated intensity of the electronic band is given by

$$\int \varepsilon d\tilde{\nu} = \frac{2\pi^2 N_A \langle \tilde{\nu} \rangle}{3hc\varepsilon_0 \ln 10} \int \phi_{10}^*(Q) |\mu_{lu}(Q)|^2 \phi_{10}(Q) dQ. \quad (\text{B1.1.10})$$

If we can get by with using only the zero-order term of (B1.1.7), we can take μ_{lu} out of the integral and use the fact that ϕ_{10} is normalized. The last equation then simplifies further to

$$\int \varepsilon d\tilde{\nu} = \frac{2\pi^2 N_A \langle \tilde{\nu} \rangle}{3hc\varepsilon_0 \ln 10} |\mu_{lu}(0)|^2 = (2.512 \times 10^{19} \text{ l mol}^{-1} \text{ cm}^{-3}) \frac{\langle \tilde{\nu} \rangle}{e^2} |\mu_{lu}(0)|^2. \quad (\text{B1.1.11})$$

Equation (B1.1.10) and equation (B1.1.11) are the critical ones for comparing observed intensities of electronic transitions with theoretical calculations using the electronic wavefunctions. The transition moment integral μ_{lu}

calculated from electronic wavefunctions is related to the absorption intensity integrated over the whole electronic transition. It is found that simple forms of electronic wavefunctions often do not give very good intensities, and high-quality wavefunctions are required for close agreement with experiment.

B1.1.3.2 EMISSION SPECTROSCOPY

The interpretation of emission spectra is somewhat different but similar to that of absorption spectra. The intensity observed in a typical emission spectrum is a complicated function of the excitation conditions which determine the number of excited states produced, quenching processes which compete with emission, and the efficiency of the detection system. The quantities of theoretical interest which replace the integrated intensity of absorption spectroscopy are the rate constant for spontaneous emission and the related excited-state lifetime.

(A) EMISSION RATE CONSTANT

Einstein derived the relationship between spontaneous emission rate and the absorption intensity or stimulated emission rate in 1917 using a thermodynamic argument [13]. Both absorption intensity and emission rate depend on the transition moment integral of equation (B1.1.1), so that gives us a way to relate them. The symbol A is often used for the rate constant for emission; it is sometimes called the Einstein A coefficient. For emission in the gas phase from a state i to a lower state j we can write

$$A_{i \rightarrow j} = \frac{16\pi^3}{3h\epsilon_0} \tilde{\nu}_{i \rightarrow j}^3 |\mu_{ij}|^2 = (7.235 \times 10^{10} \text{ cm s}^{-1}) \frac{\tilde{\nu}_{i \rightarrow j}^3}{e^2} |\mu_{ij}|^2. \quad (\text{B1.1.12})$$

(B) MOLECULAR EMISSION AND THE FRANCK—CONDON PRINCIPLE

For molecules we can use Born–Oppenheimer wavefunctions and talk about emission from one vibronic level to another. Equation (B1.1.5), equation (b1.1.6) and equation (b1.1.7) can be used just as they were for absorption. If we have an emission from vibronic state ub to the lower state la , the rate constant for emission would be given by

$$A_{ub \rightarrow la} = \frac{16\pi^3}{3h\epsilon_0} \tilde{\nu}_{ub \rightarrow la}^3 \left| \int \phi_{ub}^*(Q) \mu_{ul}(Q) \phi_{la}(Q) dQ \right|^2. \quad (\text{B1.1.13})$$

If we can use only the zero-order term in equation (B1.1.7) we can remove the transition moment from the integral and recover an equation involving a Franck–Condon factor:

$$A_{ub \rightarrow la} = \frac{16\pi^3}{3h\epsilon_0} |\mu_{ul}(0)|^2 \tilde{\nu}_{ub \rightarrow la}^3 \left| \int \phi_{ub}^*(Q) \phi_{la}(Q) dQ \right|^2. \quad (\text{B1.1.14})$$

Now the spectrum will show various transitions originating with state ub and ending on the various vibrational levels la of the lower electronic state. Equation (B1.1.14) (or B1.1.13) if we have to worry about variation of transition

moment) gives us a way of comparing the intensities of the bands. The intensities will be proportional to the $A_{ub \rightarrow \lambda, \alpha}$ provided that we measure the intensity in photons per unit time rather than the more conventional

units of energy per unit time. The first part of the expression in (B1.1.14) is the same for all the transitions. The part that varies between bands is the Franck–Condon factor multiplied by the cube of the frequency. Equation (B1.1.8) for absorption intensity also had a frequency factor, but the variation in frequency has more effect in emission spectroscopy because it appears to a higher power. Equation (B1.1.14) embodies the Franck–Condon principle for emission spectroscopy.

(C) EXCITED-STATE LIFETIME

We now discuss the lifetime of an excited electronic state of a molecule. To simplify the discussion we will consider a molecule in a high-pressure gas or in solution where vibrational relaxation occurs rapidly, we will assume that the molecule is in the lowest vibrational level of the upper electronic state, level u_0 , and we will further assume that we need only consider the zero-order term of equation (B1.1.7). A number of radiative transitions are possible, ending on the various vibrational levels l of the lower state, usually the ground state. The total rate constant for radiative decay, which we will call $A_{u_0 \rightarrow \lambda}$, is the sum of the rate constants, $A_{u_0 \rightarrow \lambda \alpha}$. By summing the terms in equation (B1.1.14) we can get an expression relating the radiative lifetime to the theoretical transition moment μ_{ul} . Further, by relating the transition moment to integrated absorption intensity we can get an expression for radiative rate constant involving only experimental quantities and not dependent on the quality of the electronic wavefunctions:

$$\begin{aligned} A_{u_0 \rightarrow l} &= \frac{16\pi^3 n^2}{3h\epsilon_0} \langle \tilde{\nu}_f^{-3} \rangle_{Av}^{-1} \frac{g_l}{g_u} |\mu_{ul}(0)|^2 \\ &= (7.235 \times 10^{10} \text{ cm s}^{-1}) n^2 \frac{g_l \langle \tilde{\nu}_f^{-3} \rangle_{Av}^{-1}}{g_u e^2} |\mu_{ul}(0)|^2 \end{aligned} \quad (\text{B1.1.15})$$

or

$$\begin{aligned} A_{u_0 \rightarrow l} &= \frac{8\pi c n^2 \ln 10}{N_A} \langle \tilde{\nu}_f^{-3} \rangle_{Av}^{-1} \frac{g_l}{g_u} \int \epsilon \, d \ln \tilde{\nu} \\ &= (2.881 \times 10^{-9} \text{ s}^{-1} \text{ l}^{-1} \text{ mol cm}^4) \langle \tilde{\nu}_f^{-3} \rangle_{Av}^{-1} n^2 \frac{g_l}{g_u} \int \epsilon \, d \ln \tilde{\nu}. \end{aligned} \quad (\text{B1.1.16})$$

These equations contain the peculiar average fluorescence frequency $\langle \tilde{\nu}_f^{-3} \rangle_{Av}^{-1}$, the reciprocal of the average value of $\tilde{\nu}^{-3}$ in the fluorescence spectrum. It arises because the fluorescence intensity measured in photons per unit time has a ν^3 dependence. For completeness we have added a term n^2 , the square of the refractive index, to be used for molecules in solution, and the term g_l / g_u , the ratio of the degeneracies of the lower and upper electronic states, to allow for degenerate cases [14]. It is also possible to correct for a variation of transition moment with nuclear configuration if that should be necessary [15].

$A_{u_0 \rightarrow \lambda}$ is the first-order rate constant for radiative decay by the molecule. It is the reciprocal of the intrinsic mean life of the excited state, τ_0 :

-16-

$$1/\tau_0 = A_{u_0 \rightarrow l}.$$

If there are no competing processes the experimental lifetime τ should equal τ_0 . Most commonly, other processes such as non-radiative decay to lower electronic states, quenching, photochemical reactions or

energy transfer may compete with fluorescence. They will reduce the actual lifetime. As long as all the processes are first-order in the concentration of excited molecules, the decay will remain exponential and the mean life τ will be reduced by a factor of the fluorescence quantum yield, Φ_f , the fraction of the excited molecules which emit:

$$\tau = \Phi_f \tau_0. \quad (\text{B1.1.17})$$

B1.1.3.3 SELECTION RULES

Transition intensities are determined by the wavefunctions of the initial and final states as described in the last sections. In many systems there are some pairs of states for which the transition moment integral vanishes while for other pairs it does not vanish. The term ‘selection rule’ refers to a summary of the conditions for non-vanishing transition moment integrals—hence observable transitions—or vanishing integrals so no observable transitions. We discuss some of these rules briefly in this section. Again, we concentrate on electric dipole transitions.

(A) ATOMS

The simplest case arises when the electronic motion can be considered in terms of just one electron: for example, in hydrogen or alkali metal atoms. That electron will have various values of orbital angular momentum described by a quantum number l . It also has a spin angular momentum described by a spin quantum number s of $\frac{1}{2}$, and a total angular momentum which is the vector sum of orbital and spin parts with quantum number j . In the presence of a magnetic field the component of the angular momentum in the field direction becomes important and is described by a quantum number m . The selection rules can be summarized as

$$\Delta l = \pm 1 \quad \Delta j = 0, \pm 1 \quad \Delta m = 0, \pm 1.$$

This means that one can see the electron undergo transitions from an s orbital to a p orbital, from a p orbital to s or d, from a d orbital to p or f, etc, but not s to s, p to p, s to d, or such. In terms of state designations, one can have transitions from $^2S_{1/2}$ to $^2P_{1/2}$ or to $^2P_{3/2}$, etc.

In more complex atoms there may be a strong coupling between the motion of different electrons. The states are usually described in terms of the total orbital angular momentum L and the total spin angular momentum S . These are coupled to each other by an interaction called spin-orbital coupling, which is quite weak in light atoms but gets rapidly stronger as the nuclear charge increases. The resultant angular momentum is given the symbol J . States are named using capital letters **S**, **P**, **D**, **F**, **G**, . . . to designate L values of 0, 1, 2, 3, 4, A left superscript gives the multiplicity ($2S + 1$), and a right subscript gives the value of J , for example 1S_0 , 3P_1 or $^2D_{5/2}$.

-17-

There is a strict selection rule for J :

$$\Delta J = 0, \pm 1 \quad \text{with the restriction that } J = 0 \text{ to } J = 0 \text{ is forbidden.}$$

There are approximate selection rules for L and S , namely

$$\Delta L = 0, \pm 1 \quad \text{and} \quad \Delta S = 0.$$

These hold quite well for light atoms but become less dependable with greater nuclear charge. The term ‘intercombination bands’ is used for spectra where the spin quantum number S changes: for example, singlet–triplet transitions. They are very weak in light atoms but quite easily observed in heavy ones.

(B) ELECTRONIC SELECTION RULES FOR MOLECULES

Atoms have complete spherical symmetry, and the angular momentum states can be considered as different symmetry classes of that spherical symmetry. The nuclear framework of a molecule has a much lower symmetry. Symmetry operations for the molecule are transformations such as rotations about an axis, reflection in a plane, or inversion through a point at the centre of the molecule, which leave the molecule in an equivalent configuration. Every molecule has one such operation, the identity operation, which just leaves the molecule alone. Many molecules have one or more additional operations. The set of operations for a molecule form a mathematical group, and the methods of group theory provide a way to classify electronic and vibrational states according to whatever symmetry does exist. That classification leads to selection rules for transitions between those states. A complete discussion of the methods is beyond the scope of this chapter, but we will consider a few illustrative examples. Additional details will also be found in [section A1.4](#) on molecular symmetry.

In the case of linear molecules there is still complete rotational symmetry about the internuclear axis. This leads to the conservation and quantization of the component of angular momentum in that direction. The quantum number for the component of orbital angular momentum along the axis (the analogue of L for an atom) is called Λ . States which have $\Lambda = 0, 1, 2, \dots$ are called $\Sigma, \Pi, \Delta, \dots$ (analogous to S, P, D, \dots of atoms). Σ states are non-degenerate while Π, Δ , and higher angular momentum states are always doubly degenerate because the angular momentum can be in either direction about the axis. Σ states need an additional symmetry designation. They are called Σ^+ or Σ^- according to whether the electronic wavefunction is symmetric or antisymmetric to the symmetry operation of a reflection in a plane containing the internuclear axis. If the molecule has a centre of symmetry like N_2 or CO_2 , there is an additional symmetry classification, g or u, depending on whether the wavefunction is symmetric or antisymmetric with respect to inversion through that centre. Symmetries of states are designated by symbols such as Π_g, Π_u, Σ_g^+ , etc. Finally, the electronic wavefunctions will have a spin multiplicity ($2S + 1$), referred to as singlet, doublet, triplet, etc. The conventional nomenclature for electronic states is as follows. The state is designated by its symmetry with a left superscript giving its multiplicity. An uppercase letter is placed before the symmetry symbol to indicate where it stands in order of energy: the ground state is designated X, higher states of the same multiplicity are designated A, B, C, \dots in order of increasing energy, and states of different multiplicity are designated a, b, c, \dots in order of increasing energy. (Sometimes, after a classification of states as A, B, C, etc has become well established, new states will be discovered lying between, say, the B and C states. Then the new states may be designated B', B'' and so on rather

-18-

than renaming all the states.) For example, the C_2 molecule has a singlet ground state designated as $X^1\Sigma_g^+$, a triplet state designated a $^3\Pi_u$ lying only 700 cm^{-1} above the ground state, another triplet 5700 cm^{-1} higher in energy designated $b^3\Sigma_g^-$, a singlet state designated A $^1\Pi_u$ lying 8400 cm^{-1} above the ground state and many other known states [16]. A transition between the ground state and the A state would be designated as $A^1\Pi_u-X^1\Sigma_g^+$. The convention is to list the upper state first regardless of whether the transition is being studied in absorption or emission.

The electronic selection rules for linear molecules are as follows. $\Delta\Lambda = 0, \pm 1$. $\Delta S = 0$. Again, these are really

valid only in the absence of spin-orbital coupling and are modified in heavy molecules. For transitions between Σ states there is an additional rule that Σ^+ combines only with Σ^+ and Σ^- combines only with Σ^- , so that transitions between Σ^+ states and Σ^- states are forbidden. If the molecule has a centre of symmetry then there is an additional rule requiring that $g \leftrightarrow u$, while transitions between two g states or between two u states are forbidden.

We now turn to electronic selection rules for symmetrical nonlinear molecules. The procedure here is to examine the structure of a molecule to determine what symmetry operations exist which will leave the molecular framework in an equivalent configuration. Then one looks at the various possible point groups to see what group would consist of those particular operations. The character table for that group will then permit one to classify electronic states by symmetry and to work out the selection rules. Character tables for all relevant groups can be found in many books on spectroscopy or group theory. Here we will only pick one very simple point group called C_{2v} and look at some simple examples to illustrate the method.

The C_{2v} group consists of four symmetry operations: an identity operation designated E , a rotation by one-half of a full rotation, i.e. by 180° , called a C_2 operation and two planes of reflection passing through the C_2 axis and called σ_v operations. Examples of molecules belonging to this point group are water, H_2O ; formaldehyde, H_2CO ; or pyridine, C_5H_5N . It is conventional to choose a molecule-fixed axis system with the z axis coinciding with the C_2 axis. If the molecule is planar, it is conventionally chosen to lie in the yz plane with the x axis perpendicular to the plane of the molecule [17]. For example, in H_2CO the C_2 or z axis lies along the C–O bond. One of the σ_v planes would be the plane of the molecule, the yz plane. The other reflection plane is the xz plane, perpendicular to the molecular plane.

Table B1.1.1 gives the character table for the C_{2v} point group as it is usually used in spectroscopy. Because each symmetry operation leaves the molecular framework and hence the potential energy unchanged, it should not change the electron density or nuclear position density: i.e. the square of an electronic or vibrational wavefunction should remain unchanged. In a group with no degeneracies like this one, that means that a wavefunction itself should either be unchanged or should change sign under each of the four symmetry operations. The result of group theory applied to such functions is that there are only four possibilities for how they change under the operations, and they correspond to the four irreducible representations designated as A_1 , A_2 , B_1 and B_2 . The characters may be taken to describe what happens in each symmetry. For example, a function classified as B_1 would be unchanged by the identity operation or by $\sigma_v(xz)$ but would be changed in sign by the C_2 or $\sigma_v(yz)$ operations. Every molecular orbital and every stationary state described by a many-electron wavefunction can be taken to belong to one of these symmetry classes. The same applies to vibrations and vibrational states.

-19-

Table B1.1.1 Character table for the C_{2v} point group.

C_{2v}	E	C_2	$\sigma_v(xz)$	$\sigma_v(yz)$		
A_1	1	1	1	1	z	x^2, y^2, z^2
A_2	1	1	-1	-1	R_z	xy
B_1	1	-1	1	-1	x, R_y	xz
B_2	1	-1	-1	1	y, R_x	yz

The last two columns of the character table give the transformation properties of translations along the x , y ,

and z directions, rotations about the three axes represented by R_x , etc, and products of two coordinates or two translations represented by x^2 , xy , etc. The information in these columns is very useful for working out selection rules.

Whenever a function can be written as a product of two or more functions, each of which belongs to one of the symmetry classes, the symmetry of the product function is the direct product of the symmetries of its constituents. This direct product is obtained in non-degenerate cases by taking the product of the characters for each symmetry operation. For example, the function xy will have a symmetry given by the direct product of the symmetries of x and of y ; this direct product is obtained by taking the product of the characters for each symmetry operation. In this example it may be seen that, for each operation, the product of the characters for B_1 and B_2 irreducible representations gives the character of the A_2 representation, so xy transforms as A_2 .

The applications to selection rules work as follows. Intensities depend on the values of the transition moment integral of equation (B1.1.1):

$$\mu_{ij} = \int \Psi_i^* \mu \Psi_j \, d\tau.$$

An integral like this must vanish by symmetry if the integrand is antisymmetric under any symmetry operation, i.e. it vanishes unless the integrand is totally symmetric. For C_{2v} molecules that means the integrand must have symmetry A_1 . The symmetry of the integrand is the direct product of the symmetries of the three components in the integral. The transition moment operator is a vector with three components, μ_x , μ_y and μ_z , which transform like x , y and z , respectively. To see if a transition between state i and state j is allowed, one determines the symmetries of the three products containing the three components of μ , i.e. $\Psi_i^* \mu_x \Psi_j$ and $\Psi_i^* \mu_z \Psi_j$. If any one of them is totally symmetrical, the transition is formally allowed. If none of the three is totally symmetrical the transition is forbidden. It should be noted that being allowed does not mean that a transition will be strong. The actual intensity depends on the matrix element μ_{ij} , whose value will depend on the details of the wavefunctions.

-20-

There is a further item of information in this procedure. If one of the three component integrals is non-zero, the molecule will absorb light polarized along the corresponding axis. For example, if $\mu_{y,ij} = \int \Psi_i^* \mu_y \Psi_j \, d\tau$ is non-zero, the transition will absorb light polarized along the y axis. One may be able to observe this polarization directly in the spectrum of a crystal containing the molecules in known orientations. Alternatively, in the gas phase one may be able to tell the direction of polarization in the molecular framework by looking at the intensity distribution among the rotational lines in a high-resolution spectrum.

Analogous considerations can be used for magnetic dipole and electric quadrupole selection rules. The magnetic dipole operator is a vector with three components that transform like R_x , R_y and R_z . The electric quadrupole operator is a tensor with components that transform like x^2 , y^2 , z^2 , xy , yz and xz . These latter symmetries are also used to get selection rules for Raman spectroscopy. Character tables for spectroscopic use usually show these symmetries to facilitate such calculations.

When spectroscopists speak of electronic selection rules, they generally mean consideration of the integral over only the electronic coordinates for wavefunctions calculated at the equilibrium nuclear configuration of the initial state, $Q = 0$,

$$\mu_{lu}(0) = \int \psi_l^*(x, 0) \mu \psi_u(x, 0) \, dx. \quad (\text{B1.1.18})$$

If one of the components of this electronic transition moment is non-zero, the electronic transition is said to be allowed; if all components are zero it is said to be forbidden. In the case of diatomic molecules, if the transition is forbidden it is usually not observed unless as a very weak band occurring by magnetic dipole or electric quadrupole interactions. In polyatomic molecules forbidden electronic transitions are still often observed, but they are usually weak in comparison with allowed transitions.

The reason they appear is that symmetric polyatomic molecules always have some non-totally-symmetric vibrations. When the nuclear framework is displaced from the equilibrium position along such a vibrational coordinate, its symmetry is reduced. It can then be thought of as belonging, for the instant, to a different point group of lower symmetry, and it is likely in that group that the transition will be formally allowed. Even though $\mu_{lu}(0)$ from equation (B1.1.18) is zero, $\mu_{lu}(Q)$ from equation (B1.1.5) will be non-zero for some configurations Q involving distortion along antisymmetric normal coordinates. The total integrated intensity of an electronic band is given by (b1.1.10). It involves the square of the electronic transition moment averaged over the initial vibrational state, including the configurations in which the transition moment is not zero. In suitable cases it may be possible to calculate the first-order terms of equation (B1.1.7) from electronic wavefunctions and use them in equation (B1.1.5) to calculate an integrated absorption intensity to compare with the observed integrated intensity or oscillator strength [18].

The spin selection rule for polyatomic molecules is again $\Delta S = 0$, no change in spin in the absence of spin-orbital coupling. This rule becomes less valid when heavy atoms are included in the molecule. Spin-changing transitions can be observed by suitable techniques even in hydrocarbons, but they are quite weak. When spin-orbital coupling is important it is possible to use the symmetries of the spin wavefunctions, assign symmetries to total orbital-plus-spin wavefunctions and use group theory as above to get the selection rules.

-21-

Most stable polyatomic molecules whose absorption intensities are easily studied have filled-shell, totally symmetric, singlet ground states. For absorption spectra starting from the ground state the electronic selection rules become simple: transitions are allowed to excited singlet states having symmetries the same as one of the coordinate axes, x , y or z . Other transitions should be relatively weak.

(C) VIBRONIC SELECTION RULES

Often it is possible to resolve vibrational structure of electronic transitions. In this section we will briefly review the symmetry selection rules and other factors controlling the intensity of individual vibronic bands.

In the Born–Oppenheimer approximation the vibronic wavefunction is a product of an electronic wavefunction and a vibrational wavefunction, and its symmetry is the direct product of the symmetries of the two components. We have just discussed the symmetries of the electronic states. We now consider the symmetry of a vibrational state. In the harmonic approximation vibrations are described as independent motions along normal modes Q_i and the total vibrational wavefunction is a product of functions, one wavefunction for each normal mode:

$$\phi(Q) = \varphi_{v_1}(Q_1)\varphi_{v_2}(Q_2)\varphi_{v_3}(Q_3)\dots \quad (\text{B1.1.19})$$

Each such normal mode can be assigned a symmetry in the point group of the molecule. The wavefunctions for non-degenerate modes have the following simple symmetry properties: the wavefunctions with an odd vibrational quantum number v_i have the same symmetry as their normal mode Q_i ; the ones with an even v_i are totally symmetric. The symmetry of the total vibrational wavefunction $\phi(Q)$ is then the direct product of the symmetries of its constituent normal coordinate functions $\varphi_{v_i}(Q_i)$. In particular, the lowest vibrational state,

with all $v_i = 0$, will be totally symmetric. The states with one quantum of excitation in one vibration and zero in all others will have the symmetry of that one vibration. Once the symmetry of the vibrational wavefunction has been established, the symmetry of the vibronic state is readily obtained from the direct product of the symmetries of the electronic state and the vibrational state. This procedure gives the correct vibronic symmetry even if the harmonic approximation or the Born–Oppenheimer approximation are not quite valid.

The selection rule for vibronic states is then straightforward. It is obtained by exactly the same procedure as described above for the electronic selection rules. In particular, the lowest vibrational level of the ground electronic state of most stable polyatomic molecules will be totally symmetric. Transitions originating in that vibronic level must go to an excited state vibronic level whose symmetry is the same as one of the coordinates, x , y , or z .

One of the consequences of this selection rule concerns forbidden electronic transitions. They cannot occur unless accompanied by a change in vibrational quantum number for some antisymmetric vibration. Forbidden electronic transitions are not observed in diatomic molecules (unless by magnetic dipole or other interactions) because their only vibration is totally symmetric; they have no antisymmetric vibrations to make the transitions allowed.

The symmetry selection rules discussed above tell us whether a particular vibronic transition is allowed or forbidden, but they give no information about the intensity of allowed bands. That is determined by [equation \(B1.1.9\)](#) for absorption or [\(B1.1.13\)](#) for emission. That usually means by the Franck–Condon principle if only the zero-order term in [equation \(B1.1.7\)](#) is needed. So we take note of some general principles for Franck–Condon factors (FCFs).

-22-

Usually the normal coordinates of the upper and lower states are quite similar. (When they are not it is called a Duschinsky effect [19] and the treatment becomes more complicated.) Because of the product form of the vibrational wavefunctions of [equation \(B1.1.19\)](#) the FCF is itself a product of FCFs for individual normal modes. If there is little or no change in the geometry of a given normal mode, the FCF for that mode will be large only if its vibrational quantum number does not change. But for modes for which there is a significant change in geometry, the FCFs may be large for a number of vibrational levels in the final state. The spectrum then shows a series of vibronic peaks differing in energy by the frequency of that vibration. Such a series is referred to as a progression in that mode.

Most commonly, the symmetry point group of the lower and upper states will be the same. Then only totally symmetric vibrations can change equilibrium positions—a change in a non-totally-symmetric mode would mean that the states have configurations belonging to different point groups. So one may expect to see progressions in one or more of the totally symmetric vibrations but not in antisymmetric vibrations. In symmetry-forbidden electronic transitions, however, one will see changes of one quantum (or possibly other odd numbers of quanta) in antisymmetric vibrations as required to let the transition appear.

An example of a single-absorption spectrum illustrating many of the effects discussed in this section is the spectrum of formaldehyde, H_2CO , shown in figure B1.1.2 [20]. This shows the region of the lowest singlet–singlet transition, the $A^1A_2-X^1A_1$ transition. This is called an $n \rightarrow \pi^*$ transition; the electronic change is the promotion of an electron from a non-bonding orbital (symmetry B_2) mostly localized on the oxygen atom into an antibonding π^* orbital (symmetry B_1) on the C–O bond. By the electronic selection rules, a transition from the totally symmetric ground state to a 1A_2 state is symmetry forbidden, so the transition is quite weak with an oscillator strength of 2.4×10^{-4} . The transition is appearing with easily measured intensity due to coupling with antisymmetric vibrations. Most of the intensity is induced by distortion along the out-of-plane coordinate, Q_4 . This means that in [equation \(B1.1.7\)](#) the most significant derivative of μ_{lu} is the one with respect to Q_4 . The first peak seen in figure B1.1.2, at 335 nm, has one quantum of vibration v_4 excited in the upperstate. The band is designated as which means that vibration number 4 has 1 quantum of excitation in the

upper state and 0 quanta in the lower state. The symmetry of Q_4 is B_1 , and combined with the A_2 symmetry of the electronic state it gives an upper state of vibronic symmetry B_2 , the direct product $A_2 \times B_1$. It absorbs light with its electric vector polarized in the y direction, i.e. in plane and perpendicular to the C–O bond.

Figure B1.1.2. Spectrum of formaldehyde with vibrational resolution. Several vibronic origins are marked. One progression in ν_2 starting from the origin is indicated on the line along the top. A similar progression is built on each vibronic origin. Reprinted with permission from [20]. Copyright 1982, American Chemical Society.

-23-

If the 0–0 band were observable in this spectrum it would be called the origin of the transition. The 4_0^1 band is referred to as a vibronic origin. Starting from it there is a progression in ν_2 , the C–O stretching mode, which gets significantly longer in the upper state because the presence of the antibonding π electron weakens the bond. Several of the peaks in the progression are marked along the line at the top of the figure.

Several other vibronic origins are also marked in this spectrum. The second major peak is the 4_0^3 band, with three quanta of ν_4 in the upper state. This upper state has the same symmetry as the state with one quantum. Normally, one would not expect much intensity in this peak, but it is quite strong because the excited state actually has a non-planar equilibrium geometry, i.e. it is distorted along Q_4 . Every vibronic origin including this one has a progression in ν_2 built on it. The intensity distribution in a progression is determined by the Franck–Condon principle and, as far as can be determined, all progressions in this spectrum are the same.

At 321 nm there is a vibronic origin marked 5_0^1 . This has one quantum of ν_5 , the antisymmetric C–H stretching mode, in the upper state. Its intensity is induced by a distortion along Q_5 . This state has B_2 vibrational symmetry. The direct product of B_2 and A_2 is B_1 , so it has B_1 vibronic symmetry and absorbs x-polarized light. One can also see a $4_0^2 6_0^1$ vibronic origin which has the same symmetry and intensity induced by distortion along Q_6 .

A very weak peak at 348 nm is the 4_0^2 origin. Since the upper state here has two quanta of ν_4 , its vibrational symmetry is A_1 and the vibronic symmetry is A_2 , so it is forbidden by electric dipole selection rules. It is actually observed here due to a magnetic dipole transition [21]. By magnetic dipole selection rules the 1A_2 – 1A_1 electronic transition is allowed for light with its magnetic field polarized in the z direction. It is seen here as having about 1% of the intensity of the symmetry-forbidden electric dipole transition made allowed by vibronic coupling, or an oscillator strength around 10^{-6} . This illustrates the weakness of magnetic dipole transitions.

(D) ROTATIONAL SELECTION RULES

If the experimental technique has sufficient resolution, and if the molecule is fairly light, the vibronic bands discussed above will be found to have a fine structure due to transitions among rotational levels in the two states. Even when the individual rotational lines cannot be resolved, the overall shape of the vibronic band will be related to the rotational structure and its analysis may help in identifying the vibronic symmetry. The analysis of the band appearance depends on calculation of the rotational energy levels and on the selection rules and relative intensity of different rotational transitions. These both come from the form of the rotational wavefunctions and are treated by angular momentum theory. It is not possible to do more than mention a simple example here.

The simplest case is a ${}^1\Sigma\text{--}{}^1\Sigma$ transition in a linear molecule. In this case there is no orbital or spin angular momentum. The total angular momentum, represented by the quantum number J , is entirely rotational angular momentum. The rotational energy levels of each state approximately fit a simple formula:

$$E_J = BJ(J + 1) - DJ^2(J + 1)^2.$$

The second term is used to allow for centrifugal stretching and is usually small but is needed for accurate work. The quantity B is called the rotation constant for the state. In a rigid rotator picture it would have the value

-24-

and is usually quoted in reciprocal centimetres. I is the moment of inertia. In an actual molecule which is vibrating, the formula for B must be averaged over the vibrational state, i.e. one must use an average value of $1/I$. As a result B varies somewhat with vibrational level. The values of B and the moments of inertia obtained from the spectra are used to get structural information about the molecule. The bonding and hence the structure will be different in the two states, so the B values will generally differ significantly. They are called B' and B'' . The convention is to designate quantities for the upper state with a single prime and quantities for the lower state with a double prime.

The rotational selection rule for a ${}^1\Sigma\text{--}{}^1\Sigma$ transition is $\Delta J = \pm 1$. Lines which have $J' = J'' - 1$ are called P lines and the set of them is called the P branch of the band. Lines for which $J' = J'' + 1$ are called R lines and the set of them the R branch. (Although not seen in a ${}^1\Sigma\text{--}{}^1\Sigma$ transition, a branch with $J' = J''$ would be called a Q branch, one with $J' = J'' - 2$ would be an O branch, or one with $J' = J'' + 2$ would be an S branch, etc.) Individual lines may be labeled by giving J'' in parentheses like R(1), P(2), etc. For lines with low values of J , the R lines get higher in energy as J increases while the P lines get lower in energy with increasing J . If B'' and B' are sufficiently different, which is the usual case in electronic spectra, the lines in one of the two branches will get closer together as J increases until they pile up on top of each other and then turn around and start to move in the other direction as J continues to increase. The point at which the lines pile up is called a band head. It is often the most prominent feature of the band. If $B'' > B'$, this will happen in the R branch and the band head will mark the high-energy or short-wavelength limit of each vibronic band. Such a band is said to be shaded to the red because absorption or emission intensity has a sharp onset on the high-energy side and then falls off gradually on the low-energy or red side. This is the most common situation where the lower state is bound more tightly and has a smaller moment of inertia than the upper state. But the opposite can occur as well. If $B'' < B'$ the band head will be formed in the P branch on the low-energy side of the vibronic band, and the band will be said to be shaded to the violet or shaded to the blue. Note that the terms red for the low-energy direction and violet or blue for the high-energy direction are used even for spectra in the ultraviolet or infrared regions where the actual visible red and blue colours would both be in the same direction.

The analysis of rotational structure and selection rules for transitions involving Π or Δ states becomes considerably more complicated. In general, Q branches will be allowed as well as P and R branches. The coupling between different types of angular momenta—orbital angular momentum of the electrons, spin angular momentum for states of higher multiplicity, the rotational angular momentum and even nuclear spin terms—is a complex subject which cannot be covered here: the reader is referred to the more specialized literature.

B1.1.3.4 PERTURBATIONS

Spectroscopists working with high-resolution spectra of small molecules commonly fit series of rotational lines to formulae involving the rotational constants, angular momentum coupling terms, etc. However, occasionally they find that some lines in the spectrum are displaced from their expected positions in a systematic way. Of course, a displacement of a line from its expected position means that the energy levels of one of the states are displaced from their expected energies. Typically, as J increases some lines will be seen to be displaced in one direction by increasing amounts up to a maximum at some particular J , then for the next J the line will be displaced in the opposite direction, and then as J increases further the lines will gradually approach their expected positions. These displacements of lines and of state energies are called perturbations [22].

-25-

They are caused by interactions between states, usually between two different electronic states. One hard and fast selection rule for perturbations is that, because angular momentum must be conserved, the two interacting states must have the same J . The interaction between two states may be treated by second-order perturbation theory which says that the displacement of a state is given by

$$\Delta E_1 = \frac{|H'_{12}|^2}{E_1^0 - E_2^0}$$

where H'_{12} is the matrix element between the two states of some small term H' in the Hamiltonian which is unimportant in determining the expected energies of the states. This interaction always has the effect of pushing the two states apart in energy by equal and opposite displacements inversely proportional to the zero-order separation of the two states. The perturbation is observed when the vibronic level of the state with the larger B value lies slightly lower in energy than a vibronic level of the other state. Then with increasing J the energy of the rotating level of the first state gets closer and closer to the energy of the second state and finally passes it and then gets farther away again. The maximum displacements occur at the J values where the two energies are the closest.

The spectral perturbations are observed in a transition involving one of the interacting states. Sometimes it is possible also to see an electronic transition involving the other of the interacting states, and then one should see equal but opposite displacements of rotational levels with the same J .

An interesting example occurs in the spectrum of the C_2 molecule. The usual rule of absorption spectroscopy is that the transitions originate in the ground electronic state because only it has sufficient population. However, in C_2 transitions were observed starting both from a $^3\Pi_u$ state and from a $^1\Sigma_g^+$ state, so it was not clear which was the ground state. The puzzle was solved by Ballik and Ramsay [23] who observed perturbations in a $^3\Sigma_g^- - ^3\Pi_u$ transition due to displacements of levels in the $^3\Sigma_g^-$ state. They then reinvestigated a $^1\Pi_u - ^1\Sigma_g^+$ transition known as the Phillips system, and they observed equal and opposite displacements of levels in the $^1\Sigma_g^+$ state, thus establishing that the $^1\Sigma_g^+$ and $^3\Sigma_g^-$ states were perturbing each other. For example, in the $\nu = 4$ vibrational level of the $^1\Sigma_g^+$ state, the $J = 40$ rotational level was displaced to lower energy by 0.26 cm^{-1} ; correspondingly, in the $\nu = 1$ vibrational level of the $^3\Sigma_g^-$ state, the $J = 40$ level was displaced upwards by 0.25 cm^{-1} . The values have an uncertainty of 0.02 cm^{-1} , so the displacements of the levels with the same J are equal and opposite within experimental error. Similarly, the $J = 42$ level in the $^1\Sigma_g^+$ state was displaced upwards by 0.17 cm^{-1} and the $J = 42$ level of the $^3\Sigma_g^-$ state displaced downwards by 0.15 cm^{-1} . These observations established that these particular levels were very close to each other in energy and the authors

were able to prove that the ${}^1\Sigma_g^+$ was lower by about 600 cm^{-1} than the ${}^3\Pi_u$ state and was the ground state. Absorption spectra of C_2 are typically observed in the vapour over graphite at high temperatures. At 2500 K the value of kT is about 1700 cm^{-1} , much greater than the energy separation of the two states. Since the ${}^1\Sigma_g^+$ state is non-degenerate and the ${}^3\Pi_u$ state has a sixfold degeneracy, most of the molecules are actually in the upper state. This accounts for the observation of absorptions starting from both states.

The perturbations in this case are between a singlet and a triplet state. The perturbation Hamiltonian, H' , of the second-order perturbation theory is spin-orbital coupling, which has the effect of mixing singlet and triplet states.

-26-

The magnitude of the perturbations can be calculated fairly quantitatively from high-quality electronic wavefunctions including configuration interaction [24].

B1.1.4 EXAMPLES

B1.1.4.1 PHOTOPHYSICS OF MOLECULES IN SOLUTION

To understand emission spectroscopy of molecules and/or their photochemistry it is essential to have a picture of the radiative and non-radiative processes among the electronic states. Most stable molecules other than transition metal complexes have all their electrons paired in the ground electronic state, making it a singlet state. Figure B1.1.3 gives a simple state energy diagram for reference. Singlet states are designated by the letter S and numbered in order of increasing energy. The ground state is called S_0 . Excited singlet states have configurations in which an electron has been promoted from one of the filled orbitals to one of the empty orbitals of the molecule. Such configurations with two singly occupied molecular orbitals will give rise to triplet states as well as singlet states. A triplet state results when one of the electrons changes its spin so that the two electrons have parallel spin. Each excited singlet state will have its corresponding triplet state. Because the electron-electron repulsion is less effective in the triplet state, it will normally be lower in energy than the corresponding singlet state.

Figure B1.1.3. State energy diagram for a typical organic molecule. Solid arrows show radiative transitions; A: absorption, F: fluorescence, P: phosphorescence. Dotted arrows: non-radiative transitions.

Spectroscopists observed that molecules dissolved in rigid matrices gave both short-lived and long-lived emissions which were called fluorescence and phosphorescence, respectively. In 1944, Lewis and Kasha [25] proposed that molecular phosphorescence came from a triplet state and was long-lived because of the well known spin selection rule $\Delta S = 0$, i.e. interactions with a light wave or with the surroundings do not readily change the spin of the electrons.

-27-

Typical singlet lifetimes are measured in nanoseconds while triplet lifetimes of organic molecules in rigid solutions are usually measured in milliseconds or even seconds. In liquid media where diffusion is rapid the triplet states are usually quenched, often by the nearly ubiquitous molecular oxygen. Because of that, phosphorescence is seldom observed in liquid solutions. In the spectroscopy of molecules the term fluorescence is now usually used to refer to emission from an excited singlet state and phosphorescence to emission from a triplet state, regardless of the actual lifetimes.

If a light beam is used to excite one of the higher singlet states, say S_2 , a very rapid relaxation occurs to S_1 , the lowest excited singlet state. This non-radiative process just converts the difference in energy into heat in the surroundings. A radiationless transition between states of the same multiplicity is called internal conversion. Relaxation between states of the same multiplicity and not too far apart in energy is usually much faster than radiative decay, so fluorescence is seen only from the S_1 state. These radiationless processes in large molecules are the analogue of the perturbations observed in small molecules. They are caused by small terms in the Hamiltonian such as spin-orbital coupling or Born-Oppenheimer breakdown, which mix electronic states. The density of vibrational levels of large molecules can be very high and that makes these interactions into irreversible transitions to lower states.

Once the excited molecule reaches the S_1 state it can decay by emitting fluorescence or it can undergo a further radiationless transition to a triplet state. A radiationless transition between states of different multiplicity is called intersystem crossing. This is a spin-forbidden process. It is not as fast as internal conversion and often has a rate comparable to the radiative rate, so some S_1 molecules fluoresce and others produce triplet states. There may also be further internal conversion from S_1 to the ground state, though it is not easy to determine the extent to which that occurs. Photochemical reactions or energy transfer may also occur from S_1 .

Molecules which reach a triplet state will generally relax quickly to state T_1 . From there they can emit phosphorescence or decay by intersystem crossing back to the ground state. Both processes are spin forbidden and again often have comparable rates. The T_1 state is often also important for photochemistry because its lifetime is relatively long. Both phosphorescence and intersystem crossing are dependent on spin-orbital coupling and are enhanced by heavy atoms bound to the molecule or in the environment. They are also enhanced by the presence of species with unpaired electrons such as O_2 because electron exchange can effect such transitions without actually requiring the spin of an electron to be reversed. O_2 is found to quench both fluorescence and phosphorescence, and it is often necessary to remove oxygen from solutions for precise emission measurements.

B1.1.4.2 WIDTHS AND SHAPES OF SPECTRAL LINES

High-resolution spectroscopy used to observe hyperfine structure in the spectra of atoms or rotational structure in electronic spectra of gaseous molecules commonly must contend with the widths of the spectral lines and how that compares with the separations between lines. Three contributions to the linewidth will be mentioned here: the natural line width due to the finite lifetime of the excited state, collisional broadening of lines, and the Doppler effect.

The most fundamental limitation on sharpness of spectral lines is the so-called natural linewidth. Because an

excited state has a finite lifetime, the intensity of light it emits falls off exponentially as a function of time. A beam of light whose intensity varies with time cannot have a single frequency. Its spectral distribution is the Fourier transform of its temporal shape. For an exponential decay the spectral distribution will have the form

-28-

$$I(\nu) = I(\nu_0) \frac{(1/4\pi\tau)^2}{(\nu - \nu_0)^2 + (1/4\pi\tau)^2} \quad (\text{B1.1.20})$$

where ν_0 is the frequency of the centre of the band and τ is the mean life of the excited state. The same formula applies to lines in the absorption spectrum. This shape is called a Lorentzian shape. Its full width at half maximum (FWHM) is $1/(2\pi\tau)$. The shorter the lifetime, the broader the line. Another way to think about the width is to say that the energy of a state has an uncertainty related to its lifetime by the uncertainty principle. If the transition is coupling two states, both of which have finite lifetimes and widths, it is necessary to combine the effects.

Spectral lines are further broadened by collisions. To a first approximation, collisions can be thought of as just reducing the lifetime of the excited state. For example, collisions of molecules will commonly change the rotational state. That will reduce the lifetime of a given state. Even if the state is not changed, the collision will cause a phase shift in the light wave being absorbed or emitted and that will have a similar effect. The line shapes of collisionally broadened lines are similar to the natural line shape of equation (B1.1.20) with a lifetime related to the mean time between collisions. The details will depend on the nature of the intermolecular forces. We will not pursue the subject further here.

A third source of spectral broadening is the Doppler effect. Molecules moving toward the observer will emit or absorb light of a slightly higher frequency than the frequency for a stationary molecule; those moving away will emit or absorb a slightly lower frequency. The magnitude of the effect depends on the speed of the molecules. To first order the frequency shift is given by

$$\Delta\nu = \nu_0(v_x/c)$$

where v_x is the component of velocity in the direction of the observer and c is the speed of light.

For a sample at thermal equilibrium there is a distribution of speeds which depends on the mass of the molecules and on the temperature according to the Boltzmann distribution. This results in a line shape of the form

$$I(\nu) = I(\nu_0) \exp\left[\frac{-Mc^2}{2\nu_0^2 RT}(\nu - \nu_0)^2\right]$$

where M is the atomic or molecular mass and R the gas constant. This is a Gaussian line shape with a width given by

$$\text{FWHM} = \frac{2\nu_0}{c} \left(\frac{2RT \ln 2}{M}\right)^{1/2}.$$

The actual line shape in a spectrum is a convolution of the natural Lorentzian shape with the Doppler shape. It must be calculated for a given case as there is no simple formula for it. It is quite typical in electronic

spectroscopy to have the FWHM determined mainly by the Doppler width. However, the two shapes are quite different and the Lorentzian shape

-29-

does not fall off as rapidly at large $(\nu - \nu_0)$. It is likely that the intensity in the wings of the line will be determined by the natural line shape.

Collisional broadening is reduced by the obvious remedy of working at low pressures. Of course, this reduces the absorption and may require long path lengths for absorption spectroscopy. Doppler widths can be reduced by cooling the sample. For many samples this is not practical because the molecules will have too low a vapour pressure. Molecular beam methods and the newer technique of jet spectroscopy can be very effective by restricting the motion of the molecules to be at right angles to the light beam. Some other techniques for sub-Doppler spectroscopy have also been demonstrated using counter-propagating laser beams to compensate for motion along the direction of the beam. The natural linewidth, however, always remains when the other sources of broadening are removed.

B1.1.4.3 RYDBERG SPECTRA

The energies of transitions of a hydrogen atom starting from the ground state fit exactly the equation

where R is the Rydberg constant, E_1 is the ionization energy of the atom (which in hydrogen is equal to the Rydberg constant) and n is the principal quantum number of the electron in the upper state. The spectrum shows a series of lines of increasing n which converge to a limit at the ionization energy.

Other atoms and molecules also show similar series of lines, often in the vacuum ultraviolet region, which fit approximately a similar formula:

Such a series of lines is called a Rydberg series [26]. These lines also converge to the ionization energy of the atom or molecule, and fitting the lines to this formula can give a very accurate value for the ionization energy. In the case of molecules there may be resolvable vibrational and rotational structure on the lines as well.

The excited states of a Rydberg series have an electron in an orbital of higher principal quantum number, n , in which it spends most of its time far from the molecular framework. The idea is that the electron then feels mainly a Coulomb field due to the positive ion remaining behind at the centre, so its behaviour is much like that of the electron in the hydrogen atom. The constant δ is called the quantum defect and is a measure of the extent to which the electron interacts with the molecular framework. It has less influence on the energy levels as n gets larger, i.e. as the electron gets farther from the central ion. The size of δ will also depend on the angular momentum of the electron. States of lower angular momentum have more probability of penetrating the charge cloud of the central ion and so may have larger values of δ . Actual energy levels of Rydberg atoms and molecules can be subject to theoretical calculations [27]. Sometimes the higher states have orbitals so large that other molecules may fall within their volume, causing interesting effects [28].

-30-

B1.1.4.4 MULTIPHOTON SPECTROSCOPY

All the previous discussion in this chapter has been concerned with absorption or emission of a single photon. However, it is possible for an atom or molecule to absorb two or more photons simultaneously from a light beam to produce an excited state whose energy is the sum of the energies of the photons absorbed. This can happen even when there is no intermediate stationary state of the system at the energy of one of the photons. The possibility was first demonstrated theoretically by Maria Göppert-Mayer in 1931 [29], but experimental observations had to await the development of the laser. Multiphoton spectroscopy is now a useful technique [30, 31].

The transition probability for absorption of two photons can be described in terms of a two-photon cross section δ by

$$-dI = \delta I^2 N dl$$

where I is a photon flux in photons $\text{cm}^{-2} \text{s}^{-1}$, N is the number of molecules per cubic centimetre, and l is distance through the sample. Measured values of δ are of the order of $10^{-50} \text{ cm}^4 \text{ s photon}^{-1} \text{ molecule}^{-1}$ [32]. For molecules exposed to the intensity of sunlight at the earth's surface this would suggest that the molecule might be excited once in the age of the universe. However, the probability is proportional to the square of the light intensity. For a molecule exposed to a pulsed laser focused to a small spot, the probability of being excited by one pulse may be easily observable by fluorescence excitation or multiphoton ionization techniques.

One very important aspect of two-photon absorption is that the selection rules for atoms or symmetrical molecules are different from one-photon selection rules. In particular, for molecules with a centre of symmetry, two-photon absorption is allowed only for $g \leftrightarrow g$ or $u \leftrightarrow u$ transitions, while one-photon absorption requires $g \leftrightarrow u$ transitions. Therefore, a whole different set of electronic states becomes allowed for two-photon spectroscopy. The group-theoretical selection rules for two-photon spectra are obtained from the symmetries of the x^2 , xy , etc. terms in the character table. This is completely analogous to the selection rules for Raman spectroscopy, a different two-photon process.

A good example is the spectrum of naphthalene. The two lowest excited states have B_{2u} and B_{1u} symmetries and are allowed for one-photon transitions. A weak transition to one of these is observable in the two-photon spectrum [33], presumably made allowed by vibronic effects. Much stronger two-photon transitions are observable at somewhat higher energies to a B_{3g} and an A_g state lying quite close to the energies predicted by theory many years earlier [34].

An interesting aspect of two-photon spectroscopy is that some polarization information is obtainable even for randomly oriented molecules in solution by studying the effect of the relative polarization of the two photons. This is readily done by comparing linearly and circularly polarized light. Transitions to A_g states will absorb linearly polarized light more strongly than circularly polarized light. The reverse is true of transitions to B_{1g} , B_{2g} , or B_{3g} states. The physical picture is that the first photon induces an oscillating u-type polarization of the molecule in one direction. To get to a totally symmetric A_g state the second photon must reverse that polarization, so is favoured for a photon of the same polarization. However, to get to, say, a B_{3g} state, the second photon needs to act at right angles to the first, and in circularly polarized light that perpendicular polarization is always strong. Figure B1.1.4 shows the two-photon fluorescence excitation spectrum of naphthalene in the region of the g states [35]. One peak shows stronger absorption for circularly polarized, one for linearly polarized light. That confirms the identification as B_{3g} and A_g states respectively.

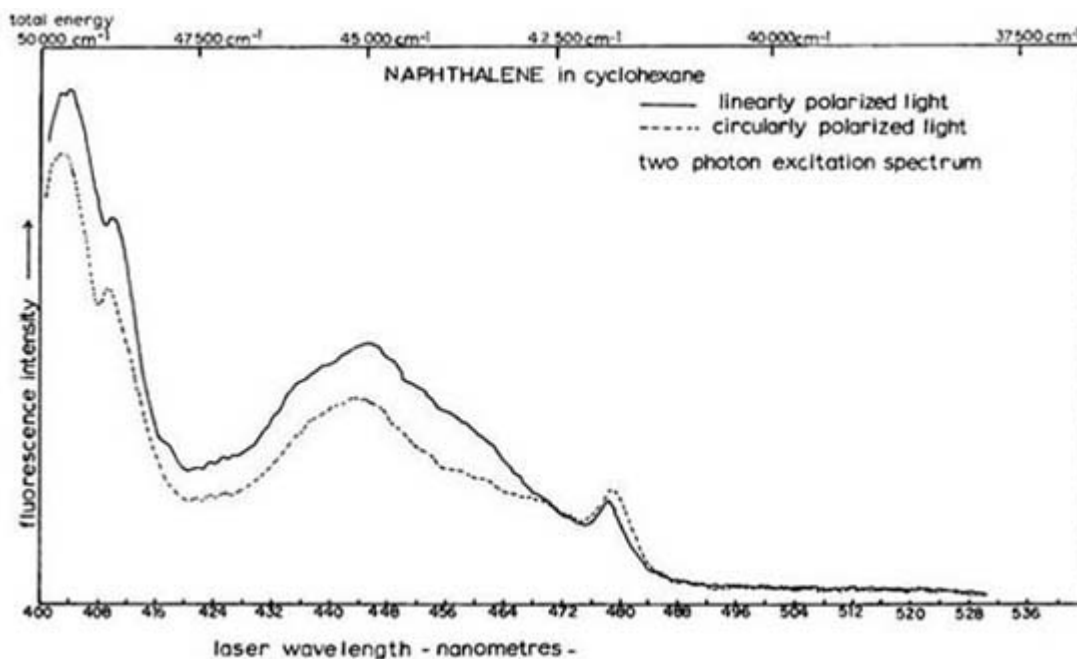

Figure B1.1.4. Two-photon fluorescence excitation spectrum of naphthalene. Reprinted from [35]. Courtesy, Tata McGraw-Hill Publishing Company Ltd, 7 West Patel Nagar, New Dehli, 110008, India.

Three-photon absorption has also been observed by multiphoton ionization, giving Rydberg states of atoms or molecules [36]. Such states usually require vacuum ultraviolet techniques for one-photon spectra, but can be done with a visible or near-ultraviolet laser by three-photon absorption.

B1.1.4.5 OTHER EXAMPLES

Many of the most interesting current developments in electronic spectroscopy are addressed in special chapters of their own in this encyclopedia. The reader is referred especially to [sections B2.1](#) on ultrafast spectroscopy, [C1.5](#) on single molecule spectroscopy, [C3.2](#) on electron transfer, and [C3.3](#) on energy transfer. Additional topics on electronic spectroscopy will also be found in many other chapters.

B1.2 Vibrational spectroscopy

Charles Schmittenmaer

B1.2.1 INTRODUCTION

B1.2.1.1 OVERVIEW

Vibrational spectroscopy provides detailed information on both structure and dynamics of molecular species. Infrared (IR) and Raman spectroscopy are the most commonly used methods, and will be covered in detail in this chapter. There exist other methods to obtain vibrational spectra, but those are somewhat more specialized and used less often. They are discussed in other chapters, and include: inelastic neutron scattering (INS), helium atom scattering, electron energy loss spectroscopy (EELS), photoelectron spectroscopy, among others.

Vibrational spectra span the frequency range 10–4000 cm⁻¹ (10 cm⁻¹ = 1.2 meV = 0.03 kcal mol⁻¹ = 0.11 kJ mol⁻¹, and 4000 cm⁻¹ = 496 meV = 10.3 kcal mol⁻¹ = 42.9 kJ mol⁻¹), depending on the strength of the bond

and the reduced mass of the vibrational mode. Very weakly bound species, such as clusters bound only by van der Waals forces, or condensed phase modes with very large effective reduced masses, such as intermolecular modes in liquids or solids, or large amplitude motions in proteins or polymers, have very low frequency vibrations of 10–100 cm^{-1} . Modes involving many atoms in moderately large molecules absorb in the range 300–1200 cm^{-1} . The region 600–1200 cm^{-1} is referred to as the fingerprint region because while many organic molecules will all have bands due to vibrations of C–H, C = O, O–H and so on, there will be low frequency bands unique to each molecule that involve complicated motions of many atoms. The region 1200–3500 cm^{-1} is where most functional groups are found to absorb. Thus, the presence or absence of absorption at a characteristic frequency helps to determine the identity of a compound. The frequency of the absorption can be justified in terms of the masses of the atoms participating, the type of motion involved (stretch versus bend) and the bond strengths. The H_2 molecule has a reasonably large force constant and the smallest reduced mass, which results in the highest vibrational frequency at 4400 cm^{-1} . The width and intensity of an absorption feature provide information in addition to the absorption frequency. In favourable cases in the gas phase the width is determined by the vibrational lifetime or even the lifetime of a molecule if the vibrational energy is greater than the bond strength. The intensity yields information on the nature of the vibrational motion, and can also be used to determine the temperature of the sample.

Infrared and Raman spectroscopy each probe vibrational motion, but respond to a different manifestation of it. Infrared spectroscopy is sensitive to a change in the dipole moment as a function of the vibrational motion, whereas Raman spectroscopy probes the change in polarizability as the molecule undergoes vibrations. Resonance Raman spectroscopy also couples to excited electronic states, and can yield further information regarding the identity of the vibration. Raman and IR spectroscopy are often complementary, both in the type of systems that can be studied, as well as the information obtained.

Vibrational spectroscopy is an enormously large subject area spanning many scientific disciplines. The methodology, both experimental and theoretical, was developed primarily by physical chemists and has branched far and wide over the last 50 years. This chapter will mainly focus on its importance with regard to physical chemistry.

-2-

B1.2.1.2 INFRARED SPECTROSCOPY

For many chemists, the most familiar IR spectrometer is the dual beam instrument that covers the region 900–3400 cm^{-1} ; it is used for routine analysis and compound identification. Typically, each of the functional groups of a molecule have unique frequencies, and different molecules have different combinations of functional groups. Thus, every molecule has a unique absorption spectrum. Of course, there can be situations where two molecules are similar enough that their spectra are indistinguishable on a system with moderate signal-to-noise ratio, or where there are strong background absorptions due to a solvent or matrix that obscures the molecular vibrations, so that it is not possible to distinguish all compounds under all circumstances; but it is usually quite reliable, particularly if one is comparing the spectrum of an unknown to reference spectra of a wide variety of compounds. Ease of implementation and reasonably unambiguous spectra have led to the widespread use of IR spectroscopy outside of physical chemistry.

Within physical chemistry, the long-lasting interest in IR spectroscopy lies in structural and dynamical characterization. High resolution vibration–rotation spectroscopy in the gas phase reveals bond lengths, bond angles, molecular symmetry and force constants. Time-resolved IR spectroscopy characterizes reaction kinetics, vibrational lifetimes and relaxation processes.

B1.2.1.3 RAMAN SPECTROSCOPY

Raman spectrometers are not as widespread as their IR counterparts. This is partially due to the more stringent

requirements on light source (laser) and monochromator. As is the case with IR spectroscopy, every molecule has a unique Raman spectrum. It is also true that there can be ambiguity because of molecular similarities or impurities in the sample. Resonance Raman spectroscopy allows interfering bands to be eliminated by selectively exciting only specific species by virtue of their electronic absorption, or coupling to a nearby chromophore. This is particularly helpful in discriminating against strong solvent bands. For example, the first excited electronic state of water is at about 7 eV (~175 nm excitation wavelength), whereas many larger molecules have electronic transitions at much lower photon energy. By using the resonant enhancement of the Raman signal from the excited electronic state, it is possible to obtain a factor of 10^6 enhancement of the dissolved molecule.

One of the well known advantages of resonance Raman spectroscopy is that samples dissolved in water can be studied since water is transparent in the visible region. Furthermore, many molecules of biophysical interest assume their native state in water. For this reason, resonance Raman spectroscopy has been particularly strongly embraced in the biophysical community.

B1.2.2 THEORY

B1.2.2.1 CLASSICAL DESCRIPTION

Both infrared and Raman spectroscopy provide information on the vibrational motion of molecules. The techniques employed differ, but the underlying molecular motion is the same. A qualitative description of IR and Raman spectroscopies is first presented. Then a slightly more rigorous development will be described. For both IR and Raman spectroscopy, the fundamental interaction is between a dipole moment and an electromagnetic field. Ultimately, the two

can only couple with each other if they have the same frequency, otherwise the time average of their interaction energy is zero.

The most important consideration for a vibration to be IR active is that its dipole moment *changes* upon vibration. That is to say, its dipole derivative must be nonzero. The time-dependence of the dipole moment for a heteronuclear diatomic is shown in figure B1.2.1. Classically, an oscillating dipole radiates energy at the oscillation frequency. In a sense, this is true for a vibrating molecule in that when it is in an excited vibrational state it can emit a photon and lose energy. However, there are two fundamental differences. First, it does not continuously radiate energy, as a classical oscillator would. Rather, it vibrates for long periods without radiating energy, and then there is an instantaneous jump to a lower energy level accompanied by the emission of a photon. It should be noted that vibrational lifetimes in the absence of external perturbations are quite long, on the millisecond timescale. The second difference from a classical oscillator is that when a molecule is in its ground vibrational state it cannot emit a photon, but is still oscillating. Thus, the dipole can oscillate for an indefinitely long period without radiating any energy. Therefore, a quantum mechanical description of vibration must be invoked to describe molecular vibrations at the most fundamental level.

Figure B1.2.1. Schematic representation of the dependence of the dipole moment on the vibrational coordinate for a heteronuclear diatomic molecule. It can couple with electromagnetic radiation of the same frequency as the vibration, but at other frequencies the interaction will average to zero.

The qualitative description of Raman scattering is closely related. In this case, the primary criterion for a Raman active mode is that the polarizability of the molecule changes as a function of vibrational coordinate. An atom or molecule placed in an electric field will acquire a dipole moment that is proportional to the size of the applied field and the ease at which the charge distribution redistributes, that is, the polarizability. If the polarizability changes as a function of vibration, then there will be an induced dipole whose magnitude changes as the molecule vibrates, as depicted in [figure B1.2.2](#) and this can couple to the EM field. Of course, the applied field is oscillatory, not static, but as we will see below there will still be scattered radiation that is related to the vibrational frequency. In fact, the frequency of the scattered light will be the sum and difference of the laser frequency and vibrational frequency.

-4-

Figure B1.2.2. Schematic representation of the polarizability of a diatomic molecule as a function of vibrational coordinate. Because the polarizability *changes* during vibration, Raman scatter will occur in addition to Rayleigh scattering.

Before presenting the quantum mechanical description of a harmonic oscillator and selection rules, it is worthwhile presenting the energy level expressions that the reader is probably already familiar with. A vibrational mode ν , with an equilibrium frequency of $\tilde{\nu}_e$ (in wavenumbers) has energy levels (also in wavenumbers) given by $E_\nu = \tilde{\nu}_e(\nu + 1/2)$, where ν is the vibrational quantum number, and $\nu \geq 0$. The notation can become a bit confusing, so note that: ν (Greek letter nu) identifies the vibration, $\tilde{\nu}_e$ is the vibrational frequency (in wavenumbers), and ν (italic letter 'v') is the vibrational quantum number. It is trivial to extend this expression to a molecule with n uncoupled harmonic modes,

$$E_{\nu_1, \nu_2, \nu_3, \dots, \nu_n} = \sum_{i=1}^n \tilde{\nu}_i (\nu_i + 1/2) \quad (\text{B1.2.1})$$

where $\tilde{\nu}_i$ is the equilibrium vibrational frequency of the i th mode.

Of course, real molecules are not harmonic oscillators, and the energy level expression can be expanded in powers of $(v + 1/2)$. For a single mode we have

$$E_v = \tilde{\nu}_e(v + 1/2) - \tilde{x}_e \tilde{\nu}_e(v + 1/2)^2 + \dots$$

where \tilde{x}_e is the anharmonicity constant. This allows the spacing of the energy levels to decrease as a function of vibrational quantum number. Usually the expansion converges rapidly, and only the first two terms are needed. Harmonic oscillator and anharmonic oscillator potential energy curves with their respective energy levels are compared in [figure B1.2.3](#).

-5-

Figure B1.2.3. Comparison of the harmonic oscillator potential energy curve and energy levels (dashed lines) with those for an anharmonic oscillator. The harmonic oscillator is a fair representation of the true potential energy curve at the bottom of the well. Note that the energy levels become closer together with increasing vibrational energy for the anharmonic oscillator. The anharmonicity has been greatly exaggerated.

There usually is rotational motion accompanying the vibrational motion, and for a diatomic, the energy as a function of the rotational quantum number, J , is

$$E_J = B_e J(J + 1) - D_e [J(J + 1)]^2$$

where B_e and D_e are the equilibrium rotational constant and centrifugal distortion constant respectively. The rotational constant is related to the moment of inertia through $B_e = h/8\pi^2 I_e c$, where h is Planck's constant, I_e is the equilibrium moment of inertia, and c is the speed of light in vacuum. As the molecule rotates faster, it elongates due to centrifugal distortion. This increases the moment of inertia and causes the energy levels to become closer together. This is accounted for by including the second term with a negative sign. Overall, the vibration-rotation term energy is given by

$$E_{v,J} = \tilde{\nu}_e(v + 1/2) - \tilde{x}_e \tilde{\nu}_e(v + 1/2)^2 + B_e J(J + 1) - D_e [J(J + 1)]^2 - \alpha_e(v + 1/2)J(J + 1). \quad (\text{B1.2.2})$$

The only term in this expression that we have not already seen is α_e , the vibration-rotation coupling constant. It accounts for the fact that as the molecule vibrates, its bond length changes which in turn changes the moment of inertia. Equation B1.2.2 can be simplified by combining the vibration-rotation constant with the rotational constant, yielding a vibrational-level-dependent rotational constant,

$$B_v = B_e - \alpha_e(v + 1/2)$$

so the vibration–rotation term energy becomes

-6-

$$E_{v,J} = \tilde{\nu}_e(v + 1/2) - \tilde{x}_e \tilde{\nu}_e(v + 1/2)^2 + B_v J(J + 1) - D_e [J(J + 1)]^2.$$

B1.2.2.2 QUANTUM MECHANICAL DESCRIPTION

The quantum mechanical treatment of a harmonic oscillator is well known. Real vibrations are not harmonic, but the lowest few vibrational levels are often very well approximated as being harmonic, so that is a good place to start. The following description is similar to that found in many textbooks, such as McQuarrie (1983) [2]. The one-dimensional Schrödinger equation is

$$-\frac{\hbar^2}{2\mu} \frac{d^2\psi}{dx^2} + U(x)\psi(x) = E\psi(x) \quad (\text{B1.2.3})$$

where μ is the reduced mass, $U(x)$ is the potential energy, $\psi(x)$ is the wavefunction and E is the energy. The harmonic oscillator wavefunctions which solve this equation yielding the energies as given in [equation B1.2.1](#) are orthonormal, and are given by

$$\psi_v(x) = N_v H_v(\alpha^{1/2}x) e^{-\alpha x^2/2}$$

where $\alpha = (k\mu/\hbar^2)$, N_v are normalization constants given by

$$N_v = \frac{1}{(2^v v!)^{1/2}} \left(\frac{\alpha}{\pi}\right)^{1/4}$$

and H_v are the Hermite polynomials. The Hermite polynomials are defined as [1]

$$H_v(x) = (-1)^v e^{x^2} \frac{d^v}{dx^v} e^{-x^2}.$$

Upon inspection, the first three are seen to be

$$H_0(x) = 1 \quad H_1(x) = 2x \quad H_2(x) = 4x^2 - 2$$

and higher degree polynomials are obtained using the recursion relation

$$H_{v+1}(x) = 2xH_v(x) - 2vH_{v-1}(x). \quad (\text{B1.2.4})$$

-7-

The first few harmonic oscillator wavefunctions are plotted in figure B1.2.4.

Figure B1.2.4. Lowest five harmonic oscillator wavefunctions ψ and probability densities $|\psi|^2$.

Upon solving the Schrödinger equation, the energy levels are $E_v = \tilde{\nu}_e(v + 1/2)$, where $\tilde{\nu}_e$ is related to the force constant k and reduced mass μ through

$$\tilde{\nu}_e = \frac{1}{2\pi c} \left(\frac{k}{\mu} \right)^{1/2} .$$

Since the reduced mass depends only on the masses of the atoms ($1/\mu = 1/m_1 + 1/m_2$ for a diatomic), which are known, measurement of the vibrational frequency allows the force constant to be determined.

The electric dipole selection rule for a harmonic oscillator is $\Delta v = \pm 1$. Because real molecules are not harmonic, transitions with $|\Delta v| > 1$ are weakly allowed, with $\Delta v = \pm 2$ being more allowed than $\Delta v = \pm 3$ and so on. There are other selection rules for quadrupole and magnetic dipole transitions, but those transitions are six to eight orders of magnitude weaker than electric dipole transitions, and we will therefore not concern ourselves with them.

The selection rules are derived through time-dependent perturbation theory [1, 2]. Two points will be made in the following material. First, the Bohr frequency condition states that the photon energy of absorption or emission is equal

to the energy level separation of the two states. Second, the importance of the transition dipole moment is shown and, furthermore, it is also shown that the transition dipole moment for a vibrational mode is in fact the change in dipole as a function of vibration, that is, the dipole derivative. The time-dependent Schrödinger equation is

$$\hat{H}\Psi = i\hbar \frac{\partial \Psi}{\partial t}. \quad (\text{B1.2.5})$$

The time- and coordinate-dependent wavefunction for any given state is

$$\Psi_v(x, t) = \psi_v(x) e^{-iE_v t/\hbar}$$

where $\psi_v(x)$ is a stationary state wavefunction obtained by solving the time-independent Schrödinger equation (B1.2.3). The Hamiltonian is broken down into two parts, $\hat{H} = \hat{H}_0 + \hat{H}^{(1)}$, where \hat{H}_0 is the Hamiltonian for the isolated molecule, and $\hat{H}^{(1)}$ describes the interaction Hamiltonian of the molecule with the electromagnetic field. In particular, the interaction energy between a dipole and a monochromatic field is

$$\hat{H}^{(1)} = -\mu E = -\mu E_0 \cos 2\pi \nu t.$$

Consider a two-state system, where

$$\Psi_1(x, t) = \psi_1(x) e^{-iE_1 t/\hbar} \quad \text{and} \quad \Psi_2(x, t) = \psi_2(x) e^{-iE_2 t/\hbar}.$$

These wavefunctions are orthogonal. Assume that the system is initially in state 1, and that the interaction begins at $t = 0$. Since there are only two states, at any later time the wavefunction for the system is

$$\Psi(t) = a_1(t)\Psi_1(t) + a_2(t)\Psi_2(t)$$

where the coefficients $a_1(t)$ and $a_2(t)$ are to be determined. We know that $a_1(0) = 1$ and $a_2(0) = 0$ from the initial conditions. By substitution into equation (B1.2.5), we have

$$a_1(t)\hat{H}^{(1)}\Psi_1 + a_2(t)\hat{H}^{(1)}\Psi_2 = i\hbar\Psi_1 \frac{da_1}{dt} + i\hbar\Psi_2 \frac{da_2}{dt}.$$

We can find the time-dependent coefficient for being in state 2 by multiplying from the left by ψ_2^* , and integrating over spatial coordinates:

-9-

$$a_1(t) \int \psi_2^* \hat{H}^{(1)} \Psi_1 d\tau + a_2(t) \int \psi_2^* \hat{H}^{(1)} \Psi_2 d\tau = i\hbar \frac{da_1}{dt} \int \psi_2^* \Psi_1 d\tau + i\hbar \frac{da_2}{dt} \int \psi_2^* \Psi_2 d\tau.$$

This expression can be simplified considerably since ψ_2 and ψ_1 are orthogonal which implies that Ψ_2 and Ψ_1 are orthogonal as well. Furthermore, $a_{11}(t) \approx a_1(0) = 1$ and $a_2(t) \approx a_2(0) = 0$ since $\hat{H}^{(1)}$ is a small perturbation:

(B1.2.6)

where we have used Dirac bracket notation for the integral, i.e.

$$\langle \psi_2 | \hat{H}^{(1)} | \psi_1 \rangle \equiv \int \psi_2^* \hat{H}^{(1)} \psi_1 d\tau.$$

In order to evaluate equation B1.2.6, we will consider the electric field to be in the z -direction, and express the interaction Hamiltonian as

$$\hat{H}^{(1)} = -\mu_z E_{0z} \cos 2\pi \nu t = -\frac{\mu_z E_{0z}}{2} (e^{i2\pi \nu t} + e^{-i2\pi \nu t}).$$

Before substituting everything back into equation B1.2.6, we define the *transition dipole moment* between states 1 and 2 to be the integral

$$(\mu_z)_{21} \equiv \langle \psi_2 | \mu_z | \psi_1 \rangle. \quad (\text{B1.2.7})$$

Now, we substitute it into equation B1.2.6 to get

$$\frac{da_2}{dt} \propto (\mu_z)_{21} E_{0z} \left\{ \exp \left[\frac{i(E_2 - E_1 + h\nu)t}{\hbar} \right] + \exp \left[\frac{i(E_2 - E_1 - h\nu)t}{\hbar} \right] \right\}$$

and then integrate from 0 to t to obtain

$$a_2(t) \propto (\mu_z)_{21} E_{0z} \left\{ \frac{1 - \exp[i(E_2 - E_1 + h\nu)t/\hbar]}{E_2 - E_1 + h\nu} + \frac{1 + \exp[i(E_2 - E_1 - h\nu)t/\hbar]}{E_2 - E_1 - h\nu} \right\}.$$

There are two important features of this result. The energy difference between states 1 and 2 is $\Delta E = E_2 - E_1$. When $\Delta E \approx h\nu$, the denominator of the second term becomes very small, and this term dominates. This is the well known

Bohr frequency condition. The second important feature is that $(\mu_z)_{21}$ must be nonzero for an allowed transition, which is how the selection rules are determined.

The molecular dipole moment (not the transition dipole moment) is given as a Taylor series expansion about the equilibrium position

$$\mu = \mu_0 + \left(\frac{d\mu}{dx} \right) x + \left(\frac{d^2\mu}{dx^2} \right) x^2 + \dots = \mu_0 + \mu_1 x + \mu_2 x^2 + \dots$$

where x is the displacement from equilibrium, μ_0 is the permanent dipole moment and μ_1 is the dipole derivative and so on. It is usually fine to truncate the expansion after the second term. Now we need to evaluate $(\mu_z)_{21}$ for the harmonic oscillator wavefunctions. Using [equation \(B1.2.7\)](#), we have

$$(\mu_z)_{j,i} = N_j N_i \int_{-\infty}^{\infty} H_{xj}(\alpha^{1/2}x) e^{-\alpha x^2/2} \mu H_{xi}(\alpha^{1/2}x) e^{-\alpha x^2/2} dx$$

which can be expanded by substituting $\mu = \mu_0 + \mu_1 x$:

$$\begin{aligned} (\mu_z)_{j,i} &= N_j N_i \mu_0 \int_{-\infty}^{\infty} H_{xj}(\alpha^{1/2}x) e^{-\alpha x^2/2} H_{xi}(\alpha^{1/2}x) e^{-\alpha x^2/2} dx \\ &+ N_j N_i \mu_1 \int_{-\infty}^{\infty} H_{xj}(\alpha^{1/2}x) e^{-\alpha x^2/2} x H_{xi}(\alpha^{1/2}x) e^{-\alpha x^2/2} dx. \end{aligned} \quad (\text{B1.2.8})$$

The first term is zero if $i \neq j$ due to the orthogonality of the Hermite polynomials. The recursion relation in [equation \(B1.2.4\)](#) is rearranged

$$x H_v(x) = v H_{v-1}(x) + \frac{1}{2} H_{v+1}(x)$$

and substituted into the second term in [equation \(B1.2.8\)](#),

$$(\mu_z)_{j,i} = \frac{N_j N_i}{\alpha} \mu_1 \int_{-\infty}^{\infty} H_{xj}(\xi) \left[xi H_{xi-1}(\xi) + \frac{1}{2} H_{xi+1}(\xi) \right] e^{-\xi^2} d\xi$$

where we have let $\xi = \alpha^{1/2}x$. Clearly, this integral will be nonzero only when $j = (i \pm 1)$, yielding the familiar $\Delta v = \pm 1$ harmonic oscillator selection rule. Furthermore, the overtone intensities for an anharmonic oscillator are obtained in a straightforward manner by determining the eigenfunctions of the energy levels in a harmonic oscillator basis set, and then summing the weighted contributions from the harmonic oscillator integrals.

-11-

B1.2.2.3 RAMAN SPECTROSCOPY

NORMAL RAMAN SPECTROSCOPY

Raman scattering has been discussed by many authors. As in the case of IR vibrational spectroscopy, the interaction is between the electromagnetic field and a dipole moment, however in this case the dipole moment is induced by the field itself. The induced dipole is $\mu_{\text{ind}} = \alpha E$, where α is the polarizability. It can be expressed in a Taylor series expansion in coordinate displacement

$$\alpha = \alpha_0 + \left(\frac{d\alpha}{dx} \right) x + \left(\frac{d^2\alpha}{dx^2} \right) x^2 + \dots = \alpha_0 + \alpha' x + \alpha'' x^2 + \dots$$

Here, α_0 is the static polarizability, α' is the change in polarizability as a function of the vibrational coordinate, α'' is the second derivative of the polarizability with respect to vibration and so on. As is usually the case, it is possible to truncate this series after the second term. As before, the electric field is $E = E_0 \cos 2\pi \nu_0 t$, where ν_0 is the frequency of the light field. Thus we have

$$\mu_{\text{ind}} = (\alpha_0 + \alpha' x) E_0 \cos 2\pi \nu_0 t. \quad (\text{B1.2.9})$$

The time dependence of the displacement coordinate for a mode undergoing harmonic oscillation is given by $x = x_m \cos 2\pi \nu_v t$, where x_m is the amplitude of vibration and ν_v is the vibrational frequency. Substitution into equation (B1.2.9) with use of Euler's half-angle formula yields

$$\begin{aligned}\mu_{\text{ind}} &= \alpha_0 E_0 \cos 2\pi \nu_0 t + \alpha' (x_m \cos 2\pi \nu_v t) E_0 \cos 2\pi \nu_0 t \\ &= \alpha_0 E_0 \cos 2\pi \nu_0 t + \frac{E_0 \alpha' x_m}{2} [\cos 2\pi (\nu_0 - \nu_v) t + \cos 2\pi (\nu_0 + \nu_v) t].\end{aligned}$$

The first term results in Rayleigh scattering which is at the same frequency as the exciting radiation. The second term describes Raman scattering. There will be scattered light at $(\nu_0 - \nu_v)$ and $(\nu_0 + \nu_v)$, that is at sum and difference frequencies of the excitation field and the vibrational frequency. Since $\alpha' x_m$ is about a factor of 10^6 smaller than α_0 , it is necessary to have a very efficient method for dispersing the scattered light.

The bands on the low frequency side of the excitation frequency $(\nu_0 - \nu_v)$ are referred to as the Stokes lines, consistent with the terminology used in fluorescence, whereas those on the high frequency side $(\nu_0 + \nu_v)$ are the anti-Stokes lines. It is a bit unfortunate that this terminology was chosen, since the Raman process is fundamentally different from fluorescence. In particular, fluorescence is the result of a molecule absorbing light, undergoing vibrational relaxation in the upper electronic state, and re-emitting a photon at a lower frequency. The timescale for fluorescence is typically of the order of nanoseconds. The Raman process, on the other hand, is an instantaneous scattering process that occurs on a femtosecond timescale. The photon is never absorbed by the molecule. It is usually clear whether fluorescence or Raman scattering is being observed, but there are situations where it is ambiguous. We shall not pursue the issue any further here, however.

-12-

It is well known that the intensity of scattered light varies as the fourth power of the frequency, and based on this alone one would predict the Stokes lines to be less intense than the anti-Stokes by a factor of

$$\frac{I_{\text{Stokes}}}{I_{\text{anti-Stokes}}} = \frac{(\nu_0 - \nu_v)^4}{(\nu_0 + \nu_v)^4}$$

which is 0.68 for a 1000 cm^{-1} vibration excited at 488 nm ($20\,492 \text{ cm}^{-1}$). In reality, the Stokes lines are *more* intense, typically by a factor of 2 to 10,000, as the vibrational frequency varies from 200 to 2000 cm^{-1} . This is easily justified when the Boltzmann population of initial states is taken into account. As seen in figure B1.2.5 the Stokes transitions correspond to the molecule being initially in a low energy state, usually $\nu = 0$, whereas it must be in an excited vibrational state if it is going to undergo an anti-Stokes process. The ratio of populations of two energy levels is given by

$$P_{12} = e^{-\Delta E_{12}/kT}$$

where ΔE_{12} is the energy difference between the two levels, k is Boltzmann's constant and T is the temperature in Kelvin. Since the Stokes lines are more intense than anti-Stokes, only the Stokes lines for a Raman spectrum are typically presented, and the abscissa is labelled with the frequency offset $(\nu_0 - \nu_v)$ rather than the actual frequency of scattered light.

Figure B1.2.5. Comparison of several light scattering processes. (a) Rayleigh scattering, (b) Stokes and anti-Stokes Raman scattering, (c) pre-resonance Raman scattering, (d) resonance Raman scattering and (e) fluorescence where, unlike resonance Raman scattering, vibrational relaxation in the excited state takes place. From [3], used with permission.

-13-

Additional information about the vibration can be obtained through the depolarization ratio. This is the ratio of the intensity of scattered light that is polarized in a plane perpendicular to the incident radiation relative to that the scattered light that is polarized parallel to the incident polarization, $\rho = I_{\perp}/I_{\parallel}$. For totally symmetric modes, $\rho = 0$, while $0 < \rho < 3/4$ for non-totally symmetric modes [1, 3]. The polarization ratio can actually be greater than 3/4 for a resonantly enhanced Raman band [3].

Consistent with the notion that Raman scattering is due to a change in polarizability as a function of vibration, some of the general features of Raman spectroscopy [3] are:

- (1) it is more sensitive to stretching modes than bending modes, especially totally symmetric modes;
- (2) the intensity increases with bond order (i.e. double bond vibrations are more intense than single bond vibrations);
- (3) for modes involving only one bond, the intensity increases with increasing atomic number of the atoms;
- (4) for cyclic molecules, breathing modes are strongest.

RESONANCE RAMAN SPECTROSCOPY

Resonance Raman spectroscopy has been discussed by many authors [4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14 and 15]. If the excitation frequency is resonant with an excited electronic state, it is possible to dramatically increase the Raman cross-section. It is still a scattering process without absorption, but the light and polarizability can now couple much more efficiently. Resonant enhancements of 10^4 to 10^6 are achievable. A second important fact is that the vibrational modes that are coupled to the electronic transition are selectively enhanced, which greatly aids in structural determination. Another implication is that much lower concentrations can be used. A typical neat liquid might have a concentration of roughly 5 to 50 mol Γ^{-1} . It is possible for resonant enhanced Raman bands of a molecule to be as strong or stronger than the solvent bands even at a concentration of 10^{-6} M. This is useful because it is often desirable to maintain low enough concentrations such that the solute molecules do not interact with each other or aggregate. Finally, excited state vibrational dephasing rates can be determined.

The sum-over-states method for calculating the resonant enhancement begins with an expression for the resonance Raman intensity, $I_{i,f}$ for the transition from initial state i to final state f in the ground electronic state, and is given by [14]

$$I_{i,f} = \frac{2^7 \pi^5}{3^2 c^4} I_0 \sum_{\rho, \sigma} |(\alpha_{\rho\sigma})_{i,f}|^2 (\nu_L \pm \nu_v)^4$$

where I_0 is the incident intensity, ν_L is the laser frequency, ν_v is the vibrational frequency and $(\alpha_{\rho\sigma})_{i,f}$ is the $\rho\sigma$ th element of the Raman scattering tensor,

$$(\alpha_{\rho\sigma})_{i,f} = \sum_r \frac{(M_\rho)_{i,r} (M_\sigma)_{r,f}}{E_{r,i} - E_L + i\Gamma_r} + \frac{(M_\sigma)_{i,r} (M_\rho)_{r,f}}{E_{r,f} + E_L + i\Gamma_r}. \quad (\text{B1.2.10})$$

Here, $(M_\rho)_{a,b}$ is the ρ th component of the electronic transition moment from state a to b , $E_{r,i}$ and $E_{r,f}$ are the energy

-14-

differences between the resonant excited state and the initial and final states, respectively, $E_L - h\nu_L$ is the photon energy of the laser radiation, and Γ_r is the excited state vibrational dephasing rate. The Raman scattering tensor has two contributions, the so-called A and B terms:

The B -type enhancement is smaller than the A -type, and is usually, though not always, negligible. Therefore, we will concentrate on the A term [14],

where ρ and σ are pure electronic transition moments, and $\langle i | r \rangle$ and $\langle r | f \rangle$ are vibrational overlap integrals. In many cases, a single diagonal component of the scattering tensor dominates, which leads to a simplified expression,

(B1.2.11)

where $\langle e | M_z | g \rangle$ is the transition dipole moment for the electronic transition between ground state g and electronically excited state e , and r are the vibrational levels in the excited electronic state with vibrational energy $E_{i,r}$ relative to the initial vibrational level in the ground electronic state. From the form of this equation, we see that the enhancement depends on the overlap of the ground and excited state wavefunctions (Franck–Condon overlap), and is strongest when the laser frequency equals the energy level separation. Furthermore, systems with very large dephasing rates will not experience as much enhancement, all other factors being equal.

If there is only significant overlap with one excited vibrational state, equation (B1.2.11) simplifies further. In fact, if the initial vibrational state is $v_i = 0$, which is usually the case, and there is not significant distortion of the molecule in the excited electronic state, which may or may not hold true, then the intensity is given by

It is also possible to determine the resonant Raman intensities via a time-dependent method [16]. It has the

advantages that the vibrational eigenstates of the excited electronic state need not be known, and that it provides a physical picture of the dynamics in the excited state. Assuming only one ground vibrational state is occupied, the Raman cross section is [16, 17]

-15-

where ω_L is the laser frequency, ω_s is the frequency of the scattered light, (M_{ge}^0) is the electronic transition dipole, $\hbar\omega_i$ is the zero point vibrational energy of the initial state, $\langle f | i(t) \rangle$ is the overlap of the final state with the time-evolving state on the upper electronic state potential energy surface and the $\exp[-g(t)]$ term accounts for solvent-induced electronic dephasing. Unlike the sum-over-states method, the only excited state information needed is the potential energy surface in the immediate vicinity of where the initial state is projected onto the excited state.

B1.2.3 SPECTROMETERS

B1.2.3.1 INFRARED SPECTROMETERS

In the most general terms, an infrared spectrometer consists of a light source, a dispersing element, a sample compartment and a detector. Of course, there is tremendous variability depending on the application.

LIGHT SOURCES

Light sources can either be broadband, such as a Globar, a Nernst glower, an incandescent wire or mercury arc lamp; or they can be tunable, such as a laser or optical parametric oscillator (OPO). In the former case, a monochromator is needed to achieve spectral resolution. In the case of a tunable light source, the spectral resolution is determined by the linewidth of the source itself. In either case, the spectral coverage of the light source imposes limits on the vibrational frequencies that can be measured. Of course, limitations on the dispersing element and detector also affect the overall spectral response of the spectrometer.

Desirable characteristics of a broadband light source are stability, brightness and uniform intensity over as large a frequency range as possible. Desirable characteristics of a tunable light source are similar to those of a broadband light source. Furthermore, its wavelength should be as jitter-free as possible. Having a linewidth of 0.001 cm^{-1} is meaningless if the frequency fluctuates by 0.01 cm^{-1} on the timescale of scanning over an absorption feature.

The region $4500\text{--}2850 \text{ cm}^{-1}$ is covered nicely by f-centre lasers, and $2800\text{--}1000 \text{ cm}^{-1}$ by diode lasers (but there are gaps in coverage). Difference frequency crystals allow two visible beams whose frequencies differ by the wavelengths of interest to be mixed together. Using different laser combinations, coverage from greater than $5000\text{--}1000 \text{ cm}^{-1}$ has been demonstrated. The spectral range is limited only by the characteristics of the difference frequency crystal. The ultimate resolution of a laser spectrometer is dictated by the linewidth of the tunable light source. If the linewidth of the light source is broader than the absorption linewidth, then sensitivity is diminished, and the transition will appear broader than it actually is.

When extremely high resolution is not required, an attractive alternative is found in OPOs. An OPO is based on a nonlinear crystal that converts an input photon into two output photons whose energies add up to the input photon's energy. They can be rapidly tuned over a relatively large range, $5000\text{--}2200 \text{ cm}^{-1}$, depending on the nonlinear crystal. In the IR, commonly used crystals are LiNbO_3 and KDP (KH_2PO_4). The wavelengths of the two output beams are determined by the angle of the nonlinear crystal. That is, it will only

function when the index of refraction of the crystal in the direction of propagation is identical for all three beams. If narrow linewidths are required, it is necessary to seed the OPO with a weak beam from a diode laser. Thus, the parametric oscillation does not have to build up out of the noise, and is therefore more stable.

-16-

DISPERSING ELEMENTS

Dispersing elements must be used when broadband IR light sources are employed; either diffraction gratings or prisms can be used. Gratings are made by depositing a metal film, usually gold, on a ruled substrate. They can be used over a broad spectrum because the light never penetrates into the substrate. However, the reflectivity of the coating can be wavelength dependent. The useable range is determined by the pitch of the rulings. A grating suitable for use from 1000 to 3000 cm^{-1} would have 100–200 lines mm^{-1} . If there are too many lines per millimetre, then it acts like a mirror rather than a grating. If it has too few, then the efficiency is greatly reduced.

Prisms can also be used to disperse the light. They are much easier to make than gratings, and are therefore less expensive, but that is their only real advantage. Since the light has to pass through them, it is necessary to find materials that do not absorb. Greater dispersion is obtained by using materials with as high an index of refraction as possible. Unfortunately, materials with high index are also close to an absorption, which leads to a large nonlinear variation in index as a function of frequency.

When dispersing elements are used, the resolution of the spectrometer is determined by the entrance slit width, the exit slit width, the focal length and the dispersing element itself. Resolving power is defined as

$$R = \lambda / \Delta\lambda = \nu / \Delta\nu$$

that is, the central wavelength (or frequency) of the light exiting the spectrometer relative to its linewidth (or bandwidth). Higher resolving powers allow closely spaced lines to be distinguished.

DETECTORS

The detector chosen is just as important as the light source. If the sample is absorbing light, but the detector is not responding at that frequency, then changes in absorption will not be recorded. In fact, one of the primary limitations faced by spectroscopists working in the far-IR region of the spectrum (10–300 cm^{-1}) has been lack of highly sensitive detectors. The type of detector used depends on the frequency of the light. Of course, at any frequency, a bolometer can be used, assuming the detection element absorbs the wavelength of interest. A bolometer operates on the principle of a temperature-dependent resistance in the detector element. If the detector is held at a very low temperature, 2–4 K, and has a small heat capacity, then incoming energy will heat it, causing the resistance to change. While these detectors are general, they are susceptible to missing weak signals because they are swamped by thermal blackbody radiation, and are not as sensitive as detectors that have a response tied to the photon energy. At frequencies between 4000 and 1900 cm^{-1} , InSb photodiodes are used, HgCdTe detectors are favoured for frequencies between 2000 and 700 cm^{-1} , and copper-doped germanium (Cu:Ge) photoconductors are used for frequencies between 1000 and 300 cm^{-1} [18]. More recently, HgCdTe array detectors have become available that respond in the range 3500–900 cm^{-1} [19].

B1.2.3.2 RAMAN SPECTROMETERS

While Raman spectroscopy was first described in a paper by C V Raman and K S Krishnan in 1928, it has

only come into widespread use in the last three decades owing to the ready availability of intense monochromatic laser light

-17-

sources. Oddly enough, prior to 1945, Raman spectroscopy using Hg arc lamps was the method of choice for obtaining vibrational spectra since there was not yet widespread availability of IR spectrometers [5]. Just as with IR spectrometers, a Raman spectrometer consists of a light source, a dispersing element, a sample compartment and a detector. Again, there is tremendous variability depending on the application.

LIGHT SOURCES

The light source must be highly monochromatic so that the Raman scattering occurs at a well-defined frequency. An inhomogeneously broadened vibrational linewidth might be of the order of 20 cm^{-1} , therefore, if the excitation source has a wavelength of 500 nm, its linewidth must be less than 0.5 nm to ensure that it does not further broaden the line and decrease its intensity. This type of linewidth is trivial to achieve with a laser source, but more difficult with an arc lamp source.

Fixed frequency laser sources are most commonly used. For example, the Ar^+ laser has lines at 514, 496, 488, 476 and 458 nm. Sometimes a helium–neon laser is used (628 nm), or a doubled or tripled YAG (532 or 355 nm, respectively). Other wavelengths are generated by employing a Raman shifter with a variety of different gases. It is also desirable to have tunability, in order to carry out resonance Raman studies wherein one selectively measures the vibrations most strongly coupled to the electronic state being excited. Tunable lasers can be either line-tunable or continuously tunable. Thanks to the high sensitivity of photomultiplier tubes, the light source need only provide moderate power levels, $\sim 10\text{--}100 \text{ mW}$ for example. In fact, one must be careful not to use too much power and damage the sample.

DISPERSING ELEMENTS

Due to the rather stringent requirements placed on the monochromator, a double or triple monochromator is typically employed. Because the vibrational frequencies are only several hundred to several thousand cm^{-1} , and the linewidths are only tens of cm^{-1} , it is necessary to use a monochromator with reasonably high resolution. In addition to linewidth issues, it is necessary to suppress the very intense Rayleigh scattering. If a high resolution spectrum is not needed, however, then it is possible to use narrow-band interference filters to block the excitation line, and a low resolution monochromator to collect the spectrum. In fact, this is the approach taken with Fourier transform Raman spectrometers.

DETECTORS

Because the scattered light being detected is in the visible to near UV region, photomultiplier tubes (PMTs) are the detector of choice. By using a cooled PMT, background counts can be reduced to a level of only a few per second. For studies with higher signal levels, array detectors such as optical multichannel analysers (OMAs), or CCD arrays can be used. This allows a complete spectrum to be obtained without having to scan the monochromator.

RESOLUTION

The resolution of the Raman spectrum is determined by the monochromator. Furthermore, since the light being measured is in the visible region, usually around $20\,000 \text{ cm}^{-1}$, the resolution of the monochromator must be significantly better than that of its IR counterpart because the resolving power is described by $\Delta\nu/\nu$. That is, for

a 2000 cm^{-1} vibration a resolving power of 20,000 is needed to get the same resolution as that obtained in an IR spectrometer with a resolution of only 2000.

B1.2.3.3 FOURIER TRANSFORM TECHNIQUES

Fourier transform techniques do not change the underlying absorption or scattering mechanisms that couple light with matter. The data acquisition and processing are significantly different, however. In short, the difference is that the data are collected interferometrically in the time domain and then Fourier transformed into the frequency domain for subsequent analysis. These types of instruments are often used in experiments where broad spectral coverage with moderate sensitivity and frequency resolution is needed. This is often encountered when other aspects of the experiment are more difficult, such as surface studies. There is, however, ongoing research directed towards time-resolved FTIR with nanosecond time resolution [20, 21]. The basic requirements are a broadband light source, a beamsplitter, two delay lines (one fixed and one variable), a detector, and a computer to run the show and Fourier-transform the data.

The underlying concept behind an FTIR spectrometer can be understood when considering what happens when a beam of monochromatic light with wavelength λ is sent through a Michelson interferometer, shown schematically in [figure B1.2.6](#) [22]. If the pathlength difference between the two beams is zero, then they will constructively interfere, yielding an intensity at the detector of I_0 . Now consider what happens if the movable mirror is displaced by a distance $d = \lambda/4$. This will cause the optical path of that beam to change by an amount $\delta = \lambda/2$, and lead to destructive interference at the detector, with no power being measured. If the mirror is displaced by another $\lambda/4$, then the two beams will once again constructively interfere, leading to full intensity at the detector. The intensity as a function of mirror position is shown in [figure B1.2.7\(a\)](#). The intensity as a function of optical delay, δ , is described by

$$I(\delta) = \frac{I(\tilde{\nu})}{2} [1 + \cos(2\pi \tilde{\nu} \delta)]$$

where $\tilde{\nu}$ is the the frequency of interest and $I(\tilde{\nu})$ is its intensity. Similarly, [figure B1.2.7\(b\)](#) shows the intensity as a function of mirror position when two frequencies with equal amplitudes are present, and $f_1 = 1.2f_2$. [Figure B1.2.7\(c\)](#) depicts these same two frequencies, but with the amplitude of the lower frequency twice as large as that of the higher frequency. Finally, [figure B1.2.7\(d\)](#) shows the result for a Gaussian distribution of frequencies. For a discrete distribution of frequencies, the intensity as a function of optical delay is

$$I(\delta) = \frac{1}{2} \sum_{i=1}^n I(\tilde{\nu}_i) [1 + \cos(2\pi \tilde{\nu}_i \delta)]$$

and if there is a continuous distribution of frequencies, it is

$$I(\delta) = \frac{1}{2} \int_0^{\infty} I(\tilde{\nu}_i) [1 + \cos(2\pi \tilde{\nu}_i \delta)] d\tilde{\nu}.$$

While the data are collected in the time domain by scanning a delay line, they are most easily interpreted in the frequency domain. It is straightforward to connect the time and frequency domains through a Fourier transform

$$I(\tilde{\nu}) = 4 \int_0^{\infty} [I(\delta) - I(0)/2] \cos(2\pi \tilde{\nu} \delta) d\delta.$$

Two scans are required to obtain an absorption spectrum. First, a blank reference scan is taken that characterizes the broadband light source. Then a scan with the sample in place is recorded. The ratio of the sample power spectrum to the reference power spectrum is the transmission spectrum. If the source has stable output, then a single reference scan can be used with many sample scans.

Figure B1.2.6. Schematic representation of a Michelson interferometer. From Griffiths P R and de Haseth J A 1986 Fourier transform infrared spectroscopy *Chemical Analysis* ed P J Elving and J D Winefordner (New York: Wiley). Reprinted by permission of John Wiley and Sons Inc.

Figure B1.2.7. Time domain and frequency domain representations of several interferograms. (a) Single frequency, (b) two frequencies, one of which is 1.2 times greater than the other, (c) same as (b), except the high frequency component has only half the amplitude and (d) Gaussian distribution of frequencies.

The interferogram is obtained by continuously scanning the movable mirror and collecting the intensity on the detector at regular intervals. Thus, each point corresponds to a different mirror position, which in turn corresponds to a different optical delay. Several scans can be averaged together because the scanning mechanism is highly reproducible.

The spectral resolution of the Fourier transformed data is given by the wavelength corresponding to the maximum optical delay. We have $\lambda_{\max} = \delta_{\max}$, and therefore $\Delta\tilde{\nu} = 1/\delta_{\max}$. Therefore, if 0.1 cm^{-1} spectral resolution is desired, the optical delay must cover a distance of 10 cm. The high frequency limit for the transform is the Nyquist frequency which is determined by the wavelength that corresponds to two time steps: $\lambda_{\min} = 2\Delta\delta$, which leads to $\tilde{\nu}_{\max} = 1/(2\Delta\delta)$. The factor of two arises because a minimum of two data points per period are needed to sample a sinusoidal waveform. Naturally, the broadband light source will determine the actual content of the spectrum, but it is important that the step size be small enough to accommodate the highest frequency components of the source, otherwise they

will be folded into lower frequencies, which is known as ‘aliasing’. The step size for an FT-Raman instrument must be roughly ten times smaller than that in the IR, which is one of the reasons that FT-Raman studies are usually done with near-IR excitation.

There are several advantages of FT techniques [23]. One is the Jaquinot (or throughput) advantage. Since there are fewer optical elements and no slits, more power reaches the detector. Assuming that the noise source is detector noise, which is true in the IR, but not necessarily for visible and UV, the signal-to-noise (S/N) ratio will increase. A second advantage of FT techniques is that they benefit from the Fellgett (or multiplex) advantage. That is, when collecting the data, absorptions at all frequencies simultaneously contribute to the interferogram. This is contrasted with a grating spectrometer where the absorption is measured only at a single frequency at any given time. Theoretically, this results in an increase in the S/N ratio by a factor of

$$\sqrt{\frac{\tilde{\nu}_{\max}}{\Delta\tilde{\nu}}} = \sqrt{\frac{\delta_{\max}}{2\Delta\delta}}$$

This assumes that both spectra have the same resolution, and that it takes the same amount of time to collect the whole interferogram as is required to obtain one wavelength on the dispersive instrument (which is usually a reasonable assumption). Thus, $\tilde{\nu}_{\max}/\Delta\tilde{\nu}$ interferograms can be obtained and averaged together in the same amount of time it takes to scan the spectrum with the dispersive instrument. Since the S/N ratio scales with the square root of the number of scans averaged, the square root of this number is the actual increase in S/N ratio.

B1.2.4 TYPICAL EXAMPLES

There are thousands of scientists whose work can be classified as vibrational spectroscopy. The following examples are meant to show the breadth of the field, but cannot be expected to constitute a complete representation of all the fields where vibrational spectroscopy is important.

B1.2.4.1 LASER IR

For the highest resolution and sensitivity, laser-based spectrometers must be used. These have the advantage that the resolution depends on the linewidth of the laser, rather than the monochromator. Furthermore, at any given moment, all of the power is at the frequency of interest, rather than being spread out over the whole IR spectrum. Due to the fact that the emission from any given laser typically has only 100–1500 cm^{-1} of tunability, and there can be difficulty maintaining narrow linewidths, the spectral coverage can be limited.

High resolution spectroscopic measurements in the gas phase yield the most detailed structural information possible. For example, measurements of weakly-bound complexes in the far-IR [24, 25] and IR [26, 27] have provided the most exact information on their structure and steady-state dynamics. Of course, a much higher level of theory must be used than was presented in [section B1.2.2.1](#). Quite often the modes are so strongly coupled that all vibrational degrees of freedom must be treated simultaneously. Coriolis coupling and symmetry-allowed interactions among bands, i.e. Fermi resonances, are also quite significant, and must be treated explicitly. Direct measurement of the low frequency van der

Waals modes in weakly-bound complexes has been discussed in [section B1.4](#), *Microwave and Terahertz Spectroscopy*, and will not be repeated here.

A recent review of high-resolution, direct IR laser absorption spectroscopy in supersonic slit jets provides a prototypical example [26]. Figure B1.2.8 displays the experimental set-up. There are three different IR sources employed. The first utilizes difference frequency mixing of a single mode tunable ring dye laser with a single mode Ar^+ laser in a LiNbO_3 crystal to obtain light in the 2–4 μm region ($5000\text{--}2500\text{ cm}^{-1}$) with a frequency stability of 2 MHz ($6.7\times 10^{-5}\text{ cm}^{-1}$). The second uses cryogenically cooled, single mode, lead-salt

diodes to cover 4–10 μm ($2500\text{--}1000\text{ cm}^{-1}$) with a frequency resolution of 15 MHz ($5 \times 10^{-4}\text{ cm}^{-1}$). The third is a difference frequency scheme between a single mode dye laser and a single mode Nd:YAG laser which accesses wavelengths below 2 μm (frequencies greater than 5000 cm^{-1}). A long pathlength is achieved by combining a slit jet expansion with a multipass cell. This enhances the sensitivity by over two orders of magnitude.

Figure B1.2.8. Schematic diagram of a slit jet spectrometer for high resolution IR studies of weakly-bound species. From [26], used with permission.

One of the systems studied is the Ar–HF van der Waals (vdW) dimer. This rare gas–molecule complex has provided a wealth of information regarding intermolecular interactions. The vdW complex can be thought of in terms of the monomer subunit being perturbed through its interaction with the rare gas. The rotational motion is hindered, and for certain modes can be thought of as extremely large amplitude bending motion. Furthermore, there is low frequency intermolecular stretching motion. In a weakly-bound complex, the bends, stretches and internal rotations are all coupled with each other. The large spectral coverage has allowed for the measurement of spectra of Ar–HF with $\nu_{\text{HF}} = 1$ and 2. By combining these measurements with those made in the far-IR [28], intermolecular potential energy

surfaces for $\nu_{\text{HF}} = 0, 1$ and 2 have been determined. Quite small amounts of internal energy ($\sim 150\text{ cm}^{-1}$) allow the complex to fully sample the angular degree of freedom. Interestingly, the barrier to internal rotation is about the same for $\nu_{\text{HF}} = 0$ or 1, but significantly larger when $\nu_{\text{HF}} = 2$.

In addition to the dependence of the intermolecular potential energy surface on monomer vibrational level, the red-shifting of the monomer absorption as a function of the number of rare gas atoms in the cluster has been studied. The band origin for the $\nu_{\text{HF}} = 1 \leftarrow 0$ vibration in a series of clusters $\text{Ar}_n\text{--HF}$, with $0 < n < 5$, was measured and compared to the HF vibrational frequency in an Ar matrix ($n = \infty$). The monomer vibrational frequency ν_{HF} red shifts monotonically, but highly nonlinearly, towards the matrix value as sequential Ar atoms are added. Indeed, roughly 50% of the shift is already accounted for by $n = 3$.

CAVITY RINGDOWN SPECTROSCOPY

The relatively new technique of cavity ringdown laser absorption spectroscopy, or CRLAS [29, 30, 31 and 32], has proven to be exceptionally sensitive in the visible region of the spectrum. Recently, it has been used in the IR to measure O–H and O–D vibrations in weakly-bound water and methanol clusters [33]. The concept of cavity ringdown is quite straightforward. If a pulse of light is injected into a cavity composed of two very highly reflective mirrors, only a very small fraction will escape upon reflection from either mirror. If mirrors with 99.996% reflectivity are used, then the photons can complete up to 15 000 round trip passes, depending on other loss factors in the cavity. This makes the effective pathlength up to 30,000 longer than the physical pathlength of the sample. Currently, dielectric coatings for IR wavelengths are not as efficient as those for the visible, and the highest reflectivity available is about 99.9–99.99%, which leads to sensitivity enhancements of several hundred to several thousand. It is best to use pulses with a coherence length that is less than the cavity dimensions in order to avoid destructive interference and cancellation of certain frequencies.

The light leaking out of the cavity will decay exponentially, with a time constant that reflects the round-trip losses. When an absorbing sample is placed in the cavity, there are additional losses and the exponential time constant will become shorter. More highly absorbing samples will affect the time constant to a larger extent, and the absolute absorption is determined. The experiment is shown schematically in figure B1.2.9. One of the most important attributes of CRLAS is that it is relatively insensitive to laser pulse intensity fluctuations since the ringdown time constant, not the transmitted intensity, is measured.

Figure B1.2.9. Schematic representation of the method used in cavity ringdown laser absorption spectroscopy. From [33], used with permission.

To date, the IR-CRLAS studies have concentrated on water clusters (both H₂O and D₂O), and methanol clusters. Most importantly, these studies have shown that it is in fact possible to carry out CRLAS in the IR. In one study, water cluster concentrations in the molecular beam source under a variety of expansion conditions were characterized [34]. In a second study OD stretching bands in (D₂O)_n clusters were measured [35]. These bands occur between 2300

-24-

and 2800 cm⁻¹, a spectral region that has been largely inaccessible with other techniques. Cooperative effects in the hydrogen-bonded network were measured, as manifested in red shifts of OD stretches for clusters up to (D₂O)₈. These data for additional isotopes of water are necessary to fully characterize the intermolecular interactions.

For methanol clusters [36], it was found that the dimer is linear, while clusters of 3 and 4 molecules exist as monocyclic ring structures. There also is evidence that there are two cyclic ring trimer conformers in the molecular beam.

B1.2.4.2 RESONANCE RAMAN SPECTROSCOPY

The advantages of resonance Raman spectroscopy have already been discussed in section B1.2.2.3. For these reasons it is rapidly becoming the method of choice for studying large molecules in solution. Here we will present one study that exemplifies its attributes. There are two complementary methods for studying proteins.

First, it is possible to excite a chromophore corresponding to the active site, and determine which modes interact with it. Second, by using UV excitation, the amino acids with phenyl rings (tryptophan and tyrosine, and a small contribution from phenylalanine) can be selectively excited [4]. The frequency shifts in the resonance Raman spectrum associated with them provide information on their environment.

There has been extensive work done on myoglobin, haemoglobin, Cytochrome-*c*, rhodopsin and bacteriorhodopsin. In fact, there are literally hundreds of articles on each of the above subjects. Here we will consider haemoglobin [12]. The first three of these examples are based on the protohaeme unit, shown in figure B1.2.10.

Figure B1.2.10. Structure of the protohaeme unit found in haemoglobin and myoglobin.

Haemoglobin is made up of four protohaeme subunits, two are designated α and two are designated β . The protohaeme unit with surrounding protein is shown in figure B1.2.11. The binding curve of O₂ suggests a two state model, where haemoglobin binds O₂ more strongly when the concentration is higher. Thus, it will strongly bind O₂ in the lungs where the concentration is high, and then release it in tissues where the O₂ concentration is low. The high affinity and low affinity states are referred to as the R state and T state, respectively [37]. The R and T states each

have a distinct structure, and have been characterized crystallographically. Therefore, there are three primary issues:

- (1) What is the behaviour of the haeme macrocycles?
- (2) What is the interaction between the iron and the nearby histidines?
- (3) What are the structural dynamics of the tetramer as a whole? The haemoglobin bound to O₂ (HbO₂) is not photoactive, so the CO adduct, HbCO, is used instead.

Figure B1.2.11. Biologically active centre in myoglobin or one of the subunits of haemoglobin. The bound CO molecule as well as the proximal and distal histidines are shown in addition to the protohaeme unit. From Rousseau D L and Friedman J M 1988 *Biological Applications of Raman Spectroscopy* vol 3, ed T G Spiro (New York: Wiley). Reprinted by permission of John Wiley and Sons Inc.

Information about the haeme macrocycle modes is obtained by comparing the resonance Raman spectra of deoxyHb with HbCO. The d–d transitions of the metal are too weak to produce large enhancement, so the Soret band of the macrocycle, a π to π^* transition, is excited instead. It has been found that the vinyl groups do not participate in the conjugated system [4]. This is based on the fact that the vinyl C=C stretch does not exhibit resonant enhancement when the π to π^* transition is excited. On the other hand, it is found that both totally symmetric and nontotally symmetric modes of the macrocycle are all at a lower frequency in the HbCO photoproduct spectra relative to deoxyHb. This is interpreted to mean that the photoproduct has a slightly expanded core relative to the deoxy structure [12, 13]. Given that there is a structural change in the haeme centre, it is expected that the interaction of the iron with the proximal histidine should also be affected.

The Fe–N^{His} mode is at 222 cm⁻¹ in the R state and 207 cm⁻¹ in the T state for the α subunits, but only shifted to 218 cm⁻¹ T state for the β subunits. This is consistent with the interpretation that the Fe–imidazole interactions are weakened more in the T state of the α subunits than β subunits. Time-resolved resonance Raman studies have shown that the R \rightarrow T switch is complete on a 10 μ s timescale [38]. Finally, UV excitation of the aromatic protein side chains yields

-26-

frequency shifts that indicate a change in the quaternary structure, and this occurs on the same timescale as the frequency shifts in the Fe–N^{His} modes.

B1.2.4.3 TIME-RESOLVED SPECTROSCOPY

Time-resolved spectroscopy has become an important field from x-rays to the far-IR. Both IR and Raman spectroscopies have been adapted to time-resolved studies. There have been a large number of studies using time-resolved Raman [39], time-resolved resonance Raman [7] and higher order two-dimensional Raman spectroscopy (which can provide coupling information analogous to two-dimensional NMR studies) [40]. Time-resolved IR has probed neutrals and ions in solution [41, 42], gas phase kinetics [43] and vibrational dynamics of molecules chemisorbed and physisorbed to surfaces [44]. Since vibrational frequencies are very sensitive to the chemical environment, pump-probe studies with IR probe pulses allow structural changes to

be monitored as a reaction proceeds.

As an illustrative example, consider the vibrational energy relaxation of the cyanide ion in water [45]. The mechanisms for relaxation are particularly difficult to assess when the solute is strongly coupled to the solvent, and the solvent itself is an associating liquid. Therefore, precise experimental measurements are extremely useful. By using a diatomic solute molecule, this system is free from complications due to coupling of vibrational modes in polyatomics. Furthermore, the relatively low frequency stretch of roughly 2000 cm^{-1} couples strongly to the internal modes of the solvent.

Infrared pulses of 200 fs duration with 150 cm^{-1} of bandwidth centred at 2000 cm^{-1} were used in this study. They were generated in a two-step procedure [46]. First, a $\beta\text{-BaB}_2\text{O}_4$ (BBO) OPO was used to convert the 800 nm photons from the Ti:sapphire amplifier system into signal and idler beams at 1379 and 1905 nm, respectively. These two pulses were sent through a difference frequency crystal (AgGaS_2) to yield pulses centred at 2000 cm^{-1} . A 32-element array detector was used to simultaneously detect the entire bandwidth of the pulse [45].

Two isotopic combinations of CN^- ($^{13}\text{C}^{15}\text{N}^-$ which has a stretching frequency of 2004 cm^{-1} and $^{12}\text{C}^{14}\text{N}^-$ with a stretching frequency of 2079 cm^{-1}) in both H_2O and D_2O yield a range of relaxation times. In particular, it is found that the vibrational relaxation time decreases from 120 to 71 ps in D_2O as the vibrational frequency increases from 2004 to 2079 cm^{-1} . However, in H_2O , the relaxation time is roughly 30 ps for both isotopomers. The vibrational relaxation rate is highly correlated to the IR absorption cross section of the solvent at the frequency of solute vibration, which indicates that Coulombic interactions have a dominant role in the vibrational relaxation of CN^- .

B1.2.4.4 ACTION SPECTROSCOPY

The term ‘action spectroscopy’ refers to those techniques that do not directly measure the absorption, but rather the consequence of photoabsorption. That is, there is some measurable change associated with the absorption process. There are several well known examples, such as photoionization spectroscopy [47], multi-photon ionization spectroscopy [48], photoacoustic spectroscopy [49], photoelectron spectroscopy [50, 51], vibrational predissociation spectroscopy [52] and optothermal spectroscopy [53, 54]. These techniques have all been applied to vibrational spectroscopy, but only the last one will be discussed here.

Optothermal spectroscopy is a bolometric method that monitors the energy in a stream of molecules rather than in the light beam. A well collimated molecular beam is directed toward a liquid helium cooled bolometer. There will be energy

deposited in the bolometer from the translational kinetic energy of the molecules as well as any internal energy they may have. A narrow linewidth (2 MHz) infrared laser illuminates the molecular beam, typically in a multipass geometry. As the laser frequency is scanned the molecules will absorb energy when the frequency corresponds to a transition frequency. At that point, the energy deposited in the bolometer will change.

The optothermal spectrum will faithfully represent the absorption spectrum provided that the molecules do not fluoresce prior to arrival at the detector. Fluorescence is not a problem because infrared fluorescence lifetimes are of the order of milliseconds. The transit time from the laser-molecular beam interaction region to the detector is tens of μs . Furthermore, it is possible to determine if the absorbing species is a stable monomer, or weakly bound cluster. When a stable monomer absorbs a photon, the amount of energy measured by the bolometer increases. When a weakly-bound species absorbs a photon greater than the dissociation energy, vibrational predissociation will take place and the dissociating fragments will not hit the bolometer element,

leading to a decrease in energy measured by the bolometer. It is also possible to place the bolometer off-axis from the collimated molecular beam so that only dissociating molecules will register a signal.

A nice example of this technique is the determination of vibrational predissociation lifetimes of $(\text{HF})_2$ [55]. The HF dimer has a nonlinear hydrogen bonded structure, with nonequivalent HF subunits. There is one ‘free’ HF stretch (ν_1), and one ‘bound’ HF stretch (ν_2), which rapidly interconvert. The vibrational predissociation lifetime was measured to be 24 ns when exciting the free HF stretch, but only 1 ns when exciting the bound HF stretch. This makes sense, as one would expect the bound HF vibration to be most strongly coupled to the weak intermolecular bond.

B1.2.4.5 MICROSCOPY

It is possible to incorporate a Raman or IR spectrometer within a confocal microscope. This allows the spatial resolution of the microscope and compound identification of vibrational spectroscopy to be realized simultaneously. One of the reasons that this is a relatively new development is because of the tremendous volume of data generated. For example, if a Raman microscope has roughly $1 \mu\text{m}$ spatial resolution, and an area of $100 \mu\text{m} \times 100 \mu\text{m}$ is to be imaged, and the frequency region from 800 cm^{-1} – 3400 cm^{-1} is covered with 4 cm^{-1} spectral resolution, then the data set has 6 million elements. Assuming each value is represented with a 4 byte number, the image would require 24 M Bytes of storage space. While this is not a problem for current computers, the capacity of a typical hard drive on a PC from around 1985 (IBM 8088) was only 20 M Byte. Also, rapid data transfer is needed to archive and retrieve images. Furthermore, in order to obtain the spectrum at any spatial position, array detectors (or FT methods) are required. A representative experimental set-up is shown in figure B1.2.12 [3].

-28-

Figure B1.2.12. Schematic diagram of apparatus for confocal Raman microscopy. From [3], used with permission.

Raman microscopy is more developed than its IR counterpart. There are several reasons for this. First, the diffraction limit for focusing a visible beam is about 10 times smaller than an IR beam. Second, Raman spectroscopy can be done in a backscattering geometry, whereas IR is best done in transmission. A microscope is most easily adapted to a backscattering geometry, but it is possible to do it in transmission.

Raman microscopy is particularly adept at providing information on heterogeneous samples, where a

conventional spectrometer would average over many domains. It has found applications in materials science and catalysis; earth, planetary and environmental sciences; biological and medical sciences; and even in art history and forensic science [3]. For example, consider a hypothetical situation where someone owned what they believed to be a mediæ val manuscript from the 12th century. One could easily identify a small region of green colour to non-destructively analyse using Raman microscopy. If it happens that the dye is identified as phthalocyanine green, which was not discovered until 1938, then one can be certain that the manuscript is not authentic, or that it has undergone restoration relatively recently.

B1.2.5 CONCLUSIONS AND FUTURE PROSPECTS

Vibrational spectroscopy has been, and will continue to be, one of the most important techniques in physical chemistry. In fact, the vibrational absorption of a *single* acetylene molecule on a Cu(100) surface was recently reported [56]. Its endurance is due to the fact that it provides detailed information on structure, dynamics and environment. It is employed in a wide variety of circumstances, from routine analytical applications, to identifying novel (often transient) species, to providing some of the most important data for advancing the understanding of intramolecular and intermolecular interactions.

B1.3.1 INTRODUCTION

Light, made monochromatic and incident upon a sample, is scattered and transmitted at the incident frequency—a process known as Rayleigh scattering. Early in 1928 C V Raman and K S Krishnan reported [1, 2 and 3] the visual discovery of a new form of secondary radiation. Sunlight, passed through a blue–violet filter, was used as the light source incident upon many different organic liquids and even vapours. A green filter was placed between the sample and the viewer. The filters were sufficiently complementary to suppress the strong Rayleigh scattering and leave at longer wavelengths a feeble new kind of scattered radiation. Impurity fluorescence was discounted, for the signal was robust under purification and it also was strongly polarized. It was suggested that the incident photons had undergone inelastic scattering with the material—much as the Compton scattering of x-rays by electrons. Almost simultaneously, G Landsberg and L Mandelstam [4] reported a new kind of secondary radiation from crystalline quartz illuminated by the lines of the mercury vapour lamp. Spectrograms revealed a feeble satellite line to the red of each of the Rayleigh scattered mercury lines. In each case the displacement came close to a characteristic vibrational frequency of quartz at $\sim 480\text{ cm}^{-1}$. They wondered whether their new secondary radiation might not be of the same type as that seen by Krishnan and Raman. Such inelastic scattering of photons soon came to be called (spontaneous) Raman scattering or, given its quantized energy displacements, simply (spontaneous) Raman spectroscopy [5].

The 70 years since these first observations have witnessed dramatic developments in Raman spectroscopy, particularly with the advent of lasers. By now, a large variety of Raman spectroscopies have appeared, each with its own acronym. They all share the common trait of using high energy (‘optical’) light to probe small energy level spacings in matter.

This chapter is aimed at any scientist who wishes to become acquainted with this broad and interesting field. At the start we outline and present the principles and modern theoretical structure that unifies the many versions of Raman spectroscopies currently encountered. Then we sketch, briefly, individual examples from the contemporary literature of many of the Raman spectroscopies, indicating various applications. Though the theoretical structure is intended to stand on its own when discussing any one subject, there is no pretence of completeness, nor depth—this is not a review. But it is hoped that through the selected citations the interested reader is easily led into the broader literature on any given topic—including investigations yet to appear.

The study of small energy gaps in matter using the ‘optical’ spectral region (say the near-IR, visible and UV) offers many advantages over direct one-photon spectroscopies in the IR, far IR or even the microwave. First,

it is instrumentally convenient. Second, one can readily avoid the problem of absorbing solvents when studying dissolved solutes. Finally, in the optical region, additional strong resonances (usually involving electronic transitions) are available which can enhance the Raman scattered intensity by many orders of magnitude. This has created the very lively field of resonance Raman spectroscopy—arguably one of the most popular current Raman based spectroscopies. Resonance Raman spectroscopy not only provides greatly amplified signals from specific Raman resonances in the ground state, but it also exposes useful properties of the upper electronic potential energy hypersurface that is reached in the optical resonance.

-2-

In general, the coupling of light with matter has as its leading term the electric field component of the electromagnetic (EM) radiation—extending from the microwave into the vacuum ultraviolet. In the optical region (or near optical), where the Raman spectroscopies are found, light fields oscillate in the ‘petahertz’ range (of the order of 10^{15} cycles per second). So for technical reasons the signals are detected as photons (‘quadrature in the field’)—not as the oscillating field itself. As in any spectroscopy, Raman spectroscopies measure eigenvalue differences, dephasing times (through the bandwidths, or through time-resolved measurements) and quantitative details concerning the strength of the light/matter interaction—through the scattering cross-sections obtained from absolute Raman intensities. The small energy gap states of matter that are explored in Raman spectroscopy include phonon-like lattice modes (where Brillouin scattering can be the Raman scattering equivalent), molecular rotations (rotational Raman scattering), internal vibrations of molecules (vibrational Raman scattering) and even low lying electronic states (electronic Raman scattering). Also spin states may be probed through the magnetic component of the EM field. With the introduction of lasers, the Raman spectroscopies have been brought to a new level of sensitivity as powerful analytic tools for probing samples from the microscopic level (microprobes) to remote sensing. Not only have lasers inspired the development of new techniques and instrumentation, but they also have spawned more than 25 new kinds of Raman spectroscopy. As we shall see, this growth in experimental diversity has been accomplished by increasingly comprehensive theoretical understanding of all the spectroscopies.

The many Raman spectroscopies are found as well defined subgroups among the ‘electric field’ spectroscopies in general. (In this chapter, the magnetic field spectroscopies are mentioned only in passing.) First, except for very high intensities, the energy of interaction of light with matter is sufficiently weak to regard modern spectroscopies as classifiable according to perturbative orders in the electric field of the light. Thus any given spectroscopy is regarded as being *linear* or *nonlinear* with respect to the incident light fields. In another major classification, a given spectroscopy (linear or nonlinear) is said to be *active* or *passive* [6, 7]. The *active* spectroscopies are those in which the principal event is a change of state population in the material. In order to conserve energy this must be accompanied by an appropriate change of photon numbers in the light field. Thus net energy is transferred between light and matter in a manner that survives averaging over many cycles of the perturbing light waves. We call these the Class I spectroscopies. They constitute all of the well known absorption and emission spectroscopies—whether they are one-photon or multi-photon. The *passive* spectroscopies, called Class II, arise from the momentary exchange of energy between light and matter that induces a macroscopically coherent, oscillating, electrical polarization (an oscillating electric dipole density wave) in the material. As long as this coherence is sustained, such polarization can serve as a source term in the wave equation for the electric field. A new (EM) field (the signal field) is produced at the frequency of the oscillating polarization in the sample. Provided the polarization wave retains some coherence, and matches the signal field in direction and wavelength (a condition called ‘phase matching’), the new EM field can build up and escape the sample and ultimately be measured ‘in quadrature’ (as photons). In their extreme form, when no material resonances are operative, the Class II events (‘spectroscopies’ is a misnomer in the absence of resonances!) will alter only the states of the EM radiation and none of the material. In this case, the material acts *passively* while ‘catalysing’ alterations in the radiation. When resonances are present, Class II events become spectroscopies; some net energy may be transferred between light and matter, even as one focuses experimentally not on population changes in the material, but on alterations of the radiation. Class II events include all of the resonant and nonresonant, linear and nonlinear *dispersions*. Examples of Class II spectroscopies are classical diffraction and reflection (strongest at the linear level) and a whole array of light-scattering phenomena such as frequency summing (harmonic generation),

frequency differencing, free induction decay and optical echoes.

The Class II (passive) spectroscopies

-3-

- (i) may or may not contain resonances,
- (ii) can appear at all orders of the incident field (but only at odd order for isotropic media (gases, liquids, amorphous solids)),
- (iii) have a cross-section that is quadratic in concentration when the signal wave is homodyne detected and
- (iv) require phase-matching through experimental design, because the signal field must be allowed to build up from the induced polarization over macroscopic distances.

In [table B1.3.1](#) and [table B1.3.2](#), we assemble the more than twenty-five Raman spectroscopies and order them according to their degree of nonlinearity and by their class ([table B1.3.1](#) for Class I, [table B1.3.2](#) for Class II).

A diagrammatic approach that can unify the theory underlying these many spectroscopies is presented. The most complete theoretical treatment is achieved by applying statistical quantum mechanics in the form of the time evolution of the light/matter *density operator*. (It is recommended that anyone interested in advanced study of this topic should familiarize themselves with density operator formalism [[8](#), [9](#), [10](#), [11](#) and [12](#)]. Most books on nonlinear optics [[13](#), [14](#), [15](#), [16](#) and [17](#)] and nonlinear optical spectroscopy [[18](#), [19](#)] treat this in much detail.) Once the density operator is known at any time and position within a material, its matrix in the eigenstate basis set of the constituents (usually molecules) can be determined. The ensemble averaged electrical polarization, \mathbf{P} , is then obtained—the centrepiece of all spectroscopies based on the electric component of the EM field.

Following the section on theory, the chapter goes on to present examples of most of the Raman spectroscopies that are organized in [table B1.3.1](#) and [table B1.3.2](#).

The Class I (active) spectroscopies, both linear and nonlinear [[6](#), [7](#)],

- (i) always require resonances,
- (ii) appear only at odd order in the incident fields, which are acting ‘maximally in quadrature’. (That is, in polarizing the medium all but one of the fields act in pairs of Fourier components—also known as ‘in quadrature’ or as ‘conjugate pairs’. When this happens, the electrical polarization must carry the same frequency, wavelength, and wave vector as the odd, unpaired field. Since this odd order polarization acts conjugately with the odd incident field, the ‘photon’ picture of the spectroscopy survives.),
- (iii) have a cross-section that is linear in concentration of the resonant species and
- (iv) do not require phase matching by experimental design, for it is automatic.

B1.3.2 THEORY¹

The oscillating electric dipole density, \mathbf{P} (the polarization), that is induced by the total incident electric field, \mathbf{E} is the principal property that generates all of the spectroscopies, both linear and nonlinear. The energy contained in \mathbf{P} may be used in part (or altogether) to shift the population of energy states of the material, or it may in part (or altogether) reappear in the form of a new EM field oscillating at the same frequency. When the population changes, or energy loss or gain in the light is detected, one is engaged in a Class I spectroscopy. On the other hand, when properties of the new field are being measured—such as its frequency, direction (wavevector), state of polarization and amplitude (or intensity)—one has a Class II spectroscopy.

Normally the amplitude of the total incident field (or intensity of the incident light) is such that the light/matter coupling energies are sufficiently weak not to compete seriously with the ‘dark’ matter Hamiltonian. As already noted, when this is the case, the induced polarization, \mathbf{P} is treated perturbatively in orders of the total electric field. Thus one writes

$$\mathbf{P} = \overbrace{X^{(1)}\mathbf{E}}^{\mathbf{P}^{(1)}} + \overbrace{X^{(2)}\mathbf{E}\mathbf{E}}^{\mathbf{P}^{(2)}} + \overbrace{X^{(3)}\mathbf{E}\mathbf{E}\mathbf{E}}^{\mathbf{P}^{(3)}} + \dots \overbrace{X^{(s)}\mathbf{E}\dots\mathbf{E}}^{\mathbf{P}^{(s)}} + \dots \quad (\text{B1.3.1})$$

where the successive terms clearly appear with increasing order of nonlinearity in the total field, \mathbf{E} . At this point, all properties appearing in equation (B1.3.1) are mathematically pure real. The response function of the material to the electric field acting at s th order is the electrical susceptibility, $X^{(s)}$ (it is an $s + 1$ rank tensor). Each element of this tensor will carry $s + 1$ subscripts, a notation that is used, understandably, only when necessary. Furthermore, the events at, say the s th order, are sometimes referred to as ‘ $s + 1$ -wave-mixing’—the additional field being the new EM field derived from $\mathbf{P}^{(s)}$.

All *nonlinear* (electric field) spectroscopies are to be found in all terms of equation (B1.3.1) except for the first. The latter exclusively accounts for the standard linear spectroscopies—one-photon absorption and emission (Class I) and linear dispersion (Class II). For example, the term at third order contains by far the majority of the modern Raman spectroscopies ([table B1.3.1](#) and [table B1.3.2](#)).

It is useful to recognize that in the laboratory one normally configures an experiment to concentrate on one particular kind of spectroscopy, even while all possible light/matter events must be occurring in the sample. How can one isolate from equation (B1.3.1) a spectroscopy of interest? In particular, how does one uncover the Raman spectroscopies? We shall see how passage to the complex mathematical representation of the various properties is invaluable in this process. It is useful to start by addressing the issue of distinguishing Class I and Class II spectroscopies at any given order of nonlinearity.

B1.3.2.1 CLASS I AND CLASS II SPECTROSCOPIES AND THE COMPLEX SUSCEPTIBILITIES

All Class I spectroscopies at any order can be exposed by considering the long-term exchange of energy between light and matter as judged by the nonvanishing of the induced power density over many cycles of the field. The instantaneous power density at s th order is given by $\{\mathbf{E} \cdot \frac{\partial \mathbf{P}^{(s)}}{\partial t}\}$. For this product to survive over time, we ask that its normalized integral over a time T , which is much longer than the optical period of the field, should not vanish. This is called the cycle averaged, s th order power density. It is expressed as

$$W^{(s)} = \frac{1}{T} \int_0^T dt \left\{ \mathbf{E} \cdot \frac{\partial \mathbf{P}^{(s)}}{\partial t} \right\}. \quad (\text{B1.3.2})$$

For $W^{(s)} > 0$, one has absorption; for $W^{(s)} < 0$, emission. Multiphoton absorption and emission fall into this class. The Class I Raman spectroscopies clearly exhibit a net absorption of energy in Stokes scattering and a net emission of energy in anti-Stokes scattering. Though $\mathbf{P}^{(s)}$ involve s actions of the total field, the light/matter energy exchange is always in the language of photons. A net energy in the form of photons is destroyed (absorbed) as the quantum state population of the material moves upward in energy; a net energy in the form of photons is created (emitted) as the

population moves downward in energy. To survive the integration, the instantaneous power density should not oscillate rapidly (if at all), certainly not at optical frequencies. Since \mathbf{E} is intended to consist entirely of fields that oscillate at optical frequencies, the power density can have a non-oscillating term only when the field

appears altogether an *even* number of times. Since it appears s times in $\mathbf{P}^{(s)}$ (equation (B1.3.1)) and once in \mathbf{E} , all Class I spectroscopies exist only when $s + 1$ is even, or s is odd (see equation (B1.3.2)).

Furthermore, the non-oscillating component of the integrand can best be sorted out by going to the complex representation of the total field, the polarization, and the susceptibility. The mathematically pure real quantities in equation (B1.3.2) can be written in their complex representation as follows:

$$\mathbf{E} = \frac{1}{2}(\boldsymbol{\varepsilon} + \boldsymbol{\varepsilon}^*) \quad (\text{B1.3.3})$$

$$\mathbf{P}^{(s)} = \frac{1}{2}(\mathbf{p}^{(s)} + \mathbf{p}^{(s)*}) \quad (\text{B1.3.4})$$

and

$$\mathbf{X}^{(s)} = \frac{1}{2}(\chi^{(s)} + \chi^{(s)*}) \quad (\text{B1.3.5})$$

in which $\boldsymbol{\varepsilon}$, $\mathbf{p}^{(s)}$ and $\chi^{(s)}$ are, in general, complex quantities whose real parts are given by \mathbf{E} , $\mathbf{P}^{(s)}$ and $\mathbf{X}^{(s)}$, respectively. Introducing equation (B1.3.4)–equation (B1.3.5) into equation (B1.3.2), and applying the cycle average theorem for the integral [20], one finds that for all spectroscopies at s th order involving long-term light/matter energy exchange (Class I, in particular), the signal measured as a net energy exchange, $S_1^{(s)}$, is proportional to the cycle averaged power density, or $S_1^{(s)} \propto W^{(s)} \propto \text{Im } \chi^{(s)}$. If the complex susceptibility, $\chi^{(s)}$, is pure real, there can be no long term energy exchange between light and matter. There can be no Class I spectroscopies based on a susceptibility component for which $\text{Im } \chi^{(s)} = 0$.

Consider an ensemble composed of N constituents (such as molecules) per unit volume. The (complex) density operator for this system is developed perturbatively in orders of the applied field, and at s th order is given by $\rho^{(s)}$. The (complex) s th order contribution to the ensemble averaged polarization is given by the trace over the eigenstate basis of the constituents of the product of the dipole operator, $N \boldsymbol{\mu}$ and $\rho^{(s)}$: $\mathbf{p}^{(s)} = \text{Tr}\{N \boldsymbol{\mu} \rho^{(s)}\}$. In turn, an expression for $\chi^{(s)}$ is obtained, which, in the frequency domain, consists of a numerator containing a product of $(s + 1)$ transition moment matrix elements and a denominator of s complex energy factors. These complex energies express light/matter resonances and allow $\chi^{(s)}$ to become a complex quantity, its $\text{Im } \chi^{(s)}$ part (pure real) being responsible for Class I spectroscopies. The light/matter resonances introduce the imaginary component to $\chi^{(s)}$ and permit a Class I spectroscopy to exist.

As noted, the Class II spectroscopies are based on detecting the new EM field that is derived from the induced polarization, $\mathbf{P}^{(s)}$, at s th order. Here $\mathbf{P}^{(s)}$, oscillating at optical frequencies, acts as the source term in Maxwell's equation to create the new optical field, \mathbf{E}_{new} , at the same frequency. Again, we recognize $\boldsymbol{\varepsilon}_{\text{new}} \propto \mathbf{p}^{(s)} \propto \chi^{(s)}$.

Since optical fields oscillate too quickly for direct detection, they are measured ‘in quadrature’—as photons (see below). There are two ways to achieve quadrature. One is *homodyne* detection in which the new field is measured at

-6-

its quadrature, $\boldsymbol{\varepsilon}_{\text{new}} \boldsymbol{\varepsilon}_{\text{new}}^* = |\boldsymbol{\varepsilon}_{\text{new}}|^2$. These signals must be proportional to $|\chi^{(s)}|^2$. Thus $S_{\text{I}}^{(s)}$ (homodyne) $\propto |\chi^{(s)}|^2$ and all phase information in $\chi^{(s)}$ is lost. Such is the case for almost all of the Class II spectroscopies, especially the Raman events at third order.

The second way to achieve quadrature is to introduce another field, \mathbf{E}_{lo} , (called a local oscillator) designed in frequency and wavevector to conjugate (go into quadrature) in its complex representation with the new field of interest. Thus in the heterodyne case, the signal photons are derived from $\boldsymbol{\varepsilon}_{\text{new}} \boldsymbol{\varepsilon}_{\text{lo}}^*$, or $S_{\text{II}}^{(s)}$ (heterodyne) $\propto \chi^{(s)}$.

In heterodyne detected $s + 1$ wave mixing, phase information is retained and one can take a full measure of the complex susceptibility, including its phase. The phase of the complex induced polarization, $\mathbf{p}^{(s)}$, determines how its energy will partition between Class I (absorbed or emitted) and Class II (a new EM wave is launched) spectroscopies.

Consider all of the spectroscopies at third order ($s = 3$). To be as general as possible, suppose the total incident field consists of the combination of three experimentally distinct fields ($j = 1, 2, 3$). These can differ in any combination of their frequency, polarization and direction of incidence (wavevector). Thus the total field is written as

$$\mathbf{E} = \sum_{j=1}^3 \mathbf{E}_j. \quad (\text{B1.3.6})$$

In using the complex representation (equation (B1.3.4)), the j th electric field is given as

$$\mathbf{E}_j = \frac{1}{2}(\epsilon_j + \epsilon_j^*) \quad (\text{B1.3.7})$$

where (using Euler's identity)

$$\epsilon_j = \mathbf{E}_j^0 e^{-i(\mathbf{k}_j \cdot \mathbf{r} - \omega_j t)} \quad (\text{B1.3.8})$$

$$\epsilon_j^* = (\mathbf{E}_j^0)^* e^{i(\mathbf{k}_j^* \cdot \mathbf{r} - \omega_j^* t)}. \quad (\text{B1.3.9})$$

Here \mathbf{E}_j^0 is the amplitude of the j th field and the real part of ω_j is its (circular) frequency or 'colour'. The real part of \mathbf{k}_j is the product of the unit vector of incidence inside the sample, \mathbf{e}_k , and its amplitude, $\frac{2\pi n_j}{\lambda_j}$. Here $\frac{\lambda_j}{n_j}$ is the wavelength of the j th field inside the sample— λ_j being the wavelength inside a vacuum and n_j being the (real) index of refraction of the sample at ω_j . As implied, all three properties may be complex: the amplitude because of an added phase to the field and/or a field that is elliptically (or circularly) polarized; the frequency because the field may be growing or decaying in time and the wavevector because the field may be decaying and growing according to its location within the sample.

The total field (equation (B1.3.6) with equation (B1.3.7)) is now

$$\mathbf{E} = \frac{1}{2} \sum_{j=1}^3 (\epsilon_j + \epsilon_j^*). \quad (\text{B1.3.10})$$

It is only a matter of inserting this 'hexanomial', equation (B1.3.10), into equation (B1.3.1) to organize all possible three-beam spectroscopies that might appear at any given order.

B1.3.2.2 THE 'GENERATORS' FOR ALL THIRD ORDER SPECTROSCOPIES FROM THE COMPLEX REPRESENTATION OF THE FIELD

In order to develop the theoretical structure that underlies each of the many Raman spectroscopies at third

order, we use the above complex representation of the incident fields to produce the ‘generators’ of all possible electric field spectroscopies at third order. After this exercise, it is a simple matter to isolate the subset that constitutes the entire family of Raman spectroscopies.

At third order, one must expand $\frac{1}{8}(\sum_{i=1}^3(\epsilon_i + \epsilon_i^*) \sum_{j=1}^3(\epsilon_j + \epsilon_j^*) \sum_{k=1}^3(\epsilon_k + \epsilon_k^*))$ to enumerate the ‘generators’ of all possible third order spectroscopies. In this case, any given generator consists of an ordered list of these complex fields, such as $\epsilon_i \epsilon_j \epsilon_k^*$. The ordering of the fields in each generator represents a time ordering of the actions of the applied fields. This can be of physical significance. Clearly this expansion must give 216 terms (6^3). These 216 terms or generators can be arranged into 108 pairs of mutually conjugate generators, since the total electric field is itself a quantity that is pure real. Of these 108 paired terms, exactly 27 are in the category of what is termed *nondegenerate* four wave mixing (ND4WM), where the signal frequency must be very far from any of the incident optical frequencies. These 27 pairs can generate only Class II spectroscopies and (it turns out) none of the Raman spectroscopies. The generic pair for these ND4WM processes is $\epsilon_i \epsilon_j \epsilon_k + \epsilon_i^* \epsilon_j^* \epsilon_k^*$, where each of i, j or k can be fields 1, 2 or 3. (Henceforth the factor of $\frac{1}{8}$ shall be suppressed since it is common to all 216 generators.) The simple algebra of exponents is applied to such a product using [equation \(B1.3.9\)](#) and [equation \(B1.3.10\)](#). Thus, one sees how the polarization wave generated from such a term must oscillate at a frequency much larger than any of the incident colours, namely at the (real part of) $\omega_p = \omega_i + \omega_j + \omega_k$. The polarization wave must have a wavevector given by

$$\text{Re}(\mathbf{k}_p) = \text{Re}(\mathbf{k}_i + \mathbf{k}_j + \mathbf{k}_k) = 2\pi \left(\left(\frac{n_i}{\lambda_i} \right) \mathbf{e}_{\mathbf{k}_i} + \left(\frac{n_j}{\lambda_j} \right) \mathbf{e}_{\mathbf{k}_j} + \left(\frac{n_k}{\lambda_k} \right) \mathbf{e}_{\mathbf{k}_k} \right).$$

The appropriate (complex) susceptibility tensor for this generator is $\chi^{(3)}(\omega_p = \omega_i + \omega_j + \omega_k)$.

When resonances, or near resonances, are present in the 4WM process, the ordering of the field actions in the perturbative treatment ([equation \(B1.3.1\)](#)), can be highly significant. Though the three-colour generators ($\epsilon_i \epsilon_j \epsilon_k, \epsilon_j \epsilon_k \epsilon_i, \epsilon_k \epsilon_i \epsilon_j, \dots$) have identical frequency and wavevector algebra, their associated susceptibility functions ($\chi^{(3)}(\omega_p = \omega_i + \omega_j + \omega_k), \chi^{(3)}(\omega_p = \omega_j + \omega_k + \omega_i), \chi^{(3)}(\omega_p = \omega_k + \omega_i + \omega_j), \dots$) are, in general, different. As a result of the different colour ordering, two of their three energy denominator factors must differ. For this reason, the field ordering in each generator, together with its own response function, must be regarded individually.

The fourth electromagnetic wave, \mathbf{E}_{new} , shall henceforth be called the signal wave, $\mathbf{E}_s = \frac{1}{2}(\epsilon_s + \epsilon_s^*)$. It always must carry the same frequency as that of the polarization wave ($\omega_p = \omega_s$). It is launched by the collapse of this wave, provided that the polarization extends coherently over at least a few wavelengths of the incident light and that $\mathbf{k}_p = \mathbf{k}_s$.

The latter condition corresponds to the phase matching requirement already mentioned—the wavelength and direction of the material polarization wave must match those of the new EM wave as closely as possible. However, for all Class I spectroscopies, this condition is automatically achieved because of quadrature. In fact, this is true for all ‘quadrature’ spectroscopies—the Class I spectroscopies being the principal such, but, as noted, it is a nontrivial requirement in the ‘nonquadrature’ Class II spectroscopies, particularly in optically dispersive media.

In the complex mathematical representation, ‘quadrature’ means that, at the $(s + 1)$ wave mixing level, the product of s input fields constituting the s th order generator and the signal field can be organized as a product of $(s + 1)/2$ conjugately paired fields. Such a pair for field i is given by One sees that the exponent algebra for

such a pair removes all dependence on the $\text{Re}(\omega_i)$ and $\text{Re}(\mathbf{k}_i)$, thus automatically removing all oscillations as well as satisfying the phase-matching requirement. A necessary (but not sufficient) requirement for full quadrature is for s to be odd and also that half of the $s + 1$ fields be found to act conjugately with respect to the other half. Thus, for $s + 1$ fields, whenever the number of nonconjugate fields differs from the number of conjugate fields, one can only have ‘nonquadrature’. Phase matching then must become an issue. This must always be the case for odd-wave mixing (s is even), and it is also true for the above set of 27 frequency summing generators (for ND4WM). Thus for the currently considered generator, $\epsilon_i \epsilon_j \epsilon_k$, all three fields (i, j and k) act nonconjugately, so quadrature at the four-wave level simply is not possible.

B1.3.2.3 THE FIELD GENERATORS FOR ALL THIRD ORDER RAMAN SPECTROSCOPIES

We are now prepared to uncover all of the third order Raman spectroscopies (table B1.3.1 and table B1.3.2) and, in doing so, indicate how one might proceed to reveal the Raman events at higher order as well. Of the 108 pairs of conjugate generators, the remaining 81, unlike the above 27, are characterized by having one of the three fields acting conjugately with respect to the remaining two. Nine of these 81 terms generate fully degenerate 4WM. They constitute the ‘one-colour’ terms: and with susceptibility $\chi^{(3)}(\omega_s = \omega_i)$, since $\omega_s = -\omega_i + \omega_i + \omega_i = \omega_i$ with wavevector $\mathbf{k}_s = -\mathbf{k}_i + \mathbf{k}_i + \mathbf{k}_i = \mathbf{k}_i$. Their full degeneracy is evident since all four fields carry the same frequency (apart from sign). Resonances appear in the electric susceptibilities when, by choice of incident colours and their signs, one or more of their energy denominators (s in number at s th order) approaches a very small value because the appropriate algebraic colour combination matches material energy gaps. All Raman spectroscopies must, by definition, contain at least one low frequency resonance. When using only optical frequencies, this can only be achieved by having two fields acting conjugately and possessing a difference frequency that matches the material resonance. Further, they must act in the first two steps along the path to the third order polarization of the sample. These first two steps together prepare the Raman resonant material coherence and can be referred to as the ‘doorway’ stage of the Raman 4WM event.

Suppose the incident colours are such that the required Raman resonance (ω_R) appears at $\omega_1 - \omega_2 \approx \omega_R$ (with $\omega_1 > \omega_2$). Thus the appropriate generators for the two-step doorway stage, common to all of the Raman spectroscopies, must be and , (and their conjugates, and). These differ only in the permutation of the ordering of the actions of fields 1 and 2. The usual algebra of exponents tells us that this doorway stage produces an intermediate polarization that oscillates at $\omega_1 - \omega_2 \approx \omega_R$. The resonantly produced Raman coherence having been established, it remains only to probe this intermediate polarization, that is, to convert it into an optical polarization from which the signal at optical frequencies is prepared. This is accomplished by the action of the third field which converts the low frequency Raman coherence into an optical one. This in turn, leads to the signal. This last two-step event can be referred to as the ‘window’ stage of the 4WM process. Obviously there are at most only six possible choices for this

third field: ϵ_j and ϵ_j^* with $j = 1, 2, 3$. In this way we have isolated from the original 108 4WM generators the 12 that are responsible for all of the Raman spectroscopies. The choice of the probe field determines the frequency of the signal as well as its wavevector. While all types of Raman signal must be present at some level of intensity in any given experiment, it is a matter of experimental design—the detected ω_s and the aperture selected \mathbf{k}_s —as to which one Raman spectroscopy is actually being studied.

This classification by field generators in the complex field representation goes a long way towards organizing the nonlinear spectroscopies that carry at least one resonance. However it must be remembered that, in emphasizing a field ordering that locates the essential Raman resonance, we have neglected any other possible resonant and all nonresonant contributions to the third order polarization. While any additional resonance(s) are important to both Class I and Class II spectroscopies, the nonresonant contributions play no role in Class I spectroscopies, but must not be ignored in Class II studies. If one starts with the generator $\epsilon_1 \epsilon_2^* \epsilon_3$ and then permutes the ordering of the three distinct complex field amplitudes, one arrives at 6 (3!) generators, only two

of which induce the Raman resonance at $\omega_1 - \omega_2 \approx \omega_R$ ($\epsilon_1 \epsilon_2^* \epsilon_3$ and $\epsilon_2^* \epsilon_1 \epsilon_3$). The remaining four can only polarize the material without this Raman resonance ($\omega_3 \neq \omega_1, \omega_2$), but, if otherwise resonant, it can interfere with the Raman lineshape. Also when the issue of time resolved spectroscopies arises, the time ordering of field actions is under experimental control, and the active field generators are limited not only by requirements of resonance but by their actual time ordering in the laboratory.

In any case, the polarizing action upon the material by a given generator must be followed in more detail. In density matrix evolution, each specified field action transforms either the ‘ket’ or the ‘bra’ side of the density matrix. Thus for any specified s th order generator, there can be 2^s detailed paths of evolution. In addition, evolution for each of the $s!$ generators corresponding to all possible field orderings must be considered. One then has altogether 2^s paths of evolution. For $s = 3$ there are 48—eight for each of six generators.

B1.3.2.4 TIME EVOLUTION OF THE THIRD ORDER POLARIZATION BY WAVE MIXING ENERGY LEVEL (WMEL) DIAGRAMS. THE RAMAN SPECTROSCOPIES CLASSIFIED

The general task is to trace the evolution of the third order polarization of the material created by each of the above 12 Raman field operators. For brevity, we choose to select only the subset of eight that is based on two colours only—a situation that is common to almost all of the Raman spectroscopies. Three-colour Raman studies are rather rare, but are most interesting, as demonstrated at both third and fifth order by the work in Wright’s laboratory [21, 22, 23 and 24]. That work anticipates variations that include infrared resonances and the birth of doubly resonant vibrational spectroscopy (DOVE) and its two-dimensional Fourier transform representations analogous to 2D NMR [25].

Interestingly, three-colour spectroscopies at third order can only be of Class II, since the generators cannot possibly contain any quadrature. Maximal quadrature is necessary for Class I.

For the two-colour spectroscopies, maximal quadrature is possible and both Class I and Class II events are accounted for. Thus we trace diagrammatically the evolution to produce a signal field caused by the eight generators: (i) the four $(\epsilon_1 \epsilon_2^*) \epsilon_1^*$, $(\epsilon_1 \epsilon_2^*) \epsilon_2^*$, $(\epsilon_1 \epsilon_2^*) \epsilon_1$ and $(\epsilon_1 \epsilon_2^*) \epsilon_2$ and (ii) the four with the first two fields permuted, $(\epsilon_2^* \epsilon_1) \epsilon_1^*$, $(\epsilon_2^* \epsilon_1) \epsilon_2^*$, $(\epsilon_2^* \epsilon_1) \epsilon_1$ and $(\epsilon_2^* \epsilon_1) \epsilon_2$.

In each case we have indicated the doorway stage using parentheses. We note how in each of the two groups (i) and

The appropriate (complex) susceptibility tensor for this generator is $\chi^{(3)}(\omega_p = \omega_i + \omega_j + \omega_k)$.

When resonances, or near resonances, are present in the 4WM process, the ordering of the field actions in the perturbative treatment (equation (B1.3.1)), can be highly significant. Though the three-colour generators ($\epsilon_i \epsilon_j \epsilon_k$, $\epsilon_j \epsilon_k \epsilon_i$, $\epsilon_k \epsilon_i \epsilon_j$, . . .) have identical frequency and wavevector algebra, their associated susceptibility functions ($\chi^{(3)}(\omega_p = \omega_i + \omega_j + \omega_k)$, $\chi^{(3)}(\omega_p = \omega_j + \omega_k + \omega_i)$, $\chi^{(3)}(\omega_p = \omega_k + \omega_i + \omega_j)$, . . .) are, in general, different. As a result of the different colour ordering, two of their three energy denominator factors must differ. For this reason, the field ordering in each generator, together with its own response function, must be regarded individually.

The fourth electromagnetic wave, E_{new} , shall henceforth be called the signal wave, $E_s = \frac{1}{2}(\epsilon_s + \epsilon_s^*)$. It always must carry the same frequency as that of the polarization wave ($\omega_p = \omega_s$). It is launched by the collapse of this wave, provided that the polarization extends coherently over at least a few wavelengths of the incident light and that $\mathbf{k}_n = \mathbf{k}_s$.

The latter condition corresponds to the phase matching requirement already mentioned—the wavelength and direction of the material polarization wave must match those of the new EM wave as closely as possible. However, for all Class I spectroscopies, this condition is automatically achieved because of quadrature. In fact, this is true for all ‘quadrature’ spectroscopies—the Class I spectroscopies being the principal such, but, as noted, it is a nontrivial requirement in the ‘nonquadrature’ Class II spectroscopies, particularly in optically dispersive media.

In the complex mathematical representation, ‘quadrature’ means that, at the $(s + 1)$ wave mixing level, the product of s input fields constituting the s th order generator and the signal field can be organized as a product of $(s + 1)/2$ conjugately paired fields. Such a pair for field i is given by $\epsilon_i \epsilon_i^* = |\epsilon_i|^2$. One sees that the exponent algebra for such a pair removes all dependence on the $\text{Re}(\omega_i)$ and $\text{Re}(\mathbf{k}_i)$, thus automatically removing all oscillations as well as satisfying the phase-matching requirement. A necessary (but not sufficient) requirement for full quadrature is for s to be odd and also that half of the $s + 1$ fields be found to act conjugately with respect to the other half. Thus, for $s + 1$ fields, whenever the number of nonconjugate fields differs from the number of conjugate fields, one can only have ‘nonquadrature’. Phase matching then must become an issue. This must always be the case for odd-wave mixing (s is even), and it is also true for the above set of 27 frequency summing generators (for ND4WM). Thus for the currently considered generator, $\epsilon_i \epsilon_j \epsilon_k$, all three fields (i, j and k) act nonconjugately, so quadrature at the four-wave level simply is not possible.

B1.3.2.3 THE FIELD GENERATORS FOR ALL THIRD ORDER RAMAN SPECTROSCOPIES

We are now prepared to uncover all of the third order Raman spectroscopies (table B1.3.1 and table B1.3.2) and, in doing so, indicate how one might proceed to reveal the Raman events at higher order as well. Of the 108 pairs of conjugate generators, the remaining 81, unlike the above 27, are characterized by having one of the three fields acting conjugately with respect to the remaining two. Nine of these 81 terms generate fully degenerate 4WM. They constitute the ‘one-colour’ terms: $\epsilon_i^* \epsilon_i \epsilon_i + \text{cc}$, $\epsilon_i \epsilon_i^* \epsilon_i + \text{cc}$ and

$\epsilon_i \epsilon_i \epsilon_i^* + \text{cc}$ ($i = 1, 2, \text{ or } 3$) with susceptibility $\chi^{(3)}(\omega_s = \omega_i)$, since $\omega_s = -\omega_i + \omega_i + \omega_i = \omega_i$ with wavevector $\mathbf{k}_s = -\mathbf{k}_i + \mathbf{k}_i + \mathbf{k}_i = \mathbf{k}_i$. Their full degeneracy is evident since all four fields carry the same frequency (apart from sign). Resonances appear in the electric susceptibilities when, by choice of incident colours and their signs, one or more of their energy denominators (s in number at s th order) approaches a very small value because the appropriate algebraic colour combination matches material energy gaps. All Raman spectroscopies must, by definition, contain at least one low frequency resonance. When using only optical frequencies,

chromophore). This matter–bath interaction is an important, usually dominant, source of damping of the macroscopic coherence. The radiative blackbody (bb) background is another ever-present bath that imposes radiative damping of excited states, also destroying coherences.

For $s = 3$, the time evolution of the system is tracked by following the stepwise changes in the bra state, $\langle j|$, or the ket state, $|k\rangle$, of the system caused by each of the three successive field interventions. This perturbative evolution of the density operator, or of the density matrix, is conveniently depicted diagrammatically using double sided Feynman diagrams or, equivalently, the WMEL diagrams. The latter are preferred since light/matter resonances are explicitly exposed. In WMEL diagrams, the energy levels of the constituents of the matter are laid out as solid horizontal lines to indicate the states (called ‘real’) that are active in a resonance, and as dashed horizontal lines (or no lines) when they serve as nonresonant (‘virtual’) states. The perturbative evolution of the density matrix is depicted using vertically oriented arrows for each of the field actions that appears in a given generator. These arrows are placed from left to right in the diagram in the same order as the corresponding field action in the generator. The arrow length is scaled to the frequency of the acting field. Solid arrows indicate evolution from the old ket (tail of arrow) to the new ket (head of arrow); dashed arrows indicate evolution from the old bra (tail of arrow) to the new bra (head of arrow). For a field acting nonconjugately, like ϵ_i , the frequency is positively signed, ω_i , and the arrow for a ket change points up

and that for a bra change points down. When the field acts conjugately, ω_1 , the frequency is negatively signed, $-\omega_1$, and a ket changing arrow points down, while a bra changing arrow points up. These rules allow one to depict diagrammatically any and all density matrix evolutions at any order. Given the option of a bra or a ket change at each field action, one sees how a given s th order generator leads to 2^s diagrams, or paths of evolution. Normally only some (if any) encounter resonances. A recipe has been published [6] that allows one to translate any WMEL diagram into the analytic expression for its corresponding electrical susceptibility. After s arrows have appeared (for an s th order evolution), the $(s + 1)$ th field is indicated for any WMEL diagram of the nonquadrature class by a vertical wavy *line segment* whose vertical length scales to the signal frequency. For the WMEL diagrams of the full quadrature sort, the $(s + 1)$ th field must be conjugate to one of the incident fields, so the wavy segment becomes a wavy arrow; either solid (ket-side action) or dashed (bra-side action).

Of the four possible WMEL diagrams for each the and doorway generators, only one encounters the Raman resonance in each case. We start with two parallel horizontal solid lines, together representing the energy gap of a Raman resonance. For ket evolution using ω_1 , we start on the left at the lowest solid line (the ground state, g) and draw a long solid arrow pointing up ($+\omega_1$), followed just to the right by a shorter solid arrow pointing down ($-\omega_2$) to reach the upper solid horizontal line, f . The head of the first arrow brings the ket to a virtual state, from which the second arrow carries the ket to the upper of the two levels of the Raman transition. Since the bra is until now unchanged, it remains in g ($\langle g|$); this doorway event leaves the density matrix at second order off-diagonal in which is not zero. Thus a Raman coherence has been established. Analogously, the doorway action on the ket side must be short solid arrow down ($-\omega_2$) from g to a virtual ket state, then long arrow up ($+\omega_1$) to f from the virtual state. This evolution also produces χ . Both doorway actions contain the same Raman resonance denominator, but differ in the denominator appearing at the first step; the downward action is inherently anti-resonant ('N' for nonresonant) in the first step, the upward action is potentially resonant ('R' for resonant) in the first step and is therefore stronger. Accordingly, we distinguish these two doorway events by labels D_N and D_R , respectively (see figure B1.3.2). In resonance Raman spectroscopy, this first step in D_R is fully resonant and overwhelms D_N . (The neglect of D_N is known as the rotating wave approximation.) It is unnecessary to explore the bra-side version of these doorway actions, for they would appear in the fully conjugate version of these doorway events. Each of the doorway steps, D_R

-12-

and D_N , may be followed by any one of eight window events. The WMEL diagrams for the window events consist of the arrow for the last step of the third order polarization and the wavy segment for the signal wave. There are eight such window diagrams since each of the two steps can involve two colours and either bra- or ket-side evolution. These eight window WMEL diagrams are shown in figure B1.3.2(a) and figure B1.3.2(b) and are identified alphabetically. These also carry potentially resonant and anti-resonant properties in the third energy denominator (the first window step) and accordingly are labelled W_R and W_N , where, as before, $W_R > W_N$. If the third step is completely resonant, $W_R \gg W_N$, and W_N may be completely neglected (as with $D_R \gg D_N$).

Figure B1.3.2. The separate WMEL diagrams for the doorway and window stages of the Raman spectroscopies. Solid and dashed vertical arrows correspond to ket- and bra-side light/matter interactions, respectively. The signal field is denoted by the vertical wavy line (arrow). The ground and final molecular levels (solid horizontal lines) are labelled g and f , while the virtual levels (dashed horizontal lines) are labelled j and k . The associated generators are given below each diagram. The doorway/window stages are classified as potentially resonant (D_R/W_R) or certainly nonresonant (D_N/W_N). In addition, the window stages are labelled alphabetically in order to distinguish the Raman techniques by their window stage WMEL diagram(s)

(as in table B1.3.1 and table B1.3.2 and figure B1.3.1). (a) The doorway and window stage WMEL diagrams for SR, SRS and RRS. (b) The doorway and window stage WMEL diagrams for CARS and CSRS.

-13-

It is now possible to label every one of the Raman spectroscopies listed in [table B1.3.1](#) and [table B1.3.2](#) according to its essential doorway/window WMEL diagram. This is shown in the third column of those tables. Again, the analytic form of the associated susceptibilities is obtained by recipe from the diagrams. When additional resonances are present, other WMEL diagrams must be included for both Class I and Class II spectroscopies. For the Class II spectroscopies, all of the nonresonant WMEL diagrams must be included as well.

B1.3.2.5 THE MICROSCOPIC HYPERPOLARIZABILITY TENSOR, ORIENTATIONAL AVERAGING, THE KRAMERS–HEISENBERG EXPRESSION AND DEPOLARIZATION RATIOS

As implied by the trace expression for the macroscopic optical polarization, the macroscopic electrical susceptibility tensor at any order can be written in terms of an ensemble average over the microscopic nonlinear polarizability tensors of the individual constituents.

(A) MICROSCOPIC HYPERPOLARIZABILITY AND ORIENTATIONAL AVERAGING

Consider an isotropic medium that consists of independent and identical microscopic chromophores (molecules) at number density N . At s th order, each element of the macroscopic susceptibility tensor, given in laboratory Cartesian coordinates A, B, C, D , must carry $s + 1$ (laboratory) Cartesian indices (X, Y or Z) and therefore number altogether $3^{(s+1)}$. Thus the third order susceptibility tensor contains 81 elements. Each tensor element of the macroscopic susceptibility is directly proportional to the sum over all elements of the corresponding microscopic, or molecular, hyperpolarizability tensor. The latter are expressed in terms of the four local (molecule based) Cartesian coordinates, a, b, c, d (each can be x, y , or z —accounting for all 81 elements of the *microscopic* tensor). To account for the contribution to the macroscopic susceptibility from each molecule, one must sum over all molecules in a unit volume, explicitly treating all possible orientations, since the projection of a microscopic induced dipole onto the X, Y and Z laboratory coordinates depends very much on the molecular orientation. This is accomplished by averaging the microscopic hyperpolarizability contribution to the susceptibility over a normalized distribution of orientations, and then simply multiplying by the number density, N . Let the orientational averaging be denoted by $\langle \dots \rangle$. For any macroscopic tensor element, $\chi_{ABCD}^{(3)}$, one finds

$$\chi_{ABCD}^{(3)} = \frac{L^3}{\hbar^3 \epsilon_0} N \sum_{a,b,c,d} \langle (A, a)(B, b)(C, c)(D, d) \rangle \gamma_{abcd} \quad (\text{B1.3.11})$$

where (A, a) etc are the direction cosines linking the specified local Cartesian axes with specified laboratory axes and L is a ‘local’ field factor. (The field experienced by the molecule is the incident field altered by polarization effects.) Often the \hbar^{-S} factor is absorbed into the definition of the s th order hyperpolarizability.

The microscopic polarization involves four molecular based transition moment vectors—the induced dipole is along a , the first index. The transition moments along b, c and d are coupled to the laboratory axes, B, C and D , respectively, along which the successive incident (or black-body) fields are polarized. The four transition moment unit vectors have been extracted and projected onto the laboratory axes: A —the direction of the induced macroscopic polarization, B —the polarization of the first acting field, C —the polarization of the second acting field and D —the polarization of the third acting field. The product of the four direction cosines is subjected to the orientational averaging process, as indicated. Each such average belongs to its

corresponding scalar tensor element γ_{abcd} . It is important to sum over all

-14-

local Cartesian indices, since all elements of γ can contribute to each tensor element of $\chi^{(3)}$. At third order, the averaging over the projection of microscopic unit vectors to macroscopic, such as those in equation (B1.3.11), is identical to that found in two-photon spectroscopy (another Class I spectroscopy at third order). This has been treated in a general way (including circularly polarized light) according to molecular symmetry considerations by Monson and McClain [26].

For an isotropic material, all orientations are equally probable and all such products that have an odd number of ‘like’ direction cosines will vanish upon averaging². This restricts the nonvanishing tensor elements to those such as $\chi_{AAAA}^{(3)}$, $\chi_{ABBA}^{(3)}$ etc. Similarly for the elements γ_{abcd} . Such orientational averaging is crucial in dictating how the signal field in any spectroscopy is polarized. In turn, polarization measurements can lead to important quantitative information about the elements of the macroscopic and microscopic tensors.

The passage from microscopic to macroscopic (equation (B1.3.11)) clearly exposes the additivity of the microscopic hyperpolarizabilities. Significantly, it is seen immediately why $\chi^{(3)}$ is linear in concentration, N . This brings out one of the major distinctions between the Class I and Class II spectroscopies (see item (iii) in section B1.3.1). The signals from Class I, being proportional to $\text{Im } \chi^{(3)}$, are *linear* in concentration. Those (homodyne signals) from Class II are proportional to $|\chi^{(3)}|^2$ and therefore must be *quadratic* in concentration. (However, Class II spectroscopies that are heterodyne detected are proportional to $\chi^{(3)}$ and are linear in N .)

(B) THE MICROSCOPIC HYPERPOLARIZABILITY IN TERMS OF THE LINEAR POLARIZABILITY: THE KRAMERS–HEISENBERG EQUATION AND PLACZEK LINEAR POLARIZABILITY THEORY OF THE RAMAN EFFECT

The original Placzek theory of Raman scattering [30] was in terms of the linear, or first order microscopic polarizability, α (a second rank tensor), not the third order hyperpolarizability, γ (a fourth rank tensor). The Dirac and Kramers–Heisenberg quantum theory for linear dispersion did account for Raman scattering. It turns out that this link of properties at third order to those at first order works well for the electronically nonresonant Raman processes, but it cannot hold rigorously for the fully (triply) resonant Raman spectroscopies. However, provided one discards the important line shaping phenomenon called ‘pure dephasing’, one can show how the third order susceptibility does reduce to the treatment based on the (linear) polarizability tensor [6, 27].

What is the phenomenon ‘pure dephasing’ that one cannot formally encounter in the linear polarizability theories of Raman spectroscopies? It arises when theory is obliged to treat the environment of the spectroscopically active entity as a ‘bath’ that statistically modulates its states. In simple terms, there are two mechanisms for the irreversible decay of a coherent state such as a macroscopically coherent polarization wave. One involves the destruction by the bath of the local induced dipoles that make up the wave (a lifetime effect); the other involves the bath induced randomization of these induced dipoles (without their destruction). This latter mechanism is called pure dephasing. Together, their action is responsible for dephasing of a pure coherence. In addition, if the system is inherently inhomogeneous in the distribution of the two-level energy gap of the coherence, the local coherences will oscillate at slightly different frequencies causing, as these walk off, the macroscopic coherence, and its signal, to decay—even while the individual local coherences might not. This is especially important for the Class II spectroscopies. Unlike the first two dephasing mechanisms, this third kind can be reversed by attending to signals generated by the appropriate Fourier components of the subsequent field actions. The original macroscopic coherence will be reassembled (at least partially) in due course, to produce a renewed signal, called an ‘echo’. For an electronic coherence made by a single optical field, this happens at the four-wave mixing level. However for the Raman spectroscopies, *two* (conjugately acting) optical fields are needed to create the vibrational coherence, and hence the true Raman echo appears at the eight-wave mixing level

where $\chi^{(7)}$ is the important susceptibility. (We shall see that a *quasi* Raman echo can be exploited at the $\chi^{(5)}$ level.)

The important and frequently ignored fact is that Raman theory based on the polarizability tensor cannot contain the randomization mechanism for dephasing (pure dephasing). This mechanism is especially important in electronically resonant Raman spectroscopy in the condensed phase. The absence of pure dephasing in linear polarizability theory arises simply because the perturbative treatment upon which it is based involves the *independent* evolution of the bra and the ket states of the system. Conversely, the third order susceptibility approach, based on the perturbative development of the density operator, links together the evolution of the bra and ket states and easily incorporates pure dephasing. Furthermore, in resonance Raman spectroscopy, it is the pure dephasing mechanism that governs the interesting competition between resonance fluorescence and resonance Raman scattering [6]. In the linear polarization theory these are fixed in their relation, and the true resonance fluorescence component becomes an indistinguishable part of the Raman line shape. (However, interestingly, if the exciting light itself is incoherent, or the exciting light consists of sufficiently short pulses, even the linear polarizability theory tells how the resonance fluorescence-like component becomes distinguishable from the Raman-like signal [20].)

At the linear level, the microscopic induced dipole vector on a single molecule in the local Cartesian coordinate system is simply written as $\mu^{(1)} = \alpha \mathbf{E}$ where \mathbf{E} is the applied field also expressed in the local Cartesian system. In full matrix language, in which the local second rank polarizability tensor is exposed, we can write:

If we neglect pure dephasing, the general tensor element of the third order hyperpolarizability relates to those of the first order polarizability tensor according to

$$(B1.3.12)$$

Here, the linear polarizability, $\alpha_{bc}(\omega_1, \omega_2)$, corresponds to the doorway stage of the 4WM process while to the window stage. We also see the (complex) Raman resonant energy denominator exposed. Of the three energy denominator factors required at third order, the remaining two appear, one each, in the two linear polarizability tensor elements.

In fact, each linear polarizability itself consists of a sum of two terms, one potentially *resonant* and the other *anti-resonant*, corresponding to the two doorway events, D_R and D_N , and the window events, W_R and W_N , described above. The hyperpolarizability chosen in equation (B1.3.12) happens to belong to the generator. As noted, such three-colour generators cannot produce Class I spectroscopies (full quadrature with three colours is not possible). Only the two-colour generators are able to create the Class I Raman spectroscopies and, in any case, only two colours are normally used for the Class II Raman spectroscopies as well.

For linear polarizability elements that are pure real, we see that (from equation (B1.3.12))

$$\text{Im}[\gamma_{abcd}] = \frac{-\gamma_R}{(\omega_1 - \omega_2 - \omega_R)^2 + \gamma_R^2} \alpha_{bc} \alpha_{ad}.$$

When $\omega_1 = \omega_2$ (two colours), this is relevant to the Class I Raman spectroscopies (see section B1.3.2.1). In

this case we expose a Lorentzian Raman lineshape with an HWHM of γ_R . At this point, the notation for the elements of the polarizability tensor suppresses the identity of the Raman transition, so it is now necessary to be more specific.

Consider Raman transitions between thermalized *molecular* eigenstate g (ground) and *molecular* eigenstate f (final). The quantum mechanical expression for α_{bc} responding to colours i and j is the famous (thermalized) *Kramers–Heisenberg equation* [29]

$$(\alpha_{bc}(\omega_i, \omega_j))_{gf} = \sum_n \left(\frac{\langle g|\mu_b|n\rangle\langle n|\mu_c|f\rangle}{\omega_{ng} - \omega_i} + \frac{\langle g|\mu_c|n\rangle\langle n|\mu_b|f\rangle}{\omega_{ng} + \omega_j} \right) \quad (\text{B1.3.13})$$

where the notation on the left-hand side recognizes the Raman transition between molecular eigenstates g and f . The sum on n is over all molecular eigenstates. One should be reminded that the ‘ground state’ should actually be a thermal distribution over Boltzmann weighted states. Thus at the hyperpolarizability level, one would write $\sum_g W_g (\gamma_{abcd})_{gf}$, where W_g is the appropriate Boltzmann weighting factor, $\exp[-\hbar\omega_g/kT]$. This detail is suppressed in what follows.

To branch into electronic, vibrational and rotational Raman spectroscopy, the Born–Oppenheimer (B–O) approximation must be introduced, as needed, to replace the molecular eigenstates as rovibronic products. For example, consider vibrational Raman scattering within the ground electronic state (or, analogously, within any other electronic state). For scattering between vibrational levels v and v' in the ground electronic state, we expand the molecular eigenstate notation to $|g\rangle \equiv |g\rangle|v\rangle$ and $|f\rangle \equiv |g\rangle|v'\rangle$ (the intermediate states, $|n\rangle$, may be left as molecular eigenstates). The curved bracket refers to the electronic eigenstate and the straight bracket to the vibrational states (where until now it referred to the molecular eigenstate). Now equation (B1.3.13) becomes

$$(\alpha_{bc}(\omega_i, \omega_j))_{vv'} = \langle v| \left[\sum_n \left(\frac{\langle g|\mu_b|n\rangle\langle n|\mu_c|g\rangle}{\omega_{ng} - \omega_i} + \frac{\langle g|\mu_c|n\rangle\langle n|\mu_b|g\rangle}{\omega_{ng} + \omega_j} \right) \right] |v'\rangle.$$

We note that the expression in brackets is just the $b c$ tensor element of the *electronic* polarizability in the ground electronic state, $\alpha_{bc}^{\text{el}}(\omega_i, \omega_j)$. Thus

$$(\alpha_{bc}(\omega_i, \omega_j))_{vv'} = \langle v|\alpha_{bc}^{\text{el}}(\omega_i, \omega_j)|v'\rangle. \quad (\text{B1.3.14})$$

Since the vibrational eigenstates of the ground electronic state constitute an orthonormal basis set, the off-diagonal matrix elements in equation (B1.3.14) will vanish unless the ground state electronic polarizability depends on nuclear coordinates. (This is the Raman analogue of the requirement in infrared spectroscopy that, to observe a transition, the electronic dipole moment in the ground electronic state must properly vary with nuclear displacements from

equilibrium.) Indeed such electronic properties do depend on nuclear coordinates, for in the B–O approximation electronic eigenstates are parametrized by the positional coordinates of the constituent nuclei. For matrix elements in vibrational space, these coordinates become variables and the electronic polarizability (or the electronic dipole moment) is expanded in a Taylor series in nuclear displacements. Usually the normal mode approximation is introduced into the vibrational space problem (though it need not be) and the expansion is in terms of the normal displacement coordinates, $\{\Delta Q_i\}$, of the molecule. Thus for the electronic

polarizability we have:

$$\alpha_{bc}^{\text{el}} = (\alpha_{bc}^{\text{el}})_0 + \sum_{i=1} \left(\frac{\partial \alpha_{bc}^{\text{el}}}{\partial Q_i} \right)_0 \Delta Q_i + \frac{1}{2} \sum_{i=1} \sum_{j=1} \left(\frac{\partial^2 \alpha_{bc}^{\text{el}}}{\partial Q_i \partial Q_j} \right)_0 \Delta Q_i \Delta Q_j + \dots \quad (\text{B1.3.15})$$

the leading term of which is unable to promote a vibrational transition because

$$\langle v | (\alpha_{bc}^{\text{el}})_0 | v' \rangle = (\alpha_{bc}^{\text{el}})_0 \langle v | v' \rangle = (\alpha_{bc}^{\text{el}})_0 \delta_{vv'}. \quad (\text{The } v = v' \text{ situation corresponds to Rayleigh scattering for which}$$

this leading term is the principal contributor.) The ΔQ_i in the second term is able to promote the scattering of fundamentals, since $\langle v | \Delta Q_i | v + 1 \rangle$ need not vanish. The $\Delta Q_i \Delta Q_j$ in the third set of terms can cause scattering of the first overtones ($i = j$) and combination states ($i \neq j$), etc, for the subsequent terms. As usual in spectroscopy, point group theory governs the selection rules for such matrix elements. As already noted these are identical to the two-photon selection rules [26], though here in vibrational space.

This linear polarizability theory of Raman scattering [30] forms the basis for bond polarizability theory of the Raman effect. Here the polarizability derivative is discussed in terms of its projection onto bonds of a molecule and the concept of additivity and the transferability of such bond specific polarizability derivatives can be discussed, and even semiquantitatively supported. Further, the vibronic (vibrational–electronic) theory of Raman scattering appears at this level. It introduces the Herzberg–Teller development for the nuclear coordinate dependence of electronic states, therefore that of the electronic transition moments and hence that of the electronic polarizability. This leads to the so-called ‘A’, ‘B’ and ‘C’ terms for Raman scattering, each having a different analytical form for the dispersive behaviour of the Raman cross-section as the exciting light moves from a nonresonant region towards an electronically resonant situation. An early review of these subjects can be found in [31].

For excitation at a wavenumber $\bar{\nu}_1$, ($\bar{\nu}_1 = \omega_1/2\pi c$), and the Raman wavenumber at $\bar{\nu}_R$, the total Raman cross-section for scattering in isotropic media^{3, 4} onto a spherical surface of 4π radians, for all analysing polarizations, for excitation with linearly polarized or unpolarized light, and integration over the Raman line, we have in terms of rotational invariants of the linear polarizability:

$$\sigma_R(\bar{\nu}_1) = \frac{32\pi^3}{9} \left(\frac{e^2}{4\pi\epsilon_0\hbar c} \right)^2 \bar{\nu}_1 (\bar{\nu}_1 \pm \bar{\nu}_R)^3 \{ \Sigma^0 + \Sigma^1 + \Sigma^2 \}. \quad (\text{B1.3.16})$$

The upper sign is for anti-Stokes scattering, the lower for Stokes scattering. The factor in the parentheses is just the fine-structure constant and Σ^0 , Σ^1 , Σ^2 are the three rotationally invariant tensor elements of the hyperpolarizability (or the linear polarizability when pure dephasing is ignored), which are given by:

$$\Sigma^0 = \frac{1}{3} \sum_{\rho, \sigma} \gamma_{\sigma\rho\rho\sigma} \approx \frac{1}{3\Omega} \left| \sum_{\rho} \alpha_{\rho\rho} \right|^2 \quad (\text{B1.3.17})$$

$$\Sigma^1 = \frac{1}{2} \sum_{\rho, \sigma} (\gamma_{\rho\rho\sigma\sigma} - \gamma_{\rho\sigma\rho\sigma}) \approx \frac{1}{4\Omega} \sum_{\rho, \sigma \neq \rho} |\alpha_{\rho\sigma} - \alpha_{\sigma\rho}|^2 \quad (\text{B1.3.18})$$

and

$$\Sigma^2 = \frac{1}{2} \sum_{\rho,\sigma} (\gamma_{\rho\rho\sigma\sigma} + \gamma_{\rho\sigma\rho\sigma}) - \frac{1}{3} \sum_{\rho,\sigma} \gamma_{\rho\sigma\sigma\rho} \approx \frac{1}{4\Omega} \sum_{\rho,\sigma \neq \rho} |\alpha_{\rho\sigma} + \alpha_{\sigma\rho}|^2 + \frac{1}{6\Omega} \sum_{\rho,\sigma} |\alpha_{\rho\rho} - \alpha_{\sigma\sigma}|^2 \quad (\text{B1.3.19})$$

where Ω is the Raman resonant energy denominator, $\omega_1 - \omega_2 - \omega_R + i\gamma_R$. With appropriate algebra, one finds that their sum is given by: $\Sigma^0 + \Sigma^1 + \Sigma^2 = \sum_{\rho,\sigma} \gamma_{\rho\rho\sigma\sigma}$, or in terms of the linear polarizability tensor elements: $\Sigma^0 + \Sigma^1 + \Sigma^2 = \frac{1}{\Omega} \sum_{\rho,\sigma} |\alpha_{\rho\sigma}|^2$.

Experimentally, it is these invariants (equation (B1.3.17), equation (B1.3.18) and equation (B1.3.19)) that can be obtained by scattering intensity measurements, though clearly not by measuring the total cross-section only.

Measurement of the total Raman cross-section is an experimental challenge. More common are reports of the differential Raman cross-section, $d\sigma_R/d\Omega$, which is proportional to the intensity of the scattered radiation that falls within the element of solid angle $d\Omega$ when viewing along a direction that is to be specified [15]. Its value depends on the design of the Raman scattering experiment.

In the appendix, we present the differential Raman scattering cross-section for viewing along any wavevector in the scattering sphere for both linearly and circularly polarized excitation. The more conventional geometries used for exciting and analysing Raman scattering are discussed next.

Suppose the exciting beam travels along X , and is linearly (l) polarized along Z . A popular experimental geometry is to view the scattered light along Y (at $\pi/2$ radians to the plane defined by the wavevector, and the polarization unit vector, e_Z , of the exciting light). One analyses the Z polarized component of the scattered light, called I_{\parallel} (I_Z), and the X polarized component, called I_{\perp} (I_X). (Careful work must properly correct for the finite solid angle of detection.) The two intensities are directly proportional to the differential cross-section given by

$$\left(\frac{d\sigma}{d\Omega}\right)_{\parallel} = 4\pi^2 \left(\frac{e^2}{4\pi\epsilon_0\hbar c}\right)^2 \bar{v}_1 (\bar{v}_1 \pm \bar{v}_R)^3 \left(\frac{5\Sigma^0 + 2\Sigma^2}{15}\right) \quad (\text{B1.3.20})$$

-19-

and

$$\left(\frac{d\sigma}{d\Omega}\right)_{\perp} = 4\pi^2 \left(\frac{e^2}{4\pi\epsilon_0\hbar c}\right)^2 \bar{v}_1 (\bar{v}_1 \pm \bar{v}_R)^3 \left(\frac{5\Sigma^1 + 3\Sigma^2}{30}\right). \quad (\text{B1.3.21})$$

The depolarization ratio is defined as

$$\rho_1 = \frac{I_{\perp}}{I_{\parallel}} \quad (\text{B1.3.22})$$

which for the present case of an orientationally averaged isotropic assembly of Raman scatterers reduces to:

$$\rho_1 = \frac{5\Sigma^1 + 3\Sigma^2}{10\Sigma^0 + 4\Sigma^2}. \quad (\text{B1.3.23})$$

This result is general, for it includes the case where the tensor elements are complex, regardless of whether or

not the hyperpolarizability tensor is built of the linear polarizability.

Another frequent experimental configuration uses naturally (n) polarized incident light, with the same viewing geometry and polarization analysis. Such light may be regarded as polarized equally along Z (as before) and along the viewing axis, Y . Given the I_{\perp} and I_{\parallel} as defined in the linearly polarized experiment, one can reason that now with naturally polarized excitation $I_Z \propto I_{\parallel} + I_{\perp}$ (where the additional I_{\perp} term along Z originates from the Y polarized excitation). Similarly we expect that $I_X \propto 2I_{\perp}$, one I_{\perp} from each of the two excitation polarizations. The differential Raman cross-sections for naturally polarized excitation are defined as

$$\left(\frac{d\sigma}{d\Omega}\right)_X = 4\pi^2 \left(\frac{e^2}{4\pi\epsilon_0\hbar c}\right)^2 \bar{\nu}_1(\bar{\nu}_1 \pm \bar{\nu}_R)^3 \left(\frac{5\Sigma^1 + 3\Sigma^2}{30}\right)$$

and

$$\left(\frac{d\sigma}{d\Omega}\right)_Z = 4\pi^2 \left(\frac{e^2}{4\pi\epsilon_0\hbar c}\right)^2 \bar{\nu}_1(\bar{\nu}_1 \pm \bar{\nu}_R)^3 \left(\frac{10\Sigma^0 + 5\Sigma^1 + 7\Sigma^2}{60}\right).$$

Thus one predicts that the depolarization ratio for excitation with natural light should be

$$\rho_n = \frac{I_X}{I_Z} = \frac{2I_{\perp}}{I_{\parallel} + I_{\perp}} = \frac{2\rho_1}{1 + \rho_1} = \frac{10\Sigma^1 + 6\Sigma^2}{10\Sigma^0 + 5\Sigma^1 + 7\Sigma^2} \quad (\text{B1.3.24})$$

-20-

or

$$\rho_1 = \frac{\rho_n}{2 - \rho_n}$$

two well known relations. Of course, if one does not measure the polarization of the scattered light for either experiment, the detector collects signal from the sum of the differential cross sections, $(\frac{d\sigma}{d\Omega})_{\parallel(Z)} + (\frac{d\sigma}{d\Omega})_{\perp(X)}$.

Similar reasoning shows that were one to view along the X , Y and Z axes and polarization analyse the signal each time, whether excited by linearly or by naturally polarized light, the total intensity should be given by $I_{\text{total}} \propto I_{\parallel} + 2I_{\perp}$. Given [equation \(B1.3.23\)](#), if we add its denominator to twice the numerator we find that $I_{\text{total}} \propto \{\Sigma^0 + \Sigma^1 + \Sigma^2\}$, a reassuring result.

Knowledge of the depolarization ratios allows one to classify easily the Raman modes of a molecule into symmetric and asymmetric vibrations. If a molecule is undergoing a totally symmetric vibration, the depolarization ratio, ρ_1 (ρ_n) will be less than 3/4 (6/7) and we say that the vibration is polarized (p). On the other hand, for asymmetric vibrations, the depolarization ratio will have a value close to 3/4 (6/7) and we say these vibrations are depolarized (dp) [34]. It should be stated that these values for ρ are only valid when the scattered radiation is collected at right angles to the direction of the incident light. If different geometry is used, ρ_1 and ρ_n are accordingly changed (see [the appendix](#)).

An interesting phenomenon called the ‘noncoincidence effect’ appears in the Raman spectroscopies. This is seen when a given Raman band shows a peak position and a bandwidth that differs (slightly) with the

polarization. It can be attributed to varying sensitivity of the different tensor elements to interchromophore interactions.

B1.3.3 RAMAN SPECTROSCOPY IN MODERN PHYSICS AND CHEMISTRY

Raman spectroscopy is pervasive and ever changing in modern physics and chemistry. In this section of the chapter, sources of up-to-date information are given followed by brief discussions of a number of currently employed Raman based techniques. It is impractical to discuss every possible technique and impossible to predict the many future novel uses of Raman scattering that are sure to come, but it is hoped that this section will provide a firm launching point into the modern uses of Raman spectroscopy for present and future readers.

B1.3.3.1 SOURCES OF UP-TO-DATE INFORMATION

There are three very important sources of up-to-date information on all aspects of Raman spectroscopy. Although papers dealing with Raman spectroscopy have appeared and will continue to appear in nearly every major chemical physics–physical chemistry based serial, *The Journal of Raman Spectroscopy* [35] is solely devoted to all aspects, both theoretical and experimental, of Raman spectroscopy. It originated in 1973 and continues to be a constant source of information on modern applications of Raman spectroscopy.

Advances in Infrared and Raman Spectroscopy [36] provides review articles, both fundamental and applied, in the fields

-21-

of both infrared and Raman spectroscopy. This series aims to review the progress in all areas of science and engineering in which application of these techniques has a significant impact. Thus it provides an up-to-date account of both the theory and practice of these two complementary spectroscopic techniques.

The third important source for information on modern Raman spectroscopy are the books cataloguing the proceedings of the *International Conference on Raman Spectroscopy (ICORS)* [37]. *ICORS* is held every two years at various international locations and features hundreds of contributions from leading research groups covering all areas of Raman spectroscopy. Although the published presentations are quite limited in length, they each contain references to the more substantial works and collectively provide an excellent overview of current trends in Raman spectroscopy. A ‘snapshot’ or brief summary of the 1998 conference appears at the end of this chapter.

Through these three serials, a researcher new to the field, or one working in a specialized area of Raman spectroscopy, can quickly gain access to its current status.

B1.3.3.2 SURVEY OF TECHNIQUES

With the theoretical background presented in the previous sections, it is now possible to examine specific Raman techniques. Of the list in [table B1.3.1](#), we briefly discuss and provide references to additional information for the Class I spectroscopies—spontaneous Raman scattering (SR), Fourier transform Raman scattering (FTRS), resonance Raman scattering (RRS), stimulated Raman scattering (SRS), and surface enhanced Raman scattering (SERS)—and in [table B1.3.2](#), the Class II spectroscopies—coherent Raman scattering (CRS), Raman induced Kerr-effect spectroscopy (RIKES), Raman scattering with noisy light, time resolved coherent Raman scattering (TRCRS), impulsive stimulated Raman scattering (ISRS) and higher

order and higher dimensional Raman scattering.

First we discuss some Class I spectroscopies.

(A) SPONTANEOUS RAMAN SCATTERING (SR)

Conventional spontaneous Raman scattering is the oldest and most widely used of the Raman based spectroscopic methods. It has served as a standard technique for the study of molecular vibrational and rotational levels in gases, and for both intra- and inter-molecular excitations in liquids and solids. (For example, a high resolution study of the vibrons and phonons at low temperatures in crystalline benzene has just appeared [38].)

In this earliest of Raman spectroscopies, there is only one incident field (originally sunlight or lines of the mercury lamp; today a single laser source). This is field 1 in the above language and it appears in quadrature in the two generators, and , relevant to SR. [Figure B1.3.2\(a\)](#) shows that these generators lead to four WMEL diagrams: $D_R W_R(A)$, $D_R W_N(B)$, $D_N W_R(A)$, $D_N W_N(B)$. The first is the strongest contributor (it is potentially resonant, R, in both the first and last steps). The last term is the weakest (being nonresonant, N, in both the first and last steps). We note that at the 4WM level, in all four terms, not only is field 1 in quadrature, but field 2 is likewise in quadrature (since for window events A and B, we have $\varepsilon_s = \varepsilon_2$, namely the signal field is conjugate to the action of field 2). Now, since quadrature means photons, the Raman scattering event has destroyed a photon at ω_1 , while it has created a new photon at ω_2 .

-22-

The unique feature in spontaneous Raman spectroscopy (SR) is that field 2 is not an incident field but (at room temperature and at optical frequencies) it is resonantly drawn into action from the zero-point field of the ubiquitous blackbody (bb) radiation. Its active frequency is spontaneously selected (from the infinite colours available in the blackbody) by the resonance with the Raman transition at $\omega_1 - \omega_2 = \omega_R$ in the material. The effective bb field intensity may be obtained from its energy density per unit circular frequency, $\frac{\hbar\omega_s^3}{\pi^2c^3}$, the

Einstein A coefficient at ω_2 . When the polarization field at frequency ω_s , $\mathbf{p}^{(3)}(\omega_s = \omega_1 - \omega_2 - \omega_1)$, produces an electromagnetic field which acts conjugately with this selected blackbody field (at $\omega_s = \omega_2$), the scattered Raman photon is created. Thus, one simply has growth of the blackbody radiation field at ω_2 , since full quadrature removes all oscillatory behaviour in time and all wavelike properties in space.

Unlike the typical laser source, the zero-point blackbody field is spectrally ‘white’, providing all colours, ω_2 , that seek out all $\omega_1 - \omega_2 = \omega_R$ resonances available in a given sample. Thus all possible Raman lines can be seen with a single incident source at ω_1 . Such multiplex capability is now found in the Class II spectroscopies where broadband excitation is obtained either by using modeless lasers, or a femtosecond pulse, which on first principles must be spectrally broad [32]. Another distinction between a coherent laser source and the blackbody radiation is that the zero-point field is spatially isotropic. By performing the simple wavevector algebra for SR, we find that the scattered radiation is isotropic as well. This concept of spatial incoherence will be used to explain a certain ‘stimulated’ Raman scattering event in a subsequent section.

For SR, a Class I spectroscopy, there must be a net transfer of energy between light and matter which survives averaging over many cycles of the optical field. Thus, the material must undergo a state population change such that the overall energy (light and matter) may be conserved. In Stokes vibrational Raman scattering ([figure B1.3.3\(a\)](#)), the chromophore is assumed to be in the ground vibrational state $|g\rangle$. The launching of the Stokes signal field creates a population shift from the ground state $|g\rangle$ to an excited vibrational state $|f\rangle$. Conversely, in anti-Stokes vibrational Raman scattering ([figure B1.3.3\(b\)](#)), the chromophore is assumed to be

initially in an excited vibrational state, $|f\rangle$. Thus, the launching of the anti-Stokes field leaves the chromophore in the ground vibrational state, $|g\rangle$. This process is typically weaker than the Stokes process since it requires that an excited vibrational population exist (usually $W_f \ll W_g$). In thermal equilibrium, the intensity of the anti-Stokes frequencies compared to the Stokes frequencies clearly is reduced by the Boltzmann factor, $W_f/W_g = \exp[-\hbar\omega_{fg}/kT]$ [17]. Let us now discuss the apparatus used for the production and detection of the Raman scattered radiation.

-23-

(a)

(b)

Figure B1.3.3. The full WMEL diagram (of the $D_R W_R$ sort) for spontaneous (or stimulated) (a) Stokes Raman scattering and (b) anti-Stokes Raman scattering. In Stokes scattering, the chromophore is initially in the ground vibrational state, g , and $\omega_1 > \omega_2$. In spontaneous anti-Stokes scattering, the chromophore must be initially in an excited vibrational state, f . Also note that in (b), ω_2 is (arbitrarily) defined as being greater than ω_1 .

-24-

(B) RAMAN INSTRUMENTATION

Dramatic advances in Raman instrumentation have occurred since 1928. At the beginning, various elemental

lamps served as the incident light source and photographic plates were used to detect the dispersed scattered light. Mercury arc lamps were primarily used since they had strong emission lines in the blue region of the visible spectrum (see [equation \(B1.3.16\)](#)). As in all spectroscopies, detection devices have moved from the photographic to the photoelectric.

Even while Raman spectrometers today incorporate modern technology, the fundamental components remain unchanged. Commercially, one still has an excitation source, sample illuminating optics, a scattered light collection system, a dispersive element and a detection system. Each is now briefly discussed.

Continuous wave (CW) lasers such as Ar⁺ and He–Ne are employed in commonplace Raman spectrometers. However laser sources for Raman spectroscopy now extend from the edge of the vacuum UV to the near infrared. Lasers serve as an energetic source which at the same time can be highly monochromatic, thus effectively supplying the single excitation frequency, $\bar{\nu}_1$. The beams have a small diameter which may be focused quite easily into the sample and are convenient for remote probing. Finally, almost all lasers are linearly polarized, which makes measurements of the depolarization ratio, [equation \(B1.3.22\)](#), relatively straightforward.

The laser beam is typically focused onto the sample with a simple optical lens system (though microscopes are also used). The resultant scattered radiation is often collected at 90° from the incident beam propagation and focused onto the entrance of a monochromator. The monochromator removes extraneous light from the Raman radiation by use of a series of mirrors and optical gratings. Two features of the monochromator for maximum resolution are the slit width and, for monochromatic detection, the scanning speed. The resolution of the Raman spectrum is optimized by adjusting the slit width and scanning rate, while still maintaining a strong signal intensity.

After passing through the monochromator, the signal is focused onto the detection device. These devices range from photomultiplier tubes (PMTs) in which the signal is recorded at each frequency and the spectrum is obtained by scanning over a selected frequency range, to multichannel devices, such as arrays of photodiodes and charge coupling devices, which simultaneously detect the signal over a full frequency range. One may choose a specific detection device based on the particulars of an experiment. Sensitive detection of excited vibrational states that are produced in the Class I Raman spectroscopies is an alternative that can include acoustic detection of the heat released and resonance enhanced multiphoton ionization (REMPI). For special applications microspectroscopic techniques and fibre optic probes ('optodes') are used.

This basic instrumentation, here described within the context of spontaneous Raman scattering, may be generalized to most of the other Raman processes that are discussed. Specific details can be found in the citations.

(C) FOURIER TRANSFORM RAMAN SCATTERING (FTRS)

Normal spontaneous Raman scattering suffers from lack of frequency precision and thus good spectral subtractions are not possible. Another limitation to this technique is that high resolution experiments are often difficult to perform [39]. These shortcomings have been circumvented by the development of Fourier transform (FT) Raman spectroscopy [40]. FT Raman spectroscopy employs a long wavelength laser to achieve viable interferometry,

typically a Nd:YAG operating at 1.064 μm . The laser radiation is focused into the sample where spontaneous Raman scattering occurs. The scattered light is filtered to remove backscatter and the Raman light is sent into a Michelson interferometer. An interferogram is collected and detected on a near-infrared detector (typically

an N₂ cooled Ge photoresist). The detected signal is then digitized and Fourier transformed to obtain a spectrum [41]. This technique offers many advantages over conventional Raman spectroscopy. The 1.064 μm wavelength of the incident laser is normally far from electronic transitions and reduces the likelihood of fluorescence interference. Also near-IR radiation decreases sample heating, thus higher powers can be tolerated [42]. Since the signal is obtained by interferometry, the FT instrument records the intensity of many wavelengths. Such simultaneous detection of a multitude of wavelengths is known as the multiplex advantage, and leads to improved resolution, spectral acquisition time and signal to noise ratio over ordinary spontaneous Raman scattering [39]. The improved wavelength precision gained by the use of an interferometer permits spectral subtraction, which is effective in removing background features [42]. The interferogram is then converted to a spectrum by Fourier transform techniques using computer programs. By interfacing the Raman setup with an FT-IR apparatus, one has both IR and Raman capabilities with one instrument.

Other than the obvious advantages of reduced fluorescence and high resolution, FT Raman is fast, safe and requires minimal skill, making it a popular analytic tool for the characterization of organic compounds, polymers, inorganic materials and surfaces and has been employed in many biological applications [41].

It should be noted that this technique is not without some disadvantages. The blackbody emission background in the near IR limits the upper temperature of the sample to about 200°C [43]. Then there is the ν^4 dependence of the Raman cross-section (equation (B1.3.16) and equation (B1.3.20)–equation (B1.3.21)) which calls for an order of magnitude greater excitation intensity when exciting in the near-IR rather than in the visible to produce the same signal intensity [39].

(D) RESONANCE RAMAN SCATTERING (RRS)

As the incident frequencies in any Raman spectroscopy approach an electronic transition in the material, the $D_R W_R$ term in Raman scattering is greatly enhanced. One then encounters an extremely fruitful and versatile branch of spectroscopy called resonance Raman scattering (RRS). In fact, it is fair to say that in recent years RRS (Class I or Class II) has become the most popular form of Raman based spectroscopy. On the one hand, it offers a diagnostic approach that is specific to those subsystems (even minority components) that exhibit the resonance, even the very electronic transition to which the experiment is tuned. On the other hand, it offers a powerful tool for exploring potential-energy hypersurfaces in polyatomic systems. It forms the basis for many time resolved resonant Raman spectroscopies (TRRRSs) that exploit the non-zero vibronic memory implied by an electronic resonance. It has inspired the time-domain theoretical picture of RRS which is formally the appropriate transform of the frequency domain picture [44, 45]. Here the physically appealing picture arises in which the two-step doorway event (D_R) prepares (vertically upward) a vibrational wave-packet that moves (propagates) on the upper electronic state potential energy hypersurface. In the window stage (W_R) of the 4WM event, this packet projects (vertically downward), accordingly to its lingering time on the upper surface, back onto the ground state to complete the third order induced optical polarization that leads to the new fourth wave.

RRS has also introduced the concept of a ‘Raman excitation profile’ (REP_{*j*} for the *j*th mode) [46, 47, 48, 49, 50 and 51]. An REP_{*j*} is obtained by measuring the resonance Raman scattering strength of the *j*th mode as a function of the excitation frequency [52, 53]. How does the scattering intensity for a given (the *j*th) Raman active vibration vary with excitation frequency within an electronic absorption band? In turn, this has led to transform theories that try to predict

the REP_{*j*} from the ordinary absorption band (ABS), or the reverse. Thus one has the so-called forward transform, ABS → REP_{*j*}, and the inverse transform, REP_{*j*} → ABS [54, 55 and 56]. The inverse transform is a formal method that transforms an observed REP_{*j*} into the electronic absorption band that is responsible for resonantly scattering mode *j*. This inverse transform raises theoretical issues concerning the frequently

encountered problem of phase recovery of a complex function (in this case the complex Raman susceptibility), knowing only its amplitude [57].

One group has successfully obtained information about potential energy surfaces without measuring REPs. Instead, easily measured second derivative absorption profiles are obtained and linked to the full RRS spectrum taken at a single incident frequency. In this way, the painstaking task of measuring a REP is replaced by carefully recording the second derivative of the electronic absorption spectrum of the resonant transition [58, 59].

The fitting parameters in the transform method are properties related to the two potential energy surfaces that define the electronic resonance. These curves are obtained when the two hypersurfaces are cut along the j th normal mode coordinate. In order of increasing theoretical sophistication these properties are: (i) the relative position of their minima (often called the displacement parameters), (ii) the force constant of the vibration (its frequency), (iii) nuclear coordinate dependence of the electronic transition moment and (iv) the issue of mode mixing upon excitation—known as the Duschinsky effect—requiring a multidimensional approach.

We have seen how, by definition, all Raman spectroscopies must feature the difference frequency resonance that appears following the two-step doorway stage of the 4WM process. Basically, RRS takes advantage of achieving additional resonances available in the two remaining energy denominator factors found at third order (and, of course, still more at higher order). The two remaining energy factors necessarily involve an algebraic sum of an odd number of optical frequencies (one for the first step in the doorway stage, and three for the initial step in the window event). Since the algebraic sum of an odd number of optical frequencies must itself be optical, these additional resonances must be at optical frequencies. Namely, they must correspond to electronic transitions, including (in molecules) their dense rotational– (or librational–) vibrational substructure. The literature is filled with a great many interesting RRS applications, extending from resonances in the near-IR (dyes and photosynthetic pigments for example) to the deep UV (where backbone electronic resonances in proteins and nucleic acids are studied). These increasingly include TRRRS in order to follow the folding/unfolding dynamics of substructures (through the chromophore specificity of RRS) in biologically important molecules [60, 61 and 62].

The reader must turn to the literature to amplify upon any of these topics. Here we return to the two-colour generator/WMEL scheme to see how it easily can be adapted to the RRS problem.

Let us consider RRS that contains both of the available additional resonances, as is normally the case (though careful choices of colours and their time sequence can isolate one or the other of these). First, we seek out the doorway events that contain not only the usual Raman resonance after the two fields, 1 and 2, have acted conjugately, but also the new resonance that appears after the first field has acted. The appropriate doorway generators remain $\epsilon_1\epsilon_2^*$ and $\epsilon_2^*\epsilon_1$, in order to retain the Raman resonance. There are now two fully resonant doorway WMEL diagrams, which we shall call $D_{RR}(A_{12*})$ and $D_{RR}(B_{12*})$. These diagrams are shown in [figure B1.3.4](#) in which the full manifold of sublevels for each electronic state is intimated. In doorway channel A, vibrational coherences are produced in the ground electronic state g , as usual, but now they are enhanced by the electronic resonance in step 1 (ϵ_1). However, in doorway channel B, vibrational coherences are produced in the excited electronic state, e , as well. Interestingly, since A is a ket–ket event and B is a ket–bra event (which differ by an overall sign), these two coherences must differ in

phase by π (180°). This may be important in any 4WM experiment that is phase sensitive (heterodyned Class II) and in which the window event does not reverse this phase difference.

Figure B1.3.4. The two fully resonant doorway stages for resonance Raman scattering (RRS), in which the manifold of vibrational sublevels for each electronic state is indicated. (a) Doorway stage $D_{RR}(A_{12*})$, in which a vibrational coherence is produced in the ground electronic state, g . It is a ket–ket evolution. (b) Doorway stage $D_{RR}(B_{12*})$, where a vibrational coherence is created in the excited electronic state, e . It is a ket–bra evolution. The coherences in both doorway stages are enhanced by the electronic resonance in their identical step 1 (generated by ϵ_1).

Frequently, femtosecond pulses are used in such electronically resonant spectroscopy. Such pulses usually have near-transform limited bandwidths and can spectrally embrace a fair range of vibrational coherences. Thus, even when a single central colour is chosen to define the femtosecond exciting pulse, actually a broad band of colours is available to provide a range for both ω_1 and ω_2 . Instead of preparing single well-defined vibrational coherences using sharply

-28-

defined colours, now vibrational wavepackets are made in both the ground (channel A) and excited states (channel B). These must evolve in time, for they are not eigenstates in either potential energy hypersurface. The nature of the 4WM signal is sensitive to the location of the wavepacket in either hypersurface at the time the window event takes place. Such wavepackets, prepared from a spectrum of colours contained coherently within a femtosecond pulse, are termed ‘impulsively’ prepared (see impulsive Raman scattering for further details).

Whenever coherences in the upper manifold are particularly short lived, doorway channel A will dominate the evolution of the polarization at least at later times. In that case, the fringes seen in the 4WM signal as the time between the doorway and window stages is altered (with a delay line) reflect those Raman frequencies in the ground state that can be spectrally embraced by the femtosecond pulse. Then the Fourier transform of the fringes leads to the conventional spontaneous RRS of the ground state. Indeed, in the absence of electronic resonance, channel B reverts to a purely nonresonant doorway event (D_N) and only channel A reveals Raman resonances—those in the electronic ground state [62].

Whatever the detection technique, the window stage of the 4WM event must convert these evolved vibrational wavepackets into the third order polarization field that oscillates at an ensemble distribution of optical frequencies. One must be alert to the possibility that the window event after doorway channel B may involve resonances from electronic state manifold e to some higher manifold, say r . Thus channel B followed by an ϵ_3 (ket) or a ϵ_3^* (bra) event might be enhanced by an e -to- r resonance. However, it is normal to confine the window event to the e -to- g resonances, but this is often simply for lack of substantive e -to- r information. Given that the third field action can be of any available colour, and considering only g -to- e resonances, one has, for any colour ω_3 , only two possibilities following each doorway channel. Channel A should be followed by an ϵ_3 (ket up) or an ϵ_3^* (bra up) event; channel B should be followed by a ϵ_3 (bra down) or a ϵ_3^* (ket down) event.

Before looking more closely at these, it is important to recognize another category of pump–probe Raman experiments. These are often referred to as ‘transient Raman’ pump–probe studies. In these, a given system is ‘pumped’ into a transient condition such as an excited vibronic state, or a photochemical event such as dissociation or radical formation [63, 64 and 65]. Such pumping can be achieved by any means—even by high energy radiation [66, 67 and 68]—though normally laser pumping is used. The product(s) formed by the pump step is then studied by a Raman probe (often simply spontaneous Raman, sometimes CARS). Since the transient state is normally at low concentrations, the Raman probing seeks out resonant enhancement, as we are describing, and also means must be taken to stay away from the luminescence background that is invariably caused by the pump event. Often, time gated Fourier transform Raman in the near-IR is employed

(that spectral region being relatively free of interfering fluorescence) and yet upper *e*-to-*r* type resonances may still be available for RRS. Since transient systems are ‘hot’ by their very nature, both anti-Stokes as well as Stokes spontaneous Raman scattering can be followed to time the vibrational relaxation in transient excited states (see [69, 70]).

Returning to the original pump–probe RRS, it is a simple matter to complete the 4WM WMEL diagrams for any proposed RRS. Usually RRS experiments are of the full quadrature sort, both spontaneous RRS as well as homodyne detected femtosecond RRS. The latter fit most pump–probe configurations.

Let us, for example, present the full WMEL diagrams for full quadrature RRS with two colours, 1 and 2. (Recall that three colours cannot lead to full *Q* at the 4WM level.) Given the $\epsilon_1 \epsilon_2^*$ doorway generator for channels A and B, the generator for the first step of the window event must either be ϵ_1^* or ϵ_2 , and the corresponding signal must conjugate

-29-

either with ϵ_2^* ($\epsilon_s = \epsilon_2$) or with ϵ_1 ($\epsilon_s^* = \epsilon_1^*$), respectively. In the former case, field 1 will have acted twice (and conjugately) to help produce the third order polarization and signal field directed along k_2 . In the latter case, field 2 has acted twice (and conjugately) to help produce a third order polarization along $-k_1$. Of the two fields, the most intense clearly is the candidate for the twice acting field. The weaker field, then, is examined for the signal.

In addition, we have asked that a third resonance exist in the window stage. For channel A this requires that the window event begin either with *ket up* using ϵ_2 , or with *bra up* using ϵ_1^* , while the window event following channel B should begin either with *bra down* using ϵ_2 or with *ket down* using ϵ_1^* . The corresponding four WMEL diagrams are shown in figure B1.3.5.

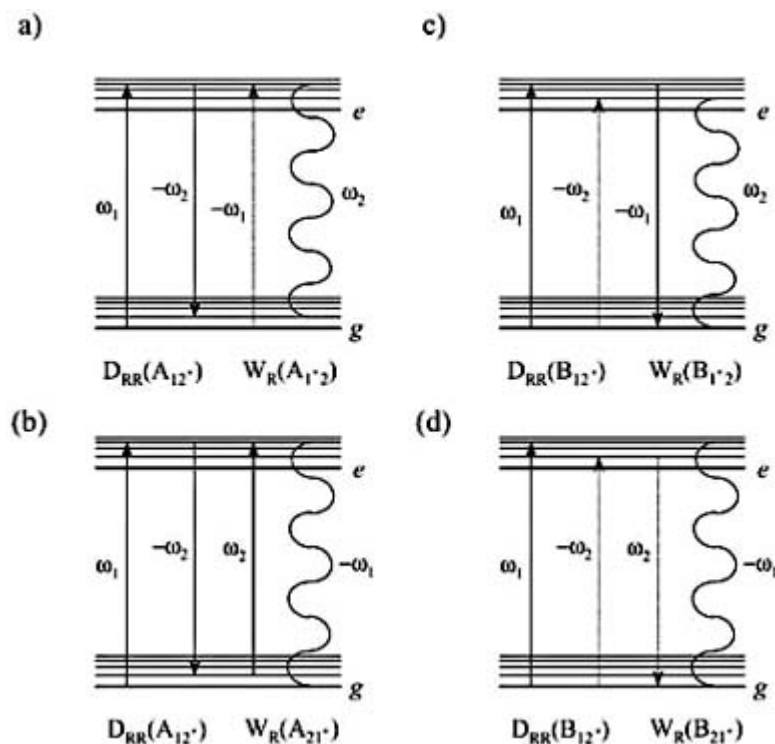

Figure B1.3.5. Four WMEL diagrams for fully resonant Raman scattering (RRS). Diagrams (a) and (b) both have doorway stage $D_{RR}(A_{12}^*)$ (Figure B1.3.4(a)), in which a vibrational coherence is created in the ground electronic state, *g*. For the window event in (a), field 1 promotes the bra from the ground electronic state, *g*, to

an excited electronic bra state, e . In this window stage $W_R(A_{1*2})$, the third field action helps produce the third order polarization, which in turn gives rise to a signal field with frequency ω_2 . For the window event $W_R(A_{21*})$ in (b), field 2 acts to promote the ket in the ground electronic state into one in the excited electronic state. Now a signal field with frequency $-\omega_1$ is created. Both diagrams (c) and (d) have doorway stage $D_{RR}(B_{12*})$ (figure B1.3.4(b)), in which a vibrational coherence is created in the excited electronic state, e . At the window stage $W_R(B_{1*2})$ (c) field 1 demotes the ket from one in electronic state e to one in the ground electronic state g . A consequent third order polarization leads to a signal field at frequency ω_2 . At the window stage $W_R(B_{21*})$ (d) the bra is demoted by field 2 to the ground electronic state to produce a signal field at frequency $-\omega_1$. Full quadrature is achieved in all four diagrams.

-30-

In these WMEL diagrams, the outcome of the collapse of the polarization, the second step of the window stage (the curvy line segment), depends on the phase difference between the induced s th order polarization and the new $(s + 1)$ th electromagnetic field [7]. If this difference is 0° , then the energy contained in the polarization is fully converted into population change in the medium (pure Class I spectroscopies). At third order, channel A populates vibrational levels in the ground electronic state; channel B populates vibrational levels in the excited electronic state. However if this phase difference is 90° , the energy is converted fully into the new $(s + 1)$ th electromagnetic field and the material is unchanged (pure Class II spectroscopies). If the phase difference lies between 0 and 90° , as is almost always the case, then both outcomes occur to some extent and the experimentalist may perform either a Class I or a Class II spectroscopy.

As we have already seen, in such a full quadrature situation, phase matching is automatic (the signal is collinear with either of the incident fields), so the experiment then measures changes in one or more properties of one of the incident fields—either the first appearing light pulse, or the second appearing light pulse. These are distinguished both in order of appearance and by their wavevector of incidence. At full quadrature, the obvious property to measure is simply the intensity (Class I) as one (or more) of the time parameters is changed. With this example, it should be a simple matter to explore WMEL diagrams for any other RRS spectroscopies, in particular the nonquadrature ones.

(E) STIMULATED RAMAN SCATTERING (SRS)

Since the inception of the laser, the phenomenon called stimulated Raman scattering (SRS) [71, 72, 73 and 74] has been observed while performing spontaneous Raman experiments. Stimulated Raman scattering is inelastic light scattering by molecules caused by presence of a light field that is stronger than the zero-point field of the blackbody. Thus SRS overtakes the spontaneous counterpart. SRS, like SR, is an active Class I spectroscopy. For the case of Stokes scattering, this light field may be a second laser beam at frequency ω_2 , or it may be from the polarization field that has built up from the spontaneous scattering event. Typically in an SRS experiment one also observes frequencies other than the Stokes frequency: those at $\omega_1 - 2\omega_R$, $\omega_1 - 3\omega_R$, $\omega_1 - 4\omega_R$ etc which are referred to as higher order Stokes stimulated Raman scattering and at $\omega_1 + \omega_R$ (anti-Stokes) and $\omega_1 + 2\omega_R$, $\omega_1 + 3\omega_R$, $\omega_1 + 4\omega_R$ (higher order anti-Stokes stimulated Raman scattering) [19]. This type of scattering may arise only after an appreciable amount of Stokes scattering is produced (unless the system is not at thermal equilibrium).

First order stimulated Stokes scattering experiences an exponential gain in intensity as the fields propagate through the scattering medium. This is given by the expression [75]

$$I_S(z) = I_S(0) e^{g_S I_L z}$$

where z is the path length, I_L is the intensity of the incident radiation and $I_S(0)$ is the intensity of the quantum noise associated with the vacuum state [15], related to the zero-point bb field. g_S is known as the stimulated

Raman gain coefficient, whose maximum occurs at exact resonance, $\omega_L - \omega_S = \omega_R$. For a Lorentzian lineshape, the maximum gain coefficient is given by

-31-

$$g_{S_{\max}} = \frac{8\pi^2 c^2 N}{\hbar \omega_L \omega_S^2 n_S n_L} \frac{d\sigma_R}{d\Omega} \frac{1}{\gamma_R}$$

where ω_S is the frequency of the Stokes radiation and γ_R is the HWHM of the Raman line (in units of circular frequency) [75]. This gain coefficient is seen to be proportional to the spontaneous differential Raman cross section ($d\sigma_R/d\Omega$), (the exact nature of which depends on experimental design (see [equation \(B1.3.20\)](#) and [equation \(B1.3.21\)](#)) and also to the number density of scatterers, N . This frequency dependent gain coefficient may also be written in terms of the third order nonlinear Raman susceptibility, $\chi^{(3)}(\omega_S)$. As with SR, only the imaginary part of $\chi^{(3)}(\omega_S)$ contributes to Stokes amplification (the real part accounts for intensity dependent (nonlinear) refractive indices). For the definition of $\chi^{(3)}$ used here ([equation \(B1.3.11\)](#) and [equation \(B1.3.12\)](#)), their relation is given by

$$g_S(\omega_S) = \frac{-2\omega_S}{\epsilon_0^2 n_S n_L c^2} \text{Im } \chi_{AAAA}^{(3)}(\omega_S)$$

where the magnitude of $\text{Im } \chi^{(3)}(\omega_S)$ is negative, thus leading to a positive gain coefficient [33]. For this expression, only the component of the scattered radiation parallel to the incident light is analysed.

Once an appreciable amount of Stokes radiation is generated, enough scatterers are left in an excited vibrational state for the generation of anti-Stokes radiation. Also, the Stokes radiation produced may now act as incident radiation in further stimulated Raman processes to generate the higher order Stokes fields. Although the Stokes field is spatially isotropic, scattered radiation in the forward and backward directions with respect to the incident light traverses the longest interaction length and thus experiences a significantly larger gain (typically several orders of magnitude larger than in the other directions [33]). Thus the first and higher order Stokes frequencies lie along the direction of the incident beam.

This is not the case for stimulated anti-Stokes radiation. There are two sources of polarization for anti-Stokes radiation [17]. The first is analogous to that in [figure B1.3.3\(b\)](#) where the action of the blackbody ($-\omega_2$) is replaced by the action of a previously produced anti-Stokes wave, with frequency ω_A . This radiation actually experiences an attenuation since the value of $\text{Im } \chi^{(3)}(\omega_A)$ is positive (leading to a negative ‘gain’ coefficient). This is known as the stimulated Raman loss (SRL) spectroscopy [76]. However the second source of anti-Stokes polarization relies on the presence of Stokes radiation [17]. This anti-Stokes radiation will emerge from the sample in a direction given by the wavevector algebra: $\mathbf{k}_A = 2\mathbf{k}_l - \mathbf{k}_S$. Since the Stokes radiation is isotropic ($-\mathbf{k}_S$), the anti-Stokes radiation (and subsequent higher order radiation) is emitted in the form of concentric rings.

(F) SURFACE ENHANCED RAMAN SCATTERING (SERS)

We have seen that the strength of Raman scattered radiation is directly related to the Raman scattering cross-section (σ_R). The fact that this cross-section for Raman scattering is typically much weaker than that for absorption ($\sigma_R \ll \sigma_{\text{abs}}$) limits conventional SR as a sensitive analytical tool compared to (linear) absorption techniques. The complication of fluorescence in the usual Raman techniques of course tends to decrease the signal-to-noise ratio.

It was first reported in 1974 that the Raman spectrum of pyridine is enhanced by many orders of magnitude when

-32-

the pyridine is adsorbed on silver metal [77]. This dramatic increase in the apparent Raman cross-section in the pyridine/silver system was subsequently studied in more detail [78, 79]. The enhancement of the Raman scattering intensity from molecules adsorbed to surfaces (usually, though not exclusively, noble metals) has come to be called the surface enhanced Raman spectroscopy (SERS). Since these early discoveries, SERS has been intensively studied for a wide variety of adsorbate/substrate systems [80, 81, 82 and 83]. The pyridine/silver system, while already thoroughly studied, still remains a popular choice among investigators both for elucidating enhancement mechanisms and for analytical purposes. The fluorescence of the adsorbed molecules does not experience similarly strong enhancement, and often is actually quenched. So, since the signal is dominated by the adsorbate molecules, fluorescence contamination is relatively suppressed.

The metal substrate evidently affords a huge ($\sim 10^{10}$ and even as high as 10^{14} [84, 85]) increase in the cross-section for Raman scattering of the adsorbate. There are two broad classes of mechanisms which are said to contribute to this enhancement [86, 87 and 88]. The first is based on electromagnetic effects and the second on 'chemical' effects. Of these two classes the former is better understood and, for the most part, the specific mechanisms are agreed upon; the latter is more complicated and is less well understood. SERS enhancement can take place in either physisorbed or chemisorbed situations, with the chemisorbed case typically characterized by larger Raman frequency shifts from the bulk phase.

The substrate is, of course, a necessary component of any SERS experiment. A wide variety of substrate surfaces have been prepared for SERS studies by an equally wide range of techniques [87]. Two important substrates are electrochemically prepared electrodes and colloidal surfaces (either deposited or in solution).

A side from the presence of a substrate, the SERS experiment is fundamentally similar to the standard conventional Raman scattering experiment. Often a continuous wave laser, such as an argon ion laser, is used as the excitation source, but pulsed lasers can also be used to achieve time resolved SERS. Also, as in conventional Raman scattering, one can utilize pre-resonant or resonant conditions to perform resonant SERS (often denoted SERRS for surface enhanced resonant Raman scattering). SERRS combines the cross-section enhancement of SERS with the electronic resonance enhancement of resonance Raman scattering. In fact, through SERRS, one can achieve extraordinary sensitivity, with reports appearing of near-single-molecule-based signals [84, 85, 89].

We now move on to some Class II spectroscopies.

(G) COHERENT RAMAN SCATTERING (CRS)

The major Class II Raman spectroscopy is coherent Raman scattering (CRS) [90, 91, 92 and 93]. It is an extremely important class of nearly degenerate four-wave mixing spectroscopies in which the fourth wave (or signal field) is a result of the coherent stimulated Raman scattering. There are two important kinds of CRS distinguished by whether the signal is anti-Stokes shifted (to the blue) or Stokes shifted (to the red). The former is called CARS (coherent anti-Stokes Raman scattering) and the latter is called CSRS (coherent Stokes Raman scattering). Both CARS and CSRS involve the use of two distinct incident laser frequencies, ω_1 and ω_2 ($\omega_1 > \omega_2$). In the typical experiment ω_1 is held fixed while ω_2 is scanned. When $\omega_1 - \omega_2$ matches a Raman frequency of the sample a resonant condition results and there is a strong gain in the CARS or CSRS signal intensity. The complete scan of ω_2 then traces out the CARS or CSRS spectrum of the sample. (Figure B1.3.2 (b)) shows representative WMEL diagrams for the CARS and CSRS processes.) There are, in actuality, 48 WMEL diagrams (including the nonresonant contributions) that one must

consider for either of these two processes. These have been displayed in the literature ([98] (CARS) and [99] (CSRS)). For both processes, a pair of field–matter interactions produces a vibrational coherence between states $|g\rangle$ and $|f\rangle$ (see D_R and D_N of [figure B1.3.2\(b\)](#)). For the CARS process, the third field, having frequency ω_1 , acts in phase (the same Fourier component) with the first action of ω_1 to produce a polarization that is anti-Stokes shifted from ω_1 (see $W_R(E)$ and $W_N(F)$ of [figure B1.3.2\(b\)](#)). For the case of CSRS the third field action has frequency ω_2 and acts in phase with the earlier action of ω_2 ($W_R(C)$ and $W_N(D)$ of [figure B1.3.2\(b\)](#)). Unlike the Class I spectroscopies, no fields in CARS or CSRS (or any homodyne detected Class II spectroscopies) are in quadrature at the polarization level. Since homodyne detected CRS is governed by the modulus square of $\chi^{(3)}$ ($I_{\text{CRS}} \propto |\chi^{(3)}|^2$), its lineshape is not a symmetric lineshape like those in the Class I spectroscopies, but it depends on both the resonant and nonresonant components of $\chi^{(3)}$, $\chi_R^{(3)}$ and $\chi_N^{(3)}$, respectively. Thus

$$|\chi^{(3)}|^2 = |\chi_R^{(3)} + \chi_N^{(3)}|^2 = |\chi_R^{(3)}|^2 + \chi_N^{(3)}(\chi_R^{(3)} + \chi_R^{*(3)}) + (\chi_N^{(3)})^2$$

and one is faced with both an absorptive component $|\chi_R^{(3)}|^2$ and a dispersive component, $\chi_N^{(3)}(\chi_R^{(3)} + \chi_R^{*(3)})$. $\chi_N^{(3)}$ can, to a very good approximation, be taken to be a (pure real) constant over the width of the Raman line.) As a result, the CRS lineshape is asymmetric and more complicated due to this nonresonant background interference.

The primary advantages of CARS and CSRS include an inherently stronger signal than spontaneous Raman scattering (the incident fields are stronger than the zero-point blackbody fields) and one that is directional (phase matched). These characteristics combine to give the technique a much lower vulnerability to sample fluorescence and also an advantage in remote sensing. For CARS, fluorescence is especially avoided since the signal emerges to the blue of the incident laser frequencies and fluorescence must be absent (unless it were biphotonically induced). The primary disadvantage of CARS and CSRS is the interference of the nonresonant part of $\chi^{(3)}$ in the form of the dispersive cross-term. A class of techniques called polarization CRS utilizes the control over the polarization of the input beams to suppress the nonresonant background interference [94, 95]. On the other hand, the background interference necessarily carries information about the nonresonant component of the electric susceptibility which is sometimes a sought after quantity.

(H) RAMAN INDUCED KERR EFFECT SPECTROSCOPY (RIKES)

The nonresonant background prevalent in CARS experiments (discussed above), although much weaker than the signals due to strong Raman modes, can often obscure weaker modes. Another technique which can suppress the nonresonant background signal is Raman induced Kerr-effect spectroscopy or RIKES [96, 97].

A RIKES experiment is essentially identical to that of CW CARS, except the probe laser need not be tunable. The probe beam is linearly polarized at 0° (\rightarrow), while the polarization of the tunable pump beam is controlled by a linear polarizer and a quarter waveplate. The pump and probe beams, whose frequency difference must match the Raman frequency, are overlapped in the sample (just as in CARS). The strong pump beam propagating through a nonlinear medium induces an anisotropic change in the refractive indices seen by the weaker probe wave, which alters the polarization of a probe beam [96]. The signal field is polarized orthogonally to the probe laser and any altered polarization may be detected as an increase in intensity transmitted through a crossed polarizer. When the pump beam is linearly polarized at 45° (\nearrow), contributions from the nonlinear background susceptibility exist ($\chi_{\text{eff}}^{(3)} = 3[\chi_{\text{AABB}}^{(3)} + \chi_{\text{ABAB}}^{(3)}]$). If the quarter-wave plate is adjusted to give circularly polarized light (\odot), the nonresonant background will disappear

, provided [19].

A unique feature of this Class II spectroscopy is that it occurs in full quadrature, and thus the phase-matching condition is automatically fulfilled for every propagation direction and frequency combination (for isotropic media). Characteristic WMEL diagrams for this process are given by diagrams B and G of [figure B1.3.2\(a\)](#). From these diagrams, one may notice that the frequency of the signal field is identical to that of one of the incident fields, thus one must carefully align the crossed polarizer to eliminate contamination by the probe beam.

A common technique used to enhance the signal-to-noise ratio for weak modes is to inject a local oscillator field polarized parallel to the RIKE field at the detector. This local oscillator field is derived from the probe laser and will add coherently to the RIKE field [96]. The relative phase of the local oscillator and the RIKE field is an important parameter in describing the optical heterodyne detected (OHD)-RIKES spectrum. If the local oscillator at the detector is in phase with the probe wave, the heterodyne intensity is proportional to $\text{Re}\{\chi_{\text{eff}}^{(3)}\}$. If the local oscillator is in phase quadrature with the probe field, the heterodyne intensity becomes proportional to $\text{Im}\{\chi_{\text{eff}}^{(3)}\}$. Thus, in addition in to signal-to-noise improvements, OHD-RIKES, being a heterodyne method, demonstrates a phase sensitivity not possible with more conventional homodyne techniques.

Still another spectroscopic technique used to suppress the nonresonant background is ASTERISK. The setup is identical to a conventional CARS experiment, except three independent input fields of frequencies, ω_1 , ω_2 and ω_3 are used. The relative polarization configuration (not wavevectors) for the *three* incident fields and the analyser (e_s) is shown in [figure B1.3.6](#) where the signal generated at ω_s will be polarized in the x -direction. (Both θ and ϕ are defined to be positive angles, as denoted in [figure B1.3.6](#).) The recorded spectra will be relatively free of the nonresonant background (for $\theta = \phi \simeq 45^\circ$, the detected intensity will be proportional to $|\chi_{\text{ABAB}}^{(3)} - \chi_{\text{ABBA}}^{(3)}|^2$; however one must satisfy the phase matching condition: $\Delta\mathbf{k} = \mathbf{k}_1 - \mathbf{k}_2 + \mathbf{k}_3 - \mathbf{k}_s$. In transparent materials, a greater than three-orders-of-magnitude reduction of the nonresonant background occurs as compared to its 25–100-fold suppression by RIKES [96].

Figure B1.3.6. The configuration of the unit polarization vectors \mathbf{e}_1 , \mathbf{e}_2 , \mathbf{e}_3 and \mathbf{e}_s in the laboratory Cartesian basis as found in the ASTERISK technique.

(i) RAMAN SCATTERING WITH NOISY LIGHT

In the early 1980s, it was shown that noisy light offers a time resolution of the order of the noise correlation time, τ_c , of the light (typically tens to several hundreds of femtoseconds)—many orders of magnitude faster than the temporal profile of the light (which is often several nanoseconds, but in principle can be CW) [100, 101 and 102]. A critical review of many applications of noisy light (including CRS) is given by Kobayashi [103]. A more recent review by Kummrow and Lau [104] contains an extensive listing of references.

A typical noisy light based CRS experiment involves the splitting of a noisy beam (short autocorrelation time, broadband) into identical twin beams, B and B', through the use of a Michelson interferometer. One arm of the interferometer is computer controlled to introduce a relative delay, τ , between B and B'. The twin beams exit the interferometer and are joined by a narrowband field, M, to produce the CRS-type third order polarization in the sample ($\omega_B - \omega_M \approx \omega_R$). The delay between B and B' is then scanned and the frequency-resolved signal of interest is detected as a function of τ to produce an *interferogram*. As an interferometric spectroscopy, it has come to be called $I^{(2)}$ CRS ($I^{(2)}$ CARS and $I^{(2)}$ CSRS), in which the ' $I^{(2)}$ ' refers to the two, twin incoherent beams that are interferometrically treated [105]. The theory of $I^{(2)}$ CRS [106, 107] predicts that the so-called radiation difference oscillations (RDOs) should appear in the 'monochromatically' detected $I^{(2)}$ CRS interferogram with a frequency of $\Delta \equiv \omega_M + 2\omega_R - \omega_D$, where ω_D is the detected frequency, ω_M is the narrowband frequency and ω_R the Raman (vibrational) frequency. Since ω_D and ω_M are known, ω_R may be extracted from the experimentally measured RDOs. Furthermore, the dephasing rate constant, γ_R , is determined from the observed decay rate constant, γ , of the $I^{(2)}$ CRS interferogram. Typically for the $I^{(2)}$ CRS signal $\omega_D \approx \omega_M + 2\omega_R$ and thus $\Delta \approx 0$. That is, the RDOs represent strongly *down-converted* (even to zero frequency) Raman frequencies. This down-conversion is one of the chief advantages of the $I^{(2)}$ CRS technique, because it allows for the characterization of vibrations using optical fields but with a much smaller interferometric sampling rate than is needed in FT-Raman or in FT-IR. More explicitly, the Nyquist sampling rate criterion for the

RDOs is much smaller than that for the vibration itself, not to mention that for the near-IR FT-Raman technique already discussed. This is particularly striking for high energy modes such as the C–H vibrations [108]. Modern applications of $I^{(2)}$ CRS now utilize a 'two-dimensional' time–frequency detection scheme

which involves the use of a CCD camera to detect an entire $I^{(2)}$ CARS spectrum at every delay time [109]. These are called Raman spectrograms and allow for a greatly enhanced level of precision in the extraction of the Raman parameters—a precision that considerably exceeds the instrumental uncertainties.

The understanding of the underlying physical processes behind $I^{(2)}$ CRS (and noisy light spectroscopies in general) has been aided by the recent development of a diagrammatic technique called factorized time correlation (FTC) diagram analysis for properly averaging over the noise components in the incident light [110, 111 and 112] in any noisy light based spectroscopy (linear or nonlinear).

(J) TIME RESOLVED COHERENT RAMAN SCATTERING (TRCRS)

With the advent of short pulsed lasers, investigators were able to perform time resolved coherent Raman scattering. In contrast to using femtosecond pulses whose spectral width provides the two colours needed to produce Raman coherences, discussed above, here we consider pulses having two distinct centre frequencies whose difference drives the coherence. Since the 1970s, picosecond lasers have been employed for this purpose [113, 114], and since the late 1980s femtosecond pulses have also been used [115]. Here we shall briefly focus on the two-colour femtosecond pulsed experiments since they and the picosecond experiments are very similar in concept.

The TR-CRS experiment requires a femtosecond scale light source (originally a rhodamine 6G ring dye laser [115, 116]) and a second longer pulsed (typically several picoseconds) laser operating at a different frequency. The femtosecond source at one colour is split into two pulses having a relative and controllable delay, τ , between them. Each of these two pulses acts once and with the same Fourier component, one in the doorway stage, the other in the window stage. The third, longer pulsed field at the second colour and in a conjugate manner participates with one of the femtosecond pulses in the doorway event to produce the Raman coherence. This polarization then launches the TR-CRS signal field which can be either homodyne or heterodyne detected. This signal must decay with increasing τ as the Raman coherence is given time to decay before the window event takes place.

For homodyne detection, the TR-CRS intensity (for Lorentzian Raman lines) is of the form [115]

$$I_{\text{TR-CRS}} \propto \left| \sum_j e^{-2\gamma_j \tau} e^{-i\omega_j \tau + i\phi_j} \right|^2 \quad (\text{B1.3.25})$$

where j runs over all Raman active modes contained within the bandwidth of the femtosecond scale pulse. The parameters γ_j , ω_j and ϕ_j are the dephasing rate constant, the Raman frequency and phase for the j th mode. One can see from equation (B1.3.25) that for a single mode $I_{\text{TR-CRS}}$ is a simple exponential decay, but when more modes are involved $I_{\text{TR-CRS}}$ will reveal a more complicated beat pattern due to the cross-terms.

TR-CRS has been used to study many molecules from benzene [115, 116, 117 and 118] to betacarotene [119].

(K) IMPULSIVE STIMULATED RAMAN SCATTERING (ISRS)

In discussing RRS above, mention is made of the ‘impulsive’ preparation of wavepackets in both the excited electronic potential surface and the ground state surface. In the absence of electronic resonance only the latter channel is operative and ground state wavepackets can be prepared in transparent materials using the spectral width of femtosecond light to provide the necessary colours. Such impulsive stimulated Raman scattering (ISRS) was first performed by Nelson *et al* on a variety of systems including acoustic modes in glasses [120]

and librational and intramolecular vibrations in liquids [121].

To date, there are two types of configuration employed in ISRS: three-pulse [121] and two-pulse [121]. In both cases, (an) excitation pulse(s) provide(s) the necessary frequencies to create a vibrational wavepacket which proceeds to move within the potential surface. After a delay time τ , a probe pulse having the same central frequency enters the sample and converts the wavepacket into an optical polarization and the coherent fourth wave is detected. For the case of two-pulse ISRS, the transmitted intensity along the probe pulse is followed. In three-pulse ISRS (defined by three wavevectors), the coherently scattered radiation is detected along its unique wavevector. The intensity of the scattered (transmitted) pulse as a function of τ shows damped oscillations at the frequency of the Raman mode (roughly the reciprocal of the recurrence time as the packet oscillates between the two walls of the potential curve). If the pulse durations are longer than the vibrational period (the spectral width is too small to embrace the resonance), no such oscillations can occur. Since in ISRS the spectral width of each pulse is comparable to the Raman frequency, each pulse contains spectral components that produce Stokes and anti-Stokes scattering. These oscillations occur due to the interference between the Stokes and anti-Stokes scattering processes [122]. These processes differ in phase by 180° (the WMEL rules can show this). This expected phase difference has been demonstrated when heterodyne detection is used (the optical Kerr effect probed by an E_{10}) and the signal is frequency resolved [123].

As already mentioned, electronically resonant, two-pulse impulsive Raman scattering (RISRS) has recently been performed on a number of dyes [124]. The main difference between resonant and nonresonant ISRS is that the beats occur in the absorption of the probe rather than the spectral redistribution of the probe pulse energy [124]. These beats are $\frac{\pi}{2}$ out of phase with respect to the beats that occur in nonresonant ISRS (cosine-like rather than sinelike). RISRS has also been shown to have the phase of oscillation depend on the detuning from electronic resonance and it has been shown to be sensitive to the vibrational dynamics in both the ground and excited electronic states [122, 124].

(L) HIGHER ORDER AND HIGHER DIMENSIONAL TIME RESOLVED TECHNIQUES

Of great interest to physical chemists and chemical physicists are the broadening mechanisms of Raman lines in the condensed phase. Characterization of these mechanisms provides information about the microscopic dynamical behaviour of material. The line broadening is due to the interaction between the Raman active chromophore and its environment.

It has been shown that spontaneous or even coherent Raman scattering cannot be used to distinguish between the fast homogeneous and the slow inhomogeneous broadening mechanisms in vibrational transitions [18, 125]. One must use higher order (at least fifth order) techniques if one wishes to resolve the nature of the broadening mechanism. The ability of these higher order techniques to make this distinction is based on the echo phenomena very well known for NMR and mentioned above for D4WM with electronic resonances. The true Raman echo experiment is a time resolved seventh order technique which has recently been reported by Berg *et al* [126, 127, 128 and 129]. It is thus an 8WM

process in which two fields are needed for each step in the normal 4WM echo. A Raman echo WMEL diagram is shown in figure B1.3.7. It is seen that, as in CRS, the first two pulsed field actions create a vibrational coherence. This dephases until the second pair of field actions creates a vibrational population. This is followed by two field actions which again create a vibrational coherence but, now, with opposite phase to the first coherence. Hence one obtains a partial rephasing, or echo, of the macroscopic polarization. The final field action creates the seventh order optical polarization which launches the signal field (the eighth field). Just as for the spin echo in NMR or the electronic echo in 4WM, the degree of rephasing (the

magnitude of the echo) is determined by the amount of slow time scale (inhomogeneous) broadening of the two-level system that is present. Spectral diffusion (the exploration of the inhomogeneity by each chromophore) destroys the echo.

Figure B1.3.7. A WMEF diagram for the seventh order Raman echo. The first two field actions create the usual Raman vibrational coherence which dephases and, to the extent that inhomogeneity is present, also weakens as the coherence from different chromophores ‘walks off’. Then such dephasing is stopped when a second pair of field actions converts this coherence into a population of the excited vibrational state *f*. This is followed by yet another pair of field actions which reconvert the population into a vibrational coherence, but now one with phase opposite to the first. Now, with time, the ‘walked-off’ component of the original coherence can reassemble into a polarization peak that produces the Raman echo at frequency $\omega_s = 2\omega_1 - \omega_2 = \omega_1 + \omega_{fg} = \omega_2 + 2\omega_{fg}$.

An alternative fifth order Raman quasi-echo experiment can also be performed [130, 131, 132, 133 and 134]. Unlike the true Raman echo which involves only two vibrational levels, this process requires the presence of three very nearly evenly spaced levels. A WMEF diagram for the Raman quasi-echo process is shown in figure B1.3.8. Here again the first two field actions create a vibrational coherence which is allowed to dephase. This is followed by a second pair of

field actions, which, instead of creating a population, creates a different vibrational coherence which is of opposite phase and roughly the same order of magnitude as the initial coherence. This serves to allow a rephasing of sorts, the quasi-echo, provided the levels are in part inhomogeneously spread. The final field action creates the fifth order optical polarization that launches the signal field (the sixth field in this overall six-wave mixing process).

Figure B1.3.8. A W MEL diagram for the three-colour fifth order 'quasi-Raman echo'. As usual, the first pair of field actions creates the fg Raman coherence which is allowed both to dephase and 'walk off' with time. This is followed by a second pair of field actions, which creates a different but oppositely phased Raman coherence (now hf) to the first. Its frequency is at $\omega_3 - \omega_1 = \omega_{hf}$. Provided that ω_{hf} frequencies are identified with an inhomogeneous distribution that is similar to those of the ω_{fg} frequencies, then a quasi-rephasing is possible. The fifth field action converts the newly rephased Raman polarization into the quasi-echo at $\omega_s = 2\omega_3 - \omega_1 = \omega_3 + \omega_{hf}$.

As one goes to higher orders, there are many other processes that can and do occur. Some are true fifth or seventh order processes and others are 'cascaded' events arising from the sequential actions of lower order process [135]. Many of these cascaded sources of polarization interfere with the echo and quasi-echo signal and must be handled theoretically and experimentally.

The key for optimally extracting information from these higher order Raman experiments is to use two time dimensions. This is completely analogous to standard two-dimensional NMR [136] or two-dimensional 4WM echoes. As in NMR, the extra dimension gives information on coherence transfer and the coupling between Raman modes (as opposed to spins in NMR).

With the wealth of information contained in such two-dimensional data sets and with the continued improvements in technology, the Raman echo and quasi-echo techniques will be the basis for much activity and will undoubtedly provide very exciting new insights into condensed phase dynamics in simple molecular materials to systems of biological interest.

This survey of Raman spectroscopies, with direct or implicit use of WMEL diagrams, has by no means touched upon all of the Raman methods ([table B1.3.1](#) and [table B1.3.2](#)). We conclude by mentioning a few additional methods without detailed discussion but with citation. The first is Raman microscopy/imaging [[137](#)]. This technique combines microscopy and imaging with Raman spectroscopy to add an extra dimension to the optical imaging process and hence to provide additional insight into sample surface morphology. (Microscopy is the subject of another chapter in this encyclopedia.) The second is Raman optical activity [[138](#), [139](#)]. This technique discriminates small differences in Raman scattering intensity between left and right circularly polarized light. Such a technique is useful for the study of chiral molecules. The third technique is Raman-SPM [[140](#)]. Here Raman spectroscopy is combined with scanning probe microscopy (SPM) (a subject of another chapter in this encyclopedia) to form a complementary and powerful tool for studying surfaces and interfaces. The fourth is photoacoustic Raman spectroscopy (PARS) which combines CRS with photoacoustic absorption spectroscopy. Class I Raman scattering produces excited vibrational or rotational states in a gas whose energies are converted to bulk translational heating. A pressure wave is produced that is detected as an acoustic signal [[141](#), [142](#)]. The fifth is a novel 5WM process ($\chi^{(4)}$) which can occur in noncentrosymmetric isotropic solutions of chiral macromolecules [[143](#)]. This technique has been given the acronym BioCARS since it has the potential to selectively record background free vibrational spectra of biological molecules [[143](#), [144](#)]. It could be generalized to BioCRS (to include both BioCSRS and BioCARS). The signal is quite weak and can be enhanced with electronic resonance. Finally, we touch upon the general class of spectroscopies known as hyper-Raman spectroscopies. The spontaneous version is called simply hyper-Raman scattering, HRS, a Class I spectroscopy, but there is also the coherent Class II version called CHRS (CAHRS and CSHRS) [[145](#), [146](#) and [147](#)]. These 6WM spectroscopies depend on $\chi^{(5)}$ (Im $\chi^{(5)}$ for HRS) and obey the three-photon selection rules. Their signals are always to the blue of the incident beam(s), thus avoiding fluorescence problems. The selection rules allow one to probe, with optical frequencies, the usual IR spectrum (one photon), not the conventional Raman active vibrations (two photon), but also new vibrations that are symmetry forbidden in both IR and conventional Raman methods.

Although the fifth order hyper- (H-) Raman analogues exist for most of the Raman spectroscopies at third order (HRS [[148](#)], RHRS [[149](#), [150](#)], CHRS [[145](#), [146](#) and [147](#)], SEHRS [[151](#), [152](#) and [153](#)], SERHRS [[154](#)]), let us illustrate the hyper-Raman effect with HRS as the example. In this three-photon process, the scattered radiation contains the frequencies $2\omega_1 \pm \omega_R$ (Stokes and anti-Stokes hyper-Raman scattering), at almost twice the frequency of the incident light. The WMEL diagrams are identical to those of SR, except each single action of the incident laser field (ω_1) must be replaced by two simultaneous actions of the laser field. (The WMEL diagrams for any other 'hyper' process may be obtained in a similar manner.)

Experimentally, this phenomenon is difficult to observe ($I_{\text{HRS}}/I_{\text{SR}} 10^{-5}$); however again electronic resonance enhancement is seen to greatly increase the signal intensity [[148](#)].

B1.3.4 APPLICATIONS

To emphasize the versatility of Raman spectroscopy we discuss just a few selected applications of Raman based spectroscopy to problems in chemical physics and physical chemistry.

B1.3.4.1 APPLICATIONS IN SURFACE PHYSICS

In addition to the many applications of SERS, Raman spectroscopy is, in general, a useful analytical tool having many applications in surface science. One interesting example is that of carbon surfaces which do not support SERS. Raman spectroscopy of carbon surfaces provides insight into two important aspects. First, Raman spectral features correlate with the electrochemical reactivity of carbon surfaces; this allows one to study surface oxidation [[155](#)]. Second, Raman spectroscopy can probe species at carbon surfaces which may account for the highly variable behaviour of carbon materials [[155](#)]. Another application to surfaces is the use

of Raman microscopy in the nondestructive assessment of the quality of ceramic coatings [156]. Finally, an interesting type of surface which does allow for SERS are Mellfs (metal liquid-like films) [157]. Mellfs form at organic–aqueous interfaces when colloids of organic and aqueous metal sols are made. Comparisons with resonance Raman spectra of the bulk solution can give insight into the molecule–surface interaction and adsorption [157].

B1.3.4.2 APPLICATIONS IN COMBUSTION CHEMISTRY

Laser Raman diagnostic techniques offer remote, nonintrusive, nonperturbing measurements with high spatial and temporal resolution [158]. This is particularly advantageous in the area of combustion chemistry. Physical probes for temperature and concentration measurements can be debatable in many combustion systems, such as furnaces, internal combustors etc., since they may disturb the medium or, even worse, not withstand the hostile environments [159]. Laser Raman techniques are employed since two of the dominant molecules associated with air-fed combustion are O₂ and N₂. Homonuclear diatomic molecules unable to have a nuclear coordinate-dependent dipole moment cannot be diagnosed by infrared spectroscopy. Other combustion species include CH₄, CO₂, H₂O and H₂ [160]. These molecules are probed by Raman spectroscopy to determine the temperature profile and species concentration in various combustion processes.

For most practical applications involving turbulent flames and combustion engines, CRS is employed. Temperatures are derived from the spectral distribution of the CRS radiation. This may either be determined by scanning the Stokes frequency through the spectral region of interest or by exciting the transition in a single laser shot with a broadband Stokes beam, thus accessing all Raman resonances in a broad spectral region (multiplexing) [161]. The spectrum may then be observed by a broadband detector such as an optical multichannel analyser [162]. This broadband approach leads to weaker signal intensities, but the entire CRS spectrum is generated with each pulse, permitting instantaneous measurements [163]. Concentration measurements can be carried out in certain ranges (0.5–30% [161]) by using the nonresonant susceptibility as an *in situ* reference standard [158]. Thus fractional concentration measurements are obtained from the spectral profile.

evenly spaced levels. A WMEL diagram for the Raman quasi-echo process is shown in figure B1.3.8 Here again the first two field actions create a vibrational coherence which is allowed to dephase. This is followed by a second pair of field actions, which, instead of creating a population, creates a different vibrational coherence which is of opposite phase and roughly the same order of magnitude as the initial coherence. This serves to allow a rephasing of sorts, the quasi-echo, provided the levels are in part inhomogeneously spread. The final field action creates the fifth order optical polarization that launches the signal field (the sixth field in this overall six-wave mixing process).

Figure B1.3.8. A W MEL diagram for the three-colour fifth order ‘quasi-Raman echo’. As usual, the first pair of field actions creates the fg Raman coherence which is allowed both to dephase and ‘walk off’ with time. This is followed by a second pair of field actions, which creates a different but oppositely phased Raman coherence (now hf) to the first. Its frequency is at $\omega_3 - \omega_1 = \omega_{hf}$. Provided that ω_{hf} frequencies are identified with an inhomogeneous distribution that is similar to those of the ω_{fg} frequencies, then a quasi-rephasing is possible. The fifth field action converts the newly rephased Raman polarization into the quasi-echo at $\omega_s = 2\omega_3 - \omega_1 = \omega_3 + \omega_{hf}$.

As one goes to higher orders, there are many other processes that can and do occur. Some are true fifth or seventh order processes and others are ‘cascaded’ events arising from the sequential actions of lower order process [135]. Many of these cascaded sources of polarization interfere with the echo and quasi-echo signal and must be handled theoretically and experimentally.

The diagnostic themes in art and archeology are to identify pigments and materials that are used in a given sample, to date them (and determine changes with time) and to authenticate the origins of a given specimen. Diagnosis for forensic purposes may also be considered. In medicine, the principal aim is to provide fast (tens of seconds or faster for *in vivo* studies), noninvasive, nondestructive Raman optical methods for the earliest detection of disease, malignancies being those of immediate interest. In a recent review [173], reference is made to the large variety of subjects for Raman probing of diseased tissues and cells. These include plaques in human arteries and malignancies in breasts, lungs, brain, skin and the intestine. Hair and nails have been studied for signs of disease—metabolic or toxic. Teeth, as well as implants and prostheses, have been examined. Foreign inclusions and chemical migration from surgical implants have been studied.

Another application to biomedicine is to use Raman probing to study DNA biotargets and to identify sequence genes. In fact SERS has been applied to such problems [174].

B1.3.4.5 ANALYTICAL/INDUSTRIAL APPLICATIONS

Examples that use Raman spectroscopy in the quantitative analysis of materials are enormous. Technology that takes Raman based techniques outside the basic research laboratory has made these spectroscopies also available to industry and engineering. It is not possible here to recite even a small portion of applications. Instead we simply sketch one specific example.

Undeniably, one of the most important technological achievements in the last half of this century is the microelectronics industry, the computer being one of its outstanding products. Essential to current and future advances is the quality of the semiconductor materials used to construct vital electronic components. For example, ultra-clean silicon wafers are needed. Raman spectroscopy contributes to this task as a monitor, in real time, of the composition of the standard SC-1 cleaning solution (a mixture of water, H₂O₂ and NH₄OH) [175] that is essential to preparing the ultra-clean wafers.

B1.3.5 A SNAPSHOT OF RAMAN ACTIVITY IN 1998

In conclusion, we attempt to provide a ‘snapshot’ of current research in Raman spectroscopy. Since any choice of topics must be necessarily incomplete, and certainly would reflect our own scientific bias, we choose, instead, an arbitrary approach (at least one not that is not biased by our own specialization). Thus an abbreviated summary of the topics just presented in the keynote/plenary lectures at *ICORS XVI* in Cape Town, South Africa, is presented. Each of the 22 lectures appears in the *Proceedings (and Supplement) of the 16th International Conference on Raman Spectroscopy (1998)*, edited by A M Heyns (Chichester: Wiley) in a four-page format, almost all containing a short list of references. Rather than ourselves searching for seminal citations, we instead give the e-mail address of the principal author, when available. Though the intent in this procedure is to expose the wide scope of current Raman activity, it is hoped that the reader who is looking for more details will not hesitate to seek out the author in this fashion, and that the authors will not feel put upon by this manner of directing people to their work. To relate to [table B1.3.1](#) and [table B1.3.2](#), the acronym is given for the principal Raman spectroscopy that is used for each entry.

Keynote lecture. T G Spiro, e-mail address: spiro@princeton.edu (RRS and TRRRS). Review of protein dynamics followed by TRRRS selective to specific structural and prosthetic elements.

-44-

Plenary 1. D A Long, tel.: + 44 - 1943 608 472. Historical review of the first 70 years of Raman spectroscopy

Plenary 2. S A Asher *et al*, e-mail address: asher@vms.cis.pitt.edu/asher+ (RRS, TRRRS). UV RRS is used to probe methodically the secondary structure of proteins and to follow unfolding dynamics. Developing a library based approach to generalize the method to any protein.

Plenary 3. Ronald E Hester *et al*, e-mail address: reh@york.ac.uk (SERS). Use of dioxane envelope to bring water insoluble chromophores (chlorophylls) into contact with aqueous silver colloids for SERS enhancement. PSERRS—‘protected surface-enhanced resonance Raman spectroscopy’.

Plenary 4. George J Thomas Jr *et al*, e-mail address: thomasgj@cctr.umkc.edu (RS). Protein folding and assembly into superstructures. (Slow) time resolved RS probing of virus construction via protein assembly into an icosahedral (capsid) shell.

Plenary 5. Manuel Cardona, e-mail address: cardona@cardix.mpi-stuttgart.de (RS). Studies of high T_c superconductors. These offer all possible Raman transitions—phonons, magnons, free carrier excitations, pair

breaking excitations and mixed modes.

Plenary 6. Shu-Lin Zhang *et al*, e-mail address: slzhang@pku.edu.cn (RS). Studies of phonon modes of nanoscale one-dimensional materials. Confinement and defect induced Raman transitions.

Plenary 7. S Lefrante, e-mail address: lefrant@cnrs-imn.fr (RRS and SERS). Raman studies of electronic organic materials from conjugated polymers to carbon nanotubes. New insight into chain length distribution, charge transfer and diameter distribution in carbon nanotubes offered by Raman probing.

Plenary 8. J Greve *et al*, e-mail address: J.Greve@tn.utwente.nl (RS). Confocal direct imaging Raman microscope (CDIRM) for probing of the human eye lens. High spatial resolution of the distribution of water and cholesterol in lenses.

Plenary 9. J W Nibler *et al*, e-mail address: niblerj@chem.orst.edu (CARS and SRS). High resolution studies of high lying vibration–rotational transitions in molecules excited in electrical discharges and low density monomers and clusters in free jet expansions. Ionization detected (REMPI) SRS or IDSRS. Detect Raman lines having an FWHM of 30 MHz (10^{-3} cm^{-1}), possibly the sharpest lines yet recorded in RS. Line broadening due to saturation and the ac Stark effect is demonstrated.

Plenary 10. Hiro-o Hamaguchi, e-mail address: hhama@chem.s.u-tokyo.ac.jp (time and polarization resolved multiplex 2D-CARS). Two-dimensional (time and frequency) CARS using broadband dye source and streak camera timing. Studies dynamic behaviour of excited (pumped) electronic states. Follows energy flow within excited molecules. Polarization control of phase of signal (NR background suppression).

Plenary 11. W Kiefer *et al*, e-mail address: wolfgang.kiefer@mail.uni-wue.de (TR CARS). Ultrafast impulsive preparation of ground state and excited state wavepackets by impulsive CARS with REMPI detection in potassium and iodine dimers.

-45-

Plenary 12. Soo-Y Lee, e-mail address: scileesy@nus.edu.sg (RRS). Addresses fundamental theoretical questions in the phase recovery problem in the inverse transform (REP to ABS). See above.

Plenary 13. Andreas Otto, e-mail address: otto@rz.uni-duesseldorf.de (SERS). A survey of problems and models that underlie the SERS effect, now two decades old. Understanding the role of surface roughness in the enhancement.

Plenary 14. A K Ramdas *et al*, e-mail address: akr@physics.purdue.edu (RS). Electronic RS studies of doped diamond as potential semiconducting materials. A Raman active $1s(p_{3/2})-1s(p_{1/2})$ transition of a hole trapped on a boron impurity both in natural and ^{13}C diamond. A striking sensitivity of the transition energy to the isotopic composition of the host lattice.

Plenary 15. B Schrader *et al*, e-mail address: bernhard.schrader@uni-essen.de (NIR-FTRS). A review of the use of Raman spectroscopy in medical diagnostics. Its possibilities, limitations and expectations. Emphasizes the need for a library of reference spectra and the applications of advanced analysis (chemometry) for comparing patient/library spectra.

Plenary 16. N I Koroteev *et al*, e-mail address: Koroteev@nik.phys.msu.su (CARS/CSRS, CAHRS, BioCARS). A survey of the many applications of what we call the Class II spectroscopies from third order and beyond. 2D and 3D Raman imaging. Coherence as stored information, quantum information (the ‘qubit’). Uses terms CARS/CSRS regardless of order. BioCARS is fourth order in optically active solutions.

Plenary 17. P M Champion *et al*, e-mail address: champ@neu.edu (TRRRS). Femtosecond impulsive preparation and timing of ground and excited state Raman coherences in heme proteins. Discovery of coherence transfer along a de-ligation coordinate. See above for further comment.

Plenary 18. Robin J H Clark, e-mail address: r.j.h.clark@ucl.ac.uk (RS). Reports on recent diagnostic probing of art works ranging from illuminated manuscripts, paintings and pottery to papyri and icons. Nondestructive NIR microscopic RS is now realistic using CCD detection. Optimistic about new developments.

Plenary 19. H G M Edwards, e-mail address: h.g.m.edwards@bradford.ac.uk (NIR-FTRS). A review of recent applications of RS to archeology—characterizing ancient pigments, human skin, bone, ivories, teeth, resins, waxes and gums. Aging effects and dating possibilities. Emphasizes use of microscopic Raman.

Plenary 20. M Grimsditch, e-mail address: marcos_grimsditch@qmgate.anl.gov (magnetic field based RS). Low frequency Raman scattering from acoustic phonons is known as Brillouin scattering (BS). However any kind of small quantum Raman scattering is likewise called BS. Ferromagnetic materials offer spin that precesses coherently in the presence of an applied field. Such spin waves or magnons can undergo quantum jumps by the inelastic scattering of light. Experiments (and energy level spacing theory) involving surface magnons in very thin multilayer slabs (such as Fe/Cr/Fe) are discussed. The energy spacing (the Brillouin spectrum) depends on the applied magnetic field, and the RS (or BS) theory is driven by the magnetic component of the electromagnetic field, not the electric (as discussed exclusively in the present chapter).

-46-

Plenary 21A. Alian Wang *et al*, e-mail address: alianw@levee.wustl.edu (RS). (Unable to attend ICORS, but abstract is available in proceedings.) With technological advances, Raman spectroscopy now has become a field tool for geologists. Mineral characterization for terrestrial field work is feasible and a Raman instrument is being designed for the next rover to Mars, scheduled for 2003.

Plenary 21B. A C Albrecht *et al*, e-mail address: aca7@cornell.edu ($I^{(2)}$ CRS) (substituting for plenary 21A). Discusses four new applications using a ‘third’ approach to the Class II spectroscopies (see above). Raman spectrograms from $I^{(2)}$ CARS and $I^{(3)}$ CARS are seen to (i) decisively discriminate between proposed mechanisms for dephasing of the ring breathing mode in liquid benzene, (ii) detect the presence of memory in the Brownian oscillator model of dephasing, (iii) determine with very high accuracy Raman frequency shifts and bandwidths with changing composition in binary mixtures. Moreover these are successfully related to the partial pressures as they change with composition and (iv) to provide a new, definitive, way to discriminate between two competing processes at fifth order (6WM)—cascaded third order or true fifth order.

Clearly the broad survey of current activity in Raman spectroscopy revealed by this simple snapshot promises an exciting future that is likely to find surprising new applications, even as present methods and applications become refined.

APPENDIX

Here we examine the viewing angle dependence of the differential Raman cross-section for the cases of linearly polarized and circularly polarized incident light⁵. The angles used in such experiments are shown in figure B1.3.A.9. Experiments involving circularly polarized light are entirely defined in terms of the scattering angle, ζ , the angle between the wavevectors of the incident (\mathbf{k}_i) and scattered (\mathbf{k}_s) light. For experiment involving linearly polarized light, two angles are needed: ξ , the angle between \mathbf{k}_s and the unit vector along the direction of polarization of the incident light (\mathbf{e}_i) and η , the polar angle of \mathbf{k}_s in the plane perpendicular to \mathbf{e}_i . The polarization of the scattered light is analysed along the two axes \mathbf{e}_a and \mathbf{e}_b , where \mathbf{e}_b is chosen to be perpendicular to \mathbf{e}_i . The differential Raman cross-sections for the two analysing directions are

[176]

$$\left(\frac{d\sigma}{d\Omega}\right)_a = 4\pi^2 \left(\frac{e^2}{4\pi\epsilon_0\hbar c}\right)^2 \bar{v}_1 (\bar{v}_1 \pm \bar{v}_R)^3 \left(\frac{\cos^2 \xi (5\Sigma^1 + 3\Sigma^2)}{30} + \frac{\sin^2 \xi (10\Sigma^0 + 4\Sigma^2)}{30} \right) \quad (\text{B1.3.A1})$$

and

$$\left(\frac{d\sigma}{d\Omega}\right)_b = 4\pi^2 \left(\frac{e^2}{4\pi\epsilon_0\hbar c}\right)^2 \bar{v}_1 (\bar{v}_1 \pm \bar{v}_R)^3 \left(\frac{5\Sigma^1 + 3\Sigma^2}{30}\right). \quad (\text{B1.3.A2})$$

-47-

The total differential cross-section (equation (B1.3.A1) + equation (B1.3.A2)) is then

$$\left(\frac{d\sigma}{d\Omega}\right)_{\xi,\eta} = \left(\frac{d\sigma}{d\Omega}\right) \left(1 - \frac{1 - \rho_1}{1 + \rho_1} \cos^2 \xi\right) \quad (\text{B1.3.A3})$$

and the depolarization ratio

$$\rho(\xi, \eta) = \frac{\rho_1}{1 - (1 - \rho_1) \cos^2 \xi} \quad (\text{B1.3.A4})$$

where ρ_1 is given by [equation \(B1.3.23\)](#) and $(d\sigma/d\Omega)$ is the total differential cross section at 90° , $(d\sigma/d\Omega)_\parallel + (d\sigma/d\Omega)_\perp$, ([equation \(B1.3.20\)](#) and [equation \(B1.3.21\)](#)). From expression (B1.3.A3) and expression (B1.3.A4), one can see that no new information is gained from a linearly polarized light scattering experiment performed at more than one angle, since the two measurables at an angle (ξ, η) are given in terms of the corresponding quantities at 90° .

Figure B1.3.A.9. Diagram depicting the angles used in scattering experiments employing linearly and circularly polarized light. The subscripts i and s refer to the incident and scattered beam respectively.

For a circularly polarized light experiment, one can measure the cross sections for either right (r) or left (l) polarized scattered light. Suppose that right polarized light is made incident on a Raman active sample. The general expressions for the Raman cross sections are [176]

-48-

$$\left(\frac{d\sigma}{d\Omega}\right)_r = 4\pi^2 \left(\frac{e^2}{4\pi\epsilon_0\hbar c}\right)^2 \bar{\nu}_1 (\bar{\nu}_1 \pm \bar{\nu}_R)^3 \left(\begin{array}{l} \frac{1}{12}(1 + \cos \zeta)^2 \Sigma^0 \\ + \frac{1}{24}[(1 + \cos \zeta)^2 + 2 \sin^2 \zeta] \Sigma^1 \\ + \frac{1}{120}[(1 + \cos \zeta)^2 + 12(1 - \cos \zeta)] \Sigma^2 \end{array} \right)$$

and

In analogy with the depolarization ratio for linearly polarized light, the ratio of the two above quantities is known as the reversal coefficient, $R(\zeta)$, given by

$$R(\zeta) \equiv \frac{\left(\frac{d\sigma}{d\Omega}\right)_l}{\left(\frac{d\sigma}{d\Omega}\right)_r} = \frac{1 - \frac{1-\rho_1}{2(1+\rho_1)} \sin^2 \zeta - \frac{1-R(0)}{1+R(0)} \cos \zeta}{1 - \frac{1-\rho_1}{2(1+\rho_1)} \sin^2 \zeta + \frac{1-R(0)}{1+R(0)} \cos \zeta} \quad (\text{B1.3.A5})$$

where the zero angle reversal coefficient, $R(0)$, is $6\Sigma^2/(10\Sigma^0 + 5\Sigma^1 + \Sigma^2)$. Measurement of the reversal coefficient (equation (B1.3.A5)) at two appropriate scattering angles permits one to determine both ρ_1 and $R(0)$. Thus, only with circularly polarized light is one able to quantify all three rotational tensor invariants [176].

ACKNOWLEDGMENTS

One of us, ACA, also wishes to thank Dr David Klug for his provision of space, time, and a fine scientific atmosphere during a two month sabbatical leave at Imperial College, which turned out to involve considerable work on this material. The most helpful editing efforts of Professor R J H Clark have been very much appreciated. Finally, gratitude goes to Dr Gia Maisuradze for a careful reading of the manuscript and to Ms Kelly Case for her most attentive and effective reading of the proofs.

¹ A version of this material appears in a special issue of the *Journal of Physical Chemistry* dedicated to the Proceedings of the International Conference on Time-Resolved Vibrational Spectroscopy (TRVS IX), May 16–22 1999, Tucson, Arizona. See: Kirkwood J C, Ulness D J and Albrecht A C 2000 On the classification of the electric field spectroscopies: applications to Raman scattering *J. Phys. Chem. A* **104** 4167–73.

²In fact averaging over an odd number of direction cosines need not always vanish for an isotropic system. This is the case for solutions containing chiral centres which may exhibit even order signals such as 'BioCARS' in [table B1.3.2](#).

RS (or BS) theory is driven by the magnetic component of the electromagnetic field, not the electric (as discussed exclusively in the present chapter).

Plenary 21A. Alian Wang *et al*, e-mail address: alianw@levee.wustl.edu (RS). (Unable to attend ICORS, but abstract is available in proceedings.) With technological advances, Raman spectroscopy now has become a field tool for geologists. Mineral characterization for terrestrial field work is feasible and a Raman instrument is being designed for the next rover to Mars, scheduled for 2003.

Plenary 21B. A C Albrecht *et al*, e-mail address: aca7@cornell.edu (I⁽²⁾CRS) (substituting for plenary 21A). Discusses four new applications using a ‘third’ approach to the Class II spectroscopies (see above). Raman spectrograms from I⁽²⁾CARS and I⁽³⁾CARS are seen to (i) decisively discriminate between proposed mechanisms for dephasing of the ring breathing mode in liquid benzene, (ii) detect the presence of memory in the Brownian oscillator model of dephasing, (iii) determine with very high accuracy Raman frequency shifts and bandwidths with changing composition in binary mixtures. Moreover these are successfully related to the partial pressures as they change with composition and (iv) to provide a new, definitive, way to discriminate between two competing processes at fifth order (6WM)—cascaded third order or true fifth order.

Clearly the broad survey of current activity in Raman spectroscopy revealed by this simple snapshot promises an exciting future that is likely to find surprising new applications, even as present methods and applications become refined.

Here we examine the viewing angle dependence of the differential Raman cross-section for the cases of linearly polarized and circularly polarized incident light⁵. The angles used in such experiments are shown in [figure B1.3.A.9](#) Experiments involving circularly polarized light are entirely defined in terms of the scattering angle, ζ , the angle between the wavevectors of the incident (\mathbf{k}_i) and scattered (\mathbf{k}_s) light. For experiment involving linearly polarized light, two angles are needed: ξ , the angle between \mathbf{k}_s and the unit vector along the direction of polarization of the incident light (\mathbf{e}_i) and η , the polar angle of \mathbf{k}_s in the plane perpendicular to \mathbf{e}_i . The polarization of the scattered light is analysed along the two axes \mathbf{e}_a and \mathbf{e}_b , where \mathbf{e}_b is chosen to be perpendicular to \mathbf{e}_i . The differential Raman cross-sections for the two analysing directions are [176]

Figure B1.3.A.9. Diagram depicting the angles used in scattering experiments employing linearly and circularly polarized light. The subscripts i and s refer to the incident and scattered beam respectively.

$$\left(\frac{d\sigma}{d\Omega}\right)_a = 4\pi^2 \left(\frac{e^2}{4\pi\epsilon_0\hbar c}\right)^2 \bar{v}_1 (\bar{v}_1 \pm \bar{v}_R)^3 \left(\frac{\cos^2 \xi (5\Sigma^1 + 3\Sigma^2)}{30} + \frac{\sin^2 \xi (10\Sigma^0 + 4\Sigma^2)}{30} \right) \quad (\text{B1.3.A1})$$

and

$$\left(\frac{d\sigma}{d\Omega}\right)_b = 4\pi^2 \left(\frac{e^2}{4\pi\epsilon_0\hbar c}\right)^2 \bar{v}_1 (\bar{v}_1 \pm \bar{v}_R)^3 \left(\frac{5\Sigma^1 + 3\Sigma^2}{30}\right). \quad (\text{B1.3.A2})$$

The total differential cross-section (equation (B1.3.A1) + equation (B1.3.A2)) is then

$$\left(\frac{d\sigma}{d\Omega}\right)_{\xi,\eta} = \left(\frac{d\sigma}{d\Omega}\right) \left(1 - \frac{1 - \rho_1}{1 + \rho_1} \cos^2 \xi\right) \quad (\text{B1.3.A3})$$

and the depolarization ratio

$$\rho(\xi, \eta) = \frac{\rho_1}{1 - (1 - \rho_1) \cos^2 \xi} \quad (\text{B1.3.A4})$$

where ρ_1 is given by [equation \(B1.3.23\)](#) and $(d\sigma/d\Omega)$ is the total differential cross section at 90° , $(d\sigma/d\Omega)_\parallel + (d\sigma/d\Omega)_\perp$, ([equation \(B1.3.20\)](#) and [equation \(B1.3.21\)](#)). From [expression \(B1.3.A3\)](#) and [expression \(B1.3.A4\)](#), one can see that no new information is gained from a linearly polarized light scattering experiment performed at more than one angle, since the two measurables at an angle (ξ, η) are given in terms of the corresponding quantities at 90° .

For a circularly polarized light experiment, one can measure the cross sections for either right (r) or left (l) polarized scattered light. Suppose that right polarized light is made incident on a Raman active sample. The general expressions for the Raman cross sections are [176]

$$\left(\frac{d\sigma}{d\Omega}\right)_r = 4\pi^2 \left(\frac{e^2}{4\pi\epsilon_0\hbar c}\right)^2 \bar{\nu}_1(\bar{\nu}_1 \pm \bar{\nu}_R)^3 \begin{pmatrix} \frac{1}{12}(1 + \cos \zeta)^2 \Sigma^0 \\ + \frac{1}{24}[(1 + \cos \zeta)^2 + 2 \sin^2 \zeta] \Sigma^1 \\ + \frac{1}{120}[(1 + \cos \zeta)^2 + 12(1 - \cos \zeta)] \Sigma^2 \end{pmatrix}$$

and

$$\left(\frac{d\sigma}{d\Omega}\right)_l = 4\pi^2 \left(\frac{e^2}{4\pi\epsilon_0\hbar c}\right)^2 \bar{\nu}_1(\bar{\nu}_1 \pm \bar{\nu}_R)^3 \begin{pmatrix} \frac{1}{12}(-1 + \cos \zeta)^2 \Sigma^0 \\ + \frac{1}{24}[(-1 + \cos \zeta)^2 + 2 \sin^2 \zeta] \Sigma^1 \\ + \frac{1}{120}[(-1 + \cos \zeta)^2 + 12(1 + \cos \zeta)] \Sigma^2 \end{pmatrix}.$$

In analogy with the depolarization ratio for linearly polarized light, the ratio of the two above quantities is known as the reversal coefficient, $R(\zeta)$, given by

$$R(\zeta) \equiv \frac{\left(\frac{d\sigma}{d\Omega}\right)_l}{\left(\frac{d\sigma}{d\Omega}\right)_r} = \frac{1 - \frac{1-\rho_1}{2(1+\rho_1)} \sin^2 \zeta - \frac{1-R(0)}{1+R(0)} \cos \zeta}{1 - \frac{1-\rho_1}{2(1+\rho_1)} \sin^2 \zeta + \frac{1-R(0)}{1+R(0)} \cos \zeta} \quad (\text{B1.3.A5})$$

where the zero angle reversal coefficient, $R(0)$, is $6\Sigma^2/(10\Sigma^0 + 5\Sigma^1 + \Sigma^2)$. Measurement of the reversal coefficient (equation (B1.3.A5)) at two appropriate scattering angles permits one to determine both ρ_1 and $R(0)$. Thus, only with circularly polarized light is one able to quantify all three rotational tensor invariants [176].

ACKNOWLEDGMENTS

One of us, ACA, also wishes to thank Dr David Klug for his provision of space, time, and a fine scientific atmosphere during a two month sabbatical leave at Imperial College, which turned out to involve considerable work on this

material. The most helpful editing efforts of Professor R J H Clark have been very much appreciated. Finally, gratitude goes to Dr Gia Maisuradze for a careful reading of the manuscript and to Ms Kelly Case for her most attentive and effective reading of the proofs.

²In fact averaging over an odd number of direction cosines need not always vanish for an isotropic system. This is the case for solutions containing chiral centres which may exhibit even order signals such as 'BioCARS' in [table B1.3.2](#).

³ Here, we have averaged over all possible orientations of the molecules. (See [26].)

⁴ Raman cross-sections, based on the linear polarizability, are now routinely subject to quantum chemical calculations. These may be found as options in commercial packages such as 'Gaussian 98' (Gaussian Inc., Pittsburgh, PA).

⁵ This treatment is essentially that given in [176].

B1.4 Microwave and terahertz spectroscopy

Geoffrey A Blake

B1.4.1 INTRODUCTION

Spectroscopy, or the study of the interaction of light with matter, has become one of the major tools of the natural and physical sciences during this century. As the wavelength of the radiation is varied across the electromagnetic spectrum, characteristic properties of atoms, molecules, liquids and solids are probed. In the

optical and ultraviolet regions ($\lambda \sim 1 \mu\text{m}$ up to 100 nm) it is the electronic structure of the material that is investigated, while at infrared wavelengths ($\sim 1\text{--}30 \mu\text{m}$) the vibrational degrees of freedom dominate.

Microwave spectroscopy began in 1934 with the observation of the $\sim 20 \text{ GHz}$ absorption spectrum of ammonia by Cleeton and Williams. Here we will consider the microwave region of the electromagnetic spectrum to cover the 1 to $100 \times 10^9 \text{ Hz}$, or 1 to 100 GHz ($\lambda \sim 30 \text{ cm}$ down to 3 mm), range. While the ammonia microwave spectrum probes the inversion motion of this unique pyramidal molecule, more typically microwave spectroscopy is associated with the pure rotational motion of gas phase species.

The section of the electromagnetic spectrum extending roughly from 0.1 to $10 \times 10^{12} \text{ Hz}$ ($0.1\text{--}10 \text{ THz}$, $3\text{--}300 \text{ cm}^{-1}$) is commonly known as the far-infrared (FIR), submillimetre or terahertz (THz) region, and therefore lies between the microwave and infrared windows. Accordingly, THz spectroscopy shares both scientific and technological characteristics with its longer- and shorter-wavelength neighbours. While rich in scientific information, the FIR or THz region of the spectrum has, until recently, been notoriously lacking in good radiation sources—earning the dubious nickname ‘the gap in the electromagnetic spectrum’. At its high-frequency boundary, most coherent photonic devices (e.g. diode lasers) cease to radiate due to the long lifetimes associated with spontaneous emission at these wavelengths, while at its low-frequency boundary parasitic losses reduce the oscillatory output from most electronic devices to insignificant levels. As a result, existing coherent sources suffer from a number of limitations. This situation is unfortunate since many scientific disciplines—including chemical physics, astrophysics, cosmochemistry and planetary/atmospheric science to name but a few—rely on *high-resolution* THz spectroscopy (both in a spectral and temporal sense). In addition, technological applications such as ultrafast signal processing and massive data transmission would derive tremendous enhancements in rate and volume throughput from frequency-agile THz synthesizers.

In general, THz frequencies are suitable for probing low-energy light–matter interactions, such as rotational transitions in molecules, phonons in solids, plasma dynamics, electronic fine structure in atoms, thermal imaging of cold sources and vibrational–rotation–tunnelling behaviour in weakly bound clusters. Within the laboratory, THz spectroscopy of a variety of molecules, clusters and condensed phases provides results that are critical to a proper interpretation of the data acquired on natural sources, and also leads to a better understanding of important materials—particularly hydrogen-bonded liquids, solids and polymers that participate in a variety of essential (bio)chemical processes.

For remote sensing, spectroscopy at THz frequencies holds the key to our ability to remotely sense environments as diverse as primaeval galaxies, star and planet-forming molecular cloud cores, comets and planetary atmospheres.

-2-

In the dense interstellar medium characteristic of sites of star formation, for example, scattering of visible/UV light by sub-micron-sized dust grains makes molecular clouds optically opaque and lowers their internal temperature to only a few tens of Kelvin. The thermal radiation from such objects therefore peaks in the FIR and only becomes optically thin at even longer wavelengths. Rotational motions of small molecules and rovibrational transitions of larger species and clusters thus provide, in many cases, the only or the most powerful probes of the dense, cold gas and dust of the interstellar medium.

Since the major drivers of THz technology have been scientists, particularly physicists and astrophysicists seeking to carry out fundamental research, and not commercial interests, a strong coupling of technology development efforts for remote sensing with laboratory studies has long characterized spectroscopy at microwave and THz frequencies. In many respects the field is still in its infancy, and so this chapter will present both an overview of the fundamentals of microwave and THz spectroscopy as well as an assessment of the current technological state of the art and the potential for the future. We will begin with a brief overview of the general characteristics of THz spectrometers and the role of incoherent sources and detection

strategies in the THz region, before turning to a more detailed description of the various coherent THz sources developed over the past decade and their applications to both remote sensing and laboratory studies.

B1.4.2 INCOHERENT THZ SOURCES AND BROADBAND SPECTROSCOPY

B1.4.2.1 PRINCIPLES AND INSTRUMENTATION

Like most other fields of spectroscopy, research at THz frequencies in the first half of the twentieth century was carried out with either dispersive (i.e. grating-based) or Fourier transform spectrometers. The much higher throughput of Fourier transform spectrometers compared to those based on diffraction gratings has made THz Fourier transform spectroscopy, or THz FTS, the most popular incoherent technique for acquiring data over large regions of the THz spectrum. This is especially true for molecular line work where THz FTS resolutions of order 50–100 MHz or better have been obtained [1]. With large-format detector arrays, such as those available at optical through near- to mid-infrared wavelengths, grating- or Fabry–Perot-based instruments can provide superior sensitivity [2], but have not yet been widely utilized at THz frequencies due to the great difficulty of fabricating arrays of THz detectors.

The components of THz spectrometers can be grouped into three main categories: sources (e.g. lasers, Gunn oscillators, mercury-discharge lamps), propagating components (e.g. lenses, sample cells, filters) and detectors (e.g. bolometers, pyroelectric detectors, photoacoustic cells). Propagating components in the FIR are well established (see [3] for an excellent overview of technical information). In the area of detectors, recent progress has placed them ahead of source technology. For example, spider-web Si bolometers developed by Bock *et al* [4] have an electrical NEP (noise-equivalent power) of $4 \times 10^{17} \text{ W Hz}^{-1/2}$ when cooled to 300 mK. For those who desire less exotic cryogenic options, commercially available Si-composite bolometers offer an electrical NEP of $1 \times 10^{-13} \text{ W Hz}^{-1/2}$, operating at liquid helium temperature (4.2 K), and an electrical NEP of $3 \times 10^{-15} \text{ W Hz}^{-1/2}$, operating at 1.2 K (pumped L_{He}). Combining these into large-format arrays remains a considerable technological challenge, although arrays of several tens of pixels on a side are now beginning to make their way into various telescopes such as the Caltech Submillimeter Observatory and the James Clerk Maxwell Telescope [5, 6]. In addition, their electrical bandwidths are typically only between a few hundred hertz and 1 kHz. Fast-modulation schemes cannot therefore be used, and careful attention must be paid to $1/f$ noise in experiments with Si bolometers. Hot-electron bolometers based on InSb offer electrical

-3-

bandwidths of 1 MHz, but without cyclotron-assisted resonance, InSb THz bolometers cannot be used above $\nu = 25\text{--}30 \text{ cm}^{-1}$ [7]. Similarly, photoconductors based on Ga:Ge offer high electrical speed and good quantum efficiency, but due to the bandgap of the material are unusable below $50\text{--}60 \text{ cm}^{-1}$ [8].

In practice, the NEP of a room-temperature THz spectrometer is usually limited by fluctuations (shot-noise) in the ambient blackbody radiation. Using an optical bandwidth $\Delta\nu = 3 \text{ THz}$ (limited by, for example, a polyethylene/diamond dust window), a field of view (at normal incidence) $\theta = 9^\circ$ and a detecting diameter (using a so-called Winston cone, which condenses the incident radiation onto the detecting element) $d = 1.1 \text{ cm}$, values that are typical for many laboratory applications, the background-limited NEP of a bolometer is given by

(B1.4.1)

where k is the Boltzmann constant, $T = 300 \text{ K}$, Δf (the electronic amplified bandwidth) = 1 Hz, and λ (the band-centre wavelength) $\approx 200 \text{ }\mu\text{m}$. The equation above uses the Rayleigh–Jeans law, which is valid for $\nu \gg 17$

THz. Therefore, for laboratory absorption experiments, a typical FIR detector provides an estimated detection limit (NEP/source power) of 10^{-4} with a source output of 20 nW. In general, high-sensitivity bolometers saturate at an incident-power level of $\approx 1 \mu\text{W}$ or less, resulting in an ultimate detection limit of 10^{-7} . For yet higher dynamic range, a filter element (e.g. cold grating, prism, or etalon) must be placed before the detector to reduce background noise, or the background temperature must be lowered. Note the $(\Delta\nu)^{1/2}$ dependence in equation (B1.4.1), which means that the optical bandwidth must be reduced to ~ 30 GHz to drop the NEP by a factor of ten. *Thus, unlike shorter wavelength regions of the electromagnetic spectrum, due to the high background luminosity in the THz, spectroscopic sensitivity in the laboratory is limited by the source power, in comparison to the background power, incident on the detector—not by shot-noise of the available spectroscopic light sources.* As higher-power light sources are developed at THz frequencies, lower-NEP detectors can be utilized that are less prone to saturation, and shot-noise will become the limiting factor, as it is in other regions of the electromagnetic spectrum.

For broadband THz FTS instruments this large background actually leads to a ‘multiplex disadvantage’ in that the room-temperature laboratory background can easily saturate the sensitive THz detectors that are needed to detect the feeble output of incoherent THz blackbody sources, which drop rapidly as the wavelength increases. The resulting sensitivity is such that signal-to-noise ratios in excess of 100 are difficult to generate at the highest feasible resolutions of 50–100 MHz [1], which is still quite large compared to the 1–2 MHz Doppler-limited line widths at low pressure. For low-resolution work on condensed phases, or for the acquisition of survey spectra, however, THz FTS remains a popular technique. Beyond wavelengths of ~ 1 mm, the sensitivity of FTS is so low that the technique is no longer competitive with the coherent approaches described below.

B1.4.2.2 THZ FTS STUDIES OF PLANETARY ATMOSPHERES

Rather different circumstances are encountered when considering THz remote sensing of extraterrestrial sources. The major source of THz opacity in the Earth’s atmosphere is water vapour, and from either high, dry mountain sites or from space there are windows in which the background becomes very small. Incoherent instruments which detect the faint emission from astronomical sources can therefore be considerably more sensitive than their laboratory

-4-

counterparts. Again, grating- or etalon-based and FTS implementations can be considered, with the former being preferred if somewhat coarse spectral resolution is desired or if large-format detector arrays are available.

In planetary atmospheres, a distinct advantage of THz studies over those at optical and infrared wavelengths is the ability to carry out spectroscopy without a background or input source such as the sun. Global maps of a wide variety of species can therefore be obtained at any time of day or night and, when taken at high enough spectral resolution, the shapes of the spectral lines themselves also contain additional information about vertical abundance variations and can be used to estimate the atmospheric temperature profile. The ‘limb sounding’ geometry, in which microwave and THz emission from the limb of a planetary atmosphere is imaged by an orbiting spacecraft or a balloon, is particularly powerful in this regard, and excellent reviews are available on this subject [9]. The observing geometry is illustrated in [figure B1.4.1](#) which also presents a portion of the Earth’s stratospheric emission spectrum near 118 cm^{-1} obtained by the balloon-borne Smithsonian Astrophysical Observatory limb-sounding THz FTS [10].

B1.4.3 COHERENT THZ SOURCES AND HETERODYNE SPECTROSCOPY

B1.4.3.1 PRINCIPLES AND INSTRUMENTATION

The narrow cores of atmospheric transitions shown in [figure B1.4.1](#) can be used, among other things, to trace the wind patterns of the upper atmosphere. For such work, or for astronomical remote-sensing efforts, resolutions of the order of $30\text{--}300\text{ m s}^{-1}$ are needed to obtain pressure broadening or kinematic information, which correspond to spectral resolutions of $(\nu/\Delta\nu) \sim 1\text{--}10 \times 10^6$. Neither FTS nor grating-based spectrometers can provide resolution at this level and so other techniques based on coherent radiation sources must be used. The most important of these is called heterodyne spectroscopy. Heterodyne spectroscopy uses nonlinear detectors called mixers, in order to downconvert the high-frequency THz radiation into radiofrequency or microwave signals that can be processed using commercial instrumentation. An outline of a heterodyne receiver is presented in [figure B1.4.2](#). In such a receiver, an antenna (dish) collects radiation from space, and this radiation is focused onto a detector operating in heterodyne mode, which means that the incoming signal is mixed with the output of a coherent source (called the local oscillator, or LO). Now, if a device can be constructed that responds quadratically, rather than linearly, to the two input beams, the output, $S(t)$, of such a device is given by

$$\begin{aligned}
 S(t) &\propto e(t)^2 \\
 S(t) &\propto 1/2(E_1^2 + E_2^2) + 1/2[E_1^2 \cos(2\omega_1 t) + E_2^2 \cos(2\omega_2 t)] \\
 &\quad + E_1 E_2 \cos[(\omega_1 t + \omega_2 t) + (\phi_1 + \phi_2)] \\
 &\quad + \underbrace{E_1 E_2 \cos[(\omega_1 - \omega_2)t + (\phi_1 - \phi_2)]}_{\text{DIFFERENCE-FREQUENCY FIELD}}
 \end{aligned}
 \tag{B1.4.2}$$

where the identities $2\cos\alpha\cos\beta = \cos(\alpha+\beta) + \cos(\alpha-\beta)$ and $\cos^2\alpha = 1/2(1 + \cos 2\alpha)$ are invoked. The last term is a field oscillating at a frequency equal to the difference between the two incidental fields—representing the beat-note between ν_1 and ν_2 .

Figure B1.4.1. Top: schematic illustration of the observing geometry used for limb sounding of the Earth's atmosphere. Bottom: illustrative stratospheric OH emission spectra acquired by the SAO FIRS-2 far-infrared balloon-borne FTS in autumn 1989. The spectra are from a range of tangent heights (h = tangent height in the drawing), increasing toward the bottom, where the data are represented by solid curves; nonlinear least-square fits to the measurements, based on a combination of laboratory data, the physical structure of the stratosphere and a detailed radiative transfer calculation, are included as dashed curves. The OH lines are $F_1({}^2\Pi_{3/2}, 7/2^- \rightarrow 5/2^+$ and $7/2^+ \rightarrow 5/2^-$ (the hyperfine structure is unresolved in these measurements). Other major contributing lines are also identified [10].

figure continued on next page.

Figure B1.4.2. (A) Basic components of an astronomical heterodyne receiver. The photomicrograph in (B) presents the heart of a quasi-optical SIS mixer and its associated superconducting tuning circuits, while the image in (C) shows the fully assembled mixer, as it would be incorporated into a low-temperature cryostat (J Zmuidzinas, private communication).

If $\nu_1 = \nu_{LO}$ and $\nu_2 = \nu_{SKY} \approx \nu_{LO}$, the sum frequency lies at THz frequencies, while the difference lies at radio or microwave frequencies, and is called the intermediate frequency, or IF. The IF can be amplified and recorded (for example, on a spectrum analyser or by a digital correlator or filterbank) across a range of frequencies simultaneously. The fact that the IF power is proportional to the product of the remote-signal power and the LO power results in two main advantages: (a) the signal-to-noise ratio is enhanced by using an LO power that is much higher than that of the remote signal and (b) the spectral resolution is set by the linewidth of the LO, which can be as narrow as desired.

Among the first THz mixers to be constructed were those based on room-temperature Schottky diodes [11]. Over the past decade, new mixers based on superconducting tunnel junctions have been developed that have effective noise levels only a few times the quantum limit of $T_{\text{mixer}} = h\nu/k$ [12]. However, certain conditions must be met in order to exploit these advantages. For example, while the LO power should be strong compared to the remote signal and to the noise, it must not be so strong as to saturate the detecting element. Roughly speaking, the optical coupled LO power level is about 1 μW for SIS (superconductor–insulator–superconductor) mixers and 100 nW for superconductive Nb HEBs (hot-electron bolometers, or transition

edge bolometers, TEBs). In addition, since the overlap between the remote signal and the LO is important, the spatial distribution of the LO output must be well coupled to the receiver's antenna mode. Although this requirement imposes experimental complexity, it also provides excellent rejection of ambient background radiation.

As noted above, at THz frequencies the Rayleigh–Jeans approximation is a good one, and it is typical to report line intensities and detector sensitivities in terms of the Rayleigh–Jeans equivalent temperatures. In frequencies range where the atmospheric transmission is good, or from airborne or space-borne platforms, the effective background temperature is only a few tens of Kelvin. Under such conditions, SIS mixers based on Nb, a particular implementation of which is pictured in [figure B1.4.2](#) can now perform up to 1.0 THz with $T_{\text{mixer}} = 130$ K [13]. The earliest SIS microwave and millimetre-wave receivers utilized waveguide components, but as the operating frequencies have been pushed into the THz region, quasi-optical designs such as those shown in [figure B1.4.2](#) become attractive. Such designs may also be easier to incorporate into THz receiver arrays. Recently, alternative superconducting Nb hot-electron mixers that rely on a diffusion-based relaxation mechanism have been demonstrated with $T_{\text{mixer}} = 750$ K between 1 and 2.5 THz [14]. These devices are expected to operate up to at least several tens of THz—if coherent sources are available as LOs. Thus, THz source technology plays a key role in setting the spectroscopic sensitivity for both laboratory and remote-sensing experiments.

B1.4.3.2 THZ REMOTE SENSING WITH HETERODYNE RECEIVERS

Heterodyne spectroscopy has been particularly critical to the study of the Earth's stratosphere, where the improved resolution and sensitivity compared to the FTS spectra shown in [figure B1.4.1](#) have led to the collection of global maps of species important to ozone chemistry and atmospheric dynamics (O_3 , ClO, SO_2 , H_2O , O_2 , etc: see [9] for an extended overview), and of the dense interstellar medium. Although human beings have been systematically observing astronomical objects for thousands of years, until the advent of radioastronomy in the 1960s we possessed little knowledge of what, if anything, exists in the space between stars. Optical observations revealed only stars, galaxies and nebulae; if matter existed in the vast, dark interstellar medium, it was not detectable. However, the discovery of the first polyatomic microwave in the interstellar medium, water (H_2O), ammonia (NH_3) and formaldehyde (H_2CO), by microwave remote sensing (in 1968 [15]) set off an exciting era of discovery.

To date, researchers have identified more than 100 different molecules, composed of up to 13 atoms, in the interstellar medium [16]. Most were initially detected at microwave and (sub)millimetre frequencies, and the discoveries have reached far beyond the mere existence of molecules. Newly discovered entities such as diffuse interstellar clouds, dense (or dark) molecular clouds and giant molecular cloud complexes were characterized for the first time. Indeed, radioastronomy (which includes observations ranging from radio to submillimetre frequencies) has dramatically changed our perception of the composition of the universe. Radioastronomy has shown that most of the mass in the interstellar medium is contained in so-called dense molecular clouds, which have tremendous sizes of 1–100 light years, average gas densities of 10^2 – 10^3 cm^{-3} , and temperatures in the range of 10–600 K. An overview of the THz emission from a cold, dense interstellar cloud is presented in [figure B1.4.3](#) [17].

figure continued on next page.

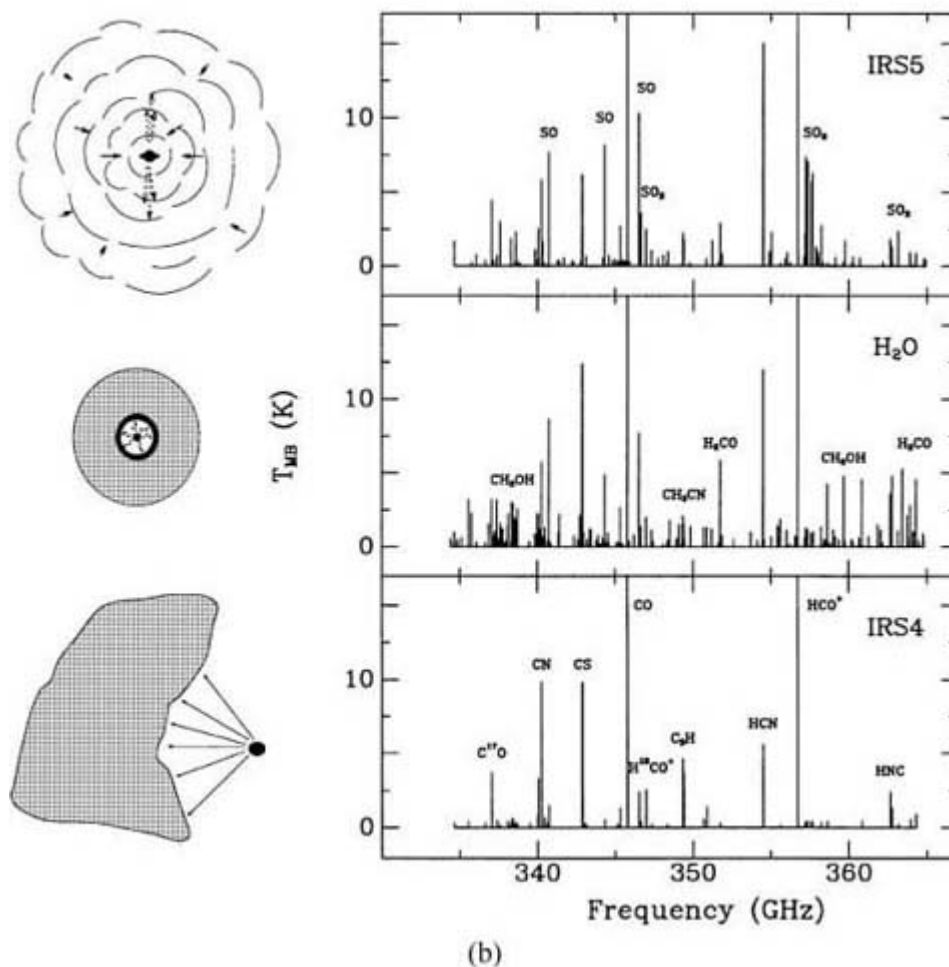

Figure B1.4.3. (a) A schematic illustration of the THz emission spectrum of a dense molecular cloud core at 30 K and the atmospheric transmission from ground and airborne altitudes (adapted, with permission, from [17]). (b) The results of 345 GHz molecular line surveys of three cores in the W3 molecular cloud; the graphics at left depict the evolutionary state of the dense cores inferred from the molecular line data [21].

In addition to striking differences from one cloud to another, each dense molecular cloud is inhomogeneous, containing clumps, or cores, of higher-density material situated within envelopes of somewhat lower density. Many of these higher-density cores are active sites of star formation, with the youngest stars being detectable only in the IR or FIR. Star formation is of major interest in astrophysics, and it contains a wealth of interesting chemical reactions and physical phenomena (for excellent reviews, see [18, 19 and 20]). Optical observations are unable to characterize interstellar clouds due to absorption and scattering, both of which have an inverse wavelength dependence, by the pervasive dust particles inside these clouds. Thus, microwave and THz spectroscopy is responsible for identifying most of the hundred or so interstellar molecules to date, and continues to dominate the fields of molecular astrophysics and interstellar chemistry. The power of heterodyne spectroscopy in examining the differences between dense clouds undergoing star (and presumably planet) formation is shown in the right panel of [figure B1.4.3](#) which depicts the

345 GHz spectral line surveys of three regions of the W3 giant molecular cloud complex [21]. From such studies, which reveal dramatic differences in the THz spectrum of various objects, molecular astrophysicists hope to classify the evolutionary state of the cloud, just as optical spectra are used to classify stars.

High angular resolution studies with modern THz telescopes and interferometric arrays can even probe the

material destined to become part of planetary systems. In the accretion discs around young stars, for example, a range of simple organic species have now been detected at (sub)millimetre wavelengths [22]. Such accretion disks are the assembly zones of planets, and the first steps in THz imaging their outer regions and in understanding the means by which they evolve have been taken [23]. The physical and chemical conditions in these objects can now be compared to that observed in primitive solar system objects such as comets and icy satellites. The recent apparitions of comets Hyakutake and Hale–Bopp, for example, have provided a wealth of new observations at IR, THz and microwave frequencies that have led to a much improved understanding of the origin and evolution of planetesimals in the outer solar system [24]. Future work in high-resolution THz imaging will be dramatically enhanced by the Atacama Large Millimeter Array (ALMA), which will operate over the 1 cm to 350 μm interval at an altitude of 16 000 ft in the Atacama desert of northern Chile [25].

Ultimately, studies from ground-based observatories are limited by absorption in the Earth's atmosphere. For example, no studies above ≈ 1 THz are possible even from mountain-top observatories. Two major instruments, SOFIA and FIRST, are poised to change this situation dramatically. SOFIA (for Stratospheric Observatory For Infrared Astronomy [26]) will carry a 2.7 m telescope in a 747SP aircraft to altitudes of 41 000–45 000 feet. At these altitudes, nearly 60–70% of the THz spectrum up to the mid-IR is accessible (figure B1.4.3), and both incoherent and heterodyne spectrometers are being constructed as part of the initial instrument suite. SOFIA will become operational in 2002. On somewhat longer timescales, FIRST (the Far-InfraRed Space Telescope [27]) will carry 0.4–1.2 THz SIS and 1.2–1.9/2.4–2.7 THz antenna coupled HEB receivers at the focal plane of a 4 m telescope into space. Like SOFIA, FIRST will also include incoherent spectrometers and imagers to take advantage of the low background flux and to survey larger regions of the THz spectrum and sky.

B1.4.4 SPECTROSCOPY WITH TUNABLE MICROWAVE AND THZ SOURCES

B1.4.4.1 PRINCIPLES AND BACKGROUND

Long before the invention of the laser, coherent radiation sources such as electron beam tubes (e.g. klystrons and backward wave oscillators, or BWOs) were in use by microwave spectroscopists to examine the direct absorption rotational spectroscopy of molecules. Being the interface between microwave spectroscopy (generally associated with low-energy rotational transitions of molecules) and mid-IR spectroscopy (generally associated with vibrational transitions of molecules), THz spectra such as those outlined in figure B1.4.3 probe the high-frequency rotations of molecules and certain large-amplitude vibrational motions. As the rotational energy levels of a molecule depend largely on its moment of inertia, which is determined by the molecular structure, high-resolution spectroscopy of gas phase molecules provides the most precise information available on molecular geometries.

Rotational transition frequencies acquired in the THz region expand upon and complement those acquired in the microwave. Two types of molecules undergo rotational transitions that fall in the FIR: molecules with rotation about an axis having a small moment of inertia, and molecules in high- J states. FIR spectra of the first type of molecules are

important for determining their equilibrium geometry, as many light molecules (H_2O , NH_3 , HF, etc) only have transitions in the submillimetre and FIR regions. Due to the high rotational energy in the second type of species (high- J molecules), interactions between the vibrational and rotational motions, namely, centrifugal distortion and Coriolis perturbations, become important. Given high enough spectral resolution and accuracy ($\Delta\nu/\nu \leq 10^{-5}$), shifts in rotational frequencies and changes in selection rules resulting from these interactions

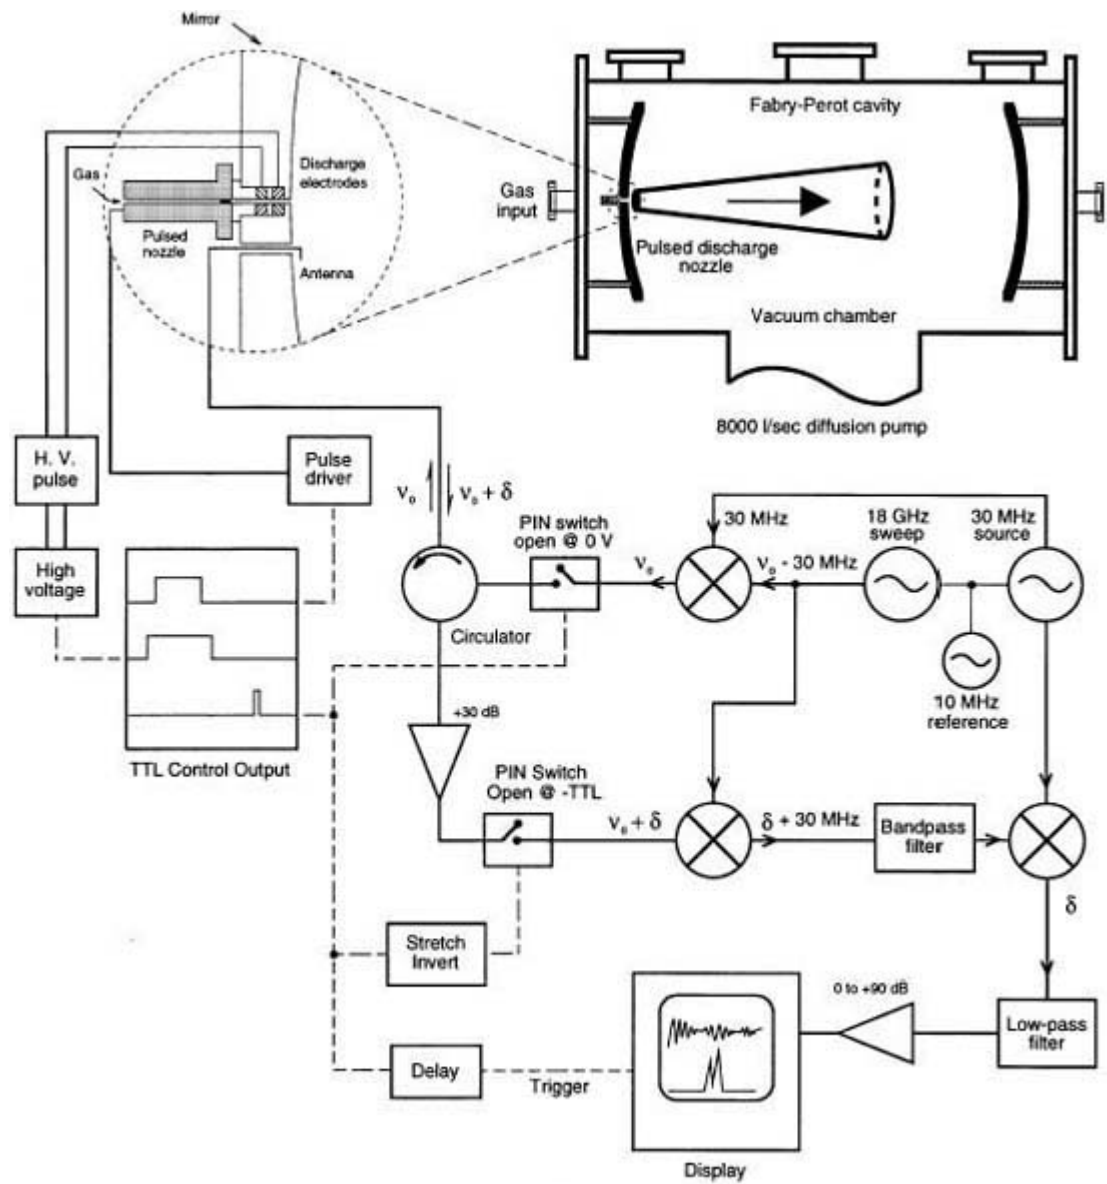

become significant. Thus, FIR spectroscopy of high- J transitions enables detailed characterization of molecular Hamiltonians far beyond the rigid rotor approximation, giving more accurate zero-point rotational constants and rough estimates of the shapes of potential energy surfaces. Finally, for very large molecules or weakly bound clusters, the softest vibrational degrees of freedom can be probed at THz frequencies, as is outlined in greater detail below.

B1.4.4.2 FOURIER TRANSFORM MICROWAVE SPECTROSCOPY

At microwave frequencies, direct absorption techniques become less sensitive than those in the THz region due to the steep dependence of the transition intensities with frequency. A variant of heterodyne spectroscopy, pioneered by Flygare and Balle [28], has proven to be much more sensitive. In this approach, molecules are seeded into or generated by a pulsed molecular beam which expands into a high- Q microwave cavity. The adiabatic expansion cools the rotational and translation degrees of freedom to temperatures near 1–10 K, and thus greatly simplifies the rotational spectra of large molecules. In addition, the low-energy collisional environment of the jet can lead to the growth of clusters held together by weak intermolecular forces.

A microwave pulse from a tunable oscillator is injected into the cavity by an antenna, and creates a coherent superposition of rotational states. In the absence of collisions, this superposition emits a free-induction decay signal, which is detected with an antenna-coupled microwave mixer similar to those used in molecular astrophysics. The data are collected in the time domain and Fourier transformed to yield the spectrum whose bandwidth is determined by the quality factor of the cavity. Hence, such instruments are called Fourier transform microwave (FTMW) spectrometers (or Flygare–Balle spectrometers, after the inventors). FTMW instruments are extraordinarily sensitive, and can be used to examine a wide range of stable molecules as well as highly transient or reactive species such as hydrogen-bonded or refractory clusters [29, 30].

An outline of an FTMW instrument used in the study of large, polar, carbonaceous species is shown in [figure B1.4.4](#). In this instrument, the FTMW cavity is mated to a pulsed electric discharge/supersonic expansion nozzle [31, 32]. Long-chain carbon species, up to that of HC₁₇N, as shown in [figure B1.4.4](#), can be studied with this technique, as can a wide variety of other molecules and clusters. With the jet directed along the axis of the cavity, the resolution is highly sub-Doppler, with the slight complication that a Doppler doublet is formed by the difference between the laboratory and molecular beam reference frames. Studies of the rotational spectra of hydrogen-bonded clusters have also been carried out by several groups using FTMW instruments, a topic we shall return to later. FT-THz instruments can, in principle, be built using the highly sensitive THz SIS or HEB mixers outlined above, and would have extraordinary sensitivities. In order to saturate the rotational or rovibrational transitions, however, high-power THz oscillators are needed, but are not yet available.

B1.4.4.3 CW THZ SOURCES AND MOLECULAR SPECTROSCOPY

At frequencies up to ~ 150 – 200 GHz, solid-state sources such as YIG-tuned oscillators or Gunn diode oscillators are now available with power outputs of up to 100 mW. The harmonic generation of such millimetre-wave sources is relatively efficient for doubling and tripling (≥ 10 – 15%), but for higher harmonics the power drops rapidly ($P_{\text{out}}(1 \text{ THz}) \leq 0.1$ – $10 \mu\text{W}$). Nevertheless, harmonic generation was used as early as the 1950s to record the submillimetre wave spectra of stable molecules [33]. Harmonics from optimized solid-state millimetre-wave sources are now used to drive astronomical heterodyne receivers up to 900–1100 GHz [34], and the prospects for operation up to 2–3 THz are promising.

Even higher output power (~ 1 – 10 mW) is available from rapidly tunable BWOs up to 1–15 THz. BWOs are capable laboratory sources where they operate, and offer wide tunability and excellent spectral purity, especially when phase locked to the harmonics of lower-frequency microwave or millimetre-wave oscillators [35]. The high output power of BWOs and the relatively strong intrinsic strengths of pure rotational transitions of polar molecules gives BWO spectrometers very high sensitivity, and also enables them to utilize nonlinear methods such as Lamb dip spectroscopy. An example for the CO molecule is presented in figure B1.4.5 [36]. The resulting resolution is truly exceptional and leads to among the most precise molecular

constants ever determined. Pioneered in the former Soviet Union, THz BWOs are finding increased applications in a number of laboratories.

Figure B1.4.5. The Lamb dip spectrum of the CO 6–5 transition obtained with the Cologne THz BWO spectrometer. The dip is of order 30–40 kHz in width and the transition frequency is determined to 0.5 kHz [36].

BWOs are typically placed in highly overmoded waveguides, and the extension of this technology to higher frequencies will, by necessity, require a number of innovative solutions to the very small-scale structures that must be fabricated. Their size and weight also preclude them from space-based applications (e.g. FIRST). Thus, electronic oscillators are unlikely to cover all THz spectroscopy and/or remote sensing applications over the full range of 1–10 THz in the short term, and a number of alternative THz radiation sources are therefore under investigation. Among the most promising of these, over the long term, are engineered materials such as quantum wells that either possess high nonlinearity for THz mixing experiments [37] or that can be tailored to provide direct emission in the FIR [38]. Tunable laser sources are the ultimate goal of such development programmes, but while THz spontaneous emission has been observed, laser action is still some time in the future.

A number of mixing experiments have therefore been used to generate both pulses and CW THz radiation. Among these, diode-based mixers used as upconvertors (that is, heterodyne spectroscopy ‘in reverse’) have been the workhorse FIR instruments. Two such techniques have produced the bulk of the spectroscopic results:

(1) GaAs-based diode mixers that generate tunable sidebands on line-tunable FIR molecular gas lasers [39, 40], and (2) CO_2 laser-based THz difference frequency generation in ultrafast metal–insulator–metal (MIM) diodes [41, 42]. Both types of mixers have sufficient instantaneous bandwidth to place any desired millimetre-wave frequency on the carrier radiation, and respond well at THz frequencies. Having been used for many years in astronomical receiver applications, GaAs mixer technology is more mature than that for MIM diodes, and its conversion, noise and coupling mechanisms are better understood at present. In addition, their conversion efficiencies are good up to at least 4–5 THz, and several to several tens of microwatts are available from GaAs Schottky diode laser sideband generators. It is thus possible to construct THz spectrometers based on laser sideband generation that operate at or near the shot-noise limit, and this sensitivity has been used to

investigate a wide range of interesting reactive and/or transient species, as is described in [section \(B1.4.4.6\)](#).

While the conversion efficiency of MIM diodes is not as good as that of their GaAs counterparts, they are considerably faster, having also been used at IR and even visible wavelengths! Thus, MIM-based THz spectrometers work over wider frequency ranges than do GaAs FIR laser sideband generators, but with less output power. As described above, this translates directly into spectrometer sensitivity due to the high laboratory background in the THz region. Thus, where intense FIR gas laser lines are available, sideband generators are to be preferred, but at present only MIM-diode spectrometers can access the spectroscopically important region above 200 cm^{-1} [42]. Also, because it is easy to block CO_2 laser radiation with a variety of reststrahlen solid-state filters, there is no fixed-frequency FIR gas laser carrier to reject in MIM spectrometers, and this simplifies the overall experimental design. MIM spectrometers that perform third-order mixing of two CO_2 laser lines and a tunable microwave source have also been constructed. This approach leads to very wide tunability and eliminates the need to scan the CO_2 lasers, and only decreases the output power by a small amount. Thus, it is possible to phase lock the CO_2 and microwave sources, leading to a direct synthesis approach to THz radiation to very high frequencies indeed. This is not feasible for the FIR laser sideband generators, and so the MIM approach has provided extremely accurate THz frequency standards for calibration gases such as CO, HF and HCl, which can then be used as secondary standards in a number of other techniques [41].

While extremely useful in the laboratory, the size and power requirements of both FIR laser sideband generators and MIM-based CO_2 laser spectrometers are excessive for space-borne applications. Research on other THz generation approaches by mixing has therefore continued. One particularly interesting approach from a technology and miniaturization point of view is optical heterodyne conversion, in which optical radiation is converted to THz light by semiconducting materials pumped above their band gaps. The use of optical or near-IR lasers to drive the process results in wide tunability and spectral coverage of the THz spectrum. Such approaches, described next, also have the considerable advantage of leveraging the rapid technological innovations in diode-pumped lasers and fast optoelectronic devices required for emerging industries such as optical telecommunications and optical computing. They therefore ‘break the mould’ of traditional THz LO development by small groups focused on scientific problems, and rapid developments can be expected with little or no investment by the THz community. Finally, as described next, both ultrafast time-resolved and CW high-resolution spectroscopies can be carried out using these approaches.

B1.4.4.4 TIME DOMAIN THZ SPECTROSCOPY

Free-electron lasers have long enabled the generation of extremely intense, sub-picosecond THz pulses that have been used to characterize a wide variety of materials and ultrafast processes [43]. Due to their massive size and great expense, however, only a few research groups have been able to operate them. Other approaches to the generation of sub-picosecond THz pulses have therefore been sought, and one of the earliest and most successful involved semiconducting materials. In a photoconductive semiconductor, carriers (for n-type material, electrons)

in the valence band absorb the incident radiative power (if $h\nu_0 \geq E_{\text{bandgap}}$) and are injected into the conduction band. Once they are in the conduction band, the electrons become mobile, and, if there is an applied bias, they begin to drift toward the photoconductor electrodes. Some of the electrons will reach the electrodes while some will encounter sites of ionic impurities. The latter electrons are trapped by the impurity sites and removed from the conduction band. As early as two decades ago, pulsed optical lasers were used by Auston and co-workers to generate and detect electrical pulses in DC biased voltage transmission lines [44]. For the earliest used materials such as GaAs and Si, the pulse widths were of order nanoseconds due to their long recombination times. The discovery of materials such as radiation-damaged silicon-on-sapphire and of low-temperature-grown (LTG) GaAs changed this situation dramatically.

Especially with LTG GaAs, materials became available that were nearly ideal for time-resolved THz spectroscopy. Due to the low growth temperature and the slight As excess incorporated, clusters are formed which act as recombination sites for the excited carriers, leading to lifetimes of ≤ 250 fs [45]. With such recombination lifetimes, THz radiators such as dipole antennae or log-periodic spirals placed onto optoelectronic substrates and pumped with ultrafast lasers can be used to generate sub-picosecond pulses with optical bandwidths of 2–4 THz. Moreover, *coherent* sub-picosecond detection is possible, which enables both the real and imaginary refractive indices of materials to be measured. The overall sensitivity is $>10^4$, and a variety of solid-state and gas phase THz spectra have been acquired with such systems [46, 47], an excellent overview of which may be found in [48].

Recently, it has been shown that both the detection and generation of ultrafast THz pulses can be carried out using the electro-optic effect in thin films of materials such as ZnTe, GaAs and InP that are pumped in the near-IR [49]. The generation efficiency is similar to that of the photoconducting antenna approach, but the electro-optic scheme offers two extremely significant advantages. First, the detection bandwidth can be extremely large, up to 30–40 THz under optimum conditions [49]. Second, it is possible to directly *image* the THz field with such spectrometers. Such approaches therefore make possible the THz imaging of optically opaque materials with a compact, all solid-state, room-temperature system [50]!

The great sensitivity and bandwidth of electro-optic approaches to optical–THz conversion also enable a variety of new experiments in condensed matter physics and chemistry to be conducted, as is outlined in [figure B1.4.6](#). The left-hand side of this figure outlines the experimental approach used to generate ultrafast optical and THz pulses with variable time delays between them [51]. A mode-locked Ti:sapphire laser is amplified to provide approximately 1 W of 100 fs near-IR pulses at a repetition rate of 1 kHz. The ~ 850 nm light is divided into three beams, two of which are used to generate and detect the THz pulses, and the third of which is used to optically excite the sample with a suitable temporal delay. The right-hand panel presents the measured relaxation of an optically excited TBNC molecule in liquid toluene. In such molecules, the charge distribution changes markedly in the ground and electronically excited states. In TBNC, for example, the excess negative charge on the central porphyrin ring becomes more delocalized in the excited state. The altered charge distribution must be accommodated by changes in the surrounding solvent. This so-called solvent reorganization could only be indirectly probed by Stokes shifts in previous optical–optical pump–probe experiments, but the optical–THz approach enables the solvent response to be *directly* investigated. In this case, at least three distinct temporal response patterns of the toluene solvent can be seen that span several temporal decades [51]. For solid-state spectroscopy, ultrafast THz studies have enabled the investigation of coherent oscillation dynamics in the collective (phonon) modes of a wide variety of materials for the first time [49].

(a)

figure continued on next page.

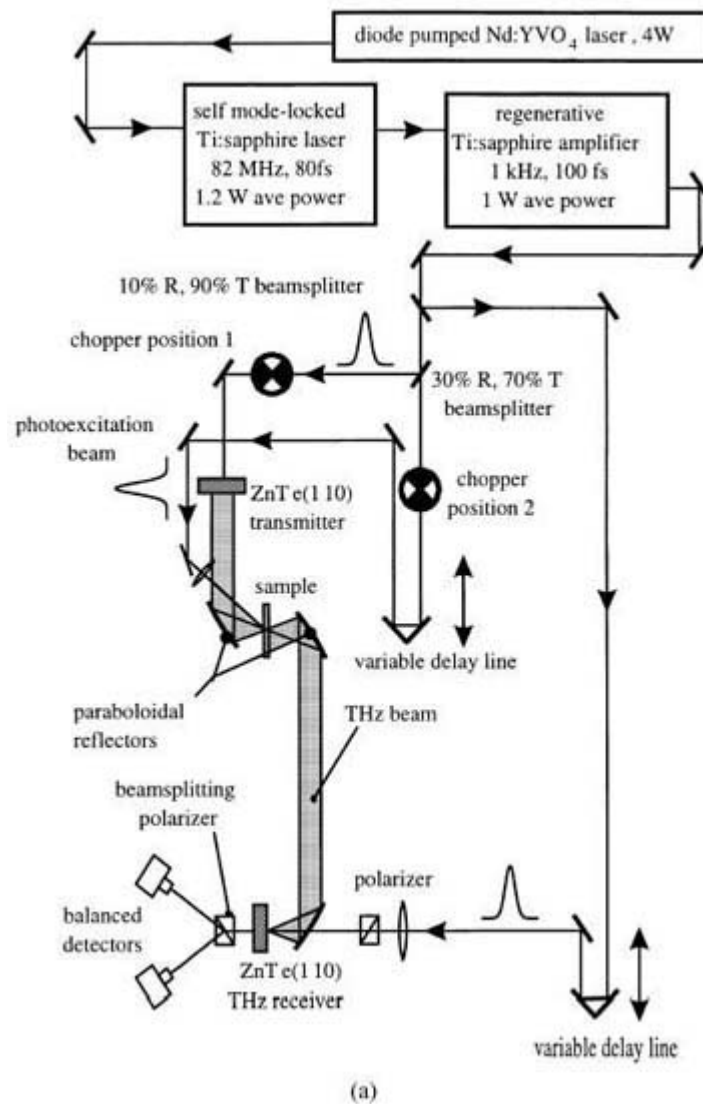

Figure B1.4.6. Left: an experimental optical THz pump–probe set-up using sub-picosecond THz pulse generation and detection by the electro-optic effect. Right: the application of such pulses to the relaxation of optically excited TBNC in toluene. The THz electric field used for these experiments is shown in the upper-right inset. Three exponential decay terms, of order 2, 50 and 700 ps, are required to fit the observed temporal relaxation of the solvent [51].

B1.4.4.5 THZ OPTICAL-HETERODYNE CONVERSION IN PHOTOCONDUCTORS

For CW applications of optical-heterodyne conversion, two laser fields are applied to the optoelectronic material. The non-linear nature of the electro-optic effect strongly suppresses continuous emission relative to ultrashort pulse excitation, and so most of the CW research carried out to date has used photoconductive antennae. The CW mixing process is characterized by the average drift velocity \bar{v} and carrier lifetime τ_0 of the mixing material, typically

LTG GaAs. If $\tau_0 \bar{v} \geq \delta$, the electrode spacing, then a significant amount of current will be generated by the photo-excitation. That is

$$i(t) = \frac{N_c(t)e\bar{v}}{\delta} \quad (\text{B1.4.3})$$

where N_c is the number of carriers. The rate equation for the photo-excitation-recombination process can be written as

$$\frac{dN_c(t)}{dt} = aP_0 - \frac{N_c(t)}{\tau_0} \quad (\text{B1.4.4})$$

where a is a proportionality constant and P_0 is the average power of the incident field over a few optical periods. The time-average is of interest here because τ_0 in a semiconductor is always longer than an optical cycle and, therefore, the output current will not respond directly to the optical oscillations. Since the THz waves are generated with optical light, $\omega \equiv (\omega_1 - \omega_2) \ll \omega_1 \approx \omega_2$. Thus, integrating the right-hand side of the expression above over a few cycles of $\omega_1 \approx \omega_2$ yields

$$P_0 = E_1^2 + E_2^2 + 2E_1E_2 \cos(\omega t + \phi_1 - \phi_2). \quad (\text{B1.4.5})$$

Substitution yields

$$\frac{dN_c}{dt} = a[E_1^2 + E_2^2 + 2E_1E_2 \cos(\omega t + \phi_1 - \phi_2)] - \frac{N_c}{\tau_0}. \quad (\text{B1.4.6})$$

By solving the differential equation above and using the single-pump case ($P_2 = 0$) to determine a , it can be shown that the photo-current is

$$i(t) = \frac{e\eta}{h\nu_0} \frac{\tau_0\bar{v}}{\delta} \left[P_1 + P_2 + 2\sqrt{\frac{P_1P_2}{1 + \omega^2\tau_0^2}} \cos(\omega t - \phi) \right] \quad (\text{B1.4.7})$$

where $\nu_0 \equiv \nu_1 \approx \nu_2$, P_1 and P_2 are the incident optical powers, $\phi = \tan^{-1}(\omega\tau_0)$ and η , the quantum efficiency, is the number of carriers excited per incident photon. Recognizing that $\bar{v} = \mu E$ (where μ is the carrier mobility and E is the electric field),

$$i(t) = \frac{e\eta}{h\nu_0} \frac{\tau_0\mu E}{\delta} \left[P_1 + P_2 + 2\sqrt{\frac{P_1P_2}{1 + \omega^2\tau_0^2}} \cos(\omega t - \phi) \right]. \quad (\text{B1.4.8})$$

Separating the DC and oscillatory parts of the above equation gives

$$i_{dc} = \frac{e\eta}{h\nu_0} \frac{\tau_0\mu E}{\delta} (P_1 + P_2) \quad (\text{B1.4.9})$$

$$(\text{B1.4.10})$$

$$i_{\text{THz}}(t) = \frac{e\eta}{h\nu_0} \frac{\tau_0 \mu E}{\delta} 2 \sqrt{\frac{P_1 P_2}{1 + \omega^2 \tau_0^2}} \cos(\omega t - \phi).$$

Thus, the beating of the two incident optical fields generates a modulation in the photo-excitation of the carriers, which in turn results in an oscillating electrical signal. Initial microwave experiments using an interdigitated electrode geometry by Brown *et al* [52] showed a flat frequency response up to 25 GHz with a conversion efficiency of 0.14%, in agreement with the signal level predicted by the theoretical analysis outlined above. At THz frequencies, the power decays rapidly from such structures due to the parasitic capacitance of the electrode structure and the finite carrier lifetime. Free-space radiation is generated by coupling the electrodes to a planar THz antenna. At 1 THz, the observed conversion efficiency is roughly 3×10^{-6} , and the damage threshold is of order $1 \text{ mW } \mu\text{m}^{-2}$. To alleviate these limitations, travelling-wave structures have now been developed that eliminate the capacitive roll-off and allow large-device active areas to be pumped. Powers in excess of $1 \text{ } \mu\text{W}$ can now be achieved above 2 THz for input drive levels of 300–400 mW [53].

This power level is sufficient for laboratory spectroscopy or for use as a THz local oscillator, and such travelling-wave structures can be used over at least a decade of frequency (0.3–3 THz, for example) without moving parts. Further, compact, all solid-state spectrometers, such as that outlined in [figure B1.4.7](#) can now be constructed using CW diode laser and optical tapered amplifier technology [54]. The major challenge in working with diode lasers is, in fact, their instantaneous line widths ($\geq 15 \text{ MHz}$) and long-term frequency stability ($\sim 100\text{--}200 \text{ MHz}$), both of which need considerable improvement to be useful as THz LOs. The main source of both instabilities is the notorious susceptibility of diode lasers to optical feedback. However, this susceptibility can be used to one's advantage by sending a small fraction of the laser output into a high-finesse ($F \geq 60$) optical cavity such that the diode laser 'sees' optical feedback only at cavity resonances. By locking the diode lasers to different longitudinal modes of an ultrastable reference cavity, it is possible to construct direct synthesis spectrometers that can be absolutely calibrated to $\Delta\nu/\nu < 10^{-8}$ or better. To demonstrate the continuous tunability and frequency stability of such an instrument, the lower panel of [figure B1.4.7](#) presents a submillimetre spectrum of acetonitrile in which the transition frequencies are measured to better than 50 kHz. Future improvements to such systems should allow similar measurements on both stable and transient species up to at least 5–6 THz.

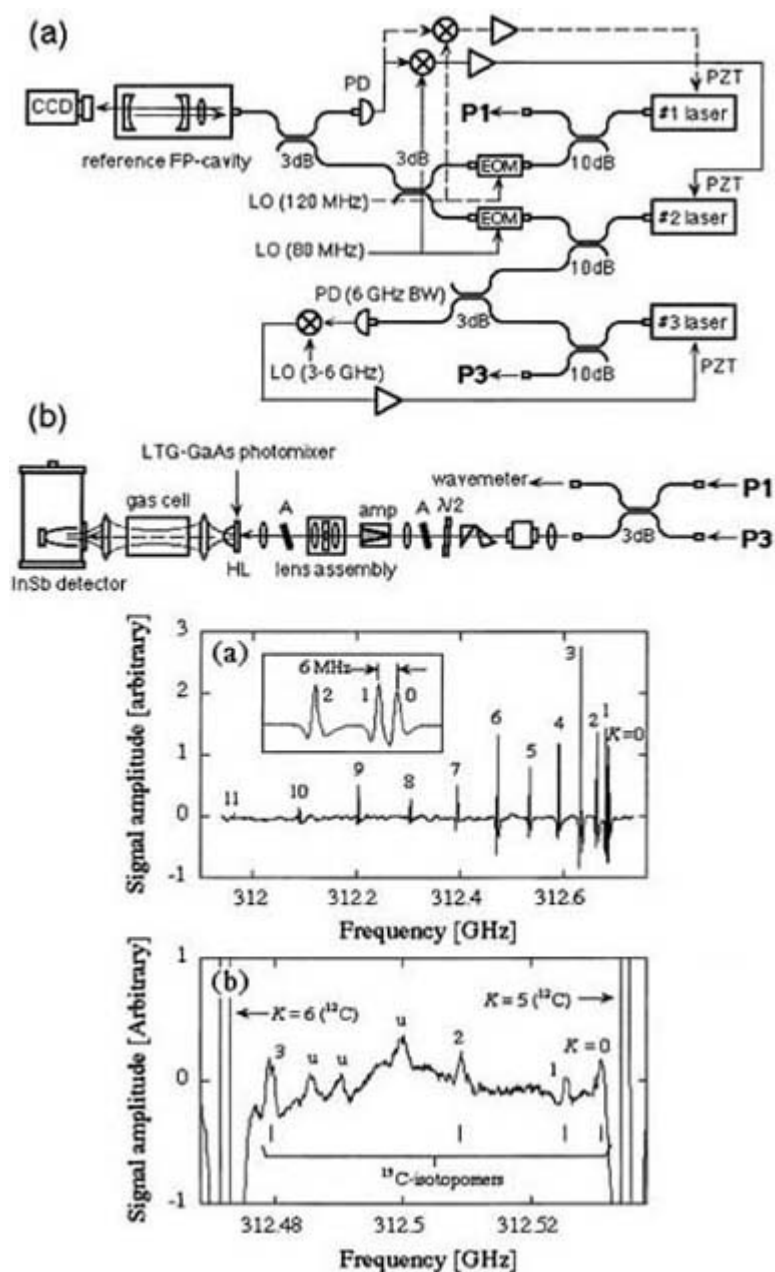

Figure B1.4.7. Top: THz generation by optical-heterodyne conversion in low-temperature GaAs. (a) The three DBR laser system that synthesizes a precise difference frequency for the THz photomixer spectrometer, (b) the MOPA system and the set-up for spectroscopy. Bottom: second-derivative absorption spectrum of the $\text{CH}_3\text{CN } J_K = 16_K \rightarrow 17_K$ rotational transitions near 312 GHz. (a) The spectrum for ordinary $^{12}\text{CH}_3$, ^{12}CN . The inset is an expanded view of the $K = 0-2$ lines. (b) The $K = 0-3$ lines of CH_2 , ^{13}CN [54].

B1.4.4.6 THZ SPECTROSCOPY OF HYDROGEN-BONDED AND REFRACTORY CLUSTERS

Among the most interesting transient species that can be studied at THz frequencies are those involving collections of molecules held together by van der Waals or hydrogen bonding forces. In no small measure this is true because hydrogen bonds are ubiquitous in nature. From the icy mantles covering interstellar dust to the nuclei of living cells, hydrogen bonds play crucial roles in the regulation and evolution of both inorganic and living systems. Accurate, fully anisotropic, descriptions of the intermolecular forces involved in these and other weak interactions are therefore assuming an increasingly pivotal role in modern molecular science,

particularly in molecular biology [54]. Within chemical physics, the anisotropy of intermolecular forces plays a central role in understanding the dynamics associated with photoinitiated reactions in clusters [55], to name but one example.

Over the past century, much of the data underlying current descriptions of van der Waals and hydrogen bonds were obtained from measurements of second virial coefficients, pressure broadening, and other classical properties. Experimental advances during the past three decades have led to many techniques capable of interrogating intermolecular forces, most notably scattering experiments and the spectroscopic study of isolated clusters. Despite this long-standing interest, however, truly quantitative, microscopic models of these forces have only become available in recent years as advances in *ab initio* theory, high-resolution spectroscopy and eigenvalue generation on complex potential energy surfaces have converged, to enable the fitting of fully anisotropic force fields to experimental data for systems with two, three and four degrees of freedom [57].

The weak interactions in clusters are mathematically modelled by means of a multi-dimensional intermolecular potential energy surface, or IPS. Microwave spectroscopy, carried out primarily with the elegant, extraordinarily sensitive and sub-Doppler resolution FTMW technique outlined previously, probes the very lowest region of the ground-state surface; visible and IR spectroscopy probes states above the dissociation energy of the adduct (the latter of which are described elsewhere in this encyclopaedia). None are, in themselves, direct probes of the total ground-state IPS. Indeed, while microwave, IR and UV/Vis instruments have produced structural parameters and dynamical lifetimes for literally dozens of binary (and larger) weakly bound complexes (WBCs) over the past two decades [58, 59, 60, and 61], recent calculations which explicitly allow coupling between all the degrees of freedom present in the cluster reveal that structural parameters alone are not sufficient to accurately characterize the IPS [62].

Weak interactions are characterized by binding energies of at most a few kcal/mole and by IPSs with a very rich and complex topology connected by barriers of at most a few hundred cm^{-12} . Rotational, tunnelling and intermolecular vibrational states can therefore become quite strongly mixed, hence the general term of vibration–rotation–tunnelling (VRT) spectroscopy for the study of eigenvalues supported by an IPS [63, 64]. The VRT states in nearly all systems lie close to or above the tunnelling barriers, and therefore sample *large* regions of the potential surface. In addition, as they become spectroscopically observable, the number, spacings and intensities of the tunnelling splittings are intimately related to the nature of the tunnelling *paths* over the potential surface.

Thus, by measuring the intermolecular vibrations of a WBC, ultimately with resolution of the rotational, tunnelling and hyperfine structure, the most sensitive measure of the IPS is accessed directly. The difficulty of measuring these VRT spectra is the fact that they lie nearly exclusively at THz frequencies. As expected, the ‘stiffer’ the interaction, the higher in frequency these modes are found. In general, the total 0.3–30 THz interval must be accessed, although for the softest or heaviest species the modes rarely lie above 10–15 THz.

For WBCs composed of stable molecules, planar jet expansions produce sufficiently high concentrations that direct absorption THz studies can be pursued for clusters containing $\lesssim 6$ small molecules using FIR laser sidebands. Research on water clusters has been particularly productive, and has been used to investigate the structures and large-amplitude dynamics of the clusters outlined in the top panel of figure B1.4.8 [65, 66, 67 and 68]. In addition, as the bottom panel illustrates, not only are the VRT modes directly sampled by such work, but the available spectral resolution of $\lesssim 1$ MHz enables full rotational resolution along with a detailed investigation of the VRT and hyperfine splittings. The high resolution is also essential in untangling the often overlapping bands from the many different clusters formed in the supersonic expansion.

For clusters beyond the dimer, each of the monomers can both accept and donate hydrogen bonds, which leads to a rich suite of large-amplitude motions. Their spectroscopic manifestations are illustrated for the water trimer in [figure B1.4.9](#). The most facile motion in this system is the ‘flipping’ of one of the non-bonded hydrogen atoms through the plane of the oxygen atoms. This motion is sufficiently fast that it produces symmetric top rovibrational spectra even though at any one instant the molecule is always asymmetric. Six of these flipping motions lead to the same structure, a process known as ‘pseudorotation’, and leads to the manifold of states produced in the bottom panel of [figure B1.4.9](#). The exchange of bound *versus* free hydrogen atoms in a monomer leads to the hyperfine splittings of the individual transitions, as is illustrated in the top panel of the same figure. From a comparison of such spectra with detailed calculations, a variety of IPS properties can be extracted to experimental precision.

Molecules like those presented in [figure B1.4.4](#) form another interesting suite of targets from a THz perspective. Such chains can be treated as rigid rods, and as they get longer their lowest bending frequencies move rapidly into the FIR. For example, the lowest frequencies of a variety of chains are as follows:

Cyanopolyynes, $\text{HC}_3\text{N} \rightarrow \text{HC}_{25}\text{N}$	222 \rightarrow 8 cm^{-1}
Polyacetylenes, $\text{HC}_4\text{N} \rightarrow \text{HC}_{20}\text{H}$	220 \rightarrow 19 cm^{-1}
Carbon clusters, $\text{C}_3 \rightarrow \text{C}_{20}$	63 \rightarrow 17 cm^{-1}
C_nN radicals, $\text{C}_3\text{N} \rightarrow \text{C}_{19}\text{N}$	144 \rightarrow 4 cm^{-1} .

A real advantage of working in the FIR is that both polar and non-polar chains may be searched for. Indeed, the lowest bending frequency of C_3 has been studied in the laboratory [69], and tentatively detected toward the galactic centre source Sgr B2 [70]. Other large molecules such as polycyclic aromatic hydrocarbons (anthracene, pyrene, perylene, etc) or ‘biomolecules’ such as glycine or uracil also possess low-frequency FIR vibrations, and can be produced in sizable quantities in supersonic expansions through heated planar nozzles [71]. The study of such species is important cosmochemically, but is quite difficult at microwave frequencies where the rotational spectra are weak, and nearly impossible at IR or optical wavelengths due to the extinction present in dense molecular clouds and young stellar objects.

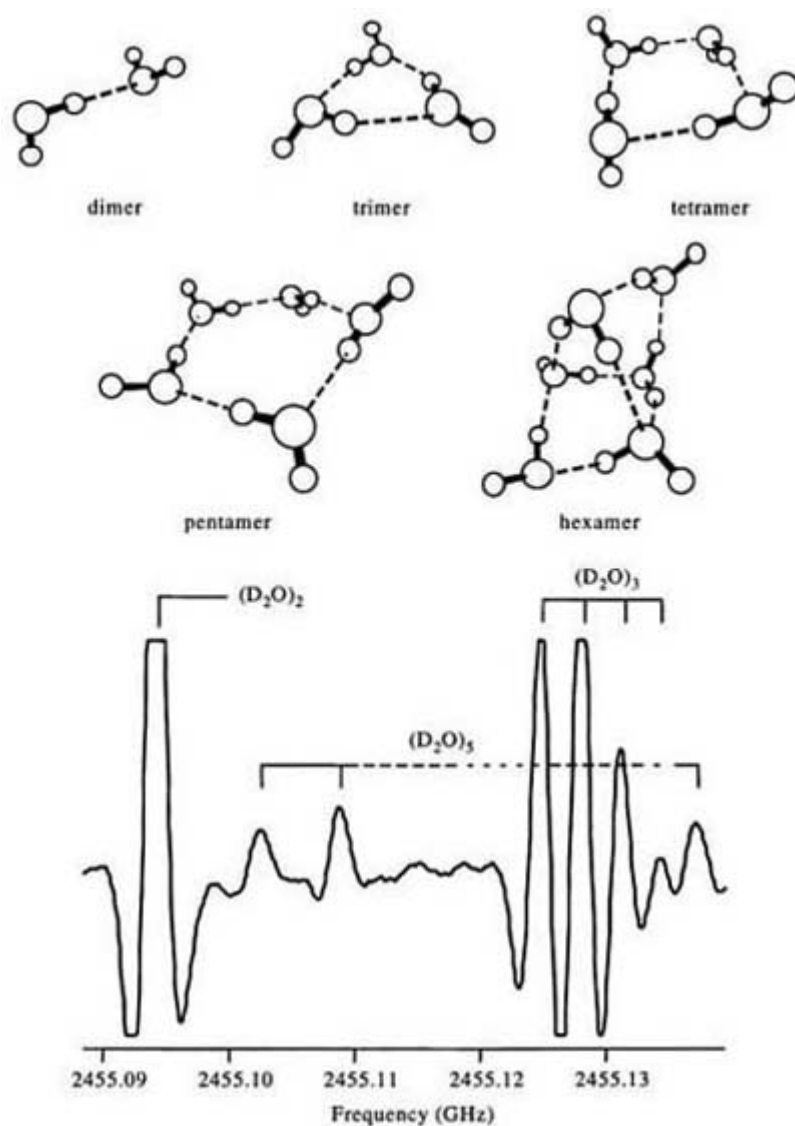

Figure B1.4.8. Top: the lowest-energy structures of water clusters, $(\text{H}_2\text{O})_n$, from $n = 2 - 6$. Bottom: a sample ~ 2.5 THz spectrum of such clusters formed in a pulsed planar supersonic expansion [65].

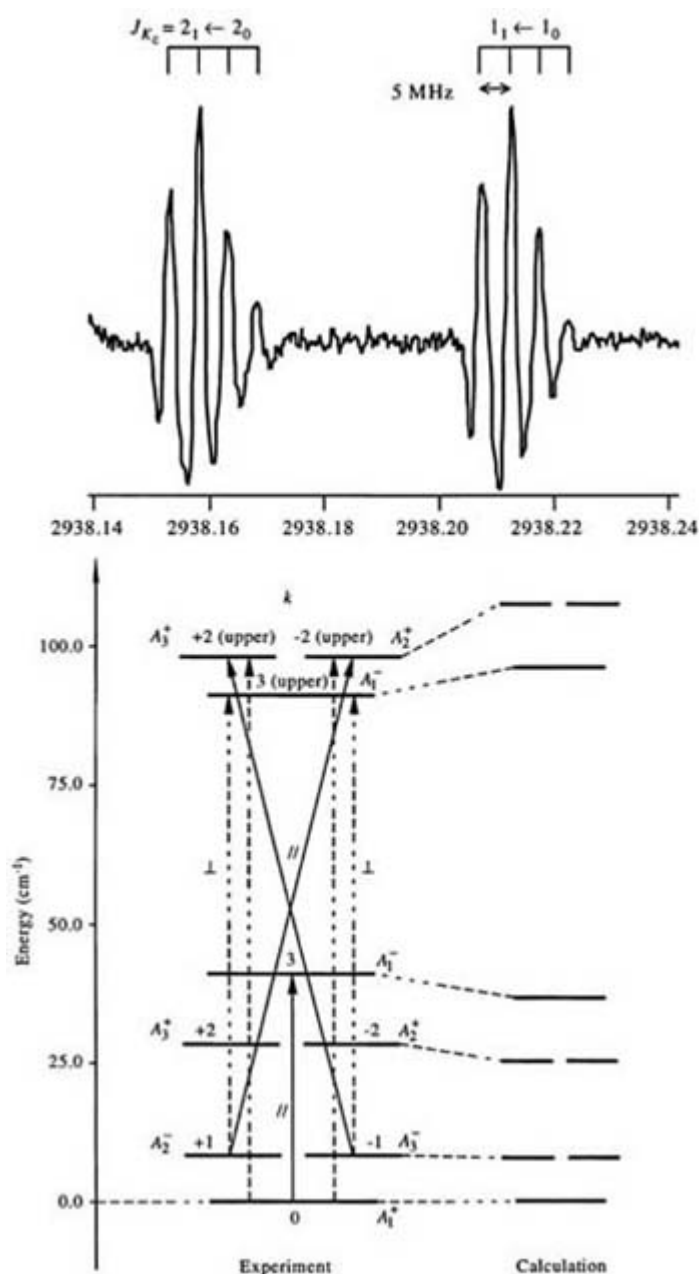

Figure B1.4.9. Top: rotation–tunnelling hyperfine structure in one of the ‘flipping’ modes of $(\text{D}_2\text{O})_3$ near 3 THz. The small splittings seen in the Q -branch transitions are induced by the bound–free hydrogen atom tunnelling by the water monomers. Bottom: the low-frequency torsional mode structure of the water dimer spectrum, including a detailed comparison of theoretical calculations of the dynamics with those observed experimentally [65]. The symbols next to the arrows depict the parallel ($\Delta k = 0$) versus perpendicular ($\Delta K = \pm 1$) nature of the selection rules in the pseudorotation manifold.

B1.4.5 OUTLOOK

Technology developments are revolutionizing the spectroscopic capabilities at THz frequencies. While no one technique is ideal for all applications, both CW and pulsed spectrometers operating at or near the fundamental limits imposed by quantum mechanics are now within reach. Compact, all-solid-state implementations will soon allow such spectrometers to move out of the laboratory and into a wealth of field and remote-sensing applications. From the study of the rotational motions of light molecules to the large-amplitude vibrations of

clusters and the collective motions of condensed phases, microwave and THz spectroscopy opens up new windows to a wealth of scientifically and technologically important fields. Over the coming decade, truly user-friendly and extraordinarily capable instruments should become cost affordable and widely available, enabling this critical region of the electromagnetic spectrum to be fully exploited for the first time.

B1.5 Nonlinear optical spectroscopy of surfaces and interfaces

Jerry I Dadap and Tony F Heinz

B1.5.1 INTRODUCTION

B1.5.1.1 NONLINEAR OPTICS AND SPECTROSCOPY

Nonlinear optics is the study of the interaction between intense electromagnetic radiation and matter. It describes phenomena arising when the response of a medium to the electric field of light leaves the linear regime associated with the familiar and ubiquitous effects, such as reflection, refraction and absorption, comprising classical optics. In the presence of a sufficiently intense light source, the approximation of linearity breaks down. A new and much broader class of optical phenomena may be observed. Prototypical among these nonlinear optical effects is the production of light at new frequencies. Indeed, nonlinear optics is generally considered to have begun in 1961 when Franken and coworkers demonstrated optical second-harmonic generation (SHG) by insertion of a quartz crystal along the path of a laser beam [1]. In addition to the generation of new frequencies from excitation of a monochromatic source, nonlinear optical effects lead to the coupling between beams of identical and disparate frequencies, as well as to the action of a beam of light on itself.

Given the complexity of materials, it is perhaps surprising that a linear response to an applied optical field should be so common. This situation reflects the fact that the strength of electric fields for light encountered under conventional conditions is minute compared to that of the electric fields binding atoms and solids together. The latter may, for example, be estimated as $E_a \sim 1 \text{ V \AA}^{-1} = 10^8 \text{ V cm}^{-1}$. Since the irradiance of a light beam required to reproduce this electric field strength is $\sim 10^{13} \text{ W cm}^{-2}$, we may understand why a linear approximation of the material response is adequate for conventional light sources. With the advent of the laser, with its capability for producing high optical power and a high degree of coherence, this situation has changed. Under laser radiation, nonlinear optical effects are readily observed and widely exploited.

Over the past decades, nonlinear optics has come to have a broad impact on science and technology, playing a role in areas as diverse as telecommunications, materials processing and medicine. Within the context of chemical science, nonlinear optics is significant in providing new sources of coherent radiation, in permitting chemical processes to be induced under intense electromagnetic fields and in allowing matter to be probed by many powerful spectroscopic techniques. In this chapter, we shall be concerned only with the spectroscopic implications of nonlinear optics. In particular, our attention will be restricted to the narrowed range of spectroscopic techniques and applications related to probing surfaces and interfaces. This subject is a significant one. Surfaces and interfaces have been, and remain, areas of enormous scientific and technological importance. Sensitive and flexible methods of interface characterization are consequently of great value. As the advances discussed in this chapter reveal, nonlinear optics offers unique capabilities to address surface and interface analysis.

-2-

B1.5.1.2 PROBING SURFACES AND INTERFACES

The distinctive chemical and physical properties of surfaces and interfaces typically are dominated by the nature of one or two atomic or molecular layers [2, 3]. Consequently, useful surface probes require a very high degree of sensitivity. How can this sensitivity be achieved? For many of the valuable traditional probes of surfaces, the answer lies in the use of particles that have a short penetration depth through matter. These particles include electrons, atoms and ions, of appropriate energies. Some of the most familiar probes of solid surfaces, such as Auger electron spectroscopy (AES), low-energy electron diffraction (LEED), electron energy loss spectroscopy (EELS) and secondary ion mass spectroscopy (SIMS), exploit massive particles both approaching and leaving the surface. Other techniques, such as photoemission spectroscopy and inverse photoemission spectroscopy, rely on electrons for only half of the probing process, with photons serving for the other half. These approaches are complemented by those that directly involve the adsorbate of interest, such as molecular beam techniques and temperature programmed desorption (TPD). While these methods are extremely powerful, they are generally restricted to—or perform best for—probing materials under high vacuum conditions. This is a significant limitation, since many important systems are intrinsically incompatible with high vacuum (such as the surfaces of most liquids) or involve interfaces between two dense media. Scanning tunnelling microscopy (STM) is perhaps the electron-based probe best suited for investigations of a broader class of interfaces. In this approach, the physical proximity of the tip and the probe permits the method to be applied at certain interfaces between dense media.

Against this backdrop, the interest in purely optical probes of surfaces and interfaces can be easily understood. Since photons can penetrate an appreciable amount of material, photon-based methods are inherently appropriate to probing a very wide class of systems. In addition, photons, particularly those in the optical and infrared part of the spectrum, can be produced with exquisite control. Both the spatial and temporal properties of light beams can be tailored to the application. Particularly noteworthy is the possibility afforded by laser radiation of having either highly monochromatic radiation or radiation in the form of ultrafast (femtosecond) pulses. In addition, sources of high brightness are available, together with excellent detectors. As a consequence, within the optical spectral range several surface and interface probes have been developed. (Complementary approaches also exist within the x-ray part of the spectrum.) For optical techniques, one of the principal issues that must be addressed is the question of surface sensitivity. The ability of light to penetrate through condensed media was highlighted earlier as an attractive feature of optics. It also represents a potential problem in achieving the desired surface sensitivity, since one expects the bulk contribution to dominate that from the smaller region of the surface or interface.

Depending on the situation at hand, various approaches to achieving surface sensitivity may be appropriate for an optical probe. Some schemes rely on the presence of distinctive spectroscopic features in the surface region that may be distinguished from the response of the bulk media. This situation typically prevails in surface infrared spectroscopy [4] and surface-enhanced Raman scattering (SERS) [5, 6 and 7]. These techniques provide very valuable information about surface vibrational spectra, although the range of materials is somewhat restricted in the latter case. Ellipsometry [8, 9 and 10] permits a remarkably precise determination of the reflectivity of an interface through measurements of the polarization properties of light. It is a powerful tool for the analysis of thin films. Under appropriate conditions, it can be pushed to the limit of monolayer sensitivity. Since the method has, however, no inherent surface specificity, such applications generally require accurate knowledge and control of the relevant bulk media. A relatively recent addition to the set of optical probes is reflection difference absorption spectroscopy (RDAS) [10, 11]. In this scheme, the lowered symmetry of certain surfaces of crystalline materials is exploited in a differential measurement of reflectivity that cancels out the optical response of the bulk media.

In this chapter, we present a discussion of the nonlinear spectroscopic methods of second-harmonic generation (SHG) and sum-frequency generation (SFG) for probing surfaces and interfaces. While we have previously described the relative ease of observing nonlinear optical effects with laser techniques, it is still clear that linear optical methods will always be more straightforward to apply. Why then is nonlinear spectroscopy an attractive option for probing surfaces and interfaces? First, we may note that the method retains all of the advantages associated with optical methods. In addition, however, for a broad class of material systems the technique provides an *intrinsic* sensitivity to interfaces on the level of a single atomic layer. This is a very desirable feature that is lacking in linear optical probes. The relevant class of materials for which the nonlinear approach is inherently surface sensitive is quite broad. It consists of interfaces between all pairs of centrosymmetric materials. (Centrosymmetric materials, which include most liquids, gases, amorphous solids and elemental crystals, are those that remain unchanged when the position of every point is inverted through an appropriate origin.) The surface sensitivity of the SHG and SFG processes for these systems arises from a simple symmetry property: the second-order nonlinear optical processes of SHG and SFG are forbidden in centrosymmetric media. Thus, the bulk of the material does not exhibit a significant nonlinear optical response. On the other hand, the interfacial region, which necessarily breaks the inversion symmetry of the bulk, provides the desired nonlinear optical response.

Because of the generality of the symmetry principle that underlies the nonlinear optical spectroscopy of surfaces and interfaces, the approach has found application to a remarkably wide range of material systems. These include not only the conventional case of solid surfaces in ultrahigh vacuum, but also gas/solid, liquid/solid, gas/liquid and liquid/liquid interfaces. The information attainable from the measurements ranges from adsorbate coverage and orientation to interface vibrational and electronic spectroscopy to surface dynamics on the femtosecond time scale.

B1.5.1.3 SCOPE OF THE CHAPTER

In view of the diversity of material systems to which the SHG/SFG method has been applied and the range of the information that the method has yielded, we cannot give a comprehensive account of the technique in this chapter. For such accounts, we must refer the reader to the literature, particularly as summarized in various review articles [12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26 and 27] and monographs [10, 28, 29]. Our aim here is only to present an overview of the subject in which we attempt to describe the basic principles. The chapter is organized in the following fashion. We first outline basic theoretical considerations relevant to the technique, both in a brief general discussion of nonlinear optics and in a specific description of the nonlinear response of interfaces. After a few words about experimental techniques for surface SHG/SFG measurement, we devote the remainder of the chapter to describing the type of information that may be extracted from the nonlinear measurements. We have attempted at least to mention the different classes of information that have been obtained, such as adsorbate coverage or vibrational spectroscopy. In most cases, the corresponding approach has been widely and fruitfully applied in many experimental studies. Although we offer some representative examples, space does not permit us to discuss these diverse applications in any systematic way.

B1.5.2 THEORETICAL CONSIDERATIONS

B1.5.2.1 GENERAL BACKGROUND ON NONLINEAR OPTICS

(A) ANHARMONIC OSCILLATOR MODEL

In order to illustrate some of the basic aspects of the nonlinear optical response of materials, we first discuss the anharmonic oscillator model. This treatment may be viewed as the extension of the classical Lorentz model of the response of an atom or molecule to include nonlinear effects. In such models, the medium is treated as a collection of electrons bound about ion cores. Under the influence of the electric field associated with an optical wave, the ion cores move in the direction of the applied field, while the electrons are displaced in the opposite direction. These motions induce an oscillating dipole moment, which then couples back to the radiation fields. Since the ions are significantly more massive than the electrons, their motion is of secondary importance for optical frequencies and is neglected.

While the Lorentz model only allows for a restoring force that is linear in the displacement of an electron from its equilibrium position, the anharmonic oscillator model includes the more general case of a force that varies in a nonlinear fashion with displacement. This is relevant when the displacement of the electron becomes significant under strong driving fields, the regime of nonlinear optics. Treating this problem in one dimension, we may write an appropriate classical equation of motion for the displacement, x , of the electron from equilibrium as

$$m \left[\frac{d^2 x}{dt^2} + 2\gamma \frac{dx}{dt} + \omega_0^2 x - (b^{(2)} x^2 + b^{(3)} x^3 + \dots) \right] = -eE(t). \quad (\text{B1.5.1})$$

Here $E(t)$ denotes the applied optical field, and $-e$ and m represent, respectively, the electronic charge and mass. The (angular) frequency ω_0 defines the resonance of the harmonic component of the response, and γ represents a phenomenological damping rate for the oscillator. The nonlinear restoring force has been written in a Taylor expansion; the terms $m(b^{(2)} x^2 + b^{(3)} x^3 + \dots)$ correspond to the corrections to the harmonic restoring force, with parameters $b^{(2)}$, $b^{(3)}$, ... taken as material-dependent constants. In this equation, we have recognized that the excursion of the electron is typically small compared to the optical wavelength and have omitted any dependence of the driving term $-eE$ on the position of the electron.

Here we consider the response of the system to a monochromatic pump beam at a frequency ω ,

$$E(t) = E(\omega) \exp(-i\omega t) + \text{c.c.} \quad (\text{B1.5.2})$$

where the complex conjugate (c.c.) is included to yield an electric field $E(t)$ that is a real quantity. We use the symbol E to represent the electric field in both the time and frequency domain; the different arguments should make the interpretation clear. Note also that $E(\omega)$ and analogous quantities introduced later may be complex. As a first

approximation to the solution of [equation B1.5.1](#), we neglect the anharmonic terms to obtain the steady-state motion of the electron

$$x(t) = \frac{-eE(\omega)}{m} \frac{\exp(-i\omega t)}{\omega_0^2 - 2i\gamma\omega - \omega^2} + \text{c.c.} \quad (\text{B1.5.3})$$

This solution is appropriate for the regime of a weak driving field $E(t)$. If we now treat the material as a collection of non-interacting oscillators, we may write the induced polarization as a sum of the individual

dipole moments over a unit volume, i.e. $P(t) = -Nex(t)$, where N denotes the density of dipoles and local-field effects have been omitted. Following [equation B1.5.2](#), we express the $P(t)$ in the frequency domain as

$$P(t) = P(\omega) \exp(-i\omega t) + \text{c.c.} \quad (\text{B1.5.4})$$

We may then write the amplitude for the harmonically varying polarization as proportional to the corresponding quantity for the driving field, $E(\omega)$:

$$P(\omega) = \chi^{(1)}(\omega) E(\omega). \quad (\text{B1.5.5})$$

The constant of proportionality,

$$\chi^{(1)}(\omega) = \frac{Ne^2}{m} \frac{1}{\omega_0^2 - 2i\gamma\omega - \omega^2} \quad (\text{B1.5.6})$$

represents the linear susceptibility of the material. It is related to the dielectric constant $\varepsilon(\omega)$ by $\varepsilon(\omega) = 1 + 4\pi\chi^{(1)}(\omega)$.

Up to this point, we have calculated the linear response of the medium, a polarization oscillating at the frequency ω of the applied field. This polarization produces its own radiation field that interferes with the applied optical field. Two familiar effects result: a change in the speed of the light wave and its attenuation as it propagates. These properties may be related directly to the linear susceptibility $\chi^{(1)}(\omega)$. The index of refraction, $n = \text{Re}[\sqrt{1 + 4\pi\chi^{(1)}}]$, is associated primarily with the real part of $\chi^{(1)}(\omega)$. It describes the reduced (phase) velocity, c/n , of the optical wave travelling through the medium compared to its speed, c , in vacuum. The imaginary part, $\text{Im}[\chi^{(1)}(\omega)]$, on the other hand, gives rise to absorption of the radiation in the medium. The frequency dependence of the quantities $\text{Re}[\chi^{(1)}(\omega)]$ and $\text{Im}[\chi^{(1)}(\omega)]$ are illustrated in [figure B1.5.1](#). They exhibit a resonant response for optical frequencies ω near ω_0 , and show the expected dispersive and absorptive lineshapes.

Figure B1.5.1 Anharmonic oscillator model: the real and imaginary parts of the linear susceptibility $\chi^{(1)}$ are

plotted as a function of angular frequency ω in the vicinity of the resonant frequency ω_0 .

If we now include the anharmonic terms in [equation B1.5.1](#), an exact solution is no longer possible. Let us, however, consider a regime in which we do not drive the oscillator too strongly, and the anharmonic terms remain small compared to the harmonic ones. In this case, we may solve the problem perturbatively. For our discussion, let us assume that only the second-order term in the nonlinearity is significant, i.e. $b^{(2)} \neq 0$ and $b^{(i)} = 0$ for $i > 2$ in [equation B1.5.1](#). To develop a perturbational expansion formally, we replace $E(t)$ by $\lambda E(t)$, where λ is the expansion parameter characterizing the strength of the field E . Thus, [equation B1.5.1](#) becomes

$$\ddot{x} + 2\gamma\dot{x} + \omega_0^2 x - b^{(2)}x^2 = -\lambda eE(t)/m. \quad (\text{B1.5.7})$$

We then write the solution of equation B1.5.7 as a power series expansion in terms of the strength λ of the perturbation:

$$x = \lambda x^{(1)} + \lambda^2 x^{(2)} + \lambda^3 x^{(3)} + \dots. \quad (\text{B1.5.8})$$

If we substitute the expression for B1.5.8 back into B1.5.7 and require that the terms proportional to λ and λ^2 on both sides of the resulting equation are equal, we obtain the equations

$$\ddot{x}^{(1)} + 2\gamma\dot{x}^{(1)} + \omega_0^2 x^{(1)} = -eE(t)/m \quad (\text{B1.5.9})$$

$$\ddot{x}^{(2)} + 2\gamma\dot{x}^{(2)} + \omega_0^2 x^{(2)} - b^{(2)}(x^{(1)})^2 = 0. \quad (\text{B1.5.10})$$

We immediately observe that the solution, $x^{(1)}$, to [equation B1.5.9](#) is simply that of the original harmonic oscillator problem given by [equation B1.5.3](#). Substituting this result for $x^{(1)}$ into the last term of [equation B1.5.10](#) and solving for the second-order term $x^{(2)}$, we obtain two solutions: one oscillating at twice the frequency of the applied field and a static part at a frequency of $\omega = 0$. This behaviour arises from the fact that the square of the term $x^{(1)}(t)$, which now acts as a source term in [equation B1.5.10](#), possesses frequency components at frequencies 2ω and zero. The material response at the frequency 2ω corresponds to SHG, while the response at frequency zero corresponds to the phenomenon of optical rectification. The effect of a linear and nonlinear relation between the driving field and the material response is illustrated in figure B1.5.2.

Figure B1.5.2 Nonlinear dependence of the polarization P on the electric field E . (a) For small sinusoidal input fields, P depends linearly on E ; hence its harmonic content is mainly that of E . (b) For a stronger driving electric field E , the polarization waveform becomes distorted, giving rise to new harmonic components. The second-harmonic and DC components are shown.

In analogy to [equation B1.5.3](#), we can write the steady-state solution to [equation B1.5.10](#) for the SHG process as

$$x^{(2)}(t) = x^{(2)}(2\omega) \exp(-2i\omega t) + \text{c.c.} \quad (\text{B1.5.11})$$

The amplitude of the response, $x^{(2)}(2\omega)$, is given by the steady-state solution of [equation B1.5.10](#) as

$$x^{(2)}(2\omega) = \frac{(e/m)^2 b^{(2)} E(\omega)^2}{D(2\omega)D^2(\omega)} \quad (\text{B1.5.12})$$

-8-

where the quantity $D(\omega)$ is defined as $D(\omega) \equiv \omega_0^2 - \omega^2 - 2i\gamma\omega$. Similarly, the amplitude of the response at frequency zero for the optical rectification process is given by

$$x^{(2)}(0) = \frac{2(e/m)^2 b^{(2)} E(\omega)E(\omega)^*}{D(0)D(\omega)D(-\omega)}. \quad (\text{B1.5.13})$$

Following the derivation of the linear susceptibility, we may now readily deduce the second-order susceptibility $\chi^{(2)}(2\omega = \omega + \omega)$ for SHG, as well as $\chi^{(2)}(0 = \omega - \omega)$ for the optical rectification process. Defining the second-order nonlinear susceptibility for SHG as the relation between the square of the relevant components of the driving fields and the nonlinear source polarization,

$$(\text{B1.5.14})$$

$$P(2\omega) = \chi^{(2)}(2\omega)E(\omega)E(\omega)$$

we obtain

$$\chi^{(2)}(2\omega = \omega + \omega) = \frac{-(e^2/m^2)Nb^{(2)}}{D(2\omega)D^2(\omega)}. \quad (\text{B1.5.15})$$

As we shall discuss later in a detailed fashion, the nonlinear polarization associated with the nonlinear susceptibility of a medium acts as a source term for radiation at the second harmonic (SH) frequency 2ω . Since there is a definite phase relation between the fundamental pump radiation and the nonlinear source term, coherent SH radiation is emitted in well-defined directions. From the quadratic variation of $P(2\omega)$ with $E(\omega)$, we expect that the SH intensity $I_{2\omega}$ will also vary quadratically with the pump intensity I_ω .

If we compare the nonlinear response of $\chi^{(2)}(2\omega = \omega + \omega)$ with the linear material response of $\chi^{(1)}(\omega)$, we find both similarities and differences. As is apparent from equation B1.5.15 and shown pictorially in [figure B1.5.3](#) $\chi^{(2)}(2\omega = \omega + \omega)$ exhibits a resonant enhancement for frequencies ω near ω_0 , just as in the case for $\chi^{(1)}(\omega)$. However, in addition to this so-called one-photon resonance, $\chi^{(2)}(2\omega = \omega + \omega)$ also displays a resonant response when 2ω is near ω_0 or $\omega \approx \omega_0/2$. This feature is termed a two-photon resonance and has no analogue in linear spectroscopy. Despite these differences between $\chi^{(1)}$ and $\chi^{(2)}$, one can see that both types of response provide spectroscopic information about the material system. A further important difference concerns symmetry characteristics. The linear response $\chi^{(1)}$ may be expected to be present in any material. The second-order nonlinear response $\chi^{(2)}$ requires the material to exhibit a non-centrosymmetric character, i.e. in the one-dimensional model, the $+x$ and $-x$ directions must be distinguishable. To understand this property, consider the potential energy associated with the restoring force on the electron. This potential may be written in the notation previously introduced as $V(x) = \frac{1}{2}m\omega_0^2x^2 - \frac{1}{3}mb^{(2)}x^3 + \dots$. The first term is allowed for all materials; the second term, however, cannot be present in centrosymmetric materials since it clearly differentiates between a displacement of $+x$ and $-x$. Thus $b^{(2)} = 0$ except in non-centrosymmetric materials. This symmetry distinction is the basis for the remarkable surface and interface sensitivity of SHG and SFG for bulk materials with inversion symmetry.

-9-

Figure B1.5.3 Magnitude of the second-order nonlinear susceptibility $\chi^{(2)}$ versus frequency ω , obtained from the anharmonic oscillator model, in the vicinity of the single- and two-photon resonances at frequencies ω_0 and $\omega_0/2$, respectively.

(B) MAXWELL'S EQUATIONS

We now embark on a more formal description of nonlinear optical phenomena. A natural starting point for this discussion is the set of Maxwell equations, which are just as valid for nonlinear optics as for linear optics.

In the absence of free charges and current densities, we have in cgs units:

$$\nabla \times \mathbf{H} = \frac{1}{c} \frac{\partial \mathbf{D}}{\partial t} \quad (\text{B1.5.16})$$

$$\nabla \times \mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{B}}{\partial t} \quad (\text{B1.5.17})$$

$$\nabla \cdot \mathbf{B} = 0 \quad (\text{B1.5.18})$$

$$\nabla \cdot \mathbf{D} = 0 \quad (\text{B1.5.19})$$

where \mathbf{E} and \mathbf{H} are the electric and magnetic field intensities, respectively; \mathbf{D} and \mathbf{B} are the electric displacement and magnetic induction, respectively. In the optical regime, we generally neglect the magnetic response of the material and take $\mathbf{B} = \mathbf{H}$. The material response is then incorporated into the Maxwell equations through the displacement vector \mathbf{D} . This quantity is related to the electric field \mathbf{E} and the polarization \mathbf{P} (the electric dipole moment per unit volume) by

$$\mathbf{D} = \mathbf{E} + 4\pi \mathbf{P}. \quad (\text{B1.5.20})$$

-10-

The polarization \mathbf{P} is given in terms of \mathbf{E} by the constitutive relation of the material. For the present discussion, we assume that the polarization $\mathbf{P}(\mathbf{r})$ depends only on the field \mathbf{E} evaluated at the same position \mathbf{r} . This is the so-called dipole approximation. In later discussions, however, we will consider, in some specific cases, the contribution of a polarization that has a non-local spatial dependence on the optical field. Once we have augmented the system of [equation B1.5.16](#), [equation B1.5.17](#), [equation B1.5.18](#), [equation B1.5.19](#) and [equation B1.5.20](#) with the constitutive relation for the dependence of \mathbf{P} on \mathbf{E} , we may solve for the radiation fields. This relation is generally characterized through the use of linear and nonlinear susceptibility tensors, the subject to which we now turn.

(C) NONLINEAR OPTICAL SUSCEPTIBILITIES

If the polarization of a given point in space and time (\mathbf{r}, t) depends only on the driving electric field at the same coordinates, we may write the polarization as $\mathbf{P} = \mathbf{P}(\mathbf{E})$. In this case, we may develop the polarization in power series as $\mathbf{P} = \mathbf{P}_L + \mathbf{P}_{NL} = \mathbf{P}^{(1)} + \mathbf{P}^{(2)} + \mathbf{P}^{(3)} + \dots$, where the linear term is $\mathbf{P}_i^{(1)} = \sum_j \chi_{ij}^{(1)} E_j$ and the nonlinear terms include the second-order response $\mathbf{P}_i^{(2)} = \sum_{jk} \chi_{ijk}^{(2)} E_j E_k$, the third-order response $\mathbf{P}_i^{(3)} = \sum_{jkl} \chi_{ijkl}^{(3)} E_j E_k E_l$, and so forth. The coefficients $\chi_{ij}^{(1)}$, $\chi_{ijk}^{(2)}$, and $\chi_{ijkl}^{(3)}$, are, respectively, the linear, second-order nonlinear and the third-order nonlinear susceptibilities of the material. The quantity $\chi_{ijk\dots}^{(n)}$, it should be noted, is a tensor of rank $n + 1$, and $ijkl$ refer to indices of Cartesian coordinates. The simple formulation just presented does not allow for the variation of the optical response with frequency, a behaviour of critical importance for spectroscopy. We now briefly discuss how to incorporate frequency-dependent behaviour into the polarization response. To treat the frequency response of the material, we consider an excitation electric field of the form of a superposition of monochromatic fields

$$\mathbf{E}(t) = \sum_m \mathbf{E}(\omega_m) e^{-i\omega_m t} \quad (\text{B1.5.21})$$

where the summation extends over all positive and negative frequency components. Since $\mathbf{E}(t)$ represents a physical field, it is constrained to be real and $\mathbf{E}(-\omega_m) = \mathbf{E}(\omega_m)^*$. In the same manner, we can write the polarization \mathbf{P} as

$$\mathbf{P}(t) = \sum_n \mathbf{P}(\omega_n) e^{-i\omega_n t}. \quad (\text{B1.5.22})$$

Here the collection of frequencies in the summation may include new frequencies ω_n in addition to those in summation of equation B1.5.21 for the applied field. The total polarization can be separated into linear, \mathbf{P}_L , and nonlinear, \mathbf{P}_{NL} , parts:

$$\mathbf{P}(t) = \mathbf{P}_L(t) + \mathbf{P}_{NL}(t) = \mathbf{P}^{(1)}(t) + \mathbf{P}^{(2)}(t) + \mathbf{P}^{(3)}(t) + \dots \quad (\text{B1.5.23})$$

where $\mathbf{P}_L(t) = \mathbf{P}^{(1)}(t)$ and $\mathbf{P}_{NL}(t) = \mathbf{P}^{(2)}(t) + \mathbf{P}^{(3)}(t) + \dots$, and the terms in \mathbf{P} correspond to an expansion in powers of the field \mathbf{E} .

-11-

The linear susceptibility, $\chi_{ij}^{(1)}$, is the factor that relates the induced linear polarization to the applied field:

$$P_i^{(1)}(\omega_n) = \sum_j \chi_{ij}^{(1)}(\omega_n) E_j(\omega_n). \quad (\text{B1.5.24})$$

$\chi_{ij}^{(1)}(\omega_n)$ in this formulation gives rise, as one expects, to a polarization oscillating as the applied frequency ω_n , but may now incorporate a strength that varies with ω_n , as illustrated earlier in the harmonic oscillator model. Similarly, we can define the corresponding frequency-dependent second-order, $\chi_{ijk}^{(2)}$, and third-order, $\chi_{ijkl}^{(3)}$, susceptibility tensors by

$$P_i^{(2)}(\omega_q + \omega_r) = p \sum_{jk} \chi_{ijk}^{(2)}(\omega_q + \omega_r, \omega_q, \omega_r) E_j(\omega_q) E_k(\omega_r) \quad (\text{B1.5.25})$$

$$P_i^{(3)}(\omega_q + \omega_r + \omega_s) = p \sum_{jkl} \chi_{ijkl}^{(3)}(\omega_q + \omega_r + \omega_s, \omega_q, \omega_r, \omega_s) E_j(\omega_q) E_k(\omega_r) E_l(\omega_s) \quad (\text{B1.5.26})$$

where the quantity p is called the degeneracy factor and is equal to the number of distinct permutations of the applied frequencies $\{\omega_q, \omega_r\}$ and $\{\omega_q, \omega_r, \omega_s\}$ for the second- and third-order processes, respectively. The inclusion of the degeneracy factor p ensures that the nonlinear susceptibility is not discontinuous when two of the fields become degenerate, e.g. the nonlinear susceptibility $\chi_{ijk}^{(2)}(\omega_1 + \omega_2, \omega_1, \omega_2)$ approaches the value $\chi_{ijk}^{(2)}(2\omega_1, \omega_1, \omega_1)$ as ω_2 approaches the value ω_1 [32]. As can be seen from equation B1.5.25 and equation B1.5.26, the first frequency argument of the nonlinear susceptibility is equal to the sum of the rest of its

frequency arguments. Note also that these frequencies are not constrained to positive values and that the complete material response involves both the positive and negative frequency components. We now consider some of the processes described by the nonlinear susceptibilities. For the case of the second-order nonlinear optical effects (equation B1.5.25), three processes can occur when the frequencies ω_1 and ω_2 are distinct. This can be seen by expanding equation B1.5.25:

$$P_i^{(2)}(\omega_3) = 2 \sum_{jk} \chi_{ijk}^{(2)}(\omega_3, \omega_1, \omega_2) E_j(\omega_1) E_k(\omega_2) \quad (\text{B1.5.27})$$

$$P_i^{(2)}(2\omega_\alpha) = \sum_{jk} \chi_{ijk}^{(2)}(2\omega_\alpha, \omega_\alpha, \omega_\alpha) E_j(\omega_\alpha) E_k(\omega_\alpha) \quad \alpha = 1, 2 \quad (\text{B1.5.28})$$

$$P_i^{(2)}(\mathbf{0}) = 2 \left[\sum_{jk} \chi_{ijk}^{(2)}(\mathbf{0}, \omega_1, -\omega_1) E_j(\omega_1) E_k^*(\omega_1) + \sum_{jk} \chi_{ijk}^{(2)}(\mathbf{0}, \omega_2, -\omega_2) E_j(\omega_2) E_k^*(\omega_2) \right]. \quad (\text{B1.5.29})$$

-12-

These effects correspond, respectively, to the processes of sum-frequency generation (SFG), SHG and optical rectification.

For the case of third-order nonlinear optical effects (equation B1.5.26), a wide variety of processes are described by the different possible combinations of applied frequencies. We shall not attempt to catalogue them here. The most intuitive case is that of third-harmonic generation ($3\omega = \omega + \omega + \omega$), corresponding to addition of three equal frequencies. When one of the frequencies is zero (i.e. a DC field) one obtains the so-called electric-field induced SHG (EFISH) process ($2\omega = \omega + \omega + 0$). Several third-order effects have found significant use in both frequency and time-domain spectroscopy. These include notably coherent anti-Stokes Raman scattering, stimulated Raman scattering, general and degenerate four-wave mixing and two-photon absorption [30, 31].

(D) SYMMETRY PROPERTIES

The second-order nonlinear susceptibility tensor $\chi^{(2)}(\omega_3, \omega_2, \omega_1)$ introduced earlier will, in general, consist of 27 distinct elements, each displaying its own dependence on the frequencies ω_1 , ω_2 and $\omega_3 (= \pm \omega_1 \pm \omega_2)$. There are, however, constraints associated with spatial and time-reversal symmetry that may reduce the complexity of $\chi^{(2)}$ for a given material [32, 33 and 34]. Here we examine the role of spatial symmetry.

The most significant symmetry property for the second-order nonlinear optics is inversion symmetry. A material possessing inversion symmetry (or centrosymmetry) is one that, for an appropriate origin, remains unchanged when all spatial coordinates are inverted via $\mathbf{r} \rightarrow -\mathbf{r}$. For such materials, the second-order nonlinear response vanishes. This fact is of sufficient importance that we shall explain its origin briefly. For a centrosymmetric material, $\chi^{(2)}$ should remain unchanged under an inversion operation, since the material by hypothesis does not change. On the other hand, the nature of the physical quantities \mathbf{E} and \mathbf{P} implies that they must obey $\mathbf{E} \rightarrow -\mathbf{E}$ and $\mathbf{P} \rightarrow -\mathbf{P}$ under the inversion operation [35]. The relation $P_i^{(2)} = \sum_{jk} \chi_{ijk}^{(2)} E_j E_k$ then yields $\sum_{jk} \chi_{ijk}^{(2)} E_j E_k = -\sum_{jk} \chi_{ijk}^{(2)} E_j E_k$, whence $\chi_{ijk}^{(2)} = \mathbf{0}$. A further useful symmetry relation applies specifically to SHG process. Since the incident fields $E_j(\omega)$ and $E_k(\omega)$ are identical, we may take

$\chi_{ijk}^{(2)} = \chi_{ikj}^{(2)}$ without loss of information.

For materials that exhibit other classes of spatial symmetry not including centrosymmetry, we expect that $\chi_{ijk}^{(2)}$ will be non-vanishing but will display a simplified form [37]. To see how this might work, consider a crystal in which the x and y directions are equivalent. The nonlinear response of the medium would consequently be equivalent for an applied optical field polarized along either the x or y direction. It then follows, for example, that the nonlinear susceptibilities $\chi_{zxx}^{(2)}$ and $\chi_{zyy}^{(2)}$ are equal, as are other elements in which the indices x and y are exchanged. This reduces the complexity of $\chi^{(2)}$ significantly. Table B1.5.1 presents the form of the second-order nonlinear susceptibility relevant for the classes of symmetry encountered at isotropic and crystalline surfaces and interfaces.

(E) QUANTUM MECHANICAL DESCRIPTION

Having now developed some of the basic notions for the macroscopic theory of nonlinear optics, we would like to discuss how the microscopic treatment of the nonlinear response of a material is handled. While the classical nonlinear

-13-

oscillator model provides us with a qualitative feeling for the phenomenon, a quantitative theory must generally begin with a quantum mechanical description. As in the case of linear optics, quantum mechanical calculations in nonlinear optics are conveniently described by perturbation theory and the density matrix formalism [36, 37]. The heart of this microscopic description is the interaction Hamiltonian $H_{\text{int}} = -\mathbf{\mu} \cdot \mathbf{E}(t)$, which characterizes the interaction of the system with the radiation and is treated as a perturbation. Here $\mathbf{\mu} = -e\mathbf{r}$ is the electric dipole operator and $\mathbf{E}(t)$ is the applied optical field. Applying this formalism with first-order perturbation theory to calculate the induced dipole moment $\mathbf{\mu}$, we obtain a linear susceptibility that is proportional to the product of two matrix elements of $\mathbf{\mu}$, $(\mu_i)_{gn}(\mu_j)_{ng}$, where $(\mu_i)_{gn} \equiv \langle g | \mu_i | n \rangle$. This product may be viewed as arising from a process in which a photon is first destroyed in a real or virtual transition from a populated energy eigenstate $|g\rangle$ to an empty state $|n\rangle$; a photon is then emitted in the transition back to the initial state $|g\rangle$.

The second-order nonlinear optical processes of SHG and SFG are described correspondingly by second-order perturbation theory. In this case, two photons at the driving frequency or frequencies are destroyed and a photon at the SH or SF is created. This is accomplished through a succession of three real or virtual transitions, as shown in figure B1.5.4. These transitions start from an occupied initial energy eigenstate $|g\rangle$, pass through intermediate states $|n'\rangle$ and $|n\rangle$ and return to the initial state $|g\rangle$. A full calculation of the second-order response for the case of SFG yields [37]

$$\chi_{ijk}^{(2)}(\omega_3, \omega_2, \omega_1) = -\frac{N}{\hbar^2} \sum_{g,n,n'} \frac{(\mu_i)_{gn}(\mu_j)_{nn'}(\mu_k)_{n'g}}{(\omega_3 - \omega_{ng} + i\Gamma_{ng})(\omega_2 - \omega_{n'g} + i\Gamma_{n'g})} \rho_g^{(0)} \quad (\text{B1.5.30})$$

+ seven similar terms.

As for the linear response, the transitions occur through the electric-dipole operator $\mathbf{\mu}$ and are characterized by the matrix elements $(\mu_i)_{gn}$. In equation B1.5.30, the energy denominators involve the energy differences $\hbar\omega_{ng} \equiv E_n - E_g$ and widths $\hbar\Gamma_{ng}$ for transitions between eigenstates $|n\rangle$ and $|g\rangle$. The formula includes a sum over different possible ground states weighted by the factor $\rho_g^{(0)}$ representing the probability that state $|g\rangle$ is occupied. It is assumed that the material can be treated as having localized electronic states of density N per unit volume and that their interaction and local-field effects may be neglected. Corresponding expressions

result for delocalized electrons in crystalline solids [36, 37].

The frequency denominators in the eight terms of equation B1.5.30 introduce a resonant enhancement in the nonlinearity when any of the three frequencies ($\omega_1, \omega_2, \omega_3$) coincides with a transition from the ground state $|g\rangle$ to one of the intermediate states $|n'\rangle$ and $|n\rangle$. The numerator of each term, which consists of the product of the three dipole matrix elements $(\mu_i)_{gn}(\mu_j)_{n'n}(\mu_k)_{n'g}$, reflects, through its tensor character, the structural properties of the material, as well as the details of the character of the relevant energy eigenstates.

Figure B1.5.4 Quantum mechanical scheme for the SFG process with ground state $|g\rangle$ and excited states $|n'\rangle$ and $|n\rangle$.

B1.5.2.2 NONLINEAR OPTICS OF THE INTERFACE

The focus of the present chapter is the application of second-order nonlinear optics to probe surfaces and interfaces. In this section, we outline the phenomenological or macroscopic theory of SHG and SFG at the interface of centrosymmetric media. This situation corresponds, as discussed previously, to one in which the relevant nonlinear response is forbidden in the bulk media, but allowed at the interface.

(A) INTERFACIAL CONTRIBUTION

In order to describe the second-order nonlinear response from the interface of two centrosymmetric media, the material system may be divided into three regions: the interface and the two bulk media. The interface is defined to be the transitional zone where the material properties—such as the electronic structure or molecular orientation of adsorbates—or the electromagnetic fields differ appreciably from the two bulk media. For most systems, this region occurs over a length scale of only a few Ångströms. With respect to the optical radiation, we can thus treat the nonlinearity of the interface as localized to a sheet of polarization. Formally, we can describe this sheet by a nonlinear dipole moment per unit area, $\mathbf{P}_s^{(2)}$, which is related to a second-order bulk polarization $\mathbf{P}^{(2)}$ by $\mathbf{P}^{(2)}$ by $\mathbf{P}^{(2)}(x, y, z, t) = \mathbf{P}_s^{(2)}(x, y, t)\delta(z)$. Here z is the surface normal direction, and the x and y axes represent the in-plane coordinates (figure B1.5.5).

Figure B1.5.5 Schematic representation of the phenomenological model for second-order nonlinear optical effects at the interface between two centrosymmetric media. Input waves at frequencies ω_1 and ω_2 , with corresponding wavevectors $\mathbf{k}_1(\omega_1)$ and $\mathbf{k}_1(\omega_2)$, are approaching the interface from medium 1. Nonlinear radiation at frequency ω_3 is emitted in directions described by the wavevectors $\mathbf{k}_1(\omega_3)$ (reflected in medium 1) and $\mathbf{k}_2(\omega_3)$ (transmitted in medium 2). The linear dielectric constants of media 1, 2 and the interface are denoted by ε_1 , ε_2 , and ε' , respectively. The figure shows the xz -plane (the plane of incidence) with z increasing from top to bottom and $z = 0$ defining the interface.

The nonlinear response of the interface may then be characterized in terms of a surface (or interface) nonlinear susceptibility tensor $\chi_s^{(2)}$. This quantity relates the applied electromagnetic fields to the induced surface nonlinear polarization $\mathbf{P}_s^{(2)}$:

$$\mathbf{P}_s^{(2)}(\omega_3) = \chi_s^{(2)}(\omega_3 = \omega_1 + \omega_2) : \mathbf{E}(\omega_1)\mathbf{E}(\omega_2). \quad (\text{B1.5.31})$$

In this equation as well as in the succeeding discussions, we have suppressed, for notational simplicity, the permutation or degeneracy factor of two, required for SFG.

To define this model fully, we must specify the linear dielectric response in the vicinity of our surface nonlinear susceptibility. We do this in a general fashion by introducing a (frequency-dependent) linear dielectric response of the interfacial region ε' , which is bounded by the bulk media with dielectric constants ε_1 and ε_2 . For simplicity, we consider all of these quantities to be scalar, corresponding to isotropic linear optical properties. The phenomenological model for second-order nonlinear optical effects is summarized in figure B1.5.5 (An alternative convention [38, 39] for defining the surface nonlinear susceptibility is one in which the fundamental fields $\mathbf{E}(\omega_1)$ and $\mathbf{E}(\omega_2)$ are taken as their value in the lower medium and the polarized sheet is treated as radiating in the upper medium. This convention corresponds in our model to the assignments of $\varepsilon'(\omega_1) = \varepsilon_2(\omega_1)$, $\varepsilon'(\omega_2) = \varepsilon_2(\omega_2)$, and $\varepsilon'(\omega_3) = \varepsilon_1(\omega_3)$.)

From the point of view of tensor properties, the surface nonlinear susceptibility $\chi_s^{(2)}$ is quite analogous to the bulk nonlinear response $\chi_{ijk}^{(2)}$ in a non-centrosymmetric medium. Consequently, in the absence of any symmetry constraints, $\chi_s^{(2)}$ will exhibit 27 independent elements for SFG and, because of symmetry for the last two indices, 18 independent elements for SHG. If the surface exhibits certain in-plane symmetry properties, then the form of $\chi_s^{(2)}$ will be simplified

correspondingly. For the common situation of an isotropic surface, for example, the allowed elements of

$\chi_s^{(2)}$ may be denoted as $\chi_{s,\perp\perp\perp}^{(2)}$, $\chi_{s,\perp\parallel\parallel}^{(2)}$, $\chi_{s,\parallel\perp\parallel}^{(2)}$, and $\chi_{s,\parallel\parallel\perp}^{(2)}$ where \perp corresponds to the z direction and \parallel refers to either x or y . For the case of SHG, where the fundamental frequencies are equal, $\omega_1 = \omega_2 \equiv \omega$, the tensor elements $\chi_{s,\perp\perp\perp}^{(2)}$ and $\chi_{s,\parallel\parallel\perp}^{(2)}$ are likewise equivalent. The non-vanishing elements of $\chi_s^{(2)}$ for other commonly encountered surface symmetries are summarized in table B1.5.1.

Table B1.5.1 Independent non-vanishing elements of the nonlinear susceptibility, $\chi_s^{(2)}$ for an interface in the xy -plane for various symmetry classes. When mirror planes are present, at least one of them is perpendicular to the y -axis. For SHG, elements related by the permutation of the last two elements are omitted. For SFG, these elements are generally distinct; any symmetry constraints are indicated in parentheses. The terms enclosed in parentheses are antisymmetric elements present only for SFG. (After [71])

Symmetry class	Independent non-vanishing elements
1	$xxx, xxy, xyy, xyz, xxz, xzz, yxx, yxy, yxz, yyy, yyz, yzz, zxx,$ zxy, zxz, zyy, zyz, zzz
[3pt] m	$xxx, xyy, xzx, xzz, yxy, yyz, zxx, zxz, zyy, zzz$ $xzx, xyz, yxz, yzy, zxx, zyy, zxy, zzz$
$2mm$	xzx, yzy, zxx, zyy, zzz
3	$xxx=-xyy=-yyx(=-yxy)$ $yyy=-yxx=-xyx(=-xxy), yzy=xzx,$ $zxx=zyy, xyz=-yxz$ $zzz, (zxy=-zyx)$
$3m$	$xxx=-xyy=-yxy(=-yyx)$ $yzy=xzx, zxx=zyy, zzz$
4,6, ∞	$xxz=yyz, zxx=zyy, xyz=-yxz, zzz, (zxy=-zyx)$
$4mm, 6mm, \infty m$	$xxz=yyz, zxx=zyy, zzz$

The linear and nonlinear optical responses for this problem are defined by ϵ_1 , ϵ_2 , ϵ' and $\chi_s^{(2)}$, respectively, as indicated in figure B1.5.5. In order to determine the nonlinear radiation, we need to introduce appropriate pump radiation fields $E(\omega_1)$ and $E(\omega_2)$. If these pump beams are well-collimated, they will give rise to well-collimated radiation emitted through the surface nonlinear response. Because the nonlinear response is present only in a thin layer, phase matching [37] considerations are unimportant and nonlinear emission will be present in both transmitted and reflected directions.

-17-

Here we model the pump beams associated with fields $E(\omega_1)$ and $E(\omega_2)$ as plane waves with wavevectors $\mathbf{k}_1 = \hat{\mathbf{k}}_1 \omega_1 \sqrt{\epsilon_1(\omega_1)}/c$ and $\mathbf{k}_2 = \hat{\mathbf{k}}_2 \omega_2 \sqrt{\epsilon_1(\omega_2)}/c$. The directions of the reflected and transmitted beams can then be obtained simply through conservation of the in-plane component of the wavevector, i.e. $k_{1x}(\omega_1) + k_{1x}(\omega_2) = k_{1x}(\omega_3) = k_{2x}(\omega_3)$. This is the nonlinear optical analogue of Snell's law. For the case of SHG, this equation may be reduced to $n(\omega) \sin \theta_\omega = n(2\omega) \sin \theta_{2\omega}$ for the angle of the incident pump radiation, θ_ω , and the angle of the emitted nonlinear beams, $\theta_{2\omega}$. The refractive indices in this equation correspond to those of the relevant bulk medium through which the beams propagate. For reflection in a non-dispersive medium, we obtain simply $\theta_\omega = \theta_{2\omega}$, as for the law of reflection. For the transmitted beam, the relation in the absence of dispersion reduces to the usual Snell's law for refraction.

A full solution of the nonlinear radiation follows from the Maxwell equations. The general case of radiation from a second-order nonlinear material of finite thickness was solved by Bloembergen and Pershan in 1962 [40]. That problem reduces to the present one if we let the interfacial thickness approach zero. Other equivalent solutions involved the application of the boundary conditions for a polarization sheet [14] or the

use of a Green's function formalism for the surface [38, 39].

From such a treatment, we may derive explicit expressions for the nonlinear radiation in terms of the linear and nonlinear response and the excitation conditions. For the case of nonlinear reflection, we obtain an irradiance for the radiation emitted at the nonlinear frequency ω_3 of

$$I(\omega_3) = \frac{8\pi^3 \omega_3^2 \sec^2 \theta |e'(\omega_3) \cdot \chi_s^{(2)} : e'(\omega_1) e'(\omega_2)|^2 I(\omega_1) I(\omega_2)}{c^3 [\varepsilon_1(\omega_3) \varepsilon_1(\omega_1) \varepsilon_1(\omega_2)]^{1/2}} \quad (\text{B1.5.32})$$

where $I(\omega_1)$ and $I(\omega_2)$ denote the intensities of the pump beams at frequencies ω_1 and ω_2 incident from medium 1; c is the speed of light in vacuum; θ is the angle of propagation direction of the nonlinear radiation relative to the surface normal. The vectors $e'(\omega_1)$, $e'(\omega_2)$ and $e'(\omega_3)$ represent the *unit* polarization vectors $\hat{e}_1(\omega_1)$, $\hat{e}_1(\omega_2)$, and $\hat{e}_1(\omega_3)$, respectively, adjusted to account for the linear optical propagation of the waves. More specifically, we may write

$$e'(\omega) = F_{1 \rightarrow 2} \hat{e}_1(\omega). \quad (\text{B1.5.33})$$

Here the 'Fresnel transformation' $F_{1 \rightarrow 2}$ describes the relationship between the electric field $E\hat{e}_1$ in medium 1 (propagating towards medium 2) and the resulting field Ee' at the interface. For light incident in the x - z plane as shown in [figure B1.5.5](#) $F_{1 \rightarrow 2}$ is a diagonal matrix whose elements are

$$F_{1 \rightarrow 2}^{xx} = 2\varepsilon_1 k_{2,z} / (\varepsilon_2 k_{1,z} + \varepsilon_1 k_{2,z}) \quad (\text{B1.5.34})$$

$$F_{1 \rightarrow 2}^{yy} = 2k_{1,z} / (k_{1,z} + k_{2,z}) \quad (\text{B1.5.35})$$

$$F_{1 \rightarrow 2}^{zz} = 2(\varepsilon_1 \varepsilon_2 / \varepsilon') k_{1,z} / (\varepsilon_2 k_{1,z} + \varepsilon_1 k_{2,z}) \quad (\text{B1.5.36})$$

-18-

where the quantity $k_{i,z}$ denotes the magnitude of the z -component of the wavevector in medium i at the relevant wavelength (ω_1 , ω_2 or ω_3).

The treatment of this section has been based on an assumed nonlinear surface response $\chi_s^{(2)}$ and has dealt entirely with electromagnetic considerations of excitation and radiation from the interface. A complete theoretical picture, however, includes developing a microscopic description of the surface nonlinear susceptibility. In the discussion in [section B1.5.4](#), we will introduce some simplified models. In this context, an important first approximation for many systems of chemical interest may be obtained by treating the surface nonlinearity as arising from the composite of individual molecular contributions. The molecular response is typically assumed to be that of the isolated molecule, but in the summation for the surface nonlinear response, we take into account the orientational distribution appropriate for the surface or interface, as we discuss later. Local-field corrections may also be included [41, 42]. Such analyses may then draw on the large and well-developed literature concerning the second-order nonlinearity of molecules [43, 44]. If we are concerned with the response of the surface of a clean solid, we must typically adopt a different approach: one based on delocalized electrons. This is a challenging undertaking, as a proper treatment of the *linear* optical properties of surfaces of solids is already difficult [45]. Nonetheless, in recent years significant progress has been made in developing a fundamental theory of the nonlinear response of surfaces of both metals [46, 47,

48, 49, 50 and 51] and semiconductors [52, 53, 54 and 55].

(B) BULK CONTRIBUTION

For centrosymmetric media the spatially local contribution to the second-order nonlinear response vanishes, as we have previously argued, providing the interface specificity of the method. This spatially local contribution, which arises in the quantum mechanical picture from the electric-dipole terms, represents the dominant response of the medium. However, if we consider the problem of probing interfaces closely, we recognize that we are comparing the nonlinear signal originating from an interfacial region of monolayer thickness with that of the bulk media. In the bulk media, the signal can build up over a thickness on the scale of the optical wavelength, as dictated by absorption and phase-matching considerations. Thus, a bulk nonlinear polarization that is much weaker than that of the dipole-allowed contribution present at the interface may still prove to be significant because of the larger volume contributing to the emission. Let us examine this point in a somewhat more quantitative fashion.

The higher-order bulk contribution to the nonlinear response arises, as just mentioned, from a spatially non-local response in which the induced nonlinear polarization does not depend solely on the value of the fundamental electric field at the same point. To leading order, we may represent these non-local terms as being proportional to a nonlinear response incorporating a first spatial derivative of the fundamental electric field. Such terms correspond in the microscopic theory to the inclusion of electric-quadrupole and magnetic-dipole contributions. The form of these bulk contributions may be derived on the basis of symmetry considerations. As an example of a frequently encountered situation, we indicate here the non-local polarization for SHG in a cubic material excited by a plane wave $\mathbf{E}(\omega)$:

$$P_{b,i}^{(2)}(2\omega) = \gamma \nabla_i [\mathbf{E}(\omega) \cdot \mathbf{E}(\omega)] + \zeta E_i(\omega) \nabla_i E_i(\omega). \quad (\text{B1.5.37})$$

The two coefficients γ and ζ describe the material response and the Cartesian coordinate i must be chosen as a principal axis of the material.

-19-

From consideration of the quantum mechanical expression of such a non-local response, one may argue that the dipole-forbidden bulk nonlinear polarization will have a strength reduced from that of the dipole-allowed response by a factor of the order of (a/λ) , with a denoting a typical atomic dimension and λ representing the wavelength of light. On the other hand, the relevant volume for the bulk contribution typically exceeds that of the interface by a factor of the order of (λ/a) . Consequently, one estimates that the net bulk and surface contributions to the nonlinear radiation may be roughly comparable in strength. In practice, the interfacial contribution often dominates that of the bulk. Nonetheless, one should not neglect *a priori* the possible role of the bulk nonlinear response. This situation of a possible bulk background signal comparable to that of the interface should be contrasted to the expected behaviour for a conventional optical probe lacking interface specificity. In the latter case, the bulk contribution would be expected to dominate that of the interface by several orders of magnitude.

(C) OTHER SOURCES

As we have discussed earlier in the context of surfaces and interfaces, the breaking of the inversion symmetry strongly alters the SHG from a centrosymmetric medium. Surfaces and interfaces are not the only means of breaking the inversion symmetry of a centrosymmetric material. Another important perturbation is that induced by (static) electric fields. Such electric fields may be applied externally or may arise internally from a depletion layer at the interface of a semiconductor or from a double-charge layer at the interface of a liquid.

Since the electric field is a polar vector, it acts to break the inversion symmetry and gives rise to dipole-allowed sources of nonlinear polarization in the bulk of a centrosymmetric medium. Assuming that the DC field, E_{DC} , is sufficiently weak to be treated in a leading-order perturbation expansion, the response may be written as

$$P_{\text{DC}}^{(3)}(2\omega) = \chi^{(3)} : E(\omega)E(\omega)E_{\text{DC}} \quad (\text{B1.5.38})$$

where $\chi^{(3)}$ is the effective third-order response. This process is called electric-field-induced SHG or EFISH.

A different type of external perturbation is the application of a magnetic field. In contrast to the case of an electric field, an applied magnetic field does not lift the inversion symmetry of a centrosymmetric medium. Hence, it does not give rise to a dipole-allowed bulk polarization for SHG or SFG [23, 56]. A magnetic field can, however, modify the form and strength of the interfacial nonlinear response, as well as the bulk quadrupole nonlinear susceptibilities. This process is termed magnetization-induced SHG or MSHG. Experiments exploiting both EFISH and MSHG phenomena are discussed in [section B1.5.4.7](#).

B1.5.3 EXPERIMENTAL CONSIDERATIONS

In this section, we provide a brief overview of some experimental issues relevant in performing surface SHG and SFG measurements.

B1.5.3.1 EXPERIMENTAL GEOMETRY

The main panel of [figure B1.5.6](#) portrays a typical setup for SHG. A laser source of frequency ω is directed to the sample, with several optical stages typically being introduced for additional control and filtering. The combination of a

halfwave plate and a polarizer is used to specify the orientation of the polarization of the pump beam. It can also serve as a variable attenuator to adjust the intensity of the incoming beam. A lens then focuses the beam onto the sample. A low-pass filter is generally needed along the path of the fundamental radiation prior to the sample to remove any unwanted radiation at the frequency of the nonlinear radiation. This radiation may arise from previous optical components, including the laser source itself.

Figure B1.5.6 Experimental geometry for typical SHG and SFG measurements.

The reflected radiation consists of a strong beam at the fundamental frequency ω and a weak signal at the SH frequency. Consequently, a high-pass filter is introduced, which transmits the nonlinear radiation, but blocks the fundamental radiation. By inserting this filter immediately after the sample, we minimize the generation of other nonlinear optical signals from succeeding optical components by the fundamental light reflected from the sample. After this initial filtering stage, a lens typically recollimates the beam and an analyser is used to select the desired polarization. Although not always essential, a monochromator or bandpass filter is often desirable to ensure that only the SH signal is measured. Background signals near the SH frequency, but not associated with the SHG process, may arise from multiphoton fluorescence, hyper-Raman scattering and other nonlinear processes described by higher-order nonlinear susceptibilities. Detection is usually accomplished through a photomultiplier tube. Depending on the nature of the laser source, various sensitive schemes for

electronic detection of the photomultiplier may be employed, such as photon counting and gated integration. In conjunction with an optical chopper in the beam path, lock-in amplification techniques may also be advantageous.

One of the key factors for performing surface SHG/SFG measurements is to reduce all sources of background signals, since the desired nonlinear signal is always relatively weak. This goal is accomplished most effectively by exploiting the well-defined spectral, spatial and temporal characteristics of the nonlinear radiation. The first of these is achieved by spectral filtering, as previously discussed. The second may be achieved through the use of appropriate apertures; and the last, particularly for low-repetition rate systems, can be incorporated into the electronic detection scheme. When

-21-

the excitation is derived from two non-collinear beams, the nonlinear emission will generally travel in a distinct direction ([figure B1.5.6](#) inset). In this case, one can also exploit spatial filters to enhance spectral selectivity, since the reflected pump beams will travel in different directions. This property is particularly useful for SFG experiments in which the frequency of the visible beam and the SF signal are relatively similar.

For some experiments, it may be helpful to obtain a reference signal to correct for fluctuations and long-term drift in the pump laser. This correction is best accomplished by performing simultaneous measurements of the SHG or SFG from a medium that has a strong $\chi^{(2)}$ response in a separate detection arm. By this means, one may fully compensate for variations not only in pulse energy, but also in the temporal and spatial substructure of the laser pulses. Some experiments may require measurement of the phase of the nonlinear signal [57]. Such phase measurements rely on interference with radiation from a reference nonlinear source. The required interference can be achieved by placing a reference nonlinear crystal along the path of the laser beam immediately either before or after the sample [58]. For effective interference, we must control both the amplitude and polarization of the reference signal. This may be achieved by appropriate focusing conditions and crystal alignment. The phase of the reference signal must also be adjustable. Phase control may be obtained simply by translating the reference sample along the path of the laser, making use of the dispersion of the air (or other medium) through which the beams propagate.

B1.5.3.2 LASER SOURCES

In order to achieve a reasonable signal strength from the nonlinear response of approximately one atomic monolayer at an interface, a laser source with high peak power is generally required. Common sources include Q-switched (~ 10 ns pulsewidth) and mode-locked (~ 100 ps) Nd:YAG lasers, and mode-locked (~ 10 fs–1 ps) Ti:sapphire lasers. Broadly tunable sources have traditionally been based on dye lasers. More recently, optical parametric oscillator/amplifier (OPO/OPA) systems are coming into widespread use for tunable sources of both visible and infrared radiation.

In typical experiments, the laser fluence, or the energy per unit area, is limited to the sample's damage threshold. This generally lies in the range $\ll 1$ J cm⁻² and constrains our ability to increase signal strength by increasing the pump energy. Frequently, the use of femtosecond pulses is advantageous, as one may obtain a higher intensity (and, hence, higher nonlinear conversion efficiency) at lower fluence. In addition, such sources generally permit one to employ lower average intensity, which reduces average heating of the sample and other undesired effects [59]. Independently of these considerations, femtosecond lasers are, of course, also attractive for the possibilities that they offer for measurements of ultrafast dynamics.

B1.5.3.3 SIGNAL STRENGTHS

We now consider the signal strengths from surface SHG/SFG measurements. For this purpose, we may recast

expression [B1.5.32](#) for the reflected nonlinear radiation in terms of the number of emitted photon per unit time as

$$S = \frac{8\pi^3 \omega_3}{\hbar c^3 [\epsilon_1(\omega_3) \epsilon_1(\omega_2) \epsilon_1(\omega_1)]^{1/2}} \frac{\sec^2 \theta P_{\text{avg}}(\omega_1) P_{\text{avg}}(\omega_2)}{t_p R_{\text{rep}} A} |e'(\omega_3) \cdot \chi_s^{(2)} : e'(\omega_1) e'(\omega_2)|^2. \quad (\text{B1.5.39})$$

The quantities in this formula are defined as in [equation B1.5.32](#), but with the laser parameters translated into more convenient terms: P_{avg} is the average power at the indicated frequency; t_p is the laser pulse duration; R_{rep} is the pulse

-22-

repetition rate; and A is the irradiated area at the interface. The last three defined quantities are assumed to be equal for both excitation beams in an SFG measurement. If this is not the case, then t_p , R_{rep} , A , as well as the average power $P_{\text{avg}}(\omega_i)$, have to be replaced by the corresponding quantities within the window of spatial and temporal overlap.

From this expression, we may estimate typical signals for a surface SHG measurement. We assume the following as representative parameters: $\chi^{(2)} = 10^{-15}$ esu, $\epsilon_1 = 1$, and $\sec^2 \theta = 4$. For typical optical frequencies, we then obtain $S \approx 10^{-2} (P_{\text{avg}})^2 / (t_p R_{\text{rep}} A)$, where P_{avg} , A , R_{rep} and t_p are expressed, respectively, in W, cm^2 , Hz and s. Many recent SHG studies have been performed with mode-locked Ti:sapphire lasers. For typical laser parameters of $P_{\text{avg}} = 100$ mW, $A = 10^{-4}$ cm^2 , $R_{\text{rep}} = 100$ MHz, and $t_p = 100$ fs, one then obtains $S \approx 10^5$ counts per second as a representative nonlinear signal.

B1.5.3.4 DETERMINATION OF NONLINEAR SUSCEPTIBILITY ELEMENTS

The basic physical quantities that define the material for SHG or SFG processes are the nonlinear susceptibility elements $\chi_{s,ijk}^{(2)}$. Here we consider how one may determine these quantities experimentally. For simplicity, we treat the case of SHG and assume that the surface is isotropic. From symmetry considerations, we know that $\chi_{s,ijk}^{(2)}$ has three independent and non-vanishing elements: $\chi_{s,\perp\perp\perp}^{(2)}$, $\chi_{s,\perp\parallel\parallel}^{(2)}$, and $\chi_{s,\parallel\perp\parallel}^{(2)} = \chi_{s,\parallel\parallel\perp}^{(2)}$. The individual elements $\chi_{s,\parallel\perp\perp}^{(2)}$ and $\chi_{s,\parallel\perp\parallel}^{(2)}$ can be extracted directly by an appropriate choice of input and output polarizations. Response from the $\chi_{s,\perp\parallel\parallel}^{(2)}$ element requires s-polarized pump radiation and produces p-polarized SH emission; excitation of the $\chi_{s,\perp\perp\perp}^{(2)}$ element requires a mixed-polarized pump radiation and can be isolated by detection of s-polarized radiation. The measurement of $\chi_{s,\perp\perp\perp}^{(2)}$ is bit more complicated: to isolate it would require a pump electric field aligned normal to the surface, thus implying a pump beam travelling parallel to the surface (the limit of grazing incidence).

An alternative scheme for extracting all three isotropic nonlinear susceptibilities can be formulated by examining [equation B1.5.39](#). By choosing an appropriate configuration and the orientation of the polarization of the SH radiation $e'(2\omega)$ such that the SHG signal vanishes, one obtains, assuming only surface contribution with real elements $\chi_{s,ijk}^{(2)}$,

$$e'(2\omega) \cdot \chi_s^{(2)} : e'(\omega) e'(\omega) = \sum_{ijk} e'_i(2\omega) \chi_{s,ijk}^{(2)} e'_j(\omega) e'_k(\omega) = 0.$$

Expanding this equation, we deduce that

$$e'_\perp(2\omega)[\chi_{s,\perp\perp\perp}^{(2)}e'_\perp(\omega)e'_\perp(\omega) + \chi_{s,\perp\parallel\parallel}^{(2)}e'_\parallel(\omega)e'_\parallel(\omega)] + 2e'_\parallel(2\omega)\chi_{s,\perp\perp\parallel}^{(2)}e'_\perp(\omega)e'_\parallel(\omega) = 0. \quad (\text{B1.5.40})$$

The magnitudes of e'_i ($i = \perp, \parallel$) contain the Fresnel factors from [equation B1.5.34](#), [equation B1.5.35](#) and [equation B1.5.36](#), which depend on the incident, reflected and polarization angles. Experimentally, one approach is to fix the input polarization and adjust the analyser to obtain a null in the SH signal [60]. By choosing distinct configurations such that the corresponding three equations from [equation B1.5.40](#) are linearly independent, the relative values of $\chi_{s,\perp\perp\perp}^{(2)}$, $\chi_{s,\perp\parallel\parallel}^{(2)}$, and $\chi_{s,\perp\perp\parallel}^{(2)} = \chi_{s,\parallel\parallel\perp}^{(2)}$ may be inferred. This method has been implemented, for example, in determining the three susceptibility elements for the air/water interface [61]. The procedure just described is suitable for

-23-

ascertaining the relative magnitudes of the allowed elements of $\chi_s^{(2)}$.

A determination of the absolute magnitude of the elements of $\chi_s^{(2)}$ may also be of value. In principle, this might be accomplished by careful measurements of signal strengths from [equation \(B1.5.32\)](#) or [equation \(B1.5.39\)](#). In practice, such an approach is very difficult, as it would require precise calibration of the parameters of the laser radiation and absolute detection sensitivity. The preferred method is consequently to compare the surface SHG or SFG response to that of a reference crystal with a known bulk nonlinearity inserted in place of the sample. Since the expected signal can be calculated for this reference material, we may then infer the absolute calibration of $\chi_s^{(2)}$ by comparison. It should be further noted that the phase of elements of $\chi_s^{(2)}$ may also be established by interference measurements as indicated in [section B1.5.3.1](#).

B1.5.4 APPLICATIONS

The discussion of applications of the SHG and SFG methods in this section is directed towards an exposition of the different types of information that may be obtained from such measurements. The topics have been arranged accordingly into seven general categories that arise chiefly from the properties of the nonlinear susceptibility: surface symmetry and order, adsorbate coverage, molecular orientation, spectroscopy, dynamics, spatial resolution and perturbations induced by electric and magnetic fields. Although we have included some illustrative examples, a comprehensive description of the broad range of materials probed by these methods, and what has been learned about them, is clearly beyond the scope of this chapter.

B1.5.4.1 SURFACE SYMMETRY AND ORDER

Spatial symmetry is one of the basic properties of a surface or interface. If the symmetry of the surface is known *a priori*, then this knowledge may be used to simplify the form of the surface nonlinear susceptibility $\chi_s^{(2)}$, as discussed in [section B1.5.2.2](#). Conversely, in the absence of knowledge of the surface symmetry, we may characterize the form of $\chi_s^{(2)}$ experimentally and then make inferences about the symmetry of the surface or interface. This provides some useful information about the material system under study, as we shall illustrate in this section. Before doing so, we should remark that the spatial properties being probed are averaged over a length scale that depends on the precise experimental geometry, but exceeds the scale of an optical wavelength. In the following paragraphs, we consider two of the interesting cases of surface symmetry: that corresponding to the surface of a crystalline material and that of a surface with chiral character.

(A) CRYSTALLINE SURFACES

All of the symmetry classes compatible with the long-range periodic arrangement of atoms comprising crystalline surfaces and interfaces have been enumerated in [table B1.5.1](#). For each of these symmetries, we indicate the corresponding form of the surface nonlinear susceptibility $\chi_s^{(2)}$. With the exception of surfaces with four-fold or six-fold rotational symmetries, all of these symmetry classes give rise to a $\chi_s^{(2)}$ that may be distinguished from that of an isotropic surface with mirror symmetry, the highest possible surface symmetry.

-24-

An experimental analysis of the surface symmetry may be carried out in various ways. For a fixed crystal orientation, the surface symmetry may be probed by modifying the angle of incidence and polarization of the input and output beams. This approach is often employed for samples, such as those in ultrahigh vacuum, that are difficult to manipulate. An attractive alternative method is to probe the rotational anisotropy simply by recording the change in the nonlinear signal as the sample is rotated about its surface normal. The resulting data reflect directly the symmetry of the surface or interface. Thus, the rotational pattern for the (111) surface of a cubic centrosymmetric crystal with $3m$ symmetry will also have three-fold symmetry with mirror planes. A surface with four-fold symmetry, as in the case of the (001) surface of a cubic material, will give rise to a rotational anisotropy pattern that obeys four-fold symmetry. From [table B1.5.1](#), we see that it will, however, do so in a trivial fashion by giving a response equivalent to that of an isotropic material, i.e. lacking any variation with rotation of the crystal surface.

As an illustration, we consider the case of SHG from the (111) surface of a cubic material ($3m$ symmetry). More general treatments of rotational anisotropy in centrosymmetric crystals may be found in the literature [[62](#), [63](#) and [64](#)]. For the case at hand, we may determine the anisotropy of the radiated SH field from [equation B1.5.32](#) in conjunction with the form of $\chi_s^{(2)}$ from [table B1.5.1](#). We find, for example, for the p-in/p-out and s-in/s-out polarization configurations:

$$E_{\text{p-in/p-out}}^{(2\omega)} = a_0 + a_3 \cos(3\psi) \quad (\text{B1.5.41})$$

$$E_{\text{s-in/s-out}}^{(2\omega)} = b_3 \sin(3\psi) \quad (\text{B1.5.42})$$

where a_0 , a_3 and b_3 are constants. The angle ψ corresponds to the rotation of the sample about its surface normal and is measured between the plane of incidence and the $[11\bar{2}]$ direction in the surface plane.

[Figure B1.5.7](#) displays results of a measurement of the rotational anisotropy for an oxidized Si(111) surface [[65](#)]. For the case shown in the top panel, the results conform to the predictions of [equation B1.5.42](#) (with $I(2\omega) \propto |E^{(2\omega)}|^2$) for ideal $3m$ symmetry. The data clearly illustrate the strong influence of anisotropy on measured nonlinear signals. The lower panels of [figure B1.5.7](#) are perturbed rotational anisotropy patterns. They correspond to data for vicinal Si(111) surfaces cut at 3° and 5° , respectively, away from the true (111) orientation. The full lines fitting these data are obtained from an analysis in which the lowered symmetry of these surfaces is taken into account. The results show the sensitivity of this method to slight changes in the surface symmetry.

-25-

Figure B1.5.7 Rotational anisotropy of the SH intensity from oxidized Si(111) surfaces. The samples have either ideal orientation or small offset angles of 3° and 5° toward the $[11\bar{2}]$ direction. Top panel illustrates the step structure. The points correspond to experimental data and the full lines to the prediction of a symmetry analysis. (From [65].)

SH anisotropy measurements of this kind are of use in establishing the orientation of a crystal face of a material, as suggested by figure B1.5.7. The method is also of value for monitoring and study of crystal growth processes [66]. Consider, for example, the growth of Si on Si(111) surface. The crystalline surface exhibits strong rotational anisotropy, corresponding to the $3m$ symmetry of the surface. This will also be the case when a crystalline Si layer is grown on the sample. If, however, the overlayer is grown in an amorphous state, as would occur for Si deposition at

room temperature, then the anisotropy will be reduced: the disordered overlayer will exhibit isotropic symmetry on the length scale of the optical wavelength. A further application of rotational anisotropy measurements has been found in the characterization of surface roughness [67].

(B) CHIRAL INTERFACES

An important distinction among surfaces and interfaces is whether or not they exhibit mirror symmetry about a plane normal to the surface. This symmetry is particularly relevant for the case of isotropic surfaces (∞ -symmetry), i.e. ones that are equivalent in every azimuthal direction. Those surfaces that fail to exhibit mirror symmetry may be termed chiral surfaces. They would be expected, for example, at the boundary of a liquid comprised of chiral molecules. Magnetized surfaces of isotropic media may also exhibit this symmetry. (For a review of SHG studies of chiral interfaces, the reader is referred to [68].)

Given the interest and importance of chiral molecules, there has been considerable activity in investigating the corresponding chiral surfaces [68, 69 and 70]. From the point of view of performing surface and interface spectroscopy with nonlinear optics, we must first examine the nonlinear response of the bulk liquid. Clearly, a chiral liquid lacks inversion symmetry. As such, it may be expected to have a strong (dipole-allowed) second-order nonlinear response. This is indeed true in the general case of SFG [71]. For SHG, however, the permutation symmetry for the last two indices of the nonlinear susceptibility tensor combined with the requirement of isotropic symmetry in three dimensions implies that $\chi^{(2)} = 0$. Thus, for the case of SHG, the surface/interface specificity of the technique is preserved even for chiral liquids.

A schematic diagram of the surface of a liquid of non-chiral (a) and chiral molecules (b) is shown in [figure B1.5.8](#). Case (a) corresponds to ∞m -symmetry (isotropic with a mirror plane) and case (b) to ∞ -symmetry (isotropic). For the ∞m -symmetry, the SH signal for the polarization configurations of s-in/s-out and p-in/s-out vanish. From [table B1.5.1](#), we find, however, that for the ∞ -symmetry, an extra independent nonlinear susceptibility element, $\chi_{s,xyz}^{(2)} = -\chi_{s,yxz}^{(2)}$, is present for SHG. Because of this extra element, the SH signal for p-in/s-out configuration is no longer forbidden, and consequently, the SH polarization must no longer be strictly p-polarized. [figure B1.5.8\(c\)](#) shows the SH signal passing through an analyser as a function of its orientation for a racemic mixture (squares) and for a non-racemic mixture (circle) of molecules in a Langmuir–Blodgett film [70]. For the racemic mixture (squares), which contains equal amounts of both enantiomers, the effective symmetry is ∞m . Hence, the p-in/s-out signal vanishes and the response curve of [figure B1.5.8](#) is centred at 90° . For the case of the non-racemic mixture, the effective symmetry is ∞ . A p-in/s-out SH signal is present and leads, as shown in [figure B1.5.8\(c\)](#), to a displacement in the curve of the SH response versus analyser setting.

Figure B1.5.8 Random distribution of (a) non-chiral adsorbates that gives rise to a surface having effective ∞ m-symmetry; (b) chiral molecules that gives rise to effective ∞ -symmetry. (c) SH intensity versus the angle of an analyser for a racemic (squares) and a non-racemic (open circles) monolayer of chiral molecules. The pump beam was p-polarized; the SH polarization angles of 0° and 90° correspond to s- and p-polarization, respectively. (From [70].)

This effect of a change in the SH output polarization depending on the enantiomer or mixture of enantiomer is somewhat analogous to the linear optical phenomenon of optical rotary dispersion (ORD) in bulk chiral liquids. As such, the process for SH radiation is termed SHG-ORD [70]. In general, chiral surfaces will also exhibit distinct radiation characteristics for left- and right-polarized pump beams. Again, by analogy with the linear optical process of circular dichroism (CD), this effect has been termed SHG-CD [69].

B1.5.4.2 ADSORBATE COVERAGE

A quantity of interest in many studies of surfaces and interfaces is the concentration of adsorbed atomic or molecular species. The SHG/SFG technique has been found to be a useful probe of adsorbate density for a wide range of interfaces. The surface sensitivity afforded by the method is illustrated by the results of [figure B1.5.9](#) [72]. These data show the dramatic change in SH response from a clean surface of silicon upon adsorption of a fraction of a monolayer of atomic hydrogen.

Figure B1.5.9 Dependence of the magnitude (full circles) and the phase (open squares) of the nonlinear susceptibility $\chi_s^{(2)}$ of Si(111) 7×7 on the coverage of adsorbed atomic hydrogen for an excitation wavelength of 1064 nm. (From [72].)

We now consider how one extracts quantitative information about the surface or interface adsorbate coverage from such SHG data. In many circumstances, it is possible to adopt a purely phenomenological approach: one calibrates the nonlinear response as a function of surface coverage in a preliminary set of experiments and then makes use of this calibration in subsequent investigations. Such an approach may, for example, be appropriate for studies of adsorption kinetics where the interest lies in the temporal evolution of the surface adsorbate density N_s .

For other purposes, obtaining a measure of the adsorbate surface density directly from the experiment is desirable. From this perspective, we introduce a simple model for the variation of the surface nonlinear susceptibility with adsorbate coverage. An approximation that has been found suitable for many systems is

$$\chi_s^{(2)}(N_s) = \chi_{s,0}^{(2)} + N_s \alpha^{(2)}. \quad (\text{B1.5.43})$$

From a purely phenomenological perspective, this relationship describes a constant rate of change in the nonlinear susceptibility of the surface with increasing adsorbate surface density N_s . Within a picture of adsorbed molecules, $\alpha^{(2)}$ may be interpreted as the nonlinear polarizability of the adsorbed species. The quantity $\chi_{s,0}^{(2)}$ represents the nonlinear response in the absence of the adsorbed species.

If we consider the optical response of a molecular monolayer of increasing surface density, the form of equation B1.5.43 is justified in the limit of relatively low density where local-field interactions between the adsorbed species may be neglected. It is difficult to produce any rule for the range of validity of this approximation, as it depends strongly on the system under study, as well as on the desired level of accuracy for the measurement. The relevant corrections, which may be viewed as analogous to the Clausius–Mossotti corrections in linear optics, have been the

subject of some discussion in the literature [41, 42]. In addition to the local-field effects, the simple proportionality of variation in $\chi_s^{(2)}(N_s)$ with N_s frequently breaks down for reasons related to the physical and chemical nature of the surface or interface. In particular, inhomogeneous surfaces in which differing binding sites fill in different proportions may give rise to a variation in $\chi_s^{(2)}(N_s)$ that would, to leading order, vary with

relative populations of the different sites. Also, inter-adsorbate interactions that lead to shifts in energy levels or molecular orientation, as will be discussed later, will influence the nonlinear response in a manner beyond that captured in [equation B1.5.43](#).

Despite these caveats in the application of [equation B1.5.43](#), one finds that it provides reasonable accuracy in many experimental situations. The SH response for the H/Si system of [figure B1.5.9](#) for example, is seen to obey the simple linear variation of $\chi_s^{(2)}(N_s)$ with N_s of [equation B1.5.43](#) rather well up to an adsorbate coverage of about 0.5 monolayers. These data are also interesting because they show how destructive interference between the terms $\chi_{s,0}^{(2)}$ and $N_s\alpha^{(2)}$ can cause the SH signal to decrease with increasing N_s . In this particular example, the physical interpretation of this effect is based on the strong nonlinear response of the bare surface from the Si dangling bonds. With increasing hydrogen coverage, the concentration of dangling bonds is reduced and the surface nonlinearity decreases. For a system where $\chi_{s,0}^{(2)}$ is relatively small and the nonlinear response of the adsorbed species is significant, just the opposite trend for the variation of $\chi_s^{(2)}(N_s)$ with N_s would occur.

The applications of this simple measure of surface adsorbate coverage have been quite widespread and diverse. It has been possible, for example, to measure adsorption isotherms in many systems. From these measurements, one may obtain important information such as the adsorption free energy, $\Delta G^\circ = -RT\ln(K_{eq})$ [21]. One can also monitor the kinetics of adsorption and desorption to obtain rates. In conjunction with temperature-dependent data, one may further infer activation energies and pre-exponential factors [73, 74]. Knowledge of such kinetic parameters is useful for technological applications, such as semiconductor growth and synthesis of chemical compounds [75]. Second-order nonlinear optics may also play a role in the investigation of physical kinetics, such as the rates and mechanisms of transport processes across interfaces [76].

Before leaving this topic, we would like to touch on two related points. The first concerns the possibility of an absolute determination of the surface adsorbate density. [Equation B1.5.43](#) would suggest that one might use knowledge, either experimental or theoretical, of $\alpha^{(2)}$ and an experimental determination of $\chi_s^{(2)}(N_s)$ and $\chi_{s,0}^{(2)}$ to infer N_s in absolute terms. In practice, this is problematic. One experimental issue is that a correct measurement of $\chi_s^{(2)}$ in absolute terms may be difficult. However, through appropriate comparison with the response of a calibrated nonlinear reference material, we may usually accomplish this task. More problematic is obtaining knowledge of $\alpha^{(2)}$ for the adsorbed species. The determination of $\alpha^{(2)}$ in the gas or liquid phase is already difficult. In addition, the perturbation induced by the surface or interface is typically significant. Moreover, as discussed later, molecular orientation is a critical factor in determining the surface nonlinear response. For these reasons, absolute surface densities can generally be found from surface SHG/SFH measurements only if we can calibrate the surface nonlinear response at two or more coverages determined by other means. This situation, it should be noted, is not dissimilar to that encountered for many other common surface probes.

The second issue concerns molecular specificity. For a simple measurement of SHG at an arbitrary laser frequency, one cannot expect to extract information of the behaviour of a system with several possible adsorbed species. To make the technique appropriate for such cases, one needs to rely on spectroscopic information. In the simplest implementation, one chooses a frequency for which the nonlinear response of the species of interest is large or dominant. As will

be discussed in [section B1.5.4.4](#), this capability is significantly enhanced with SFG and the selection of a frequency corresponding to a vibrational resonance.

B1.5.4.3 MOLECULAR ORIENTATION

The nonlinear response of an individual molecule depends on the orientation of the molecule with respect to the polarization of the applied and detected electric fields. The same situation prevails for an ensemble of molecules at an interface. It follows that we may garner information about molecular orientation at surfaces and interfaces by appropriate measurements of the polarization dependence of the nonlinear response, taken together with a model for the nonlinear response of the relevant molecule in a standard orientation.

We now consider this issue in a more rigorous fashion. The inference of molecular orientation can be explained most readily from the following relation between the surface nonlinear susceptibility tensor and the molecular nonlinear polarizability $\alpha^{(2)}$:

$$(B1.5.44)$$

Here the ijk coordinate system represents the laboratory reference frame; the primed coordinate system $i'j'k'$ corresponds to coordinates in the molecular system. The quantities $T_{ii'}$ are the matrices describing the coordinate transformation between the molecular and laboratory systems. In this relationship, we have neglected local-field effects and expressed the in a form equivalent to summing the molecular response over all the molecules in a unit surface area (with surface density N_s). (For simplicity, we have omitted any contribution to not attributable to the dipolar response of the molecules. In many cases, however, it is important to measure and account for the background nonlinear response not arising from the dipolar contributions from the molecules of interest.) In equation B1.5.44, we allow for a distribution of molecular orientations and have denoted by $\langle \rangle$ the corresponding ensemble average:

$$(B1.5.45)$$

Here $f(\theta, \varphi, \psi)$ is the probability distribution of finding a molecule oriented at (θ, φ, ψ) within an element $d\Omega$ of solid angle with the molecular orientation defined in terms of the usual Euler angles ([figure B1.5.10](#)).

-31-

Figure B1.5.10 Euler angles and reference frames for the discussion of molecular orientation: laboratory frame (x, y, z) and molecular frame (x', y', z') .

Equation B1.5.44 indicates that if we know $\chi_{s,ijk}^{(2)}$ and $\alpha_{i'j'k'}^{(2)}$, we may infer information about the third-order orientational moments $\langle T_{ii'} T_{jj'} T_{kk'} \rangle$. Since calibration of absolute magnitudes is difficult, we are generally concerned with a comparison of the relative magnitudes of the appropriate molecular ($\alpha^{(2)}$) and macroscopic ($\chi^{(2)}$)

$\chi_s^{(2)}$) quantities. In practice, the complexity of the general relationship between $\alpha^{(2)}$ and $\chi_s^{(2)}$ means that progress requires the introduction of certain simplifying assumptions. These usually follow from symmetry considerations or, for the case of $\alpha^{(2)}$, from previous experimental or theoretical insight into the nature of the expected molecular response.

The approach may be illustrated for molecules with a nonlinear polarizability $\alpha^{(2)}$ dominated by a single axial component $\alpha_{z'z'z'}^{(2)}$, corresponding to a dominant nonlinear response from transitions along a particular molecular axis. Let us further assume that all in-plane direction of the surface or interface are equivalent. This would naturally be the case for a liquid or amorphous solid, but would not necessarily apply to the surface of a crystal. One then obtains from [equation B1.5.44](#), the following relations between the molecular quantities and surface nonlinear susceptibility:

$$\chi_{s,\perp\perp\perp}^{(2)} = \chi_{s,zzz}^{(2)} = N_s \langle \cos^3 \theta \rangle \alpha_{z'z'z'}^{(2)} \quad (\text{B1.5.46})$$

$$\chi_{s,\perp\parallel\parallel}^{(2)} = \chi_{s,zzx}^{(2)} = \frac{1}{2} N_s \langle \cos^3 \theta \sin^2 \theta \rangle \alpha_{z'z'z'}^{(2)} \quad (\text{B1.5.47})$$

$$\chi_{s,\parallel\perp\parallel}^{(2)} = \chi_{s,\parallel\parallel\perp}^{(2)} = \chi_{s,xzx}^{(2)} = \frac{1}{2} N_s \langle \cos^3 \theta \sin^2 \theta \rangle \alpha_{z'z'z'}^{(2)}. \quad (\text{B1.5.48})$$

-32-

Notice that $\chi_{s,\perp\parallel\parallel}^{(2)} = \chi_{s,\parallel\perp\parallel}^{(2)} = \chi_{s,\parallel\parallel\perp}^{(2)}$, so that only two of the three nonlinear susceptibility tensor elements allowed for an isotropic surface are independent. From [equation B1.5.46](#), [equation B1.5.47](#) and [equation B1.5.48](#), we may form the ratio

$$\frac{2\chi_{s,\parallel\perp\parallel}^{(2)} + \chi_{s,\perp\perp\perp}^{(2)}}{\chi_{s,\perp\perp\perp}^{(2)}} = \frac{\langle \cos \theta \rangle}{\langle \cos^3 \theta \rangle}. \quad (\text{B1.5.49})$$

Thus, a well-defined measure of molecular orientation is inferred from the measurement of the macroscopic quantities $\chi_{s,ijk}^{(2)}$. For the case of a narrow and isotropic distribution, i.e. $f(\theta) = \delta(\theta - \theta_0)$, the left-hand side term of [equation B1.5.49](#) becomes $\langle \cos \theta \rangle / \langle \cos^3 \theta \rangle = \sec^2 \theta_0$, for which the mean orientation θ_0 is directly obtained. For a broad distribution, one may extract the mean orientation from such an expression for an assumed functional form.

As an example, the model described earlier for a molecule having a dominant nonlinear polarizability element $\alpha_{z'z'z'}^{(2)}$ has been applied to the determination of the molecular inclination θ between the molecular axis of a surfactant molecule, sodium-dodecylsulfonate (SDNS) and the surface normal at the air/water interface [77]. This tilt angle θ , shown in [figure B1.5.11](#) was determined according to [equation B1.5.46](#), [equation B1.5.47](#) and [equation B1.5.48](#) under the assumption of a narrow orientational distribution. As the [figure](#) shows, the mean molecular orientation changes with increasing surface pressure π as the molecules are forced into a more nearly vertical orientation.

Figure B1.5.11 Tilt angle θ between the molecular axis of sodium-dodecylnaphthalene-sulphonate (SDNS) and the surface normal as a function of the surface pressure π at the air/water interface. (From [77].)

-33-

In the literature, the interested reader may find treatment of molecules with differing, and more complex, behaviour for $\alpha^{(2)}$ [14]. Also of importance is the role of SFG for orientational analysis. Surface SFG may provide more orientational information, since there are additional independent elements of the surface nonlinear susceptibility. For example, an isotropic surface is characterized by three independent elements for SHG, but is described by four independent elements for SFG. The principal advantage of SFG over SHG, however, lies in its molecular specificity. As will be discussed in section B1.5.4.4, we may enhance the response of a molecular species of interest by choosing the appropriate infrared frequency for the SFG process. This behaviour helps to eliminate background signal and is useful in more complex systems with two or more molecular species present. Equally important, the excitation of a given vibration helps to define the form, and reduce the generality, of the molecular response $\alpha^{(2)}$. Further, the method may be applied for different vibrational resonances to deduce the orientation of different moieties of larger molecules [78].

B1.5.4.4 SPECTROSCOPY

The second-order nonlinear susceptibility describing a surface or interface, as indicated by the microscopic form of [equation B1.5.30](#), is resonantly enhanced whenever an input or output photon energy matches a transition energy in the material system. Thus, by scanning the frequency or frequencies involved in the surface nonlinear process, we may perform surface-specific spectroscopy. This method has been successfully applied to probe both electronic transitions and vibrational transitions at interfaces.

For studying electronic transitions at surfaces and interfaces, both SHG and SFG have been employed in a variety of systems. One particular example is that of the buried $\text{CaF}_2/\text{Si}(111)$ interface [79]. [Figure B1.5.12\(a\)](#) displays the experimental SH signal as a function of the photon energy of a tunable pump laser. An interface resonance for this system is found to occur for a photon energy near 2.4 eV. This value is markedly different from that of the energies of transitions in either of the bulk materials and clearly illustrates the capability of nonlinear spectroscopy to probe distinct electronic excitations of the interfacial region. The sharp feature appearing at 2.26 eV has been attributed to the formation of a two-dimensional exciton. It is important to point out that the measurement of the SHG signal alone does not directly show whether an observed resonance corresponds to a single- or a two-photon transition. To verify that the resonance enhancement does, in fact, correspond to a transition energy of 2.4 eV, a separate SF measurement ([Figure B1.5.12\(b\)](#)) was

performed. In this measurement, the tunable laser photon was mixed with another photon at a fixed photon energy (1.17 eV). By comparing the two sets of data, one finds that the resonance must indeed lie at the fundamental frequency of the tunable laser for this system.

-34-

Figure B1.5.12 SH and SF spectra (full dots) for the $\text{CaF}_2/\text{Si}(111)$ interface: (a) SH intensity as a function of the photon energy of the tunable laser; (b) SF intensity obtained by mixing the tunable laser with radiation at a fixed photon energy of 1.17 eV. For comparison, the open circles in (a) are signals obtained for a native-oxide covered Si(111). The full line is a fit to the theory as discussed in [79].

The SHG/SFG technique is not restricted to interface spectroscopy of the delocalized electronic states of solids. It is also a powerful tool for spectroscopy of electronic transitions in molecules. [Figure B1.5.13](#) presents such an example for a monolayer of the R-enantiomer of the molecule 2,2'-dihydroxyl-1,1'-binaphthyl, (R)-BN, at the air/water interface [80]. The spectra reveal two-photon resonance features near wavelengths of 332 and 340 nm that are assigned to the two lowest exciton-split transitions in the naphth-2-ol monomer of BN. An increase in signal at higher photon energies is also seen as a resonance as the 1B_p state of the molecules is approached. The spectra in [figure B1.5.13](#) have been obtained for differing polarization configurations. The arrangements of p-in/p-out and s-in/p-out will yield SH signals for any isotropic surface. In this case, however, signal is also observed for the p-in/s-out configuration. This response arises from the $\chi_{s,xy}^{(2)}$ element of the surface nonlinear response that is present because of the chiral character of the molecules under study, as previously discussed in [section B1.5.4.1](#).

-35-

Figure B1.5.13 Spectra of the various non-chiral [p-in/p-out (filled circles) and s-in/p-out (filled diamonds)] and chiral [p-in/s-out (triangle)] SHG signals of (R)-BN molecules adsorbed at the air/water interface. (From [80].)

In addition to probing electronic transitions, second-order nonlinear optics can be used to probe vibrational resonances. This capability is of obvious importance and value for identifying chemical species at interfaces and probing their local environment. In contrast to conventional spectroscopy of vibrational transitions, which can also be applied to surface problems [4], nonlinear optics provides intrinsic surface specificity and is of particular utility in problems where the same or similar vibrational transitions occur at the interface as in the bulk media. In order to access the infrared region corresponding to vibrational transitions while maintaining an easily detectable signal, Shen and coworkers developed the technique of the infrared-visible sum-frequency generation [81]. In this scheme, a tunable IR source is mixed on the surface with visible light at a fixed frequency to produce readily detectable visible radiation. As the IR frequency is tuned through the frequency of a vibrational transition, the SF signal is resonantly enhanced and the surface vibration spectrum is recorded. In order to examine the IR-visible SFG process more closely, let us consider an appropriate formula for the surface nonlinear susceptibility when the IR frequency $\omega_1 = \omega_{\text{IR}}$ is near a single vibrational resonance and the visible frequency $\omega_2 = \omega_{\text{vis}}$ is not resonant with an electronic transition. We may then write [81, 82]

$$\chi_{s,ijk}^{(2)}(\omega_{\text{IR}}) = \chi_{s,ijk}^{(2)\text{NR}} + \chi_{s,ijk}^{(2)\text{R}}(\omega_{\text{IR}}) = \chi_{s,ijk}^{(2)\text{NR}} + \sum_l \frac{A_{l,ijk}}{\omega_{\text{IR}} - \omega_l + i\Gamma_l} \quad (\text{B1.5.50})$$

where $\chi_{s,ijk}^{(2)\text{NR}}$ and $\chi_{s,ijk}^{(2)\text{R}}$ are the non-resonant and resonant contributions to the signal, respectively; $A_{l,ijk}$, ω_l and Γ_l are the strength, resonant frequency, linewidth of the l th vibrational mode. The quantity A_l is proportional to the product of the first derivatives of the molecular dipole moment μ_i and of the electronic polarizability α_{jk} with respect to the l th normal coordinate Q_l :

$$A_{l,ijk} \propto \frac{\partial \mu_i}{\partial Q_l} \frac{\partial \alpha_{jk}}{\partial Q_l}. \quad (\text{B1.5.51})$$

Consequently, in order for a vibrational mode to be observed in infrared-visible SFG, the molecule in its adsorbed state has to be both IR [$(d\mu_i/dQ_l) \neq 0$] and Raman [$(d\alpha_{jk}/dQ_l) \neq 0$] active.

The form of [equation B1.5.50](#) also allows us to make some remarks about the measured lineshapes in surface nonlinear spectroscopy. From this point of view, we may regard [equation B1.5.50](#) as being representative of the surface nonlinear response typically encountered near any resonance: It has a strongly varying resonant contribution together with a spectrally flat non-resonant background. The interesting aspect of this situation arises from the fact that we generally detect the *intensity* of the SH or SF signal, which is proportional to $|\chi_{s,ijk}^{(2)}|^2$. Consequently, interference between the resonant and non-resonant contributions is expected.

Depending on the relative phase difference between these terms, one may observe various experimental spectra, as illustrated in figure B1.5.14. This type of behaviour, while potentially a source of confusion, is familiar for other types of nonlinear spectroscopy, such as CARS (coherent anti-Stokes Raman scattering) [[30](#), [31](#)] and can be readily incorporated into modelling of measured spectral features.

Figure B1.5.14 Possible lineshapes for an SFG resonance as a function of the infrared frequency ω_{IR} . The measured SFG signal is proportional to $|\chi^{\text{NR}} + A/(\omega_{\text{IR}} - \omega_0 + i\Gamma)|^2$. Assuming both χ^{NR} and Γ are real and positive, we obtain the lineshapes for various cases: (a) $\chi^{\text{NR}} \ll A/\Gamma$ (b) A is purely imaginary and negative with $|\chi^{\text{NR}}\Gamma/A| > \frac{1}{2}$ (c) A is real and positive; and (d) A is real and negative. Note the apparent blue and red shifts of the peaks in cases (c) and (d), respectively.

We now present one of the many examples of interfacial vibrational spectroscopy using SFG. [Figure B1.5.15](#) shows the surface vibrational spectrum of the water/air interface at a temperature of 40 °C [[83](#)]. Notice that the spectrum exhibits peaks at 3680, 3400 and 3200 cm^{-1} . These features arise from the OH stretching mode of water molecules in different environments. The highest frequency peak is assigned to free OH groups, the next peak to water molecules with hydrogen-bonding to neighbours in a relatively disordered structure and the lowest frequency peak to water molecules in a well-ordered tetrahedrally bonded (ice-like) structure. In addition to the analogy of these assignments to water molecules in different bulk environments, the assignments are compatible with the measured temperature dependence of the spectra. The strong and narrow peak at 3680 cm^{-1} provides interesting new information about the water surface. It indicates that a substantial fraction of the surface water molecules have unbonded OH groups protruding from the surface of the water into the vapour phase. This study exemplifies the unique capabilities of

surface SFG, as there is no other technique that could probe the liquid/vapour interface in the presence of strong features of the vibrational modes of the bulk water molecules.

Figure B1.5.15 SFG spectrum for the water/air interface at 40 °C using the ssp polarization combination (s-, s- and p-polarized sum-frequency signal, visible input and infrared input beams, respectively). The peaks correspond to OH stretching modes. (After [83].)

An important consideration in spectroscopic measurements concerns the bandwidth of the laser sources. In order to resolve the vibrational resonances in a conventional approach, one needs, in the conventional scheme, a tunable source that has a narrow bandwidth compared to the resonance being studied. For typical resolutions, this requirement implies, by uncertainty principle, that IR pulses of picosecond or longer duration must be used. On the other hand, ultrafast pulsed IR sources with broad bandwidths are quite attractive from the experimental standpoint. In order to make use of these sources, two types of new experimental techniques have been introduced. One technique involves mixing the broadband IR source ($\sim 300 \text{ cm}^{-1}$) with a narrowband visible input ($\sim 5 \text{ cm}^{-1}$). By spectrally resolving the SF output, we may then obtain resolution of the IR spectrum limited only by the linewidth of the visible source [84, 85]. This result follows from the fact that $\omega_{\text{IR}} = \omega_{\text{SF}} - \omega_{\text{vis}}$ must be satisfied for the SFG process. The second new approach involves the application of a Fourier transform scheme [86]. This is accomplished by passing the IR pulses through an interferometer and then mixing these pairs of pulses with visible radiation at the surface.

B1.5.4.5 DYNAMICS

Many of the fundamental physical and chemical processes at surfaces and interfaces occur on extremely fast time scales. For example, atomic and molecular motions take place on time scales as short as 100 fs, while surface electronic states may have lifetimes as short as 10 fs. With the dramatic recent advances in laser technology, however, such time scales have become increasingly accessible. Surface nonlinear optics provides an attractive approach to capture such events directly in the time domain. Some examples of application of the method include probing the dynamics of melting on the time scale of phonon vibrations [87], photoisomerization of molecules [88], molecular dynamics of adsorbates [89, 90], interfacial solvent dynamics [91], transient band-flattening in semiconductors [92] and laser-induced desorption [93]. A review article discussing such time-resolved studies in metals can be found in

[94]. The SHG and SFG techniques are also suitable for studying dynamical processes occurring on slower time scales. Indeed, many valuable studies of adsorption, desorption, diffusion and other surface processes have been performed on time scales of milliseconds to seconds.

In a typical time-resolved SHG (SFG) experiment using femtosecond to picosecond laser systems, two (three) input laser beams are necessary. The pulse from one of the lasers, usually called the pump laser, induces the

reaction or surface modification. This defines the starting point ($t = 0$). A second pulse (or a second set of synchronized pulses, for the case of SFG) delayed relative to the first pulse by a specified time Δt is used to probe the reaction as it evolves. By varying this time delay Δt , the temporal evolution of the reaction can be followed. In order to preserve the inherent time resolution of an ultrafast laser, the relevant pulses are generally derived from a common source. For instance, in a basic time-resolved SHG experiment, where both the pump and probe pulses are of the same frequency, one simply divides the laser beam into two sets of pulses with a beam splitter. One of these pulses travels a fixed distance to the sample, while the other passes through a variable delay line to the sample. This approach provides a means of timing with sub-femtosecond accuracy, if desired. In some cases, at least one of the input beams has a different frequency from the others. Such pulses can be produced through processes such as harmonic generation or optical parametric generation from the main laser pulse.

As an example of this class of experiment, we consider an experimental study of the dynamics of molecular orientational relaxation at the air/water interface [90]. Such investigations are of interest as a gauge of the local environment at the surface of water. The measurements were performed with time-resolved SHG using Coumarin 314 dye molecules as the probe. In order to examine orientational motion, an anisotropic orientational distribution of molecules must first be produced. This is accomplished through a photoselection process in which the interface is irradiated by a linearly polarized laser pulse that is resonant with an electronic transition in the dye molecules. Those molecules that are oriented with their transition dipole moments parallel to the polarization of the pump beam are preferentially excited, producing an orientational anisotropy in the ground- and excited-state population. Subsequently, these anisotropic orientational distributions relax to the equilibrium configuration. The time evolution of the rotational anisotropy was followed by detecting the SH of a probe laser pulse as a function of the delay time, as shown in [figure B1.5.16](#). Through a comparison of the results for different initial anisotropic distributions (produced by two orthogonal linearly-polarized pump beams, as shown in the figure, as well as by circularly-polarized pump radiation), one may deduce rates for both in-plane and out-of-plane orientational relaxation. The study yielded the interesting result that the orientational relaxation times at the liquid/vapour interface significantly exceeded those for the Coumarin molecules in the bulk of water. This finding was interpreted as reflecting the increased friction encountered in the surface region where the water molecules are more highly ordered than in the bulk liquid.

-39-

Figure B1.5.16 Rotational relaxation of Coumarin 314 molecules at the air/water interface. The change in the SH signal is recorded as a function of the time delay between the pump and probe pulses. Anisotropy in the orientational distribution is created by linearly polarized pump radiation in two orthogonal directions in the surface. (After [90].)

B1.5.4.6 SPATIAL RESOLUTION

Another application of surface SHG or SFG involves the exploitation of the lateral resolution afforded by these optical processes. While the dimension of the optical wavelength obviously precludes direct access to the length scale of atoms and molecules, one can examine the micrometre and submicrometre length scale that is important in many surface and interface processes. Spatial resolution may be achieved simply by detecting the nonlinear response with a focused laser beam that is scanned across the surface [95]. Alternatively, one may illuminate a large area of the surface and image the emitted nonlinear radiation [96]. Applications of this imaging capability have included probing of magnetic domains [97] and spatially varying electric fields [98]. The application of near-field techniques may permit, as in linear optics, the attainment of spatial resolution below the diffraction limit. In a recent work [99], submicrometre spatial resolution was indeed reported by collecting the emitted SH radiation for excitation with a near-field fibre probe.

Diffraction measurements offer a complementary approach to the real-space imaging described earlier. In such schemes, periodically modulated surfaces are utilized to produce well-defined SH (or SF) radiation at discrete angles, as dictated by the conservation of the in-plane component of the wavevector. As an example of this approach, a grating in the surface adsorbate density may be produced through laser-induced desorption in the field of two interfering beams. This monolayer grating will readily produce diffracted SH beams in addition to the usual reflected beam. In addition to their intrinsic interest, such structures have permitted precise measurements of surface diffusion. One may accomplish this by observing the temporal evolution of SH diffraction efficiency, which falls as surface diffusion causes the modulation depth of the adsorbate grating to decrease. This technique has been applied to examine diffusion of adsorbates on the surface of metals [100] and semiconductors [101].

B1.5.4.7 ELECTRIC AND MAGNETIC FIELD PERTURBATION

Probing electric and magnetic fields, and the effects induced by them, is of obvious interest in many areas of science and technology. We considered earlier the influence of such perturbations in a general fashion in [section B1.5.2.2](#). Here we describe some related experimental measurements and applications. Electric fields act to break inversion and thus

-40-

may yield bulk SHG and SFG signals from centrosymmetric media surrounding the interface, in addition to any field-dependent contribution of the interface itself. The high sensitivity of SHG toward applied electric fields was first demonstrated in calcite by Terhune *et al* as early as 1962 [102]. Subsequent investigations of EFISH from centrosymmetric media have involved semiconductor/electrolyte and metal/electrolyte interfaces [103, 104 and 105], as well as metal-oxide–semiconductor interfaces [106, 107].

The generality of the EFISH process has led to a variety of applications. These include probing the surface potential at interfaces involving liquids. Such measurements rely on the fact that the EFISH field is proportional to the voltage drop across the polarized layer provided, as is generally the case, that this region is thin compared to the scale of an optical wavelength [108]. This effect also serves as a basis for probing surface reactions involving changes of charge state, such as acid/base equilibria [109]. Another related set of applications involves probing electric fields in semiconductors, notably in centrosymmetric material silicon [98, 110, 111]. These studies have demonstrated the capability for spatial resolution, vector analysis of the electric field and, significantly, ultrafast (subpicosecond) time resolution. These capabilities of SHG complement other optical schemes, such as electro-optical and photoconductive sampling, for probing the dynamics of electric fields on very fast time scales.

The influence of an applied magnetic field, as introduced in [section B1.5.2.2](#), is quite different from that of an applied electric field. A magnetic field may perturb the interfacial nonlinear response (and that of the weak bulk terms), but it does not lead to any dipole-allowed bulk nonlinear response. Thus, in the presence of magnetic fields and magnetization, SHG remains a probe that is highly specific to surfaces and interfaces. It

may be viewed as the interface-sensitive analogue of linear magneto-optical effects. The first demonstration of the influence of magnetization on SHG was performed on an Fe(110) surface [112]. Subsequent applications have included examination of other materials for which both the bulk and surface exhibit magnetization. For these systems, surface specificity is of key importance. In addition, the technique has been applied to examine buried magnetic interfaces [113]. Excellent review articles on this subject matter are presented in [23] and [114].

B1.5.4.8 RECENT DEVELOPMENTS

Up to this point, our discussion of surface SHG and SFG has implicitly assumed that we are examining a smooth planar surface. This type of interface leads to well-defined and highly collimated transmitted and reflected beams. On the other hand, many material systems of interest in probing surfaces or interfaces are not planar in character. From the point of view of symmetry, the surface sensitivity for interfaces of centrosymmetric media should apply equally well for such non-planar interfaces, although the nature of the electromagnetic wave propagation may be modified to a significant degree. One case of particular interest concerns appropriately roughened surfaces of noble metals. These were shown as early as 1974 [115] to give rise to strong enhancements in Raman scattering of adsorbed species and led to extensive investigation of the phenomenon of surface-enhanced Raman scattering or SERS [5]. Significant enhancements in the SHG signals from such surfaces have also been found [116]. The resulting SH radiation is diffuse, but has been shown to preserve a high degree of surface sensitivity. Carrying this progression from planar surfaces one step further, researchers have recently demonstrated the possibility of probing the surfaces of small particles by SHG.

Experimental investigations of the model system of dye molecules adsorbed onto surfaces of polystyrene spheres have firmly established the sensitivity and surface specificity of the SHG method even for particles of micrometre size [117]. The surface sensitivity of the SHG process has been exploited for probing molecular transport across the bilayer in liposomes [118], for measurement of electrostatic potentials at the surface of small particles [119] and for imaging

-41-

membranes in living cells [120]. The corresponding theoretical description of SHG from the surfaces of small spheres has been examined recently using the type of formalism presented earlier in this chapter [121]. Within this framework, the leading-order contributions to the SH radiation arise from the non-local excitation of the dipole and the local excitation of the quadrupole moments. This situation stands in contrast to linear optical (Rayleigh) scattering, which arises from the local excitation of the dipole moment.

B1.5.5 CONCLUSION

In this brief chapter, we have attempted to describe some of the underlying principles of second-order nonlinear optics for the study of surfaces and interfaces. The fact that the technique relies on a basic symmetry consideration to obtain surface specificity gives the method a high degree of generality. As a consequence, our review of some of the applications of the method has necessarily been quite incomplete. Still, we hope that the reader will gain some appreciation for the flexibility and power of the method. Over the last few years, many noteworthy applications of the method have been demonstrated. Further advances may be anticipated from on-going development of the microscopic theory, as well as from adaptation of the macroscopic theory to new experimental conditions and geometries. At the same time, we see continual progress in the range and ease of use of the technique afforded by the impressive improvement of the performance and reliability of high-power laser sources.

B1.6 Electron-impact spectroscopy

John H Moore

B1.6.0 INTRODUCTION

When one speaks of a ‘spectrum’, the dispersed array of colours from a luminous body comes to mind; however, in the most general sense, a spectrum is a record of the energy and probability of transitions between states of a substance. In electron spectroscopy the ‘spectrum’ takes the form of the energy distribution of electrons emanating from a sample. Electron spectroscopies are classified according to the phenomena giving rise to these electrons; historically, each technique has acquired an acronym until today one finds a veritable alphabet soup of electron spectroscopies in the scientific literature. For example, PES refers to photoelectron spectroscopy, a technique in which the detected electrons are emitted after the absorption of a photon induces transitions into the continuum beyond the first ionization potential of the sample. Electron-impact spectroscopies, the subject of this entry, entail the excitation of a transition by an electron impinging upon a sample with the subsequent measurement of the energy of the scattered electron. The spectrum is the scattered-electron intensity as a function of the difference between the incident- and scattered-electron energies—the *energy loss*.

The technologies of the various electron spectroscopies are similar in many ways. The techniques for measuring electron energies and the devices used to detect electrons are the same. All electron spectrometers must be housed in an evacuated container at pressures less than about 10^{-6} mbar since electrons cannot be transported through the atmosphere. Stray fields that perturb electron trajectories are a potential problem. To function correctly, an electron spectrometer must be shielded from the earth’s magnetic field.

Electron-impact energy-loss spectroscopy (EELS) differs from other electron spectroscopies in that it is possible to observe transitions to states below the first ionization edge; electronic transitions to excited states of the neutral, vibrational and even rotational transitions can be observed. This is a consequence of the detected electrons not originating in the sample. Conversely, there is a problem when electron impact induces an ionizing transition. For each such event there are two outgoing electrons. To precisely account for the energy deposited in the target, the two electrons must be measured in coincidence.

In comparison to optical spectroscopy, electron-impact spectroscopy offers a number of advantages. Some of these are purely technological while others are a result of physical differences in the excitation mechanism. The energy of an electron can be varied simply and smoothly by scanning the voltage applied to, and hence the potential difference between, electrodes in the spectrometer. The same technology is applicable to electrons with energies, and energy losses, in the millielectronvolt (meV) range as in the kiloelectronvolt (keV) range. At least in principle, measurements analogous to IR spectroscopy can be carried out in the same instrument as measurements akin to x-ray spectroscopy. Unlike an optical instrument, the source intensity and the transmission of an electron spectrometer are nearly independent of energy, making the electron instrument more suitable for absolute intensity measurements; however, an electron spectrometer cannot always provide resolution comparable to that of an optical instrument. Studies of rotational and vibrational excitation, particularly in surface adsorbates, are routinely carried out by electron spectroscopy with a resolution of 2 to 5 meV (16 to 40 cm^{-1}). A resolution of 5 to 30 meV is typically obtained for

-2-

electron-impact excitation of valence-electron transitions in atoms and molecules in the gas phase. Analogous studies by vis-UV spectroscopy easily provide 1 cm^{-1} resolution. For inner-shell-electron excitation, electron spectroscopy provides resolution comparable or superior to x-ray spectroscopy with discrete-line-source x-ray tubes. X-ray synchrotron sources now becoming available will provide better resolution and intensity than can be achieved with an electron spectrometer, but it must be borne in mind that an electron spectrometer is a relatively inexpensive, table-top device, whereas a synchrotron is a remote, multimillion-dollar facility. In many applications, electron-scattering experiments are more sensitive than optical experiments. This is in part due to the superior sensitivity of electron detectors. An electron multiplier has essentially unit efficiency (100%); a photomultiplier or photodiode may have an efficiency of only a few per cent. For surface analysis, electron spectroscopies have a special advantage over optical techniques owing to the short range of electrons in solids.

The mechanism by which a transition is induced by electron impact depends on the nature of the coupling between the projectile electron and the target; this in turn is influenced by the velocity and closeness of approach of the projectile to the target. There is a wide range of possibilities. A high-energy projectile electron may pass quickly by, delivering only a photon-like electric-field pulse to the target at the instant of closest approach. Less probable are hard, billiard-ball-like collisions between the projectile and one target electron. At low energies, slower, more intimate collisions are characterized by many-electron interactions. Depending upon the mechanism, the momentum transferred from projectile to target can vary from the minimum necessary to account for the transition energy to many times more. The interaction influences the type of transition that can be induced and the way in which the projectile is scattered. It is even possible for the projectile electron to be exchanged for a target electron, thus allowing for electron-spin-changing transitions. This state of affairs is a contrast to optical excitation where the momentum transfer is a constant and only 'dipole-allowed' transitions occur with significant probability.

B1.6.1.1 CROSS SECTION AND SIGNAL INTENSITY

The quantities to be measured in electron-impact spectroscopy are the probability of an electron impact's inducing a transition and the corresponding transition energy. The energy for the transition is taken from the kinetic energy of the projectile electron. Unlike the situation in optical spectroscopy, the exciting particle is not annihilated, but is scattered from the target at some angle to its initial direction. The scattering angle is a measure of the momentum transferred to the target, and, as such, is also an important variable.

The probability of a collision between an electron and a target depends upon the *impact parameter*, b , which is the perpendicular distance between the line of travel of the electron and the centre of force exerted by the target on the electron. The impact parameter is equivalent to the distance of closest approach if no potential is present between the electron and the target. For a hard-sphere collision between an infinitesimally small projectile and a target of radius r , the impact parameter must be less than r for a collision to occur, and, from simple geometry, the scattering angle $\theta = 2 \arccos(b/r)$. The scattering angle is large for small impact parameters, while for 'grazing' collisions, where b approaches r , the scattering angle is small. The probability of a collision is proportional to the cross sectional area of the target, πr^2 . Real collisions between an electron and an atom involve at least central-force-field potentials and, frequently, higher-multipole potentials, but the billiard-ball scattering model is so pervasive that collision probabilities are almost always expressed as cross sections, often denoted by the symbol σ with units of the order of the cross

-3-

section of an atom, such as 10^{-16} cm^2 or square Ångströms (Å^2). The atomic unit of cross section is the Bohr radius squared ($r_0^2 = 0.28 \times 10^{-16} \text{ cm}^2$).

In a very simple form of electron spectroscopy, known as *electron transmission spectroscopy*, the attenuation of an essentially monoenergetic beam of electrons is measured after passage through a sample. If the target is very thin or of such low density that most electrons pass through unscattered, the attenuation is small and the transmitted current, I (in units of electrons per unit time, s^{-1}), compared to the incident current, I_0 (s^{-1}), is given by

$$\frac{I}{I_0} = e^{-\sigma n \ell}$$

where n is the number density of particles in the target (typically in units of cm^{-3}), ℓ (cm) is the thickness of the target and σ is the *total electron scattering cross section*. The cross section depends upon the energy, E_0 , of the incident electrons: $\sigma = \sigma(E_0)$. The total electron scattering spectrum presented as I/I_0 as a function of E_0 bears an inverse relation to the cross section, the transmitted current decreasing as the cross section increases.

An electron-energy-loss spectrometer consists of an 'electron gun' that directs a collimated beam of electrons upon a sample, and an 'analyser' that collects electrons scattered in a particular direction (specified by θ and ϕ in spherical coordinates) and transmits to a detector those electrons with energy E . The electron-energy-loss spectrum is a plot of the scattered-electron current, I_s , arriving at the detector as a function of the energy loss, $(E_0 - E)$. The cross section for the inelastic scattering process giving rise to the observed signal depends upon the scattering angle: it is a *differential cross section*, $d\sigma/d\Omega$, where $d\Omega = \sin\theta \, d\theta \, d\phi$ in spherical coordinates. The magnitude of the cross section depends upon the incident electron energy: there will be a threshold below which the cross section is zero when the incident electron has insufficient energy to excite the transition, and there will be an incident electron energy for which the coupling between projectile and target is greatest and the cross section passes through a maximum. The instrument parameters, as well as the cross section, determine the actual signal level:

$$I_s = I_0 n \ell \left(\frac{d\sigma}{d\Omega} \right) \Delta\Omega$$

where $\Delta\Omega$ is the solid-angle field of view of the scattered-electron analyser.

The foregoing description of an electron energy-loss spectrometer assumes a monoenergetic incident electron beam and the excitation of a transition of negligible energy width. It is often the case that the transition intensity spans a range in energy, and, in addition, the incident beam has some energy spread and the analyser a finite bandpass. One must consider a cross section differential in both angle and energy, $d^2\sigma/d\Omega dE$. The signal intensity is then

$$I_s = I_0 n \ell \left(\frac{d^2\sigma}{d\Omega dE} \right) \Delta\Omega \Delta E$$

where ΔE represents a convolution of the energy spread of the source and the passband of the analyser.

-4-

B1.6.1.2 ELECTRON OPTICS

The two essential elements of an electron spectrometer are the electrodes that accelerate electrons and focus them into a beam and the dispersive elements that sort electrons according to their energies. These serve the functions of lenses and prisms in an optical spectrometer. The same parameters are used to describe these elements in an electron spectrometer as in an optical spectrometer; the technology is referred to as *electron optics*.

(A) ELECTRON LENSES

The typical electron-optical lens consists of a closely spaced pair of coaxial cylindrical tubes biased at different electrical potentials. The equipotential surfaces in the gap between the tubes assume shapes similar to those of optical lenses as illustrated in figure B1.6.1. An electron passing across these surfaces will be accelerated or decelerated, and its path will be curved to produce focusing. The main difference between the electron lens and an optical lens is that the quantity analogous to the refractive index, namely the electron velocity, varies continuously across an electrostatic lens, whereas a discontinuous change of refractive index occurs at the surface of an optical lens. Electron lenses are 'thick' lenses, meaning that their axial dimensions are comparable to their focal lengths. An important consequence is that the principal planes employed in ray tracing are separated from the midplane of the lens and lie to the low-velocity side of the lens gap, as shown in the figure. The design of these lenses is facilitated by tables of electron lens optical properties [1], and by computer programs that calculate the potential array for an arbitrary arrangement of electrodes, and trace electron trajectories through the resultant field [2]. In addition to cylindrical electrodes, electron lenses are sometimes created by closely spaced planar electrodes with circular apertures or slits. Shaped magnetic fields are also used to focus electrons, especially for electron energies much in excess of 10 keV where electrostatic focusing requires inconveniently high voltages.

Figure B1.6.1 Equipotential surfaces have the shape of lenses in the field between two cylinders biased at different voltages. The focusing properties of the electron optical lens are specified by focal points located at focal lengths f_1 and f_2 , measured relative to the principal planes, H_1 and H_2 . The two principal rays emanating from an object on the left and focused to an image on the right are shown.

(B) ELECTRON ANALYSERS

An electron ‘prism’, known as an *analyser* or *monochromator*, is created by the field between the plates of a capacitor. The plates may be planar, simple curved, spherical, or toroidal as shown in [figure B1.6.2](#). The trajectory of an electron entering the gap between the plates is curved as the electron is attracted to the positively biased (inner) plate and

repelled by the negatively biased (outer) plate. The curvature of the trajectory is a function of the electron’s kinetic energy so that the electrons in a beam projected between the plates are dispersed in energy. These devices are not only dispersive, but focusing; electrons of the same energy originating from a point source are brought to a point on a focal plane at the output side of the analyser. The energy passband, or *resolution*, of an electrostatic analyser is the range of energies, ΔE , of electrons which, entering through a slit, are transmitted through the analyser to an exit slit. This quantity depends upon the width of the slits as well as the physical dimensions of the analyser. Fixing the slit widths and analyser dimension fixes the relative resolution, $\Delta E/E$, where E is the nominal energy of transmitted electrons. The *resolving power* of an analyser is specified as $E/\Delta E$, the inverse of the relative resolution. For each type of analyser there is a simple relation between analyser dimensions and resolution; for example, the analyser with hemispherical plates has relative resolution $\Delta E/E = w/2R$, where w is the diameter of the entrance and exit apertures and R is the mean radius of the plates.

Figure B1.6.2 Electron analysers consisting of a pair of capacitor plates of various configurations: (a) the parallel-plate analyser, (b) the 127° cylindrical analyser and (c) the 180° spherical analyser. Trajectories for electrons of different energies are shown.

For an analyser of fixed dimensions, the absolute resolution, ΔE , can be improved, that is, made smaller, by reducing the pass energy, E . This is accomplished by decelerating the electrons to be analysed with a decelerating lens system at the input to the analyser. By this means, an absolute resolution as small as 2 meV has been achieved. For most practical analysers, $\Delta E/E$ is of the order of 0.01, and the pass energy in the highest-resolution spectrometers is of the order of 1 eV. The transmission of electrons of energy less than about 1 eV is generally not practical since unavoidable stray electric and magnetic fields produce unpredictable deflection of electrons of lower energies; even spectrometers of

modest resolution require magnetic shielding to reduce the magnetic field of the earth by two to three orders of magnitude.

Magnetic fields are employed in several electron-energy analysers and filters ([figure B1.6.3](#)). For very-low-energy electrons (0 to 10 eV), the ‘trochoidal analyser’ has proven quite useful. This device employs a magnetic field aligned to the direction of the incident electrons and an electric field perpendicular to this direction. The trajectory of an electron injected into this analyser describes a spiral and the guiding centre of the spiral drifts in the remaining perpendicular direction. The drift rate depends upon the electron energy so that a beam of electrons entering the device is dispersed in energy at the exit. The projection of the trajectory on a plane perpendicular to the electric field direction is a trochoid, hence the name trochoidal analyser. The Wien filter is similar in that it uses crossed electric and magnetic fields; however, the fields are perpendicular to one another and both are perpendicular to the injected electron beam direction. The Coulomb force induced by the electric field, E , deflects electrons in one direction and the Lorentz force associated with the magnetic field, \mathbf{B} , tends to deflect electrons in the opposite direction. The forces balance for one velocity, $v = |E|/|B|$, and electrons of this velocity are transmitted straight through the filter to the exit aperture. A magnetic field alone, perpendicular to the direction of an electron beam, will disperse electrons in energy. Sector magnets

such as those used in mass spectrometers are used in electron spectrometers for very-high-energy electrons, the advantage over electrostatic deflectors being that large electrical potentials are not required. Another advantage is that deflection is in the direction parallel to the magnet pole face making it possible to view the entire dispersed spectrum at one time. By contrast, energy dispersion of an electron beam in an electrostatic device results in a significant portion of the dispersed electrons striking one or the other electrode.

-7-

Figure B1.6.3 Electron energy analysers that use magnetic fields: (a) the trochoidal analyser employing an electromagnet, (b) the Wien filter and (c) the sector magnet analyser. Trajectories for electrons of different energies are shown.

(C) ELECTRON GUNS

Thermionic emission from an electrically heated filament is the usual source of electrons in an electron spectrometer. Field emission induced by a large electric-field gradient at a sharply pointed electrode may be used when fine spatial resolution is required. For very special applications, laser-induced photoemission has been used to produce nearly monoenergetic electrons and electrons with spin polarization. The filament in a thermionic source is a wire or ribbon of tungsten or some other refractory metal, sometimes coated or impregnated with thoria to reduce the work function. The passage of an electrical current of a few amps heats the filament to 1500 to 2500°C. As shown in [figure B1.6.4](#) the filament is typically mounted in a diode arrangement, protruding through a cathode and a small distance from an anode with an aperture through which electrons are extracted. The cathode is biased 30 to 50 V negative with respect to the source and the anode 50 to 100 V positive. An approximately Maxwellian energy distribution is produced. Depending on the filament temperature and the potential drop across the hot portion of the filament, this distribution is 0.3 to 0.7 eV wide. For most applications, the electron beam extracted from a thermionic source is passed through a monochromator to select a narrower band of energies from that emanating from the source.

Figure B1.6.4 Diode electron source.

(D) ELECTRON SPECTROMETERS

A typical electron energy-loss spectrometer is shown in figure B1.6.5. The major components are an electron source, a premonochromator, a target, an analyser and an electron detector. For gaseous samples, the target may be a gas jet or the target may be a gas confined in a cell with small apertures for the incident beam and for the scattered electrons. The target may be a thin film to be viewed in transmission or a solid surface to be viewed in reflection. The analyser may be rotatable about the scattering centre so the angularly differential scattering cross section can be measured. Most often the detector is an electron multiplier that permits scattered electrons to be counted and facilitates digital processing of the scattered-electron spectrum. In low-resolution instruments, the scattered-electron intensity may be sufficient to be measured with a sensitive electrometer as an electron current captured in a 'Faraday cup'.

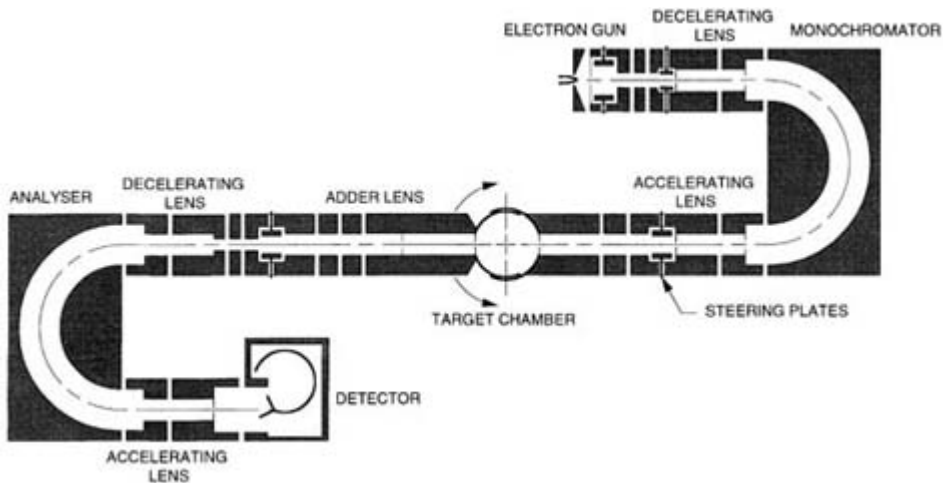

Figure B1.6.5 Typical electron energy-loss spectrometer.

Electron lens systems between each component serve a number of functions. A lens following the source focuses electrons on the entrance aperture of the premonochromator and decelerates these electrons to the pass energy required

to obtain the desired resolution. The lens following focuses electrons on the target and provides a variable amount of acceleration to permit experiments with different incident energies. The lens system at the input to the analyser again decelerates electrons and focuses on the entrance aperture of the analyser; however, this lens system has an additional function. The scattered-electron energy spectrum must be scanned. This is accomplished with an ‘adder lens’ that progressively adds back energy to the scattered electrons. The analyser is set to transmit electrons which have lost no energy; the energy-loss spectrum is then a plot of the detector signal as a function of the energy added by the adder lens. The alternative method of scanning is to vary the pass energy of the analyser; this has the disadvantage of changing the analyser resolution and transmission as the spectrum is scanned. The lens following the analyser accelerates transmitted electrons to an energy at which the detector is most sensitive, typically several hundred eV.

THEORY B1.6.2

Inelastic electron collisions can be roughly divided into two regimes: those in which the kinetic energy of the projectile electron greatly exceeds the energy of the target atom or molecule’s electrons excited by the collision, and those in which the projectile and target electron energies are comparable. In the higher-energy region the target electrons are little disturbed by the approach and departure of the projectile; the excitation occurs suddenly when the projectile is very close to the target. In the lower-energy region, the interaction proceeds on a time scale comparable to the orbital period of the target electrons; both projectile and target electrons make significant adjustments to one another’s presence. In some such cases, it may even make sense to consider the electron–target complex as a transient negative ion.

B1.6.2.1 BETHE–BORN THEORY FOR HIGH-ENERGY ELECTRON SCATTERING

Bethe provided the theoretical basis for understanding the scattering of fast electrons by atoms and molecules [3, 4]. We give below an outline of the quantum-mechanical approach to calculating the scattering cross section.

The Schrödinger equation for the projectile–target system is

$$\left[-\frac{\hbar^2}{2m} \nabla_r^2 - \frac{\hbar^2}{2m} \sum_j \nabla_{r_j}^2 + V(\mathbf{r}, \mathbf{r}_j, \mathbf{r}_N) \right] \phi(\mathbf{r}, \mathbf{r}_j) = \left[\varepsilon_0 + \frac{\hbar^2 k_0^2}{2m} \right] \phi(\mathbf{r}, \mathbf{r}_j) \quad \text{B1.6.1}$$

where r gives the position of the projectile electron and the r_j are the coordinates of the electrons in the target and the r_N are the coordinates of the nuclei; $V(\mathbf{r}, \mathbf{r}_j, \mathbf{r}_N)$ is the potential energy of interaction between the projectile and the particles (electrons and nuclei) that make up the target, as well as interactions between particles in the target; ε_0 is the energy of the target in its ground state; and $\hbar^2 k_0^2 / 2m$ is the initial kinetic energy of the projectile with wavevector k_0 and momentum $\hbar k_0$. The wave equation (B1.6.1) is inseparable because of terms in the potential-energy operator that go as $|\mathbf{r} - \mathbf{r}_j|^{-1}$. It is thus impossible to obtain an analytic solution for the wave function of the scattered electron. An approximate solution can be obtained by expanding the wave function, $\phi(\mathbf{r}, \mathbf{r}_j)$, in the complete set of eigenfunctions of the target, $\chi_m(\mathbf{r}_j)$, and of the projectile, $\psi(\mathbf{r})$. This separates the wave equation into a set of coupled differential equations each of which manifests a discrete interaction coupling two states (n and m) of the target. The interaction is

described by a matrix element:

$$V_{mn} = \int \chi_n^*(\mathbf{r}_j) V \chi_m(\mathbf{r}_j) d\mathbf{r}_j.$$

Approximate methods may be employed in solving this set of equations for the $\psi(r)$; however, the asymptotic form of the solutions are obvious. For the case of elastic scattering

$$\Psi_0(\mathbf{r}) \rightarrow e^{ik_0z} + \frac{e^{ik_0r}}{r} f_0(\theta, \phi)$$

the first term representing an incident plane wave moving in the z -direction in a spherical coordinate system and the second term an outgoing spherical wave modulated by a *scattering amplitude*, $f(\theta, \phi)$. For inelastic scattering, the solutions describe an outgoing wave with momentum $\hbar\mathbf{k}$,

$$\Psi(\mathbf{r}) \rightarrow \frac{e^{i\mathbf{k}\cdot\mathbf{r}}}{r} f(\theta, \phi).$$

In this case the projectile has imparted energy $\hbar^2(k_0^2 - k^2)/2m$ to the target. Assuming the target is initially in its ground state ($m = 0$), the collision has excited the target to a state of energy $E_n = \hbar^2(k_0^2 - k^2)/2m$.

The cross section for scattering into the differential solid angle $d\Omega$ centred in the direction (θ, ϕ) , is proportional to the square of the scattering amplitude:

$$\frac{d\sigma}{d\Omega} = \frac{k}{k_0} |f(\theta, \phi)|^2$$

where the ratio $k/k_0 = v/v_0$ accounts for the fact that, all other things being equal, the incident and scattered flux differ owing to the difference in velocity, v_0 , of the incident electron compared to the velocity, v , of the scattered electron. As a consequence of the expansion of the total wave function, the scattering amplitude can also be decomposed into terms each of which refers to an interaction coupling specific states of the target:

$$f_{mn}(\theta, \phi) = \frac{m}{2\pi\hbar^2} \int e^{-i\mathbf{k}\cdot\mathbf{r}} V_{mn} e^{i\mathbf{k}_0\cdot\mathbf{r}} d\mathbf{r} = \frac{m}{2\pi\hbar^2} \int V_{mn} e^{i\mathbf{K}\cdot\mathbf{r}} d\mathbf{r} \quad \text{B1.6.2}$$

where $\hbar\mathbf{k} = \hbar(\mathbf{k}_0 - \mathbf{k})$ is the momentum transfer in the collision.

In the high-energy regime it is appropriate to employ the Born approximation. There are three assumptions: (i) The incident wave is undistorted by the target. For a target in its ground state (specified by $m = 0$) this is equivalent to setting $V_{00} = 0$. (ii) There is no interaction between the outgoing electron and the excited target. For inelastic scattering with excitation of the final state n , this is equivalent to setting $V_{nn} = 0$. (iii) The excitation is a direct process with no involvement of intermediate states, thus $V_{mn} = 0$ unless $m = 0$. The scattering amplitude (equation (B1.6.2)) thus contains but one term:

$$f_{0n}(\theta, \phi) = \frac{m}{2\pi\hbar^2} \int e^{i\mathbf{K}\cdot\mathbf{r}} \chi_n^*(\mathbf{r}_j) V \chi_0(\mathbf{r}_j) d\mathbf{r}_j d\mathbf{r}. \quad \text{B1.6.3}$$

When the potential consists of electron–electron and electron–nucleus Coulombic interactions,

$$V = \sum_j \frac{e^2}{|\mathbf{r} - \mathbf{r}_j|} - \sum_N \frac{Z_N e^2}{|\mathbf{r} - \mathbf{r}_N|}$$

substitution in (B1.6.3) yields

$$f_{0n}(\theta, \phi) = \frac{me^2}{2\pi\hbar^2} \int \chi_n^*(\mathbf{r}_j) \sum_j \frac{e^{i\mathbf{K}\cdot\mathbf{r}}}{|\mathbf{r} - \mathbf{r}_j|} \chi_0(\mathbf{r}_j) d\mathbf{r}_j d\mathbf{r}$$

the electron–nucleus terms having been lost owing to the orthonormality of the target wave functions. The important physical implication of the Born approximation becomes clear if one first performs the integration with respect to \mathbf{r} , taking advantage of the transformation

$$\int \frac{e^{i\mathbf{K}\cdot\mathbf{r}}}{|\mathbf{r} - \mathbf{r}_j|} d\mathbf{r} = \frac{4\pi}{K^2} e^{i\mathbf{K}\cdot\mathbf{r}_j}.$$

The differential cross section for inelastic collisions exciting the n th state of the target then takes the form

$$\left(\frac{d\sigma}{d\Omega}\right)_{0n} = \frac{4e^2 m^2 k}{\hbar^4 K^4 k_0} \left| \int \chi_n^*(\mathbf{r}_j) \sum_j e^{i\mathbf{K}\cdot\mathbf{r}_j} \chi_0(\mathbf{r}_j) d\mathbf{r}_j \right|^2 = \frac{4e^4 m^2 k}{\hbar^4 K^4 k_0} |\varepsilon_n(\mathbf{K})|^2. \quad \text{B1.6.4}$$

In this expression, factors that describe the incident and scattered projectile are separated from the square modulus of an integral that describes the role of the target in determining the differential cross section. The term preceding the

integral, $4e^4 m^2 / \hbar^4 K^4$, with units of area, is the Rutherford cross section for electron–electron scattering. The integral, represented by the quantity $\varepsilon_n(\mathbf{K})$, is known as the *inelastic scattering form factor*.

In the discussion above, scattering from molecules is treated as a superposition of noninteracting electron

waves scattered from each atomic centre. In fact, there is a weak but observable interference between these waves giving rise to phase shifts associated with the different positions of the atoms in a molecule. This diffraction phenomenon produces oscillations in the differential cross section from which molecular structure information can be derived.

The interaction of the target with the incoming and outgoing electron wave must be considered at lower impact energies. This is achieved in the *distorted-wave approximation* by including V_{00} and V_{nn} in the calculation of the scattering amplitude. Higher-level calculations must also account for electron spin since spin exchange becomes important as the collision energy decreases.

B1.6.2.3 THE GENERALIZED OSCILLATOR STRENGTH

The Born approximation for the differential cross section provides the basis for the interpretation of many experimental observations. The discussion is often couched in terms of the *generalized oscillator strength*,

$$f_n(\mathbf{K}) = \frac{2m}{\hbar^2} \frac{E_n}{K^2} \left| \int \chi_n^*(\mathbf{r}_j) \sum_j e^{i\mathbf{K}\cdot\mathbf{r}_j} \chi_0(\mathbf{r}_j) d\mathbf{r}_j \right|^2 = \frac{2m}{\hbar^2} \frac{E_n}{K^2} |\varepsilon_n(\mathbf{K})|^2. \quad \text{B1.6.5}$$

Assuming the validity of the Born approximation, an ‘effective’ generalized oscillator strength can be derived in terms of experimentally accessible quantities:

$$f_n(\mathbf{K}) = \frac{\hbar^2}{2e^4 m} \frac{k_0}{k} E_n K^2 \left(\frac{d\sigma}{d\Omega} \right)_{0n}. \quad \text{B1.6.6}$$

All the quantities on the right can be measured (k_0 , k and K calculated from measurements of the incident energy, the energy-loss, and the scattering angle). For inelastic collisions resulting in transitions into the continuum beyond the first ionization potential, the cross section is measured per unit energy loss and the generalized oscillator strength *density* is determined:

$$\frac{df(\mathbf{K})}{dE} = \frac{\hbar^2}{2e^4 m} \frac{k_0}{k} E_n K^2 \frac{d^2\sigma}{d\Omega dE}. \quad \text{B1.6.7}$$

The generalized oscillator strength provides the basis of comparison between electron energy-loss spectra and optical spectra; however, there is a problem with the determination of the absolute value of the generalized oscillator strength since measurements of the differential cross section can rarely be made on an absolute basis owing to the difficulty of accurately determining the target dimension and density. The problem is overcome by a normalization of

experimentally determined generalized oscillator strengths according to the *Bethe sum rule* which requires that the sum of the $f_n(\mathbf{K})$ (equation B1.6.6) for all discrete transitions plus the integral of $df(\mathbf{K})/dE$ (equation B1.6.7) over the continuum adds up to the number of electrons in the target.

A particularly important property of the generalized oscillator strength is that, for high-energy, small-angle

scattering, the generalized oscillator strength is approximately equal to the *optical oscillator strength*, f_n^{opt} , for electric-dipole transitions induced by photon absorption. That this is so can be seen from a power-series expansion of the form factor that appears in the expression for the generalized oscillator strength ([equation B1.6.5](#)):

$$\varepsilon_n(\mathbf{K}) = \sum_{k=1}^{\infty} \int \chi_n^*(\mathbf{r}_j) \sum_j \frac{(i\mathbf{K}\cdot\mathbf{r}_j)^k}{k!} \chi_0(\mathbf{r}_j) d\mathbf{r}_j.$$

The operator in the first term goes as r_j , and is thus proportional to the optical *dipole transition moment*

$$M_{0n} = \int \chi_n^*(\mathbf{r}_j) \sum_j e\mathbf{r}_j \chi_0(\mathbf{r}_j) d\mathbf{r}_j.$$

The second term is proportional to the optical quadrupole transition moment, and so on. For small values of momentum transfer, only the first term is significant, thus

$$\lim_{k \rightarrow 0} f_n(K) = f_n^{opt}.$$

The result is that the small-angle scattering intensity as a function of energy loss (the energy-loss spectrum) looks like the optical absorption spectrum. In fact, oscillator strengths are frequently more accurately and conveniently measured from electron-impact energy-loss spectra than from optical spectra, especially for higher-energy transitions, since the source intensity, transmission and detector sensitivity for an electron scattering spectrometer are much more nearly constant than in an optical spectrometer. The proportionality of the generalized oscillator strength and the optical dipole oscillator strength appears to be valid even for incident-electron energies as low as perhaps 200 eV, but it is strictly limited to small-angle, forward scattering that minimizes momentum transfer in a collision [5]. Of course $K = 0$ is inaccessible in an inelastic collision; there must be at least sufficient momentum transferred to account for the kinetic energy lost by the projectile in exciting the target. For very-high-energy, small-angle scattering, the minimum momentum transfer is relatively small and can be ignored. At lower energies, an extrapolation technique has been employed in very accurate work.

On the other hand, there are unique advantages to electron-scattering measurements in the lower-energy, larger-scattering-angle regime in which the momentum transfer is larger than the minimum required to induce a transition. In this case, higher-order multipoles in the transition moment become significant, with the result that the cross section for the excitation of optically forbidden transitions increases relative to that for dipole-allowed transitions. The ability to vary the momentum transfer in electron-energy-loss spectroscopy yields a spectrum much richer than the optical spectrum.

B1.6.2.4 THE BETHE SURFACE: BINARY VERSUS DIPOLE COLLISIONS

An important feature of electron-impact spectroscopy in comparison to photoabsorption is that the momentum transfer can be varied. As the scattering angle increases and the incident energy decreases, higher-order terms in the expansion of $\varepsilon_n(\mathbf{K})$ become relatively more important. Large-angle, high-momentum-transfer scattering results from small impact parameters. In this case the target experiences a nonuniform electric field as the electron passes by. Significant amplitude of higher-order multipoles in a nonuniform field permits the field to

couple with higher-order multipoles of the target. Thus, for example, optically forbidden electric-quadrupole transitions are a significant feature of the low-energy, large-scattering-angle electron energy-loss spectrum. Selection rules for electronic excitation by electron impact have been treated in detail in the review by Hall and Read [6].

From the discussion above it appears that small-angle scattering events might better not be thought of as collisions at all. The excitation, which is photon-like, appears to be a consequence of the high-frequency electric pulse delivered to the target as the projectile electron passes rapidly by. These energetic, but glancing collisions are referred to as *dipole collisions*, in contradistinction to the larger-angle scattering regime of *binary collisions* where the projectile electron appears to undergo a hard collision with one of the target electrons.

A succinct picture of the nature of high-energy electron scattering is provided by the *Bethe surface* [4], a three-dimensional plot of the generalized oscillator strength as a function of the logarithm of the square of the momentum transfer, (K^2) and the energy-loss, E_n . To see how this works, consider the form of the Bethe surface for a 3D billiards game with a ‘projectile’ cue ball incident on a stationary billiard ball. This is a two-body problem so the energy-loss is uniquely determined by the momentum transfer: $E_n = \hbar^2 K^2 / 2m$. For each value of K , all the oscillator strength appears at a single value of E_n . The Bethe surface displays a sharp ridge extending from low values of K^2 and E_n (corresponding to large-impact-parameter, glancing collisions) to high values (corresponding to near ‘head on’ collisions).

A schematic of the Bethe surface for electron scattering from an atom or molecule is shown in [figure B1.6.6](#) superimposed on the surface for the two-body problem with a stationary target. The sharp ridge is broadened in the region of large momentum transfer and energy loss. These are hard collisions in which the projectile ejects an electron from the target. This is at least a three-body problem: because the recoil momentum of the ionic core is not accounted for, or, alternatively, since the target electron is not stationary, K and E_n are not uniquely related. The breadth and the shape of the ridge in the Bethe surface in the high-momentum region are a reflection of the momentum distribution of the target electron. Electron Compton scattering experiments [7, 8] and (e, 2e) experiments [9] are carried out in the high-momentum-transfer, large-energy-loss, region for the purpose of investigating the electron momentum distribution in atoms and molecules.

Figure B1.6.6 The Bethe surface. The sharp ridge corresponds to scattering from a single stationary target electron; the broadened ridge to scattering from the electrons in an atom or molecule.

The dipole region is approached as one proceeds to the low-momentum-transfer portion of the Bethe surface. For sufficiently small momentum transfer, where $2m|\hbar\mathbf{K}|^2$ approaches the binding energy of valence electrons in the target, a section through the Bethe surface has the appearance of the optical absorption spectrum. For values of the energy loss less than the first ionization energy of the target, sharp structure appears corresponding to the excitation of discrete, dipole-allowed transitions in the target. The ionization continuum extends from the first ionization potential, but, as in the photoabsorption spectrum, one typically sees sharp ‘edges’ as successive ionization channels become energetically possible. Also, as in the photoabsorption spectrum, resonance structures may appear corresponding to the excitation of metastable states imbedded in the continuum.

B1.6.2.5 LOW-ENERGY ELECTRON SCATTERING

Theoretically, the asymptotic form of the solution for the electron wave function is the same for low-energy projectiles as it is at high energy; however, one must account for the protracted period of interaction between projectile and target at the intermediate stages of the process. The usual procedure is to separate the incident-electron wave function into *partial waves*

$$e^{i\mathbf{k}_0 \cdot \mathbf{r}} = \sum_{l=0}^{\infty} (2l+1) i^l P_l(\cos \theta) j_l(k_0 r)$$

(j_l a spherical Bessel function; P_l a Legendre polynomial) and expand the wave function of the target in some complete basis set, typically the complete set of eigenfunctions for the unperturbed target. This approach allows for any distortion of the incoming and scattered electron waves, as well as any perturbation of the target caused by the

approaching charge of the projectile. Each term in the expansion for the incident wave represents an angular momentum component: $l=0$, the s-wave component; $l=1$, the p-wave component; and so on. The scattering of the incident wave is treated component by component, the interaction with each giving rise to a phase shift in that component of the outgoing wave.

To see how this works, consider elastic scattering in a situation where the electron–target interaction can be described by a simple central-force-field potential, $V(r)$, that does not fall off faster than r^{-1} at large r . In this case the wave equation for the projectile electron can be separated from the Schrödinger equation for the total electron–target system given above (equation (B1.6.1)). The wave equation for the projectile is

$$\left[-\frac{\hbar^2}{2m} \nabla_r^2 + V(r) \right] \Psi(\mathbf{r}) = \frac{\hbar^2 k_0^2}{2m} \Psi(\mathbf{r}).$$

Since the potential depends only upon the scalar r , this equation, in spherical coordinates, can be separated into two equations, one depending only on r and one depending on θ and ϕ . The wave equation for the r -dependent part of the solution, $R(r)$, is

$$\left[-\frac{\hbar^2}{2m} \frac{1}{r} \frac{\partial^2}{\partial r^2} r + \frac{\hbar^2}{2m} \frac{l(l+1)}{r^2} + V(r) \right] R(r) = \frac{\hbar^2 k_0^2}{2m} R(r) \quad \text{B1.6.8}$$

where $\hbar\sqrt{l(l+1)}/r$ is the orbital angular momentum associated with the l th partial wave. The solutions have the asymptotic form

$$R(r) \rightarrow \frac{1}{k_0 r} \sin \left(k_0 r - \frac{l\pi}{2} + \eta_l \right) \quad \text{B1.6.9}$$

and the calculation of the cross section is reduced to calculating the phase shift, η_l , for each partial wave. The phase shift is a measure of the strength of the interaction of a partial wave in the field of the target, as well as a measure of the time period of the interaction. High-angular-momentum components correspond to large impact parameters for which the interaction can generally be expected to be relatively weak. The exceptions are for the cases of long-range potentials, as when treating scattering from highly polarizable targets or from molecules with large dipole moments. In any event, only a limited number of partial waves need be considered in calculating the cross section—sometimes only one or two.

B1.6.2.6 RESONANCES

The partial wave decomposition of the incident-electron wave provides the basis of an especially appealing picture of strong, low-energy resonant scattering wherein the projectile electron spends a sufficient period of time in the vicinity

-17-

of the target that the electron–target complex is describable as a temporary negative ion. With the radial wave equation (B1.6.8) for the projectile in a central-force field as a starting point, define a fictitious potential

$$V'(r) = \frac{\hbar^2}{2m} \frac{l(l+1)}{r^2} + V(r).$$

This is a fictitious potential because it includes not only the true potential, $V(r)$, that contains the screened Coulomb potential and the polarization potential of the target, but also the term $(\hbar^2/2m)l(l+1)/r^2$ that arises from the centrifugal force acting on the projectile, a fictitious force associated with curvilinear motion. As shown in figure B1.6.7 this repulsive term may give rise to an *angular momentum barrier*. Some part of the incident-electron-wave amplitude may tunnel through the barrier to impinge upon the repulsive part of the true potential from which it is reflected to tunnel back out to join the incident wave. The superposition of these two waves produces the phase shift in the scattered wave (see equation (B1.6.9)). More interestingly, as shown in the figure, there are special incident electron energies for which the width of the well behind the barrier is equal to some integral multiple of the electron wavelength. A standing wave then persists, corresponding to an electron being temporarily trapped in the field of the target. This model describes the resonant formation of a metastable negative ion, or, more simply, a ‘resonance’.

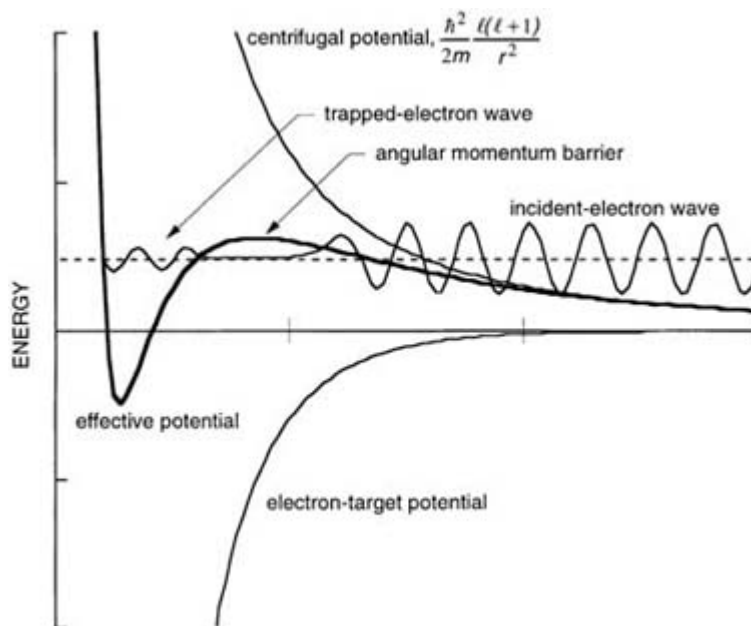

Figure B1.6.7 An angular momentum barrier created by the addition of the centrifugal potential to the electron–atom potential.

Finally, it must be recognized that all the above discussion assumes an isolated atomic or molecular target. To describe electron scattering in a complex target such as a solid, one must consider the extended nature of the valence-electron

density that constitutes a kind of electron gas enveloping the array of positively charged atomic cores. Most calculations employ a so-called ‘jellium’ model in which the mobile electrons move in the field of a positive charge smeared out into a homogeneous neutralizing density.

B1.6.3 APPLICATIONS

Electron energy-loss spectroscopy is used for obtaining spectroscopic data as a convenient substitute for optical spectroscopy, and, taking advantage of differences in selection rules, as an adjunct to optical spectroscopy. In addition, electron spectroscopy has many applications to chemical and structural analysis of samples in the gas phase, in the solid phase, and at the solid–gas interface.

B1.6.3.1 VALENCE-SHELL-ELECTRON SPECTROSCOPY

Electronic transitions within the valence shell of atoms and molecules appear in the energy-loss spectrum from a few electron volts up to, and somewhat beyond, the first ionization energy. Valence-shell electron spectroscopy employs incident electron energies from the threshold required for excitation up to many kiloelectron volts. The energy resolution is usually sufficient to observe vibrational structure within the Franck–Condon envelope of an electronic transition. The sample in valence-shell electron energy-loss spectroscopy is most often in the gas phase at a sufficiently low pressure to avoid multiple scattering of the projectile electrons, typically about 10^{-3} mbar. Recently, electronic excitation in surface adsorbates has been observed in the energy-loss spectrum of electrons reflected from metallic substrates. When the measurements

are carried out with relatively high incident-electron energies (many times the excitation and ionization energies of the target electrons) and with the scattered electrons detected in the forward direction (0° scattering angle), the energy-loss spectrum is essentially identical to the optical spectrum. As described above, this is the arrangement employed to determine oscillator strengths since forward scattering corresponds to collisions with the lowest momentum transfer. If the incident energy is reduced to about 100 eV (just a few times the target electron energies), symmetry-forbidden transitions can be uncovered and distinguished from optically allowed transitions by measuring the energy-loss spectrum at different scattering angles. An example is shown in [figure B1.6.8](#). As the incident energy approaches threshold, it becomes possible to detect electron-spin-changing transitions.

Figure B1.6.8 Energy-loss spectra of 200 eV electrons scattered from chlorine at scattering angles of 3° and 9° [10]. Optically forbidden transitions are responsible for the intensity in the 9° spectrum that does not appear in the 3° spectrum.

B1.6.3.2 INNER-SHELL-ELECTRON ENERGY-LOSS SPECTROSCOPY

Inner-shell-electron energy-loss spectroscopy (ISEELS) refers to measurements of the energy lost by projectile electrons that have promoted inner-shell electrons into unfilled valence orbitals or into the ionization continuum beyond the valence shell. Inner-shell excitation and ionization energies fall in the region between 100 eV and several kiloelectron volts. The corresponding features in the energy-loss spectrum tend to be broad and diffuse. Inner-shell-hole states of neutral atoms and molecules are very short lived; the transition energies to these states are correspondingly uncertain. The energy of a transition into the continuum is completely variable. Inner-shell-electron ionization energies cannot be uniquely determined from a measurement of the energy lost by the scattered electron since an unknown amount of energy is carried away by the undetected ejected electron. To be more precise, the electron-impact ionization cross section depends upon the energy (E_s) and angle (Ω_s) of the scattered electron as well as the energy (E_e) and angle (Ω_e) of the ejected electron; it is a fourfold differential cross section: $d^4\sigma/d\Omega_s dE_s d\Omega_e dE_e$. The intensity in the inner-shell energy-loss spectrum is proportional to this cross section integrated over E_e and Ω_e . For collisions in which the scattered electron is detected in the forward direction, the momentum transfer to the target is small and it is highly probable that the ejected-electron energy is very small. As a consequence, the ionization cross section for forward scattering is largest at the energy-loss threshold for ionization of each inner-shell electron and decreases monotonically, approximately as the inverse square of the energy loss. The basic appearance of

each feature in the inner-shell electron energy-loss spectrum is that of a sawtooth that rises sharply at the low-energy 'edge' and falls slowly over many tens of electron volts. In addition, sharp structures may appear near the edge (figure B1.6.9).

Figure B1.6.9 Energy-loss spectrum of La_2O_3 showing O K and La M_{45} ionization edges with prominent 'white line' resonances at the La edge [11].

In contrast to the broadly distributed valence-shell electron density in molecules and solids, inner-shell electron density is localized on a single atom. Molecular configuration and solid-state crystal structure have little effect upon inner-shell ionization energies. Each ionization edge in the energy-loss spectrum is characteristic of a particular type of atom; consequently, ISEELS has become an important technique for qualitative and quantitative elemental analysis. An especially useful elaboration of this technique is carried out in the transmission electron microscope where energy-loss analysis of electrons passing through a thin sample makes elemental analysis possible with the spatial resolution of the microscope [12]. A precision of the order of 100 ppm with nanometre spatial resolution has been achieved; this is close to single-atom sensitivity. A difficulty with ISEELS for analytical purposes is that each ionization edge is superimposed on the continuum associated with lower-energy ionizations of all the atoms in a sample. This continuum comprises an intense background signal which must be subtracted if the intensity at a characteristic edge is to be used as a quantitative measure of the concentration of a particular element in a sample.

Electrons arising from near-threshold inner-shell ionization have very little kinetic energy as they pass through the valence shell and may become trapped behind an angular momentum barrier in the exterior atomic potential, much as do low-energy incident electrons. This phenomenon, a wave-mechanical resonance as described above (section B1.6.2.6), gives rise to structure in the vicinity of an ionization edge in the energy-loss spectrum. For isolated molecular targets in the gas phase, the energies of near-edge resonances (relative to threshold) can be correlated with the eigenenergies of low-lying, unoccupied molecular orbitals (relative to the first ionization energy). Resonances in solid-state targets are especially prominent for fourth- and fifth-period elements where sharp threshold peaks known as 'white lines' are associated with electrons being trapped in vacant d and f bands (see figure B1.6.9). Resonance peaks have the effect of concentrating transition intensity into a narrow band of energies, thereby increasing the analytical sensitivity for these elements. Near-edge structure, being essentially a valence-shell or valence-band phenomenon, can provide important spectroscopic information about the chemical environment of the atoms in a sample.

B1.6.3.3 REFLECTED-ELECTRON ENERGY-LOSS SPECTROSCOPY

Vibrational spectroscopy of atoms and molecules near or on the surface of a solid has become an essential tool for the microscopic description of surface processes such as catalysis and corrosion. The effect of a surface on bonding is sensitively reflected by the frequencies of vibrational motions. Furthermore, since vibrational selection rules are determined by molecular symmetry that in turn is profoundly modified by the presence of a surface, it is frequently possible to describe with great accuracy the orientation of molecular adsorbates and the symmetry of absorption sites from a comparison of spectral intensities for surface-bound molecules to those for free molecules [13]. Electron spectroscopy has an advantage over optical methods for studying surfaces since electrons with energies up to several hundred electron volts penetrate only one or two atomic layers in a solid before being reflected, while the dimension probed by photons is of the order of the wavelength. Reflected-electron energy-loss spectroscopy (REELS) applied to the study of vibrational motion on surfaces represents the most highly developed technology of electron spectroscopy [14]. Incident electron energies are typically between 1 and 10 eV and sensitivity as low as a few per cent of a monolayer is routinely achieved (figure B1.6.10).

Figure B1.6.10 Energy-loss spectrum of 3.5 eV electrons specularly reflected from benzene adsorbed on the rhenium(111) surface [15]. Excitation of C–H vibrational modes appears at 100, 140 and 372 meV. Only modes with a changing electric dipole perpendicular to the surface are allowed for excitation in specular reflection. The great intensity of the out-of-plane C–H bending mode at 100 meV confirms that the plane of the molecule is parallel to the metal surface. Transitions at 43, 68 and 176 meV are associated with Rh–C and C–C vibrations.

B1.6.3.4 ELECTRON TRANSMISSION SPECTROSCOPY

An important feature of low-energy electron scattering is the formation of temporary negative ions by the resonant capture of incident electrons (see B1.6.2.6, above). These processes lead to sharp enhancements of the elastic-scattering cross section and often dominate the behaviour of the cross section for inelastic processes with thresholds lying close to the energy of a resonance [16]. Elastic-electron-scattering resonances are observed by electron transmission spectroscopy. Two types of resonance are distinguished: shape resonances and Feshbach resonances. *Shape resonances* arise when an electron is temporarily trapped in a well created in the ‘shape’ of the electron–target potential by a centrifugal barrier (figure B1.6.7). *Feshbach resonances* involve the simultaneous trapping of the projectile

π -electron systems. In order to emphasize the abrupt change in cross section characteristic of a resonance, the spectra are presented as the first derivative of the transmitted current as a function of incident-electron energy. This is accomplished by modulating the incident-electron energy and detecting the modulated component of the transmitted current. An example is shown in figure B1.6.11. Feshbach resonances fall in the 0 to about 30 eV range. They are found in electron scattering from atoms, but rarely for molecules. The study of these resonances has contributed to the understanding of optically inaccessible excited states of atoms and ions.

Figure B1.6.11 Electron transmission spectrum of 1,3-cyclohexadiene presented as the derivative of transmitted electron current as a function of the incident electron energy [17]. The prominent resonances correspond to electron capture into the two unoccupied, antibonding π^* -orbitals. The π_3^* negative ion state is sufficiently long lived that discrete vibronic components can be resolved.

B1.6.3.5 DIPOLE (E, 2E) SPECTROSCOPY

The information from energy-loss measurements of transitions into the continuum, that is, ionizing excitations, is significantly diminished because the energy of the ionized electron is not known. The problem can be overcome by

measuring simultaneously the energies of the scattered and ejected electrons. This is known as the (e, 2e) technique—the nomenclature is borrowed from nuclear physics to refer to a reaction with one free electron in the initial state and two in the final state. For spectroscopic purposes the experiment is carried out in the dipole scattering regime (see section B1.6.2.4). Two analyser/detector systems are used: one in the forward direction detects fast scattered electrons and the second detects slow electrons ejected at a large angle to the incident-electron direction (typically at the ‘magic angle’ of 54.7°). In order to ensure that pairs of electrons originate from the same ionizing collision, the electronics are arranged to record only those events in which a scattered and ejected electron are detected in coincidence (see B.1.11, ‘coincidence techniques’). The ionization energy, or binding energy, is unambiguously given by the difference between the incident electron energy and the sum of the energies of the scattered and ejected electrons detected in coincidence. Dipole (e, 2e) spectra (figure B1.6.12) are analogous to photoabsorption or photoelectron spectra obtained with tunable

UV or x-ray sources.

Figure B1.6.12 Ionization-energy spectrum of carbonyl sulphide obtained by dipole ($e, 2e$) spectroscopy [18]. The incident-electron energy was 3.5 keV, the scattered incident electron was detected in the forward direction and the ejected (ionized) electron detected in coincidence at 54.7° (angular anisotropies cancel at this ‘magic angle’). The energy of the two outgoing electrons was scanned keeping the net energy loss fixed at 40 eV so that the spectrum is essentially identical to the 40 eV photoabsorption spectrum. Peaks are identified with ionization of valence electrons from the indicated molecular orbitals.

B1.7 Mass spectrometry

Paul M Mayer

B1.7.1 INTRODUCTION

Mass spectrometry is one of the most versatile methods discussed in this encyclopedia. Ask a chemist involved in synthesis about mass spectrometry and they will answer that it is one of their most useful tools for identifying reaction products. An analytical chemist will indicate that mass spectrometry is one of the most sensitive detectors available for quantitative and qualitative analysis and is especially powerful when coupled to a separation technique such as gas chromatography. A physicist may note that high resolution mass spectrometry has been responsible for the accurate determination of the atomic masses listed in the periodic table. Biologists use mass spectrometry to identify high molecular weight proteins and nucleic acids and even for sequencing peptides. Materials scientists use mass spectrometry for characterizing the composition and properties of polymers and metal surfaces.

The mass spectrometer tends to be a passive instrument in these applications, used to record mass spectra. In chemical physics and physical chemistry, however, the mass spectrometer takes on a dynamic function as a

tool for the investigation of the physico-chemical properties of atoms, molecules and ions. It is this latter application that is the subject of this chapter, and it is hoped that it will bring the reader to a new understanding of the utility of mass spectrometry in their research.

The chapter is divided into sections, one for each general class of mass spectrometer: magnetic sector, quadrupole, time-of-flight and ion cyclotron resonance. The experiments performed by each are quite often unique and so have been discussed separately under each heading.

B1.7.2 ION SOURCES

A common feature of all mass spectrometers is the need to generate ions. Over the years a variety of ion sources have been developed. The physical chemistry and chemical physics communities have generally worked on gaseous and/or relatively volatile samples and thus have relied extensively on the two traditional ionization methods, electron ionization (EI) and photoionization (PI). Other ionization sources, developed principally for analytical work, have recently started to be used in physical chemistry research. These include fast-atom bombardment (FAB), matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ES).

B1.7.1.2 ELECTRON IONIZATION (EI)

A schematic diagram of an electron ionization (EI) ion source is shown in [figure B1.7.1](#). A typical source will consist of a block, filament, trap electrode, repeller electrode, acceleration region and a focusing lens. Sample vapour, introduced into the ion source (held at the operating potential of the instrument) through a variable leak valve or capillary interface, is ionized by electrons that have been accelerated towards the block by a potential gradient and collected at the trap electrode. A repeller electrode nudges the newly formed ions out of the source through an exit slit,

-2-

and they are accelerated to the operating kinetic energy of the instrument. A series of ion lenses is used to focus the ion beam onto the entrance aperture of the mass spectrometer.

Figure B1.7.1. Schematic diagram of an electron ionization ion source: source block (1); filament (2); trap electrode (3); repeller electrode (4); acceleration region (5); focusing lens (6).

Ionization with energetic electrons does not deposit a fixed amount of energy into a molecule. Rather, a 10 eV

beam of electrons can deposit anywhere from 0 to 10 eV of energy. For this reason, most instruments relying on electron ionization (often referred to as ‘electron impact’ ionization, a misleading expression as no actual collision between a molecule and an electron takes place) use electron beams of fairly high energy. Most analytical instruments employ electron energies of ~70 eV as it has been found that a maximum in the ion yield for most organic molecules occurs around this value. The resulting ion internal energies can be described by the Wannier threshold law [1], but at an electron energy of 70 eV this corresponds almost exactly to the photoelectron spectrum. Superimposed on this is the internal energy distribution of the neutral molecules prior to ionization. Since most ion sources operate at very low pressure ($\sim 10^{-7}$ to 10^{-6} Torr), the resulting ion population has a non-Boltzmann distribution of internal energies and thus it is difficult to discuss the resulting ion chemistry in terms of a thermodynamic temperature.

It is fairly difficult to obtain energy-selected beams of electrons (see [chapter B1.7](#)). Thus, electron beams employed in most mass spectrometers have broad energy distributions. One advantage of EI over photoionization, though, is that it is relatively simple to produce high energy electrons. All that is required is the appropriate potential drop between the filament and the ion source block. This potential drop is also continuously adjustable and the resulting electron flux often independent of energy.

B1.7.2.2 PHOTOIONIZATION (PI)

Photoionization with photons of selected energies can be a precise method for generating ions with known internal energies, but because it is bound to a continuum process (the ejected electron can take on any energy), ions are usually generated in a distribution of internal energy states, according to the equation $h\nu + E_{\text{therm}} = IE_{\text{AB}} + E_{\text{AB}^+} + E_{\text{e}}$, where $h\nu$ is the photon energy, E_{therm} is the average thermal energy of the molecule AB, IE is the ionization energy of the

molecule, E_{AB^+} is the ion internal energy and E_{e} is the kinetic energy of the departing electron. The deposition of energy into the ion typically follows the photoelectron spectrum up to the photon energy. Superimposed on this is the internal energy distribution of the original neutral molecules.

There are three basic light sources used in mass spectrometry: the discharge lamp, the laser and the synchrotron light source. Since ionization of an organic molecule typically requires more than 9 or 10 eV, light sources for photoionization must generate photons in the vacuum-ultraviolet region of the electromagnetic spectrum. A common experimental difficulty with any of these methods is that there can be no optical windows or lenses, the light source being directly connected to the vacuum chamber holding the ion source and mass spectrometer. This produces a need for large capacity vacuum pumping to keep the mass spectrometer at operating pressures. Multiphoton ionization with laser light in the visible region of the spectrum overcomes this difficulty.

B1.7.2.3 CHEMICAL IONIZATION

A third method for generating ions in mass spectrometers that has been used extensively in physical chemistry is chemical ionization (CI) [2]. Chemical ionization can involve the transfer of an electron (charge transfer), proton (or other positively charged ion) or hydride anion (or other anion).

The above CI reactions will occur if they are exothermic. In order for these reactions to occur with high efficiency, the pressure in the ion source must be raised to the milliTorr level. Also, the reagent species are often introduced in large excess so that they are preferentially ionized by the electron beam.

B1.7.2.4 OTHER IONIZATION METHODS

One feature common to all of the above ionization methods is the need to thermally volatilize liquid and solid samples into the ion source. This presents a problem for large and/or involatile samples which may decompose upon heating. Ionization techniques that have been developed to get around this problem include fast-atom bombardment (FAB) [3], matrix-assisted laser desorption ionization (MALDI) [4] and electrospray ionization (ESI) [5] (figure B1.7.2). FAB involves bombarding a sample that has been dissolved in a matrix such as glycerol with a high energy beam of atoms. Sample molecules that have been protonated by the glycerol matrix are sputtered off the probe tip, resulting in gas-phase ions. If high energy ions are used to desorb the sample, the technique is called SIMS (secondary ion mass spectrometry). MALDI involves ablating a sample with a laser. A matrix absorbs the laser light, resulting in a plume of ejected material, usually containing molecular ions or protonated molecules. In electrospray, ions are formed in solution by adding protons or other ions to molecules. The solution is sprayed through a fine capillary held at a high potential relative to ground (several keV are common). The sprayed solution consists of tiny droplets that evaporate, leaving gas-phase adduct ions which are then introduced into a mass spectrometer for analysis.

-4-

Figure B1.7.2. Schematic representations of alternative ionization methods to EI and PI: (a) fast-atom bombardment in which a beam of keV atoms desorbs solute from a matrix (b) matrix-assisted laser desorption ionization and (c) electrospray ionization.

B1.7.2.5 MOLECULAR BEAM SOURCES

Sample can be introduced into the ion source in the form of a molecular beam [6, 7] (figure B1.7.3). Molecular beams are most often coupled to time-of-flight instruments for reasons that are discussed in section (B1.7.5). The important advantage that molecular beams have over the other methods discussed in this section is their ability to cool the internal degrees of freedom of the sample. Collisions between a carrier gas (such as helium or argon) and the sample molecule in the rapidly expanding gas mixture results in rotational and vibrational cooling. Using this approach, the effective internal ‘temperature’ of the sample can be significantly less than ambient. One example of the benefits of using molecular beams is in photoionization. The photon energy can be more readily equated to the ion internal energy if the initial internal energy distribution of the neutral molecule is close to 0 K. This cooling also allows weakly bound species such as neutral clusters to be generated and their resulting PI or EI mass spectrum obtained.

-5-

Figure B1.7.3. Schematic diagram of a molecular beam generator: nozzle (1); expansion region (2); skimmer (3) and molecular beam (4).

B1.7.2.6 HIGH PRESSURE SOURCES

There are two significant differences between a high pressure ion source and a conventional mass spectrometer ion source. High pressure sources typically have only two very small orifices (aside from the sample inlet), one to permit ionizing electrons into the source and one to permit ions to leave. Total ion source pressures of up to 5–10 Torr can be obtained allowing the sample vapour to reach thermal equilibrium with the walls of the source. Because the pressures in the source are large, a 70 eV electron beam is insufficient to effectively penetrate and ionize the sample. Rather, electron guns are used to generate electron translational energies of up to 1–2 keV.

B1.7.3 MAGNETIC SECTOR INSTRUMENTS

The first mass spectrometers to be widely used as both analytical and physical chemistry instruments were based on the deflection of a beam of ions by a magnetic field, a method first employed by J J Thomson in 1913 [8] for separating isotopes of noble gas ions. Modern magnetic sector mass spectrometers usually consist of both magnetic and electrostatic sectors, providing both momentum and kinetic energy selection. The term ‘double-focusing’ mass spectrometer refers to such a configuration and relates to the fact that the ion beam is focused at two places between the ion source of the instrument and the detector. It is also possible to add sectors to make three-, four, five- and even six-sector instruments, though the larger of these are typically used for large molecule analysis. One of the staple instruments used in physical chemistry has been the reverse-geometry tandem sector mass spectrometer (‘BE’ configuration), which will be described below. The basic principles apply to any magnetic sector instrument configuration.

B1.7.3.1 INSTRUMENTATION

A schematic diagram of a reverse geometry mass spectrometer is shown in figure B1.7.4.

Figure B1.7.4. Schematic diagram of a reverse geometry (BE) magnetic sector mass spectrometer: ion source (1); focusing lens (2); magnetic sector (3); field-free region (4); beam resolving slits (5); electrostatic sector (6); electron multiplier detector (7). Second field-free region components: collision cells (8) and beam deflection electrodes (9).

(A) THE MAGNETIC SECTOR

The magnetic sector consists of two parallel electromagnets surrounding an iron core. The ion beam travels through the flight tube perpendicular to the direction of the imposed magnetic field. The path of an ion travelling orthogonal to a magnetic field is described by a simple mathematical relationship:

$$r = \frac{mv}{Bze} \tag{B1.7.1}$$

where r is the radius of curvature of the path of the ion, m is the ion's mass, v is the velocity, B is the magnetic field strength, z is the number of charges on the ion and e is the unit of elementary charge. Rearranged,

$$mv = rBze \tag{B1.7.2}$$

Most instruments are configured with a fixed value for the radius of curvature, r , so changing the value of B selectively passes ions of particular values of momentum, mv , through the magnetic sector. Thus, it is really the momentum that is selected by a magnetic sector, not mass. We can convert this expression to one involving the accelerating potential.

Magnetic sector instruments typically operate with ion sources held at a potential of between 6 and 10 kV. This results in ions with keV translational kinetic energies. The ion kinetic energy can be written as $zeV = \frac{1}{2}mv^2$ and thus the ion velocity is given by the relationship

$$v = \left(\frac{2zeV}{m} \right)^{1/2}$$

and [equation \(B1.7.2\)](#) becomes

$$m/z = \frac{B^2 r^2 e}{2V}. \quad (\text{B1.7.3})$$

In other words, ions with a particular mass-to-charge ratio, m/z , can be selectively passed through the magnetic sector by appropriate choice of a value of V and B (though normally V is held constant and only B is varied).

Magnetic sectors can be used on their own, or in conjunction with energy analysers to form a tandem mass spectrometer. The unique features of the reverse geometry instrument are presented from this point.

(B) THE FIELD-FREE REGION

The momentum-selected ion beam passes through the field-free region (FFR) of the instrument on its way to the electrostatic sector. The FFR is the main experimental region of the magnetic sector mass spectrometer. Significant features of the FFR can be collision cells and ion beam deflection electrodes. One particular arrangement is shown in [figure B1.7.4](#). A collision cell consists of a 2–3 cm long block of steel with a groove to pass the ion beam. A collision (target) gas can be introduced into the groove, prompting projectile–target gas collisions. The beam deflecting electrode assembly allows the ion beam to be deflected out of the beam path by the application of a potential difference across the assembly (see [section \(B1.7.3.2\)](#)).

(C) THE ELECTROSTATIC SECTOR (ESA)

The electrostatic sector consists of two curved parallel plates between which is applied a potential difference producing an electric field of strength E . Transmission of an ion through the sector is governed by the following relationship

$$\frac{1}{2}mv^2 = zeV = \frac{1}{2}zeEr.$$

This relationship gives an expression similar to [equation \(B1.7.1\)](#):

$$r = \frac{2V}{E}. \quad (\text{B1.7.4})$$

Adjusting the potential across the ESA plates allows ions of selected translational kinetic energy to pass through and be focused, at which point a detector assembly is present to monitor the ion flux. Note that in [equation \(B1.7.4\)](#) neither the mass nor charge of the ion is present. So, isobaric ions with one, two, three etc. charges, accelerated by a potential drop, V , will pass through the ESA at a common value of E . An ion with +1 charge accelerated across a potential difference of 8000 V will have 8 keV translational kinetic energy and be transmitted through the ESA by a field E_1 . An ion with +2 charges will have 16 keV translational energy

but will experience a field strength equivalent to $2E_1$, and so forth.

B1.7.3.2 EXPERIMENTS USING MAGNETIC SECTOR INSTRUMENTS

A single magnetic sector can be used as a mass filter for other apparatus. However, much more information of the simple mass spectrum of a species can be obtained using the tandem mass spectrometer.

(A) MASS-ANALYSED ION KINETIC ENERGY SPECTROMETRY (MIKES)

Ions accelerated out of the ion source with keV translational kinetic energies (and m/z selected with the magnetic sector) will arrive in the FFR of the instrument in several microseconds. Ions dissociating on this timescale (with unimolecular decay rate constants between 10^2 and 10^5 s⁻¹, depending on the physical geometry of the instrument) have been given the name ‘metastable ions’ [9].

In the FFR of the sector mass spectrometer, the unimolecular decomposition fragments, A⁺ and B, of the mass selected metastable ion AB⁺ will, by the conservation of energy and momentum, have lower translational kinetic energy, T , than their precursor:

$$zT_{A^+} = \frac{1}{2}m_{A^+}v^2 \quad zT_B = \frac{1}{2}m_Bv^2 \quad zT_{AB^+} = \frac{1}{2}m_{AB^+}v^2.$$

Thus we find

$$T_{A^+} = \frac{m_{A^+}}{m_{AB^+}}T_{AB^+}.$$

By scanning the ESA to pass ions with lower translational energies, the fragment ions will sequentially pass through to the detector (this is the so-called MS/MS, or MS², experiment). The final ion abundance kinetic energy spectrum ([figure B1.7.5\(a\)](#)) is converted to an ion abundance fragment m/z spectrum by the above relationships. The MIKE spectrum is the end result of all low energy unimolecular processes of the selected ions, including isomerization. Thus, isomeric ions which interconvert on the μ s timescale often have closely related, if not identical, MIKE spectra. There

are several characteristic peak shapes expected in a MIKE spectrum that are summarized in [figure B1.7.6](#).

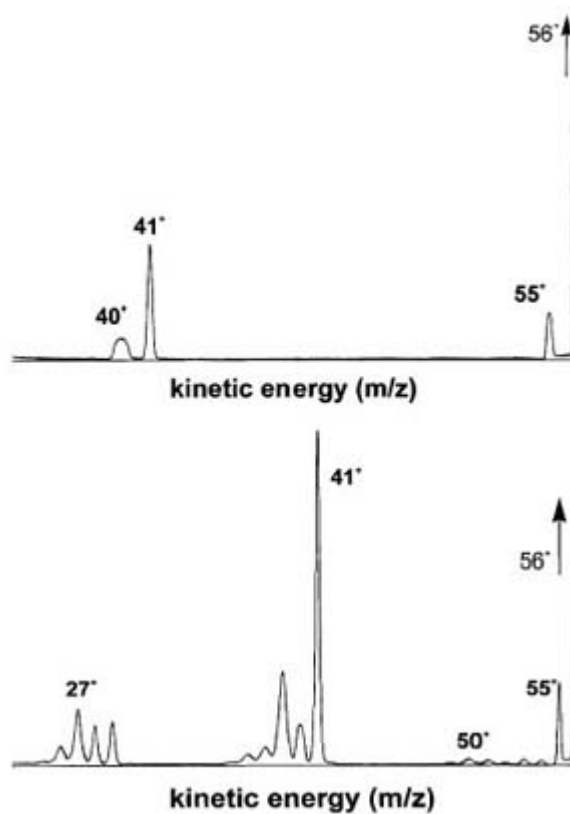

Figure B1.7.5. (a) MIKE spectrum of the unimolecular decomposition of 1-butene ions (m/z 56). This spectrum was obtained in the second field-free region of a reverse geometry magnetic sector mass

spectrometer (VG ZAB-2HF). (b) Collision-induced dissociation mass spectrum of 1-butene ions. Helium target gas was used to achieve 10% beam reduction (single collision conditions) in the second field-free region of a reverse geometry magnetic sector mass spectrometer (VG ZAB-2HF).

Figure B1.7.6. Fragment ion peak shapes expected in MIKE spectra: (a) typical Gaussian energy profile; (b) large average kinetic energy release causing z -axial discrimination of the fragment ions, resulting in a ‘dished-top’ peak; (c) competing fragmentation channels, each with its own distinct kinetic energy release, producing a ‘composite’ peak; (d) fragmentation occurring from a dissociative excited state.

(B) COLLISION-INDUCED DISSOCIATION (CID) MASS SPECTROMETRY

A collision-induced dissociation (CID) mass spectrum [10, 11] of mass selected ions is obtained by introducing a target gas into a collision cell in one of the field-free regions. The resulting high energy (keV) CID mass spectrum, obtained and analysed in the same way as a MIKE spectrum, contains peaks due to ions formed in virtually all possible unimolecular dissociation processes of the precursor ion (figure B1.7.5(b)). The timescale of the collision-induced fragmentation reactions is quite different from the MIKE experiment, ranging from the time of the collision event ($t \approx 10^{-15}$ s) to the time the ions exit the FFR. For this reason, isomerization reactions tend not to play a significant role in collision-induced reactions and thus the CID mass spectra are often characteristic of ion connectivity.

In collisional excitation, translational energy of the projectile ion is converted into internal energy. Since the excited states of the ions are quantized, so will the translational energy loss be. Under conditions of high energy resolution, it is

possible to obtain a translational energy spectrum of the precursor ions exhibiting peaks that correspond to the formation for discrete excited states (translational energy spectroscopy [12]).

It is possible in a sector instrument to perform a variety of other experiments on the projectile ions. Many involve examining the products of charge exchange with the target gas, while others allow neutral species to be studied. Some of the more common experiments are summarized in figure B1.7.7. All of the experiments

have been described for projectile cations, but anions can be studied in analogous manners.

Figure B1.7.7. Summary of the other collision based experiments possible with magnetic sector instruments: (a) collision-induced dissociation ionization (CIDI) records the CID mass spectrum of the neutral fragments accompanying unimolecular dissociation; (b) charge stripping (CS) of the incident ion beam can be observed; (c) charge reversal (CR) requires the ESA polarity to be opposite that of the magnet; (d) neutralization–reionization (NR) probes the stability of transient neutrals formed when ions are neutralized by collisions in the first collision cell. Neutrals surviving to be collisionally reionized in the second cell are recorded as ‘recovery’ ions in the NR mass spectrum.

(C) KINETIC ENERGY RELEASE (KER) MEASUREMENTS

In a unimolecular dissociation, excess product energy is typically distributed among the translational, rotational and vibrational modes in a statistical fashion. The experimentally observed phenomenon is the distribution of translational kinetic energies of the departing fragment ions (the kinetic energy release, KER) [9]. In magnetic sector instruments, the result of x -axial (i.e. along the beam path) KER is the observation of fragment ion peaks in the MIKE or CID spectra which have a broader kinetic energy spread than the precursor ion peak. In a CID, however, this spread is complicated by collisional scattering and so KER is most often discussed for peaks in MIKE spectra. If the mass

spectrometer is operated under conditions of high resolution, obtained by narrowing the y -axis beam collimating slits throughout the instrument, the widths of the fragment ion peaks are indicative of this kinetic energy release. The measured value for the KER is typically expressed as the value at half-height of the fragment ion peak, $T_{0.5}$, and is calculated with the following equation

$$T_{0.5}(\text{meV}) = \frac{m_{\text{AB}^+}^2 (\Delta V_{0.5, \text{A}^+}^2 - \Delta V_{0.5, \text{AB}^+}^2)}{16(8)m_{\text{A}^+}m_{\text{B}}}$$

where m is the mass of the various species, $\Delta V_{0.5}$ is the full width energy spread of the fragment and precursor ion peaks at half height and (8) represents the typically 8 keV translational kinetic energy of the precursor [9]. The resulting $T_{0.5}$ is in meV. Note that since knowledge of the internal energy distribution of the dissociating ions is lacking, the relationship between $T_{0.5}$ and the average KER is strictly qualitative, i.e. a large $T_{0.5}$ indicates a large average KER value. How statistical the distribution of product excess energies is will depend on the dynamics of the dissociation.

B1.7.4 QUADRUPOLE MASS FILTERS, QUADRUPOLE ION TRAPS AND THEIR APPLICATIONS

Another approach to mass analysis is based on stable ion trajectories in quadrupole fields. The two most prominent members of this family of mass spectrometers are the quadrupole mass filter and the quadrupole ion trap. Quadrupole mass filters are one of the most common mass spectrometers, being extensively used as detectors in analytical instruments, especially gas chromatographs. The quadrupole ion trap (which also goes by the name ‘quadrupole ion store, QUISTOR’, Paul trap, or just ion trap) is fairly new to the physical chemistry laboratory. Its early development was due to its use as an inexpensive alternative to tandem magnetic sector and quadrupole filter instruments for analytical analysis. It has, however, started to be used more in the chemical physics and physical chemistry domains, and so it will be described in some detail in this section.

The principles of operation of quadrupole mass spectrometers were first described in the late 1950s by Wolfgang Paul who shared the 1989 Nobel Prize in Physics for this development. The equations governing the motion of an ion in a quadrupole field are quite complex and it is not the scope of the present article to provide the reader with a complete treatment. Rather, the basic principles of operation will be described, the reader being referred to several excellent sources for more complete information [13, 14 and 15].

B1.7.4.1 THE QUADRUPOLE MASS FILTER

A schematic diagram of a quadrupole mass filter is shown in [figure B1.7.8](#). In an ideal, three-dimensional, quadrupole field, the potential ϕ at any point (x, y, z) within the field is described by [equation \(B1.7.5\)](#):

-13-

$$\phi = \frac{\phi_0}{r_0^2} (ax^2 + by^2 + cz^2) \quad (\text{B1.7.5})$$

where ϕ_0 is the applied potential, r_0 is half the distance between the hyperbolic rods and a , b and c are coefficients. The applied potential is a combination of a radio-frequency (RF) potential, $V \cos \omega t$, and direct current (DC) potential, U . The two can be expressed in the following relationship:

$$\phi_0 = U + V \cos \omega t$$

where ω is the angular frequency of the RF field (in rad s^{-1}) and is 2π times the frequency in Hertz. A potential applied across the rods (see [figure B1.7.8](#)) is flipped at radio-frequencies.

Figure B1.7.8. Quadrupole mass filter consisting of four cylindrical rods, spaced by a radius r (reproduced with permission of Professor R March, Trent University, Peterborough, ON, Canada).

Ideally, the rods in a quadrupole mass filter should have a hyperbolic geometry, but more common is a set of four cylindrical rods separated by a distance $2r$, where $r \approx 1.16r_0$ (figure B1.7.8). This arrangement provides for an acceptable field geometry along the axis of the mass filter. Since there is no field along the axis of the instrument, equation (B1.7.5) simplifies to $\phi = (\phi_0/r_0^2)(ax^2 + by^2)$.

The values of a and b that satisfy this relationship are $a = 1$ and $b = -1$, so the potential inside the quadrupole mass filter takes on the form:

$$\phi = \frac{\phi_0}{r_0^2}(x^2 - y^2).$$

The equations of motion within such a field are given by:

$$\frac{d^2x}{dt^2} + \frac{e}{mr_0^2}(U - V \cos \omega t)x = 0$$

$$\frac{d^2y}{dt^2} + \frac{e}{mr_0^2}(U - V \cos \omega t)y = 0.$$

Now, we can make three useful substitutions

$$a_x = -a_y = \frac{8eU}{m\omega^2 r_0^2} \quad q_x = -q_y = \frac{8eV}{m\omega^2 r_0^2} \quad \xi = \frac{\omega t}{2}$$

and the result is in the general form of the Mathieu equation [16]:

$$\frac{d^2u}{d\xi^2} + (a_u - 2q_u \cos 2\xi)u = 0. \tag{B1.7.6}$$

Equation (B1.7.6) describes the ion trajectories in the quadrupole field (where u can be either x or y). The stable, bounded solutions to these equations represent conditions of stable, bounded trajectories in the

quadrupole mass filter. A diagram representing the stable solutions to the equations for both the x - and y -axes (really the intersection of two sets of stability diagrams, one for the x -axis, one for the y -axis) is shown in [figure B1.7.9\(a\)](#). This figure represents the stability region closest to the axis of the instrument and is the most appropriate for the operation of the quadrupole. This stability region is also unique for a given m/z ratio. [figure B1.7.9\(b\)](#) represents the stability regions (transformed into axes of the applied DC and RF potential) for a series of ions with different m/z values. The line running through the apex of each region is called the operating line and represents the conditions (U and V) for the selective filtering of different mass ions through the instrument. The ratio of U to V is a constant along the operating line. It is apparent from [figure B1.7.9\(b\)](#) that the resolution of the quadrupole mass filter can be altered by changing the slope of the operating line. A greater slope means there is greater separation of the ions, but at the expense of sensitivity (fewer ions will have stable trajectories).

-15-

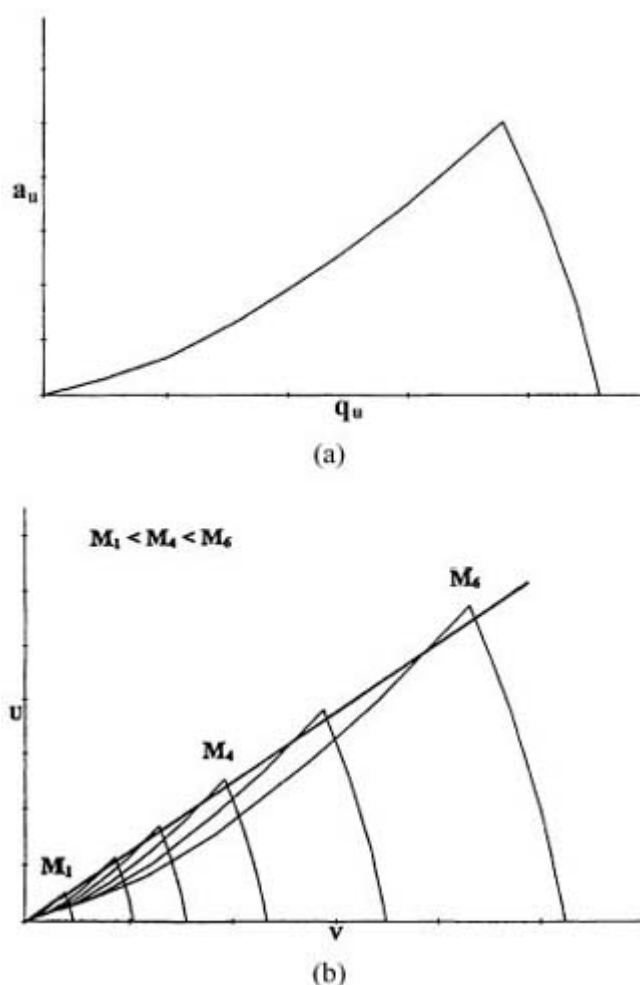

Figure B1.7.9. (a) Stability diagram for ions near the central axis of a quadrupole mass filter. Stable trajectories occur only if the a_u and q_u values lie beneath the curve. (b) Stability diagram (now as a function of U and V) for six ions with different masses. The straight line running through the apex of each set of curves is the ‘operating’ line, and corresponds to values of U/V that will produce mass resolution (reproduced with permission of Professor R March, Trent University, Peterborough, ON, Canada).

To be effective, it is necessary for the ions traversing the instrument to experience several RF cycles. Thus, unlike magnetic sector instruments, the ions formed in the ion source of a quadrupole mass filter apparatus are accelerated to only a few eV kinetic energy (typically 5–10 eV). The timescale of the experiment is therefore

much longer than for magnetic sectors, ions having to survive milliseconds rather than microseconds to be detected.

B1.7.4.2 EXPERIMENTS USING QUADRUPOLE MASS FILTERS

Aside from the single mass filter, the most common configuration for quadrupole mass spectrometers is the triple-quadrupole instrument. This is the simplest tandem mass spectrometer using quadrupole mass filters. Typically, the

-16-

first and last quadrupole are operated in mass selective mode as described above. The central quadrupole is usually an RF-only quadrupole. The lack of a DC voltage means that ions of all m/z values will have stable trajectories through the filter.

(A) COLLISION-INDUCED DISSOCIATION

Adding a collision gas to the RF-only quadrupole of a triple-quadrupole instrument permits collision-induced dissociation experiments to be performed. Unlike magnetic sector instruments, the low accelerating potential in quadrupole instruments means that low energy collisions occur. In addition, the time taken by the ions to traverse the RF only quadrupole results in many of these low energy collisions taking place. So, collisional excitation occurs in a multi-step process, rather than in a single, high-energy, process as in magnetic sector instruments.

(B) REACTIVE COLLISIONS

Since ions analysed with a quadrupole instrument have low translational kinetic energies, it is possible for them to undergo bimolecular reactions with species inside an RF-only quadrupole. These bimolecular reactions are often useful for the structural characterization of isomeric species. An example of this is the work of Harrison and co-workers [17]. They probed the reactions of CH_3NH_2^+ ions with isomeric butenes and pentenes in the RF-only quadrupole collision cell of a hybrid BEqQ instrument. The mass spectra of the products of the ion–molecule reactions were distinct for the various isomers probed. Addition of the amine to the olefin followed by fragmentation produced characteristic iminium ions only for terminal olefins without substitution at the olefinic carbons (figure B1.7.10).

Figure B1.7.10. Three mass spectra showing the results of reactive collisions between a projectile ion CH_3NH_2^+ and three isomeric butenes. (C) EQUILIBRIUM MEASUREMENTS

It is possible to determine the equilibrium constant, K , for the bimolecular reaction involving gas-phase ions and neutral molecules in the ion source of a mass spectrometer [18]. These measurements have generally focused on three properties, proton affinity (or gas-phase basicity) [19, 20], gas-phase acidity [21] and solvation enthalpies (and free energies) [22, 23]:

A common approach has been to measure the equilibrium constant, K , for these reactions as a function of temperature with the use of a variable temperature high pressure ion source (see section (B1.7.2)). The ion concentrations are approximated by their abundance in the mass spectrum, while the neutral concentrations are known from the sample inlet pressure. A van't Hoff plot of $\ln K$ versus $1/T$ should yield a straight line with slope equal to the reaction enthalpy (figure B1.7.11). Combining the PA with a value for $\Delta_{\text{basicity}} G^0$ at one temperature yields a value for ΔS^0 for the half-reaction involving addition of a proton to a species. While quadrupoles have been the instruments of choice for many of these studies, other mass spectrometers can act as suitable detectors [19, 20].

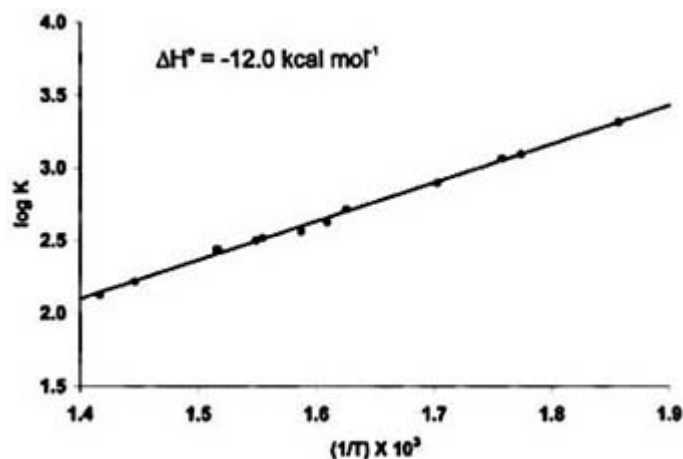

Figure B1.7.11. Van't Hoff plot for equilibrium data obtained for the reaction of isobutene with ammonia in a high pressure ion source (reproduced from data in [19]).

(D) SELECTED ION FLOW TUBE

Another example of the use of quadrupole filters in studying reactive collisions of gaseous ions is the selected ion flow tube (SIFT) [24]. This has been perhaps the most widely employed instrument for studying the kinetics of bimolecular reactions involving ions. Its development by N G Adams and D Smith sprang from the utility of the flowing afterglow (FA) technique (developed in the early 1960s by Ferguson, Fehsenfeld and Schmeltekopf [25, 26]) in the study of atmospheric reactions [27].

A schematic diagram of a SIFT apparatus is shown in figure B1.7.12. The instrument consists of five basic regions, the ion source, initial quadrupole mass filter, flow tube, second mass filter and finally the detector. The heart of the instrument is the flow tube, which is a steel tube approximately 1 m long and 10 cm in diameter. The pressure in the flow tube is kept of the order of 0.5 Torr, resulting in carrier gas flow rates of $\sim 100 \text{ m s}^{-1}$. Along the flow tube there are orifices that are used to introduce neutral reagents into the flow stream. Product ions arriving at the end of the flow tube are skimmed through a small orifice and mass analysed with a second quadrupole filter before being detected. The reactions occurring in the flow tube can be monitored as a function of carrier gas flow rate, and hence timescale. A detailed description of the extraction of rate constants from SIFT experiments is given by Smith and Adams [24]. Examples of the type of information obtained with the SIFT technique can be found in a recent series of articles by D Smith and co-workers [28, 29 and 30].

Figure B1.7.12. A schematic diagram of a typical selected-ion flow (SIFT) apparatus. (Smith D and Adams N G 1988 The selected ion flow tube (SIFT): studies of ion–neutral reactions *Advances in Atomic and Molecular Physics* vol 24, ed D Bates and B Bederson p 4. Copyright Academic Press, Inc. Reproduced with permission.)

(E) ION-GUIDE INSTRUMENTS

Another instrument used in physical chemistry research that employs quadrupole mass filters is the guided ion beam mass spectrometer [31]. A schematic diagram of an example of this type of instrument is shown in [figure B1.7.13. A](#)

mass selected beam of ions is introduced into an ion guide, in which their translational energy can be precisely controlled down to a few fractions of an electron volt. Normally at these energies, divergence of the ion beam would preclude the observation of any reaction products. To overcome this, the ions are trapped in the beam path with either a quadrupole or octapole filter operated in RF-only mode (see above). The trapping characteristics (i.e., how efficiently the ions are ‘guided’ along the flight path) of the octapole filter are superior to the quadrupole filter and so octapoles are often employed in this type of apparatus. The operational principles of an octapole mass filter are analogous to those of the quadrupole mass filter described above.

Figure B1.7.13. A schematic diagram of an ion-guide mass spectrometer. (Ervin K M and Armentrout P B 1985 Translational energy dependence of $\text{Ar}^+ + \text{XY} \rightarrow \text{ArX}^+ + \text{Y}$ from thermal to 30 eV c.m. *J. Chem. Phys.* **83** 166–89. Copyright American Institute of Physics Publishing. Reproduced with permission.)

Using a guided ion beam instrument the translational energy dependent reaction cross sections of endothermic fragmentation processes can be determined [32]. Modelling these cross sections ultimately yields their energy thresholds and a great deal of valuable thermochemical information has been derived with this technique. Precision of ± 0.2 eV can be obtained for reaction thresholds. Bimolecular reactions can also be studied and reaction enthalpies derived from the analysis of the cross section data.

B1.7.4.3 THE QUADRUPOLE ION TRAP

The quadrupole ion trap is the three dimensional equivalent to the quadrupole mass filter. A typical geometry consists of two hyperbolic endcap electrodes and a single ring electrode (figure B1.7.14). Unlike the quadrupole mass filter, however, the ion trap can be used both as a mass selective device or as an ion storage device. It is this latter ability that has led to the popularity and versatility of the ion trap. The theoretical treatment of ion trajectories inside the ion trap is similar to that presented above for the mass filter, except that now the field is no longer zero in the z -axis. It is convenient to use cylindrical coordinates rather than Cartesian coordinates and the resulting relationship describing the

-20-

potential inside the ion trap is given as:

$$\phi = \frac{\phi_0}{r_0^2} (r_0^2 - 2z_0^2)$$

where r_0 and z_0 are defined as in figure B1.7.14. The relationship $r_0^2 = 2z_0^2$ has usually governed the geometric arrangement of the electrodes. The equations of motion for an ion in the ion trap are analogous to those for the quadrupole mass filter:

$$\frac{d^2r}{dt^2} + \frac{2e}{mr_0^2}(U - V \cos \omega t)r = 0$$

$$\frac{d^2z}{dt^2} + \frac{4e}{mr_0^2}(U - V \cos \omega t)z = 0$$

and with the analogous substitutions,

$$a_z = -2a_r = \frac{-16eU}{m\omega^2(r_0^2 + 2z_0^2)}$$

$$q_z = -2q_r = \frac{-8eV}{m\omega^2(r_0^2 + 2z_0^2)}$$

$$\xi = \frac{\omega t}{2}.$$

the Mathieu equation is obtained.

-21-

Figure B1.7.14. Schematic cross-sectional diagram of a quadrupole ion trap mass spectrometer. The distance between the two endcap electrodes is $2z_0$, while the radius of the ring electrode is r_0 (reproduced with permission of Professor R March, Trent University, Peterborough, ON, Canada).

The Mathieu equation for the quadrupole ion trap again has stable, bounded solutions corresponding to stable, bounded trajectories inside the trap. The stability diagram for the ion trap is quite complex, but a subsection of the diagram, corresponding to stable trajectories near the physical centre of the trap, is shown in [figure B1.7.15](#). The interpretation of the diagram is similar to that for the quadrupole mass filter.

Figure B1.7.15. Stability diagram for ions near the centre of a quadrupole ion trap mass spectrometer. The enclosed area reflects values for a_z and q_z that result in stable trapping trajectories (reproduced with permission of Professor R March, Trent University, Peterborough, ON, Canada).

B1.7.4.4 EXPERIMENTS USING QUADRUPOLE ION TRAPS

The ion trap has three basic modes in which it can be operated. The first is as a mass filter. By adjusting U and V to reside near the apex of the stability diagram in figure B1.7.15 only ions of a particular m/z ratio will be selected by the trap. An operating line that intersects the stability diagram near the apex (as was done for the mass filter) with a fixed U/V ratio describes the operation of the ion trap in a mass scanning mode. A second mode of operation is with the potential ϕ_0 applied only to the ring electrode, the endcaps being grounded. This allows ions to be selectively stored. The application of an extraction pulse to the endcap electrodes ejects ions out of the trap for detection. A third mode is the addition of an endcap potential, $-U$. This mode permits mass selective storage in the trap, followed by storage of all ions. This latter method permits the ion trap to be used as a tandem mass spectrometer.

(A) ION ISOLATION

One of the principle uses of the ion trap is as a tandem-in-time mass spectrometer. Ions with a particular m/z ratio formed in the ion trap, or injected into the trap from an external source, can be isolated by resonantly ejecting all other

ions. This can be accomplished in a variety of ways. One method involves applying a broad-band noise field between the endcap electrodes to resonantly excite (in the axial direction) and eject all ions. The secular frequency of the ions to be stored is notched out of this noise field, leaving them in the trap. In another method, ions with lower and higher m/z ratio can be ejected by adjusting the amplitude of the RF and DC potentials so that the (a_z, q_z) value for the ion of interest lies just below the apex in [figure B1.7.15](#).

(B) COLLISION-INDUCED DISSOCIATION

A unique aspect of the ion trap is that the trapping efficiency is significantly improved by the presence of helium damping gas. Typical pressures of helium in the trap are ~ 1 milliTorr. Collisions between the trapped ions and helium gas effectively cause the ions to migrate towards the centre of the trap where the trapping field is most perfect. This causes significant improvements in sensitivity in analytical instruments. The presence of the damping gas also permits collision-induced dissociation to be performed. In the manner described above, ions with a particular m/z ratio can be isolated in the trap. The axial component of the ion motion is then excited resonantly by applying a potential across the endcap electrodes. The amplitude of this potential is controlled to prevent resonant ejection of the ions, but otherwise this is a similar experiment to that described above for mass selective ejection. The potential (often called the 'tickle' potential), increases the kinetic energy of the selected ions which in turn increases the centre-of-mass collision energy with the helium damping gas. These collisions now excite the mass selected ions causing them to dissociate. After the 'tickle' period, the trap is returned to a state where all ions can be trapped and thus the mass spectrum of the fragmentation product ions can be obtained. The CID mass spectra that are obtained in this manner are similar to those obtained with triple quadrupole instruments, in that they are the result of many low energy collisions ([figure B.1.7.16\(a\)](#)). There have been attempts to measure unimolecular reaction kinetics by probing fragment ion intensities as a function of time after excitation [[33](#)].

(a)

(b)

Figure B1.7.16. Mass spectra obtained with a Finnigan GCQ quadrupole ion trap mass spectrometer. (a) Collision-induced dissociation mass spectrum of the proton-bound dimer of isopropanol $[(\text{CH}_3)_2\text{CHOH}]_2\text{H}^+$. The m/z 121 ions were first isolated in the trap, followed by resonant excitation of their trajectories to produce CID. Fragment ions include water loss (m/z 103), loss of isopropanol (m/z 61) and loss of 42 amu (m/z 79). (b) Ion-molecule reactions in an ion trap. In this example the m/z 103 ion was first isolated and then resonantly excited in the trap. Endothermic reaction with water inside the trap produces the proton-bound cluster at m/z 121, while CID produces the fragment with m/z 61.

With the right software controlling the instrument, it is possible for the above process to be repeated n times, i.e., the ion trap is theoretically capable of MS^n experiments, though the ion concentration in the trap is always the limiting factor in these experiments.

(C) BIMOLECULAR REACTIONS

The same procedure as outlined above can be used to study ion-molecule reactions [15, 34]. Mass-selected ions will react with neutral species inside the trap. The presence of the damping gas means that stable (thermodynamic and

kinetic) complexes may be formed. Allowing the mass-selected ions to react in the trap, while storing all

reaction products, allows the course of the reactions to be followed ([figure B1.7.16\(b\)](#)). Changing the storage time allows the relative abundance of reactant and product ions to be monitored as a function of time. This introduces the possibility of measuring ion–molecule reaction rate constants with the ion trap. Since the ion internal energy distribution in such an experiment is described by a temperature near the ambient temperature of the damping gas, ion–molecule reactions can be probed as a function of temperature by raising the trap temperature. Resonant excitation of the mass-selected ions (see CID section) effectively raises their internal energy, allowing endothermic reactions with neutral species to take place (there will be a limit on the endothermicity extending from the limit on internal excitation occurring in the resonant excitation process). The degree of axial resonant excitation can be controlled and there have been attempts to relate this to an effective ‘temperature’ [35].

B1.7.5 TIME-OF-FLIGHT MASS SPECTROMETERS

Probably the simplest mass spectrometer is the time-of-flight (TOF) instrument [36]. Aside from magnetic deflection instruments, these were among the first mass spectrometers developed. The mass range is theoretically infinite, though in practice there are upper limits that are governed by electronics and ion source considerations. In chemical physics and physical chemistry, TOF instruments often are operated at lower resolving power than analytical instruments. Because of their simplicity, they have been used in many spectroscopic apparatus as detectors for electrons and ions. Many of these techniques are included as chapters unto themselves in this book, and they will only be briefly described here.

B1.7.5.1 TIME-OF-FLIGHT EQUATIONS

The basic principle behind TOF mass spectrometry [36] is the equation for kinetic energy, $zeV = \frac{1}{2}mv^2$, where the translational kinetic energy of an ion accelerated out of the ion source by a potential drop, V is zeV . If ions of mass m are given zeV kinetic energy, then the time, t_d , the ions take to travel a distance d is given by:

$$t_d = d \frac{m}{2zeV}. \quad (\text{B1.7.7})$$

In the simplest form, t_d reflects the time of flight of the ions from the ion source to the detector. This time is proportional to the square root of the mass, i.e., as the masses of the ions increase, they become closer together in flight time. This is a limiting parameter when considering the mass resolution of the TOF instrument.

The ion time of flight, as given by equation (B1.7.7), is oversimplified, however. There are a number of factors which change the final measured TOF. These are considered below.

(A) ION SOURCE RESIDENCE TIME

A schematic diagram of a simple TOF instrument is shown in [figure B1.7.17\(a\)](#). Since the ion source region of any instrument has a finite size, the ions will spend a certain amount of time in the source while they are accelerating. If the

initial velocity of the ions is v_0 , the time spent in the source, t_s , is given by

$$t_s = \frac{v_0 m}{zeV/d_s}$$

where v is the velocity of the ion, d_s is the width of the ion source and v/d_s represents the electric field strength inside the source. One obvious way to minimize this effect is to make the field strength as large as possible (by increasing V or decreasing d_s).

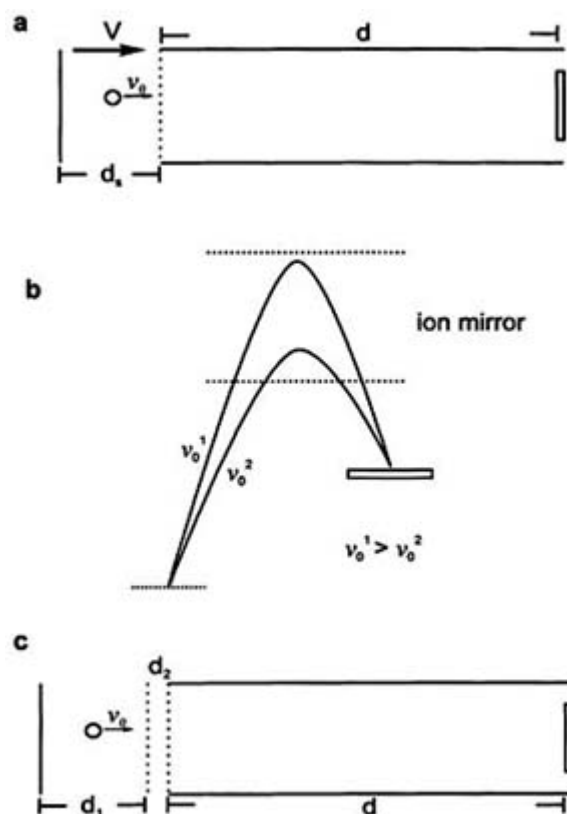

Figure B1.7.17. (a) Schematic diagram of a single acceleration zone time-of-flight mass spectrometer. (b) Schematic diagram showing the time focusing of ions with different initial velocities (and hence initial kinetic energies) onto the detector by the use of a reflecting ion mirror. (c) Wiley–McLaren type two stage acceleration zone time-of-flight mass spectrometer.

Ions generated in the ion source region of the instrument may have initial velocities isotropically distributed in three dimensions (for gaseous samples, this initial velocity is the predicted Maxwell–Boltzmann distribution at the sample temperature). The time the ions spend in the source will now depend on the direction of their initial velocity. At one extreme, the ions may have a velocity v_0 in the direction of the extraction grid. The time spent in the source will be

shorter than those with no component of initial velocity in this direction:

$$t_s = \frac{(v - v_0)m}{zeV/d_s}$$

At the other extreme, ions with initial velocities in the direction opposite to the accelerating potential must first be turned around and brought back to their initial position. From this point their behaviour is the same as described above. The time taken to turn around in the ion source and return to the initial position (t_r) is given by:

$$t_r = \frac{2v_0m}{zeV/d_s}$$

The final velocity of these two ions will be the same, but their final flight times will differ by the above turn-around time, t_r . This results in a broadening of the TOF distributions for each ion mass, and is another limiting factor when considering the mass (time) resolution of the instrument.

The final total ion time of flight in the TOF mass spectrometer with a single accelerating region can be written in a single equation, taking all of the above factors into account.

$$t_{\text{TOF}} = \frac{(2m)^{1/2}[(U_0 + zeV/d_s)^{1/2} \pm U_0^{1/2}]}{zeV/d_s} + \frac{(2m)^{1/2}d}{2(U_0 + zeV)^{1/2}}$$

where now the initial velocity has been replaced by the initial translational energy, U_0 . This is the equation published in 1955 by Wiley and McLaren [37] in their seminal paper on TOF mass spectrometry.

(B) ENERGY FOCUSING AND THE REFLECTRON TOF INSTRUMENT

The resolution of the TOF instrument can be improved by applying energy focusing conditions that serve to overcome the above stated spread in initial translational energies of the generated ions. While there have been several methods developed, the most successful and the most commonly used method is the reflectron. The reflectron is an ion mirror positioned at the end of the drift tube that retards the ions and reverses their direction. Ions with a higher kinetic energy penetrate into the mirror to a greater extent than those with lower kinetic energies. The result is a focusing (in time) at the detector of ions having an initial spread of kinetic energies (figure B1.7.17(b)). The mirror also has the effect of increasing the drift length without increasing the physical length of the instrument.

(C) SPATIAL FOCUSING

Another consideration when gaseous samples are ionized is the variation in where the ions are formed in the source. The above arguments assumed that the ions were all formed at a common initial position, but in practice they may be formed anywhere in the acceleration zone. The result is an additional spread in the final TOF distributions, since ions

made in different locations in the source experience different accelerating potentials and thus spend different

times in the source and drift tube.

Spatial focusing in a single acceleration zone linear TOF instrument naturally occurs at a distance of $2d_s$ along the drift tube, which is seldom a practical distance for a detector. Wiley and McLaren described a two stage accelerating zone that allows spatial focusing to be moved to longer distances. An example of such an instrument is shown in [figure B1.7.17\(c\)](#). The main requirement is for the initial acceleration region to have a much weaker field than the second. The equation relating the instrumental parameters in [figure B1.7.17\(c\)](#) is:

$$d = d_1 k^{3/2} \left(1 - \frac{1}{k + k^{1/2}} \frac{2d_2}{d_1} \right)$$

where $k = (\frac{1}{2}d_1E_1 + d_2E_2)/(\frac{1}{2}d_1E_1)$, and E_1 and E_2 are the field strengths in regions 1 and 2. So, if the physical dimensions of the instrument d_1 , d_2 and d are fixed, a solution can be obtained for the relative field strengths necessary for spatial focusing.

(D) OTHER IONIZATION SOURCES

Other methods of sample introduction that are commonly coupled to TOF mass spectrometers are MALDI, SIMS/FAB and molecular beams (see [section \(B1.7.2\)](#)). In many ways, the ablation of sample from a surface simplifies the TOF mass spectrometer since all ions originate in a narrow space above the sample surface. This reduces many of the complications arising from the need for spatial focusing. Also, the initial velocity of ions generated are invariably in the TOF direction.

Molecular beam sample introduction (described in [section \(B1.7.2\)](#)), followed by the orthogonal extraction of ions, results in improved resolution in TOF instruments over effusive sources. The particles in the molecular beam typically have translational temperatures orthogonal to the beam path of only a few Kelvin. Thus, there is less concern with both the initial velocity of the ions once they are generated and with where in the ion source they are formed (since the particles are originally confined to the beam path).

B1.7.5.2 EXPERIMENTS USING TOF MASS SPECTROMETERS

Time-of-flight mass spectrometers have been used as detectors in a wider variety of experiments than any other mass spectrometer. This is especially true of spectroscopic applications, many of which are discussed in this encyclopedia. Unlike the other instruments described in this chapter, the TOF mass spectrometer is usually used for one purpose, to acquire the mass spectrum of a compound. They cannot generally be used for the kinds of ion–molecule chemistry discussed in this chapter, or structural characterization experiments such as collision-induced dissociation. However, they are easily used as detectors for spectroscopic applications such as multi-photoionization (for the spectroscopy of molecular excited states) [38], zero kinetic energy electron spectroscopy [39] (ZEKE, for the precise measurement of ionization energies) and coincidence measurements (such as photoelectron–photoion coincidence spectroscopy [40] for the measurement of ion fragmentation breakdown diagrams).

Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometry is another in the class of trapping mass spectrometers and, as such is related to the quadrupole ion trap. The progenitor of FT-ICR, the ICR mass spectrometer, originated just after the Second World War when the cyclotron accelerator was developed into a means for selectively detecting ions other than protons. At the heart of ICR is the presence of a magnetic field that confines ions into orbital trajectories about their flight axis. Early ICR experiments mainly took advantage of this trapping and were focused on ion–molecule reactions. The addition of the three-dimensional trapping cell by McIver in 1970 [41, 42] led to improved storage of ions. In 1974 Comisarow and Marshall introduced the Fourier transform detection scheme that paved the way for FT-ICR [43, 44] which is now employed in virtually all areas in physical chemistry and chemical physics that use mass spectrometry.

B1.7.6.1 ION MOTION IN MAGNETIC AND ELECTRIC FIELDS

Figure B1.7.18(a) shows a typical FT-ICR mass spectrometer cubic trapping cell. The principal axes are shown in the diagram, along with the direction of the imposed magnetic field. To understand the trajectory of an ion in such a field, the electrostatic and magnetic forces acting on the ion must be described [45]. If only a magnetic field is present, the field acts on the ions such that they take up circular orbits with a frequency defined by the ion mass:

$$\omega_c = \frac{zeB}{m}$$

where ze is the charge on the ion, B is the magnetic field strength (in tesla), m is the ion mass and ω_c is the ion's cyclotron frequency (in rad s^{-1}). In modern FT-ICR instruments, magnetic fields of 6 T or more are common, with the latest being upwards of 20 T. These high field magnets are usually superconducting magnets, not unlike modern NMR instruments. Without trapping electrodes, the ions would describe a spiral trajectory and be lost from the trap.

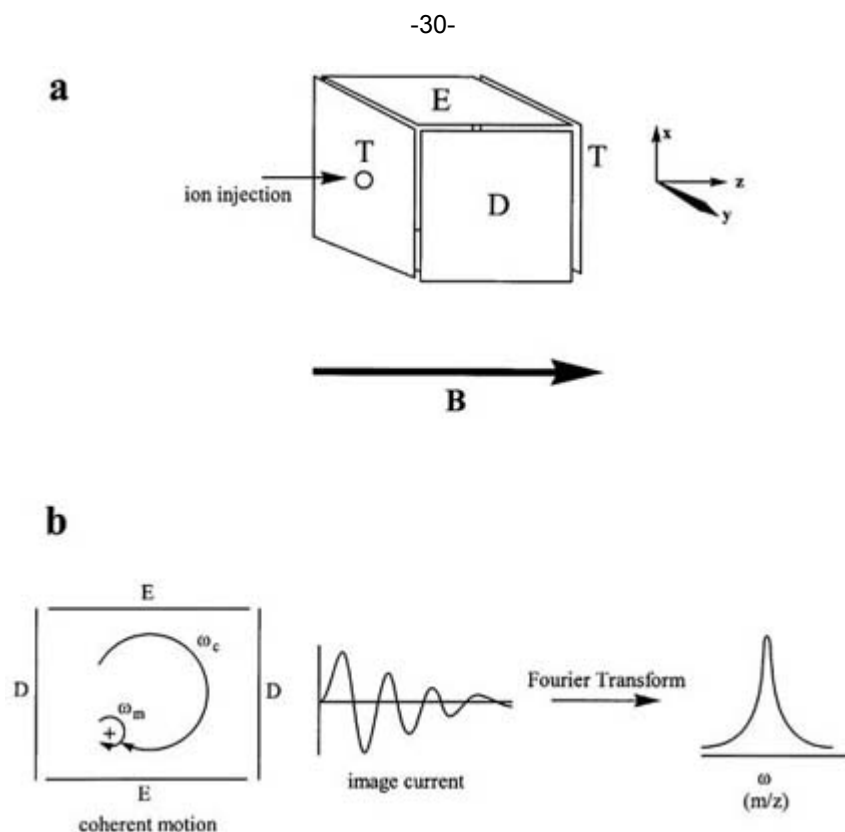

Figure B1.7.18. (a) Schematic diagram of the trapping cell in an ion cyclotron resonance mass spectrometer: excitation plates (E); detector plates (D); trapping plates (T). (b) The magnetron motion (ω_m) due to the crossing of the magnetic and electric trapping fields is superimposed on the circular cyclotron motion (ω_c) taken up by the ions in the magnetic field. Excitation of the cyclotron frequency results in an image current being detected by the detector electrodes which can be Fourier transformed into a secular frequency related to the m/z ratio of the trapped ion(s).

The circular orbits described above are perturbed by an electrostatic field applied to the two endcap trapping electrodes (figure B1.7.18(b)). In addition to the trapping motion, the crossed electric and magnetic fields superimpose a magnetron motion, ω_m , on the ions (figure B1.7.18(b)). An idealized trapping cell would produce a DC quadrupolar potential in three dimensions. The resulting ion motion is independent of the axial and radial position in the cell. In practice, however, the finite size of the trapping cell produces irregularities in the potential that affect ion motion.

(A) ION TRAPPING

The component of the DC quadrupolar potential in the z -axis direction is described by the following equation.

-31-

$$V(z) = \frac{V_T}{2} + \frac{kz^2}{2}$$

where k is a constant and V_T is the trapping potential applied to the endcap electrodes of the trapping cell. The derivative of this relationship yields a linear electric field along the z -axis.

$$E(z) = -kz.$$

From this relationship, an expression can be derived for the trapping frequency, ω_t .

$$\omega_t = \left(\frac{kze}{m} \right)^{1/2}$$

which again is a function of ion charge and mass. In theory, this trapping frequency is harmonic and independent of the ion's position in the trapping cell, but in practice, the finite size of the trapping cell produces irregularities in ω_t . The efficiency with which ions are trapped and stored in the FT-ICR cell diminishes as the pressure in the cell increases (as opposed to the quadrupole ion trap, which requires helium buffer gas for optimal trapping). For this reason, FT-ICR instruments are typically operated below 10^{-5} Torr (and usually closer to 10^{-8} Torr).

(B) ION DETECTION

In the other types of mass spectrometer discussed in this chapter, ions are detected by having them hit a detector such as an electron multiplier. In early ICR instruments, the same approach was taken, but FT-ICR uses a very different technique. If an RF potential is applied to the excitation plates of the trapping cell (figure B1.7.18(b)) equal to the cyclotron frequency of a particular ion m/z ratio, resonant excitation of the ion trajectories takes place (without changing the cyclotron frequency). The result is ion trajectories of higher

kinetic energy and larger radii inside the trapping cell. In addition, all of the ions with that particular m/z ratio take up orbits that are coherent (whereas they were all out of phase prior to resonant excitation). This coherent motion induces an image current on the detector plates of the trapping cell that has the same frequency as the cyclotron frequency (figure B1.7.18(b)). This image current is acquired over a period of time as the ion packet decays back to incoherent motion. The digitized time-dependent signal can be Fourier transformed to produce a frequency spectrum with one component, a peak at the cyclotron frequency of the ions. It is possible to resonantly excite the trajectories of all ions in the trapping cell by the application of a broad-band RF excitation pulse to the excitation electrodes. The resulting time-dependent image current, once Fourier transformed, yields a frequency spectrum with peaks due to each ion m/z in the trapping cell, and hence a mass spectrum. The intensities of the peaks are proportional to the concentrations of the ions in the cell.

B1.7.6.2 EXPERIMENTS USING FT-ICR

In many respects, the applications of FT-ICR are similar to those of the quadrupole ion trap, as they are both trapping instruments. The major difference is in the ion motion inside the trapping cell and the waveform detection. In recent

-32-

years there have been attempts to use waveform detection methods with quadrupole ion traps [46].

(A) COLLISION-INDUCED DISSOCIATION AND ION–MOLECULE REACTIONS

As with the quadrupole ion trap, ions with a particular m/z ratio can be selected and stored in the FT-ICR cell by the resonant ejection of all other ions. Once isolated, the ions can be stored for variable periods of time (even hours) and allowed to react with neutral reagents that are introduced into the trapping cell. In this manner, the products of bi-molecular reactions can be monitored and, if done as a function of trapping time, it is possible to derive rate constants for the reactions [47]. Collision-induced dissociation can also be performed in the FT-ICR cell by the isolation and subsequent excitation of the cyclotron frequency of the ions. The extra translational kinetic energy of the ion packet results in energetic collisions between the ions and background gas in the cell. Since the cell in FT-ICR is nominally held at very low pressures (10^{-8} Torr), CID experiments using the background gas tend not to be very efficient. One common procedure is to pulse a target gas (such as Ar) into the trapping cell and then record the CID mass spectrum once the gas has been pumped away. CID mass spectra obtained in this way are similar to those obtained on triple quadrupole and ion trap instruments.

(B) KINETIC STUDIES

Aside from the bimolecular reaction kinetics described above, it is possible to measure other types of kinetics with FT-ICR. Typically, for two species to come together in the gas phase to form a complex, the resulting complex will only be stable if a three body collision occurs. The third body is necessary to lower the internal energy of the complex below its dissociation threshold. Thus, complexes are generally made in high pressure ion sources. It is possible, however, for the complex to radiatively release excess internal energy. Dunbar and others [48, 49] have studied and modelled the kinetics of such ‘radiative association’ reactions in FT-ICR trapping cells because of the long time scales of the experiments (reaction progress is usually probed for many minutes). The rate constants for photon emission derived from the experimentally observed rate constants tend to be between 10 and 100 s^{-1} . It has also been found that ions can be dissociated by the absorption of blackbody radiation in the trapping cell (BIRD—blackbody infrared radiative dissociation) [50]. This technique, which is only feasible at the low pressures ($<10^{-8}$ Torr) and long trapping times inside the FT-ICR cell, allows the investigator to measure unimolecular decay rate constants of the order of 10^{-3} s^{-1} . Another approach to dissociation kinetics is time-resolved photodissociation [51]. Ions are photodissociated with laser

light in the visible and near UV and the product ion intensity is monitored as a function of time. Rate constants from 10^{-3} s^{-1} and higher can be measured with good precision using this technique.

(C) THERMOCHEMICAL STUDIES: THE BRACKETING METHOD

In an earlier section, measurements were described in which the equilibrium constant, K , for bimolecular reactions involving gas-phase ions and neutral molecules were determined. Another method for determining the proton or other affinity of a molecule is the bracketing method [52]. The principle of this approach is quite straightforward. Let us again take the case of a proton affinity determination as an example. In a reaction between a protonated base, B_1H^+ and a neutral molecule, B_2 , proton transfer from B_1 to B_2 will presumably occur only if the reaction is exothermic (in other words, if the PA of B_2 is greater than that of B_1). So, by choosing a range of bases B_1 covering a range of PA values and reacting them with a molecule of unknown PA, B_2 , the reactions leading to B_2H^+ can be monitored by the presence of this latter ion in the mass spectrum. The PA of B_2 can quickly be narrowed down provided the reference values are well established. The nature of this experiment requires that a bimolecular reaction takes place between the reference

-33-

base and unknown and thus these experiments are most commonly carried out in FT-ICR mass spectrometers, though quadrupole ion trap instruments have also been used.

B1.8 Diffraction: x-ray, neutron and electron

Edward Prince

B1.8.1 INTRODUCTION

Diffraction is the deflection of beams of radiation due to interference of waves that interact with objects whose size is of the same order of magnitude as the wavelengths. Molecules and solids typically have interatomic distances in the neighbourhood of a few Ångströms ($1 \text{ \AA} = 10^{-10} \text{ m}$), comparable to the wavelengths of x-rays with energies of the order of 10 keV. Neutrons and electrons also have wave properties, with wavelengths given by the de Broglie relation, $\lambda = h/mv$, where h is Planck's constant, m is the mass of the particle and v is its velocity. Neutron diffraction applications use neutrons with wavelengths in the range from 1 to 10 Å; most electron diffraction applications use wavelengths of the order of 0.05 Å, although low energy electron diffraction (LEED), used for studies of surfaces, employs electrons with wavelengths in the neighbourhood of 1 Å. All three techniques have extensive applications in physics, chemistry, materials science, mineralogy and molecular biology. Although perhaps the most familiar application is determination of the structures of crystalline solids, there are also applications to structural studies of amorphous solids, liquids and gases. Diffraction also plays an important role in imaging techniques such as electron microscopy.

B1.8.2 PRINCIPLES OF DIFFRACTION

B1.8.2.1 THE ATOMIC SCATTERING FACTOR

We shall first discuss the diffraction of x-rays from isolated atoms, because this case illustrates principles that can be generalized to most practical applications. Consider [1] an atom consisting of a nucleus surrounded by a spherically symmetric cloud of electrons that can be represented by a density function $\rho(\mathbf{r})$ and a plane wave that can be described by a vector \mathbf{s}_i normal to the wave front with magnitude $1/\lambda$, where λ is the wavelength. According to Huygens's principle, each point within the electron cloud is the source of a spherical wavelet whose amplitude is proportional to $\rho(\mathbf{r})$. At a distance large compared with the dimensions of the atom this spherical wavelet will approximate a new plane wave and we are interested in the amplitude of the wave formed by the interference of the wavelets originating at all points within the electron cloud. Referring to [figure B1.8.1](#) the difference in pathlength for a wave propagating in the direction of \mathbf{s}_f ($|\mathbf{s}_f| = |\mathbf{s}_i|$) and originating at point \mathbf{r} , relative to the wave originating at the origin, is $\Delta l = \lambda \mathbf{r} \cdot (\mathbf{s}_f - \mathbf{s}_i)$, and the difference in phase is therefore $\Delta\phi = 2\pi i \mathbf{r} \cdot (\mathbf{s}_f - \mathbf{s}_i)$. The *atomic scattering factor*, $f(\mathbf{s}_f)$, is the amplitude of the resultant wave in the direction parallel to \mathbf{s}_f which is the vector sum of all contributions. This is given by

$$f(\mathbf{s}_f) = C \int \rho(\mathbf{r}) \exp[2\pi i \mathbf{r} \cdot (\mathbf{s}_f - \mathbf{s}_i)] d\tau \quad (\text{B1.8.1})$$

where the integral is over the volume of the atom and C is a proportionality constant. $f(\mathbf{s}_f)$ is therefore proportional to the Fourier transform of the electron density distribution, $\rho(\mathbf{r})$.

-2-

To evaluate this integral, first let $\mathbf{Q} = 2\pi(\mathbf{s}_f - \mathbf{s}_i)$, let $Q = |\mathbf{Q}|$, let $r = |\mathbf{r}|$ and let α be the angle between \mathbf{r} and \mathbf{Q} . Now $|\mathbf{s}_f - \mathbf{s}_i| = 2|\mathbf{s}_i| \sin\theta = 2 \sin\theta/\lambda$, so that

$$\mathbf{r} \cdot (\mathbf{s}_f - \mathbf{s}_i) = 2r|\mathbf{s}_i| \sin\theta \cos\alpha = 2r \sin\theta \cos\alpha/\lambda.$$

The area of a ring around \mathbf{Q} with width $d\alpha$ at radius r is $2\pi r^2 \sin\alpha d\alpha$, so

$$d\tau = 2\pi r^2 \sin\alpha d\alpha dr.$$

Because $\rho(\mathbf{r})$ is spherically symmetric, the number of electrons in this volume element is $\rho(r) d\tau$. Letting $x = Qr \cos\alpha$, $d\alpha = -dx/(Qr \sin\alpha)$. Then, making all substitutions,

$$f(\mathbf{Q}) = C \int_0^\infty \frac{2\pi r^2}{Qr} \rho(r) dr \int_{-Qr}^{Qr} \exp(ix) dx \quad (\text{B1.8.2a})$$

$$= 4\pi C \int_0^\infty r^2 \rho(r) \frac{\sin(Qr)}{Qr} dr. \quad (\text{B1.8.2b})$$

If $\theta = 0$, so that $Q = 0$, this reduces to

$$f(0) = 4\pi C \int_0^\infty r^2 \rho(r) dr \quad (\text{B1.8.3})$$

so that the integral is the total charge in the electron cloud. The constant C has the units of a length, and is

conventionally chosen so that $f(Q)$ is a multiple of the ‘classical electron radius’, 2.818×10^{-15} m.

Figure B1.8.1. The atomic scattering factor from a spherically symmetric atom. The volume element is a ring subtending angle α with width $d\alpha$ at radius r and thickness dr .

The electron distribution, $\rho(r)$, has been computed by quantum mechanics for all neutral atoms and many ions and the values of $f(Q)$, as well as coefficients for a useful empirical approximation, are tabulated in the *International Tables for Crystallography* vol C [2]. In general, $f(Q)$ is a maximum equal to the nuclear charge, Z , for $Q = 0$ and decreases monotonically with increasing Q .

Because the neutron has a magnetic moment, it has a similar interaction with the clouds of unpaired d or f electrons in magnetic ions and this interaction is important in studies of magnetic materials. The magnetic analogue of the atomic scattering factor is also tabulated in the *International Tables* [3]. Neutrons also have direct interactions with atomic nuclei, whose mass is concentrated in a volume whose radius is of the order of 10^{-5} times the characteristic neutron wavelength. Thus $\rho(r)$ differs from zero only when $\sin(Qr)/Qr$ is effectively equal to one, so that $f(Q)$ is a constant independent of Q . Whereas the x-ray interaction depends on the total number of electrons in the cloud, and therefore on the nuclear charge, the neutron's interaction with a nucleus results from nuclear forces that vary in a haphazard manner from one isotope to another, lie within a rather narrow range and can even be negative, meaning that the Huygens wavelet from such a nucleus has a phase differing by π from the phase of one from a nucleus whose scattering factor is positive. The neutron scattering factors, or *scattering lengths*, conventionally denoted by b , have magnitudes in the range $1-10 \times 10^{-15}$ m [4].

The atomic scattering factor for electrons is somewhat more complicated. It is again a Fourier transform of a density of scattering matter, but, because the electron is a charged particle, it interacts with the nucleus as well as with the electron cloud. Thus $\rho(r)$ in equation (B1.8.2b) is replaced by $\varphi(r)$, the electrostatic potential of an electron situated at radius r from the nucleus. Under a range of conditions the electron scattering factor, $f_e(Q)$, can be represented in terms

of the x-ray atomic scattering factor by the so-called Mott–Bethe formula,

$$f_e(Q) = 2\pi \frac{me^2}{h^2\epsilon_0} [Z - f_x(Q)]/Q^2 \quad (\text{B1.8.4})$$

where m is the mass of the electron, e is its charge and ϵ_0 is the permittivity of free space.

B1.8.2.2 DIFFRACTION FROM CLUSTERS OF ATOMS

The derivation of [equation \(B1.8.1\)](#) makes no use of the assumption of spherical symmetry and it is, in fact, a very general result that the amplitude of a scattered wave is the Fourier transform of a density of scattering matter. Although there are examples of experimental observations of scattering from isolated atoms, one being the scattering of neutrons by a dilute solid solution of paramagnetic atoms in a diamagnetic matrix, diffraction from molecules, such as that of electrons in a gas, or from particles of contrasting density in a uniform medium are much more important. Examples of the latter are colloidal suspensions in a fluid and precipitates in an alloy. Note that the particles of contrasting density can also be voids: Babinet's principle requires that the amplitude of a scattered wave due to a negative difference be the complex conjugate of that due to a positive difference and, because the intensity of scattered radiation is proportional to the square of the modulus of the amplitude, the diffraction patterns are indistinguishable.

If individual scattering particles are far enough apart and their spatial distribution is such that the relative phases of their contributions to a scattered wave are random, the intensity distribution in the diffraction pattern will be the sum of contributions from all particles [5]. If the particles are identical (monodisperse) but have random orientations, or if they differ in size and shape (polydisperse), the resulting pattern will reflect an ensemble average over the sample. In either case there will be a spreading of the incident beam, so-called *small-angle scattering*. How small the angles are depends on the wavelength of the radiation and the size of the particles: long wavelengths give larger angles, but they also tend to be more strongly absorbed by the sample, so that there is a trade-off between resolution and intensity.

B1.8.2.3 DIFFRACTION FROM CRYSTALLINE SOLIDS

(A) BRAGG'S LAW

The diffraction of x-rays was first observed in 1912 by Laue and coworkers [6]. A plausible, though undocumented, story says that the classic experiment was inspired by a seminar given by P P Ewald, whose doctoral thesis was a purely theoretical study of the interaction of electromagnetic waves with an array of dipoles located at the nodes of a three-dimensional lattice. At the time it was hypothesized that crystals were composed of parallelepipedal building blocks, *unit cells*, fitted together in three dimensions and that x-rays were short-wavelength, electromagnetic radiation, but neither hypothesis had been confirmed experimentally. The Laue experiment confirmed both, but the application of x-ray diffraction to the determination of crystal structure was introduced by the Braggs.

W L Bragg [7] observed that if a crystal was composed of copies of identical unit cells, it could then be divided in many ways into slabs with parallel, plane faces whose distributions of scattering matter were identical and that if the pathlengths travelled by waves reflected from successive, parallel planes differed by integral multiples of the

wavelength there would be strong, constructive interference. Figure B1.8.2 shows a projection of parallel planes separated by a distance d and a plane wave with wavelength λ whose normal makes an angle θ with these reflecting planes. It is evident that the crests of waves reflected from successive planes will be in phase if $\lambda = 2d \sin\theta$, a relation that is known as *Bragg's law*. (It appears that W H Bragg played no role in the formulation of this relation, so it is correctly Bragg's law, not Bragg's law. In textbooks the relation is often stated in the form $n\lambda = 2d \sin\theta$, where n is the 'order' of the reflection, but in crystallography the order is conventionally incorporated in the definition of d .)

Figure B1.8.2. Bragg's law. When $\lambda = 2d \sin \theta$, there is strong, constructive interference.

(B) THE RECIPROCAL LATTICE

The vertices of the unit cells form an array of points in three-dimensional space, a *space lattice*. The edges of the parallelepiped can be defined by three non-coplanar vectors, \mathbf{a} , \mathbf{b} and \mathbf{c} , and then any lattice point can then be defined by a vector $\mathbf{r} = u\mathbf{a} + v\mathbf{b} + w\mathbf{c}$, where u , v and w are integers. Any point in the crystal can be specified by a vector $\mathbf{r} + \mathbf{x}$, where \mathbf{x} represents a vector within the unit cell. The periodicity of the crystal specifies that $\rho(\mathbf{r} + \mathbf{x}) = \rho(\mathbf{x})$. The families of parallel planes are specified by their *Miller indices*, conventionally denoted by h , k and l . The three points that define the plane closest to the origin are \mathbf{a}/h , \mathbf{b}/k and \mathbf{c}/l , with the understanding that if any of the indices is equal to zero, the plane is parallel to the corresponding vector. To find solutions to the Bragg equation it is necessary to determine the value of d . If \mathbf{a} , \mathbf{b} and \mathbf{c} are orthogonal, this is easy, but for most crystals they are not, and the computation is greatly simplified by use of the *reciprocal lattice*. The reciprocal lattice, which was introduced by J W Gibbs [8] and applied to the crystallographic problem by Ewald [9], is defined by three vectors, $\mathbf{a}^* = (\mathbf{b} \times \mathbf{c})/V$, $\mathbf{b}^* = (\mathbf{c} \times \mathbf{a})/V$ and $\mathbf{c}^* = (\mathbf{a} \times \mathbf{b})/V$, where $V = \mathbf{a} \cdot \mathbf{b} \times \mathbf{c}$ is the volume of the unit cell. It can easily be shown [10] that the vector $\mathbf{d}^* = h\mathbf{a}^* + k\mathbf{b}^* + l\mathbf{c}^*$ is perpendicular to the planes defined by the Miller indices h , k and l , and that $|\mathbf{d}^*| = 1/d$. Bragg's law then becomes $\sin\theta = \lambda|\mathbf{d}^*|/2$. Note that if $\mathbf{d}^* = s_f - s_i$, as shown in figure B1.8.3 this condition will be satisfied on the surface of a sphere (the *Ewald sphere*) passing through the origin of the reciprocal lattice whose centre is at the point $-\mathbf{s}_i$ in reciprocal space.

Figure B1.8.3. Ewald's reciprocal lattice construction for the solution of the Bragg equation. If $\mathbf{s}_f - \mathbf{s}_i$ is a vector of the reciprocal lattice, Bragg's law is satisfied for the corresponding planes. This occurs if a reciprocal lattice point lies on the surface of a sphere with radius $1/\lambda$ whose centre is at $-\mathbf{s}_i$.

(C) THE STRUCTURE AMPLITUDE

The amplitude and therefore the intensity, of the scattered radiation is determined by extending the Fourier transform of [equation \(B1.8.1\)](#) over the entire crystal and Bragg's law expresses the fact that this transform has values significantly different from zero only at the nodes of the reciprocal lattice. The amplitude varies, however, from node to node, depending on the transform of the contents of the unit cell. This leads to an expression for the *structure amplitude*, denoted by $F(hkl)$, of the form

$$F(hkl) = C \int_0^c dz \int_0^b dy \int_0^a \rho(x, y, z) \exp \left[2\pi i \left(h \frac{x}{a} + k \frac{y}{b} + l \frac{z}{c} \right) \right] dx \quad (\text{B1.8.5})$$

where $a = |\mathbf{a}|$, $b = |\mathbf{b}|$, $c = |\mathbf{c}|$ and x , y and z are the coordinates of a point in a (not necessarily orthogonal) Cartesian system defined by \mathbf{a} , \mathbf{b} and \mathbf{c} . Making use of the fact that the unit cell contents consist of atoms, each of which has its own atomic scattering factor, $f_j(d^*)$, this can be written

$$F(hkl) = C \sum_{j=1}^N f_j(d^*) \exp \left[2\pi i \left(h \frac{x}{a} + k \frac{y}{b} + l \frac{z}{c} \right) \right] \quad (\text{B1.8.6})$$

where $d^* = |\mathbf{d}^*|$ and the sum is over N atoms in the unit cell.

[Equation \(B1.8.6\)](#) assumes that all unit cells really *are* identical and that the atoms are fixed in their equilibrium positions. In real crystals at finite temperatures, however, atoms oscillate about their mean positions and also may be displaced from their average positions because of, for example, chemical inhomogeneity. The effect of this is, to a first approximation, to modify the atomic scattering factor by a convolution of $\rho(\mathbf{r})$ with a trivariate Gaussian density function, resulting in the multiplication of $f_j(d^*)$ by $\exp(-M)$, where

$$M = 8\pi^2 \overline{u_j^2} \sin^2 \theta / \lambda^2 \quad (\text{B1.8.7})$$

and $\overline{u_j^2}$ is the mean square displacement of the centre of atom j parallel to \mathbf{d}^* . The factor $\exp(-M)$ is the *atomic displacement factor*, or, in older literature, the *temperature factor* or, for early workers in the field, the *Debye–Waller factor*.

(D) DIFFRACTION OF NEUTRONS FROM NONMAGNETIC AND MAGNETIC CRYSTALS

Diffraction of neutrons [11] from nonmagnetic crystals is similar to that of x-rays, with the neutron atomic scattering factor substituted for the x-ray one. For magnetic crystals below their ordering temperatures, however, the neutron's magnetic moment interacts with an ordered array of electron spins, with the strength of the interaction being proportional to $\sin \alpha$, where α is the angle between \mathbf{d}^* and the electron spin axis, and the phases of the wavelets originating at different atoms depend on the relative orientations of their magnetic moments as well as on the path length. The electron spins may all point in the same direction, a *ferromagnet*, or those on different atoms may point in opposite directions, in equal numbers and in an ordered arrangement, an *antiferromagnet*, or they may be arranged in more complicated ways having a net magnetic moment, a so-called *ferrimagnet*. In the absence of an applied magnetic field the crystal tends to divide into domains in which the electron spins point along different, symmetry-equivalent directions and the diffracted intensities are averaged over the various possible values of the angle between the magnetic moment and \mathbf{d}^* . Furthermore, the magnetic diffraction and the nuclear diffraction do not interfere with one another, and the nuclear and magnetic intensities simply add together, although in many cases the magnetic unit cell is larger than the nuclear unit cell, which produces additional diffraction peaks.

If a magnetic field is applied to the crystal, the domains become aligned and the nuclear and magnetic wavelets *do* interfere with one another. Then the amplitude of the diffracted wave depends on the orientation of the neutron spin. In special cases, $\text{Co}_{0.92}\text{Fe}_{0.08}$ is an example, the interference may be totally destructive for one neutron spin state and the diffracted beam becomes polarized. If a crystal of one of these materials is used as a monochromator, the diffraction of this polarized beam is a particularly sensitive probe for the study of magnetic structures.

(E) DIFFRACTION OF ELECTRONS FROM CRYSTALS

Diffraction of electrons from single crystals [12] differs from the diffraction of x-rays or neutrons because the interaction of electrons with matter is much stronger. Conventional electron diffraction is performed as an adjunct to electron microscopy. In fact, the same instrument, a transmission electron microscope, commonly serves for both, with the configuration of the electron optics determining whether a diffraction pattern is magnified, or the diffracted beams are recombined to form an image. Because of the strong interaction, specimens must be thin, and accelerating

voltages must be large, of the order of 100 keV, so that the corresponding wavelength is much shorter than interatomic distances in a crystal, and the Ewald sphere is large compared with the spacing between points of the reciprocal lattice. As a result, when the direction of the incident beam is perpendicular to a reciprocal lattice plane, the small spread of the reciprocal lattice due to mosaic spread in the crystal produces a diffraction pattern that consists of spots with the structure of the reciprocal lattice plane.

Another mode of electron diffraction, low energy electron diffraction or LEED [13], uses incident beams of electrons with energies below about 100 eV, with corresponding wavelengths of the order of 1 Å. Because of the very strong interactions between the incident electrons and the atoms in the crystal, there is very little penetration of the electron waves into the crystal, so that the diffraction pattern is determined entirely by the

arrangement of atoms close to the surface. Thus, in contrast to high energy diffraction, where the pattern is formed by transmission through a thin, crystalline film, and the diffracted beams make angles of only a fraction of a degree with the incident beam, the pattern in LEED is formed by reflection from a surface, and the diffracted beam may be in any direction away from the surface. Furthermore, because there is no significant interference with scattered wavelets coming from below the surface, the reciprocal lattice can be considered to consist not of points but of lines perpendicular to the surface that will always intersect the Ewald sphere, so that even with a monochromatic incident beam there will always be a pattern of spots on a photographic plate or a fluorescent screen.

Although the structure of the surface that produces the diffraction pattern must be periodic in two dimensions, it need not be the same substance as the bulk material. Thus LEED is a particularly sensitive tool for studying the structures and properties of thin layers adsorbed epitaxially on the surfaces of crystals.

B1.8.2.4 DIFFRACTION FROM NONCRYSTALLINE SOLIDS

We have seen that the intensities of diffraction of x-rays or neutrons are proportional to the squared moduli of the Fourier transform of the scattering density of the diffracting object. This corresponds to the Fourier transform of a convolution, $P(\mathbf{s})$, of the form

$$P(\mathbf{s}) = \int \rho(\mathbf{r})\rho(\mathbf{r} + \mathbf{s}) d\mathbf{r}. \quad (\text{B1.8.8})$$

The integrand in this expression will have a large value at a point \mathbf{r} if $\rho(\mathbf{r})$ and $\rho(\mathbf{r}+\mathbf{s})$ are both large, and $P(\mathbf{s})$ will be large if this condition is satisfied systematically over all space. It is therefore a self- or autocorrelation function of $\rho(\mathbf{r})$. If $\rho(\mathbf{r})$ is periodic, as in a crystal, $P(\mathbf{s})$ will also be periodic, with a large peak when \mathbf{s} is a vector of the lattice and also will have a peak when \mathbf{s} is a vector between any two atomic positions. The function $P(\mathbf{s})$ is known as the *Patterson function*, after A L Patterson [14], who introduced its application to the problem of crystal structure determination.

(A) DIFFRACTION FROM GLASSES

There are two classes of solids that are not crystalline, that is, $\rho(\mathbf{r})$ is not periodic. The more familiar one is a glass, for which there are again two models, which may be called the random network and the random packing of hard spheres. An example of the first is silica glass or fused quartz. It consists of tetrahedral SiO_4 groups that are linked at their vertices by Si–O–Si bonds, but, unlike the various crystalline phases of SiO_2 , there is no systematic relation between

the orientations of neighbouring tetrahedra. In the random packing of spheres there is no regular arrangement of atoms even at short range and the coordination of any particular atom may have a wide variety of configurations. The two types of glass have similar diffraction properties, so we do not need to discuss them separately.

If the material is not periodic (but is isotropic), the integral in equation (B1.8.8) becomes spherically symmetric, and reduces for large values of s ($= |\mathbf{s}|$) to a constant equal to the average value of $\rho(\mathbf{r})^2$. In either the sphere-packing model or the random-network model, however, there is always a shortest interatomic distance and $\rho(\mathbf{r})$ falls to a small value between the atoms. The integrand will then have, on average, small values when s is equal to an atomic radius and large values when s is equal to a typical interatomic distance. The integrand and therefore $P(\mathbf{s})$, will have smaller ripples as s increases through additional coordination shells. Because the diffracted intensity is proportional to the Fourier transform of $P(\mathbf{s})$, it will also have broad

maxima and minima as $\sin \theta/\lambda$ increases.

(B) QUASICRYSTALS

The other type of noncrystalline solid was discovered in the 1980s in certain rapidly cooled alloy systems. D Shechtman and coworkers [15] observed electron diffraction patterns with sharp spots with fivefold rotational symmetry, a symmetry that had been, until that time, assumed to be impossible. It is easy to show that it is impossible to fill two- or three-dimensional space with identical objects that have rotational symmetries of orders other than two, three, four or six, and it had been assumed that the long-range periodicity necessary to produce a diffraction pattern with sharp spots could only exist in materials made by the stacking of identical unit cells. The materials that produced these diffraction patterns, but clearly could not be crystals, became known as *quasicrystals*.

Although details of quasicrystal structure remain uncertain, the circumstances under which diffraction patterns with ‘impossible’ symmetries can occur have become clear [16]. It is impossible to construct an object that has long-range periodicity using identical units with these symmetries, but it is not necessary for the object itself to have that symmetry. It is only necessary that its Patterson function be symmetric. The electron diffraction patterns observed by Shechtman actually have the symmetry of a regular icosahedron, and it is possible to build a structure with this symmetry using two rhombohedra, each having faces whose acute angle corners have an angle, α , equal to $2 \arctan[2/(1 + \sqrt{5})] = 63.435^\circ$. One of them has three acute angle corners meeting at a vertex, making a prolate rhombohedron, while the other has three obtuse angle corners meeting at a vertex, making an oblate rhombohedron. Large objects made from these two rhombohedra contain vectors parallel to all of the fivefold axes of the regular icosahedron, although different subsets of them appear in different, finite regions. More importantly, although there is no long range periodicity, departures from periodicity are bounded, which produces, as in a crystal, families of parallel planes with alternately higher and lower density. This in turn produces the observed, sharp diffraction spots.

B1.8.3 STRUCTURE DETERMINATION

We have thus far discussed the diffraction patterns produced by x-rays, neutrons and electrons incident on materials of various kinds. The experimentally interesting problem is, of course, the inverse one: given an observed diffraction pattern, what can we infer about the structure of the object that produced it? Diffraction patterns depend on the Fourier transform of a density distribution, but computing the inverse Fourier transform in order to determine the density distribution is difficult for two reasons. First, as can be seen from [equation \(B1.8.1\)](#), the Fourier transform is

-10-

defined for all values of s_f , but it can be measured only for values of $|s_f - s_i|$ less than $2/\lambda$. For practical reasons λ cannot be arbitrarily small, so that the Fourier transform can never be measured over its entire range. Second, the value of the Fourier transform is in general a complex number. Denoting $-\mathbf{h}$, $-\mathbf{k}$ and $-\mathbf{l}$ by \mathbf{h} , \mathbf{k} , and \mathbf{l} , respectively, [equation \(B1.8.6\)](#) shows that, for a crystal, $I(\mathbf{hkl}) = |F(\mathbf{hkl})|^2 = F(\mathbf{hkl})F(\mathbf{hkl})^*$, it will be the same independent of the phase of $F(\mathbf{hkl})$. As a result, the structural information that can be determined is either restricted to averaged properties that do not depend on phase information, or the phase must be determined by methods other than the simple measurement of diffraction intensities.

B1.8.3.1 SMALL-ANGLE SCATTERING

Materials have many properties that are important, scientifically and technologically, that do not depend on the details of long-range structure. For example, consider a solution of globular macromolecules in a solvent

of contrasting scattering density. If the solution is not too highly concentrated, so that intermolecular interactions can be neglected, the diffraction pattern will be the sum of the diffraction patterns of all individual molecules. Under these conditions all diffracted radiation makes a small angle with the incident beam. Although all molecules are identical, they can have all possible orientations relative to the incident beam, so the diffraction will be that from a spherically averaged distribution. The intensity of diffraction is proportional to the squared modulus of the Fourier transform of the density distribution, which is the Fourier transform of its Patterson function. An expression for the intensity, $I(\mathbf{Q})$, can be derived by substituting $\mathbf{P}(\mathbf{r})$ for $\rho(\mathbf{r})$ in [equation \(B1.8.2b\)](#), giving

(B1.8.9a)

where C is a scale factor dependent on the conditions of the experiment. This can be rewritten

(B1.8.9b)

The inverse of this Fourier sine transform is

(B1.8.10a)

It is conventional to express the structural information in terms of a *pair distance distribution function*, or PDDF [5], which is defined by $p(r) = r^2 P(r)$. Using this, [equation \(B1.8.10\)](#) becomes

(B1.8.10b)

-11-

[Equation \(B1.8.9a\)](#) and [Equation \(B1.8.10b\)](#) both involve integrals whose upper limits are infinite, but this does not present a serious problem, because $\mathbf{P}(\mathbf{r})$ is zero for r greater than the largest diameter of the molecule, and $I(\mathbf{Q})$ has a value significantly different from zero only for small angles. The functions $p(r)$ and $I(\mathbf{Q})$ both contain information about the sizes and shapes of the molecules. It is customary to plot the logarithm of $I(\mathbf{Q})$ as a function of Q and such a plot for a spherical molecule has broad maxima with sharp minima between them, while less symmetric molecules produce curves with smaller ripples or a smooth falloff with increasing angle. A useful property of the molecule is the radius of gyration, R_g , which is a measure of the distribution of scattering density. This may be determined from the relation

$$R_g^2 = \frac{\int_0^\infty r^2 p(r) dr}{\int_0^\infty p(r) dr}. \quad (\text{B1.8.11})$$

The volume of a uniform density molecule may be found from the relation

$$V = C'' \frac{\int_0^\infty p(r) dr}{\int_0^\infty Q^2 I(Q) dQ} \quad (\text{B1.8.12})$$

where $C'' = 8\pi^3$ if the measurements are on an absolute scale. In practice, measurements are relative to a standard sample of known structure.

Although this discussion has been in terms of molecules in solution, the same principles apply to other cases, such as precipitates in an alloy or composites of ceramic particles dispersed in a polymer. The density, $\rho(r)$, is

not relative to a vacuum, but is rather relative to a uniform medium. For x-rays this means electron densities, but for neutrons, because the atomic scattering factor is different from one isotope to another, an effect that is very large for the two stable isotopes of hydrogen, there can be wide variations in contrast depending on the isotopic compositions of the different components of the sample. This ‘contrast variation’ makes small-angle neutron scattering (SANS) a very versatile tool for the study of microstructure.

It has been shown that spherical particles with a distribution of sizes produce diffraction patterns that are indistinguishable from those produced by triaxial ellipsoids. It is therefore possible to assume a shape and determine a size distribution, or to assume a size distribution and determine a shape, but not both simultaneously.

B1.8.3.2 PAIR DISTRIBUTION FUNCTIONS

Another application in which useful information can be obtained in the absence of knowledge of the phase of the Fourier transform is the study of glasses and of crystals that contain short-range order but are disordered over long ranges. Here the objective is to determine a pair distribution function (PDF) [17], which is a generalization of the Patterson function that describes the probability of finding pairs of atoms separated by a vector $\mathbf{r}_j - \mathbf{r}_k$. For various

-12-

reasons these studies are most easily done with neutrons and most of them have been done with glasses. In a glass the long-range structure may be assumed to be isotropic. Setting $r = |\mathbf{r}_j - \mathbf{r}_k|$, the particle density, $\rho(\mathbf{r})$, at distance \mathbf{r} from another particle, can be represented to a good approximation by

$$\rho(\mathbf{r}) - \rho_0 = C \int_0^\infty Q [I_{\text{obs}}(Q) - I_{\text{inc}}] \sin(Qr) \, dQ \quad (\text{B1.8.13})$$

where ρ_0 is the mean overall density and I_{inc} is an isotropic incoherent scattering that is the only source of scattering at sufficiently large Q .

B1.8.3.3 CRYSTAL STRUCTURE DETERMINATION

(A) TRIAL AND ERROR

Laue’s original experiment established that x-rays were short-wavelength electromagnetic radiation and that crystals were composed of periodically repeated arrays of identical units, but it did not establish any scale for the wavelength or the sizes of the crystalline units. W L Bragg [18] observed that the positions of the spots in a diffraction photograph produced by zincblende, ZnS, could be explained by a model (see figure B1.8.4 in which the fundamental units were arranged on a face-centred cubic (f.c.c.) lattice. The same model explained the patterns of sodium chloride, potassium bromide and potassium iodide. (Interestingly, Bragg’s initial model for potassium chloride was based on what is now called a primitive cubic lattice. This was an artifact resulting from the near identity of the atomic scattering factors of potassium and chlorine.) By observing the relative intensities of the diffraction spots and applying elementary principles of group theory, Bragg proposed models for the arrangements of atoms that turned out to be correct.

Figure B1.8.4. Two of the crystal structures first solved by W L Bragg. On the left is the structure of zincblende, ZnS. Each sulphur atom (large grey spheres) is surrounded by four zinc atoms (small black spheres) at the vertices of a regular tetrahedron, and each zinc atom is surrounded by four sulphur atoms. On the right is the structure of sodium chloride. Each chlorine atom (grey spheres) is surrounded by six sodium atoms (black spheres) at the vertices of a regular octahedron, and each sodium atom is surrounded by six chlorine atoms.

-13-

At about the same time R A Millikan [19] measured the charge on the electron. Dividing this into the electric charge required to electroplate a gram atomic weight of silver yielded a value, good to within 1%, for Avogadro's number, the number of formula units in a mole. Knowledge of the density and of Avogadro's number leads immediately to knowledge of the size of the unit cell, and thence to knowledge of the wavelength of the radiation producing the diffraction pattern. Bragg's models for the first crystal structures were deduced from Laue photographs, which use continuum radiation, but discovery of the characteristic spectral lines of the elements followed soon after, and H G J Moseley [20] used them to straighten out several anomalies in the periodic table of the elements and to predict the existence of several elements that had not previously been observed.

With the discovery of the x-ray line spectra it became possible to determine, at least relative to the slightly uncertain wavelengths, the sizes and also the symmetries, of the unit cells and the approximate sizes of the atoms. The theory of space groups, which had been worked out by mathematicians, principally A M Schönflies, in the 19th century, has always played a vital role in structural crystallography. With the structures of most of the solid elements and many of their binary compounds it was necessary only to calculate how many atoms would fit into the unit cell and to choose from a limited set of possible positions the ones that best accounted for the relative intensities of the diffraction spots. In sodium chloride, for example, the symmetry of the diffraction pattern shows that the unit cell is a cube and the fact that the indices, h , k and l , are either all odd or all even shows that the cube is face centred. There is room for only four atoms each of sodium and chlorine and it is observed that those reflections with the indices all even are much stronger than those with the indices all odd. This is consistent with a model that has sodium atoms at the corners and at the centres of the faces of the cube and chlorine atoms at the centres of the edges and at the body centre.

Potassium chloride actually has the same structure as sodium chloride, but, because the atomic scattering factors of potassium and chlorine are almost equal, the reflections with the indices all odd are extremely weak, and could easily have been missed in the early experiments. The zincblende form of zinc sulphide, by contrast, has the same pattern of all odd and all even indices, but the pattern of intensities is different. This pattern is consistent with a model that again has zinc atoms at the corners and the face centres, but the sulphur positions are displaced by a quarter of the body diagonal from the zinc positions.

In all of these structures the atomic positions are fixed by the space group symmetry and it is only necessary to determine which of a small set of choices of positions best fits the data. According to the theory of space groups, all structures composed of identical unit cells repeated in three dimensions must conform to one of 230 groups that are formed by combining one of 14 distinct *Bravais lattices* with other symmetry operations.

These include *rotation axes* of orders two, three, four and six and *mirror planes*. They also include *screw axes*, in which a rotation operation is combined with a translation parallel to the rotation axis in such a way that repeated application becomes a translation of the lattice, and *glide planes*, where a mirror reflection is combined with a translation parallel to the plane of half of a lattice translation. Each space group has a *general position* in which the three position coordinates, x , y and z , are independent, and most also have *special positions*, in which one or more coordinates are either fixed or constrained to be linear functions of other coordinates. The properties of the space groups are tabulated in the *International Tables for Crystallography* vol A [21].

The first crystal structure to be determined that had an adjustable position parameter was that of pyrite, FeS_2 . In this structure the iron atoms are at the corners and the face centres, but the sulphur atoms are further away than in zincblende along a different threefold symmetry axis for each of the four iron atoms, which makes the unit cell primitive.

-14-

Unfortunately for modern crystallographers, all of the crystal structures that could be solved by the choose-the-best-of-a-small-number-of-possibilities procedure had been solved by 1920. Bragg has been quoted as saying that the pyrite structure was ‘very complicated’, but he wrote, in about 1930, ‘It must be realized, however, that (cases having one or two parameters) are still extremely simple. The more typical crystal may have ten, twenty, or forty parameters, to all of which values must be assigned before the analysis of the structure is complete.’ This statement is read with amusement by a modern crystallographer, who routinely works with hundreds and frequently with thousands of parameters.

(B) PATTERSON METHODS

We have seen that the intensities of diffraction are proportional to the Fourier transform of the Patterson function, a self-convolution of the scattering matter and that, for a crystal, the Patterson function is periodic in three dimensions. Because the intensity is a positive, real number, the Patterson function is not dependent on phase and it can be computed directly from the data. The squared structure amplitude is

$$|F(hkl)|^2 = I(hkl)/Lp \quad (\text{B1.8.14})$$

where $I(hkl)$ is the integrated intensity of the hkl reflection, L is the so-called *Lorentz factor*, which depends on the experimental geometry and p is a polarization factor, which is equal to one for nuclear scattering of neutrons and depends on the scattering angle, 2θ , for x-rays. From this the Patterson function is

$$P(x, y, z) = \sum_{hkl} |F(hkl)|^2 \cos[2\pi(hx + ky + lz)] \quad (\text{B1.8.15})$$

where the sum is over all values of h , k and l . In practice $I(hkl)$ can be measured only over a finite range of h , k and l and the resulting truncation introduces ripples into the Patterson function.

The Patterson function has peaks corresponding to all interatomic vectors in the density function, the height of a peak being proportional to the product of the atomic scattering factors of the two atoms. Thus, although the Patterson function contains superpositions of the structure as if each atom is in turn placed at the origin and, therefore, has so many peaks that it is difficult to interpret except for very simple structures, there are several features that give important information about the underlying density function. If one or two of the atoms in the unit cell have much higher atomic numbers and, therefore, large values of the atomic scattering factors for

x-rays, the peaks in the Patterson function that correspond to vectors between them will stand out from the rest. Peaks corresponding to vectors between the heavy atoms and lighter ones will also be higher than those corresponding to vectors between lighter atoms, which may reveal features of the environment of the heavy atom. If neutron diffraction is used to study crystals that contain atoms with negative scattering factors, especially hydrogen, but also manganese and titanium, the Patterson function will have negative regions corresponding to vectors between the negative scatterers and other atoms.

If the space group contains screw axes or glide planes, the Patterson function can be particularly revealing. Suppose, for example, that parallel to the c axis of the crystal there is a 2_1 screw axis, one that combines a 180° rotation with

-15-

a translation of $c/2$. Then for an atom at position (x, y, z) there will be another at $(-x, -y, z + \frac{1}{2})$. The section of the Patterson function at $z = \frac{1}{2}$ will therefore contain a peak at position $(2x, 2y)$ for every atom in the unique part of the cell, the *asymmetric unit*. Because this property was first applied to structure determination by D Harker, these special sections of Patterson functions are known as *Harker sections* [22]. If there is a single heavy atom in the asymmetric unit, the Harker section can completely determine the position of the atom. This plays a critical role in the method of *isomorphous replacement*, which we discuss below.

(C) MORE TRIAL AND ERROR

With diffraction data alone, in the absence of phase information, it is always possible to put restrictions on the choice of space group and in many cases it is possible to determine the space group uniquely. Careful measurement of the positions of diffraction spots determines the dimensions of the unit cell and assigns it to one of seven symmetry systems, triclinic, monoclinic, orthorhombic, trigonal, tetragonal, hexagonal, and cubic. The 14 Bravais lattices divide into five basic types, designated primitive, single-face centred, all-face centred, body centred and rhombohedral, which can be distinguished by special patterns of observed and unobserved reflections. We have already discussed the all-face centred lattice, in which the indices are either all odd or all even. In a body centred cell the sum of the indices is always even, while in a primitive cell there are no restrictions.

If one or two of the indices are zeros, there may be additional restrictions. We have seen that a 2_1 screw axis parallel to the c axis of the unit cell produces pairs of atoms at (x, y, z) and $(-x, -y, z + \frac{1}{2})$. From [equation \(B1.8.6\)](#) we can write

$$F(00l) = C \sum_{j=1}^{N/2} f_j(d^*) \{ \exp[2\pi i l z_j] + \exp[2\pi i l (\frac{1}{2} + z_j)] \} \quad (\text{B1.8.16a})$$

which can be written

$$F(00l) = C \sum_{j=1}^{N/2} f_j(d^*) [1 + (-1)^l] \exp(2\pi i l z_j). \quad (\text{B1.8.16b})$$

All terms in the sum vanish if l is odd, so $(00l)$ reflections will be observed only if l is even. Similar restrictions apply to classes of reflections with two indices equal to zero for other types of screw axis and to classes with one index equal to zero for glide planes. These *systematic absences*, which are tabulated in the *International Tables for Crystallography* vol A, may be used to identify the space group, or at least limit the

choices.

The presence of a 2_1 screw axis and a glide plane perpendicular to it implies also the existence of a centre of symmetry, so that, for an atom at (x, y, z) , there is another one at $(-x, -y, -z)$. Equation (B1.8.6) can then be written

$$F(hkl) = C \sum_{j=1}^{N/2} f_j(d^*) [\exp[2\pi i(hx_j + ky_j + lz_j)] + \exp[-2\pi i(hx_j + ky_j + lz_j)]]. \quad (\text{B1.8.17})$$

-16-

The two exponential terms are complex conjugates of one another, so that all structure amplitudes must be real and their phases can therefore be only zero or π . (Nearly 40% of all known structures belong to monoclinic space group $P2_1/c$. The systematic absences of $(0k0)$ reflections when k is odd and of $(h0l)$ reflections when l is odd identify this space group and show that it is centrosymmetric.) Even in the absence of a definitive set of systematic absences it is still possible to infer the (probable) presence of a centre of symmetry. A J C Wilson [23] first observed that the probability distribution of the magnitudes of the structure amplitudes would be different if the amplitudes were constrained to be real from that if they could be complex. Wilson and co-workers established a procedure by which the frequencies of suitably scaled values of $|F|$ could be compared with the theoretical distributions for centrosymmetric and noncentrosymmetric structures. (Note that Wilson named the statistical distributions *centric* and *acentric*. These were not intended to be synonyms for centrosymmetric and noncentrosymmetric, but they have come to be used that way.)

The knowledge that a crystal structure is centrosymmetric reduces the phase problem to one of determining signs, but it is still a formidable one. An extended trial-and-error method uses all available information, including that derived from Patterson methods, numbers of special positions in the unit cell, known interatomic distances, likely group configurations etc, to guess a trial structure and compute from it a set of signs, which are then used to compute a density map, or, more likely, a difference map, in which the Fourier coefficients are the differences between the values of $F(hkl)$ computed from the trial structure and their observed values. Features of the difference map suggest modifications to the trial structure and a new set of signs is used to compute an updated map. With luck, this procedure will converge in a few iterations to a reasonable structure.

(D) DIRECT METHODS

As the number of atoms in the asymmetric unit increases, the solution of a structure by any of these phase-independent methods becomes more difficult, and by 1950 a PhD thesis could be based on a single crystal structure. At about that time, however, several groups observed that the fact that the electron density must be non-negative everywhere could be exploited to place restrictions on possible phases. The first use of this fact was by D Harker and J S Kasper [24], but their relations were special cases of more general relations introduced by J Karle and H Hauptman [25]. Denoting by h_i the set of indices h_i, k_i, l_i , the Karle–Hauptman condition states that all matrices of the form

$$\begin{pmatrix} F(\mathbf{0}) & F(\mathbf{h}_1) & F(\mathbf{h}_2) & \cdots & F(\mathbf{h}_n) \\ F^*(\mathbf{h}_1) & F(\mathbf{0}) & F(\mathbf{h}_2 - \mathbf{h}_1) & \cdots & F(\mathbf{h}_n - \mathbf{h}_1) \\ F^*(\mathbf{h}_2) & F^*(\mathbf{h}_2 - \mathbf{h}_1) & F(\mathbf{0}) & \cdots & F(\mathbf{h}_n - \mathbf{h}_2) \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ F^*(\mathbf{h}_n) & F^*(\mathbf{h}_n - \mathbf{h}_1) & F^*(\mathbf{h}_n - \mathbf{h}_2) & \cdots & F(\mathbf{0}) \end{pmatrix}$$

must be positive definite. Defining $U(h_i)$ by $U(h_i) = F(h_i)/F(\mathbf{0})$ and taking a 3×3 matrix for an example, this

condition implies that the determinant

$$D(\mathbf{h}_1, \mathbf{h}_2) = \begin{vmatrix} 1 & U(\mathbf{h}_1) & U(\mathbf{h}_2) \\ U^*(\mathbf{h}_1) & 1 & U(\mathbf{h}_2 - \mathbf{h}_1) \\ U^*(\mathbf{h}_2) & U^*(\mathbf{h}_2 - \mathbf{h}_1) & 1 \end{vmatrix} \geq 0. \quad (\text{B1.8.18})$$

-17-

From this some tedious but straightforward algebra leads to

$$(\text{B1.8.19})$$

The two factors on the right are both positive, real numbers less than one. If the magnitudes of $U(\mathbf{h}_1)$ and $U(\mathbf{h}_2)$ are both close to one, therefore, the magnitude of the difference between the terms within the brackets on the left (complex numbers in general) must be small.

Karle and Hauptman showed that the fact that the crystal is composed of discrete atoms implies that large enough determinants of the type in [inequality \(B1.8.18\)](#) must vanish, leading to exact relations among sets of phases. For structures with moderately large numbers of atoms in the asymmetric unit ‘large enough’ may be very large indeed, and relations such as [inequality \(B1.8.19\)](#) may not represent much of a restriction on the phase of $U(\mathbf{h}_2 - \mathbf{h}_1)$. Further development of these principles by Hauptman, Karle, I L Karle, M M Woolfson and many others [26] showed that, although no one of these relations would put a significant restriction on a phase, reasonable assumptions about probability distributions would lead to statistical tests that assigned high probabilities to sufficient numbers of phases so that the correct structure could be identified in a density map. These developments, together with the revolution in computing power, have made the solution of structures with up to several hundred atoms in the asymmetric unit a matter of routine.

(E) ISOMORPHOUS REPLACEMENT

While direct methods have opened up structural chemistry with hundreds of atoms in the asymmetric unit, many of the most interesting studies are of biological macromolecules, particularly proteins, which may have thousands of atoms in the asymmetric unit. Furthermore, all biological molecules are chiral, which means that the space groups in which they crystallize can never possess centres of symmetry or mirror (or glide) planes. Although the phases of some sets of reflections may be restricted by symmetry, most structure amplitudes are complex and with large structures the statistical techniques do not supply sufficient information to be useful. The first successful method of determining phases in macromolecular structure studies was the method of *isomorphous replacement*, in which a crystal of a protein is treated chemically to incorporate a small number of heavy atoms into the crystal without disturbing very much the arrangement of the protein molecules. In favourable cases two or more heavy-atom derivatives can be prepared in which the arrangements of the heavy atoms are different. The contribution of the protein molecule to the structure amplitude is assumed to be the same in the derivatives as in the native protein and the interatomic vectors of the heavy atoms stand out sufficiently in a Patterson map to allow the heavy-atom positions to be determined.

Referring to [figure B1.8.5](#) the radii of the three circles are the magnitudes of the observed structure amplitudes of a reflection from the native protein, F_p , and of the same reflection from two heavy-atom derivatives, F_{d1} and F_{d2} . We assume that we have been able to determine the heavy-atom positions in the derivatives and F_{h1} and F_{h2} are the calculated heavy-atom contributions to the structure amplitudes of the derivatives. The centres of the derivative circles are at points $-F_{h1}$ and $-F_{h2}$ in the complex plane, and the three circles intersect at one point, which is therefore the complex value of F_p . The phases for as many reflections as possible can then be

used to compute a density map. The protein molecule is a chain of amino acid residues, whose sequence can be determined by biochemical means and each

-18-

residue consists of a backbone portion, whose length is essentially the same for all amino acids and a side chain. With lots of both skill and luck, and sophisticated computer hardware and software, a model of the chain can be fitted into the density map to obtain a trial structure that can be refined.

Figure B1.8.5. F_p , F_{d1} and F_{d2} are the measured structure amplitudes of a reflection from a native protein and from two heavy-atom derivatives. F_{h1} and F_{h2} are the heavy atom contributions. The point at which the three circles intersect is the complex value of F_p .

(F) MULTIPLE-WAVELENGTH ANOMALOUS DIFFRACTION

A technique that employs principles similar to those of isomorphous replacement is *multiple-wavelength anomalous diffraction* (MAD) [27]. The expression for the atomic scattering factor in [equation \(B1.8.2b\)](#) is strictly accurate only if the x-ray wavelength is well away from any characteristic absorption edge of the element, in which case the atomic scattering factor is real and $F(\overline{hkl}) = F(hkl)^*$. Since the diffracted intensity is proportional to $|F(hkl)|^2$, the diffraction process in effect introduces a centre of symmetry into all data, a fact that is known as Friedel's law. If the wavelength is near an absorption edge, however, the atomic scattering factor becomes complex and the phases of the contributions of an atom to $F(hkl)$ and $F(\overline{hkl})$ differ. The increasingly widespread availability of synchrotron radiation has made it possible to collect diffraction data at several wavelengths, including some near an absorption edge of one or more of the elements in the crystal. The differences between the intensities of hkl and $F(\overline{hkl})$ then serve in a role similar to that played by the differences between the intensities of native and derivative data in isomorphous replacement.

-19-

B1.8.4 EXPERIMENTAL TECHNIQUES

There are many experimental techniques for diffraction studies, depending on whether the materials producing the diffraction are crystalline or amorphous solids, liquids or gases. Crystalline materials are further subdivided according to whether the sample is a single crystal or a powder composed of many small crystals, frequently of more than one phase. All techniques include a source of radiation, a system for holding and manipulating the sample and a means of detecting the scattered radiation.

B1.8.4.1 SOURCES OF RADIATION

(A) X-RAYS

X-rays for diffraction are generated in two ways. The most common is to bombard a metallic anode in a vacuum tube with electrons emitted thermionically from a hot cathode, thereby exciting the characteristic radiation from the anode material, which is usually copper or molybdenum, although some other metals are used for special purposes. If the accelerating voltage in the tube is well above that required to eject a K shell electron from an atom of the anode material, most of the x-radiation emitted will be in the characteristic lines of the K series on top of a continuous, *Bremsstrahlung* spectrum. $K\beta$ and higher energy lines may be filtered out using a suitable metallic filter, or the characteristic line may be selected by reflection from a monochromator crystal.

The other type of x-ray source is an electron synchrotron, which produces an extremely intense, highly polarized and, in the direction perpendicular to the plane of polarization, highly collimated beam. The energy spectrum is continuous up to a maximum that depends on the energy of the accelerated electrons, so that x-rays for diffraction experiments must either be reflected from a monochromator crystal or used in the Laue mode. Whereas diffraction instruments using vacuum tubes as the source are available in many institutions worldwide, there are synchrotron x-ray facilities only in a few major research institutions. There are synchrotron facilities in the United States, the United Kingdom, France, Germany and Japan.

(B) NEUTRONS

Neutrons for diffraction experiments are also produced in two ways. Thermal neutrons from a nuclear reactor are reflected from a monochromator crystal and Bragg's law is satisfied for neutrons scattered from the sample by measuring the scattering angle, 2θ . In a spallation source short pulses of protons bombard a heavy metal target and high energy neutrons are produced by nuclear reactions. These neutrons interact with a moderator, giving a somewhat longer pulse of neutrons with a spectrum that extends down to thermal energies and therefore to wavelengths up to a few Ångströms. Diffraction from a sample a few metres away from the moderator is observed at a fixed angle and the relation between wavelength and velocity causes Bragg's law to be satisfied at some time after the initial pulse.

As with synchrotron x-rays, neutron diffraction facilities are available at only a few major research institutions. There are research reactors with diffraction facilities in many countries, but the major ones are in North America, Europe and Australia. There are fewer spallation sources, but there are major ones in the United States and the United Kingdom.

(C) ELECTRONS

As noted earlier, most electron diffraction studies are performed in a mode of operation of a transmission electron microscope. The electrons are emitted thermionically from a hot cathode and accelerated by the electric field of a conventional electron gun. Because of the very strong interactions between electrons and matter, significant diffracted intensities can also be observed from the molecules of a gas. Again, the source of electrons is a conventional electron gun.

B1.8.4.2 DETECTORS

Detectors for the three types of radiation are similar and may be classified in two categories, photographic and electronic. In addition to photographic films and plates, photographic detectors also include fluorescent screens and image plates, in which x-rays produce a latent image in a storage phosphor. In the dark the phosphor emits radiation very slowly, but exposure to light from a laser stimulates fluorescence, which then can be observed by a photomultiplier tube and converted to an electronic signal. Because neutrons interact weakly with most materials, image plates and fluorescent screens must contain one of the elements, such as gadolinium, that have isotopes with high absorption cross-sections. Photographic detection of neutrons usually uses a fluorescent screen to enhance the image.

There are many types of electronic detector. The original form of electronic detector was the Geiger counter, but it was replaced many years ago by the proportional counter, which allows selection of radiation of a particular type or energy. Proportional counters for x-rays are filled with a gas such as xenon, and those for neutrons are filled with a gas containing a neutron-absorbing isotope, usually ^3He . Recently these gases have been used to construct position-sensitive area detectors for both x-rays and neutrons.

B1.8.4.3 SINGLE-CRYSTAL DIFFRACTION

Many different geometrical arrangements are commonly used for measurements of diffraction of x-rays and neutrons from single crystals. All have a mechanism for setting the crystal so that Bragg's law is satisfied for some set of crystal planes and for placing a detector in the proper position to observe the reflection. In the original x-ray diffraction experiments of Laue and co-workers the x-rays had a broad spectral distribution, so that for any angular position of a crystal and any interplanar spacing there were x-rays with the proper wavelength to satisfy Bragg's law. Laue photographs reveal the internal symmetry of the crystal and are therefore used to determine the symmetry and orientation of the crystal. For crystal structure determination it is necessary to measure accurate intensities and it is usual to use a monochromatic beam of x-rays or neutrons.

For diffraction studies with monochromatic radiation, the crystal is commonly mounted on an Eulerian cradle, which can rotate the crystal so that the normal to any set of planes bisects the angle between the incident and reflected beams, which is set for reflection from planes with a particular value of the interplanar spacing, d .

If the detection system is an electronic, area detector, the crystal may be mounted with a convenient crystal direction parallel to an axis about which it may be rotated under the control of a computer that also records the diffracted intensities. Because the orientation of the crystal is known at the time an x-ray photon or neutron is detected at a particular point on the detector, the indices of the crystal planes causing the diffraction are uniquely determined. If

films are used, additional information is needed to index the pattern. The crystal is either oscillated through a narrow angular range, so that only a small number of planes can come into the reflecting position, or the film is moved, with a mask covering all but a small part of it, so that the exposed part of it is coordinated with the angular position of the crystal. There are two common moving-film methods, the Weissenberg method, in

which a cylindrical film is moved parallel to the rotation axis of the crystal and the precession method, in which the normal to a reciprocal lattice plane is moved along a circular cone while a flat film and a circular slit are both moved in such a way that the positions of the spots on the film correspond to the points of the reciprocal lattice plane.

One form of electron diffraction is similar to the precession method, except that the ‘single crystal’ is a grain of a polycrystalline foil. Figure B1.8.6 shows an electron diffraction pattern produced when the beam is directed down a fivefold symmetry axis of a quasicrystal. Because of the very short wavelength the cone angle is so small that it lies within the mosaic spread of the grain, and the resulting diffraction pattern, after magnification by the electron optics, closely resembles a precession pattern made with x-rays. In this technique the divergence of the electron beam is extremely small, and the diffraction spots correspond to lattice points in a plane of the reciprocal lattice that passes through the origin. The diffraction pattern therefore has a centre of symmetry. In convergent beam electron diffraction (CBED) [28] (see [figure B1.8.7](#) the divergence of the electron beam is still only a few tenths of a degree, but the resultant smearing of the Ewald sphere allows it to intersect layers of the reciprocal lattice adjacent to the one passing through the origin, so that a region of broadened diffraction spots is surrounded by one or more rings of additional spots corresponding to points in these adjacent planes. Because Friedel’s law does not apply in those planes, the pattern more closely reflects the true symmetry of the crystal.

Figure B1.8.6. An electron diffraction pattern looking down the fivefold symmetry axis of a quasicrystal. Because Friedel’s law introduces a centre of symmetry, the symmetry of the pattern is tenfold. (Courtesy of L Bendersky.)

Figure B1.8.7. A convergent beam diffraction pattern of the fivefold axis of a quasicrystal, as in [figure B1.8.6](#). The diffraction rings show that the symmetry is fivefold, not tenfold. (Courtesy of L Bendersky.)

An experimental technique that is useful for structure studies of biological macromolecules and other crystals with large unit cells uses neither the broad, ‘white’, spectrum characteristic of Laue methods nor a sharp, monochromatic spectrum, but rather a spectral band with $\Delta\lambda/\lambda \approx 20\%$. Because of its relation to the Laue method, this technique is called *quasi-Laue*. It was believed for many years that the Laue method was not useful for structure studies because reflections of different orders would be superposed on the same point of a film or an image plate. It was realized recently, however, that, if there is a definite minimum wavelength in the spectral band, more than 80% of all reflections would contain only a single order. Quasi-Laue methods are now used with both neutrons and x-rays, particularly x-rays from synchrotron sources, which give an intense, white spectrum.

B1.8.4.4 POWDER DIFFRACTION

Many scientifically and technologically important substances cannot be prepared as single-crystals large enough to be studied by single crystal diffraction of x-rays and, especially, neutrons. If a sample composed of a very large number (of order 10^{10} or more) of very small ($10\ \mu\text{m}$ or smaller) crystals are irradiated by a monochromatic beam of x-rays or neutrons, there will be some crystals with the right orientation to reflect from all possible sets of crystal planes with interplanar spacings greater than $\lambda/2$. The resulting diffraction pattern contains intensity peaks that are characteristic for any crystalline compound. The pattern corresponds to a uniform distribution of reciprocal lattice points on the surface of a sphere and analysis of the pattern to determine the size and shape of the unit cell can be a difficult (but generally computationally tractable) problem. Nevertheless, in addition to structure determination, powder diffraction is an extremely powerful tool for phase identification and, because a mixture of crystalline phases will give the characteristic patterns of all phases present, quantitative phase analysis. Also if, because of mechanical deformation, for example, the powder sample is not spherically uniform, powder diffraction can reveal the nature of the preferred orientation. Because of the weak interaction and, therefore, high penetration of the neutron, neutron powder diffraction is particularly useful for preferred orientation (texture) studies of bulk materials.

X-ray powder diffraction studies are performed both with films and with counter diffractometers. The powder photograph was developed by P Debye and P Scherrer and, independently, by A W Hull. The Debye–Scherrer camera has a cylindrical specimen surrounded by a cylindrical film. In another commonly used powder

camera, developed by A Guinier, a convergent beam from a curved, crystal monochromator passes through a thin, flat sample and is focused on the film. The common x-ray powder diffractometer uses so-called Bragg–Brentano (although it was apparently developed by W Parrish) focusing. A divergent beam from the line focus of an x-ray tube is reflected from a flat sample and comes to an approximate focus at a receiving slit.

Powder diffraction studies with neutrons are performed both at nuclear reactors and at spallation sources. In both cases a cylindrical sample is observed by multiple detectors or, in some cases, by a curved, position-sensitive detector. In a powder diffractometer at a reactor, collimators and detectors at many different 2θ angles are scanned over small angular ranges to fill in the pattern. At a spallation source, pulses of neutrons of different wavelengths strike the sample at different times and detectors at different angles see the entire powder pattern, also at different times. These slightly displaced patterns are then ‘time focused’, either by electronic hardware or by software in the subsequent data analysis.

B1.8.5 FRONTIERS

Starting from the truly heroic solution of the structure of penicillin by D C Hodgkin (née Crowfoot) and coworkers [29], x-ray diffraction has been the means of molecular structure determination (and the basis of many Nobel prizes in addition to Hodgkin’s) of important compounds, including natural products, of which minute quantities were available for analysis, enabling chemical synthesis and further study. Knowledge of the molecular structure leads in turn to an understanding of reaction mechanisms and, in the case of biological molecules in particular, to an understanding of enzyme function and how drugs can be designed to promote desirable reactions and inhibit undesirable ones.

The development of neutron diffraction by C G Shull and coworkers [30] led to the determination of the existence, previously only a hypothesis, of antiferromagnetism and ferrimagnetism. More recently neutron diffraction, because of its sensitivity to light elements in the presence of heavy ones, played a crucial role in demonstrating the importance of oxygen content in high-temperature superconductors.

The development of synchrotron x-ray sources has resulted in a vast expansion of the capability of x-ray diffraction for determining macromolecular structure, but advances are still limited by the rarity and expense of synchrotron facilities. Correspondingly, the use of neutron diffraction has always been inhibited by the relatively low intensities available and the resulting need for large samples and long data collection times. With both synchrotrons and neutron sources observation time at existing facilities is chronically oversubscribed. Thus there is a need to develop both instruments and methodologies for maximum utilization of the sources.

B1.9 Scattering: light, neutrons, X-rays

Benjamin S Hsiao and Benjamin Chu

B1.9.1 INTRODUCTION

Scattering techniques using light, neutrons and x-rays are extremely useful to study the structure, size and shape of large molecules in solids, liquids and solutions. The principles of the scattering techniques, which involve the interaction of radiation with matter, are the same. However, the data treatment for scattering from light, neutrons or x-rays can be quite different because the intrinsic property of each radiation and its interactions with matter are different. One major difference in the data treatment arises from the states of matter. Although the general equations describing the interaction between radiation and matter are valid for all classes of materials, unique analytical treatments have been made to suit the different states of matter.

In this chapter, the general principles of the scattering phenomenon and specific data treatments for the material (isotropic and anisotropic) in both solid and solution states are presented. These treatments are useful for the analysis of scattering data by light, neutrons or x-rays from different material systems such as crystalline polymers, complex fluids (including colloidal suspensions and solutions of biological species), multicomponent systems (including microemulsions and nanocomposites) and oriented polymers. For detailed theoretical derivations, the reader should refer to the many excellent textbooks and review articles that deal with the subjects of scattering from light [[1](#), [2](#), [3](#), [4](#), [5](#), [6](#) and [7](#)], neutrons [[7](#), [8](#), [9](#), [10](#) and [11](#)] and x-rays [[7](#), [11](#)],

[12](#), [13](#), [14](#) and [15](#)]. We, however, will not discuss the detailed instrumentation for different scattering experiments as this topic has been well illustrated in some of the above references [[3](#), [4](#), [5](#), [6](#) and [7](#), [9](#), [10](#), [11](#), [12](#), [13](#), [14](#) and [15](#)]. Also absent will be the analysis for thin films and interfaces which warrants a separate chapter by itself. The main focus of this chapter is to provide a comprehensive overview to the field of scattering from materials (with emphasis on polymers) including an appropriate comparison between the different techniques. Selected example studies will also be included at the end of each section to illustrate the applications of some advanced scattering techniques.

B1.9.2 INTERACTION OF RADIATION AND MATTER

In free space, electromagnetic radiation consists of simultaneous electric and magnetic fields, which vary periodically with position and time. These fields are perpendicular to each other and to the direction of wave propagation. The electromagnetic radiation consists of a wide range of wavelengths from 10^{-10} m (x-rays) to 10^4 m (low frequency radio waves). Visible light has wavelengths from 400 nm (violet) to 700 nm (red), which constitutes a very small fraction of the electromagnetic spectrum.

As the electromagnetic radiation interacts with matter, the resultant radiation may follow several pathways depending on the wavelength and the material characteristics. Scattering without loss of energy is termed elastic. Elastic scattering from the periodic structure of matter emitting radiation of wavelength with the same magnitude leads to diffraction phenomena. The radiation may be slowed down by the refraction phenomenon. The radiation may also be absorbed

-2-

by the material. The absorbed energy may be transferred to different modes of motion, dissipated as heat or re-emitted as radiation at a different frequency. Energetic photons from x-rays or ultra-violet (UV) radiation can produce dissociation of chemical bonds leading to chemical reactions ejecting photoelectrons (known as x-ray photoelectron spectroscopy, XPS, or electron spectroscopy for chemical analysis, ESCA). Fluorescence occurs when the transfer of the residual energy to electronic modes takes place. Raman scattering occurs when the energy is transferred to or from rotational or vibrational modes. The characterization techniques based on these different phenomena are described in other chapters of section B.

Light scattering arises from fluctuations in refractive index or polarizability and x-ray scattering arises from fluctuations in electron density. Both are dependent on interactions of radiation with extra-nuclear electrons ([figure B1.9.1](#)) and will be discussed together. If we consider an incident beam having an electric field $E = E_0 \cos(2\pi r/\lambda - \omega t)$, where E_0 is the magnitude, λ is the wavelength in vacuum, r is the distance of the observer from the scatterer and ω is the angular frequency. From electromagnetic radiation incident upon an atom (with polarizability, α), a dipole moment $m = \alpha E$ will be induced. The oscillating dipole will serve as a source of secondary radiation (this is scattering) with amplitude E_s [[16](#)],

$$E_s = \frac{1}{c^2 r} \frac{d^2 m}{dt^2} \cos \varphi \quad (\text{B1.9.1})$$

where c is the velocity of light and φ is the angle between the plane of the polarization and the dipole moment. Thus we obtain

$$E_s = \frac{-\alpha E_0 \omega^2}{c^2 r} \cos \varphi \cos(\omega t - \phi) \quad (\text{B1.9.2})$$

where ϕ is a phase angle which takes into account that the wave must travel a distance ($r = d$) to reach the observer ($\phi = 2\pi d/\lambda$). These equations presume that the electric field at the scattering position is not modified by the induced-dielectric environment (the Rayleigh–Gans approximation). Equation (B1.9.2) is thus termed Rayleigh scattering, which holds true for light scattering provided that the light frequency is small when compared with the resonance frequency of the electrons. For x-ray scattering, the frequency of electromagnetic radiation is higher than the resonance frequency of the electrons. In this case, Thomson scattering prevails and the scattering amplitude becomes

$$E_s = \frac{-e^2 \pi E_0}{m_0 c^2 r} \cos \varphi \cos(\omega t - \phi) \quad (\text{B1.9.3})$$

where e is the electron charge and m_0 is the electron mass. Thus, all electrons scatter x-rays equally and the x-ray scattering ability of an atom depends on the number of electrons, which is proportional to the atomic number, Z , in the atom. It should be noted that Rayleigh scattering is dependent on frequency and polarizability, but Thomson scattering is not. As a result, more polarizable molecules (larger, conjugated, more aromatic) are better Rayleigh scatterers than others. Neutron scattering depends upon nuclear properties being related to fluctuations in the neutron scattering cross

-3-

section σ between the scatterer and the surroundings. Hence, hydrogen can be a strong neutron scatterer in an isotope environment, but it is a weak electron scatterer.

Figure B1.9.1. Diagrams showing that x-ray and light scattering involve extra-nuclear electrons, while neutron scattering depends on the nature of the atomic nucleus.

The generalized scattering equation can be expressed by a complex exponential form

$$(E_s)_j = E_0 K_j \exp[i(\omega t - \phi_j)] \quad (\text{B1.9.4})$$

where the subscript j refers to the scattering from the j th element, $(E_s)_j$ represents the amplitude of the scattering of the j th scatterer and K_j is proportional to the scattering power of the j th scatterer. For a collection of scattering elements, the total field strength (amplitude) of the scattered waves is

$$E_s = \sum_j (E_s)_j = E_0 \sum_j K_j \exp[i(\omega t - \phi_j)]. \quad (\text{B1.9.5})$$

All scattering phenomena (light, x-rays and neutrons) can be interpreted in terms of this equation (B1.9.5). These techniques differ mainly in the structural entities that contribute to the K_j term. For light, the refractive index or polarizability is the principal contributor; for x-rays, the electron density is the contributor; and for neutrons, the nature of the scattering nucleus is the contributor. Equation (B1.9.5) thus represents a starting point for the discussion of the interference problem presented below.

-4-

B1.9.3 LIGHT SCATTERING

The intensity of light scattering, I_s , for an isolated atom or molecule is proportional to the mean squared amplitude

$$I_s = K \langle E_s^2 \rangle \quad (\text{B1.9.6})$$

where the constant K is equal to $c/4\pi$ for electromagnetic radiation and $\langle \rangle$ represents an average operation. Combining equations (B1.9.2) and (B1.9.6), we have

$$I_s = K \frac{\alpha^2 E_0^2 \omega^4}{c^4 r^2} \langle \cos^2 \varphi \cos^2(\omega t - \phi) \rangle. \quad (\text{B1.9.7})$$

As the average is over all values of time,

$$\langle \cos^2(\omega t - \phi_j) \rangle = \langle \cos^2 x \rangle = \left(\int_0^{2\pi} \cos^2 x \, dx \right) \left(\int_0^{2\pi} dx \right)^{-1} = \frac{1}{2} \quad (\text{B1.9.8})$$

so equation (B1.9.7) can be simplified to

$$I_s = K \frac{\alpha^2 E_0^2 \omega^4}{2c^4 r^2} \cos^2 \varphi. \quad (\text{B1.9.9})$$

The incident intensity, I_0 , is given by

$$I_0 = K \langle E^2 \rangle = K E_0^2 \langle \cos^2(\omega t - \phi) \rangle = \frac{1}{2} K E_0^2. \quad (\text{B1.9.10})$$

The ratio of the scattered to the incident intensity is given by

$$\frac{I_s}{I_0} = \frac{\alpha^2 \omega^4}{c^4 r^2} \cos^2 \varphi. \quad (\text{B1.9.11})$$

-5-

Equation (B1.9.11) is valid only for plane polarized light. For unpolarized incident light, the beam can be resolved into two polarized components at right angles to each other. The scattered intensity can thus be expressed as (figure B1.9.2)

$$I_s = I_{s1} + I_{s2}. \quad (\text{B1.9.12})$$

As a result, equation (B1.9.11) becomes

$$\frac{I_s}{I_0} = \frac{\alpha^2 \omega^4}{2c^4 r^2} (\cos^2 \varphi_1 + \cos^2 \varphi_2) = \frac{\alpha^2 \omega^4}{2c^4 r^2} (1 + \cos^2 2\theta) \quad (\text{B1.9.13})$$

where we let $\varphi_1 = 0$ and $2\theta = \varphi_2$. Note that in light scattering, one often defines $\theta = \varphi_2$ with θ being the scattering angle. Herein, we define 2θ as the scattering angle to be consistent with x-ray scattering described in B1.9.4. Since the frequency term may be converted to wavelength (in vacuum)

$$\frac{\omega^4}{c^4} = \frac{16\pi^4 \nu^4}{c^4} = \frac{16\pi^4}{\lambda^4} \quad (\text{B1.9.14})$$

where ν is the frequency, equation (B1.9.13) becomes

$$\frac{I_s}{I_0} = \frac{8\pi^4 \alpha^2}{\lambda^4 r^2} (1 + \cos^2 2\theta). \quad (\text{B1.9.15})$$

Figure B1.9.2. Resolution of a plane unpolarized incident beam into polarized scattering components.

-6-

This equation has the following implications.

- (1) At $2\theta = 0^\circ$, the scattering comprises both components of polarization of the incident beam; at $2\theta = 90^\circ$, the scattering comprises only one half of the incident beam. Consequently, the scattered light at 90° will be plane polarized.
- (2) Since $I_s \propto 1/\lambda^4$, this indicates that the shorter wavelengths (such as blue) scatter more than longer ones (such as red). Therefore, the light from a clear sky being blue is due to scattering by gas molecules in the atmosphere.

B1.9.3.1 SCATTERING FROM A COLLECTION OF OBJECTS

For random locations of N scattering objects in volume V , the scattered intensity can be found by summing the scattering from each object:

$$\frac{I_s}{I_0} = \frac{8\pi^4 N \alpha^2}{\lambda^4 r^2} (1 + \cos^2 2\theta). \quad (\text{B1.9.16})$$

A modified form of equation (B1.9.16) is usually used to express the scattering power of a system in terms of the 'Rayleigh ratio' defined as

$$R = \frac{(I_s/I_0)(r^2)}{V(1 + \cos^2 2\theta)} = \frac{8\pi^4 \alpha^2}{\lambda^4} \left(\frac{N}{V} \right). \quad (\text{B1.9.17})$$

In this case, the scattering serves as a means for counting the number of molecules (or particles, or objects) per unit volume (N/V). It is seen that the polarizability, α , will be greater for larger molecules, which will scatter more. If we take the Clausius–Mosotti equation [16]:

$$(n^2 - 1)/(n^2 + 2) = \frac{4}{3}\pi \left(\frac{N}{V} \right) \alpha \quad (\text{B1.9.18})$$

and consider $n \approx 1$ (n is the refractive index), then

$$\alpha = \frac{n - 1}{2\pi} \left(\frac{V}{N} \right). \quad (\text{B1.9.19})$$

If the scattering particles are in a dielectric solvent medium with solvent refractive index n_0 , we can define the excess

polarizability ($\alpha_{\text{ex}} = \alpha(\text{solution}) - \alpha(\text{solvent})$) as

$$(\text{B1.9.20})$$

$$\alpha_{\text{ex}} = \frac{n^2 - n_0^2}{4\pi} \left(\frac{V}{N} \right).$$

If the weight concentration C is used, $C = MN/(N_a V)$, where M is the molecular weight of the particle, N_a is Avogadro's number and $n \approx n_0$, then the above relationship becomes

$$\alpha_{\text{ex}} = \frac{(n + n_0)(n - n_0)}{4\pi C} \frac{CV}{N} = \frac{n_0}{2\pi} \left(\frac{\partial n}{\partial C} \right) \left(\frac{M}{N_a} \right) \quad (\text{B1.9.21})$$

where $\partial n/\partial C \approx (n - n_0)/C$ at constant temperature. The excess Rayleigh ratio $R_{\text{ex}} = R(\text{solution}) - R(\text{solvent})$ has the form

$$R_{\text{ex}} = \frac{2\pi^2 n_0^2}{\lambda^4 N_a} \left(\frac{\partial n}{\partial C} \right)^2 CM = HCM \quad (\text{B1.9.22})$$

where H is the optical constant for unpolarized incident light. For polarized light, the constant H can be twice as large due to the factor $(1 + \cos^2 2\theta)$. It is noted that this factor of 2 depends on the definition of R , i.e., whether the $1 + \cos^2 2\theta$ term is absorbed by R .

$$R_{\text{ex,p}} = \frac{4\pi^2 n_0^2}{\lambda^4 N_a} \left(\frac{\partial n}{\partial C} \right)^2 CM = HCM \quad (\text{B1.9.23})$$

where $R_{\text{ex,p}}$ is the excess Rayleigh ratio for polarized light. The above treatment is valid for molecules that are small compared to the wavelength of the incident beam.

B1.9.3.2 SCATTERING FROM A SOLUTION OF LARGE MOLECULES

For molecules having dimensions comparable with the wavelength, phase differences will occur between waves scattered from different regions of the molecule. These phase differences result in an angular dependence of the scattered intensity. The reduction may be expressed in terms of a particle interference factor $P(2\theta)$ such that

$$P(2\theta) = \frac{R_{\text{ex}}(\text{experimental})}{R_{\text{ex}}(\text{no interference})} \quad (\text{B1.9.24})$$

-8-

where 2θ is the scattering angle. We again caution the reader that the conventional symbol for the scattering angle by light is θ . Herein we use the symbol 2θ to be consistent with x-ray and neutron scattering described later. The interference factor also follows the expression

$$P(2\theta) = \left\langle \left[\sum_j \alpha_j \cos(\omega t - \phi_j) \right]^2 \right\rangle \left(\left[\sum_j \alpha_j \cos(\omega t) \right]^2 \right)^{-1} \quad (\text{B1.9.25})$$

where the summation is over all parts of a molecule. The nature of $P(2\theta)$ may be qualitatively deduced from figure B1.9.3. For scattering in the forward direction (θ_1) the path difference between the rays from elements A and B of the molecule ($d_B - d_A$) is less than that at the backward scattering angle ($2\theta_2$) to observer O_2 , ($d'_B - d'_A$). So, a greater phase difference occurs at $2\theta_2$. If the dimensions of the molecule (or particle) are less than the wavelength, destructive interference occurs and $P(2\theta)$ will decrease. If the molecular (or particle) dimensions are much greater than the probing wavelength, both destructive and constructive interference can occur leading to maxima and minima in $P(2\theta)$. For $2\theta = 0^\circ$, no path difference exists and $P(2\theta) = 1$. Thus, the scattering technique can be used to estimate the size of the molecule (or particle).

Figure B1.9.3. Variation of $P(2\theta)$ as a function of scattering angle.

Equation (B1.9.5) gives the total amplitudes of scattering from a collection of objects and is a good starting point for the derivation of interference phenomena associated with molecular size.

$$E_s = E_0 \sum_j K_j \exp[i\omega(t - d_j/c)] \quad (\text{B1.9.26})$$

where d_j is the distance between the scattering element and the observation point P (shown in [figure B1.9.4](#) . In [figure B1.9.4](#) , the following relationships can be approximated as

$$d_j = \mathbf{r}_j \cdot \mathbf{s}_0 + D - \mathbf{r}_j \cdot \mathbf{s}_1 = D + \mathbf{r}_j \cdot (\mathbf{s}_0 - \mathbf{s}_1) = D + (\mathbf{r}_j \cdot \mathbf{s}) \quad (\text{B1.9.27})$$

-9-

where D represents the distance between the observation point P and the origin O , \mathbf{s}_0 is the unit vector in the incident beam direction, \mathbf{s}_1 is the unit vector in the scattered beam direction and \mathbf{r}_j is the vector to the j th scattering element. Equation (B1.9.26) thus becomes

$$E_s = E_0 \sum_j K_j e^{i\omega t} e^{-i\omega(\mathbf{r}_j \cdot \mathbf{s})/c} e^{-i\omega D/c} = F e^{-ikD} \quad (\text{B1.9.28})$$

where $F = \sum E_0 K_j e^{i\omega t} e^{-ik(\mathbf{r}_j \cdot \mathbf{s})}$, which is defined as the structure or form factor of the object, and $k = \omega/c = 2\pi/\lambda$. For a system with a large number of scattering elements, the summation in equation (B1.9.28) may be replaced by an integral

$$\begin{aligned}
F &= E_0 e^{i\omega t} \sum_j K_j \exp[-ik(\mathbf{r}_j \cdot \mathbf{s})] \\
&= E_0 e^{i\omega t} \int_r \rho(r) \exp[-ik(\mathbf{r}_j \cdot \mathbf{s})] d^3r.
\end{aligned}
\tag{B1.9.29}$$

The term $E_0 e^{i\omega t}$ is related to the incident beam, which is often omitted in the theoretical derivation (as follows). The second term in (B1.9.29) represents the amplitude scattered by a three dimensional element with a volume element d^3r and $\rho(r)$ being the density profile. From now on, we will simplify the symbol for the dot product of two vectors $\mathbf{r}_j \cdot \mathbf{s}$ as $r_j s$ and other similar products. If we consider the spherical polar coordinates (figure B1.9.5), this volume element becomes

$$d^3r = \int_{\phi=0}^{2\pi} \int_{\varphi=0}^{\pi} \int_{r=0}^{\infty} r^2 \sin \varphi \, dr \, d\varphi \, d\phi \tag{B1.9.30}$$

so that more generally,

$$F = \int_{\phi=0}^{2\pi} \int_{\varphi=0}^{\pi} \int_{r=0}^{\infty} \rho(r, \varphi, \phi) e^{-ik(r_j s)} r^2 \sin \varphi \, d\phi \, d\varphi \, dr. \tag{B1.9.31}$$

For spherically symmetric systems, we can derive the following expression from (B1.9.31) [17]:

$$F = 4\pi \int_{r=0}^{\infty} \rho(r) \frac{\sin qr}{qr} r^2 \, dr \tag{B1.9.32}$$

-10-

where $q = 4\pi(\sin \theta)/\lambda$, with 2θ being the scattering angle. The interference factor described previously (equation (B1.9.25)) may be expressed in terms of the intramolecular particle scattering factor as

$$P(2\theta) = \left(\int_{r=0}^{\infty} \rho(r) \frac{\sin qr}{qr} r^2 \, dr \right) \left(\int_{r=0}^{\infty} \rho(r) r^2 \, dr \right)^{-1}. \tag{B1.9.33}$$

If we define the radius of gyration, R_g , by

$$R_g^2 = \left(\int_0^{\infty} \rho(r) r^2 \, dr \right) \left(\int_0^{\infty} \rho(r) \, dr \right)^{-1} \tag{B1.9.34}$$

then equation (B1.9.33) can be expressed as [18]

$$P(2\theta) = 1 - \frac{q^2 R_g^2}{3} + \dots = 1 - \frac{16\pi^2 R_g^2}{3\lambda^2} \sin^2(2\theta/2) + \dots. \tag{B1.9.35}$$

To measure the molecular weight of the molecule, we can modify equation (B1.9.23) to take into account the intramolecular interference in the dilute solution range,

$$\frac{HC}{R_{\text{ex}}} \cong \frac{1}{MP(2\theta)} + 2A_2C \quad (\text{B1.9.36})$$

where A_2 is the second virial coefficient. By combining (B1.9.35) with (B1.9.36), we obtain

$$\frac{HC}{R_{\text{ex}}} \cong \frac{1}{M} \left(1 + \frac{q^2 R_g^2}{3} \right) + 2A_2C. \quad (\text{B1.9.37})$$

This is the basic equation for monodisperse particles in light scattering experiments. We can derive three relationships by extrapolation.

-11-

Figure B1.9.4. Geometrical relations between vectors associated with incident and scattered light.

Figure B1.9.5. Geometrical relations between the Cartesian coordinates in real space, the spherical polar coordinates and the cylindrical polar coordinates.

$$\lim_{C \rightarrow 0} \frac{HC}{R_{\text{ex}}} \cong \frac{1}{M} \left(1 + \frac{q^2 R_g^2}{3} \right) \quad (\text{B1.9.38})$$

$$\lim_{q \rightarrow 0} \frac{HC}{R_{\text{ex}}} \cong \frac{1}{M} + 2A_2C \quad (\text{B1.9.39})$$

$$\lim_{q \rightarrow 0, C \rightarrow 0} \frac{HC}{R_{\text{ex}}} \cong \frac{1}{M}. \quad (\text{B1.9.40})$$

A graphical method, proposed by Zimm (thus termed the Zimm plot), can be used to perform this double extrapolation to determine the molecular weight, the radius of gyration and the second virial coefficient. An example of a Zimm plot is shown in [figure B1.9.6](#) where the light scattering data from a solution of poly

(tetrafluoroethylene) (PTFE) ($M_w = (2.9 \pm 0.2) \times 10^5 \text{ g mol}^{-1}$; $A_2 = -(6.7 \pm 1.3) \times 10^{-5} \text{ mol cm}^3 \text{ g}^{-2}$ and $R_g = 17.8 \pm 2.4 \text{ nm}$) in oligomers of poly(chlorotrifluoroethylene) (as solvents) at 340°C is shown [19]. The dashed lines represent the extrapolated values at $C = 0$ and $2\theta = 0$.

Figure B1.9.6. A typical Zimm plot; data obtained from a solution of poly(tetrafluoroethylene) (PTFE) ($M_w = (2.9 \pm 0.2) \times 10^5 \text{ g mol}^{-1}$; $A_2 = -(6.7 \pm 1.3) \times 10^{-5} \text{ mol cm}^3 \text{ g}^{-2}$ and $R_g = 17.8 \pm 2.4 \text{ nm}$) in oligomers of poly(chlorotrifluoroethylene) (as solvents) at 340°C . (Reprinted with permission from Chu *et al* [19].)

B1.9.3.3 CALCULATE SCATTERED INTENSITY

There are two ways to calculate the scattered intensity. One is to first calculate the magnitude of the structure factor F by summing the amplitude of scattering elements in the system and then multiply it by F^* (the conjugate of F). This method is best for the calculation of the scattered intensity from discrete particles such as spheres or rods. Two examples are illustrated as follows.

- (1) The scattering from an *isolated sphere* may be calculated from equation (B1.9.32). This derivation assumes that the sphere is uniform, with its density profile $\rho(r) = \rho_0$ if $r < r_0$ and $\rho(r) = 0$ if $r > r_0$ (surrounded by a non-scattering material). With this assumption, equation (B1.9.32) becomes

$$F_{\text{sp}} = 4\pi\rho_0 \int_{r=0}^{r_0} \frac{\sin qr}{qr} r^2 dr. \quad (\text{B1.9.41})$$

By changing the variable, $x = qr$, we obtain

$$F_{\text{sp}} = \frac{4\pi\rho_0}{q^3} \int_{x=0}^{x=U} x \sin(x) dx. \quad (\text{B1.9.42})$$

We can integrate the above equation by parts and derive

$$F_{\text{sp}} = \frac{4\pi\rho_0}{q^3}[\sin U - U \cos U] = V_{\text{sp}}\rho_0\Phi(U) \quad (\text{B1.9.43})$$

where V_{sp} is the sphere volume and

$$\Phi(U) = \text{the sphere scattering function} = \frac{3}{U^3}[\sin U - U \cos U] \quad (\text{B1.9.44})$$

with the parameter $U = qr_0$. The intensity then is proportional to F^2 ($R = K_1 FF^*$, where K_1 is a calibration constant for light scattering).

(2)

This treatment may be extended to *spheres core-shell structure*. If the core density is ρ_1 to r_1 , the shell density is ρ_2 in the range r_1 to r_2 , the density of the surrounding medium is ρ_0 , then the structure factor becomes

$$F_{\text{cs}} = V_1(\rho_1 - \rho_0)\Phi(U_1) + V_2(\rho_2 - \rho_0)\Phi(U_2)$$

The second method to calculate the scattered intensity (or R : the Rayleigh ratio) is to square the sum in I

$$R(q) = K_1 \sum_i \sum_j \rho_i \rho_j \exp[i(qr_{ij})].$$

For a continuous system with assorted scattering elements, the sum can be replaced by integration and be expressed as

$$R(q) = K_1 V \langle \eta^2 \rangle \int \gamma(r) \exp[i(qr)] d^3r$$

where V is the scattering volume, η is the heterogeneity of the fluctuation parameter defined as $\eta = \rho - \langle \rho \rangle$ and the *correlation function* defined as

$$\gamma(r_{ij}) = \langle \eta_i \eta_j \rangle.$$

Equation (B1.9.47) applies to the general scattering expression of any system. With spherical symmetry, the scattered intensity becomes [20]

$$R(q) = 4\pi K_1 V \langle \eta^2 \rangle \int_0^\infty \gamma(r) r^2 \frac{\sin(qr)}{qr} dr. \quad (\text{B1.9.49})$$

In the case of anisotropic systems with a cylindrical symmetry (such as rods or fibres), the scattered intensity can be expressed as (derivation to be made later in [section B1.9.4](#)):

$$R(q) = 4\pi K_1 V \langle \eta^2 \rangle \int_0^\infty \gamma(r) J_0(q_r r) r dr \int_0^\infty \gamma(z) \cos(q_z z) dz \quad (\text{B1.9.50})$$

where the subscript r represents the operation along the radial direction, the subscript z represents the operation along the cylinder axis, J_0 is the zero-order Bessel function and q_r and q_z are scattering vectors along the r (equator) and z (meridian) directions, respectively.

B1.9.3.4 ESTIMATE OBJECT SIZE

One of the most important functions in the application of light scattering is the ability to estimate the object dimensions. As we have discussed earlier for dilute solutions containing large molecules, [equation \(B1.9.38\)](#) can be used to calculate the ‘radius of gyration’, R_g , which is defined as the mean square distance from the centre of gravity [12]. The combined use of [equation \(B1.9.38\)](#), [equation \(B1.9.39\)](#) and [equation \(B1.9.40\)](#) (the Zimm plot) will yield information on R_g , A_2 and molecular weight.

The above approximation, however, is valid only for dilute solutions and with assemblies of molecules of similar structure. In the event that concentration is high where intermolecular interactions are very strong, or the system contains a less defined morphology, a different data analysis approach must be taken. One such approach was derived by Debye *et al* [21]. They have shown that for a random two-phase system with sharp boundaries, the correlation function may carry an exponential form.

$$\gamma(r) = e^{-r/a_c} \quad (\text{B1.9.51})$$

where a_c is a correlation length describing the dimension of heterogeneities. Substitution of (B1.9.51) into [\(B1.9.47\)](#) gives rise to the expression

-15-

$$R(q) = \frac{8\pi K_1 \langle \eta^2 \rangle a_c^3}{[1 + q^2 a_c^2]^2}. \quad (\text{B1.9.52})$$

Based on this equation, one can make a ‘Debye–Bueche’ plot by plotting $[R(q)]^{-1/2}$ versus q^2 and determine the slope and the intercept of the curve. The correlation length thus can be calculated as [21]

$$a_c = \left(\frac{\text{slope}}{\text{intercept}} \right)^{1/2}. \quad (\text{B1.9.53})$$

B1.9.4 X-RAY SCATTERING

X-ray scattering arises from fluctuations in electron density. The general expression of the absolute scattered intensity $I_{\text{abs}}(q)$ (simplified as $I(q)$ from now on) from the three-dimensional objects immersed in a different

density medium, similar to (B1.9.47), can be expressed as:

$$I(q) = K_x V \langle \eta^2 \rangle \int \gamma(r) e^{i(qr)} d^3r \quad (\text{B1.9.54})$$

where V is the volume of the scatterer, $\langle \eta^2 \rangle$ is the square of the electron density fluctuations, $\gamma(r)$ is the correlation function and K_x is a calibration constant depending on the incident beam intensity and the optical apparatus geometry (e.g. polarization factor) given by

$$K_x = I_0 \left(\frac{e^2}{m_0 c^2} \right)^2 \frac{1}{D_s^2} \frac{1 + \cos^2 2\theta}{2} \quad (\text{B1.9.55})$$

where e , m_0 are the charge and mass of an electron, c is the velocity of light, D_s is the sample to detector distance and 2θ is the scattering angle.

If the scattering system is isotropic, equation (B1.9.54) can be expressed in spherical polar coordinates (the derivation is similar to equation (B1.9.32)):

$$I(q) = 4\pi K_x V \langle \eta^2 \rangle \int_0^\infty \gamma(r) r^2 \frac{\sin(qr)}{qr} dr. \quad (\text{B1.9.56})$$

-16-

This expression is very similar to (B1.9.49). If the scattering system is anisotropic, equation (B1.9.54) can then be expressed in cylindrical polar coordinates (see figure B1.9.5 :

$$I(q) = I(q_r, \psi, q_z) = K_x V_s \langle \eta^2 \rangle \iiint \gamma(r, \varphi, z) e^{i(rq_r \cos(\varphi - \psi) + zq_z)} r dr d\varphi dz \quad (\text{B1.9.57})$$

where r represents the distance along the radial direction and z represents the distance along the cylindrical axis (in real space), q_r and q_z are correspondent scattering momenta along the r and z directions in reciprocal space, φ is the polar angle in real space and ψ is the polar angle in reciprocal space. Equation (B1.9.57) is a general expression for cylinders without any assumptions. If we consider the scatterers having the geometry of a cylinder, it is reasonable to assume $\gamma(r, \varphi, z) = \gamma(r, \varphi) \gamma(z)$, which indicates that the two correlation functions along the radial (equatorial) direction and the cylindrical (meridional) direction are independent. In addition, the term $\gamma(\varphi) = 1$ can be applied, which represents the symmetry of a cylinder. Equation (B1.9.57) thus can be rewritten as

$$I(q) = K_x V \langle \eta^2 \rangle \int_0^\infty \gamma(r) \left(\int_0^{2\pi} e^{irq_r \cos(\varphi - \psi)} d\varphi \right) r dr \int_{-\infty}^\infty \gamma(z) e^{izq_z} dz. \quad (\text{B1.9.58})$$

If we define $\delta = \varphi - \psi$ and $rq_r = u$, then

$$(\text{B1.9.59})$$

$$\int_0^{2\pi} e^{irq_r \cos(\varphi-\psi)} d\varphi = \int_0^{2\pi} e^{iu \cos \delta} d\delta = 2\pi J_0(u)$$

where $J_0(u)$ is the zeroth order Bessel function of the first kind. Also, we have

$$\begin{aligned} \int_{-\infty}^{\infty} \gamma(z) e^{izq_z} dz &= \int_{-\infty}^{\infty} \gamma(z) (\cos(zq_z) + i \sin(zq_z)) dz \\ &= \int_{-\infty}^{\infty} \gamma(z) \cos(zq_z) dz \end{aligned} \quad (\text{B1.9.60})$$

because both $\gamma(z)$ and $\cos(zq_z)$ are even functions (i.e., $\gamma(z) = \gamma(-z)$ and $\cos(zq_z) = \cos(-zq_z)$) and $\sin(zq_z)$ is an odd function. The integral of the latter ($\gamma(z)\sin(zq_z)$, an odd function) is an even function integrated from $-\infty$ to ∞ , which becomes zero. Combining equations (B1.9.59) and (B1.9.60) into equation (B1.9.58), we obtain

$$I(q) = K_x V \langle \eta^2 \rangle \int_0^{\infty} \gamma(r) 2\pi J_0(q_r r) r dr \int_0^{\infty} 2\gamma(z) \cos(q_z z) dz. \quad (\text{B1.9.61})$$

-17-

This equation is the same as (B1.9.50) for light scattering.

B1.9.4.1 PARTICLE SCATTERING

The general expression for particle scattering can best be described by the correlation function $\gamma(r)$. Using the definition in (B1.9.48), we have

$$\gamma(r) = (\Delta\rho)^2 \gamma_0(r) \quad (\text{B1.9.62})$$

where $\Delta\rho$ is the electron density difference between the particle and the surrounding medium and is assumed to be constant, $\gamma(0) = 1$ and $\gamma(r) = 1$ for $r \geq D$ (the diameter of the particle). The function $\gamma_0(r)$ can be expressed by a distribution function $G(l)$ with l being the *intersection length* or the *chord length* of the particle (figure B1.9.7) [12, 13]

$$\gamma_0(r) = \frac{1}{\bar{l}} \int_r^D (l-r) G(l) dl \quad (\text{B1.9.63})$$

with

$$\bar{l} = \int_0^D l G(l) dl. \quad (\text{B1.9.64})$$

By differentiation, we can derive

$$\frac{d\gamma_0(r)}{dr} = -\frac{1}{\bar{l}} \int_r^D G(l) dl \quad (\text{B1.9.65})$$

$$\frac{d^2\gamma_0(r)}{dr^2} = \frac{1}{\bar{l}} G(l).$$

The distance distribution function $p(r)$ has a clear geometrical definition. It is defined as

$$p(r) = \gamma(r)r^2. \quad (\text{B1.9.66})$$

For homogeneous particles, it represents the number of distances within the particle. For inhomogeneous particles, it has to take into account the different electron density of the volume elements. Thus it represents the number of pairs of difference in electrons separated by the distance r . A qualitative description of shape and internal structure of the

-18-

particle can be obtained directly from $p(r)$. In addition, several structural parameters can be determined quantitatively [22]. We can describe several analytical forms of the distance distribution function for different shapes of homogeneous particles as follows.

Figure B1.9.7. Diagram to illustrate the relationship between chord length (ℓ) and r in a particle.

- (1) Globular particles

$$p(r) = 12x^2(2 - 3x + x^3) \quad (\text{B1.9.67})$$

where $x = r/D$.

- (2) Rodlike particles

$$p(r) = \frac{1}{2\pi} \rho_c^2 A^2 (L - r) \quad (\text{B1.9.68})$$

where ρ_c is the particle electron density, A is the cross-section of the rod and L is the length of the rod particle.

- (3) Flat particles, i.e. particles elongated in two dimensions (discs, flat prisms)

$$p(r) = \frac{16}{\pi} x(\arccos(x) - x\sqrt{1-x^2}) \quad (\text{B1.9.69})$$

where $x=r/D$.

-19-

The radius of gyration of the whole particle, R_g , can be obtained from the distance distribution function $p(r)$ as

$$R_g^2 = \left(\int_0^\infty p(r)r^2 dr \right) \left(\int_0^\infty p(r) dr \right)^{-1}. \quad (\text{B1.9.70})$$

This value can also be obtained from the innermost part of the scattering curve.

$$I(q) = I(0) \exp\left(-\frac{R_g^2 q^2}{3}\right) \quad (\text{B1.9.71})$$

where $I(0)$ is the scattered intensity at zero scattering angle. A plot of $\log I(q)$ versus q^2 , which is known as the Guinier plot, should show a linear descent with a negative slope ($= -R_g^2/3$) related to the radius of gyration.

In practical data analysis, we are interested in extracting information about the size, shape and distribution of the scattering particles. The most widely used approach for this purpose is the indirect Fourier transformation method, pioneered by O Glatter [23, 24, and 25]. This approach can be briefly illustrated as follows. In dilute solutions with spherical particles, where the interparticle scattering is negligible, the distance distribution function $p(r)$ can be directly calculated from the scattering data through Fourier transformation (combining equations (B1.9.56) and (B1.9.66))

$$I(q) = 4\pi K_x V \langle \eta^2 \rangle \int_0^\infty p(r) \frac{\sin(qr)}{qr} dr. \quad (\text{B1.9.72})$$

This process is shown in figure [figure B1.9.8](#) where T_1 represents the Fourier transformation. If there are additional instrumentation effects desmearing the data (such as the slit geometry, wavelength distribution etc), appropriate inverse mathematical transformations (T_2, T_3, T_4) can be used to calculate $p(r)$. If the particle has a certain shape, the $\sin(x)/x$ term in (B1.9.72) must be replaced by the form factor according to the shape assumed. If concentrations increase, the interparticle scattering (the so-called structure factor) should be considered, which will be discussed later in [section B1.9.5](#). A unique example to illustrate the usefulness of the distance distribution function is the study of a DNA-dependent RNA polymerase core enzyme [26, 27] ([figure B1.9.9](#)). The RNA polymerase enzyme is known to have four subunits but in two possible configurations (model 1 and model 2). Model 1 has a configuration with the two larger subunits having a centre-to-centre distance of 5 nm, and model 2 has a more open configuration having a centre-to-centre distance of 7 nm. From the experimental data (open circle), it is clear that model 1 gives a better fit to the data.

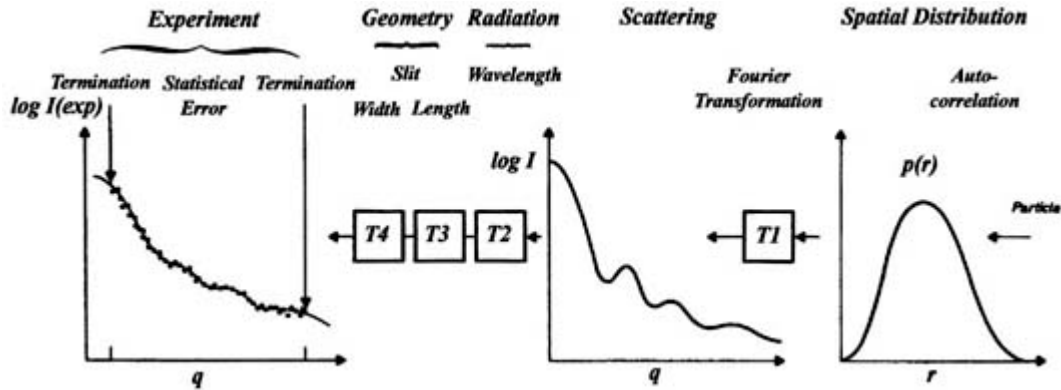

Figure B1.9.8. Schematic diagram of the relationship between a particle distribution and the measured experimental scattering data. This figure is duplicated from [14], with permission from Academic Press.

Figure B1.9.9. Comparison of the distance distribution function $p(r)$ of a RNA-polymerase core enzyme from the experimental data (open circle) and the simulation data (using two different models). This figure is duplicated from [27], with permission from Elsevier Science.

B1.9.4.2 NONPARTICULATE SCATTERING

If we consider the scattering from a general two-phase system (figure B1.9.10) distinguished by indices 1 and 2) containing constant electron density in each phase, we can define an average electron density $\bar{\rho}$ and a mean square density fluctuation as:

$$\bar{\rho} = \varphi_1 \rho_1 + \varphi_2 \rho_2 \tag{B1.9.73}$$

$$\overline{\eta^2} = (\rho_1 - \rho_2)^2 \varphi_1 \varphi_2 \tag{B1.9.74}$$

where φ and ρ are the fractions of the total volume V . Equation (B1.9.74) is directly related to the invariant Q of the system

$$Q = 2\pi^2 V \overline{\eta^2} = 2\pi^2 V (\rho_1 - \rho_2)^2 \varphi_1 \varphi_2. \quad (\text{B1.9.75})$$

In this case, the correlation function $\gamma(r)$ becomes

$$\gamma(r) = (\rho_1 - \rho_2)^2 \varphi_1 \varphi_2 \gamma_0(r) \quad (\text{B1.9.76})$$

where $\gamma_0(r)$ is the normalized correlation function, which is related to the geometry of the particle.

Figure B1.9.10. Non-particulate random two-phase system.

There are several geometrical variables that one can extract from the correlation function approach. First, a correlation

volume v_c can be defined, which is related to the extrapolated intensity at zero angle $I(0)$.

$$I(0) = V (\rho_1 - \rho_2)^2 \varphi_1 \varphi_2 v_c. \quad (\text{B1.9.77})$$

With the use of invariant Q , we obtain

$$v_c = \frac{2\pi^2}{Q} I(0). \quad (\text{B1.9.78})$$

If we consider the chord length distribution, we can express the alternating chords l_1 and l_2 as:

$$l_1 = 4 \frac{V}{S} \varphi_1 \quad l_2 = 4 \frac{V}{S} \varphi_2 \quad (\text{B1.9.79})$$

where S is the total surface area. The mean chord length thus becomes

$$\bar{l} = l_1\varphi_2 = l_2\varphi_1 = 4\frac{V}{S}\varphi_1\varphi_2. \quad (\text{B1.9.80})$$

As we will discuss in the next section, the scattered intensity $I(q)$ at very large q values will be proportional to the q^{-4} term. This is the well known Porod approximation, which has the relationship

$$\lim_{q \rightarrow \infty} I(q) = V\varphi_1\varphi_2(\rho_1 - \rho_2)^2 \frac{8\pi}{\bar{l}} \frac{1}{q^4}. \quad (\text{B1.9.81})$$

It is sometimes more convenient to normalize the absolute scattered intensity $I(q)$ and use the following expression:

$$\lim_{q \rightarrow \infty} I(q)q^4/Q = \frac{1}{\pi\varphi_1\varphi_2} \frac{S}{V}. \quad (\text{B1.9.82})$$

Thus the ratio of S/V can be determined by the limiting value of $I(q)q^4$. We will discuss the Porod approximation next.

B1.9.4.3 POROD APPROXIMATION

According to the Porod law [28], the intensity in the tail of a scattering curve from an *isotropic* two-phase structure having sharp phase boundaries can be given by [equation \(B1.9.81\)](#). In fact, this equation can also be derived from the general expression of scattering ([B1.9.56](#)). The derivation is as follows. If we assume $qr = u$ and use the Taylor expansion at large q , we can rewrite ([B1.9.56](#)) as

$$\begin{aligned} I(q) &= \frac{4\pi K_x V \langle \eta^2 \rangle}{q^3} \int_0^\infty \gamma(r) u \sin(u) du \\ &= \frac{4\pi K_x V \langle \eta^2 \rangle}{q^3} \left(\int_0^\infty \gamma(0) u \sin(u) du + \int_0^\infty \frac{\gamma'(0)}{q} u^2 \sin(u) du \right. \\ &\quad \left. + \int_0^\infty \frac{\gamma''(0)}{2q^2} u^3 \sin(u) du + \dots \right) \end{aligned} \quad (\text{B1.9.83})$$

where γ' and γ'' are the first and second derivatives of γ . The following expressions can be derived to simplify the above equation.

$$\int_0^\infty x \sin(x) dx = 0, \int_0^\infty x^2 \sin(x) dx = -2, \int_0^\infty x^3 \sin(x) dx = 0. \quad (\text{B1.9.84})$$

Then

$$I(q) = -\frac{8\pi K_x V \langle \eta^2 \rangle}{q^4} \gamma'(0) + O(q^{-2n}, d^{2n-3} \gamma(0) / dr^{2n-3}) \quad (n = 3, 4, 5 \dots). \quad (\text{B1.9.85})$$

The second term in equation (B1.9.85) rapidly approaches zero in the large q region, thus

$$\lim_{q \rightarrow \infty} I(q) = -\frac{8\pi K_x V \langle \eta^2 \rangle}{q^4} \gamma'(0). \quad (\text{B1.9.86})$$

This equation is the same as [equation \(B1.9.81\)](#), which is termed the Porod law. Thus, the scattered intensity $I(q)$ at very large q values will be proportional to the q^{-4} term, this relationship is valid only for sharp interfaces.

The least recognized forms of the Porod approximation are for the *anisotropic* system. If we consider the cylindrical scattering expression of [equation \(B1.9.61\)](#), there are two principal axes (z and r directions) to be discussed

-24-

$$I(q) = K_x V \langle \eta^2 \rangle \int_0^\infty \gamma(r) 2\pi J_0(q_r r) r dr \int_0^\infty 2\gamma(z) \cos(q_z z) dz. \quad (\text{B1.9.61})$$

where q_r and q_z are the scattering vectors along the r or z directions, respectively.

- (1) For the component of the scattered intensity along the equatorial direction (i.e., perpendicular to the cylinder direction, $q_z = 0$), [equation \(B1.9.61\)](#) can be simplified as

$$I(q_r) = K'_x V \langle \eta^2 \rangle \int_0^\infty \gamma(r) 2\pi J_0(q_r r) r dr \quad (\text{B1.9.87})$$

where $K'_x (=K_x \int_0^\infty 2\gamma(z) dz)$ is a new constant, because the integral of $\gamma(z)$ is a constant. In this equation, the correlation function $\gamma(r)$ can again be expanded by the Taylor series in the region of small r , which becomes

$$I(q_r) = \frac{2\pi K'_x V \langle \eta^2 \rangle}{q_r^2} \left(\int_0^\infty \gamma(0) u J_0(u) du + \int_0^\infty \frac{\gamma'(0)}{q_r} u^2 J_0(u) du + \int_0^\infty \frac{\gamma''(0)}{2q_r^2} u^3 J_0(u) du + \dots \right). \quad (\text{B1.9.88})$$

The following relationships can be used to simplify the above equation

$$\int_0^\infty x J_0(x) dx = 0, \int_0^\infty x^2 J_0(x) dx = -1, \int_0^\infty x^3 J_0(x) dx = 0. \quad (\text{B1.9.89})$$

Thus, we obtain

$$(\text{B1.9.90})$$

$$I(q_r) = -\frac{2\pi K'_x V \langle \eta^2 \rangle}{q_r^3} \gamma'(0) + O(q_r^{-2n-1}, d^{2n-1} \gamma(0)/dr^{2n-1}) \quad (n = 2, 3, 4 \dots).$$

This expression holds true only in the large q_r region in reciprocal space (or small r in real space). Since the second term in equation (B1.9.88) rapidly approaches zero at large q_r , we have

$$\lim_{q_r \rightarrow \infty} I(q_r) = -\frac{2\pi K'_x V \langle \eta^2 \rangle}{q_r^3} \gamma'(0). \quad (\text{B1.9.91})$$

-25-

This equation is the Porod law for the large-angle tail of the scattering curve along the equatorial direction, which indicates that the equatorial scattered intensity $I(q_r)$ is proportional to q_r^{-3} in the Porod region of an anisotropic system. Cohen and Thomas have derived the following relationships for the two-dimensional two-phase system (with sharp interfaces) such as fibres [29].

$$\langle \eta^2 \rangle = v_1(1 - v_1)(\rho_1 - \rho_2)^2 \quad (\text{B1.9.92})$$

$$\gamma'(0) = -\frac{L_I}{A} \frac{1}{\pi v_1(1 - v_1)} \quad (\text{B1.9.93})$$

where v represents the area fraction of a phase, L_I is the length of the interface between the two phases and A is the total cross sectional area.

- (2) For the component of the scattered intensity along the meridional direction (i.e., parallel to the cylinder direction, $q_r = 0$), equation (B1.9.61) can be rewritten as

$$I(q_z) = K''_x V \langle \eta^2 \rangle \int_0^\infty 2\gamma(z) \cos(q_z z) dz \quad (\text{B1.9.94})$$

where $K''_x (= K_x \int_0^\infty 2\pi \gamma(r) r dr)$ is a constant, because the integral of $\gamma(r)r$ is a constant. Again, we can expand the term $\gamma(z)$ using the Taylor series in the small z region to derive the Porod law. Equation (B1.9.94) thus becomes ($q_z z = v$).

$$I(q_z) = \frac{2K''_x V \langle \eta^2 \rangle}{q_z} \left(\int_0^\infty \gamma(0) \cos(v) dv + \int_0^\infty \frac{\gamma'(0)}{q_z} v \cos(v) dv + \int_0^\infty \frac{\gamma''(0)}{2q_z^2} v^2 \cos(v) dv + \dots \right). \quad (\text{B1.9.95})$$

The following expressions can be derived to simplify (B1.9.95)

$$\int_0^\infty \cos(x) dx = 0, \int_0^\infty x \cos(x) dx = -1, \int_0^\infty x^2 \cos(x) dx = 0. \quad (\text{B1.9.96})$$

Thus,

$$I(q_z) = -\frac{2K_x'' V_s \langle \eta^2 \rangle}{q_z^2} \gamma'(0) + O(q_z^{-2n}, d^{2n-1} \gamma(0) / dr^{2n-1}) \quad (n = 2, 3, 4 \dots). \quad (\text{B1.9.97})$$

Again, the second term in (B1.9.97) rapidly approaches zero at large q_z , thus we obtain

$$\lim_{q_z \rightarrow \infty} I(q_z) = -\frac{2K_x'' V \langle \eta^2 \rangle}{q_z^2} \gamma'(0). \quad (\text{B1.9.98})$$

If the scatterers are elongated along the fibre direction and the two phases and their interfaces have the same consistency in both radial and z directions, a different expression of the Porod law can be derived.

$$\lim_{q_z \rightarrow \infty} I(q_z) = -\frac{2K_x'' V (\rho_1 - \rho_2)^2 C}{\pi q_z^2 A} \quad (\text{B1.9.99})$$

This is the Porod law for the large angle tail of the scattering curve in the meridional direction. In this case, the scattered intensity is proportional to q_z^{-2} at large scattering angles.

B1.9.4.4 SCATTERING FROM SEMICRYSTALLINE POLYMERS

Semicrystalline polymers are ideal objects to be studied by small-angle x-ray scattering (SAXS), because electron density variations of the semicrystalline morphology (with alternating crystalline and amorphous structures) have a correlation length of several hundred Ångströms, which falls in the resolution range of SAXS (1–100 nm). In addition, the semicrystalline structures can usually be described by assuming electron density variations to occur in one coordinate only. In this case, the scattered intensity $I(q)$ can be described by a one-dimensional correlation function $\gamma_1(r)$.

The scattered intensity measured from the isotropic three-dimensional object can be transformed to the one-dimensional intensity function $I_1(q)$ by means of the Lorentz correction [15]

$$I_1(q) = I(q) 4\pi q^2 \quad (\text{B1.9.100})$$

where the term $4\pi q^2$ represents the scattering volume correction in space. In this case, the correlation and interface distribution functions become

$$\gamma_1(r) = \left(\int_0^\infty I_1(q) \cos(qr) dq \right) / Q \quad (\text{B1.9.101})$$

$$q_1(r) = \partial^2(\gamma_1(r))/\partial r^2 = \left(- \int_0^\infty I_1(q)q^2 \cos(qr) dq \right) / Q \quad (\text{B1.9.102})$$

where $Q (= \int_0^\infty I_1(q) dq = 4\pi \int_0^\infty I(q)q^2 dq)$ is the invariant. The above two equations are valid only for lamellar structures.

Lamellar morphology variables in semicrystalline polymers can be estimated from the correlation and interface distribution functions using a two-phase model. The analysis of a correlation function by the two-phase model has been demonstrated in detail before [30, 31]. The thicknesses of the two constituent phases (crystal and amorphous) can be extracted by several approaches described by Strobl and Schneider [32]. For example, one approach is based on the following relationship:

$$x_1 x_2 = \frac{B}{L} \quad (\text{B1.9.103})$$

where x_1 and x_2 are the linear fractions of the two phases within the lamellar morphology, B is the value of the abscissa when the ordinate is first equal to zero in $\gamma_1(r)$ and L represents the long period determined as the first maximum of $\gamma_1(r)$ (figure B1.9.11).

Figure B1.9.11. The analysis of correlation function using a lamellar model.

The analysis of the interface distribution function $g_1(r)$ is relatively straightforward [33]. The profile of $g_1(r)$ can be directly calculated from the Fourier transformation of the interference function or by taking the second derivative of the correlation function (B1.9.102). In the physical sense, the interface distribution function represents the probability of finding an interface along the density profile. A positive value indicates an even number of interfaces within a real space distance with respect to the origin. A negative value indicates an odd number of interfaces within the corresponding distance. With lamellar morphology, odd numbers of interfaces correspond to integral numbers of long periods. The shape of the probability distribution with distance for a given interface manifests as the shape of the corresponding peak on the interface distribution function. These distributions can be deconvoluted to reveal more detailed morphological parameters [34]. The schematic diagram of the relationships between the one-dimensional electron density profile, $\rho(r)$, correlation function,

$\gamma_1(r)$, and interface distribution function, $g_1(r)$, is shown in figure B1.9.12. In general, we find the values of the long period calculated from different methods, such as a conventional analysis by using Bragg's law, the correlation function and the interface distribution function, to be quite different. However, their trends as functions of time and temperature are usually similar. The ordering of these long periods indicates the heterogeneity of the lamellar distributions in the morphology [35].

Figure B1.9.12. The schematic diagram of the relationships between the one-dimensional electron density profile, $\rho(r)$, correlation function $\gamma_1(r)$ and interface distribution function $g_1(r)$.

In oriented systems (fibres or stretched films), the scattered image often appears as a two-bar or a four-point pattern with the scattering maximum at or near the meridian (fibre axis). The one-dimensional scattered intensity along the meridian must be calculated by the projection method using the following formalism

$$I_1(q_z) = \int_0^\infty I(q_r, q_z) q_r dq_r. \quad (\text{B1.9.104})$$

This intensity can be used to calculate the correlation function (B1.9.101) and the interface distribution function (B1.9.102) and to yield the lamellar crystal and amorphous layer thicknesses along the fibre.

Recently, a unique approach for using the correlation function method has been demonstrated to extract morphological variables in crystalline polymers from time-resolved synchrotron SAXS data. The principle of the calculation is based on two alternative expressions of Porod's law using the form of interference function [33, 36]. This approach enables a continuous estimate of the Porod constant, corrections for liquid scattering

and finite interface between the two phases, from the time-resolved data. Many detailed morphological variables such as lamellar long period, thicknesses of crystal and amorphous phases, interface thickness and scattering invariant can be estimated. An example analysis of isothermal crystallization in poly (ethyleneterephthalate) (PET) at 230°C measured by synchrotron SAXS is illustrated here. Time-resolved synchrotron SAXS profiles after the removal of background scattering (air and windows), calculated correlation function profiles and morphological variables extracted by using the two-phase crystal lamellar model are shown in figure B1.9.13. Two distinguishable stages are seen in this figure (the first stage was collected at 5 seconds per scan; the later stage was collected at 30 seconds per scan). It is seen that the long period L_c^M and crystal lamellar thickness l_c decrease with time. This behaviour can be explained by the space filling of thinner secondary crystal lamellae after the initial formation of thicker primary lamellae during isothermal crystallization [36].

-30-

Figure B1.9.13. Time-resolved SAXS profiles during isothermal crystallization (230 °C) of PET (the first 48 scans were collected with 5 seconds scan time, the last 52 scans were collected with 30 seconds scan time); calculated correlation functions $\gamma(r)$ (normalized by the invariant Q) and lamellar morphological variables extracted from the correlation functions (invariant Q , long period L_c^M , crystal lamellar thickness l_c and interlamellar amorphous thickness l_a).

-31-

B1.9.5 NEUTRON SCATTERING

Neutron scattering depends upon nuclear properties, which are related to fluctuations in the neutron scattering cross section σ between the scatterer and the surroundings. The scattered amplitude from a collection of scatterers can thus be written as (similar to (B1.9.29)):

$$F(q) = \sum b_j \exp(iqr_j) \quad (\text{B1.9.105})$$

where b_j is referred to as the ‘scattering length’ of the object j ; its square is related to the scattering cross section ($\sigma_j = 4\pi b_j^2$) of the j th object. The value of b_j depends on the property of the nucleus and is generally different for different isotopes of the same element. As neutron scattering by nature is a nuclear event and the wavelength used in neutron scattering is much larger than the nuclear dimensions, the intranuclear interference of waves due to neutron scattering need not be considered such that b_j is normally independent of scattering angle.

In neutron scattering, the scattered intensity is often expressed in terms of the differential scattering cross section:

$$\frac{\partial \sigma}{\partial \Omega} = \sum_{i,j}^N \langle b_i b_j \exp(iq(r_j - r_i)) \rangle \quad (\text{B1.9.106})$$

where $d\Omega$ is the small solid angle into which the scattered neutrons are accepted. We can mathematically divide the above equation into two parts:

$$\frac{\partial \sigma}{\partial \Omega} = \sum_{i,j}^N \langle b_i b_j \exp(iq(r_j - r_i)) \rangle \quad (\text{B1.9.107})$$

If we define

$$\overline{\Delta b^2} = \langle b^2 \rangle - \langle b \rangle^2 \quad (\text{B1.9.108})$$

we can obtain the following relationship:

$$\frac{\partial \sigma}{\partial \Omega} = N \overline{\Delta b^2} + \langle b \rangle^2 \sum_{i,j}^N \langle \exp(iq(r_j - r_i)) \rangle \quad (\text{B1.9.109})$$

where $\langle b \rangle^2 = \overline{b^2}$. The first term represents the incoherent scattering, which depends only on the fluctuations of the scattering length b occupying the different positions. The second term is the coherent scattering, which

depends on the positions of all the scattering centres and is responsible for the angular dependence of the scattered intensity. In this chapter, we shall only focus on the phenomenon of coherent scattering. Using the concept of correlation function (as in equation (B1.9.54)), we obtain

$$I(q) = \left(\frac{\partial \sigma}{\partial \Omega} \right)_{\text{coh}} = K_n b^2 \int \gamma(r) e^{-iqr} d^3r \quad (\text{B1.9.110})$$

where K_n is a calibration constant depending on the incident flux and apparatus geometry. The expressions of scattered intensity for isotropic and anisotropic systems can be obtained similarly to equations (B1.9.49) and (B1.9.50).

B1.9.5.1 SCATTERING FROM MULTICOMPONENT SYSTEMS

Equation (B1.9.110) is for a system containing only one type of scattering length. Let us consider the system containing more than one species, such as a two-species mixture with N_1 molecules of scattering length b_1 and N_2 of scattering length b_2 . The coherent scattered intensity $I(q)$ becomes

$$I(q) = K_n \left\{ b_1^2 \sum_{i_1}^{N_1} \sum_{j_1}^{N_1} \langle \exp(-iqr_{ij}) \rangle + 2b_1 b_2 \sum_{i_1}^{N_1} \sum_{j_2}^{N_2} \langle \exp(-iqr_{ij}) \rangle + b_2^2 \sum_{i_2}^{N_2} \sum_{j_2}^{N_2} \langle \exp(-iqr_{ij}) \rangle \right\} \quad (\text{B1.9.111})$$

or

$$I(q) = K_n \left\{ b_1^2 \int \gamma_{11}(r) e^{-iqr} d^3r + 2b_1 b_2 \int \gamma_{12}(r) e^{-iqr} d^3r + b_2^2 \int \gamma_{22}(r) e^{-iqr} d^3r \right\} \quad (\text{B1.9.112})$$

-33-

where γ_{ij} is the correlation function between the local density of constituents i and j . We can define three partial structural factors, S_{11} , S_{12} and S_{22}

$$S_{ij}(r) = K_n \int \gamma_{ij}(r) e^{-iqr} d^3r. \quad (\text{B1.9.113})$$

Thus

$$I(q) = b_1^2 S_{11}(q) + 2b_1 b_2 S_{12}(q) + b_2^2 S_{22}(q). \quad (\text{B1.9.114})$$

If the two constituting molecular volumes are identical in a two component system, we can obtain [37, 38]

$$S_{11}(q) = S_{22}(q) = -S_{12}(q) \quad (\text{B1.9.115})$$

or

$$I(q) = (b_1 - b_2)^2 S_{11}(q) = (b_1 - b_2)^2 S_{22}(q) = -(b_1 - b_2)^2 S_{12}(q). \quad (\text{B1.9.116})$$

Let us assume that we have $p + 1$ different species; equation (B1.9.111) can be generalized as

$$I(q) = \sum_{i=1}^p b_i^2 S_{ii}(q) + 2 \sum_{i<j}^p b_i b_j S_{ij}(q). \quad (\text{B1.9.117})$$

B1.9.5.2 PROPERTIES OF $S(Q)$

As we have introduced the structure factor $S(q)$ (B1.9.113), it is useful to separate this factor into two categories of interferences for a system containing N scattering particles [9]:

$$S(q) = N[P(q) + NQ(q)]. \quad (\text{B1.9.118})$$

The first term, $P(q)$, represents the interferences within particles and its contribution is proportional to the number of particle, N . The second term, $Q(q)$, involves interparticle interferences and is proportional to the number of pairs of particles, N^2 .

Let us consider the scattered intensity from a binary incompressible mixture of two species (containing N_1 molecules of particle 1 and N_2 molecules of particle 2) as in (B1.9.112); we can rewrite the relationship as

$$I(q) = b_1^2 N_1 [P_1(q) + N_1 Q_{11}(q)] + b_2^2 N_2 [P_2(q) + N_2 Q_{22}(q)] + 2b_1 b_2 N_1 N_2 Q_{12}(q) \quad (\text{B1.9.119})$$

where $P_i(q)$ is the intramolecular interference of species i and $Q_{ij}(q)$ is the intermolecular interferences between species i and j .

Two of the most important functions in the application of neutron scattering are the use of deuterium labelling for the study of molecular conformation in the bulk state and the use of deuterium solvent in polymer solutions. In the following, we will consider several different applications of the general formula to deuteration.

- (1) Let us first consider two identical polymers, one deuterated and the other not, in a melt or a glassy state. The two polymers (degree of polymerization d) differ from each other only by scattering lengths b_H and b_D . If the total number of molecules is N , x is the volume fraction of the deuterated species ($x = N_D / N$, with $N_D + N_H = N$). According to equation (B1.9.116), we obtain

$$I(q) = (b_D - b_H)^2 S_{DD}(q) \quad (\text{B1.9.120})$$

or S_{HH} or $-S_{HD}$. The coherent scattering factor can further be expressed in terms of $P(q)$ and $Q(q)$ as (see equation (B1.9.117))

$$\begin{aligned} S_{DD} &= xNd^2P(q) + x^2N^2d^2Q(q) = (1-x)Nd^2P(q) + (1-x)^2d^2N^2Q(q) \\ &= -x(1-x)N^2d^2Q(q). \end{aligned} \quad (\text{B1.9.121})$$

Thus

$$NQ(q) = -P(q). \quad (\text{B1.9.122})$$

By combining equations (B1.9.120) and (B1.9.122), we have

$$I(q) = (b_D - b_H)^2 x(1-x)Nd^2P(q). \quad (\text{B1.9.123})$$

-35-

- (2) Next, let us consider the case of a system made up of two polymers with different degrees of polymerization d_D for the deuterated species and d_H for the other. The generalized expression of [B1.9.122](#) becomes:

$$-N_D d_D^2 P_D(q) = N_D^2 d_D^2 Q_D(q) + N_D N_H d_D d_H Q_{DH}(q). \quad (\text{B1.9.124})$$

- (3) Let us take two polymers (one deuterated and one hydrogenated) and dissolve them in a solvent (or another polymer) having a scattering length b_0 . The coherent scattered intensity can be derived from [\(B1.9.117\)](#), which gives

$$\begin{aligned} I(q) &= (b_D - b_0)^2 S_{DD}(q) + (b_H - b_0)^2 S_{HH}(q) \\ &\quad + 2(b_D - b_0)(b_H - b_0)S_{HD}(q) \end{aligned} \quad (\text{B1.9.125})$$

where

$$\begin{aligned} S_{DD} &= xNd^2P(q) + x^2N^2d^2Q(q) \\ S_{HH} &= (1-x)Nd^2P(q) + (1-x)^2N^2d^2Q(q) \\ S_{HD} &= -x(1-x)Nd^2Q(q). \end{aligned} \quad (\text{B1.9.126})$$

Thus, we have

$$I(q) = (b_D - b_H)^2 x(1-x)Nd^2P(q) + (xb_D + (1-x)b_H - b_0)^2 Nd^2[P(q) + dQ(q)]. \quad (\text{B1.9.127})$$

The second term of the above equation gives an important adjustment to contrast variation between the

solvent and the polymer. If one adjusts the scattering length b_0 of the solvent by using a mixture of deuterated and hydrogenated solvent such that

$$xb_D + (1 - x)b_H - b_0 = 0 \quad (\text{B1.9.128})$$

then we can obtain (B1.9.123). This experiment thus yields directly the form factor $P(q)$ of the polymer molecules in solution even at high polymer concentrations.

B1.9.5.4 ANALYSIS OF MOLECULAR PARAMETERS

There are many different data analysis schemes to estimate the structure and molecular parameters of polymers from the neutron scattering data. Herein, we will present several common methods for characterizing the scattering profiles, depending only on the applicable q range. These methods, which were derived based on different assumptions, have

-36-

different limitations. We caution the reader to check the limitations of each method before its application.

- (1) If we deal with a solution at very low concentrations, we can ignore the interactions between the particles and express the scattered intensity as

$$\log I(q) = \log I(0) - \frac{1}{3}q^2 R_g^2 + \dots \quad (\text{B1.9.129})$$

where R_g is the radius of gyration. This equation is similar to (B1.9.35). If one plots $\log[I(q)]$ as a function of q^2 , the initial part is a straight line with a negative slope proportional to R_g^2 , which is called the Guinier plot. This approach is only suitable for scattering in the low qR_g range and in dilute concentrations. A similar expression proposed by Zimm has a slightly different form:

$$\frac{Nd^2}{S(q)} = (1 + \frac{1}{3}q^2 R_g^2 + \dots) \quad (\text{B1.9.130})$$

where N is the number of scattering objects and d is the degree of polymerization. This equation is similar to equation (B1.9.35). Thus if one plots $1/S(q)$ as function q^2 , the initial slope is $R_g^2/3$.

The above radius of gyration is for an isotropic system. If the system is anisotropic, the mean square radius of gyration is equal to

$$\langle R_g^2 \rangle = \langle R_x^2 \rangle + \langle R_y^2 \rangle + \langle R_z^2 \rangle \quad (\text{B1.9.131})$$

where R_x , R_y and R_z are the components of the radius of gyration along the x , y , z axes. For the isotropic system

$$\langle R_x^2 \rangle = \langle R_y^2 \rangle + \langle R_z^2 \rangle = \frac{1}{3} \langle R_g^2 \rangle. \quad (\text{B1.9.132})$$

- (2) In the intermediate and high q range, the analysis becomes quite different. The qualitative interpretation for the scattering profile at the high q range may make the use of scaling argument proposed by de Gennes [39]. If we neglect the intermolecular interactions, we can write

$$S(q) = Nd^2 P(qR_g) = V\varphi d P(qR_g) \quad (\text{B1.9.133})$$

-37-

where V is the volume of the sample, φ is the volume fraction occupied by the scattering units in polymer with a degree of polymerization d and qR_g is a dimensionless quantity which is associated with a characteristic dimension. Typically, the term $P(qR_g)$ can be approximated by $(qR_g)^{-\beta}$. Since the relationships between R_g and z are known as follows:

a Gaussian chain	$R_g \approx d^{0.5}$	
a chain with excluded volume (Flory)	$R_g \approx d^{0.6}$	
a rod	$R_g \approx d^{1.0}$	(B1.9.134)
general expression	$R_g \approx d^a$.	

This leads to the following equation:

$$S(q) = V\varphi d (qd^a)^{-\beta} = V\varphi q^{-\beta} d^{1-a\beta}. \quad (\text{B1.9.135})$$

In order to have $S(q)$ independent of d , the power of d must be zero giving $a = 1/\beta$. This gives rise to the following relationships:

a Gaussian chain	$S(q) = q^{-2}$	
a chain with excluded volume (Flory)	$S(q) = q^{-1.66}$	(B1.9.136)
a rod	$S(q) = q^{-1}$	

- (3) The quantitative analysis of the scattering profile in the high q range can be made by using the approach of Debye *et al* as in equation (B1.9.52). As we assume that the correlation function $\gamma(r)$ has a simple exponential form $\gamma(r) = \exp(-r/a_c)$, where a_c is the correlation length, the scattered intensity can be expressed as

$$I(q) = \frac{8\pi a_c^3 b_v^2 \varphi (1 - \varphi)}{(1 + q^2 a_c^2)^2} \quad (\text{B1.9.137})$$

where φ is the volume fraction of the component (with scattering length b_1 and volume of the monomer of the polymer v_1), $(1 - \varphi)$ is the volume fraction of the solvent (with scattering length b_0 and volume of the monomer of the other polymer v_0) and $b_v = b_1/v_1 - b_0/v_0$. Thus the correlation length a_c can be calculated by plotting $I(q)^{-1/2}$ versus q^2 , using equation (B1.9.53) (as light scattering).

A more general case of continuously varying density was treated by Ornstein and Zernicke for scattering of

-38-

opalescence from a two-phase system [40]. They argued that

$$\gamma(r) = \text{constant} \frac{\exp(-r/\xi)}{r} \quad (\text{B1.9.138})$$

where ξ is a characteristic length. This leads to

$$S(q) = \frac{B}{1 + q^2 \xi^2} \quad (\text{B1.9.139})$$

where B is a constant.

B1.9.5.5 CALCULATE THERMODYNAMIC PARAMETER

In polymer solutions or blends, one of the most important thermodynamic parameters that can be calculated from the (neutron) scattering data is the enthalpic interaction parameter χ between the components. Based on the Flory–Huggins theory [41, 42], the scattering intensity from a polymer in a solution can be expressed as

$$\frac{1}{s(q)} = \frac{1}{\varphi z P(q)} + \frac{1}{\varphi_0} - 2\chi \quad (\text{B1.9.140})$$

where $s(q) = S(q)/N_T$ corresponds to the scattered intensity from a volume equal to that of a molecule of solvent, N_T is the ratio of the solution volume to the volume of one solvent molecule ($N_T = V/v_s$), φ is the volume fraction occupied by the polymer and φ_0 is the volume fraction occupied by the solvent, v_s is the solvent specific volume. For a binary polymer blend, equation (B1.9.140) can be generalized as:

$$\frac{1}{s(q)} = \frac{1}{\varphi_1 z_1 P_1(q)} + \frac{1}{\varphi_2 z_2 P_2(q)} - 2\chi \quad (\text{B1.9.141})$$

where the subscripts 1 and 2 represent a solution of polymer 1 in polymer 2. The generalized Flory–Huggins model in the de Gennes formalism with the random phase approximation has the form:

$$\frac{V}{I(q)} = \frac{1}{b_v^2} \left\{ \frac{1}{(C_1 M_1 / N_A) P_1(q) (v_1^s)^2} + \frac{1}{(C_2 M_2 / N_A) P_2(q) (v_2^s)^2} - \frac{2\chi}{v_0} \right\} \quad (\text{B1.9.142})$$

where b_v is the contrast factor as described before, N_A is Avogadro's number, C is the concentration, M is the molecular weight, v_s is the specific volume ($C_1 v_1^s + C_2 v_2^s = 1$) and v_0 is an arbitrary reference volume.

In the case of low concentration and low q expansion, equation (B1.9.142) can be expressed by replacing $P_i(q)$ with the Guinier approximation (B1.9.130)

$$\frac{V u_0 b_v^2}{I(q)} = \left\{ \frac{1}{\varphi_1 z_1} + \frac{1}{\varphi_2 z_2} - 2\chi \right\} + \frac{1}{3} \left\{ \frac{R_{g1}^2}{\varphi_1 z_1} + \frac{R_{g2}^2}{\varphi_2 z_2} \right\} q^2. \quad (\text{B1.9.143})$$

Thus the slope of the $I(q)^{-1}$ versus q^2 plot is related to the values of two radii of gyration.

B1.6.1 CONCLUDING REMARKS

In this chapter, we have reviewed the general scattering principles from matter by light, neutrons and x-rays and the data treatments for the different states of matter. The interaction between radiation and matter has the same formalism for all three cases of scattering, but the difference arises from the intrinsic property of each radiation. The major difference in data treatments results from the different states of matter. Although we have provided a broad overview of the different treatments, the content is by no means complete. Our objective in this chapter is to provide the reader a general background for the applications of scattering techniques to materials using light, neutrons and x-rays.

B1.10 Coincidence techniques

Michael A Coplan

B1.10 INTRODUCTION

Time is a fundamental variable in almost all experimental measurements. For some experiments, time is

measured directly, as in the determination of radioactive half-lives and the lifetimes of excited states of atoms and molecules. Velocity measurements require the measurement of the time required for an object to travel a fixed distance. Time measurements are also used to identify events that bear some correlation to each other and as a means for reducing background noise in experiments that would otherwise be difficult or impossible to perform. Examples of time correlation measurements are so-called coincidence measurements where two or more separate events can be associated with a common originating event by virtue of their time correlation. Positron annihilation in which a positron and an electron combine to yield two gamma rays, is an example of this kind of coincidence measurement. Electron impact ionization of atoms in which an incident electron strikes an atom, ejects an electron and is simultaneously scattered is another example. In such an experiment the ejected and scattered electrons originate from the same event and their arrival at two separate detectors is correlated in time. In one of the very first coincidence experiments Bothe and Geiger [1] used the time correlation between the recoil electron and inelastically scattered x-ray photon, as recorded on a moving film strip, to identify Compton scattering of an incident x-ray and establish energy conservation on the microscopic level. An example of the use of time correlation to enhance signal-to-noise ratios can be found in experiments where there is a background signal that is uncorrelated with the signal of interest. The effect of penetrating high-energy charged particles from cosmic rays can be eliminated from a gamma ray detector by construction of an anti-coincidence shield. Because a signal from the shield will also be accompanied by a signal at the detector, these spurious signals can be eliminated.

Experiments in almost all subjects from biophysics to high-energy particle physics and cosmic ray physics use time correlation methods. There are a few general principles that govern all time correlation measurements and these will be discussed in sufficient detail to be useful in not only constructing experiments where time is a parameter, but also in evaluating the results of time measurements and optimizing the operating parameters. In a general way, all physical measurements either implicitly or explicitly have time as a variable. Recognizing this is essential in the design of experiments and analysis of the results. The rapid pace of improvements and innovation in electronic devices and computers have provided the experimenter with electronic solutions to experimental problems that in the past could only be solved with custom hardware.

B1.10.2 STATISTICS

B1.10.2.1 CORRELATED AND RANDOM EVENTS

Correlated events are related in time and this time relation can be measured either with respect to an external clock or to the events themselves. Random or uncorrelated events bear no fixed time relation to each other but, on the other

-2-

hand, their very randomness allows them to be quantified. Consider the passing of cars on a busy street. It is possible to calculate the probability, $P_{\bar{n}}(n)$ that n cars pass within a given time interval in terms of the average number of cars, \bar{n} , in that interval where $P_{\bar{n}}(n)$, the Poisson distribution is given by [2].

$$P_{\bar{n}}(n) = \frac{\bar{n}^n}{n!} e^{-\bar{n}}.$$

For example, if one finds that 100 cars pass a fixed position on a highway in an hour, then the average number of cars per minute is 100/60. The probability that two cars pass in a minute is given by $\frac{1}{2}0.6^2e^{-0.6} = 0.10$. The probability that three times the average number of cars pass per unit time is 0.02. $P_{\bar{n}}(n)$ and the integral of $P_{\bar{n}}(n)$ for \bar{n} are shown in figure B1.10.1. It is worthwhile to note that only a single parameter, \bar{n} , the average value, is sufficient to define the function; moreover, the function is not symmetric about \bar{n} .

Figure B1.10.1. Poisson distribution for \bar{n} (left vertical axis). Cumulative Poisson distribution for $\bar{n} = 1$ (right vertical axis). The cumulative distribution is the sum of the values of the distribution from 0 to n , where $n = 1, 2, 3, 4, 5$ on this graph.

This example of passing cars has implications for counting experiments. An arrangement for particle counting is shown in [figure B1.10.2](#). It consists of the source of particles, a detector, preamplifier, amplifier/discriminator, counter, and a storage device for recording the results. The detector converts the energy of the particle to an electrical signal that is amplified by a low-noise preamplifier to a level sufficient to be amplified and shaped by the amplifier. The discriminator converts the signal from the amplifier to a standard electrical pulse of fixed height and width, provided that the amplitude of the signal from the amplifier exceeds a set threshold. The counter records the number of pulses from the discriminator for a set period of time. The factors that affect the measurement are counting rate, signal durations, and processing times.

-3-

Figure B1.10.2. Schematic diagram of a counting experiment. The detector intercepts signals from the source. The output of the detector is amplified by a preamplifier and then shaped and amplified further by an amplifier. The discriminator has variable lower and upper level thresholds. If a signal from the amplifier exceeds the lower threshold while remaining below the upper threshold, a pulse is produced that can be registered by a preprogrammed counter. The contents of the counter can be periodically transferred to an on-line storage device for further processing and analysis. The pulse shapes produced by each of the devices are shown schematically above them.

In counting experiments, the instantaneous rate at which particles arrive at the detector can be significantly

different from the average rate. In order to assess the rate at which the system can accept data, it is necessary to know how the signals from the detector, preamplifier, amplifier and discriminator each vary with time. For example, if signals are arriving at an average rate of 1 kHz at the detector, the average time between the start of each signal is 10^{-3} s. If we consider a time interval of 10^{-3} s, the average number of signals arriving in that interval is one; if as many as three pulses can be registered in the 10^{-3} s then 99% of all pulses will be counted. To accommodate the case of three pulses in 10^{-3} s it is necessary to recognize that the pulses will be randomly distributed in the 10^{-3} s interval. To register the three randomly distributed pulses in the 10^{-3} s interval requires approximately another factor of three in time resolution, with the result that the system must have the capability of registering events at a 10 kHz uniform rate in order to be able to register with 99% efficiency randomly arriving events arriving at a 1 kHz average rate. For 99.9% efficiency, the required system bandwidth increases to 100 kHz. Provided that the discriminator and counter are capable of handling the rates, it is then necessary to be sure that the duration of all of the electronic signals are consistent with the required time resolution. For 1 kHz, 10 kHz and 100 kHz bandwidths this means signal durations of 0.1, 0.01, and 0.001 ms, respectively. An excellent discussion of the application of statistics to physics experiments is given by Melissinos [3].

The processing times of the electronic units must also be taken into consideration. There are propagation delays associated with the active devices in the electronics circuits and delays associated with the actual registering of events by the counter. Processing delays are specified by the manufacturers of counters in terms of maximum count rate: a 10 MHz counter may only count at a 10 MHz rate if the input signals arriving at a uniform rate. For randomly arriving signals with a 10 MHz average rate, a system with a 100 MHz bandwidth is required to record 99% of the incoming events.

B1.10.2.2 STATISTICAL UNCERTAINTIES

In counting experiments the result that is sought is a rate or the number of events registered per unit time. For

-4-

convenience we divide the total time of the measurement, T , into n equal time intervals, each of length T/n . If there are N_i counts registered in interval i , then the mean or average rate is given by

$$\frac{1}{n} \sum_{i=1}^n \frac{N_i}{T/n} = \frac{N_N}{T}$$

where N_N is the total number of counts registered during the course of the experiment. To assess the uncertainty in the overall measured rate, we assume that the individual rate measurements are statistically distributed about the average value, in other words, they arise from statistical fluctuations in the arrival times of the events and not from uncertainties in the measuring instruments. Here the assumption is that all events are registered with 100% efficiency and that there is negligible uncertainty in the time intervals over which the events are registered.

When the rate measurement is statistically distributed about the mean, the distribution of events can be described by the Poisson distribution, $P_{\bar{n}}(n)$, given by

$$P_{\bar{n}}(n) = \frac{\bar{n}^n}{n!} e^{-\bar{n}}$$

where n is the number of events per unit time and the average number of events per unit time is \bar{n} . The uncertainty in the rate is given by the standard deviation and is equal to the square root of the average rate, $\sqrt{\bar{n}}$. Most significant is the relative uncertainty, $\sqrt{N}/t_T/N/t_T$. The relative uncertainty decreases as the

number of counts per counting interval increases. For a fixed experimental arrangement the number of counts can be increased by increasing the time of the measurement. As can be seen from the formula, the relative uncertainty can be made arbitrarily small by increasing the measurement time; however, improvement in relative uncertainty is proportional to the reciprocal of the square root of the measurement time. To reduce the relative uncertainty by a factor of two, it is necessary to increase the measurement time by a factor of four. One soon reaches a point where the fractional improvement in relative uncertainty requires a prohibitively long measurement time.

In practice, the length of time for an experiment depends on the stability and reliability of the components. For some experiments, the solar neutrino flux and the rate of decay of the proton being extreme examples, the count rate is so small that observation times of months or even years are required to yield rates of sufficiently small relative uncertainty to be significant. For high count rate experiments, the limitation is the speed with which the electronics can process and record the incoming information.

In this section we have examined the issue of time with respect to the processing and recording of signals and also with regard to statistical uncertainty. These are considerations that are the basis for the optimization of more complex experiments where the time correlation between sets of events or among several different events are sought.

B1.10.3 TIME-OF-FLIGHT EXPERIMENTS

Time-of-flight experiments are used to measure particle velocities and particle mass per charge. The typical experiment

requires *start* and *stop* signals from detectors located at the beginning and end of the flight path, see figure B1.10.3. The *time-of-flight* is then the time difference between the signals from the stop and start detectors. The *start* signal is often generated by the opening of a shutter and *stop* by the arrival of the particle at a *stop* detector. Alternatively, the *start* signal may be generated by the particle passing through a *start* detector that registers the passing of the particle without altering its motion in a significant way. The result of accumulating thousands of time-of-flight signals is shown in [figure B1.10.4](#) where the number of events with a given time-of-flight is plotted against time-of-flight specified as channel number. The data for the figure were acquired for a gas sample of hydrogen mixed with air. The different flight times reflect the fact that the ions all have the same kinetic energy.

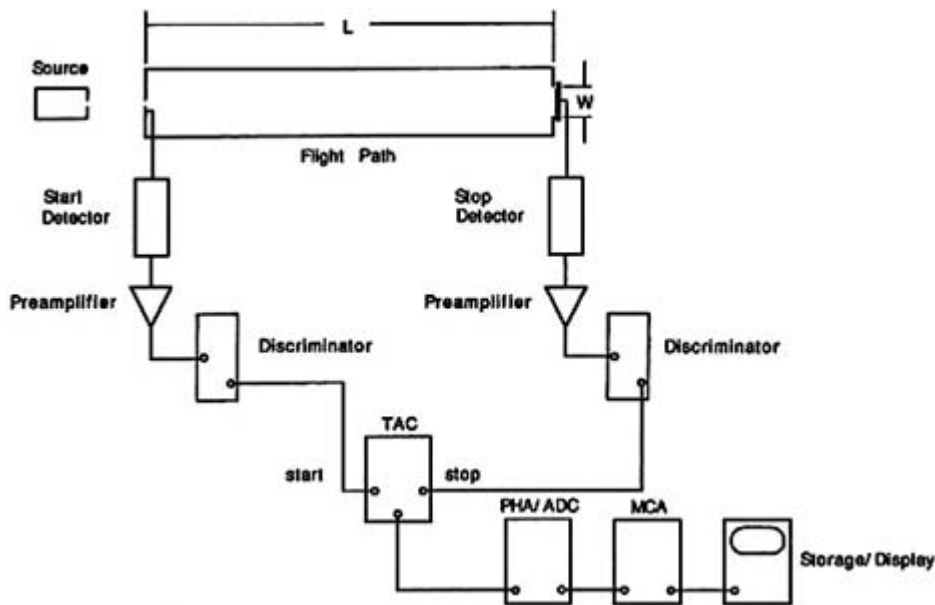

Figure B1.10.3. Time-of-flight experiment. Detectors at the beginning and end of the flight path sense the passage of a particle through the entrance and exit apertures. The width of the exit aperture, W , determines the amount of transverse velocity particles can have and still be detected at the end of the flight path. Transverse velocity contributes to the dispersion of flight times for identical particles with the same kinetic energies. Detector signals are amplified by a preamplifier; threshold discriminators produce standard pulses whenever the incoming signals exceed an established threshold level. Signals from the start and stop discriminators initiate the operation of the TAC (time-to-amplitude converter). At the end of the TAC cycle, a pulse is produced with amplitude proportional to the time between the start and stop signals. The TAC output pulse amplitude is converted to a binary number by a pulse height analyser (PHA) or analogue-to-digital converter (ADC). The binary number serves as an address for the multichannel analyser (MCA) that adds one to the number stored at the specified address. In this way, a collection of flight times, a time spectrum, is built up in the memory of the MCA. The contents of the MCA can be periodically transferred to a storage device for analysis and display.

B1.10.3.1 SOURCES OF UNCERTAINTIES

The measurement of velocity is given by $L(t_2 - t_1)$, where L is the effective length of the flight path and $t_2 - t_1$ is the difference in time between the arrival of the particle at the stop detector (t_2) and the start detector (t_1). The uncertainty

-6-

in the velocity is

$$\frac{1}{\Delta t} dL - \frac{L}{\Delta t^2} d\Delta t$$

where $\Delta t = t_2 - t_1$.

The relative uncertainty is

$$\sqrt{\left(\frac{dL}{L}\right)^2 + \left(\frac{d\Delta t}{\Delta t}\right)^2}$$

In a conventional time-of-flight spectrometer, the transverse velocities of the particles and the angular acceptance of the flight path and *stop* detector determine the dispersion in L . The dispersion in flight times is given by the time resolution of the *start* and *stop* detectors and the associated electronics. When a shutter is used there is also a time uncertainty associated with its opening and closing. A matter that cannot be overlooked in time-of-flight measurements is the rate at which measurements can be made. In the discussion the implicit assumption has been that only one particle is in the flight path at a time. If there is more than one, giving rise to multiple *start* and *stop* signals, it is not possible to associate a unique *start* and *stop* signal with each particle. It cannot be assumed that the first start signal and the first stop signals have been generated by the same particle, because the faster particles can overtake the slower ones in the flight path. When shutters are used, the opening time of the shutter must be sufficiently short to allow no more than one particle to enter the flight path at a time. These considerations give rise to constraints on the rate which measurements can be made. If the longest time-of-flight is T_{\max} , the particles must not be allowed to enter the flight path at a rate that exceeds $0.1/T_{\max}$. Detector response time and the processing time of the electronics should be taken into consideration when calculating T_{\max} . Time-of-flight experiments are inherently inefficient because the rate at which the shutter is opened is set by the time-of-flight of the slowest particle while the duration of the shutter opening is set by the total flux of particles incident on the shutter. The maximum uncertainty in the measured time-of-flight is, on the other hand, determined by T_{\min} , the time for the fastest particle to traverse the flight path.

Many of the electronics in the time-of-flight system are similar to those in the counting experiment, with the exception of the time-to-amplitude converter (TAC) and analogue-to-digital converter (ADC). The TAC has *start* and *stop* inputs and an output. The output is a pulse of amplitude (height) proportional to the time difference between the *stop* and *start* pulses. Different scale settings allow adjustment of both the pulse height and time range. Typical units also include *true start* and *busy* outputs that allow monitoring of the input *start* rate and the interval during which the unit is busy processing input signal and therefore unavailable for accepting new signals.

The output of the TAC is normally connected to the input of a pulse height analyser (PHA), or ADC and a multichannel analyser (MCA). The PHA/ADC assigns a binary number to the height of the input pulse; 0 for a zero amplitude pulse and 2^n for the maximum amplitude pulse, where n is an integer that can be selected according to the application. The binary number is used as the address for a multichannel analyser with 2^n address locations in the MCA. For each address from the PHA/ADC, a one is added to the contents of the address location. If, for example, a TAC has a range of 0 to 4 V output amplitude for *stop/start* time differences of 200 ns and the PHA/ADC assigns binary 0 to the 0 V amplitude signal and binary 255 to the 4 V amplitude signal, each of the 256 channels will correspond to 0.78 ns. With time, a histogram of flight times is built up in the memory of the MCA. [Figure B1.10.4](#) is an illustration of a time-of-flight spectrum for a sample of air that has been ionized and accelerated to 2000 eV.

Figure B1.10.4. Time-of-flight histogram for ions resulting from the ionization of a sample of air with added hydrogen. The ions have all been accelerated to the same energy (2 keV) so that their time of flight is directly proportional to the reciprocal of the square root of their mass.

An alternative to the TAC and PHA/ADC is the time-to-digital converter (TDC), a unit that combines the functions of the TAC and PHA/ADC. There are *start* and *stop* inputs and an output that provides a binary number directly proportional to the time difference between the stop and start signals. The TAC can be directly connected to a MCA or PC with the appropriate digital interface.

B1.10.3.2 ELECTRONICS LIMITATIONS

By storing the binary outputs of a PHA/ADC or a TDC in the form of a histogram in the memory of a MCA, computer analyses can be performed on the data that take full account of the limitations of the individual components of the measuring system. For the preamplifiers and discriminators, time resolution is the principal consideration. For the TAC, resolution and processing time can be critical. The PHA/ADC or a TDC provide the link between the analogue circuits of the preamplifiers and discriminators and the digital input of the MCA or PC. The conversion from analogue-to-digital by a PHA/ADC or TDC is not perfectly linear and the deviations from linearity are expressed in terms of differential and integral nonlinearities. Differential nonlinearity is the variation of input signal amplitude over the width of a single time channel. Integral nonlinearity is the maximum deviation of the measured time channel number from a least squares straight line fit to a plot of signal amplitude as a function of channel number.

B1.10.4 LIFETIME MEASUREMENTS

B1.10.4.1 GENERAL CONSIDERATIONS

Lifetime measurements have elements in common with both counting and time-of-flight experiments [4, 5]. In a lifetime experiment there is an initiating event that produces the system that subsequently decays with the emission of radiation, particles or both. Decay is statistical in character; taking as an example nuclear decay,

at any time t , each nucleus in a sample of n nuclei has the same probability of decay in the interval dt . Those nuclei that remain then have the same probability of decaying in the next interval dt . The rate of decay is given by $dN/dt = -kN$. The constant k , with units $1/\text{time}$, is called the *lifetime* and depends on the system and the nature of the decay. Integration of the first-order differential equation gives the exponential decay law, $N(t) = N_0 e^{-t/\tau}$, where N_0 is the number of systems (atoms, molecules, nuclei) initially created and $N(t)$ is the number that remain after a time t . The constant $\tau = 1/k$ can be obtained by measuring the time for the sample to decay to $1/e$ of the initial size.

A more direct method for lifetime measurements is the delayed coincidence technique [6] in which the time between an initiation event and the emission of a decay product is measured. A schematic diagram of an apparatus used for the measurement of atomic lifetimes is shown in figure B1.10.5. The slope of the graph of the natural log of the number of decay events as a function of time delay gives the lifetime directly. The precision with which the slope can be determined increases with the number of measurements. With 10^5 separate time determinations, times to 10τ can be sampled providing a range sufficient for a determination of τ to a few per cent. Enough time must be allowed between each individual measurement to allow for long decay times. This requires that the experimental conditions be adjusted so that on average one decay event is recorded for every 100 initiation events. The delayed coincidence method can routinely measure lifetimes from a few nanoseconds to microseconds. The lower limit is set by the excitation source and the time resolution of the detector and electronics. Lifetimes as short as 10 ps can be measured with picosecond pulsed laser excitation, microchannel plate photomultipliers, a GHz preamplifier and a fast timing discriminator. Instrument stability and available time set the upper limit for lifetime measurements.

-9-

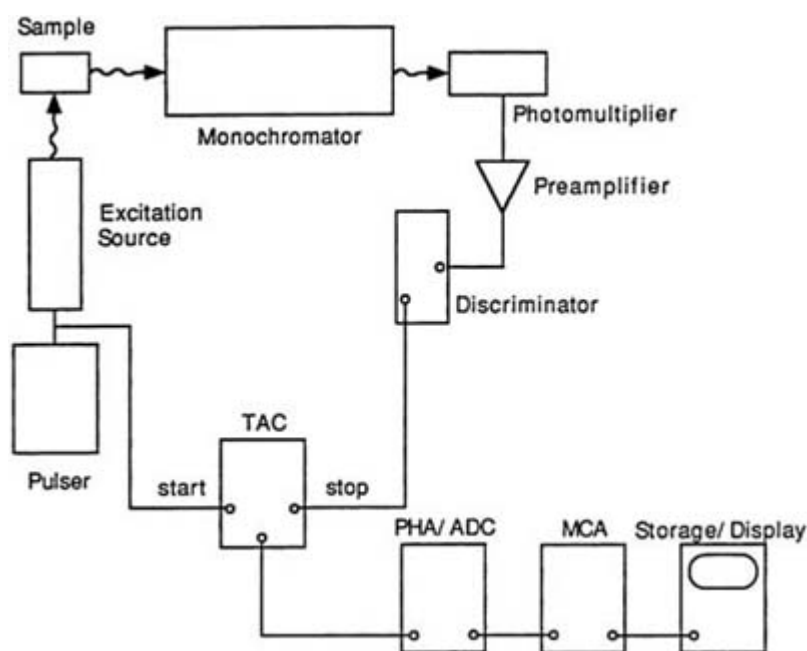

Figure B1.10.5. Lifetime experiment. A pulser triggers an excitation source that produces excited species in the sample. At the same time the pulser provides the *start* signal for a time-to-amplitude converter (TAC). Radiation from the decay of an excited species is detected with a photomultiplier at the output of a monochromator. The signal from the photomultiplier is amplified and sent to a discriminator. The output of the discriminator is the *stop* signal for the TAC. The TAC output pulse amplitude is converted to a binary number by a pulse height analyser (PHA) or analogue-to-digital converter (ADC). The binary number serves as an address for the multichannel analyser (MCA) that adds one to the number stored at the specified address. The pulser rate must accommodate decay times at least a factor of 10 longer than the lifetime of the specie under study. The excitation source strength and sample density are adjusted to have at most one detected decay event per pulse.

The delayed coincidence method has been applied to the fluorescent decay of laser excited states of biological molecules. By dispersing the emitted radiation from the decaying molecules with a polychromator and using an array of photodetectors for each wavelength region it is possible to measure fluorescent lifetimes as a function of the wavelength of the emitted radiation. The information is used to infer the conformation of the excited molecules [7].

B1.10.4.2 MULTIPLE HIT TIME-TO-DIGITAL CONVERSION

Both lifetime and time-of-flight measurements have low duty cycles. In the case of the lifetime measurements sufficient time between initiation events must be allowed to accommodate the detection of long decays. Moreover, the signal rate has to be adjusted to allow for the detection of at most one decay event for every initiation event. In the case of time-of-flight measurements enough time must be allowed between measurements to allow for the slowest particle to traverse the flight path. As with the case of lifetime measurements, each initiation event must give rise to no more than one particle in the flight path.

-10-

In order to circumvent the signal limitations of lifetime and time-of-flight measurements multiple hit time-to-digital converters can be used. Typically, these instruments have from eight to sixteen channels and can be used in the ‘common start’ or ‘common stop’ mode. When used in the common start mode a single start signal arms all of the channels with successive ‘stop’ signals directed to each of the channel inputs in sequence. In this way the signal rate can be increased by a factor equal to the number of channels in the TDC. A counter and demultiplexer/data selector [8] perform the function of routing the stop signals to the different channel inputs in sequence. A schematic diagram of the arrangement is shown in figure B1.10.6.

Figure B1.10.6. Multiple hit time-to-digital conversion scheme. Signals from the detector are routed to eight different TDC channels by a demultiplexer/data selector according to the digital output of the 3-bit counter that tracks the number of detector output signals following the initiation signal. The initiation signal is used as the common start. Not shown are the delays and signal conditioning components that are necessary to ensure the correct timing between the output of the counter and the arrival of the pulses on the common data line. Control logic to provide for the counter to reset after eight detector signals is also required.

B1.10.5 COINCIDENCE EXPERIMENTS

Coincidence experiments explicitly require knowledge of the time correlation between two events. Consider the example of electron impact ionization of an atom, [figure B1.10.7](#). A single incident electron strikes a target atom or molecule and ejects an electron from it. The incident electron is deflected by the collision and is identified as the scattered electron. Since the scattered and ejected electrons arise from the same event, there is a time correlation

-11-

between their arrival times at the detectors.

Figure B1.10.7. Electron impact ionization coincidence experiment. The experiment consists of a source of incident electrons, a target gas sample and two electron detectors, one for the scattered electron, the other for the ejected electron. The detectors are connected through preamplifiers to the inputs (start and stop) of a time-to-amplitude converter (TAC). The output of the TAC goes to a pulse-height-analyser (PHA) and then to a multichannel analyser (MCA) or computer.

Coincidence experiments have been common in nuclear physics since the 1930s. The widely used coincidence circuit of Rossi [9] allowed experimenters to determine, within the resolution time of the electronics of the day, whether two events were coincident in time. The early circuits were capable of submicrosecond resolution, but lacked the flexibility of today's equipment. The most important distinction between modern coincidence methods and those of the earlier days is the availability of semiconductor memories that allow one to now record precisely the time relations between all particles detected in an experiment. We shall see the importance of this in the evaluation of the statistical uncertainty of the results.

In a two detector coincidence experiment, of which figure B1.10.7 is an example, pulses from the two detectors are amplified and then sent to discriminators, the outputs of which are standard rectangular pulses of constant amplitude and duration. The outputs from the two discriminators are then sent to the *start* and *stop* inputs of a TAC or TDC. Even though a single event is responsible for ejected and scattered electrons, the two electrons will not arrive at the detectors at identical times because of differences in path lengths and electron velocities. Electronic propagation delays and cable delays also contribute to the *start* and *stop* signals not arriving at the inputs of the TAC or TDC at identical times; sometimes the *start* signal arrives first, sometimes

the *stop* signal is first. If the signal to the *start* input arrives after the signal to the *stop*, that pair of events will not result in a TAC/TDC output. The result can be a 50% reduction in the number of recorded coincidences. To overcome this limitation a time delay is inserted in the *stop* line between the discriminator and the TAC/TDC. This delay can be a length of coaxial cable (typical delays are of the order of 1 ns/ft) or an electronic circuit. The purpose is to ensure that the stop signal always arrives at the *stop* input of the TAC/TDC after the *start* signal. A perfect coincidence will be recorded at a time difference approximately equal to the delay time.

-12-

When a time window twice the duration of the delay time is used, perfect coincidence is at the centre of the time window and it is possible to make an accurate assessment of the background by considering the region to either side of the perfect coincidence region. An example of a time spectrum is shown in figure B1.10.8.

Figure B1.10.8. Time spectrum from a double coincidence experiment. Through the use of a delay in the lines of one of the detectors, signals that occur at the same instant in both detectors are shifted to the middle of the time spectrum. Note the uniform background upon which the true coincidence signal is superimposed. In order to decrease the statistical uncertainty in the determination of the true coincidence rate, the background is sampled over a time $\Delta\tau_B$ that is much larger than the width of the true coincidence signal, $\Delta\tau$.

B1.10.5.1 SIGNAL AND BACKGROUND
